A wide variety of techniques are commonly used to characterize DNA and RNA. Perhaps the most useful is gel electrophoresis, which takes advantage of the fact that these compounds are polyelectrolytes (23). In electrophoresis, nucleic acid molecules are separated on the basis of length by migration through a polymer gel under the influence of an electric field, with longer molecules migrating more slowly through the gel. The gel is most commonly composed of agarose, a natural polysaccharide, or cross-linked polyacrylamide. By increasing the percentage of acrylamide monomer and the number of cross-links in the gel, greater resolution of polymer lengths can be achieved. In fact, two DNA or RNA molecules that are tens to hundreds of nucleotides long but differ in length by a single nucleotide can be resolved. Most often, the polynucleotides are covalently labeled with radioactive P-32, allowing the positions of different DNA or RNA to be revealed by autoradiography or phosphorimagery. Nonradioactive detection systems employing fluorescent stains or chemoluminescent reporters are also commonly used. Detection of damaged nucleotides, identification of protein or drug binding sites, and quantitation of the thermodynamics and kinetics of molecular recognition by/of nucleic acids are just a few of the many applications of gel electrophoresis. In addition, gel electrophoresis performed on a preparative scale allows for the purification of a particular nucleic acid from a complex mixture since the desired DNA or RNA can be extracted from the gel after electrophoresis.

Additionally, capillary gel electrophoresis (CGE) has become an increasingly important method for DNA sequencing because of its high resolution (single nucleotide), fast run times, and high sensitivity (24). Capillary electrophoresis is actually a family of related separation techniques that use narrow-bore fused silica capillaries to separate a complex array of large and small molecules. High voltages are used to separate the molecules on the basis of differences in size, charge, and hydrophobicity. CGE uses a gel to perform the sieving of the DNAs or RNAs and an in-line uv or laser-induced fluorescence detector (in conjuction with staining dyes) for product analysis (25). These methods do not require the time normally spent to stain and photograph gels, and ultimately allow for high throughput analysis because of automated sample processing (26,27).

Specific polynucleotides are usually identified in gels by comparison of their mobilities with those of standards of appropriate length. However, mass spectrometry is being increasingly applied to the analysis of nucleic acids, particularly with respect to their complexes with proteins and small molecules (9,28–30). Soft ionization methods such as matrix-assisted laser desorption and electrospray are used to introduce the complexes into the gas phase but with insufficient energy so as to promote dissociation of the molecular components. The mass of the complex provides information on the identities of the components and their stoichiometries.

The thermodynamics of molecular recognition events involving polynucleotides are of great interest and can be studied by a variety of optical and calorimetric techniques. The most commonly used method involves recording the uv absorbance of a sample at 260 nm as a function of temperature (31). For example, when a DNA duplex is formed, the absorbance is lower because of stacking of the nucleobases than when the two strands are separated from one another.

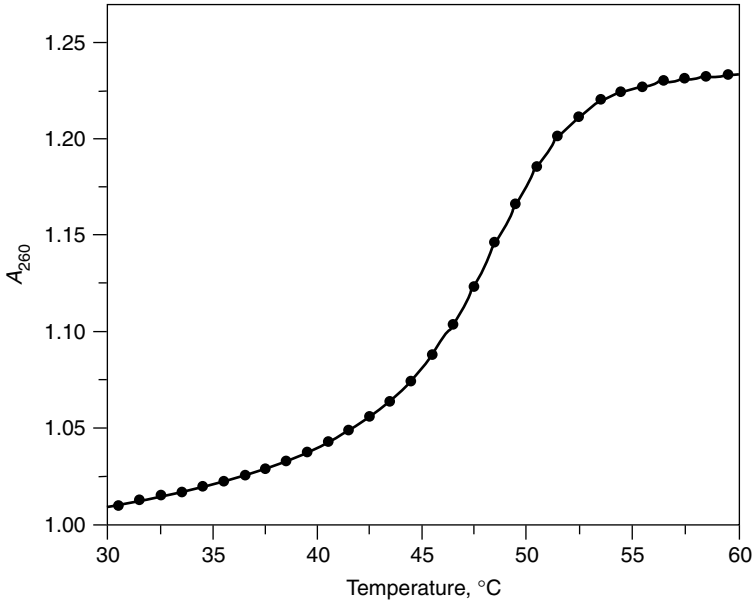

Fig. 7. Typical thermal denaturation curve plotting the uv absorbance at 260 nm (A_{260}) of a polynucleotide sample versus temperature. The "melting temperature" (T_m) of this sample is ca 48°C.

Thus, heating of a DNA duplex leads to an increase in absorbance, because the temperature is raised through the point at which there is sufficient thermal energy to disrupt the hydrogen-bonding and base-stacking interactions that are primarily responsible for the stability of the double-helix (Fig. 7). The midpoint of this transition is referred to the "melting temperature" (T_m) for the duplex. Curve-fitting of the temperature-dependent absorbance data or measurement of the concentration dependence of the T_m permits extraction of the free-energy, enthalpy, and entropy changes involved in forming a hybrid from isolated strands.

Alternatively, two different types of calorimetry can be used to analyze polynucleotides. In isothermal titration calorimetry, a solution containing one component (eg, single strand of DNA or RNA) is titrated into a solution containing the other component (eg, the complementary strand) at constant temperature (32). The amount of heat released upon binding of the two components is measured directly, and the concentration dependence permits extraction of the equilibrium binding constant and free-energy change for the reaction. Differential scanning calorimetry uses a constant concentration of the components used to form the complex of interest, and measures the heat taken up by the system as the temperature increases (33). (Or, conversely, the heat released as the system is cooled.) At the T_m, a discontinuity in the heat absorbed/released is detected and can be used to determine the enthalpy change for the transition.

Polynucleotide structures can be studied by a number of methods having varying levels of resolution. Offering the highest resolution are multidimensional nmr spectroscopy (34) and x-ray crystallography (9), both of which provide precise interatomic distances and angles. However, these are both very time-intensive

methods requiring expensive instrumentation and large amounts of material. Moreover, crystallization of nucleic acids, especially RNA, is still unpredictable. Lower resolution methods include circular dichroism (CD) spectropolarimetry (35,36) and structure probing experiments using chemical (37,38) or enzymatic (39,40) nucleases. CD relies on the differential absorption of left- and right-handed circularly polarized light by chiral chromophores or achiral chromophores bound in a chiral environment. Polynucleotides with different secondary or tertiary structures will exhibit different CD spectra, allowing, for example, distinction among the different families of DNA structures described above. In addition, molecular modeling and other computational methods are becoming increasingly sophisticated in their approaches to predicting three-dimensional structure based on primary sequence (41).

Structure probing experiments involve the use of chemical or enzymatic cleavage agents ("nucleases") to degrade the DNA or RNA backbone with predictable degrees of sequence or structure selectivity. Formation of intermolecular complexes or folding into stable tertiary structures alters the reactivity of the polynucleotide to these cleavage agents, resulting in either more or less cleavage at key positions. This can be detected using radiolabeled polynucleotide and gel electrophoresis, since cleaved substrates migrate faster than uncleaved substrates and the site of cleavage can be pinpointed. The high resolution of gel electrophoresis allows precise mapping of inter- and intramolecular interactions by this method. Figure 8 illustrates one application of this method, in which binding

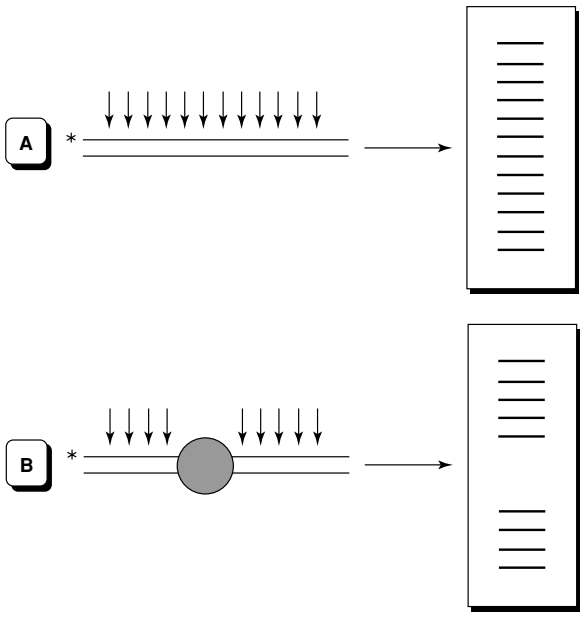

Fig. 8. Schematic of a footprinting experiment. In Part A radiolabelled DNA is cleaved by a chemical or enzymatic nuclease with no sequence selectivity (arrows). This leads to an autoradiogram exhibiting a ladder pattern corresponding to cleavage of the DNA at all positions. In Part B a ligand blocks cleavage at its binding site, leading to missing bands on the autoradiogram: the "footprint".

of a protein to a specific sequence of DNA prevents enzymatic cleavage at the binding site. The resulting "footprint" in the autoradiogram not only demonstrates that the protein is bound to the DNA, but also identifies the precise position of the binding site.

Enzymatic and Chemical Synthesis of Polynucleotides

At first glance, DNA and RNA appear to be random copolymers comprising four different monomers. However, the importance of the information encoded within nucleic acids requires that the monomers be arranged in a specific sequence. (Imagine how inefficient it would be to try to find a specific book within a library in which the books were shelved randomly.) Moreover, the replication of DNA through enzymatic means must repeatedly generate the required sequence with high fidelity. Hence, the process by which the polymer is synthesized must be under direct control at each step in the propagation. Otherwise, not only would a random sequence result, but also each molecule in the population would likely have a different sequence from all others. (While this is clearly undesirable in a biological context, the ability to synthesize randomized pools of polynucleotide sequences has been exploited in the generation of functional polynucleotides, as described henceforth.) This section will describe both enzymatic and chemical strategies for the synthesis of polynucleotides of well-defined sequences and lengths.

Enzymatic Synthesis. DNA and RNA are biosynthesized by polymerase enzymes. RNA is synthesized from a DNA strand with the assistance of an RNA polymerase enzyme. Inversely, DNA can be synthesized from an RNA strand with a reverse transcriptase (RT) enzyme. This mechanism is important because of "retroviruses" (such as HIV) in which RT makes up part of the viral replication cycle. (HIV-RT is an important target for anti-HIV therapy.) In any enzymatic synthesis of DNA or RNA, it is critical to the life of the organism that these enzymes synthesize their respective polynucleotides in a specific sequence of monomer units. The enzymes are able to accomplish this by utilizing a "template" strand to direct the synthesis. By reading the sequence of nucleobases on the template, the enzymes select the complementary monomer for incorporation into the propagating strand (Fig. 9). It was widely accepted that the polymerase enzymes accomplish this by matching the nucleotide to the template on the basis of complementary

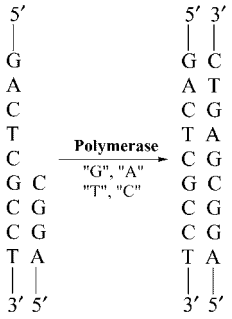

Fig. 9. Templated synthesis of DNA and RNA by polymerase enzymes.

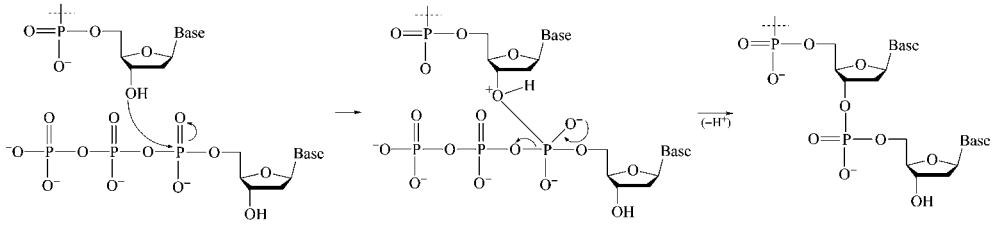

Fig. 10. Chemical reaction catalyzed by DNA polymerase. The 3′-OH of the growing DNA strand attacks the α-phosphorus of the dNTP, releasing pyrophosphate and forming a phosphodiester linkage.

hydrogen bonding. However, recent research indicates that for DNA polymerase, at least, the enzyme matches the shape of the incoming nucleotide to the template rather than reading the specific arrangement of hydrogen-bond donor and acceptor groups (42,43). The enzyme will continue to read the template strand and extend the newly synthesized strand until it reaches a particular sequence on the template, which acts as a pause or stop position indicating where the propagation should be terminated. The monomers used during DNA and RNA synthesis are nucleoside triphosphates. The reason for the triphosphate "tail" on the monomer becomes apparent when one considers the bond-forming reaction catalyzed by the polymerase enzyme: nucleophilic attack by the 3′-OH group of the propagating strand on the α-phosphate leads to release of inorganic pyrophosphate as a leaving group (Fig. 10).

Polymerase enzymes are used extensively in the laboratory for the synthesis and manipulation of DNA and RNA (44). One of the most important applications of enzymatic DNA synthesis is in the polymerase chain reaction (PCR), which is used to amplify minute quantities of DNA from a variety of sources, including crime scene evidence, archaeological specimens, or medical samples (45). In PCR, two short oligonucleotide primers are first synthesized by chemical methods. These primers are complementary to the 5′-ends of the two strands which form the DNA duplex of interest (Fig. 11). A large excess of the primers is mixed with the target DNA along with a DNA polymerase enzyme and the nucleoside triphosphate monomers. The sample is heated to disrupt the target duplex. Then, as the

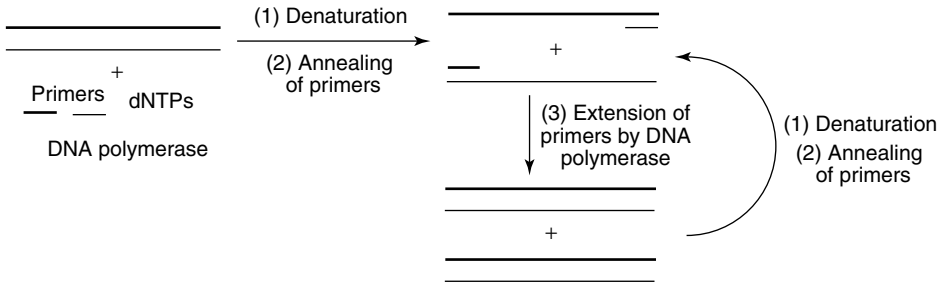

Fig. 11. The polymerase chain reaction, used to amplify small quantities of DNA through repetitive denaturation/annealing/extension cycles.

sample cools, the excess of primers competes kinetically with the complementary strands to form short primer-target duplexes. DNA polymerase then extends the primers to form full-length duplexes with both of the original strands. Subsequent heating, hybridization, and extension cycles lead to amplification of the DNA target concentration. Thus, PCR increases the amount of DNA that can be used for applications such as (*1*) diagnostic tests and assays; (*2*) *in vitro* transcription/translation to make mRNA and, ultimately, protein; and (*3*) insertion into recombinant DNA vectors for the expression of proteins of interest by organisms such as *E. coli* (bacteria) or *S. cerevisae* (yeast).

Chemical Synthesis. In the 1960s, the chemical synthesis of polypeptides was revolutionized through use of an insoluble solid support (46). A similar approach to the synthesis of polynucleotides was developed in the 1980s (47,48). Solid-phase synthesis benefits from short reaction times (because of high concentrations of reagents) and easy purification involving simple filtration, since the desired product remains covalently bound to the support.

The solid support used for DNA synthesis is usually controlled pore glass, functionalized with surface groups that permit attachment of the first monomer by an ester group. Monomers are added to the solid support in a predetermined sequence to form the desired oligo- or polynucleotide. A single round of extension, involving the addition of one monomer, actually consists of four chemical reactions (Fig. 12). In the first step, a dimethoxytrityl-protecting group is removed from the terminal 5′-OH. The next monomer is then added as the β-cyanoethyl-protected phosphoramidite. This coupling reaction forms a phosphite and is catalyzed by

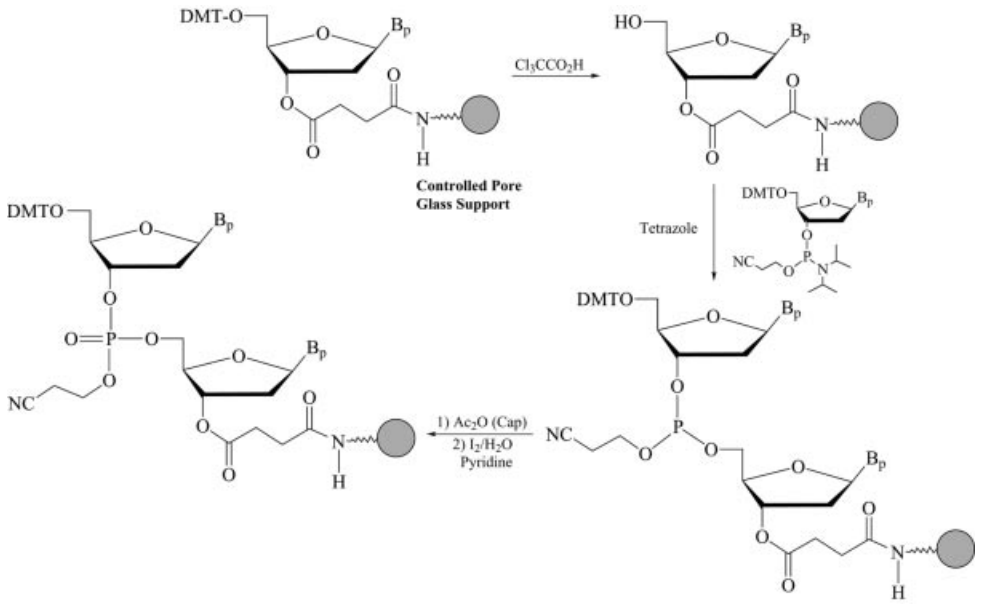

Fig. 12. The key steps in solid-phase chemical synthesis of DNA oligonucleotides. Each cycle consists of deprotection, coupling, capping, and oxidation steps and results in addition of one monomer onto the chain.

tetrazole. Any unreacted 5′-OH groups are "capped" through reaction with acetic anhydride. Finally, the phosphite is oxidized to a phosphotriester.

After the desired sequence is completed, the polynucleotide is released from the solid support, and protecting groups are removed via hydrolysis with ammonium hydroxide. The DNA is purified by gel electrophoresis or hplc and characterized by mass spectrometry. Similar methods are used to synthesize RNA oligomers, although the 2′-OH group on the ribose ring must be protected.

Solid-phase DNA and RNA synthesis are now fully automated and DNA oligomers can be purchased from many different vendors for less than $1/base. The ready availability of custom-synthesized DNA has contributed to the rapid growth in molecular biology, especially through providing primers for PCR amplification of desired DNA sequences. Other applications include synthesis of DNA oligomers for "gene-chip" analyses and libraries of DNA agents to be used in drug discovery. Furthermore, the chemical synthesis method permits the preparation of oligomers based on completely unnatural backbones, as described in the following section.

Synthetic Polynucleotide Analogues

Synthetic oligonucleotides are finding applications as antigene and antisense reagents, where sequence-specific binding to genomic DNA by triplex formation or to messenger RNA by duplex formation perturbs gene expression. The ability to selectively block expression of targeted genes is of great value both in the laboratory as well as in the clinic. However, oligonucleotides based on natural backbones are not optimized for these applications since single-stranded nucleic acids are readily degraded by nuclease enzymes and are not readily taken up by cells. Much effort has been directed toward the improvement of oligonucleotides for these applications. Modifications of the bases, sugar rings, and phosphodiester backbone (including replacement of the entire backbone) have been reported. A short list of analogues that have shown improved properties include phosphorothioates (49), PNA (peptide nucleic acid) (50,51), LNA (locked nucleic acid) (52,53), 2′-O-alkylated RNA and RNA/DNA chimeras (54), HNA (hexitol nucleic acid)(55,56), and phosphoramidates (49,57) (Fig. 13).

Antisense molecules should exhibit several properties: (*1*) high affinity and specificity for the target sequence (in order to overcome local secondary and tertiary structure); (*2*) nuclease resistance (stability to enzymes that destroy DNA and RNA); (*3*) RNase H activation (the ability to use enzymes *in vivo* to catalytically degrade a target mRNA); (*4*) spontaneous uptake by animal and human tissues; (*5*) low toxicity; and (*6*) high solubility. In addition, the ability to serve as a PCR primer is extremely useful for diagnostic applications. Finally, the ability to be incorporated into standard chemical and/or enzymatic syntheses and a low cost for synthesis of the monomer units are obviously important for commercial applications (58). The performance of various analogues are collected in Table 2. Four of the most promising synthetic analogues are described in greater detail below.

Phosphorothioates. Phosphorothioates are one of the earliest groups of DNA analogues. Phosphorothioate oligonucleotides involve a modification of the phosphodiester linkage of DNA wherein one of the nonbridging oxygen atoms is

Table 2. Properties of Oligonucleotide Analogues

Analogue	Improved affinity	Nuclease stability	RNase H activity	PCR primer	Clinical trials
DNA	−	−	+	+	−

LNA	+	+	Poor	+	−
LNA/DNA	+	+	+	+	−

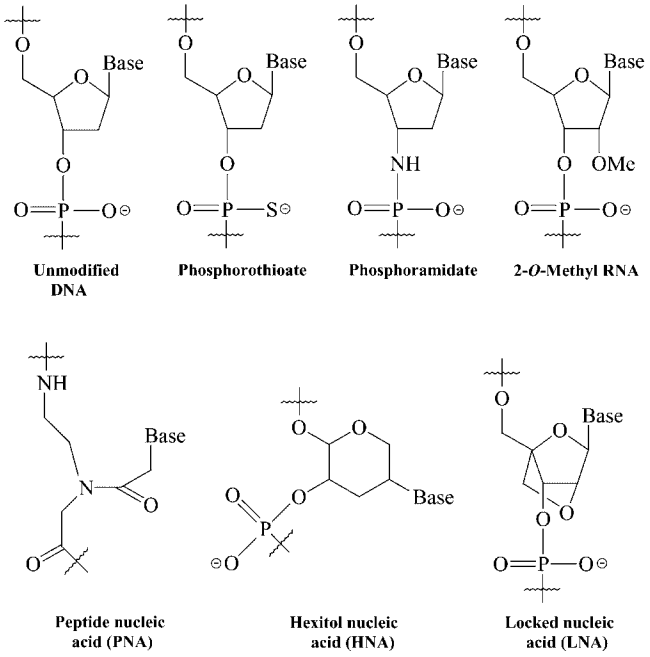

Fig. 13. Synthetic analogues of DNA and RNA, with unmodified DNA shown for comparison.

replaced by a sulfur atom (49). Phosphorothioates are one of the most commonly used analogues for antisense studies, and a great deal of clinical data has been acquired for these compounds. The first antisense oligonucleotide drug that has been approved for use is a phosphorothioate (Fomivirsen^{TM}), which is used to treat a viral infection of the eye (59).

Phosphorothioates can be incorporated into DNA sequences by solid-phase synthesis techniques. The chemical synthesis of the monomer units creates a chiral center at the modified phosphorous atom. These diastereomers can be separated for chemical synthesis, while any enzymatic incorporation results in only the

formation of the (R)-internucleotide linkage. (If the diastereomers are not separated prior to chemical synthesis, the final product will actually contain 2^n distinct compounds, where n is the number of phosphorothioate monomers incorporated into the sequence.) The use of a mixture of compounds can lead to ambiguous pharmacological results as well as regulatory issues (49).

The beneficial aspects of phosphorothioates include their ability to be spontaneously taken up by certain animal and human tissues, low toxicity, the ability to recruit RNase H, a moderate stability to nucleases and to base-catalyzed hydrolysis, and ease of synthesis. However, incorporation of phosphorothioate linkages into oligonucleotides reduces their affinity relative to unmodified DNA, enhances the tendency to form secondary structure, and increases nonspecific binding to proteins. These effects can lead directly to poor target binding. However, both laboratory and clinical data indicate that phosphorothioates can overcome these deficiencies so as to be effective antisense drugs and reagents.

PNA (Peptide Nucleic Acid). PNA is a DNA analogue where the entire phosphodiester backbone is replaced with *N*-2-aminoethylglycine backbone, and the linkage to the nucleobase is replaced with acetyl linker (50). This arrangement of atoms fits the bonding arrangement of DNA by containing six single bonds in the backbone repeat unit, and three single bonds from the backbone to the nucleobase (Fig. 13). This variation on DNA is interesting because the chemical character has been altered significantly: PNA has the attributes of both proteins and nucleic acids (60–62).

As a hybridization agent, PNA binds to RNA and DNA with significantly higher affinity (ΔT_m per monomer $\sim +3.5^\circ$C) and specificity than does unmodified DNA (63,64). The stability order for PNA, RNA, and DNA hybrids is as follows: PNA/PNA > PNA/RNA > PNA/DNA > RNA/DNA > DNA/DNA (65). This ordering is at least partially because of the uncharged character of the PNA backbone. PNA is capable of forming both antiparallel (N-terminus of the PNA aligned with the 3′-terminus of the DNA/RNA target) and parallel duplexes. The parallel duplex exhibits a T_m that is $\sim$1–2°C (per base pair) lower than the corresponding antiparallel duplex (50). In addition, homopyrimidine PNAs cooperatively form 2:1 triplexes with complementary homopurine DNAs. The first PNA strand forms a Watson–Crick duplex with the DNA strand, while the second PNA binds in the major groove by Hoogsteen hydrogen bonding (66). The x-ray structure of a PNA_2/DNA triplex shows hydrogen bonding between the backbone NH of the Hoogsteen PNA strand and phosphate oxygen of the DNA backbone (67), contributing to exceptionally high stability for these complexes. This strong binding property allows homopyrimidine PNAs to form strand displacement complexes when targeted toward duplex DNA and has led to study of PNA as an antigene agent (68).

PNAs are resistant to nuclease and protease enzymes, exhibit improved affinity and specificity relative to DNA oligonucleotides, and are efficiently prepared through solid-phase peptide synthesis. The uncharged character of PNA causes low aqueous solubility, although this is readily alleviated by the addition of lysine units at either terminus. One disadvantage of PNA as an antisense agent is that PNA/RNA duplexes do not induce RNase H activation. Thus, standard PNA cannot cause the catalytic degradation of RNA targets, although equipping the PNA with its own catalytic group is being pursued. Nevertheless, the improved

hybridization properties of PNA have allowed its use in many biotechnological applications such as hybridization arrays (69), oligonucleotide capture (70), and PCR clamping (71). PNA has also been shown to be capable of inhibiting human telomerase (72,73) and the expression of genes *in vivo* (74,75). It is also important to note that even though PNA is a DNA analogue, its self-recognizing properties and distinct chemical structure may allow its use in other applications not currently associated with nucleic acids technology.

LNA (Locked Nucleic Acid). LNA nucleotides incorporate a methylene bridge between the 2′-oxygen and 4′-carbon of ribose (Fig. 13) (52). This bridge conformationally locks the ribose into the 3′-endo conformation, thereby reducing the flexibility of the monomer and preorganizing the sugar ring into the conformation required for A-form duplexes (76). This modification results in dramatic increases in duplex stability, with ΔT_m values approaching 10°C per LNA monomer. However, as more LNA bases are incorporated, the increase per LNA base is reduced. In addition, incorporation of LNA monomers into longer oligomers (over ten bases long) leads to less duplex stabilization than in shorter sequences. These effects can reduce the overall stabilization per monomer to ∼2°C, which implies that LNA monomers will be used most effectively in short oligonucleotides (77).

The high affinity of LNAs coupled with nuclease resistance, RNase H activation, and commercial availability define LNA as the best of the RNase H activating oligonucleotide analogues to date (Table 2). It is important to note that an oligonucleotide comprised of all LNA monomers does not strongly activate RNase H, unlike LNA–DNA chimeras (ie, oligomers which contain both LNA and DNA monomers) (77). LNA–DNA chimeras have been used to produce an antisense effect on the G-protein-coupled receptor in living rat brain (78). This successful result implies both low toxicity and good potential for antisense applications. It also exemplifies another significant advantage of LNA relative to PNA: its ability to be incorporated into any phosphoramidite-based synthetic scheme. Thus, chimeric structures in which LNA residues are interspersed among DNA monomers allow the affinity enhancement due to LNA to be realized while maintaining the RNase H-activating properties of unmodified DNA. This can be extended further by also incorporating phosphorothioate residues to take advantage of their pharmacokinetic properties.

Phosphoramidates. Phosphoramidates are another commercially available DNA analogue where the 3′-oxygen of the phosphodiester center is replaced with an amino or aminoalkyl group (Fig. 13) (49). Phosphoramidates exhibit complete resistance to nuclease P1 and snake venom phosphodiesterase and a moderate improvement in affinity for DNA and RNA targets (ΔT_m per monomer = ∼4°C for 2′-fluoro N3′–P5′ phosphoramidates) (57). However, they exhibit no RNase H activity (49).

Sequence-Specific Recognition of Polynucleotides. Genetic information is stored permanently in DNA and transiently in RNA. Molecular recognition events are critical to accessing, reading, replicating, and utilizing the genome. In addition, the use of synthetic ligands to bind to specific sequences of DNA and RNA lies at the heart of numerous applications, ranging from gene therapy to molecular diagnostics. The highly divergent three-dimensional structures of natural DNA and RNA require distinct strategies for recognition of biologically relevant targets. A number of low molecular weight compounds have demonstrated

impressive recognition capabilities for polynucleotides. (79,80) However, given the polymeric nature of both DNA and RNA, it stands to reason that the most effective reagents should themselves be oligomeric or polymeric. Natural and synthetic ligands of this type that recognize DNA and RNA sequence specifically will be described in this section.

DNA. By far, the most common secondary structure for DNA is the double helix. Sequence-specific recognition of double-helical DNA relies on several factors. First, the array of functional groups exposed in the major and minor grooves can be read by DNA-binding ligands. This is referred to as "direct readout." However, more subtle factors may also be involved, such as sequence-dependent variation in the shape, flexibility, and hydration of the DNA. Ligands which discriminate among sequences based on these parameters utilize "indirect readout" of the sequence information.

DNA-binding ligands range in size from multidomain proteins (with molecular weights in excess of 10^5 kDa) to small molecules (with molecular weights as low as 300 Da). Larger ligands have greater potential for sequence-specific recognition because they can generate a more extended binding interface, where hydrogen bonding, electrostatic attractions, van der Waals contacts, and desolvation contribute to a favorable ΔG for association. Proteins recognize DNA sequences through a myriad of contacts involving all of these forces. Of the vast array of DNA-binding proteins that have been discovered and characterized, the most promising class with respect to predetermining the sequence that will be targeted is the zinc finger proteins (81). This group of proteins folds into a three-dimensional structure that is stabilized by a zinc ion which chelates four separate protein side chains. Each zinc finger domain recognizes three base pairs of DNA sequence specifically through contacts made in the major groove, and covalent linkage of separate domains through peptide chains allows for modular recognition of extended sequences. These proteins are able to function as artificial transcription factors, leading to enhanced or reduced gene expression, depending on the targeted gene (82).

The major groove of DNA is also the recognition site for triplex-forming oligonucleotides (TFOs) (12). As discussed above, Hoogsteen hydrogen bonding interactions allow sequence-specific recognition of DNA. TFOs have successfully inhibited gene expression through binding to target sequences in duplex DNA both *in vitro* (83,84) and *in vivo* (85). However, Hoogsteen recognition of DNA has not been generalized, meaning that only a relatively small subset of all possible sequences can be effectively bound by this strategy.

Numerous modifications of the natural DNA backbone have been utilized to try to improve the binding affinity and, therefore, biological utility of TFOs. PNA forms triplex structures with duplex DNA targets, although the triplex incorporates two PNA strands and one of the two DNA strands. This "strand invasion complex" leaves the second DNA strand locally displaced. Since triplex formation by this mechanism still relies on Hoogsteen hydrogen bonding, it suffers from the same sequence limitations as unmodified DNA. Strand invasion by mixed sequence PNA is generally unfavorable. However, adding a second PNA strand complementary to the displaced DNA strand leads to formation of a double-invasion complex, an approach that might be generalizable to any sequence (86).

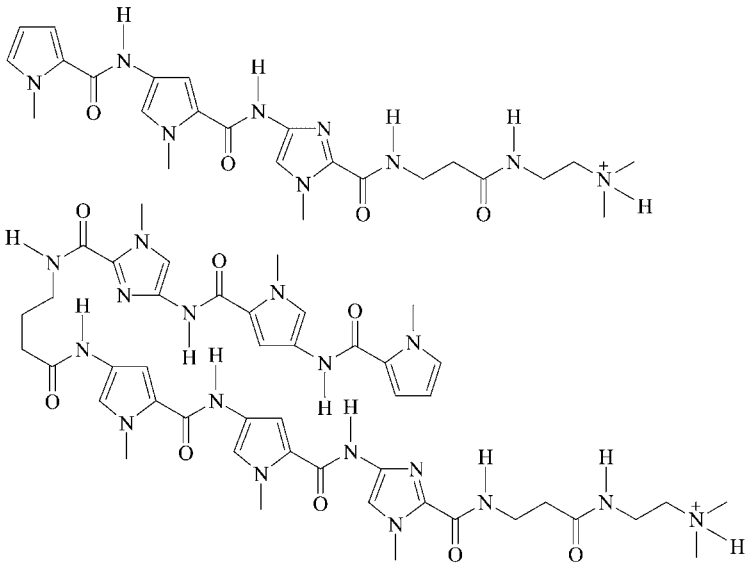

Fig. 14. Polyamide molecules that bind in the minor groove of DNA sequence-specifically. The three-ring compound binds as a cofacial dimer to give a 2:1 stoichiometry. The six-ring compound folds into a hairpin structure and binds as a 1:1 complex.

Strand invasion by LNA has not been reported. However, given the high stability offered by the LNA modifications, it is possible that these oligomers will bind sequence specifically to duplex DNA, although the stoichiometry and sequence restrictions cannot be predicted at this time.

The zinc finger proteins and TFOs access sequence information through the major groove. However, sequence discrimination can also be achieved using the information available in the minor groove of duplex DNA. In this context, a series of oligomeric ligands comprising heterocyclic groups (*N*-methylimidazole, *N*-methylpyrrole, 3-hydroxy-*N*-methylpyrrole) linked via amide connections (Fig. 14) are noteworthy. Two such molecules can bind simultaneously in a face-to-face orientation within the minor groove of DNA (87,89). Alternatively, intramolecular dimerization in the minor groove arises when two polyamides are covalently linked (90). Moreover, the precise sequence of heterocycles within the oligomer can be designed to recognize virtually any sequence of DNA. Control of gene expression using this class of ligands has been reported (91–93).

RNA. High resolution nmr, x-ray crystallography, and computational structure prediction methods are just beginning to illuminate the structural diversity embodied in RNA. Understanding the structure a particular RNA sequence folds into is of great interest, for, as with all biomolecules, the three-dimensional structure is intimately related to the function. However, with such a diverse structure-space covered by RNA, it is highly unlikely that a general protein-based approach to sequence-specific recognition can be achieved in the near future. Instead, the most successful RNA-binding strategies are based on the antisense approach, wherein an oligonucleotide or mimic is targeted to a complementary sequence within the RNA (84).

Natural systems often use antisense agents to control levels of gene expression. For example, if the protein derived from a given messenger RNA is not needed at a particular time, the expression can be downregulated by synthesizing a complementary RNA that binds to the mRNA and prevents its translation by the ribosome. This natural strategy led to the development of antisense therapeutics based on DNA oligonucleotides. In this strategy, binding of the DNA oligonucleotide is envisioned to inhibit gene expression in two ways. First, binding of the DNA to the mRNA target could prevent translation by a steric blockage of the ribosome. Of greater potential though, is the ability of DNA/RNA hybrids to activate the enzyme RNase H, which hydrolyzes the RNA component of the hybrid, leading to dissociation of the DNA antisense agent. This allows the antisense agent to potentially block translation of multiple mRNA molecules.

There are three potential pitfalls to the antisense strategy. First, unmodified DNA oligonucleotides are rapidly degraded by nuclease enzymes in the body, effectively eliminating the therapeutic activity before the DNA can ever reach the mRNA target. This deficiency has been overcome by synthesizing analogues of DNA that are stable to nuclease degradation, although these analogues also reduce the ability of RNase H to recognize the resulting hybrid with RNA (78,94,95). The second deficiency involves the possibility that the antisense agent will bind nonspecifically to other biomolecules *in vivo*. There is considerable evidence that antisense agents can affect a wide variety of biochemical pathways in addition to the expression of the specific gene being targeted. Finally, if an antisense agent successfully avoids degradation and nonspecific binding, it must still overcome the folded structure of the RNA, which can impose significant thermodynamic and kinetic obstacles to hybridization (96).

These factors point back to the need for increased understanding of RNA secondary and tertiary structure. In particular, sites that are near the surface of the folded structure and are not involved in base pairing with other portions of the RNA are likely to be the most viable targets for antisense agents. Currently, large libraries of potential antisense agents covering most of the target RNA sequence are synthesized and then screened individually for inhibition of gene expression. This can be a time-consuming and expensive procedure, especially as more costly modifications such as PNA or LNA are introduced. Rational design of antisense agents, based primarily on knowledge of the RNA structure, should significantly improve the initial phase of the drug discovery process.

Functional Polynucleotides

As mentioned above, once freed from the constraints of a complementary strand, polynucleotides can fold into a wide range of three-dimensional structures, leading to a diverse array of functions. Two specific types of functional polynucleotides are (*1*) aptamers, which bind noncovalently but selectively to ligands and (*2*) enzymes, which catalyze chemical reactions similar to protein enzymes. While a few examples of both natural aptamers and enzymes have been discovered, far more have been identified from synthetic combinatorial libraries through *in vitro* selection methods. The general approach to selection of functional polynucleotides is described below, followed by specific examples of nucleic acid–based aptamers and enzymes.

***In Vitro* Selection.** The concept of generating combinatorial libraries of molecules and then screening them for either structural or functional characteristics has reached many areas of chemistry and biology (97). Nucleic acid-based technology has followed this trend with the development of the *in vitro* selection or SELEX (Systematic Evolution of Ligands by EXponential amplification) method (98), in which a large population of randomized DNA or RNA sequences is generated and then screened for efficient binding to small molecules, proteins, metals, other nucleic acids, or even for catalytic ability (99). DNA and RNA molecules selected for binding to specific ligands are called *aptamers* (derived from aptus, "to fit"), while those *molecules that catalyze chemical reactions and fulfill criteria for enzyme activity* are referred to as *ribozymes* or *deoxyribozymes*. The generation of functional polynucleotides from randomized pools has provided considerable insight into the process of evolution at the molecular level and substantiated the idea that nucleic acids catalyzed important biological reactions before proteins were evolved for that purpose (100,101).

In the SELEX process (Fig. 15), a pool of DNA is chemically synthesized with a constant region (containing an RNA polymerase promoter and any other necessary sites for protein recognition) at the 5′-end, a run of randomized positions, and then another constant region at the 3′-end. The randomized positions are introduced by adding a mixture of all four phosphoramidites during the tetrazole-mediated coupling step in solid-phase synthesis. This yields a pool of 4^n total sequences, where n is the number of randomized positions. The pool is amplified via PCR, using primers that are specific to the two constant regions. If DNA aptamers or deoxyribozymes are desired, the pool is then subjected to its first round of selection. However, if RNA aptamers or ribozymes are to be selected, the DNA pool is first transcribed into RNA using RNA polymerase.

After the selection step, the enriched pool is then amplified. For DNA pools, PCR can be performed directly, while RNA pools require (*1*) RT to make the corresponding DNA, (*2*) PCR, and (*3*) and transcription to generate the amplified, enriched RNA pool. To allow molecular evolution to occur, rather than simple selection, mutagenic PCR can be performed. In this case, the DNA polymerase that is used to amplify the pool is prone to make errors during synthesis leading to incorporation of an incorrect nucleotide. This allows for single "mutations" to be introduced into selected sequences in an essentially random fashion. Subsequent rounds of selection and amplification ultimately lead to high affinity aptamers or high activity catalysts. Examples of these functional polynucleotides are described below.

Aptamers. A selection process, most often affinity chromatography, is used to select the sequences that bind the desired target. In this approach, the ligand of interest is covalently attached to the matrix used for chromatography. Those sequences that are retained on the column are either nonspecifically adsorbed to the matrix or specifically bound to the ligand. The adsorbed sequences can usually be rinsed away with a number of washes while the higher affinity, specifically bound sequences are retained. These sequences can then be eluted from the column with either a buffer that weakens the aptamer/small molecule interaction (such as a high salt buffer) or a buffer containing the free small molecule. The resulting enriched pool is then amplified and then subjected to further rounds of selection. The selection pressure can be increased by using higher temperature,

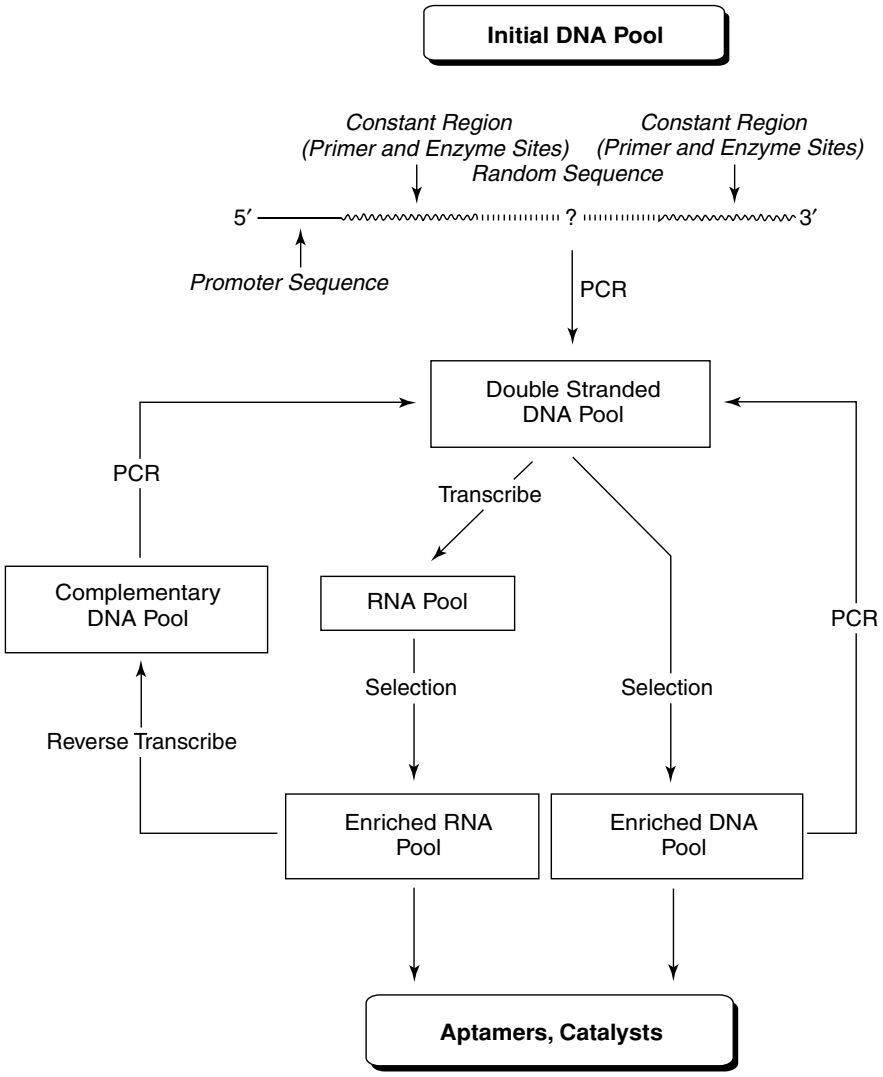

Fig. 15. Flow chart for *in vitro* selection of aptamers and catalysts from randomized DNA and RNA pools.

variations in ionic strength, and competitive binding, favoring retention of only the highest affinity aptamers on the column.

Table 3 collects examples of ligands used to select aptamers from either DNA or RNA pools. A variety of structural motifs have been effectively targeted with this procedure, including amino acids, organic dyes, and nucleotides. In addition, SELEX has been used to identify aptamers for protein targets, such as thrombin (101). It is well-known that many biological events occur because of the interaction of proteins with nucleic acids. However, the vast majority of proteins do not normally interact with DNA or RNA. Aptamers selected for binding to such

Table 3. Small Molecule Targets for Aptamer Selection

Small molecule	K_D, μm	Reference
ATP/adenosine	1	102
Guanosine	31	103
7-Methyl-GTP	0.5	104
Flavin	0.5	105
NAD	2.5	106
Arginine	0.33	107
Tryptophan	18	108
Streptomycin	1	109
Chloroamphenicol	2.1	110

proteins could disrupt the activity of these proteins, sparking great interest in the discovery of aptamers for protein recognition. The inhibition of protein activity is a primary strategy for pharmaceutical agents so that aptamers could conceivably be applied as drugs, although some modification of the DNA/RNA structure will likely be required in order to avoid enzymatic degradation *in vivo*.

Catalysts. SELEX has been used to create nucleic acids that are capable of catalyzing reactions. This idea was strongly influenced by the discovery of RNAs that catalyze RNA cleavage and ligation reactions (ribozymes) (112,113). Selection strategies have been used to screen combinatorial libraries of sequences for catalytic activity. Methods for selecting nucleic acid enzymes are somewhat different from aptamer selection strategies, since simple binding to an affinity column does not necessarily correlate with efficient catalysis. Thus, while binding to a column is a useful approach for isolation of desired sequences from the pool, the binding should be coupled to some chemical reaction. For example, selection of an RNA-cleaving DNA enzyme has been accomplished using a pool of DNA sequences with a single RNA linkage (incorporated through enzymatic extension) and capped with a biotin group (114). The randomized region is separated from the biotin cap by the RNA linkage. It is then passed through a streptavidin column, allowing all sequences to be retained on the column via the high affinity biotin/streptavidin interaction. Changing the buffer to one that promotes folding (eg, high ionic strength or addition of metal ions) allows those sequences that are able to cleave themselves to be released from the column in the selection step. These sequences are then amplified by PCR using a primer that has a biotin group attached to it. The pool is then ready for the next round of selection. Methods have also been used to create ribozymes and DNA enzymes that are capable of cleaving RNAs in a sequence-specific manner. Table 4 provides examples of reactions catalyzed by nucleic acid enzymes. These range from cleavage and ligation reactions, which have natural analogues, to glycosidic bond formation and insertion of metals into porphyrins. While the functional diversity of nucleic acid enzymes is likely to be limited in comparison with protein enzymes (because of the smaller number of functional groups present in the former), these polynucleotides are capable of performing an impressive array of functions.

Table 4. Reactions Catalyzed by Oligonucleotide Enzymes

Polynucleotide	Reaction catalyzed	Reference
RNA and DNA	Phosphodiester transfer of DNA and RNA	115–117
RNA and DNA	Phosphodiester hydrolysis of DNA and RNA	118–121
RNA and DNA	Acyl transfer	122–125
RNA	Glycosidic bond formation	126
RNA and DNA	Metal insertion into porphyrins	127,128

Use of Polynucleotides as Building Materials for Nanoconstruction

Biological structures are assembled on the nanometer or micron length scale and consist primarily of noncovalently associated subunits. The molecular recognition mechanisms that have evolved to permit assembly of such large structures provide stunning examples of "programmed synthesis," in which the final three-dimensional structure is encoded within the structures of the individual subunits. While it is the function of these assemblies that most often attracts our attention, it is the structure that permits the function. Moreover, the specific intermolecular forces that allow these assemblies to form are highly directional, allowing objects to be positioned spatially with great precision.

The sequence-specific hydrogen-bonding pattern that defines the DNA double helix protects the integrity of the genetic information and provides a molecular level mechanism for replication of the genome. However, the double helix is also beginning to serve as an inspiration for nanomaterials scientists, who see the relatively rigid, regular structure as an ideal construction scaffold (129). For example, when two objects are attached at the 5′-ends of complementary DNA strands, hybridization to form a duplex will position the two objects at a predetermined distance. Alternatively, DNA "three-way" and "four-way" junctions can be used to arrange objects in more complex patterns (Fig. 16). The "objects" positioned on the DNA scaffolding can range from small molecules that function as electron (130) or energy (131,132) donor and acceptor groups to inorganic nanoparticles (133–138). This nanoconstruction strategy is largely generalizable since a range of chemistries is available to permit attachment of the molecule of interest to a DNA oligomer.

Further elaboration into network structures can be realized if a cross-linking group is included. Two-dimensional networks formed from cross-linked four-way junctions have been imaged by atomic force microscopy (139). In addition, gold nanoparticles having dozens of copies of an attached DNA oligonucleotide can be cross-linked by another DNA oligomer to yield elegant superstructures, as revealed by electron microscopy (140). This self-assembly process also has immediate practical utility: when the nanoparticles cluster together, they undergo a color change from red to blue, providing a sensitive colorimetric indicator for the specific sequence of DNA required to form the cross-linked network (141).

Polynucleotides have other molecular recognition mechanisms that permit formation of stable three-dimensional structures. For example, folded RNAs are often stabilized by a tertiary interaction known as a GNRA tetraloop–receptor

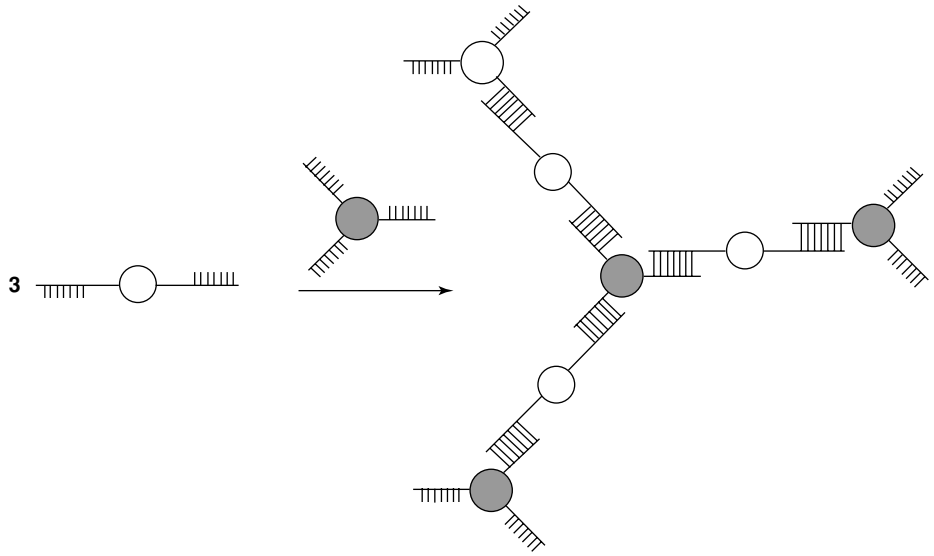

Fig. 16. Use of Watson–Crick base pairing to assemble organized, network structures.

motif. In these cases, a four-base single-stranded loop region of the RNA consisting of the sequence 5′-GNRA-3′ (where N = any base and R = G or A) binds within the major groove of a specific RNA sequence. This association does not involve Watson–Crick base pairing, yet it is sequence-specific. Short RNA sequences have been synthesized containing both a GNRA tetraloop and a receptor within a hairpin structure (142). The rigidity of the intervening duplex prevents an intramolecular association of the loop and receptor, leading to the formation of self-assembled structures through intermolecular interactions. RNA is unlikely to be a practical construction material because of its relatively high cost and low chemical stability. However, the rich variety of nonduplex secondary and tertiary structures exhibited by RNA polynucleotides can be exploited to form novel architectures.

Outlook

The biological polynucleotides DNA and RNA provide essential information for the maintenance and propagation of life. The structure and function of these polymers continue to be studied using the techniques of biology, chemistry, and physics. The growing application of polynucleotides in biotechnology and medicine, as laboratory reagents, and as nanomaterials can be attributed not only to their central importance in nature, but also to their ease of synthesis, manipulation, and characterization. The continued study and application of polynucleotides and their synthetic analogues in both biological and materials science contexts will undoubtedly lead to truly breathtaking discoveries in the future.

POLYSULFIDES

Introduction

Polysulfide polymers have the following general structure:

$$HS\text{—}(\text{—}R\text{—}S_x\text{—})\text{—}SH$$

1

where x is referred to as the rank and represents the average number of sulfur atoms in the polysulfide unit. This article is limited to polymers where R is an aliphatic group and $x > 1$. The rank x usually ranges from slightly less than 2 to about 4. A recent monograph (1) provides extensive information on the history, properties, and uses of aliphatic polysulfides. Other sulfur-containing polymers have been reviewed elswhere (2).

The history of polysulfides began over 150 years ago. In 1838, chemists in Switzerland reported that the reaction of chloraetherin (1,2-dichloroethane) with potassium polysulfide gave a rubbery, intractable, high sulfur semisolid. Subsequently there were reports of similar products obtained by various methods, but the first useful products were developed from studies in the late 1920s. This work led to the formation of the Thiokol Corp., which began production of the ethylene tetrasulfide polymer Thiokol® A in 1928. This was the first synthetic elastomer manufactured commercially in the United States. One of the first successful applications of Thiokol A [14807-96-6] was for seals where its resistance to solvents justified its relatively high price.

These new synthetic rubbers were accessible from potentially low cost raw materials and generated considerable worldwide interest. For a time, it was hoped that the polysulfide rubbers could substitute for natural rubber in automobile

tires. Unfortunately, these original polymers were difficult to process, evolved irritating fumes during compounding, and properties such as compression set, extension, and abrasion resistance were not suitable for this application.

During the 1930s, gradual improvements in the product and in how it was processed overcame some of the drawbacks of this material. Nonetheless, the applications were limited and Thiokol Corp. struggled to remain solvent. The first year Thiokol Corp. reported a profit was in 1941, 13 years after its foundation. The profitability was achieved when the U.S. Air Force discovered that the aliphatic polysulfides were useful as a fuel-resistant sealant for aircraft tanks and hoses. Polysulfides also began to be used as sealants for boat hulls and decks.

The most significant improvement came in the early 1940s when a method for preparing thiol-terminated liquid polysulfides was developed. Cure of the liquid polysulfides could be accomplished by oxidative coupling. So a rubber product could be compounded without the need of heavy mixing equipment. One of the first large-scale applications of the liquid polysulfides was as a binder for solid rocket fuel. From about 1946 until 1958, these binders were used in various rocket systems and the aliphatic polysulfides achieved commercial success. The switch to predominately liquid-fueled rockets in 1958 ended this phase of the polysulfide business.

Since then, uses have shifted toward civilian applications. Polysulfides have unusually good resistance to solvents and to the environment and they have good low temperature properties. They are particularly useful in a variety of sealant applications. For example, the outstanding resistance of polysulfides to petroleum products has made them the standard sealant for virtually all aircraft integral fuel tanks and bodies. Another important application is in insulating glass window sealants. Sealants based on liquid polysulfides have had an excellent record since the 1950s and are the worldwide market leader in these applications.

Polysulfides also have a long record as construction sealants. In 1953, the Lever House in New York was one of the first high rise buildings to abandon the traditional structural masonry for the attractive curtain wall construction. Originally, the joints were sealed with a typical oil-based caulk. Within 6 months, there were serious leakage problems through virtually every joint. The original sealant was removed and replaced with a polysulfide-based elastomeric sealant that could expand and compress with the movements of the panels. Much of this original sealant was still performing in the 1990s. Polysulfides became the first high performance elastomeric sealants to be used in building construction and have been applied successfully to many large-scale projects around the world.

Some of the early Thiokol solid rubbers are still made and used in printing rolls, solvent-resistant spray hoses, gaskets, and gas-meter diaphragms. Many of the polysulfide products have been in use since the 1940s with an excellent track record. Continuing improvements keep these products competitive.

Physical Properties

The commercial polysulfides are made from bis-chloroethylformal (formal) as shown later in equation (12). In some products 1,2,3-trichloropropane is added as a branching agent. Table 1 shows typical properties of polysulfides available from the Rohm and Haas Co.

Table 1. Properties of LP Liquid Polysulfide Polymers[a]

Property specification requirements	LP-31	LP-2	LP-32	LP-12	LP-3	LP-33	LP-977	LP-980
Viscosity at 25°C, Pa·s[a]	95–155	41–52.5	41–52.5	41–52.5	0.94–1.44	1.5–2	10–15	10–15
Moisture content, %	0.12–0.22	0.3 max	0.27 max	0.27 max	0.1 max	0.1 max	0.26 max	0.26 max
Mercaptan content, %	1.0–1.5	1.50–2.00	1.50–2.00	1.50–2.00	5.9–7.7	5.0–6.5	2.5–3.5	2.5–3.5
General properties								
Average molecular weight	8,000	4,000	4,000	4,000	1,000	1,000	2,500	2,500

[a] All products listed have flash point (PMCC) > 177°C. The specific gravity at 25°C ranges from 1.27 to 1.31. CAS Registry Number for all the LPs listed is [68611-50-7], ie, they are copolymers made from (**3**) and 1,2,3-trichloropropane, and sodium polysulfide.

[b] To convert Pa·s to P, multiply by 10.

[c] Cured compound.

[d] To convert MPa to psi, multiply by 145.

The solid polysulfide products are light brown millable rubbers. Thiokol ST [9065-29-6] (**2**) is made as in equation (12). Its Mooney viscosity (ML 1 + 3 at 100°C) ranges from 20 to 60. Thiokol FA [68611-48-3] is a copolymer made from formal (**3**) and ethylene chloride with sodium polysulfide; its Mooney viscosity (ML 1 + 4 at 121°C) ranges from 60 to 112. Both rubbers have excellent resistance to a wide range of chemicals. They also have low permeability to gases, water, and organic liquids. They have excellent low temperature flexibility, and they show superior resistance to the effects of sunlight, ozone, aging, and weathering.

$$HS(C_2H_4OCH_2OC_2H_4SS)_nC_2H_4OCH_2OC_2H_4SH$$

$$ClCH_2CH_2—O—CH_2—O—CH_2CH_2Cl$$

3

Chemical Properties

Curing Agents. The rich chemistry of the thiol end group provides versatility in modifying and curing polysulfide polymers. A recent review article describes reactions and mechanisms for curing agents commonly used with polysulfide polymers (3).

Two-Part Oxidative Curing. The most common means of curing polysulfides is by chain extension with oxidizing agents, eg, equation (1), where R—SH represents liquid polysulfide, O the oxidizing agent, and the product is a disulfide.

$$2\,R—SH + O \longrightarrow R—S—S—R + H_2O \quad (1)$$

Because thiols are easily oxidized, a host of organic and inorganic oxidants may be used. Mild oxidants such as oximes, nitro compounds, or air can be effective. Various oxidants have been used in special applications, but only a few are used in large-scale applications.

For a long time, lead(IV) oxide (PbO_2) was the most widely used oxidizing agent for the high molecular weight liquid polysulfides (mol wt > 2500). It was not suitable for lower molecular weight polymers because of the difficulty in controlling the strongly exothermic reaction. Since the early 1970s, manganese dioxide (MnO_2) has become the predominate oxidizing agent. Manganese dioxide [11129-60-5] has several advantages over lead, such as reduced toxicity, better pot life stability, and better light resistance, elasticity, and recovery for the cured rubber.

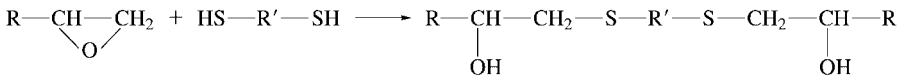
A newer curing system is sodium perborate monohydrate [10332-33-9] ($NaBO_2H_2O_2H_2O$). Since this is a well-known bleaching agent used in certain laundry cleaning formulations, it is produced on a large scale at a reasonable price. Sodium perborate offers several advantages as a curing agent for building sealants. One is that it has a light color rather than the dark color of manganese or lead oxides. Thus, it is nonstaining and sealants can be manufactured in a variety of colors. Sealants cured with sodium perborate have low modulus, excellent

elasticity, and outstanding resistance to water, weather, uv light, and mold, even without additives. They have good adhesion to most surfaces and are environmentally friendly.

One-Part Curing Systems. The inorganic peroxide curing agents for liquid polysulfides are activated by water. By formulating and packaging polysulfides under anhydrous conditions, one-part sealants are prepared. These cure when exposed to atmospheric moisture and are used in construction sealant applications. The curing agents most commonly used have been calcium peroxide, zinc peroxide/amine, zinc/lithium peroxide, or manganese dioxide. Sodium perborate is also effective in preparing light-colored, faster curing, one-part sealants.

Polysulfide polymers' resistance to moisture vapor transmission is a positive characteristic for applications like insulating glass sealants, but it is a drawback for one-part moisture curing sealants because it leads to relatively slow cure rates. Toray Thiokol has developed new faster curing one-part compositions based on polysulfides with silylthio end groups (4).

Epoxy Resins. Polysulfides may also be cured by reaction with epoxy resins according to the reaction in equation (2). Amines or other catalysts are used and often primary or secondary amine resins are cured together with the polysulfide.



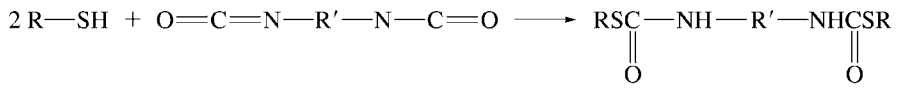
(2)

LP-3, the lowest molecular weight liquid polysulfide, is used as a reactive diluent to lower the viscosity of the formulation and to facilitate mixing and application of the resin. The liquid polysulfide also acts as a flexibilizer. The addition of LP-3 to epoxy formulations gives products with good flexibility, high impact strength, excellent chemical resistance, and good adhesion. ELP-3 [117527-71-6] (**4**) is an epoxy-terminated polysulfide derived from LP-3. An advantage of this product is its low odor, especially in comparison with the thiol-terminated LP-3.

4

Diisocyanates or Polyisocyanates. The thiol end groups of the liquid polysulfides are quite reactive with isocyanates (eq. 3). Typical diisocyanates, such as 1,3-toluene diisocyanate (*m*-TDI) and diphenylmethane-4,4′-diisocyanate (MDI), are effective in curing liquid polysulfides. Using liquid polysulfides instead of the common hydroxy-terminated polymers brings the advantages of the polysulfide to the cured product. Thus, good chemical and solvent resistance, weatherability, adhesion, etc, can be attained. The isocyanate-cured systems have some advantages over oxidative-cured systems, such as improved adhesion to plastic substrates. There are also drawbacks to this method of curing. For example, water must be eliminated from the formulation to prevent foaming. This requires additional steps to dry all of the formulation ingredients (fillers, plasticizers, liquid polysulfide, etc) and to protect them from atmospheric moisture. Also, the mix ratio must be tightly controlled to give close to stoichiometric amounts of

polysulfide and isocyanate. Actually, a slight excess of isocyanate is usually used. For the oxidative-cured formulations, a significant excess of oxidant is used and the ratio is more forgiving. Furthermore, the isocyanates are more hazardous to work with than the commonly used oxidizing curing agents.



(3)

Phenolic Resins. At elevated temperatures, phenolic resins are cured with polysulfide resins through a condensation reaction. The product may be considered a block copolymer of the rigid phenolic resin and the flexible polysulfide. Thus, the polysulfide acts to flexibilize the resulting polymer.

Miscellaneous Curing Reactions. Other functional groups can react with the thiol terminal groups of the polysulfides to cross-link the polymer chains and build molecular weight. For example, aldehydes can form thioacetals and water. Organic and inorganic acids or esters can form thioesters. Active dienes such as diacrylates can add to the thiols (5). Examples of these have been mentioned in the literature, but none have achieved commercial significance.

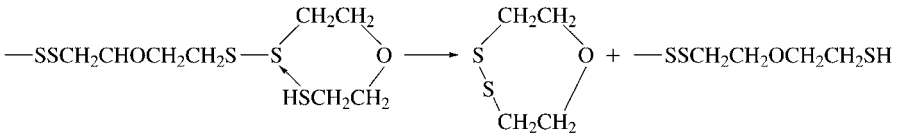
Reactions of the Disulfide Group. Besides the thiol end groups, the disulfide bonds also have a marked influence on both the chemical and physical properties of the polysulfide polymers. One of the key reactions of disulfides is nucleophilic attack on sulfur (eq. 4). The order of reactivity for various thiophiles has been reported as $(C_2H_5O)_3P > R^-, HS^-, C_2H_5S^- > C_6H_5S^- > C_6H_5P, CN^- > SO_3^{2-} > OH^- > 2,4\text{-}(NO_2)_2C_6H_3S^- > N_3^- > SCN^-, I^-, C_6H_5NH_2$ (6). These thiophiles are capable of splitting the disulfide bond and thus reducing the molecular weight of the polymers.

(4)

An important aspect of this is the splitting of the polymer chain with thiol (eq. 5) or mercaptide ion (thiol + base catalyst). In fact, sodium sulfide or organic monothiols, eg, mercaptoethanol or decylmercaptan, are utilized to lower the molecular weight of polysulfides or to limit the extent of curing reactions.

(5)

This reaction also plays a role in the degradation of polysulfides. A backbiting mechanism as shown in equation (6) results in formation of the cyclic disulfide (**5**). Steam distillation of polysulfides results in continuous gradual collection of (**5**). There is an equilibrium between the linear polysulfide polymer and the cyclic disulfide. Although the linear polymer is favored and only small amounts of the cyclic compound are normally present, conditions such as steam distillation, which removes (**5**), drives the equilibrium process toward depolymerization.



5 (6)

Another aspect of the splitting reaction (eq. 5) is that it allows for the potential recycle of cured polysulfide. Oxidatively cured polysulfides can be broken down by adding low molecular weight liquid polysulfide with mixing and heating. The resulting liquid material can be reworked and cured again (7). A related reaction is disulfide interchange (eq. 7). This process leads to redistribution of the polymers. For example, if thiol-terminated polymers made from different monomers are combined, they redistribute to form a random polymer. Thus, block copolymers of polysulfides are difficult to obtain. One way to make use of this phenomenon is shown in equation (8). Here a high molecular weight thiol-terminated polysulfide polymer is reduced to a lower molecular weight polymer with hydroxyl terminals. In this way a different functionality can be introduced into the end group.

$$\mathrm{RSSR} + \mathrm{R'SSR'} \longrightarrow 2\,\mathrm{RSSR'} \tag{7}$$

$$\mathrm{RSSR} + \mathrm{HOCH_2CH_2SSCH_2CH_2OH} \longrightarrow 2\,\mathrm{RSSCH_2CH_2OH} \tag{8}$$

Disulfide interchange also affects the physical properties of the cured polysulfide polymers. Polysulfide polymers undergo stress relaxation in a manner markedly different from conventional rubbers. Stress applied to stretch a sample of polysulfide rubber rapidly falls to zero. There is no change in the chemical and physical properties of the polymer recovered after the tests. The polysulfide polymer can be repeatedly recycled through the relaxation process. With vulcanized hydrocarbon rubbers, the stress decay takes place much more slowly and the activation energy for the relaxation is higher. Studies have attributed the behavior of the polysulfides to interchange between the polysulfide linkages of adjacent polymer chains (8). Addition of free sulfur or free thiol groups dramatically increases the rate of relaxation. Small amounts of free thiol can increase the rate several hundredfold (8).

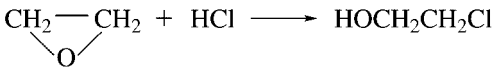
Disulfides are susceptible to attack by strong oxidizing agents and this can result in decomposition of polysulfides. For example, nitric acid causes violent decomposition of polysulfide polymers.

Manufacture and Processing

Polysulfide polymers are made commercially according to the reactions shown in equations (9), (10), (11), (12). Details of the process and alternative approaches have been described (1,9). Although other dihalides can be used, its favorable

economics, minimal competition with ring formation, and the desirable physical properties of the resulting polymer have made bis-chloroethylformal the monomer of choice. Only occasionally are other dihalides used in special applications. 1,2,3-Trichloropropane [96-18-4] is sometimes added as a branching agent.

Many of the reagents used are hazardous and require special equipment and handling. There is an ongoing effort to minimize waste from the processes. Excess 2-chloroethanol (eq. 10) is removed from the product by distillation and recycled. Little waste is generated in equations (9) and (10). In the polymerization reaction (eq. 11), excess sodium polysulfide is required to drive the reaction to completion. Specialized equipment is used for washing and collecting the high molecular weight solid polymer in order to optimize its recovery. The wash water contains NaCl, the excess sodium polysulfide, and only small amounts of organics. The amount of excess Na_2S_x is minimized. High molecular weight solid (**2**) is converted to liquid polysulfide (**2**) by reaction with NaSH and Na_2SO_3.



(9)

(10)

(11)

(12)

Formulation. Polysulfide-based sealants are formulated with appropriate ingredients to obtain the desired properties for a particular application. A typical formulation contains liquid polysulfide polymer, curing agent, cure accelerators (bases) or retarders (acids), fillers, plasticizers, thixotropes, and adhesion promoters.

For a two-part (A and B) sealant, Part A consists of liquid polysulfide, filler, plasticizer, thixotrope, and adhesion promoter. Part B contains the curing agent, plasticizer, a small amount of filler, and the accelerator or retarder. Part A can be mixed on any type of mixer that will ensure thorough dispersion. Generally, the equipment should utilize a double-arm kneading action mixer or a combination kneading action and high speed dispersing blade. Representative types are Change Can, Ross Planetary or Power Mixer, Meyers Mixer, Kneader Extruder, and Hockmeyer Mixer. Optimum dispersion of the fillers is obtained on a paint mill where the fillers are subjected to a grinding action that breaks down the agglomerates. If the mixer itself provides sufficient grinding of the pigments, then milling can be eliminated. The curing paste (Part B) can be prepared either by ball milling or three-roll paint milling. Paint milling is generally preferred; however, solvent-based pastes are best prepared in a ball mill to minimize solvent

loss. In order to obtain the most uniform results, pastes containing the accelerators or retarders should be aged for at least two weeks at room temperature prior to use.

The one-part sealant bases require drying the ingredients. Predrying the ingredients before manufacturing is cumbersome and expensive. Other alternatives include vacuum drying during manufacture, azeotropic distillation to remove water before moisture-sensitive components are added, and use of desiccants. The most common method is through the use of the desiccant barium oxide (10). The mixing is done on equipment as described, except the processes are carried out under an atmosphere of dry nitrogen and the final step is to combine the pastes into a single mix.

Specifications and Testing

Typical specifications for the polysulfide polymers are summarized in Table 1. Specifications for the sealants vary widely depending on the specific application and the needs of the applicators. Standards for sealant testing vary in different countries. Ultimately, the tests should simulate the environment the sealants will be exposed to and measure their performance under these conditions.

Examples of typical tests for sealants include those for stability, curing rate, and physical properties of cured sealants. Stability varies with formulation and storage temperature, and may range from 3 months to over 1 year. Curing characteristics include tack-free time (which varies with relative humidity and can range from hours to days), work life, and cure time. Cured sealant tests include adhesion to appropriate substrates, measurement of physical and mechanical properties (eg, tensile strength, elongation, modulus, hardness, compression and recovery, and low temperature flexibility), and assessing the effects of exposure to conditions in the environment where they will be used (uv light, water or special fluids, and a range of temperatures).

Health and Safety

As might be expected for sulfur-containing polymers, the polysulfides have a characteristic odor. Although the odor is somewhat objectionable, it probably arises from small amounts of low molecular weight dimercaptans or from cyclic sulfides or disulfides. The lower molecular weight polymers exhibit the strongest odor. Toxicity tests conducted on a representative LP brand liquid polysulfide used in a typical sealant application indicate that the polymers are not eye irritants and have a low order of oral toxicity ($LD_{50} > 5$ g/kg). Tests on the lower molecular weight liquid polysulfide products show similar findings. These materials are not eye or skin irritants, do not cause allergic skin reactions, and are not toxic when administered orally ($LD_{50} > 3.4$ g/kg). Rats exposed to a low molecular weight LP at a level of 230 mg/L for 4 h developed apparent eye and respiratory tract irritation. But this level far exceeds that which would be encountered in an industrial setting. Under the criteria set forth under OSHA's Hazard Communication Standard (29 CFR 1910.1200), liquid polysulfide products are classed as nonhazardous.

When considering sealants or other formulated products, the health and safety considerations relating to the other ingredients should be taken into account.

Economic Aspects

Worldwide production capacity of liquid polysulfides is about 36,000 t, with manufacturing sites in the United States, Japan, and Germany. Total consumption is about 27,000 t. Approximately 50% is for insulating glass sealants, 30% for construction applications, and ~10% for aircraft sealants. In addition, about 900 t of the solid polysulfide rubbers are sold each year.

Most of the polysulfide sales are in Europe, the United States, and Japan. Polysulfide sealants have ~83% of the market share of insulating glass sealants in Europe, 35% in the United States, and a total of ~60% worldwide. Polysulfides have only a modest share of the building sealant market. Polysulfides are virtually the only sealant specified for aircraft integral fuel tanks worldwide. In addition, they comprise about 90% of other aircraft sealant applications. The total volume used in the aircraft sealant market fluctuates with aircraft construction and repair.

Overall, demand for polysulfides in the United States is expected to remain flat for the next 5 years, but a 2–3% average annual increase in demand is expected in other countries (11) (see SEALANTS).

Uses

Insulating Glass Sealants. One of the largest scale applications of polysulfide polymers is as a sealant for insulating glass windows. The window consists of two panes of glass separated by a hollow spacer that is filled with desiccant to remove moisture or volatiles from the air space. This prevents condensation and fogging of the window at low temperature. Dual seal windows contain a primary seal along the edge of the spacer that is usually made from polyisobutylene (PIB). PIB has good resistance to moisture vapor transmission and extends the life of the unit. The outer edge of the unit is closed off with the secondary seal of polysulfide or other sealant material. The intermediate air space is sometimes filled with an inert gas such as argon to improve insulation and reduce noise. Polysulfide sealants have low permeability for water vapor or inert gas and can be used either in dual- or single-seal units. In the dual-seal units, if there are small leaks in the primary seal, the polysulfide provides a good backup. Other sealants such as silicones have high permeability, and can only be used in dual-seal units that rely on the integrity of the primary seal.

Besides water vapor and gas diffusion, other requirements for good edge sealants are water resistance, uv resistance, heat/cold resistance (−40 to 80°C), adhesion to glass and metal, and good characteristics for application. Polysulfide sealants have maintained an excellent record in use since the 1950s. Development of new polysulfides and sealant formulations continues in order to meet market needs of the 1990s.

Aircraft Sealants. Polysulfides have been used for sealing fuel tanks and aircraft structural components since the 1940s. There are stringent requirements for these sealants. They must have outstanding resistance to fuels and excellent adhesion to many different materials such as various metal alloys and protective coatings used in aircraft construction. The sealants must also perform in extremely variable weather conditions (12). The polysulfides have an excellent performance record.

Construction Sealants. In the 1950s, curtain wall construction became dominant in high rise buildings. This technique requires sealing of the joints against wind and weather. Sealants used up until that time were not suitable to withstand the temperature changes, sun, wind, rain, vibration, etc. Polysulfide-based sealants were developed for this application and have served in many large-scale projects since that time. Polysulfide construction sealants are used to seal glass in aluminum frames, concrete moving joints, steel/stone joints, and in other applications. For earlier sealants, in order to obtain good adhesion to the variety of substrates, primers were usually used. Besides the disadvantage of requiring application of the primer, there was the risk that the primer would not be properly or uniformly applied. More recently, polysulfide sealants have been developed that incorporate adhesion promoters in the formulation and eliminate the need for primers (13).

Below-Ground Sealants. Immersion in water for long periods or continuous exposure to high humidity are especially difficult conditions for organic-based materials to withstand. Sealants for use in water purification plants or wastewater treatment plants have special demands for physical, chemical, and microbiological properties. Polysulfide-based sealants have proved themselves useful in this area. Special consideration must also be given to the other ingredients, eg, fillers, plasticizers, adhesion promoters, or curing agents, in formulating for these applications (14).

The chemical and fuel resistance of polysulfides makes them useful as sealants and coatings for secondary containment areas, where they prevent chemicals, solvents, fuels, etc from seeping into the ground in the event of spillage or a storage tank leak (15). Polysulfide-based coatings and sealants are also used for bridges, air fields, and road construction.

Epoxy Flexibilizers. Polysulfides are useful as flexibilizers in epoxy resin formulations. Compounders can target the properties desired for a particular application through the selection and balance of the epoxy, the liquid polysulfide–epoxy ratio, curing agent, and filler. Most of the compounds are two-component: one containing the epoxy resin, the second containing polymer and curing agent. Probably, the most important factor is the ratio of polysulfide to epoxy resin. The most effective ratio ranges from 2 to 1 liquid polysulfide to epoxy. Liquid polysulfide–epoxy formulations are used for a variety of applications including adhesives, protective coatings, barrier coatings, electrical potting compounds, resilient plastic tooling materials, aggregate liquid polysulfide–epoxy mortars, and surface sealers.

Water Dispersions. Polysulfide products are offered as aqueous dispersions (Thiokol WD-6). These are useful for applying protective coatings to line fuel tanks and for concrete, wood, and in some cases fabrics, felt, leather, and paper.

It has been found that a stable emulsion can be made that contains both LP and manganese oxide curing agent. The emulsion can be thinned and applied as a spray coating. After it is applied, water evaporates and the LP cures to form a solid rubber (16).

Rubber Articles. The solid polysulfide rubber products Thiokol FA and Thiokol ST are used in the manufacture of printing rollers, printing blankets, gas-meter diaphragms, O-rings, and specialty molded items.

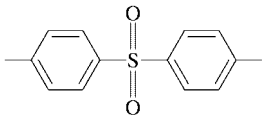
POLYSULFONES

A polysulfone is characterized by the presence of the sulfone group as part of its repeating unit. Polysulfones may be aliphatic or aromatic. Aliphatic polysulfones were synthesized by radical-induced copolymerization of olefins and sulfur dioxide and characterized many years ago. However, they never demonstrated significant practical utility because of their relatively unattractive physical properties, notwithstanding the low cost of their raw materials (1,2). The polysulfones discussed in this article are those based on an aromatic backbone structure. The term polysulfones is used almost exclusively today to denote aromatic polysulfones.

Polysulfones comprise a class of amorphous thermoplastic polymers characterized by high glass-transition temperatures, good mechanical strength and stiffness, and outstanding thermal and oxidative resistance. These polymers are characterized by the presence of the para-linked diphenylenesulfone group



as part of their backbone repeat units. By virtue of their mechanical, thermal, and other desirable characteristics, these polymers enjoy an increasingly wide and diversified range of commercial applications. The basic repeat unit of any polysulfone contains sulfone, aryl, and ether units as part of the main backbone structure. These polymers are thus often referred to in the polymer literature as poly(arylethersulfone)s. Other names include polysulfones, polyethersulfones, and polyarylsulfones, and the lack of standardized nomenclature has often resulted

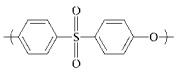
Table 1. Chemical Structures and Glass-Transition Temperatures (T_g) of Polysulfone, Polyethersulfone, and Polyphenylsulfone

Polymer	CAS nos.	Repeat unit structure	T_g, °C
Polysulfone (PSF)	[25135-51-7]		185
Polyethersulfone[a] (PES)	[25667-42-9]		220
Polyphenylsulfone (PPSF)	[25608-64-4]		220

[a]PES repeat unit structure can alternately be drawn as



in confusion over the meaning of a designation. The different designations are somewhat arbitrary and all refer to the same class of polymers.

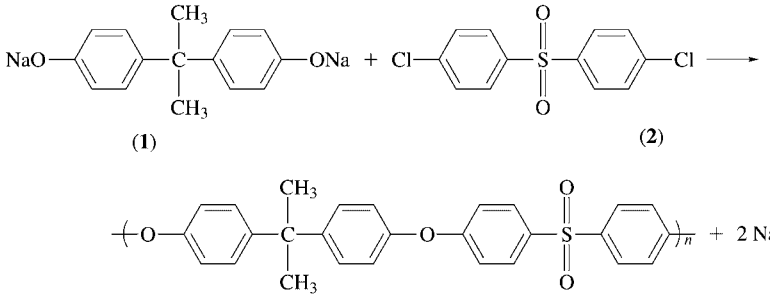
In addition to sulfone, phenyl, and ether moieties, the main backbone of polysulfones can contain a number of other connecting units. The most notable such connecting group is the isopropylidene linkage, which is part of the repeat unit of the well-known bisphenol A based polysulfone. It is difficult to clearly describe the chemical makeup of polysulfones without reference to the chemistry used to synthesize them. There are several routes for the synthesis of polysulfones, but the one which has proved to be most practical and versatile over the years involves aromatic nucleophilic substitution. In this polycondensation, equimolar quantities of 4,4′-dihalodiphenylsulfone [usually dichlorodiphenylsulfone (DCDPS)] and a bisphenol are allowed to react in the presence of base to form the aromatic ether bonds and eliminate an alkali salt as a by-product. Today, this route is employed almost exclusively for the manufacture of polysulfones on a commercial scale.

The diphenylsulfone group is supplied to the repeat unit of all polysulfones by DCDPS. Differentiation among various polysulfones comes from the choice of bisphenol. Three different and commonly used bisphenols lead to three commercially important polysulfones referred to generically by the common names polysulfone (PSF), polyethersulfone (PES), and polyphenylsulfone (PPSF). Other common shorthand designations for polysulfone and polyphenylsulfone are PSU and PPSU, respectively. The repeat units of these polymers are shown in Table 1.

Polymerization

Nucleophilic Substitution Route. Commercial synthesis of poly(arylethersulfone)s is accomplished via the nucleophilic substitution polycondensation route. This synthesis route, discovered at Union Carbide in

the early 1960s (3,4), involves reaction of the bisphenol of choice with 4,4′-dichlorodiphenylsulfone in a dipolar aprotic solvent in the presence of an alkali base. Examples of dipolar aprotic solvents include *N*-methyl-2-pyrrolidinone (NMP), dimethyl acetamide (DMAc), sulfolane, and dimethyl sulfoxide (DMSO). Examples of suitable bases are sodium hydroxide, potassium hydroxide, and potassium carbonate. In the case of polysulfone (PSF) synthesis, the reaction is a two-step process in which bisphenol A [80-05-7] is first converted *in situ* to the dialkali metal salt (1) by reaction with base (eg, two molar equivalents of NaOH), followed by the nucleophilic substitution reaction of (**3**) with 4,4′-dichlorodiphenylsulfone [80-07-9] (2). Polysulfone is typically prepared as described in Reference 5 according to equation (1), where $n = 40–60$. The minimum degree of polymerization is dictated by the minimum molecular weight required to achieve useful mechanical properties from the polymer. For polysulfone, this corresponds to a reduced viscosity of about 0.35 dL/g (in chloroform at 25°C and 0.2 g/dL concentration).



(1)

The rate of polymerization in this type of reaction depends on both the basicity of the bisphenol salt and the electron-withdrawing capacity of the activating group (in this case sulfone) in the dihalide monomer. Also affecting reactivity is the electronegativity of the halogen in the dihalide monomer. The difluoride-based sulfone monomer is more reactive than the dichloride and thus gives higher polymerization rates, but the dichloride is by far the more economical raw material. Another important consideration in reactivity and the attainment of high molecular weight is the purity of the 4,4′-isomer in the dichlorodiphenyl sulfone monomer. Chlorines in the meta position on the phenyl ring are not activated and do not undergo nucleophilic displacement. Hence, a significant presence of the 3,4′-isomer of the sulfone monomer can act as a monofunctional terminating species for the polycondensation and prevent the attainment of target molecular weights. Factors governing rates of reaction have been discussed (6).

DMSO is an effective solvent for the polymerization as it affords good solubility for both the polymer and the disodium salt of bisphenol A [2444-90-8]. Typical polymerization temperatures for polysulfone are in the range 130–160°C. At temperatures below 130°C, the polymerization slows down considerably because of poor solubility of the disodium salt of bisphenol A.

The reaction of NaOH with bisphenol A generates water. This water must be thoroughly removed from the system to allow the reaction to be driven to

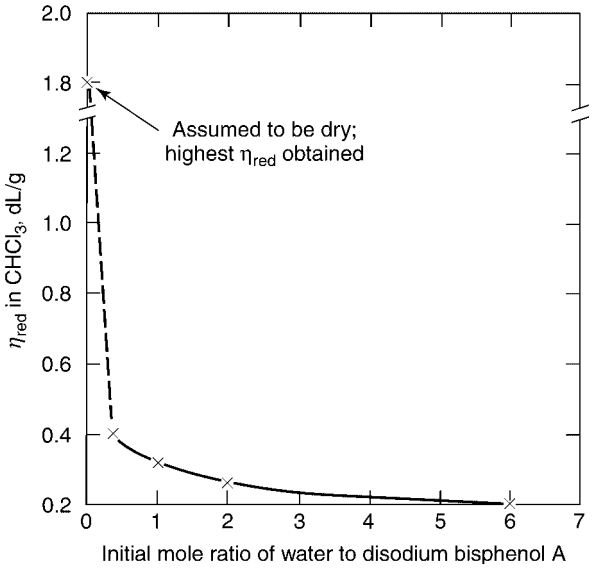


Fig. 1. Effect of water presence in polysulfone polymerization on maximum attainable polymer reduced viscosity.

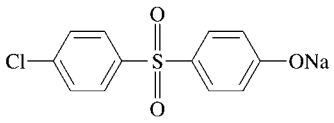
completion, and more importantly, to prevent hydrolysis of the DCDPS monomer (**4**). Failure to remove all of the water prior to the introduction of DCDPS results in regeneration of NaOH, which rapidly reacts with DCDPS to form the monosodium salt of 4-chloro-4′-hydroxydiphenylsulfone [18995-09-0] (**6**) (6).



(**3**)

With as little as 0.5% hydrolysis of the sulfone monomer, the polymerization stoichiometric balance is sufficiently upset to prevent high molecular weight polymer from being achieved. The dependence of maximum attainable PSF molecular weight on water content during polymerization can be inferred from Figure 1.

Molecular weight control for this type of condensation polymerization, eg, by nucleophilic substitution, is typically achieved by one of several methods: (*1*) the addition of a monohalogen compound such as chloromethane once target molecular weight has been achieved in the reaction vessel (such compounds terminate chain growth by reacting with available sodium phenate end groups to form nonreactive methoxyl end groups on the chains); (*2*) the use of excess DCDPS monomer to limit the maximum attainable molecular weight by means of stoichiometric imbalance; and (*3*) the use of monohydric phenols or monohalo-activated aromatic compounds as chain terminators. Generally, the first or the second method (or a combination of them) is used. In the case of termination methods (*2*) or (*3*), the terminator

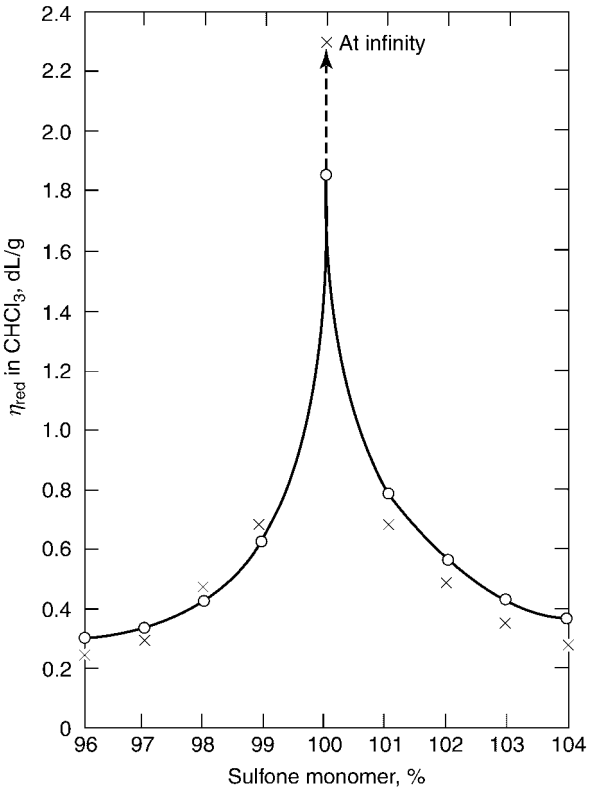


Fig. 2. Effect of stoichiometric imbalance in polysulfone polymerization on maximum attainable polymer reduced viscosity where × is theoretical and ○, experimental.

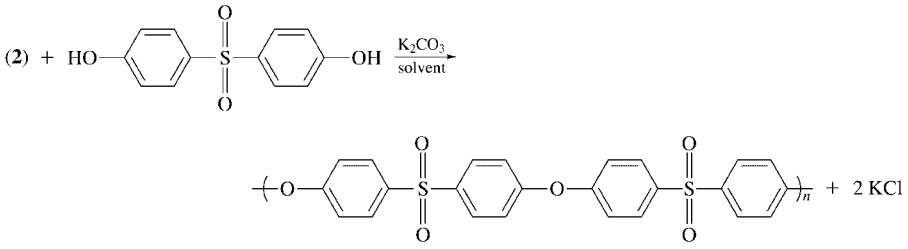
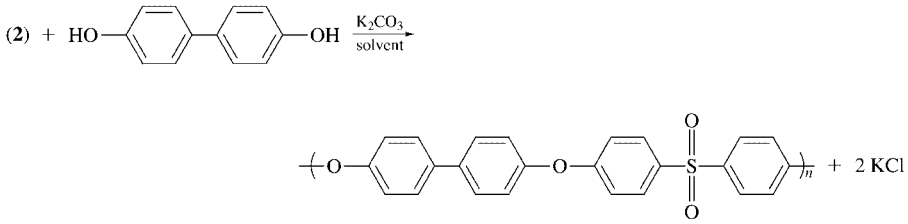
is typically added at the beginning of the reaction along with the monomer. The actual effect of any such terminator depends on its relative reactivity as well as the amount added. The terminator unbalances the stoichiometry of the two monomers, thereby placing a ceiling on the maximum attainable degree of polymerization according to Carothers' principle of functionality. A mole ratio of unity for the two parent monomers results in the highest attainable molecular weight as illustrated in Figure 2. The most favorable reaction rates are also achieved by maintaining the monomer ratio at or very near unity.

The polymerization of polyethersulfone (PES) and polyphenylsulfone (PPSF) are analogous to that of PSF, except that in the case of these two polymers, solvents that are higher boiling than DMSO are needed because of the higher reaction temperatures required. Diphenyl sulfone, sulfolane, and NMP are examples of suitable solvents for PES and PPSF polymerizations. Chlorobenzene or toluene are used as cosolvents at low concentrations. These cosolvents form an azeotrope with water as they distill out of the reaction mixture, thereby keeping the polymerization medium dehydrated. Potassium carbonate is a suitable choice for base. The syntheses of PES and PPSF also differ from that of PSF in that the reaction is carried out in a single-step process. In other words, the formation of the dipotassium salt of the bisphenol is not completed in a separate first step. Equations (2)

and (3) represent polymerizations based on the dipotassium salts of bisphenol S and biphenol to make PES and PPSF, respectively.



(2)



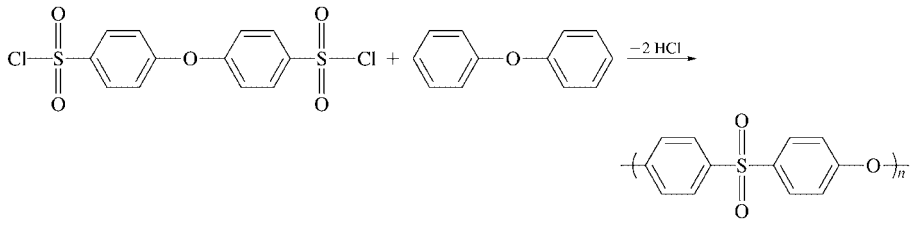
(3)

An alternative synthesis route for PES involves the partial hydrolysis of dichlorodiphenyl sulfone (**4**) with base to produce 4-chloro-4′-hydroxydiphenylsulfone [7402-67-7] followed by the polycondensation of this difunctional monomer in the presence of potassium hydroxide or potassium carbonate (7).

As a variation on the base-catalyzed nucleophilic displacement chemistry described, polysulfones and other polyarylethers have been prepared by cuprous chloride-catalyzed polycondensation of aromatic dihydroxy compounds with aromatic dibromo compounds. The advantage of this route is that it does not require that the aromatic dibromo compound be activated by an electron-withdrawing group such as the sulfone group. Details of this polymerization method, known as the Ullman synthesis, have been described (8).

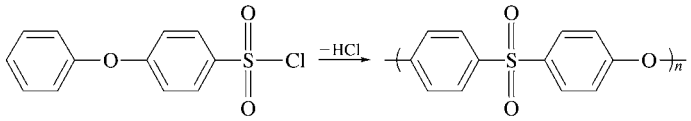
A method for the polymerization in nondipolar aprotic solvents has been developed and reported (9,10). The method relies on phase-transfer catalysis. Polysulfone is made in chlorobenzene as solvent, with (2.2.2)cryptand as catalyst (9). Less reactive crown ethers require dichlorobenzene as solvent (10). High molecular weight polyphenylsulfone can also be made by this route in dichlorobenzene; however, only low molecular weight PES is achievable by this method. Crosslinked polystyrene-bound (2.2.2)cryptand is found to be effective in these polymerizations which allow simple recovery and reuse of the catalyst.

Other Synthesis Routes. Several alternative routes to the nucleophilic substitution synthesis of polysulfones are possible. Polyethersulfone can be synthesized by the electrophilic Friedel–Crafts reaction of bis(4-chlorosulfonylphenyl)ether [121-63-1] with diphenyl ether [101-84-8] (11–13).



(4)

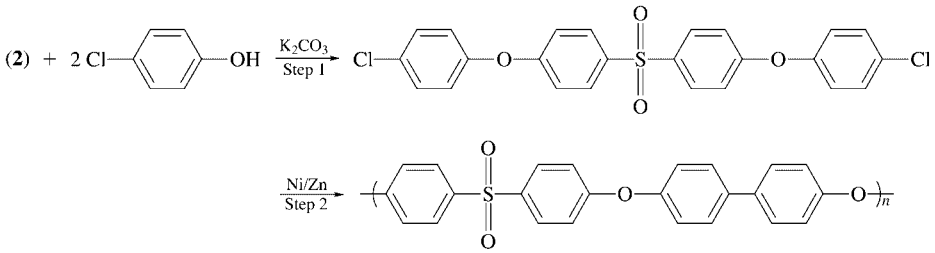
The same reaction can be carried out with 4-chlorosulfonyldiphenyl ether [1623-92-3] as a single monomer.



(5)

The single-monomer route (eq. (5)) is preferred, as it gives more para-linked repeat units and therefore a straighter backbone than the two-monomer route. Other sulfone-based polymers can be similarly produced from sulfonyl halides with aromatic hydrocarbons. The key step in these polymerizations is the formation of the carbon–sulfur bond. High polymers are achievable via this synthesis route although the resulting polymers are not always completely linear.

An elegant synthesis method which is specific to sulfone polymers containing phenyl–phenyl linkages (such as PPSF) is the nickel-catalyzed coupling of aryl dihalides. The scheme for this synthesis is composed of two steps. First, an aromatic dihalide intermediate is formed which carries the backbone features of the desired polymer. This aromatic dihalide intermediate is then self-coupled in the presence of zero-valent nickel, triphenylphosphine, and excess zinc to form the biphenyl- or terphenyl-containing polymer. Application of this two-step scheme to PPSF can be depicted as follows.



The first step in this scheme is a classical aromatic nucleophilic substitution. Details of the method have been expounded upon (14–17). References 14 and 15 are concerned with the synthesis of the diaryl halide intermediate, whereas References 16 and 17 discuss the synthesis of the polymers, with emphasis on the polymerization of PPSF by this route.

Oxidative coupling of aromatic compounds has been applied successfully to synthesize a polyarylethersulfone via the Scholl reaction (18). High molecular weight polymer was obtained by treatment of 4,4′-di(1-napthoxy)diphenylsulfone and 4,4′-di(napthoxy)benzophenone with ferric chloride. Equimolar amounts of the Lewis acid are required and the method is limited to napthoxy-based monomers and other systems that can undergo the Scholl reaction.

Properties

Structure–Property Relationships. The characteristic feature of each of the polymers in Table 1 is the highly resonant diaryl sulfone grouping. As a consequence of the high oxidation state of the sulfur atom being in its highest state of oxidation and the enhanced resonance of the sulfone group in the para position, these resins offer outstanding thermal stability and resistance to thermal oxidation. The thermal stability is further augmented by the high bond dissociation energies inherent in the aromatic backbone structure. As a result, these polymers can be melt-fabricated at temperatures of up to 400°C with no adverse consequences. The high degree of oxidative stability also allows for prolonged or continuous exposure to temperatures of anywhere between 150 and 190°C, depending on polymer, formulation, and use conditions. The ether linkages in these polymers contribute to chain flexibility, leading to mechanical toughness and favorable melt rheological properties for conventional thermoplastic fabrication. The relatively inert ether and sulfone backbone functionalities contribute to resistance against hydrolysis and chemical attack by acids and bases. Medical and food contact applications for polysulfones are possible in part because of this characteristic.

The high glass-transition temperatures (T_g) of polysulfones are attributed to the rigid phenyl rings in the backbone and also the sulfone group, which increases T_g by providing strong dipole–dipole interactions between chains and by restricting rotation of the aromatic units relative to other connecting groups. The ether groups in these polymers are the main flexibilizing units, and the T_gs of polysulfones are inversely related to the ether content in the backbone on a repeat unit weight basis. Other connecting groups either increase or decrease chain rigidity and T_g according to an increase or decrease in the conformal freedom and polarity of those units. The most convenient way to tailor properties of a polysulfone to specific needs is through the appropriate selection of the bisphenol. The T_gs of polysulfones based on the polycondensation of DCDPS with different bisphenols are listed in Table 2.

The three polysulfones in Table 1 exhibit several important common attributes, but there are distinguishing features for each member of this group. Examination of the structures of the repeat units shows that a primary distinguishing feature of PES is that it contains almost double the sulfone group content on a weight basis compared to PSF. Another differentiation is that the flexibilizing isopropylidene unit is absent in PES. As a consequence of these structural changes, the T_g of PES is 35°C higher than that of PSF. On the other hand, because the sulfone group is the most hygroscopic moiety in the backbone of these polymers and the isopropylidene group is hydrophobic, the moisture uptake at

[b]Glass-transition temperatures reported to nearest 5°C.

equilibrium is significantly lower for PSF than it is for PES (Table 3). The ability to minimize water absorption of a polymer is desirable for most engineering applications. Thus, backbone structure of a polysulfone is tied to physical properties and ultimately to performance and suitability for various applications.

Mechanical properties of aromatic polysulfones are also intimately tied to backbone structure. For the achievement of good strength and toughness together with favorable melt processing characteristics, the first and foremost requirement is a linear (unbranched) and para-linked chemical structure for the aryl groups in the backbone. The mechanism of permanent deformation is not the same in all polysulfones. Rather, it is dependent on subtle backbone structural features, the best illustration of which is the significant improvement in impact and toughness properties of PPSF over those of PES and PSF. The dependence of polysulfone mechanical toughness on backbone structural features has been discussed in detail (19).

Physical, Chemical, and Optical Properties. Aromatic polysulfones possess several common key attributes including high T_gs (generally >170°C) and a high degree of thermal oxidative stability (Table 3). Thermal oxidative stability of PSF, PES, and PPSF can be inferred from the thermogravimetric data shown in Figure 3. Because of their fully amorphous nature, these resins exhibit optical transparency. The T_g of polysulfones reduced via nucleophilic polycondensation can be tailored by the choice of the bisphenol as illustrated in Table 2. By virtue of the chemically nonlabile aromatic ether backbone, these polymers exhibit superb resistance to hydrolysis in hot water and steam environments. Furthermore, they can withstand acidic and alkali media over a wide range of concentrations and temperatures.

In addition to conferring transparency on these polymers, the amorphous noncrystallizable nature of polysulfones assures minimal shrinkage during

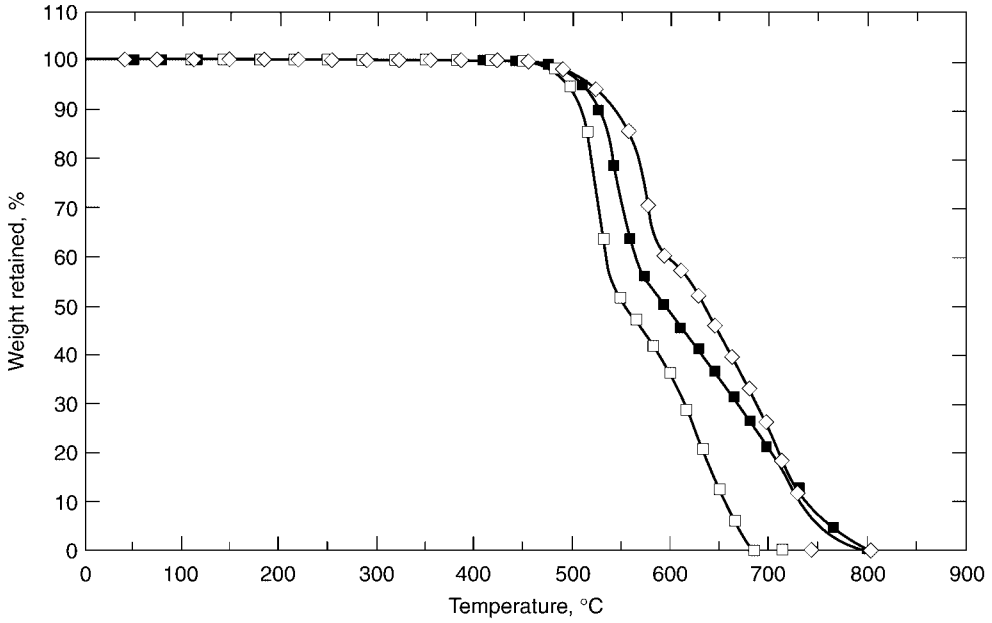

Fig. 3. Thermogravimetric analysis (TGA) curves in air for PSF (□), PES (■), and PPSF (◇). TGA in nitrogen at a heating rate of 10°C/min. From Ref. 17.

fabrication of the resins into finished parts. The absence of crystallinity also assures dimensional stability during the service life of the parts where high use temperatures are encountered. Good dimensional stability is important to many structural, engineering, and electronic applications.

Although commercially available polysulfones are transparent in their natural form, they show a slight yellow-amber tinge. This color is related to the high melt processing temperatures required during resin manufacture and finishing steps. Great progress has been made over the years in controlling and minimizing color (yellowness) in polysulfones. Among the three commercially available polysulfones, the bisphenol A based polymer (PSF) exhibits the lowest color and highest transmittance of visible light. The light transmittance value ranges given in Table 3 are based on the color ranges that are typical for commercially available grades. Because of their highly aromatic character, sulfone polymers exhibit high refractive indices relative to amorphous polymers based on olefinic or other aliphatic backbones.

Because of the presence of the sulfone moiety, polysulfones are slightly hygroscopic. Absorbed water expands linear dimensions of a polysulfone of the order of 0.010–0.012% for every 0.1 wt% of moisture absorbed. This dimensional change is relatively small, but it can be important in applications where very close dimensional tolerances are a requirement. In addition to effecting small dimensional changes, absorbed moisture causes a slight plasticization of the plastic, contributing to some lowering of stiffness and strength in hot, wet environments. This effect is again small and can easily be compensated for by judicious part design and engineering.

Mechanical Properties. Polysulfones are rigid and tough with practical engineering and strength and stiffness properties even without reinforcement. Their strength and stiffness at room temperature are high compared to traditional aliphatic backbone amorphous plastics. The polymers exhibit ductile yielding over a wide range of temperatures and deformation rates. High unnotched impact resistance has been tied to a second-order (β) transition which is observed in these polymers under dynamic mechanical thermal analysis. The β-transition occurs at around -100°C and is believed to be due to two mechanisms. The first involves 180° flips of aromatic units around the ether bond (20). The second has been proposed to be a concerted motion of the sulfone group with complexed, absorbed water (21). The presence of moisture increases the magnitude of the β-transition peak, although moisture is not necessary for the existence of the transition. The effect of polysulfone backbone structure on the sub-T_g relaxations has been the subject of detailed study (22).

The room temperature mechanical properties of bisphenol A, bisphenol S, and biphenol-based polysulfones are given in Table 4. The elongation at yield of these polymers is highest for PPSF, while PES offers slightly higher tensile strength than the other two polymers. Otherwise, the tensile and flexural properties for these three polymers are quite comparable. The main distinguishing

feature in the mechanical properties of PPSF is its "supertough" behavior exemplified by a very high value for notched impact strength. In addition, PPSF has the ability to retain a high degree of ductility after prolonged heat exposure. The data in Table 4 represent short-term mechanical properties under simple loading conditions. These values should be regarded as typical values for generic polysulfone, polyethersulfone, and polyphenylsulfone of practical molecular weights. Assessment of the mechanical performance of an engineering polymer for a specific end use should include consideration of the long-term aspects such as creep and fatigue properties where applicable. Temperature and environmental factors should also be taken into consideration.

The effect of temperature on tensile stress–strain behavior of PSF is depicted in Figure 4. The resin continues to exhibit useful mechanical properties at temperatures up to 160°C under prolonged or repeated thermal exposure. This temperature limit is extended to about 180°C in PES and PPSF. The tensile and flexural properties as well as resistance to cracking in chemical environments can be substantially enhanced by the addition of fibrous reinforcements such as chopped glass fiber. Mechanical properties at room temperature for glass fiber-reinforced polysulfone, polyethersulfone, and polyphenylsulfone are shown in Table 5.

Flammability. An important consideration in the selection of thermoplastic resins involves the need for good flame retardancy characteristics (see FLAMMABILITY). Polysulfones exhibit excellent inherent burning resistance characteristics compared with those of many engineering thermoplastics. The wholly aromatic polysulfones such as PES and PPSF possess particularly outstanding flame retardancy and very low smoke release characteristics. The flammability of PSF is also good but can be enhanced further by the addition of small proportion of a nonhalogen-based flame retardant. This forms the basis of the Udel P-1720 commercial polysulfone grade from British Petroleum. Flammability properties of various polysulfones are given in Table 6.

Table 7. Electrical Properties of PSF, PES, and PPSF

Property	ASTM test method	PSF	PES	PPSF
Dielectric strength (3.2 mm[a]), kV/mm	D149	16.6	15.5	14.6
Volume resistivity, ohm·cm	D257	7×10^{16}	9×10^{16}	9×10^{15}
Dielectric constant	D150			
At 60 Hz		3.18	3.65	3.44
At 10^3 Hz		3.17	3.65	3.45
At 10^6 Hz		3.19	3.52	3.45
Dissipation factor	D150			
At 60 Hz		0.0008	0.0019	0.0006
At 10^3 Hz		0.0008	0.0023	–
At 10^6 Hz		0.0051	0.0048	0.0076

[a]Thickness.

Electrical Properties. Polysulfones offer excellent electrical insulative capabilities and other electrical properties as can be seen from the data in Table 7. The resins exhibit low dielectric constants and dissipation factors even in the GHz (microwave) frequency range. This performance is retained over a wide temperature range and has permitted applications such as printed wiring board substrates, electronic connectors, lighting sockets, business machine components, and automotive fuse housings, to name a few. The desirable electrical properties along with the inherent flame retardancy of polysulfone make these polymers prime candidates in many high temperature electrical and electronic applications.

Resistance to Chemical Environments and Solubility. As a rule, amorphous plastics are susceptible, to various degrees, to cracking by certain chemical environments when the plastic material is placed under stress. The phenomenon is referred to as environmental stress-cracking (ESC), and the resistance of the polymer to failure by this mode is known as environmental stress-cracking resistance (ESCR). The tendency of a polymer to undergo ESC depends on several factors, the most important of which are applied stress, temperature, and the concentration of the aggressive species. Polysulfones, being completely amorphous, exhibit susceptibility to stress cracking by some organic environments. The potency of the stress-cracking agent is generally related to the match between the solubility parameter of the solvent and that of the polymer. For example, PSF, which has a solubility parameter $\delta = 21.8\ (J/cm^3)^{1/2}$, resists aliphatic hydrocarbons

Table 8. Resistance[a,b] of Natural (Unreinforced) PSF, PES, and PPSF Resins to Various Chemical Environments[c]

	Ranking		
Environment	PSF	PES	PPSF
Aliphatic hydrocarbons	1	1	1
Aromatic hydrocarbons	10	9	7
Alcohols/Glycols	2	2	2
Esters	9	8	6
Ketones	10	8	7
Chlorinated hydrocarbons	10	8	8
Aliphatic amines	2	1	1
Aromatic amines	8	7	6
Electrolyte solutions	1	1	1
Acids[b]	3	2	1
Bases	3	2	1
Ionic surfactants	1	1	1
Nonionic surfactants	5	4	3

[a]Ranking codes: 1 = excellent; 5 = good; 10 = very poor.
[b]Data are for comparative purposes only; actual resistance depends on many factors including stress, temperature, concentration, and exposure duration.
[c]Stress-cracking resistance is substantially enhanced in the presence of reinforcement such as glass fibers.
[d]Nonoxidizing.

(lower δ) and most alcohols (higher δ), but readily undergoes stress cracking by ketones, which have δ-values sufficiently close to that of the polymer.

The exact mechanism of ESC of a polymer is still not completely understood, but in essence it involves a weakening of the secondary (intermolecular) bonds between neighboring polymer chains because of the solubility of the chemical in the polymer. As a result, a number of crazes are generated at the stressed surface of the polymer; if the number of crazes is large the stress level is moderated and cracking is prevented, or at least delayed. If only a few crazes form, on the other hand, they tend to grow and propagate as cracks, resulting in rupture.

The ESCR performance of PSF, PES, and PPSF is summarized in Table 8. These polymers are highly resistant to hydrolysis by hot aqueous media, including boiling water, high pressure steam, mineral acids and alkalis, and salt solutions. This resistance is usually a key reason behind the selection of polysulfones over the other engineering plastics like polycarbonates, polyesters, polyamides, and polyetherimides (23). The resistance to stress cracking by organic solvents varies according to the one-dimensional solubility parameter concept described above. The most problematic solvents are aromatics, chlorinated hydrocarbons, ketones, and esters. The resistance of the three polysulfones to these and other environments in general follows the ascending order PSF < PES < PPSF, as illustrated in Table 8. When the aggressive environment does not actually dissolve or swell the polymer, the ESCR problem can usually be overcome by the use of a glass

fiber-reinforced grade of the polysulfone resin of interest. Glass fiber or any other effective reinforcing agent usually provides enough added load-bearing capability to compensate for the ESCR deficiency of the polymer.

Solubility of the three commercial polysulfones follows the order PSF > PES > PPSF. At room temperature, all three of these polysulfones as well as the vast majority of other aromatic sulfone-based polymers can be readily dissolved in a handful of highly polar solvents to form stable solutions. These powerful solvents include NMP, DMAc, pyridine, and aniline. 1,1,2-Trichloroethane and 1,1,2,2-tetrachloroethane are also suitable solvents but are less desirable because of their potentially harmful health effects. In addition to being soluble in the aforementioned list, PSF is also readily soluble in a host of less polar solvents by virtue of its lower solubility parameter. These solvents include tetrahydrofuran (THF), 1,4 dioxane, chloroform, dichloromethane, and chlorobenzene. The relatively broad solubility characteristics of PSF have been key in the development of solution-based hollow-fiber spinning processes in the manufacture of polysulfone asymmetric membranes (see MEMBRANE TECHNOLOGY). The solvent list for PES and PPSF is short because of the propensity of these polymers to undergo solvent-induced crystallization in many solvents. When the PES structure contains a small proportion of a second bisphenol comonomer, as in the case of RADEL A (British Petroleum) polyethersulfone, solution stability is much improved over that of PES homopolymer.

Radiation Resistance. Polysulfones exhibit resistance to many electromagnetic frequencies of practical significance, including microwave, visible, and infrared. Especially notable is the excellent resistance to microwave radiation, which has contributed to the excellent fit of polysulfones in cookware applications. Polysulfone also shows good resistance to x-rays, electron beam (24), and gamma (25,26) radiation under many practical application conditions.

Like the majority of aromatic polymers, polysulfones exhibit poor resistance to uv light. Polysulfones absorb in the uv region, with attendant discoloration and losses in mechanical properties due to polymer degradation at, and directly beneath, the exposed surface. Prolonged exposure to sunlight is therefore not recommended for these polymers in neat form. Retention of mechanical integrity is improved with pigmentation and/or reinforcement of the resin, and almost full resistance to uv is achieved when the resins are pigmented with high loadings of carbon black. Painting of the part is another option that can be used to avoid the effects of uv light. The retention of mechanical integrity of PPSF upon exposure to uv light is somewhat better than it is for either PSF or PES, especially when the resin is in an opaque form by virtue of pigmentation. This greater apparent resistance to uv is a consequence of the more inherently ductile nature of PPSF compared to both PSF and PES.

Fabrication

As with most linear amorphous polymers, polysulfones are fully thermoplastic materials and readily flow at temperatures $\geq 150^{\circ}C$ above their respective T_gs. The backbone structure is extremely thermally stable during melt processing, remaining unchanged even when subjected to several melt fabrication cycles.

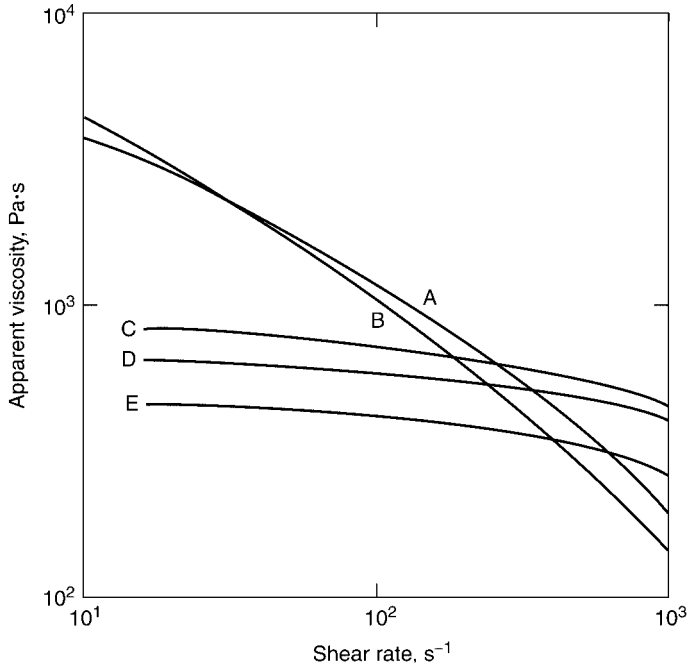

Fig. 5. Melt viscosity dependence on shear rate for various polymers: A, low density polyethylene at 210°C; B, polystyrene at 200°C; C, UDEL P-1700 (PSF) at 360°C and RADEL R-5000 (PPSF) at 380°C; D, LEXAN 104 polycarbonate at 315°C; and E, RADEL A-300 (PES) at 380°C. To convert Pa·s to P, multiply by 10.

Polysulfones can be melt-processed on conventional equipment used for thermoplastics fabrication. Typical melt viscosity behavior as a function of shear rate is shown in Figure 5 for polysulfones and some other polymers. As illustrated in these plots, the shear thinning characteristics of polysulfones are much more muted than they are for aliphatic backbone polymers such as the polyethylene and polystyrene shown to illustrate this point. The rheological behavior of polysulfones is fundamentally more similar to that of bisphenol A polycarbonate.

Injection molding is the most common fabrication technique. Polymer melt temperature for PSF injection molding can be in the range 325–400°C depending on part thickness, length, complexity, and other factors. PES and PPSF are generally molded using temperatures in the range 360–400°C. Mold temperatures suitable for PSF injection molding are in the range 100–170°C; for PES and PPSF this range is 120–190°C. Lower mold temperatures can be used but are not recommended as they can result in unacceptably high levels of molded-in residual stresses in the parts. Because of the relatively high viscosities of polysulfones and the limited shear-thinning they exhibit over the practical range of shear rates, generous sizing of runners and gates in mold design is recommended. The insensitivity to shear has the beneficial effect of resulting in parts that are low in molecular orientation, and hence are much more nearly isotropic than those molded from many other thermoplastics.

Polysulfones are easily processed by other fabrication techniques commonly used for thermoplastics, including extrusion, thermoforming, and blow molding. Extrusion into film, sheet, tubing, or profile can be accomplished on conventional extrusion equipment with a metering screw of moderate depth having a 2.5:1 compression ratio. Stock temperatures during extrusion of PSF, PES, and PPSF are in the range 315–375°C depending on grade of resin viscosity and type of product being produced. A common fabrication technique is sheet extrusion followed by thermoforming. Prior to thermoforming, the sheet must be dry to prevent foaming. The surface temperatures required to produce the necessary sag are in the range 230–260°C for PSF and 275–305°C for PES and PPSF. Blow molding of polysulfones is possible on most commercial blow molding equipment, provided the equipment is capable of maintaining melt temperatures in the range 300–360°C.

Once formed, parts made of polysulfones (particularly those produced by injection molding) can be annealed to reduce molded-in stress. Increased stiffness, dimensional stability, and resistance to creep during service life of the part are generally enhanced if molded-in stresses are reduced. More importantly, the resistance of the part to ESC or crazing is usually improved if molded-in stresses are minimized. Annealing can be easily accomplished either in an air oven or a glycerol bath. Typical time–temperature conditions for the proper annealing of polysulfones in an air oven are 1 h/170°C for PSF and 1 h/200°C for PES and PPSF. Annealing at similar temperatures by immersion in hot glycerol can be accomplished in 1–5 min. Because overannealing may result in a reduction of impact toughness, the use of conservative molding practices, most notably a hot mold and appropriate part and gating designs, to produce low stress parts is preferred whenever contact with aggressive chemical environments is anticipated for the component during its service life.

Prior to melt processing, the resin must be dried to reduce the level of absorbed atmospheric moisture, which can be as high as 0.8 wt%. For injection-molding operations, a moisture content below 0.05 wt% is appropriate, but for extrusion applications such as film or sheet the moisture level should not exceed 0.01 wt%. The presence of significant amounts of moisture during melt processing causes bubbling and foaming of the trapped moisture, which leads to structural and appearance defects in the fabricated parts. Drying to the targeted 0.05 wt%, moisture can be easily achieved in a circulating hot air oven or a dehumidifying hopper dryer in 3–4 h at 135–165°C. Drying temperatures can be increased to 180°C for PES and PPSF, if it is desired to cut down on drying time.

Post-Fabrication Operations. Sulfone polymers are amenable to most post-fabrication operations. Because of their high T_gs and inherent toughness characteristics, the resins can be machined with conventional metal working techniques such as drilling, tapping, sawing, turning, milling, and routing. They can also be polished to a high gloss. Cutting or machining oil is generally not required or recommended, but water can be used to reduce heat. Sulfone polymers can be joined by a variety of techniques. Joining sulfone polymers to themselves or to similar materials often employs ultrasonic welding, heat staking, and spin welding. Solvent bonding can also be used for self-bonding, but it is generally not recommended and should only be used as a last resort. Traditional adhesive bonding can be used, especially when polysulfone must be joined to a dissimilar material. Products manufactured from sulfone resins can also be easily finished and

decorated by printing, painting, laser etching, or by the application of hot stamping patterns. Metallic patterns and finishes can be applied by vacuum metalizing, cathode sputtering, as well as flame/arc spraying.

Blends and Alloys

The blending of two or more polymers to achieve unique property combinations of the parent polymers continues to be an attractive way to tailor existing commercial polymers to specific end use requirements. The blending of polysulfones with other polymers presents opportunities, but at the same time poses some significant technical challenges. Miscibility of PSF or PES with any nonsulfone-based polymer is extremely rare. Some examples of limited miscibility have been uncovered and discussed (27–31). Only one of these cases involves stable one-phase behavior in the melt state (31). The inert nature of the phenyl, sulfone, and ether moieties precludes interchain reactions, such as ester–ester interchange, which can facilitate the achievement of miscibility in otherwise immiscible systems. As a result, blends of PSF or PES with other nonsulfone-based polymers generally rely on interfacial adhesion and good shear mixing during compounding to produce an intimately mixed blend with good mechanical compatibility. None of the binary blends comprising PSF, PES, and PPSF are miscible, although their blends form mechanically compatible mixtures with relatively stable phase morphologies. Properties of these blends are available (32–34). Blends comprising two or more polysulfones can provide a convenient way to achieve specific properties or simply to reduce cost (35).

One of the factors precluding blending of polysulfones and commodity polymers such as styrenics and polyolefins is the fact that these polymers do not possess the requisite thermal stability to endure melt processing in the temperature range that is required for polysulfones. As a result, there are few commercially available polymer types that make good candidates for blending with polysulfones. These are, in general, other engineering thermoplastics, such as polycarbonates, some polyesters, polyimides , polyaryletherketones, and poly(phenylene sulfide) (PPS). Polymer blends involving polysulfones are discussed in numerous patents and journal articles, eg, a study (36) dealing with the interaction energies of polysulfones with several polymers as they relate to miscibility. Properties of PSF–PPS blends are well documented (37,38). Another study (39) describes the mechanical and rheological properties of PSF when blended with a thermotropic liquid crystalline polyester.

For reasons that are not fully understood, PPSF exhibits generally improved compatibility characteristics over either PSF or PES in a number of systems. An example of this is blends of PPSF with polyaryletherketones (40,41). These blends form extremely finely dispersed systems with synergistic strength, impact, and ESCR properties. Blends of PPSF with either PSF or PES are synergistic in the sense that they exhibit the supertoughness characteristic of PPSF at PSF or PES contents of up to 35 wt% (33,34). The miscibility of PPSF with a special class of polyimides has been discovered and documented (42). The miscibility profile of PPSF with a group of high temperature ($T_g > 230^\circ C$) polysulfones has been reported (43).

Proprietary blend formulations based on polysulfone, polyethersulfone, and polyphenylsulfone are sold commercially by British Petroleum to meet various end use requirements. The blends based on polysulfone are sold under the Mindel trademark. A glass fiber-reinforced blend based on PES is offered under the trade name Radel AG-360. This offers most of the performance characteristics of 30% glass fiber-reinforced polyethersulfone, but at a lower cost. Two blend product lines are offered based on PPSF. These are designated as the Radel R-4000 and R-7000 series products. The former is a lower cost alternative to Radel R PPSF homopolymer offering most of the performance attributes unique to PPSF. The R-7000 series of resins have been formulated for use in aircraft interiors for civil air transport. They exhibit a very high degree of resistance to flammability and smoke release.

Health and Safety

Polysulfones are chemically inert polymers for the most part and to date (ca 2000) have known negative health effects. These polymers have been used for many years in applications where safety is of utmost importance. Numerous grades comply with U.S. and international governmental regulations for direct contact with food. Polysulfone has been in use for food processing (qv), plumbing, and medical and prosthetic device applications since the 1960s. Various grades of polysulfone, polyethersulfone, and polyphenylsulfone meet U.S. Food and Drug Administration (FDA) requirements for direct food contact. Similar approvals are given by the U.S. National Sanitation Foundation under Standard 51 permitting use of certain polysulfone, polyethersulfone, and polyphenylsulfone resins in food processing equipment. Radel R polyphenylsulfone complies with *U.S. Pharmacopeia* Class VI requirements for use in medical device components. Many regulatory bodies around the world have sanctioned the use of various sulfone polymer grades in potable water delivery applications. Various commercial grades of polysulfone, polyethersulfone, and polyphenylsulfone are also listed in Underwriters Laboratories' Recognized Component Directory.

The thermally and oxidatively stable backbones of polysulfones preclude development of any significant amount of toxic, volatile by-products from thermal degradation when the resins are heated during melt processing. The polymers remain essentially odorless when injection-molded at temperatures of up to 380°C. At temperatures above 380°C, trace amounts of sulfur dioxide, methane, and other organic compounds and residual solvents begin to evolve. As for other plastic materials, adequate ventilation of the molding area is recommended when injection molding polysulfones.

Uses

Sulfone polymers are used in a wide variety of applications that take advantage of their hydrolytic and acid/caustic stability, clarity, high heat-deflection temperatures, as well as a number of other features. These application areas include cookware and appliances, electrical and electronic packaging and substrates,

Table 9. Examples of Uses for PSF, PES, and PPSF

Area/Use	PSF	PES	PPSF
Food service/food processing			
Microwave cookware	×	×

automotive and aerospace parts and components, and a host of industrial and plumbing uses. Table 9 shows some of the more typical applications for each of PSF, PES, and PPSF. Because they share common fundamental features, PSF, PES, and PPSF could, in principle, be used interchangeably for many applications. In those instances, PSF is selected whenever possible because of its lower cost. PES is selected over PSF in applications requiring additional heat resistance or chemical resistance. PPSF offers a substantial improvement over PES in hydrolytic stability, impact, chemical resistance, and flammability resistance, while it maintains the same thermal resistance capabilities as those of PES. It is generally selected for most demanding end uses, when both PSF and PES fall short of meeting requirements.

The polysulfones resin family offers many desirable properties for cookware products in both commercial and consumer markets. In addition to those mentioned above, other noteworthy features are resistance to hot greases and detergent solutions and microwave transparency. Coffee carafes, steam-heated food service trays, and a variety of plastic parts used in household appliances are a few examples of these uses. Sulfone polymers are also used in automated dairy processing components as an alternative to stainless steel because of their clarity, hydrolytic stability, and resistance to sterilization.

Household plumbing components have been successfully produced from polysulfone and polyphenylsulfone, and this is a growing applications area for these polymers. Such fabricated parts offer excellent hydrolytic stability as well as resistance to dissolved chlorine, which is commonly used by many municipalities as part of water purification regimes. In some cases, polysulfones are used in chemical processing equipment because of their very good resistance to some chemical environments. Examples of such uses include corrosion-resistant pipe, pumps, filter modules, support plates, and tower packing. In the case of severe chemical environments glass-reinforced grades can be used to enhance resistance and prolong service life.

In the electrical and electronic industry, sulfone polymers are used in many applications including lighting sockets, circuit breaker components, fuses, and a wide variety of connectors. High dielectric strength, low dissipation across wide temperature and frequency ranges, and flame retardancy characteristics make PSF, PES, and PPSF suitable for these and other applications. The high dimensional stability of these polymers makes them suitable for a variety of precision business machine parts. PPSF is also used as a magnet wire coating because of its high temperature capability, high dielectric strength, and toughness (44).

Medical applications such as instrument trays, devices, and handles are also commonly fabricated from PSF and PPSF. Products made from PSF and PPSF offer resistance to sterilization by using boiling water, steam, gamma radiation, ethylene oxide, and a wide range of disinfectants. PPSF is especially preferred when the sterilization environments are more severe.

One unique application area for PSF is in membrane separation uses. Asymmetric PSF membranes are used in ultrafiltration, reverse osmosis, and ambulatory hemodialysis (artificial kidney) units. Gas-separation membrane technology was developed in the 1970s based on polysulfone hollow-fiber membranes. The PRISM (Monsanto) gas-separation system based on this concept has been a significant breakthrough in gas-separation technology (see MEMBRANE TECHNOLOGY). Additional details are available on the use of polysulfone in membrane separations (45), as well as gas transport properties of polysulfone and polyethersulfone (46–50).

There are four commercial suppliers that manufacture polysulfones: BP Amoco Corp. in the United States, BASF Corp. in Germany, Sumitomo Chemical Co. in Japan, and Gharda Chemicals in India. A listing of the resins supplied by each of these companies along with the trade names particular to each of these suppliers is shown in Table 10. All four companies supply a polyethersulfone-type product. Polysulfone is supplied by three of the four (see Table 10) and, as of this writing, BP Amoco is the sole supplier of polyphenylsulfone.

Table 10. Manufacturers and Trade Names of Commercially Available Polysulfones[a]

Supplier	Polysulfone types offered	Trade name
BP Amoco	PSF	Udel
	PES	Radel A
	PPSF	Radel R
BASF	PSF	Ultrason S
	PES	Ultrason E
Gharda Chemicals	PSF	Gafone S
	PES	Gafone
Sumitomo	PES	Sumikaexcel

POLYURETHANES

The polymers known as polyurethanes include materials that incorporate the carbamate group, —NHCOO—, as well as other functional groups, such as ester, ether, amide, and urea. The name polyurethane is derived from ethyl carbamate, known as urethane. Polyurethanes are usually produced by the reaction of a polyfunctional isocyanate with a macroglycol, a so-called polyol, or other reactants containing two or more groups reactive with isocyanates. Often a combination of a macroglycol and a short-chain glycol extender is used to produce segmented block copolymers. The macroglycols are based on polyethers, polyesters, or a combination of both. In recent years diamines have also been used as comonomers in order to achieve higher reaction rates in molding and spray applications. In addition to the linear thermoplastic polyurethanes, obtained from difunctional monomers, branched or cross-linked thermoset polymers are made with higher functional monomers. Linear polymers have good impact strength, good physical properties, and excellent processibility, but limited thermal stability (owing to their thermoplasticity). Thermoset polymers, on the other hand, have higher thermal stability but sometimes lower impact strength (rigid foams). The higher functionality is obtained with higher functional isocyanates (polymeric isocyanates), or with higher functional polyols. Cross-linking is also achieved by secondary reactions. For example, urea groups are generated in the formation of water-blown flexible foams. An isocyanato group reacts with water to form a carbamic acid, which dissociates into an amine and carbon dioxide, with the latter acting as a blowing agent. The amine reacts with another isocyanate to form a urea linkage. Further reaction of the urea group with the isocyanate leads to cross-linking via a biuret group. Water-blown flexible foams contain urethane, urea, and some biuret groups in their network structure. Urea-modified segmented polyurethanes are manufactured from diisocyanates, macroglycols, and diamine extenders. Polyurethane network polymers are also formed by trimerization of part of the isocyanate groups. This approach is used in the formation of rigid polyurethane-modified isocyanurate (PUIR) foams.

The addition polymerization of diisocyanates with macroglycols to produce urethane polymers was pioneered in 1937 by O. Bayer (1). The rapid formation of high molecular weight urethane polymers from liquid monomers, which occurs

even at ambient temperature, is a unique feature of the polyaddition process, yielding products that range from cross-linked networks to linear fibers and elastomers. The enormous versatility of the polyaddition process allowed the manufacture of a myriad of products for a wide variety of applications.

The early German polyurethane products were based on tolyene diisocyanate (TDI) and polyester polyols. In addition, a linear fiber, Perlon U, was produced from the aliphatic 1,6-hexamethylene diisocyanate (HDI) and 1,4-butanediol. Commercial production of flexible polyurethane foam in the United States began in 1953. In Germany a toluene diisocyanate consisting of an isomeric mixture of 65% 2,4-isomer and 35% 2,6-isomer was used in the manufacture of flexible foam, whereas in the United States the less expensive 80:20 isomer mixture was used. In 1956, DuPont introduced poly(tetramethylene glycol) (PTMG), the first commercial polyether polyol; the less expensive polyalkylene glycols appeared by 1957. The availability of the lower cost polyether polyols based on both ethylene and propylene oxides provided the foam manufacturers with a broad choice of suitable raw materials, which in turn afforded flexible foams with a wide range of physical properties. Polyether polyols provide foams with better hydrolytic stability whereas polyester polyols give superior tensile and tear strength. The development of new and superior catalysts, such as Dabco (triethylenediamine) and organotin compounds, has led to the so-called one-shot process in 1958, which eliminated the need for an intermediate prepolymer step. Prior to this development, part of the polyol was treated with excess isocyanate to give an isocyanate-terminated prepolymer. Further reaction with water produced a flexible foam.

The late 1950s saw the emergence of cast elastomers, which led to the development of reaction injection molding (RIM) at Bayer AG in Leverkusen, Germany, in 1964. Also, thermoplastic polyurethane (TPU) elastomers and Spandex fibers were introduced during this time. In addition, urethane-based synthetic leather was introduced by DuPont under the trade name Corfam in 1963.

The late 1950s also witnessed the emergence of a new polymeric isocyanate (PMDI) based on the condensation of aniline with formaldehyde. This product was introduced by the Carwin Co. (later Upjohn and Dow) in 1960 under the trade name PAPI. Similar products were introduced by Bayer and ICI in Europe in the early 1960s. The superior heat resistance of rigid foams derived from PMDI prompted its exclusive use in rigid polyurethane foams. The large-scale production of PMDI made the coproduct 4,4′,-methylenebis(phenyl isocyanate) (MDI) readily available, which has since been used almost exclusively in polyurethane elastomer applications. Liquid derivatives of MDI are used in RIM applications, and work has been done since the 1990s to reinforce polyurethane elastomers with glass, graphite, boron, and aramid fibers, or mica flakes, to increase stiffness and reduce thermal expansion. The higher modulus thermoset elastomers produced by reinforced reaction injection molding (RRIM) are also used in the automotive industry. In 1969 Bayer pioneered an all-plastic car having RIM-molded bumpers and fascia; in 1983 the first plastic-body commercial automobile (Pontiac Fiero) was produced in the United States.

The polymerization step can be conducted in a mold, in an extruder (TPU production), or continuously on a conveyor (block foam production). Also, spraying

of the monomers onto the surface of a substrate produces polyurethane coatings. The resulting polymers can be thermoplastic, which allows reprocessing by injection molding, extrusion, blow molding, and other remelting processes, or they are thermoset polymers as used in the RIM process in the molding of automotive bumpers, or in the manufacture of cellular polyurethanes.

Polyurethanes are a primary component of the global polymer market. They amount to about 6% of the total world plastic use. The world consumption of polyurethanes in 2000 was about 8 million tons, with a global growth averaging around 3–4% a year. The Western Hemisphere uses about 3 million metric tons per annum, Western Europe approximately 2.6 million metric tons per annum, the remainder being used in Asia and Africa.

Today's global polyurethane industry has been reshaped by several mergers of the 1980s and 1990s. Some of the familiar players, such as ICI, Upjohn, Olin, Rhone Poulenc, Union Carbide, and Arco, sold their polyurethane businesses; Bayer, the principal global isocyanate producer, strengthened its position in polyether polyols by acquiring the Arco polyol business in 1999. Also Dow, the other leading producer of polyether polyols, acquired Union Carbide in 1999, which further strengthened its position in polyols. The primary polyurethane players of the new millennium are Bayer, BASF, Dow, and Huntsman, the latter through the purchase of the global ICI business. Lyondell, which acquired the TDI businesses from Olin and Rhone Poulenc, sold the Arco polyol business to Bayer in 1999, thereby indicating their intent to eventually exit polyurethanes. Over the years the primary polyurethane chemical producers underwent forward integration by buying primary polyurethane system houses, ie their principal customers. Recent examples include the acquisition of Essex, a leading producer of automotive windshield adhesives and sealants, and of Flexible Products and General Latex, which are polyurethane foam system houses, by Dow; and BASF acquired IPI International, a producer of insulation foam systems.

In Asia and South America, the primary global chemical producers formed joint ventures with primary local companies, some of which established small volume manufacturing sites. In contrast, Dow/Mitsubishi built an isocyanate distillation plant in Yokaichi, Japan, to separate PMDI/MDI feedstock. Dow has another distillation plant in Delfzjiel, Holland, which has been increased by 60% in 2000. In this plant feedstock from Dows Estarreja, Portugal, plant is separated into PMDI and MDI. Although distillation plants are less costly, the other primary producers seem to be involved in building global-size facilities in Asia. For example, BASF plans to build a new 140-kt/a TDI plant in Yosu, South Korea by 2003. A present MDI plant at this site will be simultaneously expanded to 160 kt/a. Also, several major facilities are planned for mainland China. A recent project by Bayer, the building of a major TDI plant in Taiwan, was cancelled because of local opposition to the plant. Enichem in Italy, which acquired its isocyanate technology from ICI, is a regional producer of isocyanates and polyols.

The major producers of polyurethane chemicals also manufacture TPU elastomers. DuPont was also at one time involved in polyurethanes, but it sold its TDI technology to Dow and excited the synthetic leather business. However, DuPont is still the principal force in the production of polyurethane fibers (Lycra). Through the acquisition of Uniroyal and Witco, the Crompton & Knowles Corp. became a

principal force in polyurethane elastomers, which are now sold under the trade name CK Witco. Manufacturing and marketing arrangements include a rigid foam system marketing deal between Huntsman and Shell, and a manufacturing joint venture of BASF and Shell. The latter is named Basell CV, which opened a new styrene monomer/propylene oxide plant at Moerdijk in the Netherlands with a capacity of 250 kt/a of propylene oxide. Another plant in Singapore is scheduled to open in 2002. Some of the new polyols are used to supply Huntsman, which is the only primary polyurethane company without a polyol manufacturing capability.

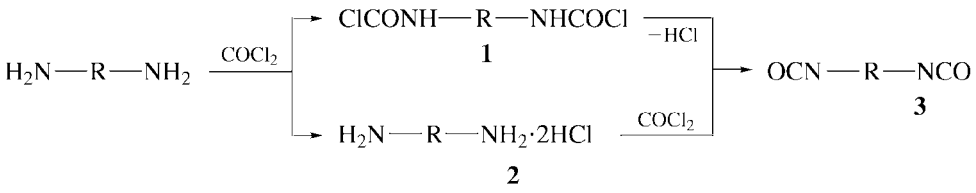
One of the current trends in polyurethanes is the gradual replacement of TDI by the less volatile PMDI or MDI in many applications. The production of PMDI/MDI is a coproduct process, which is economically viable because the market requires amounts of both isocyanates in the amounts presently produced. All primary producers remove some of the higher priced MDI (up to 50%) by vacuum distillation. A process for the manufacture of only MDI does not exist.

Elimination of chlorinated fluorocarbon (CFC) blowing agents and the reduction of emission of volatile organic compounds (VOCs) have been ongoing. The latter leads to a rapid increase in the use of water-based polyurethane dispersions in coating applications. Flexible foam producers have eliminated auxiliary blowing agents, and the rigid foam producers use water-blown formulations in combination with hydrochlorofluorocarbons (HCFCs), hydrofluorocarbons (HFCs), or hydrocarbons. Adhesives and sealants are reformulated from solvent-based products to 100% solid-and water-based systems.

Isocyanates

The synthesis, reactions, and manufacture of isocyanates were reviewed in 1997 (2), and the chemistry and technology of isocyanates is the subject of a recent book (3).

The standard method of synthesis of isocyanates is the phosgenation of amines or amine salts. The phosgenation of amines to isocyanates was pioneered by Hentschel in 1884 (4). Using this method, a solution of the diamines in chlorobenzene is added to excess phosgene in the same solvent below 20°C. The resultant slurry consisting of the dicarbamoyl chloride (**1**) and the diamine dihydrochloride (**2**) is treated with excess phosgene at temperatures up to 130°C. Upon heating above 65°C the dicarbamoyl chloride dissociates to generate diisocyanate (**3**). The conversion of **2** is very slow, and the use of polar solvents or higher pressures increases the rate of reaction.



In the laboratory a slurry of the diamine salts, obtained by treating a solution of the diamines with hydrogen chloride or carbon dioxide, is treated above 100°C until a clear solution is obtained. Instead of the toxic phosgene gas, the liquid trichloromethyl chloroformate (diphosgene) (5) or the solid bistrichloromethyl carbonate (triphosgene) (6) can be used in the laboratory. The phosgene oligomers have to be used with caution because the toxic monomer can be generated readily and all reactions have to be performed under a fume hood.

In the continuous manufacture of diisocyanates, the by-products (hydrogen chloride and excess phosgene) are vented and separated. The recovered phosgene is recycled and part of the hydrogen chloride is used in the aniline/formaldehyde condensation. The solvents used in the phosgenation of the diamines are aromatic hydrocarbons, especially chlorobenzene and *o*-dichlorobenzene. Occasionally, more polar solvents, such as ethyl acetate, dioxane, nitrobenzene, or dimethylsulfone, are used. Excess phosgene can also be used as solvent if the reaction is conducted under high pressure. Dimethylformamide (DMF) and phenyltetramethylguanidine catalyze the phosgenation reaction (7).

Aliphatic diamines are also phosgenated in a two-phase reaction using methylene chloride and aqueous sodium hydroxide. The diamine and phosgene are dissolved in methylene chloride and the form **2** is instantaneously neutralized with sodium hydroxide. The generated diisocyanate remains in the solvent phase, and excess phosgene is also neutralized with sodium hydroxide, which enhances the safety of phosgene handling. The highly exothermic reaction requires efficient cooling. A disadvantage of this process is the use of a slight excess of phosgene, which cannot be recovered.

Instead of phosgene and its oligomers, oligomeric *t*-butylcarbonates are also used to convert diamines into diisocyanates. For example, sterically hindered aromatic diamines react with di-*t*-butyldicarbonate in the presence of dimethylaminopyridine in acetonitrile at room temperature to give sterically hindered aromatic diisocyanates. In this manner 3,6-3′,6′-tetramethyl MDI is obtained in 93% yield (8). Also, aliphatic diamines react with di-*t*-butyltricarbonate at room temperature to give a high yield of the corresponding diisocyanates (9).

Since the early 1970s, attempts have been made by the principal global producers of isocyanates to avoid the use of the toxic phosgene in the manufacture of isocyanates. Attempts to produce TDI and PMDI by nonphosgene processes have failed. However, two aliphatic diisocyanates, CHDI and TMXDI, are manufactured using nonphosgene processes. Hüls and BASF have also announced plans to use nonphosgene processes for the manufacture of IPDI in their new plants which are under construction. In the new, nonphosgene chemistry, isocyanic acid, generated by thermolysis of urea, reacts with diamines to give a bis-urea derivative. Subsequent reaction with diethylamine affords tri-substituted urea derivatives, which are thermolyzed in an inert solvent in the presence of an acidic catalyst to give the diisocyanate (10). Gaseous ammonia is the only by-product in this process. Also, reaction of aliphatic diamines with carbon dioxide, in the presence of triethylamine, affords biscarbamate salts, which can be dehydrated with phosphoryl chloride to give the diisocyanate (11).

Another laboratory method of synthesis of diisocyanates is the thermolysis of bisacylazides (**4**) (Curtius reaction). For example, dicarboxylic acid chlorides react

with trimethylsilyl azide to give (**4**), which is thermolyzed in an inert solvent to give the diisocyanates (**5**), $n = 3$–10 (12).

$$\mathrm{ClCO{-}(CH_2)_n{-}COCl} + 2\ \mathrm{(CH_3)_3SiN_3} \rightarrow \underset{\mathbf{4}}{\mathrm{N_3CO(CH_2)_nCON_3}} \rightarrow \underset{\mathbf{5}}{\mathrm{OCN(CH_2)_nNCO}} + 2\ \mathrm{N_2}$$

The preparation of aliphatic diisocyanates, using bisacylazides, has to be conducted with caution because an explosion occurred in the preparation of ethylene diisocyanate by using this method (13). Ethylene diisocyanate is readily obtained by dehydrochlorination of a heterocyclic allophanoyl chloride derivative obtained in the phosgenation of ethyleneurea (14).

The commodity aromatic isocyanates TDI and PMDI/MDI are most widely used in the manufacture of urethane polymers. Tolylene diisocyanate, TDI, is a distilled 80:20 mixture of 2,4- and 2,6-isomers. However, pure 2,4-TDI and a 65:35 mixture of the 2,4- and 2,6-isomers are also commercially available. Pure 2,4-TDI, mp 19.5–21°C, is obtained on cooling of 80:20 TDI. The manufacture of TDI involves nitration of toluene, hydrogenation to the diamines, and phosgenation. Separation of the undesired ortho derivatives, such as 2,3- and 3,4-dinitrotoluene, is necessary because their presence interferes with the polymerization of TDI (15).

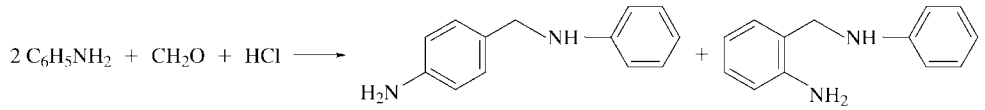
The other commodity isocyanate, PMDI/MDI, is based on benzene. Mononitration of benzene, catalytic reduction to aniline, followed by condensation of aniline with formaldehyde produces oligomeric amines, which are phosgenated to give mixtures of PMDI and MDI. MDI is separated from PMDI by continuous thin-film vacuum distillation.

PMDIs are crude products that vary in exact composition. The main constituents are 40–60% MDI; the remainder is the other isomers of MDI, triisocyanates, and higher molecular weight oligomers. Important product variables are functionality and acidity. Rigid polyurethane foams are mainly manufactured from PMDI. The so-called pure MDI is a low melting solid that is used for high performance polyurethane elastomers and spandex fibers.

Liquid MDI (Isonate 143-L) is produced by converting some of the isocyanate groups in MDI to carbodiimide groups, which react with the excess isocyanate present to form a small amount of the trifunctional four-membered ring cycloadduct (16). The presence of the cycloadduct lowers the melting point of MDI to give a liquid product. In most applications the trifunctional cycloadduct will dissociate into difunctional monomers; therefore, this type of liquid MDI can be used in the manufacture of linear polyurethanes. Liquid MDI products are also made by reaction of the diisocyanate with small amounts of glycols. These products are called prepolymers. MDI products enriched in 2,4-MDI are also available. The latter are used in the manufacture of flexible MDI foams.

The manufacture of the oligomeric amine precursors for PMDI/MDI is conducted by continuously adding formaldehyde to aniline in the presence of less than the stoichiometric amount of hydrochloric acid at room temperature in agitated reactors. The reaction mixture is gradually heated to 100°C over a period of several hours. The reaction can also be conducted under pressure at higher temperatures in order to increase the rate of reaction. However, the oligomeric amines produced in this manner contain higher amounts of 2,2′- and 2,4′-methylenedianiline

(MDA). The acid-catalyzed aniline/formaldehyde reaction proceeds in two steps. At room temperature aniline reacts with formaldehyde to form N-substituted carbonium ions which attack aniline in the para- and ortho-position to give a mixture of *p*-aminobenzylamine (PABA), (**6**), *o*-aminobenzylamine (OABA), (**7**), and oligomeric benzylamines. Subsequent heating affects dissociation of the benzylamines to give C-bonded carbonium ions, which form another C—C bond in their reaction with aniline.



6 **7**

$$\mathbf{6} + C_6H_5NH_2 + HCl \rightarrow 4,4'\text{-MDA} + 2,4'\text{-MDA} + \text{oligomers}$$

$$\mathbf{7} + C_6H_5NH_2 + HCl \rightarrow 2,4'\text{-MDA} + 2,2'\text{-MDA} + \text{oligomers}$$

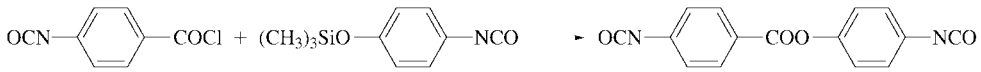
The variables affecting the product distribution are aniline concentration, hydrochloric acid concentration, and temperature. The higher the excess of aniline, the higher is the diamine concentration. Higher hydrochloric acid concentration and lower initial temperature favor the formation of 4,4′-MDA. Attempts were made over the years to replace the aqueous hydrochloric acid catalyst with slower reacting solid acidic clay catalysts, but the obtained product distribution was different, and therefore this approach was never used.

The commercial manufacture of TDI and PMDI/MDI is the continuous phosgenation under pressure of the amine precursors in an inert solvent at elevated temperatures. The by-products, hydrogen chloride and excess phosgene, are continuously vented and separated. The recovered phosgene is recycled and the hydrogen chloride is used in the aniline/formaldehyde condensation, or it is sold or reoxidized to chlorine to be reused in the manufacture of phosgene. In case of the manufacture of PMDI, some of the diisocyanate (MDI) is separated by continuous vacuum distillation using a wiped film evaporator. In this operation the residual PMDI, which still contains MDI, is only subjected to a short heat treatment. The advantage of the simultaneous manufacture of both isocyanates is a quantitative yield because the by-products of the phosgenation reaction are contained in the residual PMDI.

The current prices of the commodity aromatic isocyanates (DM/kg) are TDI: 3.6; PMDI: 2.8; MDI: 4.3. The light-stable aliphatic isocyanates are somewhat more expensive.

Several higher-priced aromatic diisocyanates, such as *p*-phenylene diisocyanate (PPDI), 1,5-naphthalene diisocyanate (NDI), and bitolylene diisocyanate (TODI), are also available. These symmetrical high melting diisocyanates give high melting hard segments in polyurethane elastomers.

Aromatic diisocyanates are also obtained in the coupling of suitable monoisocyanates. For example, reaction of 4-isocyanatobenzoyl chloride (**8**) with a trimethylsiloxy-substituted isocyanate (**9**) affords diisocyanato benzoates (**10**) (17).

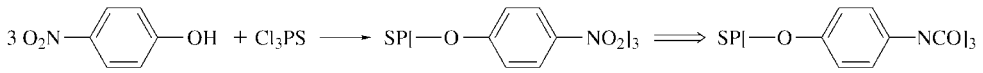


8 **9** **10**

Triad diisocyanates (**12**) are obtained in the reaction of two equivalents of 4-isocyanatobenzoyl chloride with the silylated hydroquinone derivative (**11**) (18).

11 **12**

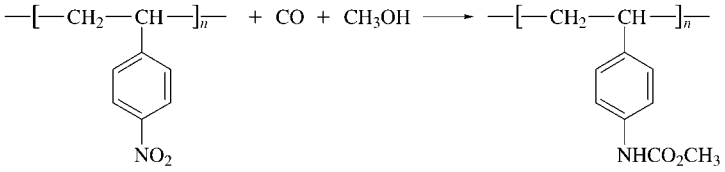
The aromatic triisocyanate (**13**) is obtained in the reaction of 4-nitrophenol and thiophosphoryl chloride, followed by reduction and phosgenation. (19). This triisocyanate is sold under the trade name Desmodur RF (Bayer) as a glue for rubber adhesive solutions.



13

Aromatic triisocyanates as cross-linkers are more readily obtained by trimerizing 2,4-TDI. In this reaction the more reactive isocyanate group in the 4-position undergoes trimerization to produce a triisocyanate (20).

Also, aromatic polyisocyanates are obtained in the copolymerization of styrene with cinnamoyl azide (21). Blocked polyisocyanates (**14**) are obtained from *p*-nitrostyrene and carbon monoxide in methanol, using a ruthenium catalyst (22).



14

Polyurethanes obtained from aromatic diisocyanates undergo slow oxidation in the presence of air and light causing discoloration, which is unacceptable in some applications. In contrast, polyurethanes obtained from aliphatic diisocyanates are color stable, although it is necessary to add antioxidants and uv-stabilizers to the formulations to maintain the physical properties of the polymers with time.

The elusive parent diisocyanate, O=C=N–N=C=O, is only stable at $-75^{\circ}C$, and therefore it is not suitable as a monomer for polyurethanes (23). The least costly aliphatic diisocyanate is hexamethylene diisocyanate (HDI), which is obtained by phosgenating the nylon intermediate hexamethylenediamine (HDA). Because of its low boiling point, HDI is mostly used in the form of its derivatives, such as biurets, allophanates, dimers, or trimers (24). Isophorone diisocyanate (IPDI) and its derivatives are also used in the formulation of rigid coatings, while hydrogenated MDI (HMDI) and cyclohexane diisocyanate (CHDI) are used in the formulation of flexible coatings and polyurethane elastomers.

HDA is commercially produced from adipic acid or butadiene. The catalytic hydrogenation of adiponitrile to HDA is common in both routes. The phosgena-

Table 1. Phosgenation Processes for Aliphatic Diisocyanates

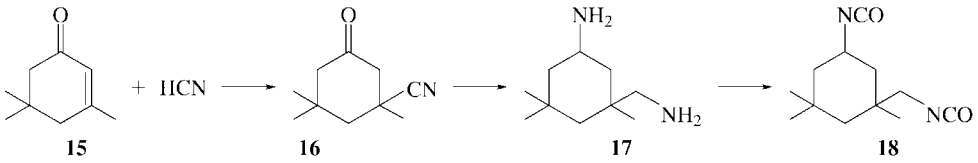
[c] Using water, sodium hydroxide, and methylene chloride.

tion of the diamine is conducted continuously in chlorobenzene. In Table 1 the advantages and disadvantages of several phosgenation processes for aliphatic diisocyanates are shown.

In a recent patent a nonphosgene synthesis of HDI is described (25). Reaction of HDA with urea and ethanol, in the presence of $Co(OAc)_2$ at 170–175°C, affords the biscarbamate, which is thermolyzed in a thin-film evaporator at 260–270°C.

The other significant aliphatic diisocyanate, IPDI, is based on isophorone chemistry. Trimerization of acetone gives isophorone (**15**), which on reaction with HCN affords the β-cyanoketone (**16**). Reductive amination of (**16**) to the diamine (**17**), followed by phosgenation, gives IPDI (**18**).



15 **16** **17** **18**

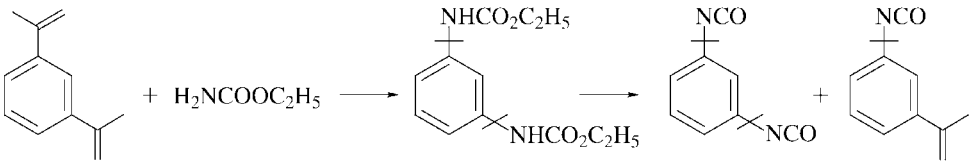
An example of a nonphosgene route to IPDI is the reaction of **17** with urea and *n*-butanol in the presence of dibutyl carbonate at 210–220°C. Thermolysis of the biscarbamate at 270–280°C at 30 mbar affords **18** (26). IPDI is a mixture of 72% cis isomers and 28% trans isomers (27).

HMDI was originally produced by DuPont as a coproduct in the manufacture of Quiana fiber. After terminating Quiana production DuPont sold the product to Bayer. Today, a crude mixture of the diamines obtained in the acid-catalyzed aniline/formaldehyde reaction is supplied by Bayer to Air Products, which is performing the ring hydrogenation. The phosgenation of the ring hydrogenated diamines is performed by Bayer. Commercial HMDI is a mixture of three stereo isomers (trans–trans, mp 65°C; cis–trans, mp 36°C; and cis–cis, mp 61°C). The direct formation of a blocked HMDI is conducted by ring hydrogenation of caprolactam blocked MDI (28).

Semicommercial aliphatic diisocyanates include *trans*-cyclohexane-1,4-diisocyanate (CHDI) and *m*-tetramethylxylylene diisocyanate (TMXDI). A coproduct in the production of TMXDI is *m*-isopropenyl-α,α-dimethylbenzyl isocyanate (TMI), which can be copolymerized with other olefins to give aliphatic polyisocyanates. These aliphatic diisocyanates are manufactured using nonphosgene routes. Akzo has developed the CHDI process based on scrap polyester fiber. Ring hydrogenation of dimethyl terephthalate (DMT), transesterification with diethylene glycol, followed by reaction with ammonia provides a diamide, which

is N-chlorinated. Hofmann rearrangement in the presence of diethylamine produces the blocked diisocyanate, which is subsequently deblocked on heating in the presence of hydrogen chloride (29). Cyclohexyl diisocyanate (CHDA) can also be obtained by catalytic hydrogenation of *p*-phenylenediamine. Most likely, this approach has economic advantages over the multistep process based on fiber scrap.

The manufacture of TMXDI, developed by American Cyanamid, is based on the reaction of *m*-isopropylidenebenzene (**19**) with ethyl carbamate to give the blocked diisocyanate (**20**). Thermolysis affords a mixture of TMXDI (**21**) and the monoisocyanate (TMI) (**22**) (30).



19 **20** **21** **22**

The coupling of ω-isocyanatocarboxylic acid chlorides (**23**) with silylated aliphatic hydroxy-isocyanates (**24**) is another method of synthesis of aliphatic diisocyanates (**25**), containing ester groups in their structure (31).

$$OCN(CH_2)_nCOCl + OCN(CH_2)_4OSi(CH_3)_3 \longrightarrow OCN(CH_2)_nCOO(CH_2)_4NCO$$

23 **24** **25**

In Table 2 the physical properties and the manufacturers of the commercial isocyanates are listed.

Blocked and Modified Isocyanates

Masked or blocked diisocyanates are used in coating applications. The blocked diisocyanates are storage-stable, nonvolatile, and easy to use in powder coatings. Blocked isocyanates are produced by reaction of the diisocyanate with blocking agents such as caprolactam, 3,5-dimethylpyrazole, phenols, oximes, acetoacetates, or malonates. Upon heating at 120–160°C, the blocked isocyanates dissociate and the generated free isocyanate reacts with hydroxyl groups available in the formulation to give high molecular weight polyurethanes. In the case of acetoacetates and malonates, the free isocyanates are not regenerated, but the adducts undergo transesterification reactions with the present polyol upon heating (32). A phenol-blocked methylene diisocyanate (**27**) is obtained in the reaction of phenyl carbamate (**26**) with formaldehyde (33).

$$2\ C_6H_5OCONH_2 + CH_2O \rightarrow C_6H_5OCONHCH_2NHCOOC_6H_5$$

26 **27**

The blocking of isocyanato groups with phenol is used in the formation of hyperbranched polyurethanesfrom a benzylalcohol derivative, having two

$NHCOOC_6H_5$ groups in the 3,5-position (34). Intramolecular dimers derived from long-chain aliphatic diisocyanates (35) and macrocyclic ureas (36) are also used as masked aliphatic diisocyanates.

Blocked aliphatic isocyanates or their derivatives are used for one-component coating systems. Masked polyols are also used for this application. For example, polyols capped with vinyl or isopropenyl ethers produce polyacetals, which do not react with isocyanates. Hydrolysis of the acetals with moist air regenerates the hydroxyl groups, which undergo polyurethane reaction with isocyanate-terminated prepolymers (37). In addition, substituted oxazolines are used as masked cross-linkers (38). Ketimine cross-linkers are also utilized in the formulation of one-component coating systems (39). Hydrolysis of ketimines produces diamines, which undergo a very fast reaction with isocyanate-terminated prepolymers. Blocked isocyanates are also used in the cross-linking of acrylic resins for automotive coatings. Incorporation of masked diisocyanates into epoxy resins lowers the moisture absorption in the derived coatings (40).

Other modified commercial diisocyanates include diisocyanate prepolymers, biurets, and isocyanurates (trimers). Asymmetric trimers (iminooxadiazine diones) are also obtained from aliphatic diisocyanates, using fluoride-based catalysts. The modifications of the commercial isocyanates are necessary to lower their melting points, or to lower their vapor pressure. The prepolymers used in the manufacture of polyurethanes are mainly urethane modified diisocyanates, formed in the reaction of the diisocyanate with a small amount of a macrodiol. Hydroxy-terminated prepolymers can also be prepared, but they are of no commercial significance. To raise the vapor pressure of aliphatic diisocyanates they are converted into allophanates, biurets, or triisocyanurates (trimers). HDI is mainly used as the biuret, (**28**), which is formed in the reaction of 3 mol of HDI with 1 mol of water, or other active hydrogen containing compounds, such as hydrated inorganic salts, tertiary alcohols, formic acid, pivalic acid, hydrogen sulfide, monoamines, or diamines.

$$3\ OCN{-}R{-}NCO + H_2O \rightarrow OCN{-}R{-}NHCON(RNCO)CONH{-}R{-}NCO$$

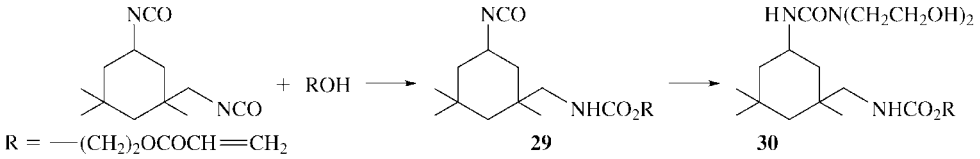
28

High temperature (>270°C) reaction of HDA with excess HDI is a commercial process to produce the HDI biuret (41). The excess HDI is removed by thin-film vacuum distillation. For the conversion of HDI into a triisocyanurate

derivative (trimer), using benzyltrimethyl ammonium hydroxide as the catalyst, it is advantageous to remove carbon dioxide from the diisocyanate by sparging with nitrogen (42). When tributylphosphine is used as the catalyst a mixture of dimers and trimers (3:2) is obtained (43). Sometimes prepolymers are used as coreactants in the trimerization of HDI (44). Also, mixtures of HDI and IPDI are used to generate the mixed trimers (45). On standing, HDI biurets slowly generate monomeric HDI; therefore, it is advantageous to use allophanates as the diisocyanate derivatives because allophanates do not dissociate on standing. Glycols, polyols, or monoalcohols are used to initiate allophanate formation.

The derivatization of IPDI is easier to accomplish because of the different reactivities of the two isocyanate groups in the molecule. For example, preferential dimerization of the primary isocyanate group is observed in the trialkylphosphine-catalyzed reaction (46). Trimerization of IPDI in the presence of quaternary ammonium salts affords mainly the isocyanurate trimer (47). Attempted biuret formation from IPDI and $Na_2SO_4 \cdot 10H_2O$ gives a mixture of ureas and biurets (48). A biuret derivative is also obtained from IPDI and HDA (49).

The use of catalysts plays a role in determining which isocyanate group in IPDI is more reactive. For example, in the reaction of IPDI with *n*-butanol at 50°C the secondary isocyanate group is 1.6 times more reactive than the primary isocyanate group in both stereoisomers. Using dibutyltin dilaurate as the catalyst, the reactivity of the secondary NCO group is about 12 times higher than the primary NCO group. However, using a tertiary amine catalyst (DABCO) the primary NCO group is 1.2 times more reactive than the secondary NCO group (50). The selective reactivities of the isocyanate groups in IPDI can be utilized to generate a diol containing an acrylic double bond for cross-linking (51). Reaction of the initially formed carbamate (**29**) with diethanolamine affords the diol (**30**).



The selective reaction of the *p*-isocyanato group in 2,4-TDI is used to produce the TDI dimer, which is a higher melting solid diisocyanate. In Table 3 some modified commercial diisocyanates are listed.

Polyols

Polyether Polyols. The polyether polyols used in the manufacture of polyurethanes are hydroxy-terminated macromolecules, with molecular weights ranging from 250 to 8000. Lyondell/Bayer has provided pilot plant diols/triols having molecular weights of 10,000 to 15,000 for lubricant and surfactant applications. The hydroxy functionality can range from 2 to 8. The economically attractive polyether polyols based on alkylene oxides are listed in Table 4.

Other speciality initiators derived from natural products are also manufactured. Examples include formose, lactose,α-methyl glucoside, and

soybean-derived polyols. Propoxylation of dairy waste also affords polyether polyols. DuPont has developed a fermentation process to convert glucose into 1,3-propanediol, a useful polyurethane extender.

The alkylene oxide polymerization is usually initiated by alkaline hydroxides, especially potassium hydroxide. In the base-catalyzed polymerization of propylene oxide (PO), some rearrangement occurs to give allyl alcohol. Further reaction of allyl alcohol with PO produces a monofunctional alcohol. Therefore, polyether polyols derived from PO are not truly difunctional. By using zinc hexacyano cobaltate as catalyst, a more difunctional polyol is obtained (52). Olin has introduced the difunctional polyether polyol under the trade name Poly-L. This product is now available from Arch Chemicals. Similar polyols free of monol contamination are available from Arco/Lyondell/Bayer and Asahi.

Ethylene oxide is manufactured by direct oxidation of ethylene, in contrast PO is only obtained in coproduct processes. The classical process, chlorination of propylene, is still used by Dow, one of the world's largest producer of polyether polyols. In contrast, all other producers use the Halcon process, based on the simultaneous production of PO and styrene monomer or *t*-butyl alcohol. In view of the demise of MTBE (methyl-*t*-butyl ether based on *t*-butyl alcohol) as a fuel additive, the styrene coproduct process (POSM) will remain as the economically viable route to PO. A recent example is the new (SMPO) plant of Basell at Moerdijk in the Netherlands. The largest producer of PO, the former Arco (now Lyondell), has sold its global polyol business to Bayer in 1999. Lyondell will also provide Bayer a long-term, low cost supply of PO. Recently, Dow announced that it also will use the POSM route to PO in a new facility.

The backbone of the polyether polyols are either PO homopolymers or random or block copolymers with ethylene oxide. Important characteristics of the polyol are their hydroxy functionality, hydroxy equivalent weight, and their

reactivity and compatibility with the other components used in the polyurethane formulation. Blending of polyols of different functionality, molecular weight, and reactivity can be used to tailor a polyol for a specific application. Since primary hydroxy groups are more reactive than secondary hydroxy groups, it is advantageous to produce block copolymers with terminal primary hydroxyl groups by using ethylene oxide last in a block copolymer. Capping with ε-caprolactone also produces primary hydroxyl groups. Trichlorobutylene oxide-derived polyols are used as fire retardants. The hydrophobicity of polyether polyols can be modified by homo- or copolymerization with 1,2-butylene oxide or styrene oxide. The higher molecular weight polyether polyols are soluble in organic solvents. Poly(PO) is soluble in water up to a molecular weight of 760, and copolymerization with ethylene oxide expands the range of water solubility. Random copolymers are obtained by polymerizing mixtures of PO and ethylene oxide. The viscosity of polyether polyols increases with hydroxyl equivalent weight.

With amine initiators the so-called self-catalyzed polyols are obtained, which are used in the formulation of rigid spray foam systems. The rigidity or stiffness of a foam is increased by aromatic initiators, such as Mannich bases derived from phenol, phenolic resins, toluenediamine, or methylenedianiline (MDA). BASF/Dow have formed a venture into Mannich polyols for spray foam applications.

In the manufacture of highly resilient flexible foams and some thermoset RIM elastomers, graft or polymer polyols are used. Graft polyols are dispersions of free-radical-polymerized mixtures of acrylonitrile and styrene partially grafted to a polyol. Polymer polyols are available from BASF, Dow, and Union Carbide. *In situ* polyaddition reaction of isocyanates with amines in a polyol substrate produces polyharnstoff dispersion (PHD) polyols, which are marketed by Bayer (53). In addition, blending of polyether polyols with diethanolamine, followed by reaction with TDI, also affords a urethane/urea dispersion (54). The polymer or PHD-type polyols increase the load bearing properties and stiffness of flexible foams. Interreactive dispersion polyols are also used in RIM applications where elastomers of high modulus, low thermal coefficient of expansion, and improved paintability are needed.

Polyester Polyols. Initially polyester polyols were the preferred raw materials for polyurethanes, but today the less expensive polyether polyols dominate the polyurethane market. An exception are the inexpensive aromatic polyester polyols, which have been introduced for rigid foam applications. These are obtained from residues of terephthalic acid production or by transesterification of DMT or poly(ethylene terephthalate) (PET) scrap with glycols. TBI of France is the first European company to manufacture aromatic polyester polyols directly from PET scrap bottles at lssoire with a capacity of 10 kt/a. Phthalates and terephthalates are also used.

Polyester polyols are based on saturated aliphatic or aromatic carboxylic acids and diols or mixtures of diols. The carboxylic acid of choice is adipic acid because of its favorable cost/performance ratio. For elastomers, linear polyester polyols of molecular weight of ca 2000 are preferred. Branched polyester polyols, formulated from higher functional glycols, are used for foam and coating applications. Polyester polyol-derived polyurethanes have a lower hydrolytic stability

compared to polyurethanes made from polyether polyols, but they have better oxidative and thermal stabilities.

In addition, polyester polyols are made by the reaction of caprolactone with diols. Poly(caprolactone diols) are used in the manufacture of TPU elastomers with improved hydrolytic stability (55). The hydrolytic stability of the poly(caprolactone diol)-derived TPUs is comparable to TPUs based on the more expensive long-chain diol adipates (56). Polyether/polyester polyol hybrids are synthesized from low molecular weight polyester diols, which are extended with PO.

The most important chain extenders are ethylene glycol, diethylene glycol, propylene glycol, 1,4-butanediol, cyclohexanedimethanol, and hyroquinone dihydroxyethyl ether. Recently, 1,3-propanediol (57) and 1,2,4-butanetriol (58) have become available as new polyurethane raw materials. Since ethylene glycol-extended polyurethanes are prone to thermal degradation, ethylene glycol is only used as a RIM extender in thermoset polyurethanes.

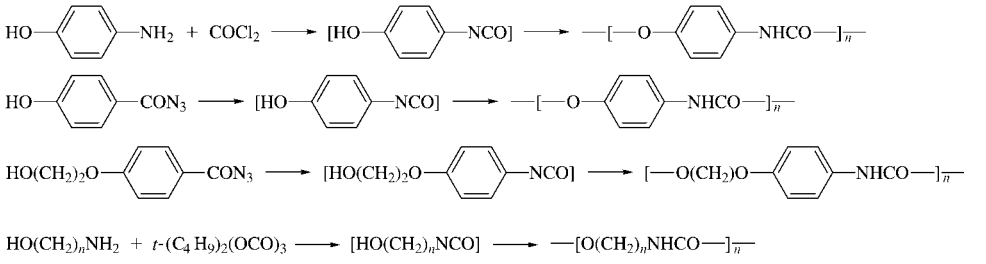
Linear Polyurethanes and Poly(urethane ureas)

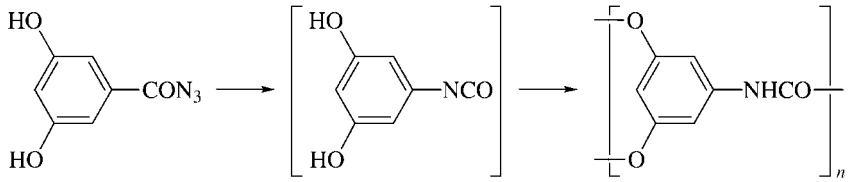
The chemistry and technology of polyurethanes is described in Reference 59. Numerous co-workers at Bayer have contributed to this book. Another important compilation of polyurethane technology can be found in Reference 60. This book is comprised of articles from Dow scientists. Also, a summary of polyurethane chemistry and technology is found in the somewhat older book compiled by ICI researchers (61).

Polyurethanes are generally obtained by reacting a difunctional hydroxy compound with a diisocyanate to yield A_2B_2 polymers. AB-type polyurethanes are obtained by cationic ring-opening polymerization of cyclic carbamates (62). Polymerization of monomers containing a hydroxyl and an isocyanate group in the monomer also affords AB polymers. The latter are usually generated *in situ* because of the incompatibility of both groups. An exception are substituted isocyanatophenols obtained in the phosgenation of aminophenols. While 4-isocyanatophenol undergoes homopolymerization after removal of the solvent, alkyl substituents adjacent to the functional groups increase the stability of isocyanatophenols (63). The reactive functional groups can also be generated from suitable precursors. For example, 4-hydroxybenzoyl azide, upon thermolysis, produces the AB homopolymer (64). From 4-(2-hydroxyethoxy)benzoyl azide the corresponding aliphatic/aromatic AB polyurethanes are obtained, the coproduct being gaseous nitrogen (65). An aliphatic AB monomer can be generated from aminoalcohols and di-*t*-butyltricarbonate. In the presence of $Zr(acac)_4$ the monomer undergoes homopolymerization. In this manner aliphatic polyurethanes $-[-(CH_2)_x-NHCO-]-_n, X = 4–12$ are obtained (66). These reactions are summarized in Table 5. Desilylation of silylated hydroxyester isocyanates with HF in pyridine also affords the corresponding AB homopolymer (67).

The generation of isocyanates from azide precursors is also utilized in the formation of hyperbranched polyurethanes **33** by thermolysis of 3,5-dihydroxybenzoyl azide (**31**) (68). The ABB-type monomer (**32**), generated *in situ*, undergoes polymerization to form a network polymer.

Table 5. AB Polyurethanes Generated from Hydroxyl Group Containing Monomers





31 **32** **33**

The majority of commercial polyurethanes are A_2B_2 polymers. The useful physical properties of polyurethanes are derived from their molecular structure and determined by the choice of building blocks as well as the supramolecular structures caused by atomic interaction between chains. The ability to crystallize, the flexibility of the chains, and spacing of polar groups are of considerable importance, especially in linear thermoplastic materials. In rigid cross-linked systems, such as polyurethane foams, other factors such as density determine the final properties.

The unique properties of linear TPUs are attributed to their long-chain structure. TPU elastomers are segmented block copolymers, comprising of hard- and soft-segment blocks. The soft-segment blocks are formed from long-chain polyester or polyether polyols and MDI; the hard segments are formed from short-chain diols, mainly 1,4-butanediol, and MDI. Under ambient conditions the higher-melting hard segments are incompatible with the soft segments, and microphase separation occurs. The hard segments aggregate into crystalline domains, in which hydrogen bonding of the —NH— groups of the urethane chain bond to neighboring carbonyl groups occurs. Upon melting, the crystalline domains are disrupted and the polymer can be processed. In Table 6 the melt temperature of hard segments formed from MDI and glycols are shown. The 1,4-butanediol extended MDI-based polyurethane has the highest melting hard segment (69).

The symmetrical MDI is more suitable for the preparation of segmented polyurethane elastomers having excellent physical properties. Segmented polyurethanes are also obtained from 2,6-TDI, but an economically attractive separation process for the TDI isomers has yet to be developed.

The melt viscosity of a TPU depends on the weight-average molecular weight and is influenced by chain length and branching. TPUs are viscoelastic

Table 6. T_m of Model Hard Segments Derived from MDI and Glycols

Poly(1,6-hexanediol carbonate)	−62	49

materials which behave like a glassy, brittle solid, an elastic rubber, or a viscous liquid, depending on temperature and time scale of measurement. With increasing temperature, the material becomes rubbery because of the onset of molecular motion. At higher temperatures a free-flowing liquid forms. The melt temperature of a polyurethane is important for processibility. Melting should occur well below the decomposition temperature. Below the glass-transition temperature (T_g), the molecular motion is frozen, and the material is only able to undergo small-scale elastic deformations. For amorphous polyurethane elastomers, the T_g of the soft segment is ca −50 to −60°C, whereas for the amorphous hard segment, T_g is in the 20–100°C range. The T_g and T_m of the more common macrodiols used in the manufacture of TPU are listed in Table 7.

Polyester and polyether diols are used together with MDI to manufacture TPU elastomers. The polyester diols are obtained from adipic acid and diols such as ethylene glycol, 1,4-butanediol, or 1,6-hexanediol. The preferred molecular weights are 1000–2000, and low acid numbers are essential to ensure optimal hydrolytic stability. Also, caprolactone-derived diols and polycarbonate diols are used. Polyether diols are mainly poly(tetramethylene glycol) (PTMG), but polyalkylene oxide-derived diols are also used. TPUs contain wax to aid in mold release and diatomaceous silica for added slip and as antiblocking agents in films. Antioxidants (hindered phenols or hindered amines) and uv-stabilizers (benzotriazoles) are also added to improve the environmental resistance.

The bulk polymerization of the polyurethane monomers is conducted by mixing the liquid monomers and catalysts at room temperature (one-step method),

or by prereacting the diisocyanates with part of the polyol to form a prepolymer, which is subsequently reacted with the remaining polyol to form the final polymer (two-step method). Part of the heat of reaction of the polymerization process is not generated if prepolymers are used. Prepolymers are often made at a ratio of NCO/OH of 2:1 in order to minimize free diisocyanate; prepolymers with a ratio of NCO/OH larger than 2:1 are called quasi prepolymers and these contain free diisocyanate. HDI or TDI prepolymers free of the diisocyanate are often made by removing the volatile diisocyanate by continuous vacuum distillation. Preformulated systems containing an isocyanate A side and a polyol B side, the latter also containing catalysts, surfactants, and blowing agents, are available from system houses. Carbodiimide-modified MDI offers advantages in polyester-based systems because of improved hydrolytic stability (70).

Solution polymerization of the monomers is also conducted in some applications. The solvents used have to be inert to isocyanates. Highly polar solvents (DMF, etc), which are excellent solvents for polyurethanes, have to be used with caution (71). Polyurethanes are also obtained by interfacial polymerization of isocyanatocarboxylic chlorides and glycols to give polyester urethanes (72).

In view of the morphological differences of MDI- and TDI-derived polyurethanes, the former are more suitable for the preparation of segmented polyurethane elastomers, while the latter are mainly used in the construction of flexible polyurethane foams. Segmented TPUs with excellent physical properties are also obtained from 2,6-TDI (73).

For economic reasons the bulk one-step polyaddition method is predominantly used to produce polyurethanes. For example, TPUs are produced by reaction extrusion. In this process the liquid monomers are mixed in a twin screw extruder, and the finished polymer is continuously extruded and pelletized. In the formulation of extrusion-grade TPUs a slight excess of the macrodiol is used. Reaction extrusion is also used in the manufacture of polyurethane engineering thermoplastics produced from MDI and higher boiling glycols, such as 1,6-hexanediol and cyclohexanedimethanol (74). These polymers were introduced by Upjohn/Dow under the trade name Isoplast. Blends of engineering plastics (ABS, acetal, nylon, polyesters, and polycarbonates) with TPUs are also finding uses in some polymer applications (75). The blends or alloys are readily produced by dry-blending and reextrusion.

Segmented elastomeric polyurethane fibers (Spandex fibers) based on MDI have also been developed. DuPont introduced Lycra in 1962. The generic name Spandex fibers designates elastomeric fibers, in which the fiber-forming substance is a long-chain polymer consisting of >85% of polyurethane. Extenders used in Spandex fibers include hydrazine and ethylenediamine. DuPont uses a dry-spinning process in which the polymer solution in DMF is extruded through a spinerette into a column of circulating hot air. Other producers that use the dry-spinning process include Bayer (Dorlastan) and Asahi Chemical Industry (Asahi Kasei Spandex). Wet-spinning processes are also used, in which isocyanate-terminated prepolymers are extruded into a nonaqueous diamine bath. Globe manufacturing is producing Glospan, using this process. Nishin Spinning Co. uses a melt extrusion process to produce Mobilon.

Poly(urethane ureas) are obtained in many aromatic isocyanate applications. For example, water-blown flexible polyurethane foam incorporates urea

linkages in its network structure. The reaction of the isocyanate with water provides an amine function, which reacts with more isocyanate to afford the urea segments. Poly(urethane ureas) are also used in elastomer applications, where diamines are used as chain extenders. Examples include cast elastomers made from TDI prepolymers and MOCA (3,3′-dichloro-4,4′-diaminodiphenylmethane) and RIM elastomers, using diethyltoluenediamine (DETDA) as a chain extender. This chemistry is also used in the formulation of spray elastomers. Aromatic amine-terminated polyols, obtained by hydrolysis of prepolymers based on 2,4-TDI and PPG or polyester polyols, are used with solid high melting aromatic diisocyanates to give one-component systems that cure without moisture. Amine-terminated polyols are also used in RIM and spray applications.

Because of the versatility of the polyurethane system it is possible to introduce comonomers which can affect the physical properties of the derived polymers. For example, photo cross-linkable polyurethanes are formulated using 2,5-dimethoxy-2,4′-diisocyanato stilbene as a monomer (76). Comonomers, having an azoaromatic chromophore, are used in optical bleaching applications (77), or in the formation of photorefractive polymers (78). The latter random polymers have second-order nonlinear optical (NLO) properties. Linear polymers are also obtained from HDI/PTMG and diacetylenic diols. These polymers can be cross-linked through the acetylenic linkages producing a network polymer with properties similar to poly(diacetylenes) (79).

Thermodegradable polyurethanes are produced from MDI, polycaprolactone diol, and 2,2-azobis(2-cyanopropanol). The polymers degrade at about 120°C, and the initial weight loss corresponds to the amount of azo groups in the polymer (80). When the polymerization of MDI and 1,4-butanediol is conducted in 60-crown-20 (60C20) or 36-crown-12 (36C12), respectively, polyrotaxenes are obtained consisting of polyurethane chains enclosed in the crown ethers (81).

Polyurethane Ionomers

The versatility of the polyurethane system is further exemplified by the formulation of ionic polymers (see IONOMERS). Polyurethane ionomers are segmented polymers in which ionic groups are separated by long-chain apolar segments (82). In the presence of water the ionic centers are hydrated. This effect enables ionomers to form stable dispersions in water, and solventless polyurethane coatings are formulated in this manner. The use of *N*-alkyldiethanolamines or dimethylol propionic acid as extenders allows incorporation of ionic groups into the polymer backbone. Also, reaction of—NH—group containing polyurethane chains with sodium hydride, followed by reaction with 1,3-propane sultone, affords ionomers. When the ionic centers are located in the hard segment, they align to form a domain morphology. Anionic dispersions have greater stability than cationic dispersions, but cationic polymers show better adhesion to glass.

Examples of the grafting of ionic groups to the urethane or urea backbone in linear polymers are shown in Table 8.

Ionic polymers are also formulated from TDI and MDI (86). Poly(urethane urea) and polyurea ionomers are obtained from divalent metal salts of *p*-aminobenzoic acid, MDA, dialkylene glycol, and 2,4-TDI (87). In the case of

Table 8. Grafting of Ionic Groups to Linear Polymers

Functional group	Acid precursor	Base	Pendant group	Reference
—NH—		KOH	$\rangle NCOCH_2CH_2COOK$	83

polyureas, the glycol extender is omitted. If TDI is used in coating applications, it is usually converted to a derivative to lower the vapor pressure. A typical TDI prepolymer is the adduct of TDI with trimethylolpropane (Desmodur L).

Liquid Crystalline Polyurethanes

Liquid crystalline polyurethanes are formulated from mesogenic diols, such as 4,4′-bis(ω-hydroxyalkoxy)biphenyls and 2,4-TDI. Examples of the mesogenic diols include 4,4′-bis(6-hydroxyhexoxy)biphenyl (88) and 4,4′-bis(2-hydroxyethoxy)biphenyl (89). More rigid diisocyanates, such as 2,5-TDI and PPDI, are also used with mesogenic diols to form liquid crystal polyurethanes (90). Partial replacement of the mesogenic diols by PTMG with different molecular weights shows that the lower molecular weight flexible spacers form a more stable mesophase and exhibit higher crystallinity (91) (see LIQUID CRYSTALLINE POLYMERS, MAIN-CHAIN; LIQUID CRYSTALLINE POLYMERS, SIDE-CHAIN).

Another approach to liquid crystal polyurethanes involves the attachment of cholesterol to the polyurethane chain utilizing the dual reactivity in 2,4-TDI. In the initial reaction of the diisocyanate with cholesterol the 4-carbamate is produced, which on reaction with diethanolamine affords a diol, which is subsequently polymerized with 2,4-TDI (92).

Liquid crystal polyurethanes are also obtained from mesogenic ester diisocyanates (17). Also, a triad diol, bis(*p*-oxymethylphenyl)terephthalate, is used with HDI, HMDI, or TDI to give liquid crystal polyurethanes (93).

Thermoset Polyurethanes

Flexible Polyurethane Foams. The largest market segment in polyurethanes consists of flexible foams. A flexible polyurethane foam results from the reaction of an aromatic diisocyanate with a mixture of a polyol, water, a surfactant, and a catalyst. Sometimes a coblowing agent is added, but this practice is no longer viable because of environmental considerations. The reaction of the diisocyanate with water generates carbon dioxide gas, which is used as the blowing agent. The simultaneously generated urea acts as a chain extender. The number of moles of water in a polyurethane flexible foam formulation is typically 1–5 times the number of equivalent moles of polyol. Most commercial flexible foam is produced from TDI. In the 2,4-isomer the initial reaction occurs at the nonhindered isocyanate group in the 4-position. The unsymmetrically substituted ureas formed in the subsequent reaction with water are more soluble in the developing polymer matrix. Low density flexible foams are not readily produced from MDI or PMDI; enrichment of PMDI with the 2,4′-isomer of MDI affords a steric environment similar to the one in TDI, which allows the production of low density flexible foams that have good physical properties (94). The use of high performance polyols based on a copolymer polyol allows production of high resiliency (HR) slabstock foam from either TDI or MDI (95).

Flexible foams are three-dimensional agglomerations of gas bubbles separated from each other by thin sections of polyurethanes and polyureas. The microstructures observed in TDI- and MDI-based flexible foams are different. In TDI foams monodentate urea segments form after 40% conversion, followed by a bidentate urea phase, which is insoluble in the soft segment. As the foam cures, annealing of the precipitated discontinuous urea phase occurs to optimize alignment through hydrogen bonding (96).

The formation of cellular products also requires surfactants to facilitate the formation of small bubbles necessary for a fine-cell structure. The most effective surfactants are polyoxyalkylene–polysiloxane copolymers. The length and ethylene oxide/PO (EO/PO) ratio of the pendant polyether chains determine the emulsification and stabilizing properties. In view of the complexity of the interaction of surfactant molecules with the growing polymer chains in foam production, it is essential to design optimal surfactants for each application. Flexible polyurethane foams require surfactants that promote improved cell-wall drainage. This allows the cell walls to become more open during the foaming reaction. Also, the shift away from TDI to MDI in molded HR foams adds new demands on foam surfactants (97).

Flexible slab or bun foam is poured by multicomponent machines at rates of >45 kg/min. One-shot pouring from traversing mixing heads is generally used. A typical formulation for furniture-grade foam having a density of 0.024 g/cm^3 includes a polyether triol (mol wt 3000); TDI; water; catalysts, ie, stannous octoate in combination with a tertiary amine; and surfactant. Coblowing agents are often used to lower the density of the foam and to achieve a softer hand. Coblowing agents are methylene chloride, methyl chloroform, acetone, and CFC 11, but the last has been eliminated because of its ozone-depletion potential. Additive systems (98) and new polyols (99) are being developed to achieve softer low density foams. Higher density (0.045 g/cm^3) slab or bun foam, also called HR foam, is

similarly produced, using polyether triols having molecular weight of 6000. The use of polymer polyols improves the load-bearing properties.

The uncatalyzed reaction of diisocyanates with macroglycols is of no significance in the formation of polyurethanes. Tailoring of performance characteristics to improve processing and properties of polyurethane products requires the selection of efficient catalysts. In flexible foam manufacturing a combination of tin and tertiary amine catalysts are used in order to balance the gelation reaction (urethane formation) and the blowing reaction (urea formation). The tin catalysts used include dibutyltin dilaurate, dibutylbis(laurylthio)stannate, dibutyltinbis-(isooctylmercapto acetate), and dibutyltinbis(isooctylmaleate). The principal tertiary amines used are Dabco (1,4-diazabicyclo[2.2.2]octane) and higher boiling linear tertiary amines, such as pentamethyldipropylenetriamine and bis(dimethylaminoethyl) ether. Hydroxy groups containing tertiary amines are also used because they become incorporated into the polymer structure, which eliminates odor formation in the foam. Delayed-action or heat-activated catalysts are of particular interest in molded foam applications. These catalysts show low activity at room temperature but become active when the exotherm builds up. In addition to the phenol salt of 1,8-diazabicyclo[5.3.0]undec-7-ene (DBU) the benzoic acid salt of Dabco is also used.

Catalysts for urethane applications are sold by Air Products (Dabco), Abbott (Polycat), Kao Corp. (Kaolizer), Tosoh Corp. (Toyocat), and Union Carbide (Niax). Organic mercury compounds were used in cast elastomers and in RIM systems to extend cream time, ie, the time between mixing of all ingredients and the onset of creamy appearance, but are no longer used today because of toxicity concerns.

For the reaction of TDI with a polyether triol, bismuth or lead compounds can also be used. However, tin catalysts are preferred mainly because of their slight odor and the low amounts required to achieve high reaction rates. Carboxylic acid salts of calcium, cobalt, lead, manganese, zinc, and zirconium are employed as cocatalysts with tertiary amines, tin compounds, and tin–amine combinations.

Flame retardants are incorporated into the formulations in amounts necessary to satisfy existing requirements. Reactive-type diols, such as *N,N*-bis(2-hydroxyethyl)aminomethyl phosphonate (Fyrol 6), are preferred, but nonreactive phosphates (Fyrol CEF, Fyrol PCF) are also used. Often, the necessary results are achieved using mineral fillers such as alumina trihydrate or melamine. Melamine melts away from the flame and forms both a nonflammable gaseous environment and a molten barrier that helps to isolate the combustible polyurethane foam from the flame. Alumina trihydrate releases water of hydration to cool the flame, forming a noncombustible inorganic protective char at the flame front. Flame-resistant upholstery fabric or liners are also used.

There are four main types of flexible slabstock foam: conventional, HR, filled, and high load-bearing foam. Filled slabstock foams contain inorganic fillers to increase the foam density and improve the load-bearing characteristics. High load-bearing formulations incorporate a polymer polyol. Slabstock flexible foam is produced on continuous bun lines. The bun forms while the material moves down a long conveyor. In flat-top bun lines, the liquid chemicals are dispensed from a stationary mixing head to a manifold at the bottom of a trough. More rectangular foams are produced by several newer processes such as Draka, Petzetakis, Hennecke, Planiblock, and Econo Foam. However, the most popular rectangular block

foam process is the Maxfoam process. The high outputs require faster and longer conveyors. An exception is the Vertifoam process in which the reaction mixture is introduced at the bottom of an enclosed expansion chamber. The chamber is lined with paper or polyethylene film, which is drawn upward at a controlled rate. Because the Vertifoam machine is much smaller than the horizontal machines, operational savings can be achieved (100). Two newer slabstock foam manufacturing processes have been developed. The Cannon CarDio process injects liquid carbon dioxide into the foam mix to reduce the density whereas the Bayer/Hennecke NovaFlex process is conducted under reduced pressure to lower the density.

The properties of thermoset flexible polyurethane foams are related to density; load-bearing properties are likewise important. Under normal service temperatures, flexible foams exhibit rubber-like elasticity to deformations of short duration but creep under long-term stress. Maximum tensile strength is obtained at densities of ca 0.024–0.030 g/cm^3. The densities are controlled by the amount of water in the formulation and may range from 0.045 to 0.020 g/cm^3 by raising the amount of water from 2 to 5%. Auxiliary blowing agents are also used to reduce density and control hardness. The size and uniformity of the cells are controlled by the efficiency of mixing and the nucleation of the foam mix. Flexible foams are anisotropic and the load-bearing properties are best when measured in the direction of foam rise.

A high rate of block foam production (150–220 kg/min) is required in order to obtain large slabs to minimize cutting waste. Bun widths range from ca 1.43 to 2.2 m, and typical bun heights are 0.77–1.25 m. In a flexible foam plant, scrap can amount to as much as 20%. Most of it is used as carpet underlay and in pillows and packaging. The finished foam blocks are stored in a cooling area for at least 12 h before being passed to a storage area or to slitters where the blocks are cut into sheets. In the production plant the fire risk must be minimized. Temperatures of up to 150°C can be reached in the interior of the foam blocks. Blowing of ambient air through the porous foam allows dissipation of the heat generated in the exothermic reaction.

Most flexible foams produced are based on polyether polyols; ca 8–10% (15–20% in Europe) of the total production is based on polyester polyols. Flexible polyether foams have excellent cushioning properties, are flexible over a wide range of temperatures, and can resist fatigue, aging, chemicals, and mold growth. Polyester-based foams are superior in resistance to dry-cleaning and can be flame-bonded to textiles.

In recent years, molded flexible foam products are becoming more popular. The bulk of the molded flexible urethane foam is employed in the transportation industry, where it is highly suitable for the manufacture of seat cushions, back cushions, and bucket-seat padding. TDI prepolymers were used in flexible foam molding in conjunction with polyether polyols. The introduction of organotin catalysts and efficient silicone surfactants facilitates one-shot foam molding, which is the most economical production method.

The need for heat curing has been eliminated by the development of cold-molded or HR foams. These molded HR foams are produced from highly reactive polyols and are cured under ambient conditions. The polyether triols used are of molecular weight 4500–6500 and are high in ethylene oxide (usually >50% primary hydroxyl content). Reactivity is further enhanced by triethanolamine, liquid

aromatic diamines, and aromatic diols. Generally, PMDI, TDI, or blends of PMDI–TDI are used. Load-bearing characteristics are improved by using polymer polyol. HR foams exhibit relatively high SAC (support) factors, ie, load ratio, excellent resiliency (ball rebound > 60%), and improved flammability properties.

Semiflexible molded polyurethane foams are used in other automotive applications such as instrument panels, dashboards, arm rests, head rests, door liners, and vibrational control devices. An important property of semiflexible foam is low resiliency and low elasticity, which results in a slow rate of recovery after deflection. The isocyanate used in the manufacture of semiflexible foams is PMDI, sometimes used in combination with TDI or TDI prepolymers. Both polyester as well as polyether polyols are used in the production of these water-blown foams. Sometimes integral skin molded foams are also produced.

Rigid Polyurethane Foams. Almost all rigid cellular polyurethanes are produced from PMDI. Some formulations, particularly those for refrigerator and freezer insulation, are based on modified TDI (golden TDI) or TDI prepolymers, but these are being replaced by PMDI formulations. The polyaddition reaction is influenced by the structure and functionality of the monomers, including the location of substituents in proximity to the reactive isocyanate group (steric hindrance) and the nature of the hydroxyl group (primary or secondary). Impurities also influence the reactivity of the system; for example, acid impurities in PMDI require partial neutralization or larger amounts of the basic catalysts. The acidity in PMDI can be reduced by heat or epoxy treatment, which is best conducted in the plant. Addition of small amounts of carboxylic acid chlorides lowers the reactivity of PMDI or stabilizes isocyanate-terminated prepolymers.

The polyols used include PO adducts of polyfunctional hydroxy compounds or amines (see Table 4). The amine-derived polyols are used in spray foam formulations where high reaction rates are required. Crude aromatic polyester diols are often used in combination with the multifunctional polyether polyols. Blending of polyols of different functionality, molecular weight, and reactivity is used to tailor a polyol for a specific application. The high functionality of the polyether polyols combined with the higher functionality of PMDI contributes to the rapid network formation required for rigid polyurethane foams.

From the onset of creaming to the end of the rise during the expansion process, the gas must be retained completely in the form of bubbles, which ultimately results in the closed-cell structure. Addition of surfactants facilitates the production of very small uniform bubbles necessary for a fine-cell structure.

Reactive or nonreactive fire retardants, containing halogen and phosphorus, are often added to meet the existing building code requirements. The most commonly used reactive fire retardants are Fyrol 6, chlorendic anhydride-derived diols, and tetrabromophthalate ester diols (PHT 4-Diol). There is a synergistic effect of nitrogen and phosphorus observed in P–N compounds. Phosphonates, such as Fryol 6, are effective in char formation, whereas phosphine oxide-derived fire retardants are reactive in the gas phase. Because the reactive fire retardants are combined with the polyol component, storage stability is important. Nonreactive fire retardants include halogenated phosphate esters, such as tris(chloroisopropyl) phosphate (TMCP) and tris(chloroethyl) phosphate (TCEP), and phosphonates, such as dimethyl methylphosphonate (DMMP). Highly halogenated aromatic compounds, borax, and melamine are also used as fire retardants in rigid foams.

Insulation foams are halocarbon-blown. Chlorofluorocarbons, eg, CFC-11 (bp 23.8°C) and CFC-12 (bp −30°C), were used extensively as blowing agents in the manufacture of rigid insulation foam. Because of the mandatory phaseout of CFCs by Jan. 1, 1996, it had become necessary to develop blowing agents that have a minimal effect on the ozone layer. As a short-term solution, two classes of blowing agents are considered: HCFCs and HFCs. For example, HCFC 141b, CH_3CCI_2F (bp 32°C), is a drop-in replacement for CFC-11, and HFC 134a, CF_3CH_2F (bp −26.5°C), was developed to replace CFC-12. HCFC 142b, CH_3CCIF_2 (bp −9.2°C), is the blowing agent used in the 1990s. Addition of water or carbodiimide catalysts to the formulation generates carbon dioxide as a coblowing agent. Longer-range environmental considerations have prompted the use of hydrocarbons such as pentanes and cyclopentane as blowing agents. Pentane-blown foams have already been used in the appliance industry in Europe. Pentane-based formulations are typically used in conjunction with water. Because rigid foams blown with alternative blowing agents have lower values [(m·W)/(m·K)] of about 19.5, as compared to 18.0 for CFC-11-blown foams, they are thus less efficient in their insulation performance. In addition, because rigid polyurethane foams at a density of 0.032 g/cm^3 are ca 97% gas, the blowing agents determine the *k*-factor (insulation value).

The catalysts used in the manufacture of rigid polyurethane foams include tin and tertiary amine catalysts. Combinations of catalysts are often used to achieve the necessary balance of reaction rates. This is especially necessary if part of the blowing agent is carbon dioxide, generated in the reaction of the isocyanate with added water. New surfactants are required for the emerging water-coblown formulations, using pentanes as the main blowing agent (101). A typical water-coblown rigid polyurethane formulation is shown in Table 9 (102).

Rigid polyurethane foam is mainly used for insulation. The configuration of the product determines the method of production. Rigid polyurethane foam is produced in slab or bun form on continuous lines, or it is continuosly laminated between either asphalt or tar paper, or aluminum, steel, and fiberboard, or gypsum facings. Rigid polyurethane products, for the most part, are self-supporting, which makes them useful as construction insulation panels and as structural elements in construction applications. Polyurethane can also be poured or frothed into suitable cavities, ie, pour-in-place applications, or be sprayed on suitable surfaces. Spray-applied polyurethane foams are produced in densities ranging from 0.021 to 0.048 g/cm^3. The lower density foams are used primarily in nonload-bearing applications, eg, cavity walls and residential stud-wall insulation, whereas the

higher density foams are used in roofing applications. Applicators can buy formulated systems consisting of the isocyanate component, as well as the polyol side containing the catalysts, surfactants, and blowing agent.

During the molding of high density rigid foam parts, the dispensed chemicals have to flow a considerable distance to fill the cavities of the mold. In the filling period, the viscosity of the reacting mixture increases markedly from the initial low value of the liquid mixture to the high value of the polymerized foam. If the viscosity increases rapidly, incomplete filling results. Chemical factors that influence flow properties are differential reactivity in the polyol components and the addition of water to the formulation. Because venting holes allow the escape of air displaced by the rising foam, a moderate degree of overpacking is often advantageous. Newer high pressure RIM machines have simplified the mold-filling procedure, so filling of intricate molds is no longer a problem.

Rigid polyurethane foam is often poured into cavities, providing both thermal insulation and physical strength. Aircraft carrier hulls and refrigerators and freezers are insulated by in-place applied rigid polyurethane foam.

Many of the rigid insulation foams produced in the 1990s are PUIR foams. In the formulation of poly(urethane isocyanurate) foams an excess of PMDI is used. The isocyanate index can range from 105 to 300 and higher. PUIR foams have a better thermal stability than polyurethane foams (103). The cyclotrimerization of the excess isocyanate groups produces heterocyclic triisocyanurate groups, which do not revert to the starting materials but rather decompose at much higher temperatures. In the decomposition of the PUIR foams a char is formed, which protects the foam underneath the char.

The formation of isocyanurates in the presence of polyols occurs via intermediate allophanate formation, ie, the urethane group acts as a cocatalyst in the trimerization reaction. By combining cyclotrimerization with polyurethane formation, processibility is improved, and the friability of the derived foams is reduced. The trimerization reaction proceeds best at 90–100°C. These temperatures can be achieved using a heated conveyor or a RIM machine. The key to the formation of PUIR foams is catalysis. Strong bases, such as potassium acetate, potassium 2-ethylhexoate, and tertiary amine combinations, are the most useful trimerization catalyst. A review on the trimerization of isocyanates is available (104).

Modification of cellular polymers by incorporating amide, imide, oxazolidinone, or carbodiimide groups has been attempted but only the PUIR foams were produced in the 1990s. PUIR foams often do not require added fire retardants to meet most regulatory requirements (105). A typical PUIR foam formulation is shown in Table 10 (106).

The physical properties of rigid urethane foams are usually a function of foam density. A change in strength properties requires a change in density. Rigid polyurethane foams that have densities of <0.064 g/cm^3, used primarily for thermal insulation, are expanded with HCFCs, HFCs, or hydrocarbons. Often water or a carbodiimide catalyst is added to the formulation to generate carbon dioxide as a coblowing agent. High density foams are often water-coblown. In addition to density, the strength of a rigid foam is influenced by the catalyst, surfactant, polyol, isocyanate, and the type of mixing. By changing the ingredients, foams can be made that have high modulus, low elongation, and some brittleness (friability), or relative flexibility and low modulus.

[a]Crude aromatic polyester.

Rigid polyurethane foams generally have an elastic region in which stress is nearly proportional to strain. If a foam is compressed beyond the yield point, the cell structure is crushed. Compressive strength values of 10–280 kPa (1–14 psi) can be obtained using rigid polyurethane foams of 0.032-g/cm^3 density. In addition, the elastic modulus, shear strength, flexural strength, and tensile strength all increase with density.

Most low density rigid polyurethane foams have a closed-cell content of $>$90%. Above 0.032 g/cm^3, closed-cell content increases rapidly and is generally $>$99% above 0.192 g/cm^3. Bun foam, produced under controlled conditions, has a very fine-cell structure with cell sizes of 150–200 μm.

The availability of PMDI also led to the development of PUIR foams by 1967. The PUIR foams have superior thermal stability and combustibility characteristics, which extend the use temperature of insulation foams well above 150°C. The PUIR foams are used in pipe, vessel, and solar panel insulation; glass-fiber-reinforced PUIR roofing panels having superior dimensional stability have also been developed.

Strong bases, such as potassium acetate, potassium 2-ethylhexoate, or amine–epoxide combinations are the most useful trimerization catalysts. Also, some special tertiary amines, such as 2,4,6-tris(*N,N*-dimethylaminomethyl) phenol (DMT-30), 1,3,5-tris(3-dimethyl-aminopropyl)hexahydro-*s*-triazine, and ammonium salts (Dabco TMR) are good trimerization catalysts.

Semirigid foams are also manufactured. These foams do not fully recover after deformation; they are used in the construction of energy-absorbing automobile bumpers. Integral skin molded foams have an attached densified water skin, which is produced during manufacture. The preferred isocyanate for integral skin foams is carbodiimide-modified liquid MDI, which is used with ethylene oxide-capped polyols or polymer polyols. Thicker skins are obtained by lowering mold temperatures and increasing the percentage of overpack.

Interpenetrating Polymer Networks (IPNs)

Polyurethanes are used extensively in the formation of IPNs because of their inertness and reaction latitudes. They are formed from isocyanate-terminated prepolymers, and chain extension and cross-linking are accomplished using mixtures of diols and triols. The other polymer component involved in the formation of the polyurethane-derived IPNs include *p*-styrene, poly(methyl

methacrylate), polyacrylate, polyacrylamide, poly(vinyl chloride)(PVC), nylon 6, unsaturated polyesters, and epoxy polymers. The urethane prepolymers, chain extenders, and cross-linkers as well as the second monomer and its respective cross-linker can be reacted sequentially or simultaneously in solution or better in bulk. The polyurethane chains in the IPNs have reduced hydrogen bonding because of the presence of the polymer chains formed from the second monomer, which interfere with hydrogen bonding.

Sometimes the formation of polyurethane IPNs is conducted under pressure. For example, a 50:50 polyurethane–polystyrene (PU–PS)IPN is obtained from MDI and PTMG, using 1,4-butanediol and trimethylolpropane as extender and cross-linker. The styrene is cross-linked with divinyl benzene. Increased pressure (up to 20,000 kg/cm^2) increases the mixing of the components as well as the degree of cross-linking (107). In a similar manner IPNs derived from HDI and polystyrene are obtained (108). A simultaneous poly(isocyanurate)–nylon 6 IPN is obtained by mixing a HDI biuret/caprolactam initiator with caprolactam monomer and a prepolymer made from HMDI and a diol at 95°C, followed by polymerization at 140°C, to afford the poly(isocyanurate) star-shaped nylon-6 IPN (109). PU–PVC IPNs are obtained from MDI and poly(caprolactone) (PCL) and PVC. It was found by nitroxide spin labeling studies that the polyurethane consists of a crystalline PCL and an amorphous PCL phase, and that PVC acts as a plasticizer between the phases (110). A polyurethane–polyester IPN with a ratio typical for sheet molding compound (SMC) is obtained from Isonate 143-L (liquid MDI) poly(caprolactone triol), an unsaturated polyester resin and styrene monomer (111). The polymerization is conducted at 60°C, using different initiators (*t*-butylperoxy-2-ethylhexanoate and cobalt naphthenate) to control the reaction rates. The polyester has a solvent effect on the polyurethane reaction. Prior to gelation, the reaction resembles a solution polymerization, and after gelation a bulk polymerization. A recent book reviews PU-derived IPNs (112).

Thermoset Polyurethane Elastomers

Thermoset polyurethanes are cross-linked polymers, which are produced by casting or RIM. For cast elastomers, TDI in combination with 3,3′-dichloro-4,4′-diphenylmethanediamine (MOCA) are often used.

RIM is another important polymerization method used in the manufacture of thermoplastic or thermoset polyurethanes. This high pressure reactive casting process is conducted in RIM machines. Differences between the low pressure casting process and the high pressure RIM process are in the speed and efficiency of mixing. The isocyanates used in the formulation of RIM systems are liquid MDI products (carbodiimide-modified MDI or MDI prepolymers) and PMDI for structural (SRIM) applications. Also, glass reinforced versions are known as RRIM. The RIM process used in the automotive industry consists of high pressure impingement mixing of reactive liquid monomers resulting in short molding cycles. The principal advantage of this process results from the fact that molds are filled with liquids, which requires only 50 lb/in.^{2} clamping pressure as compared to the 2–5 tons/in.^{2} needed for injection molding of TPUs. In order to improve the green strength of the resultant polymers diamine extenders, such as diethyl

toluenediamine (DETDA), are incorporated in the newer automotive systems. Also, internal mold release (IMR) agents based on zinc stearate compatibilized with primary amines were introduced in 1985. The IMR systems are used to reduce the need to apply external mold release agents. An IMR system offers reduced cycle times, improved productivities, less frequent mold cleaning, and lower scrap rate. In the RIM technology, aromatic diamine chain extenders, such as DETDA, are used to produce poly(urethane ureas) (113), and replacement of the polyether polyols with amine-terminated polyols produces polyureas (114). Some physical properties of RIM systems are listed in Table 11.

Polyurethane Coatings

Polyurethane coatings are used wherever applications require abrasion resistance, skin flexibility, fast curing, good adhesion, and chemical resistance. The polyaddition process allows formulation of solvent based or solventless liquid two-component systems, water-based dispersions, or powder coatings. Two-component polyurethane coatings are prepared by mixing the A and B components prior to application to the substrate. The TDI-trimethylolpropane adduct, the HDI biuret, and the isocyanurate of HDI or IPDI are often used as the polyisocyanate component. These systems cure at ambient temperature to give coatings with excellent properties. In order to increase the pot life of the coating systems, one-component moisture coatings are developed. These systems are based on PMDI, MDI, TDI, or HDI and a polyfunctional polyether polyol. These prepolymers (NCO content 3–16%) are stable when stored under dry conditions at ambient temperature. Blocked isocyanates are also used in the formulation of one-component systems. Thus, storage stable one-component coatings that are heat curable can be formulated by mixing blocked polyisocyanates with macrodiols. Also, solvent-free polyurethane powder coatings are known. Both thermoplastic and thermoset binder systems can be used in powder coatings. Thermoplastic powders are mainly used in thick coating applications (125–1000 μm). Polyester polyurethane powders use caprolactam-blocked IPDI or TDI adducts as cross-linking agents. Caprolactam does not cause yellowing and diffuses with a minimum of degassing. Powdered polyesters and blocked isocyanate adducts must be solids with melting points above 50°C to prevent agglomeration during storage. Powder coating systems also

contain pigments, fillers, catalysts (stannous octoate, etc), and small amounts of flow-control additives, and they are cured by baking at 180–200°C for 15–30 min.

Solutions (5–25% solids) of fully reacted polyurethanes based on MDI or IPDI are also used in coating applications. These coatings are used mostly as finish coats on flexible substrates. Because of concern over airborne solvents aqueous polyurethane dispersions are used today. These polymers are prepared by incorporating ionic groups into their backbone, and both cationic and anionic groups are utilized in the preparation of the ionomers. The solvent and water resistance of films formed from aqueous dispersions can be improved by cross-linking. Ionomers are also used in the formulation of speciality adhesives.

Polyurethane coatings are mainly based on aliphatic isocyanates and acrylic or polyester polyols because of their outstanding weatherability. For flexible elastomeric coatings, HMDI and IPDI are used with polyester polyols, whereas higher functional derivatives of HDI and IPDI with acrylic polyols are mainly used in the formulation of rigid coatings. Plastic coatings, textile coatings, and artificial leather are based on either aliphatic or aromatic isocyanates. For light-stable textile coatings, combinations of IPDI and IPDA (as chain extender) are used. The poly(urethane urea) coatings are applied either directly to the fabric or using transfer coating techniques. The direct-coating method is applied for rainwear because the microporous coating is permeable to air and water vapor, but not to liquid water. Microporous polyurethane sheets (poromerics) are used for shoe and textile applications. Alcantara is an artificial velour leather used in the fabrication of fashion wear. Polyurethane binder resins are also used to upgrade natural leather.

Waterborne polyurethane coatings are formulated by incorporating ionic groups into the polymer backbone. These ionomers are dispersed in water through neutralization. The experimental 1,12-dodecane diisocyanate is especially well suited for the formation of waterborne polyurethanes because of its hydrophobicity (115). Cationomers are formed from IPDI, *N*-methyldiethanolamine, and poly(tetramethylene adipate diol) (116); anionic dispersions are obtained from IPDI, PTMG, PPG, and dimethylol propionic acid (117). The ionic groups can also be introduced in the polyol segment. For example, reaction of diesterdiol, obtained from maleic anhydride and 1,4-butanediol, with sodium bisulfite produces the ionic building block, which on reaction with HDI gives a polyurethane ionomer (118). The weatherability of aliphatic polyurethane coatings is related to their structures. Polyester polyol-based polyurethanes are more uv-resistant than polyether polyol-based polyurethanes, but the latter offer better hydrolytic stability (see URETHANE COATINGS).

For baking enamels and wire and powder coatings, blocked isocyanates are used. Blocked polyurethane coatings do not cure below a certain threshold baking temperature. Catalysts, such as tertiary amines or organometallic tin compounds, are used to lower the curing temperature.

Uses

Furniture and Bedding. In most geographic regions flexible foam applications represent the largest volume uses of polyurethanes. The bulk of the use

is for furniture, automotive seating, bedding, and packaging applications. With a broad range of available load-bearing capacity and resiliency, these materials offer degrees of comfort and protection not approached by any other single cushioning material. Flexible slabstock foam is used approximately 60% in furnishings, 35% in automotive application (seating, crash pads, head-armrests, trim, sound insulation, vibration dampening, carpet backing, sun visors, instrument panels, and energy management), and 5% in packaging and other applications. Bedding applications are centered on flexible foam mattresses of a variety of sizes and densities. However, polyurethane mattresses are still encountering significant competition from traditional coil-spring mattresses. Polyurethane foam mattresses are commonly found in hospitals, hotels, universities, and other high volume institutional-type applications. Foaming in-place is often used for packaging of delicate instruments and military parts.

Carpet cushioning is another application for both prime foam and rebounded scrap foam. The prime foam is virgin foam used as a separate carpet underlay or attached directly to the back of the carpet. The latter allows rapid continuous application of liquid chemicals using reaction polymerization technologies. Systems based on prepolymers of TDI or MDI are used in combination with conventional polyols and inorganic fillers. The rebounded scrap foam is made by adhesive binding ground flexible foam scrap, and it is used as a separate carpet underlay.

A significant volume of flexible foam is used in speciality applications, some of which continue to use the earliest type flexible polyester polyurethane foam used mainly for textile lamination. Reticulatd foams are used in air filters.

Construction. Building and construction markets use rigid polyurethane foam produced as boardstock (either produced continuously, discontinuously, or cut from rigid foam buns). The boardstock is then used as roof or wall insulation for commercial and residential buildings, as well as in refrigerated buildings and metal door cores. Residential sheathing uses an aluminum foil-faced boardstock often produced using continuous lamination technologies. Rigid polyurethane foam can also be spray-applied, a technique that is well suited for retrofitting commercial roofs and industrial tank and pipe insulation.

Other significant applications for rigid polyurethane foam include domestic refrigerators and coolers, insulated trailer trucks, shipping containers, and railway cars. Marine applications utilize the flotation/buoyancy characteristics of rigid foams for recreational boats and aircraft carriers. Semirigid polyurethane foam is also used as foam-in-place packaging foam. Polyurethane products are also used in the construction of masks and other life-like surfaces, puppetry, animatronics, and props and sets, both life-size and miniature, for the movie industry.

Spraying of the foam formulation by special two-stream spray guns onto suitable surfaces is often conducted. On-site applications for spray foam include roofs, tanks, vessels, cavity walls, and pipes. Spray-applied polyurethane foams are produced in densities ranging from 1.3 to 3.0 lb/ft^2 (21–48 kg/m^3). The lower-density foams are used primarily in nonload-bearing applications (cavity walls and residential stud-wall insulation). The higher-density foams are used in roofing applications. The 1:1 volume ratio of the A and B components required for spray foams excludes the poly(isocyanurate) chemistry from this application. In spray foam formulations, PMDI in combination with the more reactive amine polyols

are used, and sometimes diamine extenders are added to increase the reaction rate.

Ships transporting liquid natural gas (LNG) are usually insulated with rigid PUIR foam laminates, which provide temperature stabilities from −180 to 150°C. The main fuel tank of the National Aeronautics and Space Administration (NASA) space shuttles is also insulated with PUIR foam. Rigid polyurethane foam is used in engineered foam-in-place packaging of industrial or scientific equipment and in the molding of furniture, simulated-wood ceiling beams, and a variety of decorative and structural furniture components. Rigid foam is also used for the repair of river barges.

Automotive Applications. The global automotive industry utilizes every variation of polyurethane technology. Examples include automotive seating, RIM bumber and fascia, RRIM for light weight rocker panels, rigid polyurethane insulation foam for the walls of refrigerated trucks and underfloor sound insulation, interior panels, and high performance paints and coatings. In 1999 a total of 1.161 million tons of polyurethanes were used in automotive applications (United States: 596 kt/a, Europe: 365 kt/a, and Asia: 200 kt/a).

Recent trends are the increased use of MDI-based flexible foams because higher density foams with good comfort are obtained. Also, dual hardness foam cushioning can be produced more easily with MDI systems. Hot cure TDI foams are being phased out. In Table 12 the distribution of the systems used in the global automotive seating production are shown.

The growth rate of polyurethane RIM/RRIM parts is slowed to only about 1% because of the need to develop products with easier recycling routes, but RRIM-based composite pickup-truck boxes weighing up to 115 kg are currently produced using two separate RRIM molding processes. This trend may positively influence the future growth rate of polyurethane parts. In 1998 RIM/RRIM consumption in Europe was 8935 kt/a, while in the United States, 39,900 kt/a was consumed. The Asian market amounted to 8205 kt/a.

Automotive shock absorbers based on 1,5-NDI and ethylene glycol adipates (Vulkollan) are used in the global automotive markets (total consumption in 1998 was 10.2 kt/a). Systems based on MDI are also used.

For door panels structural RIM molding is used, and fiber reinforced polyurethane interior materials use long fiber injection technologies or compression molding processes. A trend to eliminate PVC in interior panels

presents an opportunity for polyurethanes in skins for door and instrument panels. Also, colored polyurethane skins based on aliphatic isocyanates are backfoamed with conventional MDI-based polyurethane spray foam (Recticel process).

Aqueous two-component polyurethane systems for automotive topcoats are under development. Currently the automotive topcoats are made from solvent-based two-component or blocked one-component systems based on HDI trimer (Desmodur N) or IPDI trimer (Desmodur Z) or both in conjunction with an acrylic polyol. The polyurethane topcoats provide the vehicles with a tough and durable finish with excellent long-lasting glossy appearance ("wet look") One-component aqueous dispersions are already used in electrodeposition primers and pigmented base coats. Soft-feel polyurethane coatings are increasingly used for instrument panels and seat covers.

Polyurethane foams are increasingly used for insulation, sound proofing, and carpet backing in automotive applications. Examples include instrument panels, dashboards, armrests, door liners, sound/vibration dampening mats, bumper cores, and sun visors. These semirigid foams are mainly based on PMDI. Semirigid integral skin foams characterized by a tough elastomeric polyurethane skin formed during manufacture of the low density foam core are also used in interior trim parts. Recently Volkswagon insisted on the elimination of amine emission from polyurethane foams installed in their vehicles. The use of reactive tertiary amine catalysts which become bound to the polyurethane foam would solve this problem.

Automotive windshield and backlight sealants were introduced by Essex (now Dow Chemical) in the 1970s. Excellent tensile strength and toughness combined with good adhesion to primed glass allow automobiles to pass 40 mh rollover tests without the windshield popping out. One component windshield sealants utilize diethylmalonate blocked MDI prepolymers to ensure package stability. In the presence of both tin and mercury or bismuth salts, moisture will cure the sealant under ambient conditions. The U.S. market for automotive sealants in 1997 was 68.5 kt/a.

Antilacerent windshields were also considered by bonding single or multiple layers of polyurethanes to the interior windshield. However, the emergence of the use of air bags in cars has eliminated the need for antilacerent windshields. However, modular window gaskets are produced using the RIM process. The MDI systems based on polyether polyols, glycol, or DETDA extenders require painting in order to achieve good weatherability.

Footwear. Polyurethanes are among the most useful materials for footwear applications. The low weight and high level of comfort of microcellular polyurethane soles and their ease of production, using a reaction molding process led to rapid global adaptation of this technology. Apart from the dominant use of microcellular polyurethane elastomers in the production of shoe soles (street shoes, sport shoes, leisure shoes, and safety shoes), polyurethane flexible or semiflexible foams with or without an integral skin are commonly used to produce in-soles and ski-boot liners. Polyurethanes also offer processing advantages, such as direct molding of the shoe soles to the shoe uppers.

Two basic types of polyurethanes are available as shoe-soling products: polyester- and polyether-based systems. The polyester systems were first

introduced because of their high quality in applications such as safety shoes, boots, and sport shoes. They are also very suitable for direct soling. Lower-cost polyether systems were introduced in the 1970s. Polyether-based systems are the choice for street shoes because of their excellent hydrolytic stability. Polyether polyurethanes also provide better flex resistance at low temperature because of the lower glass transition temperature of the polyether chain. Usually a highly reactive 4000 molecular weight polyether diol is used in combination with a MDI prepolymer and 1,4-butanediol, and small amounts of triols are added to improve the green strength and demolding time. A controlled amount of water and fluorocarbon blowing agents are used in combination with tertiary amine and tin catalysts.

Millable Polyurethane Gums and Elastomers. Polyurethanes with the rheology of natural rubber, so-called *millable gums*, are made by mixing hydroxy-terminated prepolymers and isocyanate cross-linking agents, such as the 2,4-TDI dimer, and other additives on a rubber mill. The milled compound is shaped, compression molded, and heat cured. Millable polyurethane gums are used in synthetic rubber applications such as shock-damping mounts, roll covers, and parts for military vehicles.

Polyurethane elastomers containing ultra high molecular weight polyethylene (UHMWPE) as fillers show improved abrasion resistance. The UHMWPE is dispersed in the polyol in the formation of the filled polyurethanes. Commercial uses include gears, rollers, bushings, and mining screens.

Polyurethanes are also used in the construction of sport surfaces such as all-weather athletic areas, outdoor game areas, children's playgrounds, tennis courts, and multisport halls. The polyether polyurethane systems, mainly based on PMDI, are applied by a pour-in-place method. Often additional rubber granules are added to the system.

Solid polyurethane industrial tires are produced for off-road machines (fork and lift trucks, wheelchairs), pneumatic tires for tractors, backhoe loaders, soft-cast elastomer tires for heavy vehicles and skateboard and roller skate wheels. Polyurethane tires for passenger cars have not as yet been commercialized. Pneumatic tires for tractors are produced using the RIM process. Soft-cast polyurethane elastomers are also used for puncture-free tires, especially for heavy vehicles, replacing the air in pneumatic tires.

Another important application for solid polyurethane elastomers are sealing gaskets in sewage clay pipes. These gaskets are made by casting liquid elastomer systems directly onto the extremities of the pipe. The solidified elastomer will adhere well to the ceramic surface.

Elastomeric spandex fibers are used in hosiery and sock tops, girdles, brassieres, support hose, and swim wear. The use of spandex fibers in sport clothing is increasing.

Polyurethane Adhesives and Sealants. Polyurethane adhesives are known for excellent adhesion, flexibility, toughness, high cohesive strength, and fast cure rates. Polyurethane adhesives rely on the curing of multifunctional isocyanate-terminated prepolymers with moisture or on the reaction with the substrate, eg, wood and cellulosic fibers. Two-component adhesives consist of an isocyanate prepolymer, which is cured with low equivalent weight diols, polyols, diamines, or polyamines. Such systems can be used neat or as solution. The two

components are kept separately before application. Two-component polyurethane systems are also used as hot-melt adhesives.

Waterborne adhesives are preferred because of restrictions on the use of solvents. Low viscosity prepolymers are emulsified in water, followed by chain extension with water-soluble glycols or diamines. PMDI, which has a shelf life of 5–6 h in water, can be used as a cross-linker. Waterborne polyurethane coatings are used for vacuum forming of PVC sheeting to ABS shells in automotive interior door panels, for the lamination of ABS/PVC film to treated polypropylene foam for use in automotive instrument panels, as metal primers for steering wheels, in flexible packaging lamination, as shoe-sole adhesive, and as tie coats for polyurethane-coated fabrics. PMDI is also used as a binder for reconstituted wood products and as a foundry core binder.

Typical one-component elastomeric adhesive formulations are based on a linear poly(butylene adipate) of molecular weight 2000, MDI and 1,4-butanediol as chain extender. Crystallization of the soft polyol segment below 40°C, which occurs after evaporation of the solvent, causes a gain in bond strength. Upon heating of the film with an infrared lamp, the adhesive can be reactivated for bonding. The adhesive systems are manufactured by dissolving the elastomeric polyurethane in the desired solvent or solvent mixture and adding other polymers, fillers, and stabilizers. The polyurethane adhesive technology is also utilized in the formulation of architectural sealants, which are also supplied as both one- and two-component systems. These systems are often modified with epoxy, acrylic, or other polymers and with stabilizers and fillers. One-component automotive windshield sealants utilize diethyl malonate-blocked MDI prepolymers. In the presence of tin, mercury, or bismuth salts moisture will cure the sealant under ambient conditions.

Polyurethane sealant formulations use TDI or MDI prepolymers made from polyether polyols. The sealants contain 30–50% of the prepolymer; the remainder consists of pigments, fillers, plasticizers, adhesion promoters, and other additives. The curing of the sealant is conducted with atmospheric moisture.

Biomedical Polyurethane Applications. Numerous different type of aromatic and aliphatic polyether urethanes and poly(urethane ureas) as well as siloxane–urethane copolymers have been developed for many biomedical applications. The principal products are segmented TPUs based on PTMEG as the soft segment. Biomer, developed by DuPont in the 1960s, uses a diamine as extender, and solutions of the polymer in dimethyl acetamide (DMAc) became available. Biomer was later sold to Ethicon, who withdrew the product from the market in 1991. Pellethane, a TPU based on PTMEG, MDI, and 1,4-butanediol was introduced by Upjohn in the 1970s. Pellethane was used extensively in pacemaker leads, but Dow Chemical, who purchased the chemical division of Upjohn in 1985, decided not to sell Pellethane for biomedical applications, because of potential liabilities. A TPU based on a polycarbonate macroglycol and MDI was introduced recently by Cardiotech (Chromoflex). Improved biodurability was claimed for these polymers (119). Also, Bayer developed improved series of TPUs (Texin 5590), for biomedical applications based on IPDI, using a diamine extender. These poly(urethane ureas) have a higher modulus to allow easy insertion of catheters.

Male polyurethane condoms in the United States had 5% of the market in 1999. The excellent physical properties of TPU films allow the manufacture of very thin condoms by cutting and welding or by solvent dipping.

Polyurethane gels were also developed by Bayer (Levagel) for biomedical applications. These gels are based on quadrafunctional polyether polyols and aliphatic isocyanate prepolymers. The new gels are used in very soft padding for artificial limbs and in the development of wound dressing products. The gels can be foamed to enhance breathability to oxygen and water vapors to promote healing.

Binder Applications. Reconstituted wood products, such as particle boards, wafer boards, medium density fiberboards, and oriented standboards, increasingly use PMDI as a liquid adhesive to bind the wood products. Wood has many hydroxyl groups containing compounds such as cellulose, hemicellulose, and lignin. Polymeric isocyanate binder resins will react with these hydroxyl groups to form chemical bonds between the wood chips. PMDI is a 100% active liquid binder that is easily atomized and provides excellent bonding efficiencies. Dow has developed Isobind, a special PMDI for this application as well as process technology called Optimax, which is available under a licensing agreement with Carbocol Systems, Inc. The use of isocyanate binders achieves faster cure rates and lower temperature cure as compared to other binder resins. Isocyanate binders cure at about 100°C, while phenol/formaldehyde resins cure at 150°C or higher. The demands of public regulatory agencies for control of formaldehyde products, used extensively as wood binding resins, have intensified interest in formaldehyde-free isocyanate binders.

The PMDI-derived reconstituted wood products have found applications as siding materials, shelves, cabinets, furniture, and pallets. Extra large panels are finding uses in the mobile home industry, where entire walls are fabricated from a single continuous panel with greater rigidity and strength. Shipping containers of lighter weight and uniform properties can also be made. PMDI can also be used as a binder for agro waste products. For example, three-layer laminates consisting of top and bottom layers of coconut husks and a core layer consisting of wood chips provide attractive building panels. Waste straw and bagasse is also used in the manufacture of solid wood-like boards.

The use of PMDI as a binder for foundry cores, rubber waste products, and solid rocket fuel are also known. Isocyanate-terminated prepolymers, often prepared from TDI or MDI with polyether polyols are also used as binders for composite products that require elastomeric properties. Athletic surfaces are sometimes prepared from ground rubber tire scrap bonded with isocyanate-based prepolymers. Similarly, flexible polyurethane foam scrap is bonded with isocyanate prepolymers to form rebonded foam useful as carpet underlay. Solidification of incineration ashes with PMDI-based binder systems is another waste disposal application. In this manner hazardous waste materials undergo chemical fixation and detoxification.

The thickening of SMC can be accelerated using hydroxy-terminated unsaturated polyesters in conjunction with isocyanate-terminated prepolymers. Polyurethane ionomer-based sizings for glass fibers used in RRIM applications are also known.

Synthetic leather products are also produced using a urethane binder. These poromeric materials are produced from textile-length fiber mats impregnated with DMF solutions of polyurethanes. Permeability to moisture vapor is the key property needed in synthetic leather. In addition to shoe applications, poromerics are

Table 13. Major Polyurethane Applications in the United States/ Canada and Europe

used for handbags, luggage, and apparel. Polyurethane films having oxygen and water permeability are applied in bandages and wound dressings and as artificial skin for burn victims.

Economic Aspects

In 1998 a total of 2642 kt/a of polyurethanes were consumed in the United States (91%) and Canada (9%). The European consumption in 1998 was 2169 kt/a, and the Asian Pacific Region consumed 1807 kt/a of polyurethane chemicals. Therefore, the total global polyurethane consumption was of the order of 8000 kt/a in 2000. In Table 13 a comparison of significant American and European applications as percentages of the previously mentioned total amounts are shown. With the exception of footwear, the use by application in both regions is almost identical.

The flexible foam market is the largest global polyurethane consumption. In the United States and Canada a total of 1114 kt/a was used in flexible foam applications in 1998. Flexible slab foam is used predominantly in furniture, carpet underlay, and bedding; molded foam is used extensively in transportation. Carpet underlay is manufactured from either virgin or scrap polyurethane foam, which is combined with a binder adhesive.

Of the 687 kt/a of rigid foam produced in the United States and Canada in 1998, more than 50% was used in the construction industry. About 60% of this total was used in laminated boards and insulation panels; about 30% was poured at construction site. Insulated appliances (132 kt/a) and tank and pipe insulation (79 kt/a) are other important uses of rigid insulation foam. Rigid polyurethane foam is produced from PMDI. Another important application of PMDI is particle board binder resins. A total of 160 kt/a of PMDI was used in this application in the United States and Canada in 1998.

The total elastomer consumption in the United States and Canada in 1998 accounted for 245 kt/a. Automotive RIM applications accounted for 65.3 kt/a, TPU for 53.5 kt/a, and Spandex for 26.5 kt/a. Cast elastomers had the highest consumption (100 kt/a). Coatings consumption in the United States and Canada in 1998 was 237 kt/a, and powder coatings accounted for about 20% of the total. Adhesives (105 kt/a) and sealants (80 kt/a) were other important polyurethane applications.

The polyurethane industry is dominated by the multinational isocyanate producers. The principal isocyanate producers (BASF, Bayer, Dow) also manufacture polyols. Dow is one of the largest global producers of polyether polyols, and

Bayer acquired the other primary polyether polyol producer, when it purchased the polyol business of Arco (now Lyondell) in 1999. Also, in 1999 Dow further strengthened its position in polyols when it acquired Union Carbide. Polyether polyols, mainly used for flexible foam production, account for 65 wt% in a flexible foam formulation, 35% in rigid polyurethane foams, and even less in PUIR foams.

The former Olin and Rhone Poulenc TDI production facilities are still operated by Lyondell, but it is unlikely that Lyondell will continue the isocyanate business without the polyether polyol business it sold to Bayer.

Health and Safety Factors; Environmental Aspects

The primary route of exposure to most isocyanates is through inhalation. Isocyanate vapors and aerosol can irritate the mucous membranes in the respiratory tract (nose, throat, lungs) causing nasal irritation, sore throat, coughing, chest discomfort, shortness of breath, and reduced lung function. Persons with a nonspecific bronchial hyperreactivity can respond to extremely low concentrations with similar symptoms as well as asthma attack. Exposure to higher concentrations may lead to bronchitis, bronchial spasm, and pulmonary edema. These effects are usually reversible. As a result of repeated overexposure or a single large dose, certain individuals may develop isocyanate sensitization (chemical asthma), which may cause a reaction to a later exposure at very low concentrations. These symptoms, which can include chest tightness, wheezing, cough, shortness of breath, or asthmatic attack, could be immediate or delayed up to several hours after exposure. Chronic overexposure to isocyanates has been reported to cause lung damage (including decrease in lung function), which may be permanent. Sensitization can either be temporary or permanent.

Both chlorofluorocarbons and methylene chloride are used as blowing agents. Inhalation of high concentrations of chlorofluorocarbons can be dangerous and may cause anesthesia and unconsciousness. Severe acute exposures have caused cardiac arrhythmias, including ventricular fibrillation. Since chloroflurocarbon vapors are heavier than air, high concentrations can accumulate in confined or low-lying areas, displacing air or oxygen supply. Although these materials are considered nonflammable, they can heated to decomposition, generate highly toxic phosgene and carbonyl fluoride. In addition, when confined and subject to high temperatures, chlorofluorocarbons may present an explosion hazard.

Like chlorofluorocarbons, methylene chloride is difficult to ignite, but when heated to decomposition, can produce toxic materials such as hydrogen chloride, carbon dioxide, and carbon monoxide. Upon skin contact methylene chloride can cause irritation, drying, and weakening of the skin. Inhalation can cause central nervous system depression, resulting in impaired judgment and reduced motor ability. Inhalation of high concentrations causes cancer in laboratory animals. It is therefore extremely important to follow the manufacturer's recommendation for the safe use and handling of methylene chloride.

Although the products of combustion vary, virtually all polyurethane foams and materials burn, often generating a variety of toxic, potentially lethal gases

and dense smoke. The type and amount of combustion products vary with product composition, fire conditions, oxygen concentration, and other factors. As in all organic fires, the main toxicant is carbon monoxide. Like other nitrogen-containing polymers oxides of nitrogen and hydrogen cyanide can also be released. Fully cured polyurethanes present no health hazards; they are chemically inert and insoluble in water and are the most organic solvents. However, dust can be generated in fabrication, and inhalation of the dust should be avoided. Polyether-based polyurethanes are not degraded in the human body, and are therefore used in biomedical applications.

Some of the chemicals used in the production of polyurethanes, such as the highly reactive isocyanates and tertiary amine catalysts, must be handled with caution. The other polyurethane ingredients, polyols and surfactants, are relatively inert materials having low toxicity.

Isocyanate Toxicity. Isocyanates in general are toxic chemicals and require great care in handling. Oral ingestion of substantial quantities of isocyanates can be tolerated by the human body, but acute symptoms may develop from the inhalation of much smaller amounts. The inhalation of isocyanates presents a hazard for the people who work with them as well as the people who live in the proximity of an isocyanate plant. Adequate control of exposure is necessary to achieve a safe working environment. The suppliers Material Safety Data Sheets (MSDS) have to be consulted for the most current information on the safe handling of isocyanates.

Respiratory effects are the primary toxicological manifestations of repeated overexposure to diisocyanates (120). Once a person is sensitized to isocyanates, lower concentrations can trigger a response (121). Most of the industrial diisocyanates are also eye and skin irritants. Controlling dermal exposure is good industrial hygiene practice. The 1997 American Conference of Governmental Industrial Hygienists (ACGIH) exposure guideline for TDI is 0.005 ppm as a TWA-TLV (an 8-h time-weighted average concentration); the 1997 TLV for TDI in Japan is 20 ppb.

Overexposure to TDI can cause chemical bronchitis (isocyanate asthma) in sensitized individuals. Transient acute asymptomatic changes in respiratory function and deterioration of lung function following long-term repeated exposure have also been encountered. Allergic sensitization may occur within months or after years of exposure to isocyanates. Animal studies using TDI showed no teratologic response at exposure concentrations up to 0.5 ppm. A chronic gavage study indicated tumor formation in the animals, but the study was found to be of doubtful toxicological relevance because of the method used and the excessively high dose levels. Vapor exposure to MDI is limited by the low vapor pressure, corresponding to a saturated atmosphere of 0.1 mg/m^3 at 25°C. An acute aerosol inhalation study on PMDI using rats indicated that the 4-h LC_{50} is 490 mg/m^3. The current ACGIH TLV for MDI is 0.051 mg/m^3 (0.005 ppm) as a TWA. The OSHA PEL is 0.02 ppm as a ceiling limit.

The toxicity of aliphatic diisocyanates also warrants monitoring exposure to its vapors. HDI has a moderate potential for acute systemic dermal toxicity; rabbit dermal LD_{50} is 570 mL/kg. However, HDI is severely irritating to the skin and eyes. Irritation, lacrimation, rhinitis, burning sensation to throat and chest, and coughing have all been reported in humans following acute inhalation

Table 14. Acute Toxicity of Diisocyanates in Rats[a]

Isocyanate	LC_{50}, mg/kg	1 h LC_{50}, mg/m^3	Std. vapor pressure conc., ppm
HDI	710	310[b]	6.8
IPDI	>2,500	260	0.34
TDI	5,800	58–66	19.6
MDI	>31,600		0.1
NDI	>10,000		0.02[c]

[a]Ref. 122.
[b]4 h.
[c]Vapor pressure at 50°C.

exposure to HDI. HMDI has a low eye and dermal irritation potential, as well as a low potential for acute toxicity. Exposure to HMDI aerosol can cause dermal sensitization of laboratory animals. IPDI can cause skin sensitization reactions as well as eye irritation. The acute toxicity of diisocyanates in rats is shown in Table 14.

There are a multitude of governmental requirements for the manufacture and handling of isocyanates. The U.S. Environmental Protection Agency (EPA) mandates testing and risk management for TDI and MDI under Toxic Substance Control Administration (TSCA). Annual reports on emissions of both isocyanates are required by the EPA under SARA 313.

Thermal degradation of isocyanates occurs on heating above 100–120°C. This reaction is exothermic, and a runaway reaction can occur at temperatures > 175°C. In view of the heat sensitivity of isocyanates, it is necessary to melt MDI with caution and to follow suppliers' recommendation. Disposal of empty containers, isocyanate waste materials, and decontamination of spilled isocyanates are best conducted using water or alcohols containing small amounts of ammonia or detergent. For example, a mixture of 50% ethanol, 2-propanol, or butanol; 45% water; and 5% ammonia can be used to neutralize isocyanate waste and spills. Spills and leaks of isocyanates should be contained immediately, ie, by dyking with an absorbent material, such as saw dust.

The total U.S. airborne emission of volatile TDI is estimated by the International Isocyanate Institute (III) to be <25 t, or less than 0.005% of the annual U.S. production. Published data show that TDI has a 1/3 life of 8 s in air at 25°C and 50% RH, and a 0.5-s to 3-day half-life in water, depending on pH and agitation. Without agitation, isocyanates sink to the bottom of the water and react slowly at the interface. Because of this reactivity, there is no chance of bioaccumulation.

Toxicity of Tertiary Amine Catalysts. The liquid tertiary aliphatic amines used as catalysts in the manufacture of polyurethanes can cause contact dermatitis and severe damage to the eye. Inhalation can produce moderate to severe irritation of the upper respiratory tracts and the lungs. Ventilation, protective clothing, and safety glasses are mandatory when handling these chemicals.

Toxicity of Polyurethanes. These polymers can be considered safe for human use. However, exposure to dust, generated in finishing operations, should be avoided. Ventilation, dust masks, and eye protection are recommended in foam

fabrication operations. Polyurethane or polyisocyanurate dust may present an explosion risk under certain conditions. Airborne concentrations of 25–30 g/m^3 are required before an explosion occurs. Inhalation of thermal decomposition products of polyurethanes should be avoided because carbon monoxide and hydrogen cyanide are among the many products present.

Because polyurethanes are combustible, they have to be applied in a safe and responsible manner. At no time should exposed foam be used in building construction. An approved fire-resistive thermal barrier must be applied over foam insulation on interior walls and ceilings. Model U.S. building codes specify that foam plastic used on interior walls and ceilings must have a flame-spread rating, determined by ASTM E84, of <75 and smoke generation of <450. The foam plastic must be covered with a fire-resistive thermal barrier either having a finish rating of not less than 15 min or equivalent to 12.7-mm gypsum board, or having a flame-spread rating of <25, smoke generation of <450 (if covered with approved metal facing), and protection by automatic sprinklers. Under no circumstances should direct flame or excessive heat be allowed to contact polyurethane or polyisocyanurate foam. The ASTM numerical flame-spread rating is not intended to reflect hazards presented under actual fire conditions.

Recycling of Polyurethanes. For polyurethanes a wide variety of recycling procedures are considered. Examples include mechanical recycling (rebounded foam, adhesive pressing, particle bonding, regrind, injection molding, compression molding), chemical recycling (glycolysis, hydrolysis), feedstock recovery (pyrolysis, hydrogenation, gasification), and energy recovery (incineration). Especially, the large amounts of polyurethanes generated by ELV (end-of-life disposal of motor vehicles) is of present concern. An average of 20 kg of polyurethane per car is globally used.

The glycolysis procedure, pioneered by Upjohn in the 1970s (123), produces reusable polyols. In this process cut-up or pulverized polyurethane products are fed continuously or in batches into a heated reactor containing single glycol or mixtures of glycol at 185–210°C. A clear solution of a urethane polyol in the used glycol is obtained. This polyol, in admixture with virgin polyol, can be used for the manufacture of rigid polyurethane foams. Several pilot plants operate in Europe to produce polyols for rigid foam manufacture using variations of this process. In one process mixtures of polyurethane and PET scrap are used. Even rigid foam from insulated underground pipelines are recycled using the glycolysis process. The chemistry of the glycolysis process involves transesterification of the carbamate groups in the polyurethanes with the reactive solvent. In this manner three-dimensional network polymers are converted into soluble linear polyurethane group containing polyols.

In order to reuse such a polyol in flexible foam manufacture a subsequent propoxylation step becomes necessary, and Dow Chemical has developed a "tandem chemolysis" process for flexible polyurethane polyols.

Flexible polyurethane foam generated in production or recovered after use as seating foam or packaging foam can be recycled by shredding and mixing with a polyurethane binder to produce carpet underlay. Annually, ca 70 kt/a of carpet underlay produced in the United States is made from recycled flexible foam. Powdered flexible foam is also used as filler (up to 30%) in the manufacture of flexible foam products.

PRESSURE-SENSITIVE ADHESIVES

Introduction

A *pressure-sensitive adhesive* (PSA) is a viscoelastic material that adheres without the need of more than light pressure and requires no activation by water, solvent, or heat. The bond that is formed should be a permanent bond in the sense that the PSA remains bonded unless removal is desired and activated by the user. The Pressure Sensitive Tape Council suggests a number of other desirable features of many PSAs, including aggressive tack, the ability to adhere to a variety of surfaces, and to be removed cleanly without leaving residue. A common element to all PSAs is a polymeric network. This network may be uncross-linked or cross-linked, and it may also contain nonpolymeric additives that affect adhesive properties.

PSAs were first used commercially in medical applications in the late 1800s and entered commercial industrial use in the 1920s with the advent of masking tape and shortly thereafter, cellophane tape (1). The earliest PSAs used natural rubber and this elastomer remains one of the three main classes of polymers used in PSAs today. The other two are acrylics, which were introduced in the 1950s, and synthetic block copolymers, which were introduced in the 1960s. PSAs are used in a wide variety of industries today with the majority of PSAs delivered in the form of tapes or labels.

PSA Tape Construction

Because of their sticky nature, PSAs are not available as a bulk material for direct use. By far the most common method of using PSAs is as a tape, which is a thin

Encyclopedia of Polymer Science and Technology. Copyright John Wiley & Sons, Inc. All rights reserved.

coating of PSA coated on a flexible backing material. Tapes are available as rolls (eg, box-sealing tape, transparent office tape), pads or sheets (eg, labels, stamps), and individual pieces (eg, medical bandages, decals). The simplest tape form is a single-sided tape in which one side of the backing is completely coated with a PSA. More complex variations are also available: double-sided tapes, strip coated single-sided tapes (eg, repositionable notes), pattern coated single-sided tapes (eg, some wound dressings), and transfer tapes (ie, where the adhesive layer can be applied to a surface without a backing). There are an extremely large number of variations of PSA tapes available, depending on the types of PSA used, backing materials used, and the overall construction.

A general tape construction includes a thin adhesive layer (10–750 μm) attached to a film or paper backing. It is important for the adhesive to remain attached to the backing, and in some cases it is necessary to provide a chemical primer coating or a surface treatment to the backing to ensure this. Flame and corona treatments are common methods to increase the surface energy of the film. In the case of a roll of tape, the side of the tape opposite from the adhesive is usually treated with a release coating to allow for unwinding of the tape (see Fig. 1a for schematic of laminate construction). Stacks or pads of tape may also be made using the same laminate structure with the exception that a release liner is placed under the bottom piece of tape in the pad. Individual pieces of tape (eg, adhesive bandages) can also be prepared by attaching a release liner to each piece of tape (see Fig. 1b). A transfer tape can be made by replacement of the backing with a second release liner. This allows for the user to apply a free film of PSA to a surface by removing one liner, applying the tape, and then removing the second liner. Alternatively, a single liner that is coated on both sides can be used to prepare a roll form of transfer tape.

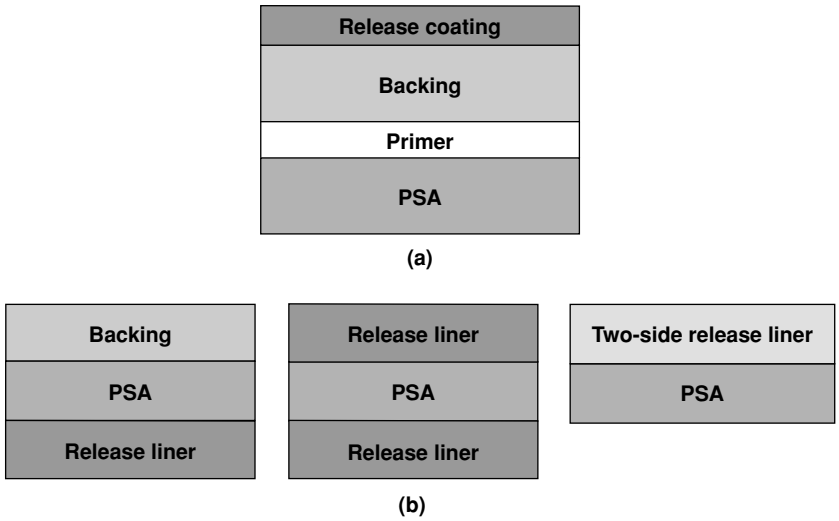

Fig. 1. (**a**) Linerless construction. (**b**) Liner constructions.

Release Surfaces. Since PSAs will adhere to many surfaces with only light to moderate pressure, it is necessary to protect the surface of the PSA until just prior to use. This is done by keeping the PSA in contact with a release surface, that is, a surface that the PSA can be easily peeled from without damaging the PSA. The force needed to remove a PSA from the release surface can vary greatly, ranging from 5 g/25 mm width (premium release) to 2000 g/25 mm width (tight release). The primary requirements are that the force is low enough to avoid splitting the adhesive layer, avoid removing the adhesive from the backing, and avoid deforming the backing during removal. The force of removal should be high enough to avoid having the PSA accidentally come free from the release surface before the user intends to apply it.

Typical release surfaces are made using a release coating, a microscopically thin layer of a low surface energy material that is applied to a supporting substrate. In a roll of tape the release coating is applied to the side of the backing opposite the PSA, so that when rolled upon itself the PSA will be in contact with the release surface (often called a low adhesion backsize in this application). Alternatively, the release coating may be provided on a separate liner that is discarded after being removed from the PSA. The most common release coatings use silicones, long alkyl chain branched polymers, and fluorinated polymers. In addition to providing a low energy surface, many release coatings also contain low molecular weight material that can provide a weak boundary layer between the adhesive and the polymerized portion of the release coating. Although effective for release purposes, the transfer of low molecular weight compounds (particularly silicones) to the surface of the adhesive can sometimes have a negative effect on its subsequent adhesion properties.

Some smooth surfaces have a low enough surface energy that they can serve as a release surface without the addition of a special coating. Many plastics, such as polyethylene, polypropylene, and poly(vinyl chloride), can be release surfaces for some adhesives. Another approach for release without a special coating employs a rough surface, such as a fabric or specially microreplicated surface, that minimizes contact of the PSA with the surface. One should be careful about the tendency of a PSA to flow and fill in crevices when roughness is used to provide release, since this can lead to variations in release force with aging.

Additives. Many PSAs contain additives that, unlike tackifiers or plasticizers, are not intended to affect the inherent PSA properties. Pigments, such as titanium dioxide, are added to change a PSA's appearance. Metal particles or carbon black can be added to provide electrical conductivity. Drugs such as nitroglycerin, nicotine, or estradiol are added for use in transdermal drug delivery.

The most commonly used additives, however, are stabilizers. These are usually added to protect the PSA from thermal-oxidative degradation or from photodegradation, and are generally present at low levels in a formulation (eg, about 0.5–2 wt%). Hindered phenols (eg, Irganox available from Ciba Specialty Chemicals) are most commonly used to prevent thermally induced oxidation, although phosphites and thioethers are also used, sometimes in combination with each other. Ultraviolet absorbers, hindered amines, or simple pigments are most commonly added for protection from photodegradation.

Types of Tape

Industrial Tape. Packaging tapes represent the largest volume of PSA tapes and typically use stiff, oriented polypropylene or polyester film backings to provide low extensibility and high shear strength. Addition of glass or plastic fibers in the lengthwise direction is used in filament tape to provide extremely high tensile strength. Masking tape, the earliest example of industrial tape, typically has a crepe paper backing saturated with rubber. The creping allows for conformability when uneven surfaces are masked, paper allows for easy hand tearability, and the rubber saturation provides resistance to paints and solvents. A number of electrical tapes use plasticized PVC or other similar soft backings to provide conformability for wire wrapping applications.

Consumer and Office Tape. Clear, cellulose acetate tape is widely used as a general-purpose office tape. Paper tapes of all types provide hand tearability and ease of printing, but are generally not used for applications where high strength is required. Strip coated labels are used as repositionable notes.

Medical. Medical tapes often have cloth or cloth-like backings for comfort and breathability. Numerous synthetic breathable, conformable nonwovens (eg, spunlaced polyester such as Sontara, a trademark of DuPont; creped polypropylene) have been developed for such purposes. In some instances, film tapes are preferred to provide a barrier for wound coverage or to increase hydration to speed transdermal drug delivery. Electrically conductive adhesives are used for electrode applications.

Labels. Labels typically have a paper backing, but film backed labels are becoming more common. Labels can be both permanent or repositionable, and water dispersible PSAs are used for compatibility with recycling operations.

Other. Specialized PSA tapes with virtually any possible backing are also available: hook-and-loop (eg, Velcro, a trademark of Velcro USA, Inc.) backing, reflective tapes, magnetic backing, furniture pads, wall hooks, carpet tiles, etc.

Specialty Constructions. Although not solely pressure-sensitive, there are a number of materials which are responsive to other stimuli to either activate, deactivate, or modify PSA-type behavior. Medical adhesives that are not tacky at room temperature, but which undergo a phase transition leading to PSA properties at body temperature, can be used for ease of handling and positioning (2). In a reverse mode, PSAs for medical use that lose their adhesive properties on demand have been developed to make tapes that can be removed with little or no trauma. This transition can be achieved by exposure to light which causes cross-linking and a subsequent stiffening of the PSA (3) or alternatively by swelling with water to effect a phase separation of a water soluble tackifier that disrupts the skin/PSA interface (4,5). Other removal approaches have included application of heating or cooling (2) to effect a phase change of part of the adhesive or application of various solvents or oils to disrupt the interface between PSA and adherend (6). Stretch release tapes allow for a clean and easy removal by using a large stretching deformation in the backing to cause a low removal force at the interface between substrate and PSA (7).

Test Methods

Three main types of test methods are used to determine the physical properties of PSAs: peel, tack, and shear (8) (see also ADHESION). Standard test methods are available for all three properties, and numerous additional variations of tests measuring these properties have also been used (9). Environmental conditions are an extremely important factor in all PSA testing. PSAs are almost always very sensitive to temperature. Many PSAs are also sensitive to humidity, particularly if stored in environments where they can either absorb or lose moisture.

Peel Adhesion. In a peel adhesion test a length of tape is adhered to a surface and then the tape is removed by lifting away from the surface in a specified manner. The results are reported as the force required for a given width of tape. It is important to note whether the mode of failure is adhesive (ie, between adhesive and substrate), transfer (ie, between adhesive and film backing), or cohesive (ie, splitting of the adhesive layer). The standard ASTM method (10) involves adhering the tape to a carefully controlled stainless steel test plate and then peeling the tape from the plate at a controlled rate of 15 cm/min and 180° angle (see Fig. 2). Substrates other than steel (eg, polyethylene, phenolic resin, skin) may be used to try to better model actual use conditions. Similarly, the rate and angle of peel may be modified where appropriate to better match actual usage conditions. Other important factors to control in a peel test include the type of rolldown with which the tape is applied (eg, hardness and diameter of roller, load applied, rate of rolldown, number of passes of roller) and the amount of time the tape is allowed to dwell prior to removal.

It should be understood that, strictly speaking, peel is a tape property rather than a PSA property. That is, the backing or other construction of the tape can often have a strong influence on the peel adhesion. The primary backing effects are the influence on actual peel angle, which can differ from the nominal angle if the backing is sufficiently stiff, and backing deformation, which can occur if the adhesive force is sufficiently large to exceed the strength of the backing.

The peel tests described above are applied rate tests, but peel tests may also be performed as applied load tests. The easiest applied load test to perform is to adhere a tape to a substrate and attach a weight to one end of the tape such that the weight hangs freely below the substrate. The rate at which the load peels the tape from the substrate is then recorded. A low load, low rate variation on this test is a so-called flagging test, in which a tape is wound around a cylinder and

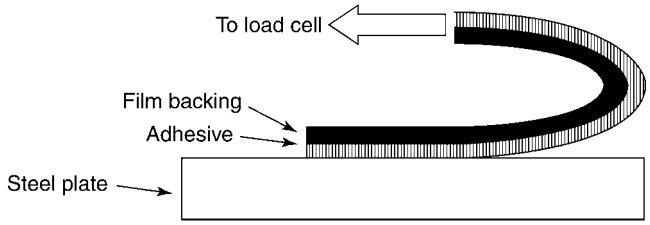

Fig. 2. 180° peel adhesion.

then the rate at which the tape unwinds is measured. In this case, the only load present is due to the weight of the tape and any stress put into the tape during application.

Tack. Tack is in many ways similar to peel adhesion in that a bond is formed and then broken in a lifting manner. When dealing with theoretical descriptions of tack, all of the same considerations that are involved with peel adhesion mechanics are employed. In a practical sense, however, the bond formed in a tack test typically exists for only a short time and is formed with a relatively light amount of force when compared to a peel test. In addition, the test is typically performed with the tape held fixed and a probe or ball being used to contact the tape.

The most common ASTM standard method is a probe tack method (11), in which a cylindrical probe is raised into contact with the adhesive surface of the tape and then pulled back (see Fig. 3). The maximum force attained during removal is reported as the tack value. Typical conditions involve an application pressure of 100 g/cm^2, a contact time of 1 s, and a removal rate of 1 cm/s, but all of these parameters may be varied with most test equipment.

Another ASTM standard method, rolling ball tack (12), involves placing a piece of tape, adhesive side up, at the base of an inclined surface. A steel ball is allowed to roll down the incline from a fixed height, and the distance that the ball travels across the adhesive surface of the tape is taken as a tack value. Longer distances of travel indicate that the tape is less tacky. Other tests involving drums, rollers, or loops of tape have also been used, but are not as common.

Although it can be influenced by backing properties, rolling ball tack is generally considered to be fairly independent of the backing. Probe tack can be more dependent on backing properties, but very flexible backings may be reinforced with more rigid backings in order to reduce the influence of backing on the tack value. More sophisticated tack tests have been developed that measure force throughout the entire debonding process in conjunction with video observation of the bond (13) or using atomic force microscopy as a probe (14).

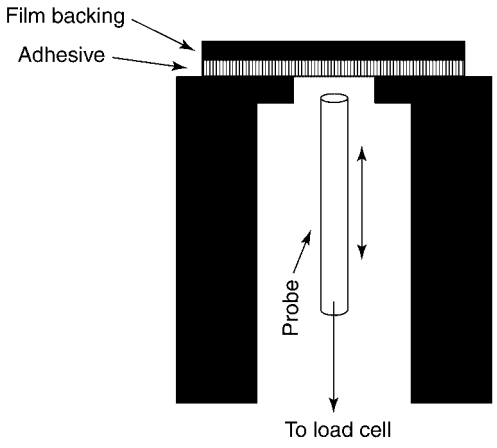

Fig. 3. Probe tack test.

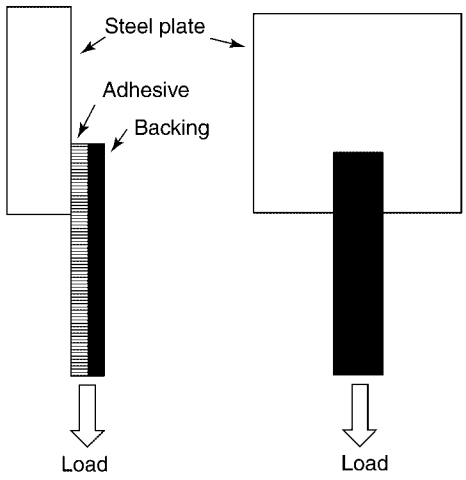

Fig. 4. Shear holding power test. Side view and front view.

Shear Holding Power. Shear represents an entirely different property from peel and tack, and is more related to bulk material properties rather than interfacial properties. The most common ASTM standard method is a holding-power test (15), in which a fixed area of a piece of tape is applied to a vertical test panel and a weight is hung from the free end of the tape (see Fig. 4). The length of time until the load of the weight pulls the tape from the test panel is recorded as the shear holding time. Of particular importance in this test is the mass of the weight used and the area of tape applied to the test panel. Typical contact areas are 0.5 × 0.5 in. (1.27 × 1.27 cm) and 1.0 × 1.0 in. (2.54 × 2.54 cm). Typical weights are 500–1000 g.

As with other pressure-sensitive adhesive tests, the temperature is an important variable and tests are typically carried out at room temperature. A variation on this method is the SAFT test (shear-adhesion-failure temperature) in which the test apparatus is placed in an oven where the temperature is set to rise at 4.5°C/min. The temperature at which the tape fails is recorded as the SAFT value.

In theory, shear is strictly a bulk property of the adhesive that is not affected by surface interactions or the backing in a tape construction. In practice, however, the shear holding power can be affected both by backing and by surface interactions. The force in the shear holding test appears to be entirely in the direction of the hanging tape, but since it is a single-overlap shear joint there are forces generated normal to the plate that can lift the tape from the plate in a peel mode (16). This can be significant for very firm adhesives that have very little tendency to slip in a shear mode, but may be easier to peel from the steel surface. A clear indication that this is occurring is when the mode of failure is described as "pop-off" (ie, the tape falls cleanly from the plate instead of slipping down the face of the plate). Another potentially interfering factor is backing deformation. This is particularly true for tapes with easily deformable backings, but can also be seen for tapes with relatively stiff backings that have adhesives that are extremely resistant to shear

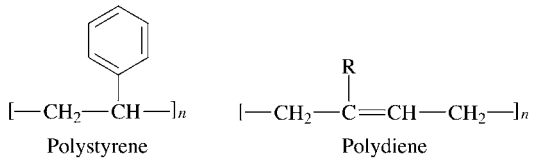
deformation. The backing deformation can cause curling or buckling of the tape that can also lead to the introduction of additional peel forces.

Rheological Tests. Other rheological tests that measure viscoelastic properties are available. Dynamic mechanical rheometry (DMA or DMTA when temperature is included) involves a parallel plate rheometer that can deform a disk of material in a shearing motion. This is done as a function of frequency of shearing and often with varying temperature. The shear storage and loss moduli, G' and G'', or the dynamic viscosity can be obtained with this test. These rheological properties can be related to tack, peel, and shear, and have found much use in development and analysis of PSAs (17). Another way to obtain shear modulus is to use a double-overlap shear apparatus in which the load is applied to a slip plate instead of directly to the tape. This configuration removes both the peel forces associated with single-overlap shear and the potential deformation that may occur in the standard shear holding test.

Materials

There are three major classes of polymers used in PSAs today: block copolymer, natural rubber, and acrylic. A number of other polymers used in smaller, specialty applications include silicones, polyisobutylenes, polyolefins, styrene-butadiene, poly(vinyl alkyl ether)s, and polyurethanes.

Block-Copolymer Rubbers. Block copolymer rubbers are thermoplastic elastomers that are the most widely used class of PSAs (see ELASTOMERS, THERMOPLASTIC). The most commonly used are ABA block copolymers, where A is polystyrene and B is a polydiene. Polyisoprene (R = CH_3) and polybutadiene (R = H) are the most common B polymers, giving SIS and SBS copolymers, respectively (see BUTADIENE POLYMERS; ISOPRENE POLYMERS).



Polystyrene Polydiene

The mechanism by which these perform is based on phase separation of the polystyrene and the polydiene. The polystyrene is generally present in an amount from 10 to 20% of the rubber, and as the minor component it phase separates into microscopic spherical domains that act as cross-links at each end of a polydiene polymer chain. Molecular weights of the entire block copolymer are typically of the order of 100,000–200,000 g/mol. At room temperature the polystyrene is glassy ($T_g \sim 100°C$) and the polydiene is rubbery ($T_g \sim -70°C$). Each SIS (or SBS) polymer chain will have each chain end anchored in a glassy polystyrene domain, with a rubbery polyisoprene link connecting them. Thus the material acts as a cross-linked rubber. When the temperature is increased to above the polystyrene T_g, the microscopic polystyrene domains can be melted, allowing the individual polymer chains to flow and this allows the material to be hot-melt processed. Upon cooling

the domain, structure is reformed. A tackifier is always needed, and plasticizers are often added as well to increase tack and reduce cost.

Block copolymers are synthesized by an organic solution anionic polymerization that can lead to high purity, fairly monodisperse, and relatively low cost polymers. The solvent is then removed from the polymer which is available commercially in the form of rubber pellets or crumb. Adhesives can be prepared by dissolving the rubber in solvent, formulating with tackifier and/or plasticizer, and subsequently coating from the same solvent. This is typically used for small volume products or for small-scale laboratory experiments.

More typical, though, is hot-melt processing of these adhesives. The rubber is blended with tackifier and/or plasticizer in a bulk mixer or extruder at elevated temperature (eg, 150–200°C), coated as a molten liquid, and cooled. The lack of need for post-curing is a significant advantage over natural rubber PSAs. The high purity and consistency of the input rubber is also an advantage when compared to natural rubber.

The high degree of cross-linking gives adhesives with high cohesive strength, but can be a disadvantage in situations where stress relaxation of the adhesive is beneficial. A number of variations on the basic SIS or SBS copolymers are available. Differing amounts of di-block, SI or SB, polymer may be included which causes incomplete cross-linking, and will typically lead to higher adhesion, better stress relaxation, and lower shear strength.

Typical formulations are shown in Table 1 (18). The rolling ball tack is clearly dependent on the amount of tackifier with lower levels of tackifier giving superior rolling ball tack. The probe tack also shows a decrease in force with increasing tackifier. Shear holding strength shows an increase with increasing coupling efficiency because of the formation of a stronger cross-link network. Interesting differences between shear holding power to steel and to kraft paper illustrate the importance of the substrate selection when testing a PSA. The peel adhesion behavior is somewhat more complicated, since it is strongly influenced both by

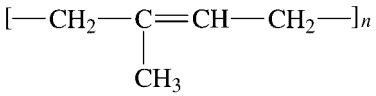
initial adhesion and by the ability of the adhesive to deform and absorb energy upon removal. Increasing tackifier levels will generally increase adhesion because of the dilution of the polymer network, which increases molecular mobility and reduces the PSA storage modulus. However, increasing tackifier will also increase the T_g of the PSA, and if the T_g reaches or exceeds the use temperature then the material will entirely lose PSA properties.

Antioxidants are usually employed to prevent oxidation of the double bond in either of the polydienes. Specialty grades are available where the polydiene has been hydrogenated, which gives much better chemical stability and uv resistance. Multiarm and star-block copolymers are some examples of specialty copolymers that can be used to modify the performance of block copolymer adhesives (19).

These PSAs are still commonly referred to in much of industry as Kraton (a trademark of Shell Chemical) adhesives, although block-copolymer rubbers are also available worldwide from several other major sources: Dexco, Enichem, and Nippon-Zeon. The most common uses of block-copolymer PSAs are in packaging tapes, although they find use in nearly all types of PSA applications.

Natural Rubber. Natural rubber is obtained from the *Hevea brasiliensis* tree as a latex. It is primarily *cis*-1,4-polyisoprene with small amounts of bound proteins and other contaminants (see RUBBER, NATURAL).



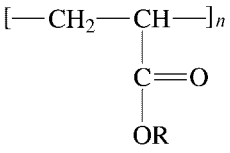
The latex is ammoniated, coagulated, and air dried or smoked to obtain gum rubber. As with most other rubbers, a tackifier must be blended with natural rubber in order to produce a PSA, since the rubber itself has a very low glass-transition temperature ($T_g \sim -70^\circ C$) and a high shear storage plateau modulus. The molecular weight of the input rubber is quite high, greater than 1,000,000 g/mol, and so the rubber is usually milled between steel rolls to break the rubber chains and reduce the molecular weight to make subsequent processing easier (20).

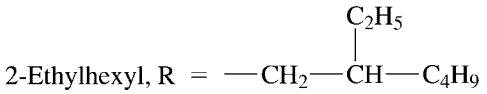
When coated from solvent, natural rubber can be used to make a PSA with a combination of good cohesive shear strength and the ability to dissipate stress within a bond. This is due to the ability of the high molecular weight of the polyisoprene to establish good shear strength without the need for cross-linking. The lack of cross-linking aids in stress relaxation. Because of the double bond in polyisoprene, natural rubber is subject to oxidation, and antioxidants are typically added to the adhesive formulations.

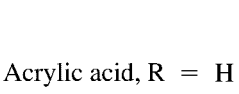
Natural rubber can also be formulated and coated directly from latex, although the costs are typically higher than compounding of gum rubber and coating from solvent. Hot-melt processing of natural rubber is a newer technology that offers the possibility of efficient, solvent-free production (21). Because the high molecular weights of the natural rubber will not survive a hot-melt extrusion or mixing process, it is necessary to post-cure hot-melt natural rubber adhesives with, for example, electron beam radiation curing if high cohesive strength is necessary.

The most common uses of natural rubber PSAs are in masking tapes, packaging tapes, duct tapes, and other cloth tapes.

Acrylics. Acrylic adhesives are copolymers produced from esters of acrylic acid (see ACRYLIC ESTER POLYMERS). An acrylic copolymer suitable for use in a PSA must contain a significant fraction of a monomer that gives a homopolymer with a low glass-transition temperature (T_g). This monomer will typically give a homopolymer with a T_g less than −20°C and usually in the range of −40 to −80°C. It is this low T_g monomer that gives the PSA its soft, tacky properties. The most common monomers used to give low T_g polymers are 2-ethylhexyl acrylate, isooctyl acrylate (3M Company manufactures isooctyl acrylate for internal consumption), and butyl acrylate.







The tacky characteristic of an acrylic copolymer was described as early as 1933 (22). On their own, these low T_g homopolymers are tacky, but they lack the cohesive strength needed to make suitable PSAs, and therefore need reinforcement to prevent the PSA from splitting and oozing during use. There are a number of methods for providing this reinforcement, including the addition of high T_g monomers to the copolymer; addition of monomers that cause intermolecular interactions between individual copolymers; covalent cross-linking of the copolymer; and physical cross-linking of the copolymer via graft or block copolymers.

The first useful acrylic PSAs were introduced in the 1950s with the incorporation of high T_g functional monomers (23), such as acrylic acid and acrylamide, used for reinforcement. This continues to be a widely used approach for acrylic PSA reinforcement. Typical acrylic PSAs contain up to 10% of these reinforcing monomers. Additional high T_g, but nonfunctional, monomers may also be added to the copolymer, with some typical examples being vinyl acetate, ethyl acrylate, methyl acrylate, and methyl methacrylate.

Graft copolymers that provide reinforcement may be prepared in a manner somewhat similar to that of the rubber block copolymers. The graft copolymers are prepared by adding macromonomers (ie, polymers with a reactive functional group on one end) during copolymerization. Typical macromonomer examples are polystyrene or poly(methyl methacrylate)s, with molecular weights between 2000 and 50,000 g/mol, that are terminated with a reactive acrylate group. The block structure that forms differs from the A–B–A rubber copolymers, since the macromonomers are incorporated into the polymer at random. The combination of polydispersity in the length of the acrylic backbone, polydispersity in the number of grafts per backbone, and polydispersity in the length of each graft generally leads to adhesives that do not possess as much elastic strength as the A–B–A rubber copolymers.

Acrylic adhesives tend to be more stable than rubber-based adhesives since they have a saturated backbone. They are also generally designed so that they function as PSAs without the need for any tackification or plasticization, although tackifiers can be added to modify adhesion or reduce cost. Both of these features help to differentiate them from rubber-based PSAs. The ability to avoid use of tackifiers and antioxidants makes acrylics a good choice for medical applications where minimal skin irritation is desired.

Acrylic PSAs can be prepared by a number of synthetic routes and the subsequent processing into a PSA tape naturally varies. The earliest synthetic method was free-radical polymerization in an organic solvent. The resulting solution is usually directly coated to make a tape or mixed with other components (eg, additional solvent, tackifier) prior to coating, but it may also be dried of solvent to provide bulk adhesive for later compounding steps.

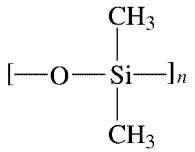
Acrylics can also be prepared in water by either emulsion or suspension polymerization. Both of these water-based polymerizations rely on the insolubility of the acrylate monomers in a continuous aqueous phase which leads to the creation of small polymeric particles dispersed in water. Although superficially similar, there are important differences between the two types of polymerization, with the most significant being that suspension particles are typically 50–500 μm in diameter, whereas emulsion particles are typically 50–200 nm in diameter (24). Emulsions are widely used since the small particle size can lead to well-stabilized dispersions and also help to effect good film forming properties. Emulsions have an advantage over solution polymers, since the molecular weight of the polymer can be controlled independently of the rate of reaction, allowing for very high molecular weights to be obtained. Suspensions are less common, but in some cases the large particle size can be used to control tape properties. One prominent example is in repositionable notes (eg, Post-It, a trademark of 3M) which take advantage of the low surface contact area of the large particles to keep adhesion at a controlled, low level.

Acrylics can also be bulk polymerized. One method for bulk polymerization involves coating a mixture of acrylic monomers along with a photoinitiator onto a film and uv curing to form the adhesive in place. Also being solventless, this can be an attractive method for making thick coatings. In addition, novel phase structure can be imparted by in place curing in some instances [eg, bicontinuous microemulsions (25)].

Acrylic PSAs find wide use in office tapes, medical tapes, packaging tapes, automotive tapes, and specialty applications where good stability is desired.

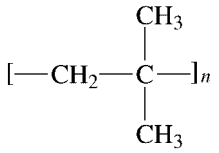
Specialty Materials.

Silicones. Most silicone PSAs are based on a poly(dimethylsiloxane) network that is chemically cross-linked during a curing process.



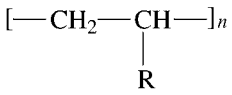
This cross-linked network is generally prepared by addition of a multifunctional, reactive silicate resin to a long chain poly(dimethylsiloxane). They can be prepared to have very high temperature performance, good solvent resistance, and low irritation in medical applications (see SILICONES). Among their disadvantages, however, is that they tend to be expensive, are usually applied from solvent, and usually need a specialty release liner, since they will not release well from most silicone-based release liners (26).

Polyisobutylene. Polyisobutylene (PIB) is an all hydrocarbon elastomer prepared by cationic polymerization of isobutylene.



The lack of double bonds gives it good chemical stability. PIB varies from a liquid to a rubber as the molecular weight is shifted from low (<5000 g/mol) to high (>100,000 g/mol). PIB PSAs are usually prepared as a mixture of PIB rubber with a tackifier or oil in a manner similar to other rubber-based PSAs. Low molecular weight PIB can also be used as a tackifier in blends with high molecular weight PIB or in blends with other rubbers as well. One advantage of a high and low molecular weight blend of PIBs is that this takes full advantage of the inherent chemical stability. These adhesives are typically used in applications where good aging or chemical resistance is needed (eg, pipe wrap, electrical tapes) or in medical applications where low skin irritation potential is beneficial. Among their disadvantages is that they are difficult to cross-link, so that they usually have low cohesive strength, and very high molecular weight PIBs need to be solvent processed since they become difficult to hot-melt process (27).

Polyolefins. A variety of amorphous poly(α-olefins) have been used as the base elastomer in PSAs.



Polypropylene, R = CH_3 Polyhexene, R = C_6H_{13},

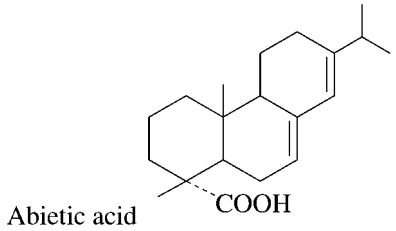
Typical polypropylene and polyethylene materials are highly crystalline and thus have little applicability in PSAs. The key to using a polyolefin in a PSA is to select one with a high degree of amorphous character. These range from amorphous polypropylene or propylene–ethylene copolymers to poly(α-olefins) with longer side chains that disrupt crystallinity (28,29). Polyolefins are usually either tackified or cross-linked to produce suitable PSA properties. The lack of double bonds provides stability benefits similar to those in PIB. The raw materials are generally low cost and can be hot-melt processed. Among their disadvantages is that they

do not yet have the wide range of formulation flexibility that can be achieved with block-copolymer or acrylic PSAs.

Tackifiers/Plasticizers

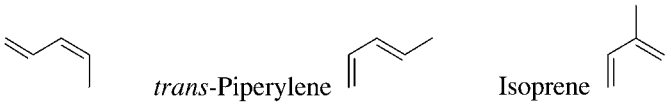
As mentioned above, tackifiers and/or plasticizers are often used as part of many PSA formulations, most particularly in synthetic and natural rubber PSAs. Tackifiers and plasticizers are low molecular weight compounds that are compatible with the base polymer of the PSA. They act as a diluent in the base polymer of the PSA because they are not part of the polymeric network made up by the base polymer (30). They must be compatible with the base polymer to avoid problems of phase separation. In particular, if the tackifier/plasticizer has a lower surface energy than the base polymer, then phase separation can create a layer of pure tackifier/plasticizer on the surface of the PSA and destroy the tack of the formulation. The most common tackifiers are based on rosin acids, small-chain hydrocarbons, and terpenes.

A typical rosin acid is abietic acid, although the acids used for most rosin-based tackifiers are chemically modified, often by hydrogenation and/or esterification to form more stable products.



Abietic acid

The small chain hydrocarbon tackifiers are oligomers with molecular weights in the range of several hundred to 2000 g/mol. They are typically obtained from petroleum feed streams and fall into three general classes. The most common C-5 aliphatic hydrocarbons are *cis*- and *trans*-piperylene and isoprene.



cis-Piperylene *trans*-Piperylene Isoprene

The similarity in chemical structure to isoprene explains why these are quite compatible with natural rubber and synthetic isoprene-based polymers (or block copolymers). The C-9 aromatic hydrocarbon resins include indene- and styrene-based oligomers. Because of the difference in chemical structure these will associate with the end-blocks in S–I–S copolymers, and thus have a reinforcing effect and improve high temperature performance. Finally, mixtures of aliphatic and aromatic hydrocarbon resins are commonly used as a way to tailor compatibility and physical properties of the resultant PSAs.

Terpenes are similar to the aliphatic hydrocarbon resins in that the most common, α- and β-pinene, can be considered to be dimers of isoprene.

α-Pinene β-Pinene

Like rosins, terpenes are derived from pine trees (via turpentine) or other natural sources, such as citrus peels.

The difference between plasticizers and tackifiers is somewhat arbitrary and the effect of this difference is described below in the section on Physical Properties. Plasticizers are typically lower in molecular weight and melting or softening point than are tackifiers. Hydrocarbon oils including aromatic, naphthenic, and paraffinic are commonly used with rubber-based adhesives. Phthalates, such as dioctyl phthalate or dibutyl phthalate, are more typically used in small amounts with acrylics. Since plasticizers are usually low molecular weight compounds, there is often more latitude in the chemical types that will be compatible with the base polymer because of the contribution from entropy of mixing.

Physical Properties

By definition a PSA must have physical properties that differ from most ordinarily encountered materials. It should behave like a liquid when it is forming a bond with a substrate, but after application it should behave like a solid in order to retain the bond. This dual liquid–solid behavior should be present without the need to make any chemical or physical modifications to the PSA, but should rather be an intrinsic material property.

When acting as a liquid it must have an appropriate surface energy that will allow it to wet a substrate. Liquids with appropriate surface energy have the capability to easily wet a substrate because of the high degree of molecular mobility that they possess. Except in very limited circumstances though, (eg, two smooth glass plates "bonded" together by a thin layer of liquid), they do not have enough strength to keep two surfaces bonded together. So in order to have the needed strength to be a PSA, a material must be a solid, but it must be capable of behaving like a liquid during the time it takes to form a bond (of the order of 1 s).

Polymers are the only class of materials that possess this combination of properties. Because of their extended, chain-like molecular structure they form networks (which may or may not be cross-linked) that resist large-scale molecular motion, and therefore provide solid-like behavior. The portions of the polymer molecule in between network junctions, however, can undergo small-scale motion that is similar to that of a liquid when viewed on a short time scale. An important feature of all PSAs is the glass transition temperature T_g of its polymeric components. If the PSA is cooled below its T_g, then it will behave like a glassy solid, since even the small-scale, between-network motions will be frozen. Above its T_g, though, the

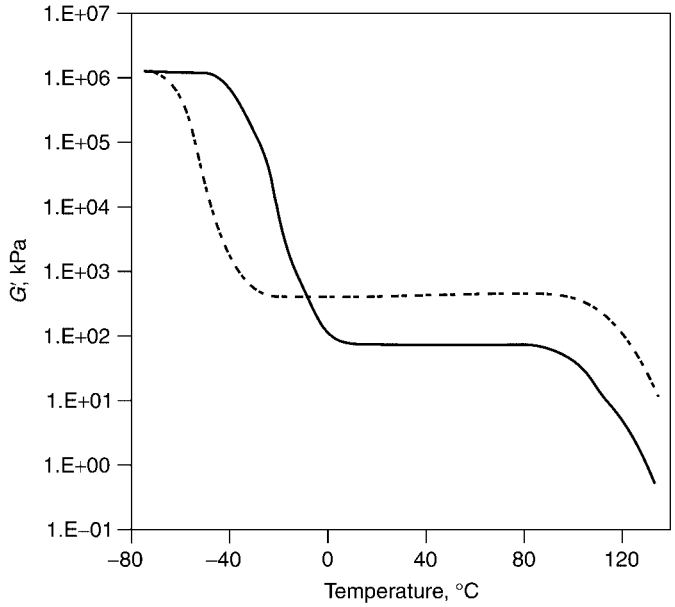


Fig. 5. Storage modulus of rubber (dotted line) and rubber+resin PSA (solid line) as a function of temperature. To convert kPa to psi, multiply by 0.145.

small-scale, between-network motion provides the liquid-like behavior needed for bonding.

The ability to form an initial bond is most generally referred to as the "tack" of a PSA. It is necessary for the glass transition of the PSA to be below the application temperature. It is also necessary, however, for the plateau storage modulus G' of the PSA to be low enough to allow the PSA to deform sufficiently to make good intermolecular contact with the adherend. The Dahlquist criterion for bonding states that G' needs to be less than 100 kPa on a 1-s time scale. This is a good general rule of thumb, although the amount of intermolecular contact will also be influenced by PSA thickness, surface roughness, and application pressure.

In Figure 5, the storage modulus of a typical cross-linked rubber is compared to that of a PSA made from a mixture of the rubber and tackifier. The rubber has a low T_g, which is why it is soft and rubbery at room (or use) temperature, but its modulus is too high for it to be a PSA. Addition of tackifier decreases the modulus below the Dahlquist criterion and allows for the mixture to be a PSA. The effect of dilution of the rubber network with a tackifier can be predicted by rubber elasticity theory using the equation below (31,32). The effect of fillers can also be predicted.

$$G_e \cong v^2(\rho/M_e)RT(1 + 2.5c + 14.1c^2)$$

where G_e is the plateau modulus, v the volume fraction of network molecules

in the continuous phase, ρ the density, M_e the entanglement spacing molecular weight, R the gas constant, T the temperature, and c the filler volume fraction. In the common case of an S–I–S block copolymer, the continuous phase comprises the polyisoprene and mid-block tackifiers and the filler volume comprises the polystyrene and end-block tackifiers.

Although the T_g of the mixture increases with additional tackifier, it is still below room temperature. Addition of more tackifier will continue to reduce the plateau storage modulus, but will eventually raise the T_g above the use temperature and the subsequent mixture would have no tack.

As described above, the distinction between plasticizers and tackifiers is somewhat arbitrary, but the important difference between the two is that addition of a plasticizer will not affect or will lower the T_g of the PSA formulation. The effect of lowering the modulus is the same as for a tackifier.

The glass-transition temperature of the mixture can be approximately calculated using the Fox equation (33):

$$\frac{1}{CT_g} = \frac{x_1}{Tg_1} + \frac{x_2}{Tg_2} + \cdots + \frac{x_n}{Tg_n} \quad (1)$$

where CT_g is the calculated glass-transition temperature; $x_1, x_2, \ldots, x_n$ are the weight fractions of the adhesive components; and $T_{g1}, T_{g2}, \ldots, T_{gn}$ are the T_g's for the individual components. More complex approximations for the glass-transition temperatures are also available (33,34).

Once a bond is created, the PSA should resist removal (unless controlled or easy removal is a desired feature for a particular product). Adhesion can be looked at as being controlled by two primary components. The *intrinsic adhesion* (also called *the work of adhesion*) between the adhesive and substrate is caused by intermolecular interactions. These can be van der Waals interactions for nonfunctional adhesives (eg, rubbers, polyolefins) or can also include hydrogen bonding, acid–base interactions, or actual covalent chemical bonding (35). The intrinsic adhesion, however, is generally small when compared to the practical strength of the adhesive bond, which is the force of adhesion that is actually measured (36). This is due to the second contribution to the force of adhesive removal, which is the ability of the adhesive to viscoelastically deform and absorb energy prior to debonding. The adhesive force for PSA bonds has been extensively analyzed using the theory of fracture mechanics (37–44). In a general sense, one can say that debonding occurs when the adhesive has been deformed sufficiently to store enough elastic stress to overcome the intrinsic work of adhesion.

In Figure 6, a generalized peel force vs peel rate curve is shown. At very low peel rate the dotted line indicates that the adhesive is undergoing cohesive failure. As the tape is slowly lifted away from the substrate the adhesive is able to undergo viscous deformation and absorb all of the energy being imparted by the peel before it can be transferred to the surface. Put another way, the viscous dissipation is rapid enough at slow peel rates to prevent the adhesive from building up enough stored elastic energy to overcome the intrinsic adhesion at the surface. The modulus of the adhesive increases with increasing rate leading to

increasing peel adhesion force. A transition will occur at a sufficiently high peel rate where the adhesive can now build up enough stored elastic energy to cleanly and smoothly remove from the substrate. Beyond this transition rate the peel force again increases with increasing peel rate (shown by the solid line) until another transition occurs to "shocky" peel. This "shocky" peel is related to the increased stiffening and glass-like behavior of the adhesive at increasing peel rate. In a roll unwind case, the unwinding tape will accelerate as it passes this shocky peel transition since the peel force will now begin to decrease with increasing rate. Since most peel is performed by pulling the tab end of a tape at a constant rate, the tape unwinding from the roll will move faster than the tab being pulled until slack accumulates in the tape, causing the effective peel rate at the roll to drop to near zero. As the tab end continues to be pulled the slack is taken up and this process is repeated to give a jerky or shocky peel. The peel force shown in Figure 3 for the shocky region (dashed line) is an average peel force, since the instantaneous peel forces measured will vary greatly.

A specific type of adhesive failure is "lift" which is a very slow low-angle peel of a tape at its edges. The optimal physical properties to resist lift often differ from those necessary to provide high short-term peel adhesion. Longer time (low frequency) material properties become important, and the ability of the adhesive or backing to relax stress over time also becomes important, since stresses imparted to the tape during application can lead to long-term failure if they cannot be dissipated.

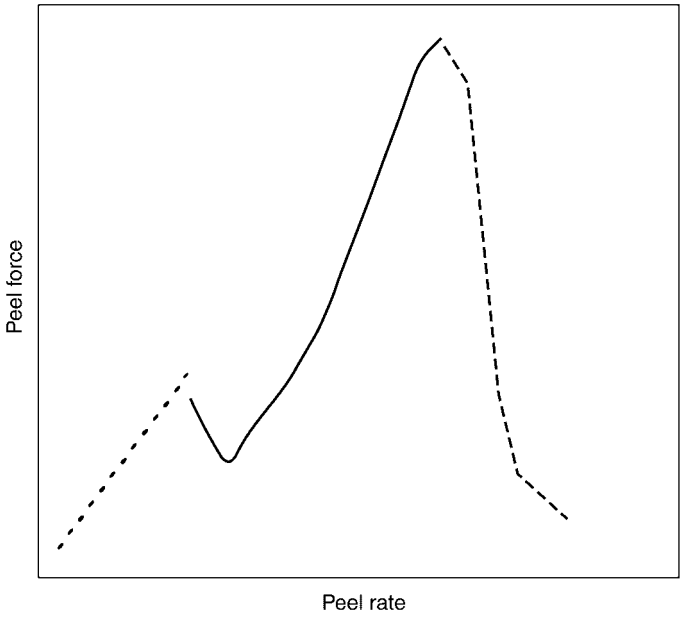

Fig. 6. Peel force vs peel rate schematic showing cohesive failure (dotted line), adhesive failure (solid line), and shocky peel (dashed line).

Another undesirable feature of a PSA tape is creep or oozing. This is most often seen with uncross-linked adhesives that undergo viscous flow over long times. This is governed by properties similar to those that govern lift, except that the ability of the adhesive to relax stress through flow (which helps reduce lift) can lead to increased creep. It is usually necessary to strike a balance between lift, creep, and the short-term tack and adhesion properties needed in a PSA tape.

General Manufacture

A wide variety of methods have been used to make PSAs and PSA tapes, ranging from multistep processes to completely integrated manufacturing methods. Synthesis of the PSA (or PSA-component-like rubber) can be a solvent-based process (eg, organic solution, emulsion, or suspension polymerization) or a solventless process (eg, reactive extrusion, bulk polymerization).

A common thread through nearly all PSA tape manufacture is a processing step where the PSA is present as part or all of a liquid phase (distinguished from the "liquid-like" behavior it shows during use) that may be applied to a surface in a thin coating. This liquid phase is obtained in three primary ways. The PSA is dissolved as a solution in organic solvent or water and the solvent or water is removed by drying after the coating step. The PSA is heated to a temperature at which it becomes molten (ie, hot-melt processing) and the PSA is cooled after the coating step. The PSA is formed by coating low molecular weight liquid compounds that may be polymerized in place after coating. General industry trends are toward solventless processes since these eliminate the use of hazardous organic solvents and the high energy usage due to drying.

The PSA is usually coated directly onto the backing film, although it may also be coated onto the release liner and subsequently laminated to the backing film. Coating on liner is usually done with soft or stretchy backings that can deform during oven drying or with cure-in-place systems where the backing may absorb the liquid prepolymer mixture before polymerization can occur.

Economic Aspects

Of the three major classes of polymers in use today, acrylics make up the largest volume of material at 33% of the total PSA market. Synthetic block-copolymer elastomer represents 25% of the total PSA market. Since these are almost universally compounded with tackifying resins, the amount of PSA produced using block copolymers could be twice as large as the amount of elastomer used. Natural rubber represents 22% of the total PSA market, but is also compounded with resin to produce a PSA, and so the total amount of PSA produced is also larger (45). This represents a shift toward acrylics from 10 years ago when the relative

amounts of acrylic, block copolymer, and natural rubber elastomer was 23, 29, and 28%, respectively (46).

Estimated production (47) volumes (by area coated) of tapes and labels in 1997 were 7.5×10^9 m^2 in the United States, 7.7×10^9 m^2 in Europe, and $(6–8) \times 10^9$ m^2 in Asia. Estimated use of PSAs (by mass) in 1998 was 250,000 t in the United States and 295,000 t in Europe. Estimated sales volumes of pressure-sensitive products in 1999 were $\$11 \times 10^9$ m^2 in the United States, $\$8.4 \times 10^9$ m^2 in Europe, and $\$1.9 \times 10^9$ m^2 in Japan, with global growth rates for these markets estimated at between 4 and 6% annually for tapes and between 7 and 11% annually for labels (47,48).

REINFORCEMENT

Introduction

In antiquity, mechanical properties were often the decisive factor in materials selection. Today, they still limit the size of our bridges and skyscrapers, and the performance of our airplanes. The second part of the twentieth century has seen significant developments in our understanding of fundamental material science, and thus also of the mechanical performance of materials. This understanding has generated profound changes in the field, leading to new families of materials, new concepts, and wide-ranging improvements in the mechanical behavior and in all other properties of materials. In our energy-conscious society, materials and structures are required to be more performant, lightweight, and cheap. The best answer to these requirements is often provided through the powerful concept of reinforcement of a "matrix" material with a second-phase dispersion (particles, fibers). This concept was already known to our ancestors. Indeed, the book of Exodus provides an often quoted reference to straw-reinforced clay bricks prepared by the Hebrews, and plant fibers in pottery artefacts were used early on in Central and South America. In these early examples however, the aim was to prevent cracking of the brittle material rather than reinforcement. The concept of reinforcement of materials by a second-phase solid is omnipresent in nature as well, from human bones (hydroxyapatite platelets within a collagen fibrillar matrix) to fingernails and rhinoceros horn (both consist of keratin fibers dispersed in a protein matrix), to the various types of wood (cellulosic fibers in a lignin matrix). A more subtle concept related to reinforcement in nature concerns the hierarchical microstructures (including the various degrees of symmetry) which so far have only partially been applied to synthetic composites, and a promising future seems to lie ahead for the observation of (and lessons to be learned from) the reinforced

Encyclopedia of Polymer Science and Technology. Copyright John Wiley & Sons, Inc. All rights reserved.

structures that appear in nature, a field commonly termed biomimetics. It is an interesting fact that many natural forms of reinforcement possess a nanometric dimension whereas most current synthetic composites include fibers in the micrometer range. Expected benefits of such "miniaturization" would range from a higher intrinsic strength of the reinforcing phase (and thus of the composite) to more efficient stress transfer, to possible new and more flexible ways of designing the mechanical properties of yet even more advanced composites. First these arguments are reviewed, then the concept of stress transfer leading to the principle of reinforcement is discussed. This is followed by specific materials aspects and by a short account of possible future forms of reinforcement.

Strength of Reinforcement

Strength as a Function of Dimension. The strength of materials increases as the scale decreases. In reinforcing fibers, for example, this is true whether the scale is taken as the diameter of the fiber or as its length. It is true too for the characteristic (or average) dimension of a reinforcing particle or a platelet. This phenomenon is usually called the size effect and has two types of explanation, based on probabilistic arguments and fracture mechanics. From a probabilistic viewpoint, Weibull (1) and Freudenthal (2) proposed a formal link between the probability of occurrence of a critical defect in a solid of (dimensionless) volume V, the concentration of defects, and the size (length, area, volume) of the solid specimen:

$$F(V) = 1 - \exp[-(V/V_0)] \tag{1}$$

where V_0 is the (dimensionless) mean volume per defect (thus, $1/V_0$ is the mean concentration of defects). As seen in equation 1, the probability of occurrence of a critical defect (and thus of failure) increases rapidly with increasing size for a given defect concentration. Equation 1 does not explicitly include any assumption regarding the physical nature of the process. Stress may then be drawn in by assuming that the original density of flaws in the material, $1/V_0$, increases as the applied stress σ increases according to some physical law. For example, if a simple power law

$$V_0^{-1} = (\sigma/a)^b \tag{2}$$

is assumed, where a and b are constants termed the scale and shape parameters, the widely used two-parameter Weibull distribution is obtained. Specifically for a fiber viewed as a chain of elementary links or elements, the weakest-link argument is involved as follows. If each element in the chain-like structure has a failure probability $F(\sigma)$ under a stress σ, then its probability of survival is $1-F(\sigma)$. The probability of survival of a chain of n elements is then $[1-F(\sigma)]^n$, from which it results immediately that the probability of failure, $F_n(\sigma)$, of the chain (or the fiber) is given by

$$F_n(\sigma) = 1 - [1 - F(\sigma)]^n \tag{3}$$

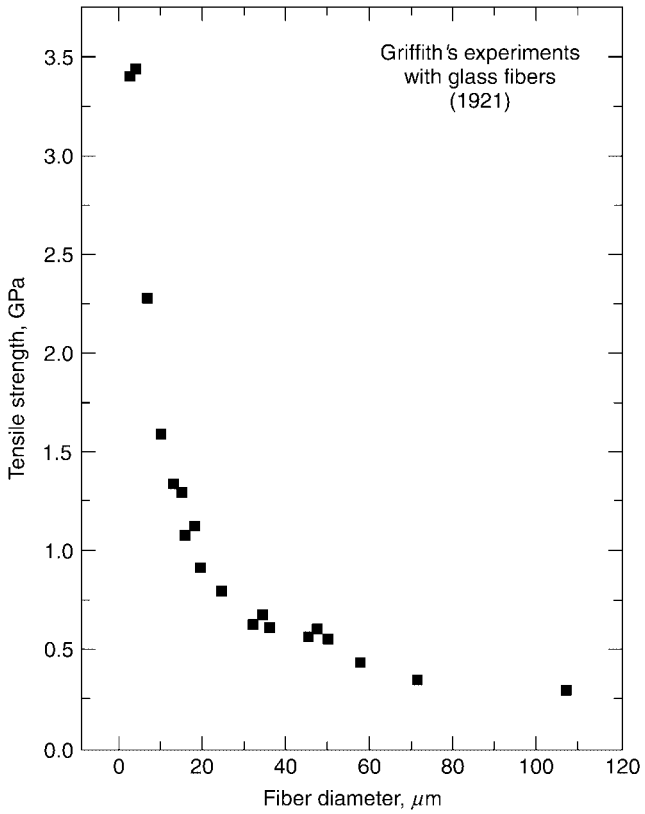

Fig. 1. Plot adapted from the 1920 experiment of Griffith with glass fibers, illustrating the effect of fiber diameter on strength (3). To convert GPa to psi, multiply by 145,000.

If the probability of failure, $F(\sigma)$, of a single element is a Weibull distribution, it is immediately apparent that the probability of failure of the chain is again a Weibull distribution with the same shape parameter b but with a lower value of the scale parameter a. The latter may easily be shown to be equivalent to a lower mean strength. Thus, the larger the specimen, the higher its probability of failure. The same conclusion is reached when fracture mechanics arguments are used, based on the original observation of Griffith (Fig. 1) with freshly drawn glass fibers of varying diameters. A dependence between strength (σ_f) and size (D) of the form

$$1/\sigma_f = p + qD^{1/2} \tag{4}$$

(p and q are constants) is obtained for reinforcing materials such as ultrahigh molecular weight polyethylene (UHMWPE) fibers and polydiacetylene fibers (4). An extensive discussion of size effects in fibers and composites may be found elsewhere (4,5).

Strength as a Function of Interfacial Area and Interaction. The mechanical effectiveness of reinforced materials is a function of the efficiency with

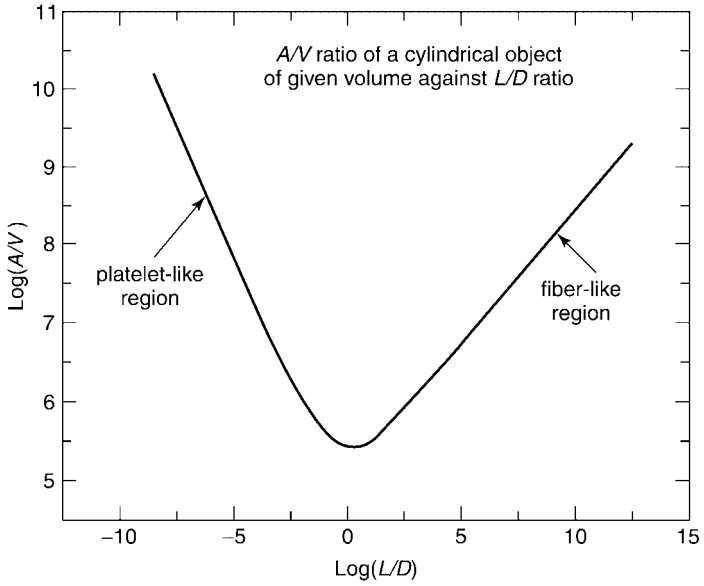

Fig. 2. Surface area-to-volume ratio (A/V) of a cylindrical object of given volume against aspect ratio (L/D). The shape of the object fluctuates between a fiber and a platelet, and maxima of the area-to-volume ratio are obtained either for a very long and thin fiber or a very wide and thin platelet. Adapted from Ref. 9.

which loads are being transferred from the external source to the reinforcing phase, via the matrix or binder. This efficiency is, in turn, a function of the available interfacial area between the reinforcing agent and the matrix, and of the quality of the interface. Generally speaking, the stress transfer efficiency increases with the area-to-volume ratio of the reinforcing agent, and with the interfacial adhesion. The first point may be illustrated by taking a small cylindrical particle of length 1 mm and diameter 5 μm, and varying its length and diameter so as to keep the volume constant. As seen in Figure 2, the shape of the particle fluctuates between a fiber and a platelet, and maxima of the area-to-volume ratio are obtained either for a very long and thin fiber or a very wide and thin platelet. Interestingly, these two cases are frequently encountered in nature's composite materials when high strength or stiffness is the determining factor. The second point, namely, the effect of interfacial adhesion on strength and stiffness of composites, has been extensively studied and the major developments are summarized in a subsequent section.

Strength as a Function of the Type of Reinforcing Material. It is possible to use simple models to select materials that a priori should be suitable as reinforcements. The theoretical tensile strength $\sigma_{\max}$ of a solid is given by (6)

$$\sigma_{\max} = (E \cdot \gamma / a_0)^{1/2} \tag{5}$$

where E and γ are the Young's modulus and the surface energy of the solid, respectively, and a_0 is the atomic spacing. When looking for strong solids, we therefore

look for substances of high elastic modulus, high surface energy, and small atomic spacing. This suggests that atoms with small atomic radii should be considered: beryllium, boron, carbon, nitrogen, oxygen, aluminum, and silicon are good choices, and the strongest materials always contain one of these elements (7). Based on the above, it would seem that polymers are not appropriate, because of their "softness" and low modulus, but this is not so. Theoretical calculations show that well-oriented high molecular weight polymers have very high moduli and strength, with the added advantage of low density. All the above considerations explain the appearance, from the early 1960s, of high performance fibers such as carbon and boron, followed by silicon carbide, Kevlar, UHMWPE, and more.

Strength and Fiber Flexibility. Flexibility of fibers used in high performance composites is necessary because of the intense bending strains and stresses applied to the fibers during operations such as weaving, knitting, and filament winding. The flexibility of a fiber will be higher when its curvature is as large as possible and when the bending moment necessary to reach a given curvature is as small as possible. Flexibility is thus defined as (for a circular fiber) $\varphi = 64/E\pi d^4$, where E and d are the fiber bending modulus and diameter, respectively (8). As seen, the effect of size (diameter) is by far the strongest, and thus nanoscale reinforcement promotes high flexibility.

The Principles of Reinforcement

When combining highly performant fibers with polymers, a composite with improved mechanical properties is formed. The stress applied from an external source to the composite is transferred to the fibers (which are the load-bearing element) through the fiber–matrix interface, and the mechanism of this stress transfer and the ensuing reinforcement effect may be described as follows. The situation is different when fibers are long or short.

Long Fibers. The composites used in the most advanced applications (in aerospace, for example) normally include long (or continuous) fibers from which laminated structures are formed. When the fibers are more rigid than the matrix (which is the case in practically important composites), assuming a perfectly bonded interface between fiber and matrix, and loading parallel to the fiber array, the transfer of stress from the applied load to the fibers is achieved from the ends of the specimen through the loading mechanism, resulting in a fairly uniform stress field in the composite. Thus, a simple rule of mixtures

$$E_{\mathrm{L}} = E_{\mathrm{f}}V_{\mathrm{f}} + E_{\mathrm{m}}V_{\mathrm{m}} \tag{6}$$

emerges for the longitudinal Young's modulus of the composite, where the subscripts f and m designate the fiber and the matrix, and E and V are the Young's modulus and fiber volume fraction respectively. Equation 6 usually provides a good fit to experiment. For the transverse Young's modulus of the composites, the often quoted inverted rule of mixtures

$$1/E_{\mathrm{T}} = (V_{\mathrm{f}}/E_{\mathrm{f}}) + (V_{\mathrm{m}}/E_{\mathrm{m}}) \tag{7}$$

does not usually provide a good fit. The semiempirical Halpin–Tsai equation

$$E_T = E_m\left[\frac{1+\varsigma\eta V_f}{1-\eta V_f}\right] \tag{8}$$

provides a better estimate, with

$$\eta = \frac{(E_f/E_m)-1}{(E_f/E_m)+\varsigma} \tag{9}$$

and where ζ is an empirical parameter which is equal to 2 for circular or square fibers. Similar equations exist for the other elastic constants (9). The strength of composites with continuous fibers is given by

(1) *Low fiber volume fraction*

$$\sigma_L = \sigma_{mu}(1-V_f) \tag{10}$$

(2) *High fiber volume fraction*

$$\sigma_L = \sigma_{fu}V_f + \sigma_m^*(1-V_f) \tag{11}$$

where σ_{mu}, σ_{fu}, and σ_m* are the strength of the matrix, the strength of the fiber, and the stress in the matrix at the strain at which the fiber breaks. In the above models, the following assumptions were made: (*1*) the fibers are more brittle and have a much higher tensile modulus than the matrix; (*2*) the fibers and the matrix behave in a linear elastic fashion until failure; (*3*) the strain in the fiber and the matrix are equal (perfect interfacial bonding); and (*4*) all fibers have the same tensile strength. For very high fiber content, a good approximation of the longitudinal properties of continuous, unidirectional composites is as follows (from eqs. 6 and 11):

$$\begin{aligned} E_L &= E_f V_f \\ \sigma_L &= \sigma_{fu} V_f \end{aligned} \tag{12}$$

In reality, none of the four assumptions above are obeyed exactly in many industrial composites: Glass fibers are often as brittle as epoxy resins; most polymer matrices behave in a nonlinear elastic or plastic fashion beyond a certain strain; the quality of interfacial bonding varies according to the composite system, and is statistical along the fiber length; and the tensile strength of fibers is statistical rather than uniform because of the presence of various defect populations (as briefly discussed earlier).

The statistical strength of fibers is usually described as follows. If the probability of failure, $F(\sigma)$, of a single fiber unit element is a Weibull distribution

$$F(\sigma) = 1 - \exp[-(\sigma/a)^b] \tag{13}$$

it is immediately apparent that the probability of a long fiber (viewed as a chain of n unit elements) is again a Weibull distribution

$$F_n(\sigma) = 1 - \exp[-n(\sigma/a)^b] \tag{14}$$

with the same shape parameter, b, but with a smaller scale parameter:

$$a_n = an^{-1/b} \tag{15}$$

Thus the strength is "self-similar." The mean strength is defined as

$$\bar{\sigma} = \int_{-\infty}^{+\infty} \sigma f(\sigma) \mathrm{d}\sigma \tag{16}$$

where $f(\sigma)$ is the density function ($=\mathrm{d}F(\sigma)/\mathrm{d}\sigma$). Using $a_n = aL^{-1/b}$, one has

$$F_{\mathrm{n}}(\sigma) = 1 - \exp\left[-(\sigma/a_{\mathrm{n}})^b\right] \tag{17}$$

where L is the (nondimensional) fiber length rather than the number of fiber elements. It is easy to show that the mean of the distribution is given by

$$\bar{\sigma} = a_n \Gamma[1 + (1/b)] \tag{18}$$

where $\Gamma(\cdot)$ is the Gamma function, the values of which can be found in tables. The coefficient of variation is

$$cv \cong 1.2/b \tag{19}$$

A higher strength variability is found in ceramic fibers (such as alumina), which have a relatively low Weibull shape parameter. Typical Weibull parameters for commercial fibers are shown in Table 1. The statistical variability of bundles and composites is a function of the fiber variability but is generally lower than

Table 1. Typical Value Ranges for the Weibull Scale and Shape Parameters of Fibers[a]

Fiber	Scale parameter, MPa[b]	Shape parameter
E-glass	3000–3500	4–6
HM carbon	1300–3000	1.7–2.6
HS carbon	1700–2100	2.8–5.3
Kevlar 49	3000–3500	7–10
UHMWPE	2200–4000	6–8
SiC	2500–4000	–
Boron	2700–3700	8–10

[a] Gauge length ~10 cm.
[b] To convert MPa to psi, multiply by 145.

that of the single fibers. Calculations of the composite statistical strength grow rapidly complex (10) and this topic is beyond the scope of the present article.

Short Fibers. Stress transfer in discontinuous fiber composites, which include the cases of either short or broken fibers, is more complex than in continuous fiber composites. The shear and tensile stress and strain fields will not, in this case, be uniform. If both the matrix and the fiber are elastic, the tensile stress profile in the fiber is given by (7)

$$\sigma_f = E_f \varepsilon \left[1 - \frac{\cosh\beta(l/2 - x)}{\cosh\beta l/2} \right] \tag{20}$$

where ε is the imposed strain (thus, the strain in the matrix away from the fiber), l is the fiber length, and the origin of the x-axis is in the middle of the fiber. The parameter β, the so-called shear-lag parameter, has units of reciprocal length and is equal to

$$\beta = \left[\left(\frac{G_m}{E_f} \right) \left(\frac{2\pi}{A_f \ln(R/r_f)} \right) \right]^{1/2} \tag{21}$$

where G_m is the matrix shear modulus, A_f and r_f are the fiber cross section and radius, respectively, and R is the distance from the fiber axis at which the matrix displacement is unaffected by the fiber presence (thus, $2R$ may be viewed as the average interfiber spacing, and R/r_f is a function of fiber packing). A simple force balance model gives the shear stress profile at the fiber–matrix interface:

$$\tau = \varepsilon (G_m E_f)^{1/2} \left(\frac{\pi r_f^2}{2A_f \ln(R/r_f)} \right)^{l/2} \left(\frac{\sinh\beta(l/2 - x)}{\cosh\beta l/2} \right) \tag{22}$$

The measured shear stresses in the matrix at the ends of fibers are in fact much larger than those given by equation 22 because of stress concentration effects. Therefore, the maximum shear stress will be the smaller of the following two stresses: the shear yield stress of the matrix, or the shear strength of the fiber–matrix interface. Whichever of these two stresses is attained first will control the load transfer phenomenon.

Based on this simple model, the composite modulus is

$$E_c = E_f V_f \left(1 - \frac{\tanh\beta l/2}{\beta l/2} \right) + E_m (1 - V_f) \tag{23}$$

From equations 20, 22, and 23, it is seen that

(1) If the fiber is long enough, the stress in the fiber will increase from zero at the two ends to a maximum value $\sigma_{fu} = E_f \varepsilon$.
(2) The shear stress has a maximum value at the fiber ends and a minimum at the center.
(3) The larger the value of the load transfer parameter β (or the smaller the length β^{-1}), the more rapid is the stress increase in the fiber from its ends.

For polymer composites, the fiber is usually elastic but the matrix is plastic beyond a certain strain level. Frictional slip and plastic flow of the matrix have been observed to occur in these systems, with some prevalence of the first mechanism. A simple equilibrium of force gives

$$\frac{l}{d} = \frac{\sigma_f}{2\tau} \tag{24}$$

where d is the fiber diameter and τ is either the matrix shear yield strength (τ_y) or more likely in polymers, the interface shear strength (τ_i). If the fiber is long enough, beyond a certain critical length l_c, there is enough stress transferred in the fiber to break it, at a stress σ_{fu}:

$$\frac{l_c}{d} = \frac{\sigma_{fu}}{2\tau_i} \tag{25}$$

Even for $l > l_c$, the average stress $\bar{\sigma}_f$ in the fiber is still less than its maximum in the center:

$$\bar{\sigma}_f = \sigma_f\left(1 - \frac{1-\beta}{l/l_c}\right) \tag{26}$$

Interfacial Adhesion. Various tests have been developed to measure the strength of the fiber–matrix adhesive bond. Two schools of thought have emerged, the first one focusing on a relatively approximate but rapid testing of comparatively large, real-life specimens, and the second on the more elaborate testing of much smaller model specimens. Both approaches have advantages and drawbacks. Examples of the first type include the well-known interlaminar shear strength (or ILSS) test and the transverse strength test. Examples of the second type include the single-fiber composite test (also called the fragmentation test), the single-fiber pull-out test, and the microbond test. Reviews of these tests exist in the literature (11). A more recent technique, microRaman spectroscopy, provides an accurate measurement of the tensile stress profile in a single fiber, and a measure of the interfacial shear strength, provided that the fiber has a Raman spectrum that includes a strain-sensitive band. There is currently no universally agreed upon method that provides a single measure of interfacial adhesion in composites. This is an area that has been the subject of intense research over the last decade and a thorough description of this field is beyond the scope of the present article.

Types of Reinforcement

The structural characteristics of a host polymer material—the matrix—may be improved by including a dispersed material—the reinforcing phase—in various ways. The dispersed phase may be continuous (fiber, tape) or discontinuous (particulate, flake, whisker). We restrict the discussion to reinforcing phases used in fiber (or whisker) form since this article deals with mechanical reinforcement effects rather than with considerations of cost reduction, electrical properties, or

other nonmechanical aspects. In polymer matrix composites, reinforcing fibers are used mainly to improve stiffness and strength. Taking stiffness as an example, the low modulus value (1–5 GPa typically) of most polymer matrices is readily and dramatically increased by the presence of glass or carbon fibers (typical modulus: 72 GPa and 250–750 GPa, respectively). Advanced fiber composite materials take advantage of the highly directional properties of fibers to generate superior structural properties. The main fibers in use for composites applications include the various types of glass and carbon/graphite, boron, silicon carbide, alumina, the aramids, and polyethylene. Fibers at the experimental stage include polybenzoxazole (PBO) and polybenzothiazole (PBT). The diameter of most of these fibers varies from a few to about one hundred microns, whereas their length ranges between a few millimeters up to fully continuous. Whiskers have diameters in the nanometer range, and lengths down to the submicron range (so do carbon nanotubes, which are briefly considered at the end of the article). Whiskers are thin, elongated single crystals with properties much superior to those of the bulk material from which they are made. Typical whiskers include aluminum oxide (Al_2O_3), silicon carbide (SiC), carbon, silicon nitride (Si_3N_4), nickel aluminide ($NiAl_3$), iron, nickel, and copper. Single fibers, which are difficult to handle individually, are usually gathered into bundles such as yarns, tows, or strands of a few hundreds up to 100,000 or more single fibers. Such spools are the starting elements in the fabrication of a structure. They are combined with polymers using various techniques, to form intermediate flat sheets ("prepregs," random mats, woven and knitted fabrics, braids, and more recent noncrimp fabrics) or direct final shapes (using filament winding, for example). The overall fiber architecture is controlled by the selection of appropriate reinforcement formats and processing routes. Table 2 shows the maximum achievable fiber volume fraction using different reinforcement formats, and compares the orientation factor which is 1 for a uniaxial array, 0.3 for a quasi-isotropic lay-up, and 0.12 for a random three-dimensional (3-D) lay-up (11). No less important is the type of fiber surface treatment applied

Table 2. Connection Between the Reinforcement Format, the Manufacturing Process, the Fiber Orientation Factor, and the Maximum Fiber Volume Fraction[a]

Reinforcement format	Applicable process	Orientation factor	Maximum fiber volume fraction
UD tow	Filament winding; pultrusion	1.00	0.80
UD prepreg	Autoclave; resin film infusion	1.00	0.65
Multiaxial prepreg	Autoclave; resin film infusion	0.31	0.60
2-D noncrimp fabric	Resin film infusion; resin transfer molding	0.30	0.55
Woven 2-D fabric	Resin transfer molding; wet lay-up	0.27	0.50
Orthogonal 3-D fabric	Resin transfer molding	0.30	0.40
Random planar	Sheet molding compound; resin transfer molding; wet lay-up	0.30	0.30
Random 3-D short fiber	Bulk molding compound; injection molding	0.12	0.20

[a]To convert GPa to psi, multiply by 145,000.
[b]Virgin strength values. Actual strength values prior to incorporation into composite are about 2.1 GPa (Ca 300,000 psi).

to enhance handling, processing, fiber–matrix adhesion, and to reduce fiber breakage or fiber-to-fiber adhesion. Many properties of the composite structures, including impact resistance and damage tolerance, are strongly dependent on the quality of the fiber–matrix interfaces.

The properties of the major fibers used in composites are given in Table 3. The specific strength against Young's modulus is plotted in Figure 3.

Glass Fibers. Glass is the most widely used reinforcing material. Its advantages include low cost, high tensile and impact strengths, and high chemical resistance. The estimated annual production of glass fibers for the year 2000 was 1800 kton, compared to 18, 12, and 5 kton for carbon, aramid, and other fiber types respectively (12). The advantages of glass fibers include low cost, high tensile and impact strengths, and high chemical resistance. Their drawbacks include a relatively low modulus, self-abrasiveness, low fatigue resistance, and poor adhesion to matrix resins. Typical compositions and properties of three glasses used for fiber manufacture, E (electrical), C (chemical), and S (high tensile strength), are given in Table 4.

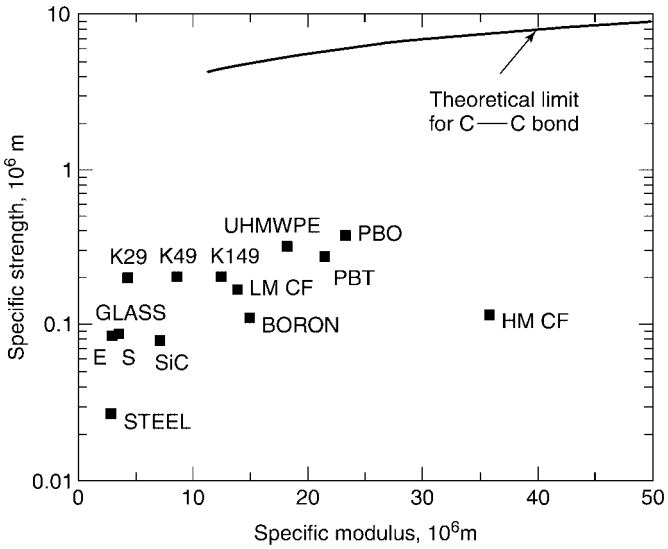

Fig. 3. Specific strength against specific Young's modulus for the major fibers used in polymer composites. The theoretical line for the C—C bond was calculated using the Orowan–Polanyi formula (eq. 5) normalized by the density ρ, namely,; $\sigma/\rho = (\gamma/\rho a_0)^{1/2}(E/\rho)^{1/2}$, with the surface energy $\gamma \approx 4.2$ J/m^2, the length of the C—C bond $a_0 \approx 0.15$ nm, $\rho = 1.8$ g/cm^3 (=17652 N/m^3).

Glass fibers are produced in either continuous filament or staple form. The glass is melted, and fibers are made by rapid mechanical drawing of the forming filaments through orifices. Silica-based glass fibers possess a tetrahedron network structure of oxygen atoms around a silicon atom, all bonded together by covalent

bonds. The oxygen atoms are shared between tetrahedra, and the resulting 3-D rigid network structure leads to isotropic properties, in contrast to those of carbon and aramid fibers, which are anisotropic. Elements such as calcium, sodium, and potassium are also present within the network (but are not linked directly to it) and form ionic bonds with the oxygen atoms. Their presence improves the fiber formability but tends to lower its stiffness and strength. The virgin glass fiber strength falls rapidly in the presence of humidity or of mineral acids, and during processing operations in which the fibers may rub against each other. A water-based thin coating called a sizing is therefore applied to the fiber during manufacture. The size usually contains a film-former polymer, a lubricant, and (usually) an organosilane coupling agent with the structure X_3SiR. The R group may react with the polymer matrix, while the X groups can hydrolyze in the presence of water to form silanol groups, which then condense with the silanol groups at the surface of the glass fibers to form siloxanes. The sizing has several roles: protection of the fiber surface from damage, binding the fibers together for easier processing, lubricating the fibers for abrasion resistance during processing, imparting antistatic properties, and increasing the fiber–matrix interfacial bonding.

Carbon or Graphite Fibers. Carbon fibers consist of small crystallites of turbostratic graphite. These resemble graphite single crystals except that the layer planes are not packed in a regular fashion along the *c*-axis direction. In a graphite single crystal, the carbon atoms in a basal plane are arranged in hexagonal arrays and held together by strong covalent bonds. Between the basal planes, only weaker van der Waals forces exist. Therefore, the single crystals are highly anisotropic with in-plane moduli of the order of 1000 GPa whereas the modulus perpendicular to the basal planes is only about 35 GPa. It is thus apparent that to produce high modulus and high strength fibers, the basal planes of graphite must be parallel to the fiber axis. There are several routes for the production of carbon fibers: from rayon-based fibers, from polyacrylonitrile (PAN), from pitch, and from pyrolitic deposition. These processes are now briefly summarized (13).

From Rayon-Based Fibers. Rayon filaments are stretched in a series of steps in an inert atmosphere at temperatures of around 2700°C (4900°F). The tension, along with the high temperatures, converts the polymer to graphite and causes the graphite layer planes to align with the fiber axis, imparting high strength and high modulus to the fibers.

From PAN. Polyacrylonitrile (PAN) is a long-chain linear polymer composed of a carbon backbone with attached carbonitrile groups. The conversion of PAN fibers into carbon fibers involves

(1) heating in an inert atmosphere or vacuum to cyclize the PAN;

(2) treating the fibers in an oxidizing atmosphere at temperatures typically in the range of 200–300°C (392–572°F) while under tension to avoid shrinkage. This treatment converts thermoplastic PAN into a nonplastic cyclic or ladder structure which is capable of withstanding the high temperatures present in the subsequent carbonization treatment. During the oxidizing treatment, considerable reorganization of the polymer chains occurs, involving 3-D linking of the parallel molecular chains by oxygen bonds

(however, some uncertainty still exists regarding the reaction mechanisms during the oxidation treatment of PAN in air). This imparts rigidity along the chain;

(3) further graphitization under stress of the stabilized PAN fibers at higher temperatures in an inert atmosphere.

From Mesophase Pitch. Coal tar pitch (a mixture of many species of hydrocarbons and heterocyclic molecules) is heated for up to 40 h at approximately 450°C (800°F), forming a viscous liquid with a high degree of molecular order known as mesophase (a form of liquid crystal). The mesophase is then rapidly spun through small orifices (spinnerets), aligning the mesophase molecules along the fiber axis. The fibers are thermoset at relatively low temperatures and then heated at 1700–3000°C (3100–5400°F).

From Pyrolitic Deposition. Pyrolitic deposition of hydrocarbons from the gas phase may lead to the formation of carbon fibers. Gases such as methane, benzene, and naphthalene can be used, with deposition temperatures of about 1100°C. A thin tube of carbon is formed on a substrate and then grows by a surface diffusion mechanism. The turbostratic carbon is formed in concentric layers parallel to the fiber axis, and fiber lengths of up to 5 cm may be obtained. Although there is little commercial use of fibers with such short length (and with poor control of the diameter), except as fillers to make polymers conductive for static charge dissipation, a highly graphitic structure results, which may be appropriate for specific applications.

The preferred orientation of a carbon fiber, and thus its modulus, can be enhanced by stretching the fiber during one of the processing stages. For carbon fibers derived from PAN, this stretch orientation is usually carried out during the low temperature heat treatment. Additional factors that might influence the elastic modulus of carbon fiber include the heat treatment temperature (HTT), boron doping, and neutron irradiation. The strength of a carbon fiber depends on the type of the precursor fiber, processing conditions (such as HTT), preoxidation conditions, and the presence of flaws and defects. The strength of PAN-based carbon fibers was observed to increase with increasing HTT and to reach a maximum value at about 1500°C (2732°F) before starting to decrease at higher HTTs. Various mechanisms have been proposed to explain this behavior. Like the modulus, the strength of a carbon fiber is significantly influenced by the preoxidation conditions of PAN fibers. Defects in carbon fibers appear, however, to be the most significant strength-limiting factor.

The surface of carbon fibers is usually oxidized to increase the adhesion with the resin matrix. Oxidizing treatments include wet chemical treatments with sodium hypochlorite or nitric acid. Such treatments generally produce two effects with epoxy resins: first, an outer, defect-laden fiber surface layer is removed; second, surface oxygen groups are added, which can interact with the resin matrix. In addition to oxidative surface treatments, there may be surface treatment with finishes or sizings to enhance compatibility of the fibers with the polymer matrix.

Carbon fibers are available with a wide range of modulus and strength. The theoretical modulus of graphite is in the vicinity of 1035 GPa, and the theoretical values of strength range from 100 to 200 GPa (7). Tensile strengths of 20 and

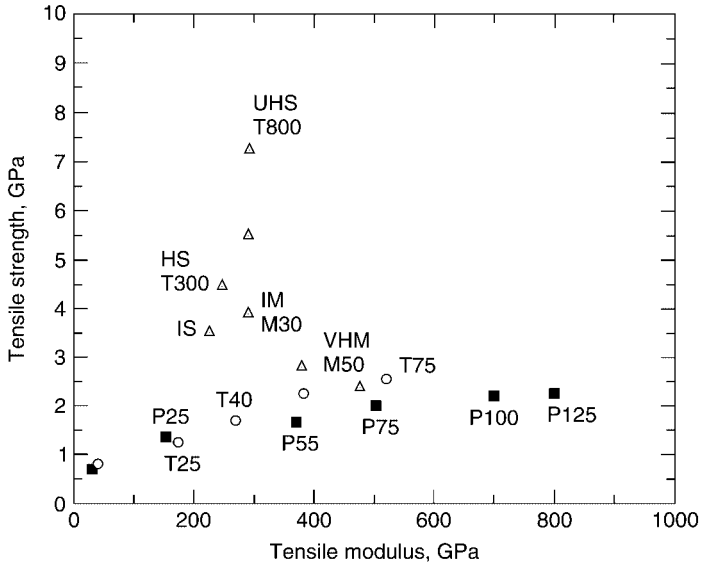

Fig. 4. Mechanical properties of major carbon fibers: ■, pitch; ○, Rayon; and △ PAN. To convert GPa to psi, multiply by 145,000.

7 GPa have been reported with carbon whiskers and continuous carbon fibers, respectively. Carbon fibers can be approximately classified into five groups in terms of their tensile modulus (E) and strength (σ_u): Ultrahigh modulus ($E >$ 400 GPa), high modulus (300 $< E <$ 400 GPa), intermediate modulus (250 $< E$ 300 GPa), high strength ($\sigma_u > 3.8$ GPa), and high strain carbon fibers ($\varepsilon_f > 1.8\%$). The properties of carbon fibers are listed in Table 3 and Figure 4. Note the negative thermal expansion coefficient in the longitudinal direction of carbon fibers, which makes them especially useful in applications requiring thermal management such as instrumentation housings with dense electronics. Finally, the more recent Conoco's carbon fiber technology is a mesophase-pitch-based product offering unique, high performance properties for a broad range of target applications. As a randomly oriented, continuous filament, nonwoven mat (CFM), it is a significant departure from traditional carbon fiber products, which are largely manufactured in tow form—and it is compatible with many high speed manufacturing operations.

Aramid Fibers. Aramid (aromatic polyamide) fibers such as Kevlar (DuPont) and Twaron (Akzo Nobel) are made of poly(paraphenylene terephthalamide). The polymer can be prepared by solution polycondensation of *p*-phenylene diamine and terephthaloyl chloride at low temperatures. The fiber is spun by extrusion of a solution of the polymer in a suitable solvent (for example, sulphuric acid), followed by stretching and thermal annealing treatment. Technora (Teijin) fibers are slightly different from Kevlar and Twaron as they consist of a copolymer: poly(paraphenylene terephthalamide-*co*-3,4-oxydiphenylene terephthalamide). Various grades of Kevlar fibers are produced (Kevlar-29, 49, and 149), Kevlar-49 being the one more commonly used in composite structures.

X-ray diffraction studies show that the structure of Kevlar-49 consists of rigid linear molecular chains that are highly oriented in the fiber axis direction, with the chains held together in the transverse direction by hydrogen bonds. Thus, the polymer molecules form rigid planar sheets. The strong covalent bonds in the fiber axis direction provide high longitudinal strength, whereas the weak hydrogen bonds in the transverse direction result in low transverse strength. Aramid fibers exhibit skin and core structures. The core consists of layers stacked perpendicular to the fiber axis that are composed of rod-shaped crystallites with an average diameter of 50 nm. These crystallites are closely packed and held together with hydrogen bonds nearly in the radial direction of the fiber.

The theoretical modulus of the poly(paraphenylene terephthalamide) molecule has been calculated to be about 250 GPa. However, the modulus of commercially available *p*-aramid fibers ranges from 60 to 186 GPa. The elastic modulus of the fiber is closely related to the crystalline orientation angle. The theoretical strength per unit weight (tenacity) of aramid fiber has been estimated to be 20.7 N/tex (235 g/den) in textile units, assuming that the fiber is composed of a perfectly oriented single crystal consisting of infinitely long polymer molecules. The current commercially available *p*-aramid yarns possess a strength of up to 2.2 N/tex (25 g/den). The aramid fibers have an elastic modulus over 20 times greater than that of nylon fibers. The more rigid and complex molecules impart higher mechanical properties and improved thermal resistance to aramid fibers. These fibers with high specific strength have great cohesiveness and a tendency to form fibrils; they absorb much more energy than brittle fibers. However, they have a highly anisotropic structure that leads to low longitudinal shear moduli, poor transverse properties, and low axial compressive strengths. This directional trade-off arises because of the much weaker lateral bonding mechanisms. While glass and carbon fiber composites show similar tensile and compressive strengths, the compressive strength of unidirectional composites containing Kevlar-49 fibers could be as low as 25% of their tensile strength. The interfacial bond strength between aramid fibers and epoxy resins is normally lower than what is experienced with carbon fiber composites. Work has been carried out on various surface coating, sizing, or plasma treatments to improve interfacial properties of aramid composites.

Further improvement in mechanical properties of aramids appears possible since calculations based on perfect alignment and crystalline order predict a theoretical modulus of about 220–245 GPa. The properties of aramid fibers are compared in Table 5. Like carbon, aramid fibers have a negative thermal expansion coefficient in the longitudinal direction. Aramids have high impact resistance, and they have found their way into the markets of soft and rigid (composite) armors.

Polyethylene Fibers. Solid-state drawing can be used to produce high modulus polyethylene fibers from high density polyethylene. The linearity and crystallinity of this polymer impart a significant degree of order in the polymer structure prior to drawing, thus permitting a highly extended chain configuration to be attained through post-fiber-formation drawing. The modulus of the fiber is proportional to the draw ratio (ratio of final fiber diameter to initial fiber diameter) of the fiber. High draw ratios are essential for producing high strength fibers. For an UHMWPE (MW$\sim 10^6$ g/mol), the natural draw ratio is around 5:1,

Table 5. Aramid Fiber Properties

[a]To convert GPa to psi, multiply by 145,000.

where further orientation can no longer be imposed. However, draw ratios of 50:1 to 70:1 are necessary to obtain high strength fibers. These draw ratios can be achieved by dissolving UHMWPE in a solvent (decalin, paraffin oil, or paraffin wax) to reduce intermolecular entanglements, making it possible to achieve greater fiber orientation. Typically, a 5–10% solution of polymer in solvent is prepared at 150°C. The dilute solution is then cooled to ∼135°C and forms a "gel," a porous, crystallized solid with minimal entanglement density. This gel is spun into fibers and then ultradrawn at 120°C to reach the final fiber diameter and strength.

Similar to other polymer-based high performance fibers, the transverse and longitudinal compressive strengths of polyethylene fibers are relatively low. Epoxy composites containing PE fibers show poor compressive response. Their interlaminar shear strength is lower than that achievable with carbon fiber composites, mainly because of the usually poor bonding between PE fibers and the epoxy matrix. This poor bonding results from their fibrillar structure and low surface energy. Cold plasma treatments of PE fiber surface are a possible way for better interfacial bonding in these composites.

The physical and chemical properties of the gel-spun PE fibers are similar to other PE fibers (eg, solid-state drawn) except that they are of extremely high strength and modulus. These fibers, similar to the aramid fibers, produce high strength and high modulus materials at a significant weight savings over conventional fibers. In fact, UHMWPE fibers, with a density of 0.97 g/cm^3, are even lighter than aramid fibers. This low density feature, coupled with high strength and modulus values, has made UHMWPE fibers the most outstanding among the currently commercial reinforcing fibers in terms of specific strength and specific modulus (Tables 3 and 6).

Because of their low softening point, PE fibers do not retain their strength at temperatures above 145°C. Therefore, these fibers should not be used as reinforcements in many injection molding or sheet molding processes. The creep resistance of these fibers under high load is rather poor. However, their good

Table 6. Comparison Between the Theoretical Strength of Polymers and the Strength of Commercial Fibers

Polymer	Density, g/cm^3	Theoretical strength, N/tex[a]	Strength of commercial fibers, N/tex[a]

resistance to aqueous and low temperature organic environments have made them attractive materials for marine tow ropes, mooring cables, fishing nets, and sail cloth. Similar to aramids, the ballistic resistance of UHMWPE is outstanding and these fibers are used in soft and rigid (composite) armors. The low dielectric and low loss tangent properties, and hence good microwave transparency, of PE fibers have made them viable candidate reinforcements for radome systems. The fibers produced include Spectra (Honeywell), Dyneema (DSM), and Toyobo (Toyobo). Future applications should include sporting goods, low temperature pressure tanks, and medical devices.

Rigid Rod Polymer Fibers. Poly(*p*-phenylene benzobisthiazole), or PBT, is a stiff chain polymer which can be synthesized and spun into the fiber form by a dry jet-wet spinning technique using a large air gap. A high draw ratio is imposed on the fiber, following spinning to create a high level of orientation. Fibers of high strength and high modulus are obtained with a further heat treatment of drawn fibers in a nitrogen environment. In addition to possessing extremely high specific modulus and strength (Table 3), PBT also has very good chemical resistance to all solvents but strong acids. Good thermal stability is another advantage associated with this fiber over all the currently available commercial polymer fibers. Physical properties are said to be retained at up to 700°C for short-term exposure and at 350°C for an extended period of time. Rigid rod polymers such as polybenzobisoxazoles (PBO) and self-reinforcing liquid crystalline polyesters can also be fabricated into a fiber form. Thermotropic liquid crystalline polymers can orient themselves into highly ordered states and can be thermally processed, as opposed to the lyotropic aramids which must be solution-processed into reinforcing fibers.

Polymer fibers have a high potential as future reinforcements, as may be seen from the comparison of theoretical and experimental strengths presented in Table 6.

Boron Fibers. Boron filaments have been used for many years as a reinforcement for both polymers and metal matrices. Boron-fiber-reinforced

composites offer a unique combination of mechanical and physical properties. The elastic modulus of boron fiber is high (Table 3), providing good stiffness to the reinforced composites. Boron fiber was first used in military aircraft, and boron-fiber-reinforced aluminum was employed for tube-shaped truss members to reinforce the space shuttle structure. However, the rapid reaction of boron fiber with molten aluminum and long-term degradation of diffusion-bonded boron/aluminum at temperatures greater than 480°C may preclude its use for high temperature applications. These drawbacks will also be a real concern in using potentially more economical fabrication methods, such as squeeze casting or low pressure high temperature pressing for metal matrix composites. Boron-fiber-reinforced metal matrix composites typically contain approximately 50% filament by volume. Major applications for boron/aluminum include tubular struts used in the mid-fuselage section of the space shuttle electronic modules. This is because boron/aluminum possesses high strength and stiffness, lightweight, high thermal conductivity, and low thermal expansion. Boron-reinforced metal composites are also being considered for uses in jet-engine fan blades, aircraft wing skins, structural support members, and landing-gear components.

Boron filament is manufactured by chemical vapor deposition (CVD), which involves the formation of solid by decomposition or reduction of gaseous molecules upon a heated substrate (tungsten or carbon filaments). The filaments are heated to approximately 1260°C and then pulled through a boron trichloride/hydrogen environment. The linear deposition rate is slow (about 50 mm/h), and many reactors must be run in parallel to achieve an appreciable production rate. The majority of the boron filaments are used in continuous fiber–epoxy composites. Boron–epoxy composites offer high strengths and stiffness in tension, compression, and bending. The high mechanical properties of boron-reinforced composites have led boron fibers to be applied for many high stress applications. Boron composites have been utilized in numerous aircraft and helicopter designs, eg, stabilizer and rudder in the F-15 fighter plane. In sports goods, a small quantity of boron–epoxy composites have been used to improve strength, stiffness, and sensitivity of rackets, fishing rods, and golf-club shafts.

Silicon Carbide Fibers. Silicon carbide (SiC) filaments are produced by a CVD technique. The β-SiC is obtained by the reaction of silane and hydrogen gases with the carbon filament being the substrate for deposition. The SiC fibers have mechanical and physical properties equal to those of boron, and can be used at higher temperatures than the present boron fiber when available in production quantities. CVD SiC fibers are primarily used for reinforcing metal and ceramic matrices. Alternatively, SiC fibers can be made from a polycarbosilane precursor which is meltspun at 350°C. The final form is obtained by pyrolyzing the fiber at 1200°C in an inert environment.

The use of advanced ceramics in applications such as gas-turbine engines has been limited partially because of their brittle nature, which often leads to catastrophic failure. However, the fracture toughness of a ceramic can be significantly improved by the addition of SiC fiber. The high mechanical properties of SiC fibers (Table 3) result in higher composite strength, stiffness, and toughness. The fibers have been evaluated in various glass, ceramic, and glass–ceramic matrices. The use of these high density fibers in polymer matrix composites has yet

to be explored. Two of the most thoroughly studied SiC fibers are Nicalon (Nippon Carbon Co) and SCS (AVCO).

The SiC fiber is qualified for use in aluminum, magnesium, and titanium. An extensive design database for hot-molded SiC reinforced 6061 aluminum is available. Property data on investment-cast SiC/Al are more limited. SiC-fiber-reinforced titanium parts typically are fabricated by press bonding or hot isostatic pressing. Composites of SiC/Ti have been shown to successfully withstand extended exposure at high temperature. SiC fibers retain usable strengths at up to 1000°C, and have the unique characteristic of retaining basic fiber strength in molten aluminum for up to half an hour. This characteristic should greatly reduce the cost and difficulty of producing SiC/Al composites.

Other Ceramic Fibers. Alumina polycrystalline filaments (Al_2O_3) are of interest mainly for metal matrix composites. They have a high resistance to oxidation, tensile strength and modulus of up to 2 and 380 GPa, respectively, and an excellent strength retention up to 1370°C. Their density is 3.95 g/cm^3. DuPont's FP polycrystalline alumina yarn has a 100% α-alumina composition, and a remarkably high compressive strength of about 6.9 GPa.

Saffil alumina–silica fibers have excellent thermal insulation behavior and resilience up to 1600°C. Their diameter is small, about 3 μm.

Additional ceramic fibers include 3M Nextel metal oxides fibers, and Quartz fibers (from Quartzel and Saint-Gobain) with excellent dielectric properties and near-zero thermal expansion coefficient.

Prospects for Alternative and/or Future Reinforcement

Self-Reinforcing Composites—Molecular Reinforcement. The idea of molecular reinforcement rests on the transfer of the fiber reinforcement concept to the molecular level. It was predicted that increasing the aspect ratio by decreasing the diameter would lead to a single molecule "fiber" as the ultimate reinforcing material (14). Liquid crystals may be formed *in situ* in a polymer by taking advantage of the self-orienting characteristics of anisotropic melts and solutions of polymers. In this way, the liquid crystals, because of their high level of orientation, take the place of fibers in a composite, and the self-reinforced resin is its own composite. Although most of the work in this area involves aromatic polyesters and copolyesters, recently published work gives a promising application of blending liquid crystal polymers with more conventional polymers in which the reinforcing component is dispersed microscopically or molecularly. The concept of developing polymers that can form liquid crystals during fabrication into structures (for example, by injection molding) is receiving considerable attention, for in this way it may be possible to produce composites with high performance economically. For a review, see Reference 15.

Natural Fiber Composites. Replacing synthetic fibers with natural fibers such as hemp and flax has both environmental and economic advantages. Unlike carbon and glass fibers, natural fibers are abundantly available from renewable resources. In terms of cost, natural fibers are cheaper than the synthetic alternatives. Natural fibers and plant-based resins have been shown to combine to produce low cost composites with good mechanical properties (a tensile strength

in the 30 MPa range has been obtained for a composite containing about 30 wt% flax, while a tensile modulus of 4.7 GPa was obtained for a 40 wt% flax composite. Similar numbers were obtained for hemp composites. Composites from renewable resources offer significant potential for new high volume, low cost applications (16).

Carbon Nanotubes. Carbon nanotubes are giant linear fullerenes (closed, convex cage molecules containing only hexagonal and pentagonal faces) having a tubular geometry, which were discovered in 1991 (17). Nanotubes may arise as concentric cylinders and form multiwalled carbon nanotubes, or as single-shell cylinders or single-wall nanotubes, which are closed at their ends. The preparation and physical properties of nanotubes are currently the subject of intense research (18,19). Estimates for the Young's modulus of a carbon nanotube are consistent with the exceptionally high values already measured for a graphene sheet, about 1.2 TPa. Single-wall carbon nanotubes are also expected to be very strong and to resist fracture under extension and compression. Unlike carbon fibers, single-wall nanotubes are remarkably flexible (by many orders of magnitudes compared to conventional high performance fibers, because of their small diameter; see the definition of flexibility above), but should regain their original shape when the stresses distorting it are removed. The excellent mechanical properties of carbon nanotubes would make them ideal for composites applications, which would have significant consequences in structural applications.

RELEASE AGENTS

Introduction

Release agents are substances that control or eliminate the adhesion between two surfaces. They find considerable use in the adhesive, food, furniture, glass, metal, plastics, rubber, printing, and packaging industries. They expedite many industrial handling and processing operations, particularly of polymers, such as calendering, casting, embossing, extrusion, forming, labeling, laminating, machining, molding, packaging, protecting, and transferring. They are known by a variety of terms descriptive of their effect, including abherents, abhesives, antiblocking agents, antistick agents, external lubricants, surface lubricants, mold-release agents, parting agents, and slip agents. Expectedly, release agents are usually applied directly to surfaces. However, it is sometimes possible to incorporate them into the bulk of the material being treated. Such processing aids are known as internal release agents. They act by migration to the surface and consequently also have an inevitable, internal lubricant effect. Likewise, materials intended as internal lubricants may also exhibit release characteristics, particularly when used at high concentration, if some of the material finds its way to the exterior.

Release agents function by either lessening intermolecular interactions between the two surfaces in contact or preventing such close contact. Thus, they can be low surface-tension materials based on aliphatic hydrocarbon or fluorocarbon groups, or they can be particulate solids. These two categories are by no means mutually exclusive; certain waxes, for instance, can exhibit characteristics of both types. The principal classes of materials used are waxes, fatty acid metal soaps, other long-chain alkyl derivatives, polymers, and fluorinated compounds.

Product Types and Requirements

Release agents are available in a wide variety of forms and are formulated for numerous modes of application. Product types include neat liquids, solutions, powders, flakes, pastes, emulsions, dispersions, sprays, and films. Some are general-purpose inert products intended for a broad range of applications, including home consumer uses, whereas others are highly specific, designed to cross-link or react *in situ* with particular substrates. As with most other formulated processing aids, there is a trend away from products containing volatile organic compounds and ozone-depleting substances, and toward water-based and high solids formulations. Users are also switching from the heavier metal soaps such as lead stearate [7428-48-0]. Another trend that helps reduce solvent and carrier use is toward semipermanent release treatments for multiple releases that have to be applied less frequently. Many products serve more than one processing function and contain other additives, such as antioxidants and wetting agents. The composition of these multifunctional and reactive products is usually proprietary information.

Suppliers of release agents vary from large, basic polymer producers to small, regional formulators and distributors. Examples from among the hundreds of such suppliers include the following: Axel Plastics Research Laboratories, Inc.; Barlocher GmbH; Chem-Pak, Inc.; Dexter Adhesive and Coating Systems; Dicronite Dry Lube; Dow Corning Corp.; DuPont Coating and Release Systems; Endura Coatings, Inc.; Ferro Corp.; Th. Goldschmidt AG; Kluber Chemie KG; Mann Formulated Products, Inc.; Price-Driscoll Corp.; Releasomers, Inc.; Rhodia, Inc.; and Witco Corp.

Many more suppliers and information about their product line can be obtained from compilations such as the *Modern Plastics World Encyclopedia* (1) and the *Thomas Register of American Manufacturers* (2). Obviously, the choice will depend on the processing conditions involved and the nature of the contacting substrates (3). In addition to ease of release, other important requirements are minimal buildup of residues on mold substrate, minimal effect on the molded article, adequate film-forming ability, compatibility with other operational conditions and procedures, health and safety requirements, and cost.

The prevention of residue buildup in polymer processing from either the mold release agent or the molding compound is a common product shortcoming (4). Should it occur, ease of cleanability of the mold surface becomes important. Undesirable effects on molded article surfaces include blistering, streaking, discoloration, stress cracking, and swelling. Film-forming ability is critical in casting and molding operations where melt flow might displace the release agent. Cohesive strength and substantivity to the mold can be enhanced by incorporation of polar groups but this may have a detrimental effect on release performance. Time is often a key operational condition. For example, water or solvent carriers must fully evaporate before a mold is filled. This can be critical in automated processes and limits release agent choice. Similarly, elevated temperature applications require good thermal and oxidative stability to prevent formation of polar, adhesive-like groups. Health and safety concerns are use specific; processing and packaging of foodstuffs and drugs requiring the most stringent consideration. Cost effectiveness, the number of acceptable releases per unit cost, is the key cost-related requirement.

These criteria guide product selection, but trials under production conditions are prudent. Some standard test methods are available that closely simulate actual end-use conditions. For example, ASTM D3354-89 (5) quantifies the degree of blocking, ie unwanted adhesion, between plastic layers. There are also standard test methods for determining coefficients of friction (D1894-95 and D3028-95) and surface gloss and haze (D2475-90 and D1003-95) that can reflect release agent effects on substrate surfaces. The impact of release additives on bulk properties must also be considered, particularly with integral additives to plastics. For example, partial solubility usually confers some plasticizing effect that may improve impact strength but could reduce heat distortion temperature. Some release additives such as metallic soaps have antioxidant and heat-stabilizer benefits that are exploited in multipurpose formulations.

Classification of Release Agents

A classification by chemical type is given in Table 1. It is neither rigorous nor complete and some materials could appear in more than one of these classifications. Polyethylene waxes [9002-88-4], for example, could be considered both as synthetic waxes and as polyolefins. The broad classes of release materials are listed in the chemical class column, and the principal types in the chemical subdivision column, with a single example in the specific examples column. No attempt has been made to incorporate actual commercial products as many are mixtures and some are of proprietary composition. For example, metallic soaps are often used in combination with hydrocarbon waxes to produce finely dispersed suspensions.

Table 1. Chemical Classification of Release Agents

Chemical class	Chemical subdivision	Specific example
Waxes	Petroleum waxes	Paraffin wax [8002-74-2]
	Vegetable waxes	Carnauba wax [8015-86-9]
	Animal waxes	Lanolin [8006-54-0]
	Synthetic waxes	Polyethylene wax [802-88-4]
Fatty acid metal soaps	Metal stearates	Magnesium stearate [557-04-0]
	Other	Calcium ricinoleate [6865-33-4]
Other long-chain alkyl derivatives	Esters	Diethylene glycol monostearate [106-11-6]
	Amides and amines	Ethylene bis(stearamide) [110-30-5]
	Acids and alcohols	Oleic acid [112-80-1]
Polymers	Polyolefins	Polypropylene [9003-07-0]
	Silicones	Polydimethylsiloxane [9016-00-6]
	Fluoropolymers	Polytetrafluoroethylene [9002-84-0]
	Natural polymers	Cellophane [9005-81-6]
	Other	Poly(vinyl alcohol) [9002-89-5]
Fluorinated compounds	Fluorinated fatty acids	Perfluorolauric acid [307-55-1]
Inorganic materials	Silicates	Talc [14807-96-6]
	Clays	Kaolin [1332-58-7]
	Other	Graphite [7782-42-5]

Many products also contain formulating aids such as solvents, emulsifiers, and biocides.

Mechanism of Release

Because release agents are used to reduce the adhesion between materials, it is self-evident that the mechanisms of adhesion and the properties that affect it are the key to understanding release phenomena. These main mechanisms are chemical reaction across the interface, interdiffusion, electrostatic attraction, surface energetics and wettability, and mechanical interlocking. Important surface and interfacial properties include surface topography, surface composition, surface energy and its effect on substrate and adhesive wettability, and the thermodynamic work of adhesion. Key bulk properties of the thin-film interfacial phase include its ability to set to a cohesive solid after wetting the substrate and its viscoelastic response to deformation controlled by factors such as degree of crystallinity, molecular weight and distribution, number of cross-links, and presence of fillers. The absence of weak boundary layers can also be crucial to developing good adhesion between phases.

Inversion of these arguments indicates that release agents should exhibit several of the following features: (*1*) act as a barrier to mechanical interlocking; (*2*) prevent interdiffusion; (*3*) exhibit poor adsorption and be unreactive with at least one of the contact phases; (*4*) have low surface tension, resulting in poor wettability, ie negative spreading coefficient, of the release substrate by the adhesive; (*5*) low thermodynamic work of adhesion; (*6*) low intermolecular forces across the interface, eg an absence of electrostatic or polar attractions; (*7*) display nonsetting or low cohesive interactions within the release phase; and (*8*) provide a weak boundary layer.

Many of these features are interrelated. Finely divided solids such as talc [14807-96-6] are excellent barriers to mechanical interlocking and interdiffusion. They also reduce the area of contact over which short-range intermolecular forces can interact. Because compatibility of different polymers is the exception rather than the rule, preformed sheets of a different polymer usually prevent interdiffusion and are an effective way of controlling adhesion, provided no additional strong interfacial interactions are thereby introduced. Surface tension and thermodynamic work of adhesion are interrelated, as shown in equations (1), (2), (3) (6), and are a direct consequence of the intermolecular forces that also control adsorption and chemical reactivity.

The work of adhesion, W_A, is the change in energy per unit surface area when two phases come into contact, as shown in equation (1) where σ_1 and σ_2 are the surface energy of each phase and σ_{12} the interfacial energy between them.

$$W_A = \sigma_1 + \sigma_2 - \sigma_{12} \quad (1)$$

If the adhesive is phase 1 and the release coating is phase 2, then the spreading coefficient S of 1 on 2 is as given in equation (2).

$$S = \sigma_2 - \sigma_1 - \sigma_{12} \quad (2)$$

Because the work of cohesion, W_C, of the adhesive is $2\sigma_1$, equation (3) follows.

$$W_A - W_C = S \tag{3}$$

Thus when the forces of adhesion are less than those of cohesion, ie when W_A is less than W_C, the spreading coefficient is negative and failure will be at the interface between the adhesive and release coating, the desired situation in a release coating application. Conversely, when the spreading coefficient is positive, undesirable cohesive failure in the adhesive or release coating will be the case. These simple, fundamental equations demonstrate the clear requirement that the release-coating surface energy be lower than that of the adhesive. Table 2 lists the surface energy of some common release substrates.

There are three broad types of intermolecular forces of adhesion and cohesion (7): quantum mechanical forces, pure electrostatic forces, and polarization forces. Quantum mechanical forces account for covalent bonding. Pure electrostatic interactions include Coulomb forces between charged ions, permanent dipoles, and quadrupoles. Polarization forces arise from dipole moments induced by the electric fields of nearby charges and other permanent and induced dipoles. Ideally, the forces involved in the interaction at a release interface must be the weakest possible. These are the polarization forces known as *London or dispersion forces* that arise from interactions of temporary dipoles caused by fluctuations in electron density. They are common to all matter and their energies range from 0.1 to 40 kJ/mol. Solid surfaces with the lowest dispersion-force interactions are those that comprise aliphatic hydrocarbons, and fluorocarbons, and that is why such materials dominate the classification table (Table 1) and the surface energy table (Table 2).

Table 2. Surface Tensions of Various Release Substrates

Substrate	Surface tension,[a] mN/m	Reference
Carnauba wax [8015-86-9]	38[b]	9
Paraffin wax [8002-74-2]	23	10
Octadecylamine monolayer [124-30-1]	22	11
Stearic acid monolayer [57-11-4]	21	11
Polyethylene [9002-88-4]	33	12
Polypropylene [9003-07-0]	29	12
Poly(dimethylsiloxane) [9016-00-6]	24	12
Poly(methylnonafluorohexylsiloxane) [115287-18-8]	16.3	12
Poly(vinyl fluoride) [24981-14-4]	28	12
Poly(vinylidene fluoride) [24937-79-9]	25	12
Polytetrafluoroethylene [9002-84-0]	18.3	12
10-Monohydroperfluoroundecanoic acid monolayer [1765-48-6]	15	13
Poly(pentadecafluorooctyl methacrylate) [29014-57-1]	10.6	12
n-Perfluoroeicosane [37589-57-4]	6.7[c]	14
Perfluorolauric acid monolayer [307-55-1]	6	13

[a] Critical surface tension of wetting, unless otherwise indicated.
[b] Extrapolated value from higher temperature measurements on liquid material.
[c] Solid surface energy, geometric mean approach.

Aliphatic fluorocarbons are the lowest surface-energy solids known. Among the hydrocarbons, the lowest surface energy values are found for surfaces comprising closely packed methyl groups. It has been shown from the studies of critical surface tension of wetting that the order of increasing surface energy of fluorocarbon and hydrocarbon constituent groups is CF_3- < -CF_2- < CH_3- < -CH_2- (8). Organic waxes and other long-chain alkyl derivatives achieve a methyl-rich surface by alignment of the alkyl chains. A related surface can be obtained with plentiful methyl groups along a polymer chain, as in the case of poly(dimethylsiloxane) [9016-00-6]. Such is the extreme localization of these atomic force fields, that there is little direct effect on surface energy from the underlying partially-polar siloxane backbone. Because of this very short, nanoscale, range of operation of dispersion forces, release can also be effected by minimizing the degree of contact between surfaces using finely divided solids. Some, such as microcrystalline wax [64742-42-3] and hydrophobic silica [7631-86-9], combine the two effects in what is sometimes referred to as a microscopic ball-bearing mechanism. Recent studies on the fundamentals of release have also pointed to the importance of a low glass-transition temperature as well as low surface energy. See, for example, the studies of Newby and Chaudhury (15) on fundamentals of release from viscoelastic adhesives. More detailed publications on specific mechanistic aspects of release agents are available, for example, metallic stearates (16), fatty amides (17), application of fluorochemicals to textiles (18), release of polyurethanes (19), and silicone-coated release papers (20).

Industrial Applications

Metal and Glass. Although one might expect that high thermal stability would be a prerequisite for release agent use with molten metals and glasses, it is not necessarily the case. Mineral oils are widely used in molding and shaping glass, despite the smoke and residue buildup entailed. Heat-resistant, graphite-containing resins are also used. Phenolic resins are used in this application and also in mold fabrication for metal castings.

In this process, sand and resin are mulled together and applied to a pattern and hardened to give a mold. Release agents prevent adhesion of the resin binder to the pattern, enabling the mold to be cleanly separated. They also improve the mold release properties after the casting of the metal. Internal mold release agents such as calcium stearate [1592-23-0] have other beneficial effects, such as reduced agglomeration of the resin-coated particles and lower muller power requirements. External release agents such as aqueous silicone emulsions or wax dispersions are used both in the mold making and casting steps. Similar release agents are used in a variety of other metal-forming operations, including the injection molding of low melting aluminum alloys, drawing of ferrous metals, and hobbing and stamping with application to both the tool and product surfaces.

Rubber, Plastics, and Textiles. Release agents are widely used to achieve release of polymers and release from polymers. They are useful in many polymer-processing applications, such as extrusion, calendering, molding, and embossing. By preventing the polymer from sticking and building up on process equipment, rejects are reduced or eliminated. In subsequent machining,

packaging, and labeling operations, abherents allow faster, more continuous handling. Release from polymer applications varies from the familiar example of fluorocarbon-treated cookware to the use of shrink films of polytetrafluoroethylene [9002-84-0] or polyethylene [9002-88-4] over rollers in the ink, printing, polymer processing, and coating industries. A significant aspect of such applications is anti-deposition coatings to reduce accumulation of pollutants and other undesirable matter. Examples include non-thrombogenic surfaces in biomedical uses, low soiling materials for solar-energy collectors, and soil-release agents in powdered detergents. Anti-redeposition agents and soil-release polymers have become important additives to today's laundry products (21).

In the extrusion of thermoplastic polymer powder or granules, release agents aid in the flow and keep the finished product from sticking when stacked. They can also reduce possibility of thermal breakdown by reducing energy requirements and cycle times. Production of granules of particularly adhesive polymers such as polystyrene [9003-53-6] would be impossible without such aids. In the mixing, sheeting, and calendering of natural rubber [9006-04-6], release agents prevent sticking to rollers, thereby maintaining continuous operation. Waxes, metal stearates, and silicones are widely used; solid abherents are popular for dusting finished, unfilled products.

Molding operations such as the manufacture of automobile seat foams and reaction injection molding and blow molding techniques consume considerable quantities of release agents. Many polymers are molded, but polyurethanes present a particular challenge, owing to the likelihood of adhesive bonding of isocyanates to the mold. Polymer films are often used to allow castings to separate from the mold. A specific example is the use of regenerated cellulose (cellophane [9005-81-6]) films in the manufacture of corrugated, glass-reinforced polyester building panels. The molds can also be made from inherently releasing polymers such as silicones.

Adhesive Transfer Processes. There are several important material-transfer applications involving polymer products that are so critically dependent on controlled adhesion that they merit separate mention from general polymer release problems. They include hot stamping foils, release coatings for pressure-sensitive adhesive (PSA) products, photocopier materials, transfer coatings, and transfer printing of textiles.

Hot stamping foils are a type of composite, decorative laminate that uses a polymer carrier film, either polyester or cellophane, together with an external release agent, usually a wax, to transfer coatings to surfaces to be decorated. The transferred coating is rapidly bonded using heat and pressure. Particular attention must be paid to foil detail and surface area, nature of the transferred coating, and avoidance of premature release during slitting and winding of the foils. Some foils are metallized by vacuum deposition; hence there must be no volatiles or migration to interfere with subsequent adhesion on hot stamping.

Silicone products dominate the PSA release liner market, but Werner-type chromium complexes such as stearato chromic chloride [12768-56-8] are also used. Various substrates are used, including coated Kraft papers and polyethylene or polyester films. Silicone coatings that cross-link to form a film are used in various forms such as solvent and solventless dispersions, and emulsions. Technical requirements include good release, no contamination of the adhesive,

adequate anchorage to the substrate, no blocking in rolls, good solvent holdout with solvent-based adhesives, and good thermal and dimensional stability. Poly(dimethylsiloxane)-based products are used for organic PSA release; fluorosilicones such as poly(methylnonafluorohexylsiloxane) [115287-18-8] are needed for silicone PSAs.

Transfer of toner material between rollers and eventually onto the paper is a demanding process. Because speed is of the essence, a combination of temperature and pressure is used to ensure adequate flow of the thermoplastic toner when fusing the image. Temperatures close to 200°C are used, requiring good thermal stability of both the rollers and the release agents. To prevent adhesion of melted toner to the heated roller, its outer layer, at least, is usually a silicone or fluorocarbon material. Often a release agent or fuser oil is also applied to the fuser roll to ensure adequate release. Silicones are widely used on account of their excellent thermal and chemical stability. Another approach is to incorporate the release agent in the toner. Polyethylene and polypropylene [9003-07-0] waxes are dispersed in the toner and migrate to the surface during the fusing step.

Transfer coating is a combination of casting and coating used to create composite materials such as simulated suede leather. A polyurethane film is cast on a release sheet and dried; a second solution is cast on the dried film and then laminated to a suitable fabric when still wet. The release paper is then stripped away when the material has dried. Flexographic printing directly onto fabrics is beset by shrinkage and register problems that are considerably eased by transfer printing from a release sheet of abherent-treated paper. This is printed on the release side by the direct gravure method, dried, and rewound. Direct gravure offers precision and color possibilities not otherwise obtainable. The roll of preprinted release is then forwarded to the fabric converters for unwinding and pressure-heat lamination of the preprint to the fabric.

Furniture. The furniture industry uses a lot of auxiliary release agents in the general gluing and veneering of wood and wood-based materials, as well as in a variety of coating processes. For example, when applying paper impregnated with phenolic and melamine resins for wood surface finishes, the reverse side of the sheet must be coated with a release agent to prevent sticking to the press surface. Mineral oils, paraffin waxes, fatty esters, and specialized paintable silicones are all used for this purpose. Silicone rubber molds are also utilized in the furniture industry; they generally have adequate release properties and require no additional release agents.

Food. Household food uses of release materials such as polyolefin refrigerator ice trays, other foodstuff molds, wax paper, release-coated pans and bake ware, and nonstick cooking sprays are very familiar. One of the oldest methods is the use of flour to release dough from preparation surfaces. Other natural abherents include confectioners' sugar, rice flour, and rice paper. The use of abherent surfaces in the food industry not only decreases product loss, but also eases equipment cleaning. semipermanent release coatings based on silicone resins and polytetrafluoroethylene can last for months whereas wax coatings are removed after each batch of cooking during cleaning and reapplied prior to the next use. Vegetable and animal fats applied pure or as emulsions are used in this way in the bakery industry. Bakery liners are also employed, and can often be reused several times. Glassine and parchment papers treated with chromium complexes

are examples. Note that the trivalent chromium complexes used do not share the hexavalent chromium health hazard.

Economic Aspects

The low surface energy and inertness of the materials used as release agents are exploited in numerous other coating applications and processing aid operations, such as water repellents, polishes, defoamers, and pigment and filler treatments. Consequently, it is difficult to obtain unambiguous economic information regarding release agent consumption. The 1997 Encyclopedia estimate quoted an earlier 1992 figure for worldwide consumption of lubricant and mold-release plastics additives of $(130–140) \times 10^3$ t. The United States, Western Europe, and the rest of the world accounted for one-third each of this activity. This is still a good estimate as the small growth in new markets is balanced by the trend toward semipermanent mold-release compounds.

Estimates can also be made for certain product types in applications that are critically dependent on release agents. For example, silicone release coatings for PSAs account for ca $\$100 \times 10^6$ in the United States, with the rest of the world consuming a similar amount. Growth is limited in many of these release applications with price increases largely offset by production and use efficiencies. Release agent product prices cover a very broad range from a few dollars per kilogram for simple solvent dispersions of stearates and paraffin waxes up to $100/kg for some complex, reactive, proprietary compositions. They may sometimes be the only alternative, but they are often cost effective even when less expensive materials can be used, because of the lower use level or less frequent application rate required. A release agent should be selected not on the basis of unit cost, but for its impact on overall processing and finishing costs.

Health and Safety Factors

Most general-purpose release agents have been developed for this market, in part because of their low toxicity and chemical inertness and do not usually present health and safety problems. Some of the solvent dispersions require appropriate care in handling volatile solvents, with some suppliers offering water-based alternatives. Some of the solids, particularly finely-divided, hydrophobic solids, can also present inhalation problems. Some of the metallic soaps are toxic, although there is a trend away from the heavier, more toxic metals such as lead. The reactive type of release coating with monomers, prepolymers, and catalysts can require specialized handling procedures. The potential user with health and safety questions is advised to consult the manufacturer directly.

Principal health and safety concerns involve contact with foodstuffs and drugs. U.S. Government regulations governing the use of additives such as release agents are listed in the *Code of Federal Regulations*. Title 21 contains the rules established by the U.S. Food and Drug Administration. Part 175 deals with indirect food additives, ie adhesives and components of coatings; part 175.300 specifically covers resinous and polymeric materials for use as components of coatings. This regulation contains a section on release agents that are the basic polymer of the coating, including polyethylene wax, polytetrafluoroethylene,

and silicones, as well as a section on surface lubricants, including glyceryl monostearate [31566-31-1]. Regulations are subject to change, and the *Code of Federal Regulations* is revised at least annually and also updated in the daily issues of the *Federal Register*. Details of regulatory practice differ between countries and a multitude of regulations exist worldwide. Local health and safety information on a particular product is best obtained directly from the formulator or manufacturer. Their skill and experience is the best defense against hazards associated with the use of release agents.

SHAPE-MEMORY POLYMERS

Introduction

Besides finding high performance materials, material scientists concentrate on designing "intelligent" and "self-repairing materials." In this context, materials showing a thermally induced shape-memory effect, such as metallic alloys or gels, have been studied intensively, and a class of polymers showing shape-memory behavior has found growing interest (1–5). The relatively easy manufacturing and programming of shape-memory polymers makes these materials a cheap and efficient alternative to well-established metallic alloys. These polymers usually surpass by far the recovery properties of shape-memory alloys, which can recover deformations of 8% at maximum. Taking into consideration the importance of polymeric materials in daily life, a very broad spectrum of possible applications for intelligent polymers opens up, covering an area from minimally invasive surgery to high performance textiles, and to self-repairing plastic components in all kinds of technical devices.

Stimuli-sensitive implant materials have a high potential for applications in minimally invasive surgery. Degradable implants could be inserted into the human body in a compressed (temporary) shape through a small incision where they obtain their shape relevant for the specific application after warming up to body temperature. After a defined time period the implant is degraded. In this case subsequent surgery to remove the implant is not necessary. For applications in biomedicine, it is necessary to have tailor-made shape-memory polymers whose thermal, mechanical, or degradation properties can be varied over a wide range. A substantially new development in this context is polymer systems. These are families of polymers in which macroscopic properties can be controlled by a

Encyclopedia of Polymer Science and Technology. Copyright John Wiley & Sons, Inc. All rights reserved.

specific variation of molecular parameters. In this way shape-memory polymers having a specific combination of properties required for specific applications can be obtained by slight variation of the molecular structure and chemical composition.

Definitions of Shape-Memory Polymer and Related Technical Terms

Shape-memory polymers are stimuli-responsive materials. Upon application of an external stimulus they have the ability to change their shape. A change in shape initiated by a change in temperature is called *thermally induced shape-memory effect*. The shape-memory effect results from the polymer's structure, that is, its morphology in combination with a certain processing and programming technology. Therefore, shape-memory behavior can be observed for several polymers that may differ significantly in their chemical composition.

The process of programming and recovering the shape of a polymer is shown schematically in Figure 1. The polymer is processed into its permanent shape by conventional methods. Afterwards, it is deformed and the desired temporary shape is fixed. The latter process is called programming. The programming process consists of heating the sample, deforming and cooling the sample, or drawing the sample at a low temperature ("cold drawing"). The permanent shape is now stored while the sample is in the temporary shape. Heating the programmed polymer above a temperature higher than the transition temperature T_{trans} results in activating the shape-memory effect. As a consequence, the recovery of the memorized, permanent shape can be observed. Cooling of the polymer below the transition temperature leads to solidification of the material. However, the polymer sample does not return to its temporary shape. The described effect is called a *"one-way" shape-memory effect*. The programming process including a mechanical deformation can be repeated. The new temporary shape is not necessarily

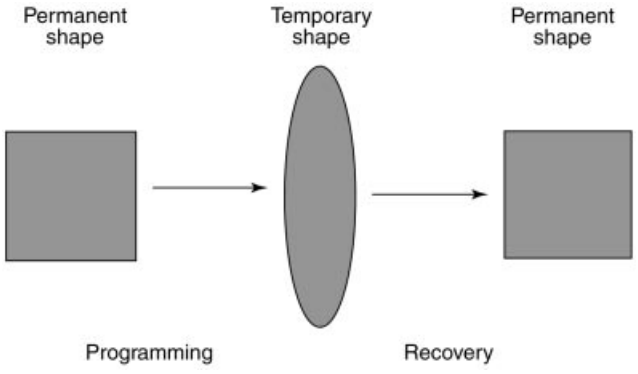

Fig. 1. Schematic demonstration of the thermally induced one-way shape-memory effect. By the programming process the permanent shape is transferred to the temporary shape. Heating up of the sample to a temperature above the switching transition T_{trans} initiates the recovery of the permanent shape. From Ref. 2.

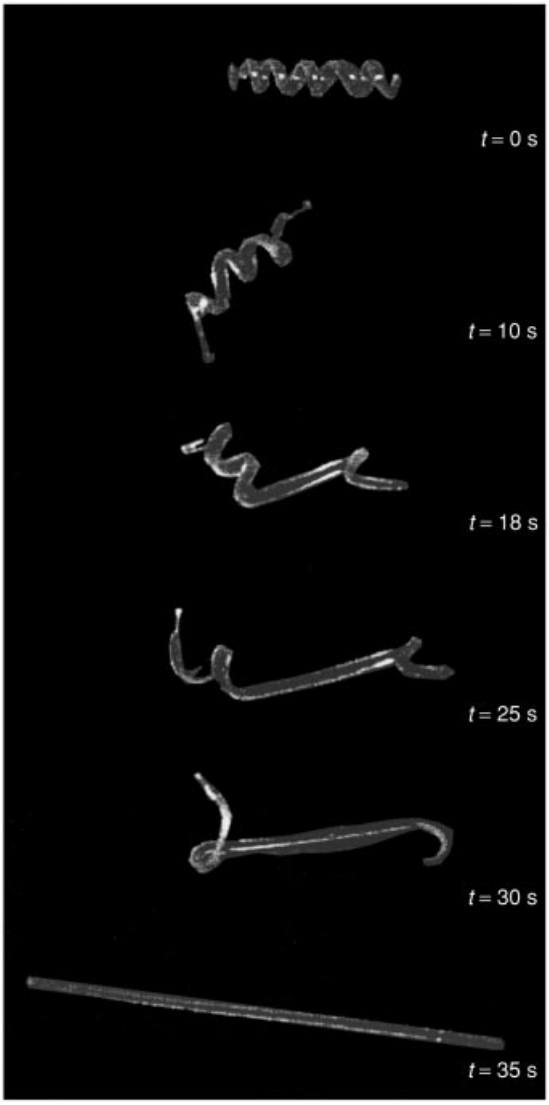

Fig. 2. The series of photos demonstrates (top–down) the transition from the temporary shape (spiral) to the permanent shape (rod) for a shape-memory network that has been synthesized of poly(ε-caprolactone)dimethacrylate and butylacrylate (comonomer content: 50 wt%). The switching temperature of this polymer is 46°C. The recovery process takes 35 s when heated up to 70°C.

supposed to match the temporary shape resulting from the former programming process.

In Figure 2, a photo sequence demonstrates impressively the performance of shape-memory polymers. The permanent shape of the polymer sample is that of a rod. This rod has been deformed to a spiral (temporary shape) during the programming process. Under the influence of hot air having a temperature of 70°C the permanent shape is recovered as soon as

the switching temperature T_{trans} is reached. With optimized programming conditions the permanent shape can be recovered with an accuracy of more than 99% (1).

Molecular Mechanism of the Shape-Memory Effect

All shape-memory polymers discussed henceforth are *elastomers*. On the molecular level they represent polymer networks consisting of segment chains that are connected by netpoints. The netpoints can be formed by entanglements of the polymer chains or intermolecular interaction of certain polymer blocks. These cross-links are called *physical netpoints*. Cross-links in the form of covalent bonds form *chemical netpoints*. An elastomer exhibits a shape-memory functionality if the material can be stabilized in the deformed state in a temperature range that is relevant for the particular application. This can be achieved by using the network chains as a kind of molecular switch. For this purpose, it should be possible to limit the flexibility of the segments as a function of the temperature. This process is supposed to be reversible. The ability to incorporate a control function into the material provides a thermal transition T_{trans} of the network chains in the temperature range of interest for the particular application. At temperatures above T_{trans} the chain segments are flexible, whereas the flexibility of the chains below this thermal transition is at least partly limited. In the case of a transition from the rubber-elastic, ie viscous, to the glassy state the flexibility of the entire segment is limited. The molecular mechanism of programming the temporary and recovering the permanent shape is demonstrated schematically in Figure 3 for a linear multiblock copolymer as an example of a thermoplastic shape-memory polymer with a crystalline hard segment.

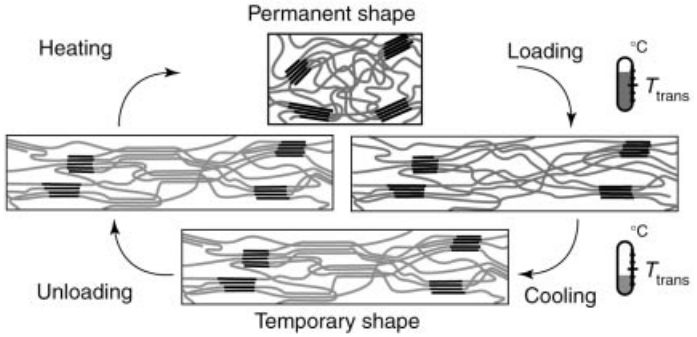

Fig. 3. Schematic demonstration of the molecular mechanism of the thermally induced shape-memory effect for a multiblock copolymer, $T_{trans} = T_m$. If the rise in temperature is higher than T_{trans} of the switching segments, these segments are flexible (marked red, here) and the polymer can be deformed elastically. The temporary shape is fixed by cooling down below T_{trans} (marked blue, here). If the polymer is heated up again the permanent shape is recovered.

Table 1. Possible Combinations of Hard-Segment- and Switching-Segment-Determining Blocks in Linear, Thermoplastic Block Copolymers with Thermally Induced Shape-Memory Effect[a]

Thermal transition determining the permanent shape at T_{perm}	Hard-segment-determining block (Block A)		Switching-segment-determining block (Block B)		Phase-separated block copolymers	
	Highest thermal transition	Second thermal transition	Highest thermal transition	Second thermal transition	T_{perm}	Possible switching transitions T_{trans}
Melting point	$T_{m,A}$	$T_{g,A}$	$T_{m,B}$	$T_{g,B}$	$T_{m,A}$	$T_{m,B}$, $T_{g,A}$, $T_{g,B}$
$T_{perm} = T_{m,A}$	$T_{m,A}$	$T_{g,A}$	$T_{m,B}$	$T_{g,B}$	$T_{m,A}$	$T_{m,B}$, $T_{g,mix}$
	$T_{m,A}$	$T_{g,A}$	$T_{g,B}$		$T_{m,A}$	$T_{g,A}$, $T_{g,B}$
	$T_{m,A}$	$T_{g,A}$	$T_{g,B}$		$T_{m,A}$	$T_{g,mix}$
Glass transition	$T_{g,A}$		$T_{m,B}$	$T_{g,B}$	$T_{g,A}$	$T_{m,B}$, $T_{g,B}$

	$T_{g,A}$		$T_{g,B}$		$T_{g,A}$	$T_{g,B}$

[a]Ref. 2.

The mechanism of the thermally induced shape-memory effect of linear block copolymers is based on the formation of a phase-separated morphology with one phase acting as molecular switch. The phase showing the highest thermal transition T_{perm} is by the formation of physical netpoints, on the one hand providing the mechanical strength of the material, especially at $T < T_{perm}$, and on the other hand the fixation determining the permanent shape. The materials are divided into two categories according to the thermal transition of the particular switching segment the shape-memory effect is based on. Either the transition temperature T_{trans} is a melting temperature T_m or a glass-transition temperature T_g. In case of a melting temperature one observes a relatively sharp transition in most cases, whereas glass transitions always extend over a broad temperature interval. In case there is no sufficient phase separation between the "hard-segment-determining" block (Block A) and the "switching-segment-determining" block (Block B), mixed glass-transition temperatures $T_{g,mix}$ between the glass transiton of the "hard-segment- and the switching-segment-determining" blocks may occur. Mixed glass-transition temperatures are also qualified to act as switching transitions for the thermally induced shape-memory effect. Table 1 gives an overview about possible combinations of "hard-segment- and switching-segment-determining" blocks in linear, thermoplastic shape-memory polymers (2).

In chemically cross-linked shape-memory networks the permanent shape is stabilized by the covalent netpoints. In analogy to linear block copolymers with shape-memory, the temporary shape of covalently cross-linked shape-memory networks can be fixed either by crystallizable segment chains or by a glass transition of the segment chains that is in the temperature range of interest.

Cyclic Thermomechanical Characterization

The shape-memory effect can be quantified by cyclic thermomechanical investigations. Typically, measurements are performed by means of a tensile tester equipped with a thermochamber. During this experiment, different test programs are applied that differ, for example, in the programming procedure (cold drawing at $T < T_{trans}$ or temporary heating up of the polymer sample to a temperature $T > T_{trans}$) or in the control parameter of the tensile tester (stress- or strain-controlled). A single cycle includes the programming of the sample and the recovery of its permanent shape.

A typical test program is described in the following: the test piece is heated up to a temperature T_{high} that is above the switching temperature T_{trans} and is elongated to the maximum strain ε_m. In case of thermoplastics, it is important not to exceed the highest thermal transition T_{perm}; otherwise, the polymer sample would melt. The sample is cooled down below the transition temperature T_{trans} to a temperature T_{low} under constant strain ε_m. In this way, the temporary shape is fixed. Retracting the clamps of the tensile tester to the original distance of 0% strain causes the sample piece to bend. After increasing the temperature to T_{high} ($>T_{trans}$) the sample contracts and the permanent shape is recovered. The cycle can begin again.

The result of such a measurement is usually presented in a tensile stress (σ)–strain (ε) curve (see Fig. 4a). This is why this test protocol is often called a two-dimensional measurement. Figure 4 schematically represents curves obtained as results from mechanical measurements. If the stretched sample is cooled down (Position ② in Fig. 4a) different effects can result in changes of the curves' course. Here, differences in the expansion coefficient of the stretched sample at temperatures above and below T_{trans}, as a consequence of the entropy elasticity and volume changes due to crystallization, are inducing changes in mechanical stress σ. The latter is the case if T_{trans} is a melting point.

The elastic modulus $E(T_{high})$ at a temperature T_{high} can be determined from the initial slope in the program step ① (Fig. 4a) also the elastic modulus of the stretched sample at a temperature T_{low} can be determined from the slope of the curve in the program step ③ (Fig. 4a). Important quantities to be determined describing the shape-memory properties of the material for a certain maximum strain ε_m are the *strain recovery rate* R_r and the *strain fixity rate* R_f. Both can be determined according to equations 1 and 3. The strain recovery rate R_r quantifies the ability of the material to memorize its permanent shape and is a measure of how far a strain that was applied in the course of the programming, $\varepsilon_m - \varepsilon_p(N-1)$, is recovered in the following shape-memory transition. For this purpose the change in strain that is applied during programming in the Nth cycle, $\varepsilon_m - \varepsilon_p(N-1)$, is compared with the change in strain that occurs with the shape-memory effect, $\varepsilon_m - \varepsilon_p(N)$:

$$R_r(N) = \frac{\varepsilon_m - \varepsilon_p(N)}{\varepsilon_m - \varepsilon_p(N-1)} \tag{1}$$

where $\varepsilon_p(N-1)$ and $\varepsilon_p(N)$ represent the strain of the sample in two successively passed cycles in the stress-free state before yield stress is applied. The *total strain*

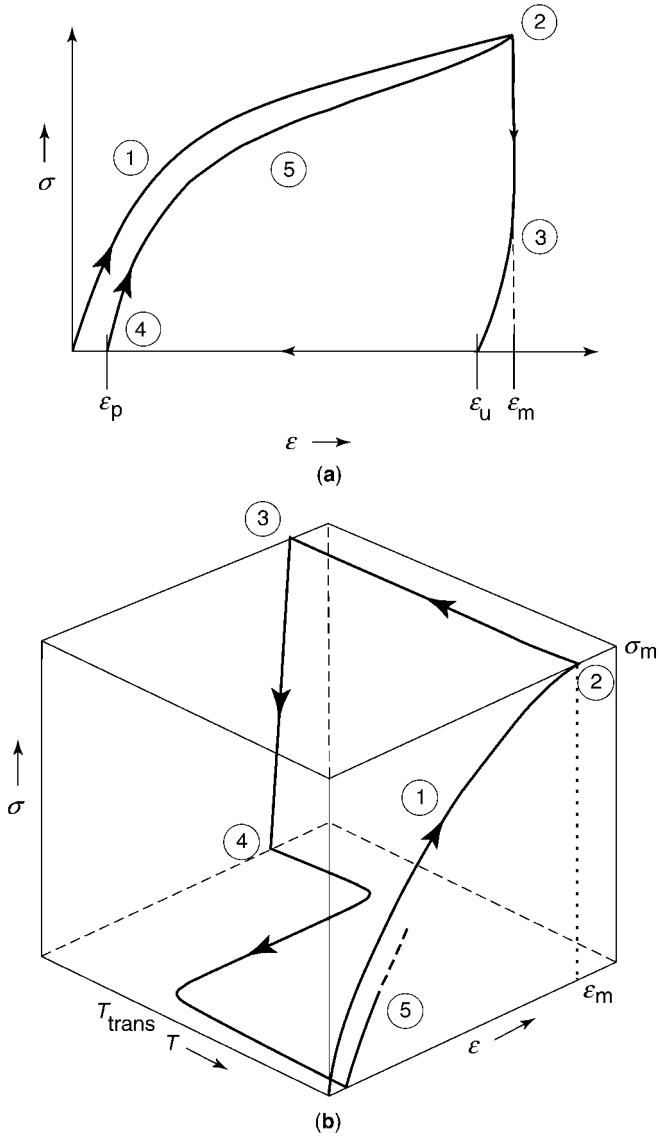

Fig. 4. Schematic demonstration of the results of the cyclic thermomechanical investigations for two different test programs: (**a**) ε–σ diagram: ① stretching to ε_m at T_{high}; ② cooling to T_{low}, while ε_m is kept constant; ③ clamp distance is driven back; ④ at $\varepsilon = 0\%$ heating up to T_{high}; ⑤ beginning of the second cycle. (**b**) ε–T–σ diagram: ① stretching to ε_m at T_{high}; ② cooling down to T_{low} with cooling rate $k_{cool} = dT/dt$ while σ_m is kept constant; ③ clamp distance is reduced unless stress-free state $\sigma = 0$ MPa is reached; ④ heating up to T_{high} with a heating rate $k_{heat} = dT/dt$ at $\sigma = 0$ MPa; ⑤ beginning of the second cycle. From Ref. 2.

recovery rate $R_{r,tot}$ is defined as the strain recovery after N passed cycles referred to the original shape of the sample piece:

$$R_{r,tot}(N) = \frac{\varepsilon_m - \varepsilon_p(N)}{\varepsilon_m} \tag{2}$$

The strain fixity rate R_f describes the ability of the switching segment to fix the mechanical deformation which has been applied during the programming process. It describes how exactly the sample can be fixed in the stretched shape after a deformation to ε_m. The resulting temporary shape $\varepsilon_u(N)$ always differs from the shape achieved by deformation.

$$R_f(N) = \frac{\varepsilon_u(N)}{\varepsilon_m} \tag{3}$$

The strain fixity rate R_f is given by the ratio of the strain in the stress-free state after the programming step in the Nth cycle, $\varepsilon_u(N)$, and the maximum strain ε_m (1).

As indicated in Figure 4 the first cycles can differ from each other. With an increasing number of cycles the curves become more similar. The process of deformation and recovery of the permanent shape becomes highly reproducible. The changes in the first cycles are attributed to the history of the sample piece. In this respect, processing and storage play an important role. During the first cycles, a reorganization of the polymer on the molecular scale takes place as a reaction on the deformation in a certain direction. Singlepolymer chains arrange in a more favorable way with regard to the deformation direction. Covalent bonds may be broken during this process. An important variable that cannot be determined by a two-dimensional measurement is T_{trans}. In this respect, the "three-dimensional" test record that is given schematically in Figure 4b is interesting. In contrast to the two-dimensional measurement, here, the sample piece is cooled down in a controlled way (constant cooling rate) at a constant tensile stress σ_m. The change in strain in this program step is influenced by the temperature dependence of the thermal expansion coefficient of the stretched polymer and volume effects, which is based on the thermal transition T_{trans}, eg, a crystallization process. Having reached T_{low} the strain is reduced until a stress-free state is reached. The sample is now heated up to T_{high} at a constant heat rate. During this experiment the tensile stress is kept constant at 0 MPa; this means that the clamps are following the shape change of the test piece. In this way, the shape change caused by the shape-memory effect is recorded as a function of the temperature. From the interpretation of the ε–T plane in the ε–T–σ diagram not only T_{trans} but also the temperature interval can be determined in which the shape-memory effect takes place (Fig. 4b).

Examples for Shape-Memory Polymers

The following examples show thermally induced shape-memory. The first three examples are exclusively physically cross-linked. These examples are two polyurethanes representing thermoplastic shape-memory polymers with $T_{trans} = T_m$ or T_g, and a high molecular weight, amorphous polynorbornene. Examples of covalently cross-linked shape-memory networks are so-called heat-shrinkable materials and a shape-memory network with a crystallizable switching segment ($T_{trans} = T_m$) that has been developed for biomedical application.

Polyurethanes with Poly(ε-caprolactone) Switching Segment. Polyesterurethanes with a "hard-segment-determining" block of 4,4′-methylenebis(phenylisocyanate) (MDI) and 1,4-butanediol can be synthesized by the prepolymer method (6–11). The highest thermal transition T_{perm} corresponding to the melting temperature of the "hard-segment-determining" blocks is found between 200 and 240°C. Poly(ε-caprolactone)diols with a number-average molecular weight (M_n) between 1600 and 8000 form the switching segments. The switching temperature for the shape-memory effect can be varied between 44 and 55°C depending on the weight fraction of the switching segments (variation between 50 and 90 wt%) and the molecular weight of the used poly(ε-caprolactone)diols. In polyurethanes with a high molecular weight of the used poly(ε-caprolactone) the "switching-segment-determining" blocks can crystallize optimally and so the temporary shape is set ideally. Moreover, a high weight fraction of "hard-segment-determining" blocks guarantees an optimum stabilization of the permanent shape. As a consequence, polyurethanes that combine a high molecular weight of the used poly(ε-caprolactone) and a high weight fraction of "hard-segment-determining" blocks show the best shape-memory properties. The strain recovery rate comes up to 98% at maximum strains ε_m of 80%. Nonetheless, the shape-memory properties are strongly influenced by the degree of the applied strain. The strain recovery rates decrease if the applied strains ε_m are increased from 80 to 250%. Decisive factors influencing the recovery properties are, besides the crystallinity of the switching segments, the formation and stability of the hard-segment-forming domains, especially, in the temperature range above the melting temperature of the switching-segment crystallites. For a content of hard-segment-forming domains below 10 wt% the hard-segment domains are not able to form stable physical cross-links. During the initial three cycles a slight increase in the switching temperature can be observed. This behavior is interpreted in terms of the destruction of weak netpoints, followed by an increasing formation of an ideal elastic network.

Polyurethanes with Poly(tetrahydrofuran) Switching Segment. Materials with a mixed glass-transition temperature $T_{g,mix}$ are systems with poly(tetrahydrofuran)- (poly(THF)-) switching-segment blocks having number-average molecular weights of 250 and 650 and a hard-segment-forming phase based on MDI and 1,4-butanediol. The hard segment is made using the prepolymer method (12,13). The highest thermal transition T_{perm} corresponds with the melting temperature of the "hard-segment-determining" blocks. The block copolymers exhibit a $T_{g,mix}$ between 16 and 54°C in case of the switching segment with M_n = 250 depending on the hard-segment content (hardsegment content between 57 and 95 wt%), a $T_{g,mix}$ between −13 and 38°C for the switching segment with M_n = 650 (hard-segment content between 32 and 87 wt%), and a $T_{g,mix}$ of −36–22°C for the switching segment with M_n = 1000 (hard-segment-content between 23 and 81 wt%). If poly(THF)diols with M_n = 2000 or 2900 are used one cannot observe a mixed T_g because of the good separation of the different blocks. Here, the occurring glass-transition temperatures are also dependent on the hard-segment content because of the hard segments' property to hinder the mobility of the switching-segment chains. The shape recovery rate increases with increasing hard-segment content, reaching values up to 99% for the material with a switching segment with

$M_n = 250$ and a hard-segment content of 75 wt%. For materials with a switching segment with $M_n = 650$ complete recovery is not reached until the hard-segment content is 87%. After approximately 100 repetitions a constant shape recovery rate of 95% is reached.

Polynorbornene. Norsorex is a linear, amorphous polynorbornene having shape-memory properties. It was developed by the companies CdF Chemie and Nippon Zeon in the late 1970s. The molecular weight of this polynorbornene is about 3×10^6 (3,14). It is produced by a ring-opening metathesis polymerization of norbornene using a tungsten–alkylidene catalyst. This polynorbornene has a content of 70–80 mol% of trans-linked norbornene units and a glass-transition temperature between 35 and 45°C (14,15). The shape-memory effect of this strictly amorphous material is based on the formation of a physically cross-linked network due to entanglements of the high molecular weight, linear polymer chains. The thermal transition from the glassy state to the rubber-elastic state can be used as switching transition (16). Consequently, upon reaching the glass-transition temperature T_g the material softens abruptly. If the chains are stretched quickly in this state and the material is rapidly cooled down again below T_g, as an answer to this, the polynorbornene chains can neither slip off each other rapidly enough nor can entanglements disentangle. By rapid cooling the induced elastic stress can be frozen within the material. After heating up again above T_g, because of the thermally induced shape-memory effect a recovery of the material's shape can be observed. The described Norsorex is not inevitably purely amorphous. There are reports of a high molecular weight polynorbornene with a high content of trans-linked norbornene units showing a tendency toward strain-induced crystallization (14,15). Because of this observation the possibility must not be excluded that crystallites acting as physical netpoints contribute to the shape-memory effect.

"Heat-Shrinkable" Polymers. Since the 1960s, polyethylene covalently cross-linked by means of ionizing radiation has found broad application as heat shrink foil or tubing especially for the insulation of electric wires or as protection against corrosion of pipe lines (17–22). These materials are marketed under the term *heat-shrinkable materials*. The mechanism of the heat-shrinking process corresponds to the thermally induced shape-memory effect. The permanent shape is fixed by covalent cross-links. The switching process is controlled by the melting temperature of the polyethylene crystallites.

Biodegradable Polymer Networks with Shape-Memory. Based on oligo(ε-caprolactone)diol representing the component to form a crystallizable switching segment, a polymer system with an AB-polymer network structure has been developed (1). For this purpose oligo(ε-caprolactone)diols have been functionalized with methacrylate end groups that can undergo a polymerization reaction. The comonomer of choice is *n*-butyl acrylate because of the low T_g (−55°C) of pure poly(*n*-butyl acrylate); this supposedly determines the amorphous network chains of the expected network. The molecular weight of the used oligo(ε-caprolactone)dimethacrylate cross-linking agent and the content of the comonomer butyl acrylate represent the molecular parameters controlling crystallinity, eg T_{trans}, and mechanical properties. The number-average molecular weights of the oligo(ε-caprolactone)dimethacrylates used were 2000 and 10,000. The cross-link density in the case of the oligo(ε-caprolactone)dimethacrylate

(M_n = 2000) was varied by addition of 11–90 wt% butyl acrylate and for the oligo(ε-caprolactone)dimethacrylate (M_n = 10,000) by addition of 20–71 wt% butyl acrylate. The cross-link density increases with decreasing content of butyl acrylate. The butyl acrylate content influences the thermal properties of the formed AB network, especially for the oligo(ε-caprolactone)dimethacrylate with M_n 2000. Here, only in the case of a very low content of butyl acrylate of 11 wt%, a melting point at a $T_m = 25^\circ$C can be observed. The corresponding homonetwork of oligo(ε-caprolactone) dimethacrylate has a melting point at $T_m = 32^\circ$C. All other networks of this series were found to be completely amorphous. For the networks of butyl acrylate and oligo(ε-caprolactone)dimethacrylate with M_n 10,000 the melting point decreases from 51 to 44°C with increasing butyl acrylate content. With increasing butyl acrylate content the mechanical properties of both materials with oligo(ε-caprolactone) segments with M_n = 2000 and 10,000 change in such a way that the values of the elastic modulus (E), the tensile strength (σ_{max}), and the tensile stress at break (σ_R) decrease for about an order of magnitude. The absolute values are an order of magnitude higher for the series with oligo(ε-caprolactone) segments with M_n = 10,000. In cyclic thermomechanical tensile tests for the network with oligo(ε-caprolactone) segments (M_n = 10,000), strain fixity rates between 95 and 85% and strain recovery rates from 98 to 93% could be obtained. After three thermocycles all materials reached a constant strain recovery rate of 99%. In *in vitro* tests these shape-memory networks appear to be promising in their biocompatibility.

SINGLE-SITE CATALYSTS

Introduction

In 1953, Karl Ziegler discovered that the activation of certain early transition metal halides with aluminum alkyls resulted in the formation of new organometallic catalysts capable of polymerizing ethylene at room temperature and ambient pressure (1–3). In 1954, Giulio Natta and co-workers from the Politecnico di Milano and Montecatini for the first time prepared crystalline isotactic polypropylene (iPP) by using the heterogeneous $TiCl_4/(C_2H_5)_3Al$ Ziegler catalyst system (4–8). Three years later, in 1957, the first PP plant went on line at the Montecatini site in Italy. Only six years later, in 1963, Karl Ziegler and Giulio Natta shared the Nobel Prize in chemistry for their landmark discoveries that laid the foundation for today's multibillion-dollar-a-year polyolefin industry (see ZIEGLER–NATTA CATALYSTS).

The industrial and academic impact of Ziegler–Natta catalysis has been tremendous (9–11). Several generations of catalysts and processes have been introduced on a commercial scale to produce a variety of polymeric materials ranging from fibers to commodity thermoplastics, engineering plastics, and elastomers. At the turn of the millennium, over 40 million tons of polyolefins per year worldwide are produced using the Ziegler–Natta technology. Modern $MgCl_2$-supported Lewis-base-modified catalyst systems produce spherical pellet-sized polyolefin replicas with catalytic activities exceeding 1 ton of polymer per gram of transition metal, thus eliminating the need for pelletizing extrusion and additional polymer purification steps. Annual demand for polyethylene (PE), the number one commodity plastic, is approaching 50 million metric tons. Polypropylene (PP) is ranked third, after poly(vinyl chloride) (PVC), and has the fastest growing market (see ETHYLENE POLYMERS; PROPYLENE POLYMERS (PP)).

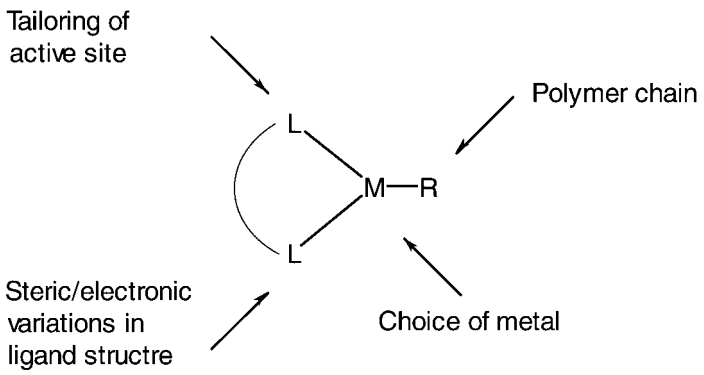

Fig. 1. General structure of single-site catalysts.

Fifty years after the initial discoveries, Ziegler–Natta catalysis remains as an outstandingly vital field. The recent rapid scientific and technological outburst of single-site transition metal catalysts is undoubtedly one of the most remarkable developments in the application of molecular organometallic chemistry to catalysis and polymer science (for reviews and general references, see Refs. 12–38). These predominantly homogeneous catalyst systems consist of well-defined active sites with the general formula [L_nMR], where L_n represents an organic ligand set bound to the transition metal M, and R is the growing polymer chain or initiating group (Fig. 1).

By variation of the organic ligand and thus the steric and electronic environment of the metal center, these catalysts can be tailored to control the olefin polymerization reaction in an unprecedented fashion. Almost any vinyl monomer, irrespective of its molecular weight or steric hindrance, can be polymerized by choosing the proper catalyst and polymerization conditions. Virtually all feasible polymer microstructures ranging from atactic to isotactic, hemiisotactic, syndiotactic, and stereoblock poly-α-olefins can be produced by rational modification of the catalyst structure. In addition, molecular weight, molecular weight distribution, comonomer content, and end-group composition of the produced polymer can be varied independently. Entirely new polyolefin materials, not accessible with traditional Ziegler–Natta catalysts, have also emerged through single-site catalyst (SSC) technologies. Notable examples include syndiotactic polystyrene, thermoplastic PP-based elastomers, as well as cycloaliphatic polymers obtained by cyclopolymerization of nonconjugated dienes or direct polymerization of cycloolefins, such as norbornene and cyclopentene (see ELASTOMERS THERMOPLASTIC; ETHYLENE-NORBORNENE COPOLYMERS).

The first generations of SSCs were based on Group 4 metallocene complexes as pioneered by Ewen, Kaminsky, and Brintzinger. More recent examples include alternative ligand systems complexed with Group 4 metals, as well as several late transition-metal-based catalyst systems developed by Brookhart, Gibson, Grubbs, and others. The less oxophilic late transition metals are even capable of incorporating a variety of polar comonomers into polyolefin chains.

This article provides a broad overview of the current status and the enormous amount of literature on single-site olefin polymerization catalysts. For the

sake of consistency, *single-site catalyst* is used in this article for describing a catalyst system or precursor consisting of essentially uniform active centers producing narrow molecular weight distribution polymers ($M_w/M_n \approx 2$), in accordance with Schulz–Flory statistics. Since several of these catalysts have two coordination sites located at the same metal center, the term *single-center catalyst* is also in common use. The references have, with a few exceptions, been selected from the open literature with the main emphasis on the well-established Group 4 metallocenes and the recently developed late transition metal catalysts. For detailed descriptions of the various catalysts and processes as well as references to the extensive patent literature, the reader is referred to the original publications cited in the bibliography and the available reviews and text books (12–38).

Evolution and Classification of SSC Systems

Classical Ziegler–Natta catalysts are multisited and heterogeneous with the polymerization taking place on edges and dislocations of transition metal halide crystals. Development of homogeneous single-site olefin polymerization catalysts was initiated by efforts to model the reaction mechanisms of the heterogeneous catalysts. In 1955, Breslow and Newburg (39,40) and Natta and co-workers (41) discovered that titanocene dichloride (Cp_2TiCl_2) could be activated for ethylene polymerization by addition of aluminum alkyls $(C_2H_5)_2AlCl$ or $(C_2H_5)_3Al$. The first soluble catalysts were inactive for polymerization of propylene and exhibited much lower activities in ethylene polymerization than their heterogeneous counterparts. Nevertheless, these and other subsequent early studies (42–49) contributed significantly to the understanding of both heterogeneous and homogeneous Ziegler–Natta catalysis.

In the mid-1970s, a series of serendipitious discoveries initiated the rapid development in single-site olefin polymerization catalysis, which in less than 25 years has revolutionized modern polymer synthesis. In 1973, Reichert and Meyer observed a remarkable increase in polymerization activity by adding small amounts of water to the $Cp_2TiCl_2/C_2H_5AlCl_2$ metallocene catalyst system (50). Similar observations were reported by Long and Breslow for $Cp_2TiCl_2/(CH_3)_2AlCl$ (51). In 1975, Sinn and Kaminsky discovered an enormous and unexpected increase in polymerization activity after addition of considerable amounts of water to the otherwise inactive $Cp_2Ti(CH_3)_2/(CH_3)_3Al$ mixture (52). The suspected formation of methylaluminoxane (MAO) by partial hydrolysis of $(CH_3)_3Al$ was subsequently supported by its controlled synthesis. The direct activation of titanocenes and zirconocenes with preformed MAO gave exceedingly active catalysts for polymerization of ethylene (53). For the first time, homogeneous metallocene-based SSCs became more active than the commercially used heterogeneous Ziegler–Natta catalyst systems. In addition, the MAO-activated Group 4 metallocenes were capable of polymerizing propylene and higher α-olefins (54,55), although only atactic polymers of prochiral monomers were obtained (because of the achiral nature of the catalytic site).

Group 4 Metallocene-Based Catalysts. Revolutionary breakthroughs occurred in the early 1980s when Ewen (56) and Kaminsky (57) reported that MAO-activated C_2 symmetric chiral *ethylene*-bridged bis(tetrahydroindenyl)

Group 4 *ansa*-metallocenes *rac*-$C_2H_4(IndH_4)_2MCl_2$ (M = Ti, Zr), developed by Brintzinger and co-workers (58–60), polymerized propylene to iPP. The prefix *ansa* from Latin (for bent, handle) was first used for compounds with an alkane bridge across an arene ring, and later adopted by Brintzinger as a short notation for metallocene derivatives with an interannular bridge.

Since the mid-1980s billions of dollars have been invested worldwide in research focusing on modifying and improving the metallocene-based olefin polymerization catalysts. Key structures are summarized in Figure 2.

In 1988, Ewen reported the first preparation of a C_s symmetric *ansa*-metallocene catalyst precursor $[(CH_3)_2C(Cp)(Flu)]ZrCl_2$ producing syndiotactic polypropylene (sPP) (61), and a few years later its C_1 symmetric modification

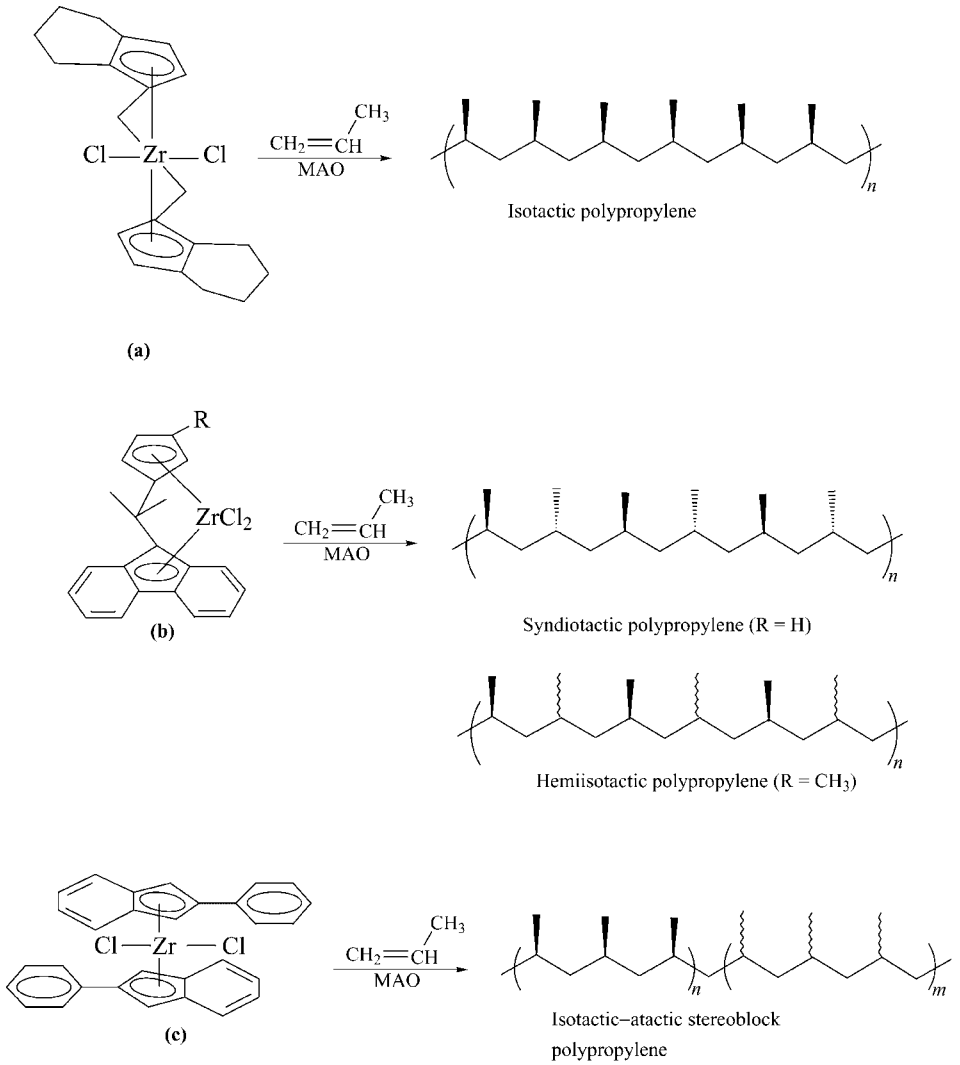

Fig. 2. Key metallocene catalysts for olefin polymerization: (**a**) *rac*-$C_2H_4(IndH_4)_2ZrCl_2$ (56–60); (**b**) $(CH_3)_2C(3\text{-R-Cp})(Flu)ZrCl_2$ (R = H, CH_3) (61,62); (**c**) $(2\text{-}C_6H_5\text{-Ind})_2ZrCl_2$ (63).

$[(CH_3)_2C(3\text{-}CH_3Cp)(Flu)]ZrCl_2$ for hemiisospecific propylene polymerization (62). In 1995, Coates and Waymouth described an unbridged bis(2-phenylindenyl) zirconocene producing elastomeric isotactic–atactic stereoblock PP (63), presumably by oscillating stereocontrol in which the catalyst switches between isospecific and aspecific conformations during the growth of a single polymer chain.

In these pseudotetrahedral bis(cyclopentadienyl) metallocenes the d^0 central transition metal (Ti, Zr, or Hf) is bound to two η^5-cyclopentadienyl-type ring ligands and two σ-ligands (usually Cl or CH_3), one or both of which are removed upon formation of the active catalyst. The most commonly employed cyclopentadienyl ligands are based on plain or substituted cyclopentadienyl (Cp), indenyl (Ind), tetrahydroindenyl ($IndH_4$), and fluorenyl (Flu) anions. Because of the high structural diversity of the available ligand structures, the steric and electronic environment of the active site can be modified by variation of the ligand size, shape, and substitution pattern (for representative examples of structural variations, see Refs. 13, 33, and 58–93). The function of the interannular *ansa*-bridging group is to lock the ancillary ligand in the desired conformation or symmetry, thus allowing steric control over the enantiodifferentiating steps in stereoselective olefin polymerization or differentiation of olefins of different sizes in copolymerization reactions.

The most notable examples of monocyclopentadienyl-based catalyst precursors are the "constrained geometry" *ansa*-monoCp-amido Group 4 complexes (25,94–105) (Fig. 3) developed by Dow Chemical Co. (106) and Exxon Chemical Co. (107) (for further references to the patent literature, see Ref. 25). The original ligand design was introduced for organoscandium complexes (108). A remarkable feature of these catalysts is the open nature of the active site which allows the incorporation of higher α-olefins, including styrene, in copolymerization with ethylene. Incorporation of vinyl-terminated macromonomers results in the formation of long-chain branched ultralow-density polyethylenes possessing unique rheological properties. The titanium-based constrained geometry catalysts (CGCs) are generally preferred over their zirconium and hafnium analogues showing higher activities and producing polymers with higher molecular weights. Several structural modifications of the CGCs including monoCp-alkoxide analogues have been described (109–111).

Monocyclopentadienyl and (monoindenyl)titanium trichlorides are generating interest as catalyst precursors for syndiospecific polymerization of styrene (112–127). A class of highly active olefin polymerization catalysts based on a (monocyclopentadienyl)titanium dimethyl cation $[CpTi(CH_3)_2]^+$, generated by

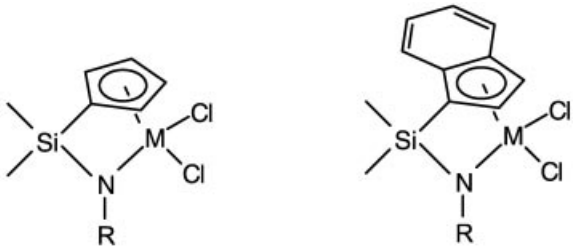

Fig. 3. Prototypical Group 4 constrained geometry catalysts (CGC). M = Ti, Zr; R = alkyl, aryl; Cp = cyclopentadienyl, tetramethylcyclopentadienyl.

methyl abstraction from $CpTi(CH_3)_3$ or $Cp*Ti(CH_3)_3$ (Cp* = pentamethylcyclopentadienyl), has been described (127–132).

Alternative Early Transition Metal Catalysts. Bis(cyclopentadienyl) Group 3 and lanthanide complexes of the type L_2MR (L = bridged or unbridged Cp or related ligands; M = Sc, Y, La, Nd, Sm, Lu; R = H, alkyl) have received interest, mainly in mechanistic studies, as single-component olefin polymerization catalysts (133–141). Other examples of potential early transition metal nonmetallocene SSC precursors (26) include the aminoborole (142), boratabenzene (143–147), diamido (148–164), and chelating alkoxide complexes (165–168) of the Group 4 metals (Fig. 4).

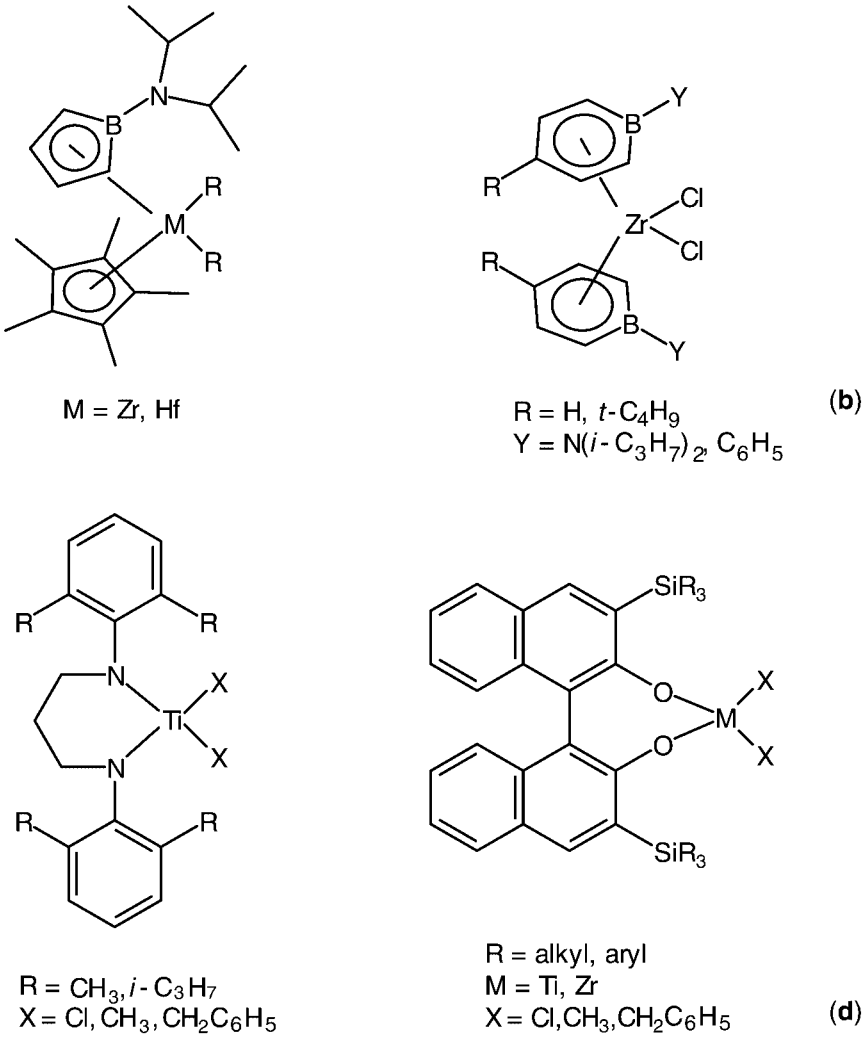

Fig. 4. Examples of potential nonmetallocene early transition metal SSC precursors: (**a**) aminoborole; (**b**) boratabenzene; (**c**) diamido; and (**d**) chelating alkoxide Group 4 metal complexes.

Group 5 metal catalysts based on various cyclopentadienyl and dianionic mixed ligand and related complexes of tantalum (169,170), niobium (171,172), and vanadium (173,174) have also been described.

Late Transition Metal Catalysts. In contrast to early transition metal catalysts, late metal systems most often dimerize or oligomerize olefins due to competing β-hydride elimination (175,176). For example, soluble Ni(II)-based ethylene oligomerization catalysts form the basis for the Shell Higher Olefin Process (SHOP) (177,178). In 1995, a series of highly electrophilic nickel(II) and palladium(II) complexes were reported (179–182). These complexes incorporate bulky diimine ligands (Fig. 5), which upon activation with MAO polymerize ethylene and α-olefins with high activities comparable to those of metallocene catalysts. In these complexes, the presence of equatorial sterically demanding aryl substituents effectively blocks the associative olefin exchange, retarding the chain transfer and resulting in high molecular weight polymers. Copolymerization of ethylene and propylene with functionalized vinyl monomers was reported shortly after the initial findings (193,194). The first reports stimulated an extensive search for other late transition metal olefin polymerization catalysts. Subsequent studies on these and related nickel and palladium systems using neutral or anionic chelating N—N, N—O, and N—P ligands have been described by several academic and industrial groups (for reviews and references to the patent literature, see Refs. 26, 195, and 196).

During 1997 and 1998, highly active iron(II)- and cobalt(II)-based ethylene polymerization catalysts bearing 2,6-bis(imino)pyridyl ligands (Fig. 5) were described independently by Brookhart (183,184), and Gibson (187,188), as well as by DuPont (185,186). Oligomerization of ethylene to linear α-olefins (189) as well

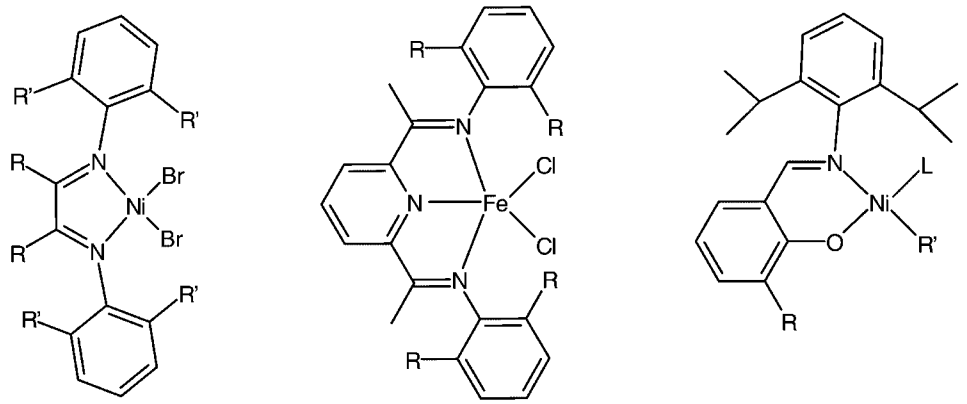

Fig. 5. Late transition metal SSC precursors based on (**a**) diimine (179–182), (**b**) 2,6-bis(imino)pyridyl (183–190), and (**c**) salicylaldimine (191,192) ligands.

as polymerization of propylene (190), using the iron-based catalysts, was reported in subsequent papers.

A family of neutral single-component salicylaldimine nickel(II) catalysts (Fig. 5) that produce high molecular weight PE, polymerize functionalized olefins, and require no cocatalyst have been reported (191,192). These catalysts can be regarded as an extension of the original SHOP oligomerization systems where the P—O chelate of the neutral SHOP catalyst has been replaced with a sterically demanding N—O ligand leading to high molecular weight products.

Catalyst Generation

Active Species and Function of the Cocatalyst. The active species in olefin polymerization is, in most cases, a coordinatively unsaturated cationic metal alkyl $[L_nMR]^+$ (197). Activity and stereoregularity of the produced polymer are determined by the steric and electronic properties of the ancillary ligand set L_n and the ion–ion interactions between the highly electrophilic metal cation and its counterion. Several methods exist for generating the active catalyst (for a review on cocatalysts for metal-catalyzed olefin polymerization, see Ref. 198). MAO is by far the most common cocatalyst (28), including large-scale industrial production. The exact composition, structure, and function of the aluminoxane cocatalysts are still a matter of controversy (199–202); controlled hydrolysis of $Al(CH_3)_3$ produces a complex mixture of cyclic and linear oligomeric MAOs, possibly containing cluster-like or supramolecular aggregates with the general formula $(CH_3AlO)_n$ (Fig. 6). The degree of oligomerization varies from 5 to 20.

In the case of Group 4 metallocene dihalide catalyst precursors L_2MX_2 (eq. 1), addition of MAO generates first a monomethyl complex L_2MXCH_3 (203,204). Excess MAO gives the dialkylated species $L_2M(CH_3)_2$. Presumably, some of the Al centers in MAO have a high propensity to abstract a methyl anion from $L_2M(CH_3)_2$ forming a weakly coordinating anion $[CH_3—MAO]^-$. The metallocene cation $[L_2MCH_3]^+$ is stabilized coordinatively by the $[CH_3—MAO]^-$ counterion, which in the presence of olefins gives way to olefin-separated ion pairs $[L_2M(olefin)CH_3]^+[CH_3—MAO]^-$. Repeated olefin insertion to the metal–alkyl bond forms the polyolefin.

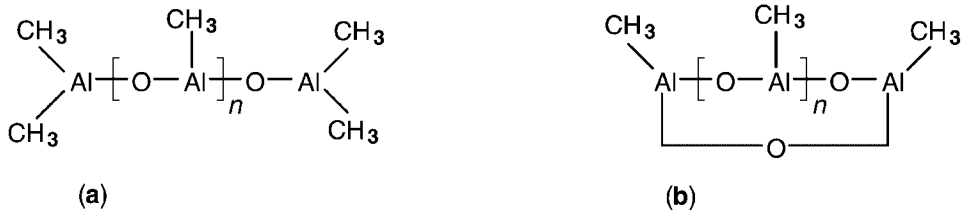

Fig. 6. Generalized structures of MAO: linear (**a**), and cyclic (**b**).

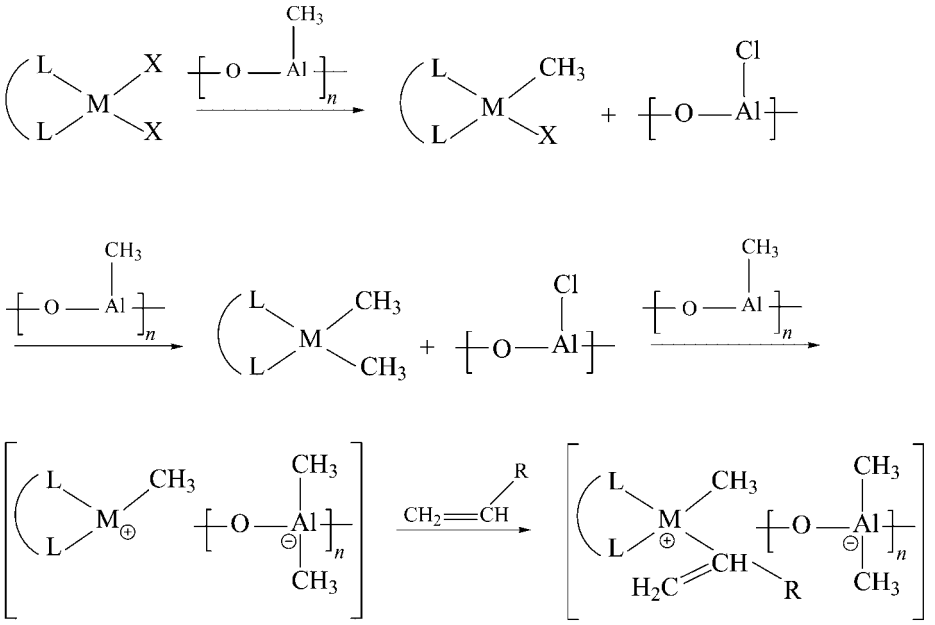


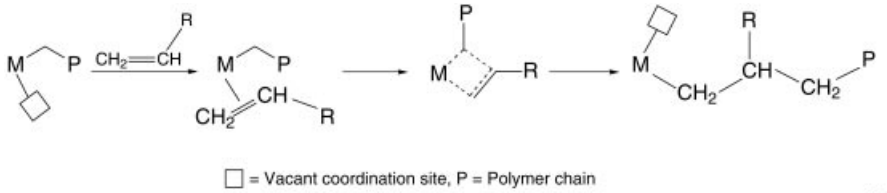
(1)

A large excess of MAO is usually required to achieve high polymerization activities. For Group 4 metallocene/MAO catalyst systems, activity maxima are generally found at [Al]:[M] ratios ranging from 1000:1 to 10,000:1. The excess MAO is possibly required to shift the equilibrium involving the metal monoalkyl and MAO to the cationic active species. In addition, MAO has been found to reactivate inactive complexes formed by hydrogen tranfer reactions and to prevent the deactivation of the catalyst by bimolecular processes. Aluminoxanes also scavenge impurities such as water and oxygen from the reaction medium.

Intensive work has been carried out to develop stoichiometric activators for metallocene and other SSCs (17,198). Early systems based on tetraphenylborate or other carborane anions exhibited only low polymerization activities as a result of the strong interaction of the cationic metal center with the counterion (197,205–213). The introduction of perfluorinated tetraphenylborate $[(C_6F_5)_4B]^-$ (214,215) produced exceedingly active cationic metallocene catalysts for polymerization of α-olefins. The application of $[(C_6F_5)_4B]^-$, $[(C_6F_5)_3BCH_3]^-$, and related fluoroarylborate counterions in various homo- and copolymerization reactions has been studied in detail (62,216–237). Methods for generating the cationic metal complex include mixing of metal dialkyl with dimethylanilinium tetrakis(perfluorophenyl)borate $[NH(CH_3)_2C_6H_5]^+[(C_6F_5)_4B]^-$, alkyl anion transfer with trityl tetrakis(perfluorophenyl)borate $[(C_6H_5)_3C]^+[(C_6F_5)_4B]^-$, and methyl abstraction from the metal dialkyl complex with $(C_6F_5)_3B$. Other base-free or weakly stabilized metal alkyl cations, including metallocene–borate–betaine complexes (238–242), other zwitterionic catalyst systems (230,243–247), and Al-, Nb-, and Ta-based perfluoroaryloxide anions (248) have been developed.

Polymerization Mechanism. The basic mechanistic steps of olefin coordination to the metal center and the subsequent insertion into the metal–carbon bond are not entirely understood. Several plausible hypotheses have been

suggested (249–257), most notably the Cossee-Arlman model based on *cis*-insertion of an α-olefin into the metal–carbon bond (eq. 2) (249–252). Both kinetic isotope studies and molecular modeling suggest that the transition state of the insertion step is stabilized by agostic interactions between the metal center and an α-hydrogen atom of the growing chain (for a review, see Ref. 20). The agostic interaction apparently increases the rigidity of the transition state resulting in an increase in the rate of olefin insertion and, in the case of chiral catalysts, an increase in stereospecificity.



(2)

The molecular weight of the produced polymer is determined by the relative rates of monomer insertion and chain termination (Fig. 7) (for a review on chain transfer processes in propylene polymerization, see Ref. 258). The dominant chain termination process in olefin polymerization involves an intramolecular β-H elimination (259,260) producing a vinylidene-terminated polymer chain and a metal hydride. Termination by β-elimination may occur either by direct hydrogen transfer from the polymer chain to the metal center, or by transfer of a β-H from the polymer chain to a carbon atom of a coordinated olefin (261). The rate of the latter process increases with olefin concentration in parallel with increased rate of propagation, whereas the rate of the former is olefin-independent. Intramolecular β-alkyl elimination (261–263) produces a metal–alkyl and an allyl-terminated chain end. Reinsertion of terminally unsaturated polymer chains results in long-chain branching. Saturated chain ends are obtained in the presence of chain-transfer agents, such as H_2 or aluminum alkyls (eg, complexed MAO). Hydrogen functions as an effective means to control the molecular weight of polyolefins (264,265),

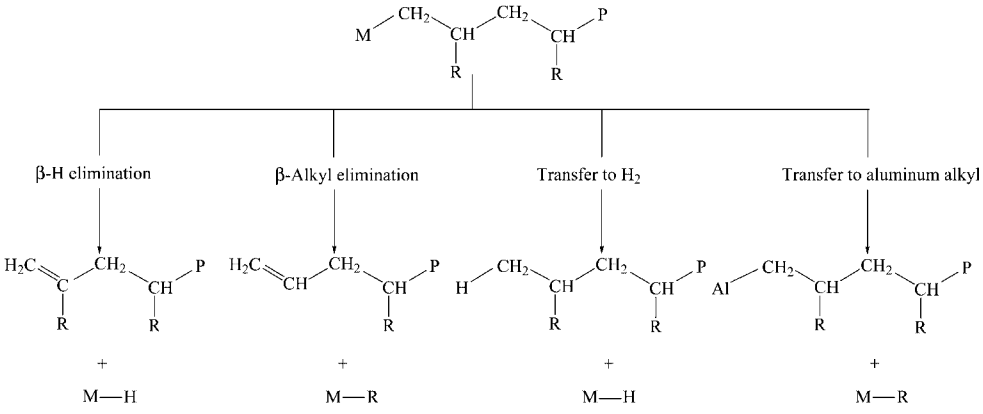


Fig. 7. Chain termination processes in olefin polymerization.

producing an alkyl-terminated chain end and a metal hydride. Transalkylation to the aluminum cocatalyst results in a metal–alkyl and an aluminum-terminated polymer chain, which for PP generates isopropyl end groups after hydrolysis of the carbon–aluminum bond (266–271). The barrier to exchange of alkyl groups between the transition metal and aluminum compounds decreases with increasing electron density at the metal center (267,271).

Mechanisms of Stereocontrol. Stereochemistry of the olefin insertion step can be controlled by both the steric environment of the active site (enantiomorphic-site control) as well as the growing polymer chain (chain end control). In chain end stereocontrol, stereospecificity arises from the chiral β-carbon atom of the last enchained monomer unit, which in turn influences the stereochemistry of monomer addition. Chain-end control is usually less effective than site control and has been observed for some achiral metallocenes at low polymerization temperatures. Partially iPP resulting from chain end stereocontrol has been obtained with Cp_2TiPh_2/MAO (56,272). The syndiospecific polymerization of 1-butene using the $Cp*_2MCl_2$/MAO (M = Zr, Hf) catalyst systems has been described (273). Predominantly sPP has been obtained under chain end control, using Brookhart's diimine nickel catalysts (274–277).

Stereoselectivity of C_2 symmetric Group 4 *ansa*-metallocenes in isospecific propylene polymerization results from an enantiomorphic-site control mechanism. Chain propagation proceeds prevailingly via 1,2 (primary) monomer insertion. Both coordination sites of the C_2 symmetric catalyst are homotopic and thus selective for the same olefin enantioface. Repulsive interactions force the coordinated propylene monomer into that enantiofacial approach to the metal–alkyl unit which has the methyl substituent of the monomer *trans* to the β-C atom of the growing polymer chain (Fig. 8). To avoid repulsive interaction with the ligand, the growing chain preferably obtains a conformation where the first C—C bond is directed toward the most open sector of the ligand framework. Repeated chain migratory insertion with the same olefin enantioface generates an isotactic polymer chain.

Experimental proof for the presented mechanism has been obtained by propylene oligomerization studies with enantiomerically pure *ansa*-metallocene catalysts (259,264,278,279). The participation of α-agostic interactions in the insertion process by polymerization of α-deuterated olefins has been demonstrated (280,281). Agostic interactions control the stabilities of the alternative transition states for propylene insertion. Of the two possible orientations of the polymer chain involving a three-membered Zr—H(α)—C(α) ring, one is sterically hindered by collision of the growing chain with a β-substituent of the chiral ligand. The other one is essentially unencumbered placing the β-C in the open position of the ligand framework. The stereochemistry of the propylene insertion step has been studied using a *s-cis*-η^4-butadiene complex derived from a C_2 symmetric bis(indenyl) *ansa*-zirconocene *rac*-$(CH_3)_2Si(Ind)_2ZrCl_2$ (242).

Syndiospecific propylene polymerization with C_s symmetric *ansa*-metallocene catalysts proceeds in an analogous fashion (Fig. 8). The growing polymer chain is directed away from the bulkier cyclopentadienyl ligand, and the favored propylene enantioface places the methyl substituent *trans* to the growing chain. Migratory insertions result in regular alternation of the monomer approach from the left and right side of the metallocene wedge, consequently producing the syndiotactic polymer (61,76).

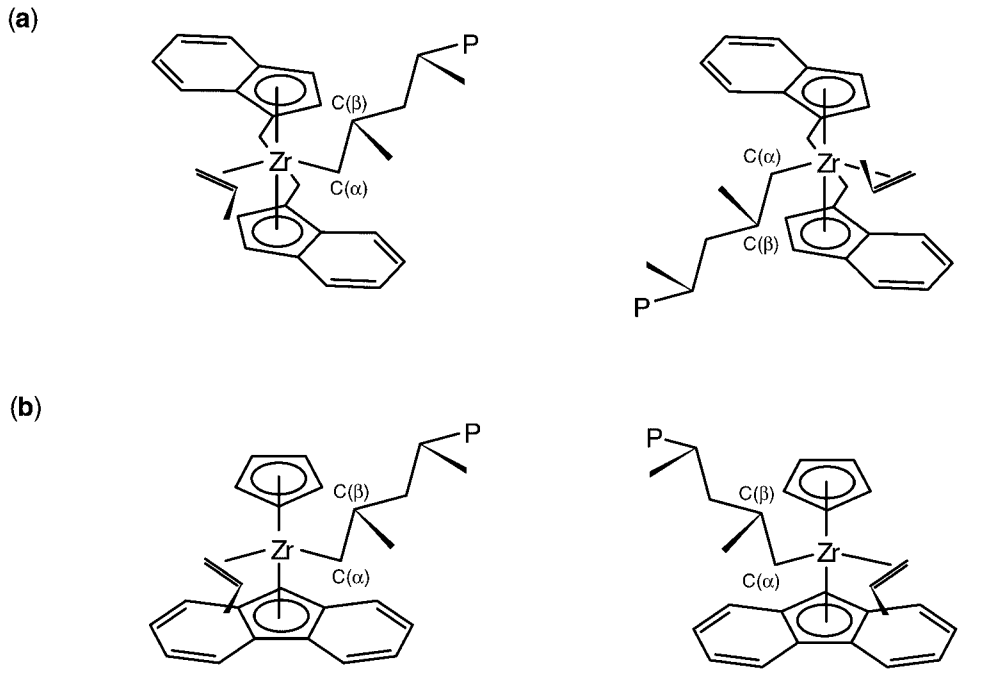

Fig. 8. Enantioselective coordination of propylene to the coordination sites of a C_2 symmetric isospecific metallocene catalyst (**a**) (only one enantiomer of the racemic pair is shown), and a C_s symmetric syndiospecific metallocene catalyst (**b**) [$(CH_3)_2C$ bridge omitted for clarity].

Theoretical Studies

Numerous theoretical studies on both early and late transition metal SSCs have appeared in recent years covering nearly all aspects of the olefin polymerization process (for reviews, see Refs. 282 and 283). The employed methodologies include molecular mechanics (284–291), ab initio electronic structure methods (292–297), density functional studies (298–303), as well as various hybrid techniques (304–308), such as the combination of quantum and molecular mechanics (QM/MM). A detailed description of these studies is outside the scope of this article; nevertheless, these theoretical investigations have played a major role in elucidating the elementary steps of olefin complexation, chain propagation, and chain termination as well as the mechanisms of stereocontrol in catalytic olefin polymerization.

Polymerization of Ethylene

The properties of polyethylene are strongly influenced by its molecular weight, molecular weight distribution, and branching content. Three major classes of polyethylene are commercially available. Conventional low density polyethylene (LDPE) is produced at high polymerization temperatures and pressures. As a

consequence of the radical polymerization mechanism, LDPE contains both short- and long-chain branching. Heterogeneous Ziegler–Natta catalysts polymerize ethylene to highly linear high density polyethylene (HDPE) characterized by excellent strength but poor melt processability. Linear low density polyethylene (LLDPE) is traditionally obtained by controlled incorporation of higher α-olefins such as 1-hexene or 1-octene into polyethylene, using Ziegler–Natta or chromium catalysts (see ETHYLENE POLYMERS, LLDPE).

In contrast to multisite heterogeneous Ziegler–Natta systems, metallocenes and other SSCs allow a precise control of the polymerization reaction resulting in narrow distribution of all molecular characteristics, including molecular weight distribution, comonomer distribution and architecture, and content of branches.

Homopolymers. Both unbridged and stereorigid (bridged) metallocenes have been employed in polymerization of ethylene. Cp_2ZrCl_2/MAO homopolymerizes ethylene with 10–100 times higher activity compared to conventional Ziegler–Natta catalysts. The insertion rate is comparable to reaction rates observed in enzymatic systems, and polymerization activities reaching 40,000 kg PE/g Zr/h have been reported for this catalyst system alone (18,22,55). Essentially linear homopolyethylenes (HDPE) are obtained in most cases using bis(cyclopentadienyl), bis(indenyl), and related metallocene catalysts. The choice of metal and ligand substitution pattern highly influences the polymerization performance. Activity generally decreases in the order of Zr > Ti > Hf. Increasing electron-donating ability of the ligand substituents appears to increase the activity in the cyclopentadienyl series whereas steric crowding has a detrimental effect. Consequently $(CpCH_3)_2ZrCl_2$ is more active than $(CpC_2H_5)_2ZrCl_2$ or $Cp*_2ZrCl_2$ (266). Substituted bis(indenyl) (71) and bis(fluorenyl) (90,309) *ansa*-metallocenes display, in some cases, very high activities exceeding those of Cp_2ZrCl_2. Molecular weight can be controlled by addition of hydrogen or by increasing the polymerization temperature. Hafnium complexes produce higher molecular weight polymers than their zirconium analogues. The stronger Hf–carbon σ-bond slows down both bond-making and bond-breaking processes resulting in a lower activity and higher molecular weight.

The nickel and palladium diimine catalysts developed by Brookhart (Fig. 5a) display some unique properties; for example, they can produce highly branched polymers from a single ethylene feedstock. Polymers derived from the nickel catalysts are generally less branched than those obtained with their palladium analogues, and products ranging from conventional LLDPE to amorphous, elastomeric, or hyperbranched materials can be obtained by variation of the metal, monomer concentration, polymerization temperature, and pressure. The branch formation is explained by a *chain walking mechanism* (179,185,186,310), where the growing polymer chain undergoes a series of β-hydride eliminations and reinsertions resulting in migration of the metal species along the polymer backbone.

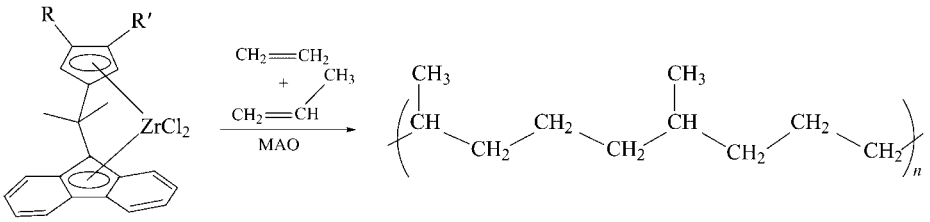
Activities of the MAO-activated nickel catalysts are comparable to those of metallocenes, and turnover frequencies of 3.9×10^5 h^{-1} corresponding to 11,000 kg PE/mol Ni/h were reported in the initial publications (179). Molecular weights can be varied from oligomers to high polymers (M_w = 30,000 to > 1,000,000) depending on the catalyst structure and polymerization conditions (185). The palladium analogues display more moderate activities, but due to the extensive "chain walking" the range of accessible materials is broadened

considerably. DuPont is currently developing its Versipol™ (E.I. du Pont de Nemours & Co., Inc.) catalyst technology based on the Brookhart-type late transition metal catalyst systems (186).

The 2,6-bis(imino)pyridyl iron catalysts (Fig. 5b) show likewise extremely high activities in homopolymerization of ethylene. Upon activation with modified MAO, turnover frequencies of greater than 10^7 h^{-1} corresponding to 330,000 kg PE/mol Fe/h have been reported (187). The highest molecular weights (M_w) exceed 500,000 (192). The recently discovered single-component nickel catalysts (Fig. 5c) can produce homopolyethylenes with $M_w > 250{,}000$ and turnover frequencies ranging from 0.5×10^6 to 3.0×10^6 g PE/mol Ni/h at low temperatures and pressures (196). The total content of methyl, ethyl, propyl, and butyl branches remains under 10 branches per 1000 carbon units under optimal polymerization conditions. At slightly elevated polymerization temperatures, activities comparable to those of the first metallocenes and Brookhart's diimino nickel catalysts were observed.

Copolymers with Propylene and Higher α-Olefins. Group 4 metallocene catalyzed copolymerization of ethylene with higher α-olefins such as 1-butene, 1-pentene, 1-hexene, or 1-octene produces well-defined copolymers with random distribution of the comonomer (311–322). The copolymerization rates are often higher than those of the corresponding homopolymerizations. Chiral C_2 symmetric *ansa*-metallocenes incorporate higher α-olefins more readily than the unbridged complexes. Syndiospecific C_s symmetric metallocene catalysts show even better copolymerization characteristics. Alternating copolymers of ethylene and 1-octene have been obtained with some *meso*-diastereomers of bridged bis(indenyl) catalysts (323). Among the various polyolefins produced using SSC technology the LLDPE-grades show perhaps the greatest industrial potential.

Copolymers of ethylene and propylene show, in some cases, elastic properties (324,325). Further incorporation of dienes, such as ethylidenenorbornene or 1,4-hexadiene, produces ethylene–propylene–diene monomer (EPDM) elastomers. Kaminsky (326) and Waymouth (327) have reported the predominantly alternating copolymerization of ethylene and propylene, using C_1 and C_s symmetric (cyclopentadienyl)(fluorenyl) *ansa*-zirconocene-based catalysts (eq. 3), demonstrating yet another example of preparation of new materials through rational exploitation of SSC systems.



R = H; R′ = CH_3;
R = H; R′ = i-C_3H_7;
R = H; R′ = t-C_4H_9;
R = R′ = CH_3.

(3)

Long-Chain Branching. The constrained geometry Group 4 catalysts of the Dow and Exxon chemical companies allow the incorporation of, besides C_4–C_{20} α-olefins, even styrene (99,328), isobutylene (329), and vinyl-terminated macromonomers into HDPE or LLDPE polyethylene chains (see Ref. 25 and references to the patent literature therein). At high polymerization temperatures (typically $T_p = 130$–$160^\circ C$) these catalysts produce controlled amounts of vinyl-terminated polymers or oligomers that are reinserted to the growing polymer chain. Typical levels of long-chain branching (LCB) range from 1 to 3 branches per 1000 carbon atoms. The resulting materials exhibit some unique properties since the presence of LCB significantly affects the melt viscosity, elasticity, shear thinning, and extension thickening of the produced polymer, thus improving its processability. Typically, the LCB-PEs exhibit the strength and toughness of LLDPE while having the melt processability of LDPE (25). Formation of very low levels of long-chain branched material has been reported also for ethylene bridged bis(indenyl) *ansa*-zirconocene/MAO catalyst systems (330–332).

Polymerization of Propylene

Stereoselective polymerization of α-olefins, especially propylene, has received an enormous amount of attention in recent years (see PROPYLENE POLYMERS (PP)). Group 4 metallocene-based SSCs allow the production of PP in a considerably wider range of composition and microstructures than any other catalytic system (Fig. 9) (for reviews, see Refs. 14, 333, and 334). The physical properties of polyolefins are strongly influenced by their microstructures. Highly stereoregular iPPs and sPPs are crystalline thermoplastics whereas stereorandom atactic polypropylene (aPP) is an amorphous elastomer. The most efficient tool for determining the microstructure and stereoregularity of poly-α-olefins is ^{13}C nmr spectroscopy. Tacticity of the polymer is commonly expressed in terms of its pentad content, which is the fraction of stereosequences containing five adjacent stereocenters. An isotactic [*mmmm*] pentad consists of a sequence of five identical stereocenters, whereas in the syndiotactic [*rrrr*] pentad the configuration of the stereocenters is regularly alternating. The [*mmmm*] pentad content of highly iPP approaches 100% whereas perfectly atactic polymers consist of a statistical mixture of all 10 possible pentads.

Because of the steric constraints of the metallocene catalysts, propylene insertion mainly proceeds in a regioregular fashion (1,2-insertion), although occasional 2,1-regioinversions are observed. The amount of regioerrors depends on the structure of the catalyst and affects the crystallinity and melting point of the produced polymer (14,84,85,334). Insertion of propylene into a growing chain with a 2,1 last-inserted unit is usually exceedingly slow because of the highly unfavorable nonbonded interactions, and the chain end may isomerize to a more reactive 3,1-unit, which would then be followed by a regioregular primary insertion.

Isolated stereoerrors result from regioregular 1,2-insertions of the wrong olefin enantioface. Alternatively, a regioregular last-inserted monomer unit may undergo an epimerization reaction producing an inversion of configuration. Recent studies (280,281,335–342) suggest that the major part of stereoerrors in iPPs in fact results from the chain end epimerization reaction, rather than from regioirregular 2,1-insertions or regioregular insertions with the incorrect enantioface.

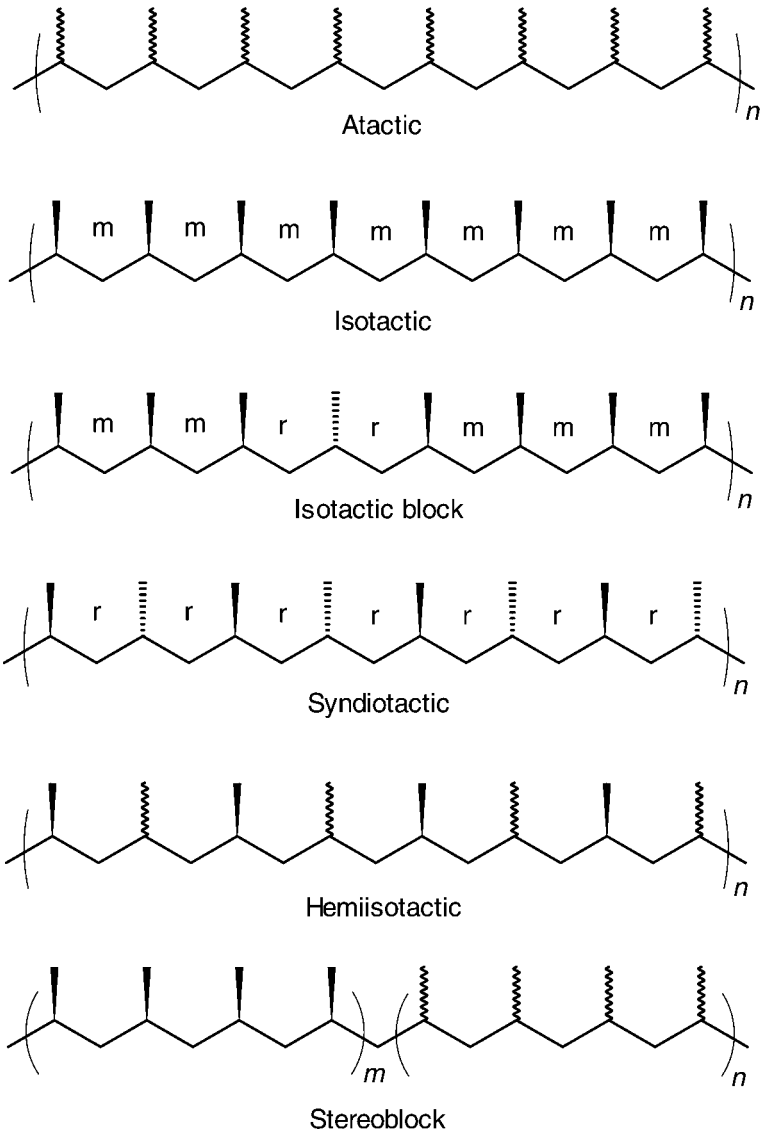


Fig. 9. PP microstructures.

Homopolymers.

Atactic Polypropylene. Low molecular weight aPP waxes can be obtained from solvent extraction of iPP prepared with heterogeneous Ziegler–Natta catalysts. The product is neither completely atactic nor fully amorphous, and finds limited use as an additive in bitumen and adhesives (22). Achiral and unbridged metallocene catalysts such as Cp_2ZrCl_2 also produce mainly low molecular weight aPP, although at low temperatures partially isotactic material has been obtained by chain end control mechanism (56). High molecular weight, fully atactic

elastomeric aPP has been obtained using a C_{2v} symmetric bis(fluorenyl) *ansa*-zirconocene catalyst $(CH_3)_2Si(Flu)_2ZrX_2$/MAO (X = Cl, CH_3) under technical production conditions (83,343). Molecular weights (M_w) ranging from 100,000 to 400,000 and polymerization activities corresponding to 1300–11,200 kg PP/mol Zr/h were obtained at $T_p = 50°C$ at variable monomer concentrations. The low densities, high transparency, softness, low modulus, and high elongation of these polymers result from the totally amorphous state of the polymer chains (22).

Isotactic Polypropylene. IPP is generally obtained with C_2 symmetric *ansa*-metallocene catalysts. In most cases, bridged bis(indenyl)- or bis(tetrahydroindenyl)-derived Group 4 complexes are used (56,57,62,65–71, 84,85,87,344,345), with a few exceptions based on C_2 symmetric substituted bis(cyclopentadienyl) analogues (346,347) and some sterically congested C_1 symmetric catalysts (72,73,78,348–354). A series of unbridged asymmetrically substituted bis(indenyl) and bis(tetrahydroindenyl) zirconocenes that produce partially iPP under enantiomorphic site control at low polymerization temperatures has been described (355–357). In these catalysts, the isospecific conformational isomer is stabilized by partially hindered ligand rotation. An unbridged bis(1-methylfluorenyl)zirconium dichloride/MAO catalyst system reportedly produces iPP even at elevated polymerization temperatures (78,358). Chiral disposal of the substituted fluorenyl ligands results from a strongly hindered rotation around the Zr—C_5 axis. Several other bridged or unbridged metallocene catalysts lacking C_2 symmetry have been employed in propylene polymerization producing PPs with variable microstructures ranging from nearly atactic to partially isotactic materials (63,64,88,89,93,359–379). Remarkable examples are the elastomeric PPs (*vide infra*) obtained with C_1 symmetric *ansa*-metallocenes (89,366–373) and the isotactic–atactic stereoblock elastomeric PPs (63,64,374–379).

The original Brintzinger-type catalyst systems based on *rac*-$C_2H_4(IndH_4)_2TiCl_2$ and its zirconocene analogue exhibit reasonably high activities in propylene polymerization; however, the molecular weights, melting points, and isotacticities of the produced iPPs are by far inferior to those of heterogeneous Ziegler–Natta catalysts when employed under technical conditions. For example, bulk polymerization of propylene at 70°C using *rac*-$C_2H_4(IndH_4)_2ZrCl_2$/MAO produces iPP with M_w = 15,000 and $T_m = 125°C$ (344), whereas commercial Ziegler–Natta grades of iPP have molecular weights between 100,000 and 500,000 and melting points ranging from 160 to 165°C. Rational structural modifications (68–71,344) of the original catalysts culminated in the 1994 publications of the Hoechst group (71) and Brintzinger (65) describing true high performance metallocene catalysts for isospecific propylene polymerization (Fig. 10). The 2,2′-dialkyl-4,4′-diaryl-substituted dimethylsilylene bridged bis(indenyl) *ansa*-zirconocene catalysts polymerize propylene to highly iPP with stereoselectivities, polymer melting points, and molecular weights comparable to those obtained with heterogeneous Ziegler–Natta catalysts (Table 1) (65,67,71,344,380–382). These metallocene-based catalysts are over 40 times more active than the conventional systems. Hydrogen gas has to be applied as a molecular weight regulator, even under technical polymerization conditions, in order to produce commercial iPP grades.

The 2,2′-alkyl substitution at the C_5 rings of the bis(indenyl) *ansa*-zirconocene catalysts dramatically improves the molecular weight of the produced

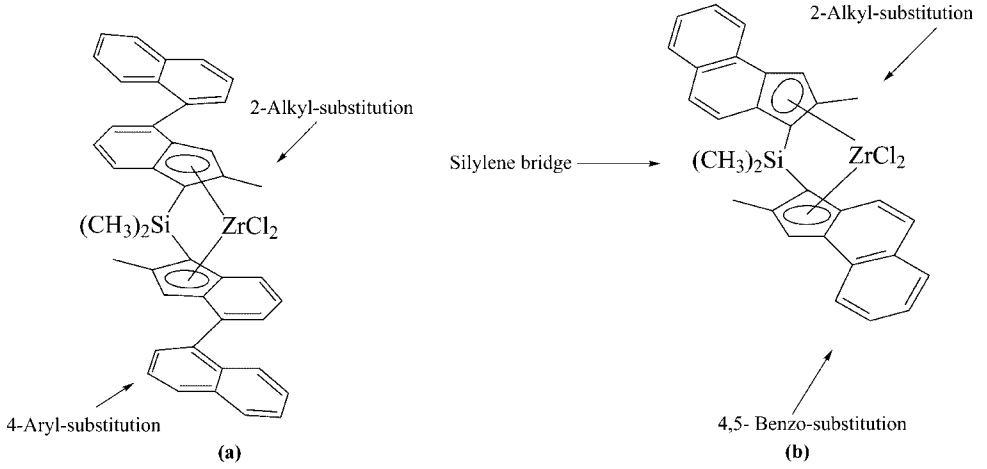

Fig. 10. High performance metallocene catalysts for isospecific polymerization of propylene. (**a**) Hoechst group (71); (**b**) Brintzinge (65).

PP (65,67,70,71,344). The observed enhancement has been explained by a combination of steric and electronic influence on the chain-termination reaction. Enhanced rigidity of the ligand framework combined with a direct steric interaction of the alkyl group with the growing polymer chain decreases the rate of β-elimination. Electron donation from the alkyl substituent may further decrease the local Lewis acidity of the central metal atom, thus reducing its tendency for β-H abstraction.

The role of the substituents in β-position to the interannular bridge, ie, 4,4′-positions of the six-membered rings of the indenyls, appears to be twofold. The gain in stereospecificity by enlarging the 4,4′-substituents from isopropyl to naphthyl, as shown in Table 1, results from indirect steric control (71). The high rotational barrier of the naphthyl substituent places it in an optimal position for interaction with the growing chain. The synergistic effect of 2-alkyl-4-aryl substitution further

[b] Technical reaction conditions (T_p = 70°C; liquid propylene; [Al]:[Zr] = 15,000:1) (Refs. 68–71 and 344).

improves the catalyst rigidity and enhances the stereospecificity. Secondly, electron donation from the aryl or alkyl substituents may stabilize the cationic active species or facilitate its formation (65,67,71). The resulting increase in polymerization activity also influences the polymer molecular weight by increasing the ratio of the rates of chain propagation vs. chain termination. Even higher polymerization activities have been reported by using the 2,2-di-*n*-propyl-4,4-di-9-phenanthryl substitution pattern (382).

The structure of the interannular bridge mainly influences the stereospecificity and polymerization activity of the bis(indenyl) catalysts. Replacement of the ethylene bridge of *rac*-$C_2H_4(Ind)_2ZrCl_2$ by a one-membered silylene (65–71) or germylene (69) bridge improves the stereoselectivity whereas a one-membered carbon bridge decreases both the stereoselectivity and molecular weight of the produced polymer (69,87,344). Longer than two-atom bridges decrease the activity and stereoselectivity because of the distortion of the molecular C_2 symmetry and narrowing of the coordination gap aperture (68,383,384). Aromatic substitution on the bridge enhances the molecular weight, although the size of the effect appears to be unpredictable (69,71,344). Electron withdrawing substituents in the six-membered rings of the indenyl ligands decrease the polymerization activity and molecular weight (75,82). Dimethylamino-substituents in the 2,2′-positions result in modest activities and stereospecificities; *rac*-$(CH_3)_2Si(2\text{-}(CH_3)_2NInd)_2ZrCl_2$/MAO polymerizes propylene to iPP with $[mmmm] = 85\%$, $T_m = 132^\circ C$, and $M_n = 30{,}000$ ($T_p = 50^\circ C$; $P = 2$ bar), albeit suffering from long induction periods apparently resulting from interaction of the amino groups with the cocatalyst (66). *tert*-Butyldimethylsiloxy-substituted analogues exhibit likewise modest activities and stereospecificities but polymerize propylene and ethylene without the induction delay (91,271).

Alkyl or silyl substitution in the 3,3′-positions of the five-membered rings of ethylene and dimethylsilylene bridged bis(indenyl) catalysts markedly decreases the polymerization activity and results in a complete loss of stereoselectivity (62,69,344,385). Bilateral coverage of the coordination sites by the 3,3′-substituents and the hydrogen atoms of the 4,4′-positions equalizes the energetic differences between the two enantiofacial orientations of the incoming propylene monomer (386). An exception to this are the single carbon bridged 3,3′-substituted catalysts *rac*-$R_2C(3\text{-}(CH_3)_3C\text{-}Ind)_2ZrCl_2$ (R = H, CH_3) (Fig. 11) (85,345) that

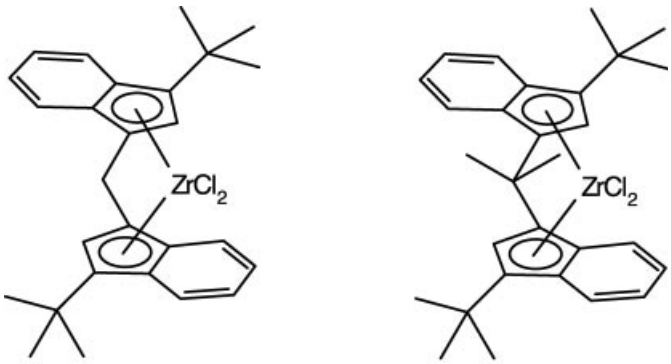

Fig. 11. Single carbon bridged isospecific metallocene catalysts.

produce highly isotactic polymers. For example, the methylene bridged complex *rac*-$H_2C(3\text{-}(CH_3)_3C\text{-}Ind)_2ZrCl_2$ and its dimethyl analogue produce, in combination with MAO, fully regioregular iPP ([*mmmm*] = 95–98%) with medium–high molecular weights (M_w = 70,000–780,000) and high melting points (T_m = 154–163°C) in the T_p range of 30–70°C (345). The polymer properties and polymerization activities are inferior to those obtained with the high-performance 2,2′-dialkyl-4,4′-diaryl-substituted Hoechst catalysts. An advantage with the Montell systems is, however, their simple and inexpensive ligand and catalyst synthesis.

Syndiotactic Polypropylene. Before the report on the first syndiospecific *ansa*-metallocene catalyst (61), only partially sPP had been obtained with vanadium-based Ziegler–Natta catalysts at low polymerization temperatures (387). The C_s symmetric metallocene-based systems are the first examples of catalysts that are capable of producing highly sPP in high yield and are practical for industrial scale-up. The properties of metallocene sPP differ substantially from those of iPP, especially in their considerably higher room temperature impact strength, higher optical clarity, and resistance against uv radiation.

The polymerization behavior of the original Ewen catalyst has been studied in detail (61,62,388). For example, bulk polymerization of propylene at 50°C using $(CH_3)_2C(Cp)(Flu)ZrCl_2$/MAO produces sPP having syndiotactic pentad content [*rrrr*] = 82%, M_w = 133,000, and T_m = 140°C (62). Higher syndiotacticities are obtained at lower polymerization temperatures. Several structural variations of the original catalyst are reported in the literature (62,74,76–78,385,389–400) (Fig. 12). Hafnocene-based catalysts exhibit a lower activity and slightly lower syndiospecificity but produce polymers with higher molecular weights. The titanium analogues suffer from both poor activities and poor stereoselectivities (389). Replacement of the isopropylidene bridge of $(CH_3)_2C(Cp)(Flu)ZrCl_2$ with an aromatic Ph_2C bridge improves both the syndiotacticity and molecular weight of the polymer (77), whereas considerably lower stereoselectivities are observed for the ethylene (78,390,396) and $(CH_3)_2Si$ (391) bridged analogues. Exceedingly active regio- and syndiospecific metallocene catalysts have been obtained by replacing the fluorenyl ligand of $(C_6H_5)_2C(Cp)(Flu)ZrCl_2$ with the sterically demanding octamethyloctahydrodibenzofluorenyl (Oct) moiety. The produced sPPs have syndiotactic pentad contents [*rrrr*] approaching 99% and melting temperatures as high as 153°C have been reported (399,400), demonstrating for the first time the dramatic effect of distal ligand perturbations on the polymer stereochemistry.

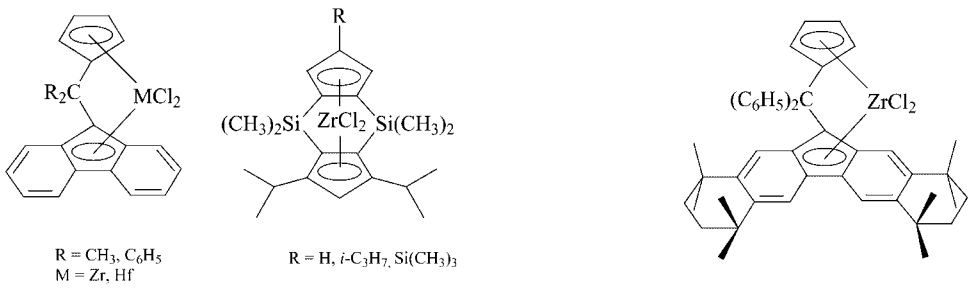

Fig. 12. Metallocene catalysts for syndiospecific polymerization of propylene.

The doubly bridged C_s symmetric bis(cyclopentadienyl)zirconocene catalysts developed by Bercaw and co-workers are likewise highly regio- and syndiospecific (397,398). Bulk polymerization of propylene at 20–70°C gave sPPs with pentad contents [*rrrr*] = 45.4–97.5% and molecular weights M_w of 130,000–1,250,000 depending on the catalyst substitution pattern and the employed polymerization temperature (76). The highest reported polymerization activity corresponding to 16,900 kg PP/g Zr/h was obtained at 70°C using the (1,2-$(CH_3)_2Si)_2$(Cp)(3,5-*i*-$(C_3H_7)_2$-Cp)$ZrCl_2$/MAO catalyst system.

Hemiisotactic PP. As first demonstrated by Ewen (62), the C_1 symmetric metallocene $(CH_3)_2$C(3-CH_3Cp)(Flu)$ZrCl_2$ produces hemiisotactic polypropylene (hitPP) consisting of alternating isotactic and stereorandom monomer placements. The two coordination sites of this catalyst are different; the isospecific site is blocked by both the Cp-methyl substituent and the fluorenyl C_6 ring whereas the aspecific site is unilaterally framed by the second fluorenyl moiety. As the growing chain occupies the more hindered site, the two conformations in which the first C—C bond is directed toward the substituted side of the Cp ring or toward the fluorenyl ring have equal probabilities. Consequently monomer insertion from the less hindered site is aspecific. At the less hindered site the polymer chain is oriented toward the open sector of the ligand framework resulting in stereospecific monomer insertion from the more hindered site, thus forming the hemiisotactic microstructure.

Copolymers with Higher α-Olefins. Several researchers (381,401–404) have copolymerized propylene with 1-hexene (402–404) and 1-octene (381,401), using various MAO-activated metallocene catalysts. Random distribution of the comonomer was observed in all cases. Comonomer incorporation is dependent on the catalyst structure; combination of benzannelation and 2-methyl substitution of silylene bridged bis(indenyl) ligands in *rac*-$(CH_3)_2Si$(2-CH_3-benz[*e*]Ind$)_2ZrCl_2$ was found to enhance both the molecular weight and comonomer content of the propylene–octene copolymers (401). Poly(propylene)-*graft*-poly(styrene) copolymers have been prepared using the *rac*-$(CH_3)_2Si$(2-CH_3-benz[*e*]Ind$)_2ZrCl_2$/MAO catalyst in copolymerization of propylene with allyl-terminated polystyrene macromonomers (405). Graft copolymers with a polystyrene content ranging from 7 to 72% were obtained. The same catalyst system was used for copolymerization of propylene with an aPP macromonomer (406).

Elastomeric Polypropylene (elPP). PPs consisting of blocks of atactic and isotactic stereosequences behave as thermoplastic elastomers. This material was identified for the first time by Natta in 1959 during fractionation studies of first generation Ziegler–Natta iPP (407). The elastomeric properties of these polymers are believed to result from cocrystallization of isotactic stereoblocks in neighboring PP chains to form a physically cross-linked elastomer. More recently, elPP has been prepared using supported tetraalkyl Group 4 catalysts (408,409).

A number of Group 4 metallocene catalysts have been shown to produce PP elastomers (Fig. 13). The production of elPP has been reported using asymmetrically substituted *ansa*-titanocene catalysts $CH_3CH((CH_3)_4Cp)$(Ind)$TiCl_2$/MAO under a variety of polymerization conditions (366–370). The formation of short isotactic sequences in predominantly atactic polymer chains was proposed to originate from sequential monomer insertion at the aspecific and isospecific coordination sites of the catalyst, although this mechanism has been challenged. elPPs

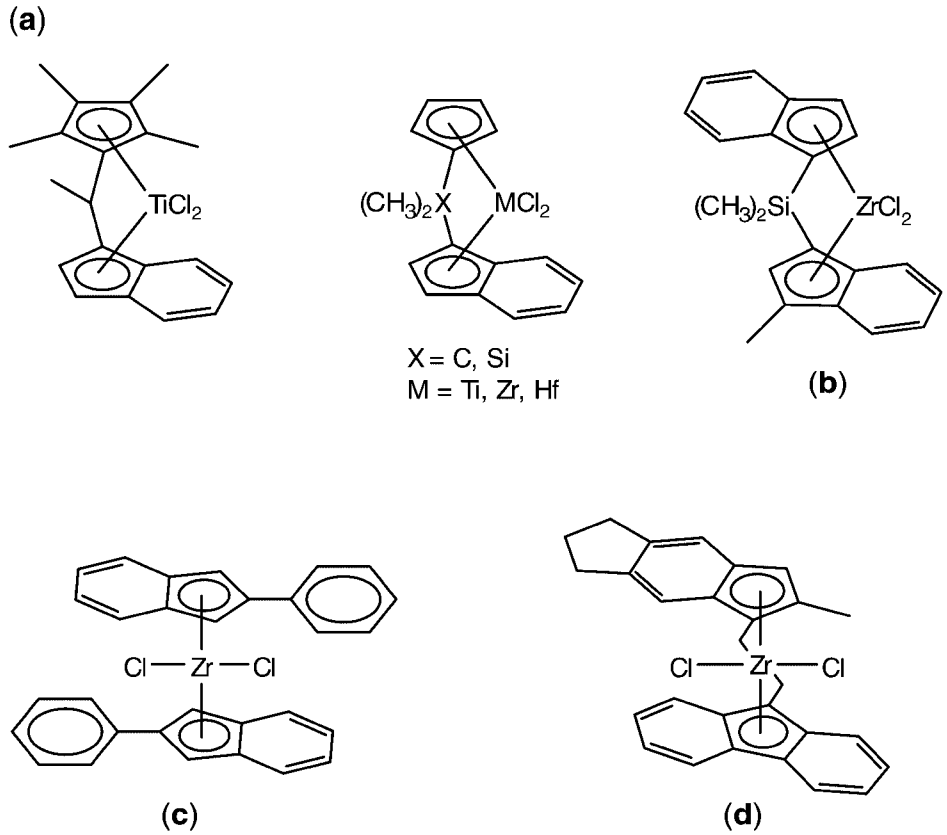

Fig. 13. Metallocene catalysts for preparation of elastomeric PP. (**a**) Titanocene Catalysts (366–370); (**b**) (371–373); (**c**) See also Figure 14 (63,64,374–379); (**d**) Zirconocene Catalysts (89).

have also been prepared using a related class of MAO-activated metallocenes $(CH_3)_2X(Cp)(Ind)MCl_2$ (X = C, Si; M = Ti, Zr, Hf) (371,372). Microstructures of the PPs produced were found to be sensitive to both catalyst structure and polymerization conditions with the hafnium-based systems yielding the best elastomeric properties. The mechanism suggested (371,372) involves random monomer insertion at the isospecific and aspecific coordination sites, respectively. In a more recent report, the preparation of high molecular weight semicrystalline elPP using the asymmetrically substituted *rac*-like diastereomer of $(CH_3)_2Si(Ind)(3\text{-}CH_3Ind)ZrCl_2$ in combination with MAO has been described (373). The obtained polymers exhibited isotactic pentad contents [*mmmm*] = 30.4–41.9% and molecular weights (M_w) of 37,000–115,000 depending on the monomer concentration and polymerization temperature.

A series of C_1 symmetric *ansa*-zirconocene catalysts based on an ethylene bridged mixed ligand (indenyl)(fluorenyl) framework has been described (89). These complexes, upon activation with MAO, retain their high activities even at elevated polymerization temperatures producing PPs of variable isotacticities [*mmmm*] = 19.9–72.1% and molecular weights (M_w) up to 230,000 depending on

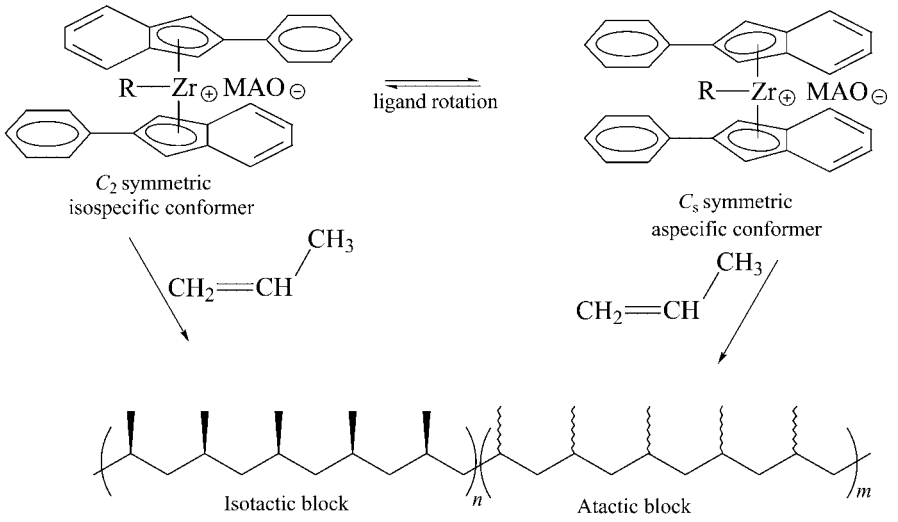

Fig. 14. Oscillating stereocontrol for production of isotactic–atactic stereoblock PP.

the employed catalyst, polymerization temperature and monomer concentration. The presence of two different coordination sites allows precise control of stereoerror formation resulting in bulk properties ranging from flexible semicrystalline thermoplastics to excellent thermoplastic elastomers.

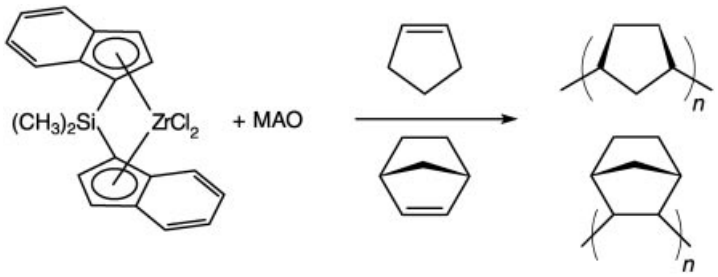
The oscillating catalysts that have been developed are based on unbridged bis(2-arylindenyl) Group 4 metallocenes that presumably interconvert between an isospecific and aspecific conformer on the time scale of the polymerization reaction producing isotactic–atactic stereoblock polymers (Fig. 14) (63,64,374–379). The size of the stereoblocks is controlled by the relative rates of chain propagation and ligand isomerization. The nature of the substituent in 2-position of the indenyl ligand is crucial for obtaining elastomeric material. The prototypical bis(2-phenylindenyl)zirconium dichloride/MAO system produces elPP having pentad contents $[mmmm] = 6.3–28.1\%$ as a function of the monomer concentration and polymerization temperature (63). The 3,5-trifluoromethyl-substituted analogue $[2\text{-}(3,5\text{-}(CF_3)_2\text{-}C_6H_5)Ind]_2ZrCl_2$ produces PP of considerably higher isotacticity and crystallinity; values up to $[mmmm] = 73\%$ were reported for the MAO-activated catalyst system (64). Several other modifications generating mainly aPP have been reported in subsequent papers (374–379).

A related strategy based on reversibly bridged donor–acceptor substituted metallocenes, potentially providing access to elastomeric polyolefins, has been described (93). In these complexes one of the cyclopentadienyl or indenyl ligands contains a donor group (eg, diethylphosphanyl or dimethylamino) whereas the other one is substituted with an acceptor (eg, dichloroboranyl). Ligand rotation can be controlled by temperature-dependent donor–acceptor interaction. For example, *rac*-$[(C_2H_5)_2P(2\text{-}CH_3Ind)][Cl_2B(2\text{-}CH_3\text{-}Ind)]ZrCl_2$ activated with triisobutylaluminum and $[NH(CH_3)_2C_6H_5]^+[(C_6F_5)_4B]^-$ produces at room temperature (bulk polymerization of propylene) highly iPP with $[mmmm] = 94\%$, $T_m = 158°C$, and $M_v = 2{,}000{,}000$. At 50°C the pentad content drops to $[mmmm] = 82\%$ and

molecular weight to $M_v = 434{,}000$, whereas the melting temperature remains high, $T_m = 154^\circ C$, indicating the formation of aPP sequences together with long isotactic blocks.

Other Monomers

Cycloolefins. A distinct feature of the Group 4 metallocene/MAO catalyst systems is their ability to polymerize cyclic olefins without ring-opening metathesis, a reaction characteristic of heterogeneous Ziegler–Natta catalysts. Cyclobutene, cyclopentene, norbornene, and dimethanooctahydronaphthalene are readily homopolymerized to isotactic polycycloalkenes, using chiral *ansa*-zirconocene catalysts (18,22,24,203,410–412) (eq. 4). Homopolymers of the cyclic olefins are not processable because of their high melting points (400–500°C) and insolubility in common organic solvents. Cycloolefin copolymers (COCs), produced by copolymerization of cyclic monomers with ethylene or propylene, are however amorphous thermoplastics exhibiting heat resistance up to 200°C combined with high rigidity, toughness, and environmental stability (18,22,24,410,413–418). The excellent stiffness and low density of COCs combined with their stability against hydrolysis and chemical degradation renders them as potential materials for compact discs, lenses, and optical fibers.



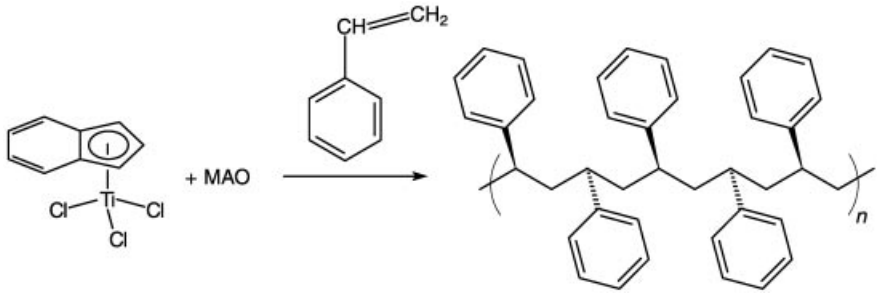
(4)

Dienes. Group 4 metallocene catalysts are capable of polymerizing both conjugated and nonconjugated dienes. Polymerization of α,ω-dienes affords cyclopolymers with remarkably high cyclo- and regioselectivities (269,270,419–425). Insertion of the terminal double bond of the nonconjugated diene into the metal–carbon bond is followed by intramolecular cyclization that produces the polymeric ring structure interspaced by methylene groups. Tacticity of the cyclopolymer is determined by the enantiofacial selectivity of the insertion step and is influenced by the symmetry and structure of the catalyst precursor. Diastereoselectivity of the cyclization step (ie, whether cis or trans rings are formed) is likewise influenced by catalyst structure and sterical environment of the active site. For example, in the polymerization of 1,5-hexadiene, Cp_2ZrX_2/MAO (X = Cl, CH_3) produces (at ambient temperature) predominantly atactic *trans*-poly(methylene-1,3-cyclopentane) (PMCP) whereas the sterically congested $Cp*_2ZrCl_2$/MAO catalyst produces mainly the atactic *cis* product (419–422). Interestingly, the *cis*-connected atactic PMCPs have melting points reaching $T_m = 171^\circ C$, whereas the

trans-PMCP showed a considerably lower melting point of $T_m = 86^\circ C$ (421). The synthesis of optically active cyclopolymers from 1,5-hexadiene using enantiomerically pure *ansa*-metallocene catalysts (423,424), the cyclopolymerization of functionalized α,ω-dienes (425), and the post-functionalization of hydroxy-terminated PMCP (269,270) are discussed separately (*vide infra*).

Styrene. Syndiotactic polystyrene (sPS) is a high melting stereoregular polymer first prepared in the mid-1980s using an undisclosed titanium-based catalyst in combination with aluminum activators (112). In contrast to isotactic polystyrene (iPS), which shows a very low crystallization rate and is thus useless for most commercial applications, sPS has a fast crystallization rate, higher melting point compared with iPS (270°C vs 230°C), superior heat and chemical resistance, as well as low specific gravity, low dielectric constant, and high modulus of elasticity. These unique properties have resulted in remarkable interest in sPS as an attractive low cost replacement for expensive engineering plastics (see SYNDIOTACTIC POLYSTYRENE).

A variety of Group 4 metal complexes, in combination with common olefin polymerization activators, have been evaluated as potential catalysts for syndiospecific polymerization of styrene (for reviews, see Refs. 114, 115, 123, and 426). Monocyclopentadienyl and monoindenyl titanocenes generally exhibit the highest activities (eq. 5) (112–127). Curiously, half-sandwich titanium-trifluoride-based catalysts are more active than their trichloride analogues (124,427,428). The polymerization mechanism for sPS formation is under debate. Kinetic studies and spectroscopic investigations of the catalytic systems suggest a cationic Ti(III) complex as the active species (123).



(5)

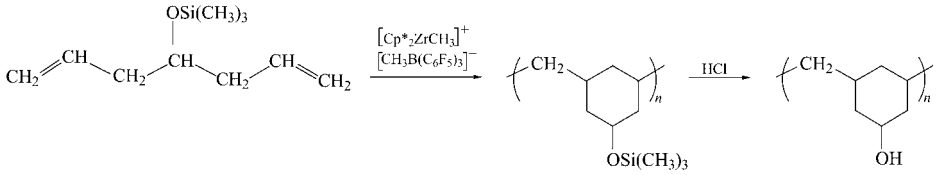
Functional Polymers

Controlled *in situ* incorporation of polar or reactive functional groups into polyolefins is a long-standing challenge (429–431). End uses of polyolefins are restricted by their chemical inertness and lack of adhesive properties. The absence of polar groups results in a poor affinity for functional additives such as dyes, paints, and antioxidants, and limits the compatibility of polyolefins with functional polymers, biomaterials, metal, and glass. Traditional Ziegler–Natta catalysts are highly oxophilic and readily poisoned by Lewis-basic comonomers (alcohols, ethers, carboxylic acids, esters, and amines). Recently, considerable advances toward functionalized polyolefins have been made by direct polymerization and

copolymerization of functional monomers over SSCs as well as by various associated indirect post-polymerization methods.

Homo- and Copolymerization of Polar Monomers.

Metallocene Catalysts. Group 4 metallocene-based catalysts are, under proper polymerization conditions, tolerant to selected polar comonomers. Various functionalized dienes and α-olefins have been polymerized using cationic metallocene catalysts (425,432,433). Polymerization activities were lower than those observed for the analogous nonpolar monomers. Silyl-protected 1,6-heptadien-4-ols are readily cyclopolymerized by the sterically hindered $[Cp*_2ZrCH_3]^+X^-$ catalyst [$X = B(C_6F_5)_4$ or $CH_3B(C_6F_5)_3$] with turnovers reaching 280 (59% conversion) (eq. 6) (425). Deprotection of the silyl group generates the corresponding polyalcohol. Tertiary amines were homo- and copolymerized using both aspecific and isospecific metallocene catalysts (425,432,433). Borate cocatalysts gave higher activities than MAO-based catalyst systems. Optimum activities were achieved using diisopropyl-substituted amine with an olefin tether of three carbon atoms. Catalyst stereospecificities were essentially insensitive to monomer functionality.



(6)

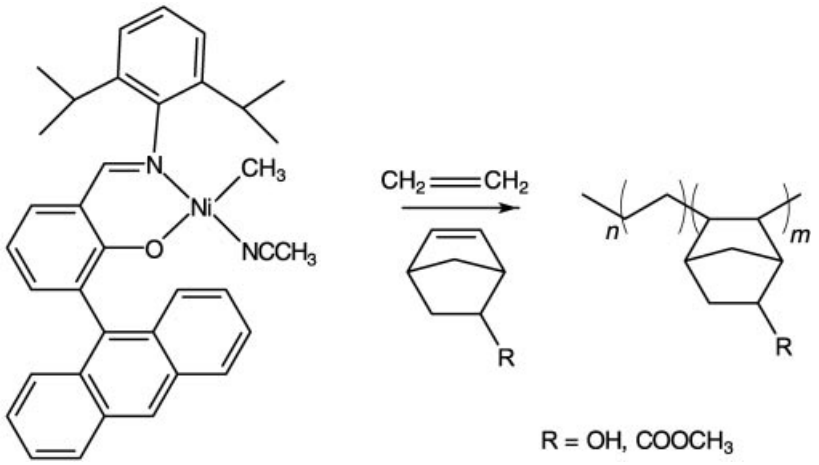
Other examples of polar comonomers incorporated by Group 4 metallocenes include silylamines (434), protected alcohols (435,436) and carboxylic acids (436), ω-chloroolefins (437), and primary long-chain hydroxyalkenes (438,439). The copolymerization of propylene with a hindered phenolic stabilizer 6-*tert*-butyl-2-(1,1-dimethylhept-6-enyl)-4-methylphenol over an isospecific metallocene/MAO catalyst system has been described (440). A novel strategy for preparation of polyolefin graft copolymers has been developed by combination of metallocene and "living" free radical polymerization techniques (441–443). Copolymerization of an alkene-substituted hindered alkoxyamine with ethylene or propylene affords well-defined macroinitiators with 2,2,6,6-tetramethylpiperidine-*N*-oxyl (TEMPO) chain ends to which polystyrene, acrylate, and butadiene side chains can be grafted in a "living" fashion.

In addition, Group 4 metallocene-type catalyst systems have been employed in living ring-opening polymerization of lactones (444–446) and carbonates (447). Various metallocene or lanthanocene complexes have been used as initiators for homo- and copolymerization of methacrylates, acrylates, and the synthesis of block copolymers (224,448–457). Single-site-type zinc alkoxide complexes have been described for ring-opening polymerization of lactides (458).

Late Transition Metal Catalysts. In contrast to early transition metals, late transition metal catalysts (26,185) are considerably less oxophilic and are tolerant to a wide range of functional groups. The α-diimine palladium complexes developed by Brookhart (179,180,183,184) copolymerize ethylene and propylene with alkyl acrylates (180,183) and protected alcohols (459) to high molecular weight

random copolymers, albeit at reduced activities. The ethylene acrylate copolymers are amorphous, highly branched materials with ~100 branches/1000 carbon atoms. Typical T_g values range from −67 to −77°C.

The neutral salicylaldimine nickel complexes described by Grubbs and coworkers (195,196) show unprecedented functional group tolerance and are capable of incorporating substituted norbornenes, carbon monoxide, and α–ω functional olefins into polyolefins with well-defined compositional distributions (eq. 7) (196). Furthermore, ethylene can be homopolymerized with these catalysts in the presence of various functional additives including acetone, water, ethyl alcohol, and triethyl amine. In the presence of 1500 equivalents of H_2O, polyethylene was produced at a rate of 5.4×10^4 g PE/mol Ni/h.



(7)

Modification of Preformed Polymers. Alkene end groups of polyolefins can be functionalized in a post-polymerization process. PPs with olefinic end groups have been prepared using the isospecific $(CH_3)_2Si(3\text{-}(CH_3)_3C\text{-}5\text{-}CH_2Cp)_2ZrCl_2$/MAO catalyst system (460). The vinylidene chain ends react further to give a range of monofunctional PPs with anhydride, silane, thiol, epoxy, borane, and carboxylic acid end groups. Thiol functionalized polymers were used as chain-transfer agents in free radical polymerizations of styrene and acrylics to form PP block copolymers. A similar approach has been applied using aluminum (461) and borane (462) reagents. Ethylene or propylene have been copolymerized with unsymmetrical dienes, using MAO-activated metallocene catalysts (463–465). Selective incorporation of the α-olefinic double bonds of the comonomers provides access to polymers containing internal unsaturations that can be converted to various functional groups.

Yet another methodology involves the metallocene-catalyzed copolymerization of olefins with borane containing monomers (466,467). The incorporated borane group can be quantitatively converted to a hydroxy group or transformed into a stable polymeric radical suitable for free radical grafting of acrylates.

Chain Transfer to Organometallic Compounds. Hydroxy-terminated poly(methylene-1,3-cyclopentane) has been prepared by selective chain transfer to aluminum in the cyclopolymerization of 1,5-hexadiene with the sterically

congested $Cp_2{*}ZrCl_2$/MAO catalyst (269,270). Aluminum alkoxide of the produced polymer was used as a macroinitiator for ring-opening polymerization of ε-caprolactone to produce diblock copolymers (270).

A similar strategy was used to prepare borane-terminated polyethylenes with $[Cp{*}_2ZrCH_3]^+X^-$ [X = $B(C_6F_5)_4$ or $CH_3B(C_6F_5)_3$] in the presence of 9-borabicyclo[3.3.1]nonane chain-transfer agent (468). The borane end group was selectively oxidized and transformed to a polymeric radical for grafting of methyl methacrylate.

Silyl-capped polyolefins have been prepared by employing organotitanium-mediated silanolytic chain-transfer processes (469,470). Various monomers including ethylene, propylene, 1-hexene, and styrene were homo- and copolymerized using the cationic $[((CH_3)_2Si((CH_3)_4Cp)(CH_3)_3CN)TiCH_3]^+X^-$, [*rac*-$C_2H_4(Ind)_2TiCH_3]^+X^-$, and $[Cp{*}_2TiCH_3]^+X^-$ [X = $B(C_6F_5)_4$] metallocene catalyst systems in the presence of organosilanes ($C_6H_5SiH_3$, $C_6H_5CH_3SiH_2$), $(CH_3)_2SiH_2$, $(C_2H_5)_2SiH_2$) (470). Silyl-linked linear A–A and star block copolymers as well as A–B block copolymers were obtained in catalytic cycles using polyfunctional silabenzenes.

Enantioselective Polymerization

The characteristic functionalities of naturally occurring polymers are, in most cases, related to their specific chiral structure. In nature, proteins, nucleic acids, and polysaccharides are constructed of readily available chiral monomers such as sugars and amino acids. Both natural and synthetic chiral polymers are finding application as chromatographic supports, polymeric reagents and catalysts, chiral membranes, and materials for preparation of cholesteric liquid crystal polymers (471,472).

High molecular weight stereoregular vinyl polymers contain mirror planes of symmetry perpendicular to the molecular axis (Fig. 15) and thus do not have inherent chirality associated with the main chain. Synthesis of chiral polymers from vinyl monomers, with the exception of low molecular weight oligomers,

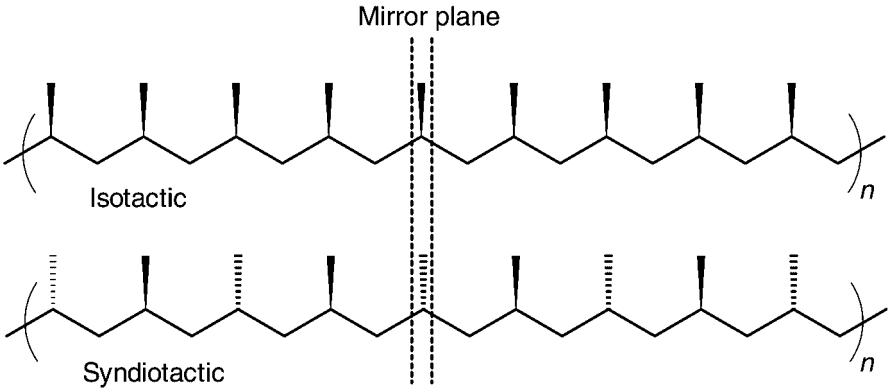


Fig. 15. Mirror planes of symmetry in stereoregular vinyl polymers.

requires more complex polymer architectures to circumvent the symmetry constraints.

Enantiomerically pure SSCs (79), readily available through resolution of the racemic C_2-symmetric Brintzinger-type *ansa*-metallocenes (59,473–475), have attracted considerable interest in catalytic and enantioselective C—C bond formation reactions (476). Despite the aforementioned symmetry concerns, these catalysts have opened new possibilities in synthesis and design of chiral macromolecules.

Polymerization and Oligomerization of Prochiral Olefins. The synthesis of optically active iPP and polybutene with the enantiomerically pure catalyst derived from (*S*,*S*)-$C_2H_4t(IndH_4)_2ZrCl_2$ has been reported (311,477). The obtained polymers showed fairly large optical activities in soaked suspensions ($[\alpha]_D = -123^\circ$, -250° for PP, $+130^\circ$ for polybutene) attributed to a helical conformation or predominant screw sense. As expected, racemization occurred when the polymer was heated or completely dissolved.

Oligomerization of α-olefins can be promoted by two methods: (*1*) reducing the monomer concentration in the polymerization medium thus favoring β-H elimination over chain propagation and (*2*) conducting the polymerization in the presence of H_2 gas. Optically active low molecular weight oligomers of propylene and butene have been prepared using the (*S*,*S*)-$C_2H_4(IndH_4)_2ZrCl_2$ catalyst at high temperature and low alkene concentration (478). The binaphtholate (*R*,*R*)-$C_2H_4(IndH_4)_2Zr$(BINOL) has been used for asymmetric oligomerization of propylene (479,480), 1-pentene (480), and 4-methyl-1-pentene (480) in the presence of hydrogen and deuterium chain-transfer agents. A detailed microstructural analysis of the oligomeric fractions showed for the first time that the stereoregulation of the polymerization reaction with these catalyst systems results from preferential addition of one enantioface of the prochiral monomer to the growing polymer chain.

Cyclopolymerization. As discussed earlier, nonconjugated dienes can be polymerized with metallocene-based catalysts to afford cyclopolymers. In contrast to linear polyolefins which have only two microstructures of maximum order (isotactic and syndiotactic), cyclic polymers have four microstructures due to the possibility of configurational isomerism (cis vs trans) in the main chain (Fig. 16). Of these the *trans*-diisotactic structure contains no mirror planes of symmetry and is chiral by virtue of its main-chain stereochemistry (481). Two criteria for chirality of this microstructure are the presence of trans rings and isotacticity (the same

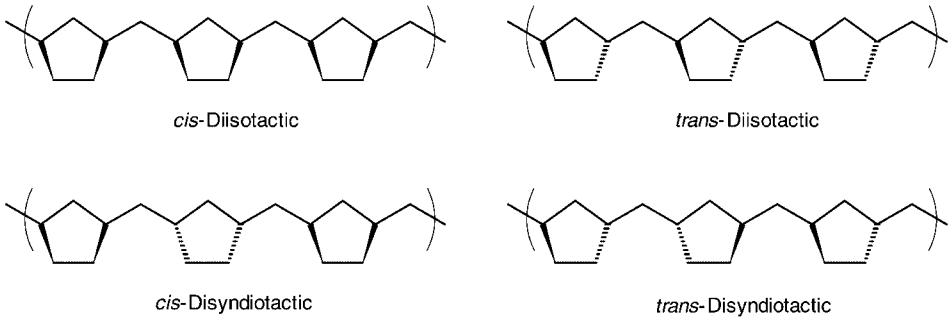

Fig. 16. Poly(methylene-1,3-cyclopentane) structures of maximum order.

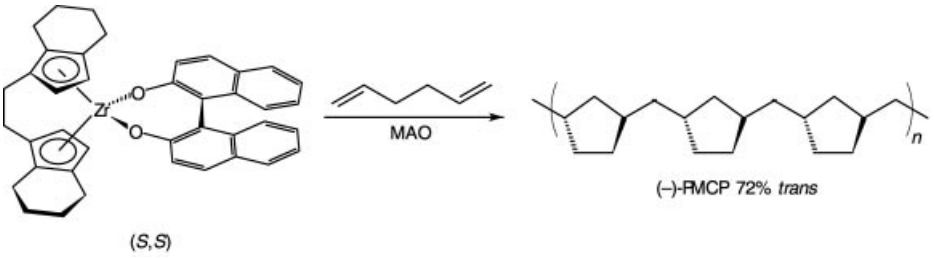
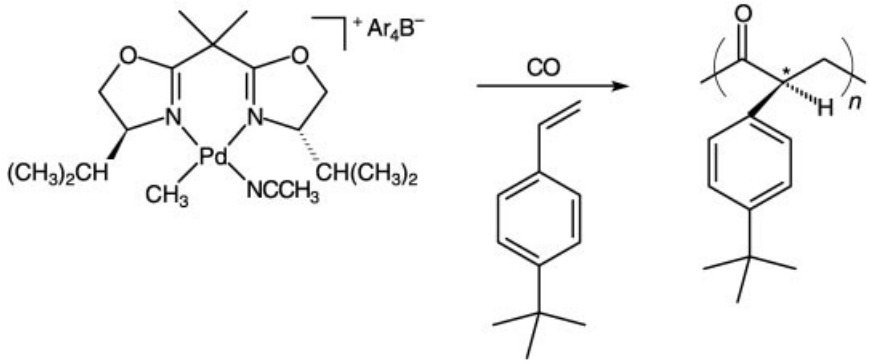
relative configuration of every other stereocenter). All other structures contain mirror planes within the repeating subunits.

Using both enantiomers of the resolved $C_2H_4(IndH_4)_2Zr$(BINOL)/MAO catalyst 1,5-hexadiene has been polymerized to obtain optically active poly(methylene-1,3-cyclopentane) (eq. 8) (423,424). The polymer obtained with the (*R*,*R*) catalyst displayed a molar optical rotation of $[\Phi]_{405}^{28} = +51.0^\circ$ ($c = 0.8$ in $CHCl_3$). Microstructural analysis by ^{13}C nmr indicated an enantiofacial selectivity of 91% for the olefin insertion step and 72% content of trans rings. Cyclopolymerization with the (*S*,*S*) catalyst gave the enantiomeric polymer with $[\Phi]_{405}^{28} = -51.2^\circ$. Interestingly, the measured optical rotations are considerably higher than that obtained for diasteromerically pure model compound *trans*-(1*R*,3*R*)-1,3-dimethylcyclopentane, possibly resulting from a preferential helical conformation in solution.



(8)

Styrenic Copolymers. Alternating copolymerization of vinyl monomers with carbon monoxide produces polyketones with stereogenic centers along the polymer backbone (482). Brookhart and co-workers have reported the copolymerization of *p-tert*-butylstyrene and CO under the enantiomorphic site control mechanism, using an enantiomerically pure cationic palladium catalyst based on a C_2-symmetric bisoxazoline ligand (eq. 9) (483). The obtained copolymer showed a high molar optical rotation of $[\Phi]_{589}^{25} = -536^\circ$ ($c = 0.5$ in CH_2Cl_2) resulting from main-chain chirality. ^1H and ^{13}C NMR analysis revealed a high degree of stereoregularity (>98%) confirming the isotactic microstructure. The narrow molecular weight distribution ($M_w/M_n = 1.4$) of this polymer is consistent with the Schulz–Flory statistics for a SSC.



(9)

Heterogenization of SSCs

Essentially homogeneous SSCs have to be supported for use in industrial gas-phase, slurry, and bulk-monomer polymerization processes (for reviews, see Refs. 484–491). Not surprisingly, most of the information on the supported catalyst systems has been published only in the patent literature (for extensive coverage, see Ref. 490). The main problems are associated with catalyst feeding, reactor fouling, and controlled particle morphology of the produced polymer. Continuous operation of gas-phase polymerization processes requires the use of free-flowing catalyst particles that can be easily fed into the reactor. Controlled growth of the polymer particles during the polymerization reaction (Fig. 17) is likewise essential, since overheating and subsequent melting of the forming polymer grains may result in sheets and lumps that disturb the agitation, fluidization, and product removal processes.

The most common inorganic supports used for heterogenization of metallocenes are various types of silica, alumina, and magnesium compounds (381,484–502), although other less conventional carrier materials based on zeolites (503–505), mesoporous (MCM-41) silica (506–510), cyclodextrin (511,512), polystyrene (513–515), polysiloxanes (516,517), and sulfated zirconia (518) have been reported. Self-supporting catalyst systems based on olefin or alkyne functionalized metallocenes have also been described (519). In this case, the initially homogeneous metallocene is incorporated into the growing polymer chain, which upon precipitation from the reaction mixture functions as a heterogeneous catalyst system.

Immobilization of metallocenes on the carrier materials can be accomplished by various methods, including (*1*) direct impregnation of the activated metal complex/aluminoxane mixture; (*2*) premodification of the support with MAO or aluminum alkyls followed by reaction with the metallocene; (*3*) anchoring of the metallocene to the support through covalent bonds followed by activation with the cocatalyst. Similar approaches can be applied to the boron-activated catalyst systems (489,490).

In most cases, properties of the polymers obtained with the supported catalysts are similar to those obtained with their homogeneous analogues. The

Fig. 17. Replication of catalyst morphology in isospecific propylene polymerization with heterogeneous metallocene catalyst: SEM image of the heterogeneous catalyst SiO_2/MAO/$(CH_3)_2$Si(2-CH_3-benz[*e*]Ind)$_2ZrCl_2$ (left), and SEM image of PP powder (ρ = 0.22 g/mL) produced in hexane with triisobutylaluminum as external activator at 40°C (right). [From Ref. 492. Copyright © John Wiley & Sons, Inc. Reprinted by permission of John Wiley & Sons, Inc.]

single-site nature of the metallocene is generally preserved, although activites are often remarkably reduced. The surrounding carrier material may increase the steric hindrance around the active sites, thus contributing to decreased overall productivities. On the other hand, enhanced site-isolation may suppress binuclear chain transfer and deactivation pathways resulting in improved molecular weights and, most notably, satisfactory activities at considerably reduced cocatalyst concentrations. Supported metallocene catalysts are commonly activated with [Al]:[M] ratios in the range of 50–400:1, far below those required for their homogeneous counterparts.

Despite the technological difficulties associated with catalyst preparation, leaching and process parameters, the number of announcements on commercial production of polyolefins with heterogeneous SSCs is, at the time of writing, rapidly increasing. The advanced supported SSCs are highly active and suitable for use as drop-in catalysts in existing commercial plants. These catalysts produce coherent polymer grains that are enlarged replicas of the catalyst particles exhibiting the desired bulk densities and other material properties. Dow and Exxon have been the key players in commercialization of SSC technologies. Both companies launched their homogeneous high pressure and solution ethylene polymerization processes in 1991. BASF commercialized its heterogeneous metallocene-based polyethylene in 1995. Several other companies, including Exxon, Mitsui Petrochemical, Borealis Polymers and Elenac (BASF/Shell joint venture), are now producing commercial grades of metallocene polyethylenes in gas-phase or slurry processes (489). Isotactic metallocene PPs are limited to speciality polymers produced by Targor (BASF/Hoechst) and Exxon. sPP, EPDM-polymers, ethylene–styrene copolymers, sPS, and cyclic olefin copolymers are, at the time of writing, in earlier development cycles.

STABILIZATION

Introduction

The performance of most polymer artifacts is adversely affected during the various stages of their lifecycle: manufacture, storage, processing/fabrication, and the service environment. Molecular oxygen is the main cause of irreversible polymer deterioration leading to loss of useful properties and ultimate mechanical failure. Its deleterious effect is accelerated by several other factors: temperature, sunlight, ozone, atmospheric pollutants, water, mechanical stress, adventitious metal, and metal ion contaminants. Most organic polymers, therefore, require protection against degradation, which can be achieved by the use of oxidation inhibitors referred to hereafter as *antioxidants* or *stabilizers*. Indeed the commercialization of some of the high tonnage polymers such as polypropylene (PP), and their use for outdoor applications, would not have been possible without the successful development of antioxidants. The use of very efficient stabilizers is also in great demand for applications involving second-life polymers, with reprocessing and recycling of thermoplastics as means of conservation of materials. Apart from cost and customer specifications, the amount of protection offered by antioxidants and stabilizers can vary enormously depending on the chemical structure of polymers, their physical and morphological characteristics, the manufacturing process, and service conditions of end-use articles (1–7).

The development of antioxidants and stabilizers started in the early part of the twentieth century as an empirical science (8–11). Progress in stabilization technology was made possible through a basic understanding of the underlying mechanisms of polymer oxidation. The terminologies used to describe antioxidants are wide ranging and reflect the polymer matrix. For example, in rubber technology, the terms antidegradants, antifatigue agents, and antiozonants are

Encyclopedia of Polymer Science and Technology. Copyright John Wiley & Sons, Inc. All rights reserved.

used, whereas in the plastics industry they are invariably referred to as melt (or processing) antioxidants, and heat and light stabilizers (or photoantioxidants). The terms primary and secondary antioxidants are also used, but the distinction is rather arbitrary and does not relate to their mechanisms of action. Although antioxidants and stabilizers are normally used at low concentrations (generally $<1\%$) they are key ingredients in the compounding of polymers. The continuous growth of polymer markets has ensured a parallel growth in demand for antioxidants and stabilizers, especially in the large tonnage polymers, with principal applications in packaging, building, automotive, electrical, and electronics systems.

This article aims to present a coherent treatment of the fundamental aspects of the science of polymer stabilization technology. The state of the art is discussed, with particular emphasis on recent developments and progress. A brief introduction to certain aspects of oxidation of polymers is given first before discussing the role of antioxidants, with examples to illustrate their basic mechanisms of action.

Oxidation of Polymers

Early works on free-radical chain theory for autoxidation of hydrocarbons (12–16) have shown that oxidation of hydrocarbons occurs autocatalytically, that is, the reaction starts slowly, possibly with a short induction period, followed by gradual increase in the rate (ascribed to the buildup of hydroperoxides) which will eventually subside giving rise to a sigmoidal curve as a function of time. The length of the short induction period is reduced or removed by the presence of initiators (eg, peroxides, azo compounds) and extended by antioxidants and stabilizers (Fig. 1). The basic autoxidation theory of hydrocarbons, involving a complex set of elementary reaction steps, was subsequently extended to oxidation of polymers (17–21). However, studies of oxidation in polymers, both in the solid phase (eg, under service conditions in presence of heat or light) and in the viscous melt during processing, are more complex than in liquid hydrocarbons because of the problems of oxygen diffusion, solubility, and effects of polymer crystallinity and morphology (4,22). The role of hydroperoxides in autoxidation of polymers cannot be overemphasized as they are associated with changes in molar mass of polymers and its properties leading ultimately to catastrophic failure (see Fig. 2).

Scheme 1 describes the free-radical process of polymer oxidation in terms of three basic steps: initiation, propagation, and termination (18). Although the origin of the first initiating macroalkyl radical is still controversial, many factors, eg, heat, mechanical stress, light, and transition metal impurities contribute to its formation (reaction (1a)). However, the direct reaction of polymers with oxygen (reaction (1b)) is generally not favored because of thermodynamic and kinetic considerations. It can only occur in polymers with very labile C—H bonds to give a relatively stable alkyl radicals that terminate, rather than propagate, the oxidation chain reaction. Oxygen can easily penetrate the amorphous regions of polymers; for example, in semicrystalline polymers these regions are highly oxidizable.

Propagation reactions involve the very fast reaction of oxygen with polymer alkyl radicals. Rate constants for reactions of most alkyl radicals with oxygen is of the order 10^7–10^9 $mol^{-1} \cdot s^{-1}$ (23). These reactions lead to the formation of macroalkylperoxyl radicals (Scheme 1, reaction 2), followed by abstraction of a

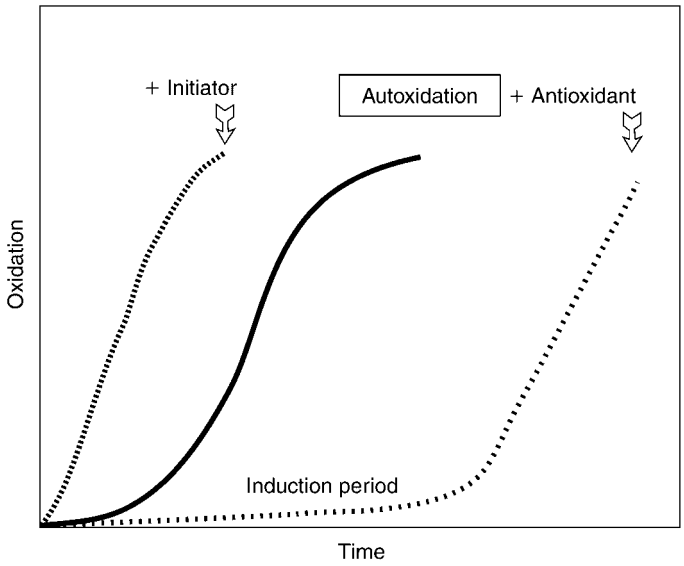

Fig. 1. Generalized scheme for changes in autoxidation curve, caused by presence of initiators and antioxidants.

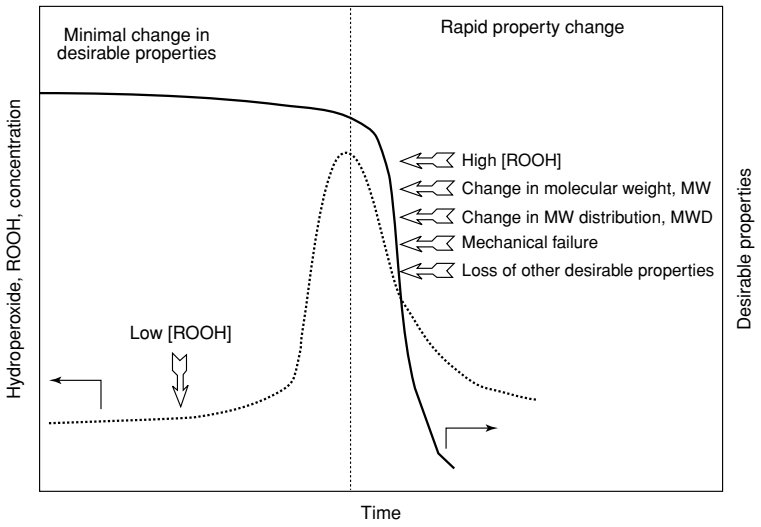

Fig. 2. Generalized scheme relating hydroperoxide concentration and loss of useful properties.

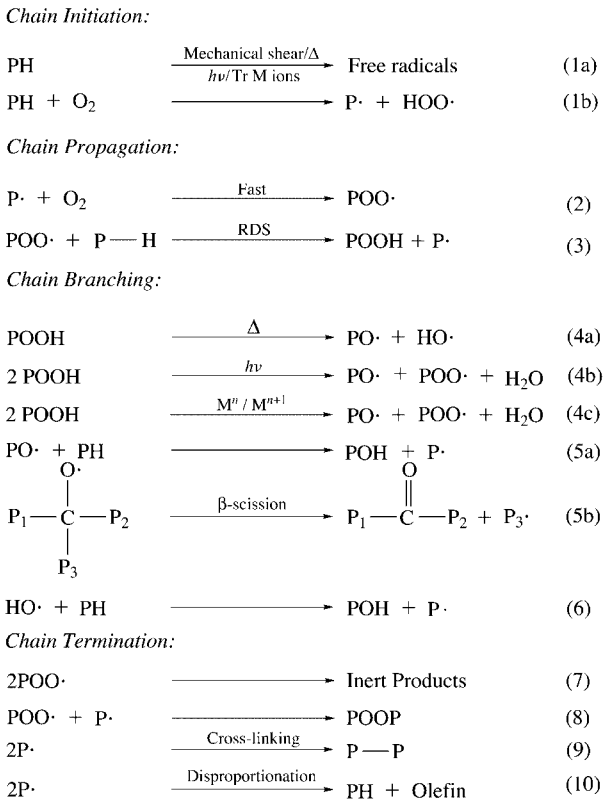
hydrogen from another polymer molecule (reaction 3). This latter reaction involves the breaking of a C—H bond and, therefore, a higher activation energy as compared to reaction 2. The rate of this reaction, which in most polymers determines the overall oxidation rate (rate determining step of autoxidation, RDS), is a function of both the C—H bond strength (allyl < benzyl and tertiary < secondary



Scheme 1. Free-radical chain reaction involved in polymer oxidation.

< primary) and the stability of the macroalkyl radical formed (21,24–26). Reaction 3 gives macrohydroperoxides, the first molecular product of the chain oxidation process. These can undergo homolysis (bond dissociation energy of RO—OH is about 175 $kJ \cdot mol^{-1}$) under the effect of heat, light, or metal ions (from polymerization or pigments), giving rise to alkoxyl and hydroxyl macroradicals (reactions 4a–4c). Both these radicals can abstract a hydrogen from another polymer molecule, leading to new macroalkyl radicals (reactions 5a and 6), which continue the chain reaction. Alkoxyl radicals can undergo further reactions, eg, β-scission (see reaction 5b), which lead to cleavage of the polymer backbone and generation of further radicals.

The oxidative process terminates eventually through combination or disproportionation reactions involving the various propagating radicals. The exact nature of the terminating step, however, depends on the structure of the substrate as well as on oxygen concentration. Since reaction 3 is rate determining, alkylperoxyl radicals are the predominant reactive species under normal oxygen pressure (ie, $[POO\cdot] > [P\cdot]$) and termination occurs primarily through reaction 7, leading to diperoxides, carbonyl compounds, and alcohols (27–31). In the presence of limited amount of oxygen, eg, during polymer extrusion, alkyl radicals predominate (ie, $[P\cdot] > [POO\cdot]$) and termination reactions 8–10 assume greater significance.

These bimolecular termination reactions can lead to cross-linking with an increase in molar mass and/or disproportionation which takes place without changes in molar mass of the polymer (reactions 9 and 10). Other polymer radical reactions, including fragmentation and addition to double bonds to give rise to further free radicals, can also take place depending on the reaction conditions. These molecular changes lead ultimately to loss of mechanical properties (eg, impact strength, tensile strength, elongation) and premature failure, modification of surface appearance (eg, crack formation, loss of gloss, "chalking"), and, in many cases, to discoloration and yellowing.

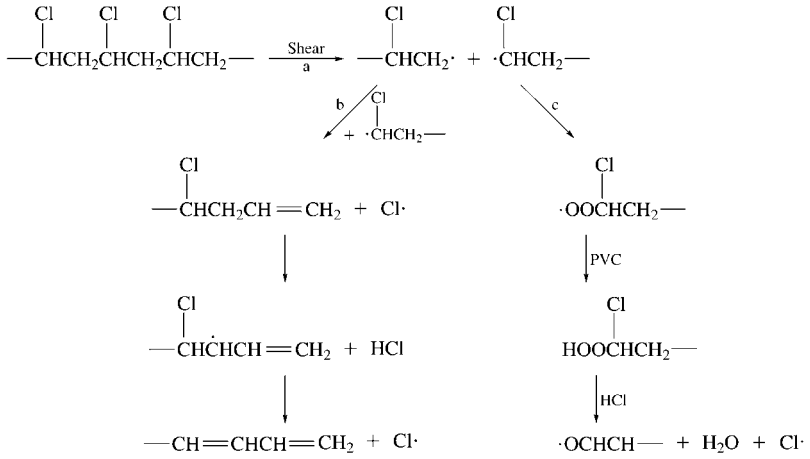
Effect of Temperature and Water. Thermal oxidation of plastics and rubbers can occur at all stages of their lifecycle but is most pronounced during melt processing. The combined effects of temperature (180–330°C) and shear lead to mechanical rupture of polymer chains and formation of reactive mechano-alkyl radical ($R\cdot$). The thermal history of a polymer, therefore, has major consequences on its subsequent in-service performance. Table 1 summarizes the factors affecting polymer degradation at different stages of its lifecycle.

The nature of the polymer matrix exerts a profound effect on the mechanochemistry of the system. For example, thermal processing of poly(vinyl chloride) (PVC) results primarily in elimination/dehydrochlorination and discoloration rather than a change in molar mass. The formation of PVC macroradicals is

Table 1. Factors Affecting Degradation of Polymers at Different Stages of Their Lifecycle

Factors governing polymer degradation	Processing[a]	Service lifetime[b]
Physical state	Melt	Solid
Temperatures	180–320°C	−30 to 150°C
Oxygen concentration	Oxygen deficient conditions	Normal oxygen level
Exposure time	Minutes	Hours to Years
Radical concentrations	$[R\cdot] \gg [ROO\cdot]$	$[ROO\cdot] \gg [R\cdot]$
Hydroperoxide, ROOH, concentration	Low	Higher
Rate of ROOH decomposition	Fast	Moderate, depending on temperature
Factors accelerating the oxidation	Heat	Heat (lower temp.)
	Shear	Uv light
	Oxygen (Limited)	Oxygen, ozone
	Impurities and defects (from polymer manufacture, see Table 2)	Oxygenated moieties (from processing, see Table 2)
		Atmospheric pollutants (PNA,[c] S and N oxides)
		Water, solvents
		Metal ions, eg, copper

[a] For example, extrusion.
[b] For example, heat, uv radiation.
[c] PNA = polynuclear aromatic compounds.



Scheme 2. Reactions of macroalkyl radical during high temperature processing of PVC.

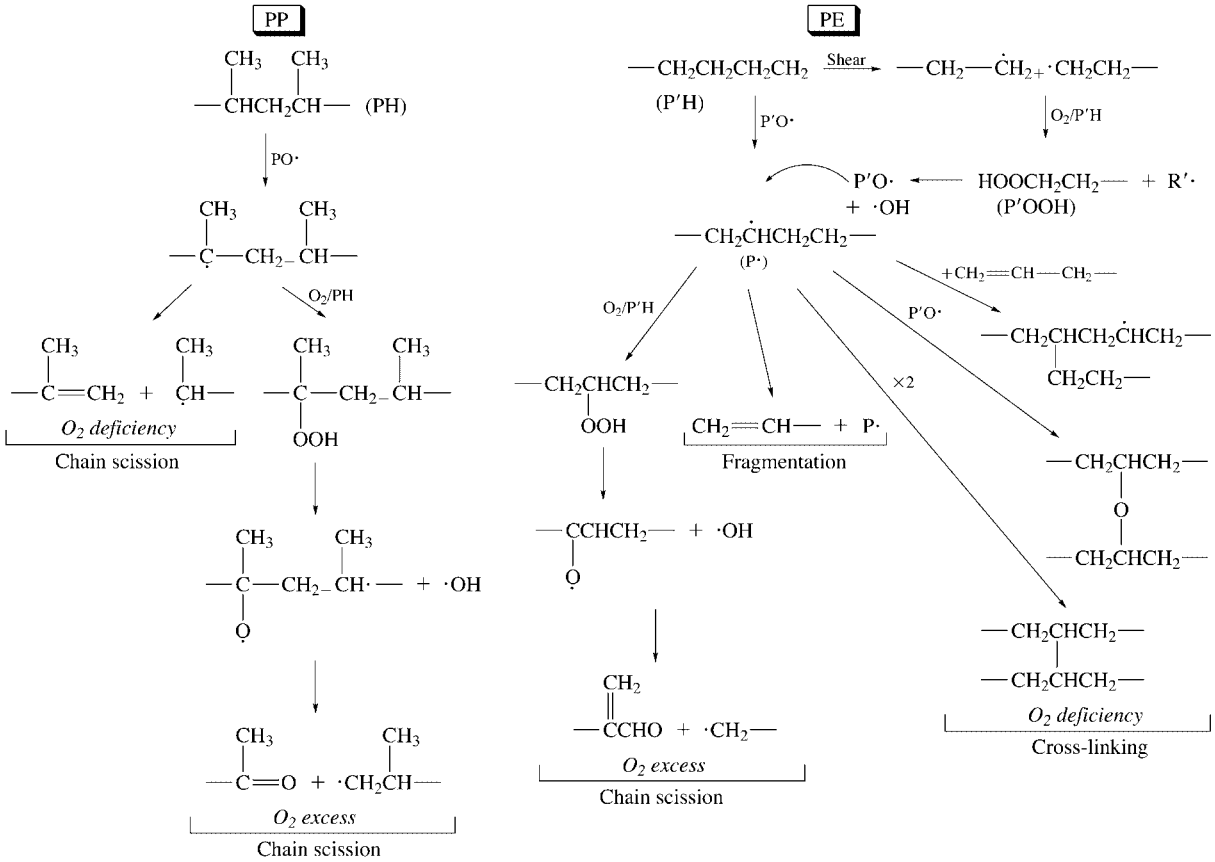
followed by two competing reactions: elimination of HCl, leading to intense discoloration of the polymer (due to formation of conjugated double bonds) (Scheme 2, route b) and peroxidation (route c). The damage was found to be greatest during the first few minutes of processing when viscosity is highest (2,32–36).

Polyolefins, on the other hand, undergo changes in molar mass although the effect is not so visible as is the case for PVC. For example, PP undergoes mainly chain scission whereas polyethylene (PE) undergoes predominantly cross-linking (37–45) (Scheme 3). The presence of various unsaturated groups (eg, vinyl, vinylidene, *trans*-vinylene) as impurities in PE plays an important role in the overall oxidation and cross-linking of the polymer. Macroalkyl and macroalkoxyl radicals are intermediates and are ultimately responsible for the formation of various impurities including macrohydroperoxides, carbonyl groups, and double bonds (see Scheme 3). Polystyrene (PS) behaves similarly to PP under processing conditions where decomposition of tertiary hydroperoxides results in chain scission and reduction in molar mass (46) (Scheme 4).

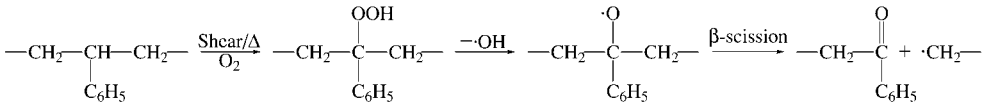
All thermoplastic polymers, therefore, show a high rate of mechano-thermal degradation in the initial stages of the processing operation, giving rise to a buildup of irregularities into the macromolecule with profound effects on polymer performance during aging (1,2,37).

Although less systematic work has been carried out on mechano-thermal oxidation of other polymers during processing, generally they degrade in similar way to that of polyolefins, styrenics, and PVC. For example, aliphatic polyamides and polyesters, which are more stable under processing conditions than polyolefins, undergo free-radical attack, after initial formation of mechano radicals, by hydrogen abstraction at methylene groups in position α to the nitrogen (polyamides) or oxygen (polyesters) atoms, resulting in peroxidation and reduction in molar mass (2,47–49) (see Scheme 5).

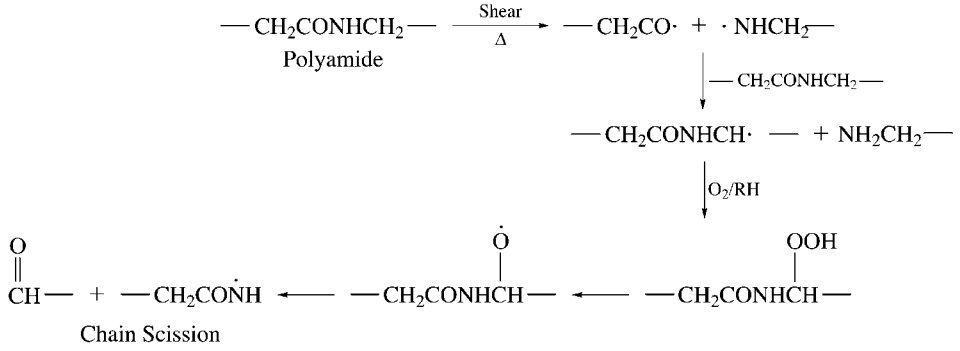
It is important to point out that these polymers, along with other heteroatom-containing polymers such as polycarbonates (PC) and poly(ethylene terephthalate) (PET), are also highly susceptible to hydrolytic degradation (Scheme 6),



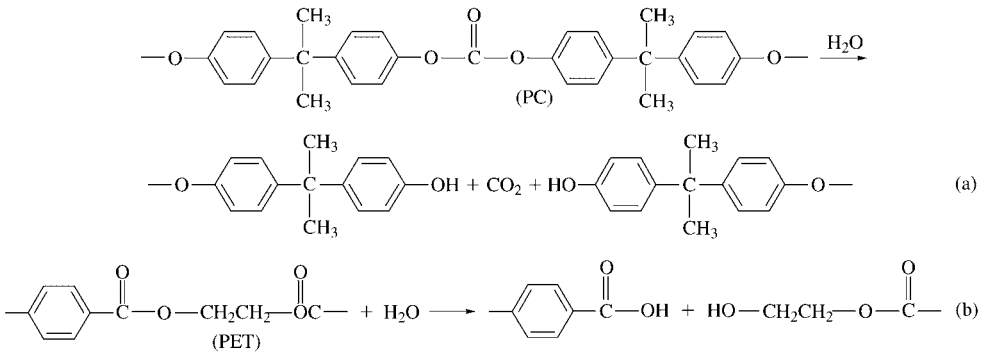
Scheme 3. Reactions of macroalkyl radicals during high temperature processing of polyolefins.



Scheme 4. Chain scission of PE hydroperoxides formed during melt processing.



Scheme 5. Reactions of polyamides during high temperature processing.



Scheme 6. Hydrolytic degradation of PC (**a**) and PET (**b**).

giving rise to chain scission, reduction in molar mass, and deterioration of mechanical properties. These polymers must be dried before melt processing, which is normally performed at temperatures of up to 300°C.

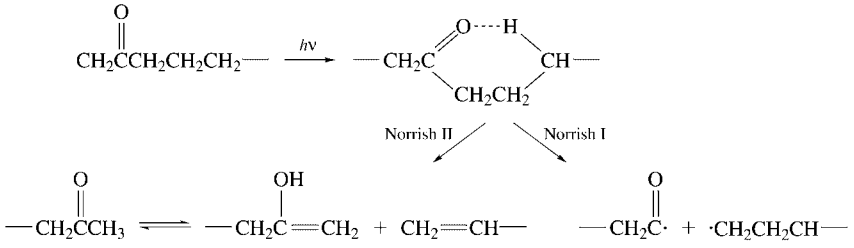
Polymers may be further subjected to the effect of temperature during their service performance, and their oxidation is referred to here as long-term thermal oxidation and is related to many applications including automotive (eg, under the bonnet), domestic appliances, and electronics systems. In addition to temperature, both polymer morphology and sample thickness influence significantly the long-term thermal oxidative behavior of polymers. As previously discussed alkylperoxyl radicals predominate under these oxidation conditions (see Table 1). For thin polymer samples ($<3 \times 10^{-3}$ cm) oxygen diffusion is not rate determining and the main termination process (in the absence of antioxidants) is a bimolecular reaction of alkylperoxyl radicals (Scheme 1, reaction 7). For thick polymer sections, and particularly at high temperatures, oxygen may become deficient

inside the sample during long-term thermal exposure, hence increasing the role of alkyl radicals in polymer oxidation which necessitates different strategies for its inhibition.

Effect of Ultraviolet Light and Outdoor Environment. The second stage of the polymer lifecycle, where oxidative degradation is a main cause for concern, occurs during outdoor exposure. The chemical impurities, eg, hydroperoxides, carbonyl compounds and unsaturation, which are generated during polymer manufacture and processing/fabrication, can further sensitize and accelerate polymer degradation under service conditions. Based purely on chemical structure, many of the polymers are intrinsically transparent to the shorter wavelengths of the sun spectrum (<290 nm). However, commercial hydrocarbon polymers, eg, PE and PP, are highly sensitive to outdoor weathering due to the presence of light absorbing impurities, especially oxygen-containing species. In view of the important role of oxygen-containing species as photoinitiators, the prior thermal history of polymers has a profound effect on their subsequent photo-oxidative behavior in service. Hydroperoxides formed during melt processing (and to a lesser extent during manufacturing and storage) are the most important photoinitiators during the early stages of polymer photo-oxidation (see Scheme 1, reaction 4b), while the derived carbonyl-containing products exert deleterious effects during the later stages by Norrish types I and II photocleavage processes, resulting in backbone scission (50–55) (Scheme 7).

It is important to point out that exposure of polymer articles to outdoor weathering results in photo-oxidation due to the direct effect of uv light (sunlight). This oxidation process is also affected by other environmental factors including heat, atmospheric pollutants, water (particularly in the case of polymers containing heteroatoms), and ozone (especially for unsaturated elastomers) (see Table 2). These factors may catalyze the formation of free radicals and light-sensitive chromophoric groups and initiate photo-oxidation (56–63). Under photo-oxidative conditions there is a high alkyl-to-alkylperoxyl radical ratio because of the higher rate of initiation, compared to oxidation under thermal conditions, and relatively low rate of oxygen diffusion in the solid polymer (22,64).

The photo-oxidative behavior of commercial polymers is widely different. The most photo-oxidizable polymers are the unsaturated rubbers with labile R—H bond and are generally heavily filled with carbon black (an effective sun-screen; see later) in outdoor applications. Similarly, rubber modified plastics, eg, high impact polystyrene (HIPS) and acrylonitrile–butadiene–styrene (ABS), are more



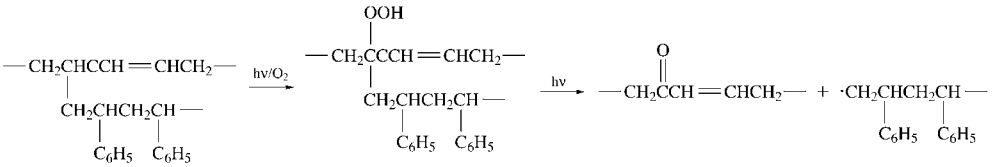
Scheme 7. Photolysis of PE (the Norrish reactions).

Table 2. Important Photoinitiators for Polyolefin Photo-oxidation

Stage	Photoinitiators
Polymer manufacture	Defects: unsaturation
	Impurities: transition metal ions present as catalyst residues
	Impurities: hydroperoxides and carbonyl compounds formed by adventitious oxidation
Processing and fabrication	Oxygenated moieties: hydroperoxides and carbonyl compounds formed by high temperature oxidation
	Transition metal ions from machinery or compounding ingredients
Environmental exposure	Atmospheric pollutants, eg, polynuclear aromatic compounds, nitrogen and sulfur oxides
	Carbonyl compounds by photolysis of hydroperoxides
	Unsaturation by photolysis of ketones
	Water
	Ozone

susceptible to photo-oxidation than polyolefins because of the rapid peroxidation of the rubber component that will sensitize the polymer to further photo-oxidation (65) (Scheme 8).

Light absorbing impurities and chromophoric groups present in commercial polyolefins (see Table 2) are responsible for their inherent photo-oxidative shortcomings (54). The photostability of the different members of the polyolefin family, however, vary significantly depending on their chemical and morphological structures; generally PP and high density polyethylene (HDPE) are more susceptible to photo-oxidation than low density polyethylene (LDPE) (37,66). PVC and PS should be relatively stable to photo-oxidation, but their thermal history exerts significant effects on their subsequent photo-oxidative behavior (67–70). The photo-oxidative stablility of engineering polymers such as aliphatic polyesters and polyamides is generally higher than that of polyolefins, albeit similar processes of peroxidation, photoinduced reactions, and chain scission are involved (71–76,76–81). Similarly, other engineering polymers such as PC, polysulphones, and poly(phenylene oxide) (PPO) are more stable to uv light than, for example, polyolefins and PVC. Prolonged outdoor exposure of these polymers lead to changes in their molar mass,



Scheme 8. Photoxidation of polybutadiene–polystyrene graft copolymer (HIPS).

reduction in mechanical properties, particularly impact strength and increasing yellowing, properties which can be particularly important in some applications, eg, the use of PC to replace glass for outdoor uses (55,81–84). The outdoor performance of all polymers can, however, be markedly improved by photo antioxidants and uv stabilizers.

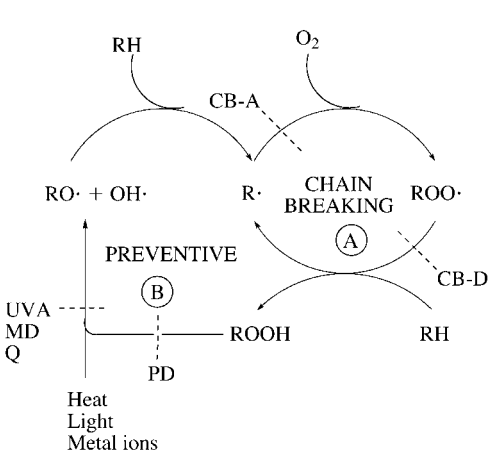
Antioxidants in Polymer Stabilization—A Mechanistic Overview

Scheme 9 shows the two main oxidative cycles. Antioxidants and stabilizers can be classified according to their mode of action in interrupting the oxidative cycles: chain breaking and preventive (85,86). Examples of some commercial antioxidants from the different classes (87) are shown in Table 3 under their "primary" mode of action, albeit most antioxidants operate by more than one mechanism.

Chain-Breaking Antioxidants. Chain-breaking (CB) antioxidants (sometimes referred to as primary antioxidants) interrupt the primary oxidation cycle by removing the propagating radicals, ROO· and R· (85,88–92). Chain breaking donor (electron or hydrogen atom donors) (CB-D) antioxidants operate by reducing ROO· to ROOH (hydrogen atom donors) (see Scheme 10, reaction 10a). To be effective, CB-D antioxidants must compete with the chain propagating step (reaction 10b) and prevent hydrogen abstraction from the polymer. The antioxidant radical (A·) generated during this process must itself be stable (nonpropagating) and leads to stable molecular products (reaction 10c). Hindered phenols and aromatic amines (see Table 3, **AOs 1–12**) are some of the important examples of commercial CB-D antioxidants (see ANTIOXIDANTS).

Chain-breaking acceptor (CB-A) antioxidants, on the other hand, act by oxidizing alkyl radicals in a stoichiometric reaction and hence are only effective under oxygen-deficient conditions (reaction 10d). Antioxidants with structures based on benzofuranone derivatives (lactones) and hydroxylamines, as well as on quinones and stable free radicals, are good examples of CB-A antioxidants (91–96). Hindered amine derivatives [often referred to as hindered amine stabilizers (HAS); eg, **AOs 25–27**, Table 3 also function by a chain-breaking mechanism and, through their transformation products, are able to trap both R· and ROO· in a cyclical regenerative mechanism (50,55,62,94,97–100); for simplified reaction mechanism, see Scheme 11.

Preventive Antioxidants. Preventive antioxidants (sometimes referred to as secondary antioxidants) interrupt the second oxidative cycle by preventing or inhibiting the generation of free radicals (see Scheme 9). The most important preventive mechanism is the nonradical hydroperoxide decomposition (PD) (86,101). Phosphite esters and sulfur-containing compounds (eg, **AOs 15–24**, Table 3) are the most important classes of peroxide decomposers. Phosphites reduce hydroperoxides to alcohols and are themselves oxidized to the corresponding phosphates with a 1:1 stoichiometry and are referred to as stoichiometric peroxide decomposers (PD-S) (Scheme 12, reaction 12a). In addition to their peroxidolytic activity, some phosphite esters also behave as catalytic peroxidolytic agents (PD-C), and others (eg, hindered aryl phosphites; (see **AOs 15–18**, Table 3) are also capable of functioning by a chain-breaking mechanism (Scheme 12, reactions 12b and 12c). The contribution of each of these modes of action to the overall mechanism



CB-A – Chain-Breaking Acceptors
Lactones
Hydroxylamines

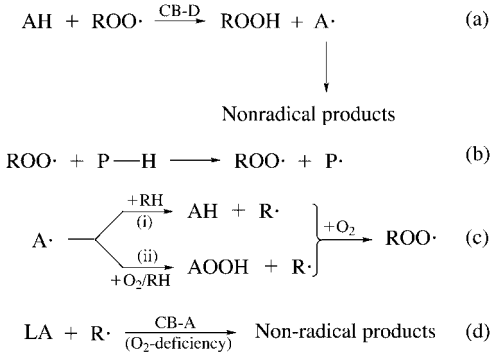
Scheme 9. Oxidative degradation processes, antioxidant mechanisms, and some examples representing different antioxidant classes.



Scheme 10. Main reactions and competing pathways involved in chain-breaking antioxidant activity, where AH is a CB-D antioxidant, eg hindered phenol, A. is the antioxidant radical, and 1A is a CB-A antioxidant.

depends on the structure of the phosphite, oxidizability of the substrate, and the reaction conditions (102–104). Reaction 12d shows the hydrolysis of phosphite esters. Sulfur compounds, eg, thioethers and esters of thiodipropionic acid and metal dithiolates (see **AOs 19–24**, Table 3), decompose hydroperoxides catalytically (PD-C) whereby one antioxidant molecule destroys several hydroperoxides through the intermediacy of sulfur acids (Scheme 13) (86,101,105–107).

Metal ion deactivators (MD) act, primarily, by retarding metal-catalyzed oxidation of polymers (see Scheme 1, reaction 4c). They are used in polymers that are in contact with metals such as copper in wires and power cables. Metal deactivators are normally polyfunctional metal chelating compounds (eg, **AOs 33**,

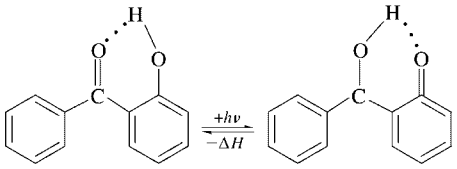
34, Table 3) that form stable metal complexes with reduced catalytic activity of the metal (108–110). Ultraviolet absorbers (UVA) act by absorbing uv light, hence retarding the formation and photolysis of hydroperoxides. Typical examples that are based on 2-hydroxybenzophenone and 2-hydroxybenzotriazole structures are given in Table 3 (**AOs 28–32**). These compounds are photostable and have high molar extinction coefficient in the spectral region 300–360 nm. Their activity is



Scheme 14. Simplified view of the energy dissipation involving *o*-hydroxybe nzophenones.

based essentially on absorption of the harmful uv radiation and its harmless dissipation as heat. For example, uv light induces intramolecular hydrogen transfer in 2-hydroxybenzophenones to give an enol which is converted, in a radiationless process, back to the original ketone (111–114) (Scheme 14).

Performance of Stabilizers and Antioxidants

The commercial success of stabilizers and antioxidants depends not only on their inherent chemical effectiveness but also on their physical characteristics, toxicological considerations, and cost. Under aggressive service conditions their performance can be dominated by their physical characteristics. They can be lost from polymers through volatilization during processing and fabrication, or by exudation and solvent extraction during end use. This problem is particularly severe in the case of semicrystalline polymers and with polymer artifacts, eg, coatings, fibers, films, with high surface-to-volume ratio (4,5). In practice, therefore, their efficiency is a product of a complex relationship between all the chemical and physical factors. Chemical factors include structure, hydrolytic-, thermal-, and photo-chemical stability of both the parent molecule and its transformation products. Physical factors include solubility, diffusivity, volatility, leachability, as well as their interactions with the polymer substrate, including chemical and morphological features.

Physical loss of antioxidants into the contact media can have severe toxicological consequences in addition to risks associated with premature failure of the polymer product. Most countries have stringent regulations regarding the use of these additives in applications involving the human environment, eg, food packaging and medical applications. Although all stabilizers and antioxidants which are licensed for use in polymers for food contact and medical applications have to undergo strict toxicity testing regimes, their approval, however, does not necessarily mean that their oxidation products (derived from the parent molecule during processing, or as a result of their protective action in the substrate) are also nontoxic.

Chemical Effects. The intrinsic chemical activity of stabilizers and antioxidants is a function of their molecular structure. This can be determined accurately in a model substrate where they are fully soluble under test conditions that eliminate physical loss. However, using the chemical activity alone as an indicator can lead to unreliable predictions on the efficiency of antioxidants in polymers under practical conditions because of the dominating influence of physical factors under certain environments.

Some stabilizers, notably aromatic amines and some hindered phenols, impart discoloration or yellowing to the polymer substrate during processing and fabrication or during long-term use. This is highly undesirable in plastics and is largely due to the formation of quinonoid-type transformation products of the parent molecule (88,89). Aromatic amines cause extensive discoloration and are therefore employed almost exclusively in the stabilization of rubbers. Some stabilizers are also sensitive toward hydrolysis, especially phosphites, and to a lesser extent, phosphonites (Scheme 12, reaction 12d). This results not only in the loss of their antioxidant activity but also in the formation of species that may lead to corrosion of machinery during processing (104). Special care must be taken, therefore, during storage and handling of hydrolytically sensitive stabilizers.

Physical Effects. High chemical efficiency of antioxidants does not itself guarantee successful long-term protection of polymers under aggressive environment where their physical loss would drastically reduce their performance. For example, although the hindered phenol BHT (**AO 1**, Table 3) has very high intrinsic chemical activity, it is ineffective in protecting thermoplastic polymers because of its rapid physical loss and depletion through volatilization from the polymer (51). Indeed the physical behavior of stabilizers is a significant factor affecting their permanency, efficiency, and acceptability, especially in polymer applications destined for aggressive service environments such as organic solvents, including dry cleaning solvents, hot water and detergents, hot oils, acids, fatty food, hot air, and intense solar radiation. Physical factors which control the effectiveness and permanence of antioxidants include distribution, solubility, diffusivity, volatility, and leachability. To tackle the problem of physical loss, further commercial developments have led to the synthesis of higher molecular mass antioxidants based on the same hindered phenol function, eg, Irganox 1010 and Irganox1 330 (**AOs 5**, **2**, Table 3), which have outperformed BHT under these conditions (1,90).

Distribution and Polymer Morphology. In order to inhibit polymer oxidation, sufficient concentration of antioxidants must be present at the various oxidation sites. Examination of the distribution of photoantioxidants in typical commercial semicrystalline polymers, such as polyolefins, has shown (5,22,115) that they are rejected into the amorphous region on the boundaries of spherulites. Such nonuniform distribution of antioxidants leads to an increase in their concentration in the amorphous region, which is most susceptible to oxidation since the crystalline phase is normally impermeable to oxygen (5). However, in the case of polymer blends, a nonuniform distribution of antioxidants can undermine the overall stability of the blend, especially if it does not occur in favor of the more oxidizable component in the formulation.

Compatibility with Polymers. Stabilizers and antioxidants are generally less soluble in polymers than in lower molar mass liquid models. Although these compounds are usually highly soluble at the elevated processing temperatures, they may, on cooling to room temperature, precipitate out as a separate phase and exude to the polymer surface, leading to a buildup of a concentration gradient near the surface, forcing further migration of antioxidant from the bulk (5,22). Thus, compounds with low solubility and high diffusion rate are prone to blooming and loss to the surrounding medium by evaporation (air stream as contact media) or through leaching (extraction by a liquid contact media), leaving behind an unprotected polymer surface. Generally, the compatibility of stabilizers in host

polymers is improved when both have similar characteristics. Thus, for example, in nonpolar hydrocarbon polymers, compatibility decreases with increasing polarity of the stabilizers and increases with the number, length, and branching of the inert alkyl substituents attached to the stabilizer function (116,117) (eg, **AOs 2–5**, **20**, **30**, Table 3).

Diffusion, Volatility, and Leachability. The permanency of stabilizers and antioxidants is affected by diffusion characteristics of the parent molecule, the nature (gas, liquid, solid) of the surrounding medium, and temperature (5,7,116). For example, the diffusion coefficient of antioxidants decreases with increasing polar interactions with the polymer, increasing molecular mass of antioxidants, and branching in their alkyl side chain.

In the presence of a stream of hot air or high temperature and low pressure (eg, during polymer melt processing) volatility becomes very important; it is governed by the rate of diffusion of antioxidants, which, in turn, determines the rate at which the surface is replenished (5). The influence of polymer sample shape and the structure and molecular mass of antioxidants on volatility has received much attention. The rate of evaporation of antioxidants from rubber and PE, for example, was found (116) to be inversely proportional to the thickness of the sample and directly proportional to its surface area. Volatility, and the other physical characteristics of antioxidants, are critically dependent on the test conditions. This is illustrated in Table 4 for a series of antioxidants containing the same hindered phenolic functional group (see A—R with R= $-CH_2COOR'$ in Table 3) but differing only in the length of the chemically inert alkyl chain, R′ (51). In a model hydrocarbon, eg, dodecane, all the antioxidants in the series show similar antioxidant activities in a closed system (measured by oxygen absorption) at the same molar concentration. In PP under the same conditions, however, the antioxidant activity of the same series of antioxidants varies by a factor of 4, the optimum occuring at $R' = C_{12}H_{25}$. In an air oven, on the other hand, only the antioxidant with $R' = C_{18}H_{37}$ (ie, Irganox 1076, **AO 4** in Table 3) has any significant activity. At 100°C, but under otherwise identical conditions, somewhat better discrimination is observed between the lower members of the series, and only the C_{12} and C_{18} analogues show significant antioxidant activities (116). Further, the antioxidant activity of this series in an air-oven test is inversely related to volatility in a nitrogen stream (see Table 4).

In liquid contact media (eg, foodstuffs, oils, solvents), the rate of loss of antioxidants from the polymer surface depends both on their diffusion coefficient and on their partition coefficient between the liquid and the polymer. This is complicated by the ability of different solvents (liquid media) to swell polymers to different extents, giving rise to an increase in the diffusion coefficient of the antioxidant, which lead to higher loss rates (7). As in the case of volatilization, the rate of leachability of antioxidants from the surface of polymers into liquid contact media increases with temperature and surface area-to-volume ratio, eg, in thin polymer samples.

Thermal Stabilization

Stabilization of polymers against the effect of temperature is required both to prevent mechano-thermal oxidation at the processing stage (melt-processing

stabilizers) and to afford protection during in-service (long-term thermal stabilizers). In addition, the thermal stability of reprocessed polymers (recycled) must be preserved and reinforced by additional stabilization for further reprocessing and end use (recycling stabilizers).

Melt-Processing Stabilizers. Melt processing of polymers in screw extruder or a shearing mixer is accompanied by degradative processes including mechanical scission of the polymer backbone and formation of macroradicals. In an extruder, where the amount of oxygen is small, the alkyl radicals play an important role and become involved in the termination of the autoxidation process (as seen earlier $[R\cdot] \gg [ROO\cdot]$; see Table 1). However, both alkyl and alkylperoxyl radicals are formed in polymer melts, and hence, antioxidants that can remove macroradicals (in a chain-breaking mechanism, CB-D and/or CB-A) and destroy hydroperoxides (in a preventive mechanism, PD) should provide effective stabilization during processing.

The choice of antioxidants for melt stabilization vary, depending on

(1) structure and oxidizability of the base polymer
(2) extrusion/processing temperature
(3) rate of application of mechanical stress
(4) type and amount of structural defects and impurities
(5) performance targets of the end-use applications.

Thus, structural differences in polyolefins result in very different levels of their oxidizability. PP, for example, is very sensitive to oxidation and cannot be processed without adequate stabilization. HDPE is less sensitive to oxidation than PP and lower antioxidant concentrations are normally needed, whereas LDPE (processed around 200°C) is more stable and may even be used (for certain

applications) without the addition of an antioxidant. Unlike PS, rubber modified styrene blends and copolymers (eg, HIPS, ABS, SAN) are very sensitive to oxidation during processing and require substantial levels of stabilizers during melt processing. PVC, on the other hand, is very highly sensitive to the presence of structural defects and impurities that contribute effectively to initiating oxidation and generating color and corrosive HCl; thus, appropriate stabilization is essential.

Chain-Breaking Antioxidants. Sterically hindered phenols (efficient CB-D antioxidants) have been used extensively as melt-processing stabilizers in plastics. The primary step in their stabilizing action involves the scavenging of alkylperoxyl radicals ($ROO^{\cdot}$), which gives rise to harmful hydroperoxides (Scheme 10, reaction a). In practice, therefore, hindered phenols are generally used in combination with a peroxide decomposer, typically a hydrolysis-resistant phosphite (1–3,37,88,90,118,119). The structure of synthetic hindered phenols used to stabilize different polymers affects their efficiency depending on the degree of steric hindrance and the nature of the para-substituents. Generally, decreasing steric hindrance in the 2- and 6-positions results in increasing the rate of hydrogen abstraction from the phenol. Similarly, the nature of para-substituents affects the extent of discoloration as it determines the nature of transformation products obtained from the parent phenol (120–124).

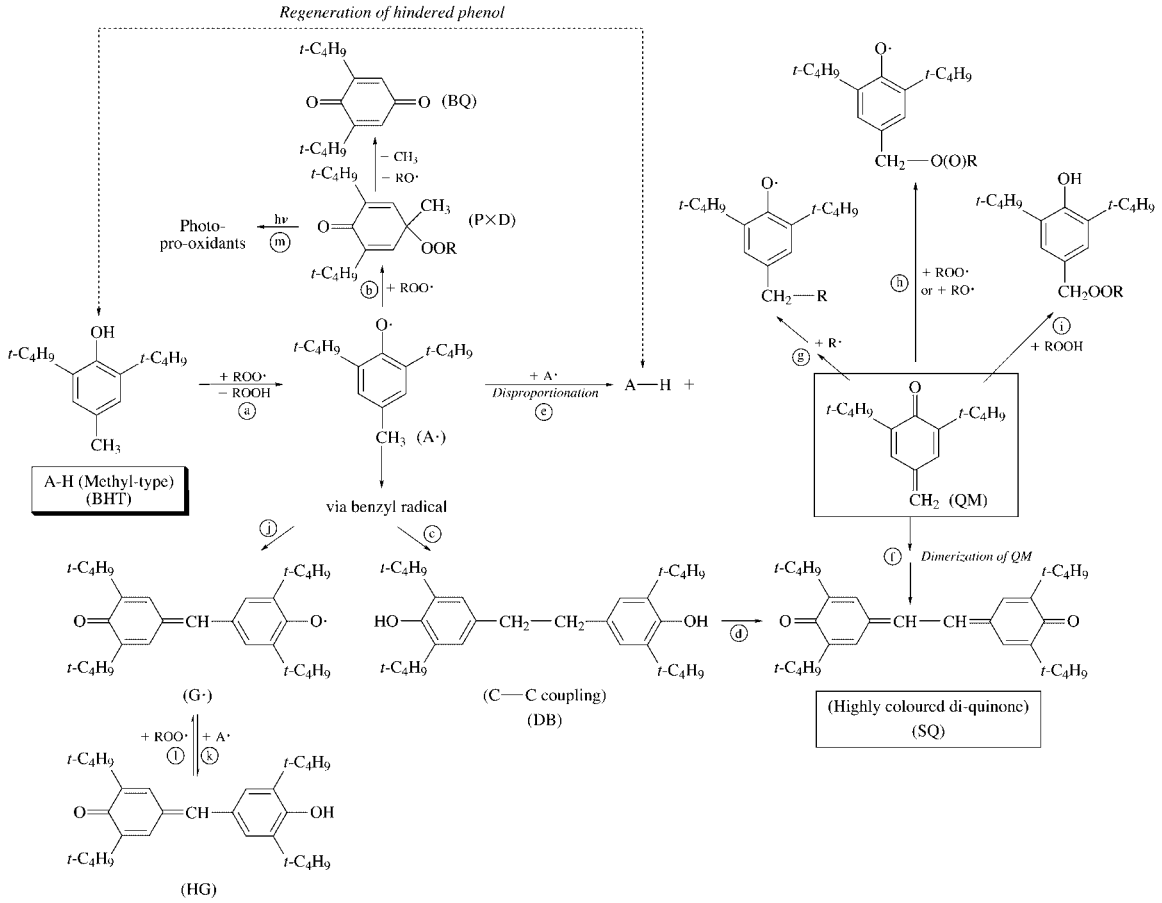
Discoloration is typically caused by the formation of colored conjugated quinonoid-type transformation products with visible absorption wavelengths, typically >400 nm (125). Schemes 15 and 16 show some key reactions of hindered phenols used for polymer stabilization to illustrate the effects of different para-substituents:

(1) Unsubstituted, mono- or di-substituted methyl group (methyl-type); typical examples include **AOs 1–3** in Table 3; and

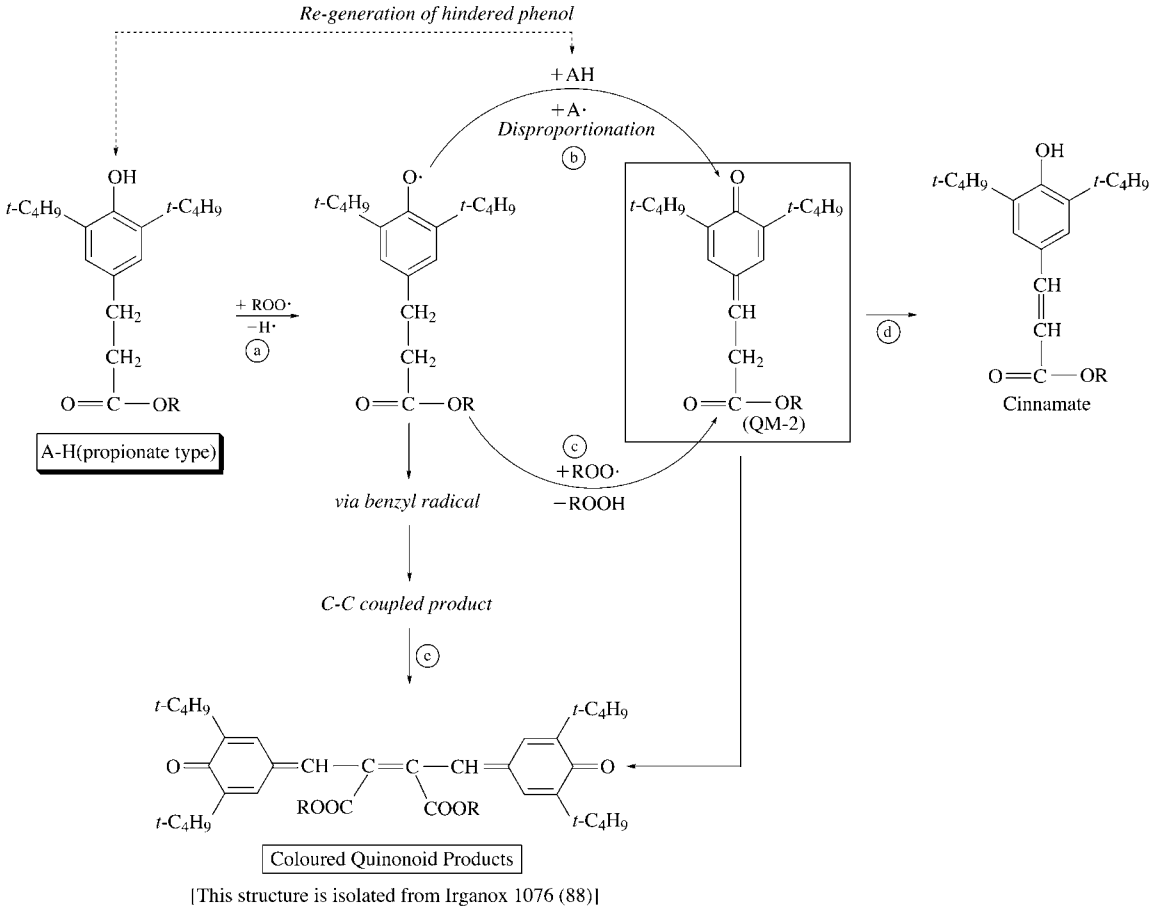
(2) Propionic acid derivative group of the general type $-CH_2CH_2COX$ (where X=OR or NR); examples include **AOs 4–7**, in Table 3 (propionate type). Propionate esters **AOs 4** and **5** are good stabilizers for polyolefins and styrenics, the propionamide **AO 6** is used in aliphatic polyamides, and the ester **AO 7** is suitable for polyesters.

The major transformations of phenolic antioxidants during melt processing, with both types of para-substitents (methyl and propionate types), consist of quinone-type products, C–C and C–O coupling product. Transformation products of antioxidants can greatly influence the extent of stabilization imparted to the polymer. Transformation products can exert anti- or pro-oxidant effects, hence synergizing or antagonizing the action of the parent antioxidant. For example, the formation of peroxydienones (PxD) (see Scheme 15, reaction b) from BHT (**AO 1**, Table 3) leads to pro-oxidant effects, whereas the C–C coupling products (DB) (eg Scheme 15, reaction c) and quinonoid products (SQ) (eg, Scheme 15, reactions d and f) exert antioxidant effects.

The mechanism of action of hindered phenols is centered on the nature of the initially formed phenoxyl radicals which undergo complex reactions, including bimolecular disproportionation, giving rise to a quinonemethide (QM) as well as



Scheme 15. Key reactions that take place during the antioxidant action of 4-methyl-containing hindered phenols.



Scheme 16. Key reactions that take place during the antioxidant action of 4-methyl-containing hindered phenols.

on the regeneration of the parent phenol for further scavenging of another ROO· radical (Scheme 15, reactions e and f; Scheme 16, reaction b) and hence increasing the stability of the polymer (90,120,121). In the case of the propionate type, the QMs can also be formed by reaction of the corresponding phenoxyl radical with a second ROO· radical (Scheme 16, reaction c); these QMs have been shown (120) to isomerize further to the corresponding cinnamate (Scheme 16, reaction d). Although the starting hindered phenols themselves are not capable of acting by CB-A mechanism (because of their inability to deactivate R·), the derived QMs and other quinonoid products are effective CB-A antioxidants. The QMs are capable of deactivating not only the alkyl radicals but also other propagating species (alkoxyl, alkyperoxyl) as well as hydroperoxides (95,126,127) (see Scheme 15, reactions g–i). Furthermore, quinones which are stable in their oxidized and reduced forms, eg, galvinoxyl (G·) and hydrogalvinoxyl (HG) may deactivate both alkyl and alkylperoxyl radicals (via CB-A and CB-D mechanisms, respectively) in a redox reaction (see Scheme 15, reactions k and l) and are thus highly efficient antioxidants. Table 5 shows a comparison of the melt-stabilizing effect of the different oxidation products of BHT in PP with the parent stabilizer molecule (95). In addition to synthetic hindered phenols, the biological hindered phenol antioxidant vitamin E (see **AO 10**, Table 3) has also been shown to be an extremely highly effective melt stabilizer (see later under Biological Antioxidant).

Hindered phenols-derived quinones are CB-A antioxidants and are also effective melt stabilizers. The bifunctional hindered phenol semiacrylate antioxidant (**AO 8**, Table 3), which acts primarily by deactivating alkyl radicals, is an effective processing stabilizer for styrene–butadiene–styrene copolymers (93,128). More recent developments have resulted in the commercialization of new CB-A antioxidants including lactone-based stabilizers and hydroxylamines. The lactone stabilizers (see **AO 13**, Table 3), which are used commercially in blends with hindered phenols and phosphites, have been shown (92,93) to be efficient in oxygen-deficient environment particularly during melt processing, by trapping the macroalkyl radicals (Scheme 17). Similarly, the hydroxylamines (see **AO 14**, Table 3), which can also scavenge the macroalkyl radicals via the intermediacy of nitrones, have been shown (91,94) to be highly efficient (Scheme 18).

Hydrogen Chloride Scavengers. The aim of melt stabilization of PVC is to reduce the formation of HCl and hydroperoxides in the polymer, and to combat the development of unsaturation, which is both the source of color and further instability (2,129–132). In general, plasticized PVC is processed at lower temperatures than rigid PVC, and lesser damage is therefore expected during its melt processing. The elimination of labile chlorine atoms from the polymer backbone is the most important stabilization mechanism for PVC. Metal carboxylates (eg, lead carbonate, calcium, barium and zinc soaps) and tetravalent derivatives of tin (eg, dibutyl tin maleate; AO 35, Table 3) are frequently used for PVC stabilization, and the dialkyl tin carboxylates are in general more effective as chlorine-trapping reagents than the metal group II carboxylates (130–132). Both dialkyl tin maleates and thioglycollates (eg, AO 36, Table 3) function by eliminating HCl. In addition, the maleates function also by removing the unsaturation and limiting color development, whereas the thioglycollates have an additional peroxidolytic function.

Peroxide Decomposers as Processing Stabilizers. Alkyl and aryl phosphite esters (see Scheme 12) are effective melt stabilizers. They are often used in combination with hindered phenols (see Table 6). Phosphites generally function by a stoichiometric peroxidolytic mechanism (PD-S); Table 7 illustrates the benefits of using the commercial phosphites TNPP (**AO 15**) and Irgafos P-EPQ (**AO 17**, Table 3) for melt stabilization (95). The unique phosphite **AO 37** and its phosphate transformation products **AOs** 38 and 39, (Table 7), which were shown (104,133–135) to operate by a catalytic mechanism (PD-C), are particularly effective at low concentration of the parent stabilizer molecule (see AO 37, Table 7) (95). Phosphites are, however, generally susceptible to hydrolysis. For example, hydrolysis of aryl phosphites leads to the formation of low molecular mass phenol and a

[c]Concentration of antioxidant in 10^{-4} mol/100 g.

hydrogen phosphite which is further hydrolyzed to phosphorous acid (Scheme 12, reaction d) (102,104). The consequence of the hydrolysis of phosphites is the reduction of flow properties of the additive system (ie, undesirable change in handling characteristics), increase in corrosion of metal surfaces, formation of dark-colored spots and gel formation. In practice, therefore, only hydrolysis-resistant phosphites (and phosphonites) are used and these are generally based on sterically hindered phenols.

Sulfur-containing compounds are highly effective **PD** antioxidants but they are more complex in their behavior than the phosphites. They react with hydroperoxides in a catalytic process, which leads to the formation of various sulfur acids that are responsible for the catalytic nonradical destruction of hydroperoxides. The "simple" dialkyl sulfides, eg, thiodipropionate esters such as Irganox PS800 and PS 802 (**AOs 19** and **20**, Table 3), function as weak melt stabilizers. They give

rise to a pro-oxidant effect in the polymer because of the generation of free radicals (see Scheme 13, reaction d) by an initial redox reaction with hydroperoxides (95). The sulfoxide transformation product (AO 40, Table 7) formed from thiodipropionate esters is more effective melt stabilizers (see Table 7) because they give rise to sulfenic acid, which is an efficient chain-breaking antioxidant (2) (see Scheme 13, reaction e). In view of the prodegradant effects of thiodipropionate esters, in practice, these sulfide antioxidants are always used in combination with CB-D antioxidants, such as Irganox 1010 (**AO 5** in Table 6), to deactivate the free radicals formed.

Long-Term Thermal Stabilizers. Under normal conditions of long-term thermal oxidation, alkylperoxyl radicals are normally present in large excess over alkyl radicals (see Table 1). In thin samples ($<3 \times 10^{-3}$ cm), oxygen diffusion is not rate determining, and the main termination process is the bimolecular reaction of alkylperoxyl radicals (Scheme 1, reaction 7). Hindered phenols and aromatic amines (CB-D) are highly effective inhibitors of these radicals and are therefore used as long-term stabilizers. In practice, they are used in combination with peroxide decomposers such as phosphite esters (see Table 8) (1).

Many sulfur-containing PD antioxidants, especially the metal dithiolates, are very effective long-term thermal stabilizers (also melt and photo antioxidants; see later). This versatility in antioxidant action is the direct consequence of their highly effective PD activity (54,105,107,136–140). Moreover, the effectiveness of dithiolate antioxidants, within any one series depends strongly on their solubility in the polymer. For example, in the case of nickel dialkyldithiophosphate (NiDRP, **AO 23**, Table 3) series, the lower molecular weight members of the series are less soluble, and less effective than the higher members (see Fig. 3) (141). The zinc dialkyl dithiocarbamate (ZnDRC, **AO 21**) series too show similar behavior (142).

In the case of PVC, long-term thermal stabilization is normally achieved by the same antioxidants used for melt stabilization. Thiotin stabilizers, eg, **AO 36**, are more effective as thermal antioxidants than the more traditional dialkyl tin

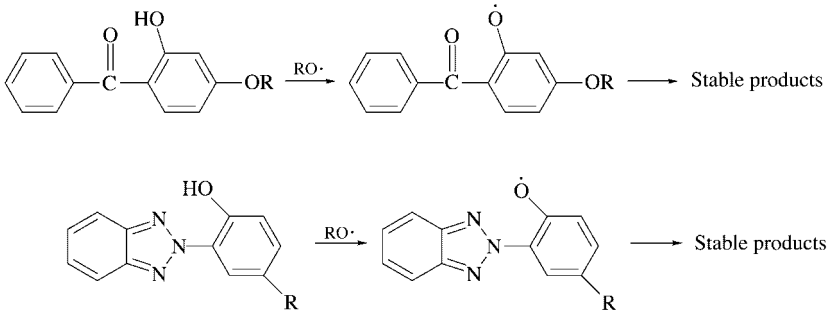
maleates, eg, **AO 35** (32) and result in drastic reduction, even disappearance, of both the unsaturation and peroxides from the polymer. This is almost certainly due to the presence of sulfur in the thiotin molecule which offers highly effective PD activity. The acidic species are formed by reaction with hydroperoxide (see Scheme 19, reactions a–c>) in a manner which is analogous to the formation of sulfur acids from thiodipropionate ester. Moreover, reaction with HCl results in the formation of thioglycollate (Scheme 19, reaction d), which adds to the developing monomeric unsaturation (formed by HCl elimination), thus removing the sensitizing allylic methylene groups (see Scheme 19, reaction e). The monosulfides formed are themselves effective macromolecular antioxidants.

Photostabilization

As with thermal stabilizers, photostabilizers must satisfy basic chemical and physical requirements. In addition, they must be photostable, ie, stable to uv light, able to withstand continuous periods of uv exposure without being prematurely destroyed, or effectively transformed into sensitizing products. There are essentially three classes of compounds that are categorized as photostabilizers: uv absorbers and pigments, peroxide decomposers including nickel complexes, and sterically hindered amine light stabilizers (see UV STABILIZERS).

Ultraviolet Absorbers and Pigments. Most of the UVA used commercially fall into two main classes of compounds: the 2-hydroxybenzophenones (eg, **AO 28**, Table 3) and the 2-hydroxybenzotriazoles (eg, **AOs 29–32**, Table 3) with the 2-hydroxy group being essential for their activity (143). These UVA operate by additional mechanisms too, for example, by removing initiating radicals (eg, alkoxyl radicals) in a weak CB-D mechanism (see Scheme 20). (144–146). Further, UVA, such as **AO 28**, synergize effectively with peroxide decomposers, eg, metal dithiolates (see Table 15 later).

Ultraviolet-screening pigments have been used extensively to protect polymers against the harmful effect of uv radiation. For example, carbon black imparts an extraordinary stabilizing power, mainly on account of its high uv-absorbing capacity. However, like other UVA, carbon black has additional photoantioxidant



Scheme 20. Chain-breaking stabilizing activity of UVA.

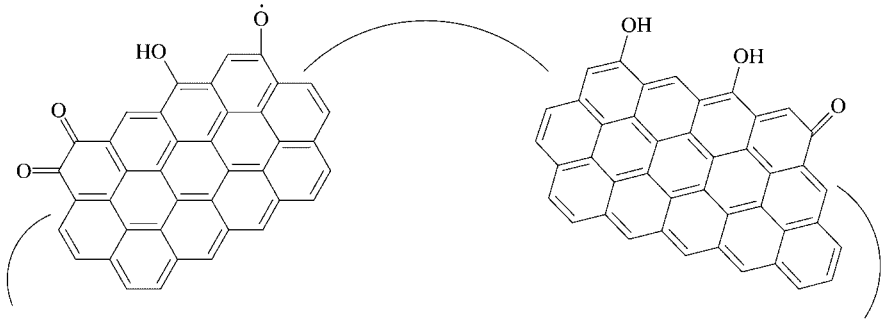


Fig. 4. Carbon black, simplified structure.

activities associated with its chemical structure (147,148). Carbon black has a highly condensed aromatic ring structure with small amounts of phenolic, ketonic, carboxyl functions, and a relatively high concentration of 'oxyl' radicals which are stabilized in the conjugated system (see Fig. 4). These structural features give carbon black its radical scavenging ability and CB function (147). Carbon black has (PD) activity too because of its acidic nature (148).

Peroxide Decomposers and Nickel Complexes. The photostability of these stabilizers vary according to the stability of their transformation products to uv light. Simple sulfides such as the thiodipropionate esters (eg, **AO 19** or **AO 20**, Table 3), which are good melt stabilizers, are unstable to light because of dissociation of their primary oxidation products to photoinitiating radicals (see Scheme 13, reaction f), and are not useful as photostabilizers. Similarly, conventional chain-breaking antioxidants, such as hindered phenols which are excellent melt and long-term stabilizers, have only very limited photostabilizing activity due to photo–pro-oxidant effects of some of their transformation products (see Scheme 15, reaction m).

Metal complexes of dithioic acids, eg, dithiocarbamates, dithiophosphates, xanthates (MDRC, MDRP, MRX, respectively) (see **AOs 21–24**, Table 3), which are highly effective catalytic peroxide decomposers (PD-C) and excellent melt stabilizers, are generally effective photostabilizers (101,105,136,137,139,149). Their

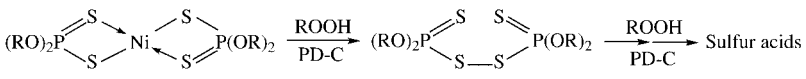
effectiveness is attributed mainly to the much higher uv stability of dithiolates as compared to simple sulfides. However, both the nature of the metal ion in the dithiolate complexes and their concentration play a crucial part in their overall effectiveness as uv stabilizers. Transition metal complexes containing Ni, Co, and Cu are more photostable than Zn- and Fe-containing complexes, and hence are more effective (see Table 9). Furthermore, the photoantioxidant activity of nickel dithiolates is greatly affected by their solubility in the polymer (117) as was shown previously in their use as thermal stabilizers (see Fig. 3). These peroxide decomposers also synergize effectively when used in combination with UVA (see Table 9). Like most other metal dithiolates, the primary oxidation product formed during the antioxidant function of NiDRP (**AO 23**, Table 3) is the corresponding disulfide, DRDS, which undergoes further oxidation to give different sulfur acids (the real catalysts for peroxide decomposition) (Scheme 21).

Processing history can have a profound effect on the photoantioxidant activity of sulfur compounds. For example, the effective melt stabilizer thiophosphoryl disulphide, DRDS, formed as the primary oxidation product of NiDRP (see Scheme 21) is further converted to a more effective photoantioxidant by oxidative processing (150) (see Table 10). Similar oxidative processing (in presence of excess oxygen or added hydroperoxide and with increasing time) results in enhanced photoantioxidant activity of other sulfur-peroxidolytic antioxidants such as the mercaptothiazolines, RMTZ (151) (see Table 10). The oxidative transformation products of RMTZ have been identified (152) as more complex thiazolines



Scheme 21. Simplified mechanism of stabilization of nickel dithiophosphate and thiophosphoryl disulfide.

formed through the intermediacy of the disulfide, DMTZ. Further oxidation progressively depletes DMTZ of its sulfur content through the loss of low molecular mass sulfur acids (see Scheme 22). The final photoproducts absorb uv light above 290 nm, which, together with the slow libration of sulfur acids, is the reason for their improved photostabilizing activity with increasing processing severity.

Hindered Amine. Significant commercial development has been based on hindered piperidines (known as HALS, Hindered Amine Light Stabilizers) (see **AOs 25** and **26**, Table 3), which have been used extensively as photostabilizers in commercial polymers. HALS is a unique class of photostabilizers which do not subscribe to the general mechanisms of photostabilization: they are not uv screens, do not quench singlet oxygen or triplet carbonyls, and do not catalyze hydroperoxide decomposition. Their effectiveness, however, has been shown to be due to their primary transformation product, the corresponding nitroxyl radicals (>NO·), which is capable of scavenging alkyl radicals in competition with oxygen,

Table 11. Ultraviolet Stabilizing Effect of HALS-Based Antioxidants in PP[a]

ie, an effective CB-A antioxidant. Its photostabilizing mechanism also involves the regeneration of the nitroxyl radical from both the corresponding hydroxylamine (>NOH an effective CB-D) and alkylhydroxylamine (37,50,96,98,100,153,154) (see Scheme 11). The overall photoantioxidant efficiency is due to the complementary nature of the acceptor- and donor-antioxidant, (CB-A/CB-D) mechanisms of the >NO·/>NOH, both of which were shown (96) to be significantly more effective than the parent amine stabilizer (see Table 11 for **AO 28** and its derivatives).

Time-Controlled Stabilization

Environmental considerations and specialty applications continue to generate new markets for polymers. The need for polymers with limited lifetime, eg, for food (especially fast-food) packaging, in agricultural products, eg, mulching films and certain medical and pharmaceutical products, has encouraged the development of degradable plastics. These products are designed for a limited lifetime use after which they degrade rapidly. Degradable plastics should ideally fulfil the following requirements (155):

(1) The degradation process should occur at a controllable and predetermined rate to allow for safe-use. During its useful service life, the polymer is stabilized and retains its mechanical strength.
(2) At the end of service life, degradation is triggered off, with rapid catastrophic failure in mechanical strength, concomitant with the formation of low molar mass polymer degradation products.
(3) Complete degradation should follow, whereby the degradation products formed above would be assimilated by microorganisms to give biomass and, ultimately, carbon dioxide and water.

One approach that meets the above requirements involves the use of transition metal dithiolates for time-controlled stabilization. These can fulfil their

stabilizing function during processing, manufacture, and throughout the short service life, but subsequently photodegrade and catalyze photo-oxidative degradation of the polymer, thus referred to as "antioxidant-photoactivators" (37,138,155–157).

Ultraviolet exposure of polyolefins containing metal dithiolate stabilizers reveals the presence of an initial induction period, which is directly proportional to the stabilizer concentration and which ends very sharply upon its consumption. The end of the induction period marks the start of photo-oxidation, which proceeds at a rate which is primarily a function of the concentration and the nature of the free metal ion produced (37,101,105,158). Although all dithiolates are powerful peroxidolytic antioxidants and excellent melt stabilizers of polymers, they exhibit different uv stability depending on the metal center. The iron complexes, eg, FeDRC, exhibit very unique concentration-dependent behavior on uv-exposure compared to their nickel analogues, eg, NiDRC. In the case of NiDRC, increasing its concentration results in an increase in the induction period to photo-oxidation and a decrease in the post-induction rate of photo-oxidation, whereas the FeDRC shows a contrasting behavior whereby both the induction period and post-induction rate increase with increase in concentration (156). Thus, at low concentrations (below 0.05%) in polyolefins the FeDRC complexes photolyze rapidly, giving a minimal induction period to photo-oxidatoin; at higher concentrations, however, a longer induction period becomes evident, followed by inversion of activity, which results in rapid photo-oxidation (see Fig. 5) (156).

Photoactivation of FeDRC complexes produces iron carboxylates which are very powerful sensitizers of photo-oxidation due to their participation in redox reactions with hydroperoxides (37) (see Scheme 23) (in contrast, NiDRC complexes are not photoactivators since the librated free metal ion has no photo–prooxidant activity). On the other hand, the observed photoinduction period at higher concentrations of FeDRC (see Fig. 5) is a direct consequence of its photoantioxidant behavior due to oxidation of the sulfur ligand to low molar mass sulfur acids

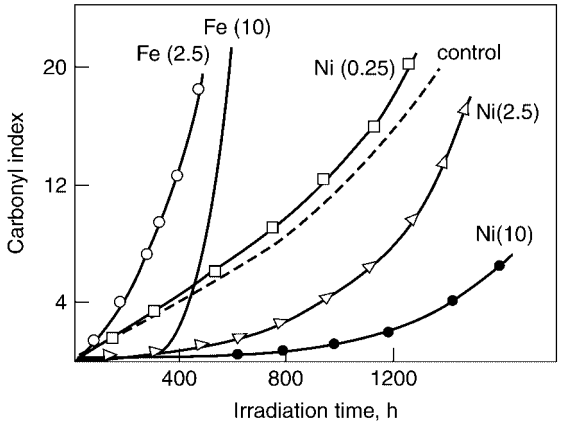

Fig. 5. Time-controlled photodegradation of LDPE stabilized with different concentrations of the photosensitize iron dithiocarbamate (FeDRC) and the photostabilizer nickel dithiocarbamate (NiDRC). Numbers on curves are antioxidant concentration in 10^{-4} mol/100 g (156).

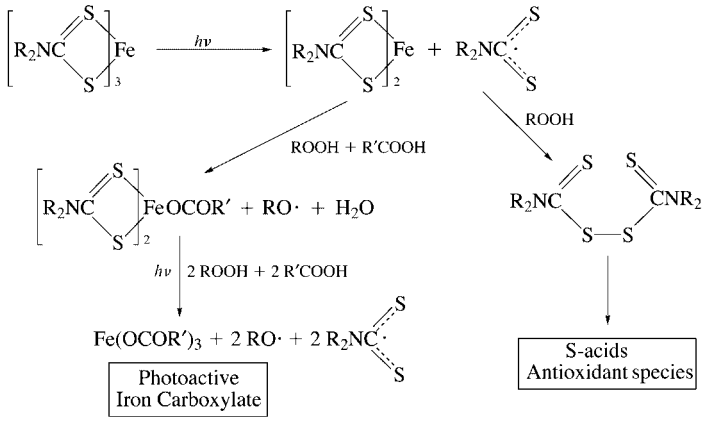

Scheme 23. Mechanism of action of the antioxidant-photoactivator FeDRC.

which are powerful antioxidants (158) by a mechanism similar to that described for the dithiophosphate.

It is this inversion in activity of FeDRC complexes from being photoantioxidants to becoming photoactivators (at the end of the induction period) which has made these antioxidant-photoactivators most suitable for the precise time-controlled stabilization. This has led to their commercial use in photobiodegradable plastics which are widely used in agricultural applications, eg, mulching films (155). In severe climates under intense uv radiation and high temperatures, two-component systems, which are based on combinations of iron and nickel dithiocarbamates, are generally used. This is mainly due to the fact that to achieve a reasonable length of the photoinduction period, a relatively high concentration of FeDRC is required, whereas a similar effect can be achieved with much lower concentrations of the more photostable nickel complexes (156). Overall, the choice of the final precise antioxidant-photoactivator system will depend on the required length of induction period and the rate of the activation process dictated by the end-use application.

Other Developments for More Efficient and Safer Stabilization

The problems of antioxidant loss from polymers in contact media, especially in human-contact applications, have generally been associated with the use of traditional low molecular mass antioxidants. Alternative types of antioxidants have been developed to address both questions of safety and efficiency. Three different approaches are highlighted here.

Higher Molar Mass Antioxidants. To address the problem of physical loss of antioxidants, oligomeric and macromolecular antioxidants were developed. A broad range of such antioxidants (both thermal- and photoantioxidants) have been synthesized (159) using a variety of methods (eg, free-radical

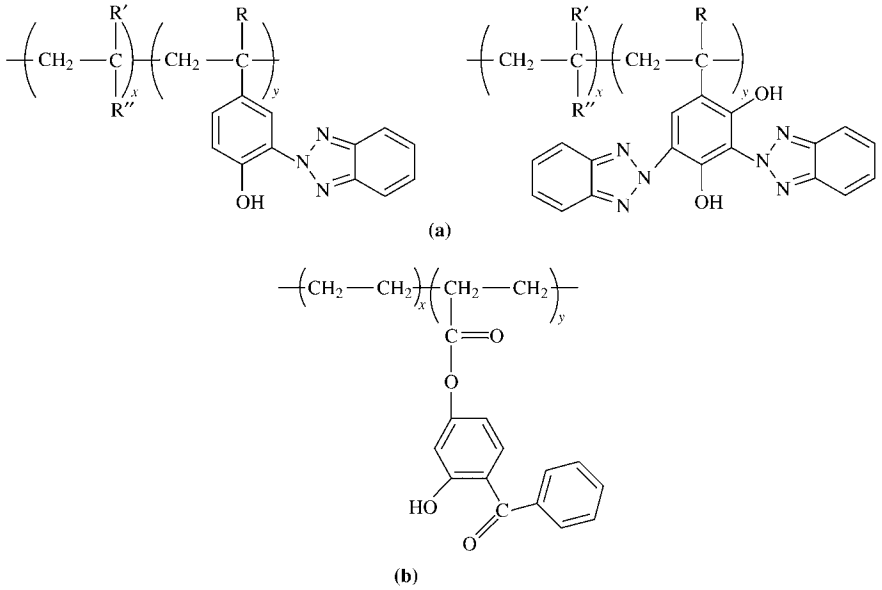
polymerization, ring-opening polymerization, and polycondensation processes). These antioxidants show superior retention, and hence superior performance under demanding service conditions, eg, at elevated temperatures in the presence of oils and other solvents (see Tables 12 and 13) (160,161). The synthetic routes to these macromolecular antioxidants are, however, generally more expensive and their characteristics are not always fully defined. Furthermore, their high molar masses could lead to a lowering of compatibility with the host polymer with serious consequences, especially in crystalline polymers, to adversely affect their performance. Indeed, only a relatively few cost-effective macromolecular antioxidants are in commercial use (159).

Reactive Antioxidants. Reactive antioxidants are compounds containing one or more antioxidant functions (the antioxidant component) and one or more chemical functions capable of reacting either with monomers (same or different) or with polymers (the reactive component). The antioxidant



Scheme 24. Examples of antioxidant modified polymers prepared by copolymerization of various monomers with reactive UVAs. (**a**) **Hydroxy benzotriazole-based antioxidants**: R=H, CH_3 (antioxidants with vinyl or isopropenyl reactive groups); R′=C_6H_5, R″=H (styrene), R′=$COCH_3$, R″=CH_3 (methyl methacrylate); R′=$COOCH_3$, R″=H (*n*-butyl acrylate). (**b**) **Hydroxy benzophenone-based antioxidant** copolymerized with ethylene.

moiety can be based on any of the conventional antioxidant functions discussed earlier, whereas the reactive group can be chosen from a variety of polymerizable or nonpolymerizable functions, eg, vinyl, allyl, α–β unsaturated acyl or amide groups (eg, acryloyl, acrylamide, methacryloyl, or methacrylamide), styrene, isopropenyl, epoxy, and mercaptan (162). There are basically two main approaches to adopt:

Copolymerization during Polymer Manufacture. Extensive work has been documented on the synthesis and successful copolymerization of a large number of polymerizable UVA containing one or two UVA functions (see Scheme 24 for selected examples) (163,164). However, the use of such antioxidants has been beset by high synthetic costs.

The use of phenolic and amino-based antioxidants (ie, thermal stabilizers) by this approach has been limited because they inhibit the free-radical polymerization process (polymerization inhibitor) leading to lower efficiency. One of the few commercial products produced is based on the polymerizable chain breaking antioxidant (**AO 12b**, Table 3), designed for NBR rubbers (Chemigum HR 665) that has been shown to offer superior antioxidant performance, especially under aggressive (hot oil/high temperature) conditions, compared to low molecular mass conventional aromatic amine antioxidants (165). In spite of the successful synthesis and copolymerization of a large number of reactive antioxidants, there is a lack of major commercial development and production of antioxidant systems

based on this approach. This is almost certainly due to both low efficiency of polymerization in the presence of certain antioxidant functions and, more importantly, to the high costs generally involved in the synthesis and production of tailor-made "speciality" materials for each specific application. However, this approach may be utilized in certain target applications where performance and reliability, especially under a demanding environment, is the ultimate design prerequisite, eg, in space and military applications.

Chemical Grafting Post Polymer Manufacture. Various chemical routes have been exploited to achieve grafting of reactive antioxidants onto preformed commercial polymers. Different routes are available, depending on the method used to achieve grafting reactions during vulcanization, by decomposition of free-radical initiators (peroxides, hydroperoxides, AIBN), by uv or γ irradiation of polymer surfaces, by mechanical scission, and during melt processing in the presence of added initiators. The main prerequisite here is that the reaction leading to chemical attachment of the antioxidant should be achieved without detriment to the overall polymer properties or the basic processes involved, eg, vulcanization in case of rubbers or melt processing/fabrication in plastics (162,166).

Reactive antioxidants containing some of the basic photoantioxidant functions (eg, HAS, UVA) and one or more polymer reactive functions can be made to react with polymers during melt processing. These reactions are normally achieved in the presence of a very small concentration of a free-radical initiator, and in some cases also in the presence of a coreactive monomer (162,166–176). Both chemical factors and processing parameters can be manipulated to achieve high levels of grafting of the functional antioxidants on the polymer. Table 14 illustrates the advantages, especially under extractive conditions, of using reactive photo-antioxidants which are highly grafted on PP, compared to traditional nonreactive (nongraftable) analogues (170–175). The grafted HAS photoantioxidant AOTP, for example, shows superior performance under extractive conditions compared to the commercial HAS, Tinuvin 770 (**AO 25**, Table 3) because it is less readily lost from the polymer during processing and service. Furthermore, both grafted HAS antioxidants, eg, AOTP (monofunctional) and AATP (bifunctional), structures in Table 14, synergize effectively when used in combination with other classes of photostabilizers, eg, UVA such as Chimassorb 81 (**AO 28**, Table 3). A graftable UVA based on a hydroxybenzophenone structure, HAEB, is also shown to give effective synergism in combination with a highly grafted hindered phenol, DBBA, when the grafting of the latter was conducted in the presence of a reactive nonantioxidant comonomer, Tris (see Table 14 for structure). The co-grafting of this polyfunctional comonomer (Tris) with mono-vinyl antioxidants (and other monofunctional additives) in extruders or internal mixers has been shown (174) to lead to the production of highly grafted antioxidants in noncross-linked polymer products without detriment to the physical and morphological characteristics (eg, crystallinity) of the polymer. Highly grafted and "permanently fixed" antioxidant concentrates (masterbatches) can be produced for blending with, and dilution in, polymers in the same way as conventional antioxidants.

It is important to point out here that there are different approaches to the grafting of antioxidants on polymers, each with its set of advantages and disadvantages. However, the behavior of grafted reactive antioxidants is similar to that

Table 14. Ultraviolet Embrittlement Times (EMT) of PP Films[a]

of their "traditional" low molecular mass analogues but offer greater permanency and stabilization of polymer compositions under more demanding conditions.

Biological Antioxidant. Safety issues and costly toxicity tests have focused attention on a new stabilization strategy that exploit the use of a fat-soluble biological antioxidant (vitamin E). α-Tocopherol (**AO 10**, Table 3), the most bioactive form of vitamin E, is a highly efficient biological chain-breaking antioxidant which is known to be involved in the natural defense mechanisms of living organisms (177,178).

Studies on vitamin E in polymers have demonstrated its high antioxidancy in different polymers, especially as a melt-processing stabilizer in polyolefins (119,179–186). Figure 6 shows the superior performance of vitamin E when compared to Irganox 1010 during melt extrusion of PE and PP at all concentrations and, in particular, at very low concentrations. Vitamin E can, therefore, be

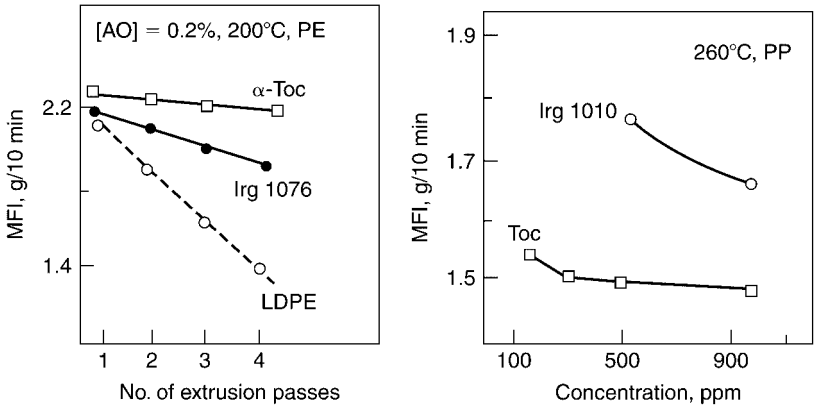

Fig. 6. The melt stabilizing activity of tocopherol and synthetic hindered phenols in PE and PP (119).

employed cost-effectively to stabilize polyolefins using only a small fraction of the concentration needed of typical synthetic hindered phenols. Its effectiveness is attributed to its efficient deactivation of macroradicals and to its oxidative transformation products which are themselves highly effective melt stabilizers (119).

In general, sterically hindered phenols contribute to some discoloration (yellowing) of polyolefins mainly through the formation of colored oxidation products, eg, quinonoid structures, and interactions with catalyst residues (187,188). The extent of discoloration depends on the chemical structure of the parent

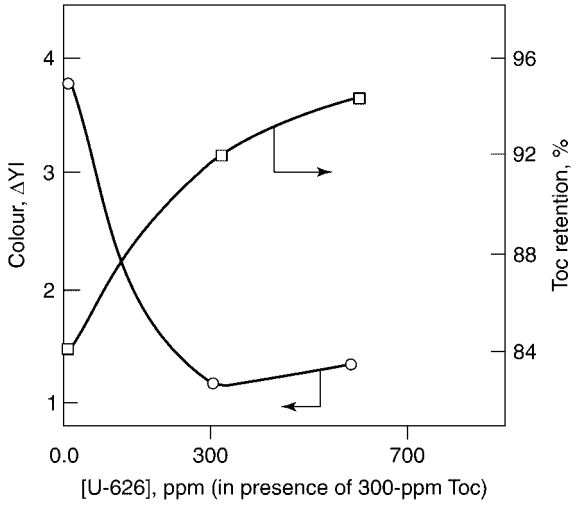

Fig. 7. Effect of the phosphite U-626 concentration in combinations containing 300-ppm Toc on color stability of PP and on the extent of tocopherol retention; PP extrusion at 260°C (119).

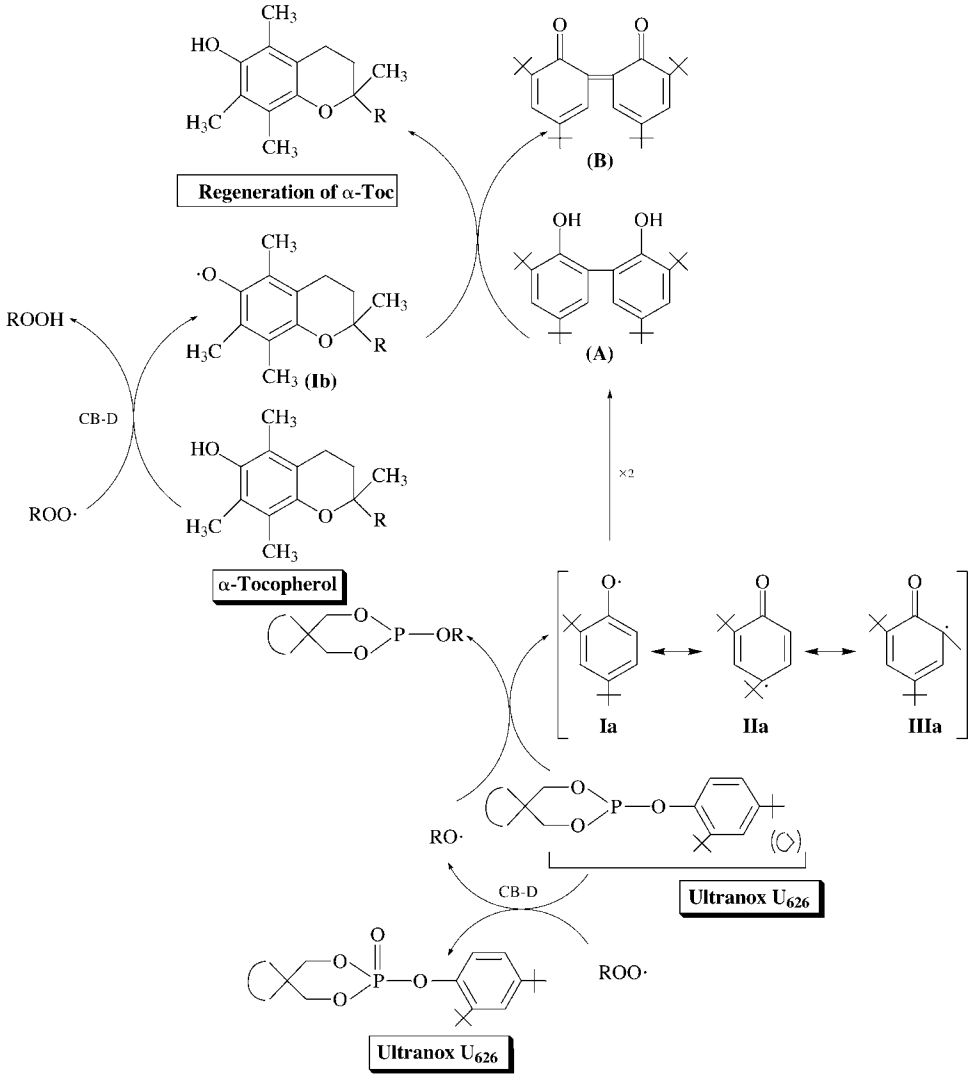
antioxidant, the oxidation products, and the type and amount of catalyst residues in the polymer. The use of a small concentration of certain co-stabilizers, such as phosphite esters, with hindered phenols result in reduced discoloration. In the case of vitamin E, the use of a small concentration of the phosphite U-626 (**AO 18**, Table 3) results in drastic reduction in discoloration, as well as an increase in the level of retention of the parent vitamin (see Fig. 7) (119). The reduction in consumption of other synthetic hindered phenol antioxidants by phosphite co-stabilizers has been reported, although the mechanism is not fully understood (189,190). In the case of the hindered aryl phosphite Ultranox U626 used in



Scheme 25. Cooperative interactions between aromatic phosphite and tocopherol, resulting in the regeneration of tocopherol.

combination with tocopherol, the evidence (191) points out to the regeneration of the parent tocopherol through a redox reaction between products of the two stabilizers. Scheme 25 illustrates this and shows that the phenoxyl radical produced through the CB activity of Ultranox U-626 undergoes a C—C coupling reaction to produce a hindered phenol dimer (**A**) which can react further with the tocopheroxyl radical in a redox process that regenerates the parent hindered phenol (119).

Synergism and Antagonism

The cooperative interaction between two or more antioxidants (or antioxidant functions) that enhances the stabilization of a polymer by more than the sum of the individual effects of the antioxidants is referred to as *synergism*. Often, the overall effectiveness of the synergistic system is much greater than can be achieved by either of the antioxidants, even at higher concentration, and hence the practical importance of synergism. Synergism can result from the combined action of two

Table 15. Synertistic and Antagonistic Effects on Photostability of LDPE processed at 150°C

[b] $\%\text{Synergism} = \frac{(E_s - E_c) - (E_1 - E_c) + (E_2 - E_c)}{E_1 - E_c + E_2 - E_c} \times 100$, where E_s is the embrittlement time of synergist; E_c is the embrittlement time of control; E_1 is the embrittlement time of antioxidant 1; and E_2 is the embrittlement time of antioxidant 2.

chemically similar antioxidants, eg, two hindered phenols (*homosynergism*), or from two different antioxidant functions present in the same stabilizer molecule, eg, Irganox 1081 (**AO 9**, Table 3) (*autosynergism*), or when separate stabilizer molecules that carry different antioxidant functions are physically blended in a stabilizer formulation (*heterosynergism*). Conversely, though infrequently, two antioxidants may interact antagonistically to cause a decrease in the sum of their individual contributions (2,51,192).

Highly effective UV-stabilizing systems can be achieved by the use of synergistic mixtures of compounds acting by different mechanisms. Table 15 illustrates the synergism obtained from combinations of different metal dithiolates with the UVA Chimassorb 81 (**AO 28**, Table 3) in LDPE (see Section on Antioxidants in Polymer Stabilization). In contrast to the synergistic effect obtained during thermal stabilization when hindered phenol antioxidants are mixed with sulfur-containing compounds, combinations of a phenolic antioxidant (eg, Irganox 1076; **AO 4**, Table 3) with metal dithiolates lead to antagonism during

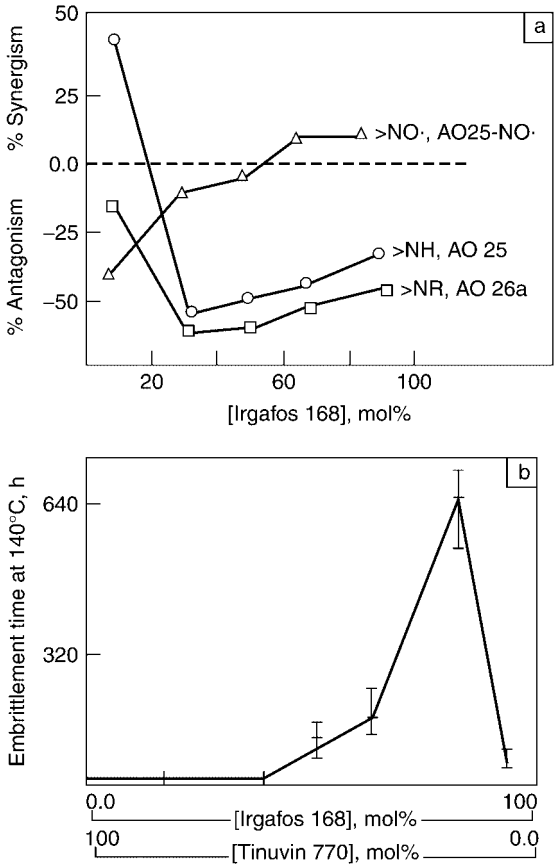

Fig. 8. Effect of molar composition of mixture of HALS and Irgafos 168 (total [AO] = 7×10^{-3} mol/kg in each case) on (**a**) extent of synergism and antagonism during photooxidation of PP (193), and (**b**) thermoxidative stability of PP in air oven (195).

photostabilization (see Table 15) (3,105). This antagonistic behavior has been attributed to sensitisation leading to photolytic destruction of the dithiolates by oxidation products of phenols, particularly stilbenequinones. Stabilizers that contain two different antioxidant functions (eg, PD and CB activities) in the same molecule, such as phenolic sulfides, show much higher molar intrinsic activity as thermal antioxidants (due to autosynergism) than conventional hindered phenols with only CB activity (51).

Hindered piperidines (HAS) exhibit a complex behavior when present in combination with other antioxidants and stabilizers. As discussed earlier (see section on Hindered Amine) these have to be oxidized first to the corresponding nitroxyl radical before becoming effective. Consequently, both CB-D and PD-C antioxidants that remove alkyl peroxyl radicals and hydroperoxides, respectively, antagonize the uv-stabilizing action of this class of compounds (see Fig. 8a) (193,194). However, since the hindered piperidines themselves are neither melt- nor thermal-stabilizers for polymers, they have to be used with conventional antioxidants and stabilizers. Effective synergism in both melt and thermal stabilization has been achieved when secondary and tertiary HALS were used in combination with both aromatic and aliphatic phosphites, the synergistic optimum depending on the structure of the phosphite (see Fig. 8b) (195). Hindered piperidines have also been reported to synergize with UVA, eg, benzotriazoles, in different polymers such as PP, PS, and ABS (53,196).

Conclusion

The combined effects of oxygen, water, heat, and light are generally extremely detrimental to the lifetime performance of polymers during processing, fabrication, and throughout the useful lifetime of its artifacts, recycling, and subsequent lifecycles. Stabilizers and antioxidants are, therefore, essential ingredients in almost all plastics formulations. Hydroperoxides are key initiators of oxidative degradation resulting in free-radical formation in polymers. Antioxidants are used to prevent the formation of hydroperoxides and/or to convert them into harmless chemicals (peroxidolytic antioxidants), or to deactivate the free radicals, eg, alkyl and alkylperoxyl, formed (chain-breaking antioxidants).

Apart from economic factors, the choice of stabilizers for end-use application is dictated by chemical, physical, and toxicological considerations. Stabilization of polymers during melt processing, heat aging, and outdoor exposure is normally achieved through the use of synergistic combinations of well-known commercial stabilizers with complementary antioxidant mechanisms. For example, the use of chain-breaking hindered phenols in combination with peroxidolytic phosphite antioxidants is a common practice to affect melt stabilization of polymers, whereas the use of different HAS in the presence or absence of uv absorbers is a general approach to photostabilisation. Ultimately, however, the selection of an antioxidant package needs to be specifically tailored for the end-use application with due attention to other critical considerations, for example, color and toxicity. Issues of efficiency and safety (including migration) of stabilizers have been at the forefront of recent progress made in the areas of macromolecular, reactive, and biological antioxidants. Further progress will almost certainly involve optimization and fine

tuning of the physical and chemical performance of the wide range of commercially available antioxidants and stabilizers.

STRESS RELAXATION. See VISCOELASTICITY.

STYRENE POLYMERS

Introduction

Polystyrene (PS), the parent of the styrene plastics family, is a high molecular weight, linear polymer. Its chemical formula $[-CH(C_6H_5)CH_2-]n$, where n (which for commercial uses) is between 800 and 1400, tells little of its properties. The main commercial form of PS (atactic PS) is amorphous and hence possesses high transparency. The polymer chain stiffening effect of the pendant phenyl groups raises the glass-transition temperature (T_g) to slightly over 100°C. Therefore, under ambient conditions, the polymer is a clear glass, whereas above the T_g it becomes a viscous liquid which can be easily fabricated, with only slight degradation, by extrusion or injection-molding techniques. It is this ease with which PS can be converted into useful articles that accounts for the very high volume (>20 billion pounds per year) used in world commerce. Even though crude oil is the source of the polymer, the energy savings and environmental impact accrued during fabrication and use, compared to alternative materials, more than offsets the short life of many PS articles (1).

Commercial manufacture of PS in North America began in 1938 by The Dow Chemical Co. The polymerization process involved loading 10-gal cans with neat styrene monomer and immersing the can in a liquid bath heated at progressively higher temperatures over several days until the monomer conversion reached 99%. The solid polymer was removed from the cans and any rust spots chipped off the cylinders of polymer with a hatchet (Fig. 1). The cylinders of polymer were finally ground into a powder and packaged for shipment to customers.

Within a few years, Dow replaced the "can process" with the more economical continuous bulk polymerization process still used today. Generally, the key problems associated with manufacture of the polymer are removal of the heat

of polymerization and pumping of highly viscous solutions. Conversion of the monomer to the polymer is energetically very favorable and occurs spontaneously on heating without the addition of initiators or catalysts. Because it is a continuous polymerization process, material-handling problems are minimized during manufacture. By almost any standard, the polymer produced is highly pure and is usually greater than 99 wt% PS; however, for particular applications processing aids are often deliberately added to the polymer. Methods for improving the toughness, solvent resistance, and upper use temperature have been developed. Addition of butadiene-based rubbers increases impact resistance, and copolymerization of styrene with comonomers such as acrylonitrile or maleic anhydride produces heat- and solvent-resistant plastics. Uses for these plastics are extensive. Packaging applications, eg, disposable cups, meat and food trays, and egg cartons, are among the largest area of use for styrene plastics. Rigid foam insulation in various forms is being used increasingly in the construction industry, and modified styrene plastics are replacing steel or aluminum parts in automobiles. These applications result in energy savings beyond the initial investment in crude oil. The cost of achieving a given property, eg, impact strength, is among the lowest for styrene plastics as compared to other competitive materials.

Properties

The general mechanical properties of styrene polymers are given in Table 1. Considerable differences in performance can be achieved by using the various styrene plastics. Within each group, additional variation is expected. In choosing an appropriate resin for a given application, other properties and polymer behavior during fabrication must be considered. These factors depend on the combination of inherent polymer properties, the fabrication technique, and the devices, eg, a mold used for obtaining the final object. Accordingly, consideration must be given to such factors as the surface appearance of the part and the development of anisotropy, and its effect on mechanical strength, ie, long-term resistance of the molding to external strain.

Physical. An extensive compilation of physical properties of PS is given in References 2 and 3. In general, a polymer must have a weight-average molecular weight (M_w) about 10 times higher than its chain entanglement molecular weight (M_e) to have optimal strength. Below M_e, the strength of a polymer changes rapidly with M_w. However, at about 10 times M_e, the strength reaches a plateau region (Fig. 2). For PS, the M_e is 18,100 (4). Thus, PS having a $M_w < 150{,}000$ is generally too brittle to be useful. This indicates why no general-purpose molding and extrusion grades of PS having $M_w < 180{,}000$ are sold commercially.

Stress–Strain. The strain energy, derived from the area under the stress–strain curve, is considered to indicate the level of strength of a polymer. High impact PS (HIPS) has a higher strain energy than an acrylonitrile–butadiene–styrene (ABS) plastic, as shown in Figure 3. However, based on different impact-testing techniques, ABS materials are generally more ductile than HIPS materials (6,7). The failure of the stress–strain curve to reflect this ductility can be related to the fact that ABS polymers tend to show only localized flow or necking tendency at low rates of extension and, therefore, fail at low elongation. HIPS extends uniformly during such tests, and the test specimen whitens over all of its length and extends well beyond the yield elongation. However, at higher testing speeds, ABS polymers deform more uniformly and give high elongations.

Tensile strengths of styrene polymers vary with temperature. Increased temperature lowers the strength. However, tensile modulus in the temperature region of most tests (−40–50°C) is affected only slightly. The elongations of PS and styrene copolymers do not vary much with temperature (−40–50°C), but the elongation

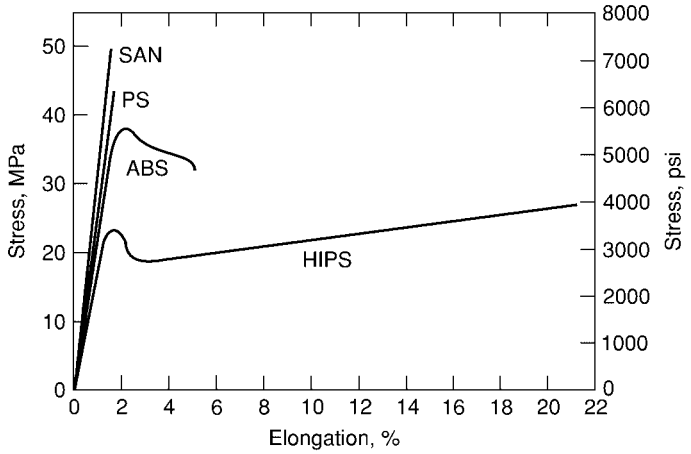

Fig. 3. Stress–strain curves for styrene-based plastics. To convert Mpa to psi, multiply by 145.

of rubber-modified polymers first increases with increasing temperature but ultimately decreases at high temperatures.

The molecular orientation of the polymer in a fabricated specimen can significantly alter the stress–strain data as compared with the data obtained for an isotropic specimen, eg, one obtained by compression molding. For example, tensile strengths as high as 120 MPa (18,000 psi) have been reported for PS films and fibers (8). Polystyrene tensile strengths below 14 MPa (2000 psi) have been obtained in the direction perpendicular to the flow.

Creep, Stress Relaxation, and Fatigue. The long-term engineering tests on plastics in extended use environments and temperatures are required for predicting the overall performance of a polymer in a given application. Creep tests involve the measurement of deformation as a function of time at a constant stress or load. For styrene-based plastics, many such studies have been carried out (9,10). Creep curves for styrene and its copolymers at room temperature show low elongation with only small variation with stress, whereas the rubber-modified polymers exhibit a low elongation region, followed by crazing and increasing elongation, usually to ca 20%, before failure (Fig. 4).

Creep tests are ideally suited for the measurement of long-term polymer properties in aggressive environments. Both the time to failure and the ultimate elongation in such creep tests tend to be reduced. Another test to determine plastic behavior in a corrosive atmosphere is a prestressed creep test in which the specimens are prestressed at different loads, which are lower than the creep load, before the final creep test (11).

Stress-relaxation measurements, where stress decay is measured as a function of time at a constant strain, have also been used extensively to predict the long-term behavior of styrene-based plastics (9,12). These tests have also been adapted to measurements in aggressive environments (13). Stress-relaxation measurements are further used to obtain modulus data over a wide temperature range (14).

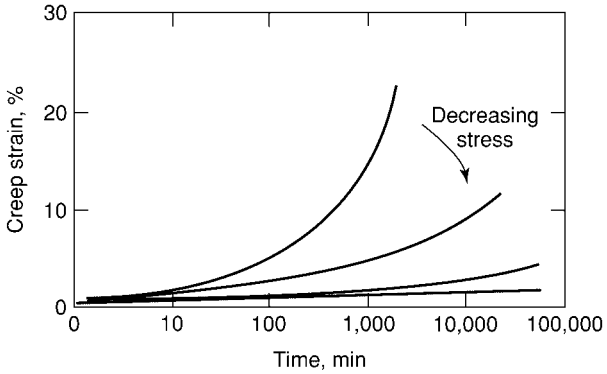

Fig. 4. Typical creep behavior for rubber-modified styrene polymers.

Fatigue is another property which is of considerable interest to the design engineer. Cyclic deflections of a predetermined amplitude, short of giving immediate failure, are applied to the specimen, and the number of cycles to failure is recorded. In addition to mechanically induced periodic stresses, fatigue failure can be studied when developing cyclic stresses by fluctuating the temperature.

Fatigue in polymers has been reviewed (15). Detailed theory and practice of fatigue testing are covered. Fatigue tests are carried out for two main reasons: to learn the inherent fatigue resistance of the material and to study the relationship between specimen design and fatigue failure. Fatigue tests are carried out both in air and in aggressive environments (16).

Melt Properties. The melt properties of PS at temperatures between 120 and 260°C are very important because it is in this temperature range that it is extruded to make sheets, foams, and films, or is molded into parts. Generally, it is desired to make parts having high strength from materials having low melt viscosity for easy melt processing. However, increased polymer molecular weight increases both strength and melt viscosity. The melt viscosity of PS can be decreased to improve its melt processability by the addition of a plasticizer such as mineral oil. However, the addition of a plasticizer has a penalty, ie, the heat-distortion temperature is lowered. In applications where heat resistance is very important, melt processability can be influenced, without a significant effect on heat resistance, by control of the polydispersity (17), by branching (18), or by the introduction of pendant ionic groups, eg, sodium sulfonate (19,20).

Impact Strength. When they fail, thermoplastic polymers typically dissipate energy either through microscopic shearing and/or crazing. Because of its inherently high entanglement molecular weight (19,000 g/mol), PS under plain strain conditions (thick parts) does not form shear bands. Thus, pure PS fails under tensile stress because of the formation of crazes (regions of microfibrils that bridge the top and bottom of a precursor crack) that rapidly develop into cracks and propagate catastrophically. Essentially, PS under plane strain conditions has a high yield stress and a low break stress. There can be very high local strains in the region of a craze, but very little material is deformed and little energy is dissipated. The crazes usually initiate at imperfections, such as surface scratches

or impurities in the bulk, and so as soon as one craze starts to form, the stress is concentrated at that site, the craze grows into a crack, and failure soon follows at very small macroscopic strain. Toughening PS involves finding ways to force it to form more crazes, thus dissipating more energy, or forcing it to deform by microscopic shear banding (21–24).

There are basically two different approaches used, and two different types of materials employed to obtain toughened PS. The first involves the use of dispersed rubber particles, which could have a variety of compositions including polybutadiene (PB) or various elastic block copolymers, in a continuous PS matrix. The second involves the use of styrenic block copolymers, or blends of block copolymers with PS homopolymer, where the block copolymer forms the continuous phase.

Dispersed rubber particles are the basis of toughening in HIPS. The toughening mechanism is quite complex, and the various ways in which dispersed rubber particles toughen PS have been discussed in detail (21–26). There are several ways in which the dispersed particles result in increased energy absorption during failure, but just two dominate. First, rubber particles result in the formation of multiple crazes, and thus the absorption of more energy. A rubber particle (assumed to be approximately spherical in shape) has a much lower modulus than PS. When a macroscopic tensile stress is applied to a medium containing soft, dispersed spheres, there is a stress concentration at the equator of the spheres, where the poles are in the direction of the applied stress. The stress at a distance from the particle is proportional to the particle size. It has been pointed out that for crazes to develop, a stress greater than that at the tip of a craze must extend at least three craze fibril dimensions into the matrix (22). Thus, while all particles result in stress concentration, small particles will not induce crazing because the critical stress does not extend far enough into the matrix. For HIPS, in which the rubber particles are composed of PB with PS occlusions, the minimum particle size to induce crazing is about 0.8 μm (22). Optimum toughening occurs with rubber particles from 1.0 to 2.0 μm.

The second major way in which rubber particles toughen PS is by allowing the formation of shear bands. Depending on the rubber particle size and volume fraction, the ligaments of PS between the rubber particles can become small enough (about 3.0 μm) so that if the rubber particles cavitate (due to triaxial stresses imposed by tensile deformation) the PS ligaments are under stress rather than strain (26). Under these conditions, the PS can shear band, thus absorbing considerable amounts of energy. Recent experimental work has emphasized the importance of shearing in addition to crazing in contributing to toughness in rubber-modified PS (24). Unfortunately, there are minimum rubber volume fractions and particle sizes for this mechanism to be effective, and those restrictions can result in significant light scattering and opacity as well.

The particle size restrictions for toughening PS depend on the mechanical properties of the rubber particle. For a HIPS rubber particle, with a Young's modulus of 333 MPa, the minimum size is 0.8 mm, while for a pure PB particle, with a Young's modulus of 47 MPa, the critical size is 0.44 mm (27). The stiffer the particle, the larger it must be. HIPS systems with bimodal particle size distributions can also be effective in toughening (28), but the bimodal particle size distribution is generally detrimental to optical clarity.

Dispersed rubber particles make other, less significant, contributions to the toughening of PS. Provided they are reasonably well adhered to the matrix and are somewhat tough, they can effectively terminate crazes and retard crazes from developing into cracks. The act of cavitation, either internal to the particle or at the particle–matrix interface, can absorb some energy, but an insignificant amount. Some adhesion of the rubber particle to the PS matrix is needed, but the exact role is not clear (23,25). In HIPS, the needed adhesion is provided by the PS that is grafted to the rubber particles during the polymerization process.

In summary, in order for dispersed rubber particles to toughen PS, they must be above a critical size, which is of the order of 0.8 μm, depending on the nature of the rubber. Higher concentrations of rubber particles will increase toughness by enabling more shear banding. Some adhesion between the rubber and matrix is also required.

HIPS materials can have a glossy or a dull surface appearance. This surface appearance is a function of surface roughness, which is caused by how much the rubber particles disrupt the surface regularity. The rubber particles near the surface can disrupt the surface by causing either depressions or elevations. These irregularities are caused not only by the nature of the rubber particles (eg, size and shape) but also by processing conditions. For example, during injection molding, the surface of the polymer is pressed against a very smooth polished mold surface and quenched locking in the smooth surface. However, when HIPS is extruded into sheets and thermoformed into parts, it is allowed to cool slowly giving the rubber particles near the surface time to relax. Polybutadiene rubber particles shrink upon cooling more than the PS matrix, thus causing depressions (29).

Material Types

General-Purpose (not rubber-toughened) PS (GPPS). GPPS is a high molecular weight ($M_w = 2–3 \times 10^5$), crystal-clear thermoplastic that is hard, rigid, and free of odor and taste. Its ease of heat fabrication, thermal stability, low specific gravity, and low cost results in moldings, extrusions, and films of very low unit cost. In addition, PS materials have excellent thermal and electrical properties, which make them useful as low cost insulating materials.

Commercial PSs are normally rather pure polymers. The amount of styrene, ethylbenzene, styrene dimers and trimers, and other hydrocarbons is minimized by effective devolatilization or by the use of chemical initiators (30). Polystyrenes with low overall volatile content have relatively high heat-deformation temperatures. The very low content of monomer and other solvents, eg, ethylbenzene, in PS is desirable in the packaging of food. The negligible level of extraction of organic materials from PS is of crucial importance in this application because of taste and odor issues.

When additional lubricants, eg, mineral oil and butyl stearate, are added to PS, easy-flow materials are produced. Improved flow is usually achieved at the cost of lowering the heat-deformation temperature. Stiff-flow PS has a high molecular weight and a low volatile level and is useful for extrusion applications. Typical levels of residuals in PS grades are listed in Table 2. Differences in molecular weight distribution are illustrated in Figure 5.

Table 2. Residuals in Typical Polystyrene, wt%

	Grade	
Polystyrene	Extrusion	Injection molding
Styrene	0.04	0.1
Ethylbenzene	0.02	0.1
Styrene dimer	0.04	0.1
Styrene trimer	0.25	0.8

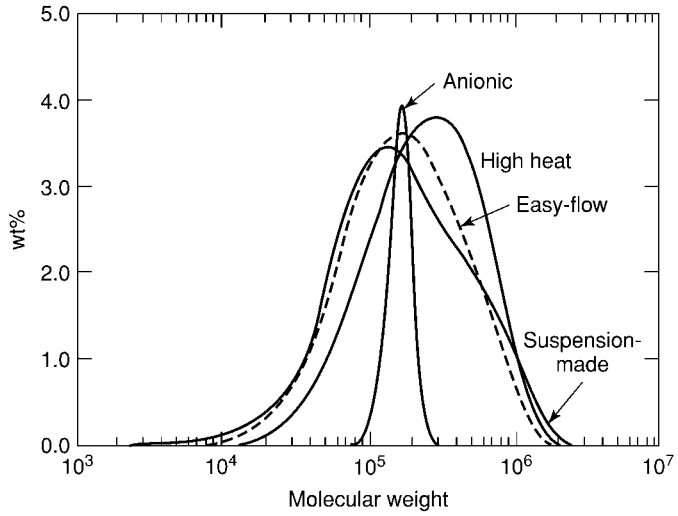

Fig. 5. Molecular weight distribution curves for representative PSs.

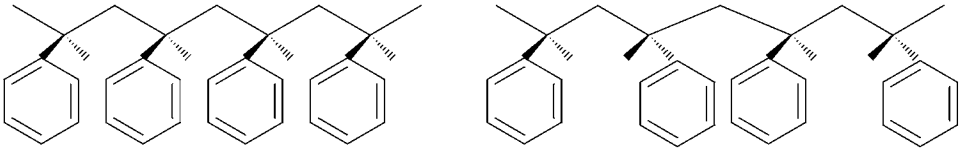
Specialty PS.

Ionomers. Polystyrene ionomers are typically prepared by copolymerizing styrene with an acid functional monomer (eg, acrylic acid) or by sulfonation of PS followed by neutralization of the pendant acid groups with monovalent or divalent alkali metals. The introduction of ionic groups into PS leads to significant modification of both solid state and melt properties. The introduction of ionic interactions in PS leads to increasing T_g, rubbery modulus, and melt viscosity (20). For the sodium salt of sulfonated PS, it has been shown that the mode of deformation changes from crazing to shear deformation as the ion content increases (31,32).

Tactic PS. Isotactic (iPS) and syndiotactic (sPS) PSs can be obtained by the polymerization of styrene with stereospecific catalysts of the Ziegler–Natta-type. Aluminum-activated $TiCl_3$ yields iPS while soluble Ti complexes [eg, $(\eta^5\text{-}C_5H_5)TiCl_3$] in combination with a partially hydrolyzed alkylaluminum [eg, methylalumoxane] yield sPS. The discovery of the sPS catalyst system was first reported in 1986 (33). As a result of the regular tactic structure, both iPS (phenyl groups cis) and sPS (phenyl groups alternating trans) are highly crystalline. Samples of iPS quenched from the melt are amorphous, but become

crystalline if annealed for some time at a temperature slightly below the crystalline melting point. The rate of crystallization is relatively slow compared to sPS and with other crystallizable polymers, eg, polyethylene or polypropylene. This slow rate of crystallization is what has kept iPS from becoming a commercially important polymer even though it has been known for over 40 years. sPS, on the other hand, crystallizes rapidly from the melt and is currently in the process of being developed for commercial use in Japan by Idemitsu Petrochemical Co. and in the United States and Europe by The Dow Chemical Co. In the amorphous state, the properties of iPS and sPS are very similar to those of conventional atactic PS. Crystalline iPS has a melting temperature of around 240°C, while sPS melts at about 270°C (34). In the crystalline state, both iPS and sPS are opaque and are insoluble in most common organic solvents.



Isotactic Syndiotactic

Stabilized PS. Stabilized PSs are materials with added stabilizers, eg, uv screening agents and antioxidants. Early stabilization systems for PS included alkanolamines and methyl salicylate (35). In recent years, improved stabilizing systems have been developed; these involve a uv-radiation absorber, eg, Tinuvin P (Ciba Specialty Chemicals) with a phenolic antioxidant. Iron as a contaminant, even at a very low concentration, can cause color formation during fabrication; however, this color formation can be appreciably retarded by using tridecyl phosphite as a costabilizer with the uv-radiation absorber and the antioxidant (36). Rubber-modified styrene polymers are heat-stabilized with nonstaining rubber antioxidants, eg, Irganox 1076 (Ciba). Typically, stabilizer formulations for PS are designed by trial and error. However, recently a predictive model was developed for PS photodegradation allowing the prediction of weatherability of PS containing a certain concentration of a uv absorber (37).

Ignition-Resistant PS. Polymers containing flame retardants have been developed. The addition of flame retardants does not make a polymer noncombustible, but rather increases its resistance to ignition and reduces the rate of burning with minor fire sources. The primary commercial developments are in the areas of PS foams (see FOAMED PLASTICS) and television and computer housings. Both inorganic (hydrated aluminum oxide, antimony oxide) and organic (alkyl and aryl phosphates) additives have been used (38). Synergistic effects between halogen compounds and free-radical initiators have been reported (39). Several new halogenated compounds and corrosion inhibitors are effective additives (40) (see CORROSION AND CORROSION INHIBITORS). The polymer manufacturer's recommendations with regard to maximum fabrication temperature should be carefully observed to avoid discoloration of the molded part or corrosion of the mold or the machine.

Antistatic PS. Additives or coatings are utilized to minimize primarily dust-collecting problems in storage (see ANTISTATIC AGENTS). Large lists of commercial antistatic additives have been published (38). For styrene-based polymers, alkyl and/or aryl amines, amides, quaternary ammonium compounds, anionics, etc are used (see ADDITIVES).

Branched PS. Random-chain branching is found, to some extent, in all commercial free-radically produced polymers. Branching takes place during manufacture by chain transfer to polymer and can also take place in the polymer after manufacture by exposure to uv or other forms of radiation. Chain branching in some polymers is known to improve certain properties and is practiced commercially (eg, polyethylene and polycarbonate). In PS, many types of branch structures have been synthesized and the effect of branch structure on properties studied. Some of the branch structures possible in PS are shown in Figure 6.

Most of the recent studies of branched PS have focused on new synthetic methodologies (41–52) and on rheological properties (53–56).

Anionic polymerization has been the polymerization mechanism most widely used to make and study branched PSs. This is likely due to the ability to control the termination step, which is required for making many of the branch architectures shown in Figure 6. However, all large-scale PS production plants utilize free-radical polymerization chemistry. This is likely due to the cost associated with monomer purification needed for the anionic chemistry (57).

The PS business is extremely cost competitive. Oftentimes, an improvement in properties which is possible with a modification that would add a few percentage to the manufacturing cost is not practical because the customer will not pay the increased cost. Any property advantage must be very significant before the customer will pay more. It is likely that branching in PS may lead to improved performance of PS in certain applications. However, it is uncertain whether the

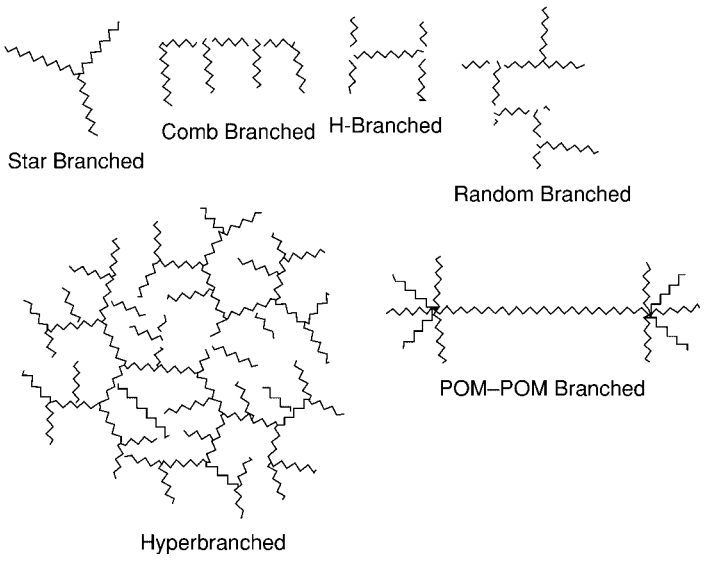


Fig. 6. Several possible PS branch architectures.

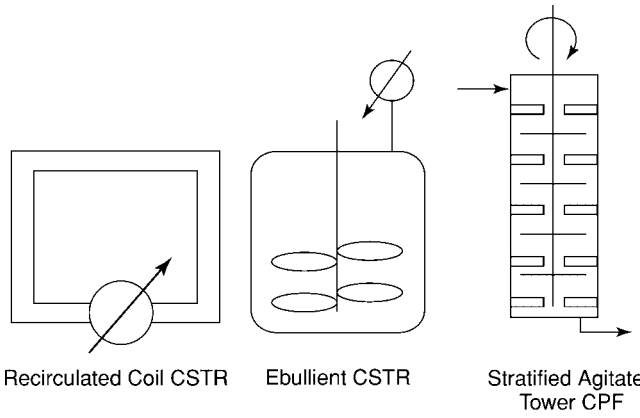

Fig. 7. Two Continuous stirred tank reactors (CSTR) and a continuous plug flow reactor (CPFR) configuration utilized for continuous mass polymerization of styrene.

increased performance will be significant enough to allow an increase in the selling price of the resin.

Since all commercial PS is currently manufactured using continuous free-radical bulk polymerization, most industrial research aimed at producing branched PS have been limited to free-radical chemistry. In general, the type of branch architecture that is possible using free-radical chemistry is limited to random-branched structures. Three reactor types are used commercially for continuous free-radical bulk polymerization of styrene (Fig. 7). These three reactor types are characterized as being either plug-flow or backmixed. Continuous plug-flow reactors (CPFR) typically have excellent radial mixing but virtually no backmixing, unless they are recirculated. These reactors are usually described as stratified agitated tower reactors. Continuous stirred tank reactors (CSTR), on the other hand, have high degrees of backmixing. They are usually single-staged and operated isothermally and at constant monomer conversion. CPFR-type reactors, on the other hand, are multistaged, having a temperature profile of typically 100–170°C. Two general configurations of CSTR reactors are utilized commercially, ie, recirculated coil and ebullient.

Typically, a few percentage by weight of a chain-transfer solvent (eg, ethylbenzene) is utilized during continuous free-radical bulk polymerization. The addition of a chain-transfer solvent to the polymerization decreases polymer molecular weight and therefore overall plant capacity when making high molecular weight products. However, the presence of some chain-transfer solvent is essential in keeping the polymerization reactor from becoming eventually fouled with gel and insoluble cross-linked polymer. The mechanism of buildup during continuous free-radical bulk polymerization without a chain-transfer solvent is likely chain transfer to polymer.

Peroxide initiators typically utilized for the manufacture of PS form *t*-butoxy (58) and/or acyloxy radical intermediates (59). These radicals have a strong propensity to abstract H-atoms. This propensity has found utility when making HIPS. For example, the use of initiators which generate *t*-butoxy radicals increases

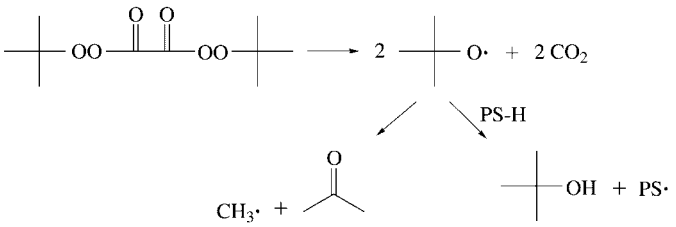

Fig. 8. Formation of *t*-butoxy radicals and their use to measure H-abstraction.

the level of grafting of PS onto PB rubber. The increase in grafting is generally thought to be due to H-abstraction from the rubber backbone by *t*-butoxy radicals (60). This raises questions regarding the extent of H-abstraction from the PS backbone during polymerization; that is, the use of initiators that generate potent H-abstracting radicals may increase the extent of long-chain branching during PS manufacture. This question has been investigated by decomposing bis(*t*-butylperoxy)oxalate in benzene solutions of PS (61,62). Bis(*t*-butylperoxy)oxalate decomposes upon heating to form two *t*-butoxy radicals and carbon dioxide. Once the *t*-butoxy radicals are formed they either abstract an H-atom or decompose to form acetone and a methyl radical (Fig. 8).

The extent of H-abstraction was determined by measuring the ratio of *t*-butyl alcohol (TBA)/acetone produced. Using cumene as a model for PS, a high level of H-abstraction was observed. However, PS showed a very low level of H-abstraction, which decreased further as the degree of polymerization (DP) of the PS was increased (Fig. 9). This was explained by the coil configuration of the PS chains restricting access of the *t*-butoxy radicals to the labile tertiary benzylic H-atoms on the PS backbone.

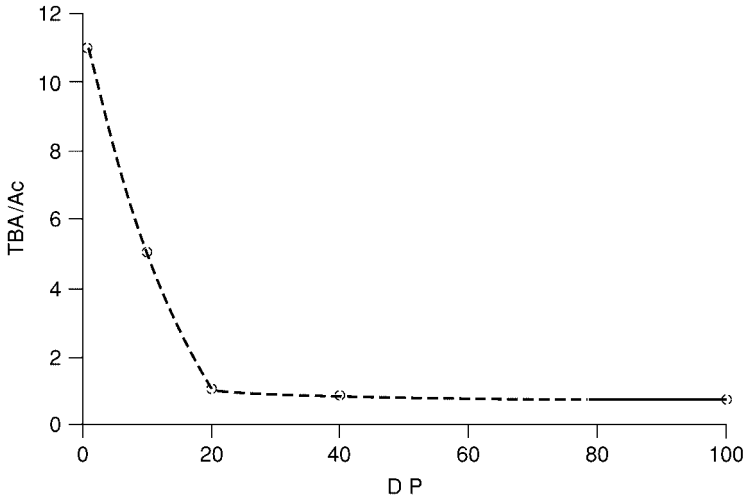

Fig. 9. H-abstraction as the ratio of *t*-butyl alcohol (TBA) to acetone (Ac) vs DP of PS (61,62).

The long-chain branching that takes place during PS manufacture in using continuous free-radical bulk polymerization reactors is extremely small. However, manufacturers of PS for film applications, where gel particles are a big problem, constantly monitor their product for gel. If the level of gel gets too high, the polymerization reactor must be cleaned to remove the coating of gel on the reactor walls. The mechanism of gel formation is not certain, but it is generally believed that a polymer layer forms on metal surfaces inside the polymerization reactor (63). The layer is dynamic, but the polymer chains that are in the layer are exposed to a free-radical environment for a longer period of time than are polymer chains in solution. The longer PS is exposed to free radicals, the more backbone H-abstraction can take place. Furthermore, the concentration of PS in the absorbed layer is very high. Thus, the "gel" effect (Trommsdorff effect) (64) may contribute to increased molecular weight growth in the layer. In any event, the layer of polymer ends up becoming higher in molecular weight than other chains. Eventually, cross-links form between the chains leading to infinite molecular weight. This effect not only can lead to the formation of gel, but can eventually result in reactor fouling if not controlled. Suspension polymerization does not have this problem. Addition of low levels (ie, 100–500 ppm) of a divinyl monomer to suspension styrene polymerization leads to the formation of branched PS without problems with reactor fouling. However, even though suspension polymerization can be used to produce branched PS, it is no longer practiced commercially for economic reasons.

The approaches to branching during continuous bulk free-radical polymerization that have been reported include the addition of a small amount of divinyl monomer (65), vinyl functional initiator (66), polyfunctional initiator (67), and vinyl functional chain-transfer agent (68) to the polymerization mixture. Researchers at Dow have investigated all of these approaches in using continuous free-radical bulk polymerization and found that they all lead to gel and eventual reactor fouling after a few days of continuous operation, even in the presence of a chain-transfer solvent. They found that only if a chain-transfer agent is added to the continuous free-radical bulk polymerization to maintain a high level of termination, could branched PS be produced without reactor fouling (69).

More recently, Dow researchers developed a new approach to making branched PS using continuous free-radical bulk polymerization, which eliminates the potential of reactor fouling by carrying out the branching after the polymer exits the polymerization reactor (70). The concept is to incorporate latent functional groups into the polymer backbone during the polymerization, which subsequently react to form a cross-link after the polymer exits the polymerization reactor (Fig. 10). The requirement is that the functional groups be inert at polymerization temperatures (100–160°C) and then during the devolatilization step while

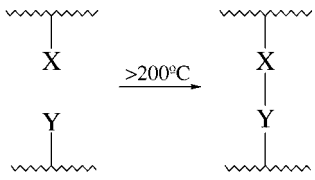

Fig. 10. General approach to post-polymerization reactor branching (cross-linking).

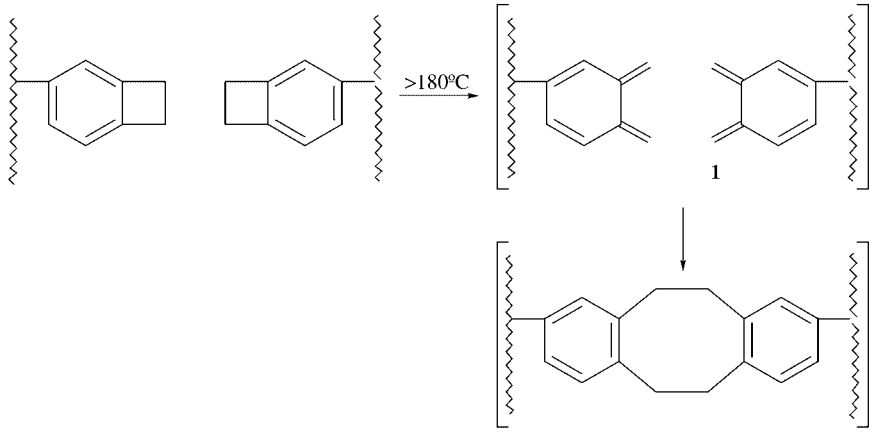

Fig. 11. Branching (cross-linking) chemistry of pendant BCB-functionalized PS.

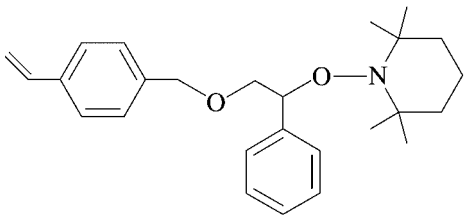
the polymer is heated to 240°C, the groups must efficiently couple in the viscous polymer melt.

The functional group that worked best was benzocyclobutene (BCB) (48,71). BCB functional initiators were used to place BCB functional groups on the PS chain ends and BCB functional comonomers were used to place BCB groups pendant along the PS backbone. BCB is a very unique molecule in that it is totally inert at temperatures <180°C. However, at temperatures >200°C the strained four-membered ring opens resulting in the formation of a highly reactive orthoquinonemethide intermediate (**1**), which couples with another orthoquinonemethide on another PS chain resulting in the formation of a cross-link (Fig. 11).

One of the key reasons that it is difficult to long-chain branch PS without formation of cross-linked gel is due to the fact that the main mechanism of termination taking place in normal free-radical polymerization processes is radical coupling. Thus, dynamic (growing) high molecular weight branched polystyryl radicals couple together. This problem can be virtually eliminated using new controlled radical polymerization techniques. Soluble hyperbranched PS, previously only prepared using anionic polymerization chemistry, has been prepared using this technique. The controlled radical polymerization process was carried out using styrene having an alkoxyamine substituent (**2**) making it an A_2B monomer, which is well known to yield soluble hyperbranched polymers (72).



2

Styrene Copolymers. Acrylonitrile, butadiene, α-methylstyrene, acrylic acid, and maleic anhydride have been copolymerized with styrene to yield commercially significant copolymers. Acrylonitrile copolymer with styrene (SAN) is the largest volume styrenic copolymer and is used in applications requiring increased strength and chemical resistance over PS. Most of these polymers have been prepared at the crossover or azeotrope composition, which is ca 24 wt% acrylonitrile (see COPOLYMERIZATION).

Copolymers are typically manufactured using well-mixed CSTR processes to eliminate composition drift that causes a loss in transparency. SAN copolymers prepared in batch or continuous plug-flow processes, on the other hand, are typically hazy because of composition drift. SAN copolymers with as little as 4 wt% difference in acrylonitrile composition are immiscible (73). SAN is extremely incompatible with PS. As little as 50 ppm of PS contamination in SAN causes haze. Copolymers with over 30 wt% acrylonitrile are available and have good barrier properties. If the acrylonitrile content of the copolymer is increased to >40 wt%, the copolymer becomes ductile. SAN copolymers constitute the rigid matrix phase of the ABS engineering plastics.

Unlike PS homopolymers, SAN copolymers turn yellow upon heating. The extent of discoloration is proportional to the percentage of acrylonitrile in the copolymer (74). Generally, the mechanism of discoloration is thought to involve cyclization of acrylonitrile polyads in the polymer backbone, as depicted in Figure 12. However, recent studies have revealed that oligomers also contribute to discoloration. Specifically, one of the SAN trimer structures containing one styrene and two acrylonitrile units was found to thermally decompose resulting in the formation of a naphthalene derivative (Fig. 13), which readily oxidizes to form a highly colored species. The relative contribution of oligomers and polymer backbone polyad cyclization to overall discoloration is about equal.

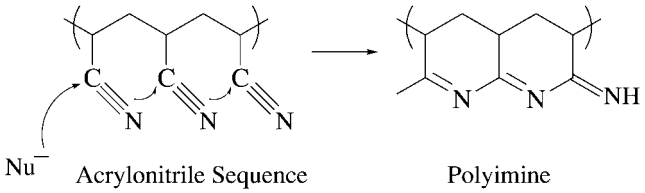


Fig. 12. Formation of red/yellow upon heating SAN triad in polymer backbone.

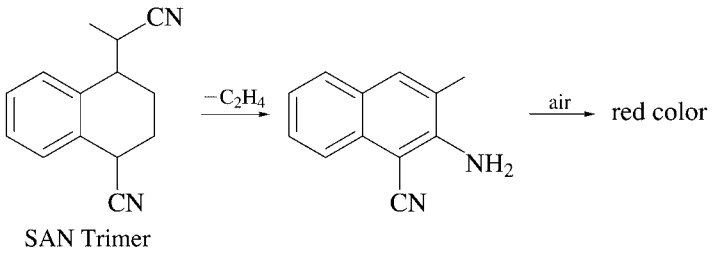

Fig. 13. Formation of red/yellow upon heating SAN trimer.

Styrene–butadiene copolymers are mainly prepared to yield rubbers (see ELASTOMERS; STYRENEUTADIENE COPOLYMERS). Many commercially significant latex paints are based on styrene–butadiene (weight ratio usually 60:40 with high conversion) copolymers (see COATINGS; PAINT). Most of the block copolymers prepared by anionic catalysts, eg, *sec*-butyl lithium, are also elastomers. However, some of these block copolymers are thermoplastic rubbers, which behave like cross-linked rubbers at room temperature but show regular thermoplastic flow at elevated temperatures (75,76). Diblock (styrene–butadiene) and triblock (styrene–butadiene–styrene) copolymers are commercially available. Typically, they are blended with PS to achieve a desirable property, eg, improved clarity/flexibility (76) (see POLYBLENDS). These block copolymers represent a class of new and interesting polymeric materials (77,78). Of particular interest are their morphologies (79–82), solution properties (83,84), and mechanical behavior (85,86).

Maleic anhydride readily copolymerizes with styrene to form an alternating structure. Accordingly, equimolar copolymers are normally produced, corresponding to 48 wt% maleic anhydride. However, by means of CSTR processes, copolymers with random low maleic anhydride contents can be produced (87). Depending on their molecular weights, these can be used as chemically reactive resins, eg, epoxy systems and coating resins, for PS-foam nucleation, or as high heat-deformation molding materials (88).

Recently, it has been discovered that styrene forms a linear alternating copolymer with carbon monoxide using palladium(II)–phenanthroline complexes. The polymers are syndiotactic and have a crystalline melting point $\sim 280^{\circ}$C (89). Currently, Shell Oil Co. is commercializing carbon monoxide α-olefin plastics based upon this technology (90).

Currently, Dow is commercializing ethylene–styrene interpolymers (ESI). Dow uses what they call a constrained-geometry metallocene catalyst (91). The classical heterogeneous Ziegler–Natta catalysts are generally ineffective for copolymerizing ethylene with styrene. ESI made by Dow have a "pseudorandom" structure meaning they do not contain any regioregularly arranged SS sequences, even at styrene contents approaching 50 mol%. Dow claims that the constrained-geometry of the catalyst (caused by the chelate ligand) plays a critical role in favoring the incorporation of the styrene. The technical significance of Dow's new catalyst is that the ESI resins are not contaminated with polyethylene or PS homopolymers, which generally results using alternate catalyst systems. A wide range of ESI resins have been prepared depending upon the ethylene/styrene ratio in the polymerization feed. Incorporation of high amounts of styrene into the copolymer requires the use of very high ratios of styrene. This presents a challenge at the end of the process because the unreacted styrene is removed by high temperature vacuum devolatilization, which can lead to some contamination by atactic PS (by spontaneous free-radical polymerization) if not done properly. ESI copolymers containing low levels of styrene are crystalline thermoplastics (92) while increasing the styrene content leads to a rapid decrease in crystallinity affording materials displaying excellent elastomeric properties (93). ESI containing about 20 mol% styrene are excellent compatibilizers for PE–PS blends (94).

Hydrogenated PSs. Dow researchers have successfully developed a new hydrogenation catalyst that allows complete hydrogenation of the phenyl rings on PS without degrading the molecular weight of the polymer (95). Complete

Table 3. Glass-Transition Temperatures of Substituted Polystyrene

Polymer	CAS registry number	T_g °C
Polystyrene	[9003-53-6]	100
Poly(*o*-methylstyrene)	[25087-21-2]	136
Poly(*m*-methylstyrene)	[25037-62-1]	97
Poly(*p*-methylstyrene)	[24936-41-2]	106
Poly(2,4-dimethylstyrene)	[25990-16-3]	112
Poly(2,5-dimethylstyrene)	[34031-72-6]	143
Poly(*p*-*tert*-butylstyrene)	[26009-55-2]	130
Poly(*p*-chlorostyrene)	[24991-47-7]	110
Poly(α-methylstyrene)	[25014-31-7]	170

hydrogenation of the phenyl rings of PS increases the glass-transition temperature (T_g) to ~140°C (96). Because of the hydrophobicity and low birefringence of the saturated polymer, it is well suited for use in optical media applications. Dow is currently planning to commercialize hydrogenated PS for use as a substrate for DVD discs.

Polymers of Styrene Derivatives. Many styrene derivatives have been synthesized and the corresponding polymers and copolymers prepared (97). The glass-transition temperatures for a series of substituted styrene polymers are shown in Table 3. The highest T_g is that of poly(α-methylstyrene), which can be prepared by anionic polymerization. Because it has a low ceiling temperature (61°C), depolymerization can occur during fabrication with the produced monomer acting as a plasticizer and lowering the heat distortion to 110–125°C (98). The polymer is difficult to fabricate because of its high melt viscosity and is more brittle than PS, but can be toughened with rubber.

Some polymers from styrene derivatives seem to meet specific market demands and to have the potential to become commercially significant materials. For example, monomeric chlorostyrene is useful in glass-reinforced polyester recipes since it polymerizes several times as fast as styrene (98). Poly(sodium styrenesulfonate) [9003-59-2] is a versatile water-soluble polymer and is used in water-pollution control and as a general flocculant (99,100). Poly(vinylbenzyl ammonium chloride) [70504-37-9] has been useful as an electroconductive resin (101). (see ELECTRICALLY-CONDUCTING POLYMERS).

Transparent Impact PS (TIPS). Rubber is incorporated into PS primarily to impart toughness. The resulting materials are commonly called high impact PS (HIPS) and are available in many different varieties. In standard HIPS resins, the rubber is dispersed in the PS matrix in the form of discrete particles. The mechanism of rubber-particle formation and rubber reinforcement and several general reviews of HIPS and other heterogeneous polymers have been published (102–108). The photomicrographs in Figure 14 show the different morphologies possible in HIPS materials prepared using various types of rubbers (109,110). If the particles are much larger than 5–10 μm, poor surface appearance of moldings, extrusions, and vacuum-formed parts are usually noted. Although most commercial HIPS contains ca 3–10 wt% PB or styrene–butadiene copolymer rubber, the presence of PS occlusions within the rubber particles gives rise to a 10–40% volume

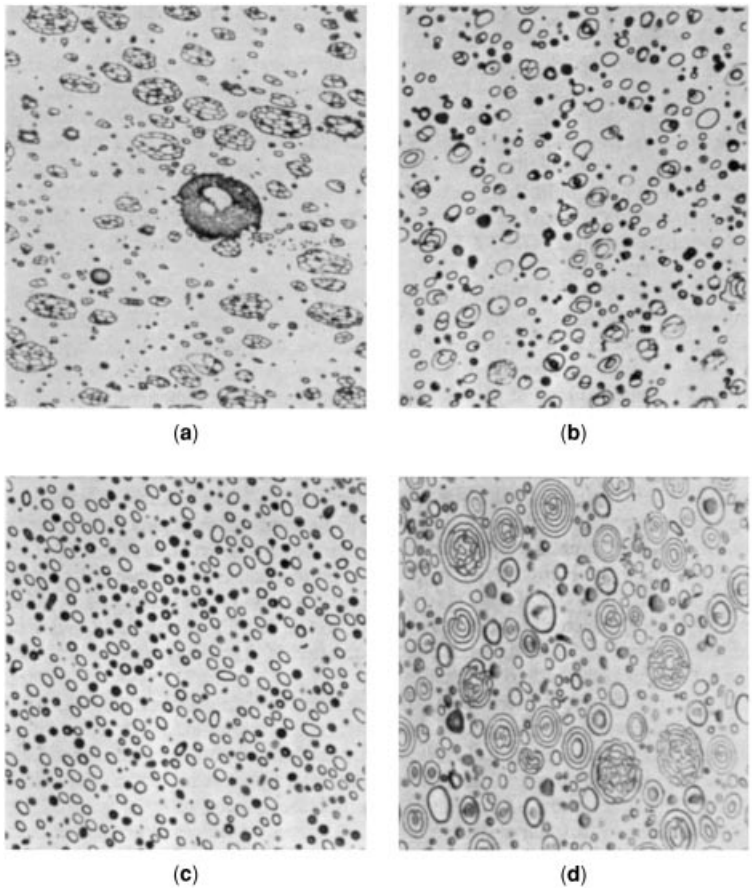

Fig. 14. Electron photomicrographs of several HIPS resins prepared using different types of rubbers.

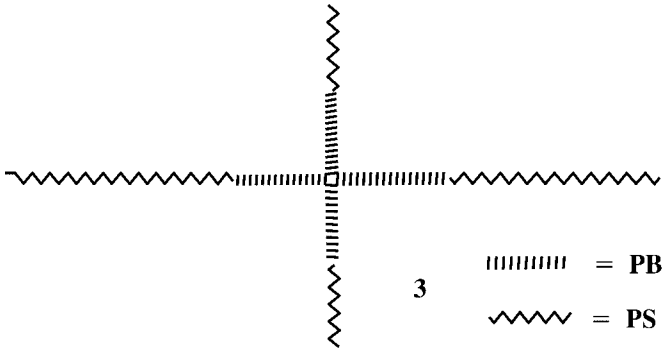
fraction of the reinforcing rubber phase (108,111). Accordingly, a significant portion of the PS matrix is filled with rubber particles. Techniques have been published for evaluating the morphology of HIPS (110,112,113).

Polystyrene, by itself, is low in cost, relatively clear (90% transparency), has a moderate tensile modulus (3.3 GPa), and is relatively brittle (G_{1c} about 150 J/m^2). For many commercial applications, the optical clarity is a significant advantage, but the pure polymer is far too brittle for many applications and so some means must be taken to toughen it. Approaches to toughening include modifying the backbone structure by introducing comonomers (for example making SAN), adding plasticizers, and blending with various rubbers and elastomers. All of these options for toughening can have a deleterious effect on the desirable properties; comonomers raise the cost, plasticizers lower the modulus, and rubber fillers can destroy transparency. HIPS resins are opaque. The opacity is due to the scattering of light as it passes through the sample. This scattering is caused because the PB rubber particles and PS phase have different refractive indices. There are two ways to solve this problem and stop the light scattering: (*1*) adjust the relative

refractive indices of the two phases so they are nearly the same or (2) shrink the sizes of the PS and rubber phases to <20 nm. Most companies that want to market products for TIPS applications utilize the latter technique and have designed high styrene content microphase separated block copolymer rubbers that when blended with PS result in very small phase domain sizes. The refractive indices of PS and PB are 1.59 and 1.51, respectively. The technique of refractive index matching can be accomplished by either raising the refractive index of PB by copolymerizing refractive index enhancing comonomers with butadiene (eg, styrene, vinylbiphenyl, vinylnaphthalene) or by reducing the refractive index of PS by copolymerizing methyl methacrylate into the PS backbone (114).

TIPS resins made by blending high styrene content (~75 wt%) styrene–butadiene block copolymers with GPPS have good slow speed toughness (ie, 30% elongation), but poor high speed toughness. Phillips Petroleum became the first company (1972) to market these resins (115). Phillips calls their styrene–butadiene block copolymer resins for TIPS blending K-resins. They have a radial or star block structure with polybutadiene at the core and PS at the tips of the arms. The PS segments have a bimodal molecular weight distribution. These materials are produced by polymerizing styrene first with *sec*-butyl lithium (sBL). Once the desired molecular weight is reached, more sBL is added followed by more styrene. The added sBL initiates new chains while styrene also adds to the existing living PS chains. The result is a bimodal mixture of polystyryl lithium. Once the styrene is all converted, butadiene is added to form a mixture of styrene–butadiene block copolymers having the same butadiene block length and two different PS block lengths. At this point, the butadiene segment is still living. Silicone tetrachloride is added as a coupling agent resulting in the formation of the star block copolymer (**3**).



3

Several other companies also market transparent styrene–butadiene block copolymers for TIPS applications. BASF markets styrene–butadiene block copolymers having a similar structure (Styrolux); however, rather than pure PB segments, they make a gradient or taper styrene–butadiene block having a T_g of −30 °C (116). Their process to make this special architecture is similar to Phillips in that they prepare a bimodal mixture of polybutadienyl lithiums. However, then a mixture of butadiene and styrene are added to make the taper block. After the taper block is made, more styrene is added to add a short PS block. A tetrafunctional coupling agent is then added to form the star structure. BASF teaches

that the purpose of the long PS block is to enhance compatibility in blends with PS (116). Fina markets linear styrene–butadiene triblock materials under the trade name Finclear. These linear triblock resins are not just simple high styrene content styrene–butadiene–styrene triblock materials. Rather, they use the taper block concept; that is, rather than having pure PS and PB segments in the block copolymer, there is a gradient change over or tapering of the styrene to butadiene segments.

Unlike for PS, very little work has been published on the fracture of block copolymers. There is a substantial amount of literature on PS toughened by blending with block copolymers. In those systems, the block copolymer is dispersed, and provided the proper particle size and modulus are obtained, substantial improvements in toughness are obtained, as described above for HIPS. For the neat block copolymers, however, fracture mechanisms are fundamentally different than for PS.

Results on the fracture of KR01 and KR03, both Phillips K-resins, have been reported (117). KR01 has an overall molecular weight of 180,000 (M_w), while for KR03 the molecular weight is 220,000 (M_w). KR03 is asymmetrical, with one long PS block, while KR01 is fairly symmetrical. The different block structures result in quite different morphologies, which in turn impart quite different fracture properties. KR01 has basically a cylindrical morphology consisting of wavy rods of polybutadiene, about 20 nm in diameter, in a PS matrix. The cylindrical morphology is expected based on the volume fraction of PB. In KR03, the PB is in a disrupted lamellar morphology. The rubber phase is in sheets about 20 nm thick, but the sheets are neither flat nor continuous, although annealing sharpens the morphology somewhat. KR01 fractures in a manner similar to PS. There are well-defined crazes, and no deformation outside of the craze region. In KR03, there is significant microcracking (better termed nanocracking), voiding in the PB phase, and significant deformation. Argon refers to the failure of KR03 as a form of crazing and he reports strains to failure of 9% and 110% for KR01 and KR03, respectively, while Phillips product literature gives corresponding values of 20% and 160%. Notched Izod impact strengths have been reported as 0.4 ft·lb/in. and 0.75 ft·lb/in. for KR01 and KR03, respectively. The change in morphology has an appreciable effect on toughness (117).

The individual components (PS and styrene–butadiene block rubber) that make up TIPS are optically transparent. Ignoring the effects of surface imperfections (scratches, roughness), blends and block copolymers become hazy and the transparency is reduced due to light scattering from regions of differing refractive index. In very qualitative terms, significant light scattering will occur when regions of differing refractive index have dimensions of the order of the wavelength of visible light. For systems with dispersed rubber particles, like HIPS, that condition means that the rubber particles must be less than about 100 nm in diameter for the material to be transparent. Unfortunately, this requirement for clarity is inconsistent with the requirement for toughness of a minimum rubber particle size of 0.8 μm. The domain sizes in block copolymers are much smaller, of the order of 20 nm, and so block copolymers tend to be highly transparent. When homopolymers are blended with blocks, however, inhomogeneities in composition and refractive index can develop, and if the dimensions are large enough, light scattering can be significant.

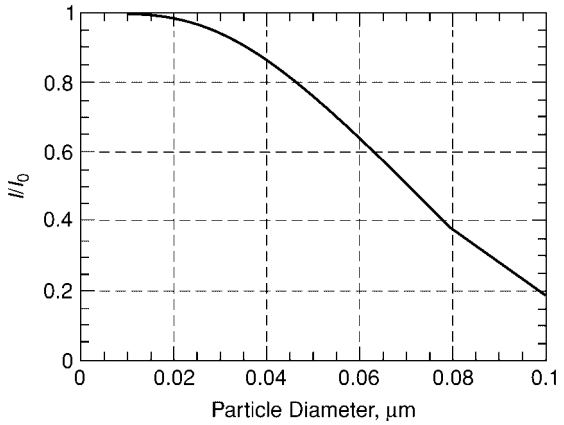


Fig. 15. Transmittance vs particle size for PB particles in a PS matrix with a path length of 1.0 mm. The calculation assumes 10 vol% of spherical particles and is for light with 0.55 μm wavelength.

Block copolymers of styrene and butadiene are highly transparent, despite the large refractive index difference between PS and PB and the fact that the blocks are phase separated. Styrolux and KR03 resins have transparencies around 90%. The transparency is due to the very small domain size, which is typically of the order of 20 nm. Spheres of equivalent size would scatter very little light, as shown from the data in Figure 15. In block copolymers the domain sizes are determined primarily by block molecular weights, and for commercial polymers the domains will always be small enough that they will not be a significant source of scattering. As long as block copolymer composition is uniform, degradation is avoided, smooth surfaces are maintained and fabricated articles are generally clear.

As a means of reducing cost and increasing modulus, GPPS is often blended with block copolymers, despite the fact that the blends tend to have inferior optical clarity than the pure block copolymers. There is some evidence that the addition of GPPS can raise the T_g of the block copolymer system (118). Several examples of how adding GPPS to block copolymers effects clarity have been provided (116,119). The solubility of the GPPS in the PS blocks depends on the relative molecular weights. With identical molecular weights the solubility is expected to be unlimited, and depending on block copolymer geometry (star vs linear) solubility may be maintained with a GPPS/block ratio of up to 1.5 (118). The reason that Styrolux and KR03 are asymmetrical, with on average one long PS block per molecule, is probably to enhance solubility of GPPS.

When GPPS of the proper molecular weight is added to a lamellar block copolymer, like KR03 or Styrolux, it is absorbed by the PS phase and hence swells it. With no added homopolymer, the block copolymer does not scatter light because all of the domains are much smaller than the wavelength of light, even though the PS domains will be larger than the butadiene domains, and to visible light the material has a uniform refractive index. If the GPPS is uniformly absorbed by the PS blocks the material remains transparent, even if the PS domains become comparable in size to the wavelength of light. In this case, the system is

transparent because the PB domains are still very small and evenly dispersed. Optically, the system is very similar to HIPS, except that it is easier to maintain the dispersion due to the block structure. As GPPS is added, the average refractive index of the material increases, but to visible light there is not a refractive index gradient that would result in scattering. The blend may begin to scatter light for one of two reasons. First, if large volumes of GPPS are added, even if miscibility with the blocks is maintained, variations in PS domain sizes can occur due to random fluctuations in morphology. When these domains become large, they will begin to scatter. If the GPPS begins to phase separate, then it will very quickly grow into domains that will cause significant scattering. The key to maintaining clarity is solubility of the added GPPS in the PS blocks. It has been shown how in a lamellar Styrolux system, added GPPS swells the PS blocks but leaves the butadiene block domains essentially unchanged (116). A blend with 60 vol% Styrolux and 40% GPPS has about 78% transmittance, compared to 90% for the pure block copolymer. Transmission electron micrographs show that the butadiene domains are essentially the same size in the blend and pure block copolymer (Fig. 16), but that the PS domains grow. Eventually, regions that are relatively high in PS develop that are large enough to scatter light. Individual PS domains are not that large by themselves. In contrast, it has also been shown that in a styrene–butadiene–styrene triblock system, added GPPS readily phase separates, forms relatively large domains of pure PS, and results in much higher light scattering.

In summary, optical clarity in TIPS systems depends on minimizing light scattering, which arises from having regions of differing refractive index. The dimensions of these scattering centers is dictated by the size of dispersed rubber particles (as in HIPS), by the morphological features in block copolymers, or by compositional fluctuations in blends of block and homopolymers. The conundrum for HIPS-type materials is that rubber particles large enough to toughen PS are also large enough to cause significant light scattering. In block copolymers, the morphological features are too small to scatter significantly and so these systems are highly transparent. Blends of high styrene content (>70 wt% styrene)

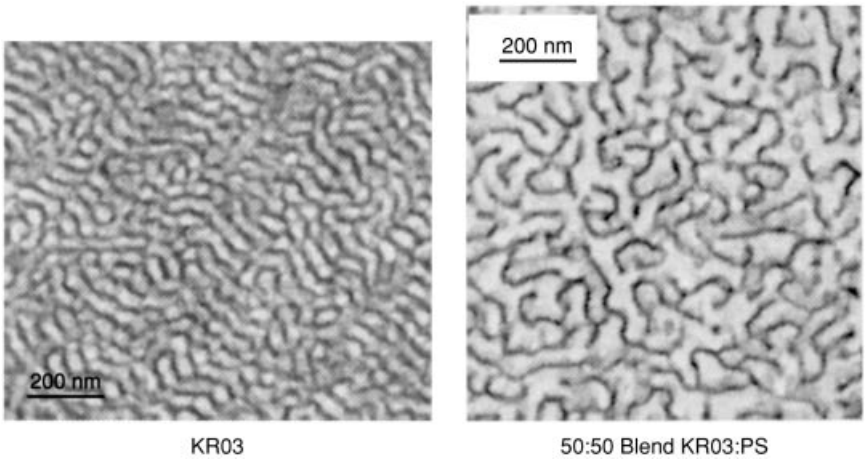

Fig. 16. TEM of KR03 and 50:50 blend of KR03 and PS.

block and GPPS remain transparent as long as gross phase separation can be prevented.

Besides transparency and toughness, modulus is also a key property for TIPS. The two approaches to toughening PS involve the addition of a relatively low modulus rubber phase. Adding rubber unavoidably lowers the modulus of the resulting composite; exactly how much depends on the resulting morphology. For systems with dispersed rubber particles, in which the PS remains the continuous phase, simple mechanical models do a good job of predicting modulus as a function of rubber phase volume fraction. In fact, measuring the dynamic modulus at small strains can be used to quantitatively evaluate the volume fraction of elastomer. The modulus of rubber-modified PS is given approximately by (120)

$$1/G = 1/G_1[1 + 1.86(\phi_1/\phi_2)]$$

where the assumption is made that the elastomer is in dispersed spherical domains, and Poisson's ratio for PS is 0.35. G is the shear modulus of the composite, G_1 the modulus of the PS matrix, and ϕ_1 and ϕ_2 the volume fractions of the PS and elastomer phases, respectively. In the case of HIPS with occluded PS in the rubber phase, the volume fraction of elastomer phase ϕ_2 is the total volume fraction of particles, not the volume of PB. A plot of modulus ratio vs effective volume fraction of rubber is given in Figure 17. At effective elastomer volume fractions up to 0.30 (including occluded and grafted PS), an upper limit on what is typically used for HIPS, the reduction in modulus is only 45%.

For lamellar morphologies, the situation is quite different. There are no good mechanical models for predicting the modulus of these systems, mostly because there is not an adequate way to describe the morphology. The modulus of a lamellar system depends on the relative volume fractions of the two phases, their individual moduli, and the orientation and aspect ratio of the lamellae. The last two parameters are almost impossible to determine in real systems; so, predicting moduli based on volume fractions and individual phase moduli is virtually impossible. If the rubber phase is co-continuous, as it is in lamellar systems like the K-resins, the modulus is significantly reduced relative to PS or HIPS. For KR03, the ratio G/G1 is typically 0.42 (121).

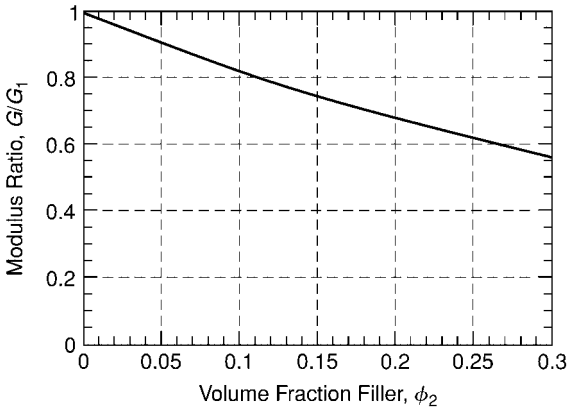

Fig. 17. Modulus ratio vs soft phase volume fraction for systems like HIPS.

Acrylonitrile–Butadiene–Styrene (ABS) Polymers. ABS polymers have become important commercial products since the mid-1950s. The development and properties of ABS polymers has been discussed in detail in Reference 122. ABS polymers, like HIPS, are two-phase systems in which the elastomer component is dispersed in the rigid SAN copolymer matrix. The electron photomicrographs in Figure 18 show the difference in morphology of mass versus emulsion ABS polymers. The differences in structure of the dispersed phases are primarily a result of differences in production processes, types of rubber used, and variation in rubber concentrations.

Because of the possible changes in the nature and concentration of the rubber phase, a wide range of ABS polymers are available. Generally, they are rigid [modulus at room temperature, 1.8–2.6 GPa, ie, (2.6–3.8) $\times$ 10^5 psi] and have excellent notched impact strength at room temperature (ca 135–400 J/m, ie,

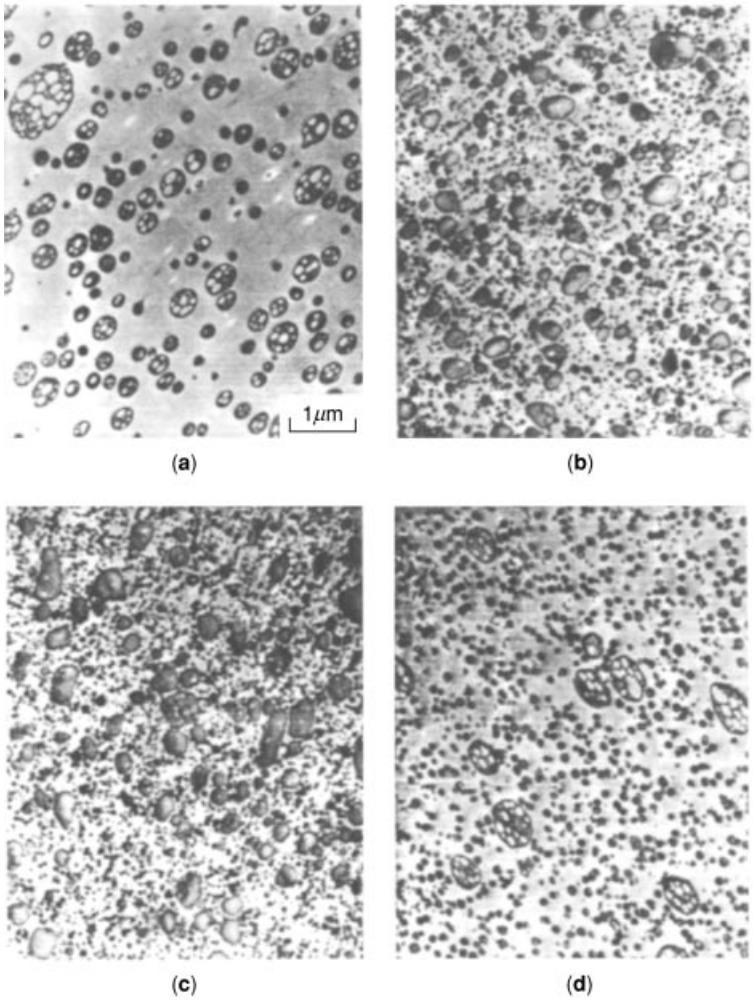

Fig. 18. Electron photomicrographs of some commercial ABS resins produced by bulk, emulsion, or a mixture of the two processes.

2.5–7.5 ft·lb/in.) and at lower temperatures, eg, at −40°C (50–140 J/m, ie, 0.94–2.6 ft·lb/in.). This combination of stiffness, impact strength, and solvent resistance makes ABS polymers particularly suitable for demanding applications. Another important attribute of several ABS polymers is their minimum tendency to orient or develop mechanical anisotropy during molding (123,124). Accordingly, uniform tough moldings are obtained. In addition, ABS polymers exhibit good ease of fabrication and produce moldings and extrusions with excellent gloss, which can be decorated by many techniques, eg, lacquer painting, vacuum metallizing, and electroplating (125–128). In the case of electroplating, the strength of the molded piece is significantly improved (123). When an appropriate decorative coating or a laminated film is applied, ABS polymers can be used outdoors (129).

ABS can be blended with bisphenol A polycarbonate resins to make a material having excellent low temperature toughness. The most important application of this blend is for automotive body panels.

When inherent outdoor weatherability is important, acrylonitrile–ethylene–styrene (AES) or acrylonitrile–styrene–acrylate (ASA) materials are typically used. These materials utilize ethylene–propylene copolymers and polybutylacrylate as the rubber phase, respectively. Ethylene–propylene and polybutylacrylate rubbers are inherently more weatherable than polybutadiene because they are more saturated leaving fewer labile sites for oxidation (130). Even though AES and ASA polymers are more weatherable than ABS, additives are needed to stabilize the materials against outdoor photochemical degradation for prolonged periods. Additive packages for AES and ASA weatherable materials generally contain both uv absorbers and hindered amine light stabilizers. Typical outdoor applications for weatherable polymers include recreational vehicles, camper tops, and swimming pool accessories. The extremely hostile environments where these stabilized AES materials are utilized still take their toll on the materials. Over very prolonged periods of use, the surface gains a chalky appearance as the polymer degrades. Serious discoloration can also result and was found to be caused by degradation of the additives (131).

High heat ABS resins are produced by adding a third monomer to the styrene and acrylonitrile to "stiffen" the polymer backbone, thus raising the T_g. Two monomers used commercially for this purpose are α-methylstyrene (132) and *N*-phenylmaleimide (133).

Not only are ABS polymers useful engineering plastics, but some of the high rubber compositions are excellent impact modifiers for poly(vinyl chloride) (PVC). Styrene–acrylonitrile-grafted butadiene rubbers have been used as modifiers for PVC since 1957 (134).

New Rubber-Modified Styrene Copolymers. Rubber modification of styrene copolymers other than HIPS and ABS has been useful for specialty purposes. Transparency has been achieved with the use of methyl methacrylate as a comonomer; styrene–methyl methacrylate copolymers have been successfully modified with rubber. Improved weatherability is achieved by modifying SAN copolymers with saturated, aging-resistant elastomers (135).

Inorganic-Reinforced Styrene Polymers. Glass reinforcement of PS and SAN markedly improves their mechanical properties. The strength, stiffness, and fracture toughness are generally at least doubled. Creep and relaxation rates are significantly reduced and creep rupture times are increased. The coefficient of

thermal expansion is reduced by more than half, and generally, response to temperature changes is minimized (136). Normally, ca 20 wt% glass fibers, eg, 6 mm long, 0.009 mm dia, E-glass, can be used to achieve these improvements. PS, SAN, HIPS, and ABS have been used with glass reinforcement.

Four approaches are currently available for producing glass-reinforced parts. These include use of preblended (reinforced molding compound; blending of reinforced concentrates with virgin resin), a direct process, in which the glass is cut and weighed automatically and blended with the polymer at the molding machine, and general inplant compounding (123). The choice of any of these processes depends primarily on the size of the operation and the corresponding economics.

Reinforcement of PS with inorganic materials other than glass has been under intense study in recent years. The inorganic materials of highest interest have a lamellar (layered) structure with at least one dimension in the nanometer scale range. Hence, addition of these inorganic materials to polymers form what are called nanocomposite materials. Many natural and synthetic lamellar inorganic materials are commercially available. The molecular structures of these materials vary widely. The biggest challenge encountered when blending nanolayered inorganic with hydrophobic polymers like PS is to end up with the inorganic nanolayers separated and evenly dispersed throughout the polymer matrix. The grouping of the layers of lamellar pieces can generally be visualized as a cabbage-like or book-like structure in which, for the purpose of making a nanocomposite, the task is to scatter the leaves or book pages uniformly throughout the polymer matrix (Fig. 19). The dimensions of the individual lamellae are on the nanometer scale and are important for enhancement of polymer physical properties.

Several approaches for the exfoliation of platelets exist in producing the PS nanocomposite. The actual mixing of the inorganic with PS can take place via compounding or by introducing it into the polymerization process. The approaches include (*1*) using the inorganic material with no modification, (*2*) chemical treatment of the inorganic material surface to alter hydrophilicity or to attach reactive functional groups, (*3*) use of compatibilizers/surfactants when mixing, (*4*) copolymerization styrene with a polar comonomer (ie, maleic anhydride) to make PS more compatible with the polar inorganic material, (*5*) physical manipulation of inorganic material (ie, freeze-drying or ball milling) (Fig. 20), and (*6*) use of polymerization mechanism to do the work of exfoliating the platelets.

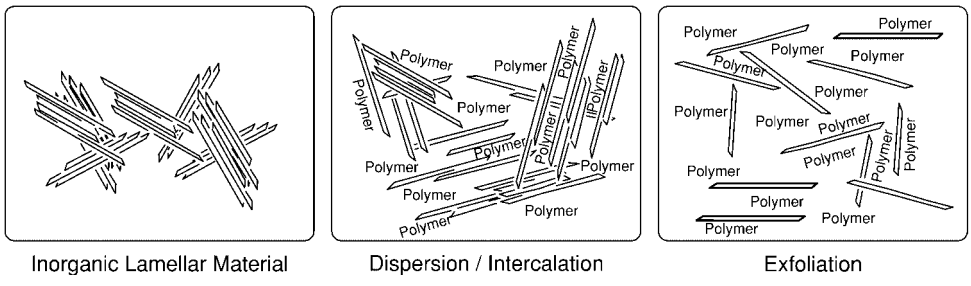

Fig. 19. Illustration of dispersed/intercalated platelets and exfoliated platelets.

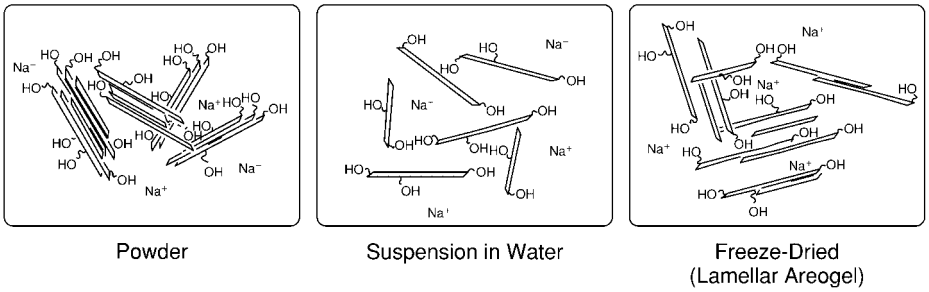

Fig. 20. Use of freeze-drying to separate lamellae.

There are advantages and disadvantages to these approaches. Method 1 is simple; however, unless working with a highly polar polymer, exfoliation and dispersion of the mismatched systems is unlikely without using a great deal of energy to mechanically separate and disperse the layered material. Methods 2–4 require the addition of compatibilizing additives, and have been shown to be quite effective. Use of these additives often results in compromising the physical properties of the parent polymer system, and benefits that might be provided by the inorganic platelets can easily be outweighed by the addition of these extra materials. Use of these additives can also add substantial cost to the composite system. Approach 5 is a useful tool when used in combination with the other approaches, but when used alone, it is difficult to obtain fully exfoliated dispersions. Using the polymerization mechanism to exfoliate the platelets (method 6) is generally not as straightforward as the other methods; however, it can be an ideal way to exfoliate and disperse platelets without the use of unwanted additives or the added expense of compounding approaches.

The synthesis of a PS/Montmorillanite clay nanocomposite prepared by combining methods 2 and 6 described earlier was published (137) (Fig. 21). They utilized living free-radical polymerization (LFRP) of styrene to provide exfoliated platelets in a PS matrix. Transmission electron micrographs and x-ray diffraction patterns support the idea of preparing nanocomposites via polymerization initiation.

Only recently have some elegant approaches for the synthesis of finely dispersed composites been reported in the academic literature (137,138). The styrene-based systems were SAN, ABS, and PS. Blends of these materials were prepared either by compounding with organically modified inorganic materials or by mixing organically modified (with or without an additional compatibilizer) with monomer prior to polymerization. Physical properties of the composites were also examined in several reports, and some changes in modulus and T_g reported. Many of these studies focused on attempts to disperse these ionic inorganic materials in the incompatible organic polymer systems. Good dispersions were obtained in some cases; however, complete exfoliation of the inorganic lamellar systems was generally not obtained. As a result, only intercalated products were made. Having exfoliated platelets of the proper aspect ratio and in the correct alignment in the polymer matrix should provide the maximum impact on physical properties; however, dispersing such a material in relatively nonpolar systems, such as styrenic polymers, remains a challenge.

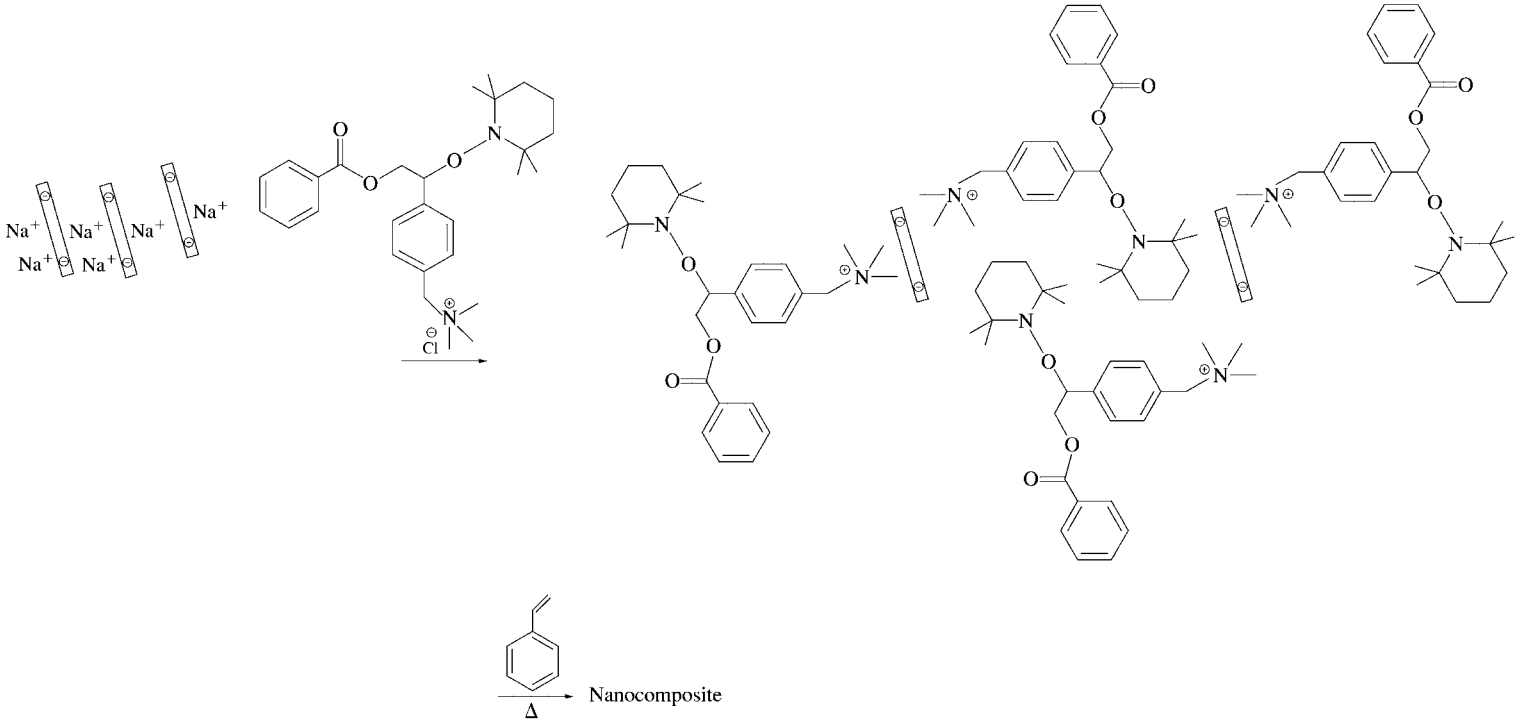

Fig. 21. LFRP of styrene to produce nanocomposites.

Degradation

Like almost all synthetic polymers, styrene plastics are susceptible to degradation by heat, oxidation, uv radiation, high energy radiation, and shear. However, in normal use, only uv radiation imposes any real limit on the general usefulness of these plastics (139,140). Thus, it is generally recommended that the use of styrene plastics in outdoor applications be avoided.

Thermal Degradation. Typically, PS loses about 10% of its molecular weight when it is fabricated. A significant amount of research has been carried out to determine the nature of the "weak links" in PS (141–144). Various initiation of degradation mechanisms have been proposed: (*1*) chain-end initiation (unzipping), (*2*) random scission initiation, and (*3*) scission of weak links in the polymer backbone. It has been suggested that chain-end initiation is the predominant mechanism at 310°C while random scission produces stable molecules. Evidence for weak link scissions comes mainly from studies showing loss of molecular weight vs. degradation time. These plots usually show a rapid initial drop in molecular weight indicating initial rapid weak link scission. However, the picture is also complicated by the fact that the mechanism of degradation is temperature-dependent. It appears that weak link scissions taking place at high temperatures initiate depolymerization while at lower temperatures, scissions simply cause a decrease in molecular weight. In any case, a clear difference in thermal stability has been shown between PS produced using a peroxide initiator and PS made without an initiator polymerization. Figure 22 shows the Arrhenius activation

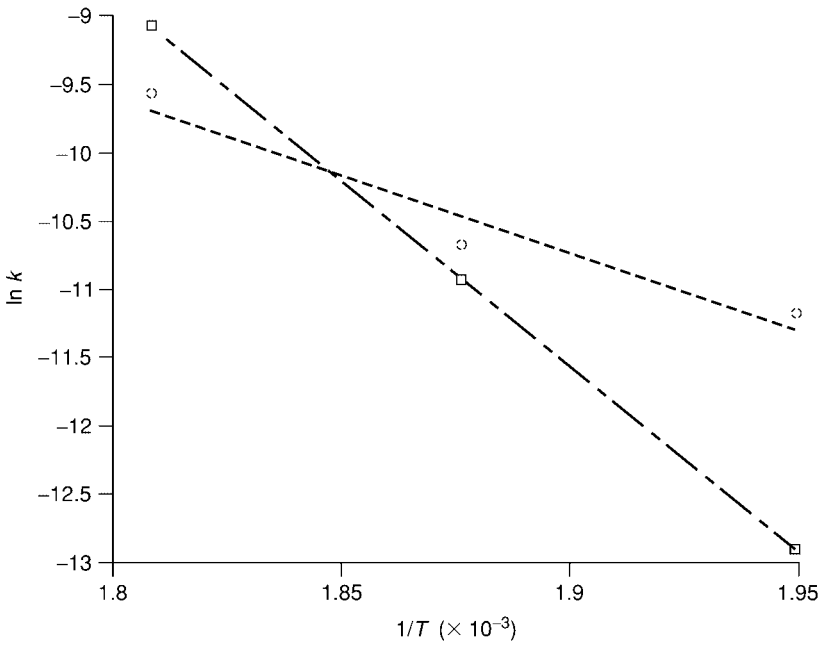

Fig. 22. Comparison of thermal stability of the PS backbone made with and without peroxide initiator ––○–– Peroxide initiated $E_a = 94.6$ kJ/mol (22.6 kcal/mol); -□—No initiator added $E_a = 226$ kJ/mol (54 kcal/mol).

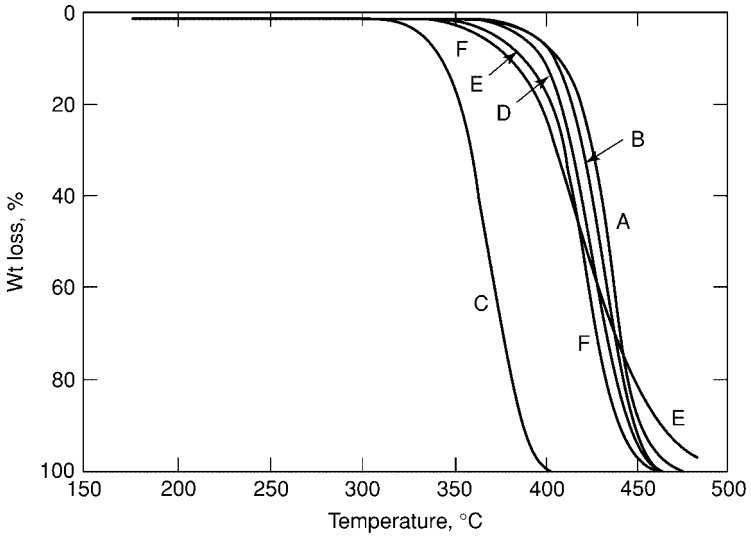

Fig. 23. Thermogravimetric analysis of polymers and copolymers of styrene in nitrogen at 10°C/min. energy for chain scission in PS made with and without a peroxide initiator. This difference in stability of the resins is likely due to the initiator derived fragments that remain in the polymer after isolation.

Poly(α-methylstyrene) unzips to monomer exclusively. Figure 23 is a comparison of the thermal stability of several copolymers. Thermal-oxidative degradation of PS occurs much faster, leading to additional volatile components consisting of aldehydes and ketones, yellowing of the polymer with a very dramatic drop in molecular weight, and some cross-linking. Rates and yields are highly oxygen- and temperature-sensitive. Figure 24 shows the magnitude of oxidative attack on PS and the extent to which an antioxidant can protect the polymer.

Environmental Degradation. In the past several years, PS has received much public and media attention. Polystyrene has been described by various environmental groups as being nondegradable, nonrecyclable, toxic when burned, landfill-choking, ozone-depleting, wildlife-killing, and even carcinogenic. These misconceptions regarding PS have resulted in boycotts and bans in various localities. Actually, PS comprises less than 0.5% of the solid waste going to landfills (Fig. 25) (145).

The approach which the plastics industry has taken in managing plastics waste is an integrated one of source reduction, recycling, incineration for energy recovery, reduction of litter, development of photodegradable plastics for specific litter prone applications, the development of biodegradable plastics, and increasing public awareness of the recyclability and value of PS. The balance of these approaches varies from year to year depending upon public concerns, political pressures, legislation, technology development, and the development of an understanding of the actual contribution of plastics to total solid waste generation.

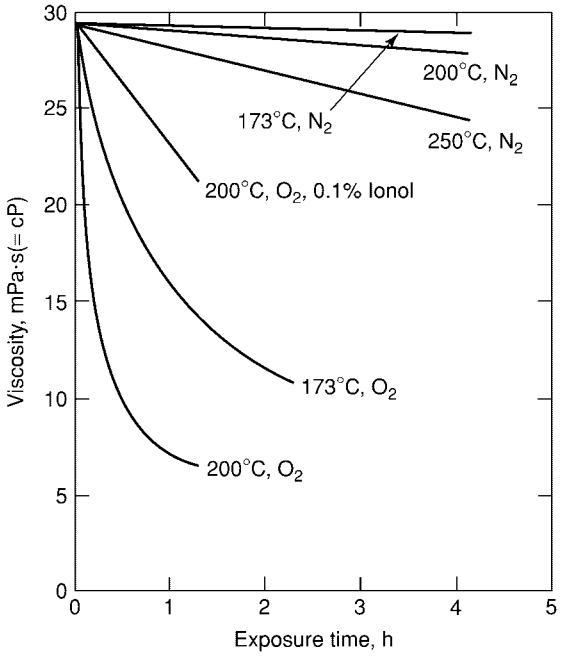

Fig. 24. Thermal and thermooxidative degradation of PS.

Currently, recycling is being the most heavily researched and developed. The National Plastics Recycling Company (NPRC) was established in 1989 through the combined efforts of the top eight U.S. PS producers (ie, Huntsman, Dow, Polysar, Fina, Arco, Mobil, Chevron, and Amoco). Its charter is to facilitate plastic recycling with the ultimate objective of recycling 25% of the PS produced in the United States each year (146).

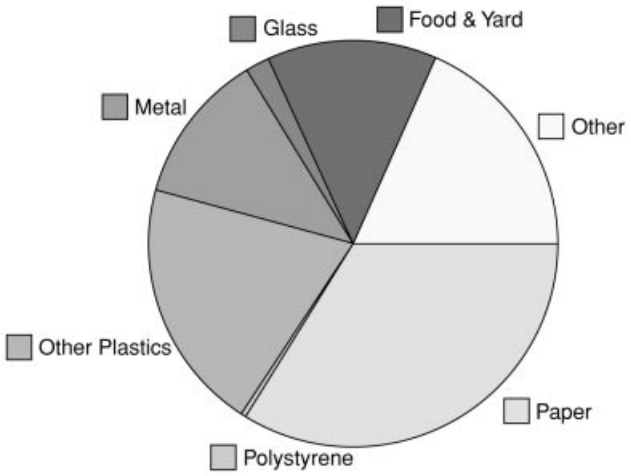

Fig. 25. Approximate composition of solid waste going into landfills in the United States (145)

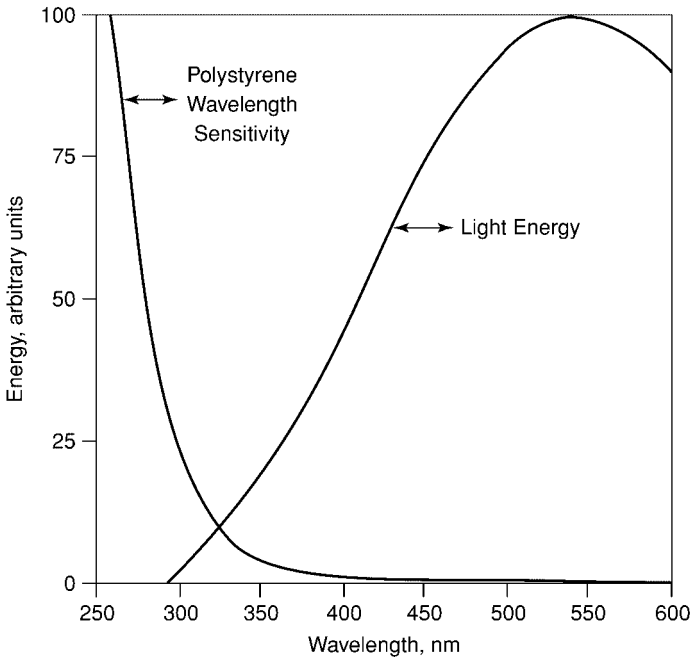

Fig. 26. Energy of the solar spectrum vs the wavelength sensitivity of PS.

Photodegradation. Natural sunlight emits energy only in wavelengths above 290 nm. Therefore, any polymer that does not absorb light energy at wavelengths above 290 nm should not be photodegradable. The activation spectrum of PS versus the intensity of the solar spectrum is shown in Figure 26. Since PS degradation is activated by radiation at wavelengths above 290 nm, it is quite photodegradable and must be stabilized by the addition of uv-absorbing additives if it is to be used in outdoor applications where durability is important.

Even though PS is naturally quite photodegradable, there have been considerable efforts to accelerate the process to produce photodegradable PS (147–152). The approach is to add photosensitizers (typically ketone-containing molecules), which absorb sunlight (eg, benzophenone). The absorbed light energy is then transferred to the polymer to cause backbone scission via an oxidation mechanism (Fig. 27). Photodegradable PS would be useful in litter prone applications (eg, fast food packaging).

A more effective approach to enhancing the rate of photodegradation of PS is to copolymerize styrene with a small amount of a ketone-containing monomer. Thus, the ketone groups are attached to the polymer during its manufacture (Fig. 28) (147,149).

Attaching the ketone groups to the polymer backbone is more efficient, on a chain scission/ketone bases, because some of the light energy that the pendant ketone absorbs leads directly to chain scission via the Norrish type II mechanism, as well as photooxidation via the Norrish type I mechanism (Fig. 29) (149).

A key problem with the manufacture of photodegradable PS containing low levels of methyl vinyl ketone and methyl isopropenyl ketone is their human

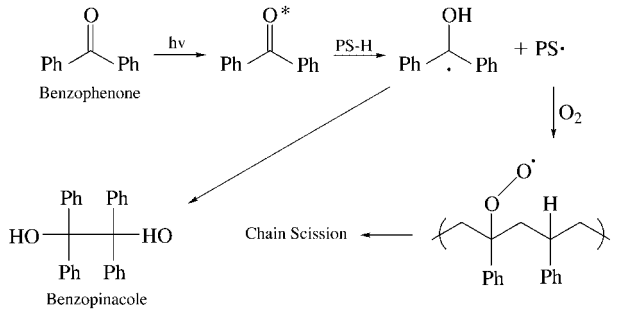

Fig. 27. The chemistry of molecular weight breakdown of PS during outdoor exposure.

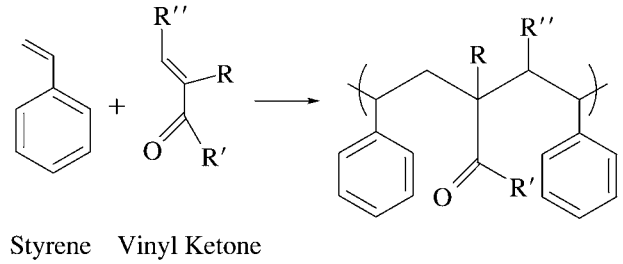

Fig. 28. Incorporation of photosensitive ketone groups into PS during manufacture.

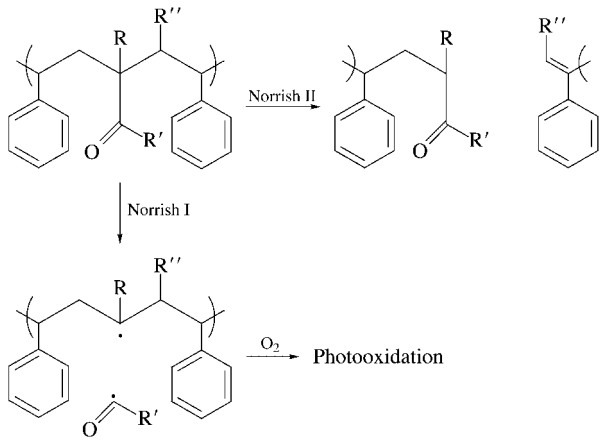

Fig. 29. Polystyrene backbone scission resulting from sunlight exposure of PS containing attached ketone groups.

toxicity. This problem has been solved by adding the ketoalcohol intermediate, formed during the vinyl ketone manufacture, to the styrene polymerization and generating the vinyl ketone *in situ*. (Fig. 30) (151,152).

A concern in the use of photodegradable PS is the environmental impact of the products of photooxidation. However, photodegraded PS is expected to be more susceptible to biodegradation because the molecular weight has been reduced,

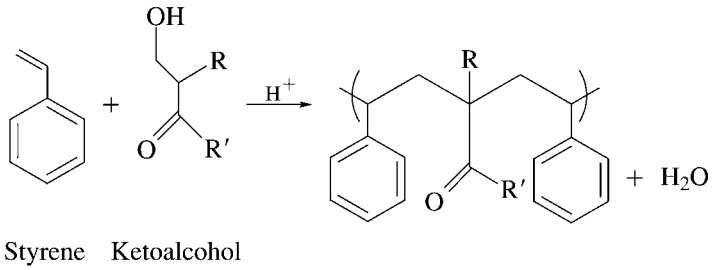

Fig. 30. Manufacture of photodegradable PS via *in situ* vinyl ketone process.

the PS chains have oxidized end groups, the incorporation of oxygen as alcohol and ketone groups has increased the hydrophilicity of the PS fragments, and the surface area has increased (153–155).

Biodegradation. Polystyrene is inherently resistant to biodegradation mainly because of its hydrophobicity. Efforts have been made to enhance the biodegradability of PS by inserting hydrolyzable linkages (eg, ester and amide) into its backbone. This was accomplished by adding monomers to the polymerization, which are capable of undergoing ring-opening copolymerization (Fig. 31) (156).

Environmental Effect of Blowing Agents. Until the mid-1980s, the most common blowing agents for extruded PS foams were chlorofluorocarbons (CFCs). However, when these materials were shown to contribute to the ozone depletion problem, there became a considerable effort to find alternative blowing agents for the manufacture of extruded PS foam. Most of the research has focused on the development of carbon dioxide foaming technology for PS (157). By contrast, PS bead foam uses hydrocarbon blowing agents (eg, pentane). Hydrocarbon blowing agents are extremely flammable and add volatile organic compounds to the atmosphere. In Europe, all PS foam is manufactured using carbon dioxide as the blowing agent.

Polymerization

Styrene and most derivatives are among the few monomers that can be polymerized by all four distinct mechanisms, ie, anionic, cationic, free-radical, and

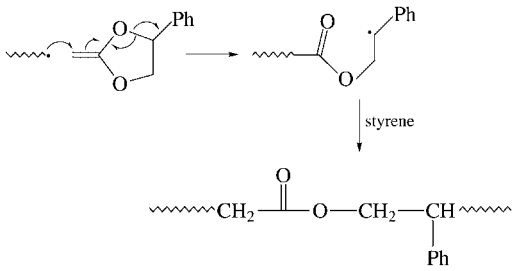

Fig. 31. Preparation of biodegradable PS by incorporating ester linkages into the backbone via ring-opening copolymerization of styrene with a cyclic ketene acetal.

Ziegler–Natta. These include processes dependent on electromagnetic radiation, which is usually a free-radical mechanism, or high energy radiation, which is either a cationic or free-radical mechanism depending on the water content of the system. All mechanisms, other than Ziegler–Natta, generally yield polymers with a high degree of random placement of the phenyl group relative to the backbone, ie, the polymers are classified as atactic and amorphous. Anionically made PS is usually atactic and amorphous, but in some cases, eg, at low temperatures, iPS has been prepared.

Each of the mechanisms used to polymerize styrene has its own unique advantages/disadvantages as summarized below.

Anionic:

Initiation, propagation, and termination steps are sequential resulting in the formation of narrow polydispersity ($M_w/M_n < 1.1$); termination step is controlled allowing control of end-group structure; polymerization feed must be purified.

Cationic:

High molecular weight polymers are difficult to make because of the instability of polystyrylcarbocation giving fast termination; polymerization feed must be purified.

Free-Radical:

Initiation, propagation, and termination steps are simultaneous resulting in the formation of broad polydispersity ($M_w/M_n > 2$); multiple termination paths lead to a variety of end groups; polymerization feed need not be purified.

Ziegler–Natta:

Metal complexes allowing stereospecific polymerization resulting in the formation of high melting crystalline tactic PS; polymerization feed must be purified.

Free-radical polymerization is the preferred industrial route because: (*1*) monomer purification is not required (158) and (*2*) initiator residues need not be removed from polymer as they have minimal effect on polymer properties. The exceptions are the styrene–butadiene block copolymers and very low molecular weight PS. These polymers are manufactured using anionic and cationic polymerization chemistry, respectively (159). Analytical standards are available for PS prepared by all four mechanisms (see INITIATORS).

Free Radical. The styrene family of monomers are almost unique in their ability to undergo spontaneous or thermal polymerization merely by heating to

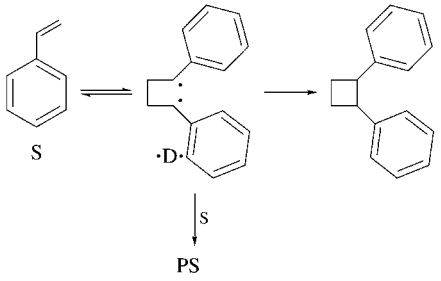

Fig. 32. Flory mechanism for spontaneous initiation of styrene polymerization

>100°C. Styrene in essence acts as its own initiator. The mechanism by which this spontaneous polymerization occurs has been studied extensively and has challenged researchers for over 50 years. Two mechanisms explaining spontaneous styrene polymerization have been proposed and supported by considerable circumstantial evidence. The oldest mechanism (160) involves a bond-forming reaction between two molecules of styrene to form a 1,4-diradical (·D·) (Fig. 32). Evidences favoring this mechanism include (*1*) the identification of *cis* and *trans* 1,2-diphenylcyclobutanes as major dimers (161,162), and (*2*) the large differences between spontaneous and chemically initiated (azobisisobutyronitrile) styrene polymerizations in the presence of the free-radical scavenger 1,1′-diphenyl-2-picrylhydrazyl (DPPH). The rate of consumption of DPPH is 25 times faster than that expected from the rate of polymerization measurements. This difference was explained by the spontaneous formation of ·D·, many of which become self-terminated before initiating polymer radicals (163). However, experiments to test the mechanism showed that there was no significant difference in the molecular weight of PS initiated by monoradicals compared with the spontaneously initiated polymerizations taken to the same monomer conversion (164).

The second mechanism (Fig. 33) (165) involves the Diels–Alder reaction of two styrene molecules to form a reactive dimer (DH) followed by a

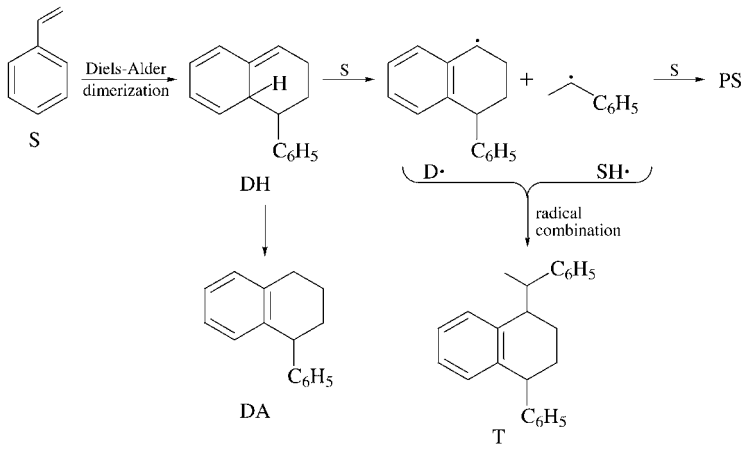

Fig. 33. Mayo mechanism for spontaneous initiation of styrene polymerization.

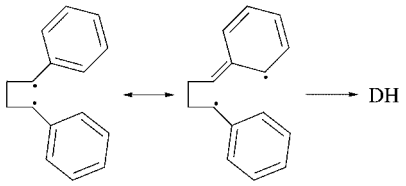

Fig. 34. Formation of the Mayo Dimer via the Flory Diradical.

molecular-assisted homolysis (MAH) between the DH and another styrene molecule. The Mayo mechanism has been generally preferred even though critical reviews (162,166) have pointed out that the mechanism is only partially consistent with the available data. Also, the postulated intermediate DH has never been isolated. Evidences supporting the mechanism include kinetic investigations (167,168), isotope effects (166), and isolation/structure determination of oligomers (166,169). Even though the reactive dimer intermediate DH has never been isolated, the aromatized derivative DA has been detected in PS (169). Also, D· has been indicated as an end group in PS using ^{1}H NMR and uv spectroscopy (170).

The Flory and Mayo proposals could be combined by the common diradical ·D·, which collapses to either DH or 1,2-diphenylcyclobutane (Fig. 34). Nonconcerted Diels–Alder reactions are permissible for two nonpolar reactants (171).

The spontaneous polymerization of styrene was studied in the presence of various acid catalysts (172) to see if the postulated reactive intermediate DH could be intentionally aromatized to form inactive DA. The results showed that the rate of polymerization of styrene is significantly retarded by acids (eg, camphorsulfonic acid) accompanied by increases in the formation of DA. This finding gave further confirmation for the intermediacy of DH since acids would have little effect on the cyclobutane dimer intermediate in the Flory mechanism.

A potentially important commercial benefit of adding an acid catalyst to the spontaneous free-radical polymerization of styrene is that a significant shift results in the rate/molecular weight curve for PS. This shift is most pronounced at high molecular weights allowing formation of high molecular weight PS at a much faster polymerization rate (Fig. 35). An explanation for this phenomenon is that the intermediate DH has a high chain-transfer constant (ie, ∼10) (173). Addition of acid immediately causes DH to aromatize, thus lowering its concentration and hence decreasing its availability to participate in chain-transfer processes. Also, the main mechanism of termination is chain coupling (174), the rate of which is most affected by radical concentration. Since the polymerization temperature can be raised in the presence of acid without increasing free-radical concentration, the propagation rate is increased relative to termination rate, thereby raising the molecular weight.

The addition of a fugitive acid such as camphorsulfonic acid to styrene polymerizations contaminates the polymer with a substance that could lead to corrosion of equipment being used to process the polymer. To solve this problem, Dow researchers added vinyl functional sulfonic acids (eg, 2-sulfoethyl methacrylate) to the polymerization (175). The acid then becomes copolymerized into the polymer, thus immobilizing it. Also, they found that the addition of as low as 10 ppm

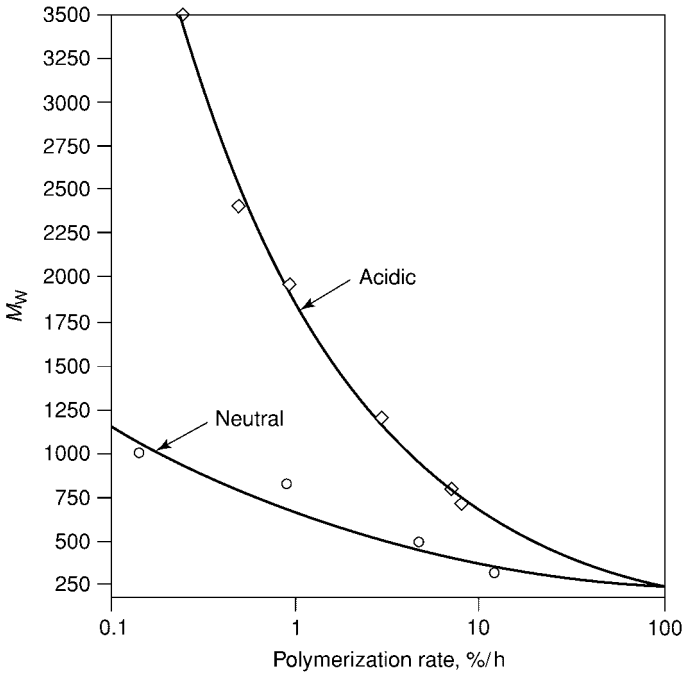

Fig. 35. Polymerization rate vs molecular weight relationship for spontaneous bulk styrene polymerization under neutral and acidic conditions.

of 2-sulfoethyl methacrylate significantly increases the production rate of high molecular weight PS (176).

Polystyrene produced by the spontaneous initiation mechanism is typically contaminated by dimers and trimers (1–2 wt%). These oligomers are somewhat volatile and cause problems during extrusion (vapors) and molding (mold sweat) operations. The use of chemicals to generate initiating free radicals significantly reduces the formation of oligomers. Oligomer production is reduced because the polymerization temperature can be lowered to slow down the Diels–Alder dimerization reaction. A wide range of free-radical initiators are available. They differ mainly in the temperature at which each generates free radicals at a useful rate. Typically, in continuous bulk polymerization processes it is best to polymerize styrene at about the 1-h half-life temperature of the initiator it contains to maximize initiator efficiency.

Initiators that have been utilized to initiate styrene polymerization can be generally categorized into three types: peroxides, azo, and carbon–carbon (177). Peroxides are thermally unstable and decompose by homolysis of the O—O bond, resulting in the formation of two oxy radicals. Azo compounds decompose by concerted homolysis of the N—C bonds on either side of the azo linkage, resulting in extrusion of nitrogen gas and the formation of two carbon-centered radicals. Carbon–carbon initiators decompose by homolysis of a sterically strained C—C bond, resulting in the formation of two carbon-centered radicals. The radicals initiate styrene polymerization and end up attached to the chain ends and may have an effect upon polymer stability (178–181).

Since most of the bulk PS reactors were originally designed to produce spontaneously initiated PS in the 100–170°C temperature range, the peroxide initiators used generally have 1-h half-lives in the range of 90–140°C. If the peroxide decomposes too rapidly, a run-away polymerization could result, and if it decomposes too slowly, peroxide exits the reactor. Since organic peroxides are significantly more expensive than styrene monomer (5–20×), it is economically prudent to choose an initiator that is highly efficient and is entirely consumed during the polymerization.

Another economically driven objective is to utilize initiators that increase the rate of polymerization of styrene to form PS having the desired molecular weight. The commercial weight-average molecular weight (M_w) range for GPPS is 200,000–400,000. For spontaneous polymerization, the M_w is inversely proportional to polymerization rate (Fig. 36).

The main reason that the M_w decreases as the polymerization temperature increases is the increase in the initiation and termination reactions leading to a decrease in the kinetic chain length (Fig. 37). At low temperature, the main termination mechanism is polystyryl radical coupling, but as the temperature increases, radical disproportionation becomes increasingly important. Termination by coupling results in higher M_w PS than any of the other termination modes.

There are typically several different product grades produced in a single-polymerization reactor, and transitioning between these products in the minimum time maximizes production yield. Most PS producers rely on the use of kinetic modeling and computer simulation to aid in the manufacture of PS to minimize

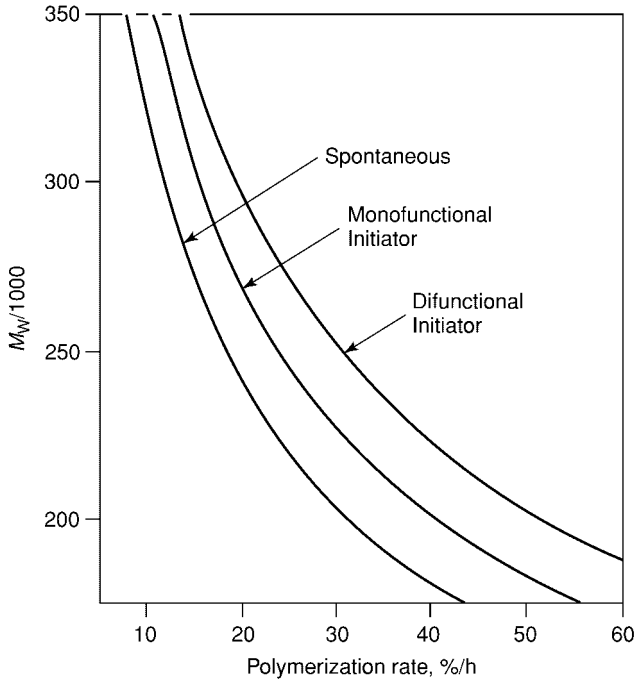

Fig. 36. Polymerization rate for PS using different types of initiators.

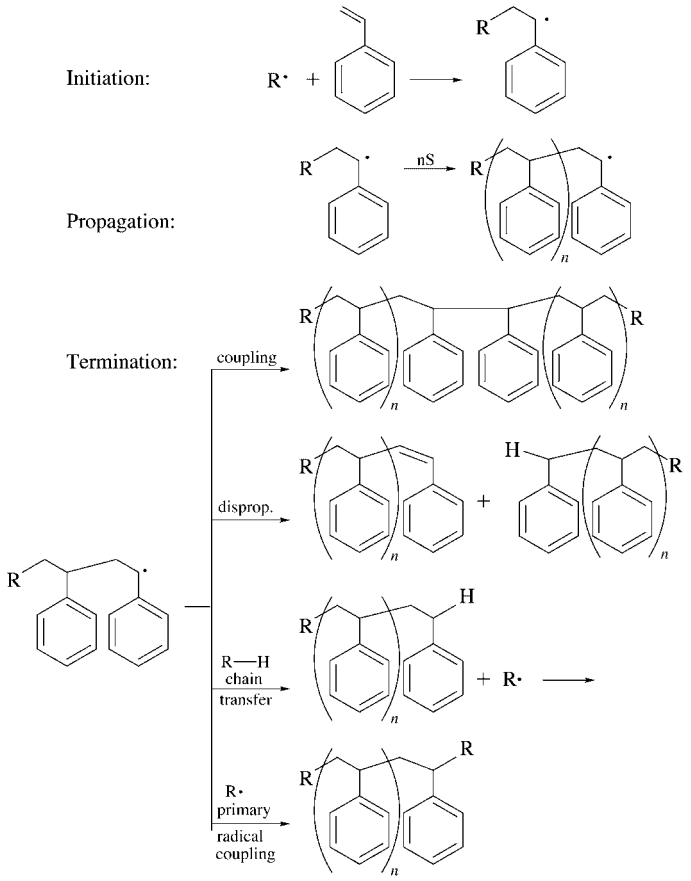

Fig. 37. General chemistry of free-radical styrene polymerization.

transition time between product grades. Kinetic models have been developed for styrene polymerization without added initiators (182–184), using one monofunctional (185–189), two monofunctional initiators with different half-lives (190), symmetrical difunctional (**4**), (191) and (**5**), (**6**), (192) and the unsymmetrical difunctional initiators (**7**), (193,194) and (**8**) (195,196). These models clearly show the polymerization rate advantage of using initiators for the manufacture of PS using continuous bulk polymerization processes (Fig. 36).

One of the key reasons for the polymerization rate advantage of using difunctional initiators is their theoretical ability to form initiator fragments, which can initiate polymer growth from two different sites within the same fragment, ultimately leading to "double-ended PS." If double-ended PS chains are produced, given that the main mechanism of termination is chain coupling, it is clear why higher M_w PS can be produced at faster rates using difunctional initiators (197). One of the goals of PS researchers has been the discovery of an initiator that truly initiates only double-ended PS chains. Because the main mechanism of termination is radical coupling, the production of pure double-ended chains would lead to the formation of ultrahigh molecular weight PS because termination by chain

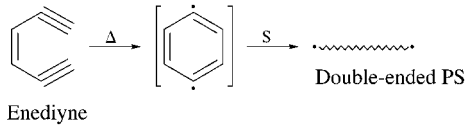

Fig. 38. Double-ended PS initiated by diradical formed during Bergman Cyclization.

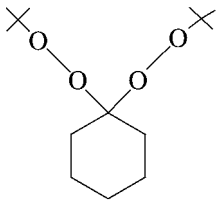
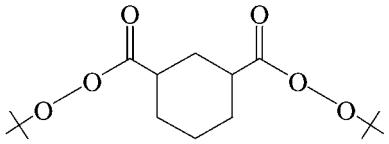
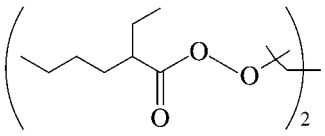
coupling would only lead to a higher molecular weight double-ended chain. There have been many attempts to develop initiators that form only diradicals. However, the discovery of diradicals that efficiently initiate styrene polymerization is a challenge (198). Dow researchers recently discovered that the *p*-phenylene diradical formed during "Bergman Cyclization" of certain enediynes can initiate double-ended PS, but commercialization of these initiators remains a challenge (Fig. 38) (199). To date, the only clear demonstration of double-ended PS has been with difunctional LFRP initiators (200).



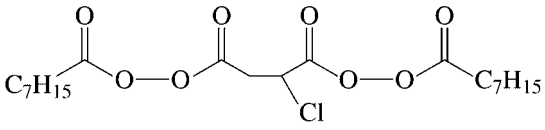
4



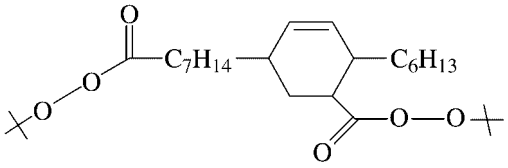
5



6



7



8

Below 80°C, radical combination is the primary termination mechanism (201). Above 80°C, both disproportionation and chain transfer with the Diels–Alder dimer are increasingly important. The gel or Trommsdorff effects, as manifested by a period of accelerating rate concomitant with increasing molecular weight, is apparent at below 80°C in styrene polymerization; although, subtle changes during the polymerization at higher temperature may be attributed to variation of the specific rate constants with viscosity (201,202).

In some cases, inhibition of polymerization can be regarded as a special type of chain transfer. This is of importance in commercial-scale operations involving styrene storage for extended periods. The majority of inhibitors are of the phenolic/quinone family. All of these species function as inhibitors only in the presence of oxygen. 4-*tert*-Butylcatechol (TBC) at 12–50 ppm is the most universally used inhibitor for protecting styrene. At ambient conditions and with a continuous supply of air, TBC has a half-life of 6–10 weeks (203). The requirement of oxygen causes complex side reactions, resulting in significant oxidation of the monomer, which causes yellow coloration especially in the vapor phase. An inert gas blanket reduces this problem and flammability hazards, but precautions must be taken to ensure an adequate level of dissolved oxygen in the liquid phase. Another family of inhibitors is that characterized by the N—O bond; these do not seem to require oxygen for effectiveness. They include a variety of nitrophenol compounds, hydroxylamine derivatives, and nitroxides (204,205). Nitric oxides are particularly useful. The unpaired electron associated with the N—O bond is very stable and yet nitroxides couple with carbon-centered radicals at diffusion-controlled rates. The alkoxyamines produced when nitroxides couple with styryl radicals are thermally labile. At elevated temperatures (generally >100°C), the C—O bond dissociates back to the precursor radicals in equilibrium with the alkoxyamine. Thus, if alkoxyamines are added to styrene, they can initiate polymerization. The nitroxide moiety is retained on the propagating chain-end and effectively supresses the termination mechanisms (ie, polystyryl radical coupling, chain transfer, and disproportionation) typical of normal free-radical polymerization. The result is that narrow polydispersity PS is produced. Once the unreacted styrene is removed from the nitroxide-terminated PS and a second monomer is added, a block copolymer can be produced.

Other miscellaneous compounds that have been used as inhibitors are sulfur and some sulfur compounds, picrylhydrazyl derivatives; carbon black, and some soluble transition-metal salts (206). Both inhibition and acceleration have been reported for styrene polymerized in the presence of oxygen. The complexity of this system has been clearly demonstrated (207). The key reaction is the alternating copolymerization of styrene with oxygen to produce a polyperoxide, which

Table 4. Chain-Transfer Constants (K_{ct}) in Free-Radical Styrene Polymerization

Compound	K_{ct}	T,°C
Benzene	0.00002	100

l-Dodecanethiol	13	130
l,l-Dimethyl-l-decanethiol	1.1	120
l-Hexanethiol	15	100

above 100°C decomposes to initiating alkoxy radicals. Therefore, depending on the temperature, oxygen can inhibit or accelerate the rate of polymerization.

Chain Transfer in Free-Radical Styrene Polymerization. The concept of chain transfer is depicted in Figure 37. Chain-transfer agents are occasionally added to styrene to reduce the molecular weight of the polymer, although for many applications this is unnecessary as polymerization temperature alone is generally sufficient to achieve molecular weight control. Some typical chain-transfer agents for styrene polymerization are listed in Table 4. The chain-transfer agents of commercial significance are α-methylstyrene dimer, terpinolene, dodecane-1-thiol, and 1,1-dimethyldecane-1-thiol. Chain transfer to styrene monomer has been reported, but recent work strongly suggests that this reaction is negligible and transfer with the Diels–Alder dimer is the actual inherent transfer reaction (208,209). Chain transfer to PS has received some attention, but experiments indicate that it is minimal (210,211). If it did occur at a significant extent, then the polymer would be branched. The chain-transfer constants of several common solvents and chain-transfer agents are shown in Table 4.

High levels of chain-transfer agents can be used to control the termination process. If the chain-transfer agent has a functional group attached to it, the functional group ends up becoming attached to the end of the PS chain. If the functionalized chain-transfer agent operates by donating an H-atom to the polystyryl radical, the functional group ends up becoming attached to only one end of the PS chain. However, this technique does not quantitatively functionalize the polymer chains because not all chains get initiated by the functionalized chain-transfer agent fragment formed by loss of the H-atom. However, if both the initiator and the chain-transfer agent contain the functional group (F), high purity one-end functional PS can be produced (Fig. 39) (212).

Another approach to control end-group structure is the use of chain-transfer agents that operate by an addition–fragmentation mechanism. This approach can lead to the formation of PS having functional groups at both ends if both the initiating and terminating fragments contain functional groups (Fig. 40).

Recently, it was found that the common chain-transfer agent α-methylstyrene dimer operates by an addition–fragmentation mechanism (Fig. 41) (213).

The use of addition–fragmentation chain-transfer agents also places a reactive double bond on one end of the polymer chain and thus yields a macromonomer.

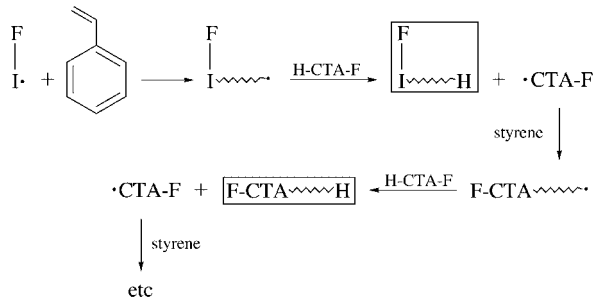

Fig. 39. Preparation of mono-end-functional PS using both a functionalized initiator and a functionalized chain-transfer agent (CTA).

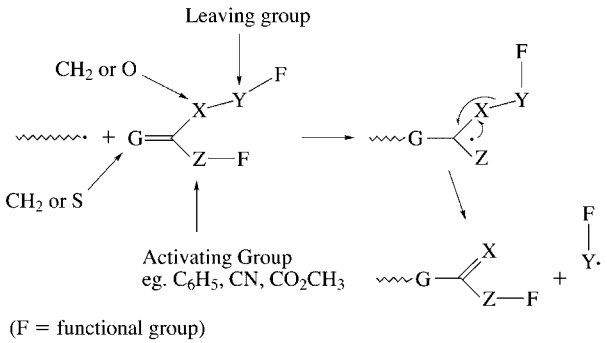

Fig. 40. Generic addition–fragmentation chain-transfer structure and the mechanism of action.

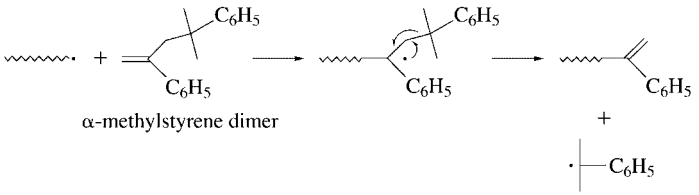

Fig. 41. Mechanism of action of α-methylstyrene dimer.

Copolymerization of the chain-end double bond with more styrene leads to branched PS.

Ionic. Instead of a neutral unpaired electron, styrene polymerization can proceed with great facility through a positively charged species (cationic polymerization) or a negatively charged species (anionic polymerization). The polymerization reaction is more sensitive to impurities than the free-radical system, and pretreatment of the monomer is generally required (214). *n*-Butyllithium (NBL) is the most widely used initiator for anionic polymerization of styrene. In solution, it exists as six-membered aggregates, and a key step in the initiation sequence is dissociation yielding at least one isolated molecule.

If the initiation reaction is very much faster than the propagation reaction, then all chains start to grow at the same time, and since there is no inherent termination step (living polymerization), the statistical distribution of chain lengths is very narrow. The average molecular weight is calculated from the mole ratio of monomer-to-initiator sites. Chain termination is usually accomplished by adding proton donors, eg, water or alcohols, or electrophiles such as carbon dioxide.

Anionic polymerization, if carried out properly, can truly be a living polymerization (215). Addition of a second monomer to polystyryl anion results in the formation of a block polymer with no detectable free PS. This technique is of considerable importance in the commercial preparation of styrene–butadiene block copolymers, which are used either alone or blended with PS as thermoplastics.

Anionic polymerization offers very fast polymerization rates because of the long lifetime of polystyryl carbanions. Early research focused on this attribute, most studies being conducted at short reactor residence times ($<$1 h), at relatively low temperatures (10–50°C), and in low chain-transfer solvents (typically benzene) to ensure that premature termination did not take place. Also, relatively low DPs were typically studied. Continuous commercial free-radical solution polymerization processes to make PS, on the other hand, operate at relatively high temperatures ($>$100°C), at long residence times ($>$1.5 h), utilize a chain-transfer solvent (ethylbenzene), and produce polymer in the range of 1000–1500 DP.

Two companies (Dow and BASF) have devoted significant research efforts to develop continuous anionic polymerization processes for PS. However, to date no PS is produced commercially using these processes. Dow researchers utilized conventional free-radical polymerization reactors of the CSTR-type (216–220) to study the anionic polymerization of styrene while BASF focused upon continuous reactors of the linear-flow-type (221). In an anionic CSTR process, initiation, propagation, and termination occur simultaneously and thus the polydispersity of the resulting PS is $\sim$2. A chain-transfer solvent (ethylbenzene) and relatively high temperatures (80–140°C) were also used. Under these conditions, the chain transfer to solvent (CTS) is extremely high since the high monomer conversions ($>$99%) achieved under steady-state operation results in a large ratio (typically, 500:1) of solvent to monomer. The result of high CTS is that very high yields of PS based on NBL (the most costly raw material) and PS having high clarity (low color) are produced (Fig. 42). Under very stringent feed purification conditions, as high as an 8000% yield based on NBL initiator (158) can be achieved. According to Figure 42, without high levels of CTS, it would be impossible to make a PS having sufficient clarity to meet the current color requirements to be sold as "prime" resin (with no CTS, 640 ppm of NBL is required to produce a PS of 1000 DP).

One of the key benefits of anionic PS is that it contains much lower levels of residual styrene monomer than free-radical PS (222). This is because free-radical polymerization processes only operate at 60–80% styrene conversion, while anionic processes operate at $>$99% styrene conversion. Removal of unreacted styrene monomer from free-radical PS is accomplished using continuous devolatilization at high temperature (220–260°C) and vacuum. This process leaves about 200–800 ppm of styrene monomer in the product. Taking the styrene to a lower level requires special assisted devolatilization processes such as steam stripping (223).

The most recent process research aimed at anionic PS is that of BASF. Unlike the Dow process, they utilize CPFR with virtually no backmixing to make narrow

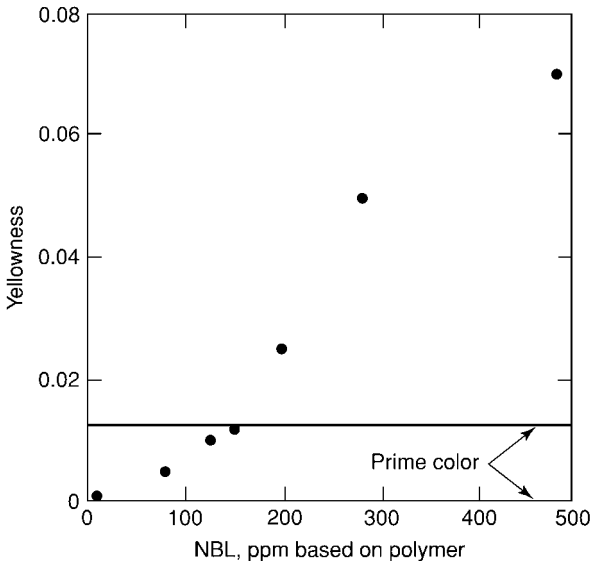

Fig. 42. Polystyrene color vs amount of *n*-butyllithium (NBL) consumed for its production in a CSTR.

polydispersity resins. In the Dow CSTR anionic process, the fast polymerization rate achieved with anionic polymerization is not a problem because the polymerization exotherm is controlled by the rate of monomer addition to the reactor; that is, the reactor is operated in a monomer-starved condition. However, in CPFR, the rate of polymerization of NBL-initiated styrene polymerization far exceeds the ability to remove heat resulting in run-away polymerization. This problem was recently solved by Asahi (224) and BASF with the addition of electron deficient metal alkyls (eg, dibutylmagnesium, diethylzinc, and triethylaluminum) to assist the butyl lithium initiator (225,226). Addition of metal alkyls accomplish two things: (*1*) the propagation rate is slowed and (*2*) the polystyryl lithium chain end is stabilized to high temperatures. The rate of the polymerization can actually be slowed to match the rate typically observed during free-radical polymerization of styrene by the addition of the proper amount of metal alkyl (Fig. 43). As the conversion of monomer to polymer proceeds, the viscosity rapidly increases forcing the need to finish the polymerization at high temperatures to be able to handle the high viscosity. It is well known that at temperatures $>100^{\circ}$C, PS lithium is unstable and decomposes by elimination of lithium hydride, resulting in the formation of dead polymer. The presence of electron deficient metal alkyls increases the thermal stability of the polystyryl chain ends so that polymerization up to high conversion and temperatures can be achieved.

The mechanism (226) involves the formation of a metal complex or aggregate between the lithium and the electron deficient metal. Styrene then inserts in the complex. This hypothesis is supported by the change in uv spectrum as the Li/Mg ratio changes. There is a shift of the λ_{max} to lower wavelength as the Mg/Li ratio approaches unity. As the Mg/Li ratio is increased to >1, the λ_{max} shifts back until at 20/1, the λ_{max} returns to match that of pure polystyryl lithium.

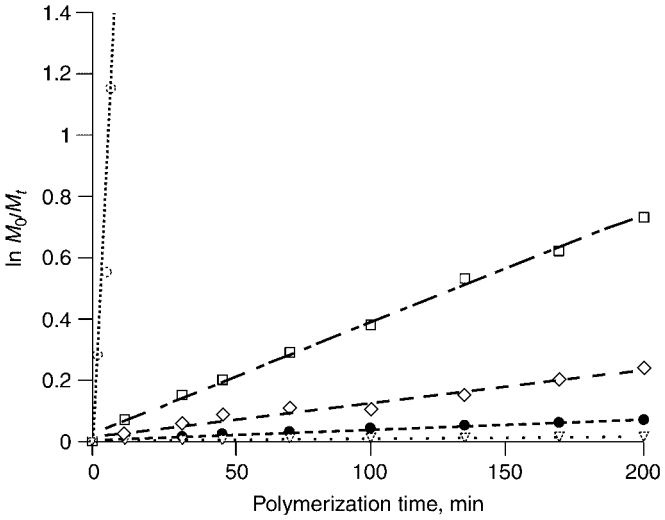

Fig. 43. Propagation rate retarding effect of adding dibutylmagnesium to butyllithium initiated anionic polymerization of styrene. ···○··· Lithium alone; -□—Mg/Li = 0.8; —◇—Mg/Li = 2; ––●–– Mg/Li = 4; ···▽··· Mg/Li = 20.

Continuous anionic polymerization, conducted above the ceiling temperature (61°C), is also useful for making thermally stable styrene-*co*-α-methylstyrene (SAMS) having high α-methylstyrene (AMS) content. Preparation of SAMS having >20 wt% of AMS units using bulk free-radical polymerization leads to very slow polymerization rates, low molecular weight polymer, and the formation of high levels of oligomers. The preparation of SAMS using an anionic CSTR polymerization reactor operating at 90–100°C allows the production of SAMS having up to about 70 wt% AMS units (Fig. 44) (227). By conducting the polymerization above the ceiling temperature, no AMS polyads of more than two units are possible. SAMS copolymers having polyads of greater than two units in length are thermally unstable (228).

Cationic polymerization of styrene can be initiated either by strong acids, eg, perchloric acid, or by Friedel-Crafts reagents with a proton-donating activator, eg, boron trifluoride or aluminum trichloride, with a trace of a protonic acid or water. Cationic polymerization of styrene can also be initiated using heterogeneous acid catalysis such as acidic clays and strong acid ion exchange resins. The solvent again plays an important role, and chain-transfer reactions are very common where the reactants are polymer, monomer, solvent, and counterion. As a result, high molecular weights are more difficult to achieve and molecular weight distributions are often comparable to those obtained from free-radical polymerizations. Commercial use of cationic styrene polymerization is reported only where low molecular weight polymers are desired (110). In recent years, considerable advances have taken place with regard to cationic polymerization of styrene. Its use in making block copolymers and even living cationic polymerizations have been reported (229).

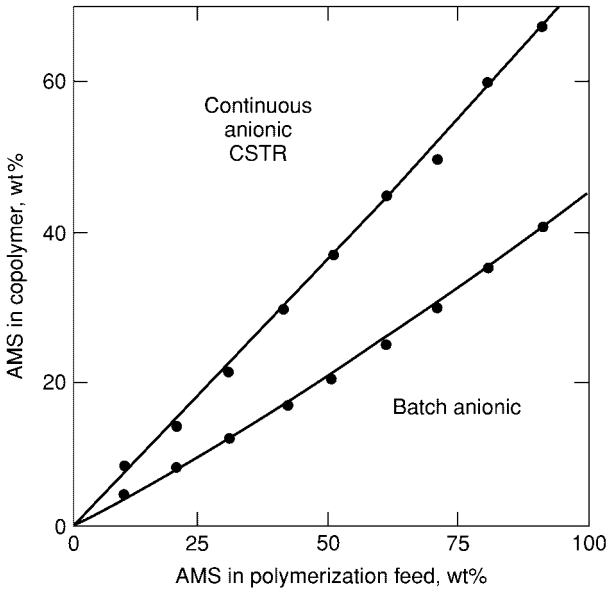

Fig. 44. Comparison of continuous (CSTR) and batch anionic production of SAMS.

Ziegler–Natta. Ziegler–Natta-initiated styrene polymerization yields stereoregular tactic PS. The tacticity can be isotactic (phenyl rings *cis* to each other) or syndiotactic (phenyl rings *trans* to each other) depending upon the initiator structure (230). Currently, all commercially important styrenic plastics are amorphous, since the vast excess of these polymers is made by a free-radical mechanism. However, Dow Chemical and Idemitsu Petrochemical Companies are working together to commercialize crystalline sPS. Dow and Idemitsu are currently manufacturing sPS using a bulk polymerization process. Since the sPS crystallizes as it forms, the polymerization process is very challenging because it requires mixing and removing the heat of polymerization from a sticky solid. Proper reactor design is required to keep the sticky mass from solidifying. The properties of sPS are quite different from atactic PS because of its crystallinity (mp = 270°C). Since sPS must be fabricated above its melting point and the polymer decomposes at 300°C, there is a very narrow fabrication temperature range. This problem is improved by copolymerizing a small amount of comonomer (eg, *p*-methylstyrene) into the polymer to lower the crystalline melting point. Because of its crystallinity, sPS finds utility in applications requiring heat resistance and solvent resistance (231) (see SYNDIOTACTIC POLYSTYRENE).

Living Free-Radical Styrene Polymerization. The requirements for a polymerization to be truly "living" are that the propagating chain-ends must not terminate during the polymerization. If the initiation, propagation, and termination steps are sequential (ie, all of the chains are initiated and then propagate at the same time without any termination), then monodisperse (ie, M_w/M_n = 1.0) polymer is produced. In general, anionic polymerization is the only mechanism that yields truly living styrene polymerization and thus monodisperse

PS. However, significant research has been conducted with the goal of achieving "living" styrene polymerization using cationic, free-radical, and Ziegler–Natta mechanisms.

Since Otsu first proposed living free-radical polymerization (LFRP) in 1982, (232,233) there has emerged a multitude of examples (234–242). However, significant controversy exists over the nature of the living chain-end and whether the process can really be called "living." Instead, terms such as pseudo-living, quasi-living, resuscitatable, stable free-radical-mediated, and dormant, have been used to better describe the process. Currently, most researchers prefer to use the term controlled radical polymerization. The process generally involves the addition of relatively stable free radicals to the polymerization. The growing polystyryl radicals are intercepted and terminated by coupling with the stable radicals thereby minimizing termination by chain transfer and the coupling of polystyryl radicals with themselves. Prior to the discovery of LFRP, stable free radicals were only added to styrene as polymerization inhibitors. They acted as radical scavengers to stop the propagation process. However, the bond formed between the polystyryl radical and some stable freeradical is somewhat labile, and styrene can insert into the bond once it is activated by heat or photolysis. The main evidences used to support the livingness of the polymerization are the increase of molecular weight with monomer conversion, the formation of narrow polydispersity PS, and the ability to prepare block copolymers. Normally, free-radical polymerizations show relatively flat molecular weight versus conversion plots. Although no one has yet demonstrated the preparation of truly monodisperse ($M_w/M_n=1.0$) PS using LFRP, polydispersities approaching 1.05 have been reported for very low molecular weight ($M_w < 20{,}000$) PS prepared in the presence of stable nitroxy radicals.

A variant of the LFRP of styrene is called atom transfer radical polymerization (ATRP). In ATRP the initiator is an activated halide. The halogen–carbon bond is broken by transfer of the halogen from the chain end to a chelated transition metal (eg, copper, iron, or ruthenium). After the resulting polystyryl radical adds a few monomer units, the halogen transfers back onto the chain-end. This process repeats itself many times resulting in the formation of PS having a controlled molecular weight. If at some point a second monomer is added to the polymerization, block copolymers are produced. Although the chemistry is potentially low in cost due to the nature of the low cost of the initiators and metal catalysts, there is a serious drawback; ie, the transition-metal catalyst is difficult to remove from the final polymer. Since the presence of traces of transition metals tend to promote degradation of polymers, some means must be developed for the easy elimination of the catalyst residues from the polymer before ATRP becomes a commercial reality.

Currently, most of the LFRP research is focused on the use of nitroxides as the stable freeradical. The main problems associated with nitroxide mediated radical polymerizations (NMRP) are slow polymerization rate and the inability to make high molecular weight narrow polydispersity PS. This inability is likely due to side reactions of the living end leading to termination rather than propagation (243). The polymerization rate can be accelerated by the addition of acids or anhydrides to the process (244). The mechanism of the accelerative effect of the acid is not certain. Another problem with nitroxides is that they work well for vinylaromatic monomers, but not for acrylate and diene monomers. This has

greatly limited their use for making styrene containing block copolymers. A way around this problem is to make the nonstyrene block using some other chemistry and then place an alkoxyamine group on one of the chain-ends. The alkoxyamine functional polymer is then dissolved in styrene and heated to >100°C where the alkoxyamine functional polymer becomes a macroinitiator for the styrene polymerization (245). There are several examples of the tandem polymerization concept, including the preparation of polymethylmethacrylate (PMMA) via normal radical polymerization using an alkoxyamine functional azoinitiator (**9**). Subsequently, styrene polymerization is initiated using the alkoxyamine functional PMMA (**10**) as a macroinitiator to make S-MMA block copolymer (**11**). The synthetic scheme is displayed in Figure 45.

The successful application of NMRP to the synthesis of pure block copolymers requires that the termination processes that typically take place during free-radical polymerization (ie, radical coupling, chain transfer, and disproportionation) be virtually eliminated.

There have been two approaches to the study of the NMRP of styrene: (*1*) *in situ* formation of the NMRP initiator (Fig. 46) (246,247) and (*2*) presynthesis of the initiator (200,248).

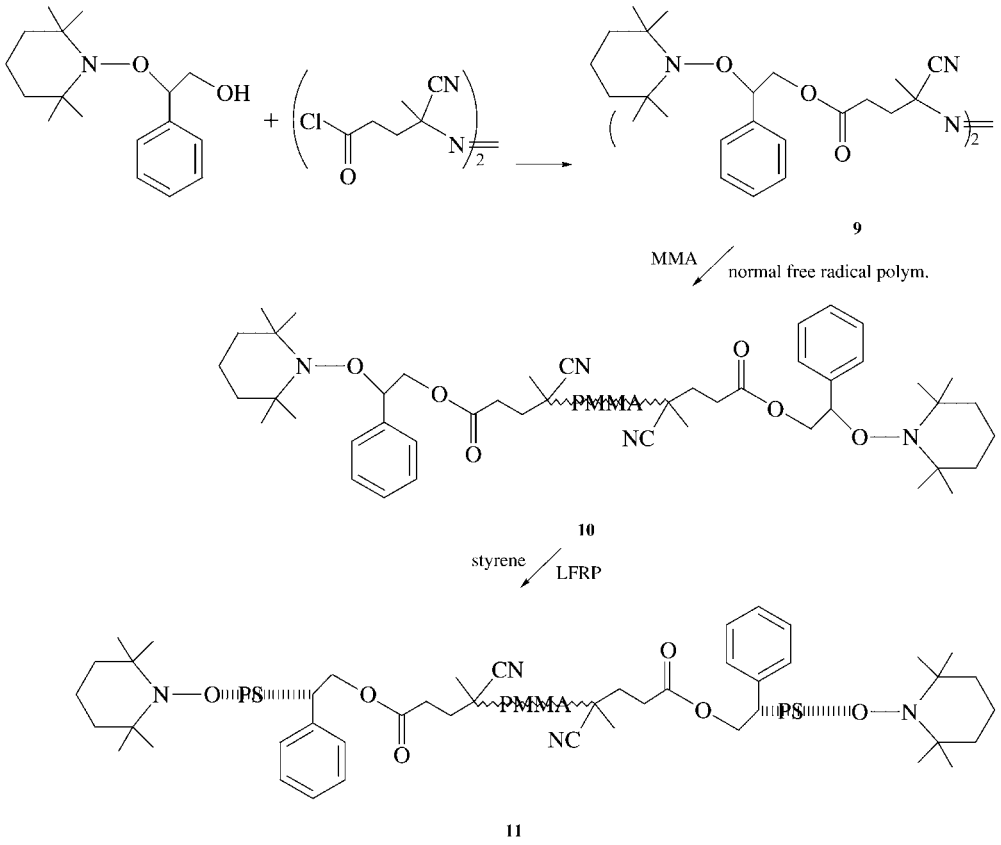

Fig. 45. Normal-living tandem polymerization approach to make styrenic block copolymers.

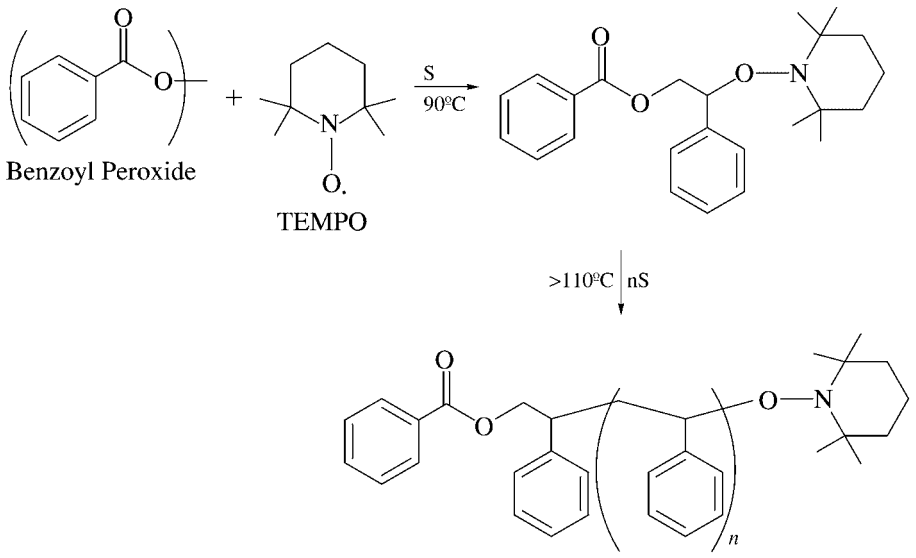

Fig. 46. *In situ* synthesis of alkoxyamine initiator during nitroxide mediated radical polymerization (NMRP) of styrene.

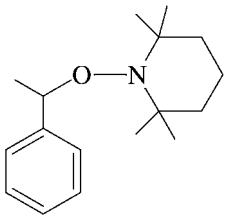
The *in situ* approach leads to the formation of multiple nitroxide initiating species and there is not perfect stoicheometry between the initiating and mediating species. With the presynthesis approach, a pure compound can be used to initiate polymerization which should lead to "cleaner chemistry." However, it has been believed that excess nitroxy radicals is important to achieve narrow polydispersity and good end-group purity (249).

There has been debate over the extent that NMRP eliminates termination processes. The thermal stability of a small molecule (**12**) that models the propagating chain-end of the NMRP of styrene has been synthesized and studied (250). Thermolysis of (**12**) in an ESR spectrophotometer showed continuous formation of 2,2,6,6-tetramethylpiperdinyloxy (TEMPO). Analysis of the residue left in the ESR tube showed decomposition products consisting primarily of styrene. They went on to study the kinetics of the decomposition and found that (**12**) decomposes in the temperature range utilized for NMRP of styrene at a rate comparable to the styrene conversion rate. Based on this observation, they concluded that end-group purity achieved by NMRP of styrene should decrease with both M_n and monomer conversion. They further concluded that this termination process would likely seriously limit the ability of NMRP for the preparation of high molecular weight (>100,000) PS having a narrow polydispersity. These conclusions have been disputed by other research groups who have attempted to prove that NMRP chemistry virtually eliminates all termination processes. These claims are supported by measuring the amount of nitroxyl moiety on the terminal chain-end. Both NMR (251) and nitrogen analyses (252) have been utilized to determine the nitroxyl content of PS made using NMRP. However, these techniques are not very sensitive and provide only an approximation of the level of nitroxide groups in the polymer. Further, it has not been conclusively established that the nitroxide

is at the chain terminus. Furthermore, because of the insensitivity of these analytical techniques, TEMPO-end capped PS samples to be analyzed have always had molecular weights <10,000. Most researchers have reported levels of nitroxide on the terminal chain end at >90% (251). The quality of nitroxide-mediated polymerization is directly linked to maintenance of alkoxyamine functionality on the PS chain end during the polymerization.



12

The level of alkoxyamine on the PS chain end during the polymerization up to high conversions and molecular weight has been measured (253). A very sensitive gpc-uv analysis technique was used to precisely quantitate the level of chromophore attached to polymers (254). They compared the end-group purity of PS made by the *in situ* and presynthesis of initiator approaches, as well as demonstrating the impact of excess nitroxide on nitroxide end-group yield. The gpc-uv technique for polymer end-group analysis requires that the initiator/mediator be tagged with a chromophore having a unique absorbance; that is, absorb at a wavelength at which PS is totally transparent (>280 nm). The chromophore chosen for study was the phenylazophenyl chromophore because of its intense absorption at >300 nm. The chromophore was attached to either the initiating or terminating fragment of the alkoxyamine initiator allowing direct quantitative comparison of both the initiating and terminal ends of PS initiated/mediated using these materials. The data show that the number of polymer chains having chromophores attached to a chain-end decreases with the number-average molecular weight (M_n). This trend is not as dramatic if the chromophore is attached to the initiating radical. M_n and styrene conversion are directly proportional. Therefore, it follows that chain-end purity also decreases rapidly with monomer conversion. This was predicted from earlier work on the thermal decomposition of a small molecule which models the dormant end during NMRF (250). Polystyrene having both a M_n >10,000 and at the same time >90% of one of its chain-ends having a chromophore were never obtained. This data has significant implications for those trying to use NMRP to make functionalized polymers and block copolymers; that is, it is impossible to make polymers having perfect structures by using this chemistry. Therefore, unless you are willing to accept styrenic polymers having some defects in the structure, this chemistry should not be used. However, this chemistry may be the best way to make certain block copolymers even though the structure produced is not perfect. For example, S-*co*-S-*alt*-MA copolymers have been synthesized using NMRP (255). At the present time, no alternative chemistry for making these block copolymers exists.

To date, no one has yet commercialized any polymers produced using an LFRP process, although several companies are aggressively evaluating the

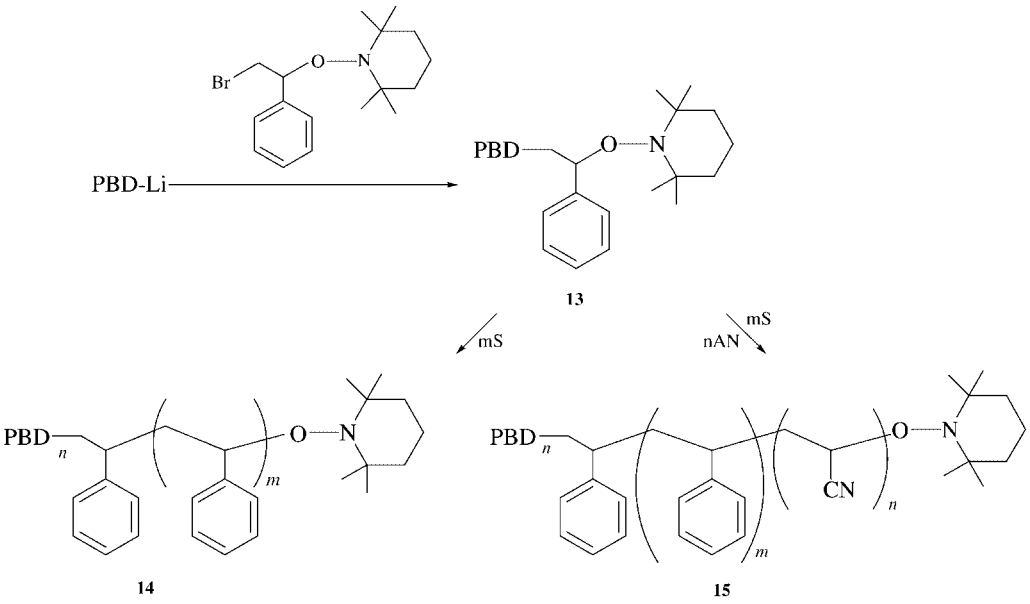


Fig. 47. Dow *in situ* block copolymer process for making HIPS/ABS toughened (256).

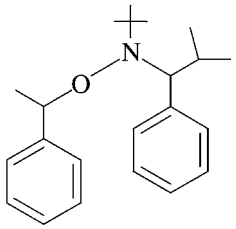
potential of the chemistry for commercial use. One of the applications of highest potential volume is the preparation of styrene–butadiene block copolymers *in situ* during the manufacture of HIPS (256). In this process (Fig. 47), butadiene is polymerized to PB using conventional anionic chemistry. Normally, after the polymerization is complete, the resulting polybutadienyl lithium (PB-Li) is terminated by the addition of a proton donor (an alcohol) to quench the carbanion. However, in the tandem process, a species capable of initiating LFRP that is connected to a group capable of terminating PB-Li is added to terminate the PB rubber (257). This results in the formation of PB that has an LFR functional group on one of its chain ends (**13**). The LFR-functionalized PB is then dissolved in styrene. The rubber styrene solution is then pumped into a typical continuous bulk PS reactor. During the polymerization process, the LFR-functionalized PB acts as a macroinitiator, resulting in the formation of a styrene–butadiene block polymer (**14**) *in situ*, simultaneously with the formation of PS. The final product is a blend of PS and a styrene–butadiene block rubber. The resulting HIPS product has properties similar to HIPS made by polymerizing a solution of styrene containing a styrene–butadiene block rubber (**14**). The same chemistry can be used to make ABS resins where the rubber phase ends up being a SAN–butadiene block copolymer (**15**).

Recently, a universal alkoxyamine initiator (**16**) was reported that allows LFRP of monomers other than styrene. This new alkoxyamine was discovered utilizing high speed combinatorial synthesis techniques. It has been used to make styrene–butadiene, S–BA, and S-MMA block copolymers directly without the need for tandem polymerization techniques (258).



16

The newest LFRP system involves reversible addition fragmentation chain transfer (RAFT) (259). PS, PMA, and PMMA having a polydispersity of <1.3 and block copolymers containing these monomers have been produced utilizing this novel chemistry. The initiators are either thioesters or thiocarbonates (260). The RAFT process is shown in Figure 48.

Amazingly, CSIRO researchers (261) used the RAFT chemistry to make an S-nBA-S triblock copolymer having an M_n of 162,000 and a polydispersity of 1.16. This was accomplished using a difunctional RAFT reagent (thiocarbonate (**17**)). The chemistry is depicted in Figure 49.

Copolymerization. Styrene spontaneously copolymerizes with many other monomers. The styrene double bond is electronegative because of the donating effect of the phenyl ring. Monomers that have electron withdrawing substituents (eg, acrylonitrile, maleic anhydride) tend to most readily copolymerize with styrene because their electropositive double bonds are attached to the electronegative styrene double bond. Spontaneous copolymerization experiments of many different monomer pair combinations indicate that the mechanism of initiation changes with the relative electronegativity difference between the monomer pairs (262).

Copolymerization makes possible dramatic improvements in one or more properties. There is a vast amount of literature on styrene-containing copolymers

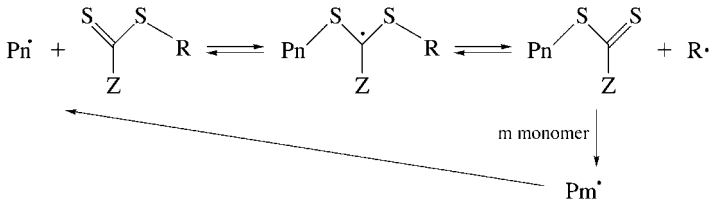


Fig. 48. Reversible addition fragmentation chain transfer (RAFT) process developed by CSIRO researchers.

Butadiene	0.5	1.40	50
m-Ethyl methacrylate	0.54	0.49	60
m-Divinylbenzene	0.65	0.60	60

[a] Monomer 1 = Styrene

(263). The reactivity ratios for the monomer pairs are listed in Table 5. Styrene–acrylonitrile (SAN) copolymers are large-volume thermoplastics with improved mechanical properties and heat and solvent resistance with some loss of color stability (see ACRYLONITRILE AND ACRYLONITRILE POLYMERS). The disparity of reactivity ratios shown in Table 5 implies an unequal insertion rate of the monomers into the copolymer; Figure 50 illustrates manifestations of this effect. Most SAN copolymers are manufactured at or near the azeotrope or crossover point (A in Fig. 50) to avoid significant drift in composition (Fig. 51) (264,265). SAN copolymers having as little as a 4 wt% difference in acrylonitrile content are not miscible (73). Therefore, the preparation of SAN under conditions where composition drift can occur leads to haze. Reactors have been designed to overcome composition drift problems on a commercial scale (266). All SAN copolymers produced in the United States are made in a mass or solution continuous process. The greater tendency of these copolymers to develop yellow coloration requires more attention to techniques of polymerization and devolatilization (267–270). The discoloration

mechanism has been linked to both acrylonitrile sequence distribution in the polymer backbone (271) and the thermal decomposition of oligomers (272–275).

Copolymers with butadiene, ie, those containing at least 60 wt% butadiene, are an important family of rubbers. In addition to synthetic rubber, these compositions have extensive uses as paper coatings, water-based paints, and carpet backing. Because of unfavorable reaction kinetics in a mass system, these copolymers are made in an emulsion polymerization system, which favors chain propagation and disfavors termination (276). The result is economically acceptable rates with desirable chain lengths. Usually, such processes are run batchwise in order to achieve satisfactory particle-size distribution.

Styrene–maleic anhydride (SMA) copolymers are used where improved resistance to heat is required. Processes similar to those used for SAN copolymers are used. Because of the tendency of maleic anhydride to form alternating copolymers with styrene, composition drift is extremely severe unless the polymerization is carried out in CSTR reactors having high degrees of backmixing.

Divinylbenzene copolymers with styrene are produced extensively as supports for the active sites of ion-exchange resins and in biochemical synthesis. About 1–10 wt% divinylbenzene is used, depending on the required rigidity of the cross-linked gel, and the polymerization is carried out as a suspension of the monomer-phase droplets in water, usually as a batch process. Several studies have been reported recently on the reaction kinetics (277,278).

Polymerization of styrene in the presence of PB rubber yields a much tougher material than PS. Although the material is usually opaque and has a somewhat lower modulus, the gain in impact resistance has placed this plastic in very wide commercial usage. The polymerization is complex because the rubber has sufficient reactivity, ie, at the allylic hydrogen and addition to 1,2-vinyl units, to graft and cross-link and the polymerization system is comprised of two phases.

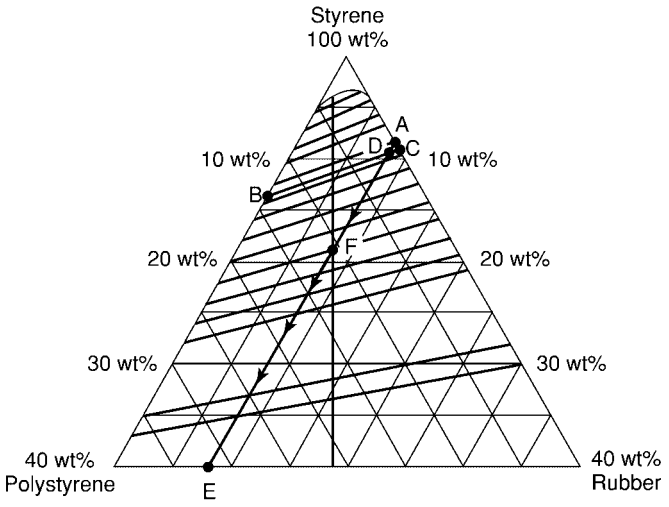

Fig. 52. Ternary phase diagram for the system styrene PS–PB rubber.

The graft copolymer of PS on polybutadiene acts as an emulsifier, stabilizing the dispersion against coalescence. Events taking place during this polymerization can be followed with the ternary phase diagram shown in Figure 52. For a feed mixture made up of 8 wt% rubber in styrene (point A) on an increment of conversion to PS (to D), phase separation occurs. Small droplets of styrene/PS, which are stabilized by the graft copolymer, are dispersed in the styrene/polybutadiene solution. The composition of the two phases is given by points B and C for the PS-rich phase and polybutadiene-rich phase, respectively. The phase-volume ratio, ie, rubber phase/PS phase, is given by the ratio DB/DC. As the reaction proceeds along the line AE, the phase composition and phase-volume ratio can be read from the tie lines. Larger droplets of PS solution form and the small, original ones remain. When the phase-volume ratio is about unity (point F), provided there is sufficient shearing agitation, the larger PS-containing droplets, which have mostly coalesced into large pools, become the continuous phase and polybutadiene-containing droplets are dispersed therein (279,280). However, the latter contain the small, original PS particles as occlusions. The particle size and size distribution are largely controlled by the applied shear rate during and after phase inversion, the viscosity of the continuous phase, the viscosity ratio of the two phases, and the interfacial tension between the phases (81,279). The viscosity parameters depend on phase compositions, polymer molecular weights, and temperatures; the interfacial tension is largely controlled by the amount and structure of the graft copolymer available at the particle surface. Phase-contrast micrographs of this phase-inversion sequence, wherein the PS phase is dark, are shown in Figure 53. If shearing agitation is insufficient, then phase inversion does not occur and the product obtained is an inter network of cross-linked rubber with PS, and its properties are much inferior. The morphology of the dispersed rubber phase remains much as formed after phase inversion, unless there is a step change in phase concentration by, eg, blending streams. Rubber-phase volume, including the occlusions, largely controls performance; for example, Table 6 illustrates Izod impact strength dependence (281).

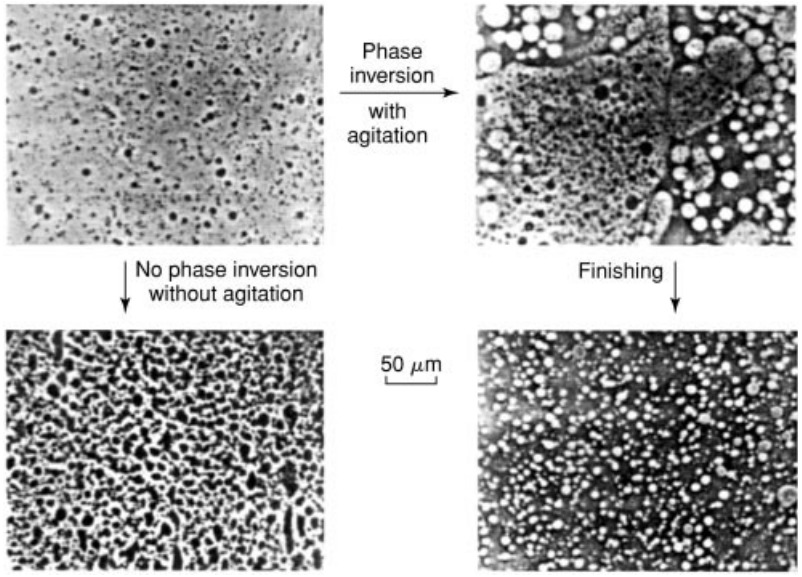

Fig. 53. Phase-contrast photomicrographs showing particle formation via phase inversion.

Once the desired particle size and morphology with sufficient graft to provide adequate adhesion between the rubber particles and the PS phase have been achieved, the integrity of the particle must be protected against deformation or destruction during fabrication by cross-linking of the polybutadiene chains. These chemical changes taking place on the rubber begin with polymerization. Either anionic or Ziegler–Natta-polymerized polybutadiene is used at 5–10 wt% styrene. If peroxide initiators are used, about half of the rubber is grafted by the time phase inversion occurs; less is grafted in the absence of peroxides (282).

Hydrogen abstraction by alkoxy radicals at any of the allylic sites yields a site for styrene polymerization, resulting in a graft (282,283). Model studies based on styrene–butadiene block copolymers show a strong influence of graft structure on particle morphology (81,82). The double bonds in polybutadiene are much less

Table 6. Dependence of Izod Impact Strength on Rubber Particle Size

reactive than those in styrene, but as conversion exceeds ca 80% and temperature approaches or exceeds 200°C, copolymerization through the polybutadiene (1,2 units) chain seems to occur and leads to cross-linking and, hence, gel formation (284).

Since the extent of grafting of PS onto PB has such a profound effect on the properties of HIPS, there has been a significant amount of research carried out to develop an understanding of the grafting process and also the development of ways to increase the extent of grafting (60,285–288).

Commercial Polymerization Processes

Polymerization. There are two problems in the manufacture of PS: removal of the heat of polymerization (ca 700 kJ/kg (300 Btu/lb)) of styrene polymerized and simultaneously handling a partially converted polymer syrup with a viscosity of ca 10^5 mPa (= cP). The latter problem strongly aggravates the former. A wide variety of solutions to these problems have been reported. For the four mechanisms described earlier, ie, free radical, anionic, cationic, and Ziegler–Natta, several processes can be used. Table 7 summarizes the processes that have been used to implement each mechanism for liquid-phase systems. Free-radical polymerization of styrenic systems, primarily in solution, is of principal commercial interest. Suspension processes are declining in importance (289,290). Emulsion processes have been reviewed (291). The historical development of styrene polymerization processes has been reviewed (289,292,293).

Two types of reactors are used for continuous solution polymerization. The first is the continuous plug-flow reactor (CPFR), approximating in the ideal case a plug-flow reactor, and the second is the continuous-stirred tank reactor (CSTR), which ideally is isotropic in composition and temperature (see REACTOR TECHNOLOGY). The CPFR usually involves conductive heat transfer to many tubes through which a heat-transfer fluid flows. Multiple temperature zones can easily be achieved in a single reactor; agitation is provided by a rotating shaft with arms down the central axis of the tubular vessel. Reactors of this type operate for long periods and handle very high viscosity partial polymers with reliable heat-transfer coefficients. CSTRs are either of the recirculated coil configuration and rely upon conduction to the cooled jacket for heat removal or are ebullient making use primarily of evaporative cooling to achieve temperature control. The limitation

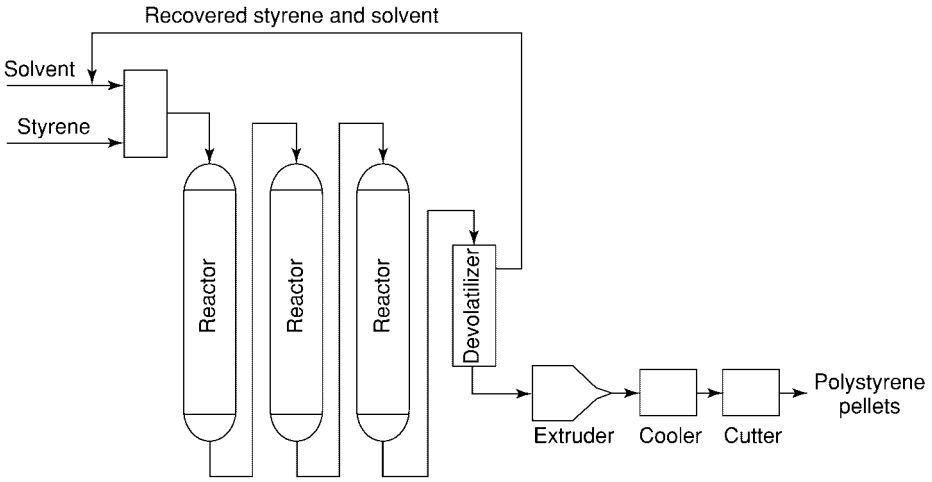

Fig. 54. Typical continuous plug-flow reactor (CPFR) polymerization process.

of this reactor occurs at high viscosity, when the rate of vapor disengagement is exceeded by the rate of vapor generation and the ability to mix in the condensed vapor. Typically, this limit occurs at 60–70 wt% solids. Figures 54 and 55 illustrate typical processes based on these two types of reactors. Most GPPS is manufactured in the United States in such facilities. The CPFR process (Fig. 54) typically uses up to 20 wt% ethylbenzene mainly to reduce viscosity, but also to eliminate reactor fouling. The three reactors may each be subdivided into three temperature-control zones, which allows for flexible control of the molecular weight distribution of the polymer as well as optimum output per reactor volume. Temperatures are 100–170°C. At ca 80 wt% solids, the partial polymer is heated from 180°C to 240°C before being devolatilized upon entering a vacuum tank. The recovered solvent and monomer are continuously recycled to the feed. The molten polymer leaves the vacuum tank and is stranded, cooled, and chopped into pellets for shipping. The CSTR process (Fig. 7) differs in that it is typically a single reactor and, therefore,

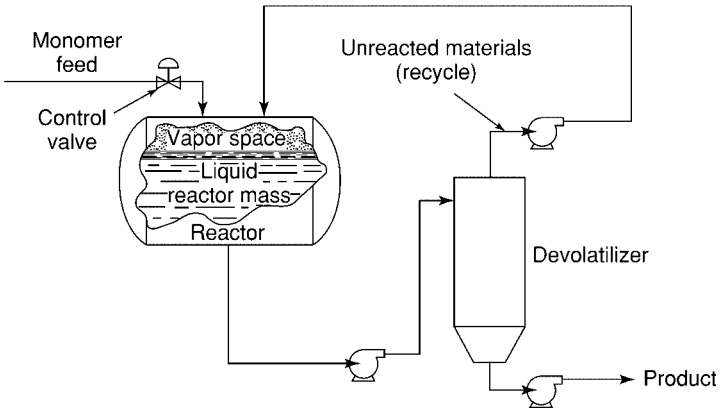

Fig. 55. Typical CSTR polymerization process.

involves a single temperature zone and operates at ca 60 wt% solids, requiring a large polymer heater to achieve adequate devolatilization (294,295). The need for a large polymer heater to achieve adequate devolatilization can be eliminated by adding a CPFR after the CSTR to carry the conversion to high solids.

There has been some research aimed at continuously converting monomer completely to polymer using reactive extrusion (296). However, this process has not yet been commercialized.

Rubber-modified PS manufacture places several additional demands: (*1*) dissolving ca 5–10 wt% polybutadiene in styrene, often a 10- to 20-h process; (*2*) shear conditions to achieve phase inversion and the desired particle size for a given product; (*3*) control of phase compositions to produce the desired particle morphology; and (*4*) sufficient time and temperature at the end of the process to achieve the necessary cross-linking, gel formation, and swelling index. Graft copolymer formation occurs throughout the polymerization, and sufficient amount of graft copolymer for phase stability is necessary at phase inversion. In the case of a CPFR system (Fig. 54), only addition of a rubber dissolver is needed to meet these requirements. For a CSTR-based system (Fig. 55), multiple reactors in series are required to avoid rapid shifts in phase compositions on mixing of one reactor effluent with the next reaction contents with loss of desirable morphology (297,298). Figure 56 shows a multizone CSTR reactor system. Phase inversion and particle sizing is accomplished in the first-stage reactor with the effluent entering a single-tank, baffled reactor operating as five stages with a common vapor space. An alternative is three CSTR reactors in series, followed by an adiabatic reactor to achieve high solids content (297). The multiple stages are necessary to achieve favorable

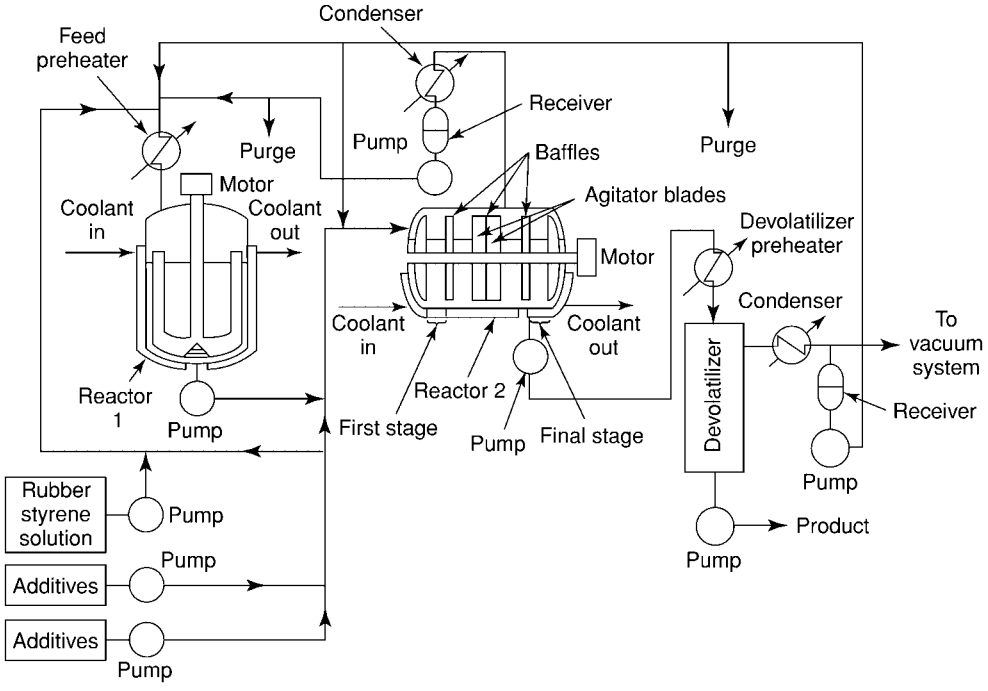

Fig. 56. Typical staged CSTR process for HIPS.

rubber-particle morphology with CSTRs; CPFR systems inherently avoid sudden phase-composition changes, unless severe internal backmixing is allowed to occur.

Generally, phase inversion and particle sizing occurs in the first reactor. Grafting rate is highest initially, and the amount formed is adequate to stabilize the particles. The shear field in the reactor is critical to the control of particle size as well as to meet the minimum shear rate for phase inversion, without which the product consists of a continuous cross-linked rubber network with markedly inferior properties (279,280). After the particles are formed and sized, only gentle agitation is applied to aid heat transfer without disturbing the particle structure. Conditions that produce the desired PS-phase molecular weight are used. Prior to devolatilization, the partial polymer is heated to ca 200°C to cross-link the rubber chains in order to protect the rubber particles from the very high shear fields during fabrication. Stranding, cooling, and chopping into pellets follows.

Polybutadiene rubbers are used almost exclusively as reinforcing agents for styrenic plastics. The very low glass-transition temperature (−80°C or lower) gives good low temperature properties, and the allylic hydrogen atom and weakly active double bonds can provide the desired degree of grafting and cross-linking. Other rubbers have been used; acrylates, ethylene–propylene–diene rubbers, polyisoprene, and polyethylene have been reported, but with limited commercial success because of their low chemical reactivity, not withstanding their acceptable glass-transition temperature (299).

Devolatilization. Current bulk polymerization processes convert styrene to about 80%. The polymer syrup exits the polymerization reactor at about 170°C. The most common devolatilization technology involves increasing the temperature of the syrup to >230°C by passage through a heat exchanger connected to a vacuum tank. The syrup foams, forming strands which fall into a vacuum tank at 5–10 mm Hg as they exit the heat exchanger. An equilibrium of styrene in the polymer and in the vapor phase takes place, which is dependent upon the temperature and the pressure in the tank. Figure 57 shows the vapor–polymer equilibrium partitioning data (calculated) for styrene in PS at various levels of vacuum (one-stage devolatilizer) (300). Typically, devolatilizers operate at ca 230–240°C and 5–10 mm Hg. Therefore, the level of residual styrene monomer left in the polymer is typically in the range of 300–500 ppm. If the polymer temperature is increased to greater than 240°C, polymer degradation begins to take place resulting in the formation of styrene monomer. Asahi researchers have solved this problem by stabilizing the polymer against unzipping by the addition of a special stabilizer (**18**), thus allowing higher temperature devolatilization to be carried out (301).

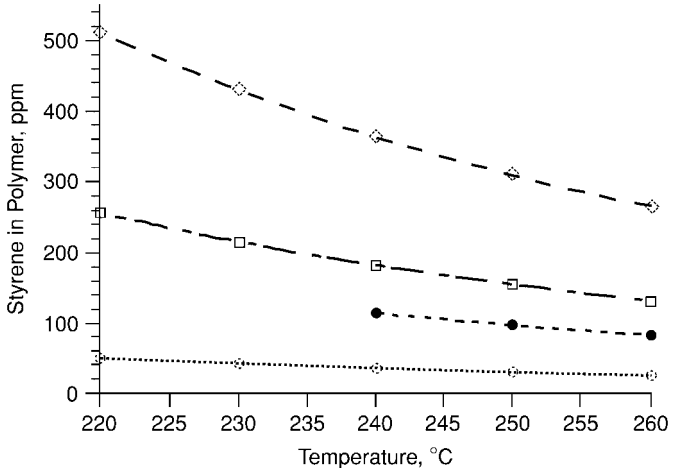

Fig. 57. Vapor-polymer equilibrium partitioning data for styrene in PS vs temperature and pressure. ···○··· 133.3 Pa; -□—667 Pa;—◇—1.33 kPa; --●-- 667 Pa + 10% water. To convert Pa to mm Hg, divide by 133.3.

Some foods packaged in PS are extremely sensitive to taste (eg, chocolate chip cookies). These sensitive applications require PS having residual styrene monomer levels below 200 ppm. It is not feasible to consistently lower the styrene level to <200 ppm without special techniques.

A new technology for lowering residuals in PS being commercialized by Dow is centrifugal devolatilization in a rotating packed bed (302,303). The basic concept involves pumping the molten PS into the center of an evacuated spinning rotor packed with metal mesh. Centrifugal force quickly pushes the polymer through the high surface area mesh where it coats the metal and volatiles quickly diffuse from the thin polymer film. The centrifugal force continues to force the polymer out of the metal mesh packing against the exterior surface of the centrifuge having a circumferential set of die holes. After being extruded from the die holes, the polymer strands are cut into pellets as the rotor rotates past a slowly moving, continuous knife blade. A drawing of the centrifugal devolatilizer is shown in Figure 58.

A very effective way to get residual styrene monomer levels below equilibrium is to replace the styrene in the vapor phase with something else. Generally, it is preferred that the material in the vapor phase be condensable, nontoxic, low cost, easily separable from the recycle, and inert (eg, water). However, simply bleeding the replacement material into the vapor space of the devolatilizer would still require significant residence time to reach equilibrium. A way to expedite the equilibrium process is to mix the replacement material with the molten polymer (304). Then as the material vaporizes in the molten polymer, it nucleates bubbles stripping styrene from the polymer while creating a vapor phase composed mainly of the stripping material. Stripping materials that have been used include nitrogen, (305), methanol (306), and water (307).

Another technique to expedite the transport of the volatile components from the molten polymer is to increase the number and rate of bubbles formed (308).

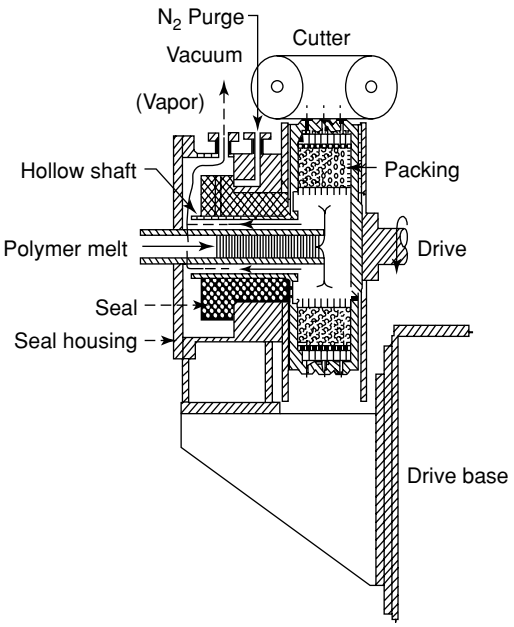

Fig. 58. Drawing of centrifugal devolatilizer being used by Dow.

Techniques that have been used to increase the number of bubbles and their rate of formation (nucleation) are the addition of chemical nucleating agents (309) and ultrasound (310). Nucleation of bubbles in the molten polymer can help expedite achievement of equilibrium in conventional falling strand devos. However, this facilitation mechanism can not get below equilibrium and thus has marginal value.

Chemically Removing Residual Monomer. Some researchers have tried to lower the level of residual styrene monomer by chemical means. The idea of adding something to molten PS that scavenges residual styrene monomer has been the subject of extensive R&D efforts over the past several decades. However, there is an inherent difficulty in this concept; that is, small molecules in very low concentration must diffuse together, find each other, and couple together in a viscous polymer. The obvious way to overcome this difficulty is to use the scavenger in higher than stoicheometric concentration. This introduces several new problems including contamination of the polymer with a new material and increased raw material costs. Styrene scavenger compounds that have been patented include unsaturated fatty acids (311) and aldehydes (312), sulfonyl hydrazides (313), cyclopentadienes (311), K-resin (314), peroxides (315), and terpenes (316).

Another option for lowering residual styrene monomer is to carry the polymerization up to high conversion. Typically, continuous bulk polymerization processes produce partial polymer syrups at about 65–80% solids. The unreacted styrene that remains is removed by evaporation. If the solids content of the polymer could be taken higher, the level of residual styrene in the polymer would be lower, especially when using a one-stage devolatilizer. In suspension polymerization, devolatilization is not even required because styrene is polymerized to $>$99.9% monomer conversion. If it were possible to polymerize styrene to very high

conversion in bulk polymerization processes, significantly lower residual styrene monomer could be achieved. Because of viscosity constraints, bulk polymerization reactors cannot operate at >80% solids. To achieve >99% monomer conversion while maintaining the solids <80% would require high levels of solvent. The problem with solvents is chain transfer. Going above 95% conversion in ethylbenzene results in an exponential increase in polydispersity due primarily to chain transfer effects. A high conversion bulk styrene polymerization process resulting in the formation of low residual PS has been patented, which solves the viscosity problem and allows going to >99.9% solids by finishing the polymerization off in an extruder (317). Extruders are not very effective heat exchangers, yet are designed for handling high viscosity materials. Thus, Kelly carried out the polymerization of pure styrene monomer without the use of a solvent in a conventional polymerization reactor to normal solids levels and then fed the partial polymer into an extruder where he finished off the polymerization. He used a mixture of initiators having different half-lives so that radicals were continuously generated. Recently, free-radical polymerization of styrene directly in an extruder using 1 wt% peroxide initiator was analyzed (318). They were not successful in making PS having a molecular weight >100,000. They got around this problem by attaching a prepolymerization reactor to the front end of the extruder to polymerize to 25% solids to make high M_w PS. The low M_w PS then made in the extruder giving them a bimodal PS. The conversion they achieved in the extruder was 98–99%.

A final technique that has been utilized to chemically remove residual styrene in PS is radiation treatment. Both beta (e-beam) and gamma radiation have been tried. E-beam appears to be the most effective form of radiation and is most suitable for continuous use (319,320). The e-beam ruptures C—H bonds, resulting in the formation of PS radicals. These radicals are very reactive and scavenge unreacted monomer. However, if no styrene is in the vicinity of the PS radical, it can do other things such as couple with another PS radical or react with oxygen. Currently, electron beam treatment of polymers is used commercially for elastomer cross-linking (wire/cable coatings) but not for monomer reduction.

Polystyrene treated with 1–4 Mrad of e-beam radiation at temperatures between 25 and 200°C shows an optimum irradiation temperature between 80 and 150°C (Fig. 59). It is interesting that all dosages tested have a temperature range for maximum effectiveness, which drifts toward lower temperature as the dosage increases (321). At all temperatures studied, weight-average molecular weight increases with e-beam dose (Fig. 60) (321).

Fabrication.

Injection Molding. There are two basic types of injection-molding machines in use: the reciprocating screw and the screw preplasticator (322). Their simple design, uniform melt temperature, and excellent mixing characteristics make them the preferred choice for injection molding. Machines with shot capacities up to 25 kg for solid injection-molded parts and 65 kg for structural foam parts are available (323,324). Large solid moldings include automotive dash panels, television cabinets, and furniture components. One-piece structural foam parts weighing 35 kg or more are molded for increased rigidity, strength, and part weight reduction (325) (see PLASTICS PROCESSING).

The injection-molding process is basically the forcing of melted polymer into a relatively cool mold where it freezes and is removed in minimum time. The shape

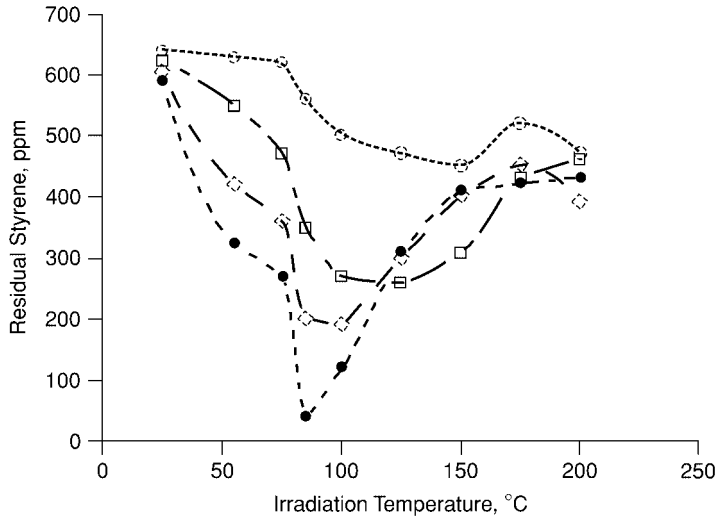

Fig. 59. Performance of different e-beam doses vs temperature (321). --○-- 10 kGy; -□—20 kGy; -◇—30 kGy; --●-- 40 kGy. To convert kGy to Mrad, divide by 10.

of a molding is defined by the cavity of the mold. Quick entry of the material into the mold followed by quick setup results in a significant amount of orientation in the molded part. The polymer molecules and, in the case of heterogeneous rubber-modified polymers, the rubber particles tend to be highly oriented at the surface of the molding. Orientation at the center of the molding tends to be significantly less because of the relaxation of the molten polymer.

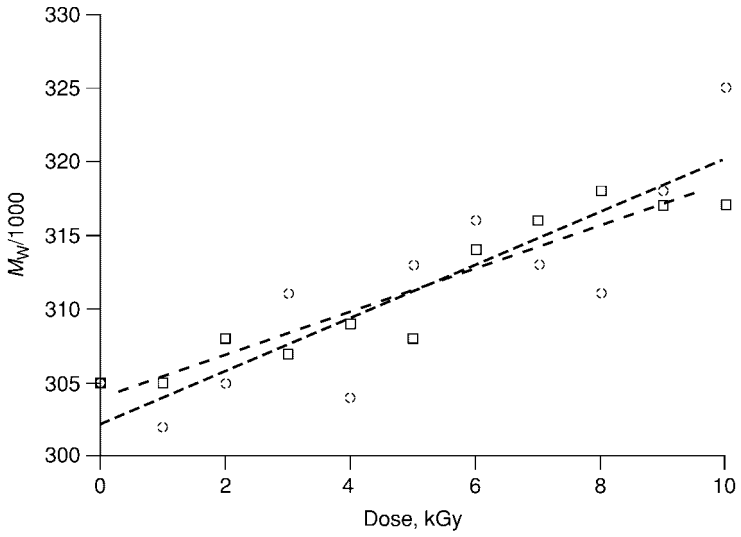

Fig. 60. Effect of dose on M_w at ambient and elevated temperature (321). --○-- 25°C; -□—85°C. To convert kGy to Mrad, divide by 10.

The anisotropy that develops during the molding operation is detrimental to the performance of the fabricated part in several ways. First, highly oriented moldings, which form particularly if low melt temperatures are used, exhibit good gloss, have an abnormally narrow use temperature range causing early warping, and, perhaps most importantly, tend to be brittle even though the material is inherently capable of producing tough parts (326). However, this development of polymer orientation during molding can also be used to advantage, as in the case of rotational orientation during the molding operation (327).

The achievement of isotropic moldings is also important when the molded part is to be decorated, ie, painted, metallized, etc Highly oriented parts that have a high frozen-in internal stress memory tend to give rise to rough or distorted surfaces as a result of the relaxing effect of the solvents and/or heat. For electroplating ABS moldings, it is particularly important to obtain isotropic moldings. Isotropy can be achieved by the use of a high melt temperature, a slow fill speed, a low injection pressure, and a high mold temperature (127,128,328,329).

Injection molding of styrene-based plastics is usually carried out at 200–300°C. For ABS polymers, the upper limit may be somewhat less, since these polymers tend to yellow somewhat if too high a temperature and/or too long a residence time are imposed.

To obtain satisfactory moldings with good surface appearance, contamination, including that by moisture, must be avoided. For good molding practice, particularly with the more polar styrene copolymers, drying must be part of the molding operation. A maximum of 0.1 wt% moisture can be tolerated before surface imperfections appear.

For achieving appropriate economics, injection-molding operations are highly automated and require few operating personnel (322). Loading of the hopper is usually done by an air-conveying system; the pieces are automatically ejected, and the rejects and sprues are ground and reused with the virgin polymer. Also, hot probes or manifold dies are used to eliminate sprues and runners.

Extrusion. Extrusion of styrene polymers is one of the most convenient and least expensive fabrication methods, particularly for obtaining sheet, pipe, irregular profiles, and films. Relatively small extruders, eg, 11.5 cm diameter, can produce well over 675 kg/h of polymer sheet. Extrusion is also the method for plasticizing the polymer in screw injection-molding machines and is used to develop the parison for blow molding. Extrusion of plastics is also one of the most economical methods of fabrication, since it is a continuous method involving relatively inexpensive equipment. The extrusion process has been studied in great detail (330,331). Single-screw extruders work extremely well with styrene-based plastics. Machines are available with *L*/*D* (length-to-diameter) ratios of 36:1 or more. Some of the longer *L*/*D* extruders are used with as many as three vent zones for removal of volatiles, often eliminating the necessity for predrying as is practiced with hygroscopic materials, eg, SAN and ABS. Where venting is inadequate, these polymers must be predried to a maximum moisture content of 0.03–0.05 wt% to obtain high quality sheet (see FILMS AND SHEETING).

Many rubber-modified styrene plastics are fabricated into sheet by extrusion primarily for subsequent thermoforming operations. Much consideration has been given to the problem of achieving good surface quality in extruded sheet (332,333).

Excellent surface gloss and sheet uniformity can be obtained with styrene-based polymers.

Considerable work has been done on mathematic models of the extrusion process, with particular emphasis on screw design. Good results are claimed for extrusion of styrene-based resins using these mathematical methods (331,334).

With the advent of low cost computers, closed-loop control of the extrusion system has become commonplace. More uniform gauge control at higher output rates is achievable with many commercial systems (335,336).

Lamination of polymer films, both styrene-based and other polymer-types, to styrene-based materials can be carried out during the extrusion process for protection or decorative purposes. For example, an acrylic film can be laminated to ABS sheet during extrusion for protection in outdoor applications. Multiple extrusion of styrene-based plastics with one or more other plastics has grown rapidly in the last 10 years.

Thermoforming and Orientation. Thermoforming of HIPS and ABS extruded sheet is of considerable importance in several industries. In the refrigeration industry, large parts are obtained by vacuum-forming extruded sheet. Vacuum forming of HIPS sheet for refrigerator-door liners was one of the most significant early developments promoting the rapid growth of the whole family of HIPS. When a thermoplastic polymer film or sheet is heated above its glass-transition temperature, it can be formed or stretched. Under controlled conditions, new shapes can be controlled; also, various amounts of orientation can be imparted to the polymer film or sheet for altering its mechanical behavior.

Thermoforming is usually accomplished by heating a plastic sheet above its softening point and forcing it against a mold by applying vacuum, air, or mechanical pressure. On cooling, the contour of the mold is reproduced in detail. In order to obtain the best reproduction of the mold surface, carefully determined conditions for the plastic-sheet temperature, ie, heating time and mold temperature, must be maintained.

Several modifications of thermoforming plastic sheet have been developed. In addition to straight vacuum forming, there are vacuum snapback forming, drape forming, and plug-assist-pressure-and-vacuum forming. Some combinations of these techniques are also practiced. Such modifications are usually necessary to achieve more uniform wall thickness in the finished deep-draw sections. Vacuum forming can also be continuous by using the sheet as it is extruded. An example of this technology is practiced with several high speed European lines in operation in the United States. Precise temperature conditioning allows carefully controlled levels or orientation in the finished part (337).

Thermoforming is perhaps the process with the lowest unit cost. Examples of thermoformed articles are refrigerator-door and food-container liners, containers for dairy products, luggage, etc Some of the largest formed parts are camper/trailer covers and liners for refrigerated-railroad-car doors (338).

Orientation of styrene-based copolymers is usually carried out at temperatures just above T_g. Biaxially oriented films and sheet are of particular interest. Such orientation increases tensile properties, flexibility, toughness, and shrinkability. PS produces particularly clear and sparkling film after being oriented biaxially for envelope windows, decoration tapes, etc Oriented films and sheet of

styrene-based polymers are made by the bubble process and by the flat-sheet or tentering process. Fibers and films can be produced by uniaxial orientation (339) (see FILMS AND SHEETING).

Blow Molding. Blow molding is a multistep fabrication process for manufacturing hollow symmetrical objects. The granules are melted and a parison is obtained by extrusion or by injection molding. The parison is then enclosed by the mold, and pressure or vacuum is applied to force the material to assume the contour of the mold. After sufficient cooling, the object is ejected.

Styrene-based plastics are used somewhat in blow molding but not as much as linear PE and PVC. HIPS and ABS are used in specialty bottles, containers, and furniture parts. ABS is also used as one of the impact modifiers for PVC. Clear, tough bottles with good barrier properties are blow-molded from these formulations.

Polystyrene or copolymers are used extensively in injection blow molding. Tough and craze-resistant PS containers have been made by multiaxially oriented injection-molded parisons (340). This process permits the design of blow-molded objects with a high degree of controlled orientation, independent of blow ratio or shape.

Additives. Processing aids, eg, plasticizers and mold-release agents (see ABHERENTS), are often added to PS. Even though PS is an inherently stable polymer, other compounds are sometimes added to give extra protection for a particular application. Rubber-modified polymers containing unreacted allylic groups are very susceptible to oxidation and require carefully considered antioxidant packages for optimum long-term performance. Ziegler–Natta-initiated polybutadiene rubbers are especially sensitive in this respect, since they often contain organocobalt residues from the catalyst complex. For food-contact applications, the additives must be FDA approved. Important additives used in styrene plastics are listed in Table 8.

Economic Aspects

Most of the styrene monomer manufactured globally goes into the manufacture of PS and its copolymers; thus the price of the two tend to parallel each other (Fig. 61).

Polystyrene is a global product with North America, Western Europe, and the Pacific consuming most of the world's production (Fig. 62). The global PS production capacity generally parallels the demand for the material (Fig. 63). However, the trend over the last 15 years has been toward narrowing the gap between capacity and demand in an effort to maximize the profitability of the business.

Characterization

Four modes of characterization are of interest: chemical analyses, ie, qualitative and quantitative analyses of all components; mechanical characterization, ie, tensile and impact testing; morphology of the rubber phase; and rheology at

Table 8. Additives Used in Styrene Plastics

Type	Compounds	Examples	Amount (wt%)	Comments
Plasticizers	Mineral oil		<4	all cause loss of heat-distortion temperature

a range of shear rates. Other properties measured are stress-crack resistance, heat-distortion temperatures, flammability, creep, and others depending on the particular application (341).

Since plastics are almost invariably modified with one or more additives, there are three components of chemical analysis: the high molecular weight portion, ie, the polymer; the additives, ie, plasticizer and mold-release agent; and the residuals remaining from the polymerization process. The high molecular weight portion is best characterized using gpc which gives molecular weight and polydispersity information. If the gpc is equipped with a diode-array detector, chromophores responsible for polymer discoloration can be located (177). The additives in the polymer are best characterized by extracting them from the polymer and analyzing the extract using high performance liquid chromatography (342). Figure 5 illustrates typical molecular weight distribution curves from gpc, and Figure 64

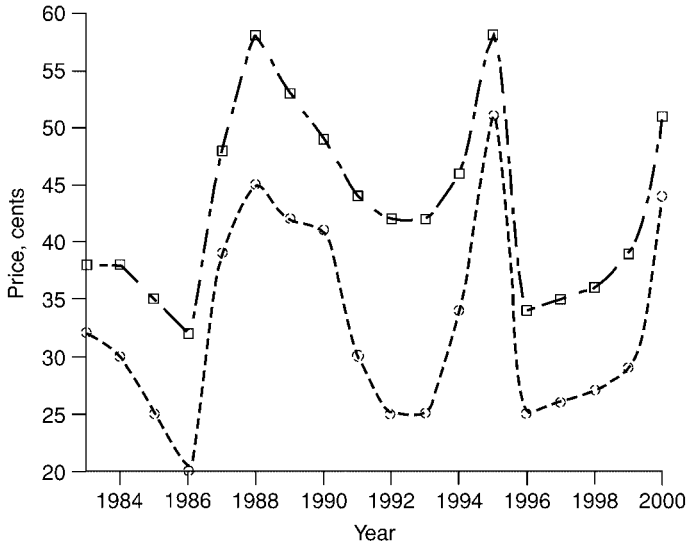

Fig. 61. Historical comparison of styrene monomer and GPPS pricing. ···○··· Styrene monomer; -□—Polystyrene.

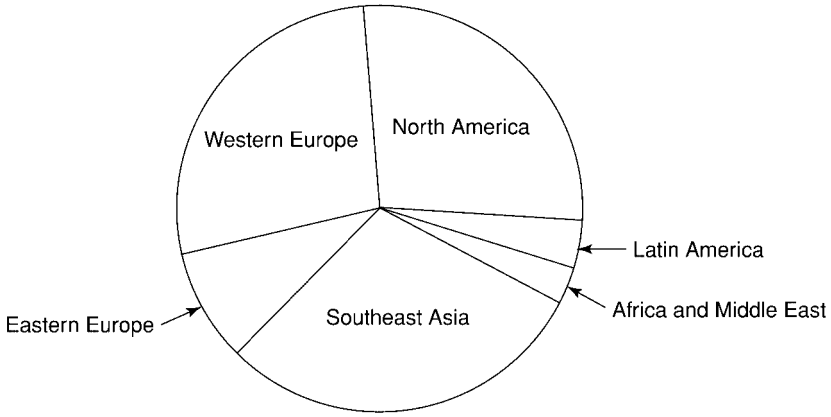

Fig. 62. Global consumption of PS by geographical area (145).

shows a capillary gas chromatogram for determining residuals. Chemical characterization techniques utilized for styrenic polymers are summarized in Table 9. Mechanical testing is carried out according to the methods listed in Table 10.

Rubber particle-size distribution is usually measured with a Coulter counter or directly from electron photomicrographs (110,343); the latter also gives details of particle morphology. Rheological studies are made with a modified tensile tester with capillary rheometer (ASTM D1238-79) or with the powerful Rheometrics mechanical spectrometer (344). For product specifications, a simple melt-flow test is used (ASTM D1238 condition G) with a measurement of the heat-distortion

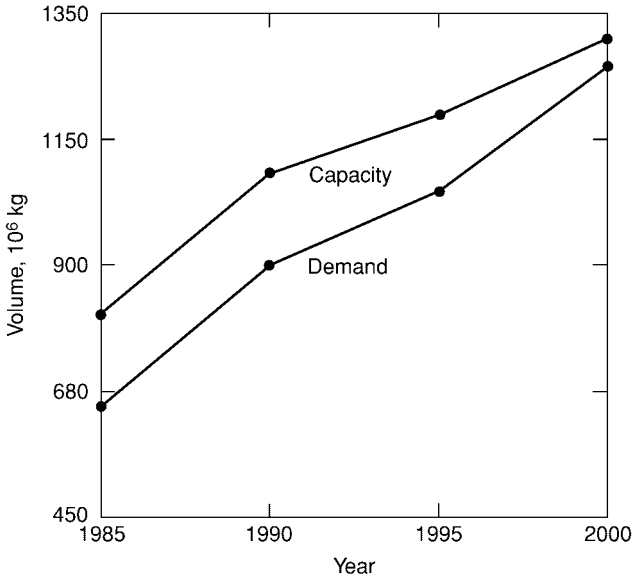

Fig. 63. Global demand vs capacity for PS since 1985 (145).

temperature (ASTM D1525). These two tests, with solution viscosity as a measure of molecular weight, have been used historically to characterize PS. However, molecular weight distribution and residuals analyses, in general, have replaced them.

Health and Safety Factors

In pellet form, styrene-based plastics have a very low degree of toxicity (345). Under normal conditions of handling and use, they should pose no unusual problems from ingestion, inhalation, or eye or skin contact. Heating of these polymers usually results in the release of some vapors. The vapors contain some styrene [TLV = 100 ppm (1974); human detection, 5–10 ppm] and, in the case of styrene–acrylonitrile copolymers, some acrylonitrile [TLV = 2 ppm (1978)] as well as very low levels of degraded and oxidized hydrocarbons and additives. The warning properties of styrene and any oxidized organics are such that the vapors normally can be detected by humans at very low levels, and hazardous concentrations are usually irritating and obnoxious. Nevertheless, adequate ventilation should be provided.

Styrene polymers burn under the right conditions of heat and oxygen supply. This can occur even when they are modified by addition of ignition-suppression chemicals. Once ignited, these polymers may burn rapidly and produce a dense black smoke. Combustion products from any burning organic material should be considered toxic. Ignition temperatures of several styrenic polymers are listed in Table 11. Fires can be extinguished by conventional means, ie, water and water fog.

Uses

PS Foams. The early history of foamed PS is given in Reference 346 and the theory of plastic foams is discussed in Reference 347. Dow became the first to commercially manufacture PS-extruded foam board for home insulation under the trade name Styrofoam (348). Foamable PS beads were developed in the 1950s by BASF under the trademark of Styropor (349–351). These beads, made by suspension polymerization in the presence of blowing agents such as pentane or hexane, or by post-pressurization with the same blowing agents, have had an almost explosive growth, with 200,000 metric tons used in 1980. Some typical physical properties of PS foams are listed in Table 12 (see FOAMED PLASTICS). Some believe that there are unlimited new opportunities for the development of new foam materials (352).

The following are commercially significant foamed PSs. Extruded planks and boards in the density range of 29 kg/m^3 and largely flame retardant are used for low temperature thermal insulation, buoyancy, floral display, novelty, packaging, and construction purposes. Foamed boards and shapes from foaming-in-place (FIP) beads (density 16–32 kg/m^3) are used for packaging, buoyancy, insulation, and numerous other applications. Batch molding of boards and shapes as well as automated molding of continuous planks are used. Extruded foamed PS sheet

17 mm thick with densities of 64–160 kg/m^3 are used largely in packaging applications. Extremely fine cell size is required for texture and strength. Special nucleating agents are employed for this purpose, eg, polymers of styrene and maleic anhydride, citric acid–sodium bicarbonate mixtures, and talc (353). High density (35–64 kg/m^3) extruded planks are used for heavy-duty structural applications. Styrene copolymer foams containing, eg, acrylonitrile for gasoline resistance are made either by extrusion or from beads. High density (480–800 kg/m^3) injection-molded objects are made from mixtures of FIP beads and PS granules or more commonly HIPS or ABS with a chemical blowing agent, eg, azodicarbonamide. These moldings have a high density skin of essentially PS and a foamed core. Foamable ABS systems, eg, laminates with ABS skins and a heat-foamable core, are used for structural applications, as in car body parts (354). Of growing commercial significance is coextruded, foam-core ABS pipe (355,356). Reducing the density of the foam core by up to one-half and using a chemical blowing agent results in about a 20% overall pipe weight and raw material usage reduction. Syntactic foams are combinations of foamable beads, eg, expandable PS or SAN copolymers. These are mixed with a resin, usually thermosetting, which has a large exotherm during curing, eg, epoxy or phenolic resins (357). The mixture is then placed in a mold and the exotherm from the resin cure causes the expandable particles to foam and forces the resin to the surface of the mold. A typical example is expandable PS in a flexible polyurethane-foam matrix used in cushioning applications (358). Sandwich panels are made either by foaming beads between the skin materials or by adhering skins to planks cut to precise dimensions. Foamed PS beads are admixed with concrete for lightweight masonry structures (359).

Extruded Rigid Foam. In addition to low temperature thermal insulation, foamed PSs are used for insulation against ambient temperatures in the form of perimeter insulation and insulation under floors and in walls and roofs. The upside-down roof system, in which foamed plastic such as Styrofoam plastic foam is applied above the tar-paper vapor seal, thereby protecting the tar paper from extreme thermal stresses that cause cracking, has been patented (360). The foam is covered with gravel or some other wear-resistant topping (see ROOFING MATERIALS).

In addition to such thermal-insulation uses in buildings, there is a potentially tremendous new area in the form of highway underlayment to prevent frost damage. Damage to roadways, roadbeds, and airfields because of frost action is a costly and aggravating problem. Conventional treatments to prevent such damage are expensive and unreliable. During the 1960s, an improved and more economical solution to the problem was developed (361). It is based on the use of thermal insulation to reduce the heat loss in the frost-susceptible subgrade soil so that no freezing occurs. Many miles of insulated pavements have been built in the United States, Canada, Europe, and Japan. The concept has proved valid, and the performance of extruded PS foam has been completely satisfactory. It is expected that the use of this concept will continue to grow as natural road-building materials continue to become more scarce and expensive and as the weight and speed of land and airborne vehicles continue to increase.

A 2.54-cm Styrofoam plastic foam with thermal conductivity of ca 0.03 W/(m·K) [(0.21 Btu·in.)/(ft·h·°F)] is equivalent to 61 cm of gravel. Any synthetic foam having compressive strength sufficiently high and thermal conductivity sufficiently low is effective. However, the resistance of PS-type foams to water, frost damage, and microorganisms in the soil makes them especially desirable. An interesting and important application of this concept was the use of Styrofoam in the construction of the Alaska Pipeline. In this case, the foam was used to protect the permafrost.

Rigid Foam from FIP Beads. Expandable PS (EPS) has been in wide use in packaging since its introduction. Applications range from pallet shipping containers for computer terminals to material-handling stacking trays to packages for fresh fruits and vegetables. Expandable PS serves as a cushioning material, a package insert for blocking and bracing, a flotation item, or as insulation.

The basic resin for EPS is in the form of beads that are expanded to a desired density before molding. Densities for packaging parts typically are 20–40 kg/m^3. Once expanded, the beads are fused in a steam-heated mold to form a specific shape. Most parts are molded of standard white resins, although several pastel colors are available.

Converters who manufacture EPS parts and components for packaging are called shape molders. Others who mold large billets, eg, measuring 0.6 × 1.2 × 2.4 m, are called block molders. The package user can obtain EPS parts without the benefits of a mold; parts can be fabricated from billets by hot-wire cutting. Whether molded or fabricated, EPS packages and their components are typically designed by careful consideration of the compression and cushioning properties of expanded PS (362).

A large number of factors that influence the foaming of foamable PS beads, eg, the molecular weight of the polymer, polymer type, blowing-agent type and content, and bead size, have been analyzed (363). It is suggested that at least part of the pentane blowing agent is present in microvoids in the glassy PS. Thus, the density of beads containing 5.7 wt% *n*-pentane is 1080 kg/m^3, compared to a value of 1050 kg/m^3 for pure PS beads and compared with a calculated density of 1020 kg/m^3 for a simple mixture in which *n*-pentane is dissolved in the PS. If all of the pentane were in voids, the calculated density would be 1120 kg/m^3. About 60% of the pentane is held in voids, with the balance presumably dissolved. *n*-Pentane present in voids has a reduced vapor pressure, which depends on the effective

Table 13. Loss of Isopentane from Foaming-in-Place Chlorostyrene Beads[a] in Open Storage, wt%[b]

[a] 420-mm beads.
[b] Initial concentration of isopentane = 6 wt%.

microcapillary diameter. Dissolved *n*-pentane in PS will also have a reduced vapor pressure, by an amount depending on the thermodynamic interaction between solvent and polymer.

An unspecified experimental styrene copolymer, possibly with acrylonitrile, shows a greatly reduced tendency to lose blowing agent on aging at 23°C (363). FIP beads from chlorostyrene likewise have a greatly enhanced ability to retain blowing agent as indicated in Table 13. The higher heat distortion of this polymer requires steam pressures of 210–340 kPa (30–50 psi) for blowing.

Various other factors that influence the foaming of PS, especially cross-linking, are described (359). In Reference 359, foaming is discussed as a viscoelastic process in which there is competition between the blowing pressure, which increases with temperature, and the thinning and rupture of cell walls with consequent collapse of the foam. The presence of cross-links reduces the tendency for cell-wall rupture. Figure 65 shows foam volumes attained as a function of temperature for various amounts of divinylbenzene. The effects of temperature and cross-linking on the kinetics of foaming is also discussed in Reference 359.

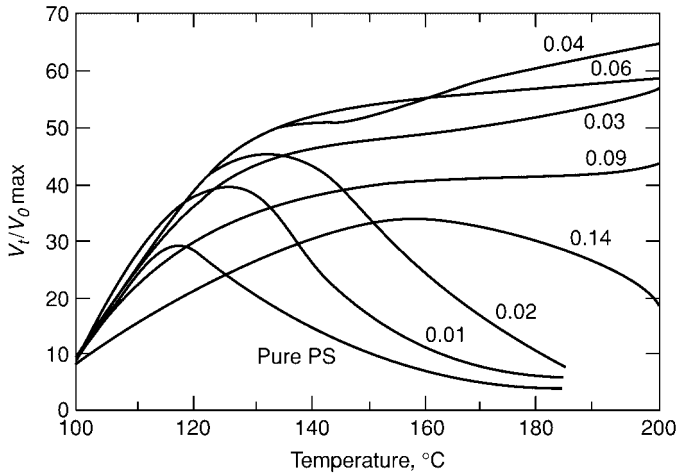

Fig. 65. Maximum foaming volume of styrene divinylbenzene copolymers containing 8.8 wt% CO_2 as a function of divinybenzene content and temperature. Numeral beside curve indicates wt% divinylbenzene. V_t/V ratio of final volume to initial volume at temperature t. Adapted from Ref. 362.

Another important factor affecting the foaming of PS beads is the differential rate of diffusion of *n*-pentane compared to steam and air. It is estimated that the quantity of *n*-pentane normally used is sufficient to produce a foaming volume of 30-fold and hence a foam density of no more than 32 kg/m^3. However, the steam and/or air that diffuses into the beads contributes to further expansion, so that foaming volumes of 60-fold or more are commonly achieved. This aspect of diffusion has been discussed in some detail (364). In cycle foaming in air, beads are allowed to equilibrate with air after each heat-foaming step through a series of stages. Foaming volumes of 200:1 have been achieved in this manner, with densities down to 3.2–4.8 kg/m^3.

Lightweight concrete is made from prefoamed EPS beads, Portland cement, and organic binders. Precast shapes are being used to provide structural strength, thermal insulation, and sound deadening.

Polystyrene as a Raw Material for Rigid Thermoplastic Foams. The low cost of PS and its high thermal stability, which provides good recycle efficiency, as well as the possibility of using low cost blowing agents, are important to the use of PS in rigid thermoplastic foams. The heat-distortion point of ca 80°C (in contrast to 65°C for PVC foam) permits its use in most construction applications. The low sensitivity of the polymer to moisture is another important factor.

Because of all of the aforementioned and possibly for other reasons, PS has been the dominant material used in rigid thermoplastic foams. Poly(vinyl chloride) is economical and has good physical properties and is flame retarding, but it has marginal heat-distortion properties for some uses and does not readily lend itself to the continuous extrusion process used for PS foam. So far, no FIP beads system based on PVC has been perfected. This could well be a result of its high vapor barrier compared to PS. Polyethylene is too permeable to retain a blowing agent and hence is ruled out as a FIP bead material, but it is commercially significant as extruded foam.

Flame Retardants. The growing use of PS foams in the construction industry has provided impetus for continuing research on flame-retardant additives (see FLAME RETARDANTS). Organic bromine compounds, eg, or pentabromomonochlorocyclohexane, have long been used for this purpose in extruded PS foam. Use of injection-molded structural foams, based on HIPS and ABS and containing flame-retardant additives, has grown rapidly since the late 1970s. A typical additive system to impart the required flame-retardant properties is bis(pentabromophenyl) oxide and a synergist, eg, antimony trioxide. Because of environmental concerns over the use of halogenated flame-retardant chemicals, research is currently focusing upon the development of halogen-free systems. Phosphorous containing compounds are currently the most heavily researched alternative.

Foamed Sheet. PS foamed sheet is used for foamed trays, egg cartons, disposable dinnerware, and packaging. Foam sheet manufacturing techniques, manufacturers' logistics, and markets are described in Reference 365. Choice of the correct blowing agent for foam sheet is critical in determining ultimate density and physical properties. Further, the choice of blowing agent may be dictated by safety considerations, eg, flammability of hydrocarbons, or environmental concerns, eg, chlorofluorocarbons (366).

Table 14. Gas and Water Vapor Permeabilities of PS Films[a]

Composition	Oxygen	CO_2	Water
Unmodified PS	3.50	14.00	1600
72:28 styrene-*stat*-acrylonitrile	0.09	4.62	2900

[a]Gas permeability units = $(cm^3 \cdot cm)/(10^{10}\ cm^2 \cdot s \cdot kPa)$.

Oriented PS Film and Sheet. Oriented PS film, in addition to having the lowest cost of any of the rigid plastic materials, offers a high degree of optical clarity, high surface gloss, and excellent dimensional stability (particularly with regard to relative humidity) and is heat shrinkable. It is not a barrier film; in fact, one of its largest uses, that of packaging field-fresh produce, depends upon its being highly permeable to oxygen and water vapor (see Table 14).

PS films have been the subject of several reviews (367–370).

Although PS is normally considered a rather brittle material, biaxial orientation imparts some extremely desirable properties, particularly in regard to an increase in elongation. Thus, the 1.5–2% of elongation normally associated with unoriented PS can become as high as 10%, depending on the exact conditions of preparation (371,372).

Several methods have been utilized in preparing biaxially oriented PS film. The bubble process is used commercially. The high softening point, coupled with the tendency of oriented film to shrink above 85°C, makes heat sealing difficult. Solvent, adhesive, and ultrasonic sealing are used in most applications. Scratch resistance, impact strength, and crease resistance are low. Although the bubble process superficially resembles the common bubble process for making polyethylene, polypropylene, and Saran film, there are a number of substantive differences, and the PS process is considerably more difficult to achieve. In the case of polyethylene, for example, crystallinity stabilizes the blown bubble, whereas with a true thermoplastic, eg, PS, one must stabilize the blown film by cooling below the T_g. This involves extremely careful control of temperature in the blowing process.

As a general rule of thumb, there is an economic break-even point at ca 0.08 mm, which coincides with the defined difference between film and sheet. Film is made more economically by the bubble method and sheet by the tenter-frame method. The exact thickness for break-even depends on technological improvements, which can be made in both processes, in the degree of control which is used in regulating them and in quality requirements.

PS film contains no plasticizers, absorbs negligible moisture, and exhibits exceptionally good dimensional stability. It does not become brittle with age nor distort when exposed to low or high humidity. Excellent machinability, ie, ability to pass through packaging machinery at high speeds and to be cut and sealed, etc, clarity, and stability are central factors in the use of oriented PS in window envelopes. These same characteristics have also led to applications of film for window cartons. An antifog film 0.025–0.032 mm thick has been used extensively for the windows of cartons for bacon. Substantial amounts of film are also employed as sheet protectors and as inserts in wallets. A thickness of 0.060–0.130 mm is customary for these applications. PS film can be printed by means of flexographic,

rotogravure, and silk-screen methods. A lamination of reverse-printed film and paper has been used for an attractive, high sparkle package for hand soap. The film is an excellent base for metallizing because of the almost complete absence of volatiles. Oriented PS film is also widely used for lamination to PS foamed sheet for preprinted decoration and/or property enhancement (373).

For PS sheet, the use responsible for its rapid growth is in meat trays, where the merchandising value is important, ie, the transparency of the package, as well as its resistance to moisture and dimensional stability. A smaller but growing use is as a photographic-film base where dimensional stability at all humidities and low gel count are both important. The thermoplastic nature of PS and the memory effects built into it through biaxial orientation make it especially suitable for packaging applications. It must be processed under pressure rather than by vacuum-forming equipment to avoid the shrinkage, which would otherwise result from the high level of orientation.

Important uses of PS are as windows in envelopes, etc, as mentioned earlier, and as produce overwrap. High optical clarity is required for mechanised reading of characters through envelope windows, a significant technological trend which is certain to enhance the use of PS film. In regard to produce overwrap, the transmission characteristics of PS for water vapor and oxygen coincide more or less with the metabolic requirements of the produce being packaged, eg, lettuce, so that in addition to giving mechanical protection to something like a head of lettuce, the produce is able to metabolize in a normal manner (374). Low cost and high optical clarity are important. In addition, the feel of PS film gives an impression of crispness as far as the product is concerned. PS film also has potential use as a type of synthetic paper (see PULP, SYNTHETIC). GPPS must be treated so that it is opaque, and this can take the form of either pigmentation, mechanical abrasion, or a surface treatment, eg, a chemical etch. HIPS is reasonably opaque. PS film can be given a suitable coating, eg, a latex-clay coating, of the kind that is used on ordinary paper for the purpose of achieving a good printable surface. There are several general discussions of gas permeabilities in plastic films (6,8,9,375,376) (see BARRIER POLYMERS).

STYRENE–BUTADIENE COPOLYMERS

Introduction

Styrene–butadiene (SB) copolymers represent one of the largest and most diverse group of polymers in use today. This has come about due to the wide range of properties that can be obtained by modification of styrene–butadiene ratio as well as other material characteristics. Copolymers that contain low levels of styrene, high in butadiene content, show elastomeric behavior, and copolymers that are styrene-rich show thermoplastic behavior. This way SB copolymers can exhibit material performance characteristics ranging from pure elastomeric, as in car tire and other flexible applications, to full thermoplastic, as in injection-molded transparent medical devices. This ability to span such large performance regimes has been a key reason for their widespread use. The other factor that has been critical to the success of SB copolymers has been the commercial availability of the monomers, styrene and butadiene. This article focuses on elastomeric and thermoplastic versions of SB copolymers. In addition to these, SB latex is also used in coatings and paint applications. SB latex is not covered here.

Monomers

Butadiene. Global consumption of butadiene monomer in 1996 was 7.5 million metric tons (1). The largest use of butadiene was for styrene–butadiene rubber, representing 28% of the total volume. Butadiene is manufactured in several different ways. The key industrial processes include recovery of butadiene from ethylene production as a by-product and dehydrogenation using either the

Encyclopedia of Polymer Science and Technology. Copyright John Wiley & Sons, Inc. All rights reserved.

Houdry process or the oxidative dehydrogenation of *n*-butenes. Finally in some Asian countries, butadiene is also produced from ethanol.

Styrene. Global consumption of styrene monomer in 1998 was 17.9 million metric tons (2). While polystyrene was the largest outlet, SB copolymers (including latexes) consumed a total of 1.95 million metric tons. Styrene monomer is produced by two processes. Ethylbenzene dehydrogenation is the most widespread process used for styrene manufacture, followed by the propylene oxide coproduct route.

Styrene–Butadiene Rubber (SBR)

Introduction of automobiles brought with it the need for materials suitable for tire manufacture. In early 1900s, natural rubber was the material of choice. During the World War I restricted access to natural rubber started development programs in Germany. One of the polymers, polydimethylbutadiene, was used for a short while. Further research between two world wars led to the development of Buna S by I.G. Farben (a new company formed by combining Bayer, BASF, and Huls of Germany in 1933). The new rubber incorporated styrene (S stands for Styrol, German name for styrene, in Buna S), improving the performance dramatically. Similarly as U.S. access to natural rubber became restricted during the World War II, a government sponsored research program, known as Government Rubber-Styrene (GR-S), was started. All the rubber producers were organized under the consortium of American Rubber Manufacturers and were overseen by the newly set up Office of Rubber Reserve. The primary product was Buna S.

After the second world war, the United States became aware of the new developments in cold SBR production, which was superior to Buna S type rubbers, and subsequently most of the production facilities in the United States were converted to run the cold SBR process. Cold SBR has become the standard process for emulsion-based SBR production across the globe.

Developments in the anionic polymerization of butadiene were adopted for manufacture of solution SBR. While the emulsion process gave primarily 1,4-cis microstructure in the final product, the solution process gave a lower level of 1,4-cis level, typically around 45%. Furthermore the cis content as well as 1,2-vinyl content could be modified. In addition, better control of branching and molecular weight distribution attainable with anionic process made solution SBR suitable for tire applications, challenging the established use of cold SBR. Developments in the anionic process also led to new copolymer structures in which blocks of polybutadiene can be coupled to blocks of polystyrene, generating a unique class of polymers. Developments in SB block copolymers led to new materials which were thermoplastic in character, unlike SBR which is an elastomer. Solution-processes-based thermoplastic SB block copolymers form the basis of the transparent impact polystyrene (TIPS) as well as the other block copolymers used in plastics modification. The block copolymers of styrene and butadiene are the subject of the second part of this article.

Polymerization Process

Butadiene and styrene can be copolymerized in a number of ways. Both ionic and free-radical initiations can be used for this purpose. This fact is reflected in

industrial production of SBRs. Initially the free-radical process was entirely based on hot emulsion processes utilizing a polymerization temperature of 50°C. Later developments showed that much improvement can be made to the product if the polymerization temperature can be lowered to around 5°C. As a result the "cold" emulsion process became the process of choice. Today the cold emulsion process accounts for the larger portion of the emulsion SBR market. Introduction of cold emulsion process and advances in anionic polymerization have demonstrated even further advantages, leading to the introduction of the solution process. The solution SBR products make up a smaller part of the consumption but their volume is increasing.

Cold SBR. Cold SBR is produced by the emulsion process (3–12). In the emulsion process an emulsion of monomers (styrene and butadiene) is formed in water by the help of an emulsifying agent, usually a soap (13). The monomers in the emulsion are polymerized by a water-soluble initiator fragment, a free radical generated from a hydroperoxide (3) or from an oxidation reduction process. As the free radical enters the emulsion droplet, a micelle, it polymerizes the monomers present.

Emulsion polymerization can be divided into three distinct phases (14) (see Fig. 1). In the nucleation stage, phase I, a free radical is generated (6,15) from the initiating species in the water phase. The most commonly used initiators are the redox systems such as persulfate with ferrous ion (16,17).

$$S_2O_8^{2+} + Fe^{2+} \rightarrow Fe^{3+} + SO_4^{2-} + SO_4^{-\cdot}$$

The free radical then has the possibility to react with monomer dispersed in the system in several states, the most significant of which is micelles (18). Micelles are monomer droplets stabilized by the emulsifying agent. An emulsifying agent contains both oil-soluble and water-soluble parts in its molecular structure, and hence forms the interphase between the water and the dispersed monomeric phase. At the start of phase I, a typical system contains 10^{18} micelles/mL and the initiation rate is around 10^{13} radicals/(mL·s). As the radicals enter the particles, the polymerization proceeds in the usual manner at a rate r_p with a propagation rate constant k_p and the monomer concentration $[M]$ in the particle (3–5,9).

$$r_p = k_p[M]$$

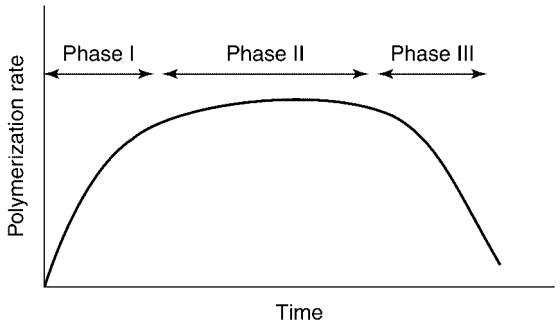

Fig. 1. Three distinct polymerization phases for emulsion polymerization of styrene and butadiene.

As the polymerization continues and monomer is converted to the polymer, the growing micelles continue to absorb more and more emulsifying agent from the medium. As the emulsifier concentration starts to decrease in the reaction medium, there comes a time when the emulsifier concentration falls below a critical micelle concentration. Micelles are formed and maintained only if the emulsifier concentration is above this critical level. The conversion of monomer is typically 15–20% in the first phase.

The growth stage of the process, phase II, starts with micelles becoming polymer particles with a thin layer of surfactant on its surface. At this stage the polymer particles are swollen with monomer that has diffused from the monomer droplets to polymer particles. Major part of the polymerization reaction takes place at the growth stage. The polymerization reaches a steady state inside the swollen polymer particles (10,11). The growth stage ends when most of the monomer is converted to polymer, reaching a conversion level of around 65%. As the monomer concentration drops, the rate of polymerization decreases dramatically as given in Figure 1.

The final stage, phase III, is characterized by complete disappearance of monomer droplets. If the steady state is not maintained by fresh monomer diffusion into the polymer particles, the polymerization rate declines. The unreacted monomer continues to polymerize at a declining rate. If this process is allowed to continue, onset of gelation can take place through chain transfer to polymer.

Rate of polymerization R_p is given by

$$R_p = k_p[M][P\cdot]$$

where $[P\cdot]$ is the concentration of active particles. $[P\cdot]$ is usually expressed as

$$[P\cdot] = \frac{10^3 N' n}{N_A}$$

where N' is the number of particles (including micelles), n is the average number of radicals per micelle plus particles, and N_A is the Avogadro number. Finally, expressing R_p in its usual units of moles per liter-second gives

$$R_P = \frac{10^3 N' n}{N_A} k_P[M]$$

The number-average degree of polymerization, X_n, in emulsion polymerization is dependent on the rate r_i at which primary radicals enter a polymer particle:

$$r_i = \frac{R_i}{N}$$

where R_i is the rate of initiation. In most cases the rate of initiation is same as the rate of termination r_t. This is because as soon as a new radical enters the particle the termination takes place immediately by biradical coupling reaction. Then the

number-average degree of polymerization, X_n, is

$$X_n = \frac{r_p}{r_i} = \frac{Nk_p[M]}{R_i}$$

Emulsion polymerization has some unique advantages in comparison to solution or bulk polymerization processes. Most of the advantages are due to the unique polymerization kinetics, such as ability to make high molecular weight monomers at faster polymerization rates. Presence of water enables good temperature control, easy heat removal, and gives lower viscosity.

Selection of components for the emulsion polymerization process is critical. Initiator system, emulsifier, chain transfer agents play a significant role in kinetics of polymerization and in defining the properties of the final product.

A simplified process diagram of cold SBR production facility is given in Figure 2 (19,20). The process can be divided into four units:

(1) Feed preparation and clean up
(2) Polymerization
(3) Coagulation
(4) Drying and packaging

Primary function of feed preparation section is to remove impurities from butadiene and styrene monomer. Both monomers contain an inhibitor as

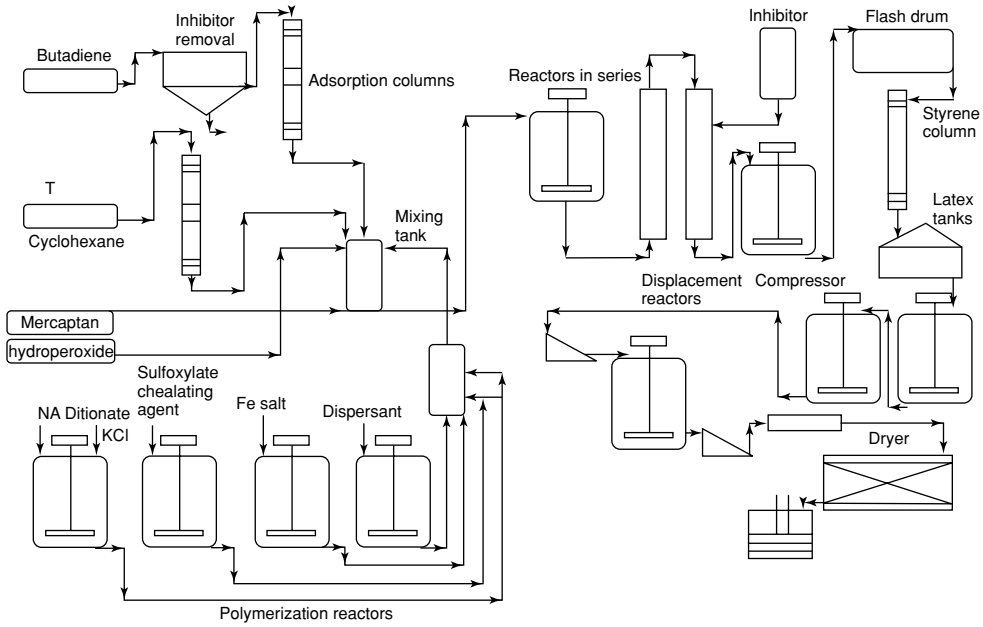

Fig. 2. Process layout showing main components of "cold" emulsion SBR process.

supplied (inhibitors are added to monomers to stop any premature polymerization during transport and storage) and it must be removed by washing with NaOH solution. Following this, water is removed from the monomer stream. Inhibitor and other oxygenated species are removed by passing styrene monomer through an activated alumina column. Other raw materials such as chain transfer agents, usually *t*-dodecyl mercaptan (or other mercaptans), hydroperoxide such as *p*-methane hydroperoxide, a solution of potassium chloride, sodium dithionate (oxygen scavenger), reducing agent such as sodium formaldehyde sulfoxylate, ferrous sulfate heptahydrate, are prepared in the feed preparation section. Similarly a solution of soaps, usually a mixture of two or more, is also prepared in the feed section.

The polymerization section consists of a series of polymerization reactors jacketed to remove the heat of polymerization. Initially the polymerization reactors are charged with deaerated water and the reactants fed to the reactor. As the polymerization reaction takes place, the heat generated is removed to maintain a reaction temperature of around 5°C, and hence the term "cold" SBR process. Once the desired level of conversion is reached in the displacement reactors, a short stopper is added to terminate the reaction. Then the unreacted monomers are removed by flashing the heated latex. All the unreacted monomers are fed into a recycle tank and returned to the start of the process (13). The latex is then fed to blending tanks to obtain the desired specification and to make the product uniform. Also, at this stage, slightly off-spec material can be blended in.

In the coagulation section, the water is separated from the polymer by chemical means and a slurry of the rubber crumb is obtained. The slurry is then filtered and washed several times. Finally the crumb is further dewatered in an expeller, dried in an expander dryer, and sent to the finishing section.

The finishing section consists of baler, film wrapper, and packaging unit.

Solution SBR Process. Solution SBR is based on the anionic process (19,21–25). There are some key differences between emulsion SBR and solution SBR processes, that form the bases for the differences between the two product groups. In the free-radical polymerization process, a polymer chain is initiated by the initiator fragment. In a fraction of a second, several thousand monomers units are added to the growing chain. The polymer chain then terminates through one of three mechanisms: (*1*) through a coupling reaction with another radical; (*2*) through disproportionation, where an electron is transferred from one radical to another; or (*3*) through a chain transfer reaction. Termination leads to a dormant polymer molecule which remains inactive until the end of the polymerization process.

In anionic polymerization, the initiator, typically alkyl lithium, initiates the polymerization process and rapidly reacts with the available monomer molecules. Then the active polymer chains remain active for the duration of the polymerization process. They will continue to polymerize any additional monomer that may be added to the system. The growing polymer chains must be deactivated specifically by the addition of a deactivator at the end of the process.

By far the most common initiator for copolymerization of styrene and butadiene is butyl lithium. Once the polymerization process is initiated, the tendency of the anionic species to add to butadiene or styrene monomer will be different. The polybutadienyl anion prefers to react with another butadiene monomer rather

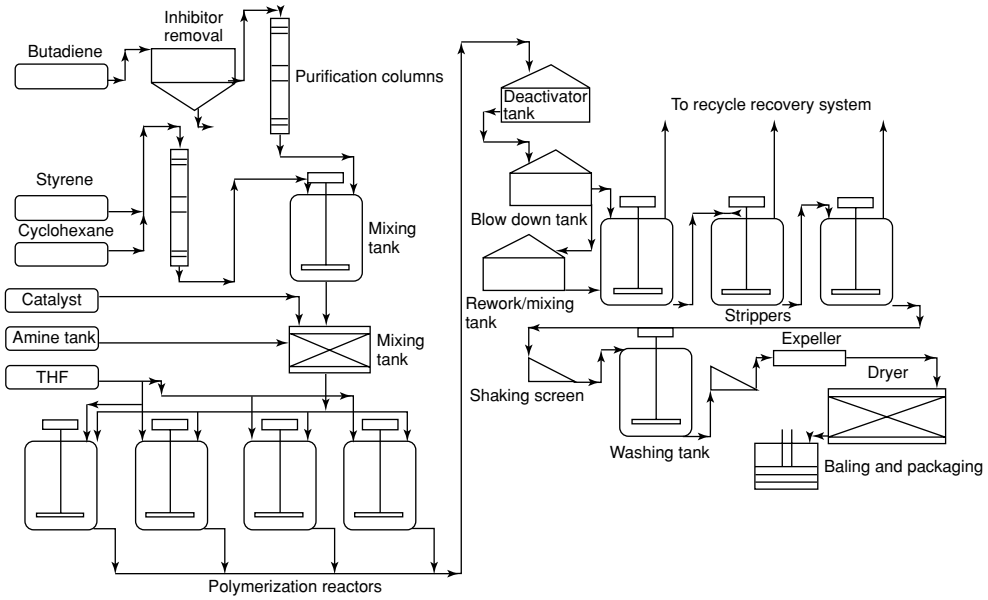

Fig. 3. Process layout showing main components of solution SBR process.

than a styrene monomer. In fact styrene can be used as a solvent for the anionic polymerization of butadiene if the polymerization reaction is terminated as soon as the butadiene monomer is depleted. If special precautions are not taken, a block copolymer of butadiene and styrene will be obtained. Especially in tire applications, it is very important to have a random copolymer. Special additives must be employed to assure random distribution of styrene units in the copolymer (26).

Solution SBR processes are based on anionic polymerization using butyl lithium initiator. A process flow diagram of the solution SBR process is given in Figure 3, showing major parts of the process. Detailed description of the process has been compiled from the information contained in a series of patents issued to major SBR producers (19,21–25).

The process is made up of three main stages:

(1) Feed preparation and clean up
(2) Polymerization
(3) Finishing

As butyl lithium initiator is very sensitive to water, inhibitor, oxygenated species, and active hydrogen-containing impurities, very stringent feed purification procedures must be carried out. Failure to have high purity will lead to deactivation of the most expensive raw material, butyl lithium [currently around $44/kg (19)]. Trace amounts of water from purified butadiene are removed by passing through a molecular sieve column. Styrene is purified by passing through an alumina column.

The polymerization section consists of a series of continuously stirred tank reactors (24,25). The solvent (25) (usually cyclohexane) and monomers are fed into the reactor and an initiator as well as a randomizer [usually tetrahydrofuran (THF)] is added. The function of the randomizer is to make sure that no blocks are formed from a single monomer (Hall, Oxolanyl Cyclic Acetals as Anionic Polymerization Modifiers #68). This is because the reactivity ratios of the monomers are not ideal. Usually the reaction temperature is kept less than 110°C to prevent deactivation of the growing chain ends (25). Once polymerization is complete, alcohol is added to terminate the polymerization reaction and the polymer solution is transferred to holding tanks to be blended to increase uniformity. Subsequent steps of washing and filtering remove all the unreacted monomers, THF, and other chemicals.

The finishing section consists of drying, bailing, wrapping, and weighing. The polymer is dried in two steps, then passed through a lump breaker to break any gels, and eventually packaged to the desired specification.

Because of the significant difference in polymerization characteristics, emulsion and solution processes produce SBR with a different balance of properties. These differences are a result of the molecular structure, branching, molecular weight distribution, and microstructure. In general, the solution SBR process provides a higher capability to modify the molecular parameters.

Some of the key advantages of solution SBR over emulsion SBR are molecular weight and molecular weight distribution control, low levels of branching, lower levels of contaminants, and higher degree of control over molecular topology. These characteristics provide improved performance to end-use applications as in tire manufacture. Solution SBR can lead to better balance between treadwear, traction, and rolling resistance. These three are the key properties that a tire manufacturer will aim to optimize (26).

The solution SBR process can control the molecular weight distribution and branching very effectively. During emulsion process the polymer chains grow in a very short while and then terminate, whereas in the solution process the growing chains are active until the monomers are consumed or a terminating agent is added. As a result the chains produced in solution process tend to be uniform in length whereas emulsion process leads to a broad distribution as chains that grow at different times in the process tend to have different molecular weight. The branching is a random process in the emulsion SBR route whereas it must be specifically incorporated by introducing branching agents during the solution process.

The monomeric unit in polybutadiene can exist in three distinct forms: 1,4-cis, 1,4-trans, and 1,2-vinyl (see Fig. 4). The relative portions of each one of these

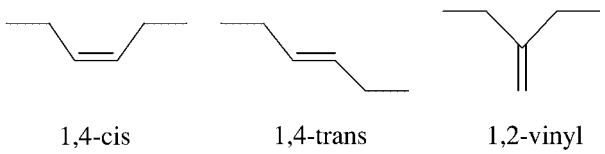

Fig. 4. Different types of microstructure for polybutadiene.

microstructures have a strong influence on the final properties of the polymer. Both the solution SBR and emulsion SBR processes give similar levels of 1,4 structures. Emulsion process gives a 1,2-vinyl level of about 20%. Depending on the specifics of the process, the solution process can give anywhere from about 8 to 60%.

Processing of SBR

SBR as manufactured, is an elastomeric material that requires further processing to convert it to a final article for end use. The processing accomplishes three key objectives. First of all it gives the article its final shape, then it incorporates additives that are required by the targeted end use, and finally causes cross-linking of the rubber. Without cross-linking, the rubber will not be usable, as it is a soft "gummy" material that would not retain its shape during use.

Typical processing of SBR is done in two stages (27). In the first stage, non-reactive components are mixed with the rubber to obtain a good dispersion. At this stage, to prevent any cross-linking, the cross-linking agents and accelerators are not added. The first-stage processing is called nonproductive stage as no cross-linking occurs at this stage. SBR (and optionally, a second rubber) is mixed with additives such as fillers, oils, antioxidants, stabilizers, and antiozonants, as well other specific additives. Fillers are added to "extend" the rubber. By far the most common filler is carbon black. Their function is usually to reduce the cost of the overall formulation and also to improve physical properties such as tensile strength. The carbon black fillers come in standard forms (28). A list of most common fillers and their function is given in Table 1. A large number of other components are used in the manufacture of SBR articles.

Oil extenders include naphthenic, aromatic, and parafinic oils. Their function is to soften the rubber for processing. Other processing oils include castor and tall oils as well as low molecular weight resins.

Once the nonproductive stock is mixed in an internal mixer in the second-stage cross-linking agents, accelerators are added to the nonproductive stock, which can then be shaped into final form and cured. The curing process is a chemical cross-linking reaction that builds bonds between rubber molecules.

SBR contains active double bonds on the polymer backbone. Cross-linking reactions are carried out by generating free radicals which react to form content bonds. Without the help of acceleration this reaction requires long times and high temperatures. By proper choice of activators and accelerators both the curing temperature and curing speed can be tailored for a given application.

By far the largest volume of SBR goes into automobile tires, representing some 80% of the total volume (30). In addition to tires, many other applications from gaskets to hoses also use SBRs. The single most important property of SBRs is their glass-transition temperature T_g. For tire applications T_g must be in a certain range, typically -70 to -50°C. Proper choice of T_g is important for control of friction and traction. If the T_g is too high, the rubber can loose its rubbery properties at low temperatures. On the other hand, too low a T_g can also cause problems. At very low T_g's, the traction at wet roads and moderate temperatures can suffer. In general, lower the T_g, better the treadwear. Tire manufacturers must

Table 1. Different Classes of Materials Used in SBR Processing and Their Function

Class	Compound	Function
Fillers	Carbon black	Reinforcing filler improves physical properties and reduces cost
	Calcium carbonate	Reduces cost and increases tensile strength. Both reinforcing (small particle) and nonreinforcing [coarse (29)] types exist
	Clay	Reduces cost and increases tensile strength
	Silica	Improves physical properties
Processing aids	Naphthenic/aromatic/ paraffinic oil	Extender (for softening of rubber)
	Castor/tall oil	Improves elongation
Vulcanization agents	Sulfur	Cross-linking
	Disulfide organic hydroperoxides	Fast accelerator, low temperature curing
	Tetramethylthiuram	Low sulfur cross-linking
Accelerators	Mercaptobenzothiazole dithiocarbomates	Fast accelerator, low temperature curing
Accelerators and activators	Zinc oxide, stearic acid diethanolamine	Cross-linking
Antioxidants	Phenolics	Nonstaining stabilizers
	Phosphites	Good stabilizers for SBR
Antiozonants	Diaryl-phenylene diamine	Low cost antiozonant

balance many compiling requirements of traction, wear, and rolling resistance by proper selection of T_g for this application. T_g has a strong influence on the hysterisis imparting rolling resistance and fuel consumption.

Two key variables that influence glass-transition temperature are styrene content and percentage of 1,2-vinyl in the microstructure. For emulsion process, the relationship between T_g and styrene content is as follows (31):

$$T_g = -78 + \frac{128S}{1.0 - 0.5S}$$

where S is the weight fraction of styrene in the copolymer.

Similarly for 1,2-vinyl content, the following relationship holds:

$$T_g = [1/(0.00578 - 0.0031S - 0.00212V + 0.00212VS)] + 273$$

where V is the weight fraction of 1,2-vinyl units in the butadiene portion of the copolymer. These equations are valid only for emulsion SBRs. In the case of solution SBR, some of the styrene units are present as short block and are not truly random copolymers.

Specifications, Testing, and Environmental Aspects

SBRs are characterized at different stages of their manufacture and use, utilizing several types of test procedures. During the manufacturing stage of the rubber, a series of tests are carried out to establish solids content (conversion), molecular weight, and chemical composition. Conversion is measured by just removing solvent and unreacted monomers, while chemical composition can be measured by either ir spectroscopy or by titration. The molecular weight and molecular weight distribution are determined by gel permeation chromatography.

Once the polymers are manufactured further characterization takes place prior to processing or during the process itself. The two key properties that are critical are T_g and Mooney viscosity. The most convenient way to measure the T_g is by differential scanning calorimeter. Mooney viscosity is an industry specific test procedure that is used for assessing the processability of the rubber. Mooney viscosity (ASTM D1646) is measured by rotation of a disk inside a cavity under pressure. This equipment does not measure the viscosity, but rather the torque required to rotate the disk at 100°C at a rate of 2 rpm. The results are usually given as

$$50 - \mathrm{ML}1 + 4(100^{\circ}\mathrm{C})$$

where 50-ML is the viscosity number, L indicates the larger of two rotor diameters used (other one being a smaller one for higher viscosity rubbers), 1 is the time in minutes that the specimen is preheated, 4 is the time in minutes after starting the motor at which the reading is taken, and 100°C indicates the temperature of the test.

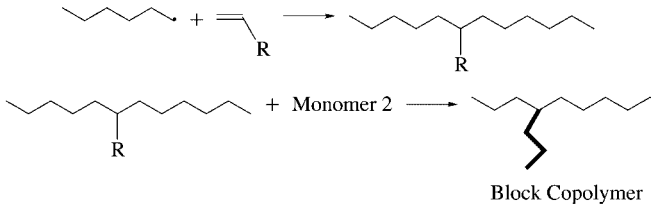
In recent years dynamic mechanical testing has become an important means in correlating the performance of tires to molecular structure. Especially *tan delta* (ratio of elastic modulus to viscous modulus) has been used for understanding rolling resistance, skid resistance, and wear (26).

During the manufacturing process, primary health and environmental concerns relate to emissions and exposure. In most countries there are strict regulations concerning exposure to styrene and butadiene monomers. In the United States the exposure limits for styrene monomer is set at a time waited average of 50 ppm. The same value for butadiene is 10 ppm. During the processing, the breakdown of additives is a major concern. Use of secondary amines are regulated in some countries through monitoring of volatile nitrosamine generation. One of the primary environmental concerns for the rubber industry is the growing mountains of used tires. No significant outlet has been found for the recycling of the rubber in tires.

Styrene–Butadiene Block Copolymers

Emulsion and solution SBRs are made up of butadiene and styrene units that are randomly distributed along the polymer backbone. In the case of free-radical-polymerization-based emulsion process, the radical center randomly polymerizes both the styrene and butadiene units. The frequency by which these monomers

are incorporated into the growing polymer chain is determined by the reactivity ratios and the concentration of the monomers. In free-radical polymerizations the growing polymer chains have very short life spans in the order of less than a second. This eliminates any possibility of using sequential monomer addition techniques to make block copolymers. The only way to make block copolymers in the free-radical process is through incorporation of active sites into the polymer backbone which at a later stage is activated by heat or radiation in the presence of another monomer as indicated below.



This route has been used extensively to make several types of block copolymers that cannot be made by anionic polymerization techniques. Systems where R is a peroxide group (32,33), diazo groups (34), hydroperoxide groups (35), or living free-radical groups (29,35) are used. Even though this route to block copolymers has been extensively investigated academically, no significant industrial application has been developed. Recent advances in living free-radical polymerizations indicate that this route might be more suitable for industrial use.

Industrially the most significant route to block copolymerization of styrene and butadiene is through anionic polymerization. The living nature of the anionic polymerization makes it possible to produce block copolymers of styrene and butadiene mostly through sequential addition of monomers.

Properties of Block Copolymers. Random copolymers of styrene and butadiene form homogeneous, one-phase systems showing typical characteristics of a single-phase polymer, such as a single T_g. In contrast the block copolymers of styrene and butadiene are two phase systems, with distinct domains of polybutadiene and polystyrene. As long as polystyrene domains are over 6000 amu in molecular weight, a two-phase system develops (36). The actual morphology of the block copolymer depends on the weight ratio of styrene and butadiene in the copolymer (Fig. 5). At low levels of styrene, a continuous polybutadiene phase develops with small spherical structures of polystyrene dispersed in the system (Fig. 6). As the styrene content of the block copolymer increases, spherical inclusions of polystyrene become elongated into cylindrical structures, becoming platelets at higher styrene levels (15–45%). At about 45% styrene level, co-continuous structures develop with alternating layers of polystyrene and polybutadiene.

The nature of SB block copolymers is defined by the weight ratio of styrene and butadiene. Those that contain more than 50 wt% butadiene are elstomers showing distinct elastomeric behavior. Industrially most polymers of this type contain 10–40 wt% styrene. As the styrene content increases the elastomeric nature of the block copolymer decreases. If the styrene content is above 50 wt% then a thermoplastic resin is obtained. These materials have the typical properties of

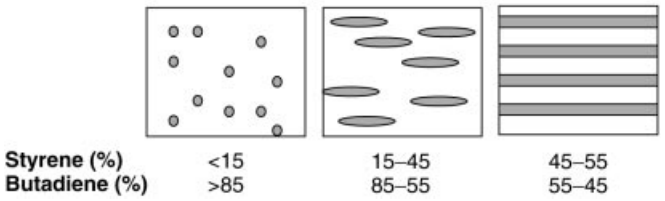


Fig. 5. Dependence of copolymer morphology on copolymer ratio in block copolymers of styrene.

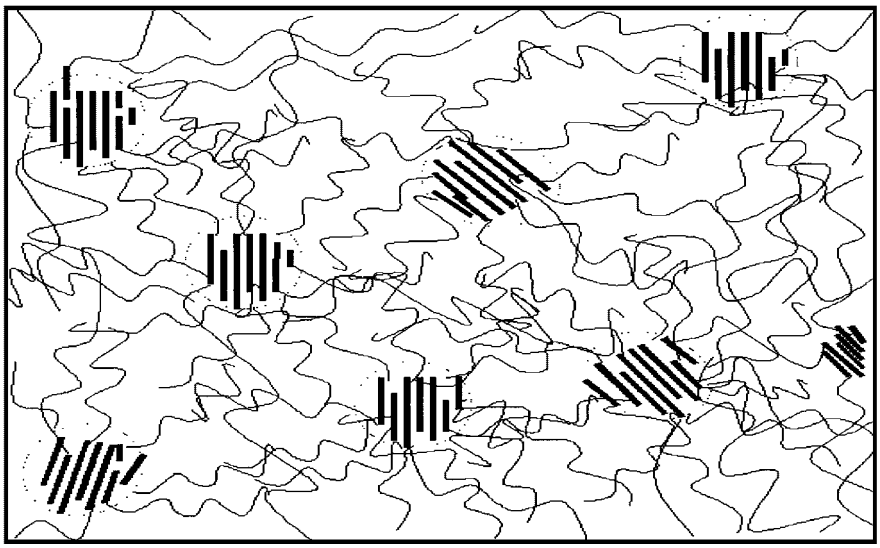

Fig. 6. A graphical representation of SB block copolymer structure at ambient temperature, with styrene content of 15% or less. Polystyrene phase (dark short lines) is presented as spherical domains dispersed in polybutadiene phase.

thermoplastic resins. As the styrene content approaches 100%, the resins become similar to high impact polystyrene (HIPS).

Manufacturing Process for Block Copolymers. Manufacturing of block copolymers is similar to solution SBR process, as they both use anionic polymerization. For elastomeric block copolymers the process is similar to solution SBR process. This is because the same feed purification and reactor layout is needed for producing elastomeric SBR polymers. The main difference between the solution SBR process and block copolymer production process is due to the fact that the styrene monomer distribution in the solution process is random while in block copolymers styrene is present as blocks (sequences of styrene monomer forming a polystyrene segment). In the process styrene and butadiene monomers are charged to the reactors at the same time. In the block copolymer process, first the butadiene segment is polymerized in the absence of styrene monomer. As the conversion of butadiene monomer nears completion, styrene monomer is added. Depending on the actual sequence, the transition from butadiene to styrene

segment can be graded, whereby the concentration of monomer units in the backbone changes from pure butadiene to a mixture of styrene and butadiene, eventually becoming pure styrene. These types of copolymers are referred to as tapered block copolymers. A short transition from butadiene to styrene units can also be achieved by making sure that all the butadiene is reacted prior to addition of styrene. In the case of triblock copolymers (SBS), two techniques are employed for manufacture. In the first case a sequential addition of monomers is used. First, styrene is polymerized until completion, followed by addition of butadiene and polymerization to completion. At the final stage, additional styrene monomer is added to form the triblock structure (Fig. 7). The second method is based on the use of bifunctional anionic initiators (37,38). With this type of initiator, the butadiene segment is produced first, followed by addition of styrene. As the bifunctional initiator grows the polymer from both ends, a triblock copolymer is obtained with two monomer addition steps versus the tri monomer addition steps of the monofunctional initiator case. Alternatively a coupling agent can also be used to produce SBS block copolymers with two steps of monomer addition (39,40). Elastomeric block copolymers can be finished in a manner similar to solution SBR if styrene content is relatively low. At above 25–30% styrene content the block copolymer looses its rubbery nature and becomes a relatively tough, difficult to bale product. At around 40% styrene content the product is powdery and cannot be baled easily. In the case of elastomeric block copolymers, unreacted monomers and solvent can be removed by steam stripping (41).

In the literature, many routes to synthesis of block copolymers are given, but on commercial scale, only the anionic solution process is used. In the case of solution SBR great care is taken to assure random distribution of monomeric units. In block copolymers great care is taken to assure that the butadiene and styrene units exist as blocks. The thermoplastic block copolymers, especially those with

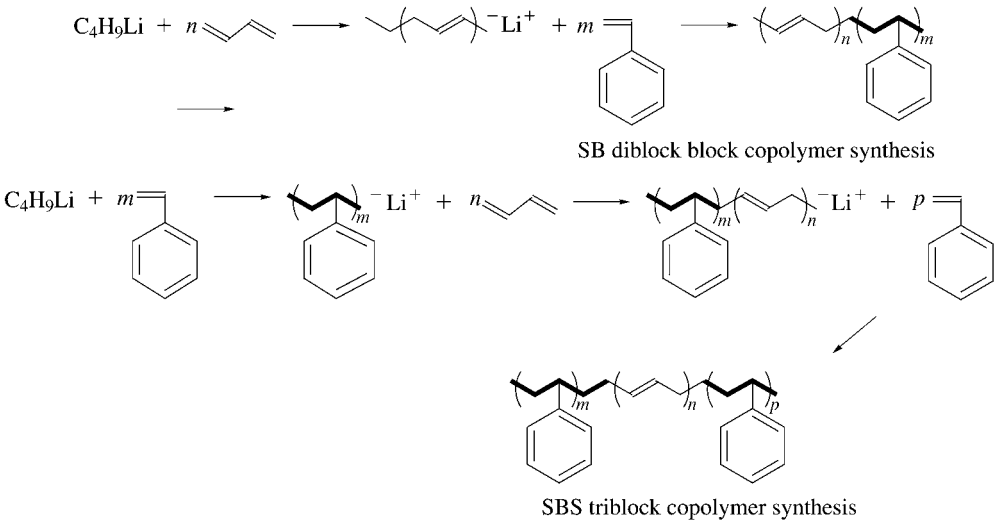

Fig. 7. Synthesis of triblock copolymers (S–B–S) with sequential monomer addition.

styrene contents above 65 wt%, can be finished with conventional thermoplastic finishing equipment.

The feed preparation and reactor sections of thermoplastic block copolymer production process are similar to the solution SBR process (36,39,40,42–45). Styrene, butadiene, and solvent are purified by distillation, followed by passing the reactants and solvent over alumina columns and molecular sieves (Fig. 8).

Thermoplastic Block Copolymers. Most well-known thermoplastic block copolymers are the K-Resin family (36,46) (Phillips Petroleum Co.). These contain about 27% butadiene in a star-block form (Fig. 9).

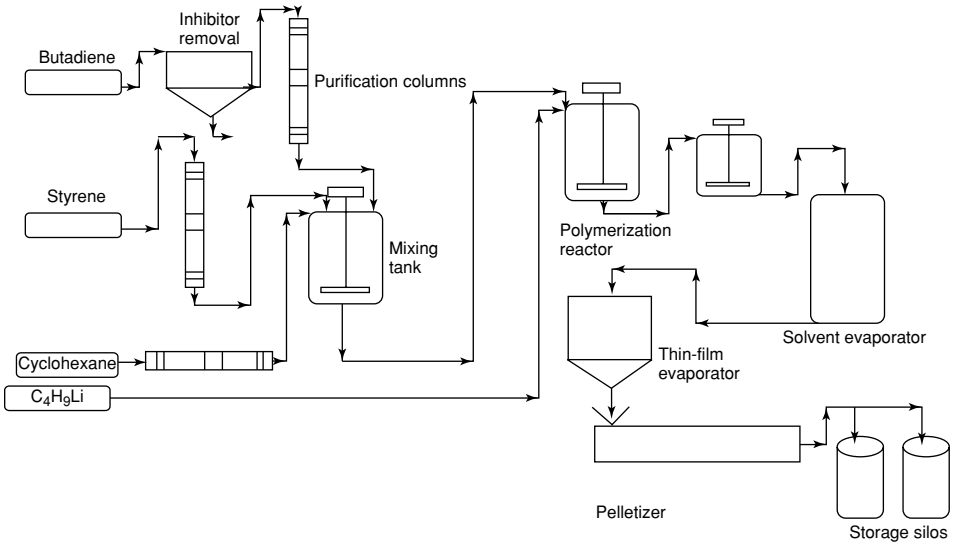

Fig. 8. Process layout showing main components of solution SB block copolymer manufacturing process.

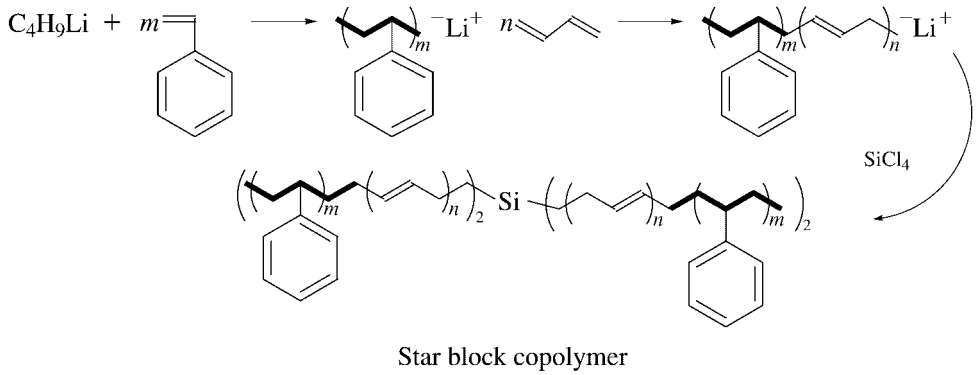

Fig. 9. Synthesis of star-block copolymers.

K-Resin is made up of a star-block copolymer where the inner polybutadiene segments are of about the same molecular weight while the outer polystyrene segments are of different molecular weight (47). This enables accurate control of polybutadiene segment thickness, ensuring improved clarity. To achieve optimum clarity, the polybutadiene segment thickness must be about one-tenth of the wavelength of visible spectrum or less (see ELASTOMERS, THERMOPLASTIC).

Processing of Block Copolymers. Elastomeric block copolymers contain blocks of styrene units that form hard segments below the glass-transition temperature of polystyrene. In most uses they do not need to be cured as the hard polystyrene segments act as cross-linking units below the glass-transation temperature of polystyrene (48,49). The block copolymers are seldom used in their pure form for fabrication of end-use articles. Most of the time they will be blended with other rubbers. By far the largest use of these types of block copolymers is for impact modification of polystyrene where they are blended with a polystyrene resin in a compounder or an extruder. They are also used in the manufacture of special grades of HIPS, mostly high gloss types, for injection molding or as a gloss layer for the co-extrusion of HIPS. One of the critical issues for thermoplastic SB block copolymer processing is cross-linking of the rubber phase. Special care must be taken to ensure processing temperatures do not exceed 240°C (51). If higher temperatures are needed, then the residence time must be minimized. Formation of cross-linked rubber is particularly important for the extrusion thermoforming process as these processes generate large amounts of recycle which is then blended with the virgin resin. In this way certain portions of the resin can end up going through the processes several times, further increasing the chances of gel formation. Presence of gel is detrimental to thermoformed articles as they cause significant problems in the appearance and wall thickness distribution for the thermoformed articles.

Economic Aspects and Use

Block copolymers of styrene and butadiene are extensively used in blends as well as neat products. Most of the blends are made with polystyrene resins, where addition of block copolymer improves the toughness of otherwise brittle polystyrene. Such materials find widespread use in food packaging, from yogurt cups to polystyrene film used for food packaging. Some volume of copolymer is also used as an impact modifier in the manufacture of specialty grades HIPS.

Block copolymers containing 20–40% styrene are also useful as impact modifiers for ignition-resistant HIPS as well as other polystyrene resins. Kraton® rubbers are available from Shell Chemical Co. and Vector® rubbers are available from Dexco Polymers (a joint venture between The Dow Chemical Co. and The Exxon Chemical Co.). Both grades are used extensively for this purpose as are other similar products from other suppliers. Kraton rubbers are usually triblock copolymers of SBS type. The center block is polybutadiene with terminal blocks of polystyrene (49–51). By far the largest use of block copolymers is in the form of TIPS resins. There are a number of suppliers, with Phillips Petroleum and BASF

Table 2. Properties of K-Resin Grades KR01 and KR03 from Philips Petroleum Co.

Property	ASTM test method	KR01	KR03
Density, g/cm^3	D1505	1.01	1.01

being the largest producers. Phillips Petroleum product is supplied under the trade name K-Resin, with several grades for extrusion and injection molding (51). BASF also supplies a number of grades under the trade name Styrolux. Clarity, toughness, and rigidity are the key combinations for TIPS, making the product very desirable for both extrusion-thermoforming and injection-molding applications. In most cases the TIPS resins are blended with polystyrene depending on the toughness requirements of the final formulation. Properties of two grades of K-Resin are given in Table 2 (51) (see ELASTOMERS, THERMOPLASTIC).

Most significant environmental issues with respect to block copolymer synthesis relate to manufacturing process, taste and odor issues in end use, and solid waste in final disposal of these polymers. Manufacturing process issues relate to industrial hygiene, exposure, and volatile organic emissions. In end use, block copolymer/polystyrene blends tend to have taste and odor issues, especially for sensitive food packaging applications.

SULFUR–CONTAINING POLYMERS

Introduction

In the last decade of the twentieth century, sulfur-containing polymers have increasingly come into attention because of their interesting properties that make them useful in a wide range of applications. They can be used as high performance engineering plastics, chemically stable ion-exchange membranes in electromembrane processes, proton-conducting electrolytes, and optical, optoelectronic, and photochemical materials. Some polymers are employed in biomedical applications, eg, sulfopolymers as biomembranes and blood-compatible materials, and polysulfates and polysulfonetes as antithrombotic or antiviral agents. The presence of sulfur, particularly in the form of disulfide bridges, plays an important role in biopolymers.

The purpose of this review is mainly to present recent advances in the area of sulfur-containing polymers that may not yet have commercial applications. Nevertheless, older but still significant material has been included at the beginning of the discussion of each class (see also POLY(ARYLENE SUFIDE)S; POLYSULFIDES; POLYSULFONES).

Poly(monosulfide)s

Polymers containing a monosulfide linkage in both the main chain and the pendent group are the subject of many detailed studies. A few reviews of the synthesis and properties of all types of polymers have been published (1–4); the nearest one covering polymer with sulfur in the main chain appeared in 1992 (3). Polysulfides with controlled and well-defined structures are easily prepared.

Encyclopedia of Polymer Science and Technology. Copyright John Wiley & Sons, Inc. All rights reserved.

Nevertheless, the only commercial poly(monosulfide) is Ryton [Philips Petroleum Co., poly(thio-1,4-phenylene) more frequently referred to as poly(*p*-phenylene sulfide) or poly(phenylene sulfide) (PPS)].

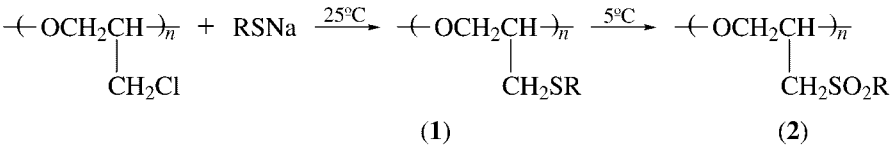
Much effort has been devoted to preparing aromatic compounds in view of their significance as reactive intermediates for the synthesis of high performance linear aromatic polymers by ring-opening polymerization (ROP) (5). In an attempt to develop a novel synthetic method for the preparation of high molecular weight poly(thioarylene)s, macrocyclic aromatic sulfides and disulfides have been intensively prepared (6–14). The coordination chemistry of macrocyclic polysulfides has also received considerable attention during the past years. The thiacrown ether polymer ligands can be used as ion-exchange resins, metal ion adsorbents, and polymeric phase-transfer catalysts (15,16). Molecular systems in which tetrathiafulvalene is incorporated into macrocycles with supplementary donor atoms are potential electroactive cation sensors (17). The π-conjugated polymers have been extensively studied because of their attractive electronic properties.

Aliphatic Poly(monosulfide)s. High molecular weight polymers may be obtained easily by ring-opening chain-growth polymerization of the smaller rings (episulfides with three and four atoms, thiiranes, and thietanes, respectively) (3,4). Nevertheless, polymers with larger aliphatic groups have been prepared only by step-growth polymerization (1,3).

The most important here have been the addition of dithiols to diolefins (3,18) and the condensation of alkali metal sulfides or dithiolates with dihalides (3,19).

In the last decade, only a few new wholly aliphatic or mixed aliphatic–aromatic poly(monosulfide)s have been reported.

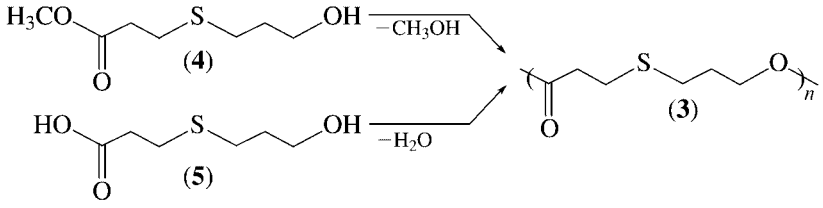
A series of poly(oxyalkylene)s such as poly[oxy((alkylthio)methyl)ethylene] (**1**), poly[oxy((alkylthio)methyl)ethylen-*co*-oxyethylene], and poly[oxy-2,2-bis((alkylthio)methyl)trimethylene] containing (alkylthio)methyl side groups were prepared from corresponding chloromethyl compounds with sodium alkanethiolates, using *N*,*N*-dimethylacetamide (DMAc) as a solvent and tetrabutylphosphonium bromide (tetra-*n*-butylphosphonium bromide) [3115-68-2] as a phase-transfer catalyst at 25 or 140°C (20). This substitution reaction gave 100% conversion with little, if any, backbone cleavage. The obtained (alkylthio)methyl-substituted polymers [intrinsic viscosities ([η]) from 1.10 to 2.68 dL/g and glass-transition temperatures (T_g) from −6 to −71°C] were successfully oxidized under mild conditions to highly polar (alkylsulfonyl)methyl-substituted poly(oxyalkylene)s (eg, **2**). The effectiveness and simplicity of these reactions make it possible to synthesize copolymers with chloro- and thioether, and/or sulfone side groups; this opens unlimited possibilities for making new polymers for various applications, including liquid crystalline polymers (21).



(**1**) (**2**)

R = CH_3, $(CH_2)_xCH_3$ (where x = 1, 2, 3, 4), $CH(CH_3)_2$

The novel partially crystalline polymer (**3**) with number-average molecular weight (M_n) of up to 5700 was prepared under various conditions by catalyzed self-condensation of 3-hydroxypropyl methoxycarbonylethyl sulfide (**4**) or 3-hydroxypropyl carboxyethyl sulfide (**5**) (22). The degree of crystallinity, melting temperature (T_m), T_g, and temperature of initial decomposition (T_d) were 36–46%, 37–47°C, −61 to −70°C, and 164–260°C, respectively. The monomers (**4**) and (**5**) were prepared by an addition of methyl 3-mercaptopropionate and 3-mercaptopropionic acid with allyl alcohol [107-18-6] catalyzed by AIBN [2,2′-azobis(2-methylpropionitrile), azobisisobutyronitrile, azodiisobutyrodinitrile, 2,2′-azobis(2-methylpropanenitrile), α,α'-azodiisobutyronitrile, 2,2′-azobis(isobutyronitrile), 2,2′-dicyano-2,2′-azopropane, Porofor-57, 2,2′-dimethyl-2,2′-azodipropionitrile, 2,2(-azobis(2-methylpropionitrile))] [78-67-1].



An addition of conjugate 1,4-benzenedithiol (A) to 1,4-divinylbenzene (1,4-diethenylbenzene, *p*-divinylbenzene) (B) [105-06-6] was investigated in detail in the presence of the AIBN initiator in toluene at 75°C (23). It was found that the polymerization proceeded without an induction period, to give a white polymer with a high molecular weight [weight-average molecular weight (M_w) = 110,000] in ∼90% yield for 2 h. In addition, it was confirmed by ^{1}H nmr, ir, and the sulfur contents that the polymer had an alternating structure of A and B units.

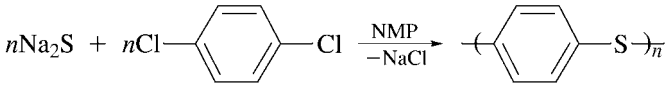
The synthesis and radical addition behavior of optically active cysteine-based monomers with mercapto and olefin groups have also been studied (24). *N*-4-vinylbenzoyl-L-cysteine methyl ester polymerized satisfactorily to afford the corresponding polysulfide (with M_n in the range of 7000–23,000) in good yields.

A novel one-pot synthesis of sulfur-containing polymers including poly(monosulfide)s (polythioethers), poly(disulfide)s, polythioesters, and polythiourethanes from a five-membered cyclic dithiocarbonate (5-phenoxymethyl-1,3-oxathiolane-2-thione) and diamines has been examined. Polythioethers with M_n = 2600–17,700 were obtained by condensation of *in situ* forming dithiol with α,α'-dibromo-*p*-xylene [623-24-5] (25). A synthesis by using a bifunctional five-membered cyclic dicarbonate and benzylamine [100-46-9] has also been reported (26).

High temperature solution condensation of 4,4′-bis(mercaptomethyl)biphenyl (MMB) (**88d**) or 4,4′-dimercaptobiphenyl (4,4′-biphenyldithiol) (MB) with various aliphatic and aromatic–aliphatic dihalogen hydrocarbons has been studied in detail. Polymers with reduced viscosity

(η_{red}) = 0.18–0.54 dL/g and in ~78–99% yield were obtained under optimum conditions. Their characteristics were T_m = 104–248°C from MMB, 215–345°C from MB and T_d = 230–270°C from MMB, 290–340°C from MB. All the polymers showed good chemical resistance. Some mechanical and electrical properties of the selected polymers were examined (27).

Poly(arylene sulfide)s. The best-known polymer in this class is PPS (**6**). The commercial product produced from dichlorobenzene and sodium sulfide (Na_2S) by polymerization in a polar solvent, eg, *N*-methyl-2-pyrrolidinone (NMP) [872-50-4], contains up to a few percent of disulfide linkages.



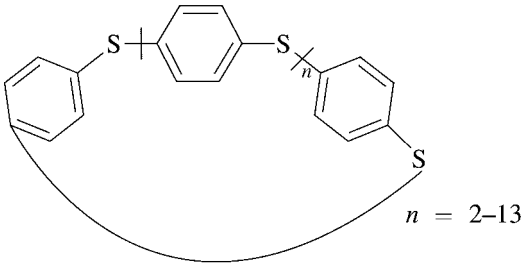
(**6**)

Linear PPS is a crystalline material with T_m ~285°C and T_g = 85°C for a degree of polymerization of ~200. PPS shows a rather good chemical and thermal resistance (T_d = 370°C) and finds a wide range of applications as a high performance thermoplastic with excellent mechanical properties (3,28,29).

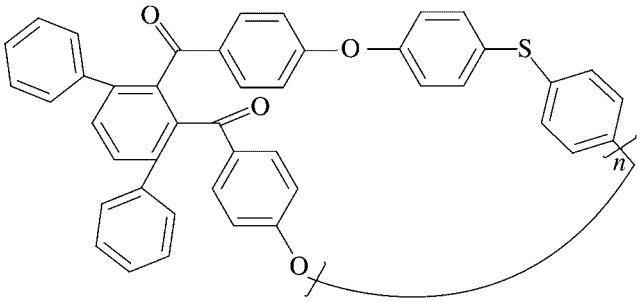
The main types of preparation of poly(arylene sufide)s can broadly be classified into electrophilic and nucleophilic reactions; the latter are much more developed. In addition, many other polycondensation, oxidation, irradiation, or electroinitiated reactions were developed for the synthesis of various aromatic or aromatic–aliphatic materials (3).

Ring-Opening Polymerization (ROP). Free-radical ROP of various macrocyclic oligomers containing an aromatic sulfide linkage has recently been intensively studied as a new facile route to obtaining high performance thermoplastic polymers. The advantageous aspects of ROP over the conventional condensation methods are the elimination of solvents, the absence of by-products, and the rapid formation of high molecular weight polymers in high yields. Another noticeable attractive feature in using cycles is their much lower melt viscosity compared with that of the polymers, which facilitates reactive injection molding (14).

It was found that heating cyclic oligomers which contain an aromatic sulfide linkage in the presence of elemental sulfur or an aromatic disulfide, eg, 2,2′-dithiobis(benzothiazole) (MBTS, 2-mercaptobenzothiazole disulfide, etc) [120-78-5] readily yields high molecular weight polymers by ROP which proceed via a free-radical mechanism (8). The free-radical nature of the polymerization was confirmed by electron spin resonance (esr) spectroscopy. Melt polymerization of the cyclic hexakis(thio-1,4-phenylene) gave only a low molecular weight polymer (12,14,30) whereas that of a lower melting mixture of cyclic oligomers (**7**) led to the formation of highly crystalline high molecular weight poly(thio-1,4-phenylene), which is compared with that of commercial PPS. Other macrocycles, eg, (**8**), also gave high polymers (M_n ~30,000) (8).

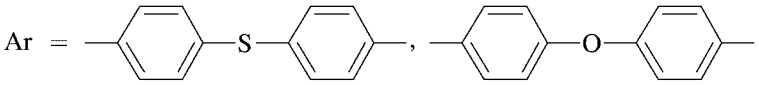


(**7**)



(**8**)

Free-radical ROP of cyclic oligo(thioarylene)s (**9**) in the presence of a small amount of an initiator (elemental sulfur or MBTS) in melt at 300°C has been studied (14).



(**9**)

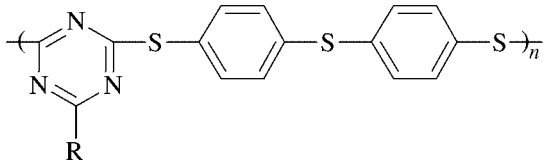
Linear poly(thioarylene)s obtained (yield 91–100%) were rather low-molecular-weight polymers (M_n = 1500–2100 with polydispersity 2.2–3.1). Their T_ms were 195–250°C, temperatures of the 10% weight loss (T_{d10}) ~490°C.

Other Methods. The electrophilic reaction of sulfur dichloride (SCl_2) or sulfur chloride (S_2Cl_2) with phenyl sulfide (diphenyl sulfide, diphenylthioether, 1,1′-thiobisbenzene) [139-66-2] in dichloromethane [75-09-2] solution at room temperature was studied in the presence of various catalysts (31). The resulting oligomeric products contained a linear structure linked by sulfide and disulfide bonds. It was found that SCl_2 showed higher reactivity than S_2Cl_2. The quantitative yield was achieved among other things with a catalyst, such as Fe, $SnCl_4$, $TiCl_4$, or $ZnCl_2$. An Fe catalyst gave a white product containing no elemental sulfur.

It has been reported that tris(2,2′-bipyridine)ruthenium(II) chloride catalyzed the photooxidative polymerization of diaryl disulfides by O_2, by which poly(thioarylene)s were efficiently prepared. The polymerization proceeded through the electrophilic reaction of the sulfonium cation which was produced selectively by the photoredox system. The ruthenium(II) complex provided the first photocatalytic system for the polymerization of diphenyl disulfide. The linear structures of the obtained polymers were confirmed (32).

Linear perfluorinated PPS was successfully prepared in 100% yield by the new method condensation of the corresponding fluorinated aryl sulfoxide via the poly(arylenesulfonium salt) as a precursor (33). The polymer had a significantly higher T_m (373°C) than that of PPS (285°C). The contact angle measurements showed that the surface energy of the polymer ($\sigma_s = 41$ mN/m) is comparable to those of poly(ethylene terephthalate) [25038-59-9] and polystyrene [9003-53-6]. High molecular weight PPS is also synthesized by this method.

New aromatic poly(monosulfide)s (**10**) (34) containing a 1,3,5-triazine ring were readily prepared with moderate yields by the aromatic nucleophilic substitution polymerization of 2,4-dichloro-1,3,5-triazine derivatives with bis(4-mercaptophenyl) sulfide (4,4′-thiodibenzenethiol) [19362-77-7] under mild conditions in the presence of a base in tetrahydrofuran (THF) [109-99-9] solution or in the *o*-dichlorobenzene/water two-phase system by using phase-transfer catalyst. The resulting polymers showed highly crystalline structures and high thermal stability (T_d ~330–410).



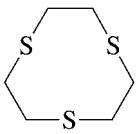
R = C_6H_5, C_6H_5NH, $C_6H_5(CH_3)N$,$(C_6H_5)_2N$, C_6H_5O, C_6H_5S

(**10**)

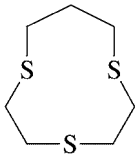
Preliminary investigations of the thermal polymerization reactions of newly obtained cyclic aromatic disulfides with *p*-diiodobenzene [624-38-4] and dibromobenzene [26249-12-7], or bis(4-bromophenyl) ether (4,4′-dibromodiphenylether, bis-*p*-bromophenyl ether, *p,p*′-dibromodiphenyl ether) [2050-47-7] as a new alternative approach to PPS and other polysulfides have been reported (9). The reactions were carried out in diphenyl ether solution at 270°C giving polymers with ~96% yield.

Macrocyclic Polythioethers. During the past decade, intensive studies have taken place of the complexation of transition metal ions with crown thioether ligands, mainly 1,4,7-trithiacyclononane (9S3) (**11**) as well as 1,4,7-trithiacyclodecane (10S3) (**12**), 1,4,7,11,14,17-hexathiacycloeicosane (20S6) (**13**), and 1,4,7,10,13,16,-hexathiacyclooctadecane (18S6) (**14**), and many articles (35–42), including reviews (35–39), dealing with the coordination chemistry of these ligand systems have been published. The crown thioether complexes of the soft

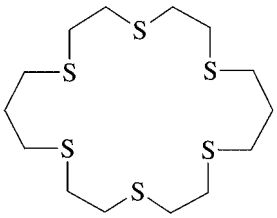
metal ions exhibit unusual stereochemical, spectroscopic, and electrochemical properties, such as the ability to stabilize uncommon oxidation states including Pd(III), Pt(III), Au(II), and Rh(II), the ability to force metals ions into unusual geometries such as octahedral Rh(I) and Au(III), the formation of metal–carbon bonds, and the ability to activate carbon–hydrogen bonds in ring-opening reactions (41).



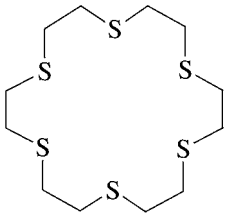
(**11**)



(**12**)

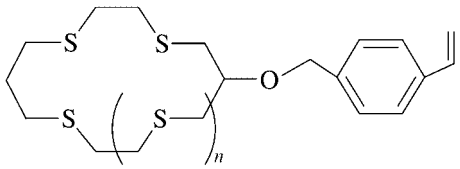


(**13**)



(**14**)

The thiacrown ether monomers (**15**) were polymerized and copolymerized with styrene [100-42-5] and *N*-vinyl-2-pyrrolidinone (*N*-vinyl-2-pyrrolidone, *N*-vinylpyrrolidone, 1-vinyl-2-pyrrolidone, 1-vinyl-2-pyrrolidinone, vinylbutyrolactam, etc) [88-12-0] by radical polymerization, giving the thiacrown ether polymer ligands which had binding selectivity for Ag(I) and Hg(II) ions. These polymers are likely to be efficient sorbents for the heavy metal ions under industrial conditions, since they can be used repeatedly under acidic conditions (15,16).



$n = 1$ or 3

(**15**)

A new method has been reported of the synthesis of thiocrowned and oxothiocrowned 1,3-dithiole-2-thiones from the key starting compound of 4,5-bis(benzylthio)-1,3-dithiole-2-thione. Intramolecular phosphite coupling reaction yielded the new tetrathiafulvalene (TTF) [31366-25-3] derivatives incorporated into thiacrown as well as oxathiacrown ether macrocycles in moderate yields. This procedure permits the isolation of asymmetric sulfur/oxygen donors not accessible by other methods (43). TTF-containing macrocycles with sulfur and selenium soft donor atoms were obtained by using a similar method (17). The cyclic voltammograms of these TTFs were discussed.

Polythiophenes. Polythiophene and its alkyl derivatives are the first class of conducting polymers with a good stability toward oxygen and moisture (3,44–46) (see ELECTRICALLY-CONDUCTING POLYMERS). High molecular weight polymers are successfully produced by the chemical oxidations (Lewis acid), the organometallic coupling (chemical), and the electropolymerization methods. Good-quality films are afforded by electropolymerization.

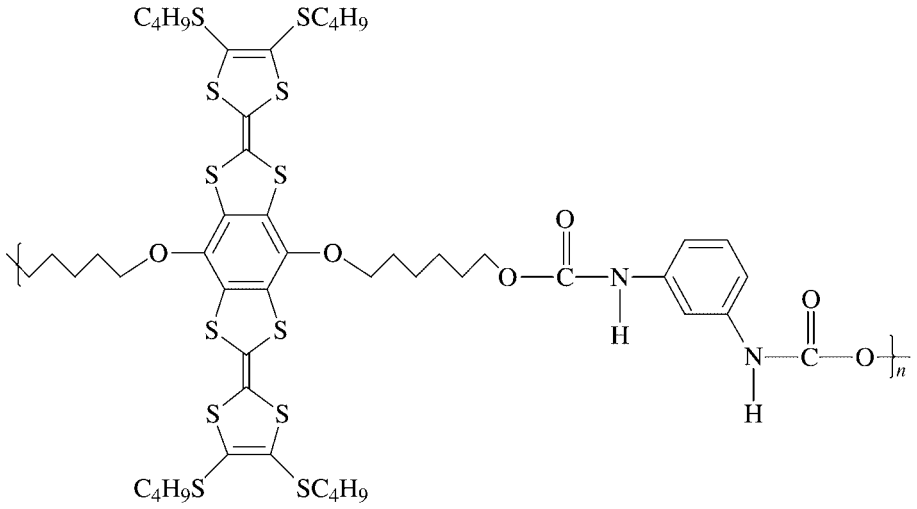
The synthesis of 3-(perfluoro)-thiophenes and 3-(polyfluoro)-thiophenes as precursors to electrically conductive polymers has been reported (47–53). The incorporation of a significant percentage of fluorine into the polymer is anticipated to allow greater control over its oxidation potential and provide better long-term chemical and thermal stability in the electrochemical environment over that of the nonfluorinated polythiophene analogs.

The novel functionalized polythiophenes, poly[3-(6-hydroxyhexyl)thiophene] and poly(3-octanethio-2,2′-bithiophene), have been used as selective coating materials for quartz crystal microbalance (QCM) sensors. These Langmuir–Blodgett film coated QCM sensors are useful in detecting heavy metal ions in aqueous solution, which are major pollutants in wastewater (54).

Tetrathiafulvalene Polymers. TTF and its derivatives form highly conductive anisotropic (quasi one-dimensional) charge-transfer complexes and radical cation salts. To obtain materials with three-dimensional conductivity, good processability, and film-forming properties, the polymeric forms of TTF are prepared. TTF can be incorporated into the polymer backbones via condensation to polyesters, polyamides, polyurethanes, and polysulfonates (55).

Several main-chain and side-chain TTF polymers have been synthesized via a multistep synthesis (55). They combine the unique properties of high molecular weight polymers, such as processability, with the outstanding electron-donating properties of TTF systems. Doping the polyurethane-type polymer (**16**) with 2,3,5,6-tetrafluoro-7,7,8,8-tetracyanoquinodimethane led to a free-standing, processable film exhibiting a moderately high electrical conductivity

of 8×10^{-4} S·cm^{-1}, which is comparable to iodine-doped nonordered polythiophene.

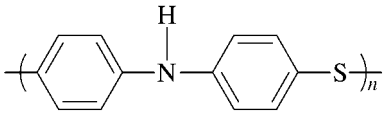


(**16**)

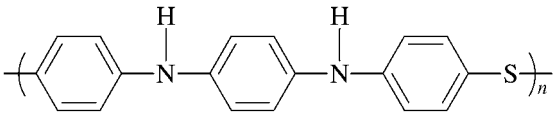
The synthesis of a fully conjugated, planar, and sulfur-rich TTF polymer, which should increase the dimensionality of the conduction process in the doped state, was also reported (55).

Conjugated Polymers. Sulfur-containing conjugated polymers have played a major role in the development of temperature-stable thermoplastic materials and in the search for materials being suitable as active components of optoelectronic and photonic devices. The new synthetic approaches to these polymers, including poly(phenantrolinebisthiazole), poly(phenylene sulfide-phenyleneamine) (PPSA), poly(tetrathiafulvalene), sulfur-containing [n]acenes, and donor-acceptor substituted poly(phenylenevinylene), were presented in a review article in 1997 (56). Two different strategies have been taken. The first one comprises the synthesis of suitably functionalized monomeric building blocks, which can be easily polymerized by common polymerization methods; the second one is based on novel methods of carbon–carbon and carbon–sulfur bond formation.

High molecular weight PPSA (M_n = 150,000) (**17**) and poly(phenylene sulfide–phenyleneamine–phenyleneamine) (PPSAA) (M_n = 68,000) (**18**) have been synthesized in high yields via their poly(sulfonium) cations through the acid-induced condensation reaction (57,58). These novel polymers represent the first hybrid structures of PPS and polyaniline (PAni). Both polymers are structurally well-defined and exhibit exceptional solubility in many solvents, including THF, *N*,*N*-dimethylformamide (DMF) [68-12-2], dimethylsulfoxide (DMSO) [67-68-5], and NMP, contrary to PPS and PAni. The electronic properties of polymer (**19**) that define this material as a prominent candidate for efficient hole-transport ability in light-emitting diodes (LEDs) have already been studied.



(**17**)



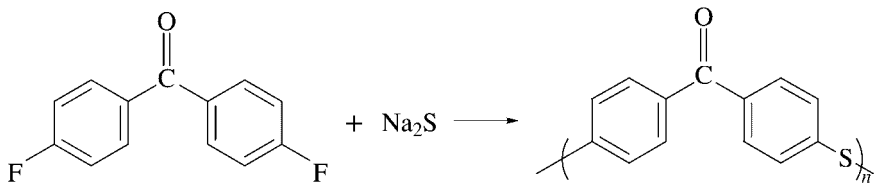
(**18**)

The first π-conjugated TTF polymer composed entirely of vinylogous, linearly fused TTF moieties was achieved by oxidative polymerization of 2-5-di(benzylidene)-1,3,4,6-tetrathiapentalene (59).

The syntheses of the first sulfonio-bridged, *p*-phenylene ladder oligomers (**44**) that have a planar ribbon-type structure have also been reported (60).

Poly(monosulfide ketone)s. Aromatic poly(monosulfide ketone)s [poly (thioether ketone)s] have been investigated in view of their potential use as high performance thermoplastics.

Poly(*p*-phenylene sulfide ketone) (**19**) (61) was prepared under different conditions by polymerization of 4,4′-difluorobenzophenone [345-92-6] (**20**) with sodium sulfide (Na_2S). Since the reaction involves nucleophilic aromatic substitution, it should be facilitated in aprotic polar solvents by increased dianion reactivity. A high molecular weight polymer [inherent viscosity (η_{inh}) = 0.95 dL/g] was obtained in solution of *N*-cyclohexyl-2-pyrrolidinone (*N*-cyclohexyl-2-pyrrolidone, 1-cyclohexyl-2-pyrrolidinone, 1-cyclohexyl-2-pyrrolidone, cyclohexyl-2-pyrrolidone, CHP) [6837-24-7], using freshly crystallized and dehydrated Na_2S. The polymer was high melting, $T_m = 335^\circ C$ and $T_g = 152^\circ C$.

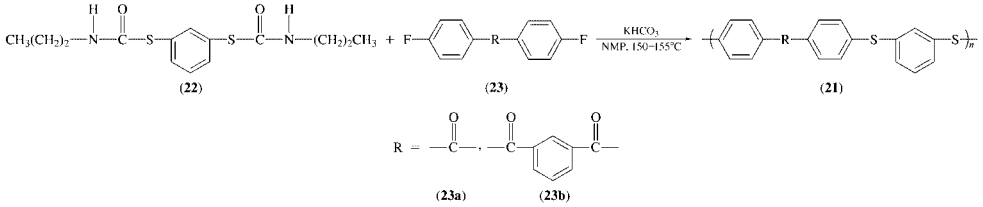


(**20**) (**19**)

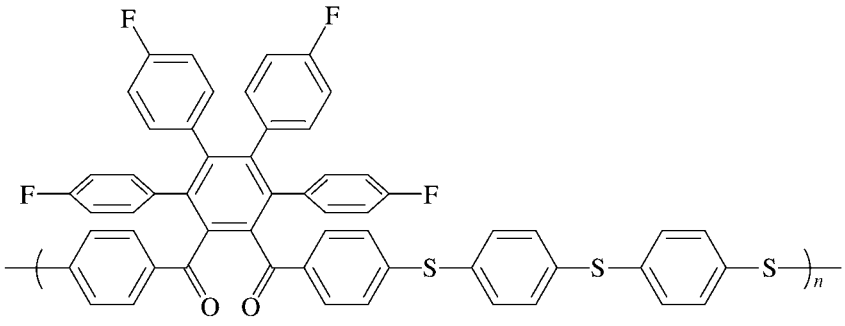
Random copoly(*p*-phenylene sulfide sulfone/ketone)s were easily prepared in high yield (~95–99%) by the solution (NMP) condensation of sodium hydrosulfide (NaSH) with bis(4-chlorophenyl) sulfone (4,4′-dichlorodiphenyl sulfone) [80-07-9] and 4,4′-dichlorobenzophenone [98-98-2]. Copolymers with sulfone/ketone molar ratios > 25:75 were amorphous, whereas those with ratios ≤ 25:75 were crystalline. These materials form tough, creaseable films and exhibit a linear increase in the T_g from 144 to 215°C, with increasing sulfone content (62).

A series of poly(thioether ketone)s or poly(thioether ether ketone)s (η_{inh} = 0.1–0.73 dL/g) were synthesized by condensation of aromatic dicarboxylic acids with aryl compounds containing ether or sulfide structures using phosphorous pentoxide/methanesulfonic acid as the condensing agent and solvent. The polymers showed T_{d10} in the range of 420–485°C in air and nitrogen atmospheres (63).

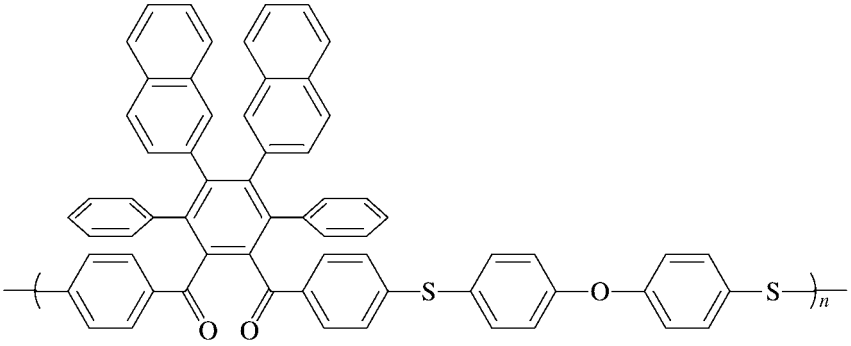
Poly(thioether ketone)s (**21**) (η_{inh} = 0.3–0.54 dL/g, tetrachloroethane, 0.5%) were also prepared in good yield (92–94%) from masked bisthiophenol (**22**) and difluoro-compounds (**23**) such as 4,4′-difluorobenzophenone [345-92-6] (**23a**) or 1,3-bis(4-fluorobenzoyl)benzene (**23b**) by solution (NMP) polymerization in the presence of $KHCO_3$. The polymers showed T_g = 106–121°C and excellent thermal stability (T_{d10} ~460–515°C in N_2 and air). This novel method eliminates the problem associated with the conventional procedure in handling the unstable bisthiophenol monomers (64).



A series of high molecular weight poly(thioether ketone)s (M_n = 55,000–100,000), eg, (**24**) and (**25**), have successfully been prepared from bis(4-mercaptophenyl) ether (4,4′-dimercaptodiphenyl ether) or bis(4-mercaptophenyl) sulfide (4,4′-dimercaptodiphenyl sulfide) by reaction with a series of ketone-activated aromatic fluoro-compounds in the presence of anhydrous K_2CO_3. The polymers are amorphous and soluble in common organic solvents. They show T_gs from 154 to 251°C and excellent thermal stability [temperatures of 5% weight loss (T_{d5}) even above 500°C] (65).



(**24**)



(**25**)

Optically active poly(γ-ketosulfide)s have also been the subject of detailed studies. Different routes to both aliphatic (66,67) and aromatic (68–70) polymers and their chirooptical properties have been described.

Poly(disulfide)s

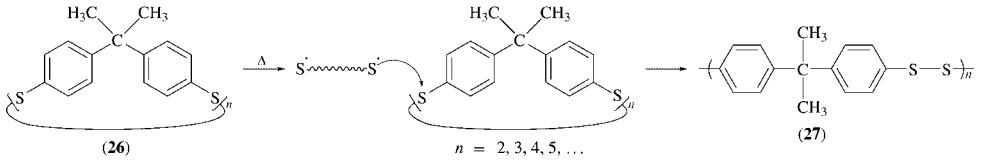
During the last several decades, aliphatic poly(polysulfide)s, including poly(disulfide)s, have been extensively investigated because of their interesting properties resulting from the presence of polysulfide linkages. The properties such as good resistance to solvents and hydrocarbon fuels, resistance to dissolution for linear polymers and to swelling for cross-linked polymers, as well as generally good low temperature properties have given them a particular position among specialty elastomers. The Thiokol Co. in the United States marketed the first synthetic polysulfide rubber under the trade name Thiokol A [poly(ethylene tetrasulfide)]. Rohm and Haas now produces and distributes Thiokols. Aliphatic poly(disulfide)s, eg, Thiokol D [poly(ethyl ether disulfide], have also been produced commercially (71,72). There are several reviews of the synthesis and properties of this class of polymers (2,3,73,74) (see POLYSULFIDES).

In the last decade, extensive efforts have been devoted to the synthesis of cyclic oligomers as precursors for the preparation of high molecular weight polymers by ROP. Although it is routine to prepare aliphatic poly(disulfide)s by ROP (75), little attention has been given to the ROP study of cyclic (aromatic disulfide)s (3,76).

A series of cyclic (aromatic disulfide) oligomers have been synthesized in high yields by a copper-catalyzed oxidation with oxygen of arenedithiols in DMAc solution (10). The aryl groups contained moieties such as isopropylidene, ketone, sulfone, ether, thioether, and phenylphosphine oxide groups. In general, these cyclic oligomers with up to nine repeating units were soluble in common organic solvents and had sharp melting points. Contrary to earlier-described cyclization reactions, which were run over 16 h under high dilution conditions, this one was complete in 3–4 h at room temperature (10).

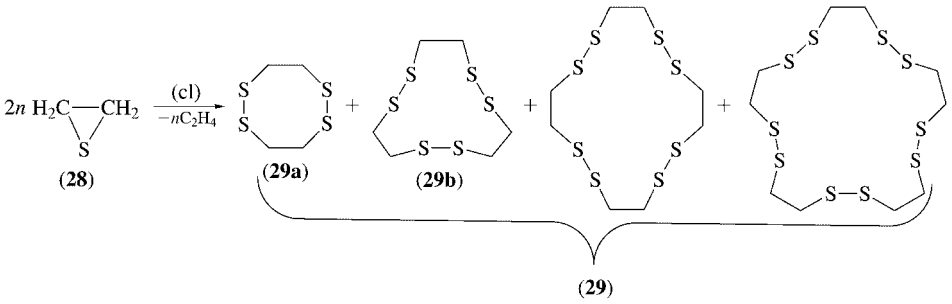
The ROP reaction of the cyclic oligomers mixture (**26**) derived from 2,2-bis(4-mercaptophenyl)propane (4,4′-isopropylidene bisthiophenol) was studied in both diphenyl ether solution and melt without adding any catalyst. It was found that

ROP began at ~150°C in solution and at ~200°C in melt. It may be supposed that the reaction is initiated by forming upon heating the radical species of (26). The highest molecular weight polymers (**27**) (M_n = 64,000–88,000) were formed at 200°C with conversion of cycles ~80% in solution and ~98% in melt. A ^{13}C nmr study indicated that structurally regular polymers were formed below 250°C (77).



Earlier attempts of ROP without adding any catalyst were performed on some cyclic bis(arylene tetrasulfide)s upon heating (78) and 1,2,3-trithiane [3325-33-5] upon standing at room temperature (77). Some cyclic (arylene) disulfides were already prepared earlier by using iodine or DMSO as oxidizing agent, mainly to study their structural geometry and their potential for complexation (79–84).

A new easier approach to cyclic poly(aliphatic disulfide)s by catalytic transformation of thiiranes by (thiirane)$W(CO)_5$ complexes has been studied (85,86). For this purpose, the new thiirane complexes such as $W(CO)_5$(thiirane) (c1), $W(CO)_5$(*cis*-dimethylthiirane) (c2), and $W(CO)_5$(*trans*-dimethylthiirane) (c3) were prepared and characterized. It was found that c1, as $W(CO)_5$(NCMe) (87) used earlier, transforms free thiirane (thiacyclopropane, ethylene sulfide) [420-12-2] (**28**) into a mixture of cyclic poly(disulfide)s (**29**), and ethylene, catalytically; the compound (**29a**) was the major product (~66%). Also, *cis*- and *trans*-dimethylthiirane were catalytically transformed by c2 and c3 with the formation of small amounts of cyclic disulfides. The mechanism of these reactions has been proposed.



Cyclic disulfides have been shown to exhibit a variety of antimicrobial properties (85,88). The compounds 1,2,5,6-tetrathiacyclooctane (**29a**) and 1,2,5,6,9,10-hexathiacyclododecane (**29b**) were tested for antimicrobial activity, using a standard disk diffusion assay. The compound (**29a**) exhibited moderate antimicrobial activity toward *Escherichia coli*.

Contrary to the extensive studies on the coordination properties of polythioether macrocycles (35–42), little information is available about cyclic

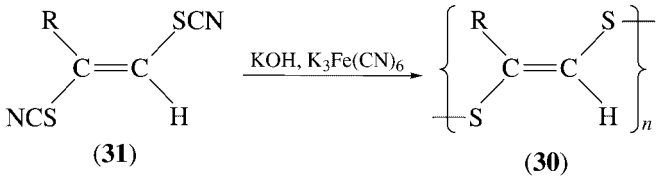
poly(disulfide)s. The first reaction which was performed with compound (**29a**) and $Ru_3(CO)_{12}$ led to the formation of two isomers of $Ru_3(CO)_7(\mu\text{-}SCH_2CH_2S)_2$, which contained bridging ethanedithiolate ligands formed by cleavage of both of the disulfide S—S bonds (89). Attempts to prepare complexes of (**29a**) and (**29b**) without cleavage of disulfide bonds were performed by reaction with CuI in acetonitrile [75-05-8] (90). Two new compounds obtained in yields of 75 and 61%, respectively, were characterized crystallographically. They exhibited interesting extended structures in the solid state that were created by the formation of bridging ligands involving η^2-coordination of the cyclic disulfides.

An interesting new approach to poly(disulfide)s with a variety of main-chain structures by one-pot oxidation polymerization of dithiols forming *in situ* from monofunctional (25) and bifunctional (91) five-membered cyclic dithiocarbonates and diamines or amines, respectively, has recently been reported. Polymers with M_n up to ~20,000 and a good yield (up to 98%) were obtained. The starting dithiocarbonates can be easily synthesized by incorporation of CS_2 into epoxides in the presence of metal halides under mild conditions (92,93).

Other oxidation processes leading to poly(disulfide)s, namely the electrochemical (anodic) oxidation of Bunte salts (bisthiosulfates) (94) as well as oligomerization and cyclization of 1,2-ethanedithiol [540-63-6] by selenium dioxide [7446-08-4] or iodine, have also been studied (95).

Poly- and copoly(disulfide)s as electroactive materials have been used successfully in the lithium/poly(ethylene oxide)/(solid redox polymerization electrodes) (Li/PEO/SRPE) battery system (96). The high level of performance of these polymeric materials in thin-film Li/PEO batteries demonstrates the versatility of the SRPE and indicates that such batteries may be useful for a wide range of applications.

Water-insoluble ethylenic poly(disulfide)s (**30**) were prepared, for the first time, by the treatment of dithiocyanates (**31**) with KOH and $K_3Fe(CN)_6$ in aqueous solution, and characterized. These simple-structure polymers become semiconductive upon chemical doping (97).



(**31**) (**30**)

R = H, $CH_3(CH_2)_3$, C_6H_5

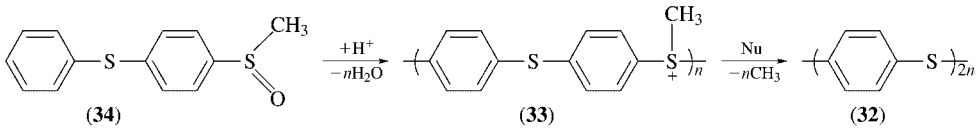
The importance of disulfide bridges in peptides and proteins is well known, and many elegant ways to form these structures have been reported (98,99). In contrast, the corresponding "trisulfide" variants reflect a rather newly appreciated area of chemical and biological interest (100).

Sulfonium Polymers. Polysulfonium salts have been extensively studied because of the versatile possibilities of their application. They can be used as ion-exchange resins, polymer supports in peptide synthesis, polymeric reagents, and

conducting materials (101). The poly(sulfonium cation) is chemically stable and soluble in common solvents, such as acetone, acetonitrile, or protic acid. These properties are applicable to the modification of the polymer in a homogeneous solution under moderate conditions.

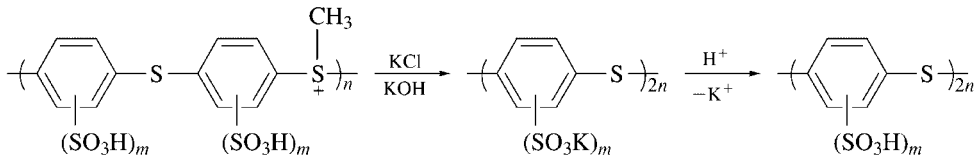
There have been reports of examples of polymers with sulfonium salt moieties applied as a catalyst to organic reactions (102) and precursors of such polymers as PPS (103–107), perfluorinated PPS (33), poly(*p*-phenylene vinylene) (PPV) (108–111) and its derivatives (112), as well as PPSA and PPSAA (57,58).

For example, the high molecular weight PPS (**32**) (M_w > 200,000) was synthesized via soluble poly[methyl-4-(phenylthio)phenylsulfonium cation] (**33**) through oxidative polymerization of methyl-4-(phenylthio)phenyl sulfoxide (**34**). The polymerization process carried out in trifluoromethanesulfonic acid (triflic acid, CF_3SO_3H) [1493-13-6] and in the presence of P_2O_5 as dehydrate agent at room temperature for 24 h quantitatively produced the high molecular weight polymer (**33**) which was converted, also quantitatively, to PPS (**32**) by nucleophilic demetylation in pyridine [110-86-1] (104,105). The polymerization of (**34**) in sulfuric acid, particularly at elevated temperature and extended reaction time, resulted in a slight sulfonation on the phenylene ring in the polymer chain.



(**34**) (**33**) (**32**)

The highly sulfonated polysulfonium salt (**35**) synthesized by the polymerization of (**34**) in the presence of SO_3 can be converted by nucleophilic demethylation with aqueous KCl to the highly sulfonated PPS (**36**) exhibiting excellent proton conductivity (113).

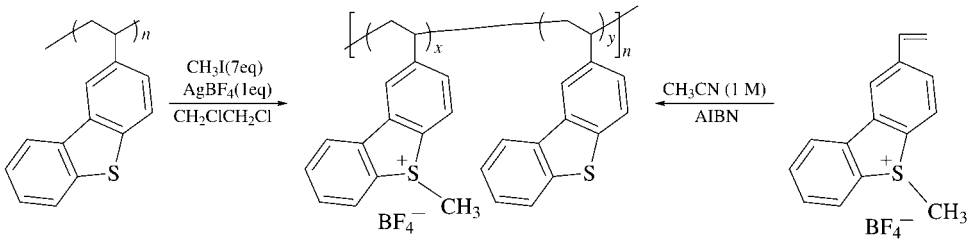


(**35**) (**36**)

Poly(arylenesulfonium salt)s are employed as new polymeric alkylation reagents because, after the dealkylation, they are converted to insoluble PPS that can easily be removed from the reaction mixture (114,115).

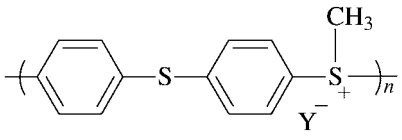
Thiophenium salt derivatives can be utilized as powerful alkylating reagents because of their remarkable instability in nucleophilic solvents (116,117). In order to investigate a similar application of poly(thiophenium salt)s, new polymers

having pendent *S*-alkyldibenzothiophenium salt moieties have been, for the first time, synthesized and characterized (118–120). Two synthetic routes to polymer (**37**) were investigated: the polymer reaction of poly(2-vinyldibenzothiophene) (**38**) with methyl iodide [74-88-4] and silver tetrafluoroborate [14104-20-2] carried out in 1,2-dichloroethane [107-06-2] at room temperature, and the radical polymerization of a vinyl monomer bearing dibenzothiophenium moieties, ie, 5-methyl-2-vinyldibenzothiophenium tetrafluoroborate (**39**), carried out in acetonitrile with an AIBN catalyst at 60°C. The former method gave the polymer in 96% yield with 71% substitution of the methyldibenzothiophenium tetrafluoroborate units, whereas the latter in 88% yield with 79% substitution. The analogous polymer with 63% substitution was also prepared by the polymer reaction of poly[2-(*p*-vinylbenzyl)dibenzothiophene] (120). The attempts of demethylation showed that the complete demethylation of the dibenzothiophenium units in polymer (**37**) was achieved at 80°C for 48 h by the reaction in acetonitrile (119). In addition, it was found that thermal decomposition of the polysulfonium polymers obtained took place in two steps; the first step was associated with demethylation. These properties suggest the possibility of utilizing these polymers as an alkylating reagent and an initiator of the cationic polymerization.

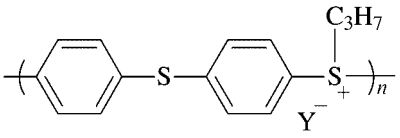


(**38**) (**37**) (**39**)

Attention has been paid to the polysulfonium salts as a new type of photochemical polymeric materials (121,122). Several kinds of poly(arylenesulfonium salt)s having methyl (**40**) propyl (**41**), and phenyl substituents (**42**, **43**) including a novel class of polyelectrolites having triphenylsulfonio groups in the main chain (**42**, **43**) were synthesized in yield up to 100% by the sulfoxide-acid system reaction from the corresponding alkyl and aryl sulfoxide monomers (105,107,115,122).

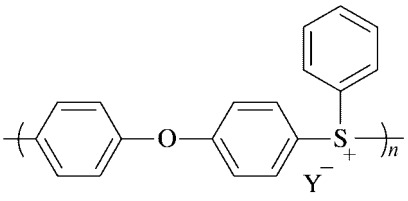


Y = CF_3SO_3, PF_6



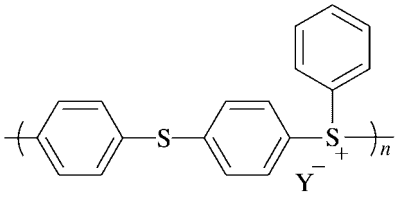
$Y = CF_3SO_3, PF_6, AsF_6, SbF_6$

(**41**)



$Y = CF_3SO_3, PF_6$

(**42**)

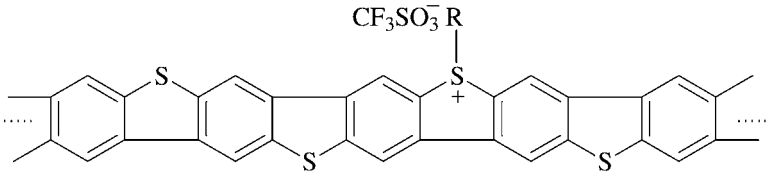


$Y = CF_3SO_3, PF_6$

(**43**)

They showed good solubility in protic acids, including formic acid [64-18-6], sulfuric acid, and CF_3SO_3H and polar organic solvents, including methanol, acetonitrile, DMF, DMSO, etc. The photochemical reactivities of the resulting polymeric sulfonium salts, eg, photolysis (photodegradation), photoinitiated polymerization, and quantum yields, were investigated in detail with comparison to those of the corresponding monomeric compounds. It was found that the photoirradiation of ultraviolet light at the π–π^* transition band resulted in the selective degradation of the polymer to the corresponding aryl or alkyl sulfide monomer. The photodegradation was accompanied by proton generation, which could be useful for the photoinitiated polymerization of epoxy compounds. The polymeric sulfonium salts were more effective than the monomeric ones because of a larger extinction coefficient at the irradiation wavelength (122).

The synthesis of the first sulfonio-bridged, *p*-phenylene ladder oligomers (**44**) that have a planar ribbon-type structure have been reported (60).



R = CH_3, $CH_3(CH_2)_5$

(**44**)

The oligomers are soluble in formic acid, sulfuric acid, and CF_3SO_3H but insoluble in common organic solvents, including methanol, acetone, acetonitrile, and chloroform. In the presence of an extended π-conjugation, two-dimensional planar structures have electronic advantages, for example, as a lower bandgap material (123).

Poly(sulfonic acid)s and Their Derivatives. Polymers substituted by sulfo groups have a wide range of applications because of their unusual properties. Water-soluble polymers are used as emulsifiers, flocculants, thickeners, tanning agents, wetting or cleaning agents, etc. They are also applied in the paint industry and in dye manufacturing (124,125). Introduction of the sulfo groups into fibers (eg, polyester fiber by using sodium-5-sulfo-dimethylisophthalate as ionic comonomer) (126) improves dyeability and imparts antistatic properties. Another important area of application is in construction engineering, eg, concrete technology as high range water reducers (superplasticizers). Lignosulfates, sulfonated melamine-formaldehyde and naphthalene-formaldehyde condensates are typical superplasticizers used commercially (127,128). Poly(3-alkylsulfonate thiophene)s (129), sulfonatoalkoxy-substituted poly(*p*-phenylene) (130), highly sulfonated PPS (113), and PAni (131) are water-soluble conductive polymers. The polyelectrolyte block copolymers, eg, poly(alkyl methacrylate)-*b*-poly(sulfonated glycidyl methacrylate) (132) and poly(ethylethylene)-*b*-poly(styrenesulfonate) (133), were found to be effective stabilizers in emulsion polymerization. Insoluble polymers are used as ion-exchange resins and they find application as membrane materials, eg, Nafion (DuPont, a sulfonated perfluoropolymer) (134,135). A great demand for chemically stable ion-exchange membranes for electromembrane processes, such as electrodialysis, polymer electrolyte membrane electrolysis, and polymer electrolyte fuel cells, has, in the past years, stimulated investigations dealing with the developing of the sulfonation process of thermally and chemically stable engineering plastics.

Sulfopolymers are employed in biomedical systems. Much effort has been expended to improve blood-contacting biomaterials, eg, segmented polyurethanes, and develop various polysulfates and polysulfonates as antithrombotic or antiviral agents.

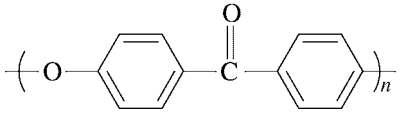
Sulfo groups (as a free acid, salt, or ester) can be introduced into polymers by homo- or copolymerization of monomers containing sulfo groups, or by direct sulfonation of the polymer.

Poly(sulfonic acid)s. There are many reports on the sulfonation of commercially available, high performance engineering plastics, including

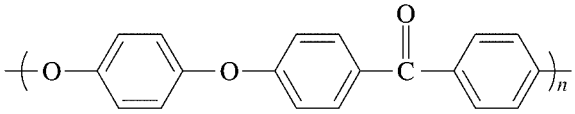
poly(*p*-phenylene) (PPP) (130), Udel [Union Carbide, poly(ether ether sulfone)] (136,137), poly(oxy-1,4-phenyleneoxy-1,4-phenylenecarbonyl-1,4-phenylene) [poly(phenylene ether ether ketone) (PEEK)] (138–144), and PPS (103,113,145–148), etc. (see POLYSULFONES; ENGINEERING THERMOPLASTICS, OVERVIEW).

The sulfonation of PEEK (**46**) in concentrated sulfuric acid or in its mixture with methanesulfonic acid [75-72-2] gives polymeric material which is soluble in organic solvents, eg, DMF (138), and good membranes with interesting properties were obtained by processing from these solutions (139–142).

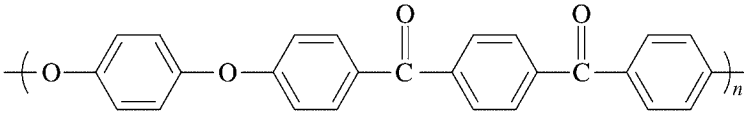
The sulfonation reaction of several kinds of commercially available poly(aryl ether ketone)s with various ether/carbonyl group ratio (0.67–2.0) (**45**, **46**, **47**, and **48**) by mixtures of sulfuric acid and oleum was studied (143). It appeared that with decreasing amounts of ether links in the polymer backbone the sulfonation is hindered, and to obtain products with the same degree of sulfonation, the SO_3 concentration of the reaction mixture has to be increased. Depending on the polymer structure, polymers with contents of sulfonate groups $\sim$1.2–2.0 meq·g^{-1} polymer were well soluble in DMF or NMP. The cationic exchange membranes with permselectivities >96% and electrical resistances <2 Ω·cm^{-2} from the polymers with a high degree of sulfonation were produced. The electrical and mechanical properties of these membranes compare very well with other membrane materials.



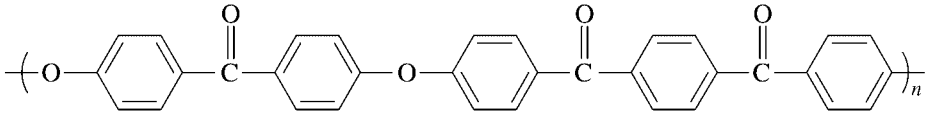
(**45**)



(**46**)



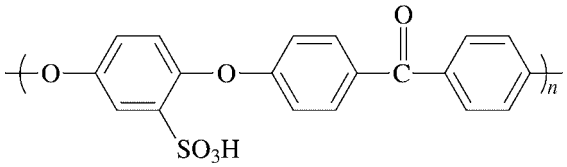
(**47**)



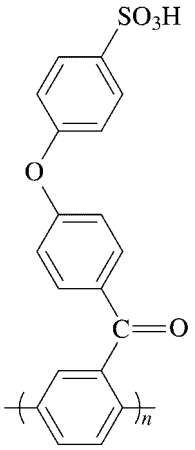
(**48**)

The electrical properties of the thermostable PEEK (**49**) and poly(4-phenoxybenzoyl-1,4-phenylene) (PPBP) (**50**) sulfonated with sulfuric acid and containing 65 mol% sulfonic acid have been studied and compared (144). Sulfonated

PPBP showed much higher and more stable proton conductivity than that of sulfonated PEEK, which is in agreement with the strong water absorption of the former polymer, as a consequence of the presence of the flexible pendent side chains. These properties may be important for future design and development of fuel cells based on polymer electrolytes.

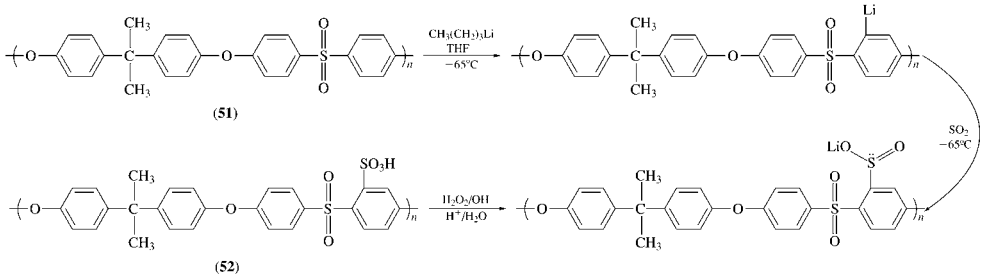


(**49**)



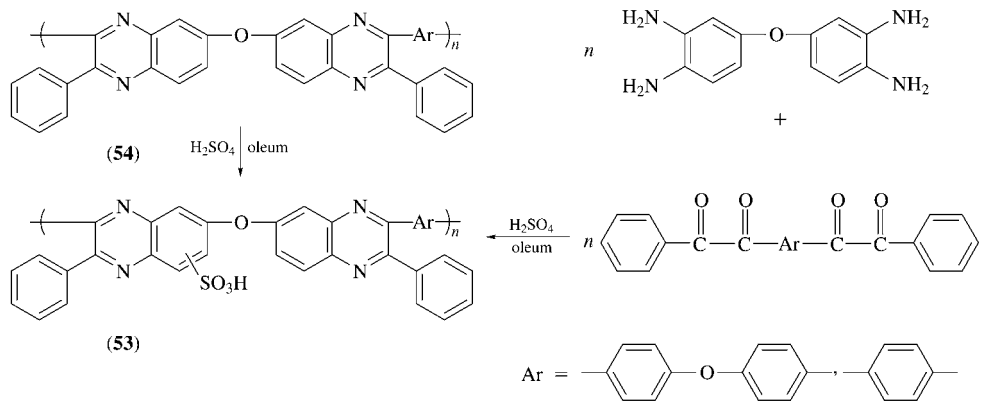
(**50**)

A new process has been developed for the sulfonation of the chemically stable engineering polymer polysulfone Udel (**51**) (137). This multistep sulfonation process described in equation (1) consists of the following steps: lithiation of the polymer at −50 to −80°C, gassing with SO_2, oxidation of the formed polymeric sulfinate with H_2O_2, NaOCl, or $KMnO_4$, and final ion-exchange of the lithium salt of the sulfonic acid in aqueous HCl. By this method the sulfonic acid group is inserted into the more hydrolysis-stable diarylsulfone part of molecule, contrary to conventional electrophically sulfonation which it undergoes at position ortho to the ether bridge of the bisphenol A [2,2-bis(4-hydroxyphenyl)propane, *p*,*p*′-isopropylidenebisphenol, dian, etc] [80-05-7] part (135). The resulting polymer (**52**) has been characterized in terms of ion-exchanges group content, conductivity, and hydrolytic stability. Membranes made from (**52**) showed good conductivity, good permselectivity (>90%), and good hydrolytic stability in 1 *N* HCl and water at temperatures of up to 80°C. This new sulfonation method can be applied to all the polymers which form soluble lithium salts.



(1)

Alternative potential materials for preparation of cation-exchange membranes are sulfonated poly(phenylquinoxaline)s (**53**) (149), which were produced by polymeric reaction sulfonation of poly(phenylquinoxaline)s (**54**) or by synthesis from monomers, directly in the sulfonating medium (eq. 2). In both cases, sulfonation was carried out in a sulfuric acid/oleum mixture (4:1) at 125°C. High strength thermally stable films showing high hydrolytic stability were cast from the solution of (**53**) in DMF. Polymers (**53**) can also be processed by compression molding.



(2)

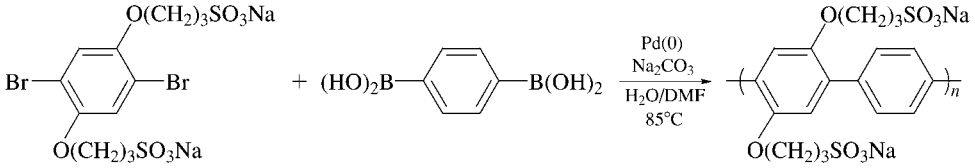
Earlier attempts to prepare highly sulfonated PPS by sulfonation with SO_3 were unsuccessful; the formation of only lightly sulfonated polymers (up to 0.5 sulfonic acid groups per phenylene, *m*) accompanied by the formation of ladder or cross-linked structures because of the stringent reaction conditions took place (145–148). The highly sulfonated PPS (*m* up to 2.0) (**36**) was successfully prepared by the polymerization of methyl-4-(phenylthio)phenyl sulfoxide (**34**) in sulfuric acid via polysulfonium salt as a soluble precursor (113). The sulfonation can be controlled by the reaction time, the temperature, and/or the addition of SO_3. The sulfonated polymer (**36**), unlike the nonsubstituted polymer, is soluble in water and methanol, and can form a transparent film. It was found that (**36**) exhibits a good water affinity and an excellent proton conductivity of up to 4.5×10^{-2} S·cm^{-1} at 80°C.

Membranes made from homogeneously sulfonated polystyrene exhibited proton conductivity equal to that of Nafion, with methanol permeability about 70% smaller than for this ionomer. This is attractive particularly in relation to the methanol fuel cell technology (150).

Other proton-exchange membranes bearing sulfonic acid groups were produced by radiation-induced grafting of styrene onto fluorinated polymers and subsequent sulfonation (151–161). Membranes produced from, eg, the high radiation resistance commercial poly(tetrafluoroethylene-*co*-hexafluoropropylene) films having degrees of grafting of 16% and above showed proton conductivity of the magnitude of $10^{-2}\ \Omega^{-1}\cdot cm^{-1}$ at room temperature, and thermal stability at temperatures up to 290°C under an oxygen atmosphere (151).

A new type of amphiphilic polymer blend comprising polystyrene (PS), poly(ethylene oxide) (PEO), and microspheres of cross-linked polystyrene sulfonic acid (PSSA) was prepared by solution blending and followed by casting. The ir and the differential scanning calorimetry (dsc) studies showed that besides providing protons, PSSA plays a role in enhancing the miscibility of PS and PEO. The influence of the mixing extent between PS and PEO on the proton conductivity has also been studied (162).

The first water-soluble, electroactive, self-doped sulfonatoalkoxy-substituted PPP, poly[2,5-bis(3-sulfonatopropoxy)-1,4-phenylene-*alt*-1,4-phenylene] (**55**), was synthesized from 1,4-benzenediboronic acid [4612-26-4] (**56**) and the disodium salt of 1,4-dibromo-2,5-bis(3-sulfonatopropoxy)benzene (**57**) by the homogeneous Suzuki coupling method (130). The polymer purified by dialysis of an aqueous solution was composed exclusively of 1,4-linkages. The ability to utilize a variety of bis(boronic acids) in this polymerization with sulfonate containing aryl halides will lead to a high degree of structural control of the optoelectronic properties of these water-soluble polymers.



(**57**) (**56**) (**55**)

As a new approach to sulfonated polymers, sulfonation of oligo(2-propenyloxy)methyloxyirane by SO_2 in presence of amines has been studied (163). It was shown that, depending on the reaction conditions, oligomeric sulfo acid or its derivatives (**58**) as well as crown polysulfonic acid (**59**) can be synthesized. Crown polysulfonic acid is produced by the copolymerization of SO_2 with double bonds of unsaturated oligomer.

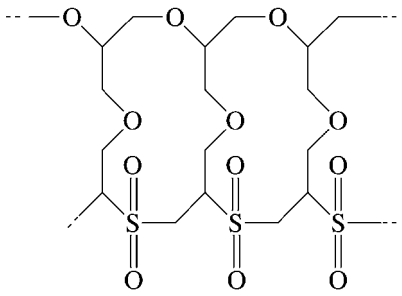
(**58**)



(**59**)

The synthesis, characterization, and some properties of novel unimolecular micelles of hydrophobically modified sodium polysulfonates as well as their potential utility for novel photochemical systems have been reviewed (164).

A novel series of water-soluble amphoteric cyclocopolymers containing the pH-responsive hydrophobic monomer, *N,N*-diallyl-*N*-methylamine [2424-01-3], and the sulfobetaine monomer, 3-(*N,N*-diallyl-*N*-methylammonio)-propanesulfonate, have been prepared in 0.5 *M* NaCl aqueous solution (pH 4.0), using 2-hydroxy-1-[4-(hydroxyethoxy)phenyl]-2-methyl-1-propanone (Irgacure 2959) as the free-radical photoinitiator (165). Equilibrium dialysis experiments demonstrated that they could be utilized to control the sequestration of organic foulants and thus have potential application as polymeric surfactants in micellar-enhanced ultrafiltration processes for water purification.

Numerous copolymers based on the ionizable monomer 2-(acrylamido)-2-methylpropanesulfonate (AMPS, 2-methyl-2-[(1-oxo-2-propenyl)amino]-1-propanesulfonic acid) [15214-89-8] and mainly vinyl or acryl comonomers were prepared and characterized because of their various application possibilities. Some of them are mentioned below.

Micelle-forming materials obtained by radical copolymerization of sodium salt of AMPS with 9-vinylphenanthrene and 1-vinylpyrene (AIBN, THF solvent, 60°C) can be used as media for photosensitized electron transfer in aqueous systems (166). Reactive microgels obtained by copolymerization of AMPS with *N,N′*-methyleneacrylamide are suitable for the immobilization of biological materials (167).

Copolymers synthesized by a sodium persulfate-initiated free-radical solution polymerization of acrylamide and AMPS (at different pH values) as a new type of super-absorbent polymer have been studied in terms of swelling or viscosity behavior in water (168).

The reaction of fluoroalkanoyl peroxides with AMPS or AMPS and the comonomers such as trimethylvinylsilane and methyl methacrylate gives novel fluoroalkylated end-capped homo- or copolymers which are able to form gels both in water and organic polar solvents such as methanol, ethanol, DMF, and DMSO under noncross-linked conditions. These AMPS polymer hydrogels have a strong metal ion binding power. Moreover, they are potent and selective inhibitors of the human immunodeficiency virus type 1 (HIV-1) replication in cell culture. One of these gelling polymers was found to possess antibacterial activity against *Staphylococcus aureus* (169).

Copolymers synthesized from AMPS and lauryl methacrylamide in different mole ratios were characterized and used as separation media in electrokinetic chromatography (170).

The new polyacrylic fibers (OHIS, Skopje) contain incorporated AMPS, which gives new and improved dyeing properties to the fiber. It can be dyed in more brilliant hues compared to Malon fiber with itaconic acid as an acidic comonomer (171).

Thermoassociative water-soluble copolymers containing AMPS and poly(ethylene oxide) [25322-68-3] grafts can be applied in the oilfield industry as thickening agents functioning at elevated temperatures (172,173).

A new water-soluble sulfonated phenolic resin as a potential superplasticizer was prepared from formaldehyde, phenol, and sodium bisulfite ($NaHSO_3$) through a four-step reaction procedure. It was found that this resin could reduce the water content and improve the workability and compressive strength of concrete. The best results were obtained for concrete containing 2 wt% resin, which are comparable with commercial superplasticizers (128,174–176).

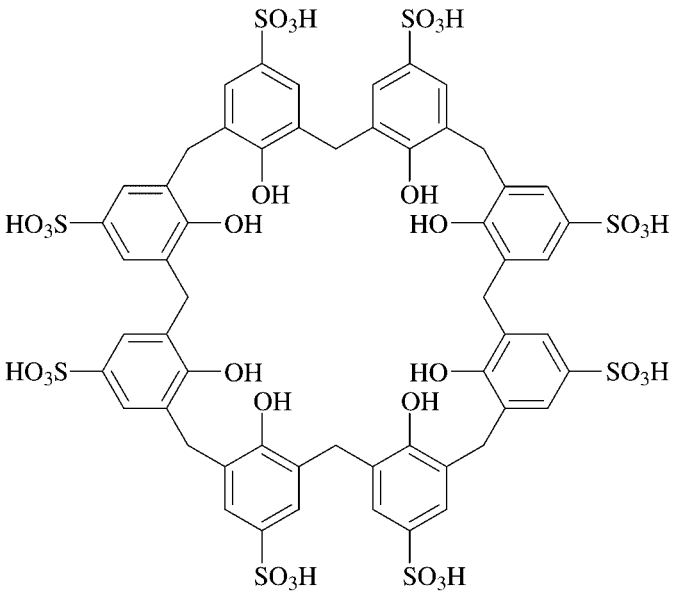
Wholly aromatic ionic polyesters such as poly(sulfo-*p*-phenylene terephthalate), poly(sulfo-*p*-phenylene bromoterephthalate), and poly(sulfo-*p*-phenylene nitroterephthalate) containing sulfonate pendent groups have been synthesized, for the first time, by an interfacial condensation procedure from commercially available hydroquinonesulfonic acid potassium salt and terephthaloyl chloride, 2-bromoterephthaloyl chloride or 2-nitroterephthaloyl chloride, respectively (177). It was found that nitro-substituted polyester forms lyotropic liquid crystalline solutions in the wide range of DMSO/water solvent mixtures (15, 30, 50, and 70 vol%), in DMF/water (50 vol%), and in pure water and DMF. Because of their decomposition upon heating at high temperature, these polyesters do not show thermotropic liquid crystal transitions in solid state.

Other lyotropic liquid crystalline polyesters based on poly(sulfo-*p*-phenylene nitroterephthalate) as well as poly(sulfo-*p*-phenylene nitroterephthalamide) have been reported (178).

Biomedical Applications. Considerable effort has been focused on the modification of segmented polyurethanes as biomaterials to improve their blood-contacting behavior, eg, preventing the occurrence of thrombosis and thromboembolization. The incorporation of the functional sulfonate groups representing key structural elements of the anticoagulant bioactive molecule, heparin [9005-49-6] (179), is a less difficult type of modification than the incorporation of the molecule itself. The various segmented polyurethanes containing sulfonate groups in the hard (180–186) and soft segment (187,188) were synthesized and characterized in order to investigate their anticoagulant effects as the consequence of the platelet

adhesion. From this study it appears that incorporation of sulfonate ions into polyurethanes directly affects the blood-contacting response of these materials. However, the effect can be beneficial or deleterious, and it appears to be dependent on the molecular location of the ions and the structure of the polymer.

The effects of the polysulfonic acid derivative 4-*t*-butylcalix[8]arene-*p*-sulfonic acid (GL 522-Y-1, Genelabs, Redwood City, Calif., U.S.) (**60**) on thrombosis *in vivo* and haemostasis *in vitro* have been investigated. On the basis of its unique antithrombotic properties, GL 522-Y-1 seems to open a new pathway in the field of antithrombotics; so far it was primarily developed as an antiviral drug (189).



(**60**)

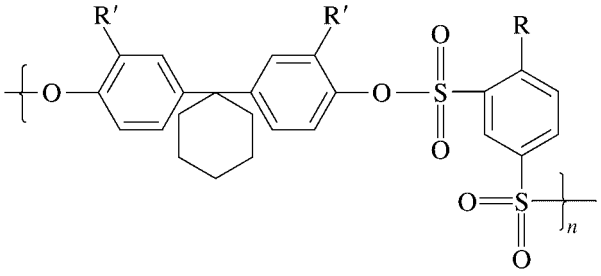
In the past few years, several compounds have been described that exhibit marked activity against respiratory syncytial virus (RSV) *in vitro* (190). Among the most potent and selective RSV inhibitors are various polyanionic substances, including polysulfonates (eg, poly(vinylsulfonate), poly(styrenesulfonate), poly(acrylamidomethylpropanesulfonate), sulfonated derivatized dextrans, etc) and polysulfates (virus adsorption). They have significantly higher selectivity index than Ribavirin (1-β-D-ribofuranosyl-1,2,4-triazole-3-carboxamide, Tribavirin; Virazole; Viramid; RTCA; Vilona; Virazid, etc) [36791-04-5], which is the only antiviral agent approved for the treatment of RSV infections.

Polysulfonates. Aromatic polysulfonates having the sulfonate ester group in the main chain possess good physical, chemical, electrical, and thermal properties. Their characteristics are high softening and melting temperatures, thermal stability of up to 300°C, resistance to alkali, acids, and oils, and solubility in halogenated aliphatic hydrocarbons. They can be processed by molding, extruding, injection molding, as well as casting from solution. These polymeric materials can be useful as coatings and adhesives (3,191). High molecular weight

polysulfonates are easily obtained by step-growth polymerization reaction of aromatic diphenols with aromatic disulfonyl dichlorides using phase-transfer catalyst (3,191–193). Wholly aliphatic polysulfonates are prepared by ROP of cyclic sulfonates (3).

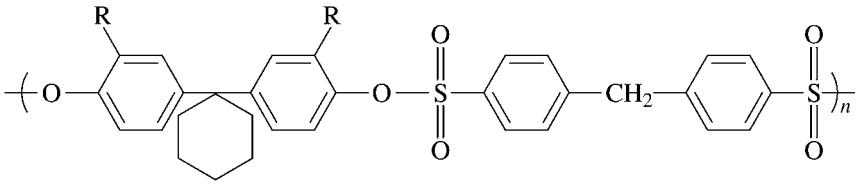
Catalyzed (benzyltriethylammonium chloride [56-37-1]) interfacial condensation of aromatic-(poly)cycloaliphatic diphenols and their bromoderivatives, including 4,4′-(1-cyclohexylidene)diphenol, 4,4′-(2-norbolidene)diphenol, 4,4′-(1-cyclohexylidene)-di-(2,6-dibromophenol), and 4,4′-(2-norbolidene)-di-(2,6-dibromophenol) with various aromatic dichlorides was studied in detail (191,194). Depending on the reaction conditions and the monomer used, the low crystalline polymers (with η_{red} ~0.2–1.7 dL/g and softening range of 160–310°C) soluble in halogenated aliphatic and aromatic hydrocarbons and DMF were obtained. They exhibited hydrolytical stability to both mineral acids and bases at room temperature and good thermal stabilities of up to 290–360°C.

More recently, similar polysulfonates, eg, (**61**) and (**62**), prepared by conventional interfacial condensation using water-chloroform as an interface, alkali as an acid acceptor, and cetyltrimethylammonium bromide [57-09-0] as an emulsifier have thoroughly been studied (195–206). In general, the polymers possess good solubility in common solvents, good acid and alkali resistance, thermal stabilities of up to 355°C, and tensile strength of up to ~20 MPa (199).



$R = H, R' = H; R = CH_3, R' = H; R = R' = CH_3$

(**61**)



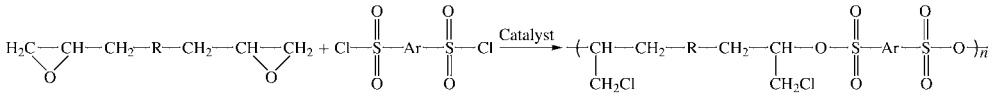
$R = H, CH_3$

(**62**)

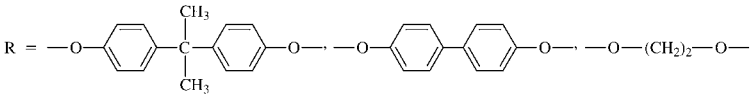
The tests of biological activities showed that polysulfonates exhibit good or moderate antibacterial activities against *Escherichia coli*, *Staphylococcus citrus*, *Aspergillus niger* and *Aspergillus awamori*, *Becillus megaterium*, etc (195–198,

200). Acoustic (ultrasonic) studies of these polysulfonates have been performed in chlorinated and aprotic solvents in order to understand their structures as well as polymer–solvent and polymer–polymer interactions (202–206).

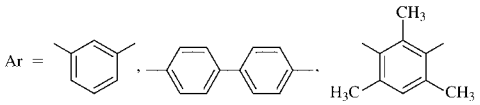
Polysulfonates with reactive pendent chloromethyl groups (**63**) can be synthesized by solution polymerization of bisepoxides (**64**) with disulfonyl chlorides (**65**) (207).



(64) (65) (63)



(64a) (64b) (64c)



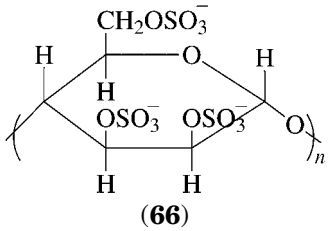
(65a) (65b) (65c)

The examination of the effect of various reaction conditions on the polymerization of (**64a**) with (**65a**) showed that the polymer with the highest molecular weight (M_n = 16,000) and good yield (95%) was obtained in 2,4-dichlorotoluene [95-73-8], using tetra-*n*-butylphosphonium bromide [3115-68-2] as a catalyst at 130°C for 24 h. From among other polymers prepared under optimum conditions, those based on (**64c**) showed low molecular weights.

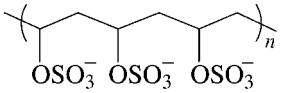
Polysulfates

Polysulfates are widely studied because of their potential biomedical applications. Heparin, a naturally occurring sulfated polysaccharide, has antithrombogenic properties and is used in cardiovascular surgery (179,208). Polysulfates in general, and sulfated polysaccharides in particular, are active against a wide variety of enveloped viruses (209,210).

Various polysulfates, eg, heparin, dextran sulfate, mannan sulfate (**66**), galactan sulfate, xylomannan sulfate, polyacetal polysulfate, poly(vinylalkoholsulfate) (**67**), and poly(acrylic acid vinylalcoholsulfate), are the most potent and selective RSV inhibitors (190).



(**66**)



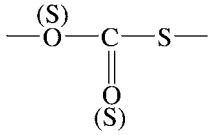
(**67**)

Heparin and other sulfated polysaccharides extracted from sea algae were found to be potent and selective inhibitors of the HIV-1 replication in cell culture as well as various enveloped viruses, including viruses that emerge as opportunistic pathogens (eg, herpes simplex virus and cytomegalovirus) in immunosuppressed [eg, AIDS (the acquired immune deficiency syndrome)] patients. As potential anti-HIV drug candidates, sulfated polysaccharides offer a number of promising features (209,210).

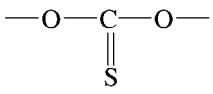
A major commercial sulfated polysaccharide is carrageenan [9000-07-1], used in ice cream and other food products (see GUMS).

Polythiocarbonates

In general, polythiocarbonates are polymers containing the structural units (**68**) with one to three sulfur atoms and unit (**69**). They are mainly prepared by ROP of the corresponding cyclic monomers, eg, ethylenethiocarbonate (1,3-dioxolan-2-thione) [20628-59-5] or 1,3-oxathiolane-2-thione, or by condensation reactions involving dithiols and adequate difunctional coupling compounds. The synthesis and properties of many kinds of polythiocarbonates were reviewed in 1992 (3).

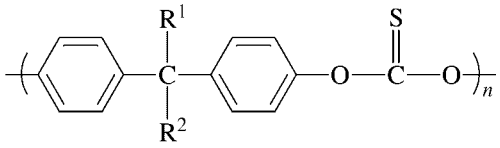


(**68**)



(**69**)

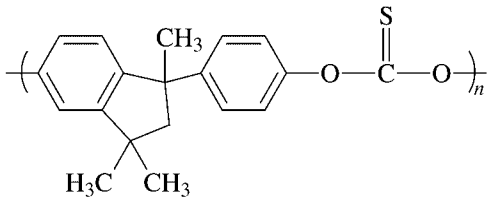
Poly(monothiocarbonate)s (**70**) (211–214), (**71**) (215), (**72**) (216), and (**73**) (217) containing oxythiocarbonyloxy linkages (**69**) are prepared from thiophosgene (carbon chlorosulfide, thiocarbonylchloride, carbonothioic dichloride) [463-71-8] and corresponding diphenols under phase-transfer conditions with quaternary ammonium and phosphonium salts as catalysts. The influence of the structure of the bisphenols and the nature of the catalyst on yields and η_{inh} have been studied. Under optimum conditions, polymers in ~90–97% yields and η_{inh} up to 1.8 (**70**), 0.09 (**71**), 0.24–0.63 (**72**), and 0.24–0.36 dL/g (**73**) (0.5 g/dL, $CHCl_3$, at 25°C) were obtained.



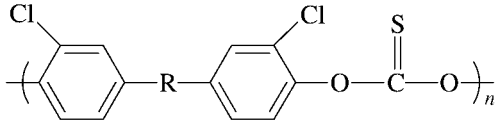
$R^1 = H, CH_3, C_2H_5$

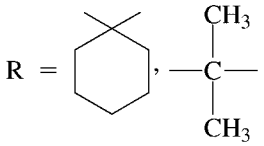
$R^2 = H, CH_3, C_2H_5, CH_3(CH_2)_2, (CH_3)_2CH, —CH_2CH(CH_3)_2, C_6H_5$

(**70**)

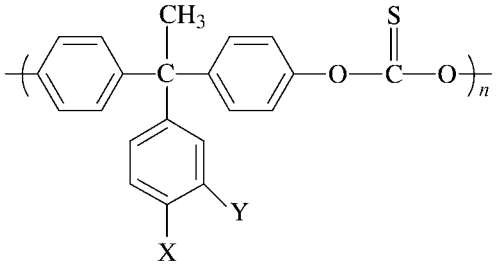


(**71**)





(**72**)



X = Cl, Y = H; X = H, Y = Cl; X = Y = Cl

(**73**)

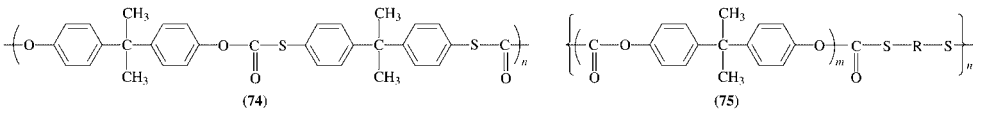
The synthesis of related poly(ester-thiocarbonate)s containing the ester group in the main chain (218,219) and in the side chain (220) as well as poly(amide-thiocarbonate)s containing the amide group in both the main (221) and side (222) chains under phase-transfer conditions have also been reported. It has been shown that this technique can be effective to prepare polythiocarbonates derived from diphenols containing Si or Ge, bis(4-hydroxyphenyl)-dimethyl-germane, bis(4-hydroxyphenyl)-diphenyl-germane, bis(4-hydroxyphenyl)-dimethyl-silane, and bis(4-hydroxyphenyl)-diphenyl-silane (223).

Thermogravimetric (TG) investigations exhibited that the thermal stability of this family of polythiocarbonates is in general lower than that of corresponding polycarbonates (224–226). The solution properties (dipole moment and partial specific volume) and chain flexibility of different polymers have been studied (227–233).

Polymers containing thiocarbonylthio —S—CO—S— and oxycarbonylthio —O—CO—S— linkages (**68**) were prepared by catalyzed interfacial condensation of aliphatic dithiols, including 1,3-propanedithiol, 1,4-butanedithiol, and 1,6-hexanedithiol (3,234), or aromatic dithiols such as 1,3-dimercaptobenzen (1,3-benzenedithiol) [626-04-0] and 2,2-bis(4-mercaptophenyl)propane (BMP) (3, 235,236) with phosgene or bisphenol A bis(chloroformate) [2024-88-6] (235), respectively.

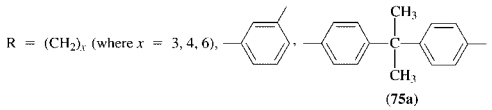
Polymers synthesized from phosgene and dithiols with BTEAC (benzyltriethylammonium chloride) [56-37-1] as phase-transfer catalyst have low $[\eta]$ (up to 0.16 dL/g) and relatively low yields (~70%). This result can be attributed to the low reactivity of the thiochloroformate groups —SCOCl, which derive from the reaction of the thiol groups with phosgene. Using the catalyst DMAP (4-dimethylaminopyridine) [1122-58-3] instead of BTEAC significantly increased molecular weight of the resulting polymers (236).

Polymers with bisphenol A moieties were obtained in high yields and with high molecular weights, particularly those obtained by using DMAP as catalyst and based on BMP (M_w = 180,000) (**74**) (236). They exhibited T_g = 58–90 and 154°C for aliphatic and aromatic dithiol BMP, respectively. Coupled block copolymers (**75**) containing both carbonate and thiocarbonate groups synthesized under the same conditions of phase-transfer catalysis in high yields (up to 95%) from the above-mentioned dithiols and bisphenol A polycarbonate oligomers were high molecular weight polymers, particularly those based on BMP (**75a**) (M_w = 170,000). Their T_gs were 124–158°C (234,236).



(74)

(75)

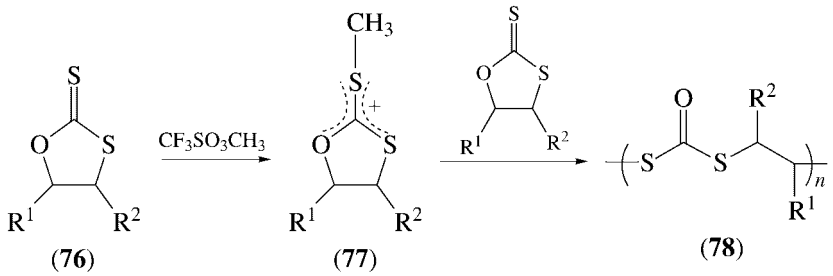


(75a)

On the basis of the TG analysis, all these polythiocarbonates are, in general, less thermally stable polymers compared with the corresponding polycarbonates

(236,237). The high refractive indices observed make these polymers, particularly poly(dithiocarbonate)s, potentially interesting for optical applications (ie, lenses and optical fibers) (238).

It has been reported that five-membered cyclic dithiocarbonates (**76**) undergo selective ROP with initiators such as $CF_3SO_3CH_3$ [333-27-7] and $CF_3SO_3C_2H_5$ [425-75-2] through the cyclic carbenium cation (**77**) leading to the formation of the corresponding poly(dithiocarbonate)s (**78**) with thiocarbonylthio linkages (239–241).

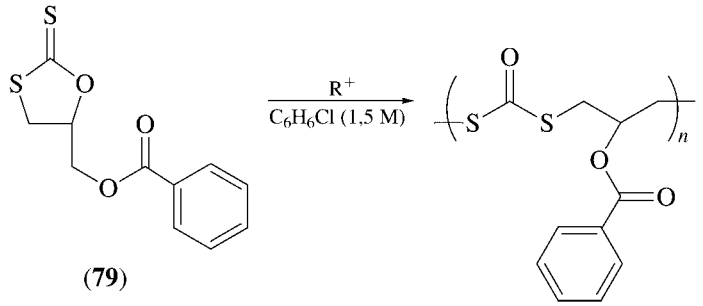


(**76**) (**77**) (**78**)

R^1 = CH_3, CH_2CH_3, CH_2Cl, $CH_2OC_6H_5$

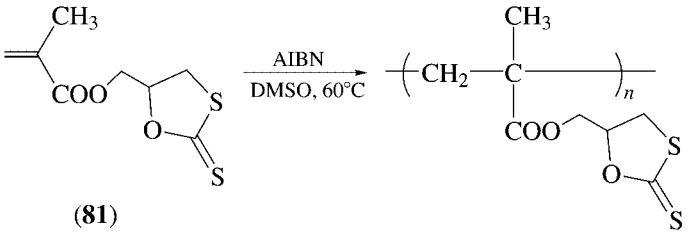
R^2 = H

The first example of the controlled living cationic ROP of the five-membered cyclic dithiocarbonate (**79**) based on the neighboring group participation initiated with CF_3SO_3H or $CF_3SO_3CH_3$ has also been demonstrated (234). This new concept of living polymerization may be applied to the design of well-defined novel functional polymers.



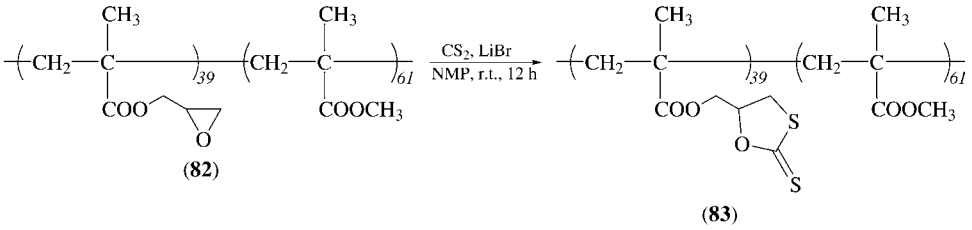
(**79**)

The high molecular weight polymethacrylate (**80**) (M_n above 100,000) bearing five-membered cyclic dithiocarbonate groups in the side chain can easily be prepared by AIBN-catalyzed homopolymerization of 5-(methacryloyloxy)methyl-1,3-oxathiolane-2-thione (**81**) (DMSO, 60°C); however the formation of some cross-linked products takes place (243). To avoid the cross-linking reaction, the comonomer methyl methacrylate and more diluted conditions were used.



(**81**) (**80**)

A novel monomer (**81**) was synthesized by the reaction of glycidyl methacrylate [106-91-2] and CS_2 in the presence of LiBr in THF solution at room temperature in 93% yield. The attempts to synthesize polymer (**80**) by polymer reaction of poly(glycidyl methacrylate) with CS_2 were unsuccessful because of the formation of the cross-linking gels. When the copolymer (**82**) (glycidyl methacrylate/methyl methacrylate = 39/61, M_n = 80,000 with polydispersity 1.71) was allowed to react with CS_2 in THF solution and LiBr as catalyst, the yellowish polymer (**83**) (M_n = 114,000 with polydispersity = 5.08) was obtained without cross-linking, soluble in many common organic solvents (243); polymer (**80**) was soluble only in DMSO and DMF. These materials are potentially the most versatile reactive polymers which react with amines to afford a polymethacrylate bearing a thiol group in the side chain as well as potential optical materials, heavy metal-affinity polymers, and photo-reactive polymers.



(**82**) (**83**)

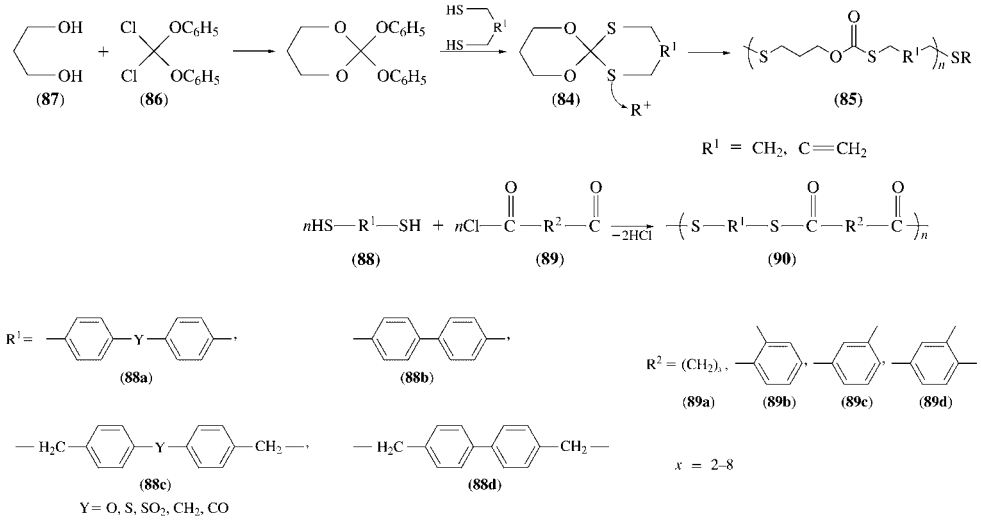
The first cationic polymerization of the sulfur-containing spiro ortocarbonates (**84**) under various initiators both in chlorobenzene [108-90-7] or dichloroethane solution and in the absence of a solvent has been studied (244). The low molecular weight poly(thioether-monothiocarbonate)s (**85**) (M_n = 700–2500 with polydispersity = 3.2–7.8) were obtained. The polymerization is believed to occur via a controlled tandem double ring-opening mechanism. Monomers (**84**) were synthesized via a two-step procedure from 1,1-dichloro-1-diphenoxymethane (**86**) and 1,3-propanediol [504-63-2] (**87**). The relative hydrolytic stability of these monomers is greater than their oxygen analogues.

Polythioesters

Contrary to their oxygen counterparts polyesters, polythioesters were not commercialized and their research interest has decreased in the last few years. This

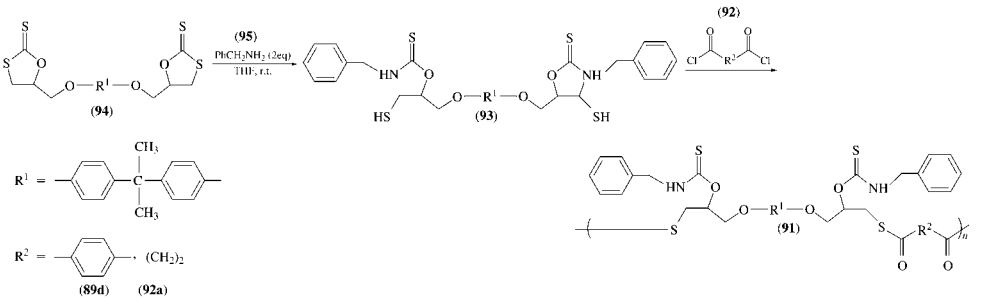
can partly be due to a more difficult and expensive approach to starting materials, eg, acid dichlorides and dithiols as well as the instability of polymers against alkalis. The synthesis and properties of the polythioesters are reviewed in References 2, 3, and 245.

Interfacial condensation of the two series of dithiols (**88**), aromatic (**88a**) and (**88b**) (246–251) or aliphatic–aromatic (**88c**) and (**88d**) (252–256) with various diacid dichlorides (**89**), aliphatic (**89a**) and isomeric phthaloyl chlorides (**89b**), (**89c**), and (**89d**) has been studied in detail as a continuation of an earlier-undertaken systematic study of linear polythioesters. High molecular weight polymers (**90**) (η_{red} up to ~2.5 dL/g) in good yields (up to ~99%) were obtained under optimum conditions. They were characterized in terms of structures, chemical and thermal resistance, and some mechanical and electrical properties. In general, polymers exhibit a good thermal resistance of up to 450°C. They are resistant to diluted alkali or mineral acids, but decompose when treated with concentrated reagents. Polymers derived from isophthaloyl chloride [99-63-8] (**89c**) and terephthaloyl chloride [100-20-9] (**89d**) are insoluble in common organic solvents, high melting (above 200°C, some even 300°C) and thermal-stable (up to 300–450°C) materials showing good mechanical properties.

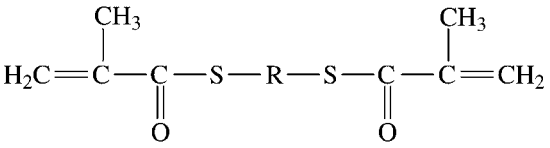


The low temperature solution polymerization of MMB (**88d**) with selected aliphatic and aromatic diacid dichlorides under optimum conditions produced significantly lower molecular weight polymers or copolymers (η_{red} ~0.2–0.6 dL/g) in up to 96% yield (257).

Polythioesters (**91**) have been prepared by condensation of terephthaloyl (**89d**) or succinyl chloride [543-20-4] (**92**) with a dithiol (**93**) generated *in situ* from bifunctional five-membered cyclic dithiocarbonate (**94**) and benzylamine [100-46-9] (**95**) in THF solution at room temperature (26). The polymers with M_n = 5100–8200 or 2900 were obtained in the presence of triethylamine [121-44-8] or pyridine [110-86-1], respectively in ~90% yields. Their T_gs were 51–76°C.



It has been reported that the novel bifunctional thiomethacrylates (**96**), which have refractive indices of 1.6 and larger, are very important and useful monomers for high index cross-linkers for optical plastics (258).



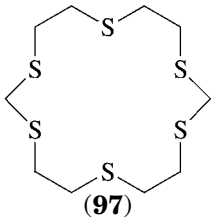
$$R = CH_2CH_2, —(CH_2CH_2Y)_nCH_2\,CH_2— \quad \text{where } Y = O, S; n = 1, 2, 3$$

Transparent resins with light weight, a high refractive index, large Abbe number, and excellent impact strength can be produced by using these good copolymerizable (eg, with styrene and acrylonitrile) cross-linking thiomethacrylates. Monomers can be prepared in high yields (84–93%) by phase-transfer catalyzed (tri-*n*-octylmethylammonium chloride [5137-55-3]) interfacial condensation of dithiols and methacryloyl chloride in the chloroform/(H_2O, KOH) system plus inhibitor.

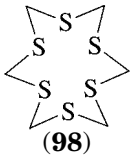
Polythioacetals

Earlier studies on polythioacetals, mainly aliphatics, revealed limited possibilities to utilize these materials as potential industrial thermoplastics because of their instability in the molten state as well as an offensive odor of some monomers and degradation products (2,259–261). Aromatic polythioacetals (262–264) and thiacrown ethers bearing thioacetal linkages (36,37,262,265–267) have recently received increasing attention.

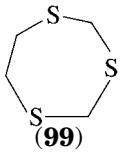
Various macrocycles, eg, **97**, **98**, **99**, **100**, and **101**, have been extensively studied in terms of the synthesis, properties, and complexation behavior.



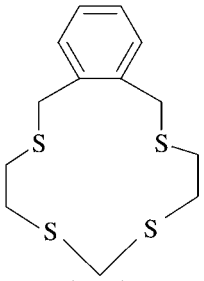
(**97**)



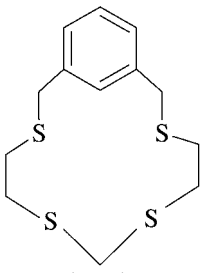
(**98**)



(**99**)



(**100**)



(**101**)

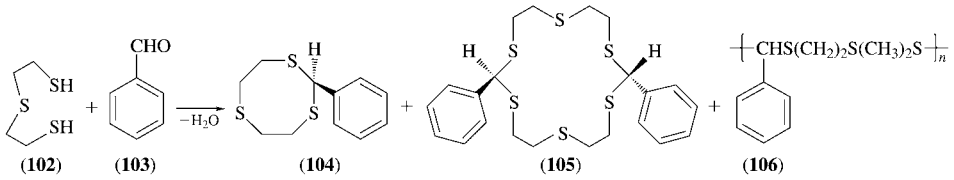
They can be prepared in roughly 50–75% yields by two different synthetic routes described in equations (3) and (4), for example, the synthesis of 1,3,6,9,11,14-hexathiacyclohexadecane (16S6) (**97**) (267). It should be noted, however, that for many cycles the only practical method of synthesis is method (4). Thus, the cycles (**100**) and (**101**) were prepared by the reaction cyclization of the *in situ* generated bis cesium salt of 3,5-dithiaheptane-1,7-dithiol with

α,α'-dibromo-*o*-xylene [91-13-4] or α,α'-dibromo-*m*-xylene [626-15-3] in 52 and 63% yield, respectively (266).

$$2NaSCH_2CH_2SCH_2CH_2SNa + 2BrCH_2Br \xrightarrow{\text{ethanol}} (\mathbf{97}) + 4NaBr \quad (3)$$

$$HSCH_2CH_2SCH_2SCH_2CH_2SH + ClCH_2CH_2SCH_2SCH_2CH_2Cl \xrightarrow{Cs_2CO_3/DMF} (\mathbf{97}) \quad (4)$$

It has been found that acid-catalyzed condensation of 2,2′-thiodiethanethiol [3570-55-6] (**102**) with carbonyl compounds (or equivalents thereof) carried out in solution can, under chosen conditions, lead to good yields to thiocrown ethers containing thioacetal units (262). A detailed examination of a prototype reaction of (**102**) with benzaldehyde [100-52-7] (**103**) showed that depending on the reaction conditions, a different distribution of the products [monomer (**104**), dimer (**105**), and polymer (**106**) of $M_n = 11{,}250$ with polydispersity = 1.9] is achieved. Products (**104**), (**105**), and (**106**) with maximum yields 87, 62, and 99% respectively, can be obtained.



(**102**) (**103**) (**104**) (**105**) (**106**)

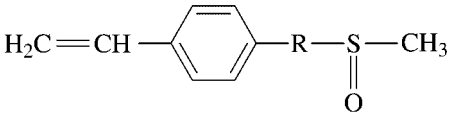
High molecular weight linear polymers with M_n ~9000–27,600 in up to 70% yield (after repeated reprecipitation from $CHCl_3$/ethyl ether) can be obtained by acid-catalyzed (*p*-toluenesulfonic acid [104-15-4]) solution (dichloromethane) polymerization of various aromatic aldehydes such as benzaldehyde and its *p*-substituted (CH_3O–, CH_2=$CHCH_2O$–, Cl-) derivatives with aliphatic dithiols such as 1,6-hexanedithiol [1191-43-1], 3,6-dioxaoctane-1,8-dithiol [14970-87-7], tetramethylene bis(3-mercaptopropionate), or aromatic dithiol bis(4-mercaptophenyl) ether (263). Nevertheless, the formation of some cyclic side products took place, which have been isolated and identified. Polyrotaxane structures were also found under special conditions (eg, at a shorter reaction period). The linear polymers exhibited $T_g = -31$ to $-13°C$ (from aliphatic dithiols) and 82°C (from aromatic dithiol) and T_d above 200°C. In contrast, the bulk polymerization catalyzed by HPF_6 [16940-81-1] generated *in situ* has produced well-defined thioacetal structure polymers in high yield up to 90% but with low molecular weights of $M_n = 2300$–5700.

Polysulfoxides

Polysulfoxides are polymers containing high reactivity sulfoxide groups towards the free-radical or ionic center and so they are used as functional polymers. Polysulfoxides are a catalyst for reactions conducted under phase-transfer conditions

(268–270). Poly(sulfinyl acrylate)s exhibit some biological activity (271,272). Membranes bearing sulfoxide moieties are permeable, particularly to polar compounds (273,274). Aliphatic polysulfoxides having sulfoxide groups in the main chain can be used as novel polymeric oxidizing reagents, compatibilizers, and polymer solvents. These novel aprotic polar polymers can also be expected to become novel reactive polymers (18,275). The chiral polysulfoxides can be utilized as stationary phases of chiral hplc column and as polymer reagents (276).

Polysulfoxides with sulfoxide group in the side chain are obtained by polymerization of monomers containing a sulfoxide group linked to the unsaturated carbon–carbon bond via aromatic or aliphatic units (**107**) (268,269,271,272,277). They are also synthesized by a Michael-type addition of dithiols to diolefins with a double bond activated by an adjacent sulfoxide group (274,278). Both methods were successfully applied to preparation of copolymers (274,277).

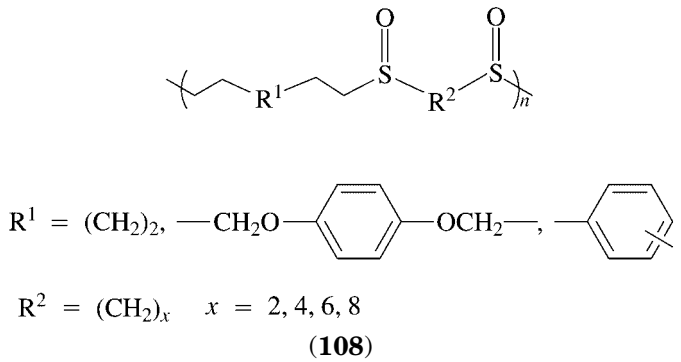


(**107**)

Polysulfoxides containing the sulfoxide group in the main chain are mainly synthesized by controlled oxidation of polysulfides using various oxidizing agents, including nitric acid, *tert*-butyl hydroperoxide [75-91-2], hydrogen peroxide [7722-84-1], peracids, or bromine, but it is difficult to avoid some sulfone formation (3). Poly(phenylene sulfoxide) of M_n ~8000 (279) and poly(*p*-phenoxyphenyl sulfoxide) of $M_n = 4800$ (280) containing no sulfone groups were obtained using nitric acid or hydrogen peroxide, respectively, as oxidizing agent. More recently, the selective and quantitative oxidation of atactic poly(propylene sulfide) to its corresponding sulfoxide was conducted by using *m*-chloroperbenzoic acid, hydrogen peroxide, or bromine under stoichiometric conditions either in homogeneous solution or in two-phase process (281).

Earlier reports dealing with oxidation of aliphatic polysulfides to polysulfoxides (19,281) contain no information about the properties of the resulting polysulfoxides.

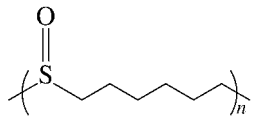
The synthesis, properties, and application of aliphatic polysulfoxides with a methylene chain between sulfur atoms of various length (**108**) have been reported (18).



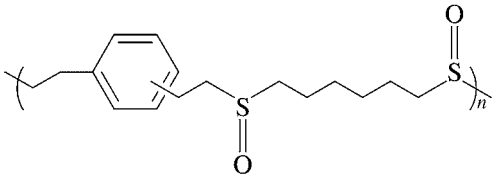
(**108**)

Polymers of M_n = 1600–6500 with polydispersity ~1.2–2.8 were prepared by addition of diolefins with dithiols and the following two-phase oxidation of the resulting polydisulfides. The effective oxidation (up to 92% of sulfoxide units) of polysulfides was conducted by using aqueous hydrogen peroxide in chloroform with or without heating. The formation of polysulfoxides was strongly supported by spectroscopic analysis. Poly(hexamethylene sulfoxide) obtained in this way was subject to Swern oxidation of primary or secondary alcohols, in which 1-octanol [111-87-5] and 6-undecanol [23708-56-7] were oxidized to give 1-octanal [124-13-0] and 6-undecanone [927-49-1], respectively, in quantitative yields (18).

The miscibility of aliphatic polysulfoxides (**109**) and (**110**) (T_g: 125°C, 7°C) with other commodity polymers was examined by comparing T_gs of the mixture of these polymers with T_gs of the original polymers by dsc. It was found that these polysulfoxides had good miscibility with poly(2-methyl-2-oxazoline) and/or poly(*N*-vinylpyrrolidinone) (275).

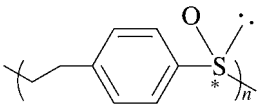


(**109**)

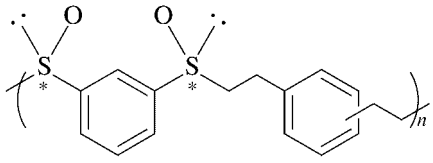


(**110**)

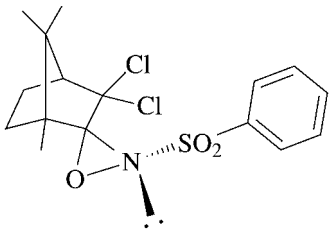
The novel highly optically active polysulfoxides (**111**) and (**112**) (276) with chiral sulfonyl groups in the main chain were prepared by asymmetric oxidation of corresponding polysulfides by using chiral *N*-sulfonyloxaziridine. The polysulfoxide with the enantiomeric excess (ee) of up to 91% was obtained in good chemoselectivity when the reaction was carried out with one equivalent of (−)-*N*-sulfonyloxaziridine (**113**) in chloroform at room temperature followed by reflux.



(**111**)



(**112**)

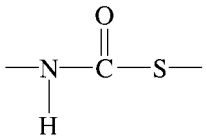


(**113**)

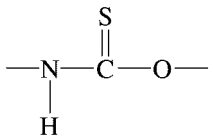
This asymmetric oxidation is the first example of introduction of chirality in good enantioselectivity into the main chain of a polymer by the polymer reaction, that is, the first example of the control of "tacticity" by polymer reaction. An earlier paper (282) described the synthesis of the liquid crystalline polymers having sulfoxide groups with low enantiomeric excess (25% ee). Another synthetic route to optical active polysulfoxides is the polymerization of optically active vinyl sulfoxides (283,284).

Polythiourethanes

Polythiourethanes (polythiocarbamates), the analogues of polyurethanes in which the ethereal or carbonyl oxygen atom of the urethane group has been replaced by sulfur [unit (**114**) and (**115**), respectively] are a relatively little-known class of polymers.



(**114**)

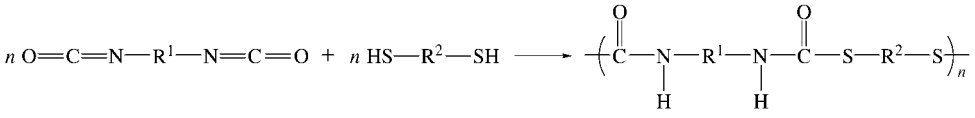


(**115**)

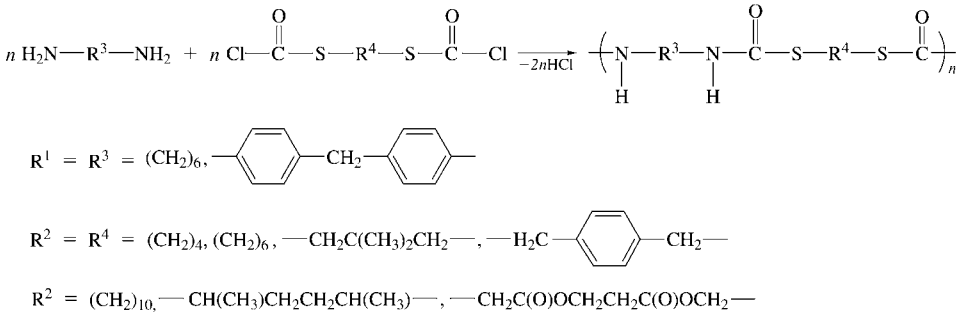
Polymers containing units (**114**) can be prepared by step-growth polymerization of diisocyanates with dithiols or bischlorothioformates with diamines. Early reports on the synthesis of these polymers concerned the melt polymerization of decamethylene diisocyanate [4538-39-0] and 1,10-decanedithiol [1191-67-9] (285,286).

Later, both the methods have been studied and compared, the addition reaction of various diisocyanates and dithiols carried out in chlorobenzene/*o*-dichlorobenzene solution with tri-*n*-propylamine [102-69-2] and DABCO (1,4-diazabicyklo[2.2.2.]octane, triethylene diamine, 2,2′-diazabicyclo[2.2.2]octane, TED, BACO) [280-57-9] as catalyst (eq. 5) and interfacial condensation of

various diamines and bischlorothioformates in the $CHCl_3/H_2O,Na_2CO_3$ system (eq. 6) (287).



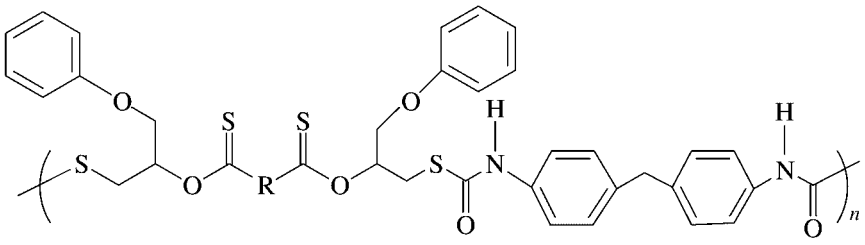
(5)

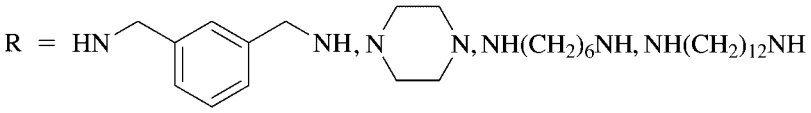


(6)

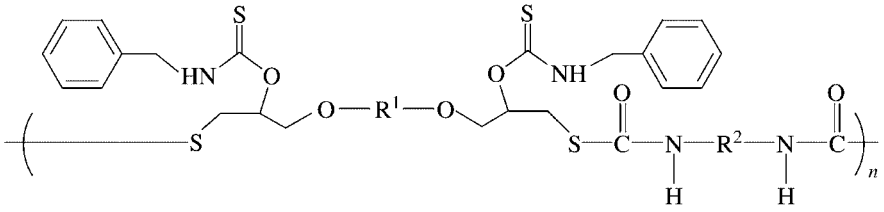
In general, the diisocyanate method was found to produce a higher yield (47–87% vs 31–73%) of the lower molecular weight polymers (η_{inh} 0.14–0.33 vs 0.30–1.20 dL/g) than that by the bischlorothioformate method. Polythiourethanes were found to be highly insoluble, odorless white powders which tend to decompose in light, in hot solvents, and in aqueous base. They melt somewhat higher than their oxygen analogues, but are less thermally stable. Some polymers form the pliable films from DMF solution.

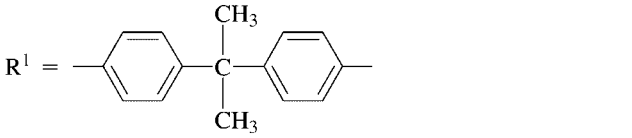
Polythiourethanes (**116**) and (**117**) have been prepared by polymerization of the corresponding diisocyanates, HDI (hexamethylene diisocyanate, 1,6-diisocyanatohexane, 1,6-hexamethylene diisocyanate, hexamethylene-1,6-diisocyanate, HMDI, etc) [822-06-0], MDI (methylene diphenyl diisocyanate, 4,4′-diphenylmethane diisocyanate, diphenylmethane-4,4′-diisocyanate, methylene bis(*p*-phenylene isocyanate), etc] [101-68-8], or 2,6-TDI (toluene-2,6-diisocyanate, 2,6-tolylene diisocyanate, 2,6-toluene diisocyanate, etc) [91-08-7] with dithiols which were formed *in situ* from monofunctional (25) or bifunctional (26) five-membered cyclic dithiocarbonates and various diamines or benzylamine [100-46-9], respectively. The reactions were carried out in THF or THF/DMAC solution with triethylamine [121-44-8] as catalyst at room temperature. The polymers in yield of 74–100% with $M_n = 6000–17{,}200$ were obtained; their T_gs were 45–89°C. Contrary to common polythiourethanes showing low solubility even in highly polar organic solvent such as DMF and DMSO, these polymers are soluble in common organic solvents, including acetone and THF.

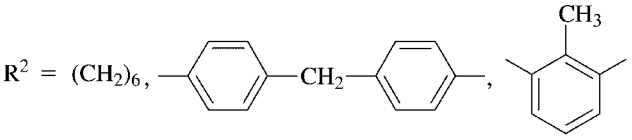




(**116**)



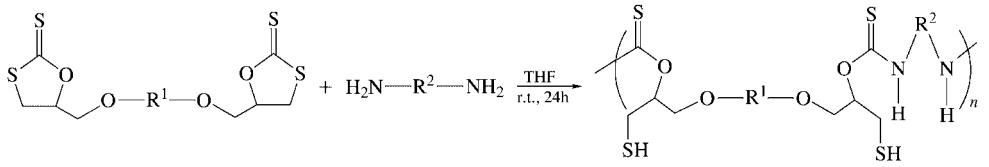




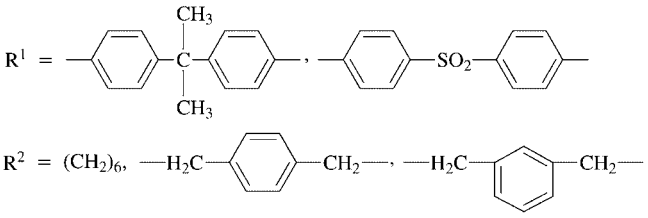
(**117**)

The SH- and NCO-terminated linear thiourethane telechelics containing units (**114**) (M_n = 520–610) were synthesized by DABCO-catalyzed addition reaction of 3,6-dioxaoctane-1,8-dithiol [14970-87-7] with various diisocyanates, including HDI, the mixture of 2,4,4-trimethylhexamethylene diisocyanate [15646-96-5] and 2,2,4-trimethylhexamethylene diisocyanate [6938-22-0], and isophorone diisocyanate [4098-71-9]. It has been shown that NCO-terminated prepolymers can be transformed into telechelics with olefinic end groups by treating with allyl alcohol [107-18-6], 2-hydroxyethyl methacrylate, or diallylamine [124-02-7] (288).

Polythiourethanes (**118**) containing units (**115**) bearing thiol groups were prepared in yield of up to 96% by the addition reaction of bifunctional five-membered cyclic dithiocarbonates (**119**) with diamines (**120**) carried out at room temperature in THF solution (93).



(**119**) (**120**) (**118**)



Their characteristics (after protection of the thiols group by acetylation) are M_n = 5700–12,000 with polydispersity = 1.38–1.65, T_{d10} = 216–248°C, T_g = 45–73°C, and the ability to form transparent films. Thus, polythiourethanes may be used as reactive polymers bearing the thiol groups which are sensitive to radical sources and applied to optical materials.

Polyesters Containing Sulfur Linkages

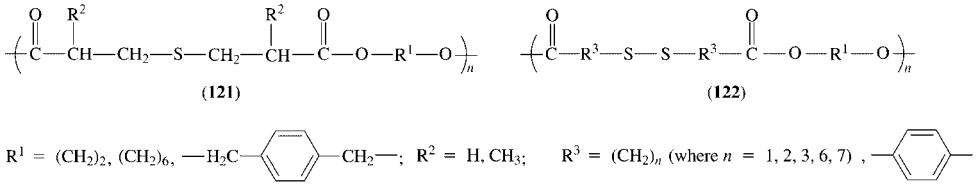
Among the thiopolyesters, polymers of linear structure containing S atoms in the main chain occupy the main position. They may find wide application as non-volatile plasticizers for such polymers as poly(vinyl chloride) and rubber modifiers. They are also useful for modifying or plasticizing elemental sulfur, which may be reacted with them by heating a mixture of the sulfur and polyester to produce such useful products as caulking compounds and compositions for striping or marking highways and other surfaces (289–294). Hydroxyl-terminated aliphatic–aromatic thiopolyesters are used as poliol components in the synthesis of high elasticity polyurethane elastomers (293,295,296). Some thiopolyesters with S atom in the side chain are used as intermediates in the synthesis of the polymers containing free thiol groups that might be of considerable usefulness as reducing agents in the thiol-disulfide system (297).

Linear thiopolyesters containing sulfur in the main chain were synthesized by step-growth polymerization of monothio- and dithiocarboxylic acids or their esters with diols and thiodiols mainly by using melt methods.

The earliest reports on thiopolyesters concern the syntheses of the low molecular weight polymers from the diethyl ester of thiodivaleric acid and some polymethylene diols (298), thiodiacetic acid [123-93-3] and 2,2′-thiodiethanol

[111-48-8] (299), and dimethyl ester of the 4,4′-thiodibenzoic acid or alkylenedithiodibenzoic acids and some polymethylene diols (300). The highly resistant high molecular weight polymers (M_n ~20,000) from 3,6-dithiaoctanedioic or 3,5-dithiaheptanedioic acid and fluorine-containing diols have also been described (301). All these reactions were carried out in melt at temperatures in the range of 160–250°C, at the first stage at atmospheric pressure and next under reduced pressure (130–400 Pa).

A few years later, various mainly aliphatic monothiopolyesters (**121**) and dithiopolyesters (**122**) (289,290) with M_n up to 10,000 were obtained by melt polymerization of the various monothio- and dithiocarboxylic acids, including 3,3′-thiodipropionic acid [111-17-1], thiodiisobutyric acid, 2,2′-dithiodiacetic acid [505-73-7], 3,3′-dithiodipropionic acid [1119-62-6], 4,4′-dithiodibutyric acid [2906-60-7], 7,7′-dithiodiheptanoic acid, 8,8′-dithiodioctanoic acid, and 4,4′-dithiodibenzoic acid with diols, including 1,2-ethanediol [107-21-1], 1,6-hexanediol [629-11-8], and 1,4-benzenedimethanol [589-29-7]. The process was typically carried out in the presence of nitrogen at temperatures 170–190°C for monothio products and 150–180°C for dithio products in two stages. First the diacid was heated with small excess of diol at atmospheric pressure. In the next stage, the low molecular weight polyester obtained earlier was submitted to transesterification by heating under reduced pressure (26–70 Pa) in the presence of a catalyst (PbO) and inhibitor of cross-linking 4-*tert*-butylcatechol [PTBC, 4-*tert*-butylpyrocatechol, TBC, 4-(1,1-dimethylethyl)-1,2-benzenediol, tertiary-butylcatechol)] [98-29-3].



(**121**) (**122**)

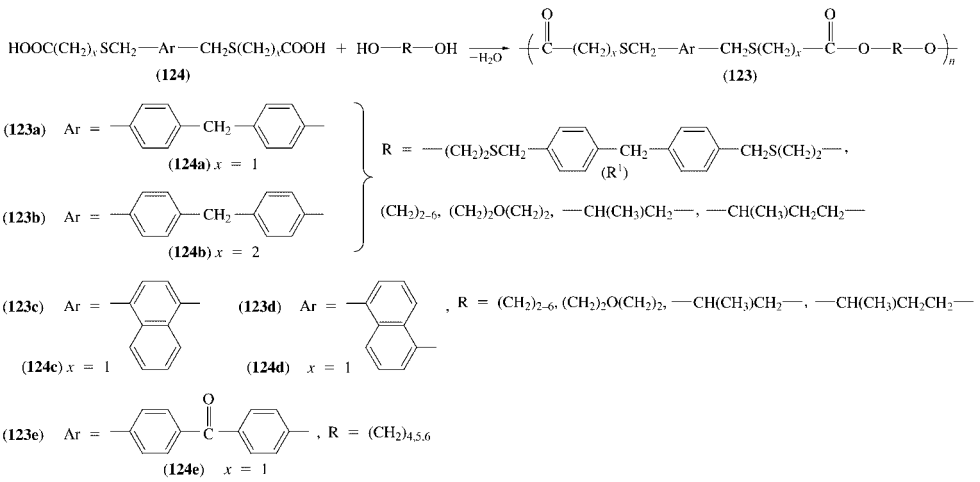
R^1 = $(CH_2)_2$, $(CH_2)_6$, —H_2C—C$_6$H$_4$—CH_2—; R^2 = H, CH_3; R^3 = $(CH_2)_n$ (where n = 1, 2, 3, 6, 7), —C$_6$H$_4$—

Some of these novel thiopolyesters were used for modifying or plasticizing elemental sulfur. In this order, thiopolyesters were heated with elemental sulfur in amounts of 10–90 wt% at a temperature range of 150–250°C, until a clear melt was obtained. The resulting polyester–sulfur compositions (PSC) showed tensile strength from 0.5 to 10 MPa and elongation at break from 17 to 240%. Their tensile strength was improved by adding such fillers as glass wool and poly(ethylene terephthalate) fiber or by using cross-linked thiopolyesters. The best results in terms of color and flexibility for the wide range of 10–90% sulfur used were achieved by using 3,3′-thiodipropionic acid.

In the last decade, extensive and systematic studies were undertaken of the synthesis structure, properties, and application of linear thiopolyesters (**123**) prepared by melt polymerization from various new aliphatic–aromatic thiodicarboxylic acids and aliphatic diols as well as aliphatic–aromatic bis[4-(2′-hydroxyethylthiomethyl)phenyl]methane (EM) (291–296,302,303).

Thiodiacids (**124**), including diphenylmethane-4,4′-bis(methylthioacetic acid) (**124a**), diphenylmethane-4,4′-bis(methylthiopropionic acid) (**124b**),

naphthalene-1,4-bis(methylthioacetic acid) (**124c**), naphthalene-1,5-bis(methylthioacetic acid) (**124d**), and benzophenone-4,4′-bis(methylthioacetic acid) (**124e**) (T_m = 167, 149, 156, 189, 116°C, respectively) were prepared from suitable dimercapto compounds by condensation with monochloroacetic acid [79-11-8] or 3-chloropropionic acid [107-94-8] in 10–20% aqueous solution of NaOH.

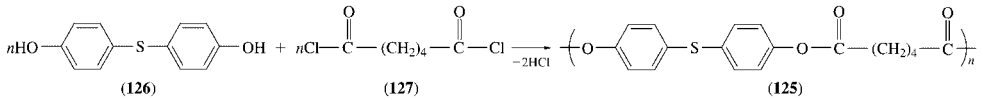


The kinetics of these esterification reactions was studied at 150, 160, and 170°C. Reaction rate constants and activation parameters from carboxyl group loss were determined using classical methods. The kinetic studies revealed that the rate of the reaction with (**124a**) was more than two times that with (**124b**) (293,303,304). From the two naphthalene-derived acids, (**124c**) showed a greater reactivity than (**124d**) (295). Thiopolyesters (M_n up to 10,000) are thick oils, waxy solids, or solids; (**123b**) and (**123d**) showed a large tendency to crystallize at room temperature. The relatively low T_gs (∼−30 to −10°C) were shown by (**123a**) and (**123b**) derived from aliphatic diols.

New PSC (291–294) with increased tensile strength in the form of thermoplastic rubber-like materials with sulfur cross-linked structure were obtained by heating thiopolyester (**123a**) or (**123b**) derived from 1,2-ethanediol [R = $(CH_2)_2$], 2,2′-oxydiethanol [111-46-6] [R = $(CH_2)_2O(CH_2)_2$], or EM (R = R^1) with 20–80% elemental sulfur at the temperature of about 220°C for 15–25 min. Depending on the nature of the thiopolyester and the amount of sulfur used, products with various degrees of hardness and elasticity characterized by tensile strength and elongation at break in the range of 0.4–21 MPa and 2–340%, respectively, were obtained. A cross-linking effect increasing the tensile strength of the PSC was achieved by introduction of diphenylmethane units with active methylene groups in the polymer chain. The formation of sulfur bridges of thiopolyesters involving these methylene groups was confirmed by solid-state ^{13}C nmr spectroscopy using cross-polarization magic-angle spinning (CP/MAS) and total sideband suppression (TOSS) techniques.

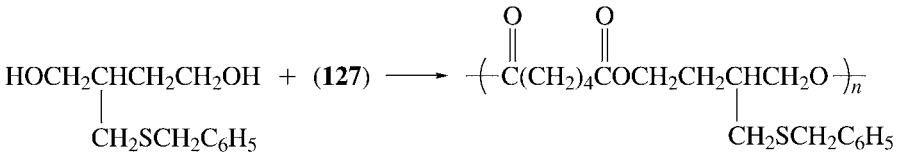
Some hydroxyl-terminated thiopolyesters (**123**) were used for preparing thiopoly(ester-urethane)s (293,295,296) (see next section). The novel thiopolyesters (**123e**) (M_n of 2000–2600), because of their structures incorporating benzophenone units, may also be considered as new diol components of uv-autopolymerizable polyurethane-(meth)acrylate oligomers.

Thiopolyester (**125**) from 4,4′-thiodiphenol [bis(4-hydroxyphenyl) sulfide, 4-hydroxyphenyl sulfide] [2664-63-3] (**126**), and adipoyl chloride [111-50-2] (**127**) was synthesized by both solution and interfacial condensation, as well as thiocopolyesters from (**126**), (**127**), and bisphenol-A (BPA) by interfacial condensation (305). Thiopolyester (**125**) under optimum interfacial polymerization conditions (tetrachloroethane as organic phase, tetra-*n*-butylammonium bromide [1643-19-2] as a phase transfer catalyst) showed a considerably higher specific viscosity value (1.64) than the polymer obtained in solution (0.18); it was a rather brittle material. Comonomer BPA was introduced into the polymer (**125**) chain in order to improve the toughness. Copolymer with the highest yield (93%) and the highest M_n (20,500) was obtained at the molar ratio (**126**)/BPA = 60/40. Its tensile strength was ~44 MPa. Polymers (**126**) with a content above 60 mol% showed a high barrier for oxygen permeability, especially the homopolymer (1.30×10^{-15} $cm^2 \cdot s^{-1} \cdot Pa^{-1}$).



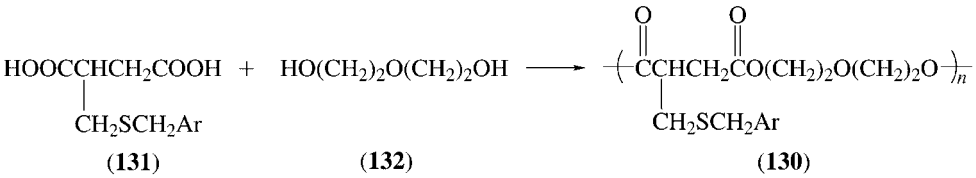
(**126**) (**127**) (**125**)

Few thiopolyesters with S atom in the side chain have been reported. The low-molecular-weight polymer (**128**) (297) with side benzylthiomethyl chains was successfully prepared by the condensation of 2-benzylthiomethyl-1,4-butanediol (**129**) with adypoil chloride (**127**) in refluxing benzene. Attempts to obtain a polymer with free thiol groups through debenzylation did not bring satisfactory results because of the simultaneous degradation of the polymer.

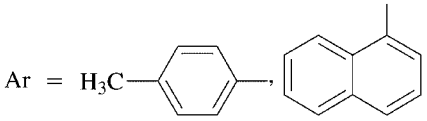


(**129**) (**128**)

Related polymers (**130**), also relatively low molecular weights (M_n up to 4400) and tolylmethylthiomethyl or naphthylmethylthiomethyl side chains, were obtained by uncatalyzed and catalyzed melt condensation of diacids (**131**), *p*-tolylmethylthiomethylsuccinic acid (**131a**), or 1-naphthylmethylthiomethylsuccinic acid (**131b**) with 2,2′-oxydiethanol (**132**) (306). Polymers showed thermal stabilities of up to ~220 or 280°C, respectively.

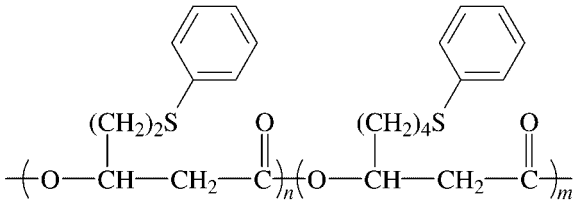


(131) (132) (130)



(131a) (131b)

Poly(3-hydroxyalkanoate) (**133**) (307) with a thiophenoxy group at the end of the side chain was obtained from *Pseudomonas putida* 27N01, a newly isolated bacterial strain, using 11-thiophenoxyundecanoic acid as the sole carbon source.



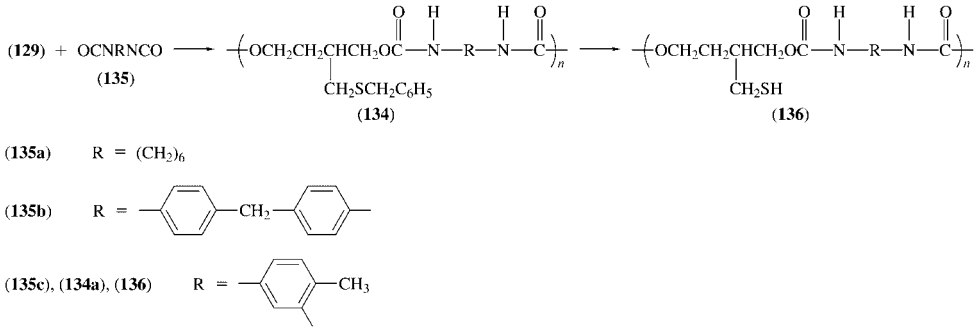
(**133**)

The polymer (M_n = 81,000 with polydispersity = 1.8, T_g = 4°C) had a white cream color and was elastomeric. This is the first report of poly(3-hydroxyalkanoates) containing a sulfur atom in the structure produced from bacteria. It may be supposed that (**133**) will usher in a new era of bacterial polymers.

Polyurethanes Containing Sulfur Linkages

Earlier studies (297) on the synthesis of thiopolyurethanes were attempted with the aim of obtaining polymers containing free sulfhydryl groups, which are compounds of considerable interest for a variety of reasons, eg, as reducing agents in the thiol-disulfide systems.

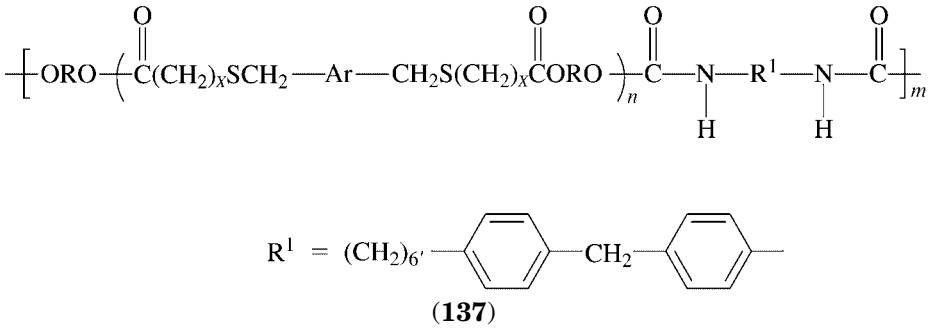
Thiopolyurethanes (**134**) with sulfur in side chain ([η] ~0.1–0.3 dL/g) prepared by solution (benzene) polymerization of the diol (**129**) with diisocyanates (**135**), HDI (**135a**), MDI (**135b**), or 2,4-TDI (2,4-toluene diisocyanate, 2,4-tolylene diisocyanate, 2,4-diisocyanatotoluene, etc) [584-84-9] (**135c**), were used as the polymeric intermediates for the synthesis of these polymers. The benzyl groups were successfully removed from polymer (**134a**) with sodium in a mixed solvent of liquid ammonium and *n*-propylamine [107-10-8], giving polymer (**136**).



The analogous thiopolyurethanes with the side tolylmethylthiomethyl or naphthylmethylthiomethyl chains (306) were obtained from 2-(*p*-tolylmethylthiomethyl)-1,4-butanediol (TB) or 2-(1-naphthylmethylthiomethyl)-1,4-butanediol and HDI or Izocyn T-80 [TDI-80, the mixture of 2,4-TDI (80 wt%) and 2,6-TDI (20 wt%)] by solution (benzene) polymerization in the presence of di-*n*-butyltin dilaurate (DBTDL) [77-58-7] as catalyst. The polymer based on TB and HDI (η_{red} = 1.17 dL/g) was a high elasticity thermoplastic elastomer with tensile strength of 2.2 MPa and elongation at break of 780%.

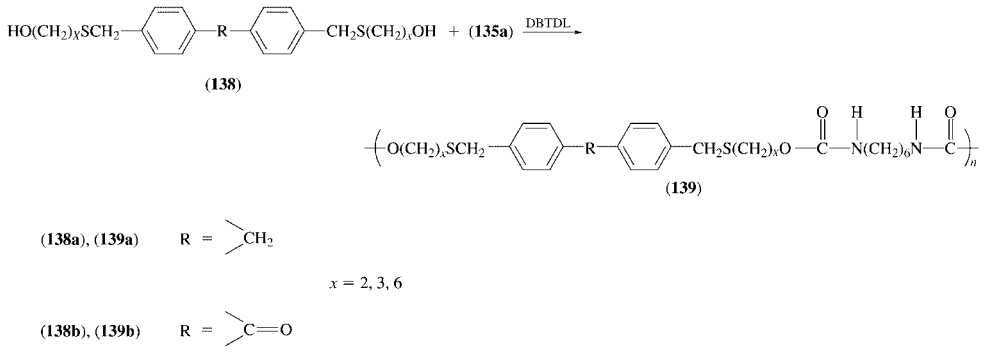
The growing interest in polyurethane elastomers because of their unique properties, as well as in sulfur-containing polymers, prompted scientists in the last decade to undertake studies on the synthesis and properties of a novel class of thiopolyurethanes containing thioether linkages in the main chain, derived from various new diol components as aliphatic–aromatic simple thiodiols (308–314) and linear thiopolyester diols (293,295,296).

High elasticity thermoplastic thiopoly(ester-urethane)s of general structure (**137**) were prepared from newly obtained hydroxyl-terminated thiopolyesters (**123c**, **123d**, **123e** with R = $(CH_2)_{4,5,6}$ and **123a**, **123b** with R = (R^1); M_n = 1600–2900) and HDI (**135a**) or MDI (**135b**) at the ratio of NCO/OH = 1 or 1.05 by melt polymerization at temperature ~130°C in the presence of DBTDL as catalyst, when a less reactive HDI was used. Their characteristics were η_{red} ~0.4–1.1 dL/g (1,1,2,2-tetrachlorethane [79-34-5], 0.5–1%), T_gs from −1 to 18°C, tensile strength of 0.6–12 MPa, elongation at break of 500–1400%, and good thermal (up to 220–260°C) and chemical resistance. Polymers from (**123d**) showed the highest tensile strength, whereas those from (**123b**) the lowest T_gs. Thiopolyurethanes from (**123a**) and (**123b**) containing diphenylmethane units with active methylene groups are new, potentially peroxide-curable polymers.



(**137**)

The DBTDL-catalyzed step-growth solution and melt polymerization reaction of the low melting thiodiols (**138**) with HDI (**135a**) at NCO/OH ratio = 1.05 produced thermoplastic nonsegmented thiopolyurethanes (**139a**) (309) and (**139b**) (308) showing partially crystalline structure (T_gs below 40°C, T_ms = 47–124°C). Higher molecular weight polymers (η_{red} = 0.63–1.24 dL/g, tetrachloroethane, 0.5–1%) were obtained by solution (DMF) polymerization. They showed tensile strength in the range of 16–50 MPa and thermal stability of up to 230–240°C.



Thiodiols (**138b**) (315) (T_m = 38–76°C), including 4,4′-bis(2-hydroxyethylthiomethyl)benzophenone (x = 2), 4,4′-bis(3-hydroxypropylthiomethyl) benzophenone (x = 3), and 4,4′-bis(6-hydroxyhexylthiomethyl)benzophenone (x = 6) and thiodiols (**138a**) (309) (T_m = 68–78°C), including bis[4-(2-hydroxyethylthiomethyl)phenyl]methane (x = 2), bis[4-(3-hydroxypropylthiomethyl) phenyl]methane (x = 3), and bis[4-(6-hydroxyhexylthiomethyl)phenyl]methane (x = 6) were prepared by condensation reaction of the corresponding dithiols 4,4′-bis(mercaptomethyl)benzophenone or bis[4-(mercaptomethyl)phenyl]methane with 2-chloroethanol [107-07-3], 3-chloro-1-propanol [627-30-5], or 6-chloro-1-hexanol [2009-83-8], respectively, in 10% aqueous solution of sodium hydroxide.

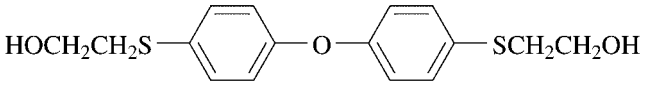
Segmented thiopolyurethanes prepared from thiodiol (**138b**) with x = 6 (308) and all thiodiols (**138a**) (310,311) as chain extenders, HDI (**135a**), and 20–80 mol% poly(tetramethylene oxide) (PTMO) [24979-97-3] of M_n = 1000 as the soft segment by one-step process in the same conditions as for nonsegmented polymers were thermoplastic elastomers (except those based on 20% PTMO) showing partially crystalline structure. The polymers exhibited definite T_gs (−70 to −60), nearly independent of the hard segment content up to 50 wt% (40–80 mol% PTMO), indicating the existence of mainly microphase-separated soft and hard segments. Higher molecular weight polymers (M_n = 12,000–45,000 with polydispersity ∼2–4) were produced by the melt polymerization process. They showed tensile strength of 6–17 MPa and elongation at break of 140–680%. In each of the series, the increased PTMO soft-segment content decreased hardness, modulus of elasticity, and tensile strength, whereas elongation at break increased.

Because their structures incorporate diphenylmethane units with active methylene groups, polymers from (**138a**) are new, potentially peroxide-curable,

HDI-based thipolyurethanes, whereas polymers from (**138b**) containing benzophenone units may find use as interesting modifiers of photosensitive polyurethane resins.

Studies on the synthesis and properties of the linear nonsegmented thiopolyurethanes based on thiodiol containing atom S attached directly to aromatic ring bis[4-(2-hydroxyethylthio)phenyl] ether (**140**) ($T_m = 94°C$) under melt and solution polymerization conditions at the NCO/OH ratio = 1 showed that these polymers are brittle, hard, or rubber-like solids unsoluble and nonfusible up to 300°C from MDI (**135b**) (312), melting at ~245°C from 2,4-TDI (**135c**) (314), and soluble in DMF and DMSO at heating and melting at ~215°C from HDI (**135a**) (313). Their T_gs were 43–52°C. All the polymers were thermally stable up to 230–270°C. The introduction of comonomer 1,6-hexanediol significantly decreased T_m and T_g, and increased the solubility of the copolymers.

The synthesis and properties of the thermoplastic segmented thiopolyurethanes derived from thiodiol (**140**), 2,4-TDI (**135c**), and 20–80% PTMO of $M_n = 650$ and 1000 under one-step solution (DMF) and melt polymerization conditions (the ratio of NCO/OH = 1, DBTDL as catalyst) have also been reported (314). The most interesting are high molecular weight polymers (η_{red} = 1.42–2.30 dL/g) obtained by melt polymerization from PTMO of $M_n = 1000$. They are rubber-like products easily soluble in organic solvents and showing high adhesion to many substrates; these polymers may be useful as glues.

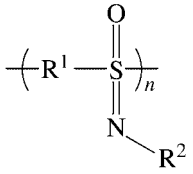


(**140**)

The reactions of some aliphatic thiodiols as 2,2′-thiodiethanol [111-48-8] or 4,4′-thiodibutanol with HDI were investigated many years ago (316).

Polysulfoximines

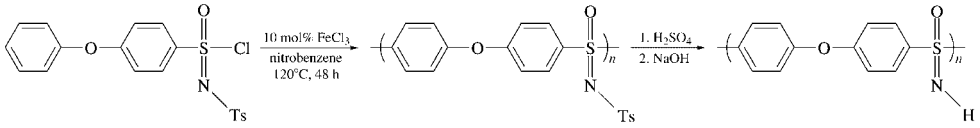
The chemical and physical properties of the polysulfoximines are of particular interest because of their rigid and unsymmetrical structure (**141**) and the polymers can be considered as new, potentially high-performance, engineering plastics. In recent years, the first preliminary studies on the synthesis and properties of this novel class of sulfur-containing polymers have been reported (317–320).



R^2 = H, alkyl, allyl, aryl, acyl, sulfonyl, etc.

(**141**)

The self-condensation of sulfonoimidoyl chlorides such as *N*-tosyl (Ts) derivative of the benzene- and 4-phenoxybenzene-sulfonimidoyl chloride (**142**) utilizing a catalytic ($AlCl_3$ or $FeCl_3$) Friedel–Crafts reaction has been studied as a way to produce these polymers. It has been found that the reaction of the former compound yielded no polymeric product, whereas that of (**142**) produced exclusively methanol-insoluble polymer (**143**) of $M_n = 14{,}500$ with polydispersity = 1.45 in 80% yield (317).



(**142**) (**143**) (**144**)

The treatment of (**143**) with concentrated sulfuric acid followed by neutralization with NaOH at room temperature gave the corresponding polymer (**144**) containing the "free" sulfoximine moiety and with M_n nearly equal to that of (**143**); the T_gs of (**143**) and (**144**) were almost equal, namely 335 and 333°C, respectively. Polymer (**144**) was much more thermally stable than (**143**) and its thermal stability (20 wt% loss temperature ~550°C) is comparable to that of poly(ether-sulfone).

SURFACE PROPERTIES

Introduction

The design of the interface between a polymer and another material has become a key aspect in many important industrial technologies because the associated interfacial properties are often crucial to the success of the application. The properties of polymer interfaces are highly dependent on the nature of the material with which it is in contact. Three types of interfaces must generally be considered: polymer–air, polymer–liquid, and polymer–solid. In reality, the properties at these interfaces do not change suddenly; instead there is a region of property gradients referred to as the "interphase" between the two coexisting phases. The polymer–air interphase is commonly referred to as a surface and is the subject of this review.

In the case of the polymer–air interphase, the usual goal of applications is to control how another material sticks to or spreads over the polymer. Many polymer applications require surfaces that have so-called nonstick properties. Classic examples include Teflon or other fluorocarbon coated fry pans touted to have nonstick properties and waxes that keep an automotive finish looking cleaner and shinier by inhibiting water from spreading dirt over the finish. There are, on the other hand, an equal number of applications where the surface must provide strong adhesion. A polymeric automobile body panel, for example, requires a surface that promotes the spreading and adhesion of various paints and finishes. Furthermore, the resulting coating applied must present a host of surface properties including scratch resistance, smoothness, and gloss, or the automobile will not be marketable.

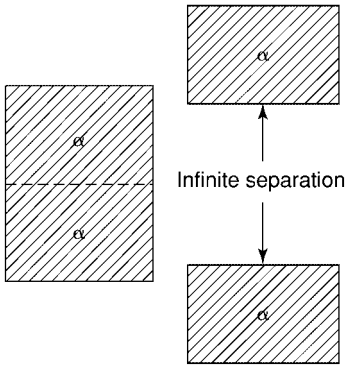

Fig. 1. Creation of two interphases from a bulk material.

Thermodynamics of the Interphase

The single most important property of a polymeric interphase is its interfacial tension. This property describes the energy required to create the interphase and can be readily defined through classical thermodynamics. The *interfacial tension* γ for a polymer–air interface (ie, the surface tension) is generally defined in terms of the work required to reversibly divide and separate a material into two parts, as depicted in Figure 1. The work required to perform the separation is called the work of cohesion, W_c, and provides an operational definition for the surface tension:

$$\gamma \equiv W_c/2 \tag{1}$$

This paradigm is not strictly valid for polymers because one cannot create this division without cutting through or breaking polymer chains. However, it is useful in illustrating the general properties of polymer interfaces. In fact, the reverse process of joining two polymers to annihilate two surfaces does provide a reasonable representation of the origin of polymer interfacial tension. In any case, the creation of a polymer surface of area A therefore requires the addition of surface free energy in the amount γA.

The thermodynamic definition of surface tension follows directly from this construction. In the presence of a surface, the total Gibbs free energy includes the normal bulk free energy terms and this new surface free energy term

$$G = H - TS + \gamma A \tag{2}$$

where G is the Gibbs free energy, S is entropy, T is temperature, and H is enthalpy. The surface tension then has the thermodynamic definition

$$\gamma \equiv \left(\frac{\partial G}{\partial A}\right)_{T,P} \tag{3}$$

With this new definition, classical thermodynamic manipulations can be applied to yield a variety of useful expressions defining properties such as the entropy of interface formation per unit area

$$\Delta S = -\frac{d\gamma}{dT} \tag{4}$$

and the enthalpy of interface formation per unit area

$$\Delta H = \gamma - T\frac{d\gamma}{dT} \tag{5}$$

The molecular origin of interfacial tension γ can also be understood through the paradigm represented by Figure 1. It is well known that molecules have mutually attractive intermolecular forces due to the combined effects of dispersive, dipole, induced dipole, and hydrogen bonding interactions. At short distances, however, Born repulsive forces result from the overlap of molecular orbitals. These two forces balance at the equilibrium separation distance r_0, setting the conditions that control the density at that temperature. The dependence of interaction forces on the separation distance is embodied in potential energy function such as the Lennard–Jones 6–12 potential shown in Figure 2, where the additive effects of short-range repulsion and longer-range attraction are evident.

In general, interaction potentials for each type of interaction lead to net forces that follow an inverse square law, and when taken collectively result in a cohesive energy expression of the form

$$W_c = (A/12\pi)\left(r_0^{-2} - r^{-2}\right) \tag{6}$$

where r is the separation distance and A is the Hamaker constant representing the cumulative strength of all types of interactions. If the separation distance is extended to infinity, and the paradigm of Figure 1 and equation (1) are applied, a relation between the macroscopic interfacial tension and the strength of molecular interactions becomes apparent:

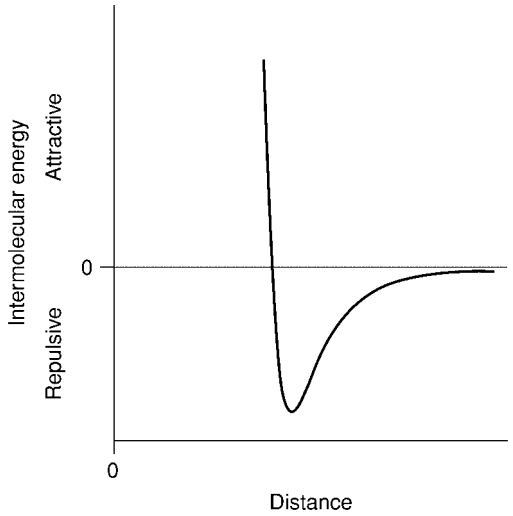

Fig. 2. A typical intermolecular potential energy diagram.

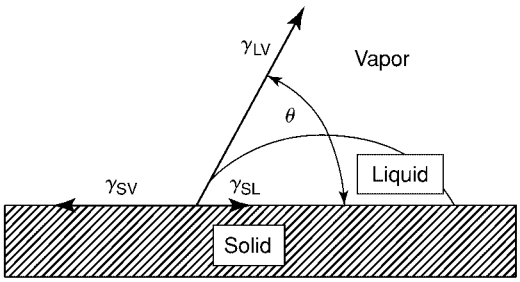

Fig. 3. The definition of the contact angle for a nonwetting liquid in contact with a solid.

$$\gamma = A/24\pi r_0^2 \tag{7}$$

The surface tension of a polymer has an important influence on the degree to which a liquid or molten polymer will wet or spread across it. A liquid in contact with a solid will exhibit a *contact angle* that is defined as the angle between the tangent to the surface of the sessile drop from the air/liquid/solid contact point and a line through the base of the liquid where it contacts the solid, as depicted in Figure 3. The equilibrium contact angle θ results from the balance of three interfacial forces described by the Young's equation (1).

$$\gamma_{SV} = \gamma_{SL} + \gamma_{LV}\cos\theta \tag{8}$$

The term γ_{SV} is the surface tension of the solid material in equilibrium with its vapor, γ_{LV} is the surface tension of the liquid material in equilibrium with its vapor, and γ_{SL} is the interfacial tension between the solid and liquid materials. Complete, spontaneous wetting occurs when $\theta = 0^\circ$, or when the spreading coefficient λ defined below is greater than or equal to zero:

$$\lambda = \gamma_{SV} - \gamma_{SL} - \gamma_{LV} \geq 0 \tag{9}$$

If a heterogeneous surface is treated as consisting of two domains, Cassie's equation can be applied as follows (2):

$$\cos\theta_c = f_1\cos\theta_1 + f_2\cos\theta_2 \tag{10}$$

where θ_c is the observed contact angle, θ_1 and θ_2 are the pure component contact angles of components 1 and 2 respectively, and f_1 is the surface fraction of component 1.

Homopolymer Surface Tension

Surface tension values for high polymers range from about 20 mN/m for highly hydrophobic materials such as poly(dimethyl siloxane) and polyfluorocarbons, to about 45 dynes/cm for polar materials such as some polyesters and polyamides.

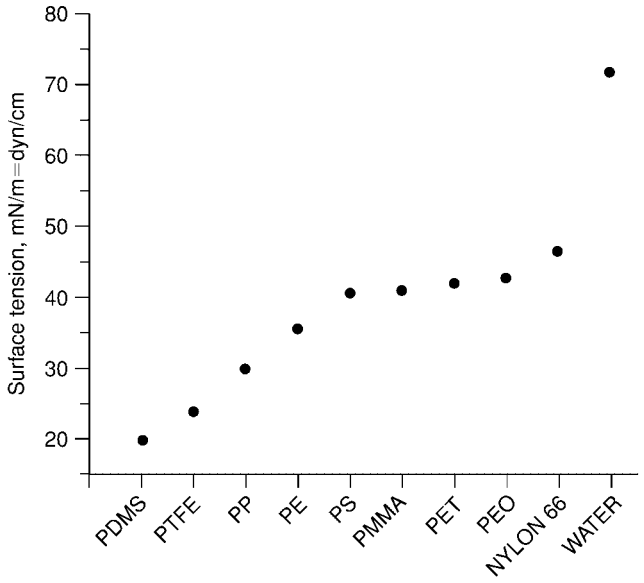

Fig. 4. Surface tension of a variety of polymers compared to that of water.

For comprehensive listings of experimental surface tension values for a wide variety of polymers, the reader is referred to several excellent references 3,4–5. The surface tension of even the most polar polymers generally fall well below that of water (as shown in Figure 4) so that in terms of surface tension, polymers should be considered at best only mildly hydrophilic. Polymers are low surface energy materials in comparison with other classes of materials by virtue of their low mass density and consequently a low interaction density, as is demonstrated in Table 1, which shows typical values for a range of different types of materials.

Table 1. Surface Tensions of Different Types of Materials[a]

Material	Temperature, °C	Surface tension, mN/m (=dyn/cm)
Aluminum (mp = 660°C)	660	873
Gold (mp = 1064°C)	1064	1130
Silicon (mp = 1450°C)	1450	725
Sodium chloride	801	114
Soda-lime glass	900	330
Titanium carbide	600	280
Graphite	720	230
Aluminum oxide	1850	950
Poly(dimethyl siloxane)	20	20.4
Poly(ethylene oxide)	20	42.9
Poly(ethylene terephthalate)	20	44.6

[a]Ref. 3.

Empirical Prediction. To this point, surface tension has been described in terms of an operational definition, a thermodynamic definition, and through its molecular origin. In practice, however, these three approaches do not constitute any pragmatic means for estimating usable values for the surface tension of polymers. The literature pertaining to homopolymer surface tension is thus replete with empirical methods for estimating this important parameter. The basis of these methods, however, is the fundamental behavior presented above. Consideration of the origin of surface forces shows clearly that any empirical expression for polymer surface tension must consider both the spatial density of interactions present and the strength of those interactions.

Group contribution methods for the estimation of polymer surface tension are cast in terms of these two factors. The strength of the interactions is represented by the dispersive solubility parameter δ^{d}, which can be calculated from tabulated values of dispersive molar attraction constants F_i according to (6)

$$\delta^{\mathrm{d};} = \sum_i F_i / v \tag{11}$$

where v is the molar volume of the unit or molecule under consideration. The surface tension for the polymer backbone can then be estimated from an empirical relationship that is reasonably successful for nonpolar polymers (5):

$$\gamma = 0.2575 \delta^2 \rho^{-1/3} \tag{12}$$

The strength of interactions is represented by the solubility parameter δ in $(\mathrm{cal/mL})^{1/2}$ and ρ is the density in g/mL. This formula predicts surface tensions that are within 5–10% of measured values (3), based upon two experimental parameters that are readily available for a large number of polymers. In the case of poly(dimethyl siloxane), the group contribution prediction for the backbone, 20.9 mN/m, compares well with the value 20.4 ± 0.07 mN/m estimated by extrapolation of experimental data to infinite molecular weight (7).

Group contribution methods are also useful because they can be applied to calculate surface tensions for a portion of the polymer molecule, for example a polymer chain end, for which there is no reliable method for direct experimental measurement. For end groups, one of several empirical relationships developed for low molecular weight compounds of various types can be employed, for example (8).

$$\gamma = 0.07147 v^{1/3} (\delta^{\mathrm{d}})^2 \tag{13}$$

Molecular Weight Dependence. Empirical expressions have also been developed to describe the molecular weight dependence of surface tension. Early expressions proposed by Wu (3)

$$\gamma^{1/4} = \gamma_\infty^{1/4} - k_{\mathrm{s}} / M \tag{14}$$

and by LeGrand and Gaines (9)

$$\gamma = \gamma_\infty - k_e/M^{2/3} \tag{15}$$

provide reasonable representations of polymer surface tensions but cannot be readily distinguished from each other by most sets of experimental data. Here, M is the number-average molecular weight, γ_∞ is the surface tension at infinite molecular weight, and k_s and k_e are proportionality constants. Theoretical considerations lead to a general expression for the molecular weight dependence of form

$$\gamma = \gamma_\infty - k/M^x \tag{16}$$

Lattice calculations (10) predict that the power law dependence varies continuously from $x = 2/3$ for low molecular weights to $x = 1$ for high molecular weights. Off-lattice Monte Carlo simulations (11) predict that $x = 1$ in the limit of high molecular weight. These predictions, however, do not take into account situations where the end group is chemically distinct from the polymer backbone. It has been proposed that k could be modified to take into account the difference in surface energies between the polymer backbone and the end group (3). It has been proposed that the value of x varies between 1/2 and 1, depending on the strength of the attractive interaction between the end group and the surface (12). When the attraction is weak, the chains are ideal and the surface concentration of end groups varies as $2/x$. For intermediate attractive forces, all end groups within a thickness equivalent to the radius of gyration are trapped at the surface, leading to $1/x^{1/2}$ dependence. For strong attraction, the chains become stretched and the additional elastic forces give rise to a surface concentration of end groups that is also proportional to $1/x^{1/2}$. Lattice calculations have been used to show that the exponent x for surface-active end groups was also approximately equal to 1/2, as opposed to 1 for the case of no surface segregation (13). Experimental studies of end functional polymers (7) showed that the surface tension was best modeled with an inverse dependence on molecular weight, ie $x = 1$. This was the only model that gave consistent values of γ_∞, extrapolated from high molecular weight data, for all the different end group types. Careful examination of these experimental data shows that the value of x changes over different ranges of molecular weight, from unity for high molecular weights to lower values for intermediate molecular weights, consistent with the results of the simulations.

Theories of Homopolymer Surface Tension. More rigorous expressions for predicting polymer surface tension have been derived from equations of state for polymers. Corresponding states principles have been employed to derive expressions for surface tensions in terms of characteristic equation of state parameters and the associated reduced temperature, pressure, and volume. One proposed expression is of the form (14)

$$\gamma = 0.095 P^{*^{2/3}} T^* / \tilde{V}^{2.1} \tag{17}$$

where P, T, and V are the pressure, temperature, and volume respectively. The asterisks indicate characteristic parameters obtained from an equation of state and

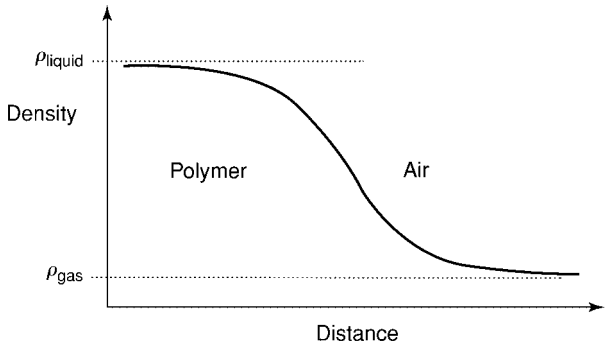

Fig. 5. The density gradient at a polymer–air interface.

the tilde indicates a parameter reduced by the characteristic parameter. A modification (15) of this treatment produces a better representation of experimental data; however the theory has two additional adjustable parameters that cannot be determined a priori.

The most successful theoretical approaches produced to date are based upon the generalized van der Waals square gradient approach (16,17). The approach considers the effects of the density gradient across a polymer–air interface, as depicted in Figure 5. The length scale of the surface gradient is normally of the order of 1 nm. Because the reduced free energy density is dependent on both reduced temperature and reduced density, it will generally vary through the interface in a manner represented in Figure 6. The double tangent construction sets the

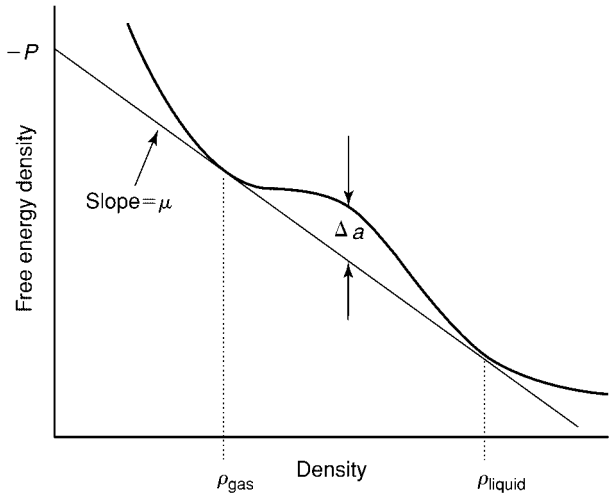

Fig. 6. Schematic representation of the surface excess free energy Δa as a function of density. The double tangent construction defines the densities of the equilibrium coexisting phases, ρ_{gas} and ρ_{liquid}. The slope of the double tangent construction is equal to the chemical potential m. Δa for a particular density is defined as the difference between the free energy density curve and the double tangent line.

chemical potentials equal for the two coexisting phases represented by the minima at reduced densities $\tilde{\rho}_{\text{gas}}$ and $\tilde{\rho}_{\text{gas}}$. The reduced surface tension is related to the excess reduced free energy density $\tilde{\Delta}$, defined in Figure 6, integrated across the surface density gradient

$$\tilde{\gamma} = 2\int_{-\infty}^{\infty} \{\tilde{\kappa}\,\Delta\tilde{\alpha}[\tilde{\rho}(z)]\}^{1/2} \mathrm{d}z \tag{18}$$

A change of variables produces a more convenient integration

$$\tilde{\gamma} = 2\int_{\tilde{\rho}_{\text{gas}}}^{\tilde{\rho}_{\text{liquid}}} (\tilde{\kappa}\,\Delta\tilde{\alpha})^{1/2} \mathrm{d}\tilde{\rho} \tag{19}$$

The square gradient coefficient $\tilde{\kappa}$ is defined by

$$\tilde{\kappa} = \frac{-\mathrm{d}\tilde{\kappa}_1}{\mathrm{d}\tilde{\rho}} + \tilde{\kappa}_2 \tag{20}$$

where the first term on the right-hand side is related to the interaction potential and assumes a value of 0.5 for purely dispersive interactions. The second term arises from nonlocal entropy effects (18) and is equal to $\tilde{T}/24\tilde{\rho}$. Equation (19) furnishes a means of determining the surface tension by a straightforward integration of an equation of state that describes $\Delta\tilde{\alpha}(\tilde{\rho},\tilde{T})$.

The use of compressible lattice fluid theory for $\Delta\tilde{\alpha}(\tilde{\rho},\tilde{T})$ in equation (19) gives a reasonable representation of both the molecular weight and temperature dependence of surface tension for poly(dimethyl siloxane) (19) as shown in Figure 7. The agreement becomes even better if the correction term $\tilde{\kappa}_2$ for surface entropy effects is included, but the value of the first square gradient coefficient must be adjusted slightly to 0.55 from the mean field value of 0.5 to achieve the excellent degree of correspondence illustrated. The use of the Flory, Orwall, and Vrij equation of state in relation 19, with equation of state parameters defined locally to provide better representation of density data, provides predictions within 1% of experiment (20). The molecular weight dependence predicted by this approach also follows equation (16), with a value of $x = 1$ for high molecular weights and a value of 2/3 for intermediate molecular weights.

It has been shown that the lattice fluid model including the nonlocal entropy effects reproduced experimental data over a wide range of temperatures (21). The reduced surface tensions for many different polymers formed a master curve when plotted against reduced temperature according to the relation

$$\tilde{\gamma} = 0.6109 - 0.6725\tilde{T} - 0.1886\tilde{T}^2 \tag{21}$$

as shown in Figure 8. This figure and Figure 7 illustrate that, over small temperature ranges, surface tension varies almost linearly with temperature, consistent with the typical linear dependence of density on temperature observed for polymers. The temperature coefficient of surface tension for polymers (3) generally falls in the range 0.05–0.07 mN/m-dyn/(cm·°C).

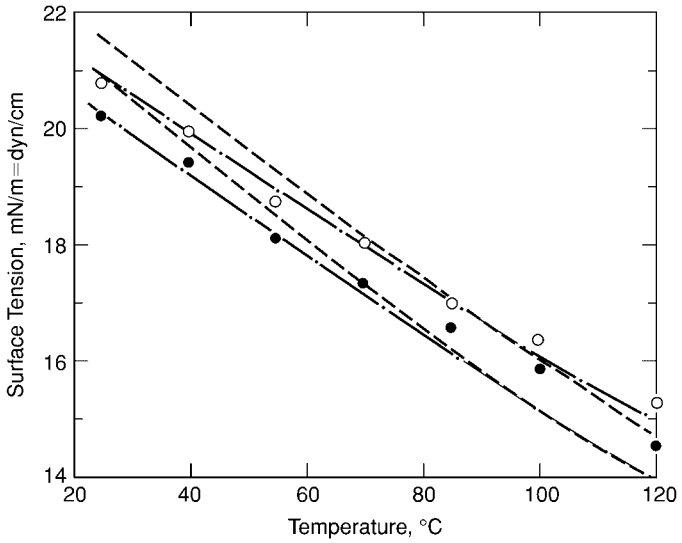

Fig. 7. Comparison of experimental surface tensions for 75,000 molecular weight PDMS (open circles) and 3900 molecular weight PS (filled circles), with the predictions of square gradient theory. The dashed lines are for $\tilde{\kappa} = 0.55$ and the dashed-dotted line is for $-\mathrm{d}\tilde{\kappa}_1/\mathrm{d}\rho = 0.40$ including the effects of nonlocal entropy effects. After Reference 19.

Surface Segregation Effects

Most commercial polymer resins that are currently available are complex multiconstituent systems that have been formulated to simultaneously optimize a number of desirable bulk properties. The formulations might include plasticizers,

antioxidants and uv stabilizers, toughening agents, compatibilizers, lubricants, extenders, fillers and other additives. The presence of minute concentrations of additives in the bulk polymer can often dominate the properties of the surface of the material as a result of surface segregation effects. That is, there is a driving force for components of lower surface energy to preferentially adsorb at the surface, thereby decreasing the surface energy of the overall system. Surface segregation is an almost universal phenomenon that occurs in miscible as well as immiscible multicomponent systems and has been well documented for polymer blends (22,23), copolymers (24), and polymer solutions (25). Perfluorinated hydrocarbons and silicones have some of the lowest surface energies known, and relatively small amounts blended into a homopolymer matrix can reduce the surface tension markedly (26,27).

Surface segregation can occur with or without the formation of a separate phase at the surface. The latter is a process that is sometimes referred to as *blooming*. If a surface phase is present, the situation reverts back to wetting of one material by another. The case to be considered here is when the mixture is a true solution. When a component i of a miscible mixture adsorbs preferentially at the surface, it affects a change in the surface energy equivalent to $\gamma_i \, \mathrm{d}A_i$, where $\mathrm{d}A_i$ is the surface area occupied by type i molecules and γ_i is the surface tension. In order to relocate the molecule in the interphase, it must demix from the bulk phase, requiring an increase of $n_i \, \mathrm{d}\mu_i$ in the bulk chemical potential energy, where n_i is the mole fraction of species i in the bulk phase and $\mathrm{d}\mu_i$ is its chemical potential change. For the overall system to come to equilibrium, there is a net balance of the bulk and surface energy changes for all p components, represented by the classical Gibbs–Duhem relation (at constant T and P), modified for the influence of an interphase

$$\sum_{i=1}^{p} n_i \mathrm{d}\mu_i = \sum_{i=1}^{p} \gamma_i \mathrm{d}A_i \tag{22}$$

Further manipulation of this relationship leads to the classic Gibbs adsorption isotherm:

$$-\mathrm{d}\gamma = \sum_i \Gamma_i \mathrm{d}\mu_i \tag{23}$$

where the surface excess of species i is defined as $\Gamma_i = n_i/A$.

Relations 22 and 23 emphasize that the surface composition of a typical multicomponent polymer may differ drastically from that of the bulk, even for a true solution. Lower surface energy components adsorb preferentially at the surface, thereby lowering the overall surface tension of the mixture. In terms of adhesion, the manifestation of surface segregation is a generally weaker interface, since lowering the surface energy will decrease the thermodynamic work of adhesion.

In practice, the process of surface segregation offers a convenient means to modify polymer surfaces by intentional segregation of a particular additive to the surface. Surface-active additives, which may generally be termed macrosurfactants, usually lower the surface energy and are subsequently used widely to create release surfaces on polymeric substrates.

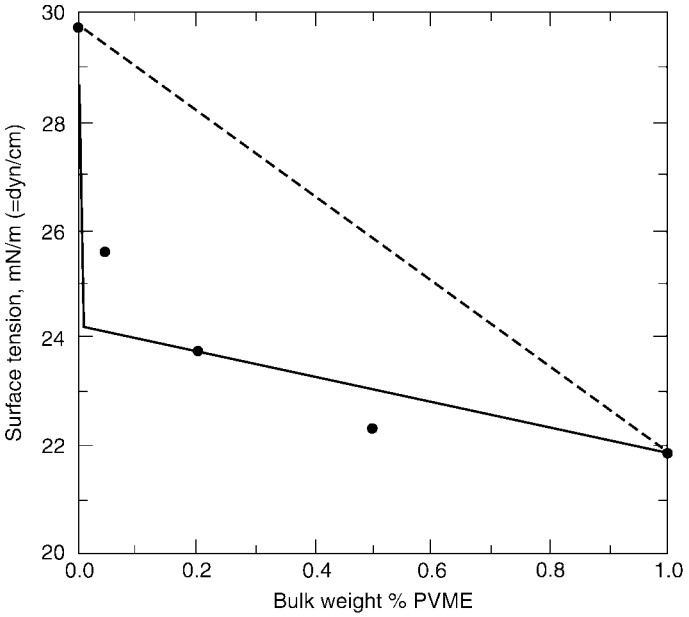

Fig. 9. Surface tension for blends of PVME and PS. From Ref. 23.

Binary Polymer Blends. Miscible polymer blends have proven to be important model systems for the study of surface segregation, and their surface properties have already been studied in some detail. Originally, surface segregation for these systems was evidenced by surface tension measurements (23), wherein the addition of small amounts of the lower surface energy constituent was found to bring about an incommensurably large decrease in the surface tension as shown in Figure 9, similar to the well-known behavior of surfactants. The surface tension can be directly related to the free energy of the system and serves as an important thermodynamic characterization of the surface state.

The characterization of surface structure for miscible blends is a more formidable task, requiring techniques that are sensitive to the composition of the blend within several nanometers of the surface. X-ray photoelectron spectroscopy (xps) provided the first direct and quantitative evaluation of surface composition and surface composition gradients for miscible polymer blends of poly(vinyl methyl ether) (PVME) and polystyrene (PS) (22,23). Since that time, the situation has changed dramatically with the advance of theory and the application of exciting new experimental techniques to this problem. In addition to xps and pendant drop tensiometry (22,23), forward recoil spectroscopy (28), neutron (29) and x-ray reflectivity (30), secondary ion mass spectroscopy (either dynamic or time-of-flight-static) (31,32), and attenuated total reflectance Fourier transform infrared spectroscopy (33–35), have been applied successfully to study surface segregation. The advent of these new tools has enabled a multitechnique experimental approach toward careful examination of the validity of current surface segregation theories (36–39).

The surface composition and near surface gradient structure of miscible binary homopolymer blends are determined by a balance between the surface energy

driving force for segregation and the exchange free energy that is associated with near surface demixing. At equilibrium, this balance represents a minimum in the overall free energy. This situation can be readily treated by mean field theories based upon the generalized van der Waals square gradient framework (40,41). If the interactions are sufficiently short-range in nature, the surface free energy for a planar interface with sharp density gradient is given by (37)

$$\gamma = \gamma_s(\phi_b) + \int_{\phi_b}^{\phi_s} [\gamma_s^{'} + 2(\kappa \Delta F)^{1/2}] d\phi \tag{24}$$

where ϕ_s and ϕ_b are the surface and bulk volume fractions of the blend component with lower surface free energy, and γ_s and F are the contributions to the free energy of a unit area of surface and a unit volume of the uniform bulk mixture, respectively. The term $\Delta F = F(\phi) - F(\phi_b^-) - (\phi - \phi_b^-)(\partial F/\partial \phi)_b$ is the free energy cost to exchange composition in the near surface gradient, which eventually balances with the free energy decrease, $\gamma_s^{'} = \partial \gamma_s / \partial \phi$, associated with the lowering of surface energy upon adsorption of the low surface energy polymer at the surface. In the weak segregation limit, the square gradient coefficient κ, which is related to the nature of the interaction potential, takes the form

$$\kappa = a^2/[36\phi(1-\phi)] \tag{25}$$

The polymers are assumed to be symmetric, with identical statistical segment lengths a.

The effect of the surface is represented by a bare surface energy, which depends only on the boundary surface volume fraction, and is defined by

$$\gamma_s(\phi_s) = -\gamma_1 \phi_s \frac{1}{2} \gamma_2 \phi_s^2 \tag{26}$$

where γ_1 is a chemical potential favoring one component at the surface, and γ_2 represents the loss of interactions between components because the presence of the surface. Bond counting arguments lead to the approximation that $\gamma_2 \cong 4b\chi$, where χ and b are the interaction parameter and unit lattice dimension [ie, equivalent to the statistical segment length a, respectively, from Flory–Huggins theory (42)]. The surface energy difference between the two pure components is $\Delta\gamma = \gamma_1 - \frac{1}{2}\gamma_2$.

The exchange free energy ΔF can be calculated from the Flory–Huggins form for the free energy of mixing (42)

$$F(\phi_A) = [\phi_A/N_A]\ln\phi_A + [(1-\phi_A)/N_B]\ln(1-\phi_A) + \phi_A(1-\phi_A)\chi \tag{27}$$

where N_A and N_B are the number of lattice units per chain for the two blend components A and B, respectively.

The surface composition is obtained by minimizing the surface tension (eq. (24)) with respect to the surface composition, yielding the boundary condition

$$-\gamma_s = \pm 2(\kappa \Delta F)^{1/2}|_{\phi=\phi_s} \tag{28}$$

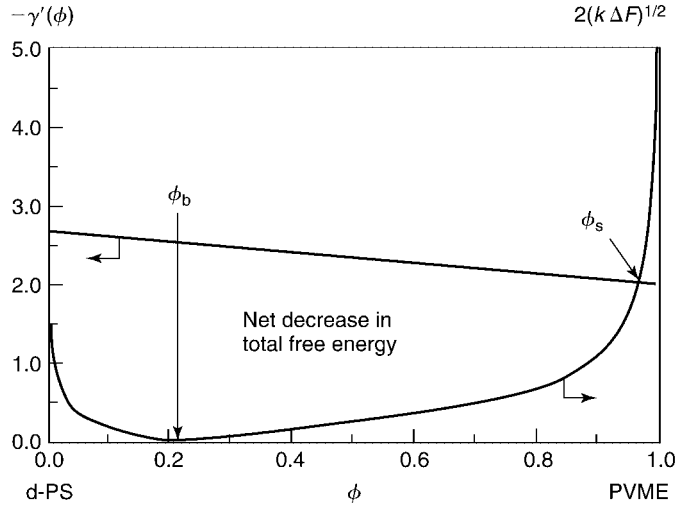

Fig. 10. Phase portrait for a blend of PVME and PS for a bulk concentration of 0.21. The surface concentration is the point at which the surface tension reduction $-\gamma'(\phi)$ equals the increase in free energy $2(k\Delta F)^{1/2}$, associated with demixing to create the surface excess of PVME.

The possibility of two signs results from the taking of a square root, but the correct sign is easily resolved as the only physically realistic solution. Equation (28) is useful in demonstrating the qualitative and quantitative aspects of the surface segregation phenomenon, through the construction of so-called *phase portraits*. A phase portrait is simply a graphical representation of the concentration dependence of the two terms in equation (28). The surface composition can be read directly off of this graph as the concentration at which the two contributions are equal, as depicted in Figure 10.

The surface composition gradient can also be readily calculated from this theory, since $d\phi/dz = 2(\kappa\,\Delta F)^{1/2}$, leading to

$$\phi(z) = -\int_{\phi_b}^{\phi_s} (\kappa/\Delta F)^{1/2} d\phi \tag{29}$$

It is evident from relations 28 and 29 that, using experimentally measured values for the binary interaction parameter, the statistical segment length and the surface energy difference between the blend components, the surface composition, and the surface concentration profile can be calculated. Simulated profiles have a form that closely approximates an exponential decay of the type

$$\phi(z) \cong \phi_b + (\phi_s - \phi_b)\exp(-z/\xi) \tag{30}$$

The surface gradient is conveniently characterized by the surface decay length ξ, which is equivalent to the bulk correlation length as $z \to \infty$. The decay length is relatively small in the strong segregation limit, but can become very large (eg, 10–20 nm) when concentration fluctuations grow near the critical point.

The majority of experimental data has been measured for two blend systems: PS/PVME, and isotopic blends of PS and poly(perdeutero-styrene). The surface compositions for PS/PVME blends were found to scale directly with the surface energy difference between the constituents (23), showing that the latter factor dominates the surface behavior, a result that might be expected for these nearly athermal blends with large surface energy differences (The PS/PVME system has an interaction parameter estimated to be -0.0011 and can be considered as effectively athermal). The square gradient theory with the Flory–Huggins free energy of mixing provides a reasonable representation of the surface tension behavior, but overestimates the surface composition at low PVME contents (43), especially when compared to literature xps data on surface composition gradients (22,23). The latter study (43) proposed that configurational entropy effects due to PVME chains flattening out at the surface and/or effects related to the concentration dependence of the Flory interaction parameter within the interphase may give rise to the discrepancies. The behavior of the isotopic blends is more complicated, since the surface energy difference and the interaction enthalpy for these blends are small. Here, there is a delicate balance between the surface energy reduction and the loss in chemical potential due to surface demixing, and it has been predicted that either component may segregate to the surface, depending on the molecular weight. Again, however, the theory tends to overestimate the observed surface composition. For an excellent general discussion of surface segregation in isotopic blends see Ref. 44. Blends of hydroxylated-PS with PVME have also been studied (33), where it was concluded that the surface segregation behavior was dominated by the bulk thermodynamics as a result of hydrogen bonding between hydroxyl groups on PS and the PVME ether linkage. The lack of significant surface segregation of PVME in these systems was attributed to the enthalpy of mixing (ie, about 3 J/cm^3) that opposes demixing of the PVME.

End-Functional Polymers. End-functional polymers are interesting model systems through which to explore the effects of functional groups on polymer surface and bulk properties (45). The generalized van der Waals approach cannot be easily adapted to treat the surface properties of heterogeneous polymers such as end-functional polymers and co-polymers. Here the incompressible lattice model (45) is the preferred approach. This model was first extended in 1988 (47) to study the surface properties of end-functional polymers and random copolymers, and a similar approach was applied to examine the structure of polymers confined between two plates (11). The theory was extended to consider the surface properties of α,ω-functional poly(dimethyl siloxane) and was found to provide excellent predictions of the molecular weight dependence of surface tension for a variety of different end groups, as demonstrated in Figure 11.

The inputs are the polymer chain length and the surface interaction parameter between end groups and repeat units (or between different monomers in the case of a copolymer)

$$\chi_s = \frac{(\gamma_e - \gamma_r)}{kT} \tag{31}$$

The subscripts e and r refer to the end group and repeat unit respectively. The effects of the bulk interaction parameter between the two components can be

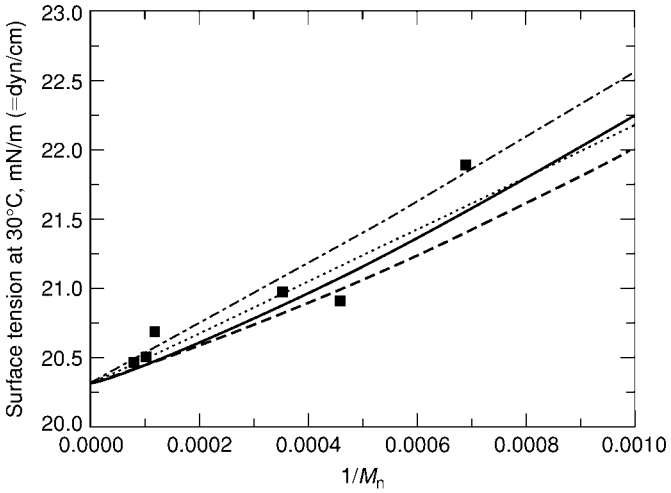

Fig. 11. Surface tension for amine-terminated PDMS (squares) as a function of $1/M_n$. The two thicker lines represent predictions from the lattice model calculations, assuming various group additivity expressions to calculate the surface interaction parameter. The two thinner lines are predictions that neglect end group segregation effects. From Ref. 7.

included at the cost of additional complexity. The lattice theory yields a table of values for the composition $\phi_{1,1}$ of component 1 in the first lattice layer as a function of χ_s, and chain length. The surface tension can readily be calculated from this table according to the relation

$$\gamma = \phi_{1,1}\gamma_1 + (1 - \phi_{1,1})\gamma_2 \tag{32}$$

where the subscripts 1 and 2 refer to the two components, eg, end group and repeat unit. If information on the pure component surface tensions is not available, they may be estimated by the group contribution methods described by equations (11–13).

The lattice model can also be used to obtain the composition depth profile of end groups at the surface. Typical profiles are shown in Figure 12. The profiles exhibit two characteristic length scales. There is an initial zone of segregation that is one lattice layer in thickness (of the order of 1 nm). The zone has an excess of end functional groups when χ_s is negative, and a depletion of end functional groups when χ_s is positive. Following the initial zone of excess or depletion, there is a second region of depletion or excess, respectively, that decays back to the bulk composition over a length scale that is related to the overall chain dimensions. A slight surface excess of end groups is predicted even when χ_s is zero as a result of the entropic preference for locating chain ends at a surface. Angle-dependent x-ray photoelectron spectroscopy measurements have documented the expected depletion zone for end-functional poly(dimethyl siloxane) with positive χ_s (49).

Several studies (50–52), have demonstrated the existence of a surface excess of fluorinated end groups for fluorosilane-terminated PS (PS-F), a system with negative χ_s. Typical behavior for these materials is shown in Table 2, which lists

Table 2. Surface Properties of PS-F

Material	M_n by gpc, g/mol	Functionality	Surface tension,[a] mN/m (=dyn/cm)	Surface fraction of end groups
PTFE			18.2 (22)

surface energies and compositions as a function of molecular weight determined by contact angle analysis (53,54) of solid samples at room temperature. The surface tension can be adjusted anywhere between that of poly(tetrafluoroethylene) (PTFE) and PS by changing the molecular weight (ie, the fraction of fluorinated end groups). The power law coefficient for the scaling of polymer surface tension with molecular weight for this system increased with molecular weight. Experimental end group concentration depth profiles for these polymers determined by with negative χ_s agree well with predicted depth profiles (55).

Studies on blends of PS with fluorocarbon-terminated PS (PS-F) documented that the low energy end group in neat PS-F adsorbed preferentially at the surface, and that PS-F is surface active in the PS matrix (56). Adsorption of the end-fluorinated PS at the styrene surface can be used as an effective means to control the wetting and dewetting properties of PS (57). A paper (58) to appear shows that xps surface composition depth profiles for these blends (53,54) compare well to the predictions of a new lattice model calculation that is an extension of the previous lattice model (48).

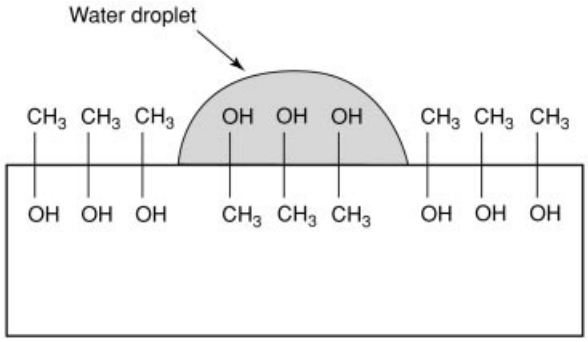

Fig. 13. Schematic diagram representing the Holly–Refojo concept (59) of surface reorganization of a functional polymer surface.

Reorganization of Heterogeneous Polymer Surfaces. The significance of the surface structure of end-functional polymers becomes apparent when considering the stability of functional polymer surfaces. The surfaces of functional and heterogeneous polymers are known to reorganize readily when exposed to water, for example as depicted in Figure 13 (59). The driving force for the phenomena is the minimization of the interfacial free energy. At an air-polymer interface, low energy hydrophobic components are favored as they lower the interfacial tension.

When the polymer is contacted with water, hydrophilic components are preferred at the water-polymer interface and the surface attempts to reconfigure to locate high energy hydrophilic components at the interface. The reorganization of end-functional PSs shown in Figure 14 (53,60) typifies this behavior. The water

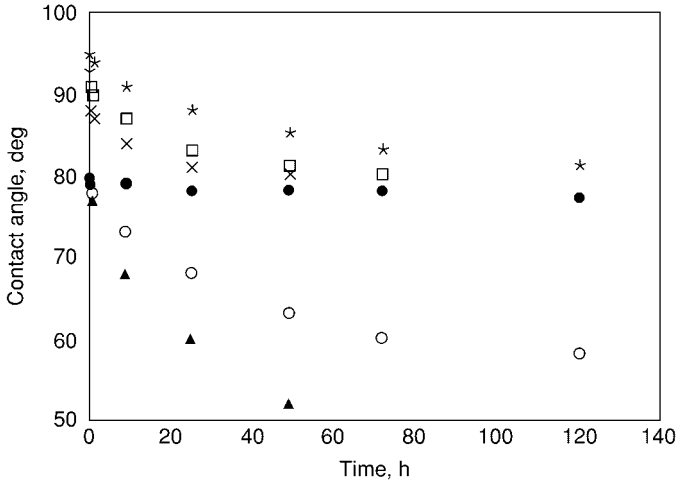

Fig. 14. Water contact angle data illustrating the reorganization of end-functional polystyrenes in the glassy state. From Ref. 60.

contact angles for PS-Fs are initially high because of a surface excess of the lower energy fluorosilane end groups (ie, χ_s is negative), but asymptote toward the value for unmodified PS when exposed to water vapor. The low energy component (ie, the fluorosilane end group) is favored at the air–polymer interface, while the highe nergy component, in this case the PS backbone, is favored at the water–polymer interface. Conversely, the water contact angle for carboxylic acid-terminated PS starts out at the value for unmodified PS because of a surface depletion of end groups, but decreases with time when exposed to water vapor as the carboxylic acid groups relocate to the surface. The reorganization process occurs even in the glassy state because it requires movement of the end groups over distances equivalent to only one or two lattice layers, consistent with the structure of excess and depletion layers illustrated in Figure 11. The temperature dependence of the process is Arrhenius in nature, demonstrating that surface reorganization necessitates only local chain motion to occur (53).

Copolymers. Random (61), block (62–64), and graft copolymers (65,66) have all been shown to be effective in reducing surface tension, though configurational constraints limit the segregation of the copolymer sequences to the interface compared to blends of identical composition as demonstrated in Figure 15. For block copolymers (see Fig. 16), surface activity increases with block length and an increasing difference in the relative surface activity of the blocks. (63,64)

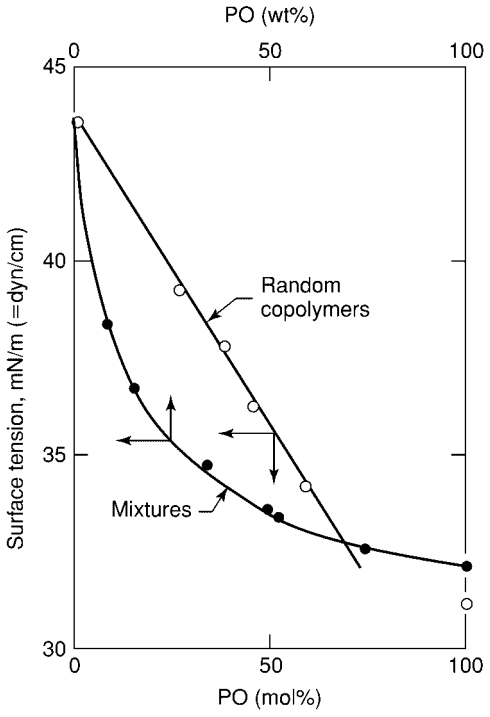

Fig. 15. A comparison of surface tension for blends and random copolymers composed of the same two monomers, polyethylene oxide and polypropylene oxide (PO). From Ref. 63.

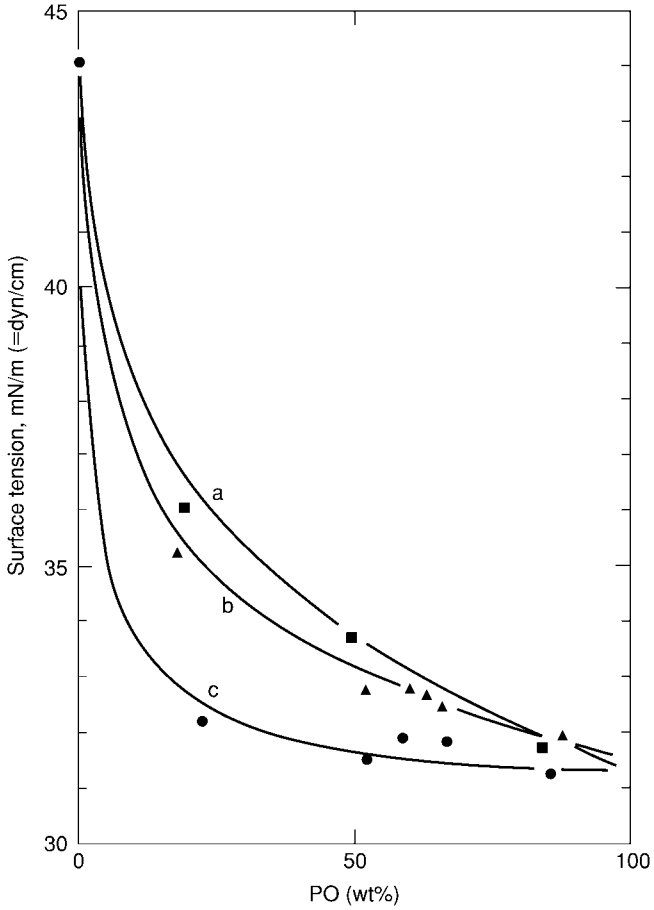

Fig. 16. The effect of sequence length on the surface tension of triblock copolymers with ethylene oxide mid-blocks and propylene oxide end-blocks. The mid-block lengths are (**a**) 16, (**b**) 30, and (**c**) 56. From Ref. 63.

For a block copolymer system where the differences in surface energy between the two components is less, wetting constraints can lead to surface heterogeneity (62). For the same composition, block copolymers, segregate more effectively to the surface than graft copolymers, which in turn are more surface active than random copolymers, though problems with microphase separation are reduced for random copolymers (61). Other chain architectures have been investigated and also been shown to be surface active (67).

Copolymers can also be used as additives to reduce surface tension. It is well known, for example, that poly(styrene-*b*-dimethyl siloxane) copolymers, PS-b-PDMS, adsorb at the surface of PS, with the low surface energy PDMS block located at the surface (68,69). The resultant PDMS-enriched surface exhibits release properties toward most substrates. The rate of migration of the block copolymers from the bulk phase to the surface (Fig. 17), however, can be very slow, depending on the bulk composition (70).

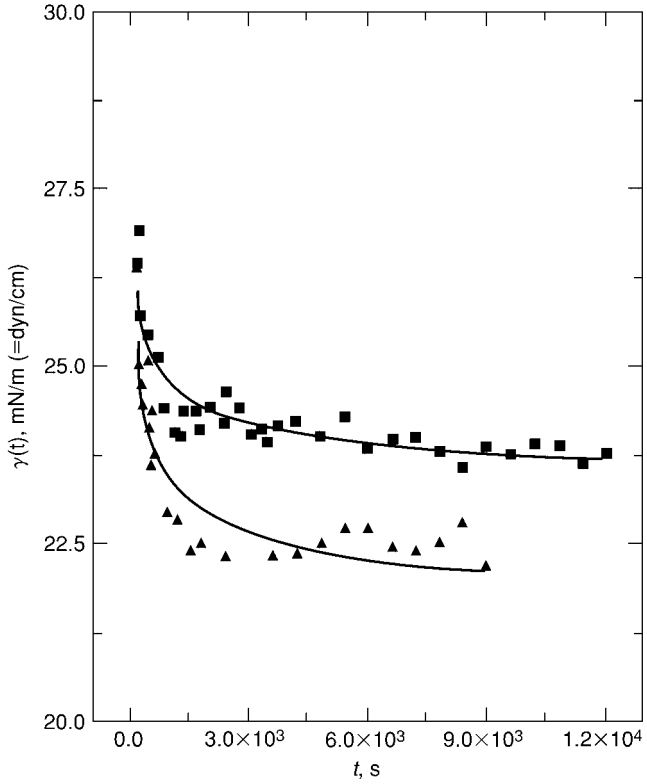

Fig. 17. Time dependence of surface tension (82) for PS-b-PDMS block copolymers added to a PS matrix as a function of bulk copolymer concentration. ■ $\phi_0=2.2\times10^{-3}$; ▲ $\phi_0=5.0\times10^{-3}$.

Surface-active block copolymer can also be employed to carry a functional group or payload to the surface of a polymer matrix. PS-b-PDMS, wherein the silicone block was terminated with a silane group, was used to create smart surfaces with selective adhesion properties (71). When the block copolymer adsorbed at the surface of PS substrates, the silane group was presented to the surface. Adhesion was observed only toward polymer coatings that could react with the silane group, that is, polymers containing vinyl functionality.

Surface Tension Measurement

Surface tensions of polymeric fluids or melts may be measured by a variety of direct techniques, with those based upon analysis of the shape of axisymmetric fluid drop profiles (3,72) the most versatile and popular. Discussions of the relative advantages and disadvantages of each technique are presented in Reference 3. Several drop geometries are possible as shown in Figure 18. The shape of these drops is governed by the Bashforth–Adams equation

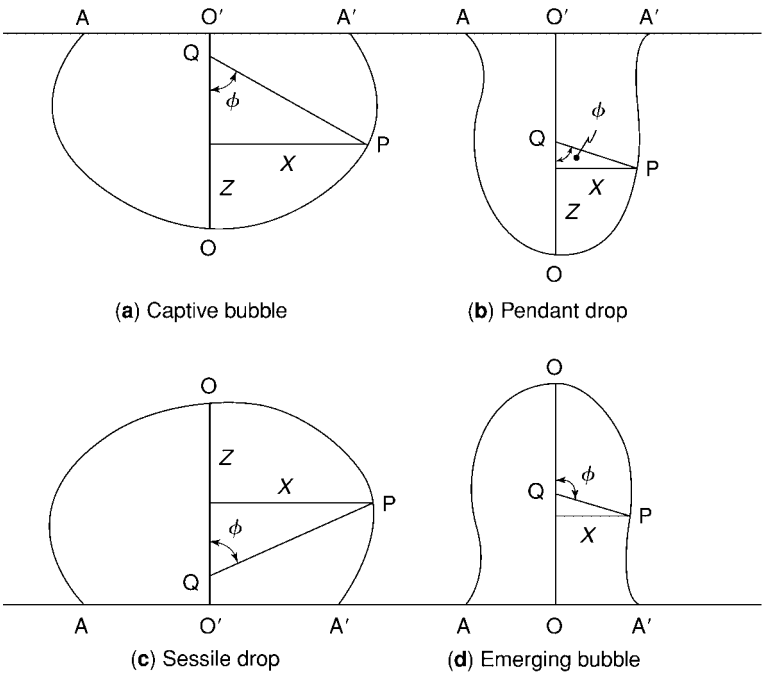

Fig. 18. Drop geometries employed in the measurement of surface tension. From Ref. 3.

$$2+\beta\left(\frac{z}{b}\right)=\frac{1}{R/b}+\frac{\sin\phi}{x/b} \tag{33}$$

where b is the radius of curvature at the drop apex, R is the principal radius in the plane of the axis of symmetry, x and z are the horizontal and vertical positions on the drop profile, respectively, and β is the shape factor defined as

$$\beta=\frac{b^2\rho g}{\gamma} \tag{34}$$

In modern techniques (19), the image of a molten polymer drop is collected by video imaging methods, and the drop profile is then obtained by application of edge detection algorithms. The shape of the drop is regressed to equation (33) to obtain a value for β and consequently for γ. For high molecular weight, viscous polymers, the time to reach an equilibrium drop shape may be limiting and other techniques may be preferred. In addition, the drop analysis techniques require knowledge of the polymer density at the temperature of the surface tension determination, which may not be readily available.

The Wilhelmy plate technique (73,74), does not require density data and can sometimes reach equilibrium much faster than the drop profile methods. This technique involves immersion of a solid plate, typically glass or platinum into the

fluid. If the fluid wets the plate, the downward force on the plate, measured by a microbalance, is

$$F = p\gamma\cos\theta - \rho g A d \tag{35}$$

where p is the perimeter of the plate, A its cross-sectional area, θ is the contact angle, and d the immersion depth. If the contact angle is zero, ie, the fluid wets the plate, a plot of F/p against d has a slope of $\rho gA/p$ and extrapolates to γ at $d = 0$. An excellent refinement of the method that involves the use of a glass thread as the plate (75), provides accurate polymer surface tensions with rapid equilibration times, even for high molecular weights.

The surface tension of a solid polymer or an inorganic substrate is difficult to measure directly and is generally estimated by indirect methods based upon equation (8). Fox and Zisman, for example, demonstrated that for solid polymers (76–78) and other substrates (79), an empirical linear relationship existed between the surface tensions γ_{SV} of a homologous series of liquids and the cosine of their contact angles on a particular substrate (see Fig. 3). When extrapolated to zero contact angle, the data produced a value for γ_C, a parameter referred to as the critical surface tension. The utility of this parameter is that spontaneous wetting should occur for all fluids with surface tensions less than γ_C. While many investigators equate γ_C directly with the surface tension γ_{SV}, of the solid, Zisman was careful in emphasizing that it is only an empirical parameter that in some way reflects the overall behavior of γ_{SV}. Critical surface tensions (3) for nonpolar fluorocarbon polymers are as low as 16 dyn/cm and those for polar polymers, such as polyacrylonitrile, are as high as 50 dyn/cm.

The theory of fractional polarity combined with Young's equation provides another means of estimating the surface tension of the solid (3). Application of the harmonic mean approximation leads to the relation

$$\gamma_{LV}(1-\cos\theta) = 4\left[\frac{\gamma_s^d\gamma_{LV}^d}{\gamma_s^d+\gamma_{LV}^d} + \frac{\gamma_s^p\gamma_{LV}^p}{\gamma_s^p+\gamma_{LV}^p}\right] \tag{36}$$

where γ^d represents the dispersive contribution to the surface tension, and γ^p the polar component of the surface tension. The total surface tension γ is given by

$$\gamma = \gamma^d + \gamma^p \tag{37}$$

The harmonic mean equation is generally considered to be applicable to low surface tension materials such as organic polymers and liquids. If γ^d and γ^p are known for two liquids, and the contact angles of those liquids on the solid of interest are measured, equation (36) produces two simultaneous equations that can be solved to find the surface tension and polarity of a solid polymer surface. Numerous assumptions have been made in developing the theory of fractional polarity. For example, it ignores the possibility of induced polarity at the interface between polar and nonpolar materials (80). These assumptions limit the application of equation (36) to systems where at least one and preferably both of the

components is relatively nonpolar. The theory breaks down when interfacial interactions lead to molecular rearrangements at the interface between solid and liquid. In addition it was found that pairs of liquids with similar dispersive and polar components of surface tension gave unreasonable results for the substrate surface tension calculated by the harmonic mean method (81).

SUSPENSION (OR PRECIPITATION) POLYMERIZATION.

See HETEROPHASE POLYMERIZATION.

SYNDIOTACTIC POLYSTYRENE

Introduction

Syndiotactic polystyrene (sPS) is a relatively new material discovery in semicrystalline polymers with a high melting point and rapid crystallization rate, which makes it possible to injection mold the material. The stereospecific polymerization was made possible by the combination of a transition metal catalyst with weakly coordinating cocatalysts, such as methylaluminoxane. The excellent balance of mechanical, electrical, solvent resistance, and dimensional stability properties combined with a relatively low price (based on styrene monomer) have made this material a competitor to existing engineering plastics. The products also have excellent heat performance and are finding application in automotive (under the hood), electrical, and electronic connector systems.

Structure, Crystallinity, and Physical Properties

Syndiotactic polystyrene, as generally polymerized with monocyclopentadienyl catalysts, has a high percentage of rrrr pentad structure. The ^{13}C nmr chemical shift for the phenyl-1 carbon and backbone methylene carbon are approximately 145.3 and 44.9 ppm, respectively (1,2). In general these polymers are found to be greater than 99% pure in syndiotactic structure as defined by nmr. sPS can be further purified of any atactic polystyrene (aPS) developed during the polymerization procedure by extraction with solvents such as methyl ethyl ketone (MEK).

The syndiotactic configuration of the backbone and the high degree of stereoregularity give rise to a semicrystalline polymer, which is able to crystallize at a high rate (3,4), and form well-structured spherulitic morphology when quiescently

crystallized from the melt (5–7). Peak crystallization rates of 7×10^{-2} at 180°C (isothermal) have been measured (3). Although sPS maintains its 100°C glass-transition temperature for the amorphous phase, its relatively high melting point (peak at ~ 270°C, Fig. 1) (8) and high crystallization rate, along with high modulus, good electrical properties, and solvent resistance make it useful as an engineering plastic material. The equilibrium melting point has been measured between 287 and 292°C using Hoffman–Weeks techniques (9,10), and the heat of fusion for 100% crystalline sPS was measured as 53.2 J/g (8).

Table 1 gives the general physical properties of unfilled sPS homopolymer.

From the melt it is now well established that sPS crystallizes primarily in an all-trans (T_4) form (α-form) with a planar zigzag backbone structure (11, 12) (see Fig. 2). A second (β-form) structure (T_2G_2) is also present, but under normal crystallization conditions the level of this structure is quite low (13–15). Calculations of the ultimate elastic modulus of the α-form sPS crystal are as high as 83 GPa (16). Experimentally, using x-ray diffraction, this has been reported at 86 GPa (12.5×10^6 psi) (17). The stiffness of the crystalline sPS is due primarily to intrachain interactions involving bond bending and stretching. The applied stress

to the backbone through the all-trans structure is carried through these bending and stretching modes, with these energy terms increasing the most under the applied stress. In addition, the bulky phenyl groups prevent very close interchain packing of the molecules in the crystal. In fact, the density of the crystalline phase of sPS is very close to that of the amorphous phase at ambient temperature and pressure and is essentially the same as that of atactic amorphous polystyrene. A volume/temperature experiment for aPS and sPS is shown in Fig. 3. At 10-MPa pressure the specific volume of the two structures below T_g is almost identical. Above T_g the crystalline sPS domains have a lower density than the liquid phase

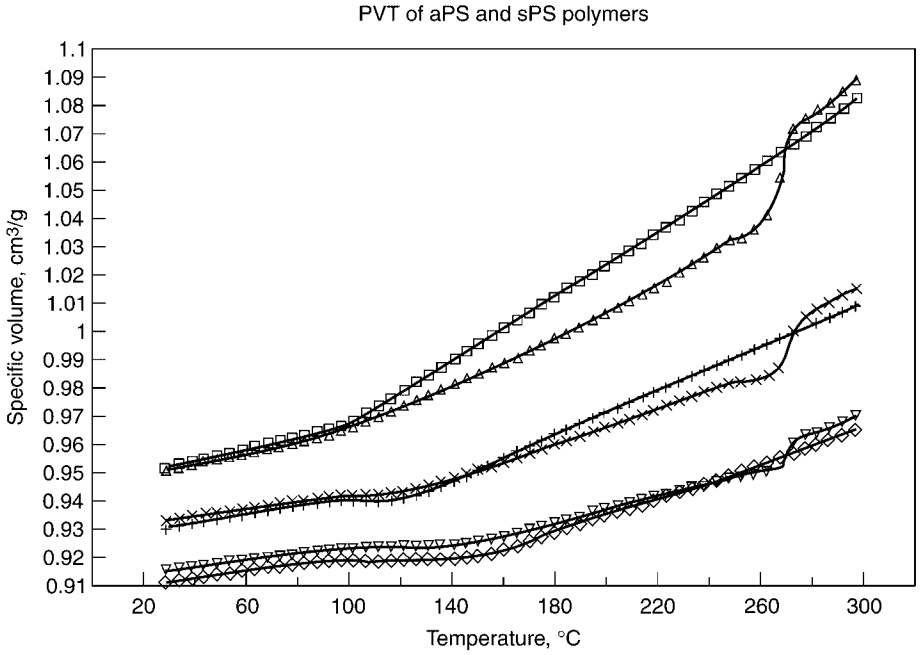

Fig. 3. Pressure/volume/temperature curves for sPS and aPS at 10, 100, and 200 MPa. □ 10 MPa aPS; + 100 MPa aPS; ◇ 200 MPa aPS; Δ 10 MPa sPS; × 100, MPa sPS; ▽ 200 MPa sPS. To convert MPa to psi, multiply by 145.

aPS, which is a very unusual property leading to improved fabricating properties for sPS. This all stems from a relatively high average cross-sectional area 70 $Å^2$ (0.7 nm^2) for each molecule of sPS because of the bulky nature of the phenyl rings. Polyethylene cross-sectional area by comparison is only 18 $Å^2$ (0.18 nm^2) (16). This high cross-sectional area leads to considerable space between polymer chains even in the crystalline phase and therefore to lower density.

Crystallized from the melt, sPS forms a crystalline morphology of well-ordered spherulites nucleated homogeneously. In neat noncontaminated sPS with 20–50°C/min cooling rates from the melt the spherulites formed are approximately 7–10 μm in diameter. Lamella thickness is generally 8–15 nm (7). It is a typical practice to add nucleators to the material to improve its apparent overall crystallization rate (18). These nucleated materials show smaller well-impinged spherulitic structures of about 2 μm in diameter. Crystallization kinetics of the bulk unnucleated polymer has been measured by several techniques and shows a dependence on molecular weight with a broad maximum rate between 190 and 240°C (3,4). When measured in a dsc experiment with a cooling rate of 10°C/min the unnucleated sPS will show a maximum for the crystallization peak of 234–236°C. Nucleated with certain organic salts [such as aluminum *p*-tert-butyl benzoate (pTBBA)] this maximum is shifted to 247–249°C (19).

Mechanical Properties

Failure and deformation mechanisms have been studied and published for sPS and have been compared to aPS (20). The semicrystalline sPS material fails with a slow, controlled crack growth while aPS fails with considerable crazing and some yield. Micrographs of fracture surfaces show that the spherulites are relatively stable structures, and it is the material at the interface of spherulites that draws and fails. A mechanism of constrained crazing and void coalescence is proposed with the spherulites themselves acting as the stress concentrators for the initiation of failure. The damage zone is then highly confined to the interspherultic regions of the semicrystalline morphology. Fig. 4 shows typical stress–strain behavior of sPS. The lack of change in Poisson's ratio for sPS is a further evidence of the lack of yielding mechanisms available in the stiff sPS material. Higher impact sPS products can be obtained using styrene–ethylene/butene–styrene block copolymers (21) or polyolefin elastomers (22) as dispersed phase toughening aids. These are added during the extrusion compounding of the formulated products. The basic mechanical properties of unfilled sPS are given in Table 2.

Reinforcement materials (such as glass fibers) or filler materials are generally compounded into sPS in order to take advantage of the high melting point and high modulus of the base resin. The addition of a well-dispersed, chemically coupled glass fiber above the percolation threshold volume creates a unique material. In general, these products are 30 and 40 wt% glass-filled products. The tensile strength of glass-filled sPS is increased to 100–130 MPa with a modulus from 7500 to 11,000 MPa. Impact properties, such as Gardner impact, are shown to be 4–7 J and notched impact strengths are 70–120 J/m. Table 3 gives typical physical and mechanical properties for commercial formulations of sPS including impact modified and ignition resistant formulations.

Solubility and Solvent Resistance

At room temperature there are no known solvents for sPS. Under ambient conditions of temperature and pressure the amorphous regions can be swollen with good solvents for aPS such as toluene, benzene, tetrahydrofuran, or dichloroethane. Chlorinated aromatics (such as trichlorobenzene, TCB) will dissolve sPS at temperatures above the glass-transition temperature (>100°C). Typically a 5–10 wt% solution can be prepared by heating the polymer with TCB at 160°C, with agitation. This solvent is generally used for solution viscosity or gel permeation chromotography.

The excellent solvent resistance of the base sPS material is useful in many applications for the formulated product. Table 4 shows the basic solvent resistance data for commercial products (23).

Polymerization

The development of coordinative polymerization of olefins during the second half of the twentieth century has been one of the most important achievements in polymer chemistry. Extensive studies have been carried out on the heterogeneous polymerizations of ethylene and propylene (24–26). Controlling the stereochemistry of polypropylene is of critical importance for the control of polymer properties. The introduction of methylaluminoxane (MAO) was a significant development in homogeneous coordinative polymerization of olefins (27,28). By utilizing MAO as a cocatalyst, metallocene catalysts exhibited outstanding polymerization activities. Furthermore, the structure of the metallocene complex could be modified to yield changes in polymer stereoregularity, molecular weight, and molecular weight distribution (29–31). Metallocenes, together with the MAO cocatalyst, have allowed the synthesis of highly stereoregular polypropylene (32,33), polyethylene with improved rheological properties (34), and ethylene copolymers with high comonomer incorporation (35).

Indeed, Ishihara and co-workers succeeded in the first preparation of sPS through activation of a transition metal complex with MAO (36,37). Typically, Group IV metallocene complexes have been used as catalysts for the polymerization of sPS. Of these, the monocyclopentadienyl-type complexes of titanium have been found to give the highest polymerization activity based on transition metal (38,39). Subsequent to the development of MAO as the sPS cocatalyst, it has been found that highly electrophilic activators, such as the tetrakis(pentafluorophenyl) borate type, can be used as cocatalysts for the production of sPS (40,41).

The syndiotacticity of sPS results from the homogeneous coordinative polymerization process (1,42). Styrene monomer complexes at a vacant coordination site on the transition metal, typically titanium, and inserts into a titanium carbon or hydride bond (Fig. 5). In the case of the growing polymer chain, the insertion occurs via cis-addition with secondary insertion so that the titanium is attached to the carbon bearing the phenyl substituent (43). Chain transfer occurs typically via β-hydride elimination, forming a titanium hydride, or via reaction with an

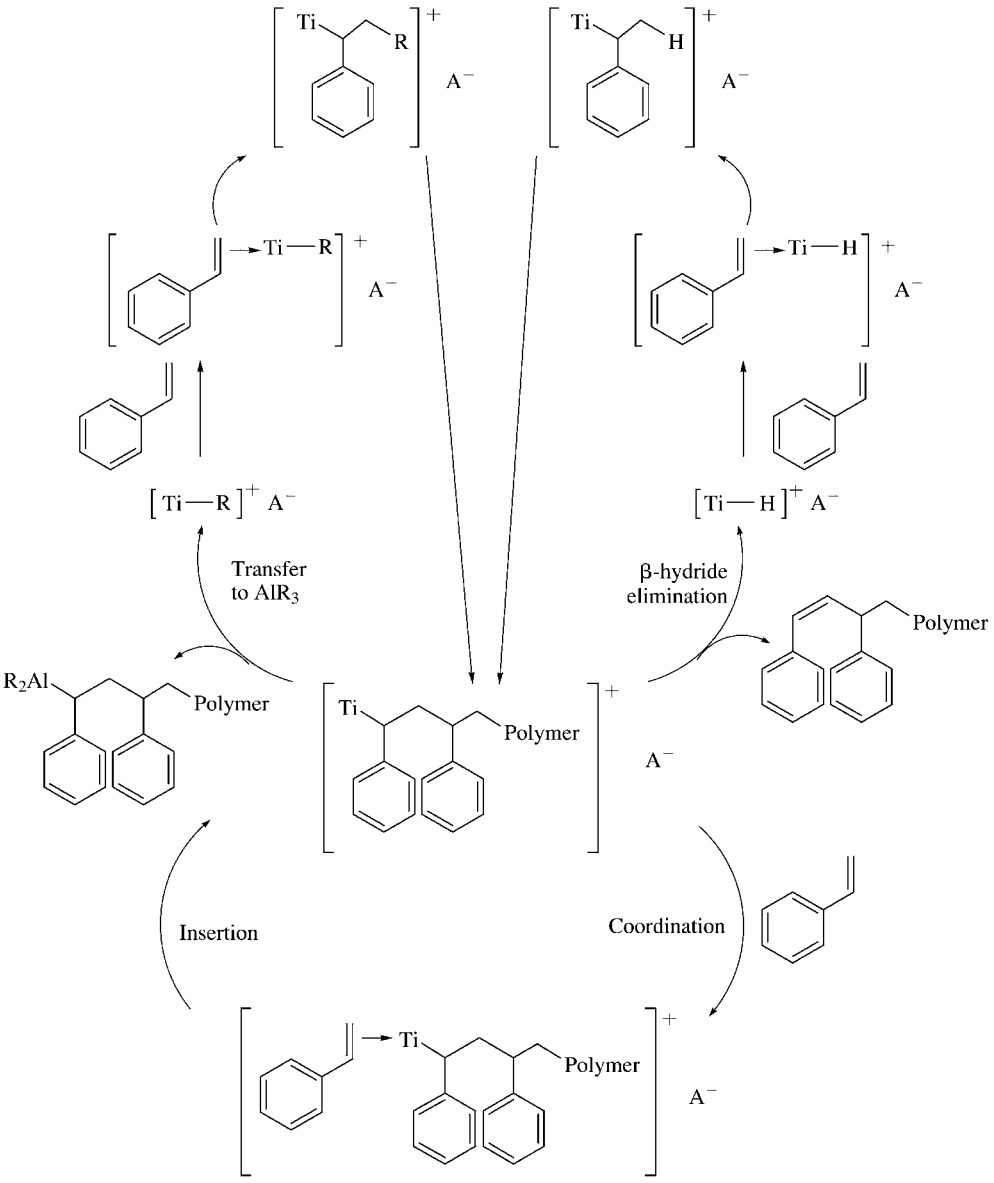

Fig. 5. Generalized schematic of sPS polymerization mechanism. Ligands on titanium omitted for clarity. A^- represents counterion, such as MAO or borate type.

aluminum alkyl species, forming a titanium alkyl (44,45). In either case, reinsertion by styrene monomer generates a new growing polymer chain at the titanium site. The characteristic backbone defects in sPS were analyzed by ^{13}C nmr spectroscopy in order to establish the mechanism of syndiospecificity (46). The defect structures were found to be consistent with a chain-end control mechanism in which the last monomer added to the growing polymer chain directs the insertion of the next monomer added to the chain.

Transition Metal Complexes. The transition metal is the site of the homogeneous coordinative polymerization of sPS and can consequently influence the polymerization activity, polymer molecular weight, and syndiospecificity, as well as other parameters. Various transition metals have been tested and reported for the polymerization of styrene monomer to sPS (1,39). Syndiotactic stereospecificity is observed for $TiCl_4$, $TiBr_4$, $Ti(OCH_3)_4$, $Ti(OC_2H_5)_4$, $[C_5H_5]TiCl_3$, $[C_5H_5]2TiCl_2$, $[(CH_3)_5C_5]TiCl_3$, $[(CH_3)_5C_5]_2TiCl_2$, $[C_5H_5]ZrCl_3$, and $Ti(acac)_2Cl_2$ (acac = acetylacetonate). Polymerization with the following catalysts leads to atactic materials: $ZrCl_4$, $[C_5H_5]_2ZrCl_2$, $[C_5H_5]_2HfCl_2$, $Nb(OC_2H_5)_5$, $Ta(OC_2H_5)_5$, $Cr(acac)_3$, $Co(acac)_3$, and $Ni(acac)_2$. Titanium complexes are more active than other transition metals for syndiotactic polymerization of styrene.

The catalytic activity of titanium complexes varies significantly with the ligands bonded to the titanium. Among those complexes active for sPS polymerization, monocyclopentadienyl-type complexes of titanium yield the highest polymerization activity based on titanium. For substituted cyclopentadienyl complexes, the polymerization activity decreases in the following order (1,47): $[(C_2H_5)(CH_3)_4C_5]Ti(OCH_3)_3 - 100 > [(CH_3)_5C_5]Ti(OCH_3)_3 - 95 > [(CH_3)_4HC_5]Ti(OCH_3)_3 - 64 > [((CH_3)_3Si)_2H_3C_5]Ti(OCH_3)_3 - 12 > [C_5H_5]Ti(OCH_3)_3 - 5$. Electron-releasing substituents on the cyclopentadienyl ligand generally yield complexes with higher polymerization activities, suggesting stabilization of the active site by the electron-donating ligands. However, pendant donor ligands, such as aminoalkyl (48), methoxyethyl (49), or even phenethyl (50), on the cyclopentadienyl ring result in lower polymerization activities. It is possible that these pendant donors hinder coordination or insertion of the styrene molecule. Furthermore, coordination of the pendant donor to MAO may occur, causing destabilization of the active site.

Biscyclopentadienyl complexes and bridged metallocene complexes of titanium show lower polymerization activities than the monocyclopentadienyl complexes (39). The catalytic activity and syndiospecificity for bridged metallocenes does increase by decreasing the bite-angle (51). Although ansa-monocyclopentadienyl-amido titanium complexes are essentially inactive for homopolymerization of styrene, efficient sPS formation with nonbridged amido cylcopentadienyl complexes of titanium has been reported (52).

Other cyclopentadienyl-type ligands on titanium have been investigated for their effect on polymerization of styrene monomer to sPS. Indenyltitanium trichloride has been reported to be a significantly more active catalyst than cyclopentadienyltitanium trichloride (53). This has spawned additional work on substituted indenyl complexes (54,55), benzindenyl complexes (56), and cyclopentaphenanthrene titanium derivatives (57). Several non-cyclopentadienyl complexes of titanium have been investigated for the polymerization of sPS. These have included benzamidinate ligands (58), bridged bisphenolato ligands (59), and pyrazoylborate ligands (60). While these complexes do yield sPS, the activities are lower than those of the monocyclopentadienyl-type complexes.

For the monocyclopentadienyl complexes of titanium, $[(CH_3)_5C_5]Ti(X)_3$, the polymerization activities decrease in the following order for the ancillary ligand X: $OCH_3 - 100 > OC_6H_5 - 98 > Cl - 45 >$ O-*t*-$C_4H_9 - 11 >$ O-*i*-$C_3HF_6 - 4$ (1). The bulky *tert*-butylalkoxide and the electron-withdrawing alkoxide cause a decrease in conversion, which may be due to a decrease in the number of active sites for

polymerization. Increased activity for the trifluoride monometallocene titanium complexes, X = F, relative to the analogous trichlorides has been reported (61). Similar results have been reported for indenyl and substituted indenyl complexes of titanium (62).

Several investigations of supported catalysts for the polymerization of sPS have been reported (63–66). Generally, two approaches have been evaluated for preparing a supported catalyst system for sPS. Either a homogeneous catalyst, such as $(C_5H_5)TiCl_3$, is attached to a solid support and activated by MAO or the MAO cocatalyst is attached to a support followed by reaction with the metallocene. Under certain conditions, high activity and syndiotacticity have been reported for these supported catalyst systems (67).

Cocatalysts. The MAO cocatalyst, basically a reaction product of (TMA) and water, was critical in the discovery of sPS (68). Prior to the introduction of MAO, the homogeneous metallocene, $(C_5H_5)_2TiCl_2$, activated with an aluminum alkyl species yielded only aPS with low activity (38). While the exact characterization of MAO has not been achieved analytically, it has generally been accepted to have an oligomeric structure with the molecular formula $(CH_3AlO)_n$ (69,70). Currently, MAO is believed to act as a cocatalyst by alkylation of the titanium catalyst and abstraction of a ligand from the catalyst. The active species formed by this process is a titanium(III) cationic species in combination with an MAO counterion (39). Evidence for a titanium(III) cationic active species in styrene polymerization with MAO activation has been obtained by esr spectroscopy (71).

In sPS polymerizations, the polymer yield can be affected by the properties of the MAO cocatalyst, such as its molecular weight and residual TMA content. The catalytic activity has been reported to increase with increasing MAO molecular weight, reaching high activity with a molecular weight in the range of approximately 500 (72). Because of the nature of the preparation of MAO, it usually contains residual TMA, which can vary with the synthesis. The residual TMA generally decreases the activity of the catalyst system (1); however, the effect is dependent upon the catalyst. In the case of $(C_5H_5)TiCl_3$ and $Ti(OC_2H_5)_4$ as catalysts, the polymerization activity is reduced by TMA in molar ratios of TMA/MAO from about 0.5 to 2 (73). The activity of the catalyst system can also depend significantly upon molar ratio of MAO/Ti (Fig. 6). The results, however, are also dependent upon the catalyst used in the polymerizations. The polymer yield, with $[(CH_3)_5C_5]Ti(OR)_3$ as the catalyst, increased with increasing MAO/Ti molar ratio, reaching a maximum at a ratio of approximately 300–500 to 1 (47).

In addition to MAO, boron compounds based on tris(pentafluorophenyl)boron and its derivatives, typically dimethylanilinium tetrakis(pentafluorophenyl) borate, have been used as cocatalysts for sPS polymerizations (40,41). Although MAO has been used in large molar excesses relative to the titanium complex, the boron compounds may be used in roughly equimolar amounts to the titanium catalyst. The boron cocatalyst reacts with a titanium alkyl species, either by protonation in the case of dimethylanilinium tetrakis(pentafluorophenyl)borate or by alkyl group abstraction in the case of tris(pentafluorophenyl)boron, to generate a titanium cationic species with a borate counterion (74–76). The esr spectral evidence has been reported for these systems, supporting a titanium(III) cationic active species (76).

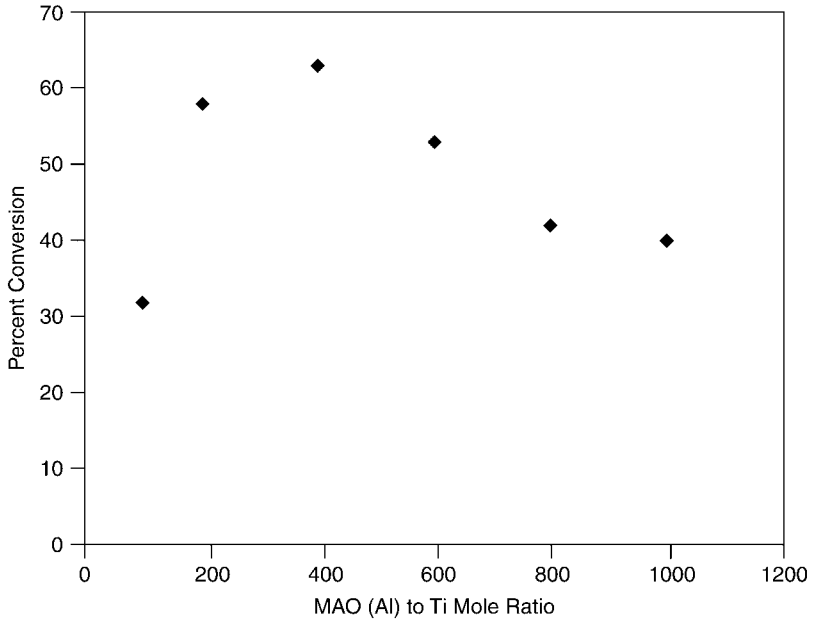

Fig. 6. Percent conversion to sPS as a function of MAO-to-titanium mole ratio for $[(CH_3)_5C_5]Ti(OCH_3)_3$ (47).

The polymerization activity of tris(pentafluorophenyl)boron has been reported to be higher than that of dimethylanilinium tetrakis(pentafluorophenyl) borate with $[(CH_3)_5C_5]Ti(CH_3)_3$ as the catalyst (77). It was proposed that the dimethylaniline coordinates to the active site and decreases the polymerization activity. The use of dimethylanilinium tetrakis(pentafluorophenyl)borate with triisobutylaluminum (TIBA) and $[(CH_3)_5C_5]Ti(CH_3)_3$ as the catalyst has been reported to yield high activity for sPS polymerization (74).

Additives. Certain additives may be included with the catalyst system of the transition metal catalyst and MAO or borate cocatalyst in order to improve the polymerization activity or perhaps to adjust a polymer property into a useful range. Activators that have been reported for sPS polymerization include aluminum alkyls, hydrogen, and organometallic compounds of tin and zinc.

Aluminum alkyls that have been investigated in catalyst systems for sPS polymerization include TMA, triethylaluminum (TEA), and TIBA (1,73,78). In conjunction with $[(CH_3)_5C_5]TiCl_3$ and MAO, the polymerization activity increases with the addition of aluminum alkyl in the following order: TMA < TEA < none < TIBA (Table 5). Aluminum alkyls can act as both reducing agents and alkylating agents for the titanium catalyst. In this case, the polymerization activity is decreased by the strong reducing agents, TMA and TEA.

Hydrogen is a well-known chain transfer agent in classical Ziegler–Natta heterogeneous polymerization and also causes a decrease in molecular weight when used in sPS polymerization (79). Additionally, as shown in Fig. 7, hydrogen significantly improves catalyst efficacy in sPS polymerization (80,81). The activation by hydrogen in sPS polymerization may be due to reactivation of dormant polymerization sites.

Table 5. Relative Polymerization Activities of Aluminum Alkyls with the Catalyst System $[(CH_3)_5C_5]TiCl_3$/MAO[a]

Aluminum alkyl	Relative activity	M_w
None	100	750,000
TMA	13	64,000
TEA	23	84,000
TIBA	560	580,000

Two other activators have been investigated for sPS catalyst systems. Tetraphenyltin, when added to the titanium and MAO catalyst system, has been reported to significantly improve the yield of sPS and cause an increase in the sPS molecular weight (82). It was proposed that mixed aluminum–tin sites may form in the MAO structure, which could affect the active site formation. The influence of diphenylzinc on the metallocene MAO catalyst system for sPS polymerization has been reported for titanium and zirconium (83).

Molecular Weight Control. Chain transfer under the usual sPS polymerization conditions occurs primarily via β-hydride elimination or chain transfer to aluminum alkyl (Fig. 5). For the $(C_5H_5)Ti(OC_4H_9)_3$/MAO catalyst system at low monomer concentration, it has been reported that the rate of β-hydride elimination is 76 times faster than chain transfer to MAO (84). Additional evidence for β-hydride elimination as the main mechanism of chain transfer has been reported from analysis of the *tert*-butylcyclopentadienyltitanium trichloride catalyst

for sPS polymerization (45). Increasing the polymerization temperature significantly decreases the polymer molecular weight, presumably by increasing the rate of β-hydride elimination (1).

However, sPS molecular weight may also be decreased by the addition of external additives, such as aluminum alkyls or hydrogen. The effect on the molecular weight depends upon the titanium catalyst but aluminum alkyls (TMA, TEA, or TIBA) are all effective at decreasing the sPS molecular weight (Table 5) (1,73). Hydrogen, in addition to increasing the catalyst efficiency, is effective as a chain transfer agent in reducing the sPS molecular weight (79–81).

Copolymerization. Polymerization of various ring-substituted styrene monomers using the characteristic sPS catalyst system $(C_5H_5)TiCl_3$/MAO yielded the corresponding syndiotactic substituted polystyrenes (38,85). Electron releasing substituents, tertiary-butyl or methyl, gave higher conversions than styrene monomer, which in turn gave higher conversion than electron withdrawing substituents, such as fluorine or chlorine. Therefore, syndiospecific copolymers of styrene with alkyl-substituted styrenes have been conveniently prepared and their physical properties studied (86–88). The copolymers exhibit a random incorporation of the comonomers in the polymer backbone. Indeed, for syndiotactic poly(styrene-*co*-*p*-methylstyrene), as the content of *p*-methylstyrene (pMS) is increased, the melting point decreases regularly from the value for sPS homopolymer. Furthermore, the lower crystallization temperatures and the breadth of the crystallization peaks by dsc suggest a slower crystallization rate for the copolymers relative to sPS.

Several reports have been published on the copolymerization of styrene and olefins, ie ethylene or butadiene, utilizing the typical sPS catalyst system. The results have depended on the specific catalyst and polymerization conditions. It has been reported that the copolymerization of styrene and ethylene with $(C_5H_5)TiCl_3$ and MAO yielded a mixture of polyethylene and sPS (89,90). An alternating copolymerization using the borane based catalyst system $[(CH_3)_5C_5]Ti(CH_2C_6H_5)_3/B(C_6F_5)_3$ has also been reported (91). No evidence of stereoregularity was found in the copolymer. The products of copolymerization of styrene and ethylene using the catalyst system $(C_5H_5)Ti(OC_6H_5)_3$/MAO have been analyzed (92), leading to the conclusion that the polymer was a random copolymer. However, the polymerization results were influenced by the nature of the MAO, the TMA content, and the polymerization conditions. Copolymerization of styrene and butadiene has been reported with the $[C_5H_5]TiCl_3$/MAO catalyst system (93). Under certain polymerization conditions, block copolymers of sPS–polybutadiene are obtained without appreciable contamination by the homopolymers. dsc and ^{13}C nmr spectroscopy were used to confirm the block structure.

Laboratory Polymerization Techniques. Syndiotactic polymerization of styrene monomer must be carried out under inert atmosphere taking utmost care to exclude oxygen, water, and other polar impurities. The monomer and any solvent must be free of oxygen, water, and polar impurities. Styrene is typically distilled from calcium hydride and stored under inert atmosphere. Alternatively, styrene is conveniently purified prior to polymerization by sparging with nitrogen or argon and passing through activated alumina (94). Furthermore, it has been reported that removal of phenylacetylene from styrene monomer via hydrogenation is beneficial for higher catalyst activity (95).

The sPS polymerization has been reported using several different laboratory scale polymerization techniques. Slurry polymerization, using a diluent such as iso-octane, is particularly convenient since the polymer precipitates from the nonsolvent as a finely divided solid (47,96). Bulk polymerization has often been reported in small laboratory reactors (97). However, in this case, a solid mass forms at low conversions as the polymer crystallizes from the polymerizing mixture. Diffusion, heat transfer, and reactor fouling may be concerns with bulk polymerization of sPS. Suspension polymerization of sPS has also been reported utilizing a perfluorinated hydrocarbon in which both the monomer and polymer are insoluble (98). Beads of sPS are obtained in good yield with kinetics similar to bulk polymerization.

Commercial Processes. Several processes have been reported in the patent literature for the production of sPS. A continuous polymerization process was disclosed using a self-cleaning type reactor comprising kneading elements arranged on rotating shafts (99,100). sPS could be produced efficiently without adhesion of the polymer to the reactor or the agitator. By distributing the catalyst addition along the axis of the reactor, improved temperature control and productivity was claimed (101). Additionally, a second stirred vessel could be added as a secondary reactor to prolong the polymerization times.

Another continuous process has been disclosed for the production of sPS in which monomer and catalyst are introduced into a reactor containing previously added fluidized sPS particles (102–104). Temperature control is achieved by partial evaporation of the monomer. A similar process was disclosed in which a nonsolvent was evaporated in order to control the polymerization temperature (105).

A different type of process has been disclosed in which sPS is produced by dispersion polymerization (106–108). A special block copolymer based on polybutadiene is used as the dispersant. The advantages of this process include being able to produce sPS in conventional stirred reactors at low viscosity with improved productivity and without reactor fouling.

Processing

Syndiotactic polystyrene formulated products are generally injection molded into useful parts for automotive, electrical, electronic, medical, and other market applications (109,110). The melt viscosity of sPS at normal processing temperatures is very low, especially in comparison to other engineering thermoplastic polymers. Syndiotactic polystyrene rheology allows it to flow in to very thin molds at relatively low pressure, and crystallize quickly with low warpage providing for fast cycle times. Table 6 shows the mold shrinkage data typical for formulated commercial products. Since sPS has very low moisture absorbance, there are no additional changes in part dimension with humidity.

Syndiotactic polystyrene will strain-induce crystallize, as well as quiescently crystallize as discussed previously. Furthermore, under certain conditions, it may also be quenched to the amorphous state. In injection molded parts, these processes may lead to skin/core differences in morphology that can be observed (111,112). With higher temperature molds ($>150^{\circ}$C) the parts are generally fully

Table 6. Typical Mold Shrinkage for Formulated sPS Commercial Products[a]

Formulation Type	Flow shrinkage,%	Cross-flow shrinkage,%
30% glass filled (GF)	0.2–0.4	0.5–0.9
40% glass filled (GF)	0.1–0.3	0.4–0.9

[a]Ref. 23.

crystallized to the first 10 μm of the surface. Fig. 8 shows a plot of percent crystallinity as a function of distance from the surface of the mold for sPS with a mold temperature of 105°C and increasing level of nucleator (pTBBA). The low crystallinity at the surface leads to higher absorbance of good solvents such as benzene. Fig. 9 illustrates the effect of mold temperature and nucleator level on the ability of molded parts to imbibe solvent (benzene). It is clear that low crystallinity at the surface correlates to higher levels of benzene up-take and is consistent with the fact that a skin/core structure is present. Syndiotactic polystyrene is generally nucleated in commercial formulations and molded at higher mold temperatures in applications where solvent resistance is critical.

Syndiotactic polystyrene can also be extruded into sheet, quenched quickly, and then tentered to form biaxially oriented film. It can also be thermoformed

from the quenched sheet to form cups, bowls, and other parts. In this case unfilled (neat) or in some cases a low level copolymer (such as pMS) can be used to decrease the quiescent crystallization rate allowing for thicker sheets and films to be made. The copolymer made with pMS disrupts the crystallization of homopolymer sPS such that the melting point is decreased. Fig. 10 shows the peak melting point as

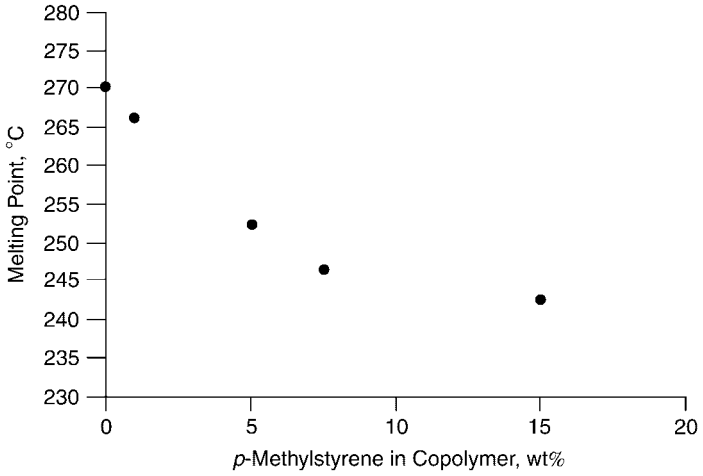

Fig. 10. Plot of melting point (as determined by dsc) versus the level of pMS in a syndiotactic copolymer with styrene.

a function of pMS content in the polymer. The decrease in melting point is a result of smaller crystallites and thinner lamellae. At pMS contents greater than 20% it is very difficult to crystallize the copolymer even with long annealing times.

Economic Aspects

Syndiotactic polystyrene is manufactured by Dow Chemical Company in Germany at announced capacity of 36,400 t/year. Idemitsu Petrochemical Company also manufactures sPS in Japan at approximately 5000 t/year. Compounding to the formulated products is done around the world at many locations. Pricing varies by formulation and product but is generally 3.30–5.50/kg at this time.

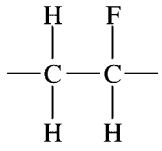
VINYL FLUORIDE POLYMERS (PVF)

Introduction

The base unit of poly(vinyl fluoride) (PVF) is shown by structure (**1**). DuPont first commercialized a film based on PVF under the trade mark Tedlar in 1961 and is the only known supplier of this polymer.



1

PVF homopolymers and copolymers have excellent resistance to sunlight degradation, chemical attack, water absorption, and solvent, and have a high solar energy transmittance rate. These properties have resulted in the utilization of PVF film and coating in outdoor and indoor functional and decorative applications. These films have found use where thermal stability, outdoor durbility, stain resistance, adherence, and release properties are required. PVF has a greater tendency to crystallize than poly(vinyl chloride). It is stable at high temperature, which is important in many of its applications.

Vinyl fluoride can be polymerized into homopolymers and copolymers with the aid of a free-radical generating catalyst (initiator), usually under high pressure. Ziegler–Natta-type catalysts can be used to prepare vinyl fluoride polymers at lower temperatures and pressures.

Monomer

Properties. Vinyl fluoride [75-02-5] (VF), CH_2=CHF (fluoroethene), is a colorless gas at ambient conditions with an ether-like odor. VF is insoluble in water under atmospheric pressure but dissolves slightly in some alcohols and ketones, such as ethanol and acetone. Tables 1–5 (1) provide data for physical, thermodynamic, and transport properties of VF.

Other than polymerization into homo- and copolymers, VF is used for the introduction of fluorine atoms into organic compounds and polymers, eg, by grafting into fibers. The net consequence of fluorine incorporation is increased chemical and

thermal stability, decreased solubility, and enhanced resistance to degradation by light. The useful range of application of grafted article at lower temperatures is also improved.

Flammability. Interstate Commerce Commission has classified VF as a flammable gas. It is flammable in air between concentrations of 2.6 ± 0.5 and 21.7 ± 1.0 vol% of VF. Mixtures of air and VF have been reported to ignite at a minimum temperature of 400°C (2).

Preparation. The first preparation of VF dates back to 1901 and the reaction of zinc with 1,1-difluoro-2-bromoethane [359-07-9] (3). Phenylmagnesium bromide in ether and potassium iodide solution can replace the metal for dehalogenation (4,5). Most approaches to VF synthesis have employed reactions of acetylene [74-86-2] with hydrogen fluoride (HF) either directly (5–8) or utilizing a catalyst (6,9–13) based on mercury or aluminum (6,9,12,14). In another process, an acetylene/HF mixture is passed over a mercuric chloride or fluoride catalyst, which also produces vinylidene fluoride and difluoroethane as by-products (10). Another synthesis (11) consists of two steps in which 1,1-difluoroethane (DFE) is

formed by adding HF to acetylene, followed by pyrolytic dehydrofluorination of DFE over an aluminum salt catalyst. Vinyl fluoride is purified by removing hydrofluoric acid in soda-lime towers and by scrubbing of acetylene in ammoniacal CuCl. Oxygen is removed by distillation.

Vinyl fluoride can be made by the reaction of ethylene [74-85-1] with HF in the presence of a palladium and $CuCl_2$ catalyst (14). A mixture of HF and $CH_2{=}CH_2$ at a 2:1 ratio, containing 35% oxygen, is passed over the catalyst at 240°C, producing VF with a 20% conversion of ethylene and 92% selectivity.

Other routes of preparation include catalytic pyrolysis of DFE (15–18); dehydrochlorination of 1-fluoro-2-chloroethanes at 500°C in the presence of ethylene dichloride, with a 15% conversion and 100% selectivity (19–23); catalytic reaction of DFE with acetylene (24,25), where VF is produced by simultaneous dehydrofluorination of CF_2HCH_3 and hydrofluorination of C_2H_2 in the presence of catalyst. An optimal yield of 77.5% is obtained at a temperature of 340°C at a 2.1:1 ratio of DFE to acetylene, and ferric oxide–cadmium oxide–aluminum oxide catalyst with a ratio of 8:4:88 (25). Another procedure involves halogen exchange of vinyl chloride [75-01-4] with HF (26–28). Highest yields were reported at 370–380°C with a two-component catalyst system, containing 96% γ-Al_2O_3 and 4% Cr_2O_3 with a vinyl chloride-to-HF ratio of 1:3 (28).

Hydrogen fluoride addition to acetylene and fluorination of vinyl chloride are the most likely commercial routes for the preparation of VF (29), although most details have not been published. Commercial VF is stabilized with terpenes such as *d*-limonene to inihibit autopolymerization.

Polymer

Properties. The physical, chemical, and electrical properties of a poly(vinyl fluoride) [24981-14-4] (PVF) film are shown in Table 6.

PVF is a semicrystalline polymer with a planar zigzag chain configuration (30). The degree crystallinity depends on the polymerization method and the thermal history of the polymer; reported values range from 20 to 60% (31). The significant variation of the degree of crystallinity is thought to be primarily a function of defect structures. Wide-line nmr and x-ray diffraction studies show the unit cell to contain two monomer units and have the dimensions of $a = 0.857$ nm, $b = 0.495$ nm, and $c = 0.252$ nm (32). Similarity to the phase I crystal form of poly(vinylidene fluoride) suggests an orthorhombic crystal (33).

The relationship of polymer structure to melting point and degree of crystallinity has been the subject of a number of studies. Head-to-head regio irregularities in PVF are known (31,34,35) and the concentration of such units has been suggested as the source of variations in melting point (36–38). Commercial PVF contains approximately 12% head-to-head linkages by ^{19}F nmr and displays a peak melting point of about 190°C (37,39–41). Both nmr and ir studies have shown PVF to be atactic (31,34,35,37,42–45) and, as such, variations in stereoregularity are not thought to be a contributor to variations in melting point.

PVF with controlled amounts of head-to-head units varying from 0 to 30% have been prepared (37,39) by using a chlorine substituent to direct the course of polymerization of chlorofluoroethylenes and then reductively dechlorinating the

products with tributyltin hydride. This series of polymers shows melting point distributions ranging from about 220°C for purely head-to-tail polymer down to about 160°C for polymer containing 30% head-to-head linkages. This study, however, does not report the extent of branching in these polymers. Further work has shown that the extent of branching has a pronounced effect upon melting temperature (40,41). Change of polymerization temperature from 90 to 40°C produces a change in branch frequency from 1.35 to 0.3%, while the frequency of monomer reversals is nearly constant (12.5 ± 1%). The peak melting point for this series varies from 186°C (polymerization at 90°C to 206°C polymerization at 40°C).

PVF displays several transitions below the melting temperature. The measured transition temperatures vary with the technique used for measurement. T_g(L) (lower) occurs at −15 to −20°C and is ascribed to relaxation, free from restraint by crystallites. T_g(U) (upper) is in the 40–50°C range and is associated

with amorphous regions under restraint by crystallites (46). Another transition at −80°C has been ascribed to short-chain amorphous relaxation and one at 150°C associated with premelting intracrystalline relaxation.

PVF has low solubility in all solvents below about 100°C (44). Polymers with greater solubility have been prepared using 0.1% 2-propanol polymerization modifier and were characterized in *N*,*N*-dimethylformamide solution containing 0.1 *N* LiBr. M_n ranged from 76,000 to 234,000 (osmometry), and M_s from 143,000 to 654,000 (sedimentation velocity). Sedimentation velocity molecular weights can be related to intrinsic viscosity, using the Mark–Houwink equation:

$$\eta = KM^a$$

Using an a value of 0.80, which is typical of an extended polar polymer in good solvent, K is determined to be 6.52×10^{-5} (47).

The conformational characteristics of PVF are the subject of several studies (33,48). The rotational isomeric state (RIS) model has been used to calculate mean square end-to-end distance, dipole moments, and conformational entropies. ^{13}C nmr chemical shifts are in agreement with these predictions (49). The stiffness parameter (δ) has been calculated (50) using the relationship between chain stiffness and cross-sectional area (51). In comparison to polyethylene, PVF has greater chain stiffness, which decreases melting entropy, ie, $(\Delta S)_m$=8.58 J/(mol·K) [2.05 cal/(mol·K)] versus 10.0 J/(mol·K) [2.38 cal/(mol·K)].

A solubility parameter of 24.5–24.7 $MPa^{1/2}$ [12.0–12.1 $(cal/cm^3)^{1/2}$] has been calculated for PVF using room temperature swelling data (52). The polymer lost solvent to evaporation more rapidly than free solvent alone when exposed to air. This was ascribed to reestablishment of favorable dipole–dipole interactions within the polymer. Infrared spectral shifts for poly(methyl methacrylate) in PVF have been interpreted as evidence of favorable acid–base interactions involving the H from CHF units (53). This is consistent with the greater absorption of pyridine than of methyl acetate, despite a closer solubility parameter match with methyl acetate.

PVF is more thermally stable than other vinyl halide polymers. High molecular weight PVF is reported to degrade in an inert atmosphere, with concurrent HF loss and backbone cleavage occurring at about 450°C (54,55). In air, HF loss occurs at about 350°C, followed by backbone cleavage around 450°C.

More recent work reports the onset of thermal degradation at lower temperatures and provides a clearer picture of the role of oxygen (56–58). In the presence of oxygen, backbone oxidation and subsequent cleavage reactions initiate decomposition. In the absence of oxygen, dehydrofluorination eventually occurs, but at significantly higher temperatures.

PVF is transparent to radiation in the uv, visible, and near-ir regions, transmitting 90% of the radiation from 350 to 2500 nm. Radiation between 7,000 and 12,000 nm is absorbed (59). Exposure to low dose γ irradiation produces cross-links in PVF and actually increases tensile strength and etching resistance, whereas the degree of crystallinity and melting point are reduced (60). PVF becomes embrittled upon exposure to electron-beam radiation of 10 MGy (10^9 rad), but resists breakdown at lower doses. It retains its strength at 0.32 MGy (32×10^6 rad) while poly(tetrafluoroethylene) is degraded at 0.02 MGy (2×10^6 rad) (61).

Polymerization

VF undergoes free-radical polymerization in both head-to-head and head-to-tail configurations. Typically, commercial PVF contains 10–12% of inverted head-to-head and tail-to-tail units (62). VF is more difficult to polymerize than other vinyl halides (60) because of the high electronegativity of fluorine, which is the most electronegative element. Low boiling point (−72°C) and high critical temperature (54.7°C) of VF necessitate high pressure polymerization similar to that required for polyethylene.

The first polymerization involved heating a saturated solution of VF in toluene at 67°C under 600 MPa (87,000 psi) for 16 h (63). In a later procedure, benzoyl peroxide was used to initiate polymerization (9,64). The product was a polymer with a density of 1.39 g/cm^3, which was soluble in hot dimethylformamide, chlorobenzene, and other solvents. A wide variety of initiators and polymerization conditions have been explored (64–66). Examples of bulk (30,31) and solution (65,67–69) polymerizations exist; however, aqueous suspension or emulsion methods are generally preferred (64,70–79). VF volatility dictates that moderately high pressures would be required. Photopolymerizations, usually incorporating free-radical initiators, are also known (64,67,68,80).

The course of VF polymerizations is dominated by the high energy and hence high reactivity of the propagating VF radical. The fluorine substituent provides little resonance stabilization, leading to a propagating intermediate which is indiscriminate in its reactions. Monomer reversals, branching, and chain-transfer reactions are common. The reactivity of the VF radical limits the choice of polymerization medium, surfactants, initiators, or other additives and makes impurity control important. Species which can participate in chain transfer or incorporate in the polymer can depress molecular weight or degrade the thermal stability characteristics of the final polymer.

The combination of triisobutylborane [1116-39-8] and oxygen has been used to polymerize VF at reduced temperature and pressure (81). Polymerization temperature was varied from 0 to 85°C, with a corresponding drop in melting point from about 230°C (polymerization at 0°C) to about 200°C (polymerization at 85°C). This dependence of melting temperature, and degree of crystallinity, has been interpreted in terms of variations in the extent of monomer reversals during polymerization (82).

VF can be polymerized by a number of techniques, including suspension, bulk, and emulsion polymerizations in batch and continuous modes. Graft and radiation-induced polymerizations of VF have also been reported.

Suspension Polymerization. In this technique, liquid VF is suspended in water with the help of a dispersion stabilizer (70). Polymerization is initiated by an organic peroxide such as diisopropyl peroxydicarbonate below the critical temperature of VF (71,72). The reaction can also be initiated by uv light and ionizing radiation (64,73). VF dispersions are usually stabilized by water-soluble polymers such as cellulose derivatives, eg cellulose ester and sodium carboxymethylcellulose, and poly(vinyl alcohol). Inorganic salts such as magnesium carbonate, barium sulfate, and alkylsulfoacids are also used.

Polymerization is also reported in the presence of a nonionic surfactant (74) using 0.5–3.0 wt% monoalkylphenyl ether of poly(ethylene glycol)s as dispersing

agent in water and 0.5–2.5 wt% diisopropyl peroxydicarbonate as initiator. Polymer yield of 12–21 wt% are obtained in 14–18 h at 30–40°C. Radiation-initiated suspension polymerization of VF in water yields PVF soluble in solvents such as dimethylformamide (73). Increased dosages of radiation give lower molecular weight polymers. Thermal stability of PVF deteriorates with an increase in the concentration of dispersing agent.

In a modified suspension polymerization, the pressure requirements are reduced. The reaction is conducted with azo catalysts (75) at 25–100°C and pressures of 2.5–10 MPa (25–100 atm) over 18–19 h. A stainless steel reactor is flushed with nitrogen charged with 150 parts acetylene-free VF, 150 parts deoxygenated distilled water, and 0.150 parts 2,2′-azobisisobutyronitrile. The reactor is heated to 70°C for 1 h, agitated, and held at 8.2 MPa (82 atm) for 18 h. The product, 75.8 parts of PVF, is collected in the form of a white cake (64). Continuous polymerization of VF is based on the modified suspension process (76).

Bulk Polymerization. In the bulk polymerization, VF is polymerized by a peroxide initiation. In an example (67), a glass ampule is filled with VF containing 6.5×10^{-2} mol/L of di-*tert*-butyl peroxide. The ampule was irradiated by uv light from a mercury lamp below 25°C. A highly porous polymer, insoluble in VF, at conversions over 90% is obtained.

Emulsion Polymerization. VF can be readily polymerized by the emulsion method at highly reduced pressures and lower temperatures as compared to the suspension technique (77). Polymerization in an aqueous emulsion facilitates the process control and the removal of reaction heat, increases the molecular weight of the resin (74), and permits high rates of reaction and high yields.

Emulsifiers such as fatty alcohol sulfates, alkane sulfonates, alkali salts of fatty acids, and others are slightly to marginally effective (77). Fluorinated surfactants, particularly perfluorinated carboxylic acids containing seven or eight fluorine atoms, are specially effective in maintaining a high rate of polymerization after about 40% conversion. Fluorinated surfactants are characterized by low values of critical concentration of micelle formation (74). They are thermally and chemically stable, and their incorporation does not impair the PVF properties.

In a typical example (77), 200 parts water, 100 parts VF, 0.6 parts of a perfluorinated carboxylic acid, 0.2 parts ammonium persulfate, and 3 parts water glass ($Na_2O/SiO_2 = 1{:}3.3$) are introduced into a stirred autoclave. The mixture is heated to 46°C, the pressure is brought to 4.3 MPa (42.5 atm), and held for 8 h. Addition of an electrolyte precipitates a white powdery PVF at 95% yield.

Radiation-Induced Polymerization. Exposure to uv radiation in the absence of free radicals does not polymerize VF, but decomposes it into acetylene and HF (83,84). Radiation can be used in the presence of initiators (64), which decomposes into free radicals. The first reported photopolymerization of VF in the presence of benzoyl, lauroyl, or acetyl peroxide resulted in a 36% yield after 2 days at 27°C under 254-nm irradiation (64).

The rate data in radiation-induced bulk polymerization of VF reveal a heterophase process (80). Polymerization is conducted at γ-ray dosage rates of 0.13–1.0 Gy/s (13–100 rad/s) using ^{60}Co source. The rate of polymerization at 38°C is proportional to the dosage rate to the power 0.42. Gas-phase polymerization of VF with γ-ray has been studied in the range of 0.1–1.0 Gy/s (10–100 rad/s). Polymerization rate increases sharply with the increase in dosage, leading

to generation of active sites in the polymer chain and branches. Radiation polymerization of VF dissolved in solvents such as tetrachloromethane leads to chain transfer and incorporation of solvent in the polymer. VF can also be polymerized in plasma.

Graft Polymerization. The most effective method for graft polymerization of VF is radiation polymerization (80). VF has been grafted to low density polyethylene, polyisobutylene, and polyamides (85–87). The density of the graft copolymers is higher than that of the starting homopolymer. Typically, VF is brought in contact with the polymer simultaneously with irradiation.

Grafting to cellulose in the absence of solvent (87) is initiated by γ-rays by means of a ^{60}Co source. The polymer-to-monomer ratio has only a minor effect on the PVF content, which is in the range of 2–5 wt%. In the presence of solvents that cause swelling of cellulose (mercerization), the PVF content increases dramatically. At a radiation of 30 kGy (3 Mrad) in the presence of dimethylformamide, the PVF content of the graft copolymer is 26.6%; in its absence it is 4.1%.

Rot resistance of cellulose improves greatly as a result of PVF grafting (87). Some of the changes that VF grafting imparts to the polymers include a reduction in solubility in solvents, enhancement of thermal stability, increased water and oil repellency, hightened resistance to acids, and increased light stability.

Adhesion, processibility, and dyeability of PVF have been improved by grafting with other monomers (80). Styrene, methyl methacrylate, vinyl acetate, and vinylidene chloride have been grafted to PVF films by using ^{60}Co γ-rays or an electron accelerator.

Continuous Polymerization. A process for continuous polymerization of VF in aqueous medium has been described (76,78). A mixture of VF, water, and a water-soluble catalyst is stirred at 50–250°C and 15–100 MPa (150–1000 atm). A small amount of a monoolefin (C_1–C_3) is continuously introduced into the reactor to inhibit the bulk polymerization of VF to low molecular weight polmer. The water-soluble catalyst generates free radicals, which initiate the polymerization. Catalysts include ammonium persulfate, organic peroxides, and water-soluble azo initiators. In a two-stage continuous polymerization the polymer particles formed in the first stage act as nucleation sites for the second reaction zone (88).

Effect of Polymerization Variables. The polymerization variables include temperature, pressure, medium, impurities, telogen, and catalyst (initiator) (64–66).

Temperature. The polymerization has a significant effect on the molecular weight of PVF. Molecular weight generally decreases as the polymerization temperature is raised, because of a more rapid chain termination and increased branching (65,89). Initiator efficiency reaches a maximum and falls off as temperature is increased (Fig. 1).

Pressure. Polymerization of VF requires high pressures (64). The rate of polymerization and the intrinsic viscosity of the polymer increase (Fig. 2) when pressure is increased. Initiators, such as benzoyl peroxide, are generally consumed more efficiently at higher pressures. Some azo initiators do not respond to pressure in the same way.

Medium. Water is the best medium for the polymerization of VF; organic solvents have also been used. However, chain transfer to solvents leads to a sharp drop in molecular weight (65,68), and hence thermostability decreases. The PVF

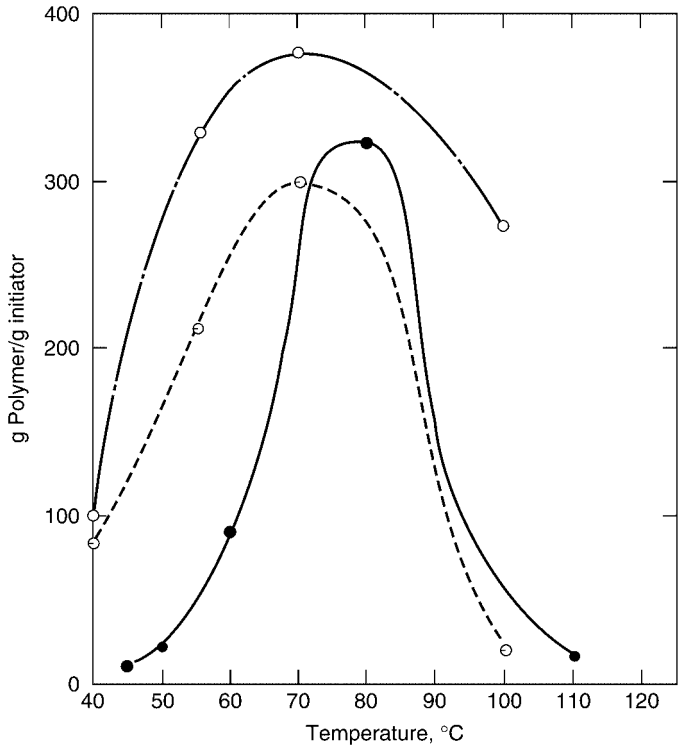

Fig. 1. Polymer yield as a function of temperature. —, 10 MPa (100 atm), 0.2% AIBN;—, 25 MPa (250 atm), 0.1% benzoyl peroxide; ——, 25 MPa (250 atm), 0.1% AIBN. From Ref. 63.

obtained is usually soluble in the solvents at the temperatures used for the polymerization reaction. A mixture of tert-butyl alcohol and water results in a high molecular weight and a high polymerization rate.

Impurities. Oxygen, acetylene, and DFE are among the impurities most likely found in VF. Oxgen up to 135 ppm appears to increase the yield, but 500 ppm inhibits the reaction slightly (65). Benzoyl peroxide at 90-MPa (900-atm) pressure is used to initiate the polymerization. At 1000-ppm acetylene content in VF, polymerization is accelerated with over 99% conversion to a highly cross-linked polymer. An increase in acetylene concentration from 0.5 to 1.0% reduced the rate by two-thirds in radiation-initiated polymerization of PVF (80). The presence of 2% acetylene reduced the yield of a low molecular weight PVF to 3%. The product was brittle and readily soluble in cyclohexane (65). VF containing up to 2.5% DFE gives a normal polymer yield; the properties of the film produced from the polymer are not affected.

Telogen. The melt viscosity of PVF can be best controlled by a chain-terminating compound (telogen), such as isopropyl alcohol or 1,3-dioxolane; toughness is not affected.

Catalysts and Initiators. The type of free-radical initiator (65) employed can have a profound effect on PVF properties, such as thermal stability and wettability.

Table 7. Melting Point and Degree of Crystallinity of Poly(vinyl fluoride) Obtained at Various Polymerization Temperatures[a,b]

Polymerization temperature, °C	Melting point, °C	Degree of crystallinity,[c] %(±2)

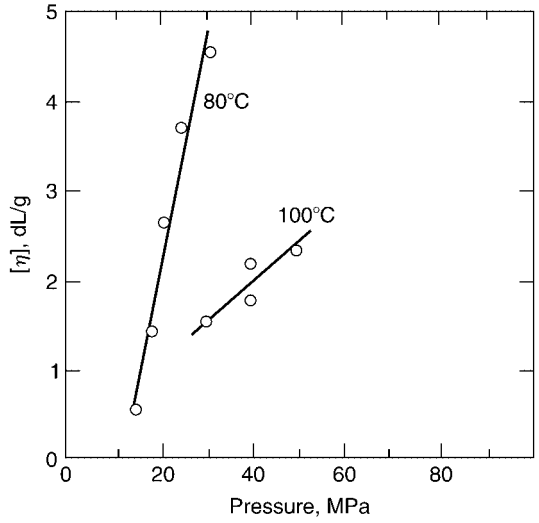

Fig. 2. Effect of polymerization pressure on intrinsic viscosity; 0.2% benzoyl peroxide initiator in aqueous medium. From Ref. 63. To convert MPa to atm, multiply by 10.

The polymer yield depends on the initiator and reaction pressure (Fig. 1). Useful water-soluble initiators include salts of inorganic peracids, organic peroxides containing hydrophilic groups, alkali metal salts of carboxylic azonitriles, and inorganic acid salts of azoamidines (76) (Table 7).

In general, polymers prepared at higher temperature tend to have low molecular weight and appear to be more branched. Increasing the initiator concentration reduces initiator efficiency and molecular weight, as evidenced by a drop in the intrinsic viscosity of the polymer.

Ziegler–Natta and Other Catalysts. Ziegler–Natta-type catalysts are used to polymerize VF. The catalysts are a mixture of transition-metal halides (titanium halides) and trialkylaluminum (triethylaluminum). Originally, olefins were polymerized by Ziegler–Natta catalysts to polymers with a high melting point, crystalline structure, and a high degree of stereoregularity

(Table 7). In an early application, VF was polymerized with a catalyst composed of diethylaluminum bromide–titanium tetrachloride–carbon tetrachloride (82). A Ziegler–Natta system based on vanadyl acetylacetonate and AlR(OR)Cl compounds gives good yields (82) at polymerization temperatures up to 50°C. A modified catalyst prepared from vanadium oxytrichloride, triisobutylaluminum, and tetrahydrofuran was found to be the most effective Ziegler–Natta system (90). However, the activity of VF with this catalyst system is much lower than that of vinyl chloride. A polymerization at low temperature and pressure utilized a triisobutyl boron catalyst activated by oxygen (82). In a similar method, oxygen was replaced by hydrogen peroxide, and polymerization was carried out in water (91). The initiator system, $AgNO_3$–tetraethyllead, is used for the polymerization of VF in dimethyl sulfoxide (69). Dimethyl sulfoxide permits the polymerization to proceed for longer periods than do other solvents by complexing of silver ions.

Copolymerization

Copolymers of VF with vinylidene fluoride [75-38-7] and tetrafluoroethylene [116-14-3] also have been prepared with this initiation system. VF tends toward alternation with tetrafluoroethylene and incorporates preferentially in copolymerization with vinylidene fluoride [see PERFLUORINATED POLYMERS, POLYTETRAFLUOROETHYLENE; VINYLIDENE FLUORIDE POLYMERS].

More recently, interpolymers of VF have been reported with tetrafluoroethylene and other highly fluorinated monomers such as hexafluoropropylene, perfluorobutylethylene, and perfluoroethylvinylether (92,93). Polymerization reaction took place in an aqueous medium using an initiator consisting of water-soluble organic azo compounds or salts inorganic peracids, examples of which include 2,2′-azobis(2-amidinopropane) dihydrochloride and ammonium persulfate. Reaction conditions were relatively mild at temperature of 60–100°C and pressure of 1–12 MPa in the absence of any surfactant.

Copolymers of VF and a wide variety of other monomers have been prepared (9,81,82,94–98). The high energy of the propagating VF radical strongly influences the course of these polymerizations. VF incorporates well with other monomers that do not produce stable free radicals, such as ethylene and vinyl acetate, but is sparingly incorporated with more stable radicals such as acrylonitrile [107-13-1] and vinyl chloride. An Alfrey-Price Q value of 0.010 ± 0.005 and an e value of 0.8 ± 0.2 have been determined (99). The low value of Q is consistent with little resonance stability and the e value is suggestive of an electron-rich monomer.

Reactivity Ratio. An extensive study covers copolymerization of various monomers with VF over a range of compositions with alkylboron or Ziegler–Natta catalysts (66). Copolymerization was carried out at 30°C in ethyl acetate or methylene chloride. Figure 3 shows the monomer–copolymer composition curves in the alkylboron-initiated copolymerization of VF with a number of monomers. The reactivity ratios given in Tables 8 and 9 indicate random arrangements of monomer units for VF–vinylidene fluoride (VF2) copolymer and formation of alternating units for VF–TFE (C_2H_4) copolymer (100).

Fabrication and Processing

Commercial PVF is insoluble at room temperature because of the large number of hydrogen bonds and high degree of crystallinity. Some latent solvents solvate PVF at temperatures above 100°C. PVF is converted to thin films and coatings. Processing of PVF, eg, by melt extrusion, depends on latent solvation of PVF in highly polar solvents and its subsequent coalescence. An example is plasticized melt extrusion of PVF into thin films (101). Pigments, stabilizers, plasticizers, and other additives can be incorporated in the film by dispersing them with the polymer in the latent solvent. The solvent is recovered by evaporation after extrusion. The extruded film can be biaxially oriented to varying degrees.

PVF can be applied to substrates with solvent-based or water-borne dispersions, or by powder-coating techniques. Viscosity modifiers are often needed to obtain a coatable dispersion. Dispersions can be applied by spraying, reverse roll coating, dip coating, and centrifugal casting. Other methods include casting on a continuous belt, extrusion into a hot liquid (102), and dipping a hot article into the dispersion (103).

Adherability of the film may be enhanced by its treatment with flame, electric (corona) discharge, boron trifluoride gas, activated gas plasma, dichromate sulfuric acid, and a solution of alkali metal in liquid ammonia (104–107). A

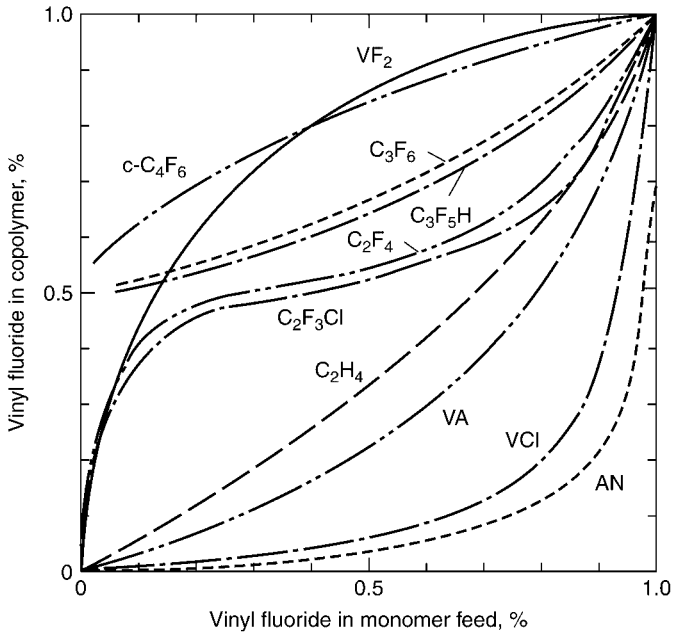

Fig. 3. Monomer–copolymer composition in the copolymerization of vinyl fluoride at 30°C with $O_2/B(i\text{-}C_4H_9)_3 = 0.5$ initiator (based on total monomer charged) and ethyl acetate as solvent. Comonomers: vinyl chloride (VCl), acrylonitrile (AN), vinyl acetate (VA), chlorotrifluoroethylene, ethylene, tetrafluoroethylene, *cis*-1-hydropentafluoropropene (C_3F_5H), hexafluoropropene (C_3F_6), hexafluorocyclobutene (c-C_4F_6), and vinylidene fluoride (VF_2). From Ref. 86.

coating of polyurethane, an alkyl polymethacrylate, or a chlorinated adhesive can be applied to PVF surfaces to enhance adhesion (102,108,109).

Economic Aspects

PVF is available from DuPont both as transparent and pigmented films and as a resin under the trademark Tedlar PVF film. Films are available in nonoriented and oriented grades in several tensile modifications and thicknesses, with either adherable or nonadherable release-grade surfaces. Nonorieted films exhibit extensive conformability to various shapes. PVF films are available in single layer and integrated multilayers where the top layer of the latter is clear and the bottom layer may possess aesthetic effects such as color, metalic appearance, or pearlescence. The 2000 prices ranged from $30 to $73 per kg. Prices for specially tailored films were significantly higher.

Health and Environment

A number of studies and reviews of the toxicological effects of exposure to VF have been conducted (110–112). A 1995 report (113) by International Agency for Research on Cancer (IARC) has evaluated the preceding data for VF and a classification of "probably carcinogenic to humans" was assigned to VF. In 1998,

American Conference of Government Industrial Hygienist (ACGIH) classified VF as an A2 carcinogen defined as "suspected human carcinogen." These classifications are based only on animal data since sufficient epidemiology data do not exist. The oncogenic potential of VF has been studied in male and female rats and mice that were administered VF via inhalation. Exposure concentrations ranged from 0 to 2500 ppm for 6 h/day, 5 days/week for up to 2 years (94). Under the conditions of this study, VF was found carcinogenic, similar to other monohaloethylenes, at concentrations of 25 ppm or greater. Mice were more susceptible than rats to the carcinogenic effects of VF and were found to metabolize VF more readily than rats or humans (114). A metabolite of VF is the suspected carcinogenic species. VF is metabolized to the suspected carcinogenic intermediate at a rate approximately one-fifth that of vinyl chloride (115–119).

VF is flammable in air between the limits of 2.6 and 22 vol%. Minimum ignition temperature for VF and air mixtures is 400°C. A small amount (<0.2%) of terpenes is added to VF so as to prevent spontaneous polymerization. The U.S. Department of Transportation has classified the inhibited VF as a flammable gas.

The self-ignition temperature of PVF film is 390°C. The limiting oxygen index (LOI) for PVF is 22.6% (120), which can be raised to 30% in antimony oxide-modified film (121). HF and a mixture of aromatic and aliphatic hydrocarbons (122) are generated from the thermal degradation of PVF. Toxicity studies, ie survival and time to incapacitation, of polymers, cellulosics (123,124), and airplane interior materials (125) expose mice to pyrolysis products and show PVF thermal degradation products to have relatively low toxicity.

Uses

The uses of PVF depend on its weatherability, strength over a wide range of temperatures, and inertness toward a wide variety of chemicals, corrosives, and staining agents. It finds wide use as a protective or decorative coating. It can be applied as a preformed film in a laminating step or from a dispersion in a coating step. It may be transparent or pigmented in a variety of colors. PVF film is laminated to cellulosics, flexible vinyls, plastics, rubbers, and resin-impregnated felt. These laminated products are applied to exterior wall panels for buildings (126,127), highway sound barriers (128), automobile trim, truck and trailer siding (129), vinyl awnings, backlit signs (130), pipe covering (131), stain-resistant wall coverings, and aircraft cabin interiors (132,133).

On metal or plastics, PVF surfaces serve as a primer coat for painting, eg, automobile parts, or where improved adhesion is desired (134). Because of its moisture impermeability and wide operating temperature range, PVF film is used to fabricate bags to contain glass-fiber mats for insulating exterior airplane walls and cargo space, and air conditioning ducts. PVF has long been used to construct bags for sampling gases (135).

Fiber-reinforced panels covered with PVF have been used for greenhouses. Transparent PVF film is used as the cover for flat-plate solar collectors (136) and photovoltaic cells (qv) (137). White PVF pigmented film is used as the bottom surface of photovoltaic cells. Nonadhering film is used as a release sheet in plastics processing, particularly in high temperature pressing of epoxy resins for circuit boards (138–140) and aerospace parts. Dispersions of PVF are coated on the exterior of steel hydraulic brake tubes and fuel lines for corrosion protection.

VINYLIDENE CHLORIDE POLYMERS

Introduction

Vinylidene chloride (VDC) copolymers were among the first synthetic polymers to be commercialized. Their most valuable property is low permeability to a wide range of gases and vapors (see BARRIER POLYMERS). From the beginning in 1939, the word Saran has been used for copolymers with high VDC content, and it is still a trademark of The Dow Chemical Co. in some countries. Sometimes the names Saran and poly(vinylidene chloride) (PVDC) are used interchangeably. This can lead to confusion because, although Saran includes the homopolymer, only copolymers have commercial importance. The homopolymer, ie, PVDC, is not commercially used because it lacks the thermal stability required for processing.

The principal solution to fabrication difficulties is copolymerization. Three types of comonomers are commercially important: vinyl chloride; acrylates, including alkyl acrylates and alkyl methacrylates; and acrylonitrile. When extrusion is the method of fabrication, other solutions include formulation with plasticizers, stabilizers, and extrusion aids plus applying improved extrusion techniques. The literature on VDC copolymers through 1994 has been reviewed (1,2).

Monomer

Properties. Pure vinylidene chloride [75-35-4] (1,1-dichloroethylene) is a colorless, mobile liquid with a characteristic sweet odor. Its properties are summarized in Table 1. Vinylidene chloride is soluble in most polar and nonpolar organic solvents. Its solubility in water (0.25 wt%) is nearly independent of temperature at 16–90°C (5).

Table 1. Properties of VDC Monomer[a,b]

Property	Value
Molecular weight	96.944
Odor	Pleasant, sweet
Appearance	Clear, liquid
Color (APHA)	0–10
Solubility of monomer in water at 25°C, wt%	0.25
Solubility of water in monomer at 25°C, wt%	0.035
Normal boiling point, °C	31.56
Freezing point, °C	−122.56
Flash point, °C	
Tag closed cup	−28
Tag open cup	−16
Flammable limits in air (ambient conditions), vol%	6.5–15.5
Autoignition temperature, °C	513[b]
Latent heat of vaporization, ΔH°_v, kJ/mol[c]	
At 25°C	26.48 ± 0.08
At normal boiling point	26.14 ± 0.08
Latent heat of fusion at freezing point, ΔH_m, J/mol[c]	6514 ± 8
Heat of polymerization at 25°C, ΔH_p, kJ/mol[c]	−75.3 ± 3.8
Heat of combustion, liquid monomer at 25°C, ΔH_c, kJ/mol[c]	1095.9
Heat of formation	
Liquid monomer at 25°C, ΔH_f, kJ/mol[c]	−25.1 ± 1.3
Gaseous monomer at 25°C, ΔH_f, kJ/mol[c]	1.26 ± 1.26
Heat capacity	
Liquid monomer at 25°C, C_p, J/(mol·K)[c]	111.27
Gaseous monomer at 25°C, C_p, J/(mol·K)[c]	67.03
Critical temperature, T_c, °C	220.8
Critical pressure, P_c, MPa[d]	5.21
Critical volume, V_c, cm^3/mol	218
Liquid density, g/cm^3	
−20°C	1.2852
0°C	1.2499
20°C	1.2137
Index of refraction, n_D	
10°C	1.43062
15°C	1.42777
20°C	1.42468
Absolute viscosity, mPa·s (=cP)	
−20°C	0.4478
0°C	0.3939
20°C	0.3302
Vapor pressure,[e] at T°C	$\log P_{kPa} = 6.1070 - 1104.29/(T = 237.697)$

[b] Inhibited with methyl ether of hydroquinone.
[c] To convert J to cal, divide by 4.184.
[d] To convert MPa to atm, divide by 0.101.
[e] P measured from 6.7 to 104.7 kPa. To convert kPa to mm Hg, multiply by 7.5 (add 0.875 to the constant to convert $\log_{kPa}$ to $\log_{mmHg}$).

Manufacture. Vinylidene chloride monomer can be conveniently prepared in the laboratory by the reaction of 1,1,2-trichloroethane [79-00-5] with aqueous alkali:

$$2\ CH_2ClCHCl_2 + Ca(OH)_2 \longrightarrow 2\ CH_2{=}CCl_2 + CaCl_2 + 2\ H_2O$$

Other methods are based on bromochloroethane [25620-54-6], trichloroethyl acetate [625-24-1], tetrachloroethane [79-34-5], and catalytic cracking of trichloroethane (6). Catalytic processes produce hydrogen chloride as by-product, rather than less valuable salts, but yields of VDC have been too low for commercial use of these processes. However, good results have been reported with metal-salt catalysts (7–9).

Vinylidene chloride is prepared commercially by the dehydrochlorination of 1,1,2-trichloroethane with lime or caustic in slight excess (2–10%) (5,10). A continuous liquid-phase reaction at 98–99°C yields ~90% VDC. Caustic gives better results than lime. Vinylidene chloride is purified by washing with water, drying, and fractional distillation. It forms an azeotrope with 6 wt% methanol (11). Purification can be achieved by distillation of the azeotrope, followed by extraction of the methanol with water. An inhibitor is usually added at this point. Commercial grades contain 200 ppm of the monomethyl ether of hydroquinone (MEHQ). Many other inhibitors for the polymerization of VDC have been described in patents, but MEHQ is the one most often used. The inhibitor can be removed by distillation or by washing with 25 wt% aqueous caustic under an inert atmosphere at low temperatures.

For many polymerizations, MEHQ need not be removed; instead, polymerization initiators are added. Vinylidene chloride from which the inhibitor has been removed should be refrigerated in the dark at −10°C, under a nitrogen atmosphere, and in a nickel-lined or baked phenolic-lined storage tank. If not used within 1 day, more inhibitor should be added.

Health and Safety Factors. Vinylidene chloride is highly volatile and, when free of decomposition products, has a mild, sweet odor. Its warning properties are ordinarily inadequate to prevent excessive exposure. Inhalation of vapor presents a hazard, which is readily controlled by observance of precautions commonly taken in the chemical industry (4). A single, brief exposure to a high concentration of VDC vapor, eg, 2000 ppm, rapidly causes intoxication, which may progress to unconsciousness on prolonged exposure. The LC_{50}/4 h in rats is 6350 ppm. However, prompt and complete recovery from the anesthetic effects occurs when the exposure is for short duration. A single, prolonged exposure and repeated short-term exposures can be dangerous, even when the concentration of the vapor is too low to cause an anesthetic effect. Such exposure may produce organic injury to the kidneys and liver. For repeated exposures, the vapor concentration of VDC should be much lower. The American Conference of Governmental Industrial Hygienists threshold limit value of 5 ppm has been established to provide an adequate margin of safety.

Vinylidene chloride is hepatotoxic, but does not appear to be a carcinogen (12–17). Pharmacokinetic studies indicate that the behavior of vinyl chloride and vinylidene chloride in rats and mice is substantially different (18). No unusual health problems have been observed in workers exposed to VDC monomer over

varying periods (19). Because VDC degrades rapidly in the atmosphere, air pollution is not likely to be a problem (20). Worker exposure is the main concern. As such, personal monitoring can be done using passive dosimeters. Refer to the dosimeter supplier for collection and analysis details.

The liquid is irritating to the skin after only a few minutes of contact. The inhibitor MEHQ may be partly responsible for this irritation. Inhibited VDC is moderately irritating to the eyes. Contact causes pain and conjunctival irritation, and possibly some transient corneal injury and iritis. Permanent damage, however, is not likely.

Peroxide Formation. In the presence of air or oxygen, uninhibited VDC forms a violently explosive complex peroxide at temperatures as low as 40°C. Decomposition products of VDC products are formaldehyde, phosgene, and hydrochloric acid. A sharp, acrid odor indicates oxygen exposure and probable presence of peroxides. This is confirmed by the liberation of iodine from a slightly acidified dilute potassium iodide solution. Formation of insoluble polymer may also indicate peroxide formation. The peroxide adsorbs on the precipitated polymer, and separation of the polymer may result in an explosive composition. Any dry composition containing more than ~15 wt% peroxide detonates from a slight mechanical shock or from heat. Vinylidene chloride that contains peroxides may be purified by being washed several times, either with 10 wt% aqueous sodium hydroxide solution at 25°C or with a fresh aqueous solution of 5 wt% sodium bisulfite. Residues in vessels containing VDC should be handled with great care, and the peroxides should be destroyed with water at room temperature.

Copper, aluminum, and their alloys should not be used in handling VDC. Copper can react with acetylenic impurities to form copper acetylides, whereas aluminum can react with VDC to form aluminum chloralkyls. Both compounds are extremely reactive and potentially hazardous.

Polymerization

Vinylidene chloride polymerizes by both ionic and free-radical reactions. Processes based on the latter are far more common (21). Vinylidene chloride is of average reactivity when compared with other unsaturated monomers. The chlorine substituents stabilize radicals in the intermediate state of an addition reaction. Because they are also strongly electron-withdrawing, they polarize the double bond, making it susceptible to anionic attack. For the same reason, a carbocation intermediate is not favored.

The 1,1-disubstitution of chlorine atoms causes steric interactions in the polymer, as is evident from the heat of polymerization (see Table 1) (22). When corrected for the heat of fusion, the heat of polymerization is significantly less than the theoretical value of −83.7 kJ/mol (−20 kcal/mol) for the process of converting a double bond to two single bonds. The steric strain apparently is neither important in the addition step because VDC polymerizes easily, nor is it sufficient to favor depolymerization. The estimated ceiling temperature for PVDC is about 400°C.

Homopolymerization. The free-radical polymerization of VDC has been carried out by solution, slurry, suspension, and emulsion methods. Solution polymerization in a medium that dissolves both monomer and polymer has been

investigated (23). The kinetic measurements lead to activation energies and frequency factors in the normal range for free-radical polymerizations of olefinic monomers. The kinetic behavior of VDC is abnormal when the polymerization is heterogeneous (24). Slurry polymerizations are usually used only in the laboratory. They can be carried out in bulk or in common solvents, eg, benzene. Poly(vinylidene chloride) is insoluble in these media and separates from the liquid phase as a crystalline powder. The heterogeneity of the reaction makes stirring and heat transfer difficult; consequently, these reactions cannot be easily controlled on a large scale. Aqueous emulsion or suspension reactions are preferred for large-scale operations. Slurry reactions are usually initiated by the thermal decomposition of organic peroxides or azo compounds. Purely thermal initiation can occur, but rates are very low (25).

Bulk Polymerization. The spontaneous polymerization of VDC, so often observed when the monomer is stored at room temperature, is caused by peroxides formed from the reaction of VDC with oxygen. Very pure monomer does not polymerize under these conditions. Irradiation by either uv or γ rays (24,26) also induces polymerization of VDC.

The heterogeneous nature of the bulk polymerization of VDC is apparent from the rapid development of turbidity in the reaction medium following initiation. The turbidity results from the presence of minute PVDC crystals. As the reaction progresses, the crystalline phase grows and the liquid phase diminishes. Eventually, a point is reached where the liquid slurry solidifies into a solid mass. A typical conversion–time curve is shown in Figure 1 for a mass polymerization

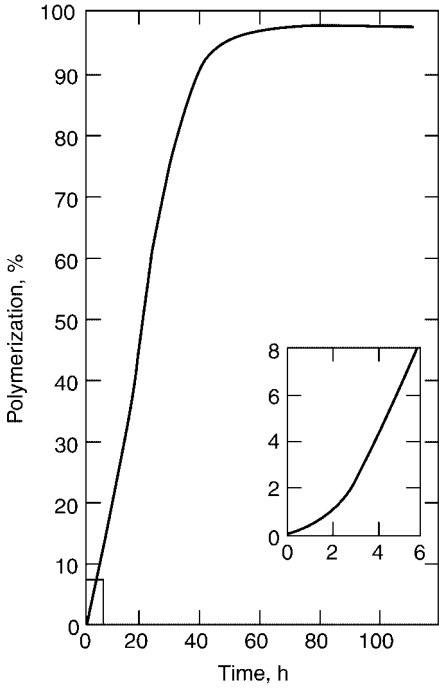

Fig. 1. Bulk polymerization of VDC at 45°C, with 0.5 wt% benzoyl peroxide as initiator (27).

catalyzed by benzoyl peroxide. The first stage of the reaction is characterized by rapidly increasing rate, which levels off in the second stage to a fairly constant value. This is often called the steady-state region. Throughout the first two stages, monomer concentration remains constant because the polymer separates into another phase. In the third stage, there is a gradual decrease in rate to zero as the monomer supply is depleted. Because the mass solidifies while monomer is still present (usually at conversions below 20%), further polymerization generates void space. The final solid, therefore, is opaque and quite porous. A similar pattern of behavior is observed when VDC is polymerized in solvents, eg, benzene, that do not dissolve or swell the polymer. In this case, however, the reaction mixture may not solidify if the monomer concentration is low.

Heterogeneous polymerization is characteristic of a number of monomers, including vinyl chloride and acrylonitrile. A completely satisfactory mechanism for these reactions has not been determined. This is true for VDC also. Earlier studies have not been broad enough to elucidate the mechanism (24,28,29). Morphologies of as-polymerized poly(vinyl chloride) (PVC) and polyacrylonitrile (PAN) are similar, suggesting a similar mechanism.

The morphology of as-polymerized PVDC is quite different (29). Nearly spherical aggregates form in the PVC and PAN systems, whereas anisotropic growth takes place in the PVDC case. The difference in morphology may be a consequence of the relative rates of polymerization and crystallization. Poly(vinylidene chloride) is unique because polymerization and crystallization probably occur nearly simultaneously. It has been reported that the average lifetime of a growing radical (τ_s) is between 0.1 and 10 s (30). The half-time ($t_{1/2}$) for crystallization of PVDC copolymers in monomer was measured to be about 1 s at 60°C and about 0.01 s at 90°C (31). This information is important for developing an understanding of a mechanism that includes a contribution from a surface reaction which has the potential for autoacceleration.

Emulsion Polymerization. Emulsion and suspension reactions are doubly heterogeneous; the polymer is insoluble in the monomer and both are insoluble in water. Suspension reactions are similar in behavior to slurry reactions. Oil-soluble initiators are used, and so the monomer–polymer droplet is like a small mass reaction. Emulsion polymerizations are more complex. Because the monomer is insoluble in the polymer particle, the simple Smith–Ewart theory does not apply (32).

A kinetic model for the particle growth stage for continuous-addition emulsion polymerization has been proposed (33). Below the monomer saturation point, the steady-state rate of polymerization, R_p, depends on the rate of monomer addition, R_a, according to the following reciprocal relationship:

$$\frac{1}{R_p} = \frac{1}{K} + \frac{1}{R_a}$$

where K depends on the number of particles and the propagation rate constant. A later study explored the kinetics of emulsion polymerization of nonswelling and swellable latex particles to define the locus of polymerization (34). There are no significant differences between the behavior of swelling and nonswelling emulsion particles and neither follows Smith–Ewart kinetics. The results indicate strongly that polymerization takes place at the particle–water interface or in a surface layer on the polymer particle.

Redox initiator systems are normally used in the emulsion polymerization of VDC to develop high rates at low temperatures. Reactions must be carried out below ~80°C to prevent degradation of the polymer. Poly(vinylidene chloride) in emulsion is also attacked by aqueous base. Therefore, reactions should be carried out at low pH.

Ionic Mechanisms. The instability of PVDC is one of the reasons why ionic initiation of VDC polymerization has not been used extensively. Many of the common initiators are sufficiently basic so as to promote E2 elimination of hydrogen chloride as the polymer is being formed. For example, butyllithium polymerizes VDC by an anionic mechanism, but the product is a low molecular weight, discolored polymer having a low chlorine content (35). Cationic polymerization of VDC seems unlikely in view of its structure (36). Some available data, however, suggest the possibility. In the low temperature, radiation-induced copolymerization of VDC with isobutylene, reactivity ratios vary markedly with temperature, indicating a change from a free-radical mechanism (37). Coordination complex catalysts may also polymerize VDC by a nonradical mechanism. Again, this speculation is based on copolymerization studies. Poly(vinylidene chloride) telomers can be prepared by using chlorine as the initiator and chain-transfer agent (38,39). Plasma polymerization of VDC in a radio-frequency glow discharge yields cross-linked polymer, which is partially degraded (40).

Copolymerization. The importance of VDC as a monomer results from its ability to copolymerize with other vinyl monomers. Its Q value equals 0.22 and its e value equals 0.36. It most easily copolymerizes with acrylates, but it also reacts, more slowly, with other monomers, eg, styrene, that form highly resonance-stabilized radicals. Reactivity ratios (r_1 and r_2) with various monomers are listed in Table 2. Many other copolymers have been prepared from monomers for which the reactivity ratios are not known. The commercially important copolymers include those with vinyl chloride (VC), acrylonitrile (AN), or various alkyl acrylates, but many commercial polymers contain three or more components, of which VDC is the principal one. Usually one component is introduced to improve the processibility or solubility of the polymer; the others are added to modify specific use properties. Most of these compositions have been described in the patent literature, and a list of various combinations has been compiled (41). A typical terpolymer might contain 90 wt% VDC, with the remainder made up of AN and an acrylate or methacrylate monomer.

Table 2. Reactivity of VDC (r_1) with Important Monomers (r_2)[a]

Monomer	r_1	r_2
Styrene	0.14	2.0
Vinyl chloride	3.2	0.3
Acrylonitrile	0.37	0.91
Methyl acrylate	1.0	1.0
Methyl methacrylate	0.24	2.53
Vinyl acetate	6	0.1

[a]Ref. 42.

Bulk copolymerizations yielding high VDC-content copolymers are normally heterogeneous. Two of the most important pairs, VDC–VC and VDC–AN, are heterogeneous over most of the composition range. In both cases and at either composition extreme, the product separates initially in a powdery form; however, for intermediate compositions, the reaction mixture may only gel. Copolymers in this composition range are swollen but not completely dissolved by the monomer mixture at normal polymerization temperatures. Copolymers containing more than 15 mol% acrylate are normally soluble in the monomers. These reactions are therefore homogeneous and, if carried to completion, yield clear, solid castings of the copolymer. Most copolymerizations can be carried out in solution because of the greater solubility of the copolymers in common solvents.

During copolymerization, one monomer may add to the copolymer more rapidly than the other. Except for the unusual case of equal reactivity ratios, batch reactions carried to completion yield polymers of broad composition distribution. More often than not, this is an undesirable result.

Vinylidene chloride copolymerizes randomly with methyl acrylate and nearly so with other acrylates. Very severe composition drift occurs, however, in copolymerizations with vinyl chloride or methacrylates. Several methods have been developed to produce homogeneous copolymers regardless of the reactivity ratio (42). These methods are applicable mainly to emulsion and suspension processes where adequate stirring can be maintained. Copolymerization rates of VDC with small amounts of a second monomer are normally lower than its rate of homopolymerization. The kinetics of the copolymerization of VDC and VC has been studied (43–46).

Studies of the copolymerization of VDC with methyl acrylate (MA) over a composition range of 0–16 wt% showed that near the intermediate composition (8 wt%), the polymerization rates nearly followed normal solution polymerization kinetics (47). However, at the two extremes (0 and 16 wt% MA), copolymerization showed significant autoacceleration. The observations are important because they show the significant complexities in these copolymerizations. The autoacceleration for the homopolymerization, ie, 0 wt% MA, is probably the result of a surface polymerization phenomenon. On the other hand, the autoacceleration for the 16 wt% MA copolymerization could be the result of Trommsdorff and Norrish-Smith effects.

Copolymers of VDC can also be prepared by methods other than conventional free-radical polymerization. Copolymers have been formed by irradiation and with various organometallic and coordination complex catalysts (26,41,48–51). Graft copolymers have also been described (52–56).

Polymer Structure and Properties

Chain Structure. The chemical composition of PVDC has been confirmed by various techniques, including elemental analysis, x-ray diffraction analysis, degradation studies, and infrared (ir), Raman, and nuclear magnetic resonance (nmr) spectroscopy. The polymer chain is made up of VDC units added head-to-tail:

$$—CH_2CCl_2—CH_2CCl_2—CH_2CCl_2—$$

Because the repeat unit is symmetrical, no possibility exists for stereoisomerism. Variations in structure can occur only by head-to-head addition, branching, or degradation reactions that do not cause chain scission, including such reactions as thermal dehydrochlorination, which creates double bonds in the structure to give, for example, $-CH_2CCl_2CH_2{=}CClCH_2CCl_2-$ and a variety of ill-defined oxidation and hydrolysis reactions that generate carbonyl groups.

The ir spectra of PVDC often show traces of unsaturation and carbonyl groups. The slightly yellow tinge of many of these polymers comes from the same source; the pure polymer is colorless. Elemental analyses for chlorine are normally slightly lower than the theoretical value of 73.2%.

The high crystallinity of PVDC indicates that no significant amounts of head-to-head addition or branching can be present. This has been confirmed by nmr spectra (57). Studies of well-characterized oligomers having degrees of polymerization (DP) of 2–10 offer further nmr evidence (38), ie, a single peak from the methylene hydrogens. Either branching or another mode of addition would produce nonequivalent hydrogens and a more complicated spectrum. However, nmr cannot detect small amounts of such structures. The ir and Raman spectra can also be interpreted in terms of the simple head-to-tail structure (58,59).

Molecular weights of PVDC can be determined directly by dilute solution measurements in good solvents (60). Viscosity studies indicate that polymers having DP from 100 to more than 10,000 are easily obtained. Dimers and polymers having DP < 100 can be prepared by special procedures (38). Copolymers can be more easily studied because of their solubility in common solvents. Gel-permeation chromatography studies indicate that molecular weight distributions are typical of vinyl copolymers.

Crystal Structure. The crystal structure of PVDC is fairly well established. Several unit cells have been proposed (61). The unit cell contains four monomer units with two monomer units per repeat distance. The calculated density, 1.96 g/cm^3, is higher than the experimental values, which are 1.80–1.94 g/cm^3 at 25°C, depending on the sample. This is typically the case with crystalline polymers because samples of 100% crystallinity usually cannot be obtained. A direct calculation of the polymer density from volume changes during polymerization yields a value of 1.97 g/cm^3 (62). If this value is correct, the unit cell densities may be low.

The repeat distance along the chain axis (0.468 nm) is significantly less than that calculated for a planar zigzag structure. Therefore, the polymer must be in some other conformation (63–65). Based on ir and Raman studies of PVDC single crystals and normal vibration analysis, the best conformation appears to be $\theta_\phi\theta_{\phi'}$, where the skeletal angle θ is 120°, and the torsional angle $\phi(\phi'$ of opposite sign) is 32.5°. This conformation is in agreement with theoretical predictions (66).

The melting temperature T_m of PVDC is independent of molecular weight above DP = 100. However, as shown in Figure 2, it drops sharply at lower molecular weights. Below the hexamer, the products are noncrystalline liquids.

The properties of PVDC (Table 3) are usually modified by copolymerization. Copolymers of high VDC content have lower melting temperatures than PVDC. Copolymers containing more than ~15 mol% acrylate or methacrylate are amorphous. Substantially more AN (25%) or VC (45%) is required to destroy crystallinity completely.

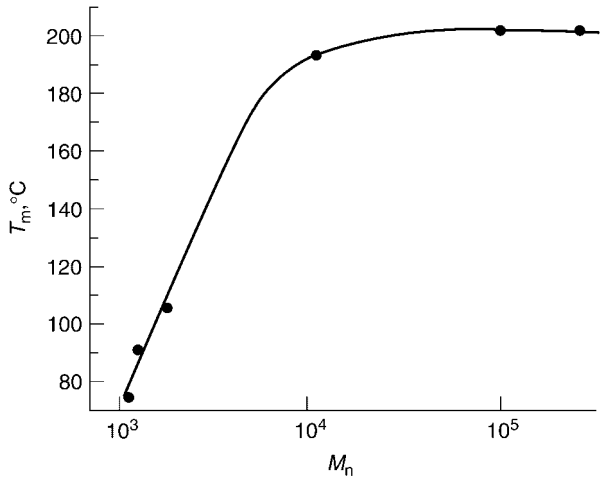

Fig. 2. Crystalline melting temperatures of PVDC (38).

The effect of different types of comonomers on T_m varies. VDC–MA copolymers more closely obey Flory's melting-point depression theory than do copolymers with VC or AN. Studies have shown that for the copolymers of VDC with MA, Flory's theory needs modification to include both lamellar thickness and surface free energy (67). The VDC–VC and VDC–AN copolymers typically have severe composition drift; therefore most of the comonomer units do not belong to crystallizing chains. Hence, they neither enter the crystal as defects nor cause lamellar thickness to decrease, and so the depression of the melting temperature is less than expected.

The glass-transition temperature T_g, of VDC copolymers has been studied extensively (68,69). The effect of various comonomers on the T_g is shown in Figure 3. In every case, T_g increases with the comonomer content at low comonomer levels, even in cases where the T_g of the other homopolymer is lower. The phenomenon has been observed in several other copolymer systems as well (71). In these cases, a maximum T_g is observed at intermediate compositions. In others, where the T_g of the other homopolymer is much higher than the T_g of

Table 3. Properties of PVDC

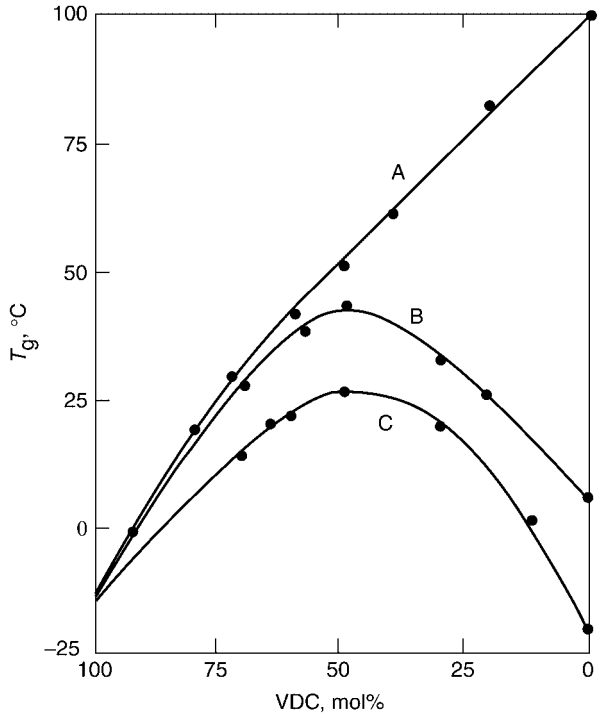

Fig. 3. Effect of comonomer structure on the glass-transition temperature of VDC copolymers (71), where A represents AN; B, MA; and C, EA.

PVDC, the glass-transition temperatures of the copolymers increase over the entire composition range. The T_g increases most rapidly at low AN levels but changes the slowest at low VC levels. This suggests that polar interactions affect the former, but the increase in T_g in the VDC–VC copolymers may simply result from loss of chain symmetry. Because of these effects, the temperature range in which copolymers can crystallize is drastically narrowed. Crystallization induction times are prolonged, and subsequent crystallization takes place at a low rate over a long period of time. Plasticization, which lowers T_g, decreases crystallization induction times significantly. Copolymers having lower glass-transition temperatures also tend to crystallize more rapidly (72).

Crystallization curves have been determined for 10 mol% acrylate copolymers of varying side-chain length. Among the acrylate copolymers, the butyl acrylate copolymer has a T_g of 8°C; the octyl acrylate, −3°C; and the octadecyl acrylate, −16°C. The rates of crystallization of these copolymers are inversely related to the glass-transition temperatures. Apparently, the long alkyl side chains act as internal plasticizers, lowering the melt viscosity of the copolymer even though the acrylate group acts to stiffen the backbone.

The maximum rates of crystallization of the more common crystalline copolymers occur at 80–120°C. In many cases, these copolymers have broad composition distributions containing both fractions of high VDC content that crystallize rapidly and other fractions that do not crystallize at all. Poly(vinylidene chloride)

probably crystallizes at a maximum rate at 140–150°C, but the process is difficult to follow because of severe polymer degradation. The copolymers may remain amorphous for a considerable period of time if quenched to room temperature. The induction time before the onset of crystallization depends on both the type and amount of comonomer; PVDC crystallizes within minutes at 25°C.

Recrystallization of a copolymer having 15 wt% VC has been found to be nucleated by material that survives the melting process plus new nuclei (72). The maximum crystallization rate occurred at 100°C; the maximum nucleation rate at 10°C. Attempts to melt all the polymer led to degradation that interfered with recrystallization.

Orientation or mechanical working accelerates crystallization has a pronounced effect on morphology. Crystals of uniaxially oriented filaments are oriented along the fiber axis (61). The long period (lamellar thickness), as determined by small-angle x-ray scattering, is 7.6 nm and decreases with comonomer content. The fiber is 43% crystalline and has a melting temperature of 195°C and an average crystal thickness of 4.5 nm. The crystal size is not greatly affected by comonomer content, but both crystallinity and melting temperature decrease with increasing comonomer.

Copolymerization also affects morphology under other crystallization conditions. Copolymers in the form of cast or molded sheets are much more transparent because of the small spherulite size. In extreme cases, crystallinity cannot be detected optically, but its effect on mechanical properties is pronounced. Before crystallization, films are soft and rubbery, with low modulus and high elongation. After crystallization, they are leathery and tough, with higher modulus and lower elongation.

Copolymers of VDC and MA have been studied by x-ray techniques (73). For example, the long period (lamellar thickness) for an 8.5 wt% MA copolymer was found to be 9.2 nm by small-angle x-ray scattering. The unit cell is monoclinic, with $a = 0.686$ and $c = 1.247$ nm by wide-angle x-ray scattering.

Significant amounts of comonomer also reduce the ability of the polymer to form lamellar crystals from solution. In some cases, the polymer merely gels the solution as it precipitates rather than forming distinct crystals. At somewhat higher VDC content, it may precipitate in the form of aggregated, ill-defined particles and clusters.

Morphology and Transitions. The highly crystalline particles of PVDC precipitated during polymerization are aggregates of thin lamellar crystals (74). The substructures are 5–10 nm thick and 100 or more times larger in other dimensions. In some respects, they resemble the lamellar crystals grown from dilute solution (75–77). The single crystals are better characterized than the as-polymerized particles. They are highly branched, with branching angles of 65–70°; the angle appears to be associated with a twin plane in the crystal (78).

Melting temperatures of as-polymerized powders are high, ie, 198–205°C as measured by differential thermal analysis (dta) or hot-stage microscopy (74). Two peaks are usually observed in dta curves: a small lower temperature peak and the main melting peak. The small peak seems to be related to polymer crystallized by precipitation rather than during polymerization.

As-polymerized PVDC does not have a well-defined T_g because of its high crystallinity. However, a sample can be melted at 210°C and quenched rapidly to

an amorphous state at $< -20^{\circ}C$. The amorphous polymer has a glass-transition temperature of $-17^{\circ}C$ as shown by dilatometry (68). Glass-transition temperature values of -19 to $-11^{\circ}C$, depending on both method of measurement and sample preparation, have been determined.

Once melted, PVDC does not regain its as-polymerized morphology when subsequently crystallized. The polymer recrystallizes in a spherulitic habit. Spherulites between crossed polarizing plates show the usual Maltese cross and are positively birefringent. The size and number of spherulites can be controlled. Quenching and low-temperature annealing generate many small nuclei that, on heating, grow rapidly into small spherulites. Slow crystallization at higher temperatures produces fewer but much larger spherulites. The melting temperature and degree of crystallinity of recrystallized PVDC also depend on crystallization conditions. The melting temperature increases with crystallization temperature, but the as-polymerized value cannot be achieved. There is no reason to believe that even these values indicate the true melting point of PVDC; it may be as high as $220^{\circ}C$. Slow, high temperature recrystallization and annealing experiments are not feasible because of the thermal instability of the polymer (79). Other transitions in PVDC have been observed by dynamic mechanical methods.

Solubility and Solution Properties. Poly(vinylidene chloride), like many high melting polymers, does not dissolve in most common solvents at ambient temperatures. Copolymers, particularly those of low crystallinity, are much more soluble. However, one of the outstanding characteristics of VDC polymers is resistance to a wide range of solvents and chemical reagents. The insolubility of PVDC results less from its polarity than from its high melting temperature. It dissolves readily in a wide variety of solvents above $130^{\circ}C$ (79). However, it should be noted that significant degradation accompanies dissolution of the polymer in polar, aprotic solvents at these temperatures.

The polarity of the polymer is important only in mixtures having specific polar aprotic solvents. Many solvents of this general class solvate PVDC strongly enough to depress the melting temperature by more than $100^{\circ}C$. Solubility is normally correlated with cohesive energy densities or solubility parameters. For PVDC, a value of 20 ± 0.6 $(J/cm^3)^{1/2}$ [10 ± 0.3 $(cal/cm^3)^{1/2}$] has been estimated from solubility studies in nonpolar solvents. The value calculated from Small's relationship is 20.96 $(J/cm^3)^{1/2}$ [10.25 $(cal/cm^3)^{1/2}$]. The use of the solubility parameter scheme for polar crystalline polymers such as PVDC has limited value. A typical nonpolar solvent of matching solubility parameter is tetrahydronaphthalene. The lowest temperature at which PVDC dissolves in this solvent is $140^{\circ}C$. Specific solvents, however, dissolve PVDC at much lower temperatures. A list of good solvents is given in Table 4. The relative solvent activity is characterized by the temperature at which a 1 wt% mixture of polymer in solvent becomes homogeneous when heated rapidly.

Poly(vinylidene chloride) also dissolves readily in certain solvent mixtures (80). One component must be a sulfoxide or *N*,*N*-dialkylamide. Effective cosolvents are less polar and have cyclic structures. They include aliphatic and aromatic hydrocarbons, ethers, sulfides, and ketones. Acidic or hydrogen-bonding solvents have an opposite effect, rendering the polar aprotic component less effective. Both hydrocarbons and strong hydrogen-bonding solvents are nonsolvents for PVDC.

Table 4. Solvents for PVDC[a]

Solvents	T,[b] °C
Nonpolar	
1,3-Dibromopropane	126
Bromobenzene	129
1-Chloronaphthalene	134
2-Methylnaphthalene	134
o-Dichlorobenzene	135

Cyclooctanone	90
Cycloheptanone	96
Di-*n*-butyl sulfoxide	98

[a]Ref. 79.
[b]Temperature at which a 1 wt% mixture of polymer in solvent becomes homogeneous.

As-polymerized PVDC is not in its most stable state; annealing and recrystallization can raise the temperature at which it dissolves (76). Low crystallinity polymers dissolve at a lower temperature, forming metastable solutions. However, on standing at the dissolving temperature, they gel or become turbid, indicating recrystallization into a more stable form.

Copolymers having enough VDC content to be quite crystalline behave much like PVDC. They are more soluble, however, because of their lower melting temperatures. The solubility of amorphous copolymers is much higher. The selection of solvents in either case varies somewhat with the type of comonomer. Some of the more common types are listed in Table 5. Solvents that dissolve PVDC also dissolve the copolymers at lower temperatures. The identification of solvents that dissolve PVDC at low temperatures makes possible the study of dilute solution properties. Both light-scattering and intrinsic-viscosity studies have been reported (60). Intrinsic viscosity–molecular weight relationships for the three solvents investigated ($[\eta]$ in dL/g) are

(1) $[\eta] = 1.31 \times 10^{-4} M_\omega^{0.69}$ N-Methylpyrrolidinone (MP)
(2) $[\eta] = 1.39 \times 10^{-4} M_\omega^{0.69}$ Tetramethylene sulfoxide (TMSO)
(3) $[\eta] = 2.58 \times 10^{-4} M_\omega^{0.65}$ Hexamethylphosphoramide (HMPA).

Table 5. Common Solvents for VDC Copolymers

Solvents	Copolymer type	Temperature, °C
Tetrahydrofuran	All	<60
2-Butanone	Low crystallinity	<80
1,4-Dioxane	All	50–100
Cyclohexanone	All	50–100
Cyclopentanone	All	50–100
Ethyl acetate	Low crystallinity	<80
Chlorobenzene	All	100–130
Dichlorobenzene	All	100–140
Dimethylformamide	High acrylonitrile	<100

The relative solvent power (HMPA > TMSO > MP) agrees with solution-temperature measurements. The characteristic ratio C_∞ is about 8 ± 1, which is slightly larger than that of a similar polymer, polyisobutylene.

The dilute solution properties of copolymers are similar to those of the homopolymer. The intrinsic viscosity–molecular weight relationship for a VDC–AN copolymer (9 wt% AN) is $[\eta] = 1.06 \times 10^{-4} M_\omega^{0.72}$ (81). The characteristic ratio is 8.8 for this copolymer.

An extensive investigation of the dilute solution properties of several acrylate copolymers has been reported (78). The behavior is typical of flexible-backbone vinyl polymers. The length of the acrylate ester side chain has little effect on properties.

Intrinsic viscosity–molecular weight relationships have been obtained for copolymers in methyl ethyl ketone. The value for a 15 wt% ethyl acrylate (EA) copolymer is $[\eta] = 2.88 \times 10^{-4} M_\omega^{0.6}$.

Earlier work characterized the molecular weights of PVDC and VDC copolymers by using the absolute viscosity of a 2 wt% solution in *o*-dichlorobenzene at 140°C. The exact correlation between this viscosity value and molecular weight is not known. Gel-permeation chromatography is the preferred method for characterizing molecular weight; studies of copolymers have been reported (82,83).

Mechanical Properties. Because PVDC is difficult to fabricate into suitable test specimens, very few direct measurements of its mechanical properties have been made. In many cases, however, the properties of copolymers have been studied as functions of composition, and the properties of PVDC can be estimated by extrapolation. Some characteristic properties of high VDC content, unplasticized copolymers are listed in Table 6. The performance of a given specimen is sensitive to morphology, including the amount and kind of crystallinity, as well as orientation. Tensile strength increases with crystallinity, whereas toughness and elongation decrease. Orientation, however, improves all three properties. The effect of stretch ratio applied during orientation on properties of VDC–VC monofilaments is shown in Table 7.

The dynamic mechanical properties of VDC–VC copolymers have been studied in detail. The incorporation of VC units in the polymer results in a drop in dynamic modulus because of the reduction in crystallinity. However, the glass-transition temperature is raised; therefore, the softening effect observed at room

Table 6. Mechanical Properties of High VDC Content Copolymers

[a]To convert MPa to psi, multiply by 145.
[b]To convert J/m to ft·lbf/in., divide by 53.38 (see ASTM D256).

temperature is accompanied by increased brittleness at lower temperatures. These copolymers are normally plasticized in order to avoid this. Small amounts of plasticizer (2–10 wt%) depress T_g significantly without loss of strength at room temperature. At higher levels of VC, the T_g of the copolymer is above room temperature and the modulus rises again. A minimum in modulus or maximum in softness is usually observed in copolymers in which T_g is above room temperature. A thermomechanical analysis of VDC–AN and VDC–MMA (methyl methacrylate) copolymer systems shows a minimum in softening point at 79.4 and 68.1 mol% VDC, respectively (84).

In cases where the copolymers have substantially lower glass-transition temperatures, the modulus decreases with increasing comonomer content. This results from a drop in crystallinity and glass-transition temperature. The loss in modulus in these systems is therefore accompanied by an improvement in low temperature performance. However, at low acrylate levels (<10 wt%), T_g increases with comonomer content. The brittle points in this range may therefore be higher than that of PVDC.

Table 7. Effect of Stretch Ratio on Tensile Strength and Elongation of a VDC–VC Copolymer[a,b]

Stretch ratio	Tensile strength, MPa[c]	Elongation, %

The long side chains of the acrylate ester group can apparently act as internal plasticizers. Substitution of a carboxyl group on the polymer chain increases brittleness. A more polar substituent, eg, an *N*-alkylamide group, is even less desirable. Copolymers of VDC with *N*-alkylacrylamides are more brittle than the corresponding acrylates even when the side chains are long (85). Side-chain crystallization may be a contributing factor.

Barrier Properties. Vinylidene chloride copolymers are unique in that they have low permeability to a wider range of gases and liquids than other polymers. VDC copolymers are "barrier polymers" in a broad sense. Historically, the operating definition of a barrier polymer meant having an oxygen permeability less than 1.0 (cm^3(STP)·mil)/(100 $in.^2$·day·atm) [2.0 nmol/(m·s·GPa)]. A more useful descriptor for a barrier polymer is related to the application. A barrier polymer would have a set of permeabilities for important molecules sufficiently low to satisfy the containment needs. Some polymers have low permeability to gases. Others have low permeability to water. Still other polymers have low permeability to flavor/aroma/solvent (F/A/S) molecules. However, only rarely does a single polymer have low permeability in more than one category. VDC copolymers have low permeability in all three categories (see BARRIER POLYMERS).

The good barrier properties of VDC copolymers are a consequence of crystallinity and low free volume in the amorphous phase. The symmetric nature of the VDC unit in the polymer leads to nested packing that is adequate for crystallization and that leaves very little "dead" volume in the amorphous phase. Both polyisobutylene and PVDC have unusually low permeability to water compared to their monosubstituted counterparts, polypropylene and PVC (86). The values listed in Table 8 include estimates for the completely amorphous polymers. The estimated value for highly crystalline PVDC was obtained by extrapolating data for copolymers.

The effect of copolymer composition on gas permeability is shown in Table 9. The inherent barrier in VDC copolymers can best be exploited by using films containing little or no plasticizers and as much VDC as possible. However, the permeabilities of even completely amorphous copolymers, eg, 60 wt% VDC–40 wt% AN or 50 wt% VDC–50 wt% VC, are low compared to that of other polymers. The primary reason is that the diffusion coefficients for molecules in VDC copolymers

are very low. This factor, together with the high crystallinity and the low solubility coefficients for many gases in VDC copolymers, results in very low permeabilities. A change from PVDC to a copolymer containing 40 wt% AN or 50 wt% VC increases the permeability 10-fold but has little effect on the solubility coefficient.

The addition of a more polar comonomer, eg, AN, increases the water vapor transmission rate more than the addition of a less polar comonomer, eg, VC, when other factors are constant. For the same reason, AN copolymers are more resistant to penetrants of low cohesive energy density. All VDC copolymers, however, are very impermeable to aliphatic hydrocarbons. Comonomers that lower T_g and increase the free volume in the amorphous phase increase permeabilities more than other comonomers. Higher acrylates are examples of this phenomenon. Plasticizers increase permeabilities for similar reasons.

The effects of plasticizers and temperature on the permeabilities of small molecules in a typical VDC copolymer have been studied thoroughly. Data for oxygen permeability are contained in Figure 4. The oxygen permeability doubles with the addition of about 1.7 phr (parts per hundred of resin) of common plasticizers or a temperature increase of about 8°C (89). The moisture (water) vapor transmission rate (MVTR or WVTR) doubles with the addition of about 3.5 phr of common plasticizers (90). The dependence of the WVTR on temperature is a little more complicated. Water vapor transmission rate is commonly reported at a constant difference in relative humidity and not at a constant partial pressure

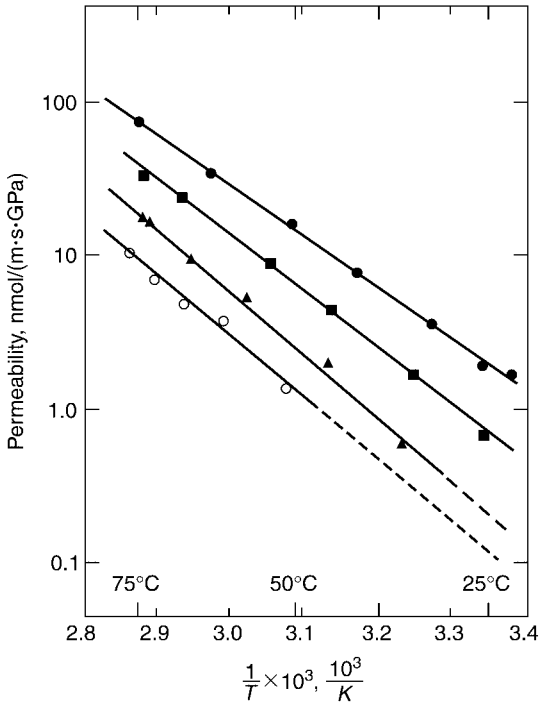

Fig. 4. Oxygen permeability in a VDC copolymer film at selected levels of plasticizer (Citroflex A-4). Plasticizer level in parts per hundred of resin (phr); ●, 7.2 phr; ■, 4.9 phr; ▲, 2.7 phr; and ○, 0.5 phr. To convert nmol/(m·s·GPa) to $(cm^3 \cdot mil)/(100\ in.^2 \cdot d \cdot atm)$, divide by 2.

difference. Hence, WVTR is a mixed term that increases with increasing temperature because both the permeability and the partial pressure at constant relative humidity increase. Carbon dioxide permeability doubles with the addition of about 1.8 phr of common plasticizers, or a temperature increase of 7°C (91).

Table 10 contains a comparison of the permeabilities of small molecules for several common polymers. The oxygen permeability is an important property for food packaging. In some cases the relative humidity is an important environmental variable. The oxygen permeability is not affected by humidity for VDC copolymers, nitrile barrier resins, poly(vinyl chloride), polystyrene, and polyolefins. The oxygen permeabilities of most nylons are increased modestly by increasing humidity, and the oxygen permeability of poly(ethylene terephthalate) is decreased modestly by increasing humidity. In contrast, the ethylene–vinyl alcohol copolymers (EVOH) are very sensitive to humidity. At low humidity, the oxygen permeabilities of EVOH are quite low. However, at the high humidity encountered in food packaging, the oxygen permeabilities of EVOH are much higher. Small changes in humidity can cause large changes in the oxygen permeabilities. Hence the data in tables need to be used carefully.

The data in Tables 11, 12, 13 describe VDC copolymers as good barriers for both gases and water. They are also good barriers to F/A/S molecules. This property for polymers has become more important since more sophisticated foods

are being packaged in plastics. The permeation of F/A/S molecules differs from the permeation of small molecules in some important ways. The diffusion coefficient D for F/A/S molecules is typically 10^2–10^5 times smaller. These molecules move slower because they need to find larger openings in the polymer. The solubility coefficient S is typically 10^2–10^6 times larger. This is related to higher boiling

temperatures. Table 11 compares the D and S of large and small molecules in several polymers. A low D and a high S may mean that the principal mechanism for flavor loss is its being lost into the package wall (also known as scalping).

Humidity does not affect the permeability, diffusion coefficient, or solubility coefficient of F/A/S molecules in VDC copolymers. Studies using *trans*-2-hexenal and *d*-limonene are compared in Table 12. The transport in an EVOH copolymer is strongly plasticized by humidity.

[b]Values for VDC copolymer and EVOH copolymer are extrapolated from higher temperatures.
[c]Permeation in the VDC copolymer and the polyolefins is not affected by humidity; the permeability and diffusion coefficient in the EVOH copolymer can be as much as 1000 times greater with high humidity.
[d]To convert MZU (10^{-20} kg·m)/(m^2·s·Pa) to nmol/(m·s·GPa), divide by molecular weight of permeant/10.

Table 13 contains some representative data for the permeation of F/A/S molecules. VDC copolymers are good barriers to the migration of F/A/S molecules. Dry EVOH copolymers are also good barriers to the migration of F/A/S molecules. However, polyolefins are not good barriers to F/A/S molecules. The fact that most glassy polymers are good barriers to the migration of F/A/S molecules is not shown in this table.

Degradation Chemistry. Vinylidene chloride polymers are highly resistant to oxidation, permeation of small molecules, and biodegradation, which makes them extremely durable under most use conditions. However, these materials are thermally unstable and, when heated above about 120°C, undergo degradative dehydrochlorination. Furthermore, the homopolymer degrades with rapid evolution of hydrogen chloride within a few degrees of its melting temperature (200°C). For this reason, the superior characteristics of the homopolymer cannot be exploited. As a consequence, the copolymers of VDC with vinyl chloride, alkyl acrylates or methacrylates, acrylonitrile or methacrylonitrile, rather than the homopolymer, have come to commercial prominence. Such copolymers have often served as substrates for a study of the degradation reaction (101–104).

The thermal degradation of VDC copolymers occurs in two distinct steps. The first involves degradative dehydrochlorination via a chain process to generate poly(chloroacetylene) sequences (103,105). Subsequent Diels–Alder-type condensation between conjugated sequences affords a highly cross-linked network, which, upon further dehydrochlorination, leads to the formation of a large-surface-area, highly absorptive carbon (1,106). The initial dehydrochlorination occurs at moderate temperatures and is a typical chain process involving distinct initiation, propagation, and termination phases (107,108). Initiation is thought to occur via carbon–chlorine bond scission promoted by a defect structure within the polymer. An effective defect site in these polymers is unsaturation (105). Introduction of a random double bond produces an allylic dichloromethylene unit activated for carbon–chlorine bond scission. Initiation by the thermally induced cleavage of this bond, followed by propagation by successive dehydrochlorination along the chain, ie, the so-called unzipping reaction, can then proceed readily (Fig. 5).

The thermal stability of these polymers is decreased by pretreatment with uv irradiation (109), electron-beam irradiation (110), and basic solvents or reagents (111,112); by an atmosphere of oxygen (109,113–116) or nitric oxide (109); and by the presence of peroxide linkages within the polymer (113,117), residues of emulsifying agents (113), organometallic initiator residues (113), ash from a previous decomposition (113), peroxide initiator residues (109–113,117–120), or metal ions (121). All the foregoing are sufficient to introduce random double bonds into the polymer structure. This can be demonstrated by examination of the treated sample by uv and ir spectroscopic methods (110). Prolonged treatment of the polymer with basic reagents leads to more extensive dehydrohalogenation (121–126). In fact, electrolysis of a solution of tetra(*n*-butyl)ammonium perchlorate in *N*,*N*-dimethylformamide generates a basic medium, presumably containing the formamide radical anion, capable of degrading the polymer (127). High energy radiation from a variety of sources may induce damage of several kinds, including carbon–carbon bond cleavage (109). A prominent radiation-induced process is carbon–chlorine bond scission followed by elimination of hydrogen chloride

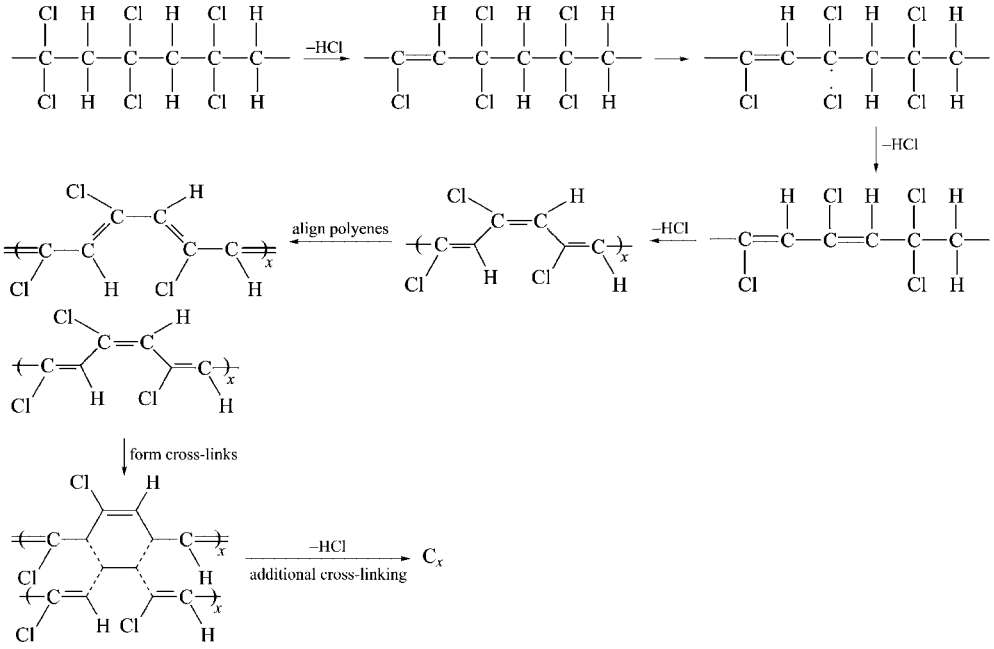

Fig. 5. Schematic of the degradation of PVDC to carbon.

(128,129). Property changes other than a decrease in thermal stability may arise as a consequence of high energy irradiation (130,131).

The principal steps in the thermal degradation of VDC polymers are formation of a conjugated polyene sequence followed by carbonization.

$$\left(CH_2{-}CCl_2\right)_n \xrightarrow{\text{fast, }\Delta} \left(CH{=}CCl\right)_n + n\,HCl \xrightarrow{\text{carbonization, slow, }\Delta} 2n\,C + n\,HCl$$

On being heated, the polymer gradually changes color from yellow to brown and finally to black. Early in the reaction, the polymer becomes insoluble, which indicates that cross-linking has occurred. The temperature of melting decreases, and the presence of unsaturation may be detected by spectroscopic (uv, ir, nmr) methods. The polymer eventually becomes infusible, and the crystal structure as detected by x-ray diffraction disappears even though the gross morphology is retained (132). The presence of carbon radicals can be detected by electron spin resonance (esr) measurements. If the temperature is raised substantially above 200°C, aromatic structures are formed. Finally, at very high temperatures (>700°C), complete carbonization occurs.

The first of these reactions, ie, the loss of the first mole of hydrogen chloride, has had the greatest impact on the end use of VDC polymers and has been the most studied and well characterized. The propensity of these polymers to undergo degradation is influenced by a wide variety of factors, including physical changes in the solid (annealing effects) and the method of preparation and purity of the polymer. The most stable polymers are those produced by bulk polymerization at low temperature with the use of a nonoxygen initiator. In general, the stability of

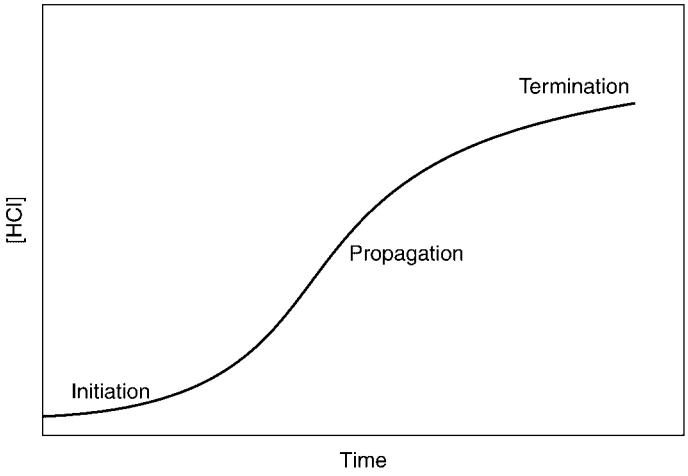

Fig. 6. Hydrogen chloride evolution for the thermal degradation of a typical VDC polymer.

the polymer reflects the method of preparation, with bulk > solution > suspension ≫ emulsion (133). In the absence of elevated temperatures, suspending agents, polar solvents, redox initiators, etc, a more perfect polymer structure is formed, ie, one containing a minimum level of unsaturation.

The impact of a less defective structure may be seen in Figure 6, which depicts hydrogen chloride evolution for the thermal degradation of a typical VDC polymer. Initiation of degradation occurs at activated allylic sites within the polymer, but initiation does not occur simultaneously at all sites. Therefore, early in the reaction, hydrogen chloride evolution increases as a function of time as initiation occurs at more and more sites. In other words, unzipping is started in an increasing number of chain segments. This gives rise to the acceleratory induction period characteristic of VDC copolymer degradation. When a greater number of initiation sites are present within the polymer, ie, at higher levels of unsaturation, the rate of hydrogen chloride evolution during the initiation phase of the degradation is greater. After unzipping has begun in all chains containing defect structures, hydrogen chloride production is essentially first order until termination by completion or other means becomes a prominent reaction. Undoubtedly, some random double-bond initiation continues to occur during propagation. However, during this period termination is roughly in balance with initiation. As the rate of termination significantly exceeds that of initiation, deceleration of degradation is observed (105,108,109). An accurate representation of the dehydrochlorination reaction over the entire range of degradation may be achieved using a kinetic expression containing two constants (107,134).

Since the low temperature degradation, ie, that which occurs at process temperatures, involves only dehydrochlorination of VDC sequences, mass loss reflecting evolution of hydrogen chloride provides a convenient means of monitoring polymer decomposition. Thus, thermogravimetry analysis (tga) is an appropriate method for assessing the degradation characteristics of VDC polymers (135,136). Rate constants may be obtained as the slopes of the appropriate linear portions of a plot of $\ln[w_\infty - w_0)/(\mathrm{w}_\infty - w_\mathrm{t})]$ versus time. The variable w_∞ is the weight of

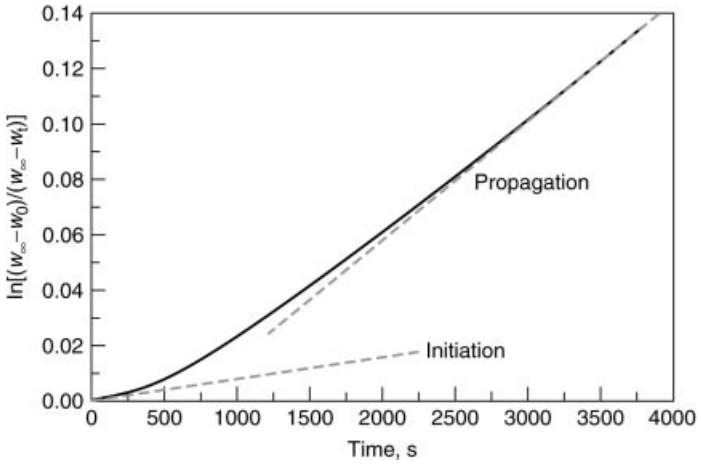

Fig. 7. Thermal degradation of a typical VDC polymer.

the sample at infinite time (t_∞) taken as that weight which would remain after 37.62% of the initial VDC component weight (corresponding to the complete loss of 1 mole of hydrogen chloride per VDC unit in the copolymer). The variable w_0 is the weight at time zero (t_0), ie, the time at which the first point was recorded, and w_t is the weight at any time t during the run. This is illustrated for a typical VDC polymer in Figure 7.

Initiation rate constants (k_i) for the degradation may be obtained by least-squares analysis of the linear segment of the early portion of this plot. Propagation rate constants (k_p) may be obtained in a similar manner from data obtained later in the run when propagation has become the dominant reaction. This is illustrated in Figures 8 and 9. Table 14 shows the rate constants obtained in this manner for the degradation of VDC/butyl acrylate copolymers.

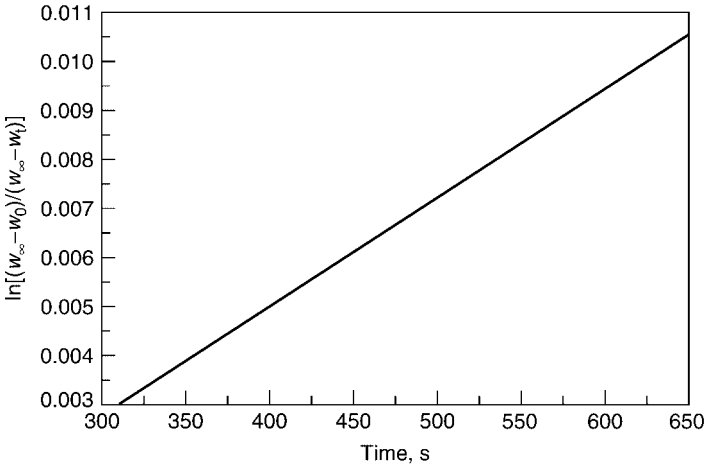

Fig. 8. Initiation rate constant (k_i) for the thermal degradation of a typical VDC polymer.

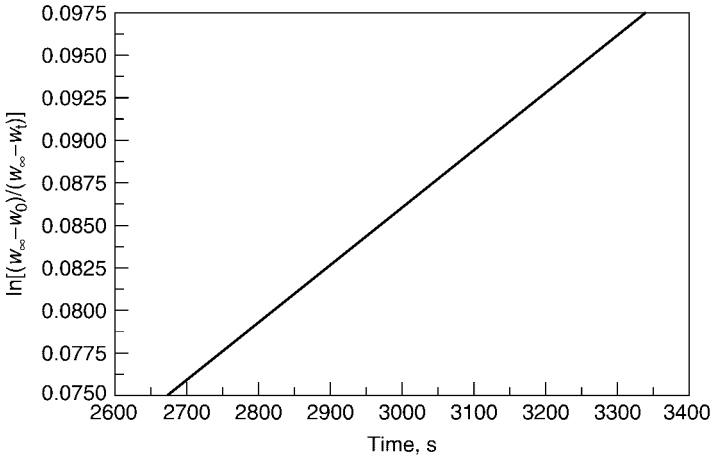

Fig. 9. Propagation rate constant (k_p) for the thermal degradation of a typical VDC polymer.

Much evidence has been accumulated to establish the radical nature of the degradation reaction (1). Prominent components of this include slight inhibition of the reaction by certain radical scavengers and changes in the esr spectrum of a sample undergoing degradation (137,138). Both suggest that radical intermediates are generated during the degradation. The exact nature of the chain-carrying species is made more apparent from the results of degradation in bibenzyl solution (103,105). Bibenzyl is an efficient radical scavenger that is converted to stilbene on interaction with a radical. Stilbene can be readily quantitated by gas–liquid partition chromatography. For the degradation of typical VDC polymers, the ratio of hydrogen chloride evolved to stilbene produced is approximately 35:1 (103,105). This is in sharp contrast to the 2:1 ratio expected for trapping of chlorine atoms with perfect efficiency and suggests that the propagating species is a radical pair that does not dissociate appreciably. Thus propagation most probably occurs by a radical chain process in which the chain-carrying species is a radical pair that decomposes to alkene and hydrogen chloride without dissociation.

Table 14. Rate Constants for the Thermal Degradation of Vinylidene Chloride/Butyl Acrylate Copolymers at 180°C

Butyl acrylate, wt%[a]	k_i, 10^{-5} s^{-1}[b]	k_p, 10^{-5} s^{-1}[b]

To some extent, the stability of VDC polymers is dependent on the nature of the comonomer present. Copolymers with acrylates degrade slowly (139,140). Apparent degradation propagation rates decrease somewhat as the acrylate content of the copolymer increases (139). The polyene sequences generated by dehydrochlorination are limited in size by the level of acrylate incorporation; that is, the acrylate molecules act as stopper units for the unzipping reaction. The impact of this chain-stopping is that the termination rate for higher acrylate content polymers is greater than for those containing smaller amounts of acrylate. Therefore, initiation and termination rates are in balance for a shorter portion of the overall reaction period. Despite the suggestion that the presence of a hydrogen-rich pendant might serve as a source of hydrogen atoms to disrupt degradation propagation (113), there is no apparent relationship between the degradation rate and the size of the alkyl portion of the acrylate comonomer (140,141).

Copolymers with AN or MA undergo degradation more readily. In addition, the degradation is more complex than that observed for acrylate copolymers. Acrylonitrile copolymers release hydrogen cyanide as well as hydrogen chloride; products of thermal degradation of MA copolymers contain methyl chloride in addition to hydrogen chloride (102,104,142,143). In both cases, degradation apparently begins in VDC units adjacent to comonomer units (142,143).

The degradation of VDC polymers in nonpolar solvents is comparable to degradation in the solid state (103,138,144,145). However, these polymers are unstable in many polar solvents (146). The rate of dehydrochlorination increases markedly with solvent polarity. In strongly polar aprotic solvents, eg, hexamethylphosphoramide, dehydrochlorination proceeds readily (144,147). This reaction is clearly unlike thermal degradation and may well involve the generation of ionic species as intermediates.

Polymers of high VDC content are reactive toward strong bases to yield elimination products and toward nucleophiles to yield substitution products. Agents capable of functioning as both a base and a nucleophile react with these polymers to generate a mixture of products (124,148–151). Weakly basic agents such as ammonia, amines, or polar aprotic solvents accelerate the decomposition of VDC copolymers. Amines function as bases to remove hydrogen chloride and introduce unsaturation along the polymer mainchain which may serve as initiation sites for thermal degradation. The overall effectiveness of a particular amine for dehydrohalogenation may be dependent on several factors, including inherent basicity, degree of steric hindrance at nitrogen, and compatibility with the polymer (152–154). Phosphines are more nucleophilic but less basic than amines. However, phosphines also promote dehydrohalogenation rather than displacement of allylic chlorine (155).

Amines can also swell the polymer, leading to very rapid reactions. Pyridine, for example, would be a fairly good solvent for a VDC copolymer if it did not attack the polymer chemically. However, when pyridine is part of a solvent mixture that does not dissolve the polymer, pyridine does not penetrate into the polymer phase (111). Studies of single crystals indicate that pyridine removes hydrogen chloride only from the surface. Kinetic studies and product characterizations suggest that the reaction of two units in each chain-fold can easily take place; further reaction is greatly retarded either by the inability of pyridine to diffuse into the crystal or by steric factors.

Aqueous bases or nucleophiles have little impact on VDC polymers, primarily because the polymer is not wetted or swollen by water. However, these polymers do slowly degrade in hot concentrated aqueous sodium hydroxide solution (121).

Lewis acids, particularly transition-metal salts, strongly promote the thermal degradation of VDC polymers (121,138,156–166,166,167). The rate of initiation of degradation is greatly enhanced in the presence of metal ions (159). The metal ion (or other Lewis acid) coordinates chlorine atoms, making them much better leaving groups. This facilitates the introduction of initial double bonds, which act as defect sites from which degradative dehydrohalogenation may propagate. Care must be taken to avoid metal ions, particularly precursors of iron chloride, during the preparation and processing of VDC polymers.

Copolymers of VDC that are free of impurities do not degrade at an appreciable rate in the absence of light below 100°C. However, when exposed to uv light, these polymers discolor (168). Again, the primary reaction seems to be dehydrochlorination. Hydrogen chloride is evolved and cross-linking occurs (109). Polyene sequences of narrow sequence length distribution are often formed (169–171). These function as initiation sites for subsequent thermal degradation (109). Laser-induced photochemistry may be used for the generation of polyene structures uncomplicated by cross-linking and graphitization (172,173). Laser-promoted dehydrohalogenation has some characteristics in common with the corresponding thermal process. Long-lived carbon radicals are formed, and the propagation of the dehydrochlorination reaction apparently proceeds via an allylic carbon radical, chlorine atom pair (173). Similar structures may be generated by chemical means (150,151,174). Other photodegradation processes, eg, hydroperoxide formation at the methylene groups, probably also occur but are less important for these polymers than is polyene formation (158).

Stabilization. The stabilization of VDC polymers toward degradation is a highly developed art and is responsible for the widespread commercial use of these materials. Although the mode of action is often not understood, some general principles of effective stabilization have been established (175). The ideal stabilizer system should

(1) absorb or combine with evolved hydrogen chloride irreversibly under conditions of use, but not strip hydrogen chloride from the polymer chain;
(2) act as a selective uv absorber;
(3) contain a reactive dienophilic moiety capable of preventing discoloration by reacting with and disrupting the color-producing conjugated polymer sequences;
(4) possess nucleophilicity sufficient for reaction with allylic dichloromethylene units;
(5) possess antioxidant activity so as to prevent the formation of carbonyl groups and other chlorine-labilizing structures;
(6) be able to scavenge chlorine atoms and other free radicals efficiently;
(7) chelate metals, eg, iron, to prevent chlorine coordination and the formation of metal chlorides.

Acid acceptors are of two general types: alkaline-earth oxides and hydroxides (176) or salts of weak acids, such as barium or calcium fatty acid salts; and

epoxy compounds, such as epoxidized soybean oil or glycidyl ethers and esters. Epoxidized oils are less effective for the stabilization of VDC polymers than for other halogenated polymers (160). The function of these materials as plasticizers and processing lubricants is probably responsible for modest improvements in processing stability. Effective light stabilizers have a chemical structure which imparts exceptional conjugative stability and very good uv absorption properties. The principal compounds of commercial interest are derivatives of salicylic acid, resorcylic acid, benzophenone, and benzotriazole. The typical hindered amine light stabilizers cannot be used in this application since they are sufficiently basic so as to promote dehydrohalogenation. This introduces allylic dichloromethylene units into the polymer mainchain, which act as initiation sites for thermal degradation. Consequently, satisfactory processing of the polymer in the presence of these additives is not possible. Examples of dienophiles that have been used are maleic anhydride and N-substituted maleimides (177).

Antioxidants are generally of two types: those that react with a free radical to stop a radical chain, that is, to scavenge chlorine atoms or peroxy radicals; and those that reduce hydroperoxides to alcohols. Phenolic antioxidants, eg, 2,6-di-*tert*-butyl-4-methylphenol and substituted bisphenols, are of the first type. Because the chain-carrying species for the degradative dehydrochlorination is a tight chlorine atom, carbon radical pair that does not dissociate appreciably during the reaction, the effectiveness of these agents is limited (161). The second type is exemplified by organic sulfur compounds and organic phosphites. The phosphites, ethylenediaminetetraacetic acid [60-00-4] (EDTA), citric acid [77-92-9], and citrates, can chelate metals. The ability of organic phosphites to function as antioxidants and as chelating agents illustrates the dual role of many stabilizer compounds. It is common practice to use a combination of stabilizing compounds to achieve optimum results (168). In addition, stabilization packages usually contain lubricants and other processing aids that enhance the effectiveness of the stabilizing compounds. The presence of these agents is particularly important to minimize the shearing component of degradation during extrusion and other processing steps (163).

Metal carboxylates have been considered as nucleophilic agents capable of removing allylic chlorine and thereby affording stabilization (162). Typical PVC stabilizers, eg, tin, lead, cadmium, or zinc esters, actually promote the degradation of VDC polymers. The metal cations in these compounds are much too acidic to be used with VDC polymers. An effective carboxylate stabilizer must contain a metal cation sufficiently acidic to interact with allylic chlorine and to facilitate its displacement by the carboxylate anion, but at the same time not acidic enough to strip chlorine from the polymer mainchain (163,167). Copper(II) carboxylates may have the balance of cation acidity and anion reactivity required to function as effective stabilizers for VDC polymers. This is reflected in Figure 10, which illustrates increasing stability of a typical VDC copolymer as it is aged at 150°C in the presence of copper(II) formate.

Vinylidene chloride polymers containing stabilizing features have been prepared. More generally, these have been polymers containing comonomer units with functionality that can consume evolved hydrogen chloride such that good radical scavenging sites are exposed (164,165,178,179).

For example, copolymers containing 4-isopropylphenyl acrylate display greater thermal stability than do the corresponding polymers containing simple

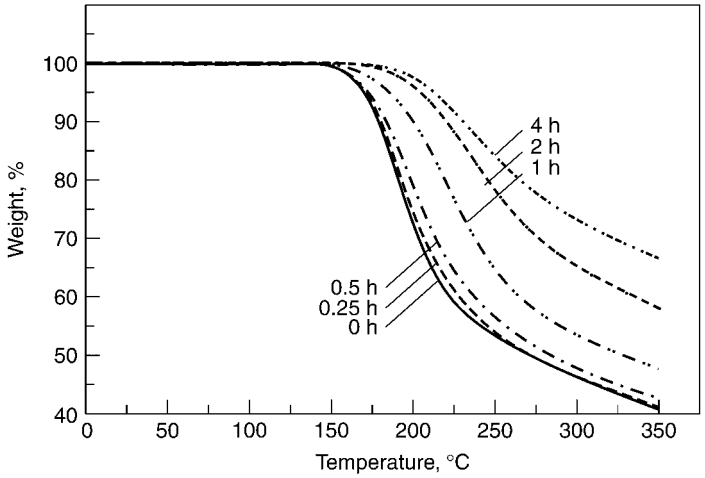

Fig. 10. Thermal degradation of a VDC/MPA (5 mol%) copolymer aged at 150°C in the presence of 5 wt% copper(II) formate for 0.25, 0.50, 1.0, 2.0, and 4.0 h.

alkyl acrylates as comonomer (164). This is illustrated in Figure 11. Stability of the copolymer increases as the level of the comonomer containing the *t*-cumyl group, capable of scavenging chlorine atoms, increases. A more quantitative reflection of this effect is provided by the rate constants displayed in Table 15. It may be noted that the magnitude of the initiation rate constant k_i decreases by a factor of 2 as the isopropylphenyl acrylate content of the polymer is increased from 0 to 5 mol%.

Commercial Methods of Polymerization and Processing

Processes that are essentially modifications of laboratory methods and that allow operation on a larger scale are used for commercial preparation of VDC polymers. The intended use dictates the polymer characteristics and, to some extent, the method of manufacture. Emulsion polymerization and suspension polymerization are the preferred industrial processes. Either process is carried out in a closed, stirred reactor, which should be glass-lined and jacketed for heating and cooling. The reactor must be purged of oxygen, and the water and monomer must be free of metallic impurities to prevent an adverse effect on the thermal stability of the polymer.

Emulsion Polymerization. Emulsion polymerization is used commercially to make VDC copolymers. In some applications, the resulting latex is used directly, usually with additional stabilizing ingredients, as a coating vehicle to apply the polymer to various substrates. In other applications, the polymer is first isolated from the latex before use. When the polymer is not used in latex form, the emulsion/coagulation process is chosen over alternative methods. The polymer is recovered in dry powder form, usually by coagulating the latex with an electrolyte, followed by washing and drying. The principal advantages of emulsion polymerization are twofold. First, high molecular weight polymers can be produced in reasonable reaction times, especially copolymers with VC. The initiation and propagation steps can be controlled more independently than in the suspension process. Second, monomer can be added during the polymerization to maintain copolymer composition control.

The disadvantages of emulsion polymerization result from the relatively high concentration of additives in the recipe. The water-soluble initiators, activators, and surface-active agents generally cause the polymer to have greater water sensitivity, poorer electrical properties, and poorer heat and light stability. These agents promote degradative dehydrochlorination during polymerization.

A typical recipe for batch emulsion polymerization is shown in Table 16. A reaction time of 7–8 h at 30°C is required for 95–98% conversion. A latex is produced with an average particle diameter of 100–150 nm. Other modifying ingredients may be present, eg, other colloidal protective agents such as gelatin or carboxymethylcellulose, initiator activators such as redox types, chelates, plasticizers, and stabilizers; and chain-transfer agents.

Commercial surfactants are generally anionic emulsifiers, alone or in combination with nonionic types. Representative anionic emulsifiers are the sodium

Table 16. Recipe for Batch Emulsion Polymerization[a]

alkylaryl sulfonates, the alkyl esters of sodium sulfosuccinic acid, and the sodium salts of fatty alcohol sulfates. Nonionic emulsifiers are of the ethoxylated alkylphenol type. Free-radical sources other than peroxysulfates may be used, eg, hydrogen peroxide, organic hydroperoxides, peroxyborates, and peroxycarbonates. Many of these are used in redox pairs, in which an activator promotes the decomposition of the peroxy compound. Examples are peroxysulfate or perchlorate activated with bisulfite, hydrogen peroxide with metallic ions, and organic hydroperoxides with sodium formaldehyde sulfoxylate. The use of activators causes the decomposition of the initiator to occur at lower reaction temperatures, which allows the preparation of a higher molecular weight polymer within reasonable reaction times. This is an advantage, particularly for copolymers of VDC with VC. Oil-soluble initiators are usually effective only when activated by water-soluble activators or reducing agents.

To ensure constant composition, the method of emulsion polymerization by continuous addition is employed. One or more components are metered continuously into the reaction. If the system is properly balanced, a steady state is reached in which a copolymer of uniform composition is produced (181). A process of this type can be used for the copolymerization of VDC with a variety of monomers. A flow diagram of the apparatus is shown in Figure 12; a typical recipe is shown in Table 17. The monomers are charged to the weigh tank A, which is kept under a nitrogen blanket. The emulsifiers, initiator, and part of the water are charged to tank B; the reducing agent and some water to tank C. The remaining water is charged to the reactor D, and the system is sealed and purged. The temperature is raised to 40°C and one tenth of the monomer and initiator charges is added, and then one tenth of the activator is pumped in. Once the reaction begins, as indicated by an exotherm and pressure drop, feeds of A, B, and C are started at programmed rates that begin slowly and gradually increase. The emulsion is maintained at a constant temperature during the run by cooling water that is pumped through the jacket. When all components are in the reactor and the exotherm begins to subside, a final addition of initiator and reducing agent completes the reaction.

Suspension Polymerization. Suspension polymerization of VDC is used commercially to make molding and extrusion resins. The principal advantage of the suspension process over the emulsion process is the use of fewer ingredients that might detract from the polymer properties. Stability is improved and water

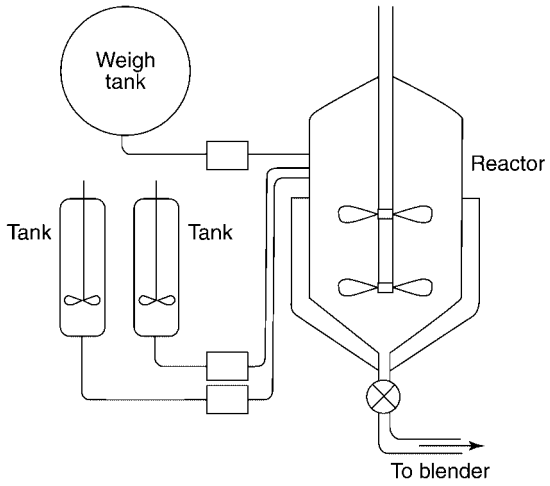

Fig. 12. Apparatus for continuous-addition emulsion polymerization of a VDC–acrylate mixture (181).

sensitivity is decreased. Extended reaction times and the difficult preparation of higher molecular weight polymers are disadvantages of the suspension process compared to the emulsion process, particularly for copolymers containing VC.

A typical recipe for suspension polymerization is shown in Table 18. At a reaction temperature of 60°C, the polymerization proceeds to 85–90% conversion in 30–60 h. Unreacted monomer is removed by vacuum stripping; then it is condensed and reused after processing. The polymer is obtained in the form of small [150–600 μm (30–100 mesh)] beads, which are dewatered by filtration or centrifugation and then dried in a flash dryer or fluid-bed dryer. Suspension polymerization involves monomer-soluble initiators, and polymerization occurs inside suspended monomer droplets, which form by the shearing action of the agitator and are prevented from coalescence by the protective colloid. It is important that the initiator be uniformly dissolved in the monomer before droplet formation. Unequal distri-

bution of initiator causes some droplets to polymerize faster than others, leading to monomer diffusion from slow-polymerizing to fast-polymerizing droplets. The fast-polymerizing droplets form polymer beads that are dense, hard, glassy, and extremely difficult to fabricate because of their inability to accept stabilizers and plasticizers. Common protective colloids that prevent droplet coalescence and control particle size are PVC, gelatin, and methylcellulose. Organic peroxides, peroxycarbonates, and azo compounds are used as initiators for VDC suspension polymerization.

The batch-suspension process does not compensate for composition drift, whereas constant-composition processes have been designed for emulsion or suspension reactions. It is more difficult to design controlled-composition processes by suspension methods. In one approach (183), the less reactive component is removed continuously from the reaction to keep the unreacted monomer composition constant. This method has been used effectively in VDC–VC copolymerization, where the slower reacting component is volatile and can be released during the reaction to maintain constant pressure. In many other cases, no practical way is known for removing the slower reacting component.

Economic Aspects

Vinylidene chloride monomer is produced commercially in the United States by The Dow Chemical Co. and PPG Industries. The monomer is produced in Europe by Imperial Chemical Industries, Ltd. and Solvin. The monomer is produced in Japan by the Asahi Chemical Co., Kureha Chemical Industries, and Kanto Denka Kogyo Co. Commercial suppliers of VDC copolymers include The Dow Chemical Co. in the United States and Solvin in Europe. Asahi Chemical Co. and Kureha Chemical Industries are suppliers of VDC resins in Japan. Additional manufacturers of exclusively VDC latexes include W. R. Grace and Rohm & Haas in the United States, and Scott-Bader in Europe. Local suppliers of VDC resins have also been reported in Russia and the People's Republic of China.

Although Saran is a generic name for VDC copolymers in the United States, it is a Dow trademark in most foreign countries. Other trademarks include Daran (W. R. Grace) and Serfene (Rohm & Haas) in the United States; Diofan and Ixan (Solvin) and Polyidene (Scott-Bader) in Europe; and Kurehalon (Kureha) in Japan. In addition, B. F. Goodrich Chemicals (GEON) and Avecia (Haloflex) supply nonbarrier VDC copolymers.

Applications

Melt Processing. Vinylidene chloride copolymers are melt processed via a variety of fabrication techniques. These include molding, monofilament fiber extrusion, monolayer blown film extrusion, multilayer cast- and blown-film extrusion, and multilayer sheet extrusion. There are a number of elements of melt processing and melt-processing equipment that are common to all of these fabrication techniques (184–187). These include proper equipment design and materials of construction, proper and accurately controlled operating conditions, and a properly formulated resin.

Because of their high crystalline melting point, VDC copolymers are generally melt fabricated near their thermal stability limits. Products of degradation are corrosive to equipment and given sufficient time will generate a char or carbon. Also, at temperatures of about 130°C and above, a number of metals, including iron, zinc, copper, and aluminum, catalyze the degradation of VDC resins. As a consequence the correct materials of construction are essential for melt processing VDC resins. High nickel alloys that are both corrosion resistant and do not catalyze resin degradation are preferred for all surfaces that are in direct contact with the polymer melt. For example, the extruder barrel liner may be made from Xaloy 306 or other high nickel, low iron containing alloy. Extruder screws may be made from Duranickel 301 with Colmonoy 56 flight lands. Other parts in direct contact with polymer melt should also be made out of Duranickel or similar material. Instruments such as melt thermocouples or pressure transducers could be Hastelloy C.

Degradation of VDC resins is a product of time at temperature. Both of these aspects should be controlled to optimize melt-processing performance. Extruders in the range of 18:1 to 24:1 length-to-diameter ratio are commonly used. Melt channels should be designed with a smooth flow pattern to minimize dead spots where polymer may degrade excessively or permit carbon buildup. The clearance between the screw tip and the extruder nosepiece should be minimized. Screen packs are also not recommended for melt-processing VDC resins. Proper instrumentation, including multiple melt thermocouples and pressure transducers, amperage or torque measurement for the extruder, and accurate screw speed measurement, is also critical.

Heat management is an important factor in melt-processing VDC resins. Screw design (188) and resin formulation combine to affect the amount of heat generated during melting and the eventual melt temperature. Vinylidene chloride polymer powders exhibit a relatively high level of frictional heating and also contain a large amount of entrained air (189). Screws are typically designed to be low work to minimize frictional and viscous heating. They must also be designed to eliminate air entrapment. Screws greater than 6.35-cm (2.5-in.) diameter for VDC resin processing also generally have two-zone cooling capability for further heat management.

Vinylidene chloride resins for melt processing are generally supplied formulated or unformulated. Formulated resins may be melt processed as supplied or with some additional additives. Unformulated resins require additives prior to melt processing. Processing additives for VDC resins include plasticizers, lubricants, and other process aids designed to control heat generation and residence

time in melt processing. Patent literature cites a wide variety of lubricants and processing aids, including acids, esters, amides, and metal salts of fatty acids; polyolefins or polyolefin waxes; and inorganic stabilizers such as magnesium hydroxide or tetrasodium pyrophosphate (190). Some of these processing aids are common to PVC melt processing as well. However, it should also be noted that some PVC melt-processing additives are incompatible with VDC resins and will actually degrade melt-processing performance.

Molding. Molded articles were among the earliest applications for VDC copolymers (184,191). Vinylidene chloride–vinyl chloride copolymers were originally developed for thermoplastic molding applications, and small amounts are still used for this purpose. When properly formulated with plasticizers and heat stabilizers, the resins can be fabricated by common methods, eg, injection, compression, or transfer molding. Conventional or dielectric heating can be used to melt the polymers. Rapid hardening is achieved by forming in heated molds to induce rapid crystallization. Cold molds result in supercooling of the polymer. Because the interior of the molded part remains soft and amorphous, the part cannot be easily removed from the mold without distortion. Mold temperatures of up to 100°C allow rapid removal of dimensionally stable parts. The range of molding temperatures is rather narrow because of the crystalline nature of the resin and thermal sensitivity. All crystallites must be melted to obtain low polymer melt viscosity, but prolonged or excessive heating must be avoided to prevent dehydrochlorination.

The metal parts of the injection molder, ie, the liner, torpedo, and nozzle, that contact the hot molten resin must be of the noncatalytic, corrosion-resistant type previously described. The injection mold need not be made of noncatalytic metals; any high grade tool steel may be used because the plastic cools in the mold and undergoes little decomposition. However, the mold requires good venting to allow the passage of small amounts of acid gas as well as air. Vents tend to become clogged by corrosion and must be cleaned periodically.

Molded parts of VDC copolymers are used to satisfy the industrial requirements of chemical resistance and extended service life. They are used in such items as gasoline filters, valves, pipe fittings, containers, and chemical process equipment. Complex articles are constructed from molded parts by welding; hot-air welding at 200–260°C is a suitable method. Molded parts have good physical properties but lower tensile strength than films or fibers, because crystallization is random in molded parts. Higher strength is developed by orientation in films and fibers. Physical properties of a typical molded VDC copolymer plastic are listed in Table 19.

Monofilament Fiber Extrusion. Monofilament fiber extrusion was another early application for VDC resins (184,191,193). Monofilament applications have included automotive seat covers, window screens, and upholstery fabrics, where the durability and ease of cleaning were important. Fabrics made from VDC copolymer monofilaments are still used today in applications such as filter fabrics, light screens, greenhouse covers, pool or bath fabrics, and shoe insoles (194). Such fabrics claim excellent resistance to flame, chemicals, uv light, moisture, and microbial attack.

Vinylidene chloride copolymer monofilaments typically range from 0.15- to 1.5-mm (0.006- to 0.06-in.) diameter. To produce these monofilaments, a molten

VDC copolymer extrudate is quenched to about room temperature in a supercooling tank to produce an amorphous polymer strand (184,191,193). This strand is then wrapped several times around smooth take-off rolls, and then wrapped several times around orienting rolls, which operate at a higher speed than the take-off rolls. The difference in roll speeds produces mechanical stretching, orienting the filament along the longitudinal axis while the polymer is crystallizing. A typical stretch ratio for this process is about 400%. The orientation process increases the fiber strength from about 55 MPa (8000 psi) to as high as 414 MPa (60,000 psi). Much of the increased tensile strength is obtained as the stretch ratio approaches 400%. Heat treatment may be used during or after stretching to affect the degree of crystallization and control the physical properties of the oriented filaments.

Monolayer Blown-Film Extrusion. One of the major applications for VDC resins is monolayer film produced via a blown-film extrusion process. Previously, VDC copolymer film extrusion was limited to just a few experts in the field. However, over the last several years, production of VDC-containing films has greatly expanded (195,196). Monolayer VDC copolymer blown-film lines are now commercially available from a number of manufacturers and a considerable number of lines have been recently installed around the world, particularly in the People's Republic of China.

Figure 13 illustrates a monolayer blown-film process for VDC resin. In this process (185,197–200) a tube of molten VDC resin is extruded downward and is immediately quenched in a cold-water supercooling bath. This bath cools the polymer melt to create a leathery polymer tube which is essentially amorphous VDC copolymer. The low temperature of the bath also controls nucleation of the crystallites and thus impacts the subsequent film-formation processes. After the supercooling bath, the amorphous tube is passed through a warming or reheat bath. This bath increases the resin temperature, which in turn will make the film more pliable and increase the rate of crystallization propagation during the

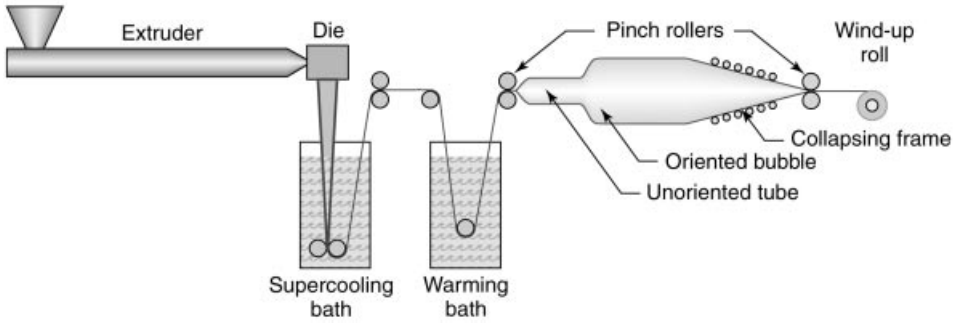

Fig. 13. Monolayer blown-film process for VDC resins (196).

subsequent film-blowing process. Exiting the warming bath, the tube passes through two sets of pinch rolls, which are arranged so that the second set of rolls travels faster than the first set. Between the two sets, air is injected into the tube to create a bubble that is entrapped by the pinch rolls. The entrapped air bubble remains stationary while the extruded tube is oriented as it passes around the bubble. In this manner, orientation is produced simultaneously in both the transverse and the longitudinal directions.

As the tube expands and orients, the amorphous polymer begins to crystallize rapidly, eventually limiting the diameter of the bubble. Adding additional air to the bubble at this point will only lengthen the bubble but will not change its overall diameter. Crystallization rate and thus bubble diameter or "blow up ratio" is controlled by a number of factors, including temperatures of the supercooling and warming baths, room temperature, polymer composition, and amount and type of plasticizer additives. These parameters as well as variables such as extrusion rate, die diameter, die gap, and drawdown ratio are combined to make a wide variety of film types and sizes. Films produced via this process generally have some shrink properties, which in many cases are advantageous. Where shrink is not desirable, films can be preshrunk via controlled heat application prior to the winding process.

Monolayer blown-film processes generally use a VDC–VC copolymer. Such resins have the combination of performance properties and optimum crystallization rate necessary for this process. Resins are generally formulated with plasticizers, lubricants, and other additives to affect performance during the extrusion process as well as in the final film applications.

Applications for VDC copolymer monolayer films fall into three major categories: household wrap, food and medical packaging, and industrial films. Food packaging includes packaging of processed meats, cheese and other dairy products, and bakery goods. Packaging types include film overwraps, shrinkable films, chub packaging, and unit packaging. Performance attributes of VDC copolymer films that are important to these applications include high barrier to oxygen, water, and other permeating molecules; clarity; resistance to fats and oils; dimensional stability; ability to be sealed and printed; and ability to withstand retort and microwave oven temperatures. Typical film properties are shown in Table 20.

Multilayer Cast- and Blown-Film Extrusion. A significant application for VDC copolymer resins is in the construction of multilayer film and sheet (202,203). This permits the design of a packaging material with a combination of properties not obtainable in any single material. A VDC copolymer layer is incorporated into multilayer film for perishable food packaging because it provides a barrier to oxygen. A special high barrier resin is supplied specifically for this application. Typically, multilayer packaging films contain outer layers of a tough, low cost polymer such as high density or linear low density polyethylene with VDC copolymer as the core layer. Cast and blown films are produced on conventional film lines with one extruder and die designed to handle the heat-sensitive nature of VDC resin. The properties of a 0.05-mm (39-mil) multilayer cast film are listed in Table 21.

Multilayer films are produced by both cast- and blown-film coextrusion. One of the key enabling technologies in the manufacture of these multilayer films has been preencapsulation of the VDC resin (205). Preencapsulation means that the VDC resin extrudate is completely encapsulated with a more thermally stable polymer, such as an ethylene–vinyl acetate copolymer, prior to entering the coextrusion die. Using this technique, the VDC resin is not directly exposed to the

[f] To convert nmol/(m^2·s·GPa) to cm^3/(100 $in.^2$·d·atm), divide by 7.9×10^4.
[g] To convert nmol/(m·s) to g/(100 $in.^2$·d), divide by 1×10^4.

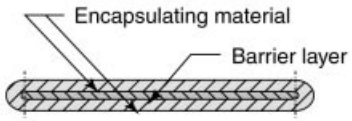

Fig. 14. Multilayer cast film showing a VDC copolymer barrier layer surrounded by a less thermally sensitive encapsulating material, such as ethylene–vinyl acetate (205). The edges are trimmed.

large surface area of the multilayer extrusion die, eliminating a greater potential for carbon formation and subsequent problems. Upon entering the die the encapsulated VDC resin is combined with other polymer layers, including tie and skin layers, to create the multilayer film.

The application of encapsulation technology to flat dies and cast film coextrusion is fairly easy to envision. As shown in Figure 14, the encapsulating material completely surrounds the VDC resin. When the edges are trimmed, a flat film with a continuous barrier layer is produced.

Blown-film coextrusion presents the added difficulty of obtaining a continuous barrier layer. A die with a crosshead mandrel is preferred over a die with a spiral mandrel, because the spiral mandrel tends to lead to long residence time in the spirals. A standard crosshead mandrel, however, results in a weld line where the barrier layer is not continuous. As shown in Figure 15, this problem is solved by providing an overlap of the barrier layer at the weld line (206). Although the barrier layer is not continuous across the weld line, sufficient overlap will create a tortuous path for permeation, and the barrier properties will be maintained

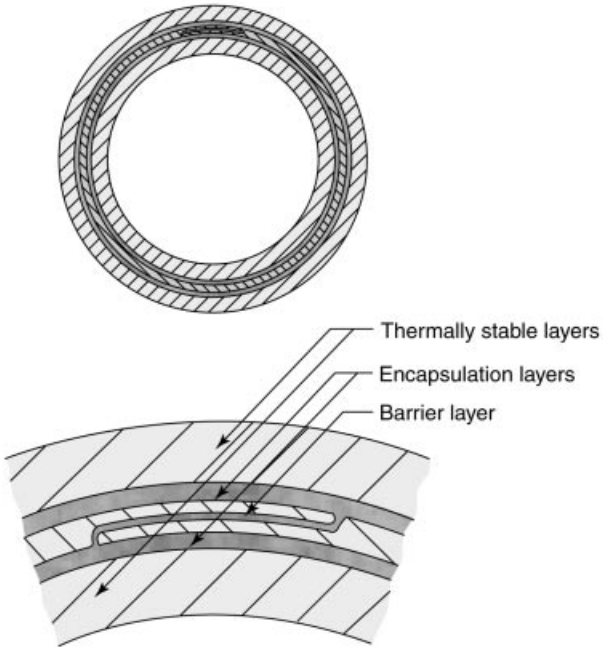

Fig. 15. Multilayer blown film with enlarged view showing overlap of barrier layer (206).

across the weld. This technology has only been recently applied to large blown-film dies. Five- to seven-layer blown-film dies up to 51-cm (20-in.) diameter have been demonstrated using this technology (207–210). These new blown-film dies also incorporate temperature isolation techniques that allow VDC resins to be coextruded with resins such as nylon that require much higher melt temperatures. Similar to the monolayer films, multilayer films are used predominately in food packaging and medical applications.

Multilayer Sheet Extrusion. Rigid containers for food packaging can be made from coextruded sheet that contains a layer of a barrier polymer (211–213). A simple example is a sheet with five layers that has a total thickness of about 1.3 mm (50 mil). The outermost layers might be polypropylene, polyethylene, polystyrene, high impact polystyrene (HIPS), or other nonbarrier polymer having good mechanical properties. The innermost barrier layer is about 125 μm (5 mil) of a VDC copolymer. Adhesive layers connect the outer layers and the barrier layer. This coextruded sheet can be formed into containers by any of several techniques, including solid-phase pressure forming and melt-phase forming. The final container has a total wall thickness of about 500 μm (20 mil) and a barrier layer that is about 50 μm (2 mil) thick. Such a container is capable of protecting oxygen-sensitive foods at ambient temperatures for a year or more. These containers are lightweight, microwavable, nonbreakable, and attractive. More sophisticated containers may have more than five layers and improved economics by including a layer of scrap or recycled polymers in the structure.

Lacquer Resins. Vinylidene chloride copolymers have several properties that are valuable in the coatings industry: excellent resistance to gas and moisture vapor transmission, good resistance to attack by solvents and by fats and oils, high strength, and the ability to be heat-sealed (214,215). These characteristics result from the highly crystalline nature of the very high VDC content of the polymer, which ranges from ~80 to 90 wt%. Minor constituents in these copolymers generally are vinyl chloride, alkyl acrylates, alkyl methacrylates, acrylonitrile, methacrylonitrile, and vinyl acetate. Small concentrations of vinylcarboxylic acids, eg, acrylic acid, methacrylic acid, or itaconic acid, are sometimes included to enhance adhesion of the polymer to the substrate. The ability to crystallize and the extent of crystallization are reduced with increasing concentration of the comonomers; some commercial polymers do not crystallize. The most common lacquer resins are terpolymers of VDC–MMA–AN (216,217). The VDC level and the MMA–AN ratio are adjusted for the best balance of solubility and permeability. These polymers exhibit a unique combination of high solubility, low permeability, and rapid crystallization (218).

Acetone, methyl ethyl ketone, methyl isobutyl ketone, dimethylformamide, ethyl acetate, and tetrahydrofuran are solvents for VDC polymers used in lacquer coatings; methyl ethyl ketone and tetrahydrofuran are most extensively employed. Toluene is used as a diluent for either. Lacquers prepared at 10–20 wt% polymer solids in a solvent blend of two parts ketone and one part toluene have a viscosity of 20–1000 mPa·s (=cP). Lacquers can be prepared from polymers of very high VDC content in tetrahydrofuran–toluene mixtures and can be stored at room temperature. Methyl ethyl ketone lacquers must be prepared and maintained at 60–70°C or the lacquer forms a solid gel. It is critical in the manufacture of polymers for a lacquer application to maintain a fairly narrow compositional distribution in the polymer to achieve good dissolution properties.

The lacquers are applied commercially by roller coating, doctor and dip coating, knife coating, and spraying. Spraying is useful only with lower viscosity lacquers, and solvent balance is important to avoid webbing from the spray gun. Solvent removal is difficult from heavy coatings, and multiple coatings are recommended where a heavy film is desired. Sufficient time must be allowed between coats to avoid lifting of the previous coat by the solvent. In the machine coating of flexible substrates, eg, paper and plastic films, the solvent is removed by ir heating or forced-air drying at 90–140°C. Temperatures of 60–95°C promote the recrystallization of the polymer after the solvent has been removed. Failure to recrystallize the polymer leaves a soft, amorphous coating that blocks or adheres between concentric layers in a rewound roll. A recrystallized coating can be rewound without blocking. Handling properties of the coated film are improved with small additions of wax as a slip agent and of talc or silica as an antiblock agent to the lacquer system. The concentration of additives is kept low to prevent any serious detraction from the vapor transmission properties of the VDC copolymer coating. For this reason, plasticizers are seldom, if ever, used.

A primary use of VDC copolymer lacquers is the coating of films made from regenerated cellulose or of board or paper coated with polyamide, polyester, polypropylene, poly(vinyl chloride), and polyethylene. The lacquer imparts resistance to fats, oils, oxygen, and water vapor (219). These coated products are used mainly in the packaging of foodstuffs, where the additional features of inertness, lack of odor or taste, and nontoxicity are required. Vinylidene chloride copolymers have been used extensively as interior coatings for ship tanks, railroad tank cars, and fuel storage tanks, and for coating of steel piles and structures (220,221). The excellent chemical resistance and good adhesion result in excellent long-term performance of the coating. Brushing and spraying are suitable methods of application.

The excellent adhesion to primed films of polyester combined with good dielectric properties and good surface properties makes VDC copolymers very suitable as binders for iron oxide pigmented coatings for magnetic tapes (222–224). They perform very well in audio, video, and computer tapes.

Vinylidene Chloride Copolymer Latex. Vinylidene chloride copolymers can be made in emulsion, and then isolated, dried, and used as coating or extrusion resins. Stable latices have been prepared and can be used directly for coatings (225–230). The principal applications for these materials are as barrier coatings on paper products and, more recently, on plastic films. The heat-seal characteristics of VDC copolymer coatings are equally valuable in many applications. They are also used for paints and as binders for nonwoven fabrics (231). Special VDC copolymer latices are used for barrier laminating adhesives, and the use of VDC copolymers in flame-resistant carpet backing is well known (232–235). VDC latices can also be used to coat poly(ethylene terephthalate) bottles to retain carbon dioxide (236).

Poly(vinylidene chloride) latices can be easily prepared by the same methods but have few uses because they do not form films. Copolymers of high VDC content are film-forming when freshly prepared but soon crystallize and lose this desirable characteristic. Because crystallinity in the final product is very often desirable, eg, in barrier coatings, a significant developmental problem has been to prevent crystallization in the latex during storage and to induce rapid

Table 22. Properties of a Typical Barrier Latex

Properties	Value
Total solids, wt%	54–56
Viscosity at 25°C, mPa·s (=cP)	25
pH	2
Color	Creamy white

Density, g/cm^3	1.30
Mechanical stability	Excellent
Storage stability	Excellent
Chemical stability	Not stable to di- or trivalent ions

crystallization of the polymer after coating. This has been accomplished by using the proper combination of comonomers with VDC.

Most VDC copolymer latices are made with varying amounts of acrylates, methacrylates, and acrylonitrile, as well as minor amounts of vinylcarboxylic acids, eg, itaconic and acrylic acids. Low foam latices having high surface tension are prepared with copolymerizable sulfonate monomers (233,235–237). The total amount of comonomer ranges from about 8 wt% for barrier latices to as high as 60 wt% for binder and paint latices. The properties of a typical barrier latex used for paper coating are listed in Table 22. Barrier latices are usually formulated with antiblock, slip, and wetting agents. They can be deposited by conventional coating processes, eg, with an air knife (238,239).

Coating speeds in excess of 305 m/min can be attained. The latex coating can be dried in forced-air or radiant-heat ovens (240,241). Multiple coats are applied, particularly in paper coating, to reduce pinholing (242). A precoat is often used on porous substances to reduce the quantity of the more expensive VDC copolymer latex needed for covering (243). The properties of a typical coating are listed in Table 23.

Vinylidene Chloride Copolymer Foams. Low density, fine-celled VDC copolymer foams can be made by extrusion of a mixture of VDC copolymer and a blowing agent at 120–150°C (244). The formulation must contain heat stabilizers, and the extrusion equipment must be made of noncatalytic metals to prevent accelerated decomposition of the polymer. The low melt viscosity of the VDC copolymer formulation limits the size of the foam sheet that can be extruded.

Expandable VDC copolymer microspheres are prepared by a microsuspension process (245). The expanded microspheres are used in reinforced polyesters, blocking multipair cable, and in composites for furniture, marble, and marine applications (246–249). Vinylidene chloride copolymer microspheres are also used in printing inks and paper manufacture (250).

Vinylidene Chloride Copolymer Ignition-Resistant Applications. The role of halogen-containing compounds in ignition and flame suppression has been studied for many years (251–256). Vinylidene chloride copolymers are an abundant source of organic chlorine, eg, often above 70 wt%. Vinylidene chloride emulsion copolymers are used in a variety of ignition-resistant binding applications (257,258). Powders dispersible in nonsolvent organic polymer intermediates, eg, polyols, are used for both reinforcement and ignition resistance in polyurethane

Table 23. Film Properties of VDC Copolymer Latex

Property	Value
Water vapor transmission at 38°C and 95% RH, nmol/(m·s)[a]	0.012[b]
Grease resistance	Excellent
Scorability and fold resistance	Moderate
Oxygen permeability at 25°C, nmol/(m·s·GPa)[c]	0.07
Heat sealability[d]	Good
Light stability	Fair
Density, g/cm^3	1.60
Color	Watery white
Clarity	Excellent
Gloss	Excellent

[a]To convert nmol/(m·s) to (g·mil)/(100 in.^{2}·d), multiply by 4.
[b]Values 0.37 g/(24 h·100 in.^{2}) for 0.5 mil.
[c]To convert nmol/(m·s·GPa) to (cm^3·mil)/(100 in.^{2}·d·atm), divide by 2.
[d]Face-to-face.

foams. Vinylidene chloride copolymer powder is also used as an ignition-resistant binder for cotton batt (259–261).

The halogenated polymers generate significantly more smoke than polymers that have aliphatic backbones, even though the presence of the halogen does increase the limiting oxygen index. Heavy-metal salts retard smoke generation in halogenated polymers (261,262). A VDC emulsion copolymer having a high AN graft can be used to make ignition-resistant acrylic fibers (263). A rubber-modified VDC copolymer combines good ignition resistance with good low temperature flexibility (264,265). The rubber-modified VDC copolymer has been evaluated in wire coating where better ignition resistance and lower smoke generation are needed.

Materials are also blended with VDC copolymers to improve toughness (265–268). Vinylidene chloride copolymer blended with ethylene–vinyl acetate copolymers improves toughness and lowers heat-seal temperatures (269,270). Adhesion of a VDC copolymer coating to polyester can be achieved by blending the copolymer with a linear polyester resin (271).

VINYLIDENE FLUORIDE POLYMERS

Introduction

Poly(vinylidene fluoride) [24937-79-9] is the addition polymer of 1,1-difluoroethene [75-38-7], commonly known as vinylidene fluoride and abbreviated VDF or VF_2. The formula of the repeat unit in the polymer is $-[CH_2–CF_2]_n-$. The preferred acronym for the polymer is PVDF, but the abbreviation PVF_2 also is used frequently. (Note: PVF is the accepted acronym for poly(vinyl fluoride), $-[CH_2\text{-}CHF]_n-$.) The history and development of PVDF technology has been reviewed (1). This article deals only with *thermoplastic* VDF-based polymers having greater than 50 wt% VDF, and not *fluoroelastomeric* copolymer versions, which have significant levels of fluoro-comonomers to impart rubber-like properties and usually less than 50 wt% VDF. (see FLUOROCARBON ELASTOMERS).

Since the commercialization of this linear fluoropolymer in the mid-1960s, the applications have expanded until the production of the monomer VDF and polymer PVDF reached significant tonnages at the end of the twentieth century, albeit with essentially the same producers during the last decade. The worldwide PVDF market in 2000 was about 21,000 t according to several industry sources. PVDF usage is expected to grow at an average of about 6% for all fluoropolymers during the first decade of the twenty-first century (2). Several manufacturers (see Table 1) have announced that there would be significant capacity increases between 2000 and 2005. Applications are increasing rapidly in China and Southeast Asia as well as Japan and Korea with a high growth projection for the next few years in these areas.

The production of VDF and PVDF requires significant investment in corrosion-resistant pyrolysis reactors and low temperature distillation columns

Table 1. Manufacturers of VDF and PVDF[a]

Producers and country of production	Trademarks
Alventia LLC–USA	
Joint venture – Solvay and Dyneon; VDF monomer only, starting 2000	
Atofina[b]–France, USA	KYNAR, KYNAR 500, KYNAR FLEX, KYNAR Superflex, KYNAR Powerflex, HYLAR
www.atofina.com (Paris)	
www.atofinachemicals.com (USA)	
Largest capacity VDF and PVDF producer; expansion underway 2002	
Ausimont–USA	
www.ausimont.com	
Large capacity VDF and PVDF	
Daikin–Japan	NEOFLON
Minimal production PVDF resins; VDF-based coating resins use trademark	
Dyneon–USA, Germany	DYNEON, HOSTAFLON
www.dyneon.com	
Not currently a PVDF producer; produces TFE-based polymers with VDF as comonomer at low content	
Creanova[c]–Germany	DYFLOR
www.creanovainc.com	
Very small amounts PVDF available	
Kirova–CHEPETSKY Khimichesky Kombinat–Russia	FLUOROPLAST
Small capacity PVDF	
Kureha Chemical Company–Japan	KF POLYMER
www.kureha.co.jp	
Moderate PVDF capacity—expansion underway for 2001	
Solvay–Belgium, USA	SOLEF
www.solvay.com	VIDAR
Large capacity Europe; USA production 2000

[c]Subsidiary of Degussa-Hüls, formerly Hüls America.

for the monomer; high pressure polymerization reactors and associated finishing equipment; and special environmental and waste handling processes. Raw material costs for the overall process of feedstock to monomer and polymer are high, depending upon the processes, but reflect to a large extent the pricing of anhydrous hydrogen fluoride, which is involved in the various manufacturing processes for VDF. Also the processes for the monomer and polymer are energy intensive. It is for these reasons that several manufacturers of PVDF have extra production capacity for VDF monomer to supply not only their internal PVDF polymer needs

but also to provide the large quantities needed by the manufacturers of VDF-based fluoroelastomers.

The demand for PVDF has been driven by a number of factors: (*1*) a unique set of properties, (*2*) the ease and versatility in processing and fabricating, (*3*) over 30 years of proven performance under various and severe thermal, chemical, radiation, weathering environments and (*4*) the need for special attributes. For example, PVDF parts are subjected to superheated steam temperatures in some chemical processes. It is used also in strong acid, chlorine, bromine, and ultrapure water systems as well as in special applications where fire resistance is required. And PVDF has been used extensively during the last 30 years in nuclear radiation environments because unlike most plastics it cross-links, retaining mechanical integrity, rather than degrades. In one of the major applications worldwide, there is now over 30 years exposure of thin PVDF-based paint coatings on monumental structures and skyscrapers documenting the durability of these coatings to protect metal from corrosion, retaining essentially the original appearance features.

During the 1990s, there has been much activity in polymerization, scientific studies, and application development related to PVDF. Many copolymer variations and compounds of PVDF have been introduced by the polymer manufacturers and their immediate resin customers. This article will reference selected recent scientific and technology advances and focus upon property profiles and uses of the various PVDF grades available. A prior encyclopedia article (3) provides extensive references to the earlier studies. Detailed information on the properties and applications is given by the PVDF manufacturers at their websites. When the term *pvdf* is used to search the *Chemical Abstracts* databases from 1992, there are approximately 500 citations per year, about half of which are patents. Hence, the freedom to operate or utilize PVDF in any application by a new user should be verified by a careful check of the patent literature. In addition, producers of PVDF should be consulted regarding proposed medical applications, especially related to body invasive or implant technology.

PVDF is a partially crystalline, linear hydrofluorocarbon polymer that contains 59.4 wt% fluorine and 3 weight percent hydrogen. The high level of intrinsic crystallinity, typically near 60%, confers stiffness and tough, creep resistant properties. Incorporation of various fluorinated comonomers at low levels, typically about 5–10 wt% but as much as 20 wt% in some cases, enhances the flexibility of PVDF by reducing the crystallinity, which, in general, also reduces the end use temperature ratings. Commercial processes involve polymerization in emulsion or suspension using free-radical initiators. The spatial arrangement of the alternating CH_2 and CF_2 groups along the polymer chain and the strong dipole moment of the CF_2 accounts for the unique polarity, unusually high dielectric constant, complex polymorphism, and high piezoelectric and pyroelectric activity of the polymer when processed appropriately (4–6).

PVDF has the characteristic resistance of fluoropolymers to harsh chemical, thermal, ultraviolet, weathering, and oxidizing or high energy, ionizing radiation environments. The chemical resistance of this hydrofluorocarbon polymer is not as broad as exhibited by perfluoropolymers because the somewhat acidic hydrogen atoms along the chain are reactive in strongly basic media, leading to the formation of fluoride salt by-products (7,8). This chemical susceptibility has, in fact,

been turned to advantage in preparing PVDF samples for adherence to a variety of substrates as well as introducing reactive functionality for chemical grafting; the mechanism of the surface chemistry has been studied (9).

PVDF homopolymers and copolymers with various fluoroolefins have a wide range of applications including wire and cable products, electronic devices, chemical process equipment, use as a weather-resistant binder for exterior architectural finishes, and many specialized uses such as a stable binder for electroactive constituents in electrochemical cells. The polymer is readily melt-processed without processing aids or stabilizers using conventional molding or extrusion equipment; porous membranes are cast from solutions; and coatings are deposited from dispersions of PVDF using latent solvents, which solubilize the polymer at elevated temperatures, along with other additives to enhance the appearance, properties, and function. Certain grades of PVDF are used extensively for fluid handling components which convey high purity chemicals and ultrapure water because the resins may be fabricated easily into parts that have very low levels of extractable ionic or organic species and also very smooth surfaces that inhibit microbial fouling.

PVDF exhibits an unusual compatibility with other polymers having strong polar groups or carbonyl groups. This miscibility aspect has led to the development of many alloys and mixed systems for coatings, membranes, and extruded products.

In summary, PVDF fulfills special requirements in a variety of niche applications because of its unique characteristics. Hence, the broad and growing usage of this polymer is understandable. VDF usage also is increasing in other fluoropolymer and fluoroelastomer applications.

Monomer

Preparation. The principal industrial route to VDF involves dehydrochlorination of 1-chloro-1,1-difluoroethane (HCFC-142b) [75-68-3]. The principal producers are ATOFINA and Solvay in Europe and the United State and Ausimont and Alventia in the United States. Many patents exist for this and other similar preparative routes based upon dehydrohalogenation of various chlorofluorohydrocarbons or related compounds. Research efforts have escalated because the HCFC production will be curtailed in the mid-2000 period as a result of environmental concerns. Kureha (Japan) announced that their expansion would involve production of VDF from 1,1-difluoroethane (HFC-152a).

Properties. VDF is a colorless, flammable, and nearly odorless gas that has a very low boiling point like other small molecules with fluorine bonds. The physical properties are listed in Table 2. It is usually polymerized above its critical temperature and pressure, typically at pressures well above 3 MPa (30 atm), and approaching 10 MPa (100 atm) in some commercial processes; the polymerization is highly exothermic. Considering the flammability limits, caution must be exercised in any handling system.

Storage and Shipment. VDF (HFC-1132a) can be stored or shipped in gas cylinders or high-pressure tube trailers without polymerization inhibitors. Terpene and quinone inhibitors, however, may be used as a safety element where

Table 2. Physical Properties of VDF, $CH_2{=}CF_2$

	Units/conditions	Value
Molecular weight	Da	64.038
Boiling point	°C	−84
Freezing point	°C	−144
Vapor pressure	kPa @ 21°C	3683
Critical pressure	kPa	4434

Heat of polymerization	kJ/mol @ 25°C	−474.21
Water solubility	cm3/100 g @ 25°C/10 kPa	6.3

there might be uncertain environmental storage conditions. Liquid VDF can cause frostbite upon contact with the skin.

Health and Safety Factors. The combustion products are toxic. The OSHA website www.osha-slc.gov/ChemSamp_data/CH_275620.html provides the following information and full definitions of each classification code for environmental exposure and health factors as of year-end 2000.

Classification	Ratings	Comment
ACGIH TLV	500-ppm TWA	Not classifiable as a human carcinogen
NIOSH REL	1-ppm TWA; 5-ppm ceiling (15 min)	
IARC	Group 3	Not classifiable as to its carcinogenicity to humans

Uses. The variety of fluoropolymers and fluoroelastomers incorporating VDF in the main chain is extensive. The commercially important thermoplastic copolymers are based upon hexafluoropropylene HFP (10,11) chlorotrifluoroethylene (CTFE) (12,13) and co- or ter-polymers with tetrafluoroethylene (14). Telomerization of VDF to form fluorinated oligomers by radical addition has been reviewed (15).

Polymerization

VDF and other fluoromonomers are polymerized usually in aqueous medium in either emulsion or suspension. VDF polymerization in nonaqueous media is an active research area. VDF can copolymerize with fluorinated and some nonfluorinated monomers. Several aspects of VDF copolymerization with an array of fluorinated and nonfluorinated monomers have been reviewed (16,17); the reactivity ratios along with the Q and e parameters, which are measures of reactivity and polarity, respectively, have also been compiled. The interest in these

copolymers centers upon introducing functionality in the PVDF chain for subsequent reactions.

Only emulsion and suspension polymerization of VDF are commercially practiced because water provides a sufficient heat sink for the large heat release associated with VDF polymerization. Only one VDF-copolymer with nonfluorinated comonomers, maleic monoesters, and allyl glycidal ethers has been commercialized for battery applications (18); all other reported VDF-copolymers with nonfluorinated olefins have been laboratory or patent examples (3).

Polymerization procedures, temperature, pressure, recipe ingredients, monomer feeding strategy, and post-polymerization processing are variables that influence product characteristics and quality (19–26). The variety of commercial VDF-copolymers has been reviewed (27). VDF–HFP copolymers having decreased extractable oligomers and improved solution clarity and processability, especially important to lithium ion battery applications, have been claimed (28).

The degree of polymerization of commercial PVDF ranges from 1000 to 2500 VDF units. During radical-initiated polymerization, the "head-to-tail" addition of monomer units predominates where the "head" is $-CF_2\cdot$ and the "tail" is $-CH_2\cdot$. Reversed monomeric addition leading to "head-to-head" ($-CF_2-CF_2-$) and "tail-to-tail" ($-CH_2-CH_2-$) or so-called defect structures occurs. Commercial grades exhibit a wide range of 3–7 mol% defect structures as determined usually by nmr (29). The level increases with increasing polymerization temperature (30). The defect linkages affect significantly the crystallization processes and ultimate morphology (31,32).

In the emulsion process, a water-soluble *perfluorinated*-emulsifying agent is used to avoid radical scavenging reactions during polymerization and produce stable latex with a desired solid content. Typically, perfluoroalkylcarboxylate salts are cited in many VDF polymerization process patents. VDF can be polymerized without surfactant similar to conventional monomers (33,34), but only at low solid contents. Both inorganic peroxy compounds [eg, persulfates] and organic peroxides [eg, percarbonates (21)] may be employed as initiators. Other initiator systems such as a redox system (35) or a combination of fluoroaliphatic sulfinate and bromate (36) can also initiate VDF polymerization. Operating pressures can range from 1 to 20 MPa (10–200 atm) and temperature from 10 to 130°C. In a typical recipe, the polymer particles are solid and partial crystalline with diameters ranging from 100 to 250 nm depending upon the surfactant level. Particles are formed in the early stage by a homogeneous nucleation mechanism since VDF is in the vapor state. Various chain-transfer agents can be used such as chlorofluorohydrocarbons, fluorohydrocarbons, esters, and mercaptans.

VDF and suitable comonomers can be polymerized as a microemulsion where fluorinated oil-in-water microemulsion and fluorinated surfactant are present (37–39). The core-shell structure of these self-assembling systems and their distinctive polymerization features along with the range of particle size distribution have been reported (40).

Colloidal dispersants such as cellulose derivatives or vinyl alcohol are generally used in suspension polymerization of VDF to prevent coalescence and agglomeration of particles during polymerization. The polymerization pressure is similar to that of emulsion polymerization. Organic oil-soluble initiators such as peroxides, peroxycarbonates, or peroxypivalates are used depending upon

polymerization temperature, which ranges from 20 to 110°C (41–46). The molecular weight is regulated using oil-soluble chain-transfer agents such as dialkyl ethers and dialkyl carbonates. The reactor product is a slurry of suspended particles, usually spheres 15 to 120-μm diameter (41,43).

A suspension polymerization can be carried out using a radical photoinitiator with uv–visible light. Thus, photogeneration of radicals allows a lowering of the polymerization temperature (40). Lowering the polymerization temperature reduces the number of defect structures in PVDF.

Alloys of PVDF and PVDF copolymers with acrylic polymers are produced by a multistage aqueous dispersion polymerization. These intimately mixed polymer particles have found various industrial applications; particularly, in the waterborne high performance coasting application. In the early stages of the polymerization, the fluoropolymer portion is produced under standard condition with 50- to 150-nm particles. In a later stage, acrylic monomers are added to the reactor in the presence of persulfates under atmospheric pressure. The final morphology of the alloy, which ranges from a core-shell to an inter-penetrated structure to an intimate blend morphology, depends upon the composition of the fluoropolymer particles, the acrylic type, and the feed schedule (47–53).

The nonaqueous media used for VDF polymerization is either fluorocarbons or carbon dioxide under high pressure conditions. Fluorocarbons (54,55) and partially fluorinated hydrocarbons with no significant chain-transfer activities (56) are reported to be a suitable media for VDF polymerization.

VDF polymerization technology based upon super critical or liquid carbon dioxide as polymerization media has been reported (57–62). This technology offers an advantage in the polymer isolation step where a clean dry polymer is produced simply by depressurization. The residual monomer(s) and CO_2 can be recycled back to the reactor. PVDF is not soluble in CO_2 (58–60) and as a result, additional polymeric stabilizers are required to produce stable particles. Adequate CO_2 density for polymerization requires pressure significantly higher (typically $>$100 bar) than a conventional emulsion polymerization.

Telomerization of VDF in methanol with *tert*-butyl peroxide as the initiator is reported; polymerization kinetics along with telomer characterization are discussed (63). Microwave-stimulated, low pressure plasma polymerization of VDF gives a polymer film that is less than 10 μm thick (64). Highly regular PVDF polymer with minimized head-to-head addition was synthesized (65). Perdeuterated PVDF has also been prepared and described (66). The effectiveness of 1,1,1-trifluoro-2,2-dichloroethane (HCFC-123) as a chain transfer agent producing thermally stable PVDF in emulsion polymerization has been claimed (67).

Polymer Properties

Compared to the softer and mechanically less robust perfluorocarbon polymers, PVDF has high mechanical strength, abrasion resistance, and excellent resistance to both creep under long-term stress and fatigue upon cyclic loading (68,69). It also has excellent thermal stability and resists damage from most chemicals and solvents as well as from ultraviolet and high energy radiation. Typical design properties are shown in Table 3 for the homopolymers. The resin form is not

Table 3. Design Properties of PVDF Homopolymers[a]

Properties	Value or description
Appearance in film form	Transparent to translucent
Melting transitions, crystalline, °C	155–192
Specific gravity	1.75–1.80
Refractive index, n_D at 25°C	1.42
Mold shrinkage, average %	2–3
Flammability	Self extinguishing, no dripping
Tensile strength, MPa[b]	
25°C	42–58.5
100°C	34.5

[a]Values are ranges for the variety of *commercially* available grades or representative single point values. The values for any given test reflect the specific polymerization process and subsequent thermal/mechanical history of the sample. To assure consistent results in some tests, it is essential to anneal the samples in order to approach a thermodynamically stable morphology. See Ref. 27 for a compilation of VDF-copolymer properties.

[b]To convert MPa to psi, multiply by 145.

[c]To convert GPa to psi, multiply by 145,000.

[d]To convert J/m to ft·lbf/in., divide by 53.38.

hygroscopic and adsorption pickup is less than 0.05 wt% of surface water under ambient room conditions.

The properties of PVDF homopolymers and copolymers are sensitive to the chemical composition, molecular mass characteristics, and molecular architecture. These attributes are dictated by the polymerization method and ingredients, the method of isolation, and the thermal/mechanical history during isolation and subsequent processing.

From a composition viewpoint, the choice of initiator and chain-transfer agent determines end groups that affect thermal stability. These ingredients also dictate molecular mass characteristics involving the distribution of chain lengths and the molecular weight affecting processing and, ultimately, those properties related to the morphology of the solid polymer. The processing, morphology, properties, and end use performance are affected by the branching, cross-linking, differences in the content of defect structures, and other chain irregularities which exist in the PVDF polymers prepared under different conditions and ingredients. A 1999 study contrasts two commercial PVDF polymers based upon different polymerization chemistries (70), revealing differences in end groups and other properties related to composition.

Several of the key properties of PVDF homopolymers and copolymers depend upon the crystalline content and type of crystalline structure. The polymer chains involve long sequences of VDF units and can exist in several conformations. Figure 1 shows the alpha, beta, and gamma forms. The thermodynamically more stable alpha form involves a crankshaft configuration of the chain, which minimizes the steric interference between fluorine atoms along the chain. The beta form places the fluorines along one face of the chain, which is in a zigzag conformation. The gamma form is essentially a distortion of the alpha, where periodically one of the "cranks" is twisted out of the main chain geometry. Two other forms have been identified under very special conditions (71), but these so-called delta and epsilon forms are not typical of the structures existing in normal production or fabrication of parts. The effect of molecular weight and chain end groups on crystal forms of PVDF oligomers has been studied by several techniques (72) with interesting conclusions about the effect of the size of end groups upon conformational disorder in the crystals. A complex morphology involving the alpha and gamma forms occurs and dominates the spherulitic characteristics of the PVDF when the melted polymer is allowed to solidify at temperatures near the melting point (73). The reorganization rate of metastable crystals in PVDF and HFP-copolymers is dependent upon molecular weight (74).

Amorphous PVDF regions have a density of 1.68 (75), the alpha and gamma polymorphs 1.92 and 1.93, respectively, and the beta polymorphs 1.97 g/cm^3 (76). The density of the homopolymer PVDF cooled quickly from the melt is 1.76–1.78 g/cm^3. The melt density of PVDF homopolymers and VDF/HFP-copolymers is approximately 1.45–1.48 g/cm^3 at 230°C and 1 bar (77), ie a volumetric shrinkage factor of almost 20% occurs in cooling from the melt to the solid.

Depending upon the conditions, the linear PVDF chain configurations crystallize into spherulites that are lamellae of polymer chain segments. The alpha configuration is the thermodynamically stable form and predominates in the solid when molten PVDF is cooled. The beta configuration occurs in mixtures with carbonyl functional polymers or when a PVDF film sample is stretched. The gamma

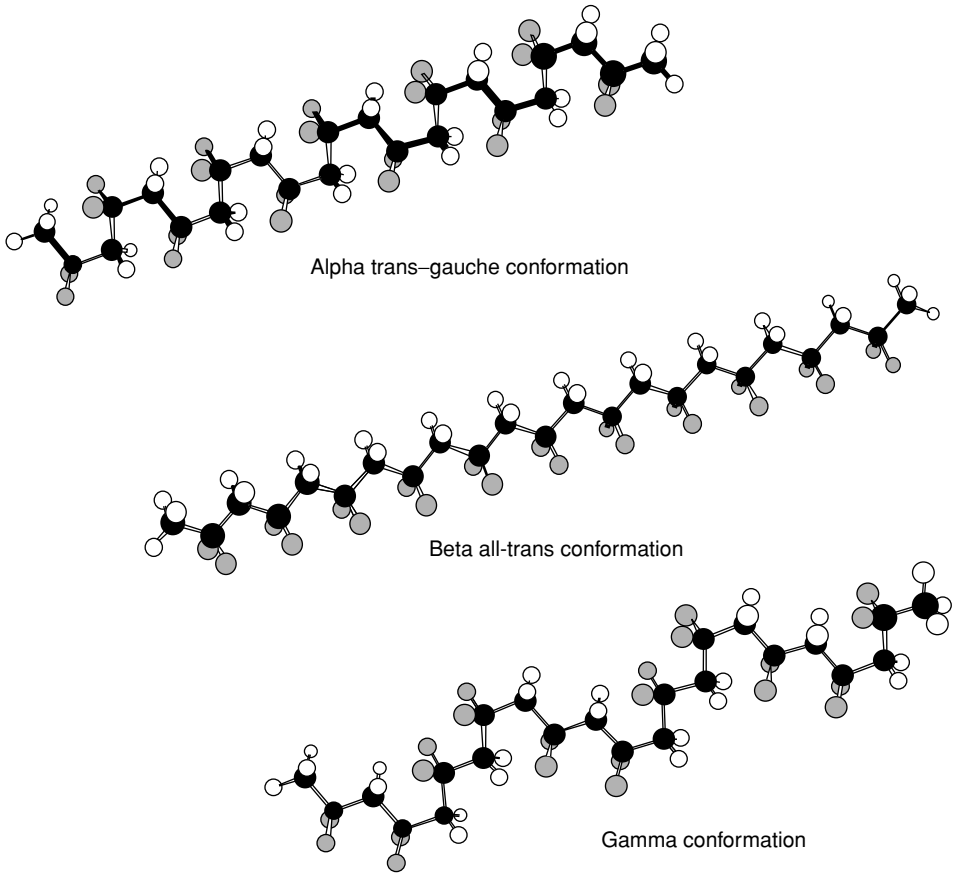

Fig. 1. Main polymorphs of PVDF.

form will develop when solid PVDF is exposed to certain chemicals. The heat of crystallization is high ranging from 50 to 58 J/g. The rates of crystallization are not only dependent upon backbone chain conformation dynamics, but also reflect the polymerization technique, which determines defect structures and end groups as well as molecular mass characteristics. PVDF crystallization may be nucleated by a variety of agents. In the absence of nucleating agents, emulsion PVDF samples show small crystallites developing slowly from the molten state compared to suspension polymer samples, which will show rapid development of very large crystallites under the same thermal conditions (rate of cooling and hold times at temperatures).

Many of the performance related properties (Table 3) in a given application (Table 4) depend upon the crystalline characteristics of the part. Interestingly, the content of defect structures determines the crystalline form; in the range of 11–14% levels, the beta form develops, whereas the alpha predominates at either extreme of this range (71,73,106). A detailed review of the effects of crystallization conditions upon the phases and morphology includes a summary of crystallographic, infrared, and thermal studies as well as related scanning electron

Table 4. Applications Profile for PVDF Homopolymers and Copolymers in Key Markets

Market applications	PVDF attributes	Comments
Coatings and paints	Solution characteristics are related to chemical composition and method of polymerization. Some processes utilize dispersions of PVDF particles with latent solvents to solubilize the PVDF at temperatures above ambient room conditions	Differences in solution behavior are exhibited by the various PVDF grades because of intrinsic chain composition (defect structures, end groups, comonomers, etc) and molecular mass characteristics
Binder for long lasting, weather resistant finishes for metals (primed galvanized steel, aluminum) used on sidings, roofing tiles, and other building components (78,79)	Photostability and resistance to radical attack. Film forming at reasonable temperatures. Long term weathering protection achieved at 25-μm film thickness.	These organosol paint formulations utilize inorganic pigments and < 30 wt% acrylic polymers, which enhance adhesion and confer other important attributes for a successful product. Major application worldwide. Thirty years of demonstrated weathering resistance (81). Often referenced as "architectural coatings"
	Formability of coated metal dependent upon coating application and storage conditions. (80)	Powder coating versions have been developed (82,83)
Decorative films for lamination to surfaces; automotive trim applications; aircraft interior surfaces in-mold lining processes (84)	Resistance to weather and chemicals; thermoformable; stain resistance; cleanability. Ability to solvent cast very thin, pigmented formulations onto carrier films, creating extremely smooth surfaces. Extruded films also	Becoming a major U.S. application. Two major film manufacturers. Both homopolymers and copolymer grades utilized to make films (85)
Corrosion resistant coatings tank liners (86)	Chemical resistant and ease of forming relatively thick coatings from liquid systems. Extruded PVDF tubing and sheet; easily thermoformed. Bead welding with PVDF rod to form seamless joints in liners	Primer coating and several applications of liquid system necessary to build to 1–2 mm thickness; drying temperatures around 250°C. Copolymer grades usually used for extruded tank lining sheets for lining tanks

Chemical processing equipment (25)	Note that PVDF may be adequate for high pH environments in applications where the surface degradation and fluoride leaching is not problematic, eg, alkaline waste streams (87)	Differences in chemical stress resistance are related to the different crystal structure of suspension and emulsion PVDF, the latter usually showing better performance
Flexible tubing for deep sea oil transport, (88)	Special PVDF grades are available (ATOFINA) having cold temperature flexibility important to installation conditions, high temperature chemical resistance	Major application. Hot, sulfurous oil at high pressure is a harsh chemical environment. Long service life requirement. Worldwide application
Packing for distillation towers	Chemical resistance, ease of molding complex shapes	Preferred over metal in many chemical processes because of corrosion issues with metals
High purity water systems; semiconductor facilities; pharmaceutical systems	Very low ionic and organic extractables; smooth surfaces inhibit microbial fouling. Operations at 90°C and in ozonated water (89)	Major application for special grades processed in special equipment to achieve low contamination resin
Piping for chemicals	Chemical resistance to strong acids and oxidizers; relatively high temperature stability	Pipe linings and solid pipe products. In one process, a solid PVDF tube with a wall thickness of several mm is hammered to a slightly smaller diameter than original, inserted into steel pipe, and allowed to relax to a tight fit, exemplifying the toughness of PVDF.
Pumps and instrument parts (90)	Chemical resistance at high temperatures Ease of molding complex shapes	Nonporous nature compared to PTFE parts High modulus reinforced compounds available from compounders

Table 4. (Continued)

Market applications	PVDF attributes	Comments
Fuel handling systems including underground storage tank systems and automotive fuel lines (91,92)	Very low permeation by hydrocarbons and oxygen containing additives achieved as a very thin barrier layer, typically about 50–250 μm	In general, these products are composites of less expensive polymers with the PVDF layer incorporated as an inner liner or embedded barrier
Electrical and Electronic	Note: High dielectric constant and dielectric loss factor are factors to be considered in any application	PVDF is not suitable as a primary insulation on AC power wiring because of absorption of the electromagnetic field and heating
Jacketing of cables for plenum areas including signaling, communication, and power lines	Flexible PVDF grades with additives as jackets on plenum cables have passed the severe UL910 modified Steiner tunnel test to qualify the products as low smoke and flame propagating assemblies meeting strict specifications	Another major application area for flexible PVDF copolymers only in the United State at this time. European and rest of the world specifications based upon fire testing may lead to further markets worldwide based upon this technology
Insulating compounds for jacketing wire and cable assemblies, cathodic protection, industrial power control systems, high temperature wiring	Radiation cross-linking improves toughness and abrasion resistance in these applications. PVDF copolymer responds readily to electron beam irradiation (93,94)	The compounds usually are mixtures of polymers and additives with PVDF being the major portion. It is the PVDF susceptibility to efficient cross-linking that allows economical processing rates
Speciality Applications		
Microporous membranes	PVDF is one of the few fluoropolymers that can be processed in solution. See Ref. 95 for a typical process and references to past technology	The technology involves casting a PVDF solution onto a surface covered with a nonsolvent, followed by special processing of the paper-like sheet. Extensive literature and patents
Toners	Triboelectric characteristics allowing charging of the carbonaceous powder. Thermoplastic nature important to fusion process. See Ref. 96 for a leading reference	PVDF is an essential ingredient at low levels in almost all commercial toners for photocopiers and many laser printers

Fishing lines and nets, Musical strings (97)	No water absorption; invisible in water; high knot strength; high specific gravity	Japanese application almost exclusively. Nylon monofilaments blended with PVDF have high knot strength and improved surface smoothness (98). Blends with polyethylene fibers (99)
Processing aid for polyolefins	PVDF copolymers at <1000 ppm in typical blown film applications is effective in reducing melt fracture and allowing increased extrusion rates	Developing market for PVDF in competition with established fluoroelastomer products
Monofilament for fabrics used in filtering wood pulp during bleaching	Chemical resistance to bleaching agents and other paper mill process chemicals	PVDF fabric replaced perforated stainless steel 25 years ago because of operational issues with metal corrosion
Lithium ion batteries; separators; electrode binder, (100–102)	Electrochemical stability at over 4 V is key property; high purity; solution casting; ability to cast thin electrodes from very high (>80%) carbon formulations	Relatively new application developing during late 1990s. Several hundred tons market in 2000, mainly in Japan
Piezo- and pyroelectric transducers for motion sensors, hydrophones, audio devices, etc; supercapacitors (103); electrolytic capacitors (104); aircraft interior sound control	Orientation under high electrical fields of the beta crystallites in thin films achieves high sensitivity to changes in shape because of pressure (piezo) or temperature (pyro). Considered a ferroelectric material because the remnant polarization is stable. Piezo film for active cancellation of noise in sound absorbing foam laminate	Very small volume application with significant impact over the years in the development of sensitive devices for military as well as security applications. Major research efforts since 1970s for this reason. Russian facilities had significant PVDF development efforts during the cold war “Foam-smart skin” concept (105)

microscopic evidence (5). The crystallization behavior of a mixture of PVDF samples, one with a low and the other a high content of defect structures, led to the interesting observation that the blended mixture crystallized faster than crystals formed in the individual samples (107), again emphasizing the importance of defect structures in affecting the properties of PVDF.

The complicated PVDF chain dynamics and the strong thermodynamic driving force to crystallize confer a complex set of intrinsic transitions as a function of temperature, which ultimately are reflected in the physical properties and behavior under various test conditions. The heat of fusion is approximately 100 J/g and depends upon the level of defects in the sample. Thermodynamic data for the amorphous and crystalline PVDF are tabulated at the website web.utk.edu/~athas/databank/vinyl/pvf2

The glass transition (T_g) of the amorphous PVDF regions is in the range of -40 to -30°C, depending upon the sample and test method. Other sub-T_g transitions have been studied recently by dielectric relaxation spectroscopy (108). These studies also indicate correlations with other techniques and identify a 50°C molecular chain transition as probably related to the amorphous region at the surfaces of crystals (109). Permeation characteristics are very sensitive to these transitions as well as the usual environmental parameters (110). Water molecules trapped in the amorphous regions are monomeric, not associated and clustered as in the liquid state (111).

The crystalline content in homopolymer PVDF samples that solidify quickly from the molten state is typically near 50%, increasing with time to higher levels approaching as a maximum 70%, again dependent upon the method of preparation and finishing. Because of the high crystallinity, the hardness or resistance to indentation of solid PVDF samples is retained up to within 10–15°C of the softening and melting transition region. Copolymers of VDF show lower levels of crystallinity (25–40%) depending upon the level of the comonomer and the method of preparation.

Unlike most crystalline polymers, PVDF exhibits thermodynamic compatibility with other polymers (112). Blends of PVDF and poly(methyl methacrylate) (PMMA), are miscible over a wide range of compositions (113–115). A variety of analytical techniques indicates specific hydrogen bonding between the oxygen of the carbonyl group and the acidic hydrogens along the PVDF chain (116). The same phenomenon explains the types of effective solvents for PVDF: cyclohexanone, dimethylsulfoxide, dimethylacetamide, phosphate esters, and other liquids with carbonyl functionality. Generally, the morphology of the polymer blends becomes even more complex than for the homopolymer PVDF because the polar or hydrogen-bonding interactions are not strong enough to overcome the strong thermodynamic driving force for PVDF crystallization. Studies indicate that the beta PVDF chain conformation develops in blends with acrylic polymers (116,117). Recently, blends with polymers containing imide moieties have been claimed (118). Ternary blends of PMMA, poly(vinyl acetate), and PVDF have been studied as a completely miscible system (119). Addition of 10–30 wt% PMMA improves the transparency of the PVDF films or coatings in the uv–visible spectrum. The relationship between the optical transmission and compatibility of PVDF/PMMA blends is reported (120); in general, films of the blends with at least 15 wt% PMMA are very transparent (>90% transmissivity).

Fabrication and Processing

PVDF is available commercially in a wide range of melt flow rates and with various additives to enhance processing or end use properties. A variety of forms are available—latex and fine powders from emulsion processes and granules from either suspension or emulsion processes.

In melting processes, it is essential to consider the full range of shear rate characteristics of the polymer. Moreover, polymerization techniques have been developed which make different versions of the same composition and polymerization ingredients behave rheologically differently. The rheological characteristics specified for a given commercial PVDF grade should be a consideration in developing a melt-based process to produce parts. Figure 2 shows the different shear behavior of two homopolymer PVDF samples prepared by polymerization with different recipes. Hence, a process such as fusion of powders to a contiguous film requires Newtonian flow at zero shear conditions (curve A), which is achieved by a narrow molecular weight distribution and low molecular weight mass. A high speed extrusion generally would proceed with less surface fracture or melt instabilities given a broad molecular weight distribution or shear-thinning melt, which is sample B, having a high molecular weight mass.

Both homopolymers and copolymers may be shaped from the molten state without extrusion aids or thermal stabilizers. A broad operating window exists for melt processing between the points when crystallites begin to melt and the onset of thermal decomposition. Figure 3 superimposes the thermal gravimetric analysis (tga) curve and the differential scanning calorimeter (dsc) graph for the melting phenomenon. Conventional equipment is used in processing molten PVDF. Longevity of equipment can be extended with special alloys on surfaces that contact the melt, but usually are not necessary.

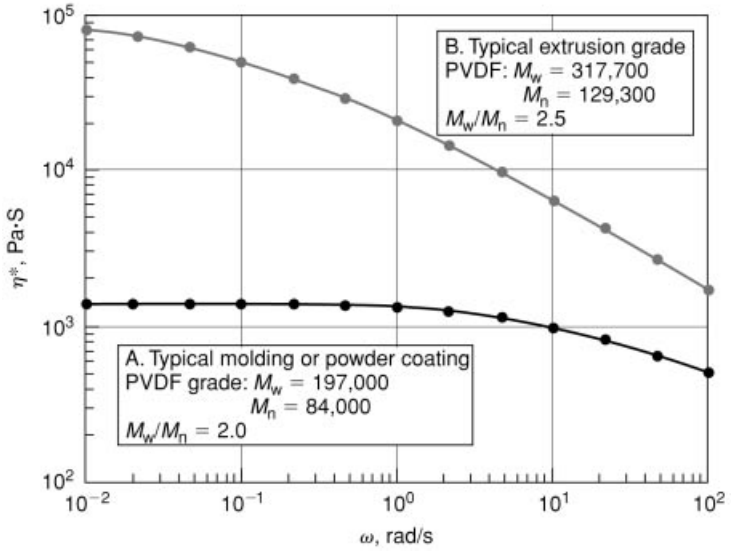

Fig. 2. Rheological profiles for two commercial PVDF grades. The melt rheology converges at high shear rates above 100 rad/s.

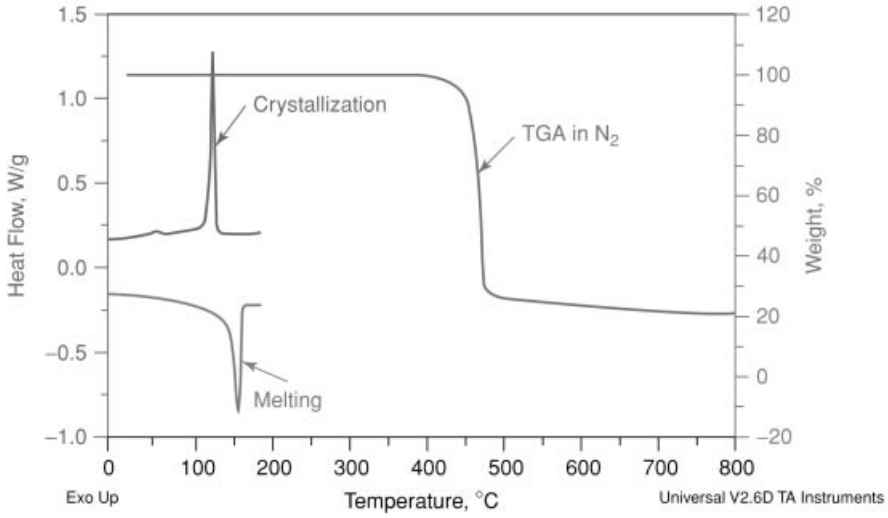

Fig. 3. Thermal gravimetric analysis and differential scanning calorimetry of a PVDF homopolymer.

All the common extrusion and molding techniques can be used to process PVDF into shapes. Typical molding temperatures in the cylinder and nozzle are 180–240°C for injection types, and for molds are 50–90°C. As a crystalline polymer, it shows relatively high mold shrinkage of about 3%, reflecting the high degree of crystallization and the difference between the solid and molten densities as mentioned earlier. In most cases, it is prudent to develop appropriate post-forming annealing cycles, typically 15°C or more above the crystallization temperature (Table 3), to stabilize the parts. Hence, the design of molds requires careful considerations of final part tolerances before cutting metal.

PVDF is not hazardous under typical melt processing conditions. At temperatures approaching 300°C, the onset of a thermal degradation will be evident as a darkening of the resin. This discoloration arises from the dehydrofluorination reaction forming the conjugated polyene structures that absorb strongly in the visible spectrum. It is helpful, in fact, as a very sensitive indicator of overheating. Immediate remedial action should be taken to reduce the heat. At temperatures well above 300°C and approaching 350°C, thermal decomposition accelerates, leading to release of hydrogen fluoride. The tga curve (Fig. 3) shows that the decomposition is essentially quantitative with respect to carbonaceous residue and hydrogen fluoride evolution at about 400°C.

Before ingredients are added to PVDF to make compounds, a thorough laboratory study should be conducted in properly vented ovens at temperatures that might be encountered in the range of operating conditions. Certain additives such as titanates and silicates catalyze the thermal decomposition of molten PVDF at temperatures lower than typical for the natural resin, leading to dangerously high pressures in the equipment because of by-product gases. Generally, metal oxides catalyze degradation at high processing temperatures, eg, the oxides of titanium, manganese, and iron. Resin producers should be consulted for melt processing

recommendations whenever additives are utilized in compounds. Frequently, the compounds include an acid-scavenging agent like zinc or calcium oxide to react with any hydrogen fluoride that might form during processing.

Coextrusion and lamination processes have been described extensively in the patent literature. The technology usually involves multilayer structures utilizing, as an adhesive layer, a compound of PVDF with another material, which provides the bonding to the substrate. In this way, the full benefits of a thin film of PVDF may be realized (121). Another approach using acrylic alloys with PVDF sometimes achieves adherence to various substrates without the "tie layer" necessary for the pure PVDF film (122). The full breadth of options available by these technologies to protect surfaces with weatherable PVDF surfaces has been reviewed (123). Surface PVDF layers on polyolefins has been a particular technology of interest with respect to suitable finishes in cost effective parts for exterior automotive and agricultural equipment applications (124).

Powder grades usually are used whenever compounds are prepared in order to achieve homogeneity of the blends. Latex grades are utilized in some applications where it is possible to dry and fuse the material under conditions producing a coating upon the substrate, typically fabrics.

Solid PVDF parts may be joined by various fusion methods; the manufacturers should be consulted for recommendations. Fusion methods are preferred over solvent joints because the strength is much greater and for the ease in preparation. Vibration welding has been practiced. Because of the high dielectric loss, ie absorption of microwave electromagnetic radiation, rf-induction heating methods have been used to soften or melt PVDF parts. Welds may be particularly susceptible to stress cracking in strongly basic solutions where discoloration develops as a result of dehydrofluorination (7,8).

Economic Aspects

The extensive use of PVDF has developed in spite of the relatively high price and specific gravity compared to the commodity nonfluoroplastic polymers and the widely known thermoplastic engineering resins. Compared to all other common fluoropolymers, PVDF is the least expensive on a volume basis. Over the last decade the market pricing of standard PVDF grades has remained remarkably constant around $14–15/kg. See www.plasticstechnology.com for updated pricing comparisons.

Health and Safety Factors

PVDF is nontoxic, odorless, and has no taste. Extraction testing has led to a listing with the FDA as being suited to single use contact with food (125); this applies to both homopolymer and copolymers with low content of HFP (<20 wt%). Various manufacturers have qualified specific grades with appropriate agencies and standards organizations for a variety of applications including potable water systems, home construction, medical applications, food contact, and packaging. Some of the agencies or standards involved are the U.S. Department of Agriculture, 3A Sanitary Standards, Food & Drug Administration, National Sanitation Founda-

tion, U.S. *Pharmacopeia* USP Class 6, and others. See the producers websites for specific applications having the appropriate approvals.

PVDF powders are not explosive, but the MSDS guidelines for personal protective equipment should be followed. The powder is not removed readily by dry cleaning; it should be brushed from dark clothing. Storage of large quantities of PVDF should adhere to local regulations regarding possible hazards in fire environments.

Uses

The major applications of PVDF are summarized in Table 4. Since the 1996 version of this encyclopedia series (3), an increasing interest has developed in the use of PVDF as a binder and polymeric separator in lithium ion batteries. The literature since 1998 also has numerous references to the use of PVDF in fuel cells, eg, in membranes (102) and electrodes (126); it is a technology anticipated to become a significant factor in electrical vehicles before 2010. These two technology areas, both of which reflect the electrochemical stability and chemical resistance attributes of PVDF, may lead to major applications for PVDF. In a related application area, the use of PVDF films for electrostatic capacitors is being investigated because it has a very high DC current breakdown voltage (770 MV/m) and a large maximum energy density capability (28.9 J/cm). Both attributes are related to the very high dielectric constant (Table 3) (103). Note that some PVDF grades are more suited to this application by virtue of purity than others are because ionic impurities lead to dielectric breakdown at relatively low voltages.

Several Japanese patent applications since 1992 discuss the processing technology necessary to manufacture monofilaments for fishing lines and nets or other monofilament applications, which must have extremely high tensile strength and knot strength (127). It is claimed that PVDF monofilaments are not visible to the fish in seawater (refractive index $\approx$ 1.31 compared to 1.42 for homopolymer PVDF).

Since the original Timmerman patent in 1964 (128) on the radiation response of PVDF, the use of PVDF in wire and cable applications has increased dramatically with electron beam irradiation as the key process step to cross-link the PVDF compounds for higher temperature capability (93,94). In general, the copolymers cross-link more efficiently than homopolymer grades. A certain PVDF homopolymer, which is polymerized at high temperatures with organic peroxides, seems to be an exception among the various homopolymer grades. Presumably, because of the particular polymerization process, this resin has been used as insulation on signal wiring since the late 1970s; it can be extruded at very high rates and cross-links more readily under ebeam irradiation than other homopolymer grades. PVDF polymers cannot be considered a generic grouping like polyethylene, which according to density or polymerization catalyst have essentially the same properties. PVDF properties and suitability for any given application are a sensitive function of the polymerization and isolation methods of the polymer, which differ for each producer.

Table 3 indicates the excellent radiation resistance to 61 Mev beta emissions from cobalt-60. A process to etch "tracks" of high energy, heavy nuclei in PVDF films has been developed in order to make nuclear track microfilters (129).

Another recent advance in PVDF technology involves coating applications using the acrylic–fluoropolymer lattices which are produced by sequential polymerizations (see as given earlier). Initial reports indicate improved paint properties than heretofore produced by mixing and blending techniques (130).

As space exploration, development of speciality military and oceanic equipment, and advances in telecommunication equipment and connection systems evolve during the next millennium, the use of PVDF will expand because of its unique set of properties and useful functions in various designs. In addition, the ease of processing by a variety of techniques into complex shapes and relatively simple and straightforward fabrication methods will be significant factors in choosing PVDF for these future applications.

VISCOELASTICITY

Introduction: Perspectives on the Fundamentals of Polymer Viscoelasticity

Viscoelasticity is a phenomenon that has been known since the middle of the nineteenth century when workers such as Weber (1), the Kohlrausches (2), and others were interested in using natural fibers, such as silk, to hold needles in measuring devices such as ammeters. They found hysteretic and time-dependent effects that were difficult to explain fully and to characterize. Later, Boltzmann (3) developed his superposition principle and linear viscoelasticity began to have a formal framework for understanding the phenomenology of the inelastic effects observed earlier (4). While other early pioneers such as Andrade (5) and Zener (6) observed anelasticity or viscoelasticity in metals, the real impetus for understanding viscoelasticity came with the commercial development in the middle of the twenieth century of high molecular weight polymers. One reason for this is that polymers exhibit non-Newtonian behavior in the melt state, which is attributable to both elastic effects and shear-rate-dependent viscosity. This leads to important time and rate effects during the processing of polymers. In addition, once processed, polymers are generally used at less than 200 K from the glass-transition temperature. Hence, even in the "solid-like" state, polymeric materials exhibit time- and frequency-dependent mechanical (and other) properties that have been categorized as viscoelastic. In the current work, the linear and nonlinear viscoelastic responses of polymers from both phenomenological and molecular views are surveyed. An overview of the viscoelastic behavior of polymers in solution, melt, glassy, and semicrystalline states is provided.

Material Functions—Linear Viscoelasticity. One of the most important aspects of both the phenomenological and the molecular theories of

Encyclopedia of Polymer Science and Technology. Copyright John Wiley & Sons, Inc. All rights reserved.

viscoelasticity is the ability to characterize the *material functions*. The material functions are the properties that allow one to relate the stress response to a strain (deformation) history and vice versa through a *constitutive* equation. In linear viscoelasticity theory, generally isotropic descriptions are dealt with; that is, the properties are the same in all directions. However, a material may be anisotropic and still have properties that vary with the direction of the test (7). Here only the isotropic case is considered and it is recognized that straight forward extensions can be made to the anisotropic case. In addition, only homogeneous materials, for which the properties are the same at all points within the material, only are discussed.

Stress and Strain Definitions. As remarked, the material functions relate the stress and strain responses of the material through a constitutive equation. For the elastic material, there is no time dependence and the relationships are relatively simple. In the case of linear viscoelasticity, equations that take into account the time history of the stresses or strains are required. First, stress and strain are defined.

The infinitesimal strain tensor is defined in various ways; here the notation of Timoshenko and Goodier (8) is adopted in terms of the displacements u_i of a material element and as depicted in Figure 1a.

$$\varepsilon_{ij} = \frac{1}{2}\left(\frac{\partial u_i}{\partial x_j} + \frac{\partial u_j}{\partial x_i}\right) \tag{1}$$

and the full strain matrix in terms of the ε_{ij} is written as

$$\varepsilon_{ij} = \begin{bmatrix} \varepsilon_{11} & \varepsilon_{12} & \varepsilon_{13} \\ \varepsilon_{21} & \varepsilon_{22} & \varepsilon_{23} \\ \varepsilon_{13} & \varepsilon_{23} & \varepsilon_{33} \end{bmatrix} \tag{2}$$

Similarly, the stress tensor can be defined in terms of the forces acting on the faces of an element and these are given by the following expression (see Fig. 1b):

$$\sigma_{ij} = \begin{bmatrix} \sigma_{11} & \sigma_{12} & \sigma_{13} \\ \sigma_{21} & \sigma_{22} & \sigma_{23} \\ \sigma_{13} & \sigma_{23} & \sigma_{33} \end{bmatrix} \tag{3}$$

Note that when $i \neq j$, it is common to write the shear strain $\gamma_{ij} = 2\varepsilon_{ij}$ and shear stress $\tau_{ij} = \sigma_{ij}$. In addition, $\gamma_{ij} = \gamma_{ji}$ and $\tau_{ij} = \tau_{ji}$.

Elastic Material Functions. The material functions that are used here for an isotropic, elastic material are the shear modulus G, the extensional modulus E, the bulk modulus K, and the Poisson's ratio ν. However, any two of these provides the full set of information needed to describe such a material, as they are not all independent. For simple deformations, the definitions of these moduli are

$$\begin{gathered} \text{Extensional modulus: } E = \frac{\sigma_{11}}{\varepsilon_{11}} \\ \text{Bulk modulus: } K = \frac{P}{\varepsilon_v} \quad \textit{where} \quad \mathrm{P} = \frac{\sigma_{11} + \sigma_{22} + \sigma_{33}}{3} \quad \text{and} \quad \varepsilon_v = \varepsilon_{11} + \varepsilon_{22} + \varepsilon_{33} \\ \text{Poisson's ratio: } \nu = \frac{\varepsilon_{11}}{\varepsilon_{22}} \end{gathered} \tag{4}$$

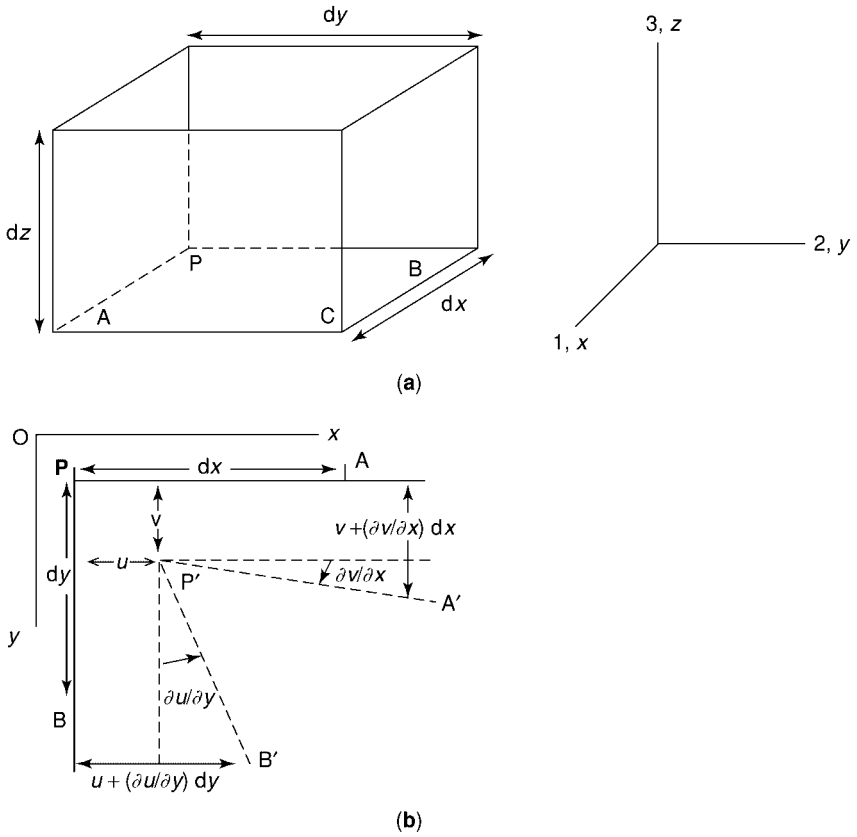

Fig. 1. (**a**) Three-dimensional depiction of elementary material point (dx, dy, dz) and the two-dimensional sketch of the displacements in the x and y directions of the cube that define the strains. The displacement of the point P has components u, v, w, and the displacement in the x direction of a nearby point A is $u+\partial u/x$; and the increase in length of PA due to a deformation would be $(\partial u/\partial x)$ dx, making the unit elongation in the x direction $\partial u/\partial x$. Similarly, unit elongations in the y and z directions would be given by $\partial v/\partial y$ and $\partial w/\partial z$. After Timoshenko (8). (**b**) Considering the distortions of the angular elements PA and PB in this two-dimensional depiction, the displacements of the point A in the y direction and of B in the x direction are given by $v+(\partial v/\partial)$ dx and $u+(\partial u/\partial y)$ dy, respectively. The small angles in the figure (distortion of the P′B′ and P′A′ relative to PB and PA) are given by $\partial v/\partial x$ and $\partial u/\partial y$. Hence, it is seen that the original right angle APB distorts to A′P′B′ by an amount $(\partial v/\partial x + \partial u/\partial y)$, which is the shearing strain between the planes xz and yz. After Timoshenko (8). (**c**) Representation of the components of stress acting on an elementary cube. After Timoshenko (8).

And the relations between the moduli are

$$G = \frac{E}{2(1+v)}$$
$$K = \frac{E}{(1-2v)} \tag{5}$$
$$E = \frac{9KG}{3K+G}$$

and one more constant referred to as the Lamé constant λ is defined as

$$\lambda = \frac{vE}{(1+v)(1-2v)} \tag{6}$$

The ways in which the moduli are obtained through experimental measurements are discussed subsequently. Still working with an elastic material, one can now define the relationships between the stresses and the strains. In this case, this is the linear elastic constitutive relation:

$$\sigma_{ij} = \lambda \delta_{ij} \varepsilon_{kk} + 2G\varepsilon_{ij} \tag{7}$$

where δ_{ij} is the Kronecker delta. For simple geometries of deformation, such as those used in experiments, equation 7 can be simplified as

$$\begin{gathered} \text{Simple extension: } \sigma_{11} = \lambda \varepsilon_{kk} + 2G\varepsilon_{11} = E\varepsilon_{11} \\ \text{Simple shear: } \sigma_{12} = \tau_{12} = \lambda \varepsilon_{kk}(0) + 2G\varepsilon_{12} = G\gamma_{12} \end{gathered} \tag{8}$$

Hence, one can relate the stresses to any applied state of strain. Furthermore, the strains can be determined as functions of the applied stresses. Note that, in general, the theory of elasticity does not demand the development of compliance functions, which relate strains to stresses, as they are the inverse of the moduli. In the case of viscoelasticity, this is not so, and both modulus and compliance functions are developed in the next section.

The Viscoelastic Material Functions. In linear viscoelasticity, the moduli discussed for the elastic case can be recast as time- or frequency-dependent functions. The same is true for the compliance functions that are discussed here. For simplicity, consider the shear modulus G which becomes $G(t)$ or $G^*(\omega)$ in the case of the viscoelastic material. An important point here is that the viscoelastic modulus functions all exhibit time (frequency) dependence. Hence, one will have functions for $K(t)$ and $E(t)$ [or, eg, $G(t)$ and $\nu(t)$] and these are required in the case of a three-dimensional strain or stress field.

The general approach to discussing linear viscoelasticity comes from the Boltzmann superposition principle represented as a *hereditary* integral. For the shear stress as a function of shear strain, one obtains

$$\tau_{12}(t) = \int_0^t G(t-t') \frac{\mathrm{d}\gamma_{12}}{\mathrm{d}t'} \mathrm{d}t' \tag{9}$$

and for the strain as a function of the stress,

$$\gamma_{12}(t) = \int_0^t J(t-t') \frac{\mathrm{d}\tau_{12}}{\mathrm{d}t'} \mathrm{d}t' \tag{10}$$

Here it is emphasized that the definition of the elastic compliance $J = 1/G$ is not valid for the viscoelastic compliance $J(t)$ used in equation 10. Rather it is the complex compliance $J^*(\omega) = 1/G^*(\omega)$. In addition, all the linear viscoelastic functions can be related one to the other. Full discussion of these relationships can be found in Ferry (9) and Tschoegl. (10).

As shown above, the material functions and the constitutive equation determine the relationships between the stresses and the applied deformations or vice versa. Hence, understandings of both the material functions and the form of the constitutive law are important to successful use of our current knowledge of the viscoelastic behavior of polymers. The material functions alone can give much insight into molecular viscoelasticity and the general time-dependent behavior of the material. Combined with the constitutive laws (eqs. 9 and 10), the material functions give a predictive capability of material performance in arbitrary loading histories. The next section first discusses these aspects of the material functions, using simple mechanical analogues that give some sense of viscoelastic behavior. This is followed by examples of the Boltzmann superposition represented in equations 9 and 10. Finally, the meaning of linear viscoelastic behavior is discussed as a potential means to gain insight into molecular behavior in polymers.

Mechanical Analogues.

The Maxwell Model. In the above development, discussion moves from elastic behavior to viscoelastic descriptions of material behavior. In a simple sense, viscoelasticity is the behavior exhibited by a material that has both viscous and elastic elements in its response to a deformation or load. In early days, this was often represented by elastic or viscous mechanical elements combined in different ways (9–12). The simplest models are two element models that contain a viscous element (dashpot) and an elastic element (spring). The dashpot is assumed to follow a Newtonian fluid constitutive law in which the stress is related directly to the strain rate by the following expression:

$$\tau_{12} = \eta_0 \, \dot{\gamma}_{12} \tag{11}$$

and the spring is assumed to be linearly elastic:

$$\tau_{12} = G\gamma_{12} \tag{12}$$

and when they are combined in series to form a *Maxwell* model the response is the combined response of the two elements. The Maxwell model is represented in the insert in Figure 2.

Now, imagine deforming the Maxwell model by applying a constant strain to it at a time $t = 0$. The deformation is held constant and the stress is monitored. Figure 2 shows the mechanical response of the Maxwell model to an applied deformation. The first (early time) response is that the "material" responds only elastically because the viscous damper initially behaves rigidly (at infinite rate of strain). The total deformation of the element remains constant, but it redistributes itself between the spring and the dashpot. This results in *stress relaxation* that occurs exponentially with time:

$$G(t) = \frac{\tau_{12}(t)}{\gamma_{12}} = G\mathrm{e}^{-t/\lambda} \tag{13}$$

And the reader is reminded that the stress is relaxing at constant strain. Furthermore, equation 13 allows one to introduce the concept of a relaxation time

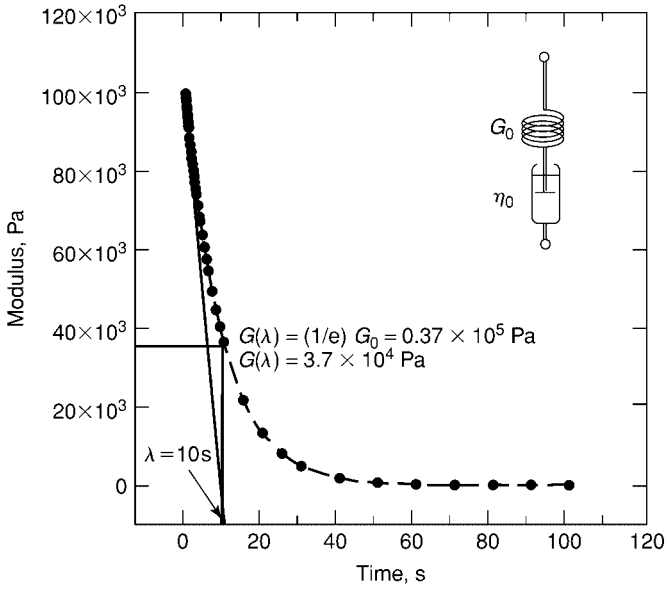

Fig. 2. Relaxation of the modulus in a stress relaxation experiment for a Maxwell element (insert). The construction shows two ways in which the relaxation time λ can be determined.

$$\lambda = \frac{\eta_0}{G} \tag{14}$$

that is, the characteristic time for the stress in the Maxwell element to decay to 1/e of its initial value (see Fig. 2). (Note the use of the symbol λ as the relaxation time and not the Lamé constant given previously. Also, τ is often used as the symbol to represent the relaxation time, but τ is used here for the shear stress.)

The Kelvin–Voigt Model. The other two-element mechanical model for viscoelasticity is the Kelvin–Voigt model in which the spring and dashpot are in parallel. In this model, the deformation or *creep* response to the imposition of a constant load is illustrated. In this instance a constant load is applied at $t = 0$ and the deformation is monitored. The Kelvin–Voigt model and its response are illustrated in Figure 3. The material property of interest in this case is the *creep compliance* $J(t)$ and it is written as

$$J(t) = \frac{\gamma_{12}(t)}{\tau_{12}} = \frac{1}{G}(1 - e^{-t/\lambda}) \tag{15}$$

And, now, the characteristic time λ is referred to as the *retardation time* because of the retarded elasticity of the material. That is, initially the load is carried by the viscous dashpot and then redistributes until, at long times, the load is carried fully by the elastic spring. Figure 3 shows the response to a loading history in which the load is applied for 100 s and then reduced to zero. Both the creep strain $\gamma(t)$ and the recoverable strain are depicted in the figure. The recoverable compliance would be obtained from the recoverable strain and the applied stress as

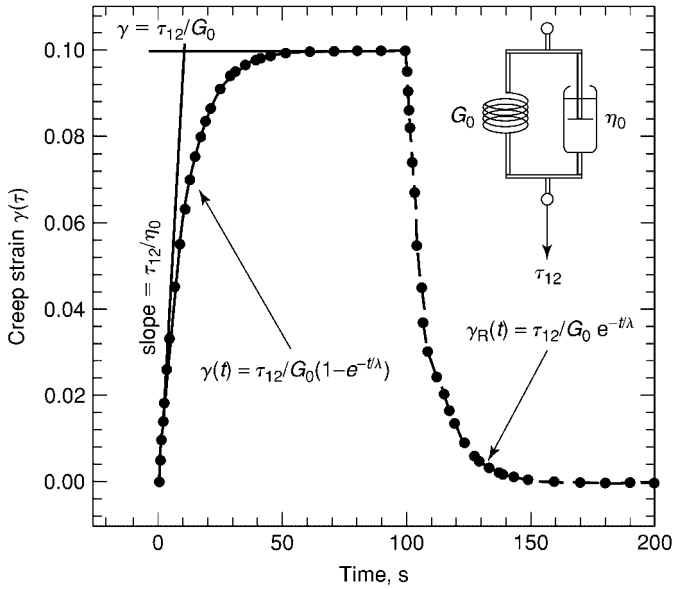

Fig. 3. Creep and recovery response for a Kelvin–Voigt model (insert).

$J_R(t) = \gamma_R(t)/\tau_{12}$, but only when the material has reached its equilibrium response is this a material property.

The Burgers Model. As a preview to the viscoelastic behavior of polymers, we next consider the four-element Burgers model that captures a "minimum" set of behaviors that is seen in polymeric materials and as discussed here (13). The insert in Figure 4 shows the Burgers model as a Maxwell model in series with a Kelvin–Voigt model. As shown in Figure 4, upon application of a constant stress τ_{12} for a time t_1 followed by its removal, the model captures the following aspects of polymer viscoelasticity:

(1) "Instantaneous" elasticity or elastic recovery (spring element G_1)
(2) Molecular "slip" (viscous element η_1)
(3) "Entropic" or rubbery elasticity (spring G_2)
(4) "Retarded" elasticity (Kelvin–Voigt element G_2 is retarded by η_2)

Polymers, as seen later, show more complex viscoelastic behaviors than does the Burgers model, but the essentials are in the Burgers model. The "instantaneous" elasticity can be thought of as the "glass-like" response; the molecular "slip" is the terminal response, as the long polymer molecules slide past each other and disentangle; the entropic elasticity occurs because of the long chains being entangled like a three-dimensional network of "entropic springs"; and the retarded elasticity occurs because of the resistance of the polymer melt to the

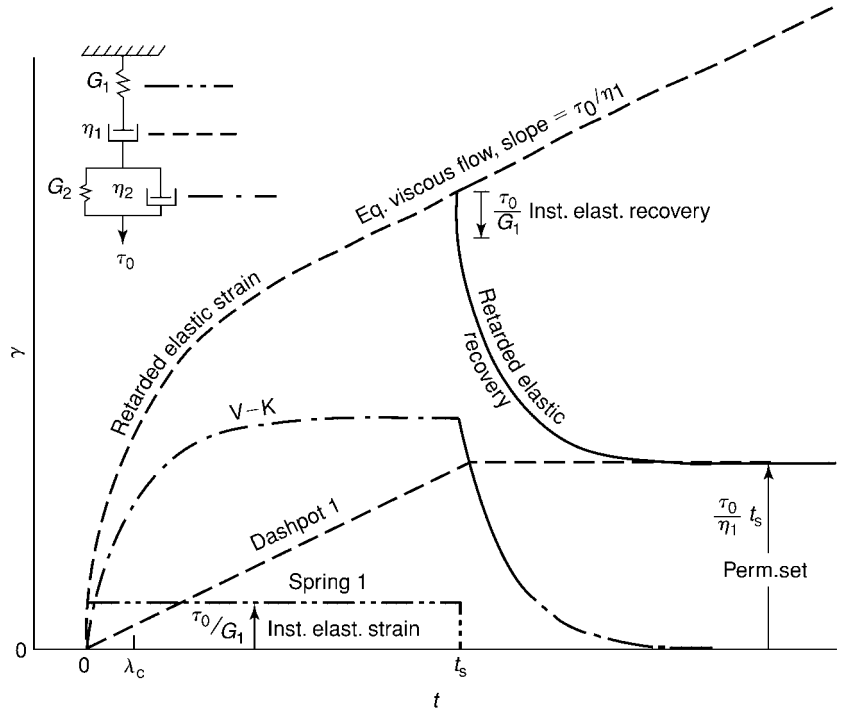

Fig. 4. Creep and recovery response for a Burgers model (insert), showing the four regions of "polymer-like" viscoelastic response as discussed in text. After Rosen (13), with permission.

forces applied by the spring. The equation for the creep compliance of the Burgers model is

$$J(t) = \frac{1}{G_1} + \frac{1}{G_2}(1 - e^{-t/\lambda}) + \frac{t}{\eta_1} \tag{16}$$

where $\lambda = \eta_2/G_2$. Upon unloading, the *recoverable compliance* $J_R(t)$ is

$$J_R(t) = J(t) - \frac{t}{\eta} \tag{17}$$

Note that equation 17 is the general equation for the recoverable compliance regardless of the model. Figure 4 gives a simplified sense of what the various aspects of polymer viscoelastic behavior are, although the actual behavior is more complex.

General Models. Clearly, one can add up springs and dashpots in a great number of ways. It is common practice to use either a generalized Maxwell model or a generalized Kelvin–Voigt model. The generalized Maxwell model, which is simply a set of Maxwell elements in parallel, is shown in Figure 5a. The generalized Kelvin–Voigt model, which is a set of Kelvin–Voigt elements in series, is shown

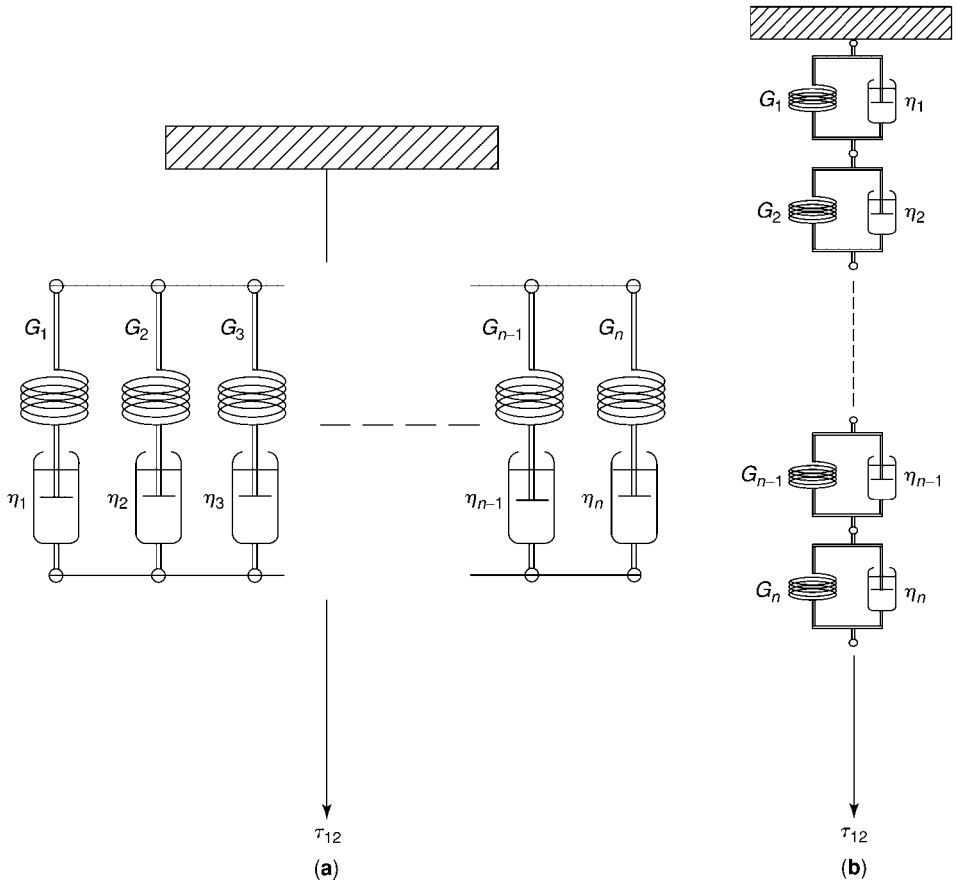

Fig. 5. (**a**) The generalized Maxwell model. (**b**) The generalized Kelvin–Voigt model.

in Figure 5b. The choice of model is primarily a matter of convenience because it is possible to find a *conjugate* Maxwell model to any Kelvin–Voigt model and vice versa (10). However, the moduli are most easily described with the Maxwell model and the equations for these are

$$G(t) = G_0 + \sum_{i=1}^{N} G_i \mathrm{e}^{-t/\lambda_i}$$

$$G'(\omega) = G_0 + \sum_{i=1}^{N} \frac{G_i \omega^2 \lambda_i^2}{1 + \omega^2 \lambda_i^2} \tag{18}$$

$$G''(\omega) = \sum_{i=1}^{N} \frac{G_i \omega \lambda_i}{1 + \omega^2 \lambda_i^2}$$

and the compliances are most easily described using the generalized Kelvin–Voigt model:

$$J(t) = J_g + \sum_{i=1}^{N} J_i(1 - e^{-t/\lambda_i}) + \frac{t}{\eta_0}$$

$$J'(\omega) = J_g + \sum_{i=1}^{N} \frac{J_i \omega^2 \lambda_i^2}{1 + \omega^2 \lambda_i^2} \tag{19}$$

$$J''(\omega) = \sum_{i=1}^{N} \frac{J_i \omega \lambda_i}{1 + \omega^2 \lambda_i^2} + \frac{\eta_0}{\omega}$$

The equation sets 18 and 19 provide a means of fitting experimental data to an arbitrary accuracy. It is important to remark, however, that the problem of actual fitting of data, while easier today than in the past because of the prevalence of high speed personal computers and commercial software, is nontrivial, and the reader who is interested in details of the treatments should refer to the appropriate literature (14–19).

Interrelationships among the Viscoelastic Material Functions. There is a continuing disagreement within the molecular viscoelasticity community about which of the above methods should be used to characterize a material (20). In fact, if one can obtain the zero shear rate viscosity and any of the other functions, these methods are all equivalent. The issue, however, revolves around the fact that some features that appear in the dynamic modulus disappear if the compliance is used as the function to represent the data and vice versa. Also, some measurements are more or less dominated by the viscosity contribution. As a result, some problems of misinterpretation of data could be averted if workers who prefer modulus representations would calculate the compliances. In addition, those who measure the compliance should calculate the moduli in order to provide the data in the format that is more common in the field because of the large number of commercial instruments that obtain dynamic moduli. The advent of modern software packages that make the interrelationships easily calculated makes this dispute seem to go away. The pathways to determine the different material functions, one from the other, are shown in Figure 6.

Boltzmann Superposition and Linear Behavior.

The Phenomenology of the Linear Theory of Viscoelasticity. One of the powers of the linear viscoelasticity theory is that it is predictive. The constitutive law that comes from Boltzmann superposition theory requires simply that the material functions discussed above be known for a given material. Then, for an arbitrary stress or deformation history, the material response can be obtained. In addition, the *elastic–viscoelastic correspondence principle* can be used so that boundary value problems such as beam bending, for which an elastic solution exists, can be solved for linear viscoelastic materials as well. Both of these subjects are treated in this section.

Boltzmann Superposition and the Constitutive Law for Linear Viscoelasticity. The underlying assumption of the Boltzmann superposition principle is that responses to loads or deformations applied to a material at different times are linearly additive. This set of assumptions leads to the constitutive laws of linear viscoelasticity theory which can be considered as a linear response theory. For discussion purposes, consider a Maxwell material that is subjected to a two-step deformation history. The history is such that a deformation $\gamma_1 = \Delta\gamma_1$

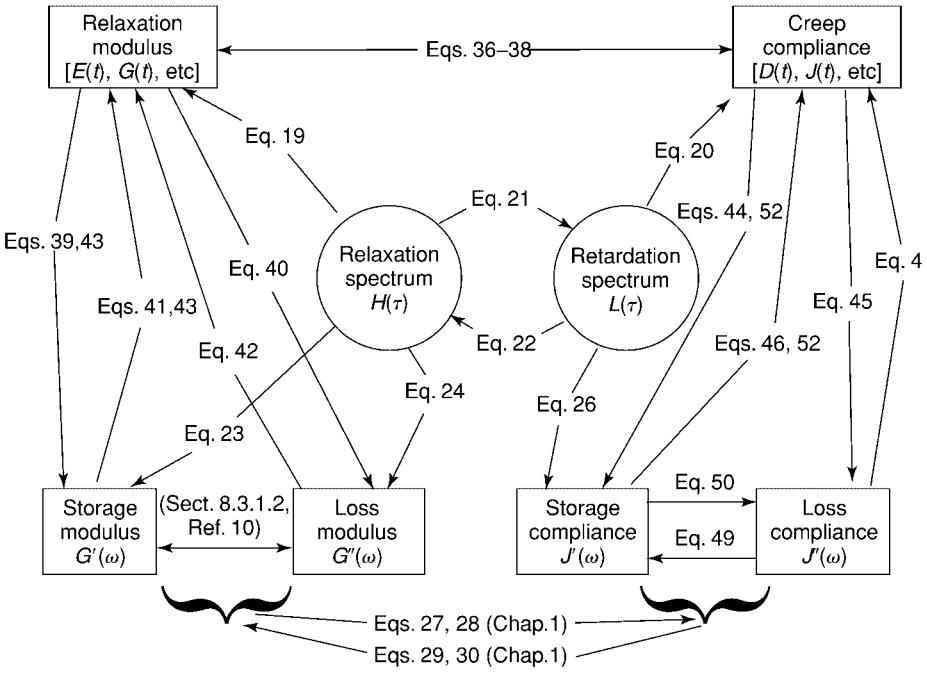

Fig. 6. Chart showing the paths to interrelate the linear viscoelastic material functions. Equation numbers refer to Chapter 3 of Ferry's book (9) unless otherwise indicated. Determination of $G'(\omega)$ from $G''(\omega)$ and $J'(\omega)$ from $J''(\omega)$ and vice versa comes from the Kramer–Kronig relation and is discussed in Tschoegl (10).

is applied at a time $t = 0$ and an additional deformation $\Delta\gamma_2$ is applied at a time t_1 so that $\gamma_2 = \gamma_1 + \Delta\gamma_2$. This can be carried on for as many steps as desired, as depicted in Figure 7a. The stress response to this deformation history is written as

$$\tau(t) = \sum_{i=1}^{N} \Delta\sigma_i(t - t_i') = \sum_{i=1}^{N} \Delta\gamma_i G(t - t_i') \tag{20a}$$

For $N = 2$

$$\tau(t) = \Delta\sigma_1(t - t_1') + \Delta\sigma_2(t - t_2') \tag{20b}$$

but $t'_1 = 0$ and $t'_2 = t_1$; therefore

$$\begin{aligned} \tau(t) &= \Delta\sigma_1(t) + \Delta\sigma_2(t - t_1) = \Delta\gamma_1 G(t) + \Delta\gamma_2 G(t - t_1) \\ &= \gamma_1 G(t) + (\gamma_2 - \gamma_1) G(t - t_1) \end{aligned} \tag{20c}$$

Figure 7b illustrates the way in which the responses add for a two-step history in which each step has the same magnitude. Equation 20a is the general form and is the discrete form of the linear superposition principle cast as a simple shear. It shows the simple linear additivity of the responses. A similar equation

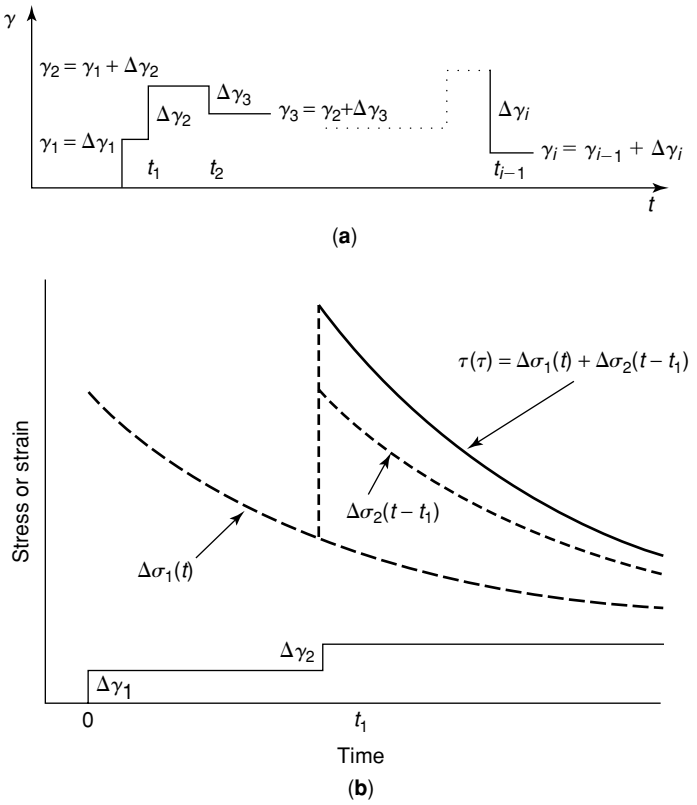

Fig. 7. (**a**) General step-strain deformation history relevant to Boltzmann-type linear superposition. (**b**) Schematic of stress additivity of responses for a Maxwell model in a two-step strain history (see text for discussion).

could be written for the strain response in terms of the stresses for a creep history. The equations can easily be generalized to include the full range of strains and stresses discussed in the next section. Furthermore, the responses can be written in terms of *hereditary integrals*:

$$\tau(t) = \int_0^t G(t - t')\frac{\mathrm{d}\gamma}{\mathrm{d}t'}\mathrm{d}t' \tag{9}$$

$$\gamma(t) = \int_0^t J(t - t')\frac{\mathrm{d}\tau}{\mathrm{d}t'}\mathrm{d}t' \tag{10}$$

Equations 9 and 10 can be solved for arbitrary strain (stress) histories to obtain the material stress (strain) response. Solution for the step-deformations requires use of the "unit Heaviside function" and is discussed in detail by Tschoegl (10) and by Findley, Onaran and co-workers. (21) Wineman and Rajagopal (22) deal with the step-strains, using Riemann–Stieltjes integrals. Other histories are more directly solvable. Also, in the linear theory the limits on the integral can be written from 0 to t rather than from $-\infty$ to t (9,10,21,22).

The final point of the current section is to illustrate that linear viscoelasticity can give rise to what looks like a "nonlinear" response. The typical example comes for a constant rate of deformation experiment. If a generalized Maxwell model is assumed, the material can be subjected to a constant rate of strain and a stress–strain curve can be plotted. As shown in Figure 8a, even though the theory behind equations 20a (or eqs. 9 and 10) is completely linear, one observes that the stress–strain response appears to be nonlinear. This is an illustration of the practicality of understanding viscoelasticity and of understanding the complex time-dependent behavior of polymeric materials. In addition, the linearity of the responses is illustrated in Figure 8b, where all the curves from Figure 8a collapse to a single curve when $\tau/(d\gamma/dt)$ vs $\gamma/(d\gamma/dt)$, (22) is plotted.

Elastic–Viscoelastic Correspondence Principle. One of the difficulties in working with time-dependent materials is solving for their response in actual conditions. For example, a composite aircraft wing might be considered as a viscoelastic beam subjected to bending moments (see Fig. 9). The problem can be solved by applying the viscoelastic constitutive equations to the problem, but in many instances this approach is tedious. Fortunately, it was shown that many classes of viscoelastic boundary-value problems can be solved if the elastic solution is known (23). This is referred to as the *elastic–viscoelastic correspondence principle*. One substitutes the Laplace transform of the viscoelastic material functions for their elastic counterparts into the elastic solution. Inversion of the Laplace transform gives the time-dependent response of the material. In the case of the pure bending of the beam just mentioned, the elastic solution for the displacements, stresses, and deflection can be written as follows (21):

$$\begin{aligned} \text{Strain:} \quad & \varepsilon(t) = -\frac{M(t)y}{E_e I} \\ \text{Stress:} \quad & \sigma(t) = -\frac{M(t)y}{I} \\ \text{Deflection:} \quad & \frac{d^2 w(x,t)}{dx^2} = \frac{M(t)}{E_e I} \end{aligned} \tag{21}$$

where $M(t)$ is the applied moment, y is the beam half thickness, I is the moment of inertia of the beam, and E_e is the elastic modulus. In the case of the viscoelastic beam, we first take the Laplace transform for the time-varying parameters and then substitute $s\hat{E}(s)$ for E_e. Then (see Ref. 21)

$$\begin{aligned} \text{Strain:} \quad & \hat{\varepsilon}(s) = -\frac{\hat{M}(s)y}{s\hat{E}(s)I} = -\frac{y}{I}\hat{J}(s)s\hat{M}(s) \\ \text{Stress:} \quad & \hat{\sigma}(s) = -\frac{\hat{M}(s)y}{I} \\ \text{Deflection:} \quad & \frac{d^2 w(x,s)}{dx^2} = \frac{\hat{M}(s)}{s\hat{E}(s)I} = \frac{\hat{J}(s)s\hat{M}(s)}{I} \end{aligned} \tag{22}$$

Note that the relationships between the viscoelastic compliance and the relaxation modulus are given by

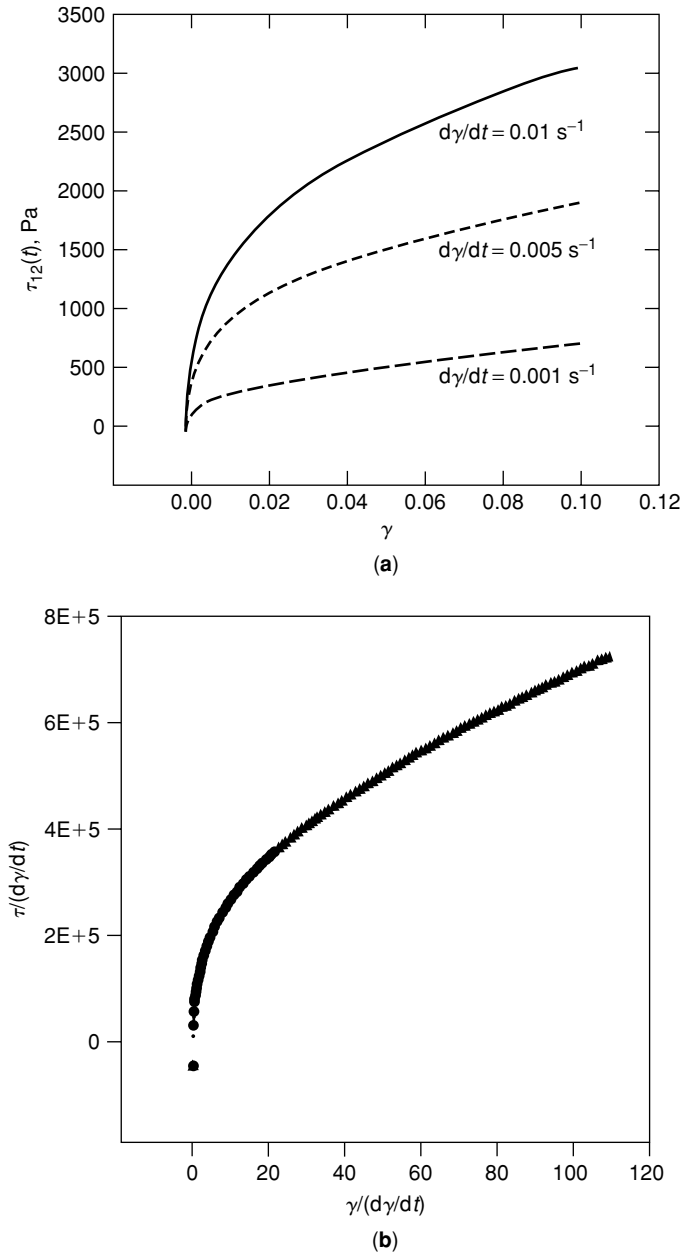

Fig. 8. (**a**) Stress–strain plot for a generalized Maxwell model to different strain rates, as depicted in figure. Plot shows "nonlinear" stress–strain behavior in spite of material model (Maxwell) following laws of linear viscoelasticity (see text). (**b**) Stress and strain data from different strain rates given in (**a**) divided by strain rate $d\gamma/dt$, demonstrating that material model follows linear viscoelasticity (see text).

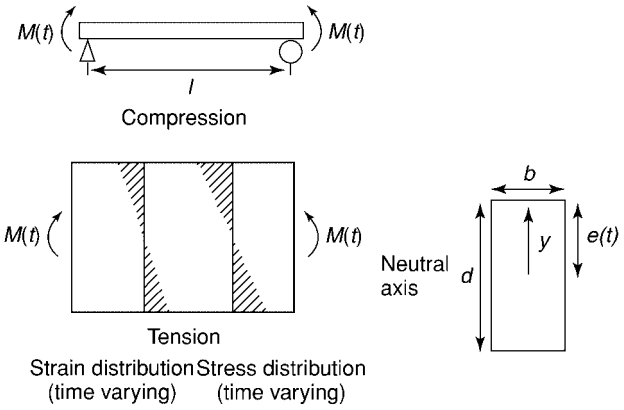

Fig. 9. Schematic of the beam-bending problem. After Findley et al. (21).

$$s\hat{E}(s) = \frac{1}{s\hat{J}(s)} \tag{23}$$

Inversion of equation 22, using the convolution transform, gives

$$\begin{aligned} \varepsilon(t) &= -\frac{y}{I}\int_0^t J(t-t')\frac{\mathrm{d}M(t)}{\mathrm{d}t'}\mathrm{d}t' \\ \sigma(t) &= -\frac{M(t)}{I} \\ \frac{\mathrm{d}^2 w(x,t)}{\mathrm{d}x^2} &= \frac{1}{I}\int_0^t J(t-t')\frac{\mathrm{d}M(t)}{\mathrm{d}t'}\mathrm{d}t' \end{aligned} \tag{24}$$

And integration of the hereditary integrals for strain and deflection gives the solution to any applied history of the moment $M(t)$. A note of caution, however, arises for mixed conditions in which the interface between the stress and the displacement boundaries is not constant. In such cases the elastic–viscoelastic correspondence principle is not applicable and the solutions become more difficult (21).

Finally, this section concludes by noting that Schapery (7,24) has shown that when the material properties are changing very slowly, an approximate solution can be obtained by substituting the viscoelastic moduli for their elastic counterparts. This will be justified in some instances. The reader should examine the literature for further consideration of the limitations of these approaches. Also, the advent of commercial finite element codes that have linear viscoelastic material elements makes the solution of such problems more routine.

Linear Viscoelastic Behavior of Polymeric Materials

General Regimes of Response. Polymeric materials exhibit a very rich set of viscoelastic responses. The responses observed depend upon the state of the

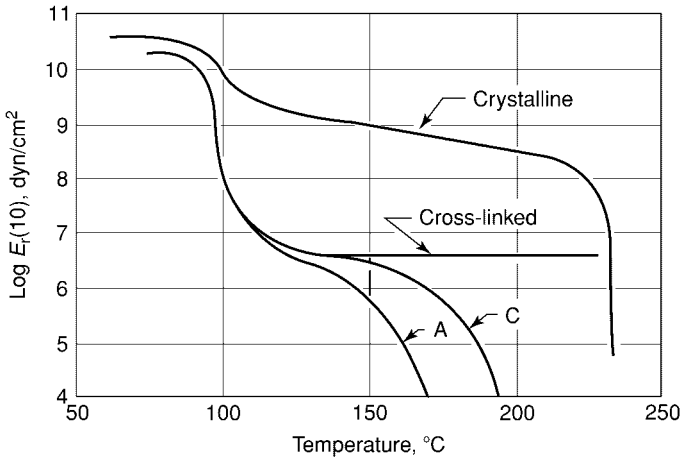

Fig. 10. The relaxation modulus (at 10 s) for a polymer measured as a function of temperature. Curves labeled A and C depict amorphous, linear polymers with the molecular weight of A being less than that of C. The cross-linked polymer is also amorphous, but cannot flow. The crystalline polymer behaves differently because it is "reinforced" by crystalline domains. After Tobolsky (25).

polymer and on its structure. The material can be in an amorphous state if it is a glass, a rubber, a melt, or a solution. In addition, the material can be semicrystalline in that crystallites partially fill or reinforce the otherwise amorphous material. Figure 10 illustrates a plot of the relaxation modulus vs T; it indicates schematically the sort of responses that are observed for an amorphous polymer as a function of temperature. Also shown is the sort of response to be obtained in a semicrystalline polymer over the same temperature range. At low temperatures, one observes a behavior that for both structures is the same as that of a high modulus material. As the glass temperature T_g is approached the amorphous material undergoes a dramatic drop in modulus by several orders of magnitude. The modulus of the semicrystalline material changes significantly, but not nearly as much. Following the modulus drop associated with the glass temperature, the amorphous polymer can exhibit a rubbery plateau due to the *entanglement network* formed by the long-chain molecules. If the molecules are not long enough the entanglement plateau will be weak or nonexistent. In the same temperature regime the semicrystalline polymer exhibits a long and slow reduction of modulus. As temperature increases, the amorphous polymer undergoes terminal flow due to the disentanglement of the molecules while the semicrystalline polymer continues changing slowly. Above the melting point of the semicrystalline polymer its modulus drops dramatically because the material has become an amorphous polymer at a temperature well above the terminal flow region. In the next sections these behaviors are discussed in more detail.

Behavior in the Amorphous State. Polymer behavior in the amorphous state can be divided into two categories: the glassy state and the fluid state. The former applies to polymers below the glass transition and is generally dominated by the segmental or local movements of the polymer chains. The fluid state of the

amorphous polymer is dominated by long-range motions of the polymer chains and the eventual onset of entanglements that give rise to very interesting viscoelastic properties. This section first describes the viscoelastic behavior of the polymer in the glassy state and through the glass temperature. This is followed by a section on the fluid-state properties that are dominated by the long-chain nature of the polymer.

Time–Temperature Superposition. In Figure 10 one observes that the viscoelastic relaxation modulus at a single time or frequency (*isochrones*) shows dramatic changes as temperature increases (25). It turns out that such behavior can be described within the context of a model which is referred to as *time–temperature superposition* or *thermo-rheological simplicity* (9,10,25). The fundamental concept here is that the relaxation times introduced above for, eg, a generalized Maxwell model, all exhibit the same temperature dependence. When thermo-rheological simplicity is valid, one can replace each λ_i in equations 18 and 19 by $a_T\lambda_i$ where the *shift factor* a_T represents the amount that the relaxation time λ_i is changed in going from some reference temperature T_R to the current temperature T. That is

$$a_T = \frac{\lambda_i(T)}{\lambda_i(T_R)} \tag{25}$$

When equation 25 is valid, it is possible to make measurements of the viscoelastic functions over a range of, say four logarithmic decades of time (frequency), at multiple temperatures and use the data to create *reduced* or *master* curves that span many more decades in time (frequency). This is useful for determining the polymer's behavior at longer or shorter times (lower or higher frequencies or rates) that would be extremely difficult to do otherwise. This can be important in both processing applications where rates can be very high and in long-term durability applications where unreasonably long times might otherwise be required to obtain test data. Figure 11 shows the actual data that were obtained for a polymeric material over a limited time range, but at multiple temperatures (25). Figure 12 shows the data reduced to a master curve using time–temperature superposition. As discussed below, the reduced curve in Figure 12 can also be related to the observed temperature dependence of the modulus depicted schematically in Figure 10.

Figure 13 shows the data for the shift factors as log a_T vs T (26). The description of the shift factors as a function of temperature is very important both for ease of application of the method to actual material behavior and because it has implications for the physical understanding of the behavior of polymeric materials. In the next three sections, the temperature dependence of the viscoelastic properties is discussed by examining the temperature dependence of the shift factors.

Properties near the Glass Temperature. In Figure 10 the curve for the amorphous polymer exhibits a behavior in which the modulus at low temperatures changes slowly as temperature increases. As the temperature approaches the glass temperature T_g, however, the modulus begins to change rapidly, dropping by up to 3 orders of magnitude, as the T_g is traversed. This is related to the changing relaxation times. Figure 12 shows a similar behavior, but now with time. At short

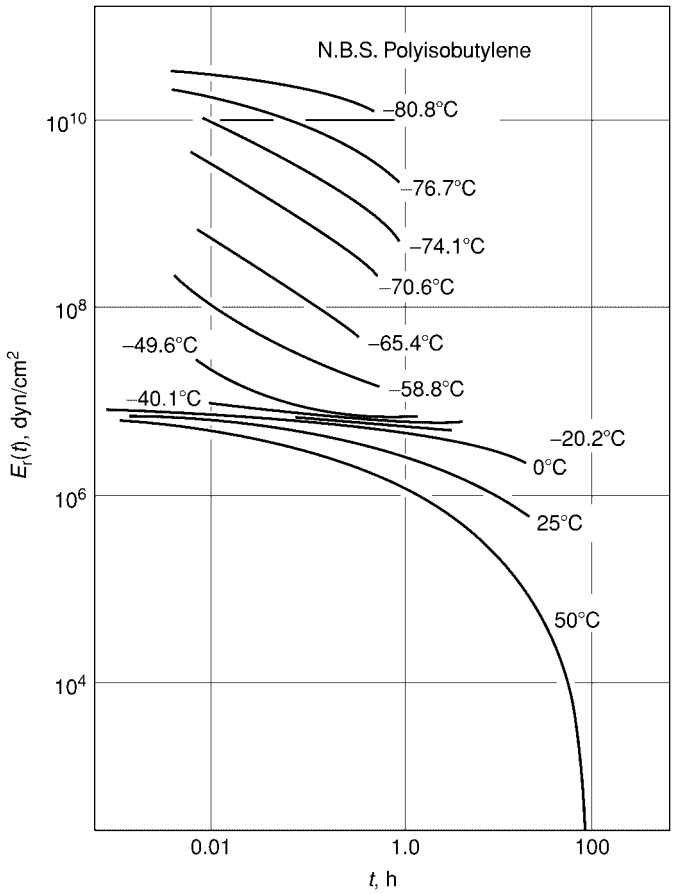

Fig. 11. Stress relaxation isotherms for a polyisobutylene amorphous polymer. After Tobolsky (25).

times, the material response changes slowly and as a glass "transition" time is approached begins to drop rapidly by the same 3 orders of magnitude. In fact, the time–temperature superposition principle allows one to go from curves in temperature space to curves in time (or frequency) space and vice versa.

When the shift factors for the relaxation times are plotted as in Figure 13, an important type of behavior is seen. Here it is observed that the shift factors increase dramatically as the temperature decreases. In fact, if one extrapolates the behavior, there is a singularity point that is reached that is about 50 K below the nominal glass temperature determined from other test methods (such as dsc). This rapid increase of the material shift factor also corresponds (eq. 25) to a rapid increase in the relaxation times as the temperature is decreased. Hence, the glass temperature is approached because the mobility in the polymer becomes so slow that, in normal experimental time scales, the molecules cannot respond to the mechanical solicitation and the material exhibits nearly solid-like properties [imagine the glassy poly(methyl methacrylate) (PMMA) that makes

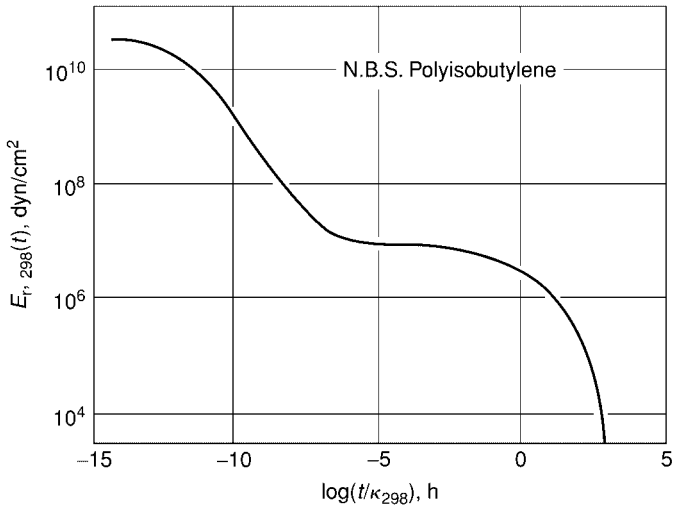

Fig. 12. Master curve generated by applying time–temperature shifting to the data given in Figure 11. (Note that $\kappa_{298} = 1/a_T$.) After Tobolsky (25).

up aircraft windows. The T_g of PMMA is about 110°C]. There are two equations that are commonly used to describe the shift factor behavior and these are discussed later. First the relationship between the viscosity and the shift factor is discussed.

The viscosity is related to the relaxation modulus through the following equation (9):

$$\eta_0 = \int_{-\infty}^{\infty} tG(t)\mathrm{dln}t \tag{26}$$

(for a Maxwell element, this would translate into $\eta_0 = G\lambda$). When the modulus is proportional to temperature T and density ρ (as in the case of rubber elasticity) the shift factor can be determined from viscosity measurements:

$$a_T = \frac{\eta_{0,T}\rho_{T_R}T_R}{\eta_{0,T_R}\rho_T T} \tag{27}$$

Hence, when the shift factor is increasing rapidly, this implies that the viscosity is also increasing rapidly.

One equation used to describe the rapid increase of the viscosity with decreasing temperature is the Vogel–Fulcher equation (27,28):

$$\eta_0 = A\mathrm{e}^{B/(T - T_\infty)} \tag{28}$$

where A is a prefactor and T_∞ is the temperature at which the viscosity extrapolates to an infinite value. Note that when $T_\infty = 0$ K, equation 28 reverts to an Arrhenius form and B would have the meaning of an activation energy (E_a/R). Equations 28 and 27 can be used together to obtain the shift factor a_T. Also, a

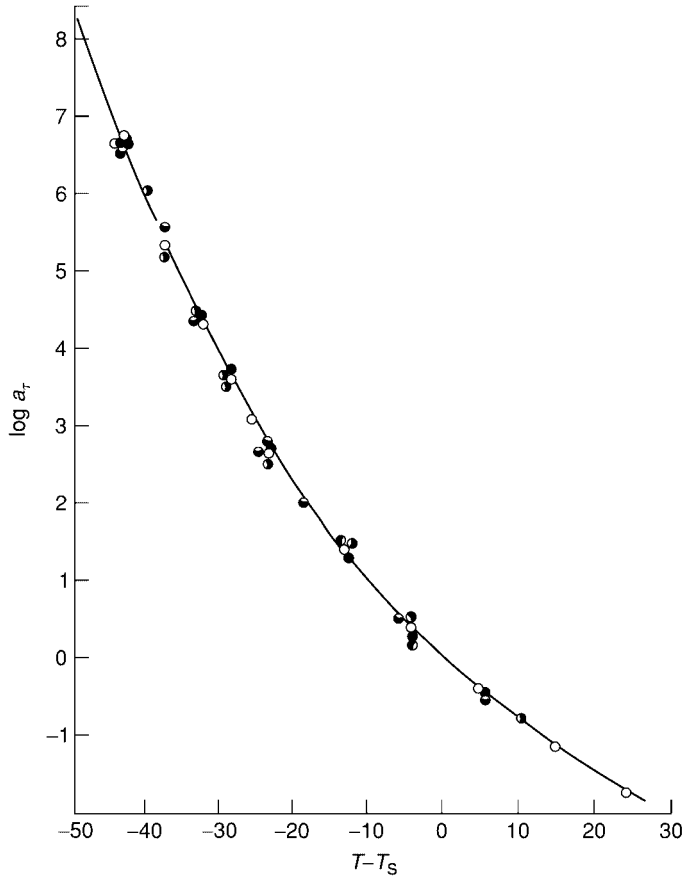

Fig. 13. Time–temperature shift factors for poly(α-methyl styrene). $T_{ref} = 204^{\circ}$C. After Fujimoto et al. (26), with permission.

similar form to equation 28 can be used to represent the temperature dependence of the relaxation times.

The other equation that is often used to describe the dependence of the shift factors on temperature is the Williams, Landel, and Ferry (WLF) equation (29):

$$\log a_T = \frac{C_1(T - T_R)}{C_2 + T - T_R} \tag{29}$$

where C_1 and C_2 are constants. The singularity in the shift factor occurs when $C_2 = -(T - T_R)$, and when $T_R = T_g$ this value is approximately 50 K, ie, the singularity occurs some 50 K below the nominal glass temperature. When $T_R = T_g$, the Vogel–Fulcher and WLF equations are related by the following expressions (9):

$$\begin{aligned} C_1 &= \frac{B}{T_g - T_\infty} \\ C_2 &= T_g - T_\infty \\ 2.303 C_1 C_2 &= B \end{aligned} \tag{30}$$

Note that for many polymers the values of the WLF parameters are close to the so-called universal values, which are $C_1 = 17.44$ and $C_2 = 51.6$ K when $T_R = T_g$. (When no other information is available, the "universal" values for C_1 and C_2 can make useful approximations to actual behavior.)

In discussing the temperature dependence of the shift factors in polymers, it is essential that a distinction be made between the segmental relaxations and the terminal relaxations. The reason for this can be seen in Figure 10 where there are two regions of rapid change in properties. The first occurs in the vicinity of the glass temperature and is due to increasing segmental or local mobility. The second occurs after the rubbery plateau and is related to the terminal relaxations that occur because of chain disentanglement in the fluid state. These two processes are now known to generally show different temperature dependences and one should be clear which relaxations are relevant in any particular situation (30–32).

Figure 13 shows the rapid increase of the shift factors (or viscosity) as T_g is approached from above. As noted previously, the point of singularity is approximately 50 K below the T_g. However, as the glass temperature is traversed, the material response does not continue to follow the WLF curve, rather it falls away from it, as shown in Figure 14 (33–35). The reasons for this are involved with the nature of the glass-transition event and the fact that the molecular mobility has become extremely low in the vicinity of the glass temperature (9,25,28,36,37). As a result, as the temperature changes, the molecules do not have enough time to relax into their equilibrium state and a glass is formed. Glasses are nonequilibrium materials and the sub-T_g behaviors are determined very much by this (36–40). Regardless of this fact, the response below T_g does not follow the WLF behavior. It can, however, follow time–temperature superposition, but with a less dramatic dependence of the shift factors on the temperature, as is seen in Figure 14. In Figure 14 there are three lines for the shift factors below T_g. In this instance, it is due to the physical aging (40) that accompanies the evolution of the nonequlibrium glass toward its equilibrium state.

Viscoelastic Relaxation Properties far below the Glass Temperature. As one moves below the glass-transition temperature, the relaxation behavior of the amorphous polymer becomes more and more sluggish as the thermal energy available to stimulate molecular motion becomes smaller. This behavior is seen in the schematic of Figure 10. However, below the glass temperature, polymers often exhibit other relaxation responses that are referred to as sub-T_g relaxations (9,41–44). A typical example is shown in Figure 15 where the dynamic responses of a series of poly(n-alkyl methyl methacrylates) as a function of temperature are shown. The reader can see that G' ($\omega = 1$ Hz) shows a smeared out "step" in response at low temperatures (approximately 0°C in the PMMA). The PMMA shows a broad peak at the same temperature in tan δ. This relaxation is referred to as the β-relaxation (relative to the α-relaxation of the glass temperature). Some

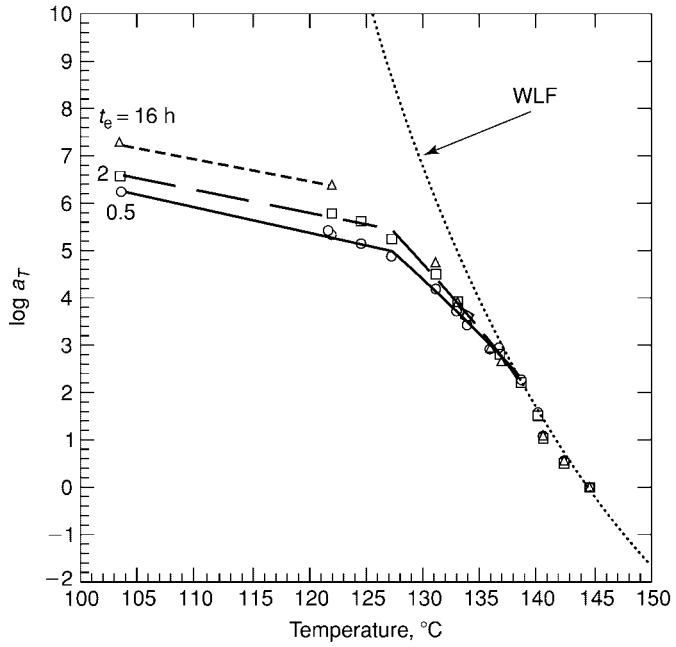

Fig. 14. Plot of shift factor (logarithm) vs T for polycarbonate, illustrating the change in behavior away from the WLF-type of temperature dependence as T_g is traversed. Also, because the glassy state is a nonequilibrium state, the material "ages." The curves at 0.5, 2, and 16 h represent the results at these aging times. After Pesce et al (33).

materials exhibit a γ-relaxation at even lower temperatures, as seen for the poly(n-butyl methacrylate) and poly(n-propyl methacrylate). The sub-T_g relaxations can affect other material properties, although the relationship between linear viscoelastic properties and, eg, failure is complicated and simple relationships not generally universal.

One important aspect of the sub-T_g relaxations is that they generally exhibit different temperature dependences than does the main glassy relaxation. The result is that time–temperature superposition is not usually valid when there is a strong sub-T_g relaxation in the polymer. An example of this is the behavior shown for poly(ethylene naphthalate) in Figure 16, where one can see that time–temperature shifting of creep data does not collapse the data to a single curve because this material has a strong β-relaxation that is not far from the glass temperature (45).

Finally, it is worth noting that the sub-T_g relaxations are often attributed to side-group motions on the polymer chain. A good example is the changing relaxation strength and position in the series of n-alkyl methacrylates that was presented in Figure 15 (44). There it is shown that both the α and the β relaxations shift systematically as the side-chain length increases from $n = 1$ (methyl) to $n = 4$ (butyl). Note, however, that the α-relaxation shifts more strongly than does the β-relaxation with increasing side-group length.

Viscoelastic Response far above the Glass Temperature: T_g The Fluid State. From Figure 10 or Figure 12 one can see the fluid state response of the

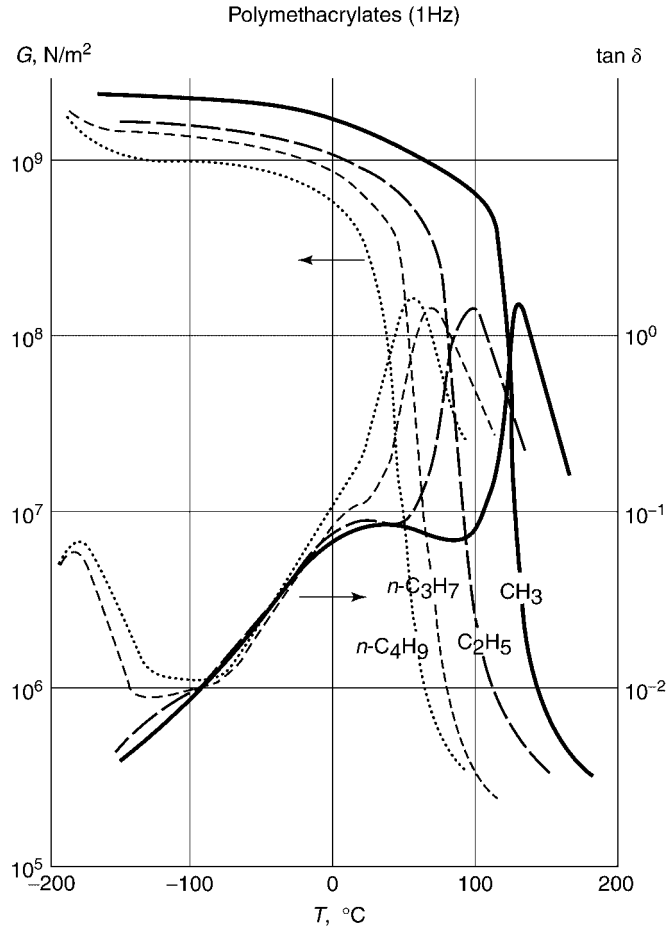

Fig. 15. Dynamic modulus and loss tangent (at 1 Hz) of a series of n-alkyl methacrylates showing how side groups change the α and β transitions. After Heijboer (44).

polymer. This is the portion of the curve at long times or high temperatures from the rubbery plateau to the end of relaxation where the polymer would take the shape of whatever container held it, ie, it is a liquid. There are several fundamental aspects to polymer behavior in this region. On the rubbery plateau, the polymer chains behave as if they were part of a three-dimensional network and their response can be described from modern rubber elasticity theories. This behavior is beyond the scope of the current review and the reader is referred to the literature for further information (46–50). At long enough times, however, the polymer chains have the opportunity to slip out of the entanglement points and the relaxation behavior seen in the terminal response regime results. The current paradigm for the viscoelastic response of polymers in this terminal flow regime is the reptation theory given by de Gennes (51) and Doi and Edwards (52–56). According to this model, the entanglement field can be represented by a tube through which the chain "reptates" along the chain direction. This is schematicized in

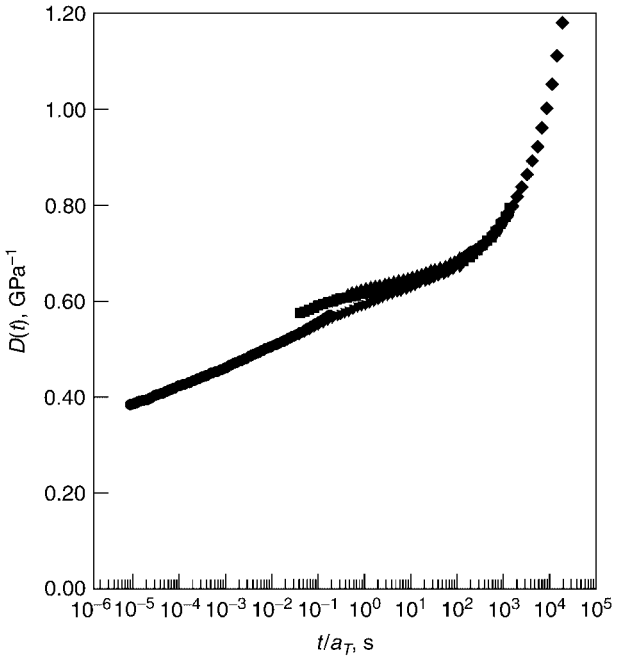

Fig. 16. Reduced curve of creep compliance vs time for PEN showing lack of time–temperature superposition (see text for discussion). ● 30°C; ▼ 50°C; ■ 80°C; ◇ 100°C. After Cerrada and McKenna (45).

Figure 17, where one can see (a) the topology of a chain in a fixed network and (b) the primitive path defined by the tube.

Before describing the reptation theory quantitatively, we first examine part of the rich set of behaviors that any theory of polymer chain dynamics in the melt state needs to be able to describe. One of the most interesting aspects of polymer melt and solution behavior is that once the material is well entangled, the viscoelastic behavior is quasi-universal. First, the zero shear rate viscosity η_0 is observed to vary with the molecular weight to a very strong power (9,57):

$$\eta_0 = AM^{\alpha} \tag{31}$$

where A is an empirical prefactor and M is the molecular weight. In fact, the observed power law dependence seems to follow very well the weight average molecular weight. This power law exponent α is generally found to be approximately 3.4. The variation of viscosity with molecular weight is shown in Figure 18 for a number of polymers from the classic work of Berry and Fox (57). The molecular weight axis also includes the concentration effect discussed shortly. The very strong molecular weight dependence of the viscosity is still not fully understood, although reptation theory has provided a very large step toward understanding.

According to the reptation theory, the dramatic slowing down of the motion of long polymer chains can be considered as similar to the motion of a chain

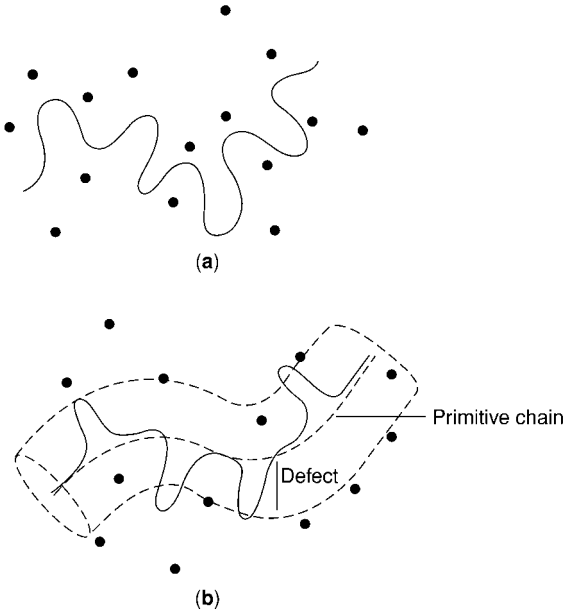

Fig. 17. Schematic of a polymer chain confined in (**a**) a fixed network of obstacles and (**b**) the primitive path representation of the same constraints as a tube. After Doi and Edwards (56), with permission.

through a network, as represented by the tube in the Doi–Edwards (DE) model. The network chains of the tube walls prevent the polymer chain from lateral motion (or at least reduce lateral motion) with the result that the chain is forced to move along the contour of the tube. The chain's Brownian movement causes it to slide back and forth within the tube until it eventually disengages. Quantitative analysis of the chain's diffusive properties leads to the estimation that the viscosity-molecular weight exponent $\alpha = 3.0$ rather than the observed 3.4. The reasons for this have been variously attributed to different mechanisms such as "primitive path" fluctuations (58), "constraint release (59)," tube fluctuations (60), and others that provide a means for the viscosity to crossover from a 3.4 power law dependence on molecular weight to a purely reptative behavior at extremely high molecular weights (61–64). There is only one set of data currently available that really bears relevance to the question of such crossover behavior and that is based on a single data point that falls well off of the 3.4 line for a polybutadiene of 1.65×10^7 g/mol molecular weight (65).

In addition to the large molecular weight dependence of the viscosity, another aspect of the chain dynamics of polymers in the terminal region is the observation that the relaxation spectrum is very broad. One measure of the breadth of the relaxation spectrum is the product of the rubbery plateau value G^0_N and the steady-state recoverable compliance J^0_e. The predicted and observed values for polymer melts are

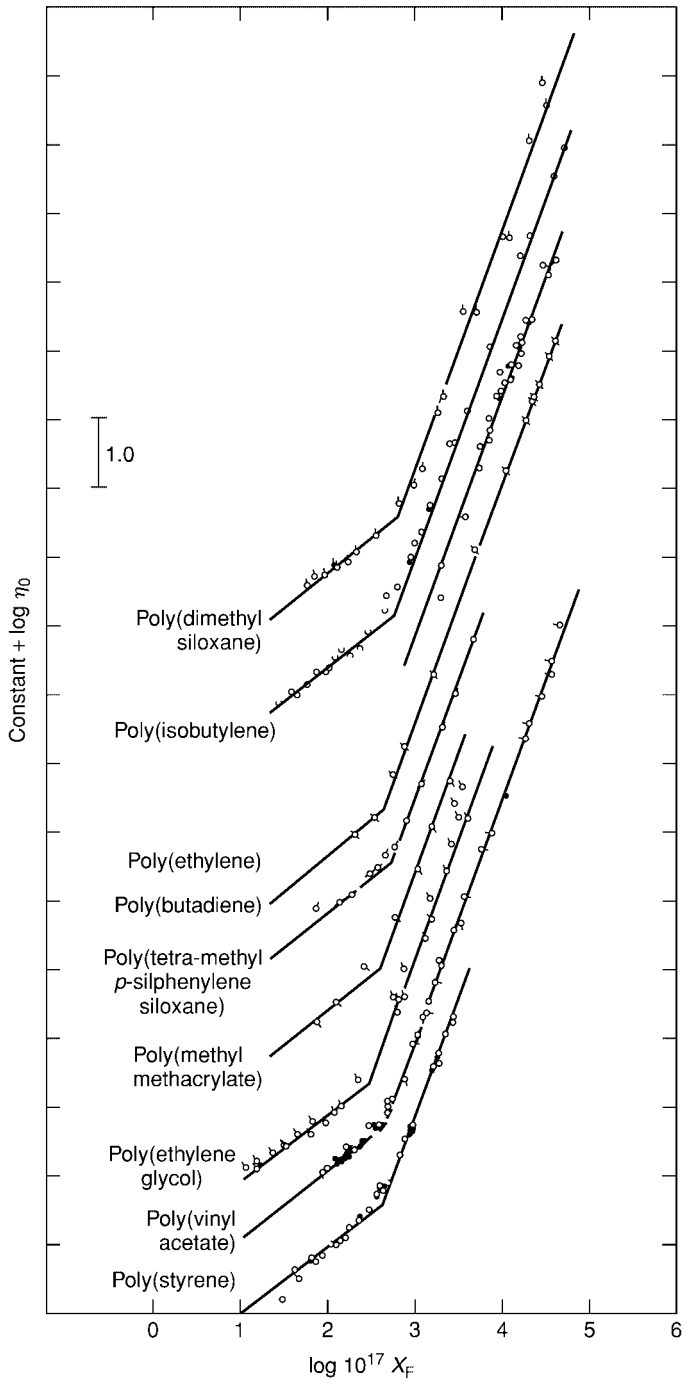

Fig. 18. Double logarithmic representation of the viscosity vs scaled molecular weight for a series of polymers, showing the change from a weak (nearly linear) dependence of viscosity on molecular weight to the entangled regime where $\eta_0 \propto M^{3.4}$. After Berry and Fox (57), with permission.

$$\begin{aligned} J_e^0 G_N^0 &\approx 2.0(\text{observed}) \\ J_e^0 G_N^0 &= 1.2(\text{reptation}) \end{aligned} \tag{32}$$

Hence, the reptation theory does not predict a broad enough relaxation spectrum and current modifications of the theory seem insufficient to describe the full range of observed viscoelastic behavior of polymer melts. Reptation theory is still the paradigm for polymer chain dynamics and provides tremendous insight into material behavior. However, as described, there are still pieces of the puzzle of polymer molecular viscoelasticity that remain to be elucidated.

Behavior of Concentrated Solutions. Another aspect of polymer chain dynamics that is important to their understanding is their behavior in entangled solution. This is particularly so because the reptation theory does not explicitly deal with the effects of concentration on the tube diameter and resulting chain dynamics. However, there are several aspects to the effects of the interactions between small molecule "solvents" or "plasticizers" that are important. The first effect is the observation that the glass-transition temperature of the material is changed, generally to lower temperatures (9,37). For the segmental relaxation, this can be reasonably well accounted for by a time–concentration superposition principle (9,66) similar to the time–temperature superposition discussed above. In the event that one is dealing with the plasticization and the segmental relaxation, the major effect is that the T_g is decreased. The other parameters in the WLF or Vogel–Fulcher equations are less impacted. The reader is directed to the extensive treatment of the problem by Ferry (9) in terms of the free-volume model of dynamics for further information.

On the other hand, the impact of the solvent as one moves into the entanglement regime is different from the simple shift in T_g, although this change is also important for understanding the behavior. The other factor that occurs is that the entanglement density decreases (perhaps the tube diameter gets larger) and the plateau modulus and steady-state recoverable compliance both change dramatically with concentration. When we work with the polymer concentration ϕ, we find that $G^0{}_N$ and $J^0{}_e$ vary as

$$G_N^0 \propto \phi^{2-2.25} \quad \text{and} \quad J_e^0 \propto \phi^{-(2-2.25)} \tag{33}$$

In Figure 18 the viscosities were found to scale as approximately $\phi^{3.4}$—the same as the molecular weight. At the same time, it has been reported (67) that the viscosity can vary by as much as ϕ^5. This difference in apparent behavior depends somewhat on the polymer–solvent system, the temperature of test relative to T_g, and whether or not the data are corrected to a constant "distance" from the glass temperature. The reason stems from the simple relation between viscosity and the relaxation modulus given in equation 26, which for a simple Maxwell model would be

$$\eta_0 = G_N^0 \lambda \tag{34}$$

Because the characteristic relaxation times λ_i vary in a way that is determined by the concentration dependence of the glass temperature, equation 34 combined

with equation 33 indicates that the method of data analysis will determine the scaling behavior observed for the viscosity as a function of concentration. When one is well above the glass transition, the λ_i can follow a dependence as strong as ϕ^3, then equation 34 with equation 33 would give (68)

$$\eta_0 \propto G_N^0 \lambda \propto \phi^2 \phi^x$$
$$\text{For } x = 3: \eta_0 \propto \phi^5 \tag{35}$$
$$\text{For } x = 1.4: \eta_0 \propto \phi^{3.4}$$

Hence, description of the dynamics of the polymer–solvent system demands complete specification of both the complex T_g–concentration relationship and the temperature(s) of test. Importantly, unlike the case of time–temperature superposition, the shift factors for the relaxation times and the viscosity will not be the same. The latter will scale, as does the viscosity, as in equation 35. However, the relaxation times themselves will scale with a much weaker concentration dependence.

Viscoelastic Response of Semicrystalline Polymers. Figure 10 illustrated the general response of the semicrystalline polymer as a function of temperature. For the amorphous polymer it was possible to show the response as a function of time (or frequency) as in Figure 12 because of time–temperature superposition principles. Unlike the amorphous polymer, the viscoelastic response of the semicrystalline polymers cannot generally be treated using time–temperature superposition. There are several reasons for this. First, the crystallites in the material may exhibit relaxations that have different temperature dependences than the amorphous phase. This would clearly lead to a breakdown of thermorheological simplicity. In addition, the amorphous phase in the semicrystalline polymer may be changed by the presence of the crystallites. This has been referred to as a rigid amorphous phase or a constrained phase. The impact of the constraint is to change the temperature dependence of the relaxation response of the constrained amorphous material relative to that of the unconstrained material. The result is that, again, time–temperature superposition does not describe the material. Figure 19 shows the viscoelastic behavior of a semicrystalline material at several temperatures (25). Tobolsky (25) made the important observation that these curves are not superimposable by simple shifting procedures. The result is that for the semicrystalline polymers, determination of the full thermo-viscoelastic response of the material can be a very time-consuming task because the ability to extrapolate outside the testing range of times or frequency is limited.

Nonlinear Viscoelastic Behavior of Polymeric Materials

General Regimes of Response. The nonlinear viscoelastic response of polymers, of course, follows some of the same classifications as does the linear response. Hence, the behavior above the glass temperature and into the terminal zone is fluid behavior, and often follows time–temperature superposition. The phenomenology of polymer melts and solutions is commonly described by

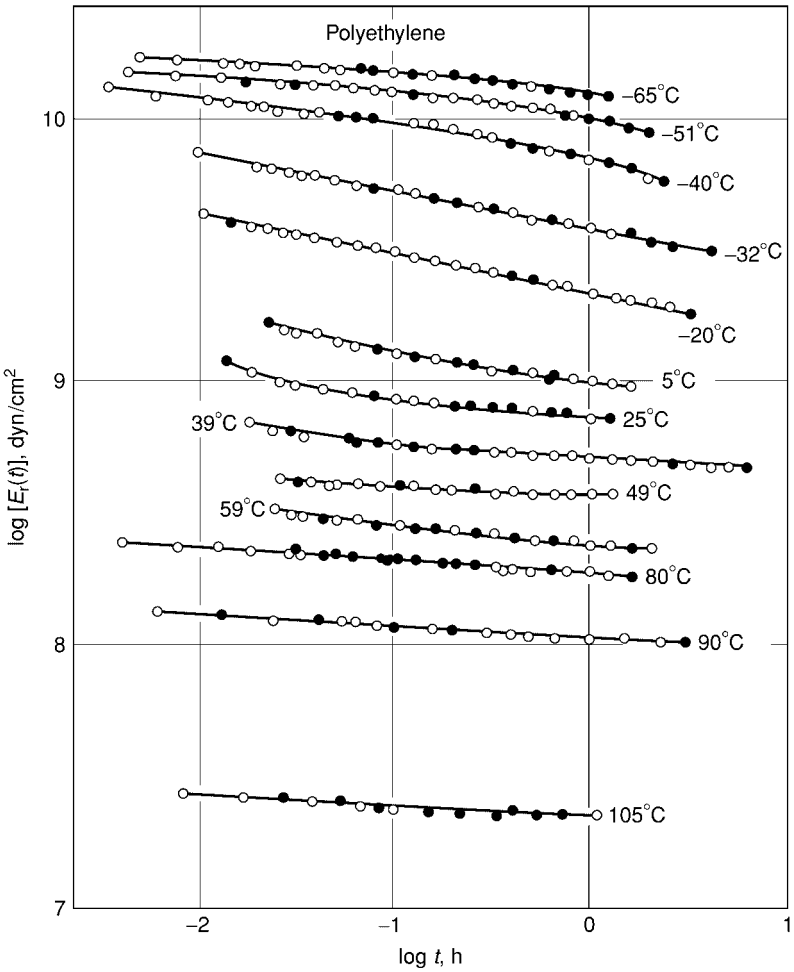

Fig. 19. Relaxation response of polyethylene in isothermal conditions, illustrating that time–temperature superposition does not generally describe the behavior of semicrystalline polymers. After Tobolsky (25).

constitutive laws that relate the stress and strain histories to each other (59,69). A brief description of the K-BKZ model (70–72) is provided as it seems to capture most of the behaviors of polymer melts and solutions subjected to large deformations or high deformation rates. At the same time the nonlinear form of the reptation model is introduced, which in early versions reduced to the K-BKZ constitutive law.

Below the glass temperature, the nonlinear viscoelastic response of polymeric materials has been much less widely studied than has the behavior of melts and solutions. One reason for this is the lack of an adequate theory of behavior. Therefore the discussion about amorphous materials below the glass temperature focuses on recent measurements of the nonlinear response as well as

attempts to apply some of the formalisms that have been applied in the melt and solution states to the behavior of glassy polymers. Finally, the behavior of semicrystalline polymers can be even more complicated and this is discussed briefly.

Behavior of Entangled Polymer Melts and Solutions: Steady-State Behavior. Before discussing the constitutive law given by the K-BKZ theory, it is important to discuss the nonlinear behavior of polymers that is observed. One such behavior is that in steady state, ie, when the material response has quit changing after the application of a stress or deformation rate. For such a situation and recalling that a Newtonian fluid follows a viscosity law in which the stress is proportional to the strain rate

$$\tau = \eta_0 \, \dot{\gamma} \tag{36}$$

where η_0 is the viscosity coefficient. While many small molecule fluids follow expression 36 extremely well, polymeric liquids exhibit *shear thinning* behavior and the viscosity is a function of the shear rate. Typical behavior is exhibited in Figure 20, where viscosity is a function of the shear rate (73). At low shear rates, one observes a Newtonian plateau, followed by a powerlaw region. After the power law region, there is some evidence that at very high shear rates there is a second Newtonian plateau where the viscosity again becomes independent of the shear rate. The power law regime can be described by an empirical equation (74):

$$\begin{aligned} \tau &= K(\dot{\gamma})^n \\ \eta &= \frac{\tau}{\dot{\gamma}} = K(\dot{\gamma})^{n-1} \end{aligned} \tag{37}$$

A possibly better description of the behavior comes from the modified Cross equation (75), particularly if there is a second Newtonian plateau:

$$\eta(T, \dot{\gamma}) = \frac{\eta_0(T)}{1 + [C\eta_0(T)\,\dot{\gamma}]^{1-n}} \tag{38}$$

This equation has the advantage of having the temperature dependence in it explicitly. When the shear-rate-dependent viscosity follows the same temperature dependence, such as WLF, as does the zero shear rate viscosity, then equation 38 is a reasonable approximation to the observed behavior. Otherwise, this is just an estimate. Figure 21 illustrates the fitting of equation 38 to some typical shear-rate-dependent data (74,76).

In addition to the observations in shear that have just been discussed, there is considerable interest in the elongational response in polymeric fluids. The elongational or Trouton viscosity η_E is three times the zero shear rate viscosity in the linear viscoelastic range. However, its behavior is more complex and, as shear rates get higher, the viscosity can even go through a maximum with increasing shear rate as illustrated in Figure 22 (77).

Behavior of Entangled Polymer Melts and Solutions: Transient Response. While the steady-state response of polymers in shear and elongational flows is of much interest, there are also many instances in which the transient response is

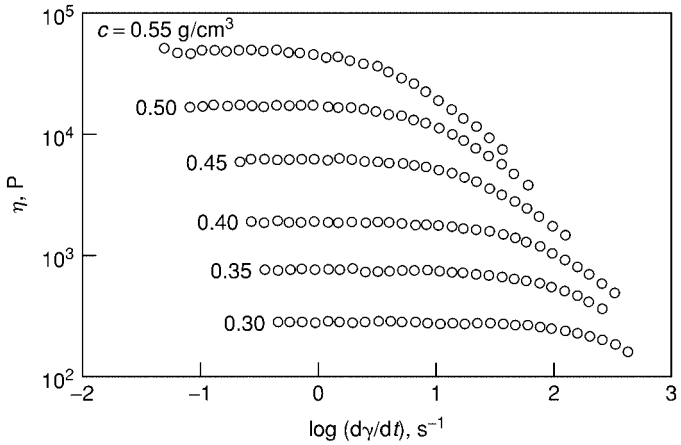

Fig. 20. Double logarithmic representation of viscosity vs. shear rate for polymer solutions having indicated concentrations. Plot illustrates shear thinning of entangled polymers as shear rate increases. After Graessley et al. (73), with permission. To convert Pa·s to P, multiply by 10.

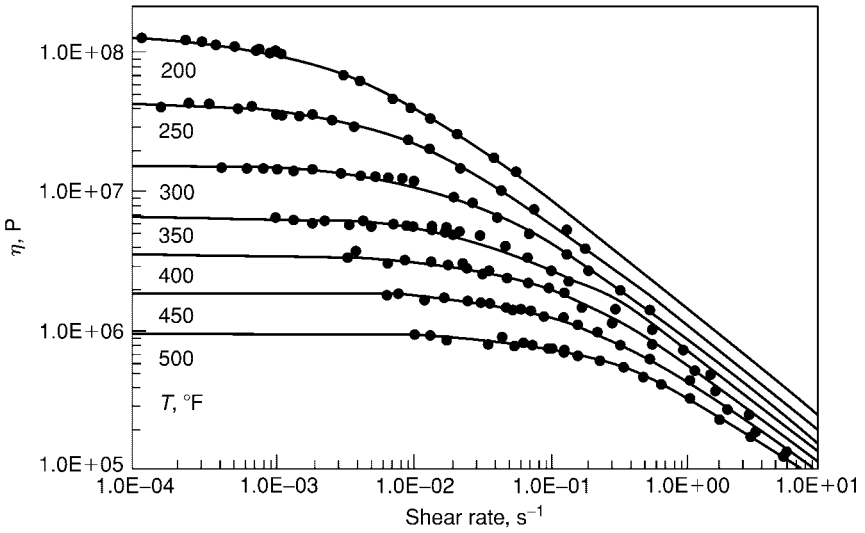

Fig. 21. Shear-rate dependence of the viscosity of a polyisobutylene material, illustrating the fit provided by equation 38. After Rosen (74), with permission. To convert Pa·s to P, multiply by 10.

important because not all processes attain steady state. There are two important transient responses in the nonlinear regime of behavior. These are the stress relaxation response in which the deformation is held constant and the stress evolution with time is followed. This was discussed above for the linear viscoelastic case. In addition, the response to a constant rate of deformation can be an important transient response to study. Also note that creep experiments are sometimes used to characterize the nonlinear response of polymeric fluids and these will also be discussed briefly.

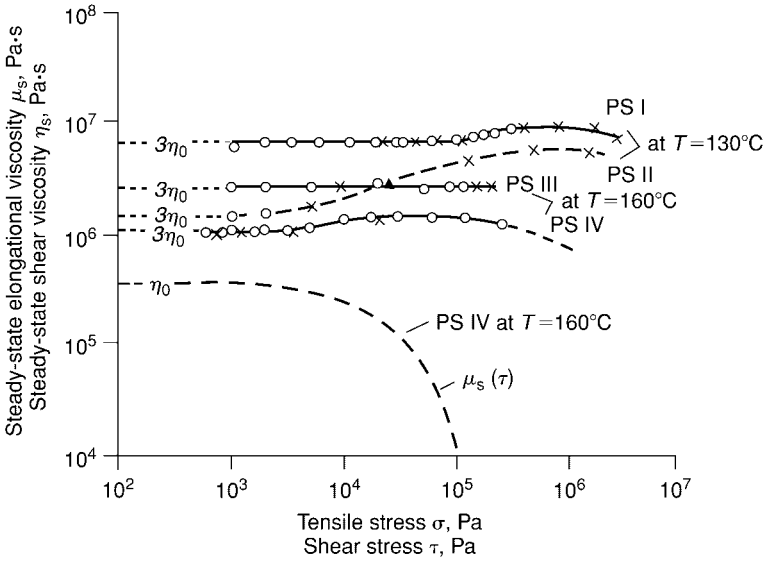

Fig. 22. Elongational viscosity as a function of shear rate for several polystyrene samples. O σ_0 = constant; X ε_0 = constant After Münstedt (77), with permission.

Transient Response: Stress Relaxation. In single-step stress relaxation experiments, the observation is that the response of a polymeric fluid becomes very deformation dependent, ie, it becomes nonlinear. Unlike the case of a linear viscoelastic response, the stress required to maintain a constant deformation is no longer simply proportional to the applied strain. Figure 23 shows the nonlinear response as log $G(\gamma, t)$ vs log t (78). As can be seen, when the strain is larger than about 0.50, the modulus begins falling onto different lines depending on the strain. In Figure 24 *isochronal* data are shown for a polymer solution as log τ_{12} vs log γ (79). If the material were linear, the plots at the different times (isochrones) would be straight with a slope of unity. This is the behavior that one observes in the limit of small strains, as indicated in the figure by the lines of slope unity at the lower deformation levels. Deviations from unity arise when the response is nonlinear; that is, the value of the modulus is a function of the strain. Finally, another way in which to consider the nonlinear behavior is to look at a plot of the relaxation modulus at different times vs the strain. A normalized form of such a plot is shown for a polymer solution in Figure 25 (80). Here, were the material response linear, the data would collapse to a line that was a constant, independent of the strain magnitude. The actual nonlinear behavior that is observed is commonly described in terms of the damping function in the Doi–Edwards model and is described subsequently.

Transient Response: Constant Rate of Deformation. The constant rate of deformation response of the linear viscoelastic material was discussed above. From that discussion, the stress-deformation response looks nonlinear even when the material is linear viscoelastic. For the nonlinear material the response will not be simply described by the linear viscoelastic laws. However, the curves will look similar at low strain rates. At higher strain rates, a stress overshoot is observed,

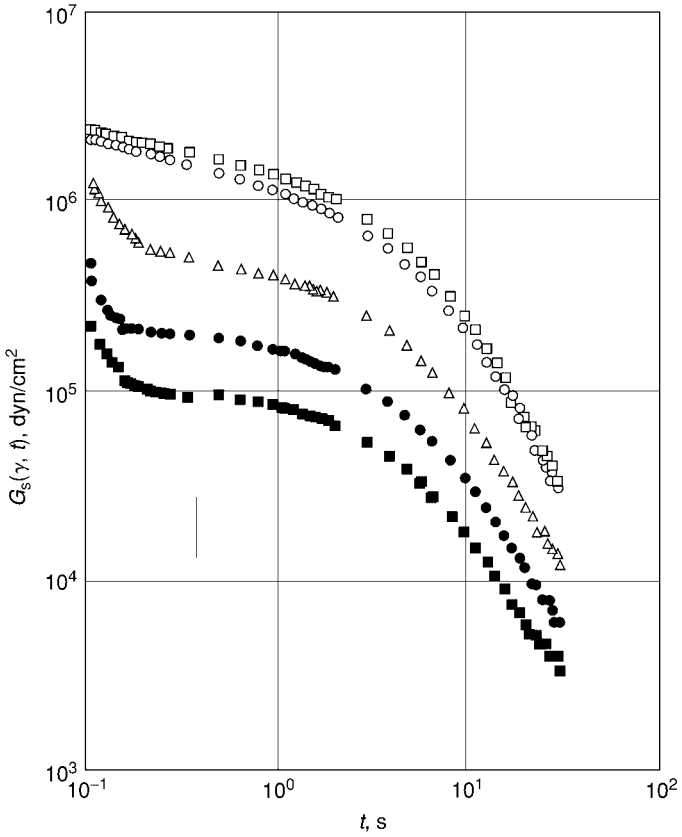

Fig. 23. Stress relaxation modulus of a concentrated polybutadiene solution subjected to increasing shear strains. From top to bottom: $\gamma = 0.333$, 0.667, 1.33, 2.00, and 2.67. After Vrentas and Graessley (78), with permission.

which cannot occur for the linear viscoelastic material. Figure 26 shows the effect of increasing the strain rate on the transient stress–time response (which is related to the strain) for a polymer solution (81). As seen, the stress overshoot becomes weaker with decreasing strain rates (when the material response may be linearly viscoelastic); however, as strain rate increases, there is an onset of a stress overshoot where the early time stress goes through a maximum before settling down to its steady-state value (from which the strain-rate-dependent viscosity would be obtained).

Transient Response: Creep. The creep behavior of the polymeric fluid in the nonlinear viscoelastic regime has some different features from what were found with the linear response regime. First, there are no ready means of relating the creep compliance to the relaxation modulus as was done in the linear viscoelastic case. In fact, the relationship between the relaxation properties and the creep properties depends entirely on the exact constitutive relationship chosen for the response of the material, and numerical inversion of the specific constitutive law is ordinarily necessary to predict creep response from the relaxation

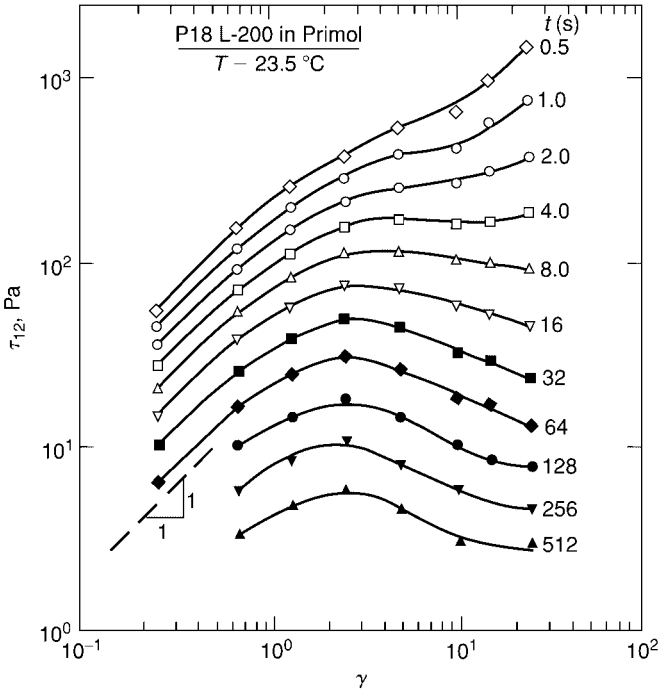

Fig. 24. Double logarithmic representation of the shear stress vs the shear strain for a polymer solution and for different isochrones, as indicated. After McKenna and Zapas (79).

behavior (or vice versa). For most cases, the material properties that appear in the constitutive equations are written in terms of the relaxation response. We discuss this subsequently in the context of the K-BKZ model.

Constitutive Description of Polymer Melt Behavior: K-BKZ and DE Descriptions. Although there are many nonlinear constitutive models that have been proposed, the focus here is on the K-BKZ model because it is relatively simple in structure, can be related conceptually to finite elasticity descriptions of elastic behavior, and because, in the mind of the current author and others (82), the model captures the major features of nonlinear viscoelastic behavior of polymeric fluids. In addition, the reptation model as proposed by Doi and Edwards provides a molecular basis for understanding the K-BKZ model. The following sections first describe the K-BKZ model, followed by a description of the DE model.

The K-BKZ Constitutive Model.

Finite Elasticity Theory: Classical Theory. The finite elasticity theories available today are very powerful and well developed from a phenomenological perspective. Because the K-BKZ (70–72) has the form of a time-dependent finite elasticity (it was developed as a "perfect elastic fluid") it is useful to briefly outline the basics of finite elasticity theory here. In the initial sections of this article, the stress and strain tensors were discussed, and it was noted that the constitutive relationships that arise between the stress and the strain include material parameters called moduli. When a material is classified as *hyperelastic* then the moduli are related to derivatives of the free energy function (often the Helmholtz free

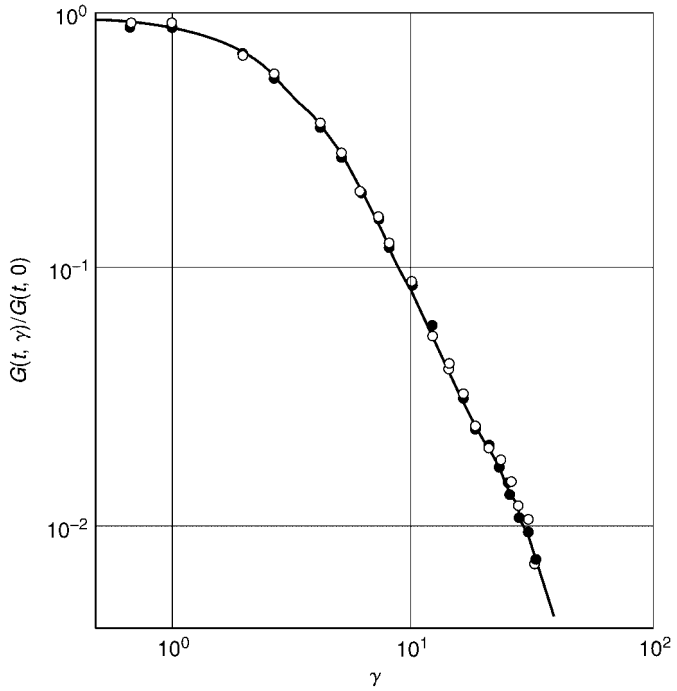

Fig. 25. Reduced nonlinear stress relaxation modulus as a function of strain for a polymer solution. This plot illustrates the strongly nonlinear or strain-dependent behavior of entangled polymers. After Osaki et al. (80), with permission.

energy) with respect to appropriate measures of the strains or deformations (83). Because here large deformations are discussed, there may be multiple possible choices for the actual deformation measurement used. In the discussion that follows, one uses the formalism developed in which the deformations are treated in the context of the Left Cauchy–Green deformation tensor B_{ij} and the free energy function $W(I_1, I_2, I_3)$ is treated as a function of the invariants of the deformation tensor. The material parameters are, then, written as derivatives of the free energy function (or strain energy density function) with respect to the invariants I_i of B_{ij}. The constitutive relationship between the stresses and deformations is then written in terms of these functions (83–86):

$$\sigma_{ij} = \frac{2}{I_3^{1/2}}\left[\left(\frac{\partial W}{\partial I_2}I_2 + \frac{\partial W}{\partial I_3}I_3\right)\Big/ + \frac{\partial W}{\partial I_1}B_{ij} - \frac{\partial W}{\partial I_2}I_3 B_{ij}^{-1}\right] \tag{39}$$

where I is the identity tensor. The invariants of B_{ij} are written in terms of the principal stretches $\lambda_i = 1 + \varepsilon_{ii}$ as

$$\begin{aligned} I_1 &= \lambda_1^2 + \lambda_2^2 + \lambda_3^2 \\ I_2 &= \frac{1}{\lambda_1^2} + \frac{1}{\lambda_2^2} + \frac{1}{\lambda_3^2} \\ I_3 &= \lambda_1^2\lambda_2^2\lambda_3^2 \end{aligned} \tag{40}$$

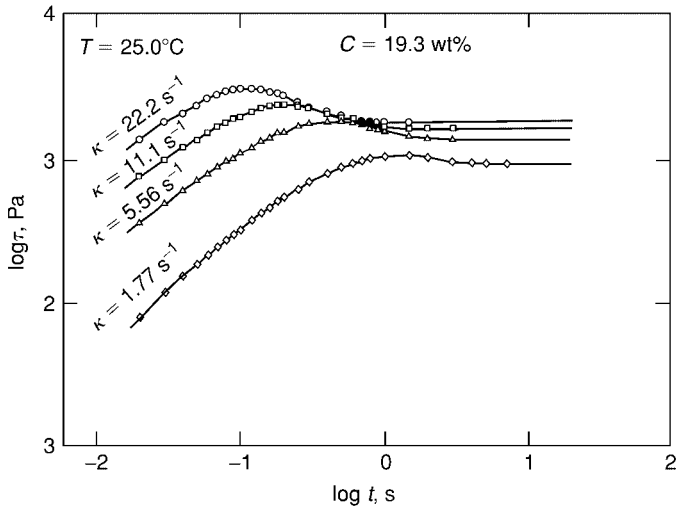

Fig. 26. Effect of strain rate on the stress-time (double logarithmic plot) behavior for a concentrated polymer solution, showing the increasing strength of the stress overshoot phenomenon with increasing strain rate. After Zapas and Phillips (81), with permission.

Note here that the λ_i's are stretches and not relaxation times as used previously. Also note that for polymer melts and solutions, the shear response function (shear modulus) is several orders of magnitude smaller than is the bulk modulus. Therefore, these materials can be treated as *incompressible*. For the linear case, the incompressibility assumption has $K \to \infty$ or $\nu \to 0.5$. Here, $I_3 = 1$ and the constitutive law for the incompressible material becomes

$$\sigma_{ij} = -p\delta_{ij} + \frac{\partial W}{\partial I_1} B_{ij} - \frac{\partial W}{\partial I_2} B_{ij}^{-1} \tag{41}$$

where p is an indeterminate hydrostatic pressure that arises because of the incompressibility condition and δ_{ij} is the Kronecker delta.

Referring to Figure 27, one can solve for the stresses in simple extension. First, the stretches are given by

$$\begin{gathered} \lambda_1 = 1 + \varepsilon_{11} \\ \lambda_2 = \lambda_3 = 1 + \varepsilon_{22} \\ \lambda_2 = \lambda_3 = \frac{1}{\lambda_1^{1/2}} (\text{because of incompressibility}) \end{gathered} \tag{42}$$

Because the material is incompressible, the stresses are only determined within an indeterminate pressure. Therefore, to represent the actual experimental conditions, it is recognized that the *principal stress difference* $\sigma_{11} - \sigma_{22}$ is being

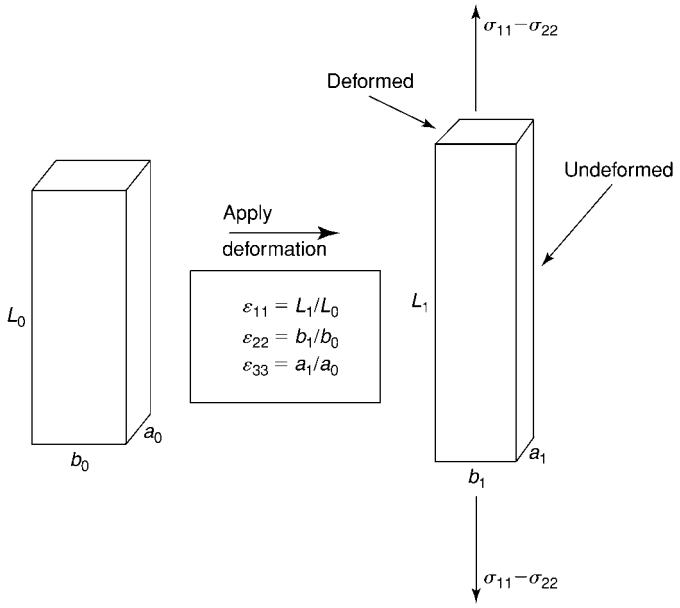

Fig. 27. Schematic of the simple extension geometry.

measured, and this is given as

$$\begin{aligned}\sigma_{11}-\sigma_{22} &= \frac{\partial W}{\partial I_1}(B_{11}-B_{22}) - \frac{\partial W}{\partial I_2}\left(B_{11}^{-1}-B_{22}^{-1}\right)\\ &= \frac{\partial W}{\partial I_1}\left(\lambda_1^2-\lambda_2^2\right) - \frac{\partial W}{\partial I_2}\left(\lambda_1^{-2}-\lambda_2^{-2}\right)\\ &= \frac{\partial W}{\partial I_1}\left(\lambda_1^2-\lambda_1^{-1}\right) - \frac{\partial W}{\partial I_2}\left(\lambda_1^{-2}-\lambda_1\right)\\ &= \left(\lambda_1^2-\lambda_1^{-1}\right)\left(\frac{\partial W}{\partial I_1}+\frac{1}{\lambda_1}\frac{\partial W}{\partial I_2}\right)\end{aligned} \tag{43}$$

The simple stress-deformation response given by equation 43 shows the strong nonlinearity that arises when the stress–strain curve for a typical rubber is plotted, even when the material is *Neo-Hookean* or *Mooney–Rivlin*, meaning that the values of $\partial W/\partial I_1 = W_1 = C_1$ and $\partial W/\partial I_2 = W_2 = C_2$ are constants. For the Neo-Hookean material, $W_1 = C_1$ and $W_2 = 0$. For the Mooney–Rivlin material (87,88), $W_1 = C_1$ and $W_2 = C_2$. Figure 28 shows plots of the stress-deformation behavior for a Neo-Hookean rubber and for a Mooney–Rivlin rubber. The figure shows that in spite of the fact that the material parameters are constants, there is a strong nonlinear response due to the geometry of deformation, ie, the $[\lambda^2 - \lambda^{-1}]$ and $1/\lambda$ terms in equation 43. Also, from equation 43 one can readily see from where the concept of the Mooney–Rivlin material arose. Dividing the equation by

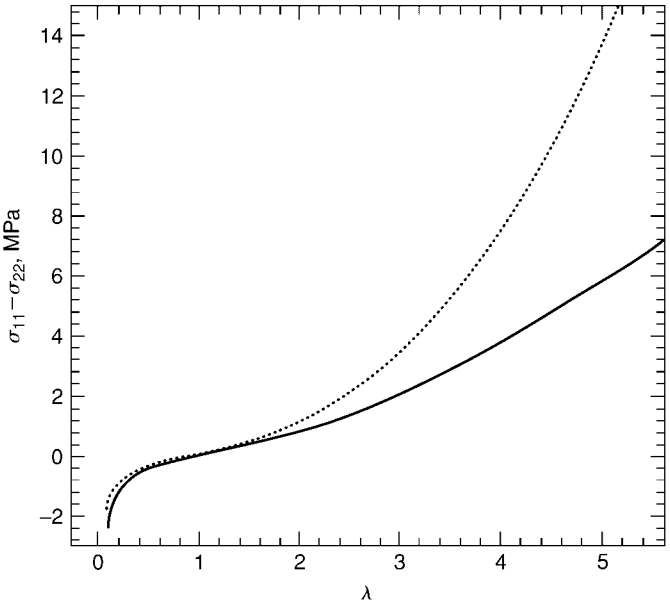

Fig. 28. Stress-stretch response for a Neo-Hookean rubber compared with that of a Mooney–Rivlin material. (————) Neo-Hookean: $C_1 = 0.24$ MPa; (· · · · ·). Mooney–Rivlin: $C_1 = 0.16$ MPa, $C_2 = 0.08$ MPa.

$[\lambda^2 - \lambda^{-1}]$, one obtains

$$\sigma_R = \frac{\sigma_{11} - \sigma_{22}}{\lambda_1^2 - \lambda_1^{-1}} = \frac{\partial W}{\partial I_1} + \frac{1}{\lambda_1}\frac{\partial W}{\partial I_2} \tag{44}$$

where σ_R is referred to as the reduced stress. For Mooney–Rivlin behavior, a plot of σ_R vs $1/\lambda_1$ gives a straight line of slope C_2 and intercept C_1. Real rubber often shows near to Mooney–Rivlin behavior in extension, but deviates in compression. For the Neo-Hookean material, the reduced stress is a constant. Figure 29a shows the calculations for the general behavior of σ_R vs $1/\lambda_1$ for the Neo-Hookean and Mooney–Rivlin materials. Figure 29b shows experimental results for two typical cross-linked rubbers, and it is seen that neither the Neo-Hookean nor the Mooney–Rivlin model would describe the behaviors exhibited (89–91). The reader is referred to reviews of various proposed strain energy functions (89,92,93) for further information.

Another important aspect of finite elasticity theory is the ability to measure the strain energy function derivatives $W_1 = \partial W/\partial I_1$ and $W_2 = \partial W/\partial I_2$. Penn and Kearsley (94) showed how this is done using data from torsional experiments. An interesting aspect about torsion in finite deformations is that in order to maintain the cylinder at a constant length, it is necessary to apply normal forces at the ends of the cylinder. If the cylinder is left unrestrained, it will lengthen in an effect referred to as the Poynting (95) effect, first observed early in the last century in experiments with metal wires. When a cylinder of length L is twisted by an amount

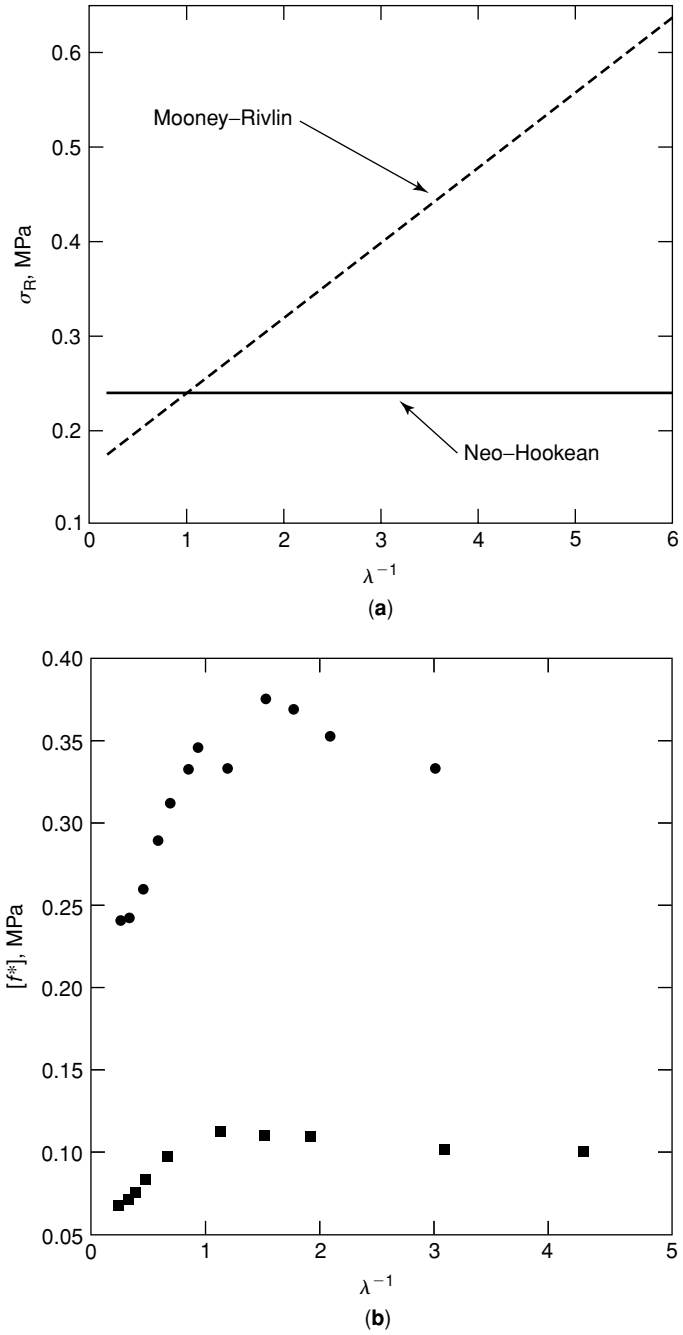

Fig. 29. (**a**) Reduced stress plot for the Neo-Hookean and Mooney–Rivlin materials of Figure 28. (**b**) Reduced stress plot for natural rubber and a polydimethylsiloxane (PDMS) rubber as indicated. Plot illustrates that actual rubber behavior may be Mooney–Rivlin-like in tension ($\lambda^{-1} < 1$), but not in compression.● Natural rubber; ■ PDMS. Plot from Han et al. (89), natural rubber data from Ref. 90, and PDMS data form reference 91.

ψ per unit length ($\psi = \theta/L$, where θ is the angle of twist) the magnitude of the torque (moment) M and the normal force N are given by the following expressions:

$$T = 4\pi\psi \int_0^R (W_1 + W_2) r^3 \mathrm{d}r \tag{45}$$

$$N = -2\pi\psi^2 \int_0^R (W_1 + 2W_2) r^3 \mathrm{d}r \tag{46}$$

where R is the cylinder radius. By differentiating each expression with respect to the limits of integration after an appropriate variable change, Penn and Kearsley (90) showed that W_1 and W_2 can be expressed as simple algebraic expressions in the torques and normal forces measured at different angles of twist, ie, deformations:

$$W_1 + W_2 = \frac{1}{4\pi\psi R^4}\left(3T + \psi\frac{\mathrm{d}t}{\mathrm{d}\psi}\right) \tag{47}$$

$$W_1 + 2W_2 = \frac{-1}{\pi\psi^2 R^4}\left(N + \psi^2\frac{\mathrm{d}N}{\mathrm{d}\psi^2}\right) \tag{48}$$

Figure 30 shows typical torque and normal force measurements for a natural rubber sample as functions of the deformation (as ψR) in a double logarithmic plot (96). The data for T, N, and their derivatives can then be obtained and used in equations 47 and 48 to solve for W_1 and W_2. Figure 31 shows typical data for the values of W_1 and W_2 as functions of deformation for a cross-linked natural rubber obtained from such measurements (94,97). Importantly, these values are related to the *damping function* of the DE model discussed subsequently. They represent the deformation dependence of the shear modulus in this instance.

Finite Elasticity Theory: The VL Representation. While the above description of the finite deformation behavior of elastic materials is very powerful, the limitation on it is that the material parameters W_1 and W_2 need to be determined in each geometry of deformation of interest. Hence, the torsional measurements described above only give values of $W_1(I_1, I_2)$ and $W_2(I_1, I_2)$ for the condition of shear (torsion is a nonhomogeneous shear) and that condition is $I_1 = \mathrm{I}_2 = 3 + \gamma^2$. More measurements need to be made to obtain the parameters in extension, compression, etc. However, in 1967, Valanis and Landel (98) proposed a strain energy function that, rather than being a function of the invariants, is a function of the stretches λ_i. The function was assumed to be separable in the stretches as

$$\hat{w}(\lambda_1, \lambda_2, \lambda_2) = w(\lambda_1) + w(\lambda_2) + w(\lambda_3) \tag{49}$$

Then, for example, in simple extension, the stress–deformation relationship becomes

$$\sigma_{11} - \sigma_{22} = \lambda_1 w'(\lambda_1) - \lambda_2 w'(\lambda_2) \tag{50}$$

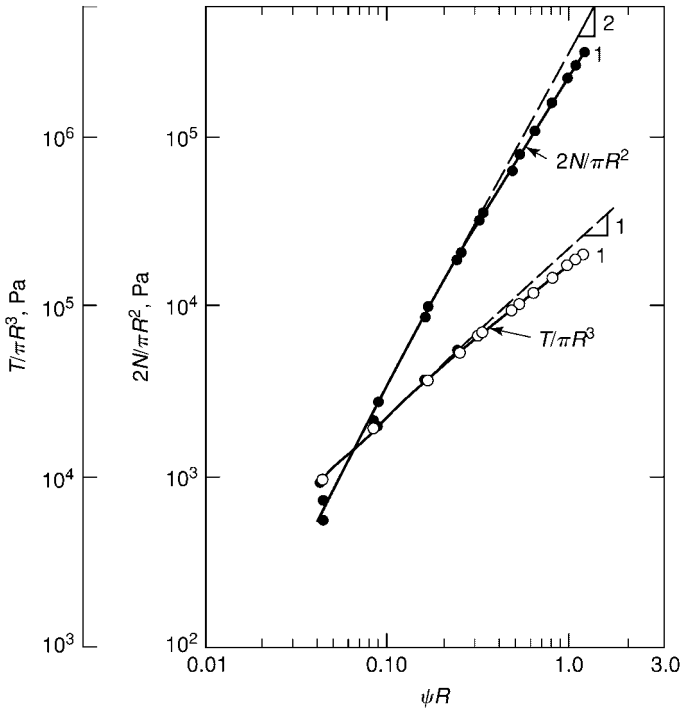

Fig. 30. Torque and normal forces (scaled by sample geometry) vs strain at outer edges of cylinder for a natural rubber sample subjected to torsional deformations. After McKenna and Zapas (96).

and it becomes a matter, for any deformation to determine the values of $w'(\lambda_i)$ and these can be obtained in any geometry of deformation. Thus, the inconvenience of performing large numbers of experiments in multiple geometries of deformation is avoided. There has been a considerable effort to establish the validity of the Valanis–Landel (VL) form of strain energy function (98–102) and it is generally found to be a very good representation of the material behavior, although some discrepancies have been observed. Some special forms of the VL function, such as the Ogden model (103,104), have been found to be very useful and are commonly used in commercial finite element modeling of rubber behavior.

Because of this usefulness it is important to have relatively simple experiments available to obtain the VL function. Kearsley and Zapas (97) have shown that either simple extension combined with simple compression or torsion with normal force measurements can be used to obtain the VL function. Valanis and Landel (98) used pure shear measurements. The equations for the torsional measurements arise from the relationship between $w'(\lambda)$ and W_1 and W_2 given by

$$w'(\lambda) - \frac{w'(1)}{\lambda} = \frac{2}{\lambda}(\lambda^2 - 1)\left(W_1 + \frac{1}{\lambda^2}W_2\right) \tag{51}$$

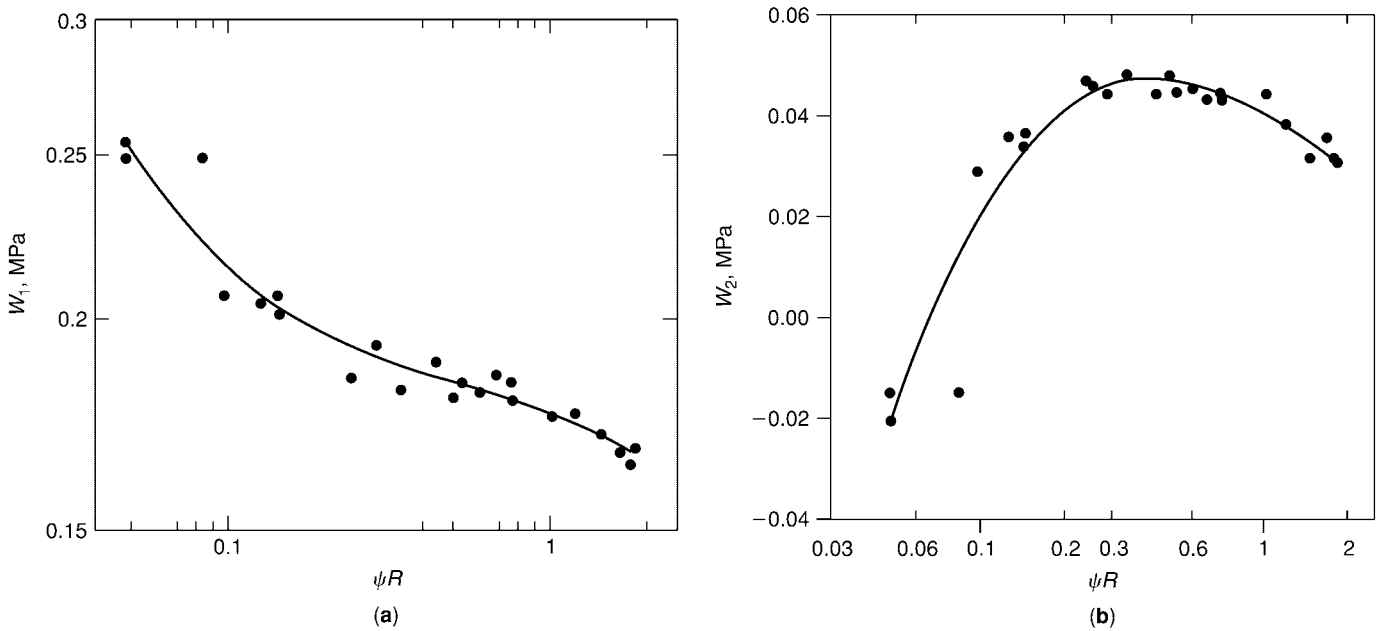

Fig. 31. (**a**) W_1 vs strain for a natural rubber material. (**b**) W_2 vs strain for a natural rubber material. Data of Penn and Kearsley (94) given in Kearsley and Zapas (97).

and the values of λ are determined from the twists of the cylinder by

$$\text{For} \quad \lambda > 1 : \lambda_{\max} = \frac{1}{2}\left[(\psi^2 R^2 + 4)^{1/2} + \psi R\right] \tag{52}$$

Thus, from torque and normal forces in torsional experiments, the VL function derivative can be obtained. Typical data for natural rubber are presented in Figures 30, 31, 32. The figures illustrate the sequence that would be used to obtain the VL function. First, obtain torque and normal force data (Fig. 30) and use equations 47 and 48 to obtain the strain energy function derivatives W_1 and W_2 (some typical results shown in Fig. 31). Finally, data of the sort shown in Figure 31 are used to obtain the VL function derivative $w'(\lambda)$. Figure 32 shows such data obtained from torsional measurements on natural rubber samples cross-linked to different extents (102).

In the case of extension and compression data, Kearsley and Zapas (97) developed a recursive method to determine the VL function from stress–strain data similar to those presented in Figure 28. The advantage in using extension and compression data rather than torsional data is that higher values of λ can be reached.

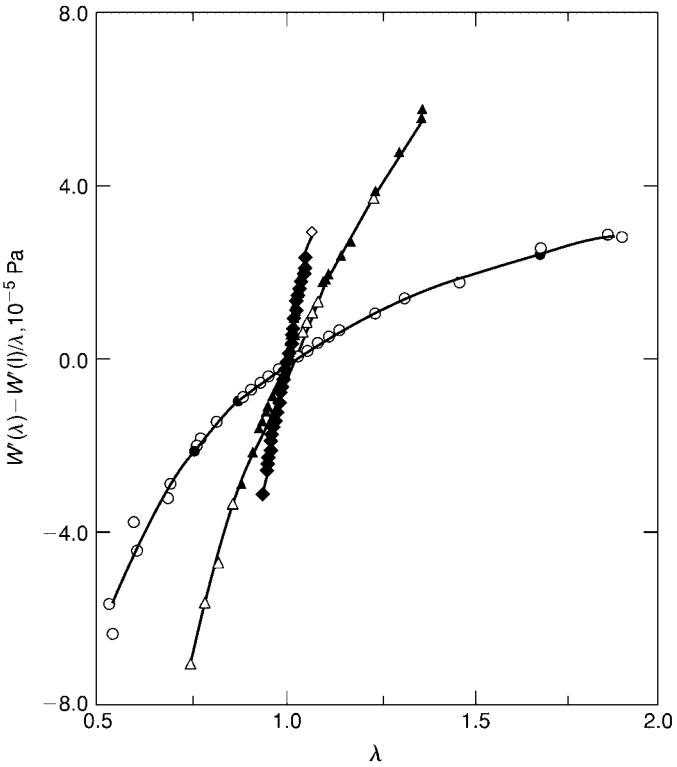

Fig. 32. The VL function (98) derivative vs stretch for natural rubber samples cured with 1, 5, and 15 parts per hundred dicumyl peroxide, as indicated. The VL function was obtained from torque and normal force measurements. ○ APHR1; △ APHR5;◇ APHR15. After McKenna et al. (102).

Finally, the power of finite elasticity theory is that once the material properties [W_1 and W_2 or $w'(\lambda)$] are known, the stresses in any deformation field can be calculated. There is an extensive literature on ways to represent the material functions and, in fact, commercial finite element codes use finite elasticity theory in calculations that can be important in applications that range from the stresses in automobile tires (105) to those in earthquake bearings for large buildings (106). One feature of the K-BKZ theory to be discussed next is that it retains the structure of finite elasticity theory and includes time-dependent properties of the viscoelastic materials that were discussed in the earlier sections of this article.

The K-BKZ Theory: Model. The K-BKZ model was developed in the early 1960s by two independent groups. Bernstein, Kearsley, and Zapas (70) of the National Bureau of Standards (now the National Institute of Standards and Technology) first presented the model in 1962 and published it in 1963. Kaye (71), in Cranfield, U.K., published the model in 1962, without the extensive derivations and background thermodynamics associated with the BKZ papers (82,107). Regardless of this, only the final form of the constitutive equation is of concern here. Similar to the idea of finite elasticity theory, the K-BKZ model postulates the existence of a strain potential function $U(I_1, I_2, t)$. This is similar to the strain energy density function, but it depends on time and, now, the invariants are those of the *relative* left Cauchy–Green deformation tensor $\boldsymbol{B}_{t,ij}$. The relevant constitutive equation is

$$\sigma_{ij}(I_1,I_2,t) = -p\delta_{ij} + \int_{-\infty}^{t} \{U_1(I_1,I_2,t-t')B_{t,ij}(t,t') - U_2(I_1,I_2,t-t')B_{t,ij}^{-1}(t,t')\}\mathrm{d}t' \tag{53}$$

Also note that the hydrostatic pressure is indeterminate because the K-BKZ is an incompressible material model. As in finite elasticity theory, the material parameters need to be obtained and, in principle, the stress response to any deformation history can be obtained. Unlike linear viscoelasticity, the integration must be carried out from $-\infty$ to t, which can lead to difficulties in numerical computer codes. This aspect of the K-BKZ theory has been discussed by (62) Larson, among others.

The relative deformation tensor $\boldsymbol{B}_{t,ij}$ assumes that the current material *configuration* (the configuration at time t) is the reference configuration. This idea is important as it is common in fluid models because fluids have no natural reference configuration while solids do. Hence, for example, the relative deformations in simple extension become

$$\lambda_{t,1} = \frac{\lambda_1(t)}{\lambda_1(t')}; \lambda_{t,2} = \frac{\lambda_2(t)}{\lambda_2(t')}; \lambda_{t,3} = \frac{\lambda_3(t)}{\lambda_3(t')} \tag{54}$$

and the invariants of $\boldsymbol{B}_{t,ij}$ are similar to those for the elastic material, but in terms of the relative deformations

$$I_1(t,t') = \left[\frac{\lambda_1(t)}{\lambda_1(t')}\right]^2 + \left[\frac{\lambda_2(t)}{\lambda_2(t')}\right]^2 + \left[\frac{\lambda_3(t)}{\lambda_3(t')}\right]^2$$

$$I_2(t,t') = \left[\frac{\lambda_1(t')}{\lambda_1(t)}\right]^2 + \left[\frac{\lambda_2(t)}{\lambda_2(t')}\right]^2 + \left[\frac{\lambda_3(t)}{\lambda_3(t')}\right]^2 \tag{55}$$

$$I_3(t,t') = 1 = \left\{\left[\frac{\lambda_1(t)}{\lambda_1(t')}\right]\left[\frac{\lambda_2(t)}{\lambda_2(t')}\right]\left[\frac{\lambda_3(t)}{\lambda_3(t')}\right]\right\}^2$$

The utility of the K-BKZ theory arises from several aspects of the model. First, it does capture many of the features, described below, of the behavior of polymeric melts and fluids subjected to large deformations or high shear rates. That is, it captures many of the nonlinear behaviors described above for steady flows as well as behaviors in transient conditions. In addition, unlike the more general *multiple integral* constitutive models (108,109), the experimental data required to determine the material properties are not overly burdensome. In fact, the information required is the single-step stress relaxation response in the mode of deformation of interest (72). If one is only interested in, eg, simple shear, then experiments need only be performed in simple shear and the exact form for $U(I_1, I_2, t)$ need not be obtained. Furthermore, because the structure of the K-BKZ model is similar to that of finite elasticity theory, if a full three-dimensional characterization of the material is needed, some of the simplifying aspects of finite elasticity theories that have been developed over the years can be applied to the behavior of the viscoelastic fluid description provided by the K-BKZ model. One such example is the use of the VL form (98) of the strain energy function discussed above (110). The next section shows some comparisons of the material response predicted by the K-BKZ theory with actual experimental data.

The K-BKZ Theory: Comparison with Experiment. The first data required to test the K-BKZ model is single-step stress relaxation data to determine the material parameters of interest. This is best seen from the following example for a simple shearing history. From equation 49, the shear stress for a simple shear deformation can be expressed as (see Ref. 72)

$$\sigma_{i,j}(t) = \int_{-\infty}^{t} -K_*[\gamma(t) - \gamma(t'), t - t']\mathrm{d}t' \tag{56}$$

where $\gamma(t) - \gamma(t')$ is the relative strain and K_* is the partial derivative of the relaxation function $K[\gamma(t) - \gamma(t'), t - t']$ with respect to the second (time) argument. For the single-step stress relaxation history in which $\gamma(t) = 0$ for $t<0$ and $\gamma(t) = \gamma$ for $t > 0$, equation 52 reduces to

$$\sigma_{ij}(t) = \int_{-\infty}^{0} -K_*[\gamma, t - t']\mathrm{d}t' \tag{57}$$

Defining $\xi = t - t'$ and performing a change of variables, equation 57 can be evaluated as

$$\sigma_{ij}(t) = \int_{\infty}^{t} K_*(\gamma, \xi)\mathrm{d}\xi = K(\gamma, t) - K(\gamma, \infty) \tag{58}$$

and because the material is a fluid, $K(\gamma, \infty) = 0$. Therefore, the shear stess is simply equal to its relaxation function $K(\gamma, t)$ for an applied shear strain of γ. As suggested by equations 56, 57, 58, one need not actually determine the values of $U_i(I_1, I_2, t)$ when the experiments of interest are always of the same geometry.

Also, because of the structure of the K-BKZ theory, torsional measurements can also be analyzed in a fashion similar to equation 58. Recall Figure 24, which depicts the single-step stress relaxation responses for a concentrated polymer solution in a torsional (parallel plate) experiment as isochronal plots of stress vs strain on double-logarithmic axes. It is worth noting that in the moderate strain regime, these data look similar to the elastic data of Figure 30. But, at large strains the curves go through a maximum. This is undoubtedly because the solutions can be deformed to a much greater magnitude than can the cross-linked rubber.

Once the single-step data are known, then integration of equation 56 (or eq. 53) for different strain histories leads to predictions for the material response in any deformation history of interest. A very powerful method of evaluating constitutive equations is the double-step strain history in which the second-step response should be able to be predicted by the model in question. Figure 33 shows the set of two-step histories that is dealt with here and subsequently. Figures 34,

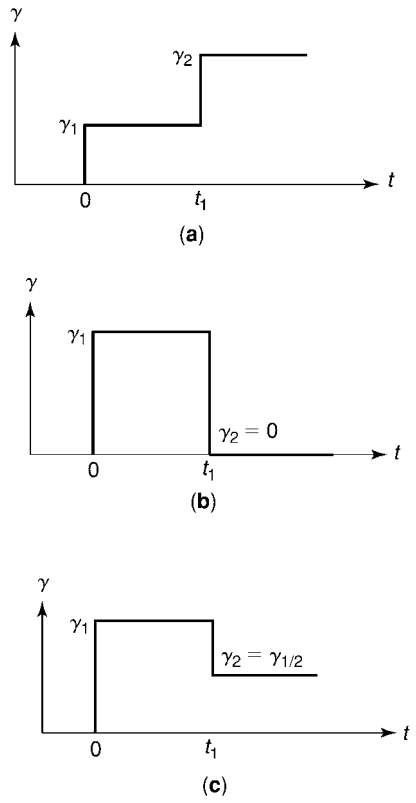

Fig. 33. Two-step strain histories. (**a**) Step-up, (**b**) step to zero deformation, and (**c**) half-step deformation histories.

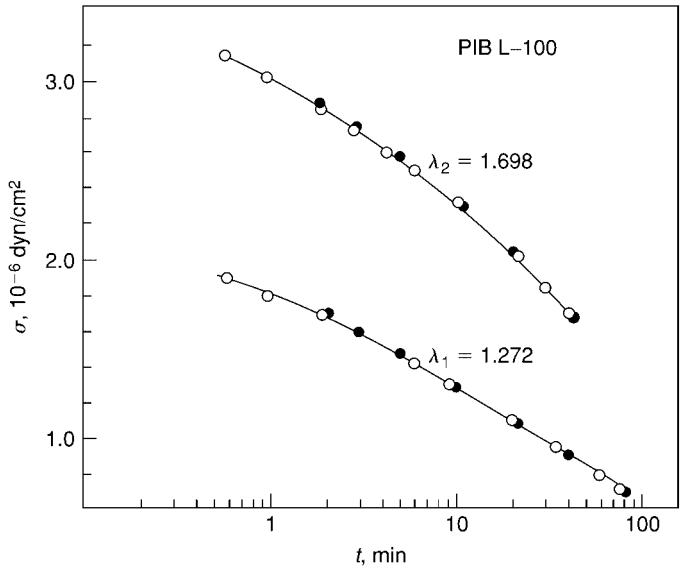

Fig. 34. Comparison of K-BKZ predictions (filled circles) with experimental data (open circles) for step-up experiment in uniaxial extension for a polyisobutylene material. After Zapas and Craft (111), with permission.

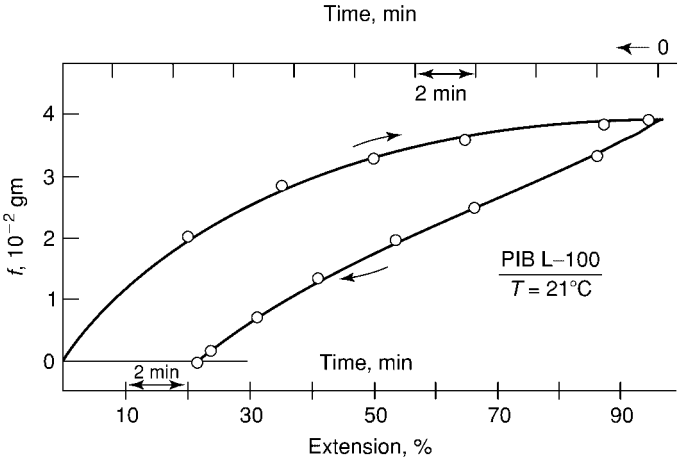

Fig. 35. Comparison of K-BKZ predictions (open circles) with experimental data (solid line) for a constant rate of strain (load–unload) history for a polyisobutylene material. After Zapas and Craft (111), with permission.

35, 36, 37, 38 show comparisons between K-BKZ predictions and the experimental data for two-step stress relaxation experiments (111), constant rate of loading and unloading experiments, creep and recovery experiments, relaxation after steady shearing flow at different shear rates, and superposition of small deformations on large ones; this last being a multiple-step experiment that could be treated as a three-step case (79) As seen, these experiments show excellent agreement

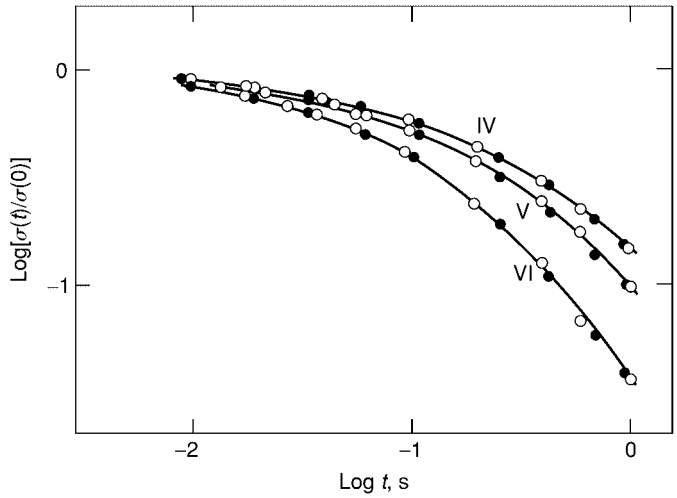

Fig. 37. Comparison of K-BKZ predictions (filled circles) with experimental data (open circles) for relaxation after a steady shearing flow. (IV) 0.177 s^{-1}; (V) 1.11 s^{-1}; (VI) 5.56 s^{-1}. After Zapas and Craft (111), with permission.

between the theory and the experiment, indicating the power of the model. Another interesting aspect of the K-BKZ theory is the predictions it makes for the normal stress responses in the so-called *half-step deformation history* in which the second step is $\frac{1}{2}$ the magnitude of the first, as depicted in Figure 33c. For any two-step history, the shear and normal stress difference responses (or torque and

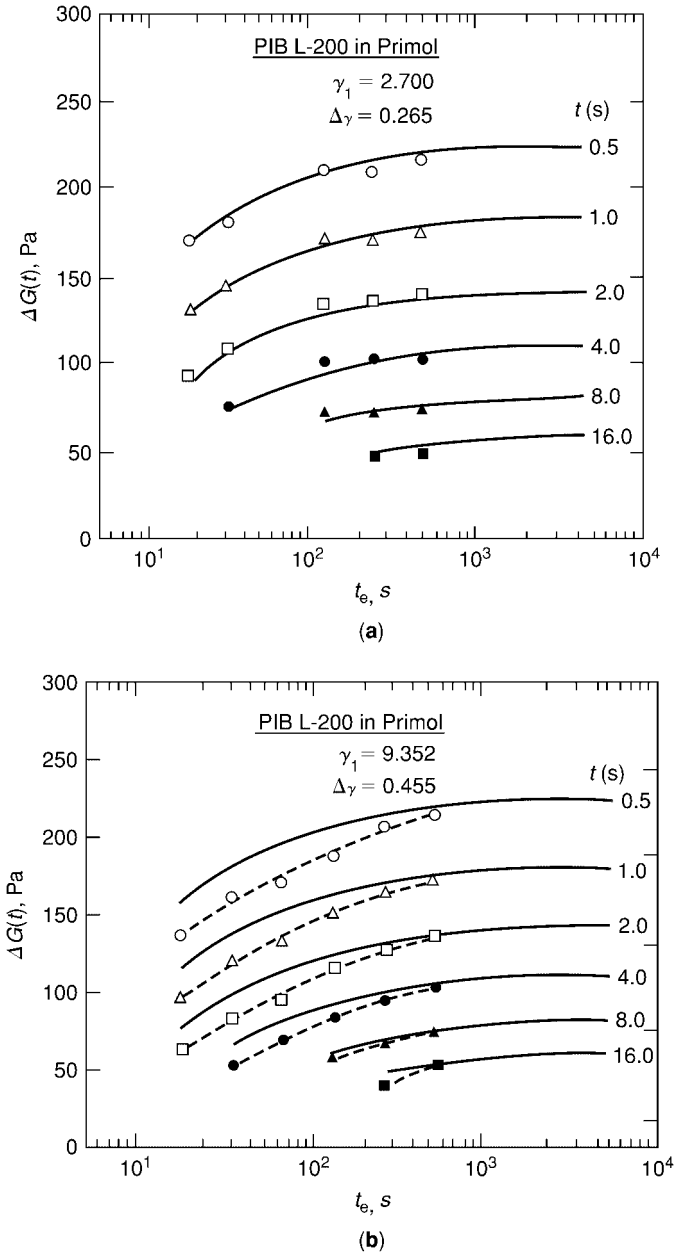

Fig. 38. Comparison of the K-BKZ predictions (lines) with data for the incremental modulus response to a small strain $\Delta\gamma$ superimposed on a large strain γ as a function of time t_e elapsed after the imposition of the large strain. Part (**a**) shows excellent agreement between the theory and experiment for $\gamma = 2.7$, while part (**b**) shows moderate deviations at small t_e values when $\gamma_1 = 9.4$. After McKenna and Zapas (79).

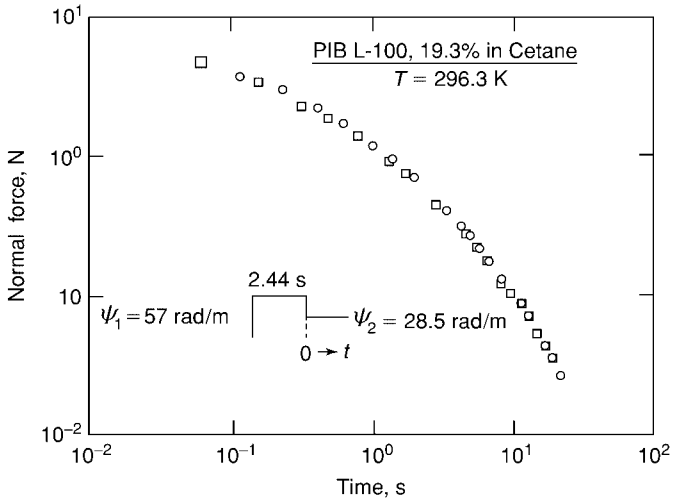

Fig. 39. Comparison of the K-BKZ prediction (squares) for the "half-step" normal stress response with the experimental behavior (open circles) for a polyisobutylene solution. After McKenna and Zapas (113).

normal force responses) can be written as (72,112–117)

$$\begin{aligned} \sigma_{12}(t-t_1) &= K(\gamma_2,t) + K(\gamma_2-\gamma_1,t-t_1) - K(\gamma_2-\gamma_1,t) \\ \sigma_{22}(t-t_1) - \sigma_{22}(t-t_1) &= H_1(\gamma_2,t) + H_1(\gamma_2-\gamma_1,t-t_1) - H_1(\gamma_2-\gamma_1,t) \\ \sigma_{22}(t-t_1) - \sigma_{33}(t-t_1) &= H_2(\gamma_2,t) + H_2(\gamma_2-\gamma_1,t-t_1) - H_2(\gamma_2-\gamma_1,t) \end{aligned} \tag{59}$$

where $K(\gamma, t)$ is the single-step stress relaxation response of the shear (or torque) and $H_i(\gamma, t)$ is that of the i^{th} principal stress difference (or normal force). On substituting torque T and normal force N for a torsional experiment into equations 59, one would see that the torque response is an odd function of the strain $[T(-\gamma) = -T(\gamma)]$ and the normal force is an even function of strain $[N(-\gamma) = N(\gamma)]$. Then, for the special $\frac{1}{2}$-step history where $\gamma_1 = 2\gamma$, the torque and normal force responses become

$$\begin{aligned} T(\psi_2,t-t_1) &= 2K(\psi_2,t) - K(\psi_2,t-t_1) \\ N(\psi_2,t-t_1) &= H(\psi_2,t-t_1) \end{aligned} \tag{60}$$

which means that the torque response depends upon the full deformation history. On the other hand, the normal force response depends only upon the time after the first step $(t - t_1)$, ie, is independent of the duration of the first step and would be equal to the magnitude of the response to a single-step deformation to a torsion magnitude of Ψ_2. Figure 39 provides the experimental evidence that this is, indeed, the behavior followed by a polyisobutylene solution. Subsequent data, however, indicate that this may not be universally true (115–117). This is discussed subsequently.

The data shown thus far describing the success of the K-BKZ theory were, generally, such that the stress never changed sign. However, it turns out that

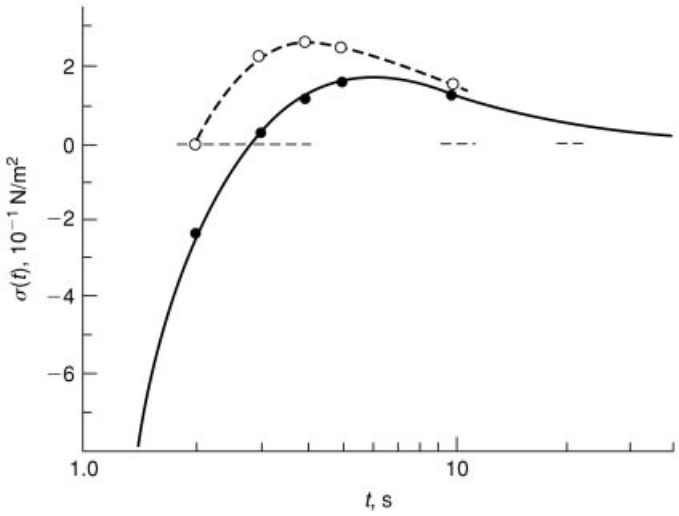

Fig. 40. Comparison of the "half-step" shear stress response predicted by the K-BKZ theory (open circles) with the experimental data (filled circles) for a polyisobutylene solution. After Zapas (118), with permission.

in *stress-reversing* flows, the K-BKZ theory seems not to work as well (62,82,107, 112,114,116,118). Figure 40 shows the shear stress response for a polyisobutylene solution in the half-step history just discussed. The response is clearly not in agreement with the K-BKZ theory prediction. Also, in some flows, predicting the pure shear behavior, which has an extensional component to it, is not consistent with the simple shear predictions (119) .

The Doi–Edwards Theory. Much of the excitement that came during the early years of the Doi–Edwards (DE) tube model (52–56) for reptation of polymer chains revolved about the fact that the use of the *independent alignment* assumption resulted in a special form of the K-BKZ model. Hence, much of the machinery that was developed in the 1960s and early 1970s to test the K-BKZ model could be implemented to test the DE model. The next sections discuss the molecular basis of the DE model, the independent alignment assumption, and how well monodisperse polymers follow the DE version of the K-BKZ model.

The Molecular Description. The fundamentals of reptation theory are best understood with the general *coarse-grained* models of a single polymer chain. If one considers the linear polymer chain to be composed of m monomers and also considers the *Rouse* approximation (120) that there are no hydrodynamic interactions [in concentrated solutions and melts this is a very good approximation (9,63)] and that the chain assumes a *Gaussian* conformation, the chain can be divided into N submolecules, each containing g monomers. The average size a of the submolecule in the Gaussian conformation is related to the step length b of the monomer (63):

$$a^2 = gb^2 \tag{61}$$

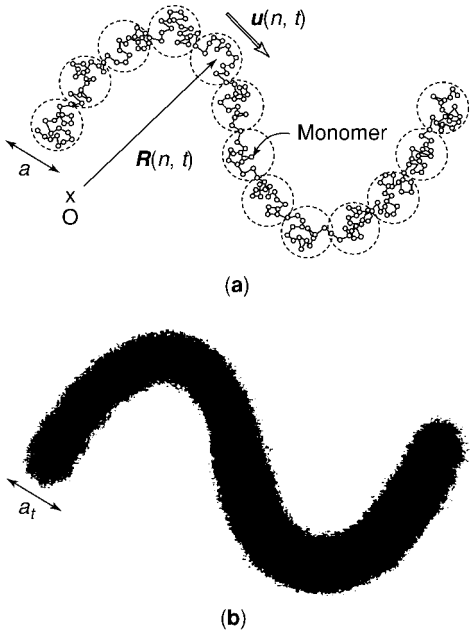

Fig. 41. Schematic representation of a real chain (**a**) and a coarse-grained chain (**b**). In the real chain depiction the small beads connected by rods are the monomeric segments and the circles represent the submolecules of the coarse-grained chain. Part (b) represents the hypothetical time-exposure photograph. After Watanabe (63), with permission.

The real chain is coarse-grained in both time and space, by dividing it into submolecules. Figure 41a shows the Rouse chain and Figure 41b illustrates a hypothetical experiment (63) in which the molecule is photographed with an exposure time t_0. When the time t_0 is large, the chain looks like a fuzzy thread with a width a_t because of the chain motion in the time interval of the "photograph." The dynamics of this Rouse chain are considered as the motion of a string of Gaussian submolecules in a viscous medium. The friction coefficient ζ on the submolecule or bead is given by

$$\zeta = g\zeta_0 \tag{62}$$

where ζ_0 is the monomeric friction coefficient. It is assumed that the force acting on a bead is represented by a Gaussian spring with a spring constant κ given by

$$\kappa = \frac{3k_B T}{a^2} \tag{63}$$

where k_B is the Boltzmann constant and T is the absolute temperature. The time-evolution of the position $\boldsymbol{R}(n,t)$ of the nth submolecule (bead) can be obtained by considering the forces acting on the the bead: frictional $\boldsymbol{F}_f$, elastic (entropic) $\boldsymbol{F}_e$,

and Brownian $\boldsymbol{F}_B$. For large N (long chains) the equation can be written as (121)

$$-\zeta\left[\frac{\partial R(n,t)}{\partial t}\right]+\kappa\frac{\partial^2 R(n,t)}{\partial n^2}+F_B(n,t)=0 \tag{64}$$

The first and second terms represent the frictional force $\boldsymbol{F}_f(n, t)$ and the elastic force $\boldsymbol{F}_e(n, t)$, respectively. The Brownian force $\boldsymbol{F}_B$ is modeled as white noise (56, 63).

Solution of equation 64 permits the determination of the dynamic properties of the chain (56,63). For this paper, the results are given for the polymer melt or concentrated solution, not for the single chain contributions to a dilute solution. The reader is referred to References 56 and 63 for more details. The properties of interest are

$$\text{Relaxation modulus: } G(t)=\frac{vk_BT}{N}\sum_{p=1}^{N}\exp\left(\frac{-2tp^2}{\lambda_{R,G}}\right) \tag{65}$$

where $\lambda_{R,G}$ is the longest relaxation time for the Rouse chain, given by

$$\lambda_{R,G}=\frac{\zeta a^2N^2}{3\pi^2k_BT} \tag{66}$$

Note that v is the number density of Rouse segments in chains of N segments in length and that are monodisperse. The index p is the eigenmode from the solution to the equation of motion. Furthermore, equation 65 is the equation for a special form of the generalized Maxwell model having constant coefficients $G_i = vk_BT$ (see eq. 18). The relaxation times are given by $\lambda_{R,G}/2p^2$.

The *zero shear rate viscosity* is calculated from (56)

$$\eta_0=\frac{v\zeta\alpha^2N}{36} \tag{67}$$

and the *steady-state (recoverable) compliance* is calculated from

$$J_s=\frac{1}{\eta_0^2}\int_0^\infty tG(t)\mathrm{d}t=\frac{2}{5vk_BT}=\frac{2M}{5\rho RT} \tag{68}$$

where ρ is the density and M is the molecular weight. Although the Rouse model was derived for dilute solutions in which there is no hydrodynamic interaction, it seems to best describe the behavior of concentrated solutions and melts that are disentangled. This is particularly so for the viscosity, which at low molecular weights seems to follow the first power prediction given by equation 67 (recall Fig. 18 at low molecular weights). Also, the equilibrium recoverable compliance of short-chain melts (both linear and cyclic) seems to follow the correct

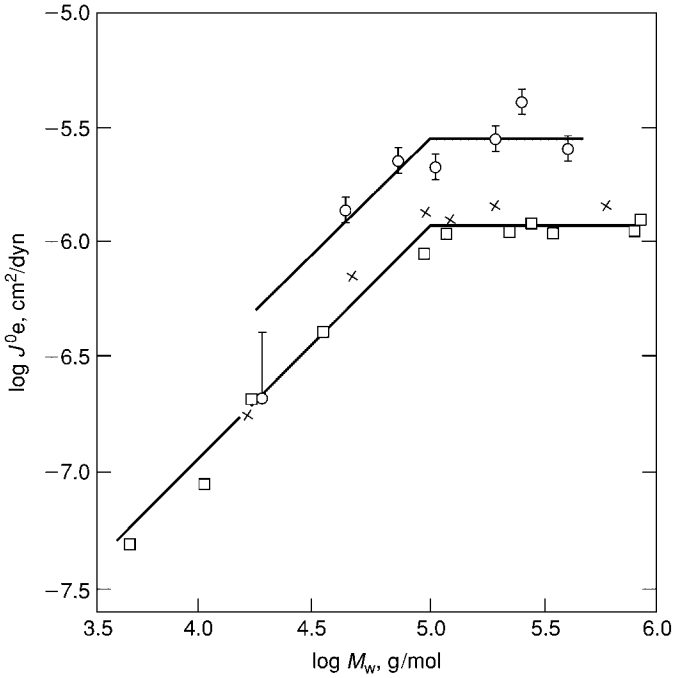

Fig. 42. Double logarithmic representation of the steady-state (recoverable) compliance as a function of molecular weight for linear (squares and crosses) and cyclic (circles) polystyrenes melts. After McKenna et al. (122).

scaling with molecular weight, as shown in Figure 42. However, once the chains get long enough to be entangled, the Rouse-like behavior no longer holds. After entanglement begins, the viscosity follows the very strong $M^{3.4}$ behavior seen in Figure 18 and the steady-state (recoverable) compliance becomes constant as seen in Figure 42 (122). It is here that a model is needed that goes beyond the Rouse model and includes entanglement effects. As noted above, the reptation model of de Gennes (51) and Doi and Edwards (52–56) is the current paradigm for polymer dynamics in the entangled state. Essentially, the DE tube model of reptation is a Rouse chain that moves through a tube that acts as a mean field of constraint. Figure 43 illustrates the movement of the chain in a tube, where the Brownian dynamics of the chain causes it to move about in the original tube until it completely disengages and the new surroundings form a new tube. Here we consider the model at length scales greater than the tube diameter a, which has been identified (57) with the (mean) distance between entanglements or a Rouse submolecule of the size of the entanglement spacing. The important parameters are the number of monomers m_e in the *entanglement segment*, the tube diameter, the friction coefficient ζ for the entanglement segment, and the number of segments in the chain N. The trajectory of bond vectors of the entanglement segments coincides with the tube axis that is referred to as the *primitive path*. These are related to the physical chain by (63)

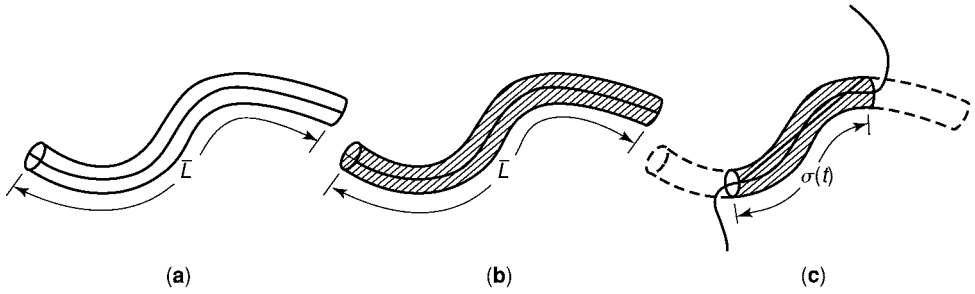

Fig. 43. Schematic of stress relaxation of a chain in the tube in the DE model for small deformations. (**a**) Prior to deformation, the tube has its equilibrium conformation. (**b**) Immediately after the deformation, the entire tube is deformed. At small strains, the contour length of the tube is unchanged. (**c**) At a later time t, the chain has partially escaped from the tube and remains partially confined by the deformed tube. The average of the contour length $\sigma(t)$ of this part of the tube is equal to $L\mu_{\text{rep}}(t)$. After Doi and Edwards (56), with permission.

$$\begin{aligned} \text{Tube diameter:} a &= m_{\text{e}}^{1/2} b \\ \text{Friction factor:} \zeta &= m_{\text{e}} \zeta_0 \\ \text{Number of segments:} N &= \frac{m}{m_{\text{e}}} \end{aligned} \tag{69}$$

where b is the effective step length of the monomer, m is the number of monomers in the chain or the degree of polymerization, and ζ_0 is the monomeric friction factor. Note that, with the exception of N, the parameters in equation 69 are independent of chain length.

In the equilibrium conformation the centerline of the tube represents a random walk with a step length that corresponds to the tube diameter. If the tube is treated as a system of slip links through which the chain can pass, the mean field of the surrounding chains results in an equivalent tensile force $\boldsymbol{F}_{\text{eq}}$ that acts on the chain ends (63,121):

$$F_{\text{eq}} = \frac{3k_{\text{B}}T}{a} \tag{70}$$

This force acts to constrain the lateral motion of the chains (tube constraints) and the average contour length of the tube coincides with the equilibrium tube length $\boldsymbol{L}_{\text{eq}}$:

$$L_{\text{eq}} = Na = \frac{R_{\text{e}}^2}{a} \tag{71}$$

where $R_{\text{e}}{}^2$ is the mean-square end-to-end distance of the unperturbed chain.

According to the DE model, the tube is fixed in space and, at equilibrium, the contour length is constant $L = L_{\text{eq}}$. This results in all entanglement segments moving together back and forth within the tube and along the tube axis. Hence, the motion is equivalent to one-dimensional diffusion within the tube along the tube axis. If one defines the position along the tube as a segment number (given by s/a, where s is the segment position), one can write an equation for the evolution

of the position $\boldsymbol{R}(n, t)$ and the unit bond vector of the nth entanglement segment $\boldsymbol{u}(n, t)$:

$$R(n,t+\Delta t)=R(n+\Delta n,t),u(n,t+\Delta t)=u(n+\Delta n,t) \tag{72}$$

where $\Delta \boldsymbol{n}$ is a normalized (by a) stochastic sliding distance and $\Delta \boldsymbol{t}$ is the time for the chain to slide this distance. Then, the Rouse chain in the tube has a curvilinear motion with a diffusion coefficient $\boldsymbol{D}_c$ that is obtained from the stochastic sliding process (61):

$$\langle \Delta n\rangle = 0, \langle \Delta n^2\rangle = \frac{2D_c}{a^2}\Delta t, \quad \text{and} \quad D_c = \frac{k_B T}{N\zeta} \tag{73}$$

The rapid motion of the entanglement segments at the chain (and tube) ends allows these to have their equilibrated configuration:

$$u = a\tilde{u}_{eq}(\text{at the chain ends}) \tag{74}$$

where $\tilde{u}_{eq}$ is an isotropically distributed unit vector.

The coarse-grained chain just discussed can be used to describe reptation dynamics at spatial scales $> a$ and time scales greater than the time $\Delta t*(a)$ for the chain to move (reptate) a distance a (63):

$$\Delta t^*(a) = \frac{Na^2\zeta}{2k_B T} \tag{75}$$

The dynamic properties for the reptation model just described are obtained by solving the equations 71, 72, 73, 74 and the linear viscoelastic properties are solved from the relationship between the stress and the chain orientation function (63). Without going into detail, the results for times longer than the tube equilibration time but shorter than the reptation time are

$$G(t) = G_N \mu_{rep}(t) \tag{76a}$$

where

$$G_N = \frac{4}{5}\upsilon N k_B T \tag{76b}$$

and

$$\mu_{rep} = \sum_{p=\text{odd}} \frac{8}{p^2\pi^2}\exp\left(-\frac{tp^2}{\lambda_{rep}}\right) \tag{76c}$$

with

$$\lambda_{rep} = \frac{\zeta N^3 a^2}{\pi^2 k_B T} \tag{76d}$$

In equation 76a the reptation time λ_{rep} is the time for the chain to escape from the tube (orientation relaxation occurs from the end to the center of the chain). G_N is the entanglement plateau modulus (this value is slightly different from that implied from rubber elasticity of an entangled network) and $\mu_{rep}(t)$ is a normalized relaxation modulus for the reptation process. In this time regime, equation 76a implies that the modulus is separable into a time function and a modulus function. This becomes important in discussing the nonlinear response, which is done, in more detail, below. Some other viscoelastic functions from the DE tube model of reptation are

$$\eta_0 = \frac{\pi^2 G_N \lambda_{rep}}{12} \tag{77}$$

$$J_s = \frac{6}{5G_N} = \frac{6}{5} J_N \tag{78}$$

At this point the reptation theory makes some strong predictions about the viscoelastic response in the linear regime, viz, the viscosity varies as N^3 and the ratio of ${J_s}^0/G_N = 6/5 = 1.2$. Note that the molecular weight dependence of the viscosity has already been discussed above, and recall that, experimentally, the viscosity varies as $N^{3.4}$. In addition, the ratio ${J_s}^0/G_N$ is observed experimentally to be in the range of 2–2.5. In spite of these failings, the reptation model is very powerful. The next section examines the stress response to deformation histories in the nonlinear range.

The DE Constitutive Equations. The DE model (52–56) made a major breakthrough in polymer viscoelasticity in that it provided an important new molecular physics based constitutive relation (between the stress and the applied deformation history). This section outlines the DE approach that built on the reptation-tube model developed above and gave a nonlinear constitutive equation, which in one simplified form gives the K-BKZ equation (70,71). The model also inspired a significant amount of experimental work. One should begin by looking at the calculation of the stresses for a material at times longer than the time it takes for the tube to equilibrate, ie, times in the reptation regime.

Doi and Edwards (56) calculate the stress considering how the conformation of the primitive chain $\boldsymbol{R}(s, t)$ is changed by the macroscopic deformation. First, one needs to know the stress equation in terms of the chain conformation, and then how the chain conformation (orientations) changes with the macroscopic deformation field. The stress equation is developed as follows:

$$\sigma_{\alpha\beta}(t) = \frac{v}{N}\left\langle \int_0^L F(t) u_\alpha(s,t) u_\beta(s,t) \mathrm{d}s \right\rangle \tag{79}$$

where $\boldsymbol{u}(s, t) = \partial \boldsymbol{R}(s, t)/\partial s$ is the unit vector tangent to the primitive chain and $F(t)$ is the tensile force acting on the primitive chain. In the equilibrium state

$$F_{eq} = \frac{3k_B T}{Na^2} L \tag{80}$$

and in the nonequilibrium state

$$F(t) = \frac{3k_B T}{Na^2} L(t) \tag{81}$$

where $L(t)$ is the tube contour at time t and L is its equilibrium value. From equations 79, 80, 81 the relationship between the stress, the contour length, and the changing chain orientation is obtained as

$$\sigma_{\alpha\beta} = \frac{3vk_B T}{N^2 a^2} \left\langle \int_0^{L(t)} L(t) \left[u_\alpha(s,t) u_\beta(s,t) - \frac{1}{3}\delta_{\alpha\beta} \right] \mathrm{d}s \right\rangle \tag{82}$$

It is now necessary to develop the equations for the relationship between the macroscopic deformations and the chain orientations. Doi and Edwards assume that the deformation is affine, ie, the primitive chain deforms in the same way as the macroscopic deformation field. Thus, a point $\boldsymbol{R}(s, -0)$ on the primitive chain is displaced as

$$R(s, -0) \rightarrow E \cdot R(s, -0) \tag{83}$$

where $\boldsymbol{E}$ is the deformation gradient tensor and its components are written as

$$E_{\alpha\beta} = \frac{\partial r'_\alpha}{\partial r_\beta} \tag{84}$$

where r′ is the coordinate in the deformed state and $\boldsymbol{r}$ is the coordinate in the undeformed state. (Note that this is similar to the definitions used earlier in defining the strains and relative deformations.)

Doi and Edwards then derive expressions for the changing contour length and change in the orientation of the primitive path. The development is beyond the scope of the current article. The important expression is that for the chain orientation tensor $\boldsymbol{Q}$ as a function of the macroscopic deformation gradient tensor:

$$Q_{\alpha\beta}(E) = \frac{\left\langle \frac{(E\cdot u)_\alpha (E\cdot u)_\beta}{|E\cdot u|} \right\rangle_0}{\langle |E\cdot u| \rangle_0} - \frac{1}{3}\delta_{\alpha\beta} \tag{85}$$

Then it is possible to determine the response of the “reptation” material to single-step stress relaxation strain histories at large deformations. The relaxation of the tube contour length $L(t)$ takes place on the time scale of the longest Rouse time of the chain in the tube and reorientation takes place over the reptation time scale λ_{rep} as the chain disengages from the tube. This is shown schematically in Figure 44. Therefore, the relaxation for times greater than the equilibration time (the Rouse time for a free chain) takes place in two steps. In the time scale during

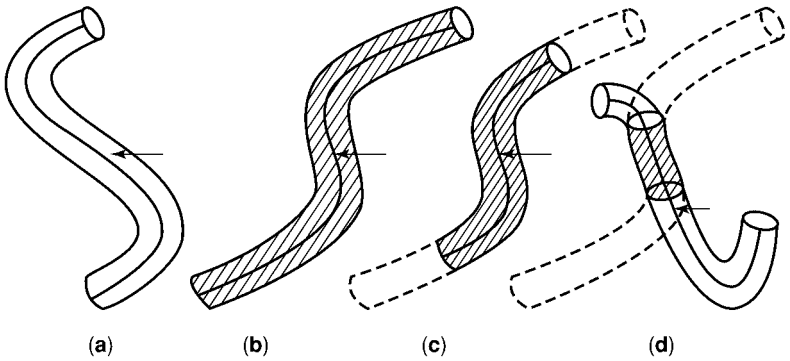

Fig. 44. Schematic of the stress relaxation process after a large step in deformation. (**a**) Equilibrium conformation of the tube prior to deformation. (**b**) Immediately after deformation, the primitive chain has been affinely deformed. (**c**) After the time λ_R, the primitive chain retracts along the tube and recovers its equilibrium contour length ($t \cong \lambda_R$). (**d**) After the time λd the primitive chain leaves the deformed tube by reptation ($t \cong \lambda_d$). After Doi and Edwards (56), with permission.

which the tube recovers its original contour length (contour length relaxation),

$$\sigma_{\alpha\beta}(t) = G_e\{1 + [\alpha(E) - 1]\exp(-t/\lambda_R)\}^2 Q_{\alpha\beta}(E), \lambda_e \le t \le \lambda_R$$
$$\text{where} \quad G_e = \frac{15}{4} G_N \quad \text{and} \quad \alpha(E) = \langle |E \cdot u| \rangle_0 \tag{86}$$

For the time after the tube has regained its original contour length, the chain begins to disengage from the tube via the reptation mechanism. The relaxation response during this time is

$$\sigma_{\alpha\beta}(t) = G_e Q_{\alpha\beta}(E) \mu_{rep}(t), t > \lambda_R \tag{87}$$

where $\mu_{rep}(t)$ is given as the relaxation function for reptation in equation 76a. Combining equations 86 and 87 one obtains the relaxation function for the two-step process:

$$\sigma_{\alpha\beta}(t) = G_e Q_{\alpha\beta}(E)\{1 + [\alpha(E) - 1]\exp(-t/\lambda_R)\}^2 \mu_{rep}(t), t > \lambda_e \tag{88}$$

For a simple shearing deformation, $\alpha(E) = \alpha(\gamma)$ and $Q_{\alpha\beta}(E) = Q_{\alpha\beta}(\gamma)$. In the linear (small deformation) regime one finds

$$\sigma(\gamma) = \left\langle \left(1 + 2\gamma u_x u_y + \gamma^2 u_y^2\right)^{1/2} \right\rangle_0 = 1 + \frac{2}{15}\gamma^2 + O(\gamma^4)$$
$$Q_{xy}(\gamma) = \frac{1}{\alpha(\gamma)} \left\langle \frac{(u_x + \gamma u_y) u_y}{\left(1 + 2\gamma u_x u_y + \gamma^2 u_y^2\right) \mathrm{k}^{1/2}} \right\rangle = \frac{4}{15}\gamma + O(\lambda^3) \tag{89}$$

and the stress response (eq. 88) becomes

$$\sigma_{xy}(t) = \frac{4}{15}\gamma G_e \mu_{rep}(t) + O(\gamma^3) \tag{90}$$

which is the linear viscoelastic response to a single-step stress relaxation history.

For larger deformations, equation 88 is used. For convenience the nonlinear relaxation modulus is defined as

$$G(\gamma,t) = \frac{1}{\gamma}\sigma_{xy}(t,\gamma) \tag{91}$$

Then, equations 88 and 91 give the following expression for the nonlinear modulus:

$$\begin{aligned} G(\gamma,t) &= G_e \frac{Q_{xy}(\gamma)}{\gamma}\{1+[\alpha(\gamma)-1]\exp(-t/\lambda_R)\}^2 \mu_{rep}(t) \\ &= h\ (\gamma) G(t)\{1+[\alpha(\gamma)-1]\exp(-t/\lambda_R)\}^2 \end{aligned} \tag{92}$$

Here $G(t)$ is the linear viscoelastic modulus and $h(\gamma)$, the *damping function* in shear is introduced. For small γ, the linear response is recovered. As γ increases, we see another relaxation in $G(\gamma, t)$ at short times that corresponds to the relaxation of the contour length. Figures 45 and 46 show the expected relaxation

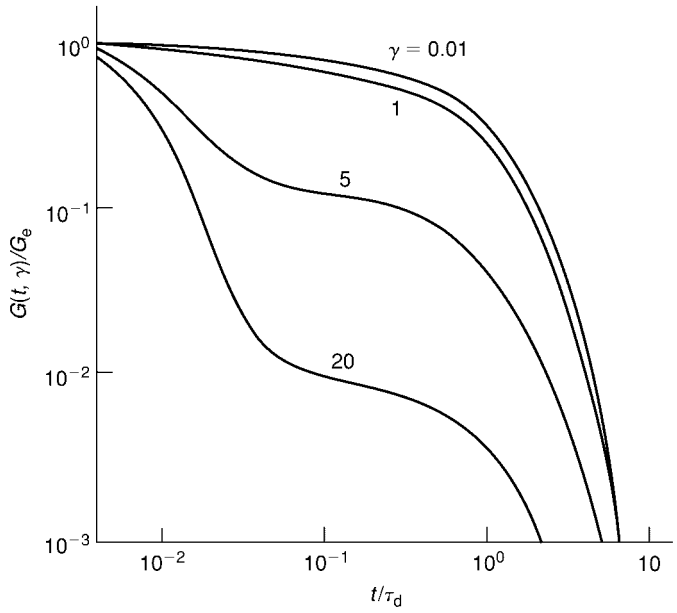

Fig. 45. Theoretical curve for the nonlinear relaxation modulus $G(t, \gamma)$ [$= G(\gamma, t)$] at different values of γ as indicated in the figure. The plot is for the case of $\lambda_d/\lambda_R = 100$. After Doi and Edwards (56), with permission.

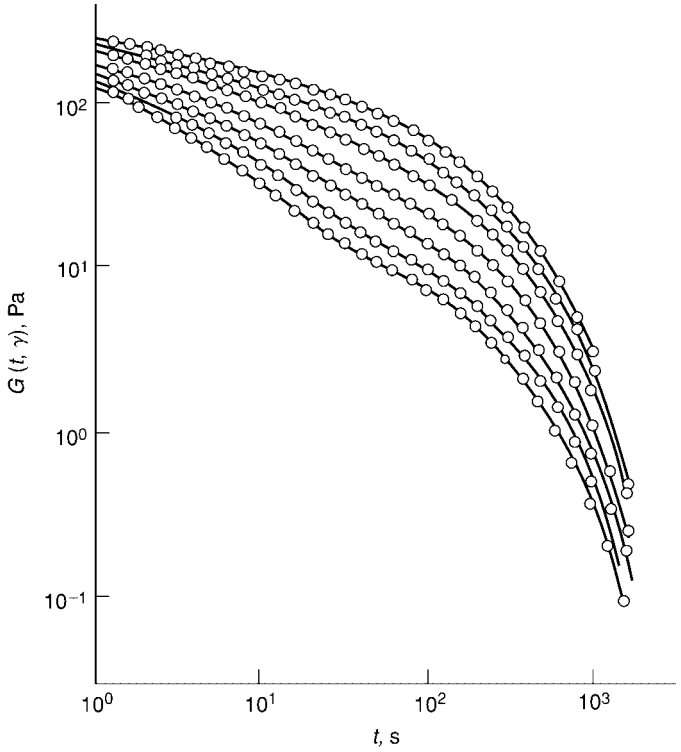

Fig. 46. Nonlinear relaxation modulus $G(t, \gamma)$ [$= G(\gamma, t)$] for a solution of polystyrene in chlorinated biphenyl ($\phi = 0.06$ g/cm^3) at 30°C. From top to bottom, shear strains γ are 0.57, 1.25, 2.06, 3.04, 4.0, 5.3, and 6.1. After Osaki et al. (123), with permission.

behavior and that obtained experimentally for a high molecular weight polymer in solution. The theoretical curves show more nearly exponential decays for both mechanisms than is seen in the actual data, which has a broader relaxational behavior. This is a well-known weakness of the DE model that is related to the relaxation function being nearly exponential in nature (the longest relaxation time is widely separated from the next time which also has a lower intensity).

In examining the single-step stress relaxation behavior of the DE model, one can also look at the normal stress responses in shearing experiments. The first and second normal stress differences are $N_1(\gamma, t)$ and $N_2(\gamma, t)$ respectively. The relevant equations are (56)

$$N_1(\gamma,t) = \frac{Q_{xx}(\gamma) - Q_{yy}(\gamma)}{Q_{xy}(\gamma)}\sigma_{xy}(\gamma,t)$$
$$N_2(\gamma,t) = \frac{Q_{yy}(\gamma) - Q_{zz}(\gamma)}{Q_{xy}(\gamma)}\sigma_{xy}(\gamma,t) \tag{93}$$

and since

$$Q_{xx}(\gamma) - Q_{yy}(\gamma) = \gamma Q_{xy}(\gamma) \tag{94}$$

$N_1(\gamma, t)$ can be written as

$$N_1(\gamma,t) = \gamma\sigma_{xy}(\gamma,t) \tag{95}$$

This relation, which also results from the K-BKZ model, is referred to as the Lodge–Meissner relationship (124) and results for materials with a finite elastic modulus at zero time.

The framework for examining arbitrary deformation histories for the "reptation" fluid has now been established and one can obtain a constitutive law for the stress response to arbitrary deformation histories. While the DE model can provide a more general constitutive equation than that to be developed now, the more general form requires numerical solution. The approximation known as the *independent alignment assumption* (IA) results in a closed form solution that gives a special case of the K-BKZ theory developed previously.

First, consider a simplification in which it is assumed that the contour length of the primitive chain remains at the equilibrium length L under the imposed deformation. This assumes an inextensible primitive chain and is seen as a reasonable approximation for slow flows or long times. Then, the deformation of the primitive chain is given by considering that the segment in the middle of the chain changes position affinely as

$$R'(0) = E \cdot R(0) \tag{96}$$

where $R(s)$ is the primitive chain conformation before deformation and $R'(s)$ is that after deformation. The primitive chain segments go from $-L/2$ to $L/2$; hence the middle is at 0.

Then the segment s' lies on the curve $E \cdot R(s)$ so that

$$R'(s') = E \cdot R(s) \tag{97}$$

s' is the contour length along the curve $E \cdot R(s'')$ from $s'' = 0$ to $s''=s$:

$$s' = \int_0^s |E \cdot u(s'')| \mathrm{d}s'' \tag{98}$$

Combination of equations 96, 97, 98 gives the transformation

$$u'(s') = \frac{E \cdot u(s)}{|E \cdot u(s)|} \tag{99}$$

Because s and s' are not equal to each other, the general constitutive equation becomes very complicated and requires numerical solution. The independent alignment approximation allows us to ignore this difference. Then, with $s' = s$ the transformation equation 99 becomes

$$u'(s) = \frac{E \cdot u(s)}{|E \cdot u(s)|} \tag{100}$$

The consequences of this approximation have been extensively investigated and the results are outlined here. In terms of the orientation tensor, the IA approximation in a single-step stress relaxation experiment in simple shear is given by

$$\begin{aligned} Q_{xy}^{\mathrm{IA}}(\gamma) &= \frac{1}{5}\gamma(\gamma \ll 1) \\ Q_{yy}^{\mathrm{IA}}(\gamma) - Q_{zz}^{\mathrm{IA}}(\gamma) &= -\frac{2}{35}\gamma^2(\gamma \ll 1) \end{aligned} \tag{101}$$

and the damping function is then given by

$$h^{\mathrm{IA}}(\gamma) = \frac{Q_{xy}^{\mathrm{IA}}(\gamma)}{\gamma/5} \tag{102}$$

which is not very different from the more general $h(\gamma)$ introduced earlier (eq. 91) over a wide range of γ (56).

Without derivation, note that Doi and Edwards developed expressions for the probability distribution function for the chain as well as the relationship between the stress and the chain orientations to arrive at an evolution equation for the stress to the chain orientation process, which is a function of the macroscopic deformations. The resulting constitutive equation is

$$\sigma_{\alpha\beta}(t) = G_{\mathrm{e}} \int_{-\infty}^{t} \left(\frac{\partial \psi(t-t')}{\partial t'} \right) Q_{\alpha\beta}^{\mathrm{IA}}[E(t,t')]\mathrm{d}t' \tag{103}$$

where $\psi(t) = \mu_{\mathrm{rep}}(t)$ is the DE relaxation function given previously. This equation is equivalent to a special form of the K-BKZ model discussed above. Note, however, that the deformation measure is somewhat different. [The reader should see Wagner and Schaeffer (125) for further discussion of the DE strain measures relative to classic strain measures.] A relaxation function $\phi_{\alpha\beta}(t, E)$ can be defined as

$$\begin{aligned} \phi_{\alpha\beta}(E,t) &= G_{\mathrm{e}} \int_{-\infty}^{0} \left(\frac{\partial \psi(t-t')}{\partial t'} \right) Q_{\alpha\beta}^{\mathrm{IA}}(E)\mathrm{d}t' \\ &= G_{\mathrm{e}} \psi(t) Q_{\alpha\beta}^{\mathrm{IA}}(E) \end{aligned} \tag{104}$$

which is the single-step stress relaxation response to the deformation represented by $Q_{\alpha\beta}{}^{\mathrm{IA}}(E)$. Then, the stress response to an arbitrary flow history is given by

$$\sigma_{\alpha\beta}(t) = \int_{-\infty}^{t} \left(\frac{\partial \phi(E,t-t')}{\partial t'} \right)_{E=E(t,t')} \mathrm{d}t' \tag{105}$$

This has the same form as the K-BKZ model described above and where the function $\phi(E, t)$ has the meaning of $K(I_1, I_2, t)$ for any given deformation (see eqs. 56, 57, 58, 59, 60). This result was a very important aspect of the DE model's success because of the broad success of the K-BKZ continuum model

that had already been established. The next sections examines some of the data that were specifically generated to test the validity of the DE model constitutive equation.

Comparison with Experiment. Of particular importance in comparing the DE model with nonlinear rheological experiments is the fact, already noted above, that the relaxation function in the linear viscoelastic regime is not broad enough to capture the actual behavior of polymers. This resulted in two important trends in the experimental tests of the DE work. First, because the K-BKZ work, eg, in two-step deformation histories, had been mostly performed on commercial polymers of broad molecular weight distribution, the tests of DE focused primarily on monodisperse polymers that were anionically polymerized. (Later developments (15,18,126–128) lead to use of broader molecular weight distributions but these will not be treated here.) Hence, much work was done, particularly by Osaki (123,129–133) and co-workers, in different two-step deformation histories where both the shear and normal stress differences could be obtained. Also, more recent work by the Venerus and Burghardt groups (115–117,134,135) has further expanded on the Osaki work. The second development was that much effort was expended to compare the form of the damping function that was measured with that given by the DE model, part of which was discussed above.

Single-Step Stress Relaxation Experiments. The damping function of the DE equation has already been compared with some of the Osaki data (Figs. 45 and 46). Here two other aspects of the Osaki work are emphazied. At long times, when the material response is dominated by the chain disengaging from the tube, the DE model gives a response that is refered to as *time–strain separable*. The possibility of time–strain separability in the response of polymer relaxation behavior was originally used by Zapas and Craft (111). Empirically, time–strain separability can be expressed by the following (see also eqs. 76a and 90):

$$G(\gamma,t) = h(\gamma)g(t) \tag{106}$$

where $h(\gamma)$ is referred to as the *shear damping function* discussed above and $g(t)$ would be a linear viscoelastic relaxation response. Osaki (123) showed that the time–strain separability appears to be valid after some characteristic time the called τ_k (now time and not stress). This is shown in Figure 47, which is a plot of $G(\gamma, t)/h(\gamma)$. If time–strain separability were valid over all times, the curves at different strains would have collapsed onto a single curve. In Figure 47 it is observed that the curves do not collapse until after the time τ_k. Unfortunately, it is not currently possible to uniquely attribute τ_k to any of the times discussed above for the tube model. It is, however, common to attribute τ_k to the finite time required for the molecule to retract along its contour length.

Another interesting aspect of the work done by Osaki was the demonstration that $h(\gamma)$ is not a universal function. Rather, it seems to depend on the number of entanglements M/M_e. The reptation theory expectation for the actual behavior in concentrated solution has been variously interpreted and there is not general agreement on the expected behavior. However, the data shown in Figure 48 are important for the understanding of polymer molecular viscoelasticity and were obtained within the important framework provided by the DE theory. From

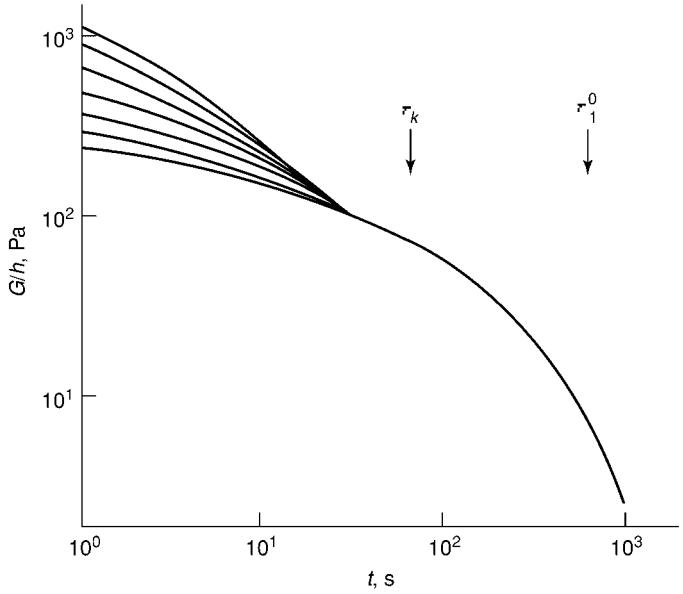

Fig. 47. Reduced relaxation modulus $G(t, \gamma)/h(\gamma)$ [$= G(\gamma, t)/h(\gamma)$] derived from data of Figure 46. The curves for $\gamma > 1.25$ shift vertically by an amount $-\log h(\gamma)$ so that they superpose in the long time regime. $\tau^0{}_1$ represents the longest relaxation time and τ_k represents the time below which superposition is not possible. After Osaki et al. (123), with permission.

Figure 48 it is seen that the damping function depends on M/M_e and on concentration. Subsequently Osaki and co-workers (123) stated that "the quantity $h(\gamma)$ scarcely varies with molecular weight or concentration." A still later work by Osaki (136), however, again shows a disagreement between experimental data and the universal $h(\gamma)$ for polystyrene solutions. In addition, Wagner and Schaeffer (119,125,137) have extensively studied the form of the universal damping function and found that it is inadequate for the description of polydisperse polymer melts.

Two-Step Stress Relaxation Experiments. As discussed above in the context of the K-BKZ model, the two-step stress relaxation experiment is a very important tool in the assessment of constitutive relations. The same has been true in the use of the two-step experiment to assess the DE model. Here, the tests in the context of the independent alignment assumption are first examined. The important aspect of the experiments performed by Osaki and co-workers is that (123,129–133) the work was performed on monodisperse polymers. The work of Venerus and Burghardt, which is further built on the work of Osaki, will also be discussed. Finally, a proposed form of constitutive model that goes beyond the independent alignment assumption and gives a tractable set of predictions for the double-step experiments is examined.

Here three types of two-step experiment are viewed and the reader is asked to recall Figure 33. The figure shows the step-up (a), the step to zero (b), and the half-step (c) histories. Both the torque and normal force responses are examined.

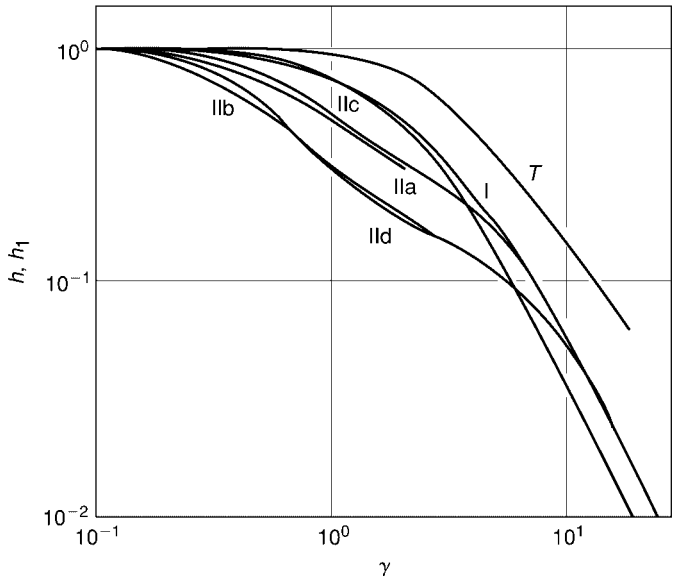

Fig. 48. Strain-dependent functions $h(\gamma)$ and $h_1(\gamma)$. The heavy line represents the DE damping function and the light lines represent experimental results $[h_1(\gamma)]$ for polystyrene solutions. For type I sample, $\phi M < 10^6$ (g·Da)/cm^3 and for type II samples $\phi M > 10^6$ (g·Da)/cm^3. For IIa, $M = 3.10 \times 10^6$ Da and $\phi = 0.329$ g/cm^3. For IIb, $M = 5.53 \times 10^6$ Da and $\phi = 0.221$ g/cm^3. For IIc and IId, $M = 7.62 \times 10^6$ Da and $\phi = 0.176$ and 0.221 g/cm^3, respectively. T is for a broad molecular weight distribution sample in which $M_w = 1.10 \times 10^6$ Da and $M_w/M_n = 4$ and $\phi = 0.21$ g/cm^3. After Osaki and Kurata (130), with permission.

In addition, because much of the data in the literature include comparisons with the DE model both with and without independent alignment, the equations for the form of the DE model that Doi proposed by suppressing the independent alignment assumption are presented. Here the results are referred to as DE-NIA. In this case for two-step stress relaxation histories recall equations 59 (DE-IA or K-BKZ)

$$\begin{aligned} \sigma_{12}(t) &= K(\gamma_2,t) + K(\gamma_2-\gamma_1,t-t_1) - K(\gamma_2-\gamma_1,t) \\ \sigma_{22}(t) - \sigma_{22}(t) &= H_1(\gamma_2,t) + H_1(\gamma_2-\gamma_1,t-t_1) - H_1(\gamma_2-\gamma_1,t) \\ \sigma_{22}(t) - \sigma_{33}(t) &= H_2(\gamma_2,t) + H_2(\gamma_2-\gamma_1,t-t_1) - H_2(\gamma_2-\gamma_1,t) \end{aligned} \tag{59}$$

and compare these with the DE-NIA equations:

$$\begin{aligned} \sigma_{12}(t) &= A(\beta)K(\gamma_2,t) + K(\gamma_2-\gamma_1,t-t_1) - [A(\beta)+B(\alpha_2,\beta)]K(\gamma_2-\gamma_1,t) \\ \sigma_{22}(t) - \sigma_{22}(t) &= A(\beta)H_1(\gamma_2,t) + H_1(\gamma_2-\gamma_1,t-t_1) - [A(\beta)+B(\alpha_2,\beta)]H_1(\gamma_2-\gamma_1,t) \\ \sigma_{22}(t) - \sigma_{33}(t) &= A(\beta)H_2(\gamma_2,t) + H_2(\gamma_2-\gamma_1,t-t_1) - [A(\beta)+B(\alpha_2,\beta)]H_2(\gamma_2-\gamma_1,t) \end{aligned} \tag{107}$$

where

$$A(\beta)=\frac{4\beta\cos(\frac{\pi\beta}{2})}{\pi(1-\beta^2)},\ B(\alpha_2,\beta)=\frac{\pi^2(1-\beta)^3}{12(\alpha_2-\beta)}\quad\text{for}\quad\beta<1$$

$$A(\beta)=\frac{4\cos(\frac{\pi}{2\beta})}{\pi(1-\beta^{-2})},B(\alpha_2,\beta)=0\quad\text{for}\quad\beta\geq 1 \tag{108}$$

$$\beta=\left(\frac{3+\gamma_2^2}{3+\gamma_1^2}\right)^{1/2},\ \alpha_2=\left[1+(\gamma_1-\gamma_2)^2\right]^{1/2}$$

As seen in the next paragraphs, the DE-NIA equations sometimes do better and sometimes worse than the DE-IA or K-BKZ equations. Also note that in all instances the measured single-step relaxation function is used rather than the theoretical DE function, which as already discussed is too narrow to capture the full breadth of the relaxation response of entangled polymers.

Step-Up. Figure 49 shows the response for a two-step history in which the second step is approximately the same magnitude as the first step, ie, $\gamma_2=2\gamma_1$. The results are from Osaki's work (138) on polystyrene solutions and illustrate that both the shear stress response and the normal stress response are well represented with the DE independent alignment approximation (ie, the K-BKZ equations). This result is similar to what was found previously for the K-BKZ model (Fig. 34) (138).

Step to Zero Deformation. Figures 50 and 51 show the response for a two-step history in which one first applies a step strain γ_1 for some time t_1 and then returns

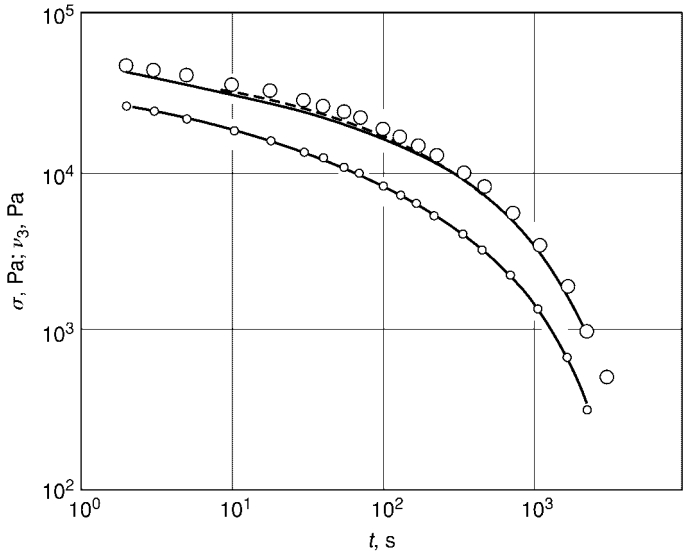

Fig. 49. Shear stress σ (○) and normal stress ν_3 (○) responses to a two-step "step-up" type of deformation history with $\gamma_1=1.47$ and $\gamma_2=2.90$ for a concentrated polystyrene solution. The solid lines are the predictions for the K-BKZ or DE-IA equations and the dashed lines are for the DE-NIA equations. After Osaki and et al. (138), with permission.

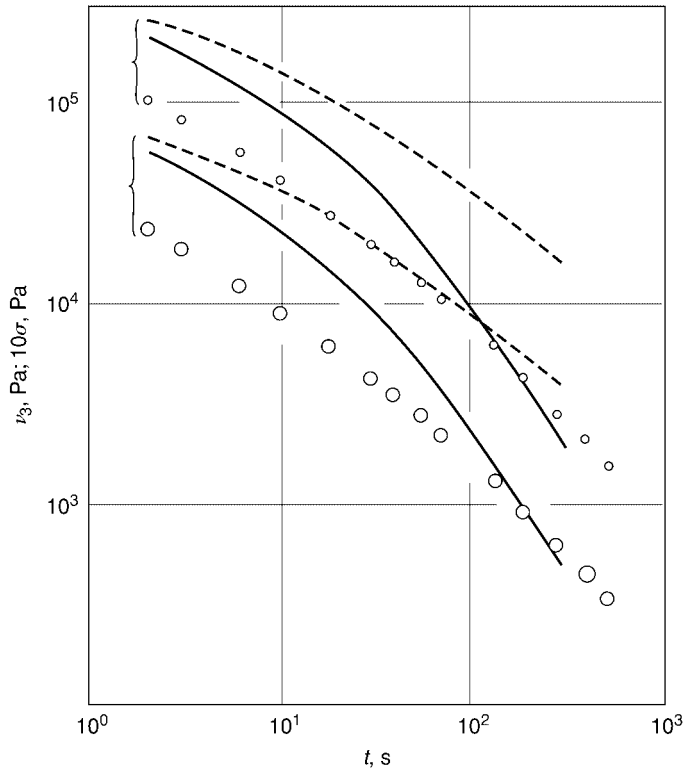

Fig. 50. Shear stress σ (○) and normal stress ν_3 (○) responses to a two-step "step to zero" type of deformation history with $\gamma_1 = 2.89$ and $\gamma_2 = 0$ for a concentrated polystyrene solution. Duration of the first step was $t_1 = 20$ s. The solid lines are the predictions for the K-BKZ or DE-IA equations and the dashed lines are for the DE-NIA equations. After Osaki et al. (138), with permission.

the material to zero deformation, $\gamma_2 = 0$. The results are, again, from Osaki (138). Figure 50 shows the results when the first step duration $t_1 = 20$ s, and it is seen that both the shear and normal stress responses are poorly represented by either the DE model with independent alignment (solid lines) or the predictions without the independent alignment assumption (dashed lines). Figure 51 shows that when t_1 gets longer ($t_1 = 200$ s) the agreement between theory and experiment improves. Also, note that both theoretical curves also begin to approach each other, as might be expected because the models are fading memory models and at very long times, the step back to zero should become equivalent to the single-step response.

Half-Step Deformation. In the discussion of the K-BKZ model, the half-step deformation was covered. Here two sets of data that go beyond what was described above are discussed. First, in the Osaki data shown in Figure 52, it is seen that the DE model with independent alignment fits the shear stress response, but not the normal stress response. Also, the theory without the independent alignment assumption does not fit the shear data. The normal stress deviation from the model prediction is interesting, as this was a "special" history for which the K-BKZ and

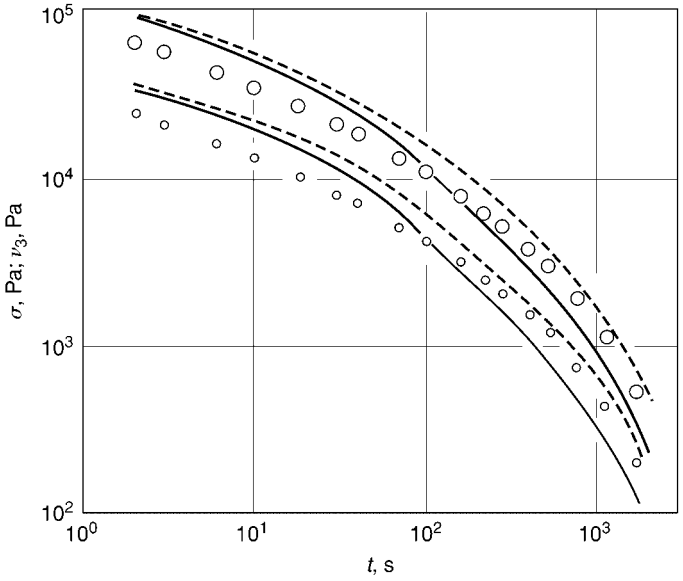

Fig. 51. Shear stress σ (○) and normal stress ν_3 (○) responses to a two-step "step-to zero" type of deformation history with $\gamma_1 = 2.89$ and $\gamma_2 = 0$ for a concentrated polystyrene solution. Duration of the first step was $t_1 = 200$ s. The solid lines are the predictions for the K-BKZ or DE-IA equations and the dashed lines are for the DE-NIA equations. After Osaki et al. (138), with permission.

DE-IA models both predicted that the normal stress response is independent of the duration of the first step (and equal to a single-step experiment with magnitude $\gamma_2 = \gamma_1/2$). Figure 52 shows that for the polystyrene solution, the single-step response for the normal stress is only in agreement with the single-step response at long times. Interestingly, Osaki's data (138) showed that the normal stress response was independent of the duration of the first step, although not equal to the single-step response. Figures 53 and 54 show a set of half-step data from Burghardt and Brown (111). The shear stress theory is not shown for comparison, but it is seen that the shear stresses go negative and then become positive, going through a maximum before joining what would be the single-step relaxation at very long times. On the other hand the normal force responses for the different values of t_1 are very interesting because they seem to become independent of the duration of the first step at a characteristic time. At short times, deviations occur. Hence, the original findings of McKenna and Zapas that the normal force response is independent of the duration of the first step, seems to only be confirmed for long times. Osaki associated this time with the value of τ_k discussed previously and where time-strain separability is applicable. An interesting aspect of this is that the observation that the normal stresses in the half-step history can independent of the duration of the first step is also observed for some polymer glasses (112–114), as discussed subsequently.

Nonlinear Viscoelastic Response of Solid-like Polymers. The study of the nonlinear viscoelastic response of solid or solid-like polymers is one that has

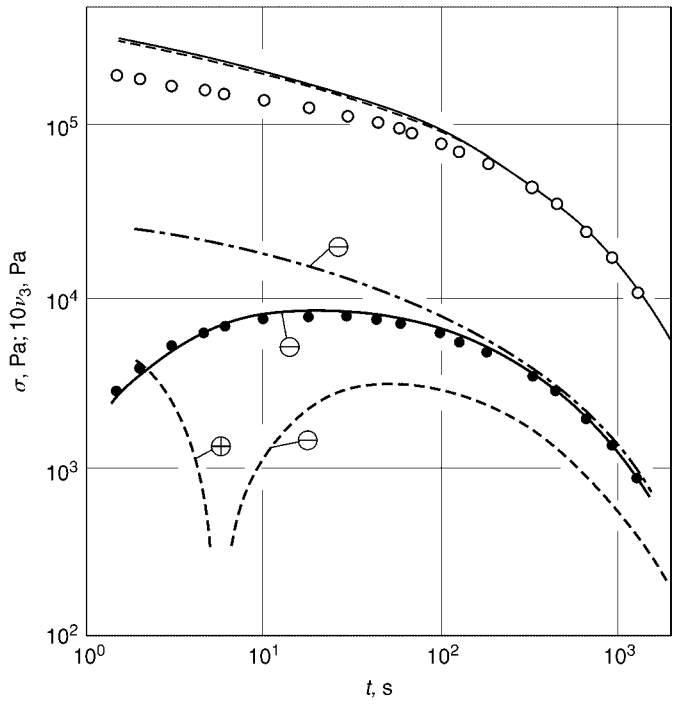

Fig. 52. Shear stress σ (○) and normal stress ν_3 (○) responses to a two-step "half-step" type of deformation history with $\gamma_1 = 2.89$ and $\gamma_2 = 1.45$ for a concentrated polystyrene solution. Duration of the first step was $t_1 = 20$ s. The solid lines are the predictions for the K-BKZ or DE-IA equations and the dashed lines are for the DE-NIA equations. Dashed-dotted line is the single-step shear stress response for $\gamma = 1.45$. After Osaki et al. (138), with permission.

been relatively neglected. One reason is that there is no real molecular framework for the description of these materials, particularly when they are amorphous. The other reason is that many workers in the field have adopted the framework of metal plasticity and then made modifications to try to adapt it to, for example, the fact that amorphous polymers do not readily admit to treatment with the physics of dislocations. In the case of semicrystalline polymers, the crystalline phase may, in some instances, succumb to a plasticity treatment, (139) but the full description of the nonlinear response requires treatment of a two-phase system. The following sections treat the problem of nonlinear behavior of solid or solid-like polymers as a problem in viscoelasticity. Primarily amorphous, glassy polymers are chosen. There are several reasons for these choices. First, the semicrystalline polymers are very complicated, as discussed briefly above, and our physical understanding of their linear viscoelastic response is still somewhat limited because of the complex interactions between amorphous and crystalline phases. Hence, while some progress has been made in dealing with the yield response of polyethylene (140,141) it is unclear how general the models are to other materials. This leaves one with the amorphous, glassy polymers. Here,

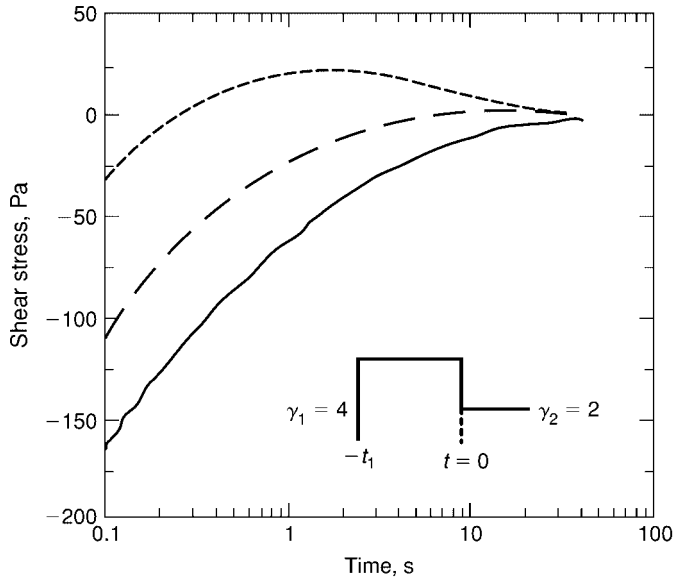

Fig. 53. Shear stress response to "half-step" type of deformation history for a concentrated polystyrene solution and for different values of the first step duration t_1. Dotted line; $t_1 =$ 1 s; dashed line; $t_1 = 4$ s; solid line; $t_1 = 16$ s. After Brown and Burghardt (134), with permission.

because the materials seem to follow time-temperature superposition in many instances, (9,33–35,40,142) there is a reasonable likelihood that a viscoelasticity framework is a good one with which to treat them. In addition, most work has focused on *post-yield* behavior, a regime to which plasticity in metals seems (inappropriately in this author's mind) applicable. With this in mind, therefore, it becomes important to investigate the *sub-yield* behavior of amorphous materials because it is the sub-yield behavior that is the precursor to yielding behavior. The latter cannot be understood until the former is. The following section deals with the K-BKZ framework and adapts it to the present investigations of the viscoelastic response of glassy polymers. Several other viscoelastic frameworks that have been, or are being, used in the study of amorphous polymers are also discussed.

The K-BKZ Framework. The above sections dealt with the K-BKZ framework for describing the nonlinear constitutive response of polymeric fluids. While the K-BKZ theory was developed for incompressible fluids, polymeric glasses are compressible in that the bulk modulus and the shear modulus are of the same order of magnitude. However, in the first work described here only torsional behavior is examined, which is nearly volume conserving (143–145). Hence, there may be reason to think that the incompressible framework is justifiable. Some aspects of compressibility are also examined and these are adapted to one instance of extension and compression behavior. Other constitutive models are also analyzed.

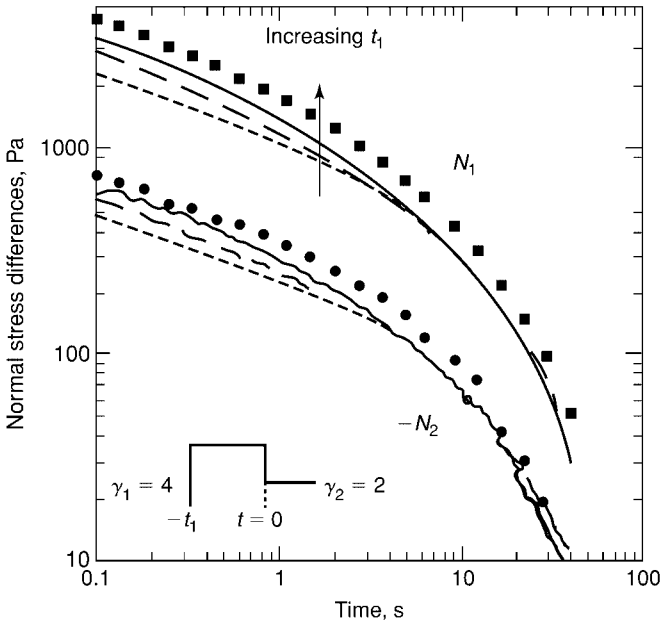

Fig. 54. Normal stress response to "half-step" type of deformation history for a concentrated polystyrene solution and for different values for the first step duration t_1. Dotted line: $t_1 = 1$ s; dashed line: $t_1 = 4$ s; solid line: $t_1 = 16$ s. Symbols represent single-step response for $\gamma = 2.0$. After Brown and Burghardt (134), with permission.

Torsional Experiments. The geometry and equations for torsion of an elastic cylinder are presented above. For the viscoelastic K-BKZ material, the equations look similar. For isochronal values of the strain potential function, one can define what looks like a time-dependent strain-energy function $W_i(I_1, I_2, t)$:

$$W_i(I_1,I_2,t) = \frac{\partial W(I_1,I_2,t)}{\partial I_i} = \int_{-\infty}^{t} \frac{\partial U(I_1,I_2,t-t')}{\partial I_i} \mathrm{d}t' \tag{109}$$

Then, isochronal values $W_i(I_1, I_2, t)$ can be used to characterize the stress relaxation behavior of solid cylinders and, similar to the behavior found for rubber, the strain energy function derivatives can be determined for different materials. There is relatively little work in this area, but the results are intriguing. Figure 55 shows the isochronal torque and normal force responses for a polycarbonate material subjected to maximum strains of approximately 0.10 at the outside radius of the cylinder. This strain is just below the yield point of the polycarbonate in torsion. These data have a similar appearance to the rubber data shown in Figure 31 at small strains (the torque follows ψR and the normal force follows $\psi^2 R^2$), but as the strain increases toward $\psi R = 0.1$, there is a strong softening in the responses as yield is approached. In the case of the rubber samples, such softening does not occur even for strains as high as $\psi R = 2.0$. The time-dependent equivalent of equations 47 and 48 can be used to analyze the torque and normal forces so as to determine the values of $W_1(I_1, I_2, t)$ and $W_2(I_1, I_2, t)$. Such data are shown for a PMMA material in Figure 56 and for the polycarbonate in Figure 57.

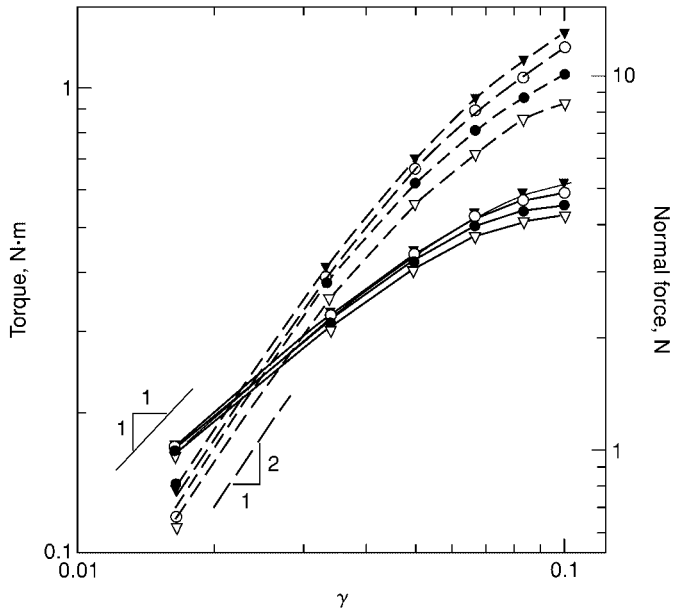

Fig. 55. Torque and normal force responses for a glassy polycarbonate material in stress relaxation conditions. *Isochrones*: ▼ 1 s; ○ 10 s; ● 100 s; ▽ 1000 s. After Pesce and McKenna (146).

Figure 58 shows the isochronal VL function behavior for the polycarbonate as a function of the stretch λ. Clearly, the behavior is very different for the material below the glass transition, that is the solid-like or glassy polycarbonate, than it is for the rubbery material in Figure 32.

Although this approach seems useful, unlike the rubbery polymers, the glassy polymers are compressible materials in the sense that the ratio of the bulk and shear moduli is near unity, rather than being in the neighborhood of 100–1000 for the rubber. This means that the forces to cause shape changes (distortions or shears) in the rubber are much smaller than those required to cause volume changes, while these forces are of approximately the same magnitudes in the glassy polymer. Hence, incompressible theory describes very well the behavior of the rubbery material, but does not obviously apply to the polymer glass. The next section examines the material compressibility issues and the extension of the VL function to the compressible case.

Issues of Material Compressibility. There is a full theory of compressible and nonlinear viscoelastic materials that would be equivalent to the compressible finite deformation elasticity theory described above (eq. 39), but more complicated because of the need to develop an expansion of the time-dependent strain potential function as a series of multiple integrals (108,109). One such formalism is discussed briefly under Lustig, Shay and Caruthers Model. Here a simplified model that is based upon the K-BKZ framework with a VL-like kernel function (98) is examined.

One important issue in dealing with the nonlinear viscoelastic response of materials is the amount of data needed to determine the material parameters

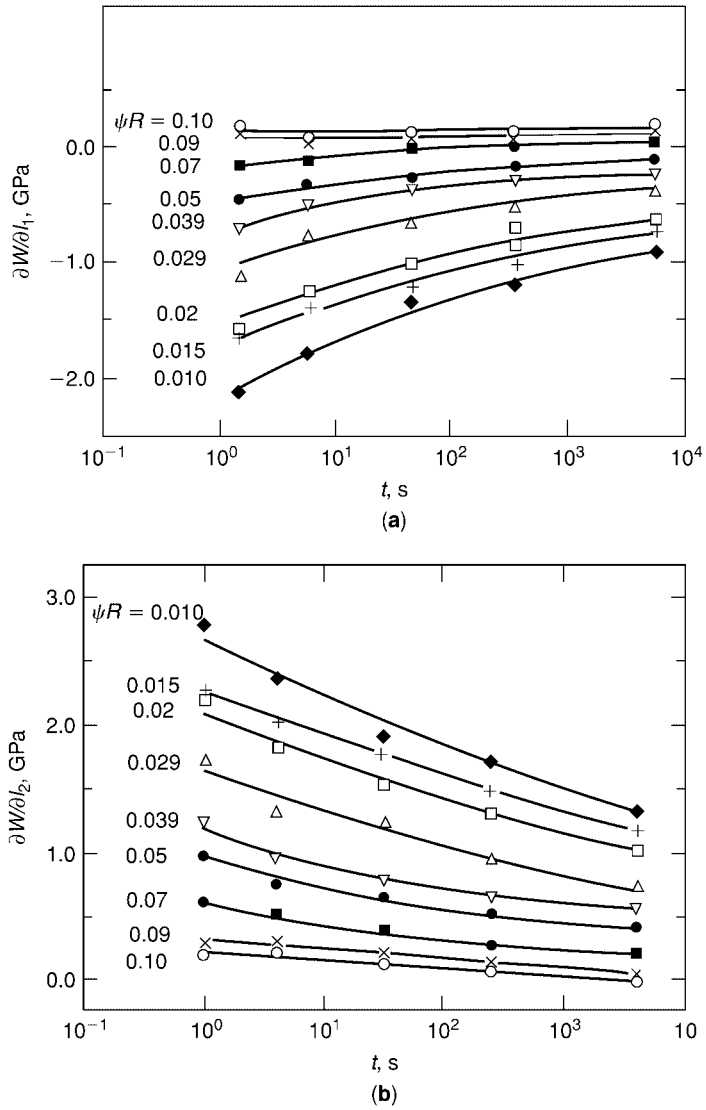

Fig. 56. Values of the time and strain-dependent strain energy function derivatives $\partial W/\partial I_1$ and $\partial W/\partial I_2$ for a glassy PMMA determined from torque and normal force measurements in single-step stress relaxation torsional experiments. After McKenna (114).

in the models. As noted above, even the general finite elasticity theory requires significant work to obtain the material parameters over the full three-dimensional deformation space. This is one reason that the VL framework is so attractive, when it works. Therefore, it is of interest to investigate whether or not the model can be extended to include compressibility. Pesce and McKenna (146) performed torsional tests on polycarbonate as described above. They then asked whether the VL function could be used to predict the tension and compression responses

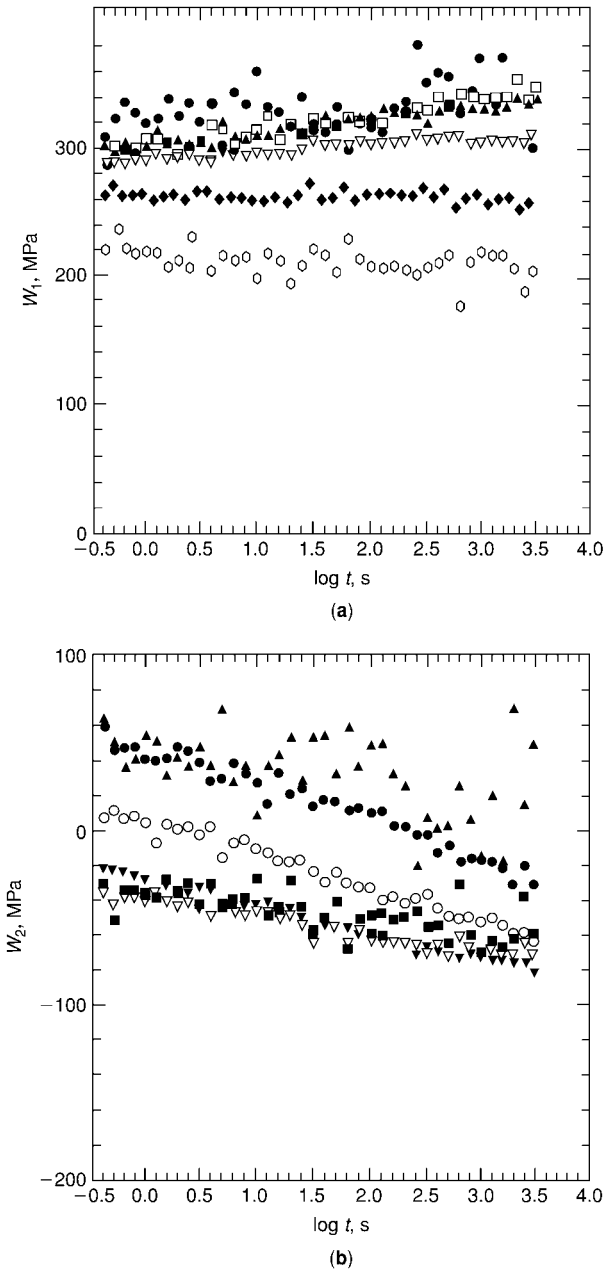

Fig. 57. Values of the time and strain-dependent strain energy function derivatives $W_1 = \partial W/\partial I_1$ and $W_2 = \partial W/\partial I_2$ for a glassy polycarbonate determined from torque and normal force measurements in single-step stress relaxation torsional experiments. (a) γ:● 0.017; □ 0.033; ▲ 0.050; ▽ 0.067;◇ 0.083; ○ 0.10. (b) γ: ▲ 0.017;● 0.033; ◦ 0.050; ▼ 0.067; ▽ 0.083; ■ 0.10. After Pesce and McKenna (146).

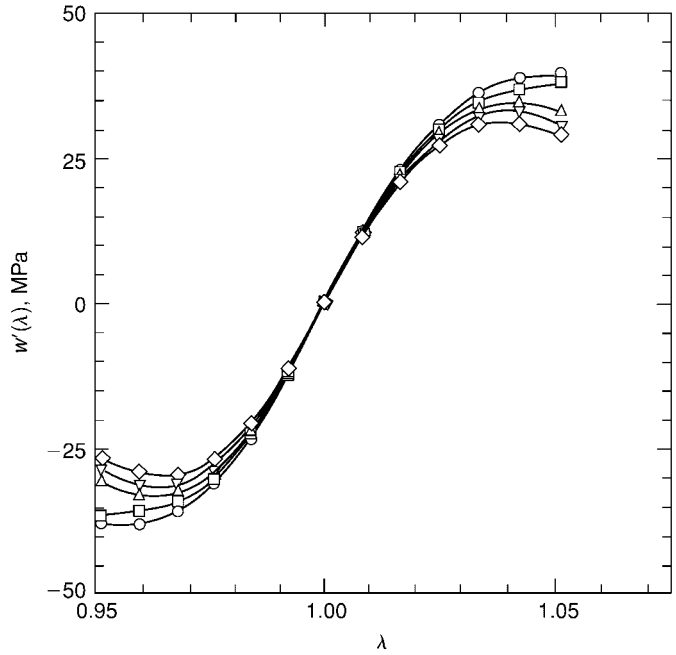

Fig. 58. The VL Valanis-Landel (98) function derivative as a function of deformation for polycarbonate as determined from data of Figures 55 and 57. ○ 0.3 s; □ 3.2 s; Δ 32 s; ∇ 320 s; ◇ 3000 s. After Pesce and McKenna (146).

of the material. An important assumption in their approach was that the VL function determined from the torsional measurements using equations 45, 46,47, 48, 49, 50, 51 (described immediately above) could be used to predict uniaxial data. When the incompressible equations 50 were applied to try to estimate the uniaxial stress-deformation data (isochronal), these equations did not work. However, upon considering the compressibility of the material good agreement with the data could be obtained. Taking, now, the strain energy density function [assumed to be separable as in the VL function (98)], one obtains

$$\hat{w}(\lambda_1,\lambda_2,\lambda_3) = w(\lambda_1) + w(\lambda_2) + w(\lambda_3) + f(\lambda_1\lambda_2\lambda_3) \tag{110}$$

where the volume $v = \lambda_1\lambda_2\lambda_3$ and the function $f(\lambda_1\lambda_2\lambda_3)$ represents the extra volume-dependent term beyond that incorporated implicitly in the principal stretches. Writing the constitutive equation for the principal stress (here the stress differences are not used), one obtains

$$\sigma_i = \frac{1}{\lambda_j\lambda_k}\left\{\frac{\partial\hat{w}}{\partial\lambda_i}\right\} \tag{111}$$

For a uniaxial deformation (extension or compression) in direction 1 and under normal ambient conditions (where $\sigma_2 = \sigma_3 \approx 0$) one can write

$$\sigma_1 = \frac{1}{\lambda_2\lambda_3}\left[\frac{\partial w}{\partial \lambda_1}\left(\frac{\partial f}{\partial v}\right)\left(\frac{\partial v}{\partial \lambda_1}\right)\right] \tag{112a}$$

$$\sigma_2 = \frac{1}{\lambda_1\lambda_3}\left[\frac{\partial w}{\partial \lambda_2} + \left(\frac{\partial f}{\partial v}\right)\left(\frac{\partial v}{\partial \lambda_2}\right)\right] \approx 0 \tag{112b}$$

Solution of equation 112b gives the relation

$$\left(\frac{1}{\lambda_1\lambda_3}\right)\left(\frac{\partial w}{\partial \lambda_2}\right) = -\frac{\partial f}{\partial v} \tag{113}$$

which when substituted into equation 112b gives the following expression for σ_1, which is similar to the equation for the principal stress differences for the incompressible material:

$$\sigma_1 = \frac{1}{\lambda_2\lambda_3} w'(\lambda_1) - \frac{1}{\lambda_1\lambda_3} w'(\lambda_2) \text{or} v\sigma_1 = \lambda_1\lambda_2\lambda_3\sigma_1 = \lambda_1 w'(\lambda_1) - \lambda_2 w'(\lambda_2) \tag{114}$$

Pesce and McKenna (140) applied equation 114 with the VL function obtained from torsional data and successfully described the uniaxial data for the same polycarbonate material to within approximately 15% up to the yield point (140). The results are shown in Figure 59. Importantly, the successful description required both a knowledge of $w'(\lambda)$ and the actual values of the lateral contraction of the material—the equivalent in the nonlinear range of the Poisson's effect in linear elasticity (or viscoelasticity).

Although the compressible VL function shows promise for the description of the response of glassy polymers in the nonlinear deformation regime, further work is required to establish the generality of the approach and how far it can be extended into the post-yield region.

Other Constitutive Model Descriptions. The above work describes a relatively simple way to think of nonlinear viscoelasticity, viz, as a sort of time-dependent elasticity. In solid polymers, it is important to consider compressibility issues that do not exist for the viscoelastic fluids discussed earlier. In this penultimate section of the article, other approaches to nonlinear viscoelasticity are discussed, hopefully not abandoning all simplicity. The development of nonlinear viscoelastic constitutive equations is a very sophisticated field that we will not even attempt to survey completely. One reason is that the most general constitutive equations that are of the multiple integral forms are cumbersome to use in practical applications. Also, the experimental task required to obtain the material parameters for the general constitutive models is fairly daunting. In addition, computationally, these can be difficult to handle, or are very CPU-time intensive. In the next sections, a class of single-integral nonlinear constitutive laws that are referred to as reduced time or material clock-type models is disscused. Where there has been some evaluation of the models, these are examined as well.

The fundamental concept of the material clock or reduced time is similar to the principle described above in the discussion of time–temperature superposition. In the mechanical constitutive models, however, the change in the stress or

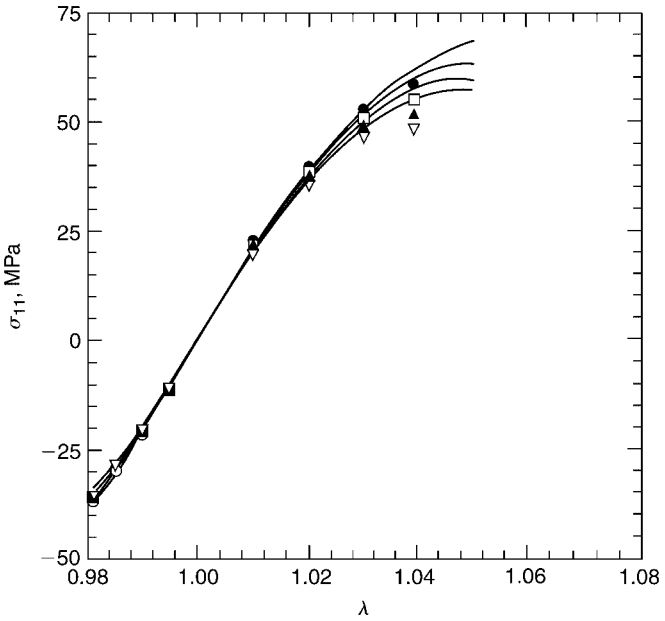

Fig. 59. Comparison between the experiment (points) and predictions (lines) from equation 114 for stress-deformation response of polycarbonate in uniaxial extension and compression.● 3.2 s; □ 32 s; ▲ 320 s; ▽ 3000 s. After Pesce and McKenna (146).

deformation induces a shift in the material relaxation time. The fact that the time depends on the state of stress (or strain) or on its history leads to additional nonlinearities in behavior from what is expected with, eg, the K-BKZ model. Physical explanations for the shifting material time are often based on free-volume ideas that are often invoked to explain time–temperature superposition. In addition, entropy changes have been invoked as have stress-activated processes.

The Schapery Model. One of the earliest models of the nonlinear viscoelastic response of polymers to use the concept of a reduced time is due to Schapery (147–149). The model is based on thermodynamic considerations and has a form similar to the Boltzmann superposition principal described previously. The model time dependences, except for the shift factors, are the same as those obtained in the linear response regime. Hence, the model is relatively easy to implement and to determine the relevant material parameters. It results in a generalization of the generalized superposition principal developed by Leaderman (150).

While the model can be formulated for three-dimensional stresses and strain states, here only the uniaxial deformation is dealt with. It is important to add that the model has both a creep formalism and a relaxation formalism. The relevant equations are presented in the next paragraphs. In addition, although this is a nonlinear theory, it is a small strain theory.

In creep experiments the equation is given as

$$\varepsilon(t) = g_0 D_0 \sigma + g_1 \int_0^t \Delta D(\psi - \psi') \frac{\mathrm{d}g_2\sigma}{\mathrm{d}t} \mathrm{d}t' \tag{115}$$

where D_0 is the zero time compliance, ΔD is the time-dependent part of the compliance, and the g_i's are material parameters. The material clock arguments are written as

$$\psi = \int_0^t \frac{\mathrm{d}\varsigma}{a_\sigma[\sigma(\varsigma)]} \quad \text{and} \quad \psi' = \int_0^{\mathrm{t}'} \frac{\mathrm{d}\varsigma}{a_\sigma[\sigma(\varsigma)]} \tag{116}$$

where a_σ is the stress shift factor.

A similar set of equations describes the stress relaxation behavior (stress as a function of strain):

$$\sigma(t) = h_\mathrm{e} E_e \varepsilon + h_1 \int \Delta E(\phi - \phi') \frac{\mathrm{d}h_2 \varepsilon}{\mathrm{d}t'} \mathrm{d}t' \tag{117}$$

Here E_e is the equilibrium modulus (infinite time modulus), ΔE is the time-dependent part of the model, and h_e and h_1 are material parameters. The reduced time arguments ϕ and ϕ' are written as

$$\phi = \int_0^t \frac{\mathrm{d}\varsigma}{a_\varepsilon[\varepsilon(\varsigma)]} \quad \text{and} \quad \phi' = \int_0^{t'} \frac{\mathrm{d}\varsigma}{a_\varepsilon[\varepsilon(\varsigma)]} \tag{118}$$

Here, note, that a_ε is the strain shift factor.

Figure 60 illustrates two-step creep and recovery data at different stresses for a reinforced polymer along with the predictions from the Schapery creep

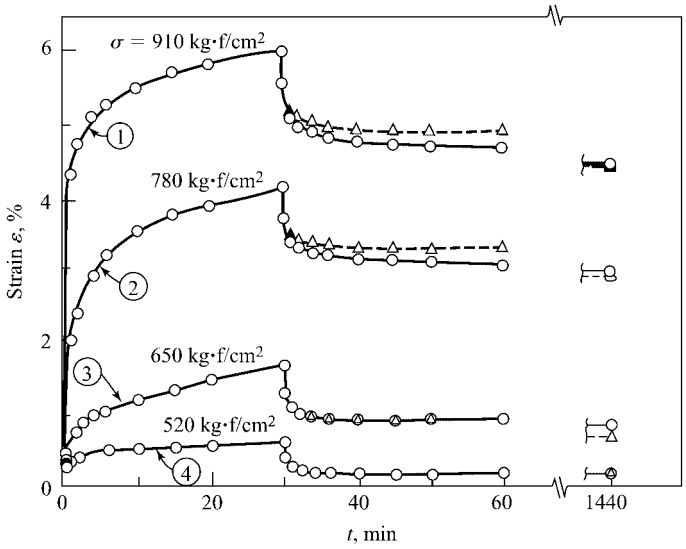

Fig. 60. Comparison of experimental (circles) creep and recovery behavior of a glass-reinforced phenolic resin with the predictions from the Schapery (147–149) nonlinear viscoelastic model. ○ Experimental Data; Δ Predicted Recovery Data (Nonlinear Theory). After Schapery (147), with permission.

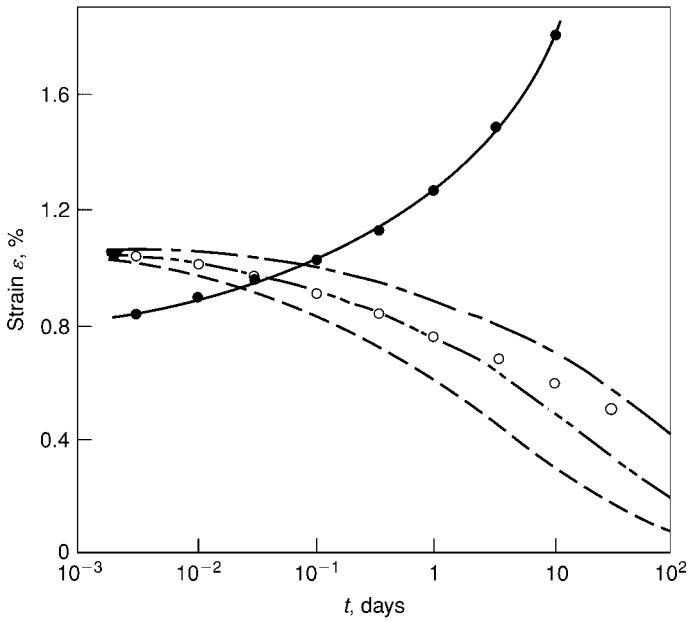

Fig. 61. Comparison of experimental (circles) creep and recovery behavior of a nitrocellulose material with the predictions from the Schapery (147–149) nonlinear viscoelastic model using different stress shift factors, as indicated. Exp. Creep Strain;—○— Exp. Recovery Strain; —— Case 1, $a_\sigma{}^{-1} = 1$;—-—Case 2, $a_\sigma{}^{-1} = 23.15$; —-Case 3, $a_\sigma{}^{-1} = 4.1$. After Schapery (147), with permission.

formulation and those obtained from simply applying a modified form of the Boltzmann superposition principle. Without going into the details of the procedures of obtaining all the parameters, it is clear that the model captures much of the observed nonlinear response, while the modified Boltzmann rule does not. (Note that the modified Boltzmann rule simply assumes additivity of responses, but without the linearity assumptions.) Figure 61 shows the creep and recovery data for a nitrocellulose film and with different values of the shift factor a_σ to try to describe the second (recovery) step. Here there is less of an agreement between the theory and the data, yet the trends are captured. In cases where materials, such as reinforced polymer matrix composites, exhibit strongly nonlinear behavior at very small strains, this set of models has been very useful (151–154). Also note that in certain deformation histories, the model can reduce to a K-BKZ type of expression and the data presented in Figure 34 was successfully described by the Schapery model (even though the deformations are fairly large).

The Zapas Strain-Clock Model and the Bernstein–Shokooh Stress-Clock Model. Although the K-BKZ theory has been highly successful, as discussed above, it also had some flaws, which lead to attempts to modify the model by incorporating material clock or reduced time concepts. In one form, Zapas introduced a strain-clock (118), ie, a change in the time scale that depended on the strain history. While the model is fully three-dimensional, for simplicity, consider

only the equations for the simple shearing case:

$$\sigma_{12}(t) = \int \{[\gamma(t) - \gamma(t')]G_*[\gamma(t) - \gamma(t'), \Phi(t,t')]\}\ \Phi\ [\gamma(t), \gamma(t'), t - t']\mathrm{d}t' \tag{119}$$

and the material time $\Phi(t, t')$ is written as

$$\Phi(t,t') = \Phi[\gamma(t), \gamma(t'), t - t'] = \int \Phi\ [\gamma(t), \gamma(\xi), t - \xi]\mathrm{d}t' \tag{120}$$

The strain-clock term (eq. 120) is a function of the entire deformation history. McKenna and Zapas used the strain-clock formalism to describe the torsional response of a PMMA material in two-step strain histories (112). The difficulty arises because the determination of material parameters requires at least the data for both the first and second step responses. Furthermore, McKenna and Zapas also assumed that the clock-form for the torque response and for the normal force response was the same. Their results were consistent with this assumption, as shown in Figure 62. However, that work also indicates that considerable experimental data are required to use the model—a constant issue in nonlinear viscoelasticity. One other interesting thing that came from the work of McKenna and Zapas (112–114) was the verification of equation 60 for the normal force. This is seen in Figure 63, where the normal force response after the half-step history is plotted against the duration of the first step for two different isochrones. As seen, for times beyond 1677 s and for both short and long isochrones, the response is both independent of the duration of the first step and the same as if the material had

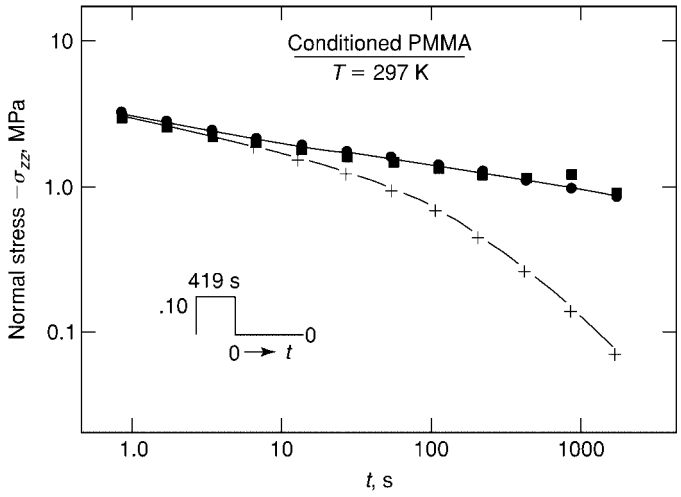

Fig. 62. Normal force response in "step to zero" type of deformation history for a PMMA polymer glass, showing the comparison between the experimental data (filled squares), the K-BKZ model predictions (crosses), and the predictions (filled circles) from the Zapas strain-clock model (118). Note that the clock terms for the normal force response were determined by fitting the shear stress response in the same experiment. After McKenna and Zapas (112).

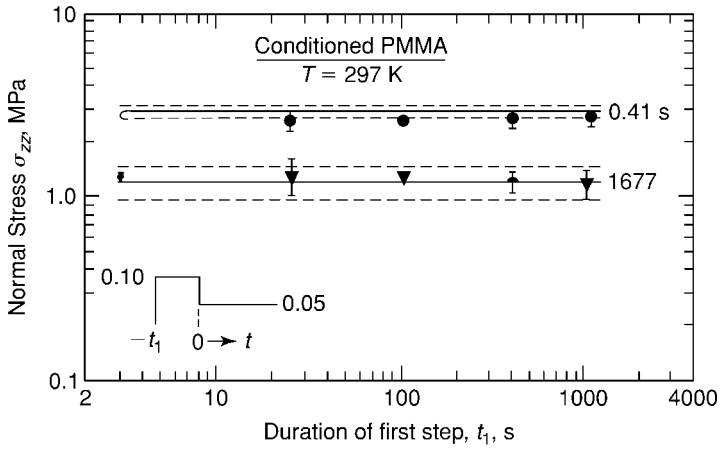

Fig. 63. "Half-step" normal force response in a PMMA polymer glass, showing that the normal force response is independent of the duration t_1 of the first step. Points are data from the second step response for $\gamma = 0.05$ after a step to $\gamma = 0.10$. Lines are data from a single-step experiment at $\gamma = 0.05$. (Solid lines: mean; dashed lines: single standard deviation). Time values of 0.41 and 1677 s are isochronal values after the imposition of the step in the deformation. After McKenna and Zapas (113).

been subjected to a step only to γ_2. The other point of import here is that, while the normal stress is following equation 60, the shear response is dramatically different. In fact, the strain-clock model fits the data, but the "reversing stress" nature of the deformation leads to a similar deviation from K-BKZ-type behavior as was seen in the polymer solution. This is shown in Figure 64. The reader is also reminded that polymer solutions seem to follow this response only at long times ($t > \tau_k$).

While the strain-clock version of the K-BKZ model seems capable of describing fairly complex nonlinear behavior, it is, at least, an inconvenient model to use. The stress-clock model of Bernstein and Shokool (155) has two features that could make it very useful. It takes less data to determine the material properties (under certain conditions) and, in the relatively small deformation regime, it can be inverted between creep and stress relaxation.

The equations in simple shear can be written as

$$\sigma_{12}(t) = \int_{-\infty}^{t} \{G_*[\gamma(t) - \gamma(t'), \beta(t,t')] b_\sigma(t')\} \mathrm{d}t' \tag{121}$$

where b_σ is the stress shift factor. The reduced time $\beta(t, t')$ is written as

$$\beta(t,t') = \int_{t'}^{t} b_\sigma(s) \mathrm{d}s \tag{122}$$

An interesting aspect of the Bernstein–Shokooh model is that the structure of the nonlinear equations is somewhat different from either the Schapery model or the Zapas strain-clock model. In the Bernstein–Shokooh model, the

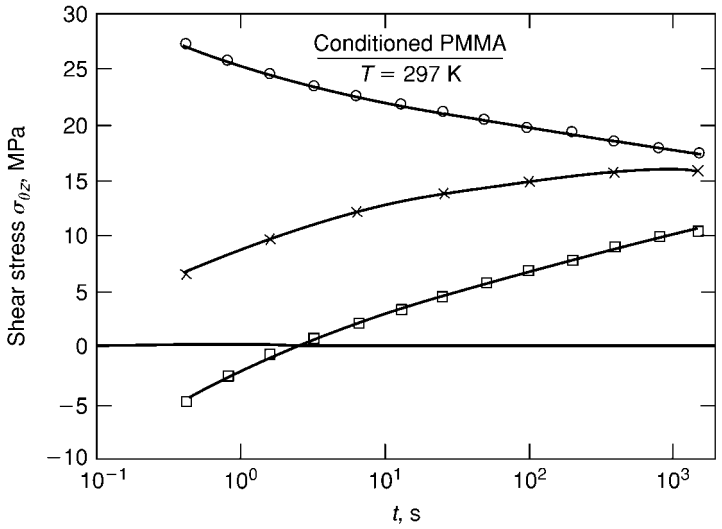

Fig. 64. "Half-step" shear stress response for a PMMA glass. Circles represent single-step stress relaxation response at $\gamma = 0.05$; crosses, K-BKZ prediction; and open squares, experimental data for second step of $\gamma = 0.05$ after a first step of $\gamma = 0.10$ having a duration $t_1 = 419$ s. After McKenna (114).

nonlinearity is set up by having the stress response to a deformation history depend also on the stress through the stress shift factor b_σ. Hence, in equation 121 there are stress terms on both sides of the equation. For the other models, including those discussed subsequently, the stresses or deformations are isolated on either side of the equation. For example, in the Schapery stress relaxation formulation (eq. 117) the stress depends on the strain and a strain-dependent material clock. Examination of equations 115 and 119 provides a similar type of conclusion for the Schapery creep formulation or the K-BKZ strain-clock equation. Hence, one might expect that the stress-clock formulation of Bernstein and Shokooh might capture a different sort of material nonlinearity from the other models. To this author's knowledge, the only other set of equations that provides a similar type of nonlinear response comes in the field of *structural recovery or physical aging* of glassy materials. The so-called Tool–Narayanaswamy–Moynihan and Kovacs–Aklonis–Hutchinson–Ramos models have been very successful to describe the kinetics of structural recovery. (The reader is referred to the relevant literature for further examination of these equations (156–160). See also AGING, PHYSICAL).

There has been relatively little testing of the Bernstein–Shokooh model. Penn did some work to describe the nonlinear response of aluminum, but this, however, was not published (161). Pesce and McKenna did some two-step stress relaxation experiments in torsion (162) using polycarbonate as the material. The results, one of which is shown in Figure 65, indicated that the model is better than the K-BKZ model, but does not perfectly describe the material response for polycarbonate.

The Knauss–Emri Model. There have been several works in the literature in which volume- or *free-volume*-dependent clocks were used to describe the

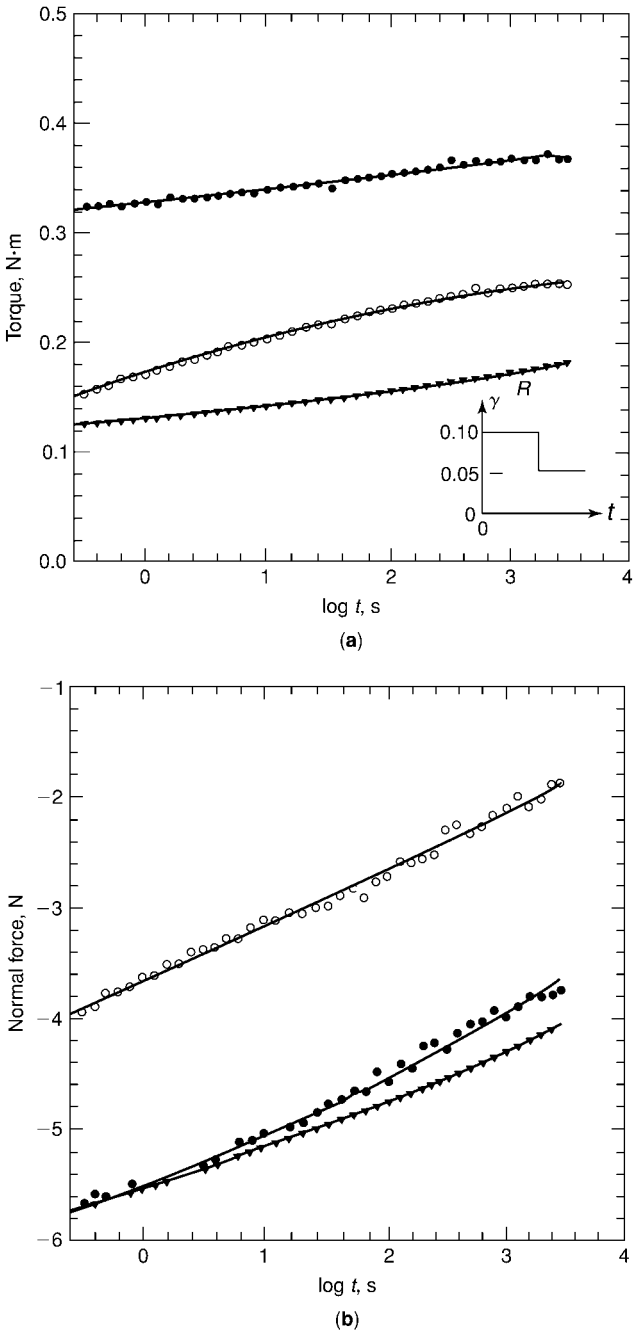

Fig. 65. "Half-step" torque (**a**) and normal force (**b**) responses for a polycarbonate glass comparing the experimental data (open circles) with the K-BKZ equation (closed circles) and the Bernstein–Shokooh stress-clock model (155) modified to an energy clock (inverted triangles) predictions. After Pesce and McKenna (162).

nonlinear viscoelastic response of polymeric glasses. The chief success among these is the Knauss–Emri model (163) in which the reduced time was defined in terms of a shift factor that depended on temperature, stress, and concentration of small molecules in such a way that the responses depended on the free volume induced by each of these parameters. For an isothermal single phase and homogeneous material, the equations are

$$\begin{aligned} S_{ij} &= 2\int_{-\infty}^{t} G(Z - Z')\frac{\partial \varepsilon_{ij}}{\partial t'}\mathrm{d}t' \\ \kappa_{ii} &= 3\int_{-\infty}^{t} K(Z - Z')\frac{\partial \varepsilon_{\mathrm{v}}}{\partial t'}\mathrm{d}t' \end{aligned} \tag{123}$$

where Z is the reduced time, S_{ij} are the deviatoric stresses, κ_{ii} is the first stress invariant, $G(t)$ and $K(t)$ are material functions, and ε_v is the dilatational strain. The dilatational strain is related to the bulk creep compliance $M(t)$ and determines the reduced time as

$$\begin{aligned} Z(t) - Z(t') &= \int_{\mathrm{t}'}^{t} = \frac{\mathrm{d}s}{\phi[\varepsilon_v(s)]} \\ \varepsilon_v(t) &= \frac{M(t)^* \mathrm{d}\kappa_{kk}}{3} \end{aligned} \tag{124}$$

where the asterisk denotes a Stieltjes convolution operation.

The Knauss–Emri model captures some of the nonlinear stress relaxation response of materials and looks like linear viscoelasticity in the reduced time variables, and hence is relatively straightforward to implement. However, the observation that material nonlinearities occur in shearing deformations as well as in compression, where the free-volume mechanisms predict decreasing mobility suggest that the model is limited in its usefulness (164,165).

The Lustig–Shay–Caruthers Model. In the past several years there has been a serious effort at the Purdue University School of Chemical Engineering under the direction of J.M. Caruthers (166–170) to adapt one such formalism to the problem of glassy materials. The formalism is that of Rational Mechanics (171) or Rational Thermodynamics, and here the Caruthers group's contributions in this area are examined briefly.

The thermoviscoelastic model is an extension of the original ideas of Coleman (171) and Noll (109) for a nonequilibrium thermodynamics referred to in the literature as *rational mechanics* or *rational thermodynamics*. Historically this approach has been controversial for a variety of reasons beyond the scope of this article. However, one very important issue in the development and uses of the rational mechanics framework has been the need to deal with multiple integral expansions of the relevant response functions and the inherent complexity that arrives in dealing with such representations. The advantage of Lustig–Shay–and Caruthers model (170) is its ability to truncate the multiple integrals and arrive at single integral representations of the material behavior. This leads to a very attractive and tractable set of equations for describing the material response. Because the single integral forms are of themselves insufficient to describe the

observed nonlinear response of glass-forming materials, a reduced time much as used in the models presented above, that depends on the configurational entropy has been introduced (170). Hence, one starts with the assumption that there exists a free energy potential functional that is time-dependent. Appropriate differentiation of the functional results in volume, enthalpy, and mechanical responses that contain sufficient information to predict strongly nonlinear behavior from laboratory determined linear viscoelastic response functions.

The detailed development that is followed is beyond the scope of this article. Here simply note that they followed a rigorous approach, beginning with a representation of the time-dependent "free energy" function $\Psi(t)$ and through appropriate simplifications and differentiations arrived at a set of equations for the entropy and stress as functions of the thermal and mechanical histories. The fluid form of the model through, single integral terms, is given by the following equations for the stress and entropy. Significantly, note that an important aspect of the model is that all the material parameters are related to response functions obtained from linear viscoelastic measurements, PVT measurements, and heat capacity measurements:

Stress:

$$\begin{aligned} T(t) = &- P^{(\infty)} I + \frac{\rho}{\rho_{\mathrm{R}}} \int_{-\infty}^{t} G_{\Delta}[I_3(t), \theta(t), t^* - \xi^*][\frac{\mathrm{d}C_t(\xi)}{\mathrm{d}\xi} - \frac{1}{3} I \frac{\mathrm{d}I_{t1}(\xi)}{\mathrm{d}\xi}]\mathrm{d}\xi \\ &+ \frac{\rho}{\rho_R} I \int_{-\infty}^{t} \frac{1}{2} K_{\Delta}[I_3(t), \theta(t), t^* - \xi^*] \frac{\mathrm{d}I_{t1}(\xi)}{\mathrm{d}\xi} \mathrm{d}\xi \\ &+ \frac{\rho}{\rho_{\mathrm{R}}} I \int_{-\infty}^{t} 2\rho_{\mathrm{R}} A_{\Delta}[I_3(t), \theta(t), t^* - \xi^*] \frac{\mathrm{d}\theta(\xi)}{\mathrm{d}\xi} \mathrm{d}\xi \end{aligned} \tag{125}$$

$$\begin{aligned} \eta(t) = \eta^{(\infty)}[I_3(t), \theta(t)] &- \int_{-\infty}^{t} A_{\Delta}[I_3(t), \theta(t), t^* - \xi^*] \frac{\mathrm{d}I_{t1}(\xi)}{\mathrm{d}\xi} \mathrm{d}\xi \\ &- \int_{-\infty}^{t} 2C_{\Delta}[I_3(t), \theta(t), t^* - \xi^*] \frac{\mathrm{d}\theta(\xi)}{\mathrm{d}\xi} \mathrm{d}\xi \end{aligned} \tag{126}$$

where P is the pressure and η is the entropy. The superscript ∞ implies the equilibrium value. ρ is the density and ρ_{R} is its value in the undeformed, reference state. I is the identity tensor, I_3 is the third absolute strain invariant of the deformation tensor (related to the volume change), $C_t(\tau)$ is the relative right Cauchy–Green strain tensor, and $I_{t1}(\tau)$ is the first relative strain invariant of $C_t(\tau)$. Note that in the Caruther's group the notation is that θ is the absolute temperature. The K_{Δ} term is the relaxation function for the bulk modulus, G_{Δ} is the shear modulus relaxation function, A_{Δ} is a constant volume thermal stress function, and C_{Δ} is the constant volume heat capacity divided by temperature. Finally, the reduced time $t*$ is defined by

$$t^* = \int_0^t \frac{\mathrm{d}\xi}{a(\xi)} \tag{127}$$

where $a(\xi)$ is a generalized shift factor that is taken to depend on the configurational entropy following the Adam–Gibbs (172) relationship:

$$\log a = M\left[\frac{1}{\eta_c \theta} - \frac{1}{\eta_{cr}\theta_r}\right] \tag{128}$$

where M is a constant, η_c and η_{cr} are the configurational entropy in the current and reference states respectively, and θ and θ_r are the temperature and reference temperature respectively. The configurational entropy can be calculated from the experimental heat capacity data, assuming that it is approximately equal to the total. The reader is referred to McWilliams (169) for further discussion. Also, note that Hodge (160) has discussed this form of shift factor in the Tool–Narayanaswamy-Moynihan equations for enthalpy recovery.

The Lustig–Shay–Caruthers model has, to date, been primarily used to estimate volume and enthalpy responses in glassy materials (see AGING, PHYSICAL)—a subset of the viscoelastic behaviors seen in solid-like or glassy polymers and not covered in this article. However, recent work between the Purdue group and Sandia National Laboratories (173) has made great strides in implementing the model into finite element codes as well as defining limits on the forms of some of the functions. The model, when finally published, will require full evaluation. At this point, the current author thinks that it will be an important contribution to the understanding of the nonlinear viscoelastic behavior of polymeric glasses.

Plasticity and Viscoplasticity and Other Models. As discussed above, the alternative representation of the nonlinear viscoelastic response of polymers is that of plasticity and viscoplasticity. In some respects, these models could be recast as viscoelastic models and they would be equivalent to some of the models discussed above. However, the perspective that glassy polymers are really fluids and do follow time–temperature superposition is lost with these models. Hence, the physical interpretation of material parameters, in this author's opinion, becomes very questionable. Therefore, only references to the major papers on polymer plasticity and viscoplasticity are given (174–177).

In addition, there are other viscoelastic models that are not dealt with here. Again, the references are provided for the reader's information (178–184).

WEATHERING

Introduction

The resistance of polymeric materials to weathering is a very important factor in their use in outdoor applications that depend on their durability. *Weathering* of a polymeric material may be defined as irreversible changes in its chemical and physical properties in a direction which is usually to the detriment of its usefulness. Changes in appearance and mechanical properties result from modification of the chemical structure of the material by its complex interaction with the environmental elements, primarily solar radiation, heat/cold, moisture (solid, liquid, and vapor), oxygen, and pollutants. Although all weather factors play a very important role in the deteriorating effect of the environment on polymeric materials, the actinic radiation of the sun is the critical factor because it initiates the reactions that lead to degradation. Testing the weatherability of polymeric materials is an essential step in development of new and improved products and in ascertaining that production lots meet the specified requirements. Most polymeric products require stabilization against the effects of the environment to obtain reasonable serviceability. In some applications, weatherability tests are carried out to assure that the materials degrade rapidly after their intended use in order to protect the environment.

The destructive effect of the weather varies with geographic location, season, time of day, cloud cover, and exposure orientation because of variations in the critical weather factors with these conditions. Different weather conditions can also be encountered in individual years. Therefore, outdoor tests in one location during a specific time interval cannot be expected to provide information on either absolute durabilities or stability rankings of materials under various service conditions. Tests are commonly carried out in environments that have the most

Encyclopedia of Polymer Science and Technology. Copyright John Wiley & Sons, Inc. All rights reserved.

severe conditions, such as subtropical or desert climates, in order to determine resistance to the worst conditions. As a result of the progressive improvement over the years in the durability of polymeric materials for outdoor applications, it is now impractical in many cases to screen potential new formulations by standard outdoor weathering tests, even those that provide severe environmental conditions. Therefore, accelerated outdoor weathering techniques and laboratory accelerated tests simulating the effects of natural weathering are required for development of weatherable formulations as well as for quality control and specification tests. Laboratory tests have the advantage of allowing control of the three main test parameters, ie, radiation, heat, and moisture, for more consistent stability evaluations and for research studies on the effect of these parameters. Development of valid laboratory accelerated tests requires measurement of the critical weather factors in the end-use environment and determination of their effects on the polymeric materials.

Weather Factors and Their Effect on Polymeric Materials

Solar Radiation. Solar radiation on the earth's surface consists of energy received both directly from the solid angle of the sun's disk and diffusely reflected by the atmosphere. The diffuse component is strongly influenced by atmospheric conditions and is generally a large fraction of the total radiation, particularly in the uv region because of the greater scattering of the shorter wavelengths (1). For this reason, the spectral power distribution (SPD) of the diffuse component differs from that of the solar beam in that it contains a higher intensity of short wavelength radiation. Thus, the type of exposure that materials receive depends on their orientation. Samples positioned for maximum direct beam exposure receive less short wavelength radiation than those positioned for maximum exposure to sky radiation.

The hemispherical (direct plus diffuse) solar spectral irradiance incident on a 37°-tilted surface facing the equator at an air mass of 1.5 and turbidity of 0.27, which is representative of average conditions in the 48 contiguous states of the United States, is shown in Figure 1 (2). It is referred to as "U.S. Standard

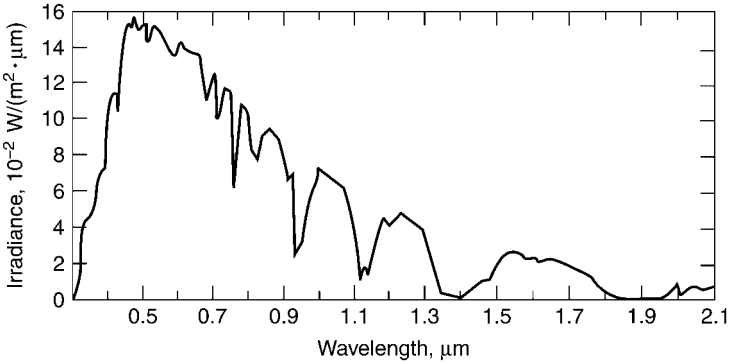

Fig. 1. Hemispherical solar spectral irradiance incident on a 37°-tilted surface facing the equator (air mass 1.5, albedo 0.2, turbidity 0.27, ozone 3.4 mm, precipitable water 14.2 mm). Based on data in Table 1 of ASTM G159-98 2. Courtesy of the American Society for Testing and Materials.

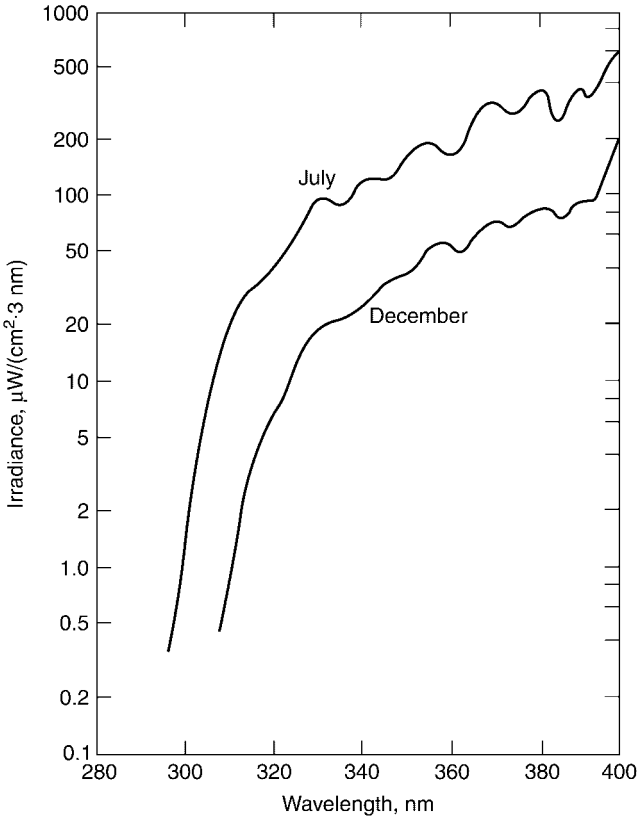

Fig. 2. Seasonal variation of direct normal solar uv spectral irradiance at 41° north latitude at noon under clear sky conditions 3. Courtesy of the American Institute of Physics.

Atmosphere." The spectral energy ranges from about 298 nm in the uv region to about 2500 nm in the near-infrared (nir) region. Both the quantity and quality of solar radiation vary with time of day, season, altitude, geographical location, and atmospheric conditions. The shorter the wavelength, the more sensitive it is to these variables. Thus, the uv portion (298–400 nm), the portion that has the largest actinic effect on most materials, varies from less than 1% to about 5% of total solar radiation. The seasonal effect of the angle of the sun on the uv SPD of direct normal solar radiation is shown in Figure 2 (3). At 41° north latitude, the short wavelength cut-on shifts from below 300 nm in the summer to about 310 nm in the winter. At all latitudes, the altitude of the sun, and thus total solar irradiance, is highest at solar noon.

Because of the small percentage of uv present in the full solar spectrum, changes in this important component cannot be detected in measurements of total solar radiation. Therefore, commercial outdoor testing facilities measure and monitor the irradiance of the uv portion alone, both total uv and narrow spectral bands of the uv, in addition to total solar radiation. Total solar uv radiation (TUVR) is typically measured between 295 and 385 nm. Irradiance is reported in watts/square meter (W/m^2) and radiant exposure, ie, irradiance integrated over time, is reported in megajoules/square meter (MJ/m^2). The average 12-month

TUVR radiant exposure is reported to be 308 MJ/m^2 at a 5° angle in a subtropical climate and 333 MJ/m^2 at latitude angle in a desert climate (4).

Spectral Effects of Solar Radiation: Activation Spectra. It is generally an accepted fact that uv radiation has a greater deteriorating effect than visible radiation on most polymeric materials. Since only radiation absorbed by a material can cause damage, and colorless materials do not absorb visible radiation, they are degraded solely by uv radiation. However, colored polymeric materials, which absorb in both the uv and visible regions, are generally degraded more severely by the uv portion of solar radiation. Dissociation of chemical bonds, a prerequisite to the chemical reactions that result in changes in appearance and mechanical properties, depends on the energies of the photons absorbed in relation to the energies of the chemical bonds. Because uv radiation has higher energy photons, it is capable of breaking stronger and more types of bonds. However, all wavelengths, whether in the uv or visible region, are not equally destructive. Degradation is wavelength specific because both absorption of radiation and its capability of breaking chemical bonds vary with wavelength. Generally, the shorter the wavelength, the more strongly it is absorbed by polymeric materials and the higher the energy of the photons. The amount of energy absorbed as a function of wavelength depends on the relative intensities of the incident wavelengths and on the absorption properties of the material.

The wavelength sensitivity of a material to a specific light source, referred to as its activation spectrum, depends on the spectral absorption properties of the material, the spectral emission properties of the light source, and the quantum efficiencies of degradation by the absorbed wavelengths. It is a graphical representation of the relative damage caused by individual spectral regions of the radiation source. The activation spectrum must be determined experimentally since quantum efficiencies cannot be predicted from fundamental principles. It generally does not equate with the spectral energy absorbed by a material. Two main techniques have been used to obtain activation spectra. One is based on the effects of narrow bands of the radiation from a polychromatic source isolated by using either interference filters or a spectrograph. The other is based on the use of uv/visible transmitting sharp cut-on glass filters to define the effects of individual spectral regions of the source while the material is exposed to all wavelengths longer than the cut-on of the filter. The techniques and the applications of activation spectra to stabilization and stability testing of polymeric materials are described and illustrated by examples in the *Handbook of Polymer Degradation*, 2nd ed. (5), and other publications (6–9).

Data obtained by both techniques on the same polymeric materials exposed to borosilicate-glass-filtered xenon arc radiation are shown in Table 1. The materials are unstabilized, commercial types. The spectral regions of the source that cause the largest change in the measured properties of the materials are listed in the column labelled "Max. Change." Although many of the samples used for the two techniques were manufactured at different times and therefore were not identical, the activation spectra are in relatively good agreement. Except for materials showing sensitivity to xenon arc radiation shorter than 300 nm, solar radiation can be expected to produce similar activation spectra based on comparable data obtained for some of the materials (5). The data show the wide range of spectral sensitivities of the different polymeric materials to solar simulated radiation

Table 1. Activation Spectra Maxima Based on Borosilicate Glass Filtered Xenon Arc Radiation

		Filter technique		Spectrographic technique	
Polymer	Measured change	Mils	Max. change, nm	Mils[a]	Max. change, nm
Acrylonitrile–butadiene–styrene	Yellowing	100	340–360	10	330

and the variation with type of degradation measured. While wavelengths shorter than 350 nm are responsible for most of the optical changes in many of the polymers, mechanical changes in the same polymers and optical changes in others are caused by wavelengths longer than 350 nm, often extending into the visible region. The wavelength sensitivity of polypropylene and acrylonitrile–butadiene–styrene based on change in mechanical properties, shifted to longer wavelength with increase in exposure. As exposure progresses, impurities are produced that are capable of absorbing longer wavelength uv radiation. In these polymers, the uv radiation of the filtered xenon arc is absorbed only by the impurities. In aromatic type polymers, the form in which they are tested has a very significant effect on the

activation spectrum. Thus, the 60-mil plaque of polyarylate is yellowed by longer wavelengths of solar-simulated radiation than the 3-mil film; the peak shifts from 350 to 385 nm with increase in thickness.

Temperature. Temperature differences in various climatic zones of the earth are responsible to a large extent for the variations in weathering. The areas exposed to the greatest solar irradiance are also those exposed to the highest temperatures. Both are usually highest near the equator and decrease with increasing latitude. Elevated temperatures can significantly influence the destructive effects of light on polymeric materials by accelerating the rate of the secondary reactions following the primary photochemical step of bond breakage and by altering these reaction processes. For example, the increase with temperature in rate of oxygen diffusion and rates of reactions of free radical fragments can alter the main mechanism of degradation. Because of differences among materials in the effect of temperature on the secondary reactions, the stability ranking of materials may change with increase in temperature.

Physical stresses result from temperature differences between the surface and bulk of polymeric materials caused by the low thermal conductivity and heat capacity of these materials. Daily and seasonal temperature cycling can cause mechanical stress in composite systems, such as between a coating and a substrate or between coating layers, because of mismatch in the thermal expansion coefficients. It often results in cracking and loss of adhesion of the coating. Even the most brittle materials will not fail in the absence of stress (10). Temperature and its cycles are also closely linked to water in all of its forms. Increase in temperature accelerates hydrolysis reactions, while reduction in temperature results in condensation as dew on the material. Freeze/thaw cycling or thermal shocks due to cool rain hitting hot, dry surfaces will induce mechanical stress which can cause structural failures in some systems, or accelerate degradation already initiated.

Daily averages and extremes of air temperature are important measurements made to quantify temperature conditions during exposure of specimens to natural weathering. However, the temperatures that materials attain is higher than that of the surrounding atmosphere. The surface temperature of exposed materials depends on the amount of radiation absorbed, the emissivity of the specimen, thermal conduction within the specimen, and exchange of heat with the surroundings through conduction and convection. A large portion of the absorbed radiation is converted to heat, and the amount absorbed is closely linked to color, with white materials absorbing only about 20% of the incident energy and black about 90%. Thus, the darker the color, the higher the temperature. Surface temperatures have been reported to reach 77°C in exposed plastic specimens (11) and 120°C inside a closed automobile exposed to sunlight (12).

Since it is not practical to measure the surface temperature of individual test specimens, black panel and white panel temperature sensors are used to represent maximum and minimum temperatures attained, respectively, by samples. The panels are thin metal substrates (stainless steel or anodized aluminum) treated on the front surface with a black or white coating that has good resistance to weathering. A thermocouple or other type of temperature sensor is attached to the center of the front or back side, preferentially the latter. The substrate can be either uninsulated, allowing ambient air to circulate on the front and back for maximum cooling, or insulated on the back to simulate specimens exposed on a

solid backing. Typically, temperatures measured by insulated black panel temperature sensors are 3–12°C higher than those by the uninsulated black panels, depending on the level of irradiance, temperature, air flow, and construction of the sensor.

Moisture. All materials used outdoors are exposed to the influence of moisture which, in combination with solar radiation, contributes significantly to the weathering of many polymeric materials. The form and amount of moisture vary widely, depending on the geographic area and ambient temperature. Moisture can take the form of humidity, dew, rain, frost, snow, or hail. The span of time over which precipitation occurs and the time the sample surface is exposed to wetness are more important in weathering of materials than the total amount of precipitation. The penetration depth of moisture into the material, and thus the influence on weathering, is substantially greater when the total amount of precipitation is distributed over a longer time period.

Moisture contributes to the weathering of polymeric materials both by reacting chemically in hydrolytic processes and by imposing mechanical stresses when it is absorbed or desorbed (10). It can also act as a solvent or carrier, eg, in leaching away plasticizers or in transporting dissolved oxygen. Examples of chemical reactions of water are hydrolysis reactions of labile bonds such as those of polyesters, polyamides, and poly(ether) urethanes and its promotion of chalking of titanium dioxide (TiO_2) pigmented coatings and building products exposed to solar radiation. Chalking results from the release of TiO_2 particles at the surface when the organic binder is degraded by the hydroxyl and perhydroxyl free radicals formed in the reaction between water, oxygen, and the titanium and hydroxyl ions produced on exposure of the pigment to uv radiation. Experience shows that chalking is most prevalent when moisture at the surface is highest; little to no chalking occurs in dry environments.

Cycling of moisture in the form of humidity or liquid water creates mechanical stresses in many materials. Absorbed water, by expanding the volume of the surface layers, results in compressive stresses on the outside and tensile stresses in the bulk. Reduction in volume of surface layers during drying is resisted by the hydrated inner layers, creating bulk compressive and surface tensile stress gradients. Cracking and loss of adhesion of coatings results. Water absorption is a diffusion controlled process, which may take weeks or months to reach equilibrium in thick forms of polymeric materials because of the slow diffusion rates. Solar radiation has a pronounced effect on the humidity-induced stresses because of the formation of polar or hydrophilic groups, which increase the tendency of the material to absorb moisture. Further, many photochemical aging processes initiated by solar radiation cause embrittlement of the surface, thus enhancing the tendency to crack under tensile stresses during the drying period. These are examples of the combined action of different weathering factors. High relative humidity levels in conjunction with heat, as, eg, in tropical and subtropical climates, often promote microbial growth. Mold, mildew, and other microbiological and botanical agents can play a significant role in material degradation, although they may not be generally thought of as weathering factors.

Commercial exposure facilities typically measure two main types of moisture: relative humidity and wet time. Measurements of relative humidity by a shaded device, such as a wet bulb/dry bulb or solid-state sensor enclosed in a

ventilated shelter, indicate the amount of water vapor in the air mass relative to its maximum capacity at the ambient temperature. *Wet time* is the amount of time liquid water is present on the surface of the material because of condensation and precipitation. It is measured either by increase in electrical conductivity of a cotton muslin wick when it is wet by rain or by the electrical potential developed in a moisture sensing galvanic cell described in ASTM G84 (13).

Oxygen. Photo-oxidation reactions, initiated by solar radiation in combination with oxygen, account for most polymer failures that occur during outdoor exposure. The penetration of oxygen into the polymer is a critical factor and is related to its rate of diffusion, which depends on the temperature, polymer type, and morphology. The importance of oxygen in the weathering process is evidenced by the fact that photo-oxidation in polymers that only weakly absorb uv, such as polyolefins, is significantly reduced toward the center of thick samples because of the limited supply of oxygen. It has been shown that oxygen diffusion and not uv radiation becomes the rate controlling process in photo-oxidation of polypropylene and polyethylene plaques at a depth at which the rate of oxygen consumption is greater than the rate at which it can be replenished from the environment (14–17). Oxygen can promote degradation in several ways:

(1) Reaction with the free radicals formed as a result of bond cleavage by solar radiation produces peroxy radicals. The latter propagate radical chain reactions that multiply the destructive effect of the radiation manifold;
(2) Reaction with sensitizers, such as ketones and certain dyes, excited by radiation to their triplet states, results in the excited singlet state of oxygen, a very reactive form of the molecule. Singlet oxygen is responsible for the rapid deterioration of many materials, particularly those with conjugated unsaturation such as natural rubber and synthetic elastomers;
(3) Oxygen can also increase the amount of solar radiation absorbed by conjugated unsaturated hydrocarbons through formation of a complex with these structural components.

Atmospheric Pollutants. Ozone is present in the earth's atmosphere both as a result of uv photolysis of oxygen in the upper atmosphere and as a result of reaction between terrestrial solar radiation and atmospheric pollutants such as nitrogen oxides and hydrocarbons from automobile exhausts. It is a powerful oxidant that can react rapidly with elastomers and other unsaturated polymeric materials to cause stiffening and cracking, particularly under mechanical stress. Other common air pollutants include sulfur oxides, hydrocarbons, nitrogen oxides, and particulate matter such as sand, dust, dirt, and soot. Some of these may react directly with organic materials, but have a much more severe effect in combination with other weather factors.

Acid rain is an important consequence of pollutants generated by modern industrial societies and has been shown to damage both organic and inorganic materials exposed to the environment. However, dilute sulfuric acid is formed only when sulfur dioxide (SO_2) and water on the surface of materials is exposed to solar radiation. It causes rapid discoloration when it reacts with pigments as well as cross-linking (10) and embrittlement (18) of polymers. The results of the action of acidic pollutants and radiation on automotive coatings has been described (19).

Acid rain enhances hydrolytic degradation and thus is an important factor in weathering of polymeric materials in which the mechanism includes hydrolysis. Acids have also been shown to interfere with the use of hindered amine light stabilizers (HALS) to improve the light stability of acrylic urethane clearcoats. It is believed that acids may reduce the effectiveness of HALS by reacting to form salts, which are then washed out of the coating. While acids generally act synergistically with radiation to accelerate the effects of weathering, acid precipitations can also slow the aging processes in polymers (20).

Outdoor Weathering Tests

Outdoor weathering tests are commonly characterized as "natural" or "accelerated." Ideally, "natural" weathering would be the result of exposure of a material in its actual intended location and orientation. The term is, however, generally used for outdoor exposure on fixed angle racks in locations and orientations that maximize the effects of weathering components, particularly solar radiation. Since these exposures will generally produce higher degradation rates than the normal end-use environments of the material, they are actually outdoor accelerated tests. In this article, "natural" exposures are divided into "static" exposure tests at fixed positions and "dynamic" exposure tests in which sample orientations are changed during the test, or in which the sun is tracked. "Accelerated" outdoor exposures include techniques that further increase either temperature or solar irradiance or both. Practices for natural and accelerated outdoor weathering of polymeric materials are described in ASTM D1435 (4) and ASTM D4364 (21), respectively.

Most natural and accelerated outdoor weathering tests in the United States are carried out in either (or both) south Florida or central Arizona. These have the two most important "benchmark" environments where materials typically fail fastest because of intensification of the weather elements responsible for degradation. South Florida has a subtropical climate with higher levels of the three critical weathering factors, solar radiation, temperature, and moisture, than are present in most end-use environments. The climate is particularly destructive to materials sensitive to moisture. A number of studies have shown that the south Florida climate has a twofold or higher weathering rate for coatings compared to that in central Europe. The central Arizona desert has become a worldwide recognized standard exposure environment for testing in a climate typical of the hot and dry conditions of the desert, having summer solar radiant exposures and temperatures that are higher than those in south Florida. The large daily and summer-to-winter temperature swings also differentiate Arizona from south Florida environments. Other test sites are in tropical and temperate climates, industrial areas, and salt air locations. The main criterion in selection of the test site is the sensitivity of the material to moisture and the type of climate in which it will be used. Often, the same materials are tested in several different climates.

Because of seasonal and year-to-year climatological variability of outdoor conditions, repeated testing during different seasons and over a period of at least 2 years is usually recommended. Results of tests conducted for less than 12 months will often depend on the particular season of the year in which they begin. In order to take into account the variability of weather, the performance of test materials

should be evaluated in comparison with that of one or more control materials having similar composition and construction and known performance rather than in terms of absolute changes. The use of two control materials, one having good durability and one having poor durability, and at least two, preferably three, replicate specimens of each test and control material is recommended.

Static Exposures. Outdoor static weathering tests can take numerous forms. Some of the variables include tilt angle, unbacked or backed exposure with various types of backing material, under glass exposure, additional wetting, and other special conditions, all of which influence the critical weathering factors. The variables of static outdoor exposures are described in detail in ASTM G7 (22) and ASTM G24 (23). The particular test variables chosen depend on the application of the material and should generally simulate the worst case in-service conditions as closely as possible. Materials used with a backing should be exposed with a similar type backing to provide higher temperatures and longer wetness times than unbacked exposures. In some cases, the backing is painted black to increase surface temperature and degradation rates. Materials intended for applications indoors or in enclosures behind specific types of glass, such as in automotive interiors, require weathering tests simulating conditions found in their specific end-use environment. Because of variation in specimen temperature and time of wetness due to location of a specimen on the exposure rack and the type or color of adjacent specimens, controls and test specimens should be placed on a single test panel or on test panels adjacent to each other.

The direction and angle of the exposed samples, measured from the horizontal, influence the amount of total radiant energy received, the quality and quantity of uv and temperature, and the time of wetness. The 45° angle is the most widely used, probably because many of the early exposure tests were carried out at temperate latitudes at which this angle was considered to be the fixed angle for optimum solar radiation for the whole year. However, in both temperate and tropical zones, exposures at 0°–20° angles contain a higher proportion of the diffuse component of incident solar radiation and therefore higher annual doses of short wavelength uv than exposures at higher angles of inclination (24,25). At 0° (horizontal) and 5° angles, samples are exposed to essentially the entire sky dome and experience higher temperatures and longer time of wetness and thus more rapid deterioration. The 5° angle is preferable because it provides for some drainage to reduce ponding and to allow some of the dirt to be washed off by rain. It is used extensively by the automotive industry for exterior applications, such as surface coatings, and may be used as an alternate to horizontal exposures for items such as indoor–outdoor carpeting, artificial turf, and roofing materials.

Samples experience maximum annual total solar radiation at an angle equal to the latitude of the exposure station, and higher annual uv radiant exposure at latitude angle minus 10°, at which they receive more diffuse radiation. At the lower angle, specimens are nearly perpendicular to the sun's radiation during the summer months when the uv content is highest (26). The 90° angle is used to simulate in-service applications of construction materials such as sidings, windows, door profiles, and automotive components, eg, doors and seat backs. However, it provides significantly lower radiant exposure, temperature, and time of wetness than a 45° or smaller angle. Therefore, the rate of degradation is usually slower for many samples exposed at this than at other fixed angles.

Dynamic Exposures. While the incidence of critical weather parameters can be modified by the setting of the static exposure angle, at any one angle it is not optimum for all seasons. Several dynamic exposure techniques have been developed to further optimize the annual radiant exposure and temperature of specimens. One consists of changing exposure orientation with seasonal changes of the sun's path. However, compared with fixed angle exposures of less than 90° in Florida and Arizona, the maximum increase in annual solar radiant exposure is only about 12% (27). In a study using this technique applied to exposure of a coating in Florida, no appreciable acceleration in degradation was obtained compared with 5° south exposure (28).

Another type of dynamic exposure uses the *Track Rack*, an equatorial mount, which is a motor-driven, follow-the-sun rack designed to maintain noontime conditions from sunrise to sunset by keeping the sample surface at a constant near-normal angle to the direct solar beam. It is often combined with variable angle exposure, but is mainly applicable to arid environments such as central Arizona where the direct beam component of solar radiation is high. Its efficiency is low in subtropical environments where the diffuse portion of solar radiation is a significant portion of the total irradiance. The option of adding water spray to Track Rack exposures provides a combination of three of the critical weather factors, increased radiant exposure, temperature, and moisture, which can significantly accelerate degradation rates of many materials over static exposures.

Accelerated Weathering Exposures. In spite of optimization of weather factors by site selection, type of backing, exposure angle, and follow-the-sun exposures, long periods of outdoor testing are required to establish the durability of modern materials. Options available for further accelerating natural weathering tests include black box enclosures for higher panel temperatures and longer wetness time than open or backed exposures and Fresnel reflectors for increased irradiance. Any major intensification of weather factors over those present under end-use conditions must be used with caution to avoid changing the types and mechanisms of degradation or altering stability rankings because of differences among materials in their response to intensified stress factors.

Black Box Exposures. The black box test was developed to simulate the air heat-sink characteristics of an automotive body and thus provide the high temperatures encountered by the surface coatings, vinyl rooftops, and decorative trim on automobiles exposed to direct sunlight. Details of the black boxes and test procedures are given in ASTM G7 (22), ASTM D4141 (29), and SAE J1976 (30). The test panels form the top surface of an open aluminum box painted with flat black paint on the outside. The box is typically positioned at 5° from the horizontal, facing the equator, but can be positioned at any angle. The insulating effect of the warmed air trapped in the box dampens out temperature variations caused by passing clouds, intermittent breezes, etc. Black box exposures also maintain surface condensation longer after daybreak, thus providing greater probability of interactions between irradiance and moisture than in other types of exposures.

Black Box under Glass Exposures. These tests were designed to simulate and accelerate the effect of interior automotive conditions. Air temperatures in the box may exceed 80°C under conditions of high outside ambient air temperature and solar irradiance. Exterior nonglass surfaces are painted flat black and interior surfaces are left unpainted. The specimens, supported on a rack in a plane parallel

to the glass cover at a distance of at least 75 mm (3 in.), can be unbacked, or backed with either expanded aluminum or a solid backing such as plywood. Liquid water is prevented from accumulating on the specimen's surface by the cover glass, and blowers inside the box circulate enclosed air for better temperature distribution. The box is typically covered with "single strength" window glass that is 2–2.5 mm thick. The requirements for under glass exposures, described in ASTM G24 (23), include exposure of new glass for at least 3 months prior to installation in test cabinets to reduce variability in test results because of rapid reduction in short wavelength uv transmission during initial exposure. After the initial pre-aging period, the glass is suitable for at least 60 months of use. Because of variability between different lots of glass, the relative performance of materials is best determined by testing them at the same time behind the same lot of glass.

Heated Black Box. The heated black box is most useful for exposures conducted in the late fall, winter, and early spring when it produces significantly higher panel temperatures than those produced by the black box. It is equipped with heaters and blowers to heat the inside air to a specified temperature during daytime hours. Heating of the backside of the panels with warm air reduces the daily variability of specimen temperatures. The heater is turned off at night to allow specimens to cool down for formation of condensation and thus for simulation of in-service conditions.

The CTH Glas-Trac™ (Controlled Temperature and Humidity, Under Glass, Sun Tracking). This equipment was designed primarily to determine the durability of automotive interior materials in an outdoor weathering chamber covered with automotive side window glass and incorporating temperature and humidity control. It combines a heated black box covered with 3-mm-thick clear tempered safety glass and a two-axis tracking system, which maintains the specimen surface perpendicular to the sun's rays from morning to evening for maximum solar irradiance. The glass cover is interchangeable with various windshield types. The exposure cabinet is controlled at $70 \pm 5^{\circ}$C air temperature during daylight hours and at $38 \pm 5^{\circ}$C air temperature/$75 \pm 10\%$ relative humidity during nighttime hours. Exposures are timed in MJ/m^2 of total uv (295–385 nm). Details of the test are given in SAE J2230 (31).

Fresnel Reflector. The maximum acceleration of aging processes in outdoor weathering is obtained by exposure on a Fresnel-reflector panel rack that provides high intensity solar radiation by following the sun and reflecting the sun's rays from an array of 10 flat mirrors onto a single target area of the test material. A blower forces air across the target to cool the test specimens and generally limits sample surface temperatures to about 15°C above the maximum temperature of equatorially mounted samples exposed to unconcentrated normal incidence radiation. Testing of samples exceeding 13 mm (0.5 in.) in thickness is not recommended because the cooling may not be sufficient for such samples. Periodic spraying with deionized water is designed to simulate and accelerate the results of conventional testing in semihumid subtropical and temperate regions. Nighttime spray cycles simulate rain and dew. Tests carried out in the absence of a programmed moisture cycle are intended to simulate conventional exposure testing in desert, arid, and semiarid regions. The test can be used to intensify either direct exposures or those behind glass. Descriptions of the device and guidelines for its use are given in ASTM D4364 (21) and ASTM G90 (32).

Since the device only concentrates the direct rays of the sun and not the diffuse radiation, it requires clear atmospheric conditions with little moisture, such as is prevalent in Arizona. The solar flux is approximately eight times as high as on an equatorial mount without mirrors, but acceleration factors over conventional outdoor tests based on elapsed time to a predetermined change in property have been reported to vary from 2 to 11 for various polymer types and compositions (11). The effectiveness of the Fresnel-reflector accelerated weathering machines depends on the quantity and quality of the uv in the direct beam component of solar radiaton. The acceleration factor will be small for materials that are degraded primarily by short solar uv wavelengths because of the deficiency of the machine in this region compared with global solar radiation. This is due to exclusion by the solar concentrator of diffuse solar radiation, which contains much of the short wavelength solar uv, and to lower reflectance of the mirrors at short wavelengths. The acceleration factor will also vary with the material tested because all materials are not affected equally by increased irradiance and temperature. Thus, the stability rankings may differ from that of natural exposure. Good correlations as well as discrepancies have been reported between Fresnel-reflector exposures and standard outdoor tests based on stability ranking of polymeric materials (28,33–37).

Timing of Exposures. Methods of "timing" outdoor weathering tests include (*1*) calendar basis—exposure for a specified number of days, months, or years; (*2*) radiant exposure basis—exposure to a specified level of solar radiant energy in a specified wavelength region based on hemispherical radiation measurements at the same tilt and azimuth angle as the test specimens; and (*3*) property change in a weathering reference material (WRM)—exposure until a specified property change has occurred in a weathering reference material exposed at the same time. Timing on a calendar basis has been the most widely used method of evaluating stabilities because of its simplicity. However, timing based on radiant exposure can reduce seasonal and year-to-year variations in weathering due to inconsistent conditions of total solar and solar uv irradiance. Timing based on property change in a WRM can reduce variations in weathering due also to other weather factors, provided its response to all factors is similar to the response of the test materials.

Studies have shown that better correlations are obtained among exposures made at different times when timing is based on incident solar uv radiation rather than on incident total solar radiation (33,38–43). Timing based on only the portion of solar uv that is responsible for the damage, ie, on the actinic portion identified by the activation spectrum of the material, should further improve correlations. Further, since all actinic wavelengths are not equally destructive, the optimum method of timing should be on the basis of "effective" radiant exposure H_{Eff}. The latter can be determined by using the activation spectrum to weight the incident radiation in accordance with equation (1).

$$E_{\mathrm{Eff}} = \sum_{\lambda_1}^{\lambda_2} E_0(\lambda) \frac{[\Delta(\lambda)]}{[\Delta(\lambda_{\mathrm{max}})]} \tag{1}$$

where E_{Eff} is the effective irradiance, $E_0(\lambda)$ is the incident irradiance at a specified wavelength, $\Delta(\lambda_{\mathrm{max}})$ is the property change at the wavelength of the activation spectrum peak, and $\Delta(\lambda)$ is the property change at a specified wavelength.

The irradiance at the wavelength corresponding to the peak of the activation spectrum ($\Delta(\lambda_{max})$) is normalized to 1.0 and irradiances at other wavelengths are multiplied by the fractional sensitivities obtained from the activation spectrum. The sum is the "effective" irradiance. The effective radiant exposure H_{Eff} is obtained by multiplying the total radiant exposure H_{Total} by the ratio of the effective irradiance divided by the total irradiance (eq. (2)).

$$H_{Eff} = \frac{E_{Eff}}{E_{Total}} H_{Total} \tag{2}$$

Laboratory Accelerated Weathering Tests

Laboratory accelerated weathering devices have been used for more than 80 years with increasing importance concomitant with the development of more weatherable materials and the need to determine in a short time the effects of natural exposures over prolonged periods. The importance of these devices lies in their ability to accelerate the weathering processes under controlled and reproducible conditions. They are particularly useful in research and development of new polymeric formulations. They are also used for quality control and specification testing. However, their application to prediction of service life under use conditions is still under development (see section on Laboratory Accelerated Versus Natural Weathering).

These devices have the unique requirement of accelerating and also simulating the effects of the natural environment. In some cases, simulation of a specialized environment is required as, eg, extreme climates or the miniclimate of the interior of an automobile. Appropriate acceleration techniques require knowledge of material-specific sensitivities to the weathering factors since validity of the tests requires that the results correlate with the effects of natural exposure, ie, that the chemical and physical changes induced in materials are similar and the stabilities of materials are correctly ranked. These requirements can only be realized if the critical weather factors in the environment are appropriately intensified so that the complex interactions of their effects are reproduced. Although the variability of weathering factors in nature precludes an exact representation of the actual conditions, the least that should be achieved is simulation of the full spectral actinic radiation of the natural source by the laboratory test source and appropriate irradiance, temperature, and moisture conditions. The ability to control the latter factors is now included in the basic design of most laboratory accelerated weathering devices.

The single most important consideration when conducting laboratory accelerated weathering tests is the SPD of the radiation source. Simulation of the incident wavelengths and relative intensities of terrestrial solar radiation is critical to simulation of the degradation caused by exposure to natural weather conditions. Both the absorption of light, which is a prerequisite to degradation, and bond breakage, the primary photochemical step following absorption of light, are wavelength dependent. The wavelengths absorbed and the fraction of the incident radiation absorbed at each wavelength are determined by the relation between the absorption properties of the material and the SPD of the light source. The

importance of simulating the SPD of the full solar uv is shown in Table 1 by the large differences in solar uv wavelengths to which different types of polymers are sensitive. Also, it is now an established fact that differences between the artificial and natural sources in the ratios of intensities of long versus short wavelength uv will change the mechanism of degradation of some aromatic type polymers and distort the antagonistic reactions caused by these spectral regions (see section on Effect of SPD of Radiation Source on Weathering). A close match to the short wavelength cut-on of solar radiation is essential when testing polymers such as polycarbonate or isophthalate based esters and others which are particularly sensitive to small changes in radiation in this region. However, the SPD of some light sources commonly used in artificial weathering devices has very little resemblance to the SPD of hemispherical solar radiation on the earth's surface, referred to as "daylight."

Carbon Arcs. Figure 3 compares the representative uv/visible emission of two types of carbon arc sources with daylight measured at noon at a 26°-tilt angle in Miami, Fla., during the spring equinox. The enclosed carbon arc uses solid and cored electrodes burning within a semisealed borosilicate glass globe that provides optical filtering of the short wavelength uv radiation and an oxygen-deficient atmosphere to enhance the efficiency of the arc. The SPD differs significantly from that of solar radiation in both the uv and visible regions. It has two long wavelength uv cyanogen emission bands that give much more intense radiation than daylight in this region and it has much weaker intensity than daylight below 350 nm and in the visible region. The enclosed carbon arc has a much weaker effect than solar radiation on materials that absorb only short wavelength uv radiation,

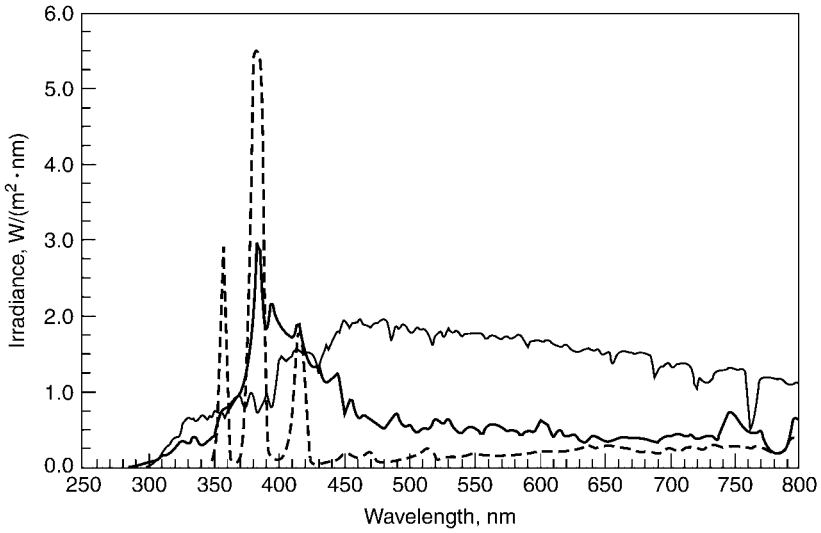

Fig. 3. Spectral power distributions of the enclosed carbon arc, the open flame carbon arc with Corex D filters, and noon daylight in Miami, Fla. at 26° south exposure during the spring equinox 5. Courtesy of Atlas Electric Devices, Reprinted with permission of Marcel Dekker, Inc. —— Daylight (Miami, Fla.); - - - - - - enclosed carbon arc; ▬▬ open flame carbon arc.

but a stronger effect on materials that also absorb long wavelength uv radiation. Therefore the stability ranking of materials that differ in uv absorption characteristics can be expected to be distorted by this source compared with exposure to daylight. Procedures for using enclosed carbon arc devices for exposure of polymeric materials are given in ASTM Standards D5031 (44), D6360 (45), and G153 (46).

The open flame carbon arc (also referred to as the Sunshine carbon arc) uses copper coated electrodes in an open flame type lamp operating in a free flow of air. The unfiltered arc emits a significant amount of short wavelength uv radiation below the solar cut-on. The SPD in Figure 3 represents the emission through Corex D® borosilicate glass filters, commonly used to improve simulation of daylight in this region. Although the filtered arc emits some wavelengths below the solar cut-on, in contrast to the enclosed carbon arc it gives a much better match to daylight in the region below 360 nm and deviates less at wavelengths longer than 360 nm. Other types of sharp cut-on glass filters can be substituted for the Corex D filters to more closely match the solar cut-on as well as to simulate daylight through window glass. When the open flame carbon arc is used without the glass filters for faster testing, reversals in stability rankings are often obtained compared with outdoor testing because of the excessive amount of high energy radiation below the solar cut-on. The latter can also cause differences in mechanism and type of degradation. Procedures for using the filtered open flame carbon arc devices for exposures of polymeric materials are given in ASTM Standards D822 (47), D1499 (48), and G152 (49).

Both types of carbon arc devices have capabilities for periodic water spray on the samples and condensation during a dark period as well as for humidity and temperature control. Both carbon arc technologies typically require daily replacement of the carbon rods, cleaning of the filters or globes, and their periodic replacement because of change in their transmission characteristics with exposure to uv radiation. There is a large volume of historical data using carbon arcs, and a number of test methods still specify their use, but this technology is largely being replaced with xenon arc systems.

Xenon Arcs. Laboratory accelerated weathering tests advanced significantly with the introduction of xenon arc devices in the 1950s in Europe and the 1960s in the United States. The properly filtered xenon arc more closely simulates terrestrial solar radiation in both the uv and visible regions than any other artificial test source. It has become established worldwide as the radiation source for optimum simulation of terrestrial solar radiation. The SPD of the water cooled xenon arc filtered with a coated infrared absorbing (CIRA) quartz inner cylinder and a soda lime glass outer cylinder is compared in Figure 4 with noon daylight in Miami, Fla., measured at a 26°-tilt angle during the spring equinox. Since the irradiance of the xenon arc can be adjusted with the voltage setting, the SPD is presented in relation to that of daylight by normalization of the two at 560 nm. The filtered xenon arc emission closely matches the spectrum of solar radiation in the uv and visible spectral regions, as well as in the region of the solar cut-on. The CIRA cylinder screens out about 50% of the 800- to 1000-nm radiation, thus reducing the excessive energy of the xenon arc compared with daylight in this region and reducing the heat it causes in materials that absorb this radiation. Other filters are used with the xenon arc to simulate exposure to daylight through window

glass for applications in which this is required. Procedures for exposure of polymeric materials in xenon arc weathering devices are given in ASTM Standards D2565 (50), D4459 (51), and G155 (52).

Unlike carbon arc exposure devices, which have minimal control over the radiation intensity, modern xenon arc devices control irradiance through electrical power management. Two related xenon arc systems have been developed: air-cooled and water-cooled. The type of cooling has some influence on the overall design and on the optical filtering system, but has a negligible effect on the SPD of the radiation. The uv radiation absorbed by any glass filters used with exposure sources cause "solarization" of the filters, resulting in decrease in their optical transmission, which is greater the shorter the wavelength. Deposition of some of the electrode material on the inside of the quartz envelope also decreases transmission. The automatic light monitoring and control systems of xenon arc devices can compensate for this to a large degree, but not completely, until such time as the lamps and filters need replacing. Xenon arc devices have capabilities for temperature control and either periodic water spray or water immersion of the samples during exposure. Some devices can also provide condensation during the dark periods and control of relative humidity during both light and dark periods.

Fluorescent Ultraviolet Lamps. The emission properties of two types of fluorescent uv lamps, UVB-313 and UVA-340, are shown in Figure 5 in comparison with the same daylight spectrum shown in previous figures. All fluorescent uv lamps are deficient in long wavelength uv radiation and, except for a few mercury emission lines in the visible region, lack the visible and nir energy present in daylight and xenon arc radiation. Thus, they are not suitable for testing materials that are sensitive to these spectral regions. Compared with stability ranking

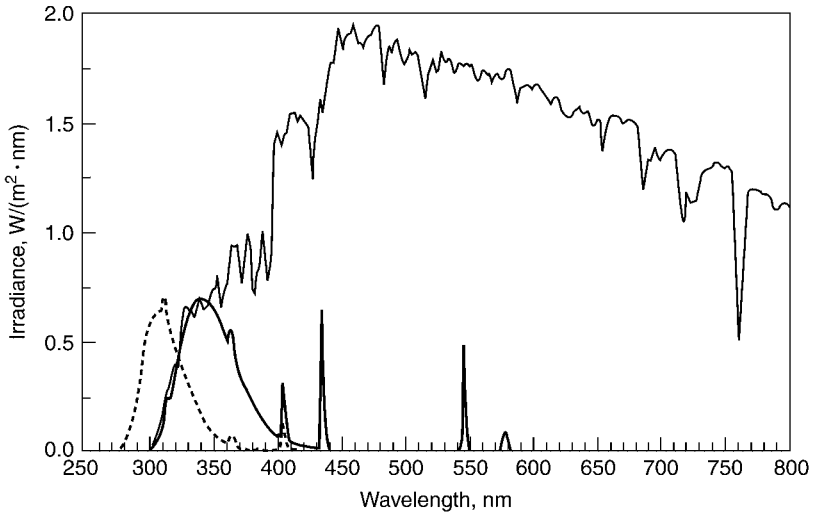

Fig. 5. Spectral power distributions of fluorescent UVB-313 lamps, fluorescent UVA-340 lamps, and noon daylight in Miami, Fla. at 26° south exposure during the spring equinox 5. by daylight, reversals have been reported for colored materials exposed to these lamps as well as to the fluorescent UVA-351 lamps, which emit somewhat longer wavelength uv (53). The UVB-313 lamps were previously commonly used because they provided rapid tests of the sensitivity of polymeric materials to uv radiation owing to the high flux of short wavelengths below the solar cut-on. However, because of the excessive short wavelength radiation, exposures to these lamps often caused reversals in stability rankings of polymers and errors in the performance of stabilizers compared with outdoor tests. These highly energetic wavelengths can initiate different mechanisms and types of degradation than the wavelengths present in solar radiation.

Since the UVB-313 type lamps generally cannot predict the outdoor performance of polymeric materials (54–56), the UVA-340 lamps are gradually replacing them in tests on polymers that are mainly sensitive to wavelengths in the 300- to 330-nm region. These lamps match the cut-on and short wavelength spectral irradiance of solar radiation quite well in this region. However, in addition to the lack of actinic effects on materials sensitive to long wavelength uv and visible radiation, heating of colored materials by absorbed visible radiation is absent. Therefore, in contrast to the temperature variations of differently colored materials exposed to a source that emits visible radiation, all materials attain the same (ambient) temperature. Thus, stability rankings will differ from those based on exposure to solar or solar-simulated radiation. Also, the mechanical stresses resulting from the heating and cooling of the absorbing surface layer are absent, resulting in reduced tendency to crack. For all these reasons, it is important to simulate the full SPD of the source to which the materials will be exposed under use conditions.

The fluorescent uv sources are typically incorporated into fluorescent uv/condensation devices in which dark periods with condensation are alternated with periods of uv radiation. The temperature is generally controlled at different levels during each of these periods. The devices may also incorporate periodic water spray on the front surface of the samples during exposure to radiation, but do not control relative humidity. Some of the modern types of these devices have capabilities for irradiance control. Procedures for exposing polymeric materials in devices with fluorescent uv lamps are given in ASTM Standards D4329 (57), D4587 (58), and G154 (59).

Metal Halide Lamps. The uv emission curve of the borosilicate filtered HMI metal halide lamp is shown in Figure 6 compared with the emission curves of daylight and filtered xenon arc radiation. It has a multiline spectrum which can be considered to be a continuum for purposes of material testing. It gives a relatively good simulation of terrestrial solar radiation in the uv region above 300 nm, but requires additional filtering of the short wavelength radiation for better simulation of daylight. Their high efficiency and low infrared output, which eliminates the need for water cooling, makes these sources ideally suited for use in large scale multiple source arrays and effective in thermal loading studies. However, metal halide lamps have technical problems which make them difficult to use in weathering systems. One is the dependence of the SPD of the radiation on the temperature of the lamp, thus requiring as constant a temperature as possible in the vicinity of the lamp. Because of the effect of temperature on the

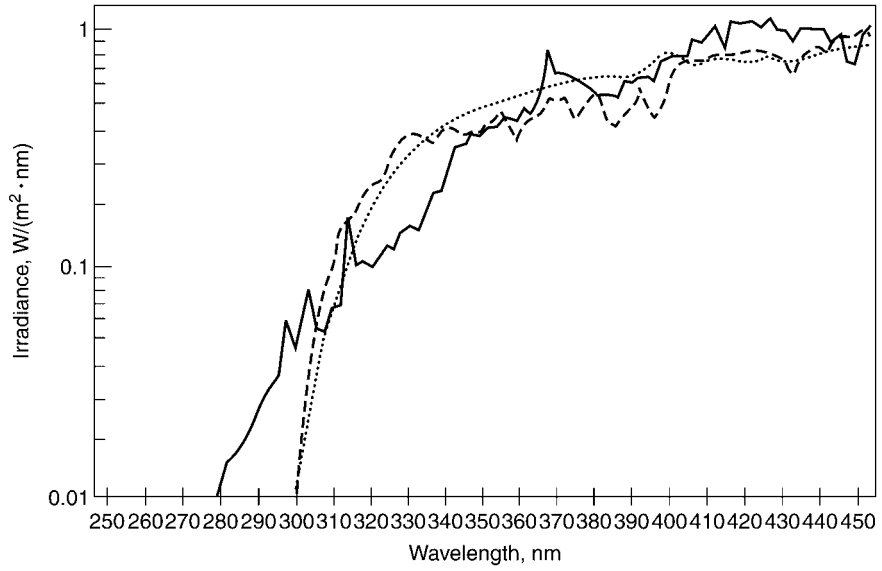

Fig. 6. Spectral power distributions of the water-cooled xenon arc with CIRA quartz inner and soda lime glass outer filters, the filtered HMI metal halide lamp, and daily average of optimum daylight in Miami, Fla. measured at normal incidence during the vernal equinox under clear sky conditions. SPD, the latter changes with change in power. Therefore, the ability to alter the level of irradiance by changing the power is limited to about 5–10%. Reduction in irradiance is accomplished either by the use of close-meshed wire filters or by increase in the distance between the lamp and the sample. The other problem is the variation in SPD from one lamp to another of the same type. It is remedied by measuring the SPD of each lamp and selecting one that is applicable.

Effect of SPD of the Radiation Source on Weathering. The wavelengths responsible for degradation of a specific polymeric material vary with the SPD of the radiation source. Differences between the laboratory accelerated test source and the natural source in the wavelengths that degrade a material, which are identified by the activation spectra (see section on Spectral Effects of Solar Radiation: Activation Spectra), can have the following consequences (53):

(1) The screening requirements of the material will differ and thus the type of uv absorber required will differ. For example, activation spectra data showed that yellowing of a polyarylate film is caused mainly by 310- to 340-nm radiation when it is exposed to fluorescent UVB lamps, but by 335- to 365-nm radiation when it is exposed to solar radiation. Thus, this artificial test source cannot provide valid data on the protective effectiveness of the additive against solar radiation.

(2) The predominant mechanism of degradation of many polymeric materials will differ if the relative intensities of short to long wavelengths responsible for degradation differ. Studies have shown that short uv wavelengths of solar radiation absorbed by the structural components of some aromatic type polymers cause photolytic reactions which lead to photo-Fries rearrangements, while longer uv wavelengths, absorbed by impurities such as hydroperoxides and unsaturated carbonyl groups, initiate photo-oxidation reactions involving free radicals.

(3) If the predominant mechanism of degradation varies with the test source, the effectiveness of stabilizers such as free radical scavengers and excited state quenchers that act by interfering with the mechanism of degradation will differ. For example, HALS can only protect polycarbonate and aromatic polyurethane against the mechanism initiated by long wavelength uv. They are ineffective against the degradation caused by short wavelength uv. Therefore, evaluation of the performance of HALS in these polymers by using a radiation source that primarily emits short wavelengths will give misleading information on their ability to protect the polymers against solar radiation. Significant differences have also been shown among various types of exposures in the protection by HALS against photo-oxidation of acrylic melamine coatings.

(4) The amount of surface versus bulk degradation, yellowing versus bleaching, bond scission versus cross-linking, chalking versus cracking and crazing in TiO_2 pigmented systems, and other diverse types of degradation will differ if the relative intensities of short versus long actinic wavelength radiation differs.

(5) Because of differences among polymeric materials in their absorption properties and in their response to the absorbed radiation, differences between

light sources in harmful wavelengths can alter the stability ranking of materials.

Irradiance in Laboratory Weathering Tests. One of the most obvious ways to shorten test time is to increase the irradiance level. However, increase in irradiance is limited by its effect on the stability ranking of materials and the mechanism of degradation. Since all materials are not affected equally by increase in irradiance, the stability ranking of materials can change with the irradiance level. The dependence of rate of degradation on irradiance level is complex. It varies with the type of material, formulation, including type of stabilizer, and wavelength of light. For most materials, the degradation rate is not a linear or other simple function of irradiance. Thus, doubling the intensity does not necessarily double the rate of degradation. For example, rates of photo-oxidation of polypropylene have been shown to be proportional to various fractional powers of the light intensity ranging from the square root to the first power (60). The distance from the surface at which oxygen diffusion becomes the rate-limiting process in photo-oxidation reactions differs with irradiance level because of its effect on oxygen depletion. The quantum yield of degradation, ie, the amount of degradation for a specific number of photons absorbed, often decreases with increasing irradiance. In a free radical process, this is partly explained by the "cage effect." Because of the higher concentrations of free radicals formed at higher irradiance levels, the likelihood of recombination is increased and reaction with oxygen and other molecules is reduced.

In many modern laboratory accelerated test devices, the irradiance in watts per square meter (W/m^2) in a specified spectral range is photometrically monitored and the lamp power is automatically adjusted to maintain constant irradiance. In xenon arc devices, it is commonly controlled at either 340 nm, referred to as "narrow band control" or over the full uv, 300–400 nm, referred to as "broad band control." In some cases, control includes the full uv and visible range, 300–800 nm. Most standard weathering tests currently specify an irradiance of 0.35 or 0.55 $W/(m^2 \cdot nm)$ measured at 340 nm, with the higher irradiance being increasingly more widely adopted. The irradiance of 0.35 $W/(m^2 \cdot nm)$ represents the daily average of irradiance measured during daylight hours under optimum conditions in Miami, ie, at normal incidence under clear sky conditions during the vernal equinox. It is half the peak irradiance of 0.68 $W/(m^2 \cdot nm)$ measured at solar noon. The irradiance level of 0.55 $W/(m^2 \cdot nm)$ at 340 nm is more representative of the type of exposures samples receive in Miami or Arizona for 3 or 4 h before and after noon. The irradiance integrated over time is the radiant exposure in Joules per square meter which may be automatically monitored. Test duration is often specified in terms of radiant exposure rather than in chronological time.

Temperature in Laboratory Weathering Tests. The temperature of materials can have a significant influence on the effect of the absorbed uv radiation by increasing the rate of secondary reactions. While degradation can be accelerated by testing at temperatures higher than materials are exposed to under use conditions, caution must be exercised to avoid obtaining unrealistic test data. Some reactions that take place at higher temperatures will generally occur at only a very low rate, or not at all, at lower temperatures. For example, specific secondary reactions may occur only at higher temperatures because of increased

rate of decomposition of hydroperoxides or increased rate of diffusion of oxygen or of free radicals formed in primary processes. Often, a different degradation mechanism is triggered at a specific temperature. Change in degradation mechanism precludes simulation of the effects of natural exposures. Since the effect of temperature varies with type of polymer and its formulations, temperatures different than those encountered in end-use environments can distort the stability rankings of materials in addition to causing unrealistic aging behavior.

In most weathering devices, the approximate temperature of dark colored specimens is simulated and regulated with the use of a black panel sensor of either the uninsulated or insulated type described in ASTM G151 (61). It serves to control the air temperature which, in combination with the surface heat caused by absorbed radiation, provides the black panel temperature specified in the test method. The heat due to absorbed radiation depends on the visible and infrared absorption properties of the materials as well as on the SPD and irradiance of the source. Generally, the black panel temperature that specified is the maximum temperature that dark samples attain under use conditions. Currently, the highest black panel temperature specified is 89°C during the light-only period in a xenon arc device used for tests on automotive interior materials such as seat covers and dashboards (62).

Moisture in Laboratory Weathering Tests. Moisture, in combination with radiation, is often a key contributor to the weathering of polymeric materials, either by participating in the chemical reactions resulting from exposure to light or by imposing mechanical stresses. The influence of moisture on weathering of polymeric materials was discussed in the section on Outdoor Weathering. The processes of photoinitiated oxidation and hydrolysis are interrelated, with high humidity enhancing photooxidative degradation. For example, in a study on the effect of relative humidity (RH) on the photodegradation of an acrylic melamine coating, both the rate and magnitude of chain scission and oxidation were shown to increase with increase in RH (63). While some polymers are themselves sensitive to moisture, often the moisture sensitivity of formulation ingredients can have a significant effect on weathering in the presence of moisture. For example, some plasticizers in PVC can be hydrolyzed under hot humid conditions by traces of the hydrogen chloride released on exposure of PVC to uv radiation, resulting in significant loss in elongation.

Moisture can be provided in laboratory accelerated weathering devices in the form of water spray, condensation, immersion, or humidity. The type of moisture present can influence the type and rate of degradation. Many test procedures include more than one type of moisture. Commonly, the front surface of samples is periodically sprayed with cool, deionized water simultaneous with exposure to light. This imparts a thermal shock to the samples, but does not simulate natural weather conditions in which rain is unaccompanied by exposure to radiation. The formation of condensation on samples during the dark period is an effective means of simulating nighttime conditions in an environment with high moisture content, such as in Florida. It is accomplished by providing high humidity conditions while cooling the back of the samples with ambient air or a water spray. High humidity can be as effective as liquid water. In many devices, during light or dark periods without water spray, relative humidity is automatically controlled to a specified level by moistening the air using either the evaporation or atomization technique.

In devices in which wetting is by immersion, the sample is immersed in water while the surface is exposed to light. Since water absorption by polymers from a humid atmosphere or by direct wetness is a diffusion-controlled process, the frequency and duration of the exposure to moisture is often a critical parameter. Weathering processes can be accelerated by more frequent swelling and contraction than occurs in practice. The length of the required wet period depends on the water diffusion coefficient and water absorption capacity of the material as well as on its thickness. Rain, humidity periods, or both ranging up to hours may be required for some polymeric types.

Stability Evaluations and Exposure Duration. Evaluations of new materials and formulations are commonly based on stability ranking, ie, comparison between changes produced in the test material and in a control material of known durability exposed at the same time. Exposure of at least three replicates of the test and control specimens is recommended to allow analysis of variance in order to determine the significance of performance differences. Periodic evaluation of test and control materials should be made to compare rates and direction of property changes as a function of exposure time or radiant exposure. Since extent of degradation is usually not a linear function of exposure, ideally stability should be evaluated in terms of the time or radiant exposure required to produce a defined property change in a material. When exposing for a single period, the latter should be selected to give the largest performance difference between test materials. The minimum exposure period should be that necessary to produce a substantial change in the property of interest in the least stable material being evaluated.

Generally, tests for quality control and specification requirements are based on a pass/fail criteria after a specified test time or radiant exposure. The pass/fail evaluation should be based on the statistically determined combined reproducibility of the test exposure and property measurement. In the absence of statistical information, performance requirements should be based on stability ranking in comparison to a control material. Timing may be based on a specified change of color in a weathering reference material, such as the AATCC Blue Wool Lightfastness Standards used in AATCC Test Methods 16, 16A, and 16C (64). However, these reference materials are only applicable to tests that have a minimum of moisture and low heat because of their sensitivity to these factors. Change in color of test specimens compared to that of the standards has also been used to rank the lightfastness of specimens.

Laboratory Accelerated Versus Natural Weathering

Laboratory accelerated weathering tests have played an important role in development of polymeric materials with highly improved weatherability. However, since all stresses present in an outdoor exposure cannot be simulated in a laboratory accelerated test, the latter cannot replace natural exposure. It is a complimentary technique, the usefulness of which largely depends on how closely it reproduces the chemistry and weathering effects caused by the slower outdoor exposures. Thus, correlation is a fundamental issue which must be considered when selecting a laboratory accelerated weathering method. It depends on reasonably representing

the critical weather factors, ie, radiation, heat, and moisture, in the service environment and accelerating their effects without distorting the type and mechanism of degradation and stability ranking. Studies have shown that appropriate laboratory accelerated tests have the potential of providing information to predict lifetimes by natural weathering. However, before drawing any final conclusions concerning the ability of a polymer to withstand the outdoor environment based on artificial weathering tests, it is necessary to validate the results by conducting outdoor exposure tests for a reasonable length of time.

Correlation. The term correlation refers to the ability of the accelerated test to produce results that agree with real-time outdoor exposures. However, the term "results that agree" as applied to weathering tests, has various meanings, which are generally unspecified. *Correlation* often refers to the ability of different types of weathering tests to rank the performance of a series of materials in the same way, ie, *rank correlation*. Since rankings of materials can vary with the amount of radiant exposure, correlation should be determined at an optimum exposure period (54). Correlation has also been based on the similarity in type(s) of degradation caused by different types of exposure. In some cases, correlation is based either on qualitative comparison of the profiles of the graphed data on property change versus time or radiant exposure, or on a linear regression analysis of the data. "Timing" exposures in terms of only the actinic portion of the radiant exposure should provide a better basis for comparison between laboratory accelerated tests and outdoor exposures (see section on Timing of Exposures).

In order to provide a reliable early evaluation of the weatherability of a polymeric material, ideally the laboratory accelerated test should satisfy all correlation criteria when compared with results of natural weathering. However, any accelerated weathering test, either artificial or natural, only approximates the field exposure conditions. Nevertheless, the closer the simulation of the natural balance of all important weathering factors by the accelerated test, the better the correlation that will be achieved with outdoor tests and end-use service results. When the balance of weather factors is altered, the balance between the various reactions that constitute the weathering processes can change. Because of the synergistic effects of the weather factors and the complex nature of the weathering processes, acceleration by intensification of one factor alone can distort failure modes and stability ranking of materials. Additionally, conditions that give good correlation with one exposure site for one type and form of material and formulation do not necessarily assure good correlation for other materials and may not be applicable to other sites. Often, good correlation between sites is not attained because of differences in exposure conditions at different outdoor sites. The extent of correlation between two types of tests may also depend on the property measured as the criterion of degradation.

In many cases, poor correlation with outdoor test results can be attributed to inadequate simulation of the SPD of the natural source. However, when using an appropriately filtered xenon arc source at an acceptable irradiance level, lack of correlation can be due to other factors that are not adequately simulated. These may be the dry/wet cycle, type of wetting, temperature and its variations, humidity conditions during exposure to the radiation source, the light/dark cycle, and atmospheric pollutants. For some materials, lack of a dark period can preclude correlation with natural exposures. Just as the season in which the outdoor

weathering test is started can affect the test results, in laboratory tests, whether the samples are exposed first to a dry period with radiation or to a wet, dark period can alter the type of degradation and stability rankings. Factors that can interfere with correlation between laboratory accelerated tests and natural exposures are described in ASTM G151 (61). In many of the test standards, exposure specifications are arbitrary and the critical weather factors are not adequately optimized to accelerate and also simulate the effects of natural exposure. Automotive weathering tests based on SAE J1885 (62) for interior materials and SAE J1960 (65) for exterior components that utilize the xenon arc and include a dark period with condensation are an attempt to more closely simulate end-use conditions. While they do not always provide acceptable correlation with outdoor tests, they have generally been an improvement over tests that lack these parameters. Simulation of the atmospheric acid precipitations in outdoor exposures has also been shown to improve correlations based on stability ranking and type of degradation for various types of polymeric materials including sealants and automotive clearcoats (19,20,66,67).

Acceleration Factors. The term correlation is often erroneously used to describe the relation between test times for the laboratory test and outdoor weathering. The appropriate term is *acceleration factor*, which is the time to failure (or change in property) under natural exposure divided by the time to failure (or change in property) by the accelerated test, both evaluated by the same criterion of degradation. Acceleration over "real time" weathering can be accomplished in several ways: (*1*) by continuous exposure to the critical weather factors, uninterrupted by the diurnal cycle, seasonal variations, and weather conditions; (*2*) by exposure to irradiance levels that are only encountered during optimum conditions outdoors; and (*3*) by setting temperatures, relative humidity, and thermal and moisture cycles to high stress levels, but not more than the maximum under end-use conditions. The acceleration factor is meaningful only if the laboratory test does not cause unnatural failure modes or distort stability ranking of the test materials. Accelerated laboratory test conditions that provide correlation with outdoor exposure, generally have an acceleration factor between 2 and 10. Unfortunately, the greater the acceleration, the poorer the correlation.

Acceleration factors are material dependent and can be significantly different for each material and for different formulations of the same material. Therefore, it is erroneous to attempt to establish a single acceleration factor for a laboratory accelerated test to be used to predict lifetimes under natural weather conditions for a variety of materials and formulations. Because of the complex nature of the interaction of the combined weather stresses with a material, there is presently no simple way to estimate the acceleration factor for a material. Increase in irradiance cannot be equated with acceleration of degradation. For most polymeric materials, the rate of degradation is not simply a linear function of the level of irradiance. Also, it does not take into account the effect of temperature, moisture, and other weather factors. Thus, there is no substitute for determining the acceleration factor for a given material experimentally.

The acceleration factor depends not only on the laboratory accelerated test, but also on the geographical, seasonal, and environmental conditions of outdoor exposure. Further, variability in rate of degradation in both laboratory accelerated and natural exposures can have a significant effect on the acceleration factor

calculated. Therefore, the latter should be based on a sufficient number of exterior and laboratory accelerated exposures and at least two, preferably three, replicate specimens in each test so that time to failure in each can be analyzed statistically. Standardizing test conditions with a reference material such as polystyrene in devices that provide for control of weather factors can improve reproducibility of laboratory tests. Often when problems related to reproducibility in the results of accelerated weathering occur, they can be traced to differences in the samples, either because of differences in polymer batches or because of nonuniformity among the test specimens. Even specimens cut from the same sheet often vary significantly. Poor reproducibility in weathering among specimens from the same production lot can be due to the nonuniform distribution of stabilizers or uv absorbing impurities that initiate the degradation. Thus, aliphatic type polymers are particularly prone to this problem since only the impurities in these polymers are capable of absorbing terrestrial solar radiation. Ultraviolet absorbing impurities are also largely responsible for the degradation of many aromatic type polymers by solar radiation and thus for nonreproducibility in weathering of these test specimens as well. Preparation of samples and their treatment during storage can also have a substantial effect on the test results.

Evaluation of Weathering Effects. The particular test method used to evaluate weathering effects depends on the type of polymer and the appearance or mechanical property most important in its application. Appearance changes include discoloration, gloss loss, haze, crazing, chalking, and other visual effects. Some of the appearance changes are measured photometrically, while others are commonly assessed subjectively by visual inspection. The image analysis technique has recently been shown to provide objective and quantitative evaluation of weathering effects on surface morphology (68). The most frequently used criteria for assessing the weather resistance of polymer products that will be subjected to mechanical stress are tensile (or flexural) strength, elongation, impact strength, hardness, and elastic modulus. These techniques and others are described in several reviews on the subject (69,70). The specific criteria used to determine the effects of weathering can significantly influence the acceleration factor and correlation between the laboratory accelerated test and outdoor weathering.

Weathering of polymeric materials proceeds from the irradiated surface inward. Therefore, except for surface effects, changes become evident only after prolonged exposure when degradation has penetrated a sufficient distance into the material. Since degradation is essentially a surface phenomenon, the effects of weathering can be detected sooner by methods that measure surface features than by methods that measure changes in mechanical properties. However, all of these macroscopic property changes require exposure in laboratory accelerated devices for an impractical length of time when evaluating weatherabilities of products designed for useful lifetimes of more than 5 years. An alternative to further intensifying exposure conditions in order to shorten test time is evaluation of weathering effects by sensitive analytical tests that detect molecular (chemical) changes. These are precursors to the macroscopic property changes and thus are indicators of the gross changes long before the latter are manifested. The methods include uv and ir spectral changes, analysis of chemical groups such as carboxyls, hydroperoxides, and free radicals, and measurements of fluorescence and chemiluminescence (69,71–73). The surface-oriented techniques are particularly sensitive

to weathering effects. The value of these methods lies in the extent to which the changes measured are related to the macroscopic changes of the polymers.

Lifetime Predictions. Laboratory accelerated tests have been used primarily for research and development and qualifications of materials, but the ultimate goal is to use them to predict long-term performance under normal use conditions. However, the prediction of service life based on data obtained under accelerated test conditions is still largely an unsolved weathering problem because it is not a simple task. The most direct approach is to determine an acceleration factor relating the exposure time required in the accelerated test device with the time required under natural weathering conditions to produce the same property change. For the reasons given in the section on Acceleration Factors, the acceleration factor must be determined for each type and formulation of a polymeric material and varies with the type of property change measured. A practical proposal for using this approach is to determine the acceleration factor during the early stages of weathering using a sensitive analytical technique for measuring chemical changes (74,75). Assuming the chemical changes and their relation to the macroscopic property changes are the same for the accelerated test and natural exposure, the slower changes measured only by the accelerated test are extrapolated to time to failure outdoors using the acceleration factor. A curve-fitting method to determine the "acceleration shift factor" (ASF) has been developed (76). to account for changes in the relation between accelerated and natural exposure with progression of weathering. The technique requires that the profiles of the graphed property change versus exposure are similar for the two types of exposures. Regression analysis is another technique for deducing lifetimes by natural weathering from lifetimes obtained by laboratory accelerated tests. It is based on measurements of property changes as a function of exposure by both types of tests. It depends on good linear relations over the period measured or finding the mathematical expression between property change and exposure that gives a linear relationship (77). However, the same limitations exist as those inherent in using acceleration factors.

There have been many other empirical approaches to predict service life from accelerated test results, some based on relations between change in polymer properties and exposure variables (78). A simple empirical method of estimating lifetimes by comparison with control materials has recently been proposed (79). The method consists of exposing the test materials in the laboratory accelerated test device simultaneously with several control materials with similar composition and construction to the test material and having a range of failure times outdoors. It requires, as do all service life methods, that the accelerated test produce the same failure modes as natural exposure. In addition, rank correlation between the two exposures should be very high. If these conditions prevail and the service life of the control materials is well defined, the service life of the test material can be bracketed by two control materials.

A variety of techniques based on scientific principles have been also investigated for prediction of weatherabilities. Studies have included mathematical modeling of the effects of weather factors on the degradation process based on data obtained by varying stress levels in laboratory accelerated tests. Various forms of exponential expressions have been used to quantitatively describe the kinetic relations between weather factors and change in properties of polymeric

materials (80–82). It was shown that an approach referred to as the concept of "exposure parameters" was able to successfully predict 2–3 years of outdoor performance of a large number of materials based on several months of accelerated testing (81,82). It has the potential for predicting long-term outdoor weatherability at any location on the basis of accelerated indoor tests using appropriate local weather factors. Mathematical modeling using reliability-based analyses, in which weathering is characterized by frequency of failures, is currently being investigated (83). It requires laboratory accelerated tests on numerous replicate specimens so that life distribution information can be extracted and translated to service life predictions. Valid prediction by either of these mathematical modeling techniques requires accurate data on natural weather conditions, reliable laboratory test data, and considerable experimental effort.

ACOUSTIC PROPERTIES

Introduction

Sound speed and sound absorption measurements in polymers are useful both as a probe of the molecular structure of polymers and as a source of engineering design properties. As a molecular probe, acoustic properties are related to such structural factors as the glass transition (qv), cross-link density, morphology (qv), and chemical composition. Thus, acoustic measurements can be used as a measure of any of these factors, or at least to monitor changes that may occur as a function of time, temperature, pressure, or some other variable. As a source of engineering properties, acoustic measurements are used for applications such as the absorption of unwanted sound and the construction of acoustically transparent windows.

A few terms and their units should be defined because not all authors use these terms in the same way.

Acoustic refers to a periodic pressure wave. The term is synonymous with *sonic* and includes waves in the audio frequency range (ie, those that can be heard by the human ear) as well as those above the audio range (*ultrasonic* and *hypersonic*) and below the audio range. Acoustic measurement is a form of dynamic mechanical measurement, though sometimes the latter term is reserved for low frequency (see also DYNAMIC MECHANICAL PROPERTIES).

Absorption is a measure of the energy removed from a sound wave as a result of conversion to heat as the wave travels through the polymer. Absorption is synonymous with *dissipation* and is related to dynamic mechanical terms: damping, loss factor, and loss tangent. Absorption is a material property, usually given the

symbol α, expressed in units of dB/cm, where a decibel (dB) is a unit based on ten times the common logarithm of the ratio of two acoustic energies. Alternatively, the natural logarithm can be used, in which case the units of α are Np/cm, where 1 Neper (Np) is equal to 8.686 dB. It is sometimes convenient to consider the amount of absorption for a specimen thickness equal to one wavelength, λ. This quantity $\alpha\lambda$ has units of dB (or Np). In contrast to absorption, the term *attenuation* includes energy loss due to scattering and reflection as well as absorption. Also, attenuation, in units of dB, is not a material property, but depends on specimen thickness and experimental configuration.

Frequency is the reciprocal of the period of the sound wave. Frequency f is expressed in Hertz (Hz), which is defined as one cycle per second. Sometimes frequencies are expressed in terms of radians. Since there are 2π radians in one cycle, the radian or circular (angular) frequency is given by $\omega = 2\pi f$.

Wavelength, λ (meters), is the distance between successive pressure (stress) peaks of the sound wave, and is the spatial periodicity of the wave. Frequency and wavelength are defined for a sinusoidal, harmonic (single-frequency) sound wave. More complicated, transient sound signals can be expressed as a superposition of harmonic waves with different frequencies.

Sound speed is a scalar quantity: the magnitude of the sound velocity vector. Sound speed will be denoted by v in this article, although c is sometimes used in the literature. Units of sound speed are meters per second (m/s).

This article covers the use of acoustics as a molecular probe of polymer structure and describes various acoustic applications of polymers. Enough theory and experimental details are given to make the presentation understandable, but the emphasis is on the experimental results for polymers. Most of the presentation is for small-amplitude waves in solid polymers. References to some specialized topics are given (see also MECHANICAL PROPERTIES; TEST METHODS).

Theory

This section covers the basic principles and governing equations for the experimental results that follow. Only the conclusions are presented here; the derivations are available in the references. Most of the presentation applies to linear wave propagation, ie, where Hooke's law is valid.

In an unbounded isotropic solid, two types of sound waves can be propagated. In the first type, called a longitudinal wave, the polymer vibrates in the direction of wave propagation. In the second type, called a shear wave, the polymer motion is perpendicular to the direction of propagation. Longitudinal waves are sometimes called dilatational, compressional, or irrotational waves. Shear waves are sometimes called distortional, isovoluminous, or transverse waves. These two types of waves propagate independently of one another and are the only two types possible in an unbounded solid.

Associated with each of the two modes of propagation, there is a sound speed and an absorption. Thus, four parameters are required to specify the acoustic properties of a solid isotropic polymer: longitudinal speed, shear speed, longitudinal absorption, and shear absorption.

Elastic Constants. One of the purposes of measuring sound speeds is to determine the elastic constants of the polymer. Longitudinal sound speed v_l, and shear sound speed v_s are related to elastic constants by

$$v_l = \left[\left(K + 4G/3 \right) / \rho \right]^{1/2} \tag{1}$$

$$v_s = (G/\rho)^{1/2} \tag{2}$$

where K is the adiabatic bulk modulus (equal to the reciprocal of the adiabatic compressibility), G is the shear modulus, and ρ is the polymer density. Equations 1 and 2 are strictly valid only when absorption is low. The absorption corrections have been given (1); the analysis proceeds by making the moduli complex, with the real part equal to the modulus and the imaginary part proportional to absorption.

For an isotropic solid, there are only two independent elastic constants. These two can be taken to be K and G as above, but it is sometimes convenient to use other elastic constants, such as Young's modulus E and Poisson's ratio σ. These constants can be calculated from K and G using the standard relations

$$E = 3G/\left(1 + G/3K\right) \tag{3}$$

$$\sigma = 0.5 - \mathrm{E}/6\mathrm{K} \tag{4}$$

When the lateral dimensions of the specimen are much greater than the wavelength, a longitudinal wave is propagated, as in equation 1. When the lateral dimensions are much less than the wavelength, an extensional wave is propagated. For such a wave, the sound speed is given by

$$v_{ext} = (E/\rho)^{1/2} \tag{5}$$

This type of propagation is most often encountered in the lower frequency range and is an alternative method to equation 3 for determining E.

In a liquid, shear stresses cannot be supported and the only type of wave that is propagated is a bulk wave:

$$v_b = (K/\rho)^{1/2} \tag{6}$$

Other definitions of elastic constants are sometimes used (2). The Lame constants λ and μ are related to K and G in the following manner:

$$\mu = G \tag{7}$$

$$\lambda = K - 2G/3 \tag{8}$$

Other elastic constants are defined starting from the generalized Hooke's law relation between stress σ and strain ε:

$$\sigma_i = C_{ij}\varepsilon_j \tag{9}$$

where $i, j = 1, \ldots, 6$ and the C_{ij} are the elastic stiffness constants. The number of independent constants in the 6×6 C_{ij} matrix depends on the crystal symmetry of the specimen. In the most anisotropic case, there are 21 independent elastic stiffness constants or elastic moduli. As the crystal structure becomes more symmetric, the number of independent constants decreases. For a cubic crystal, there are three independent constants, and for an isotropic solid only two, C_{11} and C_{12}. The C_{ij} matrix in this case is specified by

$$C_{11} = C_{22} = C_{33} = \lambda + 2\mu = K + 4G/3 \tag{10}$$

$$C_{12} = C_{13} = C_{23} = C_{21} = C_{31} = C_{32} = \lambda = K - 2G/3 \tag{11}$$

$$C_{44} = C_{55} = C_{66} = (C_{11} - C_{12})/2 = \mu = G \tag{12}$$

All other terms are zero. In a liquid, there is only one elastic constant K. Note that most polymeric solids are isotropic, either because they are amorphous or because they are polycrystalline, with a random orientation of the crystallites (see AMORPHOUS POLYMERS; SEMICRYSTALLINE POLYMERS).

In comparing elastic constants measured acoustically with those obtained in a static (very low frequency) test, note that acoustic values are measured under adiabatic conditions, while static values are isothermal. The two types of bulk modulus measurements are related by the standard thermodynamic relation

$$\frac{K}{K_T} = \frac{C_p}{C_v} = 1 + \frac{TV\alpha^2 K}{C_p} \tag{13}$$

where K and K_T are the adiabatic and isothermal bulk moduli, C_p and C_v are the specific heat capacities at constant pressure and volume, T is absolute temperature, and α is the cubic thermal expansion coefficient (3). (It is unfortunate that the same symbol α is also used for absorption; in context, there should be no confusion.) For shear modulus

$$G_S = G_T = G \tag{14}$$

ie, the adiabatic and isothermal moduli are equal. This result follows from the fact that shear deformation occurs at constant volume. The magnitude of K/K_T is on the order of 1.1 for polymers, and increases as the temperature is raised above the glass-transition temperature (4). This effect is more pronounced in polymers than in metals.

In addition to the adiabatic or isothermal difference, acoustically determined elastic constants of polymers differ from static values because polymer moduli are frequency-dependent. The deformation produced by a given stress depends on how long the stress is applied. During the short period of a sound wave, not as much strain occurs as in a typical static measurement, and the acoustic modulus is higher than the static modulus. This effect is small for the bulk modulus (on the order of 20%), but can be significant for the shear and Young's modulus (a factor of 10 or more) (5,6).

Strain dependence should also be considered when comparing acoustically measured elastic constants with statically measured values. As an example, for polyethylene at room temperature, the modulus is independent of strain up to a strain of about 10^{-4} (7). Beyond this point, the modulus decreases as the strain increases. Typically, acoustic measurements are made in the strain range 10^{-6}–10^{-9}, where the moduli are strain-independent, but static measurements often exceed the linear strain limit (8).

Sound Absorption. The absorption of sound in polymers can be high, in certain ranges of temperature and frequency, up to four orders of magnitude higher than typical for metals. The mechanisms of the high absorption are various molecular structural relaxation processes involving motion of the entire long molecular chains, or of selected short molecular segments. Second-order transitions (9) are associated with the various molecular relaxation processes, where a given molecular relaxation motion fully participates in the thermodynamic response of the polymer at temperatures above the transition temperature, and does not participate (is "frozen") at temperatures below the transition temperature.

The average time required for the specific molecular motion is an important parameter of the relaxation process. This time is called the relaxation time, τ, and it is a function of temperature and pressure. When the frequency of the dynamic stress (acoustic or vibration) is in the range of $1/\tau$, the strains in the polymer lag the applied stress, because of structural molecular relaxation, which leads to conversion of mechanical energy to heat, and to damping of the acoustic wave (or mechanical vibration). This type of mechanical response of the polymer is called *viscoelastic behavior* (see VISCOELASTICITY). At low frequencies, $f \leq 1/\tau$, the molecules have time to respond to the applied stress and the structural molecular relaxation completely follows the applied stress. Therefore, stress and strain are in phase and mechanical energy loss is low. The sound speeds, and elastic constants, in this frequency region are denoted by the subscript 0. At high frequencies, $f \geq 1/\tau$, the period of the applied stress is too short for the given molecular relaxation process to occur. Stress and strain are again in phase, sound absorption is low, and the sound speeds and elastic constants in this frequency range are denoted by the subscript ∞. The high frequency sound speeds are greater than the low frequency values, because of increased stiffness of the polymer at high frequencies (no molecular relaxation). It follows from the above discussion that sound speeds and elastic moduli of a polymer are frequency dependent in temperature (and pressure) ranges where a transition occurs. Also, at frequencies $f \approx 1/\tau$ there is a peak in the sound absorption per wavelength, $\alpha\lambda$.

The glass transition (qv), in the amorphous portions of the polymer, is the transition that dominates the acoustic properties of many polymers. At temperatures below the glass-transition temperature, T_g, or at frequencies $\geq 1/\tau_g$, the sound speeds have "glassy" values. At temperatures above T_g, or at frequencies $\leq 1/\tau_g$ the mechanical response of the polymer is 'rubbery.' (As shown in Figs. 1 and 2.)

The discussion that follows, of sound propagation in a lossy polymer, is limited to the case where the stress–strain relation in the polymer is linear. The effect of loss mechanisms on the mechanical response of polymers is included by modifying the stress–strain relations (eq. 9). At small strains, at which the behavior of the polymer is linear, the stress–strain relations are modified according to the

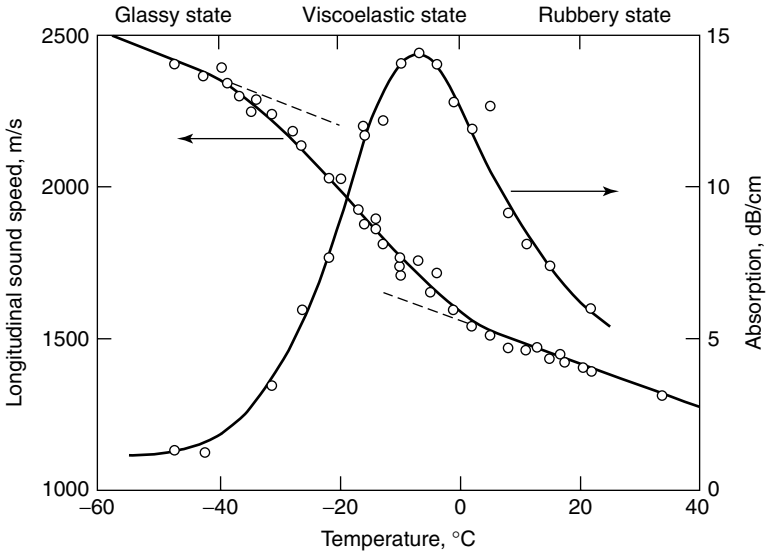

Fig. 1. The glass transition for poly(carborane siloxane)—longitudinal sound speed and absorption vs temperature at 1 MHz. Adapted from Ref. 49.

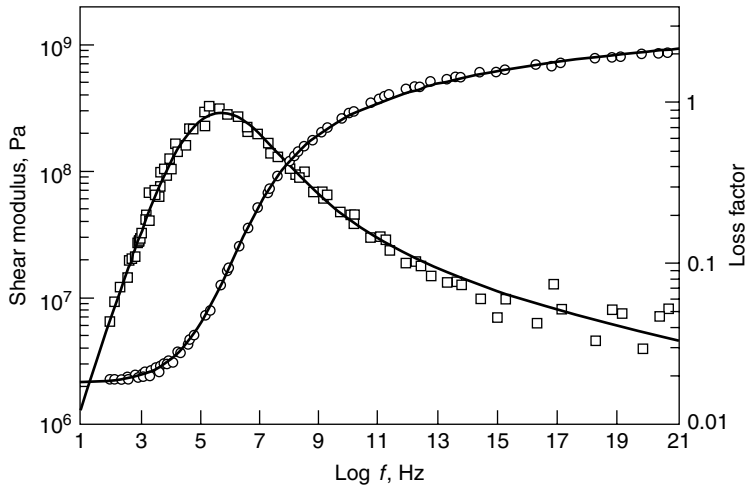

Fig. 2. The glass transition for a polyurethane (PTMG2000/MDI 3/BDO/DMPD)—shear modulus(○) and loss factor(□) vs frequency at room temperature. Adapted from Ref. 50.

Boltzman Superposition Principle (3,10). This principle states that the stress at a given point in the polymer is a function of the entire strain history at that point. Therefore, to each strain term in equation 9 is added an integral that represents contributions to the stress at a given time from strain increments at earlier times.

For example, the stress–strain relation for shear strain in an isotropic material is $\sigma = G\varepsilon$. For a viscoelastic material this relation is modified as follows:

$$\sigma(t) = G_\infty \varepsilon(t) - \int_0^\infty M(\Delta t)\varepsilon(t - \Delta t)\, \mathrm{d}\Delta t \tag{15}$$

where $\sigma(t)$ and $\varepsilon(t)$ are the shear stress and strain, at a given point in the material, at time t, and G_∞ is the high frequency (instantaneous) shear modulus. $M(\Delta t)$ is an 'after-effect,' at time t, of the strain at time $(t-\Delta t)$. Physically $M(\Delta t)$ is a relaxation function, since it describes the relaxation of molecular process excited by an imposed strain. Other stress–strain relations are modified similarly.

The Boltzman Superposition Principle is one starting point for inclusion of structural relaxation losses. An equally valid starting point is to include in equation 9 time derivatives (first-order and higher) of stress and strain. It can be shown that this approach is equivalent to the above integral representation (10). Finally, modified stress–strain relations, to describe viscoelastic response, have also been formulated using fractional derivatives (11).

A characteristic feature of viscoelastic response is the phase lag between the strain and the applied stress, due to the loss mechanisms. This phase difference is described by defining complex wave numbers, sound speeds, and elastic moduli, as follows. The relations that follow are developed specifically for a shear wave propagating through an absorbing polymer. Similar relations can be developed for longitudinal and extensional waves. Sound signals are either single-frequency (harmonic) waves, or transient signals that can be represented as a superposition of harmonic waves of different frequencies. A harmonic wave is a particularly simple case of wave motion, since in this case all quantities (stress, strain, particle displacement, etc) vary harmonically, at the same frequency. When the modified stress–strain relations are used to derive the equation for sound wave motion, the solution for a progressive, plane, harmonic wave is (11,12),

$$p = p_0\, e^{-\alpha_s x}\, e^{i(k_s' x - \omega t)} \tag{16}$$

where p is the acoustic pressure at distance x from the reference point where the pressure is p_0, $k_s' = 2\pi/\lambda_s$ is the real part of the shear wave number, where λ_s is the shear wavelength, and α_s is the sound attenuation coefficient, for shear waves, in nepers per meter. From equation 16 it follows that sound attenuation can be formally included in the wavenumber by defining a complex wavenumber,

$$k_s^* = k_s^{'} + i k_s^{''} = k_s^{'} + i\alpha_s \tag{17}$$

The expression for the shear wave now has the same form, $p = p_0 \exp[i(k_s{}^* x - \omega t)]$, as in a lossless medium. The complex wavenumber defines a complex sound speed for the material as follows:

$$v_s^* = \frac{\omega}{k_s^*} \tag{18}$$

The propagation of the wave as a function of space and time is still determined by the phase velocity, v_s, which is related to the real part of the wavenumber, $v_s = \omega/k_s{}'$.

The elastic moduli of a lossy material are also complex quantities. The relation between the complex shear wave speed and the complex shear modulus is

the same as the relation between the corresponding real quantities (eq. 2),

$$G^* = G' - iG'' = \rho v_s^{*2} \tag{19}$$

From equations 17–19 it follows that the sound attenuation coefficient is related to the complex elastic modulus,

$$\left(k_s'^2 - \alpha_s^2\right) + i(2k_s'\alpha_s) = \frac{\rho\omega^2}{G'(1+r^2)}(1+ir) \tag{20}$$

where r is called the loss factor, and is the ratio of the imaginary to the real part of the modulus,

$$r = \tan\delta = \frac{G''}{G'} \tag{21}$$

Equations 18–20 can be solved for the real and imaginary parts of the complex shear modulus (1),

$$G' = \rho v_s^2(1-r^2)/(1+r^2)2 \tag{22}$$

$$G'' = 2\rho v_s^2 r/(1+r^2)2 \tag{23}$$

A material is characterized as low loss when the attenuation per wavelength, $\alpha\lambda$, is small, $\alpha\lambda \ll 1$ or $\alpha \ll k'$. Then the loss factor is small, $r \ll 1$, and the above relations simplify to

$$k_s'^2 = \frac{\rho\omega^2}{G'} \quad \text{and} \quad \alpha_s\lambda_s = \pi r \tag{24}$$

where the shear wavelength $\lambda_s = 2\pi/k_s'$. Equation 24 is an approximation that overestimates G' by 40% when $\tan\delta = 1$, and by 1% when $\tan\delta = 0.1$. From the above equations it follows that the complex modulus is closely related to the sound speed and absorption. In particular, the frequency dependence of the real part of the elastic modulus (G') is similar to the frequency dependence of the corresponding sound phase velocity (v_s). Also, the frequency dependence of the loss factor, $\tan\delta$, is similar to the frequency dependence of $\alpha\lambda$, as shown in Figures 1 and 2.

Techniques for measuring the complex sound speeds and moduli of polymers are described in the section on test methods. The data shows that the real and imaginary components of the elastic moduli are frequency dependent. The frequency dependence is strongest for materials with high values of the loss factor r. Materials with frequency-dependent elastic moduli are called *dispersive*, and measurements and theory show that sound absorption mechanisms lead to *dispersion*. The real and imaginary part of an elastic modulus are related by the Kramers–Kronig relations, which are presented in the next section.

Kramers–Kronig Relations. The Kramers–Kronig (KK) relations are derived from the basic causality condition that the output strain cannot precede the input stress in any physical material (13–15). These relations apply to the complex, frequency-dependent elastic moduli of any material, and relate the real and imaginary components of the modulus. For example, for the complex shear modulus, $G^*(\omega) = G'(\omega) + iG''(\omega)$, the Kramers–Kronig relations are

$$G'(\omega) - G_\infty = \frac{1}{\pi} PV \int_{-\infty}^{+\infty} \mathrm{d}\omega' \, \frac{G''(\omega')}{(\omega' - \omega)} \tag{25}$$

$$G''(\omega) = -\frac{1}{\pi} PV \int_{-\infty}^{+\infty} \mathrm{d}\omega' \, \frac{G'(\omega') - G_\infty}{(\omega' - \omega)}$$

where PV is the principal value of the integral and G_∞ is the high frequency ($\omega \to \infty$) modulus. Similar relations hold for the complex bulk modulus, $K^*(\omega)$. The KK relations are significant to the acoustic designer because they show that it is not possible to select the modulus (G') and the loss factor ($\tan \delta = G''/G'$) of a material independently. The KK relation can also be used to check the consistency of experimental data. Lack of agreement between the measured loss factor and that calculated from the modulus is an indication of some experimental error. Likewise, an analytical model for a complex modulus must obey KK in order to be a physically meaningful relation.

A useful, approximate local version of the KK relation was developed by O'Donnel and co-workers (14). This approximation relates the attenuation coefficient α to the frequency derivative of the phase velocity, $\mathrm{d}v/\mathrm{d}\omega$, as follows:

$$\alpha(\omega) = \frac{\pi \omega^2}{2c^2} \frac{\mathrm{d}v}{\mathrm{d}\omega} \tag{26}$$

Equation 26 applies both to shear and longitudinal waves, where α and v are related to the real and imaginary parts of the appropriate modulus by equations 22 and 23. Examples of application of the KK relations are given in References (16) and (17). The KK relations are particularly useful for discussion of the acoustical and mechanical behavior of polymers in the viscoelastic state. In this state polymers have a high loss factor, and are used for underwater sound attenuation and for vibration damping. Equation 26 shows the trade-offs that have to be made in choosing a viscoelastic material for any specific sound attenuation or vibration damping applications. For example, it follows from equation 26 that, for shear waves, a high value of α_s requires a large $\mathrm{d}v_s/\mathrm{d}\omega$ in the viscoelastic region, which points to a material with a large relaxation strength $(G_\infty – G_0)/G_0$ and a narrow range of relaxation times. However, experience shows that in materials where the viscoelastic region occurs over a narrow range of frequencies the relaxation times, and therefore $\alpha_s(\omega)$, are strongly temperature dependent.

Equation of State. An equation of state in this context is a relation between pressure, volume, and temperature in a polymer, or a relation between any two of these variables holding the third constant. Frequently, these equations

involve the bulk modulus. Given the equation of state of a polymer, one can correlate much experimental data and extrapolate to high pressure, where measurement is difficult.

By making reasonable assumptions about the form of the intermolecular potential, it was possible to calculate bulk modulus as an analytic function of volume (18). The calculation agrees fairly well with experimental data, and with the assumption that volume is the primary factor determining bulk modulus and, by extension, sound speed.

The Gruneisen parameter is widely used in polymer equation-of-state calculations. Bulk modulus is primarily a function of volume. The volume of a polymer can be changed by varying either the pressure or the temperature, leading to two equivalent expressions for the Gruneisen parameter γ:

$$\gamma = \frac{1}{2}\left(\frac{\partial K}{\partial p}\right)_T \tag{27}$$

$$\gamma = -\frac{1}{2\alpha}\left(\frac{\partial \ln K}{\partial T}\right)_p \tag{28}$$

For solid polymers, equations 27 and 28 give approximately the same value (19).

The Gruneisen parameter also plays a role in nonlinear acoustics, and it has been shown that there is a relation between the Gruneisen parameter and ultrasonic absorption: the larger γ is, the higher the absorption (19).

Transitions. In polymer science, a change from one state to another is a transition. An important transition is the glass to rubber transition. Processes occurring at temperatures below the glass transition are called secondary transitions, even if it is not known what the two states are. The transition is identified as such through its effect on some physical property, like dynamic mechanical damping. In acoustics, processes of this type are generally called relaxations (see GLASS TRANSITION; VISCOELASTICITY).

Acoustic properties vary with frequency. Assuming this behavior can be described by a single time called the relaxation time, the frequency dependence of either longitudinal or shear waves is given by

$$v^2 = v_0^2 + \left(v_\infty^2 - v_0^2\right)\frac{\omega^2\tau^2}{1+\omega^2\tau^2} \tag{29}$$

$$\frac{\alpha\lambda}{\pi} = \frac{\left(v_\infty^2 - v_0^2\right)\omega\tau}{v_0^2 + v_\infty^2\omega^2\tau^2} \approx \frac{v_\infty^2 - v_0^2}{v_\infty^2}\frac{\omega\tau}{1+\omega^2\tau^2} \tag{30}$$

where the subscripts 0 and ∞ refer to low and high frequency limiting values, respectively, and τ is the relaxation time (20). Note that $\alpha\lambda$ is a maximum for $\omega\tau = 1$. This absorption peak is identified with a particular relaxation process or transition in the polymer.

It is generally assumed that the temperature dependence of the relaxation time is of the Arrhenius form:

$$\tau = \tau_0 \exp\left(\Delta H/RT\right) \tag{31}$$

where ΔH is the activation energy for the relaxation process, R is the gas constant, and τ_0 is a constant. Since $\tau = 1/\omega = 1/2\pi f$ at the absorption maximum, an Arrhenius plot of $\ln f$ vs $1/T$ has a slope of $-\Delta H/R$. Each point on the plot is the reciprocal temperature of the absorption peak for a given logarithmic measurement frequency. Arrhenius plots are a particularly revealing way of examining acoustic data and interpreting results in terms of molecular structure. If the Arrhenius plot is not a straight line, it is assumed that ΔH is a function of temperature.

A significant result in equations 29 and 30 is that the acoustic properties depend only on the product $\omega\tau$, not on either variable separately. Since τ is a function of temperature, as shown in equation 31, the results of changing frequency are indistinguishable from those of changing temperature (neglecting any changes in ν_0 and ν_∞). The applicability of time–temperature superposition directly follows from the form of these equations. The analytic form of the temperature dependence of the relaxation time is, however, not specified in equations 29 and 30.

The discussion so far has been limited to the single relaxation time model. In polymers, however, the measured absorption and sound speed vs frequency curves are much broader than predicted by the single relaxation time model. This observation is interpreted to mean that there is a continuous distribution of relaxation times in polymer relaxation. There has been considerable analysis of various empirical distributions of relaxation times (21). Arrhenius plots are still valid in this case, but the activation energy is interpreted as an average value. Because of the distribution of relaxation times in polymers, measurements over a broad frequency range (several decades) are required to map out a given relaxation. Experimentally, it is difficult to cover such a wide range of frequencies without using several different pieces of equipment. Acoustic measurements are then sometimes supplemented with dielectric measurements. The governing equations are strictly analogous and, in many cases, dielectric and acoustic data can be displayed on the same Arrhenius plot. A full discussion is given in Reference 21.

Hysteresis Absorption. In the vicinity of a polymer transition, the absorption vs frequency at first increases, and then decreases. In a region removed from a transition, however, absorption typically increases linearly with frequency. This behavior is referred to as hysteresis absorption and is observed in both crystalline and amorphous polymers, and also in such materials as metals and rocks. An absorption proportional to frequency can be expressed as $\alpha = cf = c\nu/\lambda$, or $\alpha\lambda =$ a constant, ie, absorption per wavelength independent of frequency is another way of describing hysteresis absorption.

It is generally assumed that the description of polymer properties requires a continuous distribution of relaxation times. Numerous forms of the distribution function have been assumed, often for mathematical simplicity or on the basis of physical intuition. It has been found that a fractional power law distribution of relaxation times of the form τ^{-m} leads to hysteresis absorption with $\alpha\lambda = m\pi/2$ (Np), when $m \leq 1$ (3). The disadvantage of this model is that attempts to justify this distribution of relaxation times on a molecular basis quantitatively have not been successful. Mathematically, almost any experimental result can be expressed in terms of a distribution of relaxation times, but there may not be any physical significance to the distribution.

It has been suggested that the origin of the hysteresis absorption is in the time delay of reorienting the polymer among the large number of metastable

equilibrium positions possible (8). The magnitude of the hysteresis absorption should depend on free volume because of two competing effects: the number of segments that reorient themselves decreases with decreasing volume, and the fraction of these segments that does not return to their original orientation increases with decreasing free volume. The second effect generally dominates, and the hysteresis absorption increases with decreasing free volume. The form of the volume dependence of the hysteresis absorption was originally assumed to be a simple linear dependence (8), but is probably more complicated (22).

Inhomogeneous Media. The inhomogeneities considered here are on the macroscopic rather than microscopic scale. The first topic considered is layered media. To begin with, consider a flat boundary between two media of different acoustic properties. When an acoustic wave traveling through one medium encounters at normal incidence the boundary with another medium, some of the acoustic energy is reflected and some transmitted (12). The sound power transmission coefficient T is given by

$$T = \frac{4Z_1Z_2}{(Z_1 + Z_2)^2} \tag{32}$$

where the subscripts refer to the two media, and the acoustic impedance Z is given by

$$Z = \rho v \tag{33}$$

Thus, the transmission properties depend on the impedance match of the two media. For a flat plate in a liquid medium

$$\frac{1}{T} = \cos^2 k_2 l + \frac{1}{4}\left(\frac{Z_2}{Z_1} + \frac{Z_1}{Z_2}\right)^2 \sin^2 k_2 l \tag{34}$$

where $k = \omega/v$, subscript 2 refers to the plate, subscript 1 refers to the liquid, and l is the thickness of the plate (12). The extension of these results to multiple layers of plane parallel plates at oblique angles of incidence, including the effect of absorption, has been considered by several authors (23,24). Some work has been done to determine polymer properties from the acoustic properties of plate transmission (25). Reflections from multiple concentric cylinders (26) and from spheres (27) have also been examined.

Another class of inhomogeneous materials of increasing practical importance is fiber-reinforced composites (qv). Usually the matrix is a polymer, such as epoxy. The reinforcement may be polymeric, such as Kevlar, or nonpolymeric, ie, glass, steel, or graphite. For a unidirectional composite with transverse isotropy, there are five independent elastic constants or moduli: C_{11}, C_{13}, C_{33}, C_{44}, and C_{66}, (28,29). Absorption measurements are particularly difficult to make on such composites. Frequently, the measured attenuation has a significant contribution as a result of scattering from the reinforcement; this is sometimes referred to as geometric dispersion.

Foamed materials can be considered to be the opposite of fiber reinforcement (see CELLULAR MATERIALS). In a foam, the gas inclusions make the matrix softer

and weaker. The introduction of even small amounts of air into a polymer can have a dramatic effect on acoustic properties. One approach to modeling the effect of a small air content ϕ on the acoustic properties of a rubber is to use Kerner's theory of composites (30):

$$K = K_0(1-\phi)/(1+3K_0\phi/4G_0) \tag{35}$$

$$G = 3G_0(1-\phi)/(3+2\phi) \tag{36}$$

$$\rho = \rho_0(1-\phi) \tag{37}$$

where the subscript 0 refers to solid rubber and the Poisson's ratio of rubber is assumed to be one-half. Longitudinal and shear sound speeds can be calculated from these equations. Absorptions can be included by making the moduli complex. In addition to Kerner's model, other models for polymer composites with microscopic inclusions have been developed (31–33). One application of such composites is for absorption of underwater sound (34). Also, this type of composite can be used as a sound-absorbing lining, at ultrasonic frequencies, in immersion tanks (35).

Nonlinear Wave Propagation. It is assumed that most acoustic measurements are made in the linear wave propagation region, ie, where Hooke's law applies. Polymers as a class, however, are more nonlinear than other solids. Nonlinear wave propagation is therefore significant in some cases.

Extensive studies of nonlinear propagation in fluids have been made (36). Although derived for fluids, the results have been applied to a number of solid polymers (37,38). In these studies, the isentropic equation of state for pressure p, in terms of density ρ, is expanded to the form

$$p - p_0 = A[(\rho-\rho_0)/\rho_0] + (B/2)[(\rho-\rho_0)/\rho_0]^2 + \cdots \tag{38}$$

The quantity B/A is the parameter of nonlinearity. From thermodynamic evaluations,

$$\frac{B}{A} = 2\rho_0 v\left(\frac{\partial v}{\partial p}\right)_T + \frac{2v\alpha T}{\rho_0 C_p}\left(\frac{\partial v}{\partial T}\right)_p \tag{39}$$

where α is the thermal-expansion coefficient. The extension of this analysis to solids involves third-order elastic constants (39). There are few measurements of third-order elastic constants for polymers. One method for determining these constants is to measure the velocities of longitudinal and shear waves in the material as a function of various applied static stresses. Hughes and Kelly (40) give the following values for polystyrene: $\ell = -18.9 \pm 0.3$, $m = -13.3 \pm 0.3$, $n = -10.0 \pm 0.1$, in units of GPa. It is found that the third-order elastic constants are related to the Gruneisen parameter. Relationships have also been found between B/A and the Gruneisen parameter (41). This is another manifestation of the fact that the Gruneisen parameter is a fundamental measure of the nonlinear behavior of a polymer.

One particular interest in nonlinear propagation in polymers is for what is known as a parametric sonar. In this application, two colinear high frequency

beams of slightly different frequency are propagated through a medium. In a perfectly elastic medium, the two waves would propagate indefinitely without interacting. In a real medium containing nonlinearity, however, there is an interaction that produces waves with the sum and difference frequencies of the two beams. Thus, a low frequency beam is generated with the highly directional character of a high frequency beam. Polymers are particularly attractive in this application because of their high nonlinearity and high absorption. Hence, the efficiency of the frequency conversion is high, and the high frequency source components are absorbed relatively quickly while the low frequency difference wave propagates much further (37).

Additive Properties. It is reasonable to assume that different chemical groups should contribute differently to the macroscopic properties of polymers. Rigid aromatic groups would be expected to raise the elastic modulus (and sound speed), while flexible aliphatic groups would be expected to lower the modulus. A quantitative expression of this idea is known as the method of additive properties and has been extensively developed and reviewed by Van Krevelen (42). In this method it is assumed that various polymer properties are determined solely from the additive contributions of their constituent groups. The groups are assumed to have unique properties that are independent of their environment. The uniqueness assumption has proven to be valid in many cases.

The simplest example of additive properties states that the molar mass M of a polymer is the sum of the molar masses of the component groups in the repeat unit. A similar equation holds for the molar volume and leads to an expression for the polymer density,

$$M = \sum N_i M_i, \quad \rho = \frac{\sum N_i M_i}{\sum N_i V_i} \tag{40}$$

where M_i is the mass of the ith component group, N_i is the number of such groups in the repeat unit, and V_i is the molar volume of the ith component group.

As applied to sound speed, the method of additive properties begins with work on liquids, where it was empirically found that

$$R = V v^{1/3} \tag{41}$$

where V is molar volume, ν is sound speed, and R is a constant, for each liquid, known as Rao's constant or the molar sound speed (43). R is an additive property, but ν is not. Since a liquid cannot support a shear stress, the sound speed in a liquid can be calculated by equation 6, so that, in terms of modulus, Rao's rule (eq. 41) can be written as

$$R = V(K/\rho)^{1/6}, \quad K = (M/V)(R/V)^6 \tag{42}$$

In applying Rao's rule to solid polymers, it should be kept in mind that the longitudinal sound speed (eq. 1) includes not only a bulk modulus term, but also a shear modulus term that must be taken into account (5). This has been done for both linear and cross-linked polymers (44–47). Van Krevelen has named the additive variable for bulk modulus the Rao function, U_R, and for shear modulus the

Table 1. Group Contributions to U_H and U_R

Group	U_H, $(cm^3/mol)(cm/s)^{1/3}$	U_R, $(cm^3/mol)(cm/s)^{1/3}$
—CH_2—	880	675
—$CH(CH_3)$—	1,875	1,650
—$CH(C_6H_5)$—	4,900	4,050
—CHCl—	1,725	1,450
—$C(CH_3)(COOCH_3)$—	4,220	3,650
—C_6H_5—$C(CH_3)_2$—C_6H_5—	11,000	8,700
—O—	400	300
—OCOO—	1,575	1,200
—CONH—	1,750	1,400

Hartmann function, U_H. The bulk and shear moduli can then be calculated from the equations,

$$K = (M/V)(U_R/V)^6 \quad \text{and} \quad G = (M/V)(U_H/V) \tag{43}$$

Group contributions to U_R and U_H for some common molecular groups, taken from Van Krevelan (42), are listed in Table 1. The bulk and shear moduli for various polymers calculated using the values from Table 1 are in good agreement with experimental values (42). Sound speeds can be predicted from the calculated elastic moduli and densities.

A limitation of the above method is that some of the required group properties are not available. This is particularly a hindrance when trying to predict the properties of polymers with novel compositions. To overcome this limitation, a new additive contribution method has been developed (48) in which the polymer properties are expressed in terms of topological variables or connectivity indices. In this method properties are determined primarily from the summation of contributions of atoms and bonds instead of groups. The pertinent properties of the handful of elements found in most polymers have been determined, allowing for the prediction of properties for most polymers having a known structure.

Sound as a Molecular Probe

Acoustic measurements have been employed as a molecular probe of polymer structure to study different aspects of molecular structure: transitions, curing (UV, visible light, thermal) (qv), density, and chemical composition in both synthetic and biological polymers.

Transitions.

Glass Transition. The acoustic properties of polymers, when plotted over broad ranges of frequency and temperature, are usually dominated by the glass transition. Typical data are shown in Figures 1 (49), and 2 (50). The change in slope of the sound speed at about −40°C is independent of frequency and is equal to the dilatometric value of T_g. This method of determining T_g has been applied to a number of polymers (51–53). The change in slope at −40°C occurs as a result of

the discontinuity in the thermal expansion coefficient and the strong dependence of modulus on density. The value of T_g determined in this manner is dependent on the density, but independent of frequency. It is important to keep in mind the difference between the glass-transition temperature, T_g, which is a fixed number, and the glass transition, which is a process that occurs at different temperatures depending on the frequency of the measurement.

Figure 1 shows the variation, in the glass-transition region, of the longitudinal sound speed and absorption with temperature at a fixed frequency, for poly(carborane siloxane). Figure 2 shows the real part of the shear modulus and the loss factor as a function of frequency, at a fixed temperature, for a polyurethane. From equation 24 it follows that the variation of the shear sound speed and absorption is similar. The longitudinal sound speed changes from ∼1500 m/s in the rubbery state to ∼2300 m/s in the glassy state. The change in the shear sound speed in the polyurethane is from ∼50 to ∼900 m/s. The large change in the shear sound speed through the glass-transition region is typical for polymers.

In small amounts, crystallinity raises T_g by limiting the motions of the amorphous regions. As the degree of crystallinity increases, the glass transition, which occurs only in the amorphous regions of the polymer, tends to be masked and may even be difficult to determine, as in the case of polyethylene. At the glass transition of an amorphous polymer, some 10–50 repeat units become free to move in cooperative thermal motion of individual chain segments, involving large-scale rearrangements of the chain backbone. Below the glass transition, these large-scale motions become frozen and cannot occur. Major changes in many physical properties, including acoustic properties, take place at the glass transition (16).

Most studies of glass transition have focused on the absorption. By repeating the measurements of Figure 1 at higher frequencies, an Arrhenius plot of the log of test frequency vs reciprocal temperature of peak absorption can be made, yielding an activation energy of about 100 kJ/mol; this is a typical value for glass transitions, albeit on the low side. A compilation of literature data for seven semicrystalline polymers has been given (54). An example of the results for polytetrafluoroethylene is shown in Figure 3. For the glass (ie α) transition, the activation energy is 700 kJ/mol, the highest value in this group. Note that an Arrhenius plot, such as Figure 3, is a convenient way to keep track of multiple transitions in a given polymer and in correlating data from various sources and various experimental techniques. Acoustic measurements over a limited range of temperature and frequency may indicate a relaxation, but it is not always clear what mechanism is producing the effect. A plot like Figure 3 is very useful in identifying the relaxation.

In the case of isotactic polypropylene, two glass transitions were found acoustically—as well as by using other techniques (55). It was shown that whereas the crystalline phase is isotactic, the amorphous phase, which gives rise to the glass transitions, includes atactic as well as isotactic chains. The atactic amorphous phase has the lower T_g.

Through consideration of Arrhenius plots of the glass transition of 14 polymers, the empirical observation was made that the lines for the various polymers all seemed to converge in one of two regions: 10^8 Hz for the more sterically restricted polymers, and 10^{18} Hz for sterically nonrestricted polymers (56). This

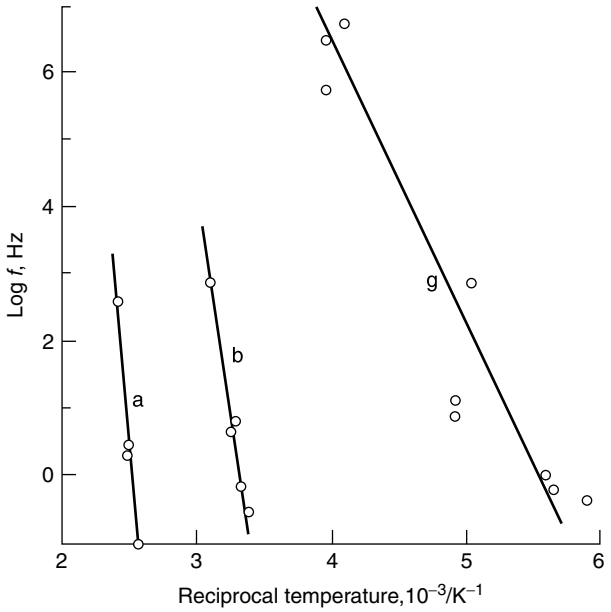

Fig. 3. Arrhenius plot for α, β, and γ transitions in polytetrafluoroethylene.

observation shows that there is a direct relation between dilatometric T_g and activation energy: the higher the T_g, the higher the activation energy. In addition to the data discussed (54,56), an even more complete summary of acoustic data on solid polymers has been compiled (57).

The glass transition provides the behavior that has the most practical significance. Secondary transitions are too small to have much effect and polymers are not generally practical to use at their melting point. The glass transition shows a large change through the transition and can be used both above and below the transition. The glass transition is a second-order phase transition, in which the primary thermodynamic functions are continuous but their first derivatives are discontinuous. For example, the specific heat capacity vs temperature is continuous through the glass transition but the derivative of the specific heat is discontinuous. The sound speeds and elastic moduli are continuous but their derivatives are discontinuous.

The most successful phenomenological model of the frequency dependence of the elastic constants around the glass transition is the Havriliak–Negami (HN) model (58)

$$(G - G_\infty)/(G_0 - G_\infty) = 1/(1 + (i\omega\tau)^\alpha)^\beta \tag{44}$$

where G_0 is the relaxed modulus (the rubbery modulus in this case), G_∞ is the unrelaxed modulus (the glassy modulus in this case), τ is the average relaxation time, and α and β are dimensionless parameters with values between 0 and 1 that, roughly, describe the width and asymmetry of the glass transition.

One application of the HN equation is that one can demonstrate an empirical relation between the height and width of the loss factor peak at the glass transition. Using measured properties of a number of polyurethanes and calculations using equation 44, it was shown (59) that high loss factor peaks are narrow and broad peaks are low. A simple relation was found between the height and width of the peak in shear sound absorption per wavelength, $\alpha_s\lambda$, as a function of frequency—namely, the product of height times width is a constant equal to 1.5 decades of frequency. These relations are important in design of polymer treatments for sound absorption and vibration damping. An example of the above relations is shown in Figure 4.

It is commonly observed that the temperature and frequency dependence of polymer relaxations are related. This is expressed qualitatively as the time–temperature superposition principle, or the frequency–temperature equivalence,

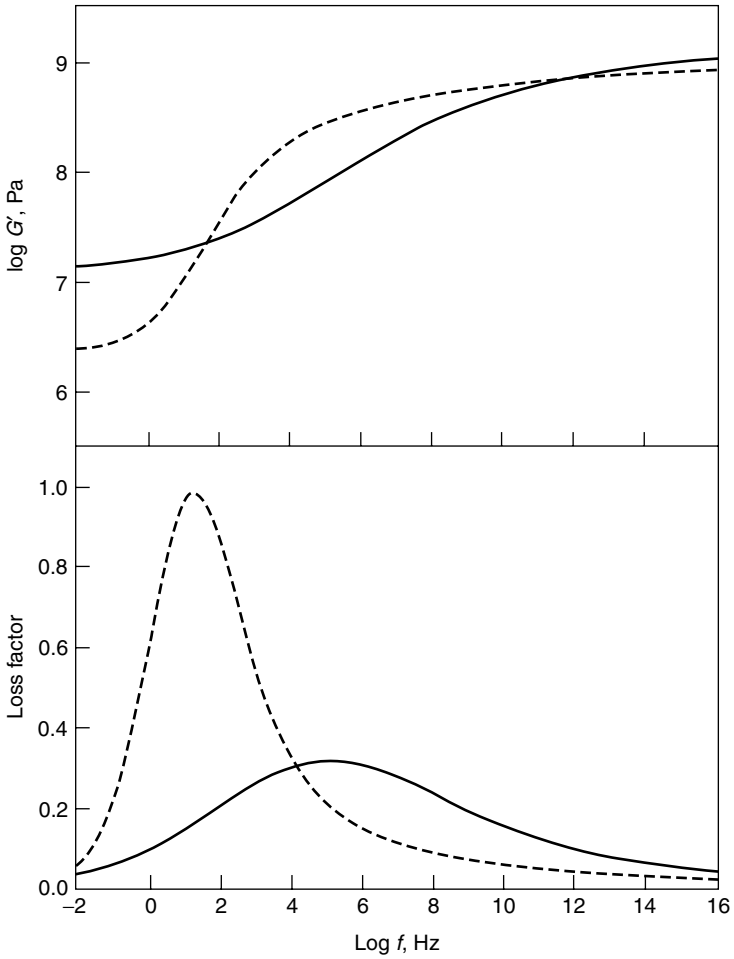

Fig. 4. Phase-separated polyurethane (solid line) compared with phase-mixed polyurethane (dashed line). The shear modulus and the loss factor are plotted as a function of frequency, through the glass-transition region. From Ref. 50.

or the method of reduced variables. A mathematical way to describe this behavior is to note that if the dispersion relation for the relaxation [eqs. 29,30, and 44] depends on frequency and temperature only through the product of frequency and a function of temperature, $\omega\tau(T)$, then the effect of a change in frequency is indistinguishable from a change in temperature. In other words, a measurement at low temperature is equivalent to a measurement at high frequency and a measurement at high temperature is equivalent to a measurement at low frequency—"equivalent" meaning that the same elastic constants and sound speeds are obtained. A material for which this equivalence holds is called thermorheologically simple. Polymers are thermorheologically simple to a greater or lesser extent. The principle is extremely useful as it allows a wide frequency range to be obtained by simply changing temperature; a frequency range that would be obtained directly only with great difficulty, if at all. A plot of modulus vs log frequency, such as Figure 2, is called a master curve.

The relation between temperature and frequency dependence is described by a function known as the shift factor, defined as the change in log frequency that is equivalent to a change in temperature. The most common analytical form of this equation is the WLF equation (3,60)

$$\log a_{\mathrm{T}} = -\frac{c_1(T - T_0)}{c_2 + (T - T_0)} \tag{45}$$

where a_{T} is the change in log frequency due to a change in temperature from a reference temperature T_0 to a measurement temperature T, and c_1 and c_2 are constants for a given polymer and reference temperature. [An extensive listing of c_1 and c_2 values is given by Ngai and Plazek (61).] This equation has been found to apply in general to polymers above their glass-transition temperatures. Below the glass-transition temperature, the Arrhenius equation has been found to be applicable (21)

$$\log a_{\mathrm{T}} = \frac{\Delta H}{R}\left(\frac{1}{T} - \frac{1}{T_0}\right) \tag{46}$$

where ΔH is the activation energy and R is the gas constant. The combination of a master curve and a shift factor curve then contains all of the temperature- and frequency-dependence information for the given polymer.

As the temperature of a polymer is raised through the glass-transition of a polymer, the moduli and sound speeds change from the high value of the glassy state to the low value of the rubbery state. There has been considerable study of the relation of the glass-transition temperature to the molecular structure of the polymer, which then relates to the elastic constants of the polymer. Examples include molecular weight, polarity, and steric effects (62). T_{g} increases asymptotically with increasing molecular weight according to the relation (63)

$$T_{\mathrm{g}} = T_{\mathrm{g},\infty} - A/M_{\mathrm{n}} \tag{47}$$

where $T_{\mathrm{g},\infty}$ is the glass-transition temperature at infinite molecular weight, A is a constant for each polymer, and M_{n} is the number-average molecular weight. The

presence of polar groups in the polymer increases the T_g. For example, poly(*cis*-1,4-isoprene) (natural rubber), with the chemical structure $-CH_2CH{=}C(CH_3)CH_2-$, has a glass-transition temperature of $-73^\circ C$ while polychloroprene (neoprene), with the chemical structure $-CH_2CH{=}C(Cl)CH_2-$, has a T_g of $-50^\circ C$. The substitution of a chlorine atom for a methyl group (with comparable size) raises the transition temperature. A correlation has been observed between the log of the average relaxation time τ in the HN equation and the reciprocal of the glass-transition temperature (64).

Secondary Transitions. Most acoustic studies of polymer transitions have been of the glass transition, but some work has been done on secondary transitions, ie, those occurring below the glass transition. One transition that has received a fair amount of study is the β relaxation in polycarbonate (65). The transition has an activation energy of 40 kJ/mol and arises from a combination of phenylene and heteroatom motion. This value, one-half to one-third the value for a glass transition, is typical of secondary transitions which involve smaller segments of the polymer. This study also found a correlation that often, but not always, exists between acoustic and dielectric measurements. The two sets of data fall on the same line and sometimes cover complementary frequency ranges. Activation energies for some secondary transitions are even smaller. The δ relaxation in poly(ethyl methacrylate), owing to ester ethyl group rotation, has an activation energy of only 9 kJ/mol (66). A study of the activation energy for the δ relaxation in polychlorotrifluoroethylene showed it to be 30 kJ/mol, and possibly associated with an uncoiling of the polymer chain. This work emphasized the usefulness of pressure as a complementary variable to temperature and frequency in the study of molecular relaxations in polymers (67).

Most of the polymers discussed so far have been linear and either amorphous or semicrystalline. The γ transition in some cross-linked epoxies is similar to that of linear polymers (68). The activation energy is 40 kJ/mol and is due to the motion of the glycol ether group.

In a detailed discussion of secondary transitions in glassy, amorphous polymers, it is shown that the β transition in polymethacrylates is caused by motion of the entire $-COOR$ group (69). This same study notes that the Arrhenius plot lines for secondary transitions of various polymers all converge to a common frequency, about 10^{13} Hz; this is the same type of empirical behavior observed for the glass transition (56).

Melting Transition. The final transition to be considered is the melting transition. Measurements at 12 MHz on linear polyethylene show that there is an absorption peak in the vicinity of the melting point and that the sound speed decreases rapidly in this region (70). Other studies show that the absorption peak does not shift with frequency and therefore is not a relaxational process (71); this type of behavior can indicate a fluctuation mechanism. The loss factor can be high in the molten region, but the shear modulus is very low. Therefore, polymers are not generally used in the molten state for damping applications.

Curing. Early measurements on polyesters, phenolic, and melamine polymers made during the curing process showed a significant rise in sound speed as the materials passed from the uncured stage, through the gel stage, to the fully cured condition (72). Absorption increased during the gel stage and then dropped in the fully cured stage (see GEL POINT). Increasing the cure temperature

increases the final sound speed and decreases the final absorption. Later work on epoxies has emphasized the difficulty in making such measurements because of temperature changes caused by the reaction exotherm, the increase of T_g, as curing proceeds, and the viscoelastic nature of the epoxies (73).

Most cure studies are done on solid polymers that have undergone various cure cycles. One study focused on the γ relaxation in diamine-cured epoxies (74). This relaxation is due to the motion of the glycol ether group, $-CH_2CHOHCH_2O-$, and is common to epoxies made with different resins and curatives. An advantage of the acoustic method is that the measurements can be made below T_g, so that the measurement process does not alter the molecular structure being measured. It was found that the absorption curve increased in height, width, and temperature as the cure temperature was raised. The activation energy was found to be dependent on the degree of cure, increasing from about 60 kJ/mol during the early stages of cure to as much as twice that value (depending on the curative) in the postcured state, as a result of steric hindrance (75).

In a curing study on resole-type phenolic, no correlation between sound speed and curing temperature was found, but both longitudinal and shear absorption decreased as the cure temperature increased (76). This behavior was related to a transition in the phenolic at about 70°C.

Another study considered the effect of cross-link density on the acoustic properties of some diamine-cured aliphatic epoxy polymers (77,78). In this case, the cross-link density was varied by altering the chain length of the aliphatic curative. The acoustic properties in the vicinity of the glass transition were found to shift—unaltered in shape—by an amount equal to the glass-transition temperature. Thus, a plot of sound speed and absorption vs $T-T_g$ gave universal curves for all polymers. In contrast, it has been shown that when the cure temperature and time are varied for another epoxy system, not only does the molecular relaxation shift, but there are also structural changes (79). Also, ultrasonic systems have been developed to monitor the cure of epoxy resins and to characterize the cure state. This is done by measuring the ultrasonic signal velocity and ultrasonic attenuation throughout the cure process (80,81).

Density. For organic liquids, it is observed that the higher the density, the higher the sound speed. Similar behavior is found with solid polymers. For polyethylene, a plot of extensional sound speed vs density is shown in Figure 5 (82). The data appear to be well represented by a straight line, though Rao's relation for liquids (eq. 41) would suggest that $v^{1/3}$ should be plotted, rather than v. The scatter in the data is such that it is inconclusive whether the linear or the cubic relation gives the best result (5,83). In the polyethylene studies, the chemical composition of the polymer was the same. Different densities resulted primarily from different degrees of crystallinity. Another study considered variations in chemical composition and plotted longitudinal sound speed vs density for 14 different polymers (52). Good correlation was found, except for the halogenated polymers. In a study of resole-type phenolic, it was found that the longitudinal sound speed correlated with density not only at room temperature, as the other studies had found, but also as a function of temperature, all on the same plot (76).

From a practical point of view, it is important to remember the correlation between sound speed and density when comparing data from different sources for the same polymer. As can be seen from Figure 5, even small changes in density

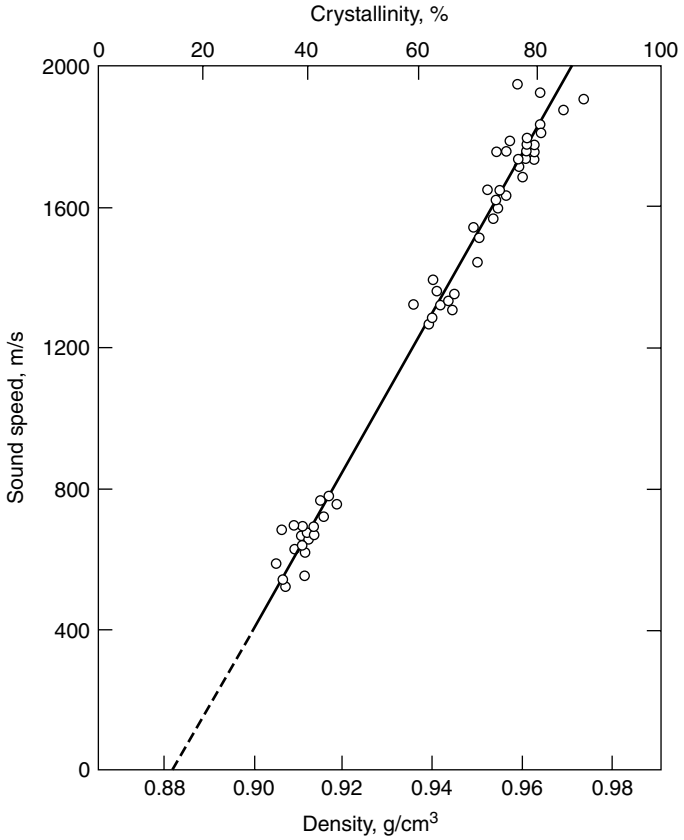

Fig. 5. Extensional sound speed vs density and crystallinity for polyethylene.

produce large changes in sound speed. This type of behavior was mentioned previously in connection with the effect produced in the vicinity of the glass transition. Also, because of the direct relation between density and crystallinity, sound speed measurements provide a means of measuring or monitoring polymer crystallinity.

From a fundamental point of view, sound speed can be said to depend primarily on volume because of the volume dependence of the intermolecular potential. Any mechanism that changes the volume of the polymer will change the sound speed by an amount determined by the volume change, and not by the mechanism producing the volume change. This is true for such diverse mechanisms as degree of crystallinity, branching, cross-linking, and temperature and pressure changes.

Sound Speed. A number of studies have been made on the effect of variations in molecular structure on sound speed. Replacing the hydrogen atoms in polyethylene with fluorine atoms lowers the sound speed, in line with the expectation that there will be a reduction in intermolecular attraction due to the larger size of the fluorine atoms (53). In this case, the sound speed also decreases because the polymer density increases. Similarly, in a series of poly(alkyl methacrylates), the sound speed decreases as the alkyl side-chain length increases (84). Again, there is a volume increase that reduces the intermolecular attraction.

The introduction of a phenylene group into an epoxy polymer structure raises the sound speed. These polymers and other phenylene-containing polymers, such as polycarbonate, polysulfone, and poly(ether sulfone), all have relatively high sound speeds (65). The aromatic ring imparts a conformational rigidity to the backbone structure of these polymers, which is responsible for the high sound speed.

So far, the molecular variations discussed were made in homopolymers. A number of studies have been made on multiple-component systems, either chemical combinations such as copolymers or physical combinations such as plasticized polymers. As an example of the former, the sound speed in copolymers of methyl methacrylate and methacrylic acid increases in a regular manner as the mole fraction of methacrylic acid increases (85).

Several studies have been made of the effect of various plasticizers (qv) on poly(vinyl chloride) (86–88). In addition to shifting the glass transition, the plasticizers lower the sound speed. Since the sound speed in the plasticizers is less than that in poly(vinyl chloride), this is not surprising. Water can be considered as a plasticizer. Its effect on poly(methyl methacrylate) is the lowering of sound speed expected from a plasticizer (89).

The sound speed in polymer blends (qv) varies with composition in a manner similar to that in copolymers. For blends of polystyrene and poly(vinyl methyl ether), the sound speed increases as the weight percent of the higher-sound-speed polystyrene increases, but the relation may not be linear because of phase inversion caused by polymer incompatibility (90) (see COMPATIBLITY). The effect of carbon black (qv) on sound speed in rubber is more complicated than in blends, but the qualitative effect is to increase the sound speed (91). In contrast, the addition of iron oxide to rubber decreases the sound speed (92). In this case, the higher density of the filler dominates, rather than the higher modulus. A decrease in sound speed is also observed when voids are present (79). In this case, the lower modulus of the voids dominates, rather than the lower density.

Additive Properties. Many of the studies cited have considered the effect on the sound speed, of substituting one component for another or an aromatic for an aliphatic. One is thus led to the possibility that there is a certain sound speed associated with each chemical component. This is indeed the case, as was first demonstrated for liquids, and then for solid polymers.

For liquids, it was empirically found that the Rao constant R of equation 41 was an additive property, which was expressed in terms of individual atom values (43). Since the measurements also showed that aromatic compounds have higher sound speed than aliphatic compounds, an R value was also assigned to the carbon–carbon double bond. It was later pointed out that better results are found by considering bonded atom groups such as C—H, C—C, O—H, etc (93). A further refinement was to use radical increments, $-CH_3$, $-CH_2-$, $-C_6H_5$, etc (94).

In an extensive account of the application of the method of additive properties to numerous polymer properties, component values determined from measurements on organic liquids were used and good agreement between predicted and measured sound speeds were found (42). This approach has now been applied to numerous linear polymers (45,46,95).

Results have also been obtained for the density and bulk modulus of crosslinked epoxies (44). Agreement is about the same as for linear polymers. Finally,

shear modulus has been related to an additive property (47). These results, along with the additive results for density and bulk modulus, show how both longitudinal and shear sound speeds are related to molecular components.

Biological Polymers. Although biopolymers are structurally and morphologically different from the polymers discussed so far, biopolymers are similar in their long-chain polymeric nature. Also, many of the techniques of studying other polymers apply to biopolymers. Perhaps the most common observation on the acoustic properties of biopolymers is that the absorption is a linear function of frequency, ie, a hysteresis absorption (96,97). Because of its appearance in very different biopolymers, hysteresis is presumed to arise whenever there is a broad spectrum of relaxation times (96), perhaps through the same mechanism postulated for other polymers (97).

In measurements on liver tissue, the absorption was found to be high, compared with blood, and sensitive to variation of protein structure (96). By making measurements on tissue that had successively more extensive destruction of the gross tissue structure, it was found that the absorption is largely independent of cellular and subcellular structure. Absorption occurs primarily at the macromolecular level. A comprehensive compilation of ultrasonic properties of mammalian tissues that gives absorption results for 30 different tissue types has been prepared (98). One conclusion of this work was that since tissue condition or preparation or both may influence ultrasonic properties, *in vivo* measurements should be encouraged. Most measurements in biopolymers have been made with longitudinal waves, but some data are available for shear sound speed and absorption (99). Some progress has been made in characterizing the pathological state of a tissue in a study that also examines hysteresis absorption and presents a theory in terms of a distribution of relaxation times (100).

The dynamic elastic properties of soft tissues, and methods of measurement (including acoustic techniques) are reviewed by Sarvazyan (101). The corresponding review for hard tissues is given by Lees (102). Propagation of acoustic waves in human tissue is of interest because acoustic waves, both at audio and ultrasonic frequencies, are widely used in medicine for imaging and identification of tumors. Recently, nuclear magnetic resonance techniques have been developed for imaging the propagation of shear waves in biopolymers (103).

Applications

In this section, results of acoustic measurements that are used directly in some applications are presented without molecular interpretation.

Sound Speed. Representative sound speeds measured at room temperature, ambient pressure, and at frequencies in the MHz range are given in Table 2, taken from various sources (49,76,85,87,104–106,108,109). (Abbreviations for polymers listed in Table 2 are given in Tables 3 and 4.). The longitudinal speeds vary from about 1000 to 3000 m/s, a range intermediate between that of metals (3000–6000 m/s) and that of liquids (900–1500 m/s). Shear speeds vary from about 700 to 1400 m/s, a range lower than the 1600 – 3300 m/s range for metals. Densities are also listed in Table 2 because the speed in a given polymer varies with density. Owing to the usual variations from batch to batch of polymer,

Table 3. Trade Names of Some Common Polymers

ABS	Generic abbreviation for a terpolymer of acrylonitrile, butadiene, and styrene
Cycolac	Poly(acrylonitrile–butadiene–styrene) or ABS (Marbon)
Delrin	Poly(methylene oxide) or polyformaldehyde (DuPont)
Kel-F	Poly(chlorotrifluoroethylene) (3M)
Kynar	Poly(vinylidene fluoride) (Pennwalt)
Lexan	Polycarbonate (General Electric)
Lucite	Poly(methyl methacrylate) (ICI)
Marlex	Polyethylene (and other polymers) (Phillips Petroleum)
Mylar	Poly(ethylene terephthalate) (DuPont)
Nylon	Generic description of a polyamide, including nylon-6 (polycaprolactam) and nylon-6,6 (polyhexamethylene adipamide)
Plexiglas	Poly(methyl methacrylate) (Rohm & Haas)
Teflon	Poly(tetrafluoroethylene) (DuPont)
TPX	Poly(4-methyl-l-pentene) (Mitsui)
Zytel	Poly(hexamethylene adapamide) or nylon-6,6 (DuPont)

Table 4. Abbreviations for Epoxy and Polyurethane Polymers

BDGE	Butanediol diglycidyl ether
BEPD	2-Butyl-2-ethyl-1,3-propanediol
D	Tri(2-ethyl hexoate) salt of tri(dimethyl amino methyl) phenol
DDA	Dodecanediamine
DEPD	2,2-Diethyl-1,3-propanediol
DETA	Diethylenetriamine
DGEBA	Diglycidyl ether of bisphenol A
DMPD	2,2-Dimethyl-1,3-propanediol
DOP	Dioctylphthalate
EMPD	2-Ethyl-2-methyl-1,3-propanediol
HDA	Hexanediamine
MBOCA	Methylene bis(*o*-chloroaniline)
MDI	4,4′-Diphenylmethane diisocyanate
MDIL	Modified MDI (liquid)
MPDA	*m*-Phenylene diamine
PDA	Propanediamine
PPG	Polypropylene glycol
PTMG	Poly(tetramethylene ether) glycol
PTMAB	Poly(tetramethylene diaminobenzoate)
RDGE	Resorcinol diglycidyl ether
TDI	Toluene diisocyanate
TETA	Triethylenetetramine
TMAB	Trimethylene-bis-*p*-aminobenzoate
Z	Aromatic eutectic mixture of methylene dianaline, MPDA, and phenyl glycidyl ether
13BDO	1,3-Butanediol
14BDO	1,4-Butanediol

Table 5. Temperature Dependence of Sound Speeds[a]

Polymer	$-dv_l/dT$, m/(s·K)	$-dv_s/dT$, m/(s·K)	Ref.

Polyethylene, high density	9.6	6.8	109
Polypropylene	15.0	6.7	109

[a]Measurements made in the vicinity of room temperature, at ambient pressure, and at frequencies in the MHz range.

the sound speeds given in Table 2 can easily differ by 1% or more from other measurements.

Table 2 is representative of the variation in speeds found from one polymer type to another. Considerable variations within one type can also occur. For example, within a series of epoxy polymers (47,77), the longitudinal speed can vary from 2000 to 3000 m/s. For poly(vinyl chloride), plasticizers (87) can lower the longitudinal speed from 2380 to 1490 m/s. The variation of sound speed with density (crystallinity) has already been mentioned (82) and is illustrated in Figure 5.

Many sound speed measurements in polymers have been made as a function of temperature, usually over a range of 100 K or less. Qualitatively, the speeds decrease as the temperature increases. Except in the vicinity of a transition, the decrease is usually linear and of greater magnitude than for metals. Representative values of the rate of decrease of sound speeds with temperature are given in Table 5. Measurements were made over a 300-K temperature range for poly(ethylene terephthalate) (111) and for styrene–butadiene–styrene block copolymers (112). Measurements for a series of polyimides were made over a 600-K range (113).

Cryogenic temperature measurements of both longitudinal and shear speeds have been made for many polymers. For polyethylene, polytetrafluoroethylene, polyformaldehyde (acetal resin), and polyamides (114,115) at low temperature, there is a plateau in the temperature dependence where sound speed becomes independent of temperature. All relaxation processes have become frozen out. For poly(methyl methacrylate), however, there is no plateau (116). Even at very low temperature, the methyl group attached to an ether link can rotate. Fluoropolymers also exhibit more complicated behavior (117). Some measurements in the range 0.2–2 K on two epoxy polymers indicate a peak rather than a plateau (118).

Measurements as a function of frequency are not common because of the experimental difficulties. Most data are available only at three or four frequencies

Table 6. Absorptions for Various Polymers[a]

Polymer	Longitudinal absorption, dB/cm	Shear absorption, dB/cm	Ref.
Poly(methyl methacrylate)	1.4	4.3	8
Poly(4-methyl-1-pentene)	1.4	6.7	105
Polyethylene, high density	3.3	25.0	8
Polyphenylquinoxaline	3.5	15.0	76
Phenolic polymer	4.1	19.0	76
Poly(ethylene oxide)	7.1		8
Polyurethane, polyether-based	7.5		49
Polyurethane, polybutadiene-based	9.1		49

[a]Measurements made at room temperature. ambient pressure, and a frequency of 2 MHz.

covering about one decade. Qualitatively, the speeds increase as the frequency increases. Longitudinal measurements on vulcanized rubber compounds at five frequencies from 0.04 to 10 MHz are available (119), as well as longitudinal and shear results for a nitrile–butadiene vulcanizate at 2, 5, and 10 MHz (120). By using time–temperature superposition, longitudinal and shear measurements at 0.5, 1, and 2 MHz as a function of temperature on an epoxy polymer have been extended to a very wide frequency range (121).

Measurements as a function of pressure are available in a few cases. Qualitatively, the speed increases as the pressure increases. Most studies have only gone as high as 200 MPa. Measurements have been made on polystyrene (122), poly(methyl methacrylate) (122), polyethylene (122), polyisobutylene (123), natural rubber vulcanizate (124), plasticized poly(vinyl chloride) (125), and polychlorotrifluoroethylene (67). Other measurements have been made up to 300 MPa for high density polyethylene (126), and up to 500 MPa for poly(methyl methacrylate) (127). Finally, measurements to 1 GPa have been made for polystyrene (126) and poly(methyl methacrylate) (128). For the latter, $dv_l/dp = 2.66$ m/(s·MPa) and $dv_s/dp = 1.07$ m/(s·MPa).

Absorption. Representative sound absorptions measured at room temperature, ambient pressure, and a frequency of 2 MHz are given in Table 6. The longitudinal absorptions vary from 1 to 10 dB/cm and the shear absorptions vary from 4 to 25 dB/cm. These values are higher than for metals. The measurements in Table 6 were not made near the glass transition; much higher values are found near the glass transition. For one epoxy, the peak longitudinal absorption at 2 MHz was 30 dB/cm (77). Rubber compounds typically have the highest peak absorptions. At 10 MHz, peak longitudinal absorptions vary from 150 dB/cm for butadiene–styrene rubber to 450 dB/cm for butyl rubber (91,119). Absorption measurements are sensitive not only to the temperature and frequency of the test, but also to the state of the polymer owing to such factors as plasticization (86,88,89,93) and crystallinity (71).

Absorption measurements as a function of temperature have been made over moderate temperature ranges for a variety of polymers, including vulcanized rubbers (91,119,120), poly(methyl methacrylate) (128), poly(4-methyl-l-pentene) (105), poly(acrylonitrile–butadiene–styrene) (ABS) (105), epoxy polymers (47,77),

polyphenylquinoxaline (76), phenolic polymer (76), fluoropolymers (53), polycarbonate (65), polysulfone (65), and poly(ether sulfone) (65). Measurements over a wide temperature range have been made for polyethylene (70) and polyimides (113).

Measurements as a function of frequency indicate hysteresis behavior when not in the vicinity of a transition (8,128). By using time–temperature superposition, a wide range of frequencies covering the glass transition of natural rubber has been obtained (124). Other frequency measurements, covering less than one decade, have been made for various polymers (65,89,91,120).

Measurements as a function of pressure have been made in a few cases. For poly(methyl methacrylate) (128), the hysteresis shear absorption at 1 GPa is about one-fourth of that at ambient pressure. For plasticized poly(vinyl chloride) (125), polyisobutylene (123), and natural rubber vulcanizate (124), upon the application of pressure, the glass transition peak shifts to higher temperature with a lower but broader peak.

Elastic Constants. For the polymers listed in Table 2 for which both longitudinal and shear sound speeds are given, the elastic constants have been calculated at room temperature, ambient pressure, and a frequency of 2 MHz; these are listed in Table 7. The moduli values are approximately 1 order of magnitude lower than those for metals. The range of Poisson's ratio values is somewhat higher than that for metals. A review of elastic properties of polymers is given by Hartmann (130).

In addition to the measurements given in Table 7, other data are available, including polyethylene as a function of density (crystallinity) (5); natural rubber vulcanizate compressibility as a function of temperature, pressure, and frequency (124); bulk and shear moduli as a function of temperature for various polymers (47, 53,131,132); and the pressure and temperature dependence of the bulk modulus of poly(methyl methacrylate) (128) and polystyrene (110).

Table 8 gives values of the real part of the extensional modulus (eqs. 3 and 5) and the loss factor. The values for most of the polymers are outside the glass-transition region, while the values for polyurethanes are typical of the glass-transition region. The high values of tan δ are of interest for sound absorption and for vibration damping.

Data on the frequency dependence of elastic moduli was obtained by Lagakos co-workers (129), who used different techniques to determine the Young's modulus E' both at kHz and at MHz frequencies. Their values for the frequency derivative of E' are given, for selected polymers, in Table 9. These values are typical for the region outside the glass transition.

In addition to chemical composition, the morphology of the polymer also affects the elastic constants. For example, the moduli of crystalline regions of a polymer are different from the amorphous regions of the same chemical composition. Also, especially in the polyurethanes, the degree of microphase separation influences elastic constants. In this case there are soft segments and hard segments (not necessarily crystalline) that are mixed or separated to varying degrees and this affects the elastic constants. An example is shown in Figure 4, where a phase-separated polyurethane (PTMG1000/MDI 3/BDO) is compared with a phase-mixed polymer (PTMG1000/MDI 3/DMPD). The data in this figure illustrates the general trend that a phase-mixed polyurethane will have low rubbery

on whether glass fibers (28) or carbon fibers (qv) (29) are used, C_{11} varies from 40 to 300 GPa and C_{12} is only about 5 GPa. The other elastic constants are generally intermediate. For the most part, the elastic constants are fiber-dominated.

The Gruneisen parameter, used in equation-of-state calculations, has been determined from acoustic measurements in a number of cases. For high density polyethylene (126), the Gruneisen parameter was calculated from the pressure dependence of the sound speed. It was found that γ varied from 3.5 to 5.5 over the

temperature range −55 to 15°C, in good agreement with the room temperature value of 5.1 found from the temperature dependence of the acoustically determined bulk modulus (109). For poly(methyl methacrylate) and polystyrene, little temperature dependence was found, both polymers having $\gamma \sim 4$. Other measurements of γ using the temperature dependence of the bulk modulus include 7.6 for phenolic polymer (76), 4.4 for polyphenylquinoxaline (76), 5.1 for poly(4-methyl-l-pentene) (105), 7.2 for poly(acrylonitrile–butadiene–styrene) (105), 5.2 for poly(methyl methacrylate) (128), 4.4 for polystyrene (110), and 11.0 for isotactic polypropylene (109).

Underwater Acoustics. Acoustically transparent materials are used in a number of underwater applications, including transducer windows, sonar domes, potting compounds, and hydrophone support structures. A commonly used class of material for these purposes is called Rho-C rubber (BF Goodrich trademark), because the impedance, $Z = \rho c$ (where c is sound speed), matches that of water. A disadvantage of Rho-C rubber is that it does not possess structural rigidity. A material sometimes used when rigidity is required is poly(acrylonitrile–butadiene–styrene). Transmission loss measurements from 100 kHz to 2 MHz, at room temperature, show that a 2-mm-thick sheet of ABS has a transmission loss at normal incidence that averages 1 dB (136). This is slightly higher than that for the rubber, but still low enough for most applications. ABS has more angle dependence than Rho-C rubber and thus does not have quite as large a field of view. Another rigid window material is poly(4-methyl-l-pentene), which, because of its low density (0.835 g/cm^3), has an impedance closer to seawater than does ABS. The calculated transmission loss for poly(4-methyl-l-pentene) is less than for ABS at normal incidence, but greater than ABS for incident angles greater than about 45° (105). Another approach to acoustically transparent structural materials is the combination of more or less flexible epoxy polymers with different types of microballoons (106). Sound speeds varying from 2890 to 1560 m/s are obtained. Many trade-offs are possible, depending on the transmission loss and rigidity required.

Acoustic lenses are used in applications such as high resolution sonar and underwater imaging for salvage, as well as for medical imaging, materials inspection systems, and ultrasonic microscopy. Three types of lenses are common: (*1*) single refractive element, liquid-filled lens, (*2*) single-element thin solid lens, and (*3*) two-element athermal solid lens (a low sound speed and high sound speed material in contact designed so that the focal length is independent of temperature over a wide range). The liquid lenses are limited to an angular resolution of 0.5° and have a temperature-dependent focal length. For single-element thin solid lenses of polyhexamethyleneadipamide, polyethylene, and polystyrene, as well as two-element athermal lenses of poly(phenylene oxide)–polydimethylsiloxane, beam widths on the order of 0.35° over a 30° field of view can be obtained (137). Even higher angular resolution has been achieved using a four-element solid lens, consisting of two doublets of polystyrene–polydimethylsiloxane (138). For this lens, a resolution of 0.2° over a 20° field of view with good temperature properties was obtained. Multilayer systems have potential use for both acoustic windows and lenses. Transmission loss measurements and calculations for one-, two-, and three-layer systems utilizing various polymers have been made (23,24).

Anechoic (echo-reducing) coatings to reduce tank-wall reflections are needed in many underwater acoustic test facilities. One effective design utilizes butyl

rubber loaded with metal particles (usually aluminum flakes) prepared so that the final product contains small gas pockets surrounding the particles (139). Even more effective than thin sheets of this material is a gradual transition from water to coating in the form of cones of the coating material. Although thicker than the sheets, the cone structure gives more than 25 dB echo reduction from 20 kHz to 1 MHz at normal incidence. Coatings for the 2–7 MHz range of interest in materials inspection and medical applications have made use of polydimethylsiloxane loaded with ferric oxide (a dense filler) and microballoons (both glass and phenolic) (135), as well as paraffin wax and polychloroprene (140).

For a parametric sonar receiver in water, the insertion of a polydimethylsiloxane cylinder in front of the receiver improved the parametric conversion gain by 20 dB and reduced the beam width by a factor of 2–3 (37).

Miscellaneous. Vibration damping is typically effected with a polymer used in the vicinity of the glass transition. Different temperature and frequency ranges are covered by using different homopolymers, blends, copolymers, plasticizers (qv), and other fillers. The application of time-temperature superposition to damping materials has been demonstrated for various polymers (141). One way of achieving a very broad transition region is through the use of interpenetrating polymer networks (142). The structure of interpenetrating polymer networks, and their acoustic and damping properties are reviewed in Reference 143. Data on the complex shear and Young's moduli for various commercial damping treatments are presented by Nashif co-workers (144). Closed-cell polyurethane foams (145) and solution blends (146) also have potential for broad application. See Reference 147 for a comprehensive review of this application (see also CELLULAR MATERIALS).

Airborne noise applications include acoustically transparent open-cell polyurethane foam (148) for use as a microphone windscreen, and acoustically absorbing polyurethane foam (149) for noise abatement. Polyester-based foam has superior mechanical properties and acoustical absorption, but poor humid aging. Polyether-based foam has better humidity resistance and is inexpensive, but has less absorption.

Also, some studies have been done on the effect of insonification on polymerization reactions. In one case, it was found that insonification produced a rapid increase in conversion during free-radical polymerization of methyl methacrylate (150).

A class of polymer materials that has extensive applications in acoustics and vibrations is that of electroactive polymers. In these polymers there is coupling between mechanical deformation and electric fields. An applied stress produces both strains and charge separation, which leads to an output voltage between opposite surfaces of the polymer. Conversly, an applied electric field produces strains in the polymer. The induced strain has a linear and a quadratic term in the applied electric field. The linear term is characteristic of piezoactive response and the quadratic term corresponds to electrostrictive response.

Examples of polymers that have a piezoactive response are poled poly(vinylidene fluoride) (PVDF) (151) and its copolymers with trifluoroethylene co(VDF-TrFE) (152), and the family of odd nylons (153) (see PIEZOELECTRIC POLYMERS). These are partially crystalline materials in which the crystalline regions have a permanent electric dipole moment. These polymers show ferroelectric switching behavior indicating that after poling they have a net

polarization. The piezoelectrically induced strain, linear in the field, for the fluorinated polymers is up to 0.3% for fields of 30 V/μm (0.8 kV/mil). Recent extensive measurements of the piezoactive coefficients for PVDF, including temperature and frequency dependence, are given in Reference 154. Applications of PVDF and copolymers include (155) high frequency loudspeakers, transducers (single and arrays) for generating and receiving ultrasound (for nondestructive testing and medical imaging), and acoustically transparent, small (point) size hydrophones for imaging underwater ultrasonic fields (156,157). Also, PVDF transducers are used as industrial acoustic and vibration sensors (154).

The strain dependence for electroded polymers that is quadratic in the field consists of two terms: one a Maxwell stress due to the attraction of free surface charge on the electrodes, and the other electrostriction, which is a change of dielectric function with strain (158), related to dipole moments induced by the applied electric field. This quadratic term occurs for all materials and does not require a permanent polar moment. A large ambient electrostriction of 4% strain has been reported for irradiated copolymers of VDF/TrFE (159), terpolymers of VDF/TrFE/CTFE (160), and for polyurethanes (161). For the case of the fluorinated copolymers the irradiation or the addition of the third monomer for the terpolymers is hypothesized to create defects and decrease the size of correlation of the polarization regions, allowing the dipoles more freedom to respond to the electric field. This results in large dielectric constants on the order of 80 (159). An electrostrictive strain of 4% deformation for polyurethanes has been measured by both optical (161,162) and capacitance methods (161,163). The frequency range for the electrostrictive response is found up to 1 kHz for polyurethanes. A space charge distribution is indicated as the electrostrictive mechanism for these polymers (164). The fluorinated terpolymers and copolymers are highly crystalline and can impart a higher stress than that of these lower-modulus urethane elastomers. Other dielectric elastomer systems that have been shown to have large electric field coupling yielding strains of 100% are acrylics and silicones. These polymers have a low modulus and their deformation has been shown to be accounted for by the quadratic Maxwell stress term (165). The design and performance of an underwater flextensional projector transducer based on an electrostrictive copolymer of VDF/TrFE is described by Z. Y. Cheng and co-workers (166).

Electrets are another type of electrically active polymer. These are materials that contain embedded electrical charges (155). Electret films are extensively used as membranes in microphones. The embedded electrical charges in the electret film eliminate the need to supply an external d-c bias voltage to the microphone.

Test Methods

A comprehensive review of measurement techniques is presented by Capps (167), who also gives data for the complex Young's modulus for a range of polymers. This data includes the rubbery, transition, and glassy regions, and parameters for time–temperature superposition (eq. 45). The measurement techniques fall broadly into three categories: wave propagation methods, resonance methods, and forced-vibration nonresonance methods. The resonance and forced-vibration

techniques are designed to measure directly the complex Young's and shear moduli, and the acoustic properties of the polymer are calculated from this data.

Wave-Propagation Methods.

Immersion Technique. A test method known as the immersion technique will be described in some detail. Other test methods will then be discussed in contrast to this method. The immersion technique is relatively simple to use and provides both longitudinal and shear sound speeds and absorption over a range of temperatures, generally in the MHz frequency range, to 1% accuracy in sound speed.

In this method, acoustic waves are generated by a piezoelectric transducer, which converts an oscillating electric field to a mechanical oscillation. Detection of acoustic waves that have traveled through a polymer specimen is done with the same type of transducer. Depending on its use, a transducer is called a transmitting transducer (transmitter) or receiving transducer (receiver). Common transducer materials are quartz and various polycrystalline ceramics, such as lead zirconate titanate (PZT), polarized in a strong electrostatic field.

Measurements are made by sending acoustic pulses, typically less than 1 ms duration, through a specimen. Pulses, rather than continuous waves, are used because it is easy to determine the time it takes for a pulse to go through a specimen by looking for the beginning of the pulse. In the immersion technique, the specimen, transmitter, and receiver are all immersed in a liquid. Pulses are sent from one transducer to the other both with and without the specimen in the path of the sound beam. From the changes in the detected signal when the specimen is removed, the speed and absorption can be calculated.

The specimen is in the shape of a circular or rectangular slab. When a specimen of lateral dimensions several times the acoustic wavelength is supported with its face perpendicular to the path of the sound beam, longitudinal waves are generated in the specimen (119,125,168). A variation of this method is to hold the specimen at an angle to the sound beam. In this way, both longitudinal and shear waves are generated in the specimen. If the angle at which the specimen is held is greater than the critical angle, the longitudinal wave is totally internally reflected and only the shear wave is propagated (29,86).

In a typical immersion apparatus, when making shear measurements, the specimen is rotated with respect to fixed transducers to obtain shear waves. In the apparatus described here, the transducers are rotated about the fixed specimen (109,169). Eight specimens are mounted on the periphery of a circle and are moved into and out of the path of the sound beam. Especially when making measurements as a function of temperature, it saves time when eight specimens are immersed at once.

PZT transducers, 2.5 cm in diameter, are used in this apparatus. The larger the transducer diameter at a given frequency, the better collimated the acoustic beam (170). In this case, at 1 MHz, the diffraction attenuation is negligible and specimen alignment is not critical. The resonant frequency of the transducer is proportional to its thickness, 0.25 cm, and is 0.75 MHz. The maximum output of the transducer is at its resonant frequency, but it can be operated below resonance without much loss, and can be operated at harmonics of the resonant frequency to obtain higher frequency measurements. In this manner, the apparatus has been

used to make measurements over the frequency range 0.1–10 MHz, though most of the data are taken at 2 MHz.

An ideal immersion liquid has a very low sound speed, is liquid over a wide temperature range, and is safe. A low viscosity silicone fluid was chosen for this apparatus. This liquid can be used to make measurements over the temperature range −50 to 150°C.

For measurements of the longitudinal speed the specimen is oriented with its face perpendicular to the sound beam. With the specimen between the transducers, the detected pulse is displayed on the oscilloscope and the position, for example, of the first peak of the pulse is noted. The specimen is then removed from the path of the sound beam. Since the speed in the immersion liquid is less than the speed in the polymer, the signal will take a longer time to reach the receiver, and the pulse will move to the right on the oscilloscope screen when the specimen is removed. The difference in transit times t for the specimen and for an equal thickness of liquid is determined from this shift in position. For a specimen of thickness L, the transit time is L/v_l, where v_l is the longitudinal speed of the specimen. The transit time through an equal thickness of liquid is L/v_{liq}, where v_{liq} is the speed in the liquid. Therefore,

$$\Delta t = L/v(\mathrm{liq}) - L/v_l \tag{48}$$

so that v_{l} can be calculated, since v_{liq} in this case (49,109) is given by

$$v(\mathrm{liq}) = 976 - 2.5(T - 25) \tag{49}$$

for v_{liq} in m/s and T in °C.

Shear speed is measured by rotating the transducers so that the sound beam strikes the specimen at an angle. At off-normal incidence, both shear and longitudinal waves are generated. When both waves are present, they overlap in the received signal and are difficult to separate. However, if and only if $v_{\mathrm{liq}} < v_{\mathrm{l}}$, there is a critical angle beyond which there is total internal reflection of the longitudinal wave, and only the shear wave propagates through the specimen. It is for this reason that a low sound speed immersion liquid is desirable. Shear speed v_{s} is calculated in a manner similar to that for v_{l}. The procedure is more involved only because the path length through the specimen is somewhat greater than the specimen thickness (109).

Longitudinal absorption is found by comparing the amplitude of the received signal with no specimen in place to that of the signal with a specimen held perpendicular to the sound beam. The amplitude will be less with the specimen in place, both because the absorption in the polymer is greater than in the liquid and because some of the sound energy is reflected when it strikes the specimen. The amount of reflection can be calculated so that the absorption can be determined (109). Shear absorption proceeds in a similar manner (109). Immersion apparatuses can be used to measure sound speeds to an accuracy of 1% or better, and absorption to 10% or better.

Delay Rod Techniques. In the delay rod technique, the acoustic path of liquid between the transducers and the specimen in the immersion apparatus is replaced with solid rods of quartz or metal (120). The purpose of the delay

rods (also called buffer rods) is to give enough separation between pulses that the complete pulse can be sent by the transmitter before the beginning of the pulse arrives at the receiver. This technique eliminates stray r-f pickup by the receiver. A very thick specimen could be used for the same purpose, but polymers are generally highly absorbing, so that thin specimens are necessary in order to detect the transmitted signal. Since there is no liquid to freeze, this technique has been used down to liquid helium temperature (114,115).

Two problems are encountered with the delay rod technique. First, there must be a good bond between the transducers and the delay rods and also between the delay rods and the specimen. Second, shear measurements cannot be made with the same transducers used for longitudinal measurements. Various bonding agents have been used. For longitudinal waves, silicone liquid, stopcock grease, and glycerin have been successfully used. For shear waves, which are more highly damped, the problem is more critical. A low molecular weight poly(α-methylstyrene) liquid and mixtures of phthalic anhydride and glycerol are effective. All of these bonding agents have the advantage of being relatively easy to remove so that the transducer can be recovered intact. An epoxy bond can give good coupling, but is difficult to remove.

Longitudinal and shear measurements are made separately with different sets of transducers. Quartz transducers are often used. Quartz crystals produce different types of vibrations depending on how they are cut. An X-cut quartz crystal is used for generating longitudinal waves. Y-cut or AC-cut quartz crystals are used to generate shear waves.

Speed and absorption measurements can be made in a similar manner to those in the immersion technique or by using a null method (114). In this method, the pulse input to the transmitter is split in two. The pulse that has traversed the specimen is then mixed with an out-of-phase signal directly from the pulsed oscillator. By properly delaying and attenuating the direct signal, a null is obtained. Using this technique, an accuracy of 0.5% in speed can be obtained.

Multiple Echo Techniques. In multiple echo techniques, pulses of sound that traverse the specimen are partially reflected at the face of the specimen and bounce back and forth with continually diminished amplitude. From the time it takes for the echo to travel from one face to the other and the reduction in its amplitude during this trip, the speed and absorption can be calculated. Since the pulse must make several trips through the specimen, this technique cannot be used for highly absorbing materials. On the other hand, the technique is very accurate.

In one version of this technique (171) that has been successfully applied to polymers (124), two transducers are bonded directly onto the specimen. Two independently controlled pulses are applied to the transmitter. The first pulse generates a series of signals at the receiver corresponding to the directly transmitted signal and its subsequent echoes. The second pulse generates a similar set of signals. The second pulse is then delayed and attenuated so that the envelope of the directly transmitted signal coincides with that of the first echo of the first pulse. By adjusting the frequency of the measurement, the coincident signals can be made to interfere destructively and cancel each other out. The required frequency depends on the transit time through the specimen and allows accurate determination of the transit time. Absorption is obtained from the

attenuation required to match the amplitude of the direct pulse with the first echo. Sound speed measurements can be made to an accuracy of 0.1% and absorption to ±1 dB.

Another version of the multiple echo technique (172,173) that has been used to make very accurate sound speed measurements in polymers makes use of a single transducer bonded directly to the specimen (110). Pulses are reflected from the opposite face and return as echoes to the front face. By adjusting the pulse repetition rate, an echo from a later pulse can be made to overlap a multiple echo from an earlier pulse. When the repetition rate is adjusted to obtain an in-phase condition, constructive interference will result in a maximum amplitude in the superimposed signals. A value of sound speed accurate to 0.05% can be obtained by observing several repetition rates that yield an in-phase condition at the transducer resonant frequency and by repeating the measurements at some other frequency, eg, 10% below resonance, and on other specimens that differ only in thickness.

Laser Ultrasonics. Ultrasonic waves can be both generated and detected in solids using lasers. Laser ultrasonic systems have been developed for measuring the velocity and attenuation of ultrasound in materials. A high-power pulsed laser is used to generate a broadband ultrasonic pulse, and the time of flight and amplitude of this pulse are measured at one or more points on the material, using a low power, continuous laser (174). The advantages of the laser system are

(1) The system is noncontact, so it does not load the sample and can be configured for fast scanning of the sample surface.
(2) The sound generation/detection regions are small, and the system can be modeled as a point source/point receiver system.
(3) The ultrasonic signals are broadband and the sound speed and attenuation are measured over a range of frequencies.

A disadvantage of the laser system is its relatively low generation and detection efficiency.

Brillouin Scattering. The scattering of light by sound waves, a phenomenon first suggested by Brillouin, has become a practical tool with the advent of the laser. Sound waves are present in solids as a result of collective thermal vibrations, called thermal acoustic phonons. Since the phonons have a velocity relative to the photons, the scattered light is Doppler-shifted by an amount directly proportional to the sound speed. Brillouin scattering is observed for both longitudinal and transverse (shear) phonons. The Brillouin scattered lines are, to a first approximation, Lorentzian in shape. The width of the line is related to the phonon lifetime, or absorption coefficient. Brillouin scattering is thus a method of measuring sound speed and absorption in the 1–10-GHz frequency range.

Measurements of Brillouin scattering using a Fabry–Perot interferometer have been made on poly(methyl methacrylate) and poly(vinyl chloride) as a function of temperature through the glass transition (175). Only longitudinal measurements were obtained with this arrangement; shear waves could not be detected. Improved measurement methods using multiple-pass Fabry–Perot interferometry have been demonstrated for polystyrene (176), poly(4-methyl-1-pentene) (177), and several other amorphous polymers (178).

Through the use of thin films 0.1–0.3 mm thick, Brillouin scattering was measured in nontransparent polymers, such as polyethylene and poly(ether sulfone) (179). This technique is also useful for studying shear waves in polymers.

Surface Acoustic Waves. All of the discussion so far has dealt with the propagation of acoustic waves in bulk polymers. In addition to longitudinal and shear waves, however, a surface or Rayleigh wave, called a surface acoustic wave, can also be propagated.

A surface acoustic wave probe for polymers has been developed (180). Periodic distortions in piezoelectric substrates are induced by application of r-f energy to sets of interdigitated electrodes laid down on the substrate by standard photolithographic and etching techniques. There are 50 finger pairs, each finger 1 miL wide, with 2 miL spacings between adjacent fingers. This device has a wavelength of 100 μm and an operating frequency of about 32 MHz. The probe has been used to detect melting, glass, and secondary transitions in thin films of various polymers.

Low Frequency Techniques. For measurements below about 100 kHz, different test methods have been developed. Progressive wave techniques have been used to measure waves in rubber rods or strips. The specimen must be sufficiently long so that there are no reflections from the end of the specimen. An electromechanical shaker is used to excite one end of the specimen and a phonograph needle pickup is moved along the length of the specimen. From the amplitude vs distance measurement, the absorption is calculated. From the phase difference between shaker and pickup, the speed is calculated. This type of apparatus is generally used to measure extensional waves, governed by Young's modulus, over a frequency range from 100 Hz to 40 kHz (181). A modification of this technique has been used to measure torsional waves, governed by the shear modulus, over a frequency range from 1 to 8 kHz (182). Since these measurements must be repeated at each frequency, this method is time consuming. The method is also limited in accuracy and the range of materials that can be measured.

A pulse technique for the kilohertz frequency range is described in Reference 17. In this method the sample was immersed in a large water-filled tank, and a large area projector and hydrophone were used, operated in a pulse mode. The longitudinal sound speed and absorption were determined from measurements of signal amplitude and time of flight. Measurements were made on a polyurethane rubber sample, $35 \times 35 \times 5.2$ cm, over the range 12.5–75 kHz and 3.9–39.6°C. (The water-filled tank is also designed to operate at pressures up to 100 psi.) Also, the dynamic shear modulus was measured, using a rheometer, and the dynamic bulk modulus was determined from the longitudinal and shear measurements.

Resonance Techniques. Resonance methods (183–185) are used for measurements below about 100 kHz. The complex modulus (usually Young's or shear) is determined over a limited frequency range at a number of fixed temperatures, usually over one to three decades of frequency and over the useful temperature range of the material. From the measured data, reduced frequency plots at constant temperature are generated by the application of the time–temperature principle (3). In these plots, the real and imaginary parts of the complex modulus are plotted over many decades of frequencies, typically, as many as six or more decades of frequency than were actually measured.

Resonance techniques have been extensively used to find polymers with high loss factors, for sound absorption and vibration-damping applications, and to

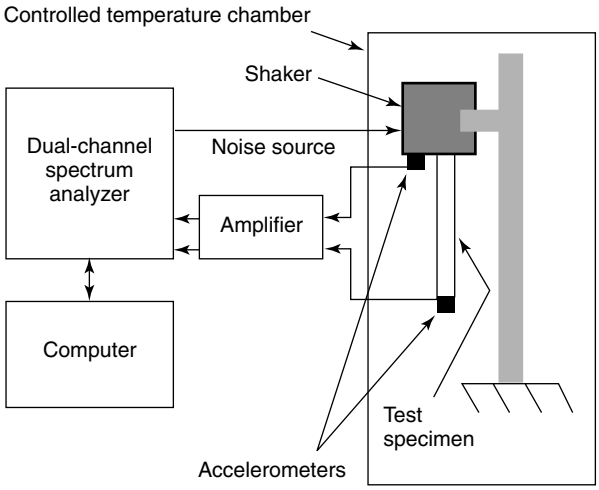

Fig. 6. Schematic diagram for the resonance apparatus.

determine relations between acoustic and elastic properties and molecular composition and morphology.

The complex dynamic Young's modulus can be determined from the response of a bar-shaped test specimen in a forced-resonance method (186). A shaker drives one end of the specimen (nominally 100 × 6 × 6 mm). Miniature accelerometers are used to measure the driving point acceleration at the shaker and the response of the test specimen as shown in Figure 6. The output signals from the accelerometers are analyzed by a dual-channel fast Fourier transform spectrum analyzer. The analyzer determines the acceleration ratio and phase difference of the two accelerometers, and also provides a random noise source to drive the shaker over a frequency range of 25 Hz to 20 kHz. The measured data are always sampled and rms-averaged at least 8 times, for low noise data, and up to 256 times, for noisy data. The displayed amplitude ratio versus frequency goes through a number of resonant peaks from which the sound speed (governed by the Young's modulus) and absorption (loss factor) are computed. The measurements are made over a temperature range of −60 to 70°C at 5° intervals.

The acceleration at selected locations on the sample can also be measured using a laser Doppler vibrometer (LDV) (187). The advantage of the LDV is that it is a noncontact measurement and does not disturb the vibration of the sample. Reference 187 describes a measurement setup that operates in the frequency range 500–2500 Hz, temperature range 0–40°C, and at pressures up to 500 psi.

Forced-Vibration Nonresonance Methods. In the forced, nonresonant method (183,188) sensors are used to measure the drive force and resulting displacement at one end of the sample. The complex modulus (shear or Young's) is determined from the amplitude ratio and relative phase of the force to the displacement. There are similarities between the resonance and nonresonance techniques. The complex modulus is measured over a limited frequency range at a number of fixed temperatures, and the time–temperature superposition principle is used

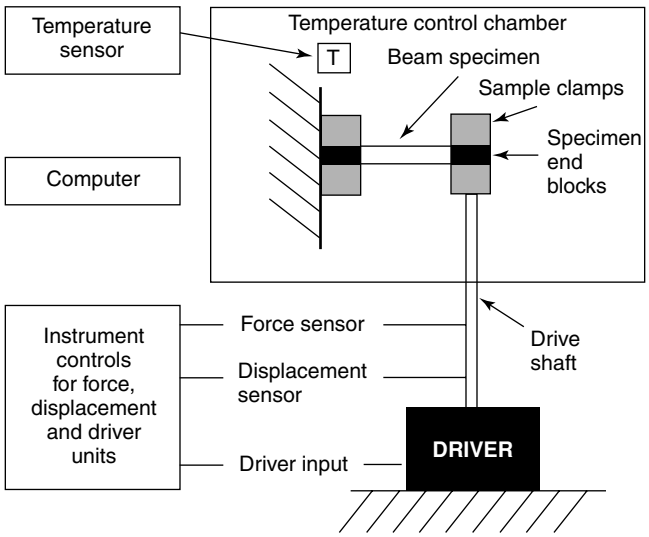

Fig. 7. Schematic diagram for the single cantilever beam apparatus for measurement of the complex Young's modulus. (A forced vibration nonresonance method.)

to generate a plot of the complex modulus over many decades of frequency. The applications of the data are similar.

In a forced, nonresonant method, the complex dynamic Young's modulus can be determined from the response of a beam mounted in a single-cantilever fixture (188) as shown in Figure 7. A thin sample (nominally $1.2 \times 10 \times 3$ mm) is clamped at both ends. One end is attached to a shaker through a driveshaft. The force and displacement are measured at the driven end at fixed frequencies. The low frequency/low mass bending solution is used together with the measured input impedance to infer the Young's modulus and loss factor. Sixteen discrete frequencies from 0.01 to 200 Hz are available, with an operating temperature range from -100 to 300°C.

ADSORPTION

Introduction

When a multicomponent system is exposed to an interface, there is a change in the concentration profile at the interfacial region. If the concentration of one or more of the components at interface increases, then these components are said to adsorb at that interface and the phenomenon is known as *adsorption*. Conversely, when there is a decrease in the concentration of one or more of the components at the interface the phenomenon is called *depletion*.

The extent of adsorption is quantified by the term *surface excess*, which has dimensions of mass/unit area. Figure 1 illustrates the concentration of the adsorbed species as a function of distance from the interface. The shaded area in Figure 1 is defined as surface excess. Mathematically it can be defined as follows:

$$\Gamma = \int_0^\infty [c(z) - c(\infty)]\, \mathrm{d}z$$

where $c(z)$ is the concentration at a distance z from the interface and $c(\infty)$ is the bulk concentration. Surface excess can be positive, zero, or negative.

Polymer Adsorption. The driving force for adsorption typically is the enthalpic interaction between the interface and the polymer segments. Exceptions include aqueous solutions near hydrophobic substrates. In that case, the driving force may include the hydrophobic interaction between water and the surface. The enthalpic interactions may be of various forms such as hydrogen bonding, interfacial tension, van der Waals attraction, polar interactions, and electrostatic attractions. This enthalpic interaction is offset by the loss in conformational entropy

due to localization of the adsorbed molecules at the interface. A balance of these two effects thus controls the extent of adsorption of a species.

Since a single chain is composed of many monomeric units, even a weakly attractive interaction between a monomeric unit and the interface gets amplified. For example, the surface–segment interaction energy for polystyrene on silica is of the order of 1.8 kT (1). If there are 100 monomeric units per chain that interact with the substrate, the net energy of interaction will be of the order of 180 kT. Because of such strong energetic interactions, polymer adsorption differs significantly from the phenomenon of small-molecule adsorption. Once adsorbed, a chain cannot easily desorb from the surface because that would require all the 100 monomeric units to leave the surface simultaneously. Consequently, the desorption rates of adsorbed chains into pure solvent are extremely slow and quite often the adsorption is irreversible. This leads to another salient feature seen in polymer adsorption, ie saturation of the surface at extremely small bulk polymer concentrations.

In the presence of an interface the conformation of the adsorbed chain gets modified. The structure of adsorbed polymer chains is defined by "trains," "loops," and "tails" (2), as shown in Figure 2. The segments of the chain that are in physical contact with the interface are called trains. Loops and tails are the parts of

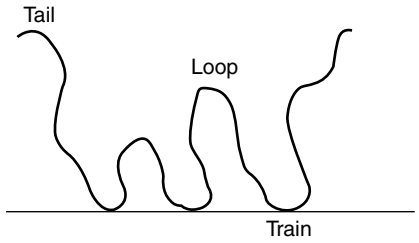

Fig. 2. Structure of an adsorbed polymer chain.

the chain that are not in direct contact with the interface. Loops are the portions of the chain between two trains, while tails are the parts that incorporate the chain ends. The presence of a train segment increases the enthalpic gain upon adsorption and the loops and tails reduce the entropic penalties upon adsorption. The equilibrium structure attained by the adsorbed chain will be a balance between these two forces. However, the structure of the adsorbed chain often does not reach thermodynamic equilibrium during the course of adsorption measurements because of the high energy barrier that has to be overcome for rearrangements in the adsorbed layer.

Techniques to Study Polymer Adsorption

The typical adsorbed amount in the case of polymer adsorption at a surface is of the order of 1–5 mg/m^2. Techniques needed to study adsorption have to be sensitive enough to detect the adsorbed mass. To increase the surface area and to improve the sensitivity of measurements, adsorption studies are done on dispersed particles where the surface area-to-volume ratio is high. Advances in instrumentation in the recent years have also resulted in the development of sensitive techniques that allow researchers to directly investigate adsorbed polymer layers on planar surfaces. In measurements of this type, the contribution from the molecules in the bulk is of the same order of magnitude as, if not lesser than, the contribution from the adsorbed layer, and it is possible to accurately account for the bulk contributions. These measurements provide important insights into the aspects of structure and dynamics of adsorbed polymers that could not be measured using dispersed particles.

Measurements on Dispersions.

Concentration Measurements. In the case of dispersed particles, the change in concentration (ΔC) of a known volume (V) of supernatant solution before and after adsorption is measured using techniques such as UV–vis and IR absorption spectroscopy. The surface excess is then related to the change in concentration as

$$\Gamma = \frac{\Delta C V}{A}$$

A is the surface area of the adsorbent. The accuracy of these measurements is limited by two factors: the sensitivity of the method used to measure ΔC and the accuracy in measuring the surface area of the adsorbent.

Scattering Techniques. The thickness of adsorbed layers can be determined using light, X-ray, and neutron scattering techniques (3). Quasi-elastic light scattering measurements on dispersion of particles measure the diffusion coefficients of particles in the dispersion. The size of these particles is related to the diffusion coefficient by the Stokes–Einstein equation. This measurement is performed on the dispersion with and without the adsorbed polymer. The difference in the radii in the two measurements is the thickness of the adsorbed layer. In these measurements it should be ensured that the particles in the dispersion are monodisperse and that there is no flocculation. In X-ray and neutron

measurements, the scattering intensity is measured as a function of the scattering angle, and the data can be modeled to determine thickness and volume profile of the adsorbed polymer chains. The experimental conditions are chosen such that the particles are invisible in the medium, so that only the adsorbed layer contributes to the scattering. This technique is called "contrast matching." In neutron scattering this is achieved by varying the isotopic composition of the solvent, while in X-ray scattering contrast matching is achieved by changing the atomic composition of the solvent. X-ray and neutron scattering can also be used to study adsorption in porous substrates.

Nuclear Magnetic Resonance (NMR) and Electron Spin Resonance (ESR). Nuclear magnetic resonance methods (4) can detect the changes in the mobility of adsorbed segments of the chain. The spin–spin relaxation time (T_2) and the spin–lattice relaxation time (T_1) are determined by the structure of the material and its state of motion. In liquids (mobile state) T_2 is almost equal to T_1. However, in the case of solids T_2 becomes very long. This difference in the behavior of T_2 due to components of the chain being in the liquid-like state (composed of loops and trains) and in the solid-like state (composed of trains) is used to estimate the fraction of the chain present in the form of trains. This fraction is called the bound fraction. Similarly, the solvent relaxation time can be used to estimate the bound fraction. The average solvent relaxation time is affected by the rate of exchange of the solvent molecules between the surface and the bulk. The presence of polymer segments on the surface can increase or decrease this rate of exchange. If the presence of train segments affects this exchange rate, the change in the solvent relaxation time can be used to estimate the bound fraction on the surface. Also, using high resolution NMR, it is possible to resolve the chemical shifts due to changes in the electronic environment of the chain segments near the interface. Using this shift, one can estimate the bound fraction in the adsorbed layer.

Electron spin resonance (5) measures the difference in the relaxation process between the segments in the loops and trains. The spectra of an adsorbed layer is deconvoluted into contributions from the loops, the tails, and the trains of the adsorbed layer by comparison with the spectra obtained in solution or melt state (mobile components) and on adsorbed oligomers at low temperatures (immobile components). It is also possible to measure the rotational correlation time of the mobile and immobile segments. The drawback of this technique is that a label has to be attached to the polymer and this might change the adsorption behavior of the chain.

Measurements on Flat Surfaces. The advantage of using flat surfaces is that adsorption measurements can be performed under well-defined conditions of surface energies and known surface area. The drawback is the increased sensitivity required of the measurement techniques.

Quartz Microbalance and Direct Microbalance Techniques. These methods provide direct measurements of the adsorbed mass. The vibration frequency of a quartz single crystal is very sensitive to the mass of the crystal. Upon adsorption, the vibration frequency shifts to lower values and the changes in the frequency can be related to the adsorbed mass. The surface excess can be determined by dividing the adsorbed mass by the surface area (6). Another method to directly measure the surface excess is the microbalance technique. In this technique, the

surface excess is estimated from the change is mass of a substrate of known surface area due to adsorption. Using microbalances capable of detecting changes of the order of 10^{-4} mg, researchers have been able to measure adsorbed amounts as low as 0.2 mg/m^2 (7).

Evanescent Wave/Spectroscopic Techniques. When a beam of light propagating in a medium of refractive index n_1 is incident on another medium of lower refractive index n_2, it will be completely reflected if the angle of incidence is greater than $\sin^{-1}(n_2/n_1)$. This phenomenon is called *total internal reflection*. Under these conditions, at the interface there exists an exponentially decaying evanescent electric field that can probe molecules that are present in the interfacial region. The penetration depth of this electric field can be determined by the wavelength of light, the incident angle, and the two refractive indices. This phenomenon is used in combination with FTIR spectroscopy to study adsorption on surfaces (8). The advantage of this technique is that *in situ* measurements can be performed, and changes in the adsorbed layer can be measured as a function of time. Typically, the penetration depth of the evanescent wave is much larger than the thickness of the adsorbed layer, and there can be a significant contribution to the absorbance from the bulk solution that has to be properly subtracted.

The same principles of total internal reflection can also be used to excite fluorescent chromophores attached to the polymer chain (9). The emitted fluorescence can be used to estimate the surface excess. In addition to subtracting the background signal, fluorescence quenching in the adsorbed layers may also have to be considered while estimating the adsorbed amount. The disadvantage of this technique is that the polymer chains have to be labeled with fluorescence molecules and that might influence the adsorption process.

Besides the adsorbed amount, it is also possible to measure the bound fraction of an adsorbed chain using IR spectroscopy. In order to do so there should be some distinguishable change in the features of the unbound and bound segments. Often there is a change in the absorption bands of functional groups upon adsorption to a substrate. This change in the IR spectra is due to physical and chemical interactions of the polymer with the substrate. For example, when poly(methyl methacrylate) adsorbs on an oxidized silicon substrate the carbonyl peak shifts to a lower wave number because of hydrogen bonding between the carbonyl and surface silanol groups (10). This change in the peak position can be experimentally resolved, and with proper calibration it is possible to estimate the bound fraction. Another method used to obtain structural information of the adsorbed layer is based on IR dichroism (11), where the ratio of absorption of p- and s-polarized components of light is measured. The dichroic ratio is defined as $D = A_z/A_x$, where A_z and A_x are the adsorptions parallel and perpendicular to the surface normal, respectively. For an isotropic chain, the dichroic ratio has a value of 1; however, if the dipole moments in the chain are preferentially oriented parallel to the surface, D is smaller than 1.

It is also possible to study exchange kinetics of the adsorbed polymers using these techniques. In the case of IR spectroscopy, exchange between deuterated and hydrogenated polymer chains at the surface can be studied as a function of time. From the rate of change in the specific absorption bands one can estimate the time constant for exchanging a chain in the solution with one on the surface. In the same way it is possible to study the kinetics of one species displacing another adsorbed

species on the surface. Similarly, fluorescence spectroscopy can be used as an alternate technique to study absorption kinetics. The fluorescent label is attached to one of the species, providing a contrast between the two adsorbing chains. The exchange kinetics is studied by monitoring the changes in the fluorescence signal as a function of time. Alternately, exchange kinetics at the surface can also be studied by fluorescence correlation spectroscopy (FCS) and fluorescence photobleaching recovery (FPR) techniques (12).

Reflectometry. Techniques described in this section are sensitive to the concentration profile of the adsorbed polymer chains. Optical reflectivity measurements are sensitive to changes in the refractive index in the adsorbed layer. Similarly, X-ray reflectivity is sensitive to the change in electron density in the adsorbed layer and neutron reflectivity is sensitive to the variation in the scattering length density in the adsorbed layer. In the last two cases it is possible to define an effective refractive index for the system. The variation of this refractive index in the adsorbed layer is used to obtain the concentration profile.

Ellipsometry is an optical technique that measures the changes in amplitude and phase of *s*- and *p*-polarized light upon reflection (13). These changes are related to the refractive index of the substrate and the thickness and refractive index of the adsorbed polymer layer. In order for this technique to work one needs a system with a high refractive index contrast between the surface and the adsorbed layer. By measuring these changes for different wavelengths of light and at different incident angles one can also determine the concentration profile of the adsorbed layer. Since this is an *in situ* measurement, ellipsometry can also be used to study adsorption kinetics as a function of time (14).

In the case of X-ray and neutron methods, the reflectivity is measured as a function of incident angle. The reflectivity data is then modeled as being made up of a number of layers varying in refractive index to determine the concentration profile (15). In the case of neutron reflectivity, the contrast can be provided using deuterated solvents. X-ray reflectivity is also most commonly used to study the thickness of dry films or adsorption at the air–liquid interface.

Hydrodynamic Measurements. Hydrodynamic methods rely on the fact that the flow of solvent past a surface having adsorbed polymers is different from the flow of solvent past an uncovered surface. The thickness measured in this technique is called the hydrodynamic thickness. The difference in pressure drop between a coated and uncoated capillary under identical flow conditions can be used to estimate hydrodynamic film thickness (16).

Surface Force Measurements. Another method to measure the thickness of adsorbed layers is by the surface force apparatus (SFA) (17). In this method two freshly cleaved mica sheets are glued to the surfaces of two crossed cylindrical lenses. Polymer chains are then allowed to adsorb on the mica sheets. In order to measure the thickness of the adsorbed layers the two cylinders are brought in contact and the force between them is measured as a function of separation. The onset of the repulsive force associated with compression of the adsorbed layer can be related to the thickness of the adsorbed layer. On the other hand, in the event of bridging between the adsorbed layers the force will be attractive. Recent advances in the instrument have made it possible to probe the effect adsorption has on the flow of fluid past a surface (18).

Adsorption at Solid–Liquid Interfaces

Adsorption of Homopolymers.

Adsorption Isotherms. Because of the strong tendency of polymer chains to adsorb at attractive surfaces, the surface gets saturated at very small bulk concentrations. Adsorption isotherms of this nature are known as "high affinity isotherms." The adsorption isotherm of polymer chains adsorbing on solid substrates depends on the polymer molecular weight, solvent quality, and polymer–surface interactions. Figure 3a illustrates the adsorption isotherms for polymer chains in a good solvent as a function of concentration. The surface excess
