The radical cation based polymers and oligomers described in the previous section may be viewed as possessing very compact radical ions, centered on boron or nitrogen. An alternative approach is to use short, readily dopable fragments of π-system, which are linked together with *m*-phenylene couplers into a conjugated polymer. The representative examples of such polymers and oligomers, reported by Dougherty and co-workers, are p-doped polyacetylene-based **9**, p-doped heterocyclic-based **10**, and electrochemically n-doped fuchsone-based **11** (36,37) (Fig. 4). Polymers **9** and **10** (DP = 15–30) and polydisperse oligomer **11** (DP ≈ 7) were obtained using polymerizations based upon Suzuki coupling or Wittig reaction. For **9** and **10**, chemical p-doping (I_2 or AsF_5) gave polyradicals with very low radical concentrations (0.002–0.18 radical/unit) and an average value of $S = 1/2$ to 3, at low temperatures. Studies of model oligomers, *m*-phenylene connected bithiophenes and bipyrroles, revealed that radical cations form diamagnetic dimers, as expected from previous reports on conducting polymers and oligomers by Miller

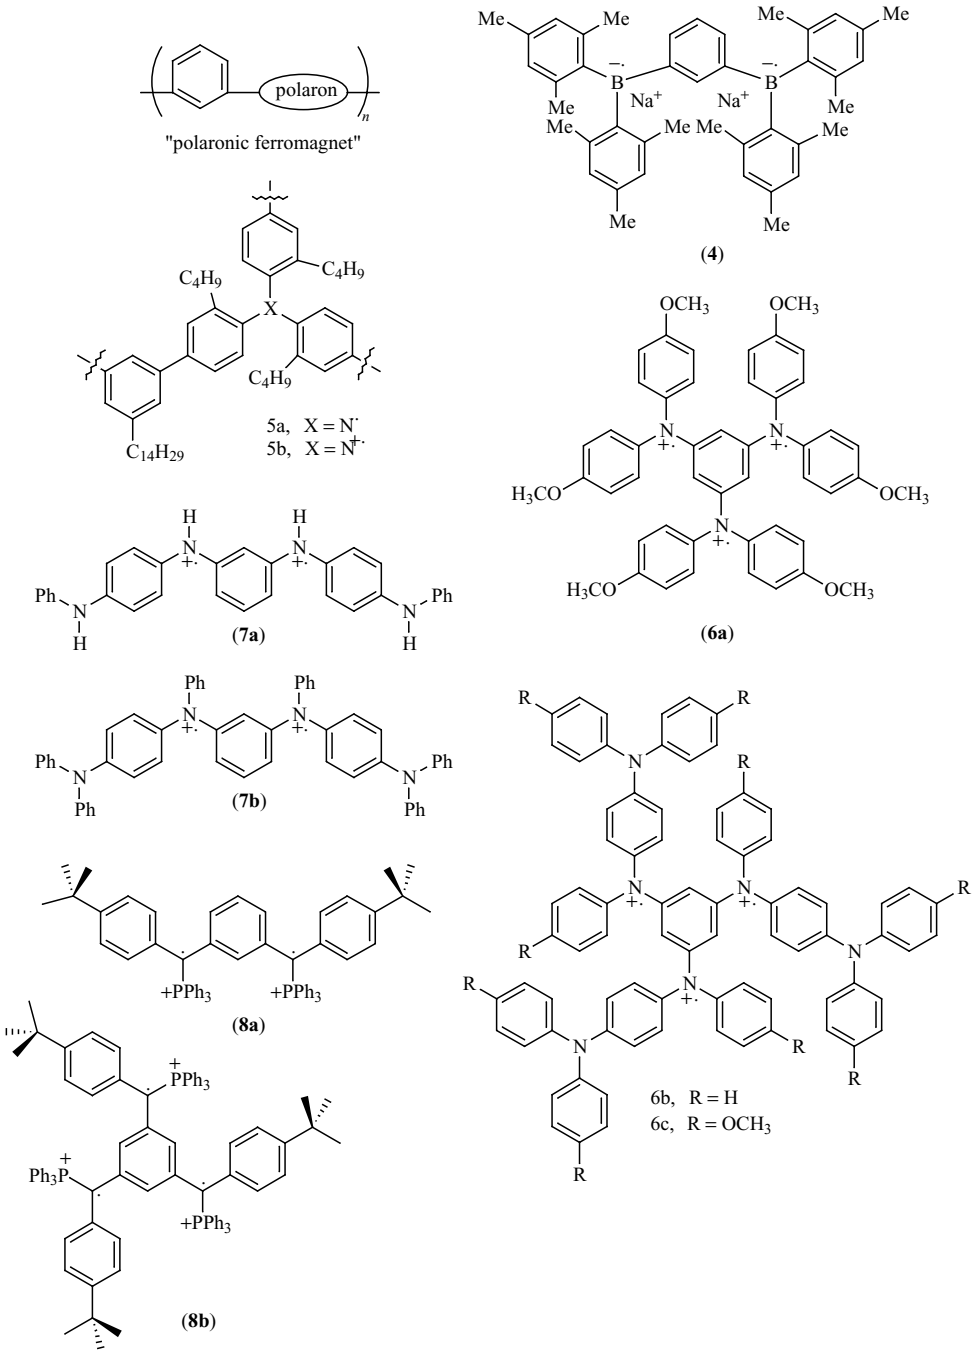

Fig. 3. Selected boron- and nitrogen-centered polaronic polyradicals.

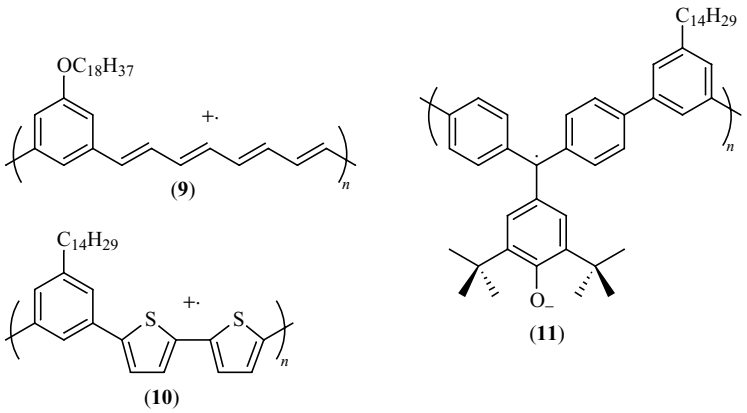

Fig. 4. Selected polaronic polyradicals with delocalized polarons.

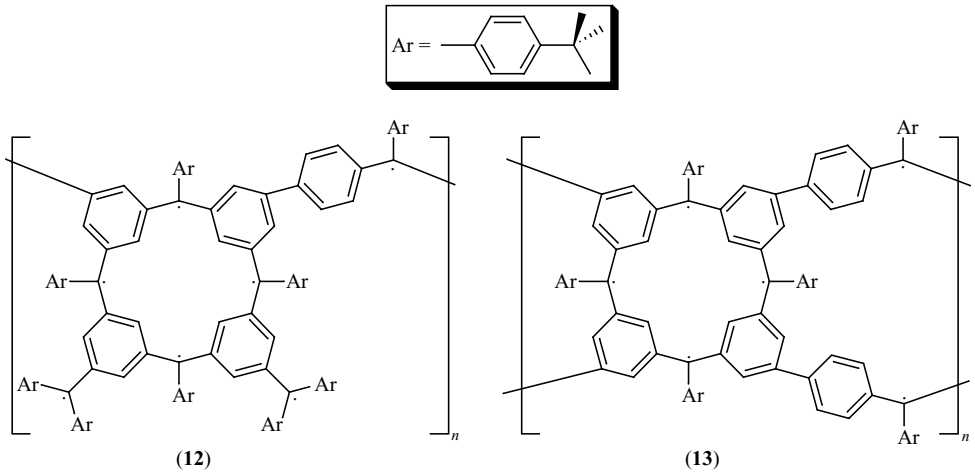
and co-workers (38); this behavior is detrimental to attaining high concentration of radicals or large values of S in p-doped polymers (39). For oligomer **11**, better-controlled electrochemical n-doping is allowed to reach radical concentrations of 0.5 radical/unit. Average values of $S \approx 2$ are reasonable in view of DP and radical concentration for **11**; the temperature dependence of magnetic moment vs temperature is also consistent with the expected strength of ferromagnetic coupling in this oligomer. Overall, oligomer **11** and Bushby's polymer **5b** are perhaps the most promising systems for "polaronic ferromagnet."

Considering difficulties involved in efficient generation and characterization of polyradicals based upon radical ions, neutral radicals remain the most appealing source of spin. Further improvements in through-bond ferromagnetic coupling in polymers were guided by the studies on model monodisperse polyarylmethyls (40). In polymers **12** and **13**, calix[4]arene macrocycles are linked with bis(biphenylene)methyls (Fig. 5). Polymer **12**, which was obtained from the corresponding poly(arylmethylether) with $M_w = 30$ kDa (MALS), had radical concentration of 0.4–0.6 radical/triarylmethyl and an average $S \approx 18$. The branching and/or cross-linking of calix[4]arene macrocycles lead to further improvements in value of S. Polymers **13**, which were obtained from the benzene soluble fractions of the corresponding poly(arylmethylether)s with $M_w = 300$–500 kDa, had an average $S > 40$ (41). Magnetic properties of polymers **13**, which were prepared from benzene insoluble fractions of the poly(arylmethylether)s, depended on polymerization time beyond the gel point. When polymerization is stopped near the gel point, polymer **13** had $S = 600$–1500; for longer polymerization time $S = 3000$–7000 was obtained. The radical concentrations for polymers **13** were approximately 0.5 radical/triarylmethyl (12).

For the first time in a conjugated organic polymer, magnetic properties beyond simple paramagnetism were observed in polymer **13**. The onset of magnetic ordering is observed near the temperature of 10 K for a typical sample with $S \approx 5000$. Overall, the magnetic properties of polymer **13** are between insulating spin glasses and blocked superparamagnets, but closer to spin glasses. The soft magnetic behavior in polymer **13** is similar to the known small molecule based organic magnets, though the ordering temperature in polymer **13** is relatively high (6–8).



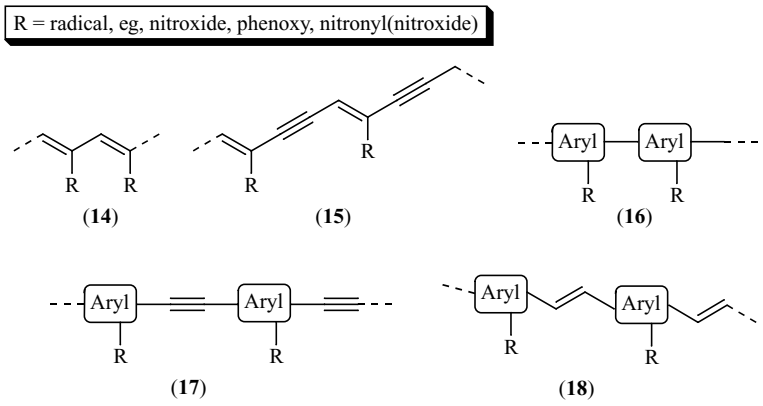
(**12**) (**13**)

Fig. 5. Calix[4]arene-based polyarylmethyl polymers.

Class II Polyradicals

Conjugated linear polymers, bearing multiple radicals as pendant groups, include several common π-systems as their conjugated backbones. Polyacetylene **14**, polydiacetylene **15**, various poly(arylene)s **16**, poly(aryleneethynylene)s **17**, and poly(arylvinylene)s **18** are among the leading examples (Fig. 6). Neutral stable radicals, such as phenoxyl, nitroxide, and nitronyl(nitroxide), are the most common pendant groups. Regioselective, typically head-to-tail, polymerizations are employed to attain the connectivity of the π-system, which is compatible with the ferromagnetic coupling. One of the advantages of pendant polymers is relatively straightforward synthesis.

Polyacetylene-based pendant polyradicals **14** were reported in late 1980s and early 1990s, as summarized in a recent review by Nishide and Kaneko (42). In



(**14**) (**15**) (**16**)

(**17**) (**18**)

Fig. 6. Polymers bearing radical pendants.

polyacetylenes, connectivity of non-Kekule π-system compatible with ferromagnetic coupling may be obtained by the attachment of conjugated pendant radical at the every other carbon of the polyene backbone (Fig. 6). Molecular weights (reported as either M_n or M_w) for many of such polymers were in the 10–100 kDa range, even for relatively bulky pendant groups, eg, galvinoxyl and diarylnitroxide. Although the radical concentrations were above 0.5 radical/unit in selected polymers, no ferromagnetic coupling was observed in any of the polyacetylene-based polymers (42). Most likely, severe out-of-plane twisting of the polyacetylene backbone, caused by the bulky radical pendants, prevents any significant exchange interactions (42). The magnetic properties of polymers **14** were compatible with $S = 1/2$ paramagnets (ie, independent, noninteracting spins-1/2).

Poly(diacetylene)-based polymers **15** (Fig. 6) were also studied but even for well-designed examples, such as polymers of 2-chloro-5-butadiynylphenyl *tert*-butylnitroxide, only low concentration of intact radicals were obtained, resulting in predominantly $S = 1/2$ paramagnetic behavior (43).

Availability of regioselective methods for polymerization of 3-substituted thiophenes and the efficient π-conjugation in the resultant polymers suggest that polythiophenes with radical pendant groups at 3-position are especially promising candidates for attaining polyradicals with $S > 1/2$ (44). Recently, three syntheses of poly[3-(3′,5′-di-*tert*-butyl-4′-oxyphenyl)thiophene] (**16a**) were reported (45–47) (Fig. 7). The $FeCl_3$-mediated and the Ni-catalyzed polymerizations of 3-(3′,5′-di-*tert*-butyl-4′-trimethysiloxyphenyl)thiophene and 2,5-dibromo-3-(3′,5′-di-*tert*-butyl-4′-trimethysiloxyphenyl)thiophene as monomers, respectively, gave polymers with M_w of 13 kDa (light scattering). However, the resultant polythiophenes lacked regioregularity and the magnetic characterization of corresponding polyradicals was lacking (45). Analogous $FeCl_3$-mediated polymerizations of 3-(3′,5′-di-*tert*-butyl-4′-methoxyphenyl)thiophene and 3-(3′,5′-di-*tert*-butyl-4′-methyloxymethoxyphenyl)thiophene gave only short oligomers (DP ≈ 6). Although the regioregularity was attained, the magnetic characterization of the corresponding polyradical (value of S, exchange interactions, yield of radicals) was not reported (46). Most recent $FeCl_3$-mediated polymerizations of 3-(3′,5′-di-*tert*-butyl-4′-acetoxyphenyl)thiophene gave polythiophenes with $M_n \approx 10$ kDa (GPC) and regioregularity reaching 96%. Although the radical concentration of 0.3 radical/unit was rather low, the average value of $S \approx 1$ was determined at cryogenic temperatures. Numerical fitting of the magnetic susceptibility data indicated a modest ferromagnetic coupling, which is comparable to that in a triplet ground state diradical with $\Delta E_{ST}/R \approx 100$ K (47). Similarly prepared poly(3-phenylgalvinoxylthiophene) (**16b**) had $M_n > 10$ kDa (GPC) and head-to-tail content of about 90% (Fig. 7). An excellent radical concentration of 0.9 radical/unit was attained but only $S = 1/2$ paramagnetic behavior was found (48). This is compatible with almost complete localization of spin density on the galvinoxyl moiety in the model monoradical **19** (48) (Fig. 7). Polythiophenes **16a** and **16b** doped with iodine showed a modest electrical conductivity (10^{-5} S·cm^{-1}) (47,48).

Another recent example of pendant poly(arylene) is poly(1,3-phenylene) (**16c**) (Fig. 7) (49). The Pd-catalyzed polymerization of *N*-*tert*-butyl-2,4-dibromoaniline and 1,3-phenylenebis(trimethylene boronate) gave poly(1,3-phenylene) with the DP of about 18 (GPC); oxidation of pendant secondary *tert*-butyl amine groups to the corresponding nitroxides yielded polymer **16c** with the radical concentration of

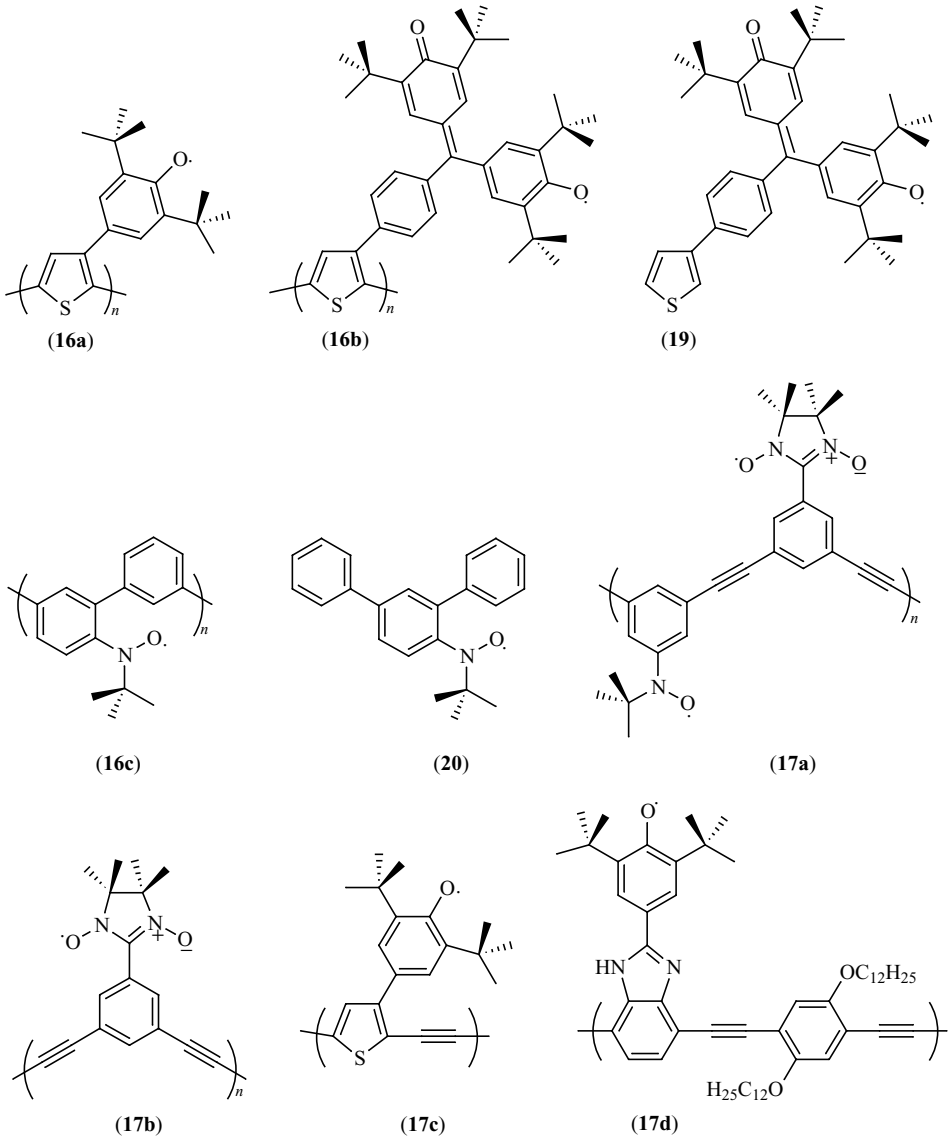


Fig. 7. Selected poly(arylene)s and poly(aryleneethynylene)s bearing radical pendants.

0.8 radical/unit. The X-ray crystallographic analysis of the model monoradical, *N*-*tert*-butyl-*N*-(2,4-diphenylphenyl)nitroxide (**20**) (Fig. 7), showed that the dihedral angle between the nitroxide moiety and the adjacent benzene ring is about 70°. This suggested that out-of-plane twisting of the pendant group might explain the failure to detect ferromagnetic coupling in polymer **16c** (49).

Various poly(aryleneethynylene)s **17** were recently reviewed by Miura (34). Because of mild reaction conditions for Pd-catalyzed C(sp)—C(sp^2) couplings, the polymerizations leading to poly(1,3-phenyleneethynylene)s **17a** may be carried

out with selected radical monomers, based upon stable radicals such as nitroxides and nitronyl(nitroxides) (Fig. 7). Even with the M_n values of 1–10 kDa and radical concentrations of about 0.8 radical/unit, no ferromagnetic coupling was detected (34). Similarly, the oxidative C(*sp*)—C(*sp*) couplings can be carried out on nitronyl(nitroxide) monomers, leading to poly(phenylenediethynylene)s with nitronyl(nitroxide) pendants **17b** (Fig. 7) (34,50). Poly(aryleneethynylene)s with phenoxyl-based pendant radicals **17c** and **17d** were prepared by polymerization of the corresponding phenol-based monomers, followed by oxidation of pendant phenols to phenoxyls (Fig. 7) (51,52). The M_n values of 1–10 kDa (GPC) were reported for the pendant-phenol polymers; however, no meaningful magnetic characterization was described for the corresponding polyradicals **17c** and **17d** (51,52).

Nishide and Kaneko reviewed numerous linear head-to-tail linked poly(1,4-phenylenevinylene)s and poly(1,2-phenylvinylene)s with pendant phenoxyls, nitroxides, galvinoxyls, and nitronyl(nitroxides) (42). For most of their polymers, molecular weights were in the 1–10 kDa range, radical concentrations were at about 0.5+ radical/unit level, and, most importantly, magnetic susceptibility measurements on neat powders revealed ferromagnetic couplings (42). The best example of such polymer was phenoxyl-based poly(1,2-phenylvinylene) (1,2-PPV) (**18a**) reported by Nishide and Lahti (53) (Fig. 8). Polymer **18a** had DP $\approx$ 17, radical concentration of $\sim$0.7 radical/unit, and an average value of $S \approx 2$ (53). For both polymer (**18b**) and the corresponding model triplet ground state diradicals (**21** and **22**), ferromagnetic couplings were measured; eg, $\Delta E_{ST}/R \approx 70$ K in **21** became only about 9 K in **22** (Fig. 8) (53). This suggested that polymer **18a** is very sensitive to defects, ie, pendant groups missing phenoxyl radical are likely to interrupt the through-bond ferromagnetic coupling.

In an attempt to increase the strength of ferromagnetic coupling, 1,2-PPV with 3,5-bearing phenoxyl radical pendants **18b** was prepared (Fig. 8). However, only oligomers with DP $\approx$ 4 and radical concentration of 0.5 radical/unit were obtained; their average value of $S \approx 1$ was disappointingly low (54). Although *m*-phenylene adequately mediates ferromagnetic coupling between phenoxyls (55), the model tetraradical **23** with the $S = 2$ ground state could not be prepared; magnetic studies of **23** revealed the radical concentration and an average value that are both similar to that of polymer **18b** (Fig. 8) (55).

Branched topologies of PPV backbone provide increased values of DP and S, compared to their linear chain counterparts. Branched polymer **24** had DP $\approx$ 70, radical concentration of 0.6 radical/unit, and an average value of $S \approx 7/2$ (Fig. 8) (56). Polymer **25** had $M_w \approx 32$ kDa (LS, 90 phenolic units), radical concentration of 0.4 radical/unit, and an average value of $S \approx 5$ (Fig. 8) (57).

Phenoxyl-based 1,2-PPVs, such as **18a**, **24**, **25**, are the most effective in mediating ferromagnetic coupling among all pendant polymers. Although the values of S for the best Class II polyradicals are still rather modest, their cross-linking via controlled incorporation of macrocycles should provide a very promising approach toward magnetic polymers (12,41,58). Another interesting course of study involves polaronic pendant polymers, as illustrated by model compounds **26** and **27**. Sugawara and co-workers prepared numerous model di- and triradicals that consist of a neutral radical(s) attached to a radical cation π-system (59–61). For example, in triradical **26**, the neutral nitronyl(nitroxide) pendants are connected

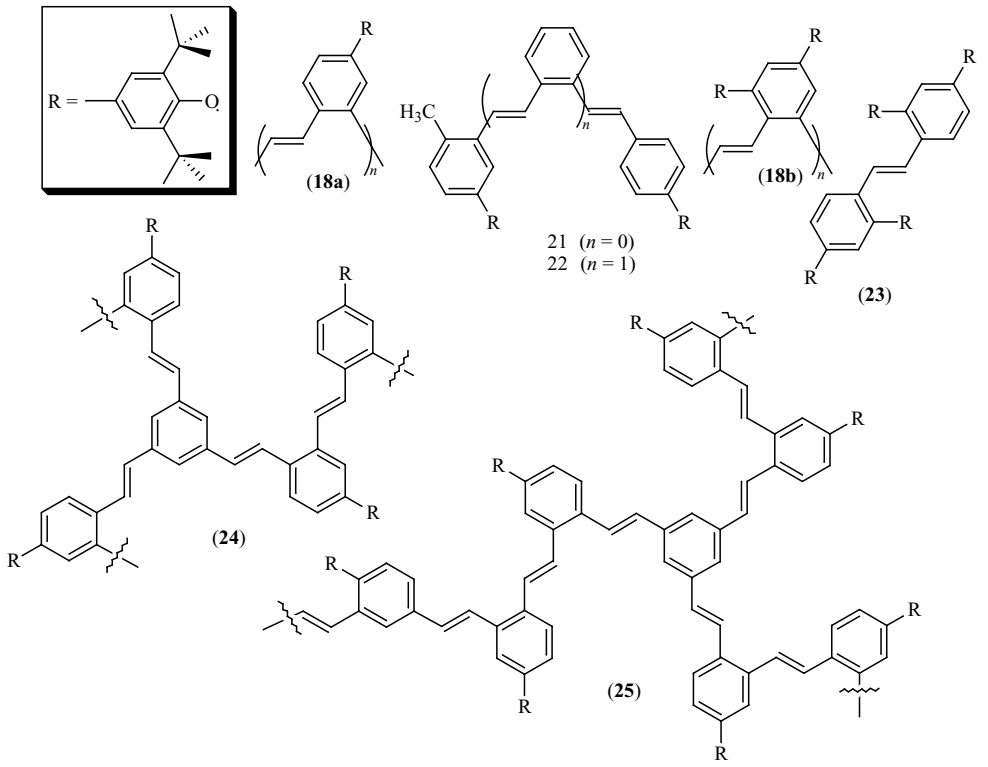

Fig. 8. Selected poly(1,2-phenylenevinylene)s bearing phenoxyl pendants.

to the polaronic (radical cation) thianthrene backbone (59). An alternative design was illustrated by van Meurs and Janssen; eg, in diradical **27**, the polaronic (radical cation) pendants are attached to the neutral 1,4-PPV backbone (62) (Fig. 9).

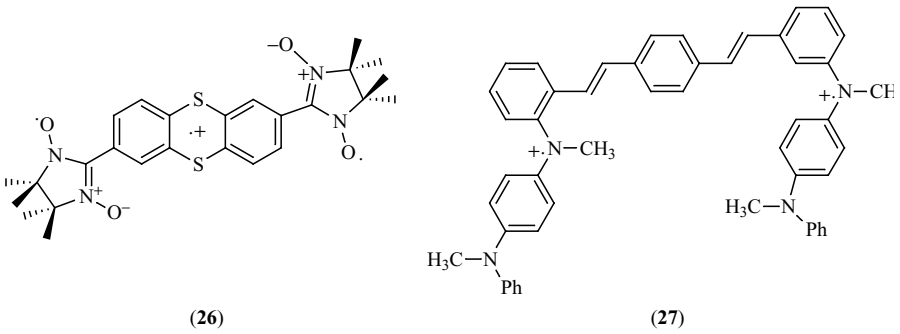

Fig. 9. Model triradical and diradical for polaronic pendant polymers.

Outlook

Among numerous designs for magnetic polymers explored so far, only a recently prepared highly cross-linked polyarylmethyls **13** showed magnetic ordering. The temperature of about 10 K, below which magnetic ordering was found, is relatively high among organic magnets. This suggests that the polymer approach to organic magnetism is very promising.

For a practical organic polymer magnet, both chemical stability and magnetic ordering at ambient conditions are important. However, polyarylmethyl-based polymer **13** has to be handled below 170 K and under oxygen-free atmosphere. Analogues of polymer **13**, where arylmethyls are replaced with ambient stable radicals, may provide the desired stability. Increase in temperature for magnetic ordering by more than an order of magnitude will require novel designs for magnetic polymers.

METAL-CONTAINING POLYMERS

Introduction

The development of organometallic chemistry in the 1950s has played an important role in the redefinition of polymer chemistry. While organic and inorganic polymers (qv) were previously the only two classes of macromolecules, the introduction of metals into polymers marked the beginning of a new field of research (see INORGANIC POLYMERS). The combination of polymeric and metallic properties has caused a surging interest in the development of metal-containing polymers over the past few decades (1–5). It is well known that depending on the elements and the types of bonding present, the properties of these polymers differ dramatically. The degree of polymerization and the nature of the metal also have strong influences on the properties of polymeric materials. It is the diverse array of electrical, electrochemical, magnetic, optical, and catalytic properties that define the applications of metal-containing polymers.

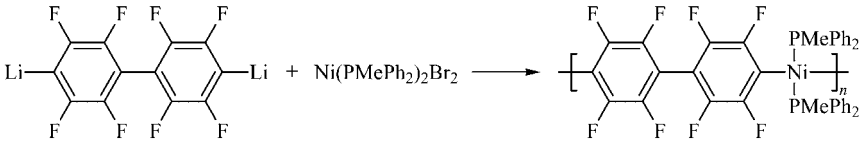
In recent years, many reviews have been dedicated to advances in the field of metal-containing polymers (6–14). Although this article classifies these polymers according to their structures, many of these polymers could have been included in more than one section. The aim of this work is to give an overview of the synthesis, properties, and applications of metal-containing polymers, with a focus on the developments that have taken place over the past two decades.

Metals in Polymer Backbones, σ-Bonded Systems

Polymers with metals σ-bonded to organic spacers in their backbones have been studied in recent years because of their electrical and optical properties (14,15). This class of organometallic polymers can be prepared via reactions occurring

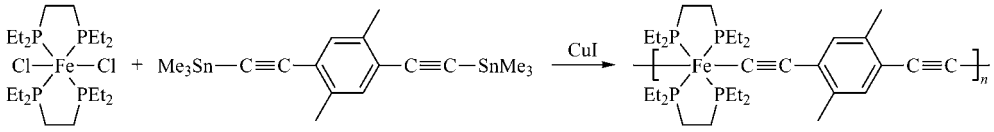
Encyclopedia of Polymer Science and Technology. Copyright John Wiley & Sons, Inc. All rights reserved.

at the metal center or at the ligand sites. Nickel complexes with bromo substituents (**2**) react with lithiated aromatic compounds (**1**) to yield the corresponding organonickel polymers (**3**) (eq. 1). The solubility of these polymers is low, and analysis of 3 indicates that their degree of polymerization is between 8 and 13 (16).



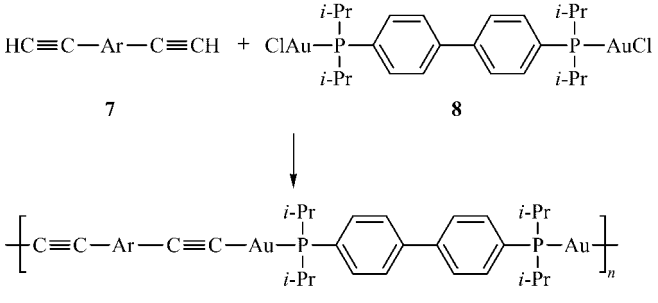
1 **2** **3** (1)

Many different transition metals have been incorporated into polymers containing C—C triple bonds in order to enhance metal $d\pi$–$p\pi^*$ back bonding, which is expected to contribute to π-electron delocalization (17–30). Although much of the research on organometallic acetylide polymers has dealt with Group 10 transition metals, the synthesis of acetylide polymers containing Ni (17), Pd (17–19), Pt (17,20–23), Fe (24,25), Ru (25,26), Os (25), Rh (23,27), Au (28,29), and Zr (30) has been reported. The incorporation of metals into polyynes generally results in materials with band gaps ranging from 2.4 to 3.2 eV, which is higher than that of many organic materials (<1 eV) (20). Lewis and co-workers demonstrated that incorporating alternating electron donor and acceptor groups into platinum acetylide polymers resulted in materials with band gaps below 2 eV (20). Equation 3 shows the synthesis of a rigid-rod iron acetylide polymer prepared via the reaction of a dichloro complex of iron (**4**) with a bistrimethylstannyl acetylide monomer (**5**), resulting in the formation of a conjugated polymer (**6**) with a weight average molecular weight of 173,000 (25).



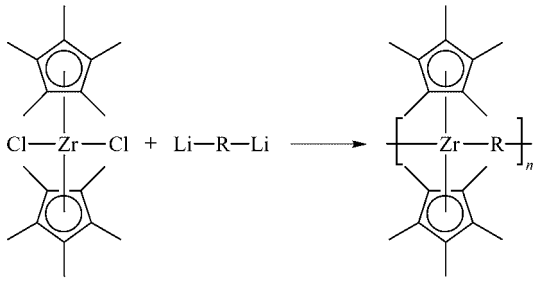
4 **5** **6** (2)

Reaction of terminal al kynes (**7**) with transition metal halides (**8**) in the presence of KOH has been used in the synthesis of gold-containing polymers (**9**) (28,29). It was found that the solubility of these polymers could be controlled through the choice of phosphine ligands at the gold centers.



7 **8** **9** (3)

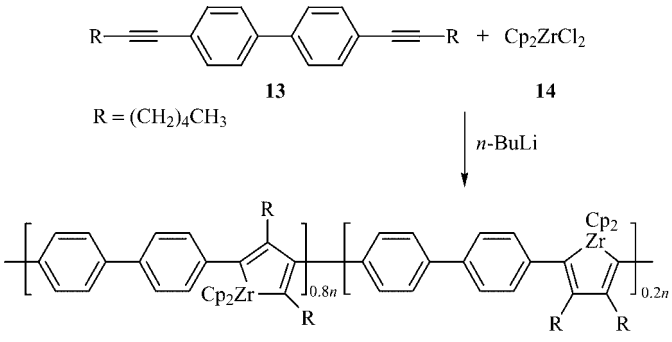
Oligomeric complexes containing metals σ-bonded and π-coordinated to organic groups have been prepared via palladium-catalyzed coupling reactions (24). The synthesis of zirconocene acetylene polymers (**12**) has been reported via the reaction (eq. 4) of bis(pentamethylcyclopentadienyl) zirconium(IV) dichloride (**10**) with dilithioacetylene or dilithiodiacetylene (**11**) R = C≡C or C≡C–C≡C (30). These polymers displayed poor solubility in organic solvents other than *n*-hexane, and their weight average molecular weights ranged from 55,000 to 68,000.



10 **11** **12** (4)

In 1973, the synthesis of titanium, zirconium, and hafnium polyesters via reaction of the dicyclopentadienylmetal dichloride complexes with disodium dicarboxylates in either aqueous or organic solvents was reported (31). Around the same time the synthesis of polyethers and amines of titanocene and polythioethers of zirconocene was also reported using similar methodologies (32,33).

Tilley and co-workers have reported the synthesis of polymers containing zirconacyclopentadiene rings in their backbones (34,35) (eq. 5). The zirconacyclopentadiene units were subsequently converted into organic functionalities while maintaining the integrity of the polymers. The synthesis of polymers containing cobaltacyclopentadiene groups within their backbones has also been investigated (36–39).

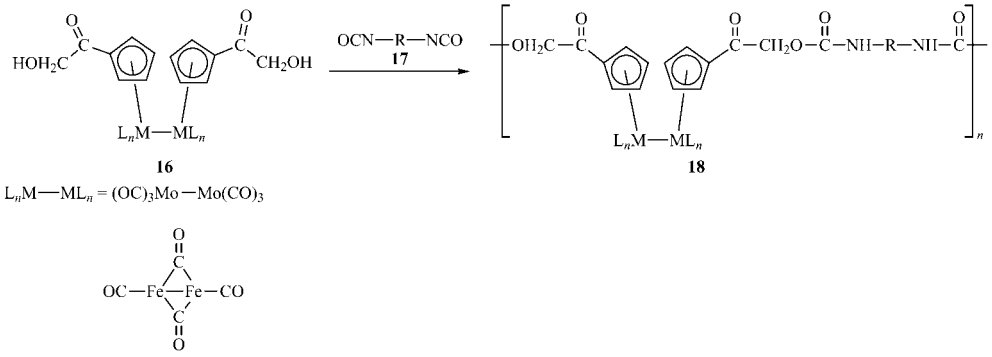


15 (5)

Polymers with Metal–Metal Bonds

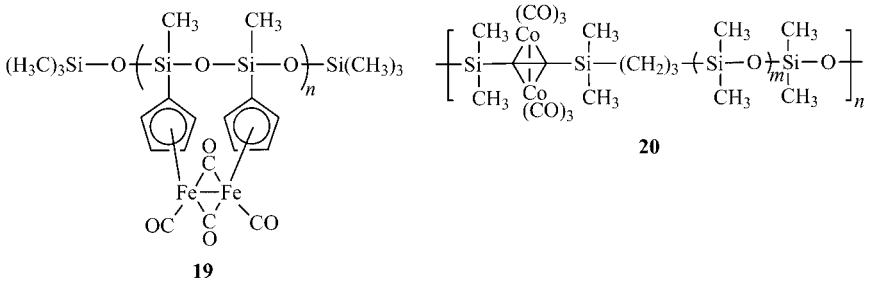
Polymers with M—M bonds represent a relatively unexplored area of organometallic polymer chemistry. This is in part due to the instability of M—M bonds; however, such classes of photoreactive polymers are important in the design of degradable plastics and medical supplies as well as lithographic materials. Tyler and

co-workers have developed photochemically reactive polymers (**18**) via condensation reactions of monomers containing Fe—Fe or Mo—Mo bonds (**16**) with organic monomers such as diisocyanates (**17**) (40–43) (eq. 6). The resulting polymers could be photolyzed, resulting in cleavage of the metal–metal bonds.

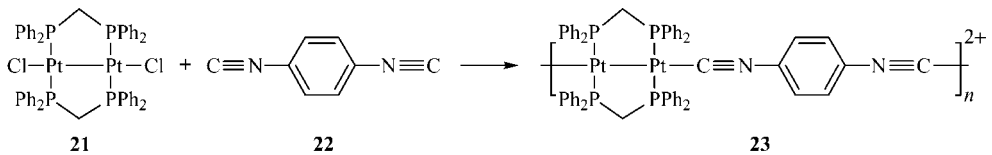


(6)

Cuadrado and co-workers have prepared a polymer with Fe—Fe bonds in its structure (**19**) via reaction of a polysiloxane with $Fe(CO)_5$ (44). The insoluble nature of this polymer indicated that cross-linking between polysiloxane chains occurred upon formation of the organoiron polymer. Silicon polymers containing Co—Co bonds (**20**) have been prepared via the reaction of $Co_2(CO)_8$ with the triple bonds of a silicon based polymer (45). Mixed metal systems were also described in which complexes containing arenes coordinated to chromium tricarbonyl were reacted with $Mo_2Cp_2(CO)_6$ or $Co_2(CO)_8$.

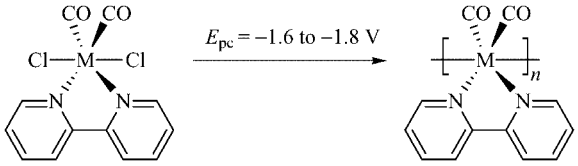


Polymeric materials containing Pt—Pt bonds in their backbones have been examined (46). The formation of platinum polymers (**23**) was achieved via reaction of the platinum complex (**21**) with diacetylides, diphosphines, or diisocyanides (**22**) (eq. 7).



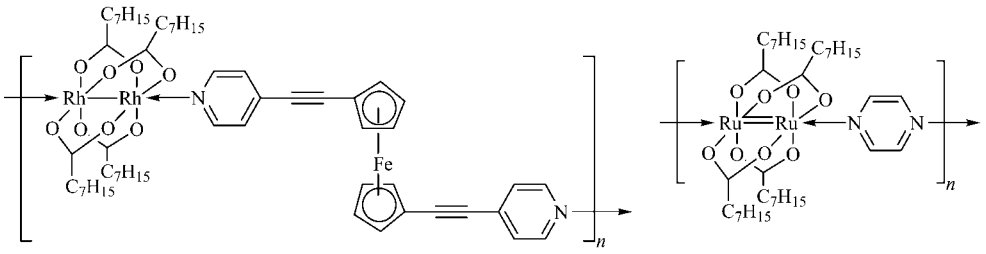
(7)

Polymers whose backbones consisted solely of metal–metal bonds have been synthesized by electrochemical reduction of ruthenium and osmium complexes (47,48). Reduction of $[M^{II}(trans\text{-}Cl_2)(bipy)(CO)_2]$ (M = Ru, Os) (**24**) to M^0 complexes generated a polymeric film (**25**) following loss of the *trans* chloride ligands (48) (eq. 8). Both the ruthenium- and osmium-based coordination polymers were selective for the reduction of carbon dioxide.



24 **25** (8)

Polymers containing metal–metal single (**26**) and multiple bonds (**27**) have also been prepared via reaction of bimetallic carboxylates with coordinating ligands (49–53). It has been found that polymeric materials containing Mo—Mo triple bonds crystallize from solutions of $Mo_2(O_2CCH_3)_4$ in bidentate ligands such as 1,2-bis(dimethylphosphino)ethane or tetramethylenediamine (53).

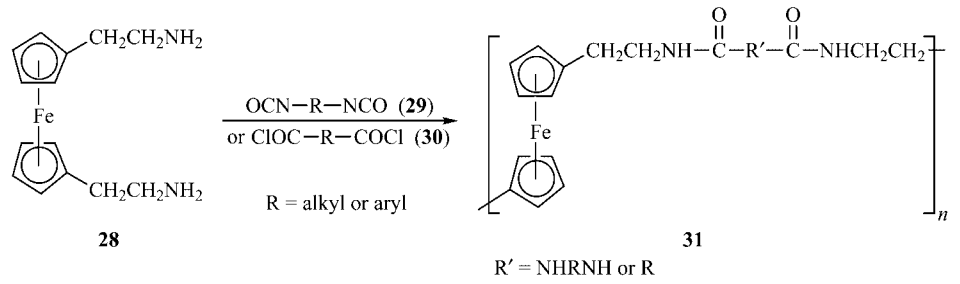


26 **27**

π-Coordinated Systems, Metallocene-Based Systems

Polymerization of ferrocene derivatives marked the beginning of a new era in polymer chemistry (54). In the early 1960s, Korshak and Nesmeyanov reported the synthesis of ferrocene-based polymers by reacting ferrocene with *tert*-butyl hydroperoxide (55,56). Neuse later reported that these polymers consisted of homoannular and heteroannular aliphatic ether-substituted units with number-average molecular weights less than 7000 (57). Methodologies using metal salts have also been implemented in the synthesis of polyferrocenylenes; however, these polymers had ambiguous structures and low molecular weights (58,59). The reaction of dihaloferrocenes with magnesium resulted in polyferrocenylenes with conductivities ranging from 10^{-2} to 10^{-4} S/cm (60–62). The conductivity of this crystalline polymer was higher than the conductivity of amorphous polyferrocenylene. In 1996, Nishihara and co-workers synthesized a soluble 1,1′-dihexylferrocene-based polymer and its electrochemical properties and photoconductivity were examined (63).

The synthesis and polymerization of a mercuriferrocene complex was reported in 1963 (64). Decomposition of this polymer gave 1,1′-diiodoferrocene or 1,1′-ferrocenedicarboxylic acid along with other products. It was later reported that poly(mercuriferrocenylene) could be converted to polyferrocenylene by reacting the poly(mercuriferrocenylene) with ferrocene at 245–260°C (65). Polymers prepared via reaction of ferrocenes functionalized with carboxylic acids, acid chlorides, alcohols, and amines have been utilized to synthesize condensation polymers containing ferrocenyl units in their backbones (54,66–69). In 1984, Rausch and co-workers reported the synthesis of polyamides and polyureas from the reaction of 1,1′-bis(β-aminoethyl)ferrocene (**28**) with diisocyanates (**29**) or diacid chlorides (**30**) (66) (eq. 9).

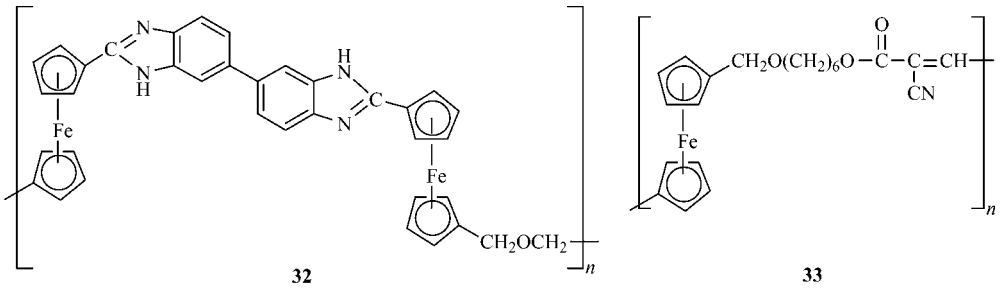


28 **31**

R′ = NHRNH or R

(9)

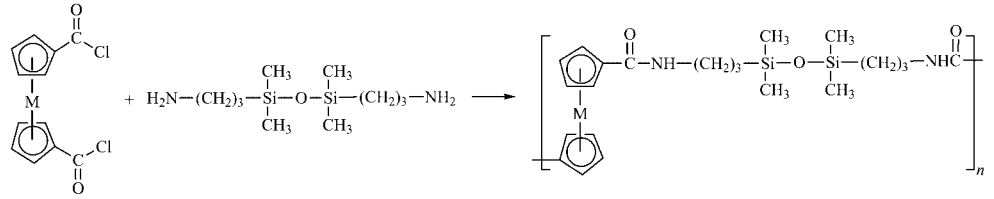
More recently, a soluble polymer (**32**) was prepared via reaction of 1,1′-ferrocenedimethanol with 4,4′-biphenyltetraamine in the presence of $[RuCl_2(P(C_6H_5)_3)_3]$ (70). Approximately 20% of the iron centers were found to be in the Fe(III) state as a result of oxidation by ruthenium complexes formed during the polycondensation reaction. Wright and co-workers have reported the synthesis of ferrocene-based polymers possessing nonlinear optical properties (**33**) (71–73). These polymers were formed by polycondensation of a difunctionalized ferrocene monomer (71).



32 **33**

Like their isoelectronic ferrocene counterparts, cobaltocenium units are resistant to strong oxidizing agents and possess interesting electrochemical behavior. The synthesis of polyesters and polyamides containing cationic cobalt units in the main chain has been reported (32,74–76). Sheats and Carraher reported the synthesis of cobaltocenium polymers containing tin, antimony, titanium, and zirconium atoms in their backbone via the reaction of the dicarboxylic

acid complex of cobaltocenium with the corresponding organometallic monomers (32,75). Cuadrado and co-workers prepared polyamides containing siloxane bridges (**36**) via condensation of 1,1′-bis(chlorocarbonyl)cobaltocenium hexafluorophosphate (**34**) with a siloxane-based diamine (**35**) (76) (eq. 10). This polymer displayed very limited solubility in polar organic solvents; however, the analogous ferrocene-based polymer had an M_n value of 10,600 (77). These ferrocene-based polymers were utilized in the production of chemically modified electrodes.

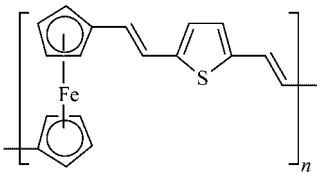


34 **35** **36**

M = Fe, $Co^+ PF_6^-$

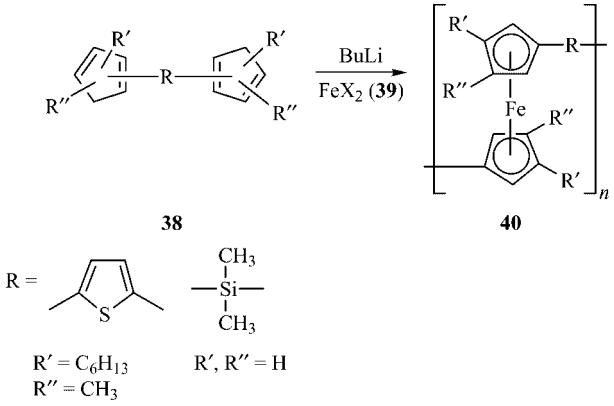
(10)

The synthesis of conjugated polymers containing ferrocene units in their backbones has received much attention in recent years (78–81). Bochmann and co-workers have described the synthesis of ferrocene-based polymers via palladium-catalyzed coupling reactions of dihalide or divinyl functionalized ferrocene monomers with aromatic spacers (**37**) (78).



37

Conjugated polymers have also been prepared via reaction of dilithio bis(3-hexyl-4-methylcyclopentadienide)arylenes (**38**) with ferrous iodide (82). Using a similar strategy, poly(ferrocenylsilane) was prepared by reaction of the dilithium salt of dicyclopentadienyldimethylsilane (**38**, R = $Si(CH_3)_2$, R′, R″ = H) with ferrous chloride (83) (eq. 11).

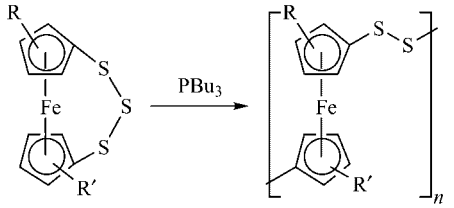


38 **40**

$R' = C_6H_{13}$, $R'' = CH_3$ R′, R″ = H

(11)

Reaction of 1,1′-ferrocenedithiol with diarylsilanes resulted in the formation of polymers containing sulfur–silicon bonds between the ferrocenyl units (84). These organometallic polymers exhibited good air and moisture stability. Ferrocene polymers containing disulfide linkages (**42**) have been synthesized by ring-opening polymerization (ROP) and desulfurization of [3]-trithiaferrocenenes (**41**) (85–87) (eq. 12). High molecular weight linear and network poly(ferrocene persulfides) were produced by reaction of the trithiaferrocenenes with $P(C_4H_9)_3$.

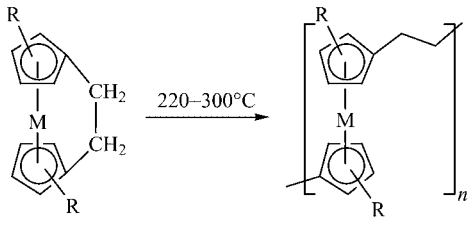


41 **42**

R, R′ = H, *n*-C_4H_9, *t*-C_4H_9 (12)

The ROP of [1]thia- and [1]selenaferrocenophanes has been accomplished thermally and in the presence of anionic initiators; however, the resulting polymers were insoluble (88). Methylation of the cyclopentadienyl rings of the [1]thiaferrocenophane, followed by ROP, allowed for the isolation of soluble poly(ferrocenyl sulfide). The cyclic voltammograms of these materials indicated the presence of two reversible oxidation processes, and it was found that these polymers possessed stronger Fe—Fe interactions than the analogous silicon-bridged materials (88). Polyferrocenes containing sulfide linkages were also prepared via thermal and cationic ROP of [2]carbathioferrocenophane (89).

Metallocenophanes containing hydrocarbon bridges have been polymerized thermally to give polymers containing insulating bridges between the cyclopentadienyl ligands (90–92) (eq. 13). It was found that if the R group in **43** was hydrogen, the resulting polymers were insoluble, whereas isomeric mixtures of **43** (R = CH_3) resulted in soluble polymetallocenes (**44**). Cyclic voltammetry of the poly(ruthenocenylethylenes) showed irreversible oxidation processes at 0.60 V, while poly(ferrocenylethylenes) underwent reversible oxidation processes at −0.27 V (92).

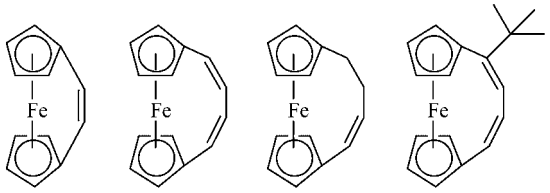


43 **44**

M = Fe, Ru
R = H, Me (13)

Ring-opening metathesis polymerization (ROMP) of ferrocenophanes containing bridging olefinic groups (**45**, **46** **48**) has been examined in order to synthesize conjugated ferrocene-based polymers (93–95). The polymers synthesized

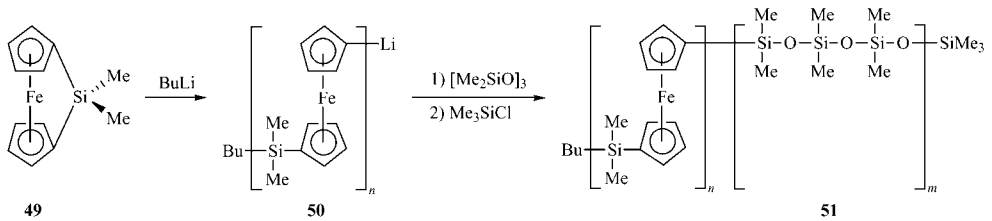
from ROMP of **45–47** were all found to be insoluble; however, copolymerization of **45** with norbornene enhanced the solubility of this polymer and its M_w and M_n were 21,000 and 11,000, respectively (94). The polymer synthesized from ROMP of the alkyl functionalized monomer (**48**) had a weight-average molecular weight in excess of 300,000 (95). Cyclic voltammetry of poly(ferrocenylvinylene) formed from **45** showed two reversible redox waves ($\Delta E = 0.25$ V), indicating interactions between the iron centers. The homopolymer formed from ROMP of **45** was more conductive than polymers of **46** and **47** (93).



45 **46** **47** **48**

The synthesis and properties of poly(ferrocenylsilanes) have been extensively reviewed (7,11,96). Thermal, anionic, and transition-metal-catalyzed ROP of [1]silaferrocenophanes has led to the production of polymers containing a variety of functional groups attached to the silicon atoms (96–102). The structures and morphologies of this class of polymer have been examined using X-ray diffraction, optical, atomic force, and scanning electron microscopy as well as other techniques (103–107). Pannell and co-workers have recently tested these materials as coatings for tapered optical-fiber gas sensors (108).

Anionic polymerization of a silicon-bridged [1]ferrocenophane using C_4H_9Li allowed for the preparation of living polymers which could be copolymerized with a number of different monomers (109) (eq. 14). The number-average molecular weights of polymer **50** ranged from 7700 to 21,000. Block copolymers containing dimethylsiloxane, ferrocenyldimethylsilane, and styrene groups with M_n values as high as 60,000 (PDI = 1.28) were also synthesized. All of the homo- and copolymers had two redox couples in their cyclic voltammograms, which were separated by 0.27–0.29 V. Thermogravimetric analysis of these materials showed weight losses beginning around 310°C, while differential scanning calorimetry showed that their glass-transition temperatures ranged from 103 to −127°C (109). Ferrocenophanes containing phosphorus (110–115), tin (116,117), germanium (118), and boron (119) bridges have also been polymerized.

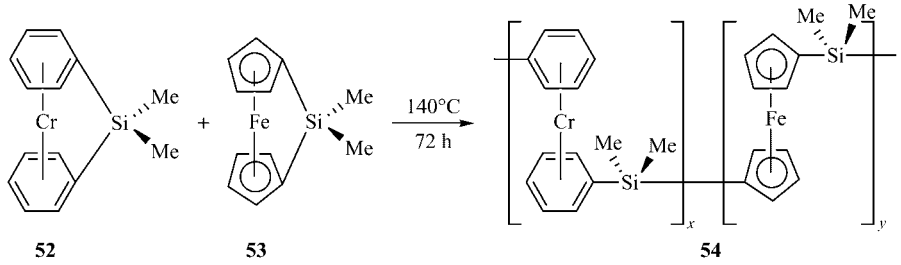


49 **50** **51**

(14)

Thermal ROP of the [1]chromarenophane (**52**) with the [1]ferrocenophane (**53**) led to the formation of copolymer **54** (eq. 15); however, ROP of **52** alone did

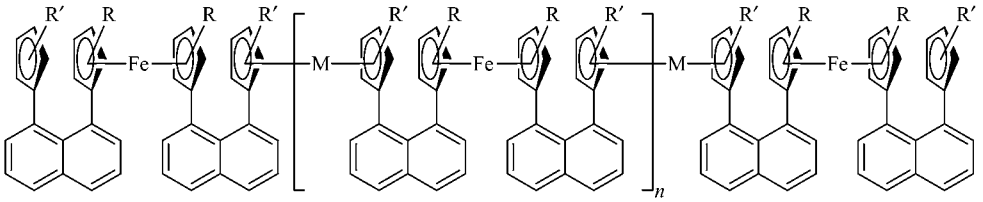
not allow for the isolation of the corresponding chromium polymer even though this monomer had significant ring strain (120).



52 53 54

(15)

Multidecker transition metal complexes have been the focus of many investigations in light of their electrical and magnetic properties (121–126). Optically active cobalt-based systems have also been prepared by Katz and co-workers (126). Rosenblum and co-workers have described a number of different routes allowing for the generation of face-to-face polymetallocenes (121–123). One methodology involved the palladium-catalyzed cross-coupling reaction of 1,8-diiodonaphthalene with metallocenylzinc chloride (M = Fe, Ru) (122). High molecular weight, soluble face-to-face polymetallocenes were isolated by incorporating alkyl groups on the cyclopentadienyl rings (121–123). The face-to-face polyferrocene had a molecular weight in the range of 18,000 when R = H, R′ = 2-octyl, while the molecular weight of **55** when R = R′ = 2-octyl was 139,000 (121). The conductivity of polymer **55** (R = H, R′ = 2-octyl) upon doping with I_2 was 6.7×10^{-3} S/cm (122). Polymers incorporating nickelocene and cobaltocene units were also synthesized; however, the solubilities of these materials were quite low. The magnetic susceptibilities of the Ni \Fe and Co \Fe oligomers were $3.51\mu_B$ and $5.2\mu_B$, respectively, while a nickelocene-based polymer had a magnetic moment of $5.3\mu_B$. In all cases, the values obtained for the polymetallocenes were greater than those of either nickelocene or cobaltocene.



M = Fe, Ni, Co
R, R′ = H, alkyl, aryl group

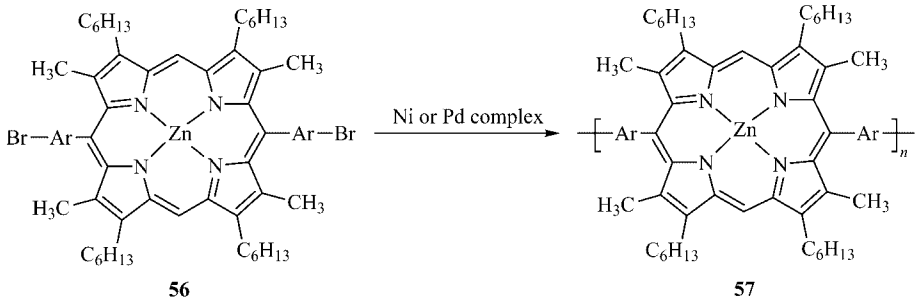
55

Grimes and co-workers have reported the synthesis of polymetallacarborane staircase oligomers containing cobalt, nickel, and ruthenium (124,125). Oligomers with up to 17 metal atoms were prepared, and electrochemical analysis of these materials indicated that although there was evidence for electron delocalization within the tetradecker stacks, there was very little intersandwich electronic communication (124).

Coordination Polymers

Conjugated polymers containing metal porphyrins in their structures have potential use in optical and electronic devices, solar energy conversion, and as enzyme mimics (127–131). High molecular weight polymetalloporphyrins are often difficult to isolate because of the poor solubility of these rigid materials. As well, the bulkiness of metalloporphyrins can inhibit the formation of an extended π-conjugated system. Many researchers are working on the synthesis of high molecular weight, soluble metalloporphyrin polymers that have good film-forming properties (127–130).

Yamamoto and co-workers have studied the synthesis of zinc porphyrin polymers (**57**) by polycondensation of **56** using Ni and Pd catalysts (128) (eq. 16). Functionalizing the zinc porphyrins and aromatic spacers with alkyl groups enhanced the solubility of these polymers. In addition, various aromatic spacers were studied in order to decrease the steric crowding surrounding the porphyrins. The molecular weights of these polymers were between 4600 and 37,900 (PDI = 1.3–1.8), and thin films of these polymers were electrochemically active and exhibited electrochromism.



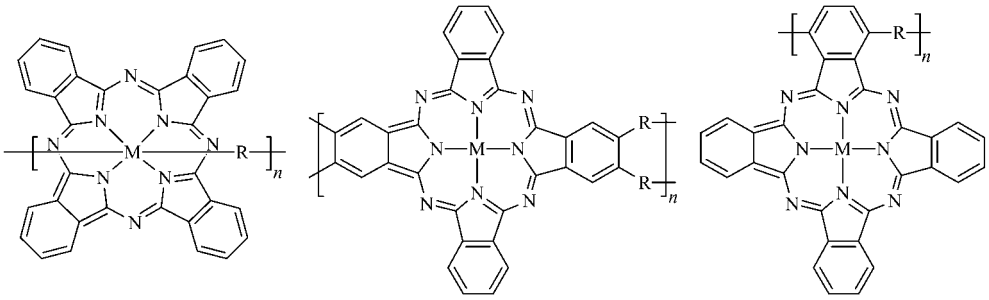
56 **57**

(16)

Anderson and co-workers found that the microscopic polarizability of porphyrins within polymers was 3 orders of magnitude greater than those of monomeric porphyrins (129). This was the largest one-photon-off-resonance third-order optical susceptibility reported for an organic substance, and was indicative of inter-porphyrin conjugation. Soluble zinc polymers were synthesized by incorporating bulky groups on the meso positions of porphyrin rings (130). The solubility of these polymers was very good in the presence of a small amount of a coordinating ligand such as pyridine.

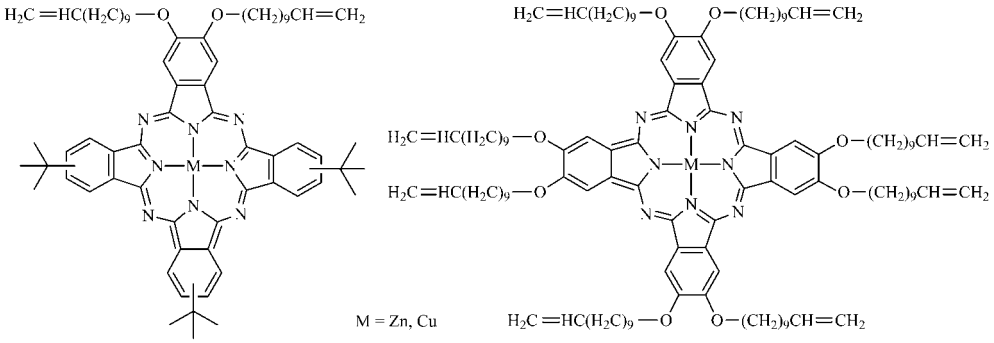
The synthesis and properties of polymetallophthalocyanines have been reviewed (132,133). Although they are structurally similar to polymetalloporphyrins, the presence of an additional four arenes and four nitrogen atoms in their structures has a strong influence on the UV–vis spectra of metallophthalocyanine polymers. These polymers can be synthesized through the metal atoms (**58**) (131–135), through two or more of the aromatic rings of the macrocyclic structure (**59**) (131–133,136), or with the phthalocyanine ring as part of a polymer side chain (**60**) (132,136–138). Cofacial phthalocyanine polymers are materials in which the macrocyclic rings are stacked in a "shish kebab" manner with the metals as part of the polymeric chain (**58**). These polymers often display excellent thermal and

chemical stability and are conducting, sometimes even in the absence of a doping agent.



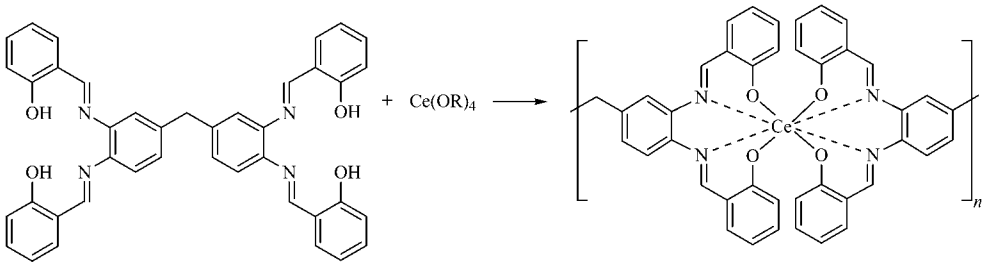
58 59 60

A recent report by Kimura and co-workers described the synthesis of copper and zinc phthalocyanine monomers substituted with either two (**61**) or eight (**62**) olefinic groups (136). Olefin metathesis of these monomers yielded a linear polymer and a three-dimensional network, respectively.



61 62

Since the late 1950s, polymers containing metals coordinated to Schiff base ligands have been reported (139). In 1961, Goodwin and Bailar prepared Schiff base polymers coordinated to Cu, Ni, Co, Fe, Cr, and Al ions (140). Since that time, many more metals have been incorporated into coordination polymers prepared using Schiff base ligands (141–146). Archer and co-workers have studied the effects of different spacers on the solubility of lanthanide coordination polymers (142–144). The incorporation of lanthanides into polymers is important since these metals introduce luminescence into materials. The use of tetradentate Schiff base ligands should shield the lanthanide ions from solvent molecules, thus decreasing the possibility of quenching the polymers' luminescent properties (143). These polymers (**65**) could be prepared via reaction of cerium ions (**64**) with ligands containing imine and phenolic groups (**63**) (142) (eq. 17). Analogous polymers containing europium and yttrium ions coordinated to bis(tetradentate) Schiff base ligands were also synthesized (143).

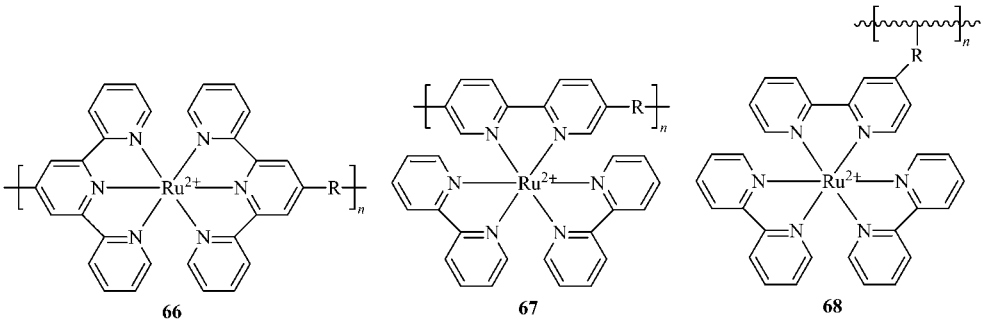


63 64 65

(17)

Polymeric systems containing interlocking rings (catenanes) and threaded rings (rotaxanes) containing metals coordinated to their structures have been studied over the past few years because of their electro- and photoactivity (147–149). A polymer containing copper ions coordinated within its structure was synthesized via polycondensation of a dicarboxylic acid with a dialcohol derivatized copper(I) catenate (147). The M_w and M_n of this polymer were determined to be 4,200,000 and 600,000, respectively. Swager and co-workers have reported the synthesis of conducting polymetallorotaxanes coordinated to zinc and copper ions (148,149).

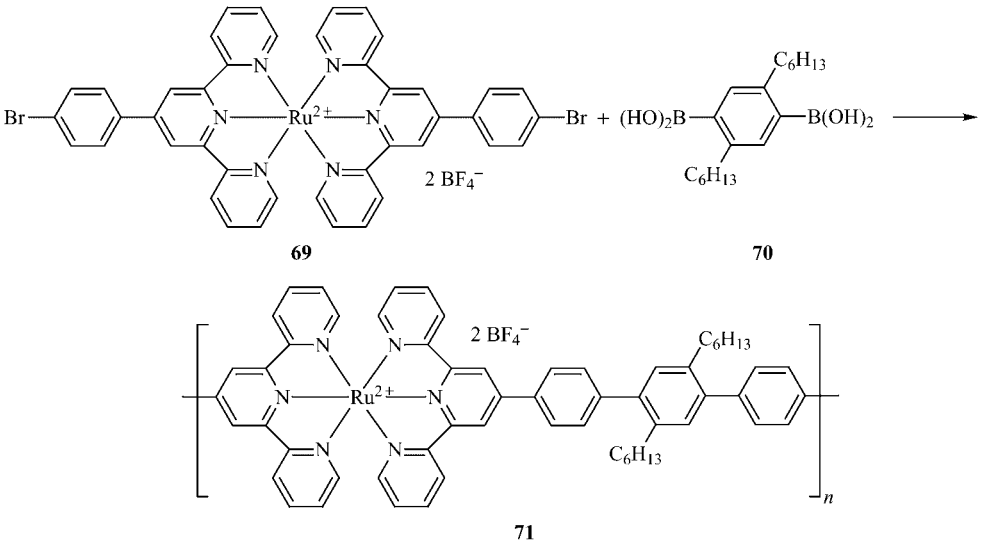
There are many examples of polymers containing transition metals coordinated to bipyridine and related ligands (150–164). The luminescent properties of tris(bipyridine)ruthenium(II) complexes have generated a great deal of interest in these materials (152–158). Polymers containing metal ions coordinated to three bipyridine or substituted pyridines can contain the metal as an integral part of the polymer skeleton (**66**) (165–168), pendent to the polymer backbone (**67**) (154–156), or in a group pendent to the polymer backbone (**68**) (157,158).



66 67 68

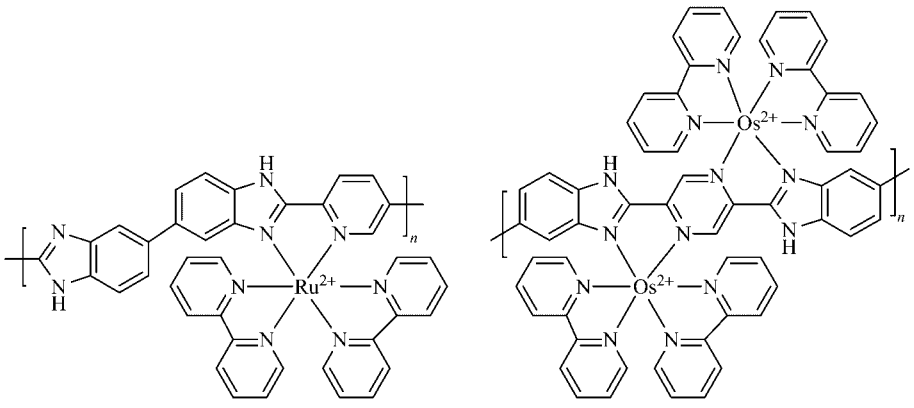
Rehahn and co-workers have described the synthesis of soluble ruthenium(II) coordination polymers by utilizing ligands that allow for the formation of unbranched polymers (150,151). The molecular weights of these polymers were in the range of 45,000, and they could be solubilized in organic or aqueous solutions depending on their counterion. This class of polymer could be prepared either via complexation of pyridine ligands to ruthenium or via polycondensation of metal-containing monomers, as shown in equation 18 (151). Petzold and Harruna have reported the synthesis of three-dimensional high performance

coordination polymers (152,153). A number of these thermally stable, soluble ruthenium-coordinated polymers were examined using optical spectroscopy.



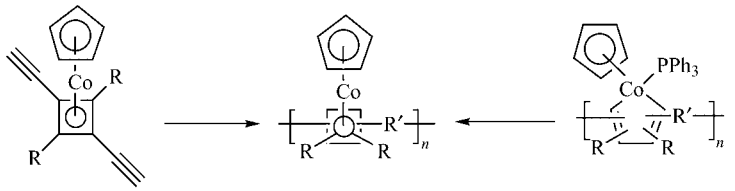
(18)

Polymers containing benzimidazole units in their backbones have also been used in the synthesis of coordination metallopolymers (159–162). Osmium and ruthenium coordinated polymers with bipyridine ligands have been prepared (159,160). These polymers (**72, 73**) possessed metal–metal interactions through their conjugated backbones. Communication between the ruthenium centers of **72** increased by deprotonating the imidazole protons (160). The osmium coordinated polymer (**73**) showed two reduction waves separated by 0.32 V, indicative of strong communication between the Os centers (159).



Metals Coordinated to the Polymer Backbone

The synthesis of polymers containing metallic moieties π-coordinated to four-, five-, and six-membered rings in their backbones has been studied. Polymers containing pendent cyclopentadienylcobalt moieties (**76**) have been prepared via direct reaction of monomers containing cyclopentadienylcobalt moieties coordinated to cyclobutadiene rings (**74**), or via rearrangement of cobaltacyclopentadiene units present in polymeric materials (**75**) (36–39,169–172) (eq. 19). Polymers containing aromatic spacers and long chain alkyl groups pendent to the cyclobutadiene rings demonstrated thermotropic liquid crystalline behavior (170,171). Bunz and co-workers have also described the synthesis of conjugated polymers containing cyclopentadienyl rings coordinated to manganese tricarbonyl units (173).



74 **76** **75**

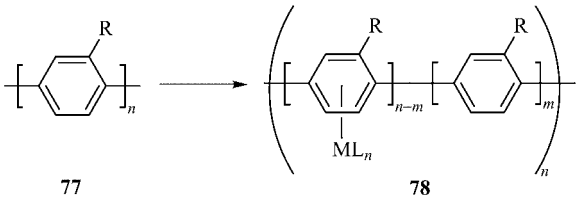
R′ = or aryl

(19)

Organometallic polymers containing arenes coordinated to metallic moieties in their backbones have also been produced via metal complexation to organic polymers (174–179). Poly(9-hexylfluorene) and poly(1-hexylindene) were complexed to manganese tricarbonyl, pentamethylcyclopentadienylcobalt, and pentamethylcyclopentadienylrhodium moieties via η^4-, η^5-, and η^6-coordination (174,175). The photoluminescence of the organometallic poly(9-hexylfluorene) had a decreased intensity relative to its organic analogue (173).

Eyring and co-workers have reported the synthesis of organometallic poly(*p*-phenylene) (PPP) via reaction of the organic polymer with $M(CO)_3(CH_3CN)_3$ or $M(CO)_6$ (M = Cr, Mo) (176). It was determined that molybdenum tricarbonyl was complexed to about 25% of the aromatic rings of this polymer. The chromium and molybdenum functionalized polymers demonstrated increased conductivity relative to organic PPP. Nishihara and co-workers subjected poly(*n*-hexylphenylene) (PHP) to ligand exchange reactions to give molybdenum tricarbonyl and cyclopentadienyliron coordinated polymers (177–179) (eq. 20). These hexyl-substituted polymers displayed better solubility than metallated PPP in organic solvents as a result of the flexible alkyl chains on its backbone. Elemental analysis of the $Mo(CO)_3$-functionalized polymer showed that 1 in every 4.8 aromatic rings was coordinated to a metallic moiety (177,178). A $Cr(CO)_3$ coordinated poly(*n*-butylphenylene) (PBP) was also synthesized; however, this ligand exchange reaction was less efficient than when $Mo(CO)_3$ was used (177). In the case of the organoiron polymer, it was found that 1 in every 1.6 aromatic rings of the complexed PHP was coordinated to a cyclopentadienyliron moiety (179). Spectroelectrochemical measurements of this organoiron polymer indicated the formation

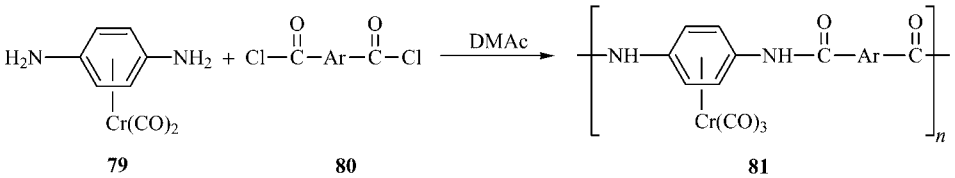
of a network between aromatic rings of neighboring polymer chains following reduction of the cationic iron centers to neutral radicals. Electrochemical and spectroscopic analysis of the organic and organometallic polymers showed that their conductivity increased upon metal coordination (2).



77 **78**

$ML_n = Mo(CO)_3$, $Cr(CO)_3$, $CpFe^+$
R = H, C_4H_9, C_6H_{13} (20)

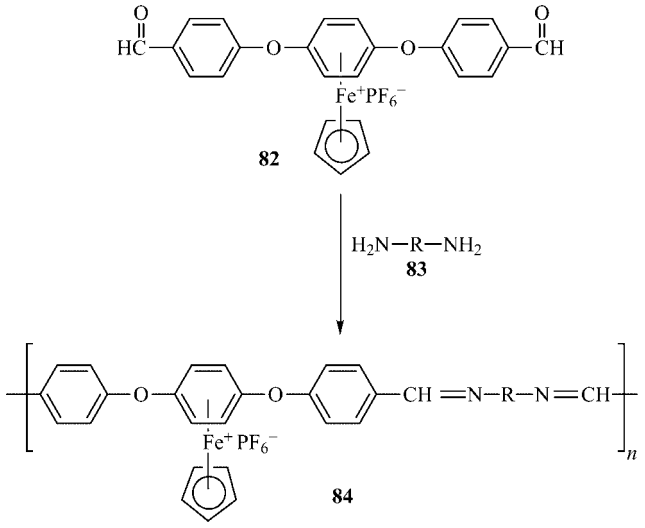
Polymeric materials coordinated to $Cr(CO)_3$, $CpFe^+$, $CpRu^+$, and Cp^*Ru^+ moieties have been produced via condensation, coupling, and nucleophilic aromatic substitution reactions. In 1987, Jin and Kim reported the synthesis of polyamides coordinated to chromium tricarbonyl moieties (**81**) via condensation reactions of phenylenediamine $Cr(CO)_3$ (**79**) with various diacid chlorides (**80**) (180) (eq. 21). An enhancement of this polymer's solubility was achieved via the incorporation of chromium tricarbonyl moieties pendent to its backbone. The viscosities of these polymers were determined in concentrated sulfuric acid and it was found that the organometallic polymers had higher viscosities than their corresponding organic polymers. Dembek reported that high molecular weight polyamides coordinated to $Cr(CO)_3$ displayed nematic liquid crystalline texture, indicating that their rigid rod nature was retained upon metal coordination even though their solubilities were enhanced significantly (165).



79 **80** **81**

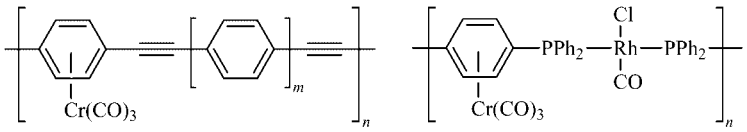
(21)

A polyimine containing chromium tricarbonyl moieties pendent to aromatic rings in its backbone was prepared via reaction of η^6-terephthaldialdehyde–$Cr(CO)_3$ with 1,3-phenylenediamine (166). The resulting conjugated polyimine was insoluble in common organic solvents because of the rigidity of its backbone. The synthesis of polyether/imines coordinated to cyclopentadienyliron moieties (**84**) has also been reported (167) (eq. 22). These polymers were prepared by reaction of a dialdehyde complex of cyclopentadienyliron (**82**) with a number of aliphatic and aromatic diamines (**83**). These polymers were soluble in polar organic solvents such as DMF and DMSO.

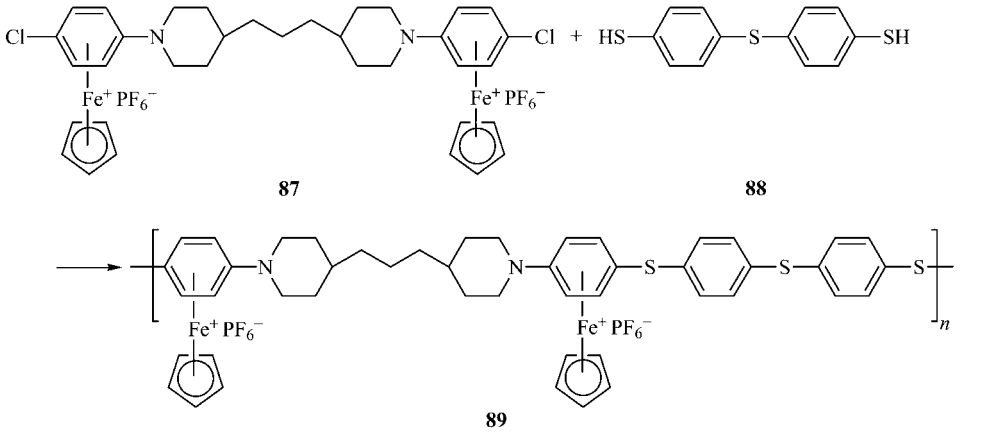


(22)

Poly(phenyl ethynyls) coordinated to chromium tricarbonyl moieties (**85**) were synthesized via palladium-catalyzed cross-coupling of η^6-1,3- and 1,4-dichloroarene chromium tricarbonyl complexes with organostannane reagents (168). Combustion analysis of these polymers indicated that their degree of polymerization was about 18, corresponding to molecular weights of about 7800. Combustion and IR analysis of polymers heated past 200°C indicated that cross-linking reactions occurred following loss of carbon monoxide from the $Cr(CO)_3$ moieties. Polymers with pendent metallic moieties as well as metals in their backbone (**86**) were also prepared (181).



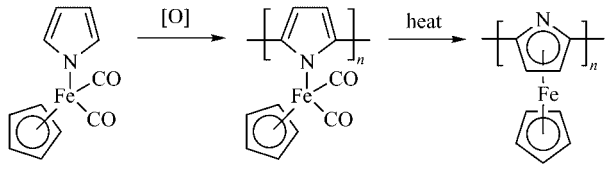
The π-coordination of transition metals to haloarenes activates the aromatic ring toward nucleophilic aromatic substitution reactions (182–189). In 1985, Segal reported the synthesis of soluble polyaromatic ethers coordinated to $CpRu^+$ moieties (182). Dembek and co-workers later prepared a number of polyaromatic ethers and thioethers coordinated to Cp^*Ru^+ moieties (183,184). The synthesis of soluble polyaromatic ethers, thioethers, and amines via S_NAr reactions of dichloroarene complexes of cyclopentadienyliron with oxygen, sulfur, and nitrogen based dinucleophiles has been reported (185–188) (eq. 23). Thermogravimetric analysis of these polymers showed two distinct weight loss steps; the first one corresponded to loss of the cyclopentadienyliron moieties while the second resulted from degradation of the polymer backbones (187). These polymers displayed very good thermal stability following loss of the metallic moieties around 220°C. The synthesis of polymers coordinated to $CpFe^+$ and Cp^*Ru^+ has also been reported (188).



(23)

Polyaromatic ethers coordinated to $CpFe^+$ moieties have also been prepared via sequential S_NAr reactions of chloroarene complexes with hydroquinone (189). The electrochemical behavior of cationic aromatic ether, thioether, and sulfone complexes of cyclopentadienyliron has been studied using cyclic voltammetry and coulometry (190). Reaction of the aromatic ether complexes with sodium cyanide resulted in the formation of neutral adducts which underwent oxidative demetallation to give the corresponding organic aromatic nitriles (191).

Brammer and co-workers have reported the use of arene chromium tricarbonyl complexes as building blocks in supramolecular assembly (192,193). Polypyrrole containing an organoiron group bonded to nitrogen has been prepared via chemical and electrochemical oxidation (194,195). When dicarbonyl(η^5-cyclopentadienyl)(η^1-pyrrolyl)iron(II) (**90**) was subjected to chemical oxidation, the conductivity of the resulting organometallic polypyrrole was 0.25 S/cm (194), while oxidation with ferric chloride resulted in a polymer with a conductivity of 5.2×10^{-5} S/cm, and electrochemical polymerization resulted in polymers with very poor electroactivity. It was found that when the polypyrrole (**91**) was refluxed in either 1,2-dichloroethane or toluene, an azoferrocene-based polymer (**92**) was formed (195) (eq. 24).



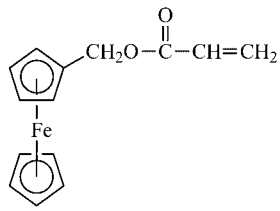
(24)

It has been reported that polymers with silole units in their backbones became coordinated to iron tricarbonyl when they were irradiated with UV light in

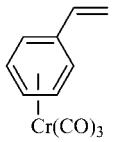
the presence of $Fe(CO)_5$ (196). This polymer was redshifted relative to its organic analogue, and was conducting upon doping.

Metallic Moieties in the Polymer Side Chains

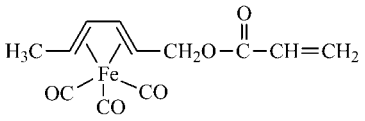
As early as 1955, the synthesis of poly(ferrocenylethylene) was reported (197), and interest in this class of polymer is still increasing (1,3–6). Pittman and co-workers described the synthesis and polymerization of a number of ferrocene-based monomers containing acrylate and methacrylate functionalities (**93**) (198). The polymerization of vinylferrocene and 3-vinylbisfulvalenediiron was also performed in order to study the electrical properties of these polymers (199). Upon oxidation of the polymer formed from the radical polymerization of 3-vinylbisfulvalenediiron, the conductivity of this mixed valence polymer was between 6×10^{-3} and $9 \times 10^{-3}\ \Omega^{-1}\cdot cm^{-1}$. Monomers of chromium and iron tricarbonyl (**94, 95**) were also homo- and copolymerization to give their corresponding organometallic polymers (200,201).



93

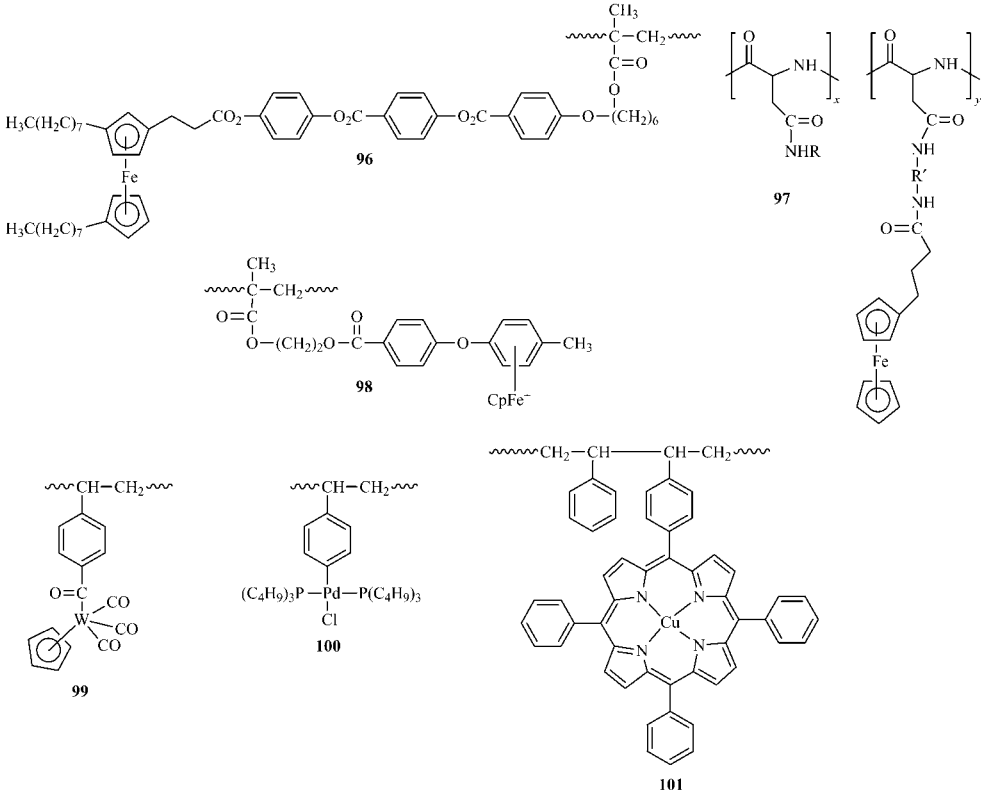


94

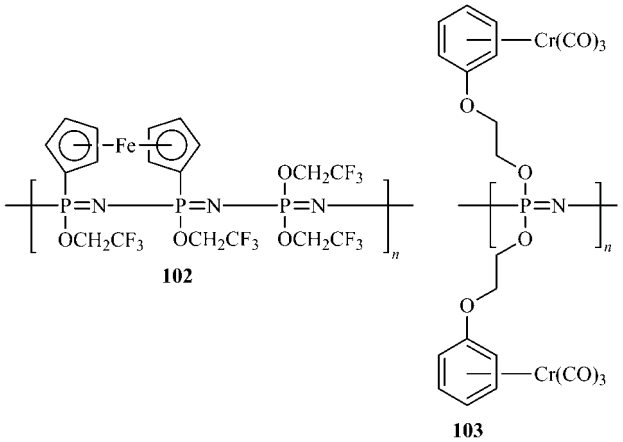


95

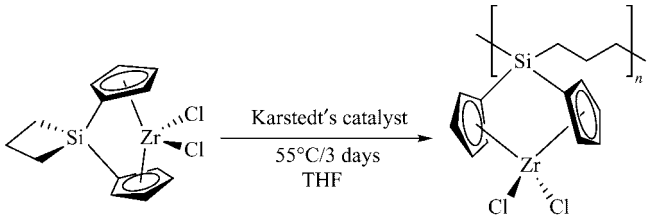
Functionalization of organometallic monomers containing olefinic groups has led to the production of organometallic polymers possessing interesting properties. Polymerization of organoiron monomers resulted in the production of liquid crystalline polymers containing ferrocene units in their side chains (**96**) (202–204). The nonlinear optical properties of polymers containing ferrocenyl groups in pendent groups have also been examined (205). The electrochemical behavior of ferrocenyl functionalized polymers has also been of interest (206). Neuse and co-workers have found that water-soluble ferrocene functionalized polymers possess interesting antiproliferative properties (**97**) (207–209). Coordination of Ru^+Cp^*, $Ru^+C_8H_{11}$, or $Ru^+H(PCy_3)_2$ to the aromatic rings of polystyrene has been reported (210). Depending on the bulkiness of the ligand attached to ruthenium, anywhere from 25 to 100% of the aromatic rings in the polymers became complexed to the ruthenium moieties. Recently, polymethacrylates with cationic cyclopentadienyliron moieties coordinated to their side chains (**98**) were prepared via radical polymerization of their corresponding organoiron monomers (211). Photolytic demetallation of the cyclopentadienyliron-coordinated polymethacrylates resulted in the isolation of the corresponding organic analogues, whose M_w's ranged from 48,000 to 68,000. Other examples of metal σ-bonded (**99**, **100**) and coordinated (**101**) monomers have also been examined (212–214).



Allcock and co-workers have described the ROP of cyclic phosphazenes containing ferrocenyl units, resulting in the isolation of the corresponding organometallic polymers (**102**) (215). Polyphosphazenes containing chromium tricarbonyl units in their side chains were also isolated following ROP of an inorganic monomer, and subsequent functionalization of this polymer with chromium tricarbonyl (**103**) (216). Differential scanning calorimetry showed that the glass-transition temperatures of the $Cr(CO)_3$ functionalized polymers were higher than their organic analogues by approximately 50°C.

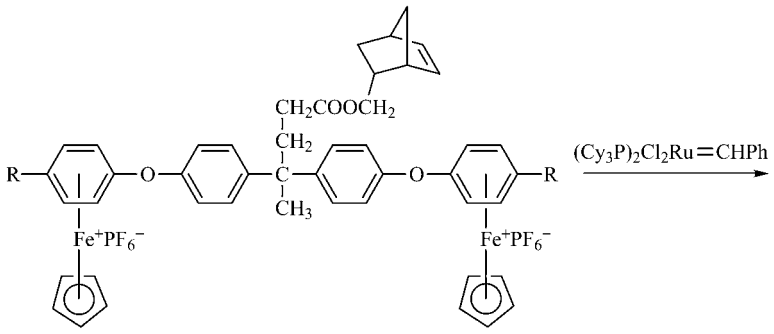


The ROP of *ansa*- and spirocyclic *ansa*-zirconocene complexes has been reported (217) (eq. 25). Polycarbosilane $[(CH_2)_3Si(\eta^5\text{-}C_5H_4)_2ZrCl_2]_n$ (**105**) was obtained from reaction of the spirocyclic silacyclobutane-bridged monomer $(CH_2)_3Si(\eta^5\text{-}C_5H_4)_2ZrCl_2$ (**104**) with Karstedt's catalyst. This polymer demonstrated moderate activity as a catalyst for ethylene polymerization.

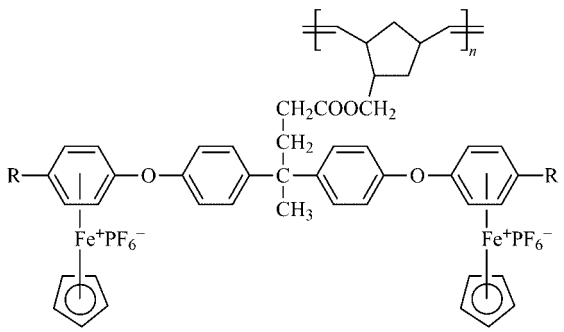


104 **105** (25)

The ROMP of norbornenes functionalized with neutral ferrocenyl moieties has been reported; the aim was to prepare redox-active polymers (218, 219) (eq. 26). The synthesis of polynorbornenes functionalized with cationic cyclopentadienyliron-coordinated aryl ethers has also been reported (220). Demetallation of metallated norbornenes and polynorbornenes led to the liberation of their organic analogues (221–223). Electrochemical analysis of the metallated polymers showed that the cationic iron centers were reduced between −1.2 and −1.4 V.



106

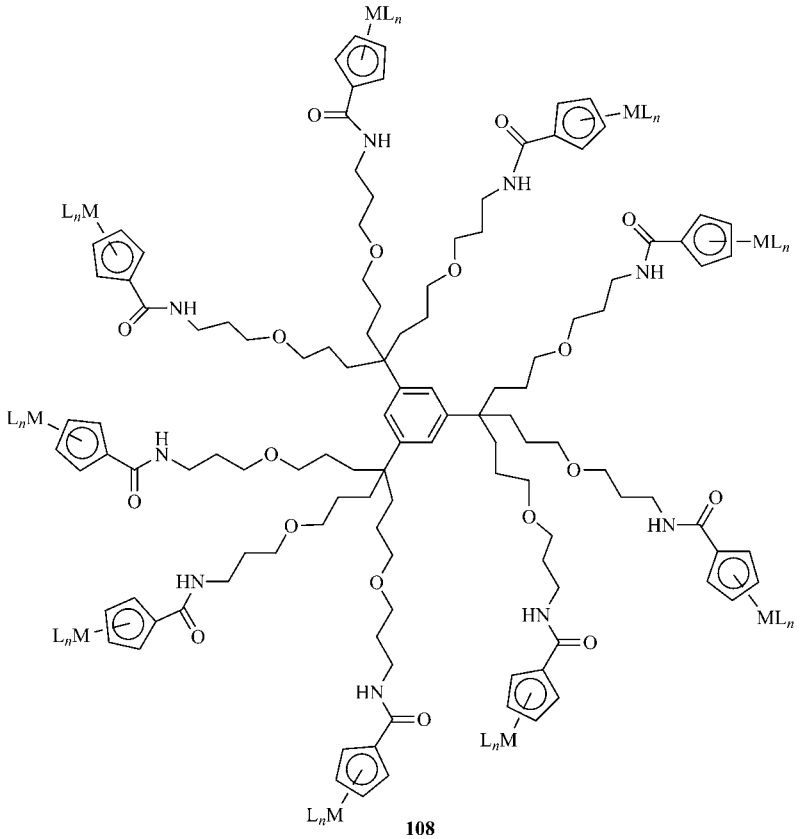


107 (26)

Dendrimers and Star Polymers

There has been considerable interest directed toward the synthesis of organometallic star polymers and dendrimers in recent years (see DENDRONIZED POLYMERS). The production of highly ordered, highly branched organometallic materials is of importance due to their electronic, optical, and biomedical applications (224–232).

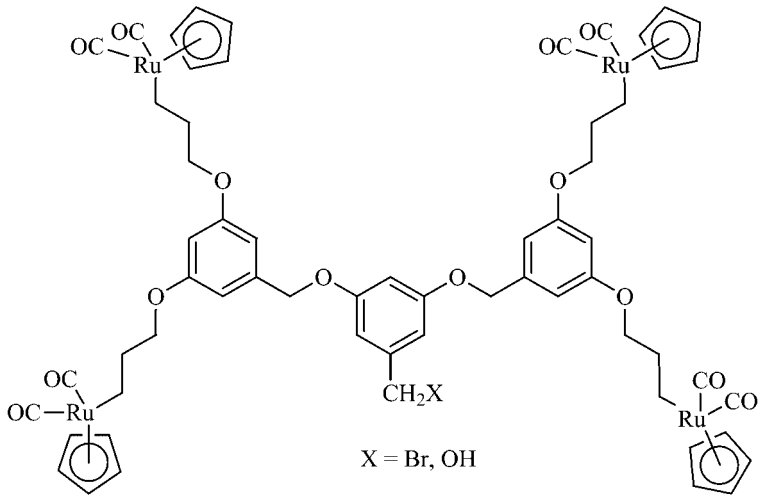
Dendritic poly(aryl ethers) containing up to 24 peripheral ferrocenyl units have been synthesized using a stepwise convergent methodology (233). Cyclic voltammetry of these dendrimers showed that the iron centers were all reversibly oxidized around $E_{\frac{1}{2}} = 0.21$ V. Astruc and co-workers have explored the synthesis and properties of a number of different classes of ferrocene-based star polymers and dendrimers (234–238). A dendrimer containing 54 ferrocene units at its periphery was synthesized and reversible oxidation of all 54 iron centers was observed (234). Chemical oxidation of the neutral iron centers to cationic species could also be accomplished using $NOPF_6$. Dendrimers containing 243 ferrocenyl units at the periphery were also synthesized via ferrocenylsilation reactions of allyl terminated dendrimers (235). Nonametallic dendrimers containing ferrocenyl (237) or cobaltocenium (238) moieties (**108**) at their periphery were synthesized via reaction of amine functionalized dendrimers with the acid chlorides of ferrocene or cobaltocene. Deschenaux and co-workers have been investigating the synthesis of ferrocenyl-based polymers with liquid crystalline properties (239,240).



108

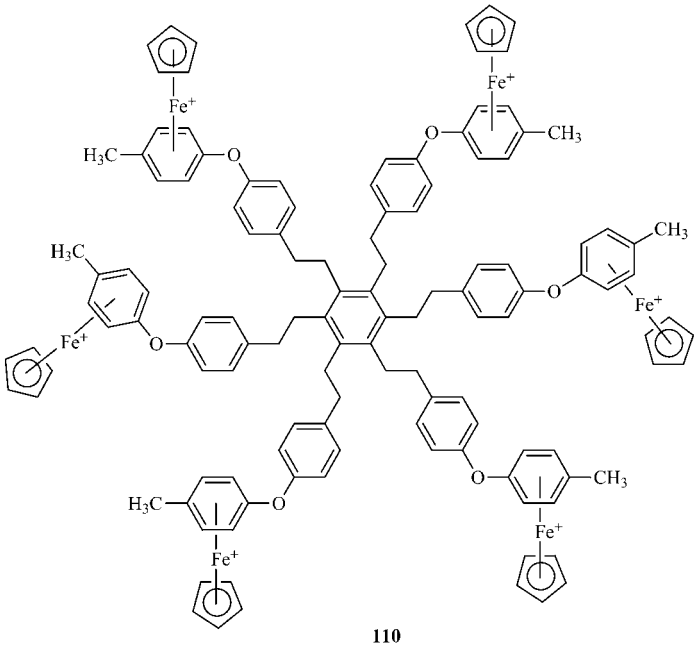
Cuadrado and co-workers have also been active in the synthesis of dendrimers containing ferrocene and cobaltocene moieties (241–244). The synthesis of propylenimine-based dendrimers with up to five generations and 64 peripheral ferrocenyl moieties underwent reversible oxidation processes at $E_{\frac{1}{2}} = 0.59$ V (241,242). The guest–host relationship of some low generation dendrimers with cyclodextrins was examined (241). Silicon-based ferrocenyl dendrimers possessing electrochemical communication between the iron centers were also synthesized (243).

Moss and co-workers have been synthesizing dendrimers containing Ru—C σ-bonds using a convergent approach (245). A fourth-generation dendrimer containing 48 organometallic moieties was prepared using complexes such as **109** as starting materials.



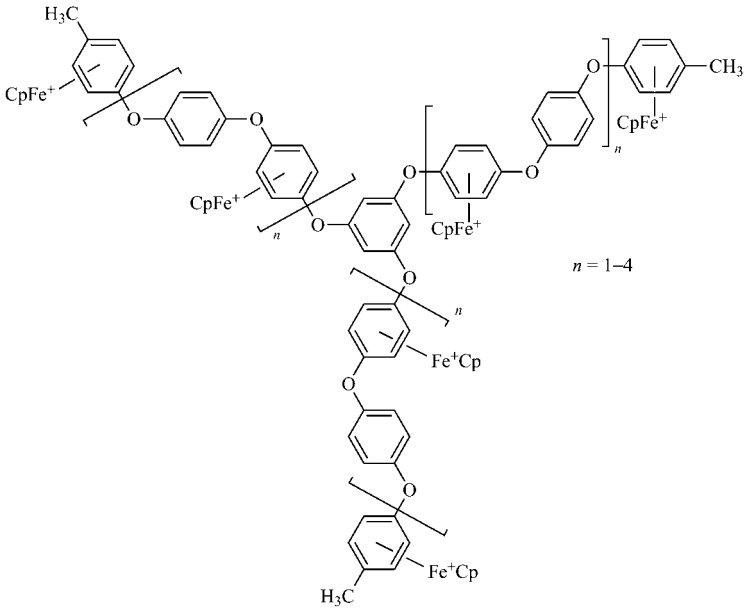
109

There has been a great deal of interest in the design of dendrimers using arene complexes of transition metals (246–252). Astruc has developed an efficient route to core molecules suitable for the synthesis of star and dendritic materials via peralkylation or allylation of methyl-substituted arene complexes of cyclopentadienyliron. The resulting branched polymers contained cationic cyclopentadienyliron moieties at the core and/or the periphery. Complexes containing aryl ethers coordinated to six $CpFe^+$ moieties (**110**) were synthesized via S_NAr reactions (248).



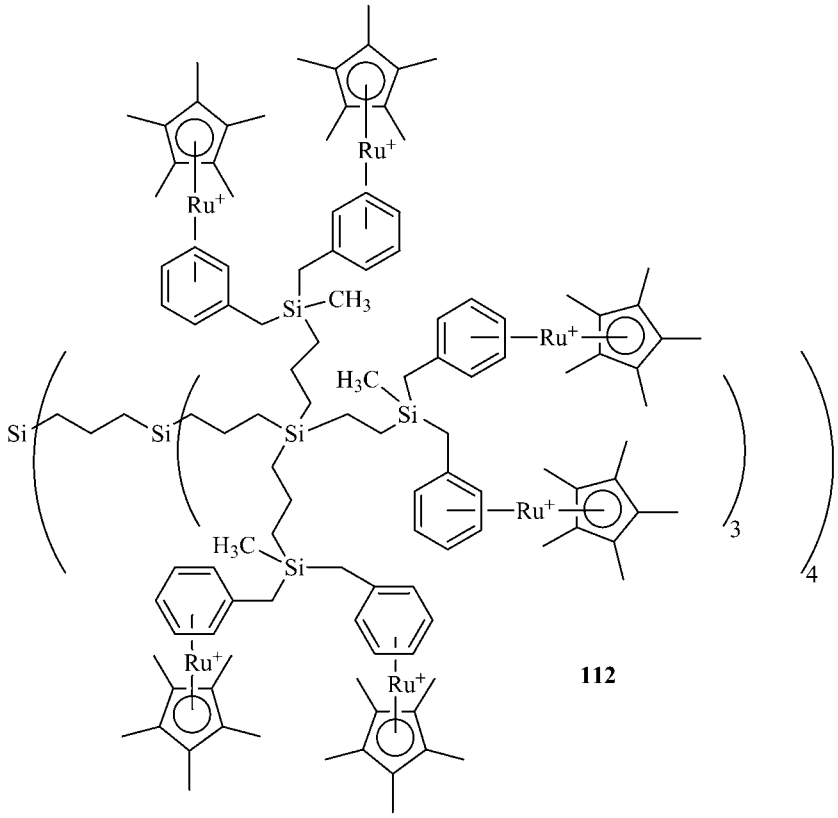
110

The synthesis of a water-soluble metallodendrimer containing six cationic cyclopentadienyliron moieties was also reported (249). This dendrimer was examined as a redox catalyst for the cathodic reduction of nitrates and nitrites to ammonia. Star-shaped polyaromatic ether complexes of cyclopentadienyliron were recently reported by Abd-El-Aziz and co-workers (250). These complexes contained up to 15 cationic cyclopentadienyliron moieties pendent to aromatic rings in the star branches (**111**). Electrochemical analysis of these star polymers showed that the iron centers underwent reversible reduction processes.



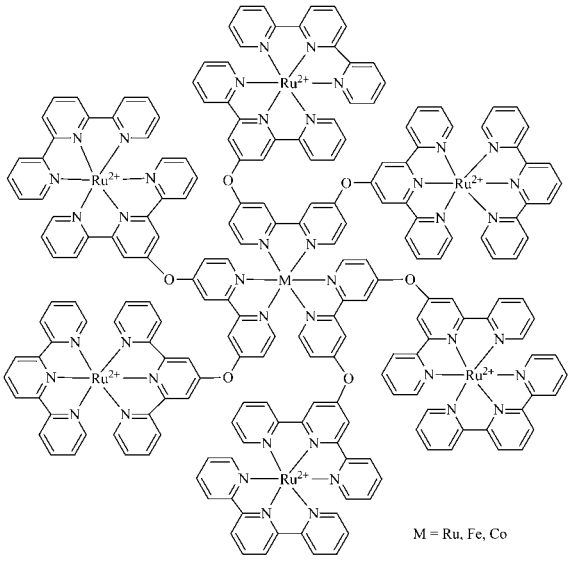
111

The synthesis of organosilane dendrimers coordinated to up to 72 Cp^*Ru^+ moieties has been reported by Tilley and co-workers (251). Mass spectrometry of the dendrimer coordinated to 72 positively charged ruthenium moieties (**112**) revealed that although the desired complex was present in the sample, complete coordination of the aromatic rings may have been hindered because of steric crowding. Organosilicon dendrimers containing chromium tricarbonyl moieties pendent to peripheral aromatic rings have also been synthesized (252). Cyclic voltammetry of these materials showed that oxidation of the chromium atoms occurred reversibly in the absence of nucleophilic species, and that the chromium tricarbonyl units behaved as isolated redox centers.



112

There are numerous examples of dendrimers and star polymers containing metal coordination complexes (253–259). The synthesis of polypyridine ruthenium coordination complexes incorporating Fe and Co (**113**) has been established (255). A ruthenium star-shaped complex with a $CpFe^+$-coordinated arene as the core has also been reported (254).



113

Platinum (260–262) and palladium (262,263) complexes have been incorporated into dendrimeric materials. Polymers incorporating both platinum and palladium units coordinated to bipyridine ligands have been reported by Puddephatt and co-workers (**114**) (262). These dendrimers were prepared via oxidative addition of a C—Br bond to a platinum complex, giving the core molecule. Further reaction with platinum or palladium complexes resulted in the homo- or heterometallic materials, respectively.

METALLOCENES

Scope

Although the traditional usage of the term *metallocene* has encompassed sandwich structures containing two rings of five carbons each bound through all atoms to a central metal atom, common parlance in the field of olefin polymerization has expanded this definition to include structures having only one C_5 ring or none. The term is now applied to all single-site catalysts (qv) (ie, all catalysts having a single, well-defined active-center structure), in some cases restricted to complexes of the early- and middle-transition metals and lanthanides, to distinguish the catalysts from the recent families discovered by Brookhart and others based on late-transition metals. For the purposes of this publication, we equate the word *metallocene* with the family of compounds containing at least one C_5 ring (or analogous heterocycle) bound to an early-transition-metal or f-block atom that, in the presence of a cocatalyst if required, effect the polymerization of ethylene and other α-olefins. We will concentrate on those complexes, predominantly bis(cyclopentadienyl)zirconium(IV) compounds, that polymerize ethylene and propylene with high efficiency.

Historical Background

Although the discovery of $(C_5H_5)_2Fe$ (ferrocene), first reported by Kealy and Paulson in 1951 (1) but recognized as a sandwich compound by Wilkinson and co-workers (2), brought into being a new family of complexes that contain the Cp_2M ($Cp = C_5H_5$) fragment, it was not until the discoveries of Sinn and Kaminsky in the late 1970s that metallocenes, and specifically zirconocenes, were recognized

Encyclopedia of Polymer Science and Technology. Copyright John Wiley & Sons, Inc. All rights reserved.

as powerful olefin polymerization catalyst precursors. (For a good discussion of the succession of discoveries leading to the Kaminsky system, see Refs. 3) This work brought together two strands of research: (*1*) the investigation of the alkylation and polymerization chemistry of Cp_2MX_2 (M = Ti, Zr) (4,5), which had begun soon after the first reports of titanocene dichloride; and (*2*) the observation that small amounts of water added to the medium of certain Ziegler–Natta ethylene polymerizations caused marked increases in the rate of enchainment. It was the finding (by many accounts serendipitous) that large amounts of moisture, when added to the conventional Ziegler–Natta cocatalyst trimethylaluminum, dramatically improved the activity of mixtures of the aluminum alkyl with metallocenes, that set into motion the wave of industrial and academic research in this area.

Although the activities of the new metallocene catalysts were quite remarkable ($>1 \times 10^6$ g(PE)/mmol(Zr)), they would have probably remained a laboratory curiosity had they not exhibited a crucial characteristic: they were homogeneous. (Here we understand homogeneous to mean soluble and also having a single active-site structure.) Single-site catalysts were known, of course, for olefin polymerization. Catalysts based on vanadium had produced polymers with molecular weight distributions (M_w/M_n) of about 2, the value expected for ideal single-site behavior in polymerization and chain transfer. However, the vanadium family of single-site catalysts had aspects of its chemistry that made it less attractive to academic work and also to commercialization. First, these catalysts are generally mixtures of vanadium complexes of hard inorganic ligands such as halides, oxides, or acetylacetonate groups, most if not all of which would be expected to be lost upon reaction with a large excess of trialkylaluminum or chlorinated aluminum alkyl compound. Because of this, the precursor to the active catalyst generally lacks modifiable substituents that persist in the active complex, making group substitution and structure–property trend analysis futile. The paramagnetism of vanadium catalysts also precludes NMR spectroscopy, a key tool for characterization. Also, because of the generally low activity and temperature sensitivity of the vanadium-based single-site catalysts, use of these catalysts in modern large-scale industrial settings has been difficult, because such important processes as Union Carbide's UNIPOL or the slurry process of Phillips Petroleum have eliminated ash removal, and also require fairly high reaction temperatures (40–110°C) for a commercially acceptable operation, as dictated by the economics of heat transfer from the reactor. The early non–aluminoxane-based titanium catalysts (such as $Cp_2TiCl_2/(C_2H_5)_2AlCl$ (4)) were homogeneous, but not extremely active.

In one stroke, the discovery of methylaluminoxane (the product of the partial hydrolysis of trimethylaluminum) gave to researchers a system of interest to both the synthetic chemist and the reaction engineer. Thus we have seen a flowering of chemical discovery and innovation in open and patent literatures alike, as investigators have taken advantage of the stability of the Cp—M linkage during polymerization and have introduced substituents that change the active-site behavior in myriad ways. Driven as much by the desire for a degree of novelty that would confer patent protection as by the thirst for knowledge, researchers have extended the range of single-site catalysts far beyond those having Cp groups. The rise of metallocenes has in large part legitimized the study of olefin polymerization among "serious" organometallic chemists, and in turn, has forced captains of industry to become more fluent with the fundamentals of synthetic and mechanistic

chemistry than seemed possible only decades ago. One suspects that the ramifications of both changes will be felt for years to come, regardless of the ultimate commercial acceptance of metallocene polymerization technology.

Properties of Metallocenes

Structure and Bonding. Both bis- and mono-Cp complexes of early transition metals are marked by a pseudo-octahedral environment, which is evident from the bond angle between the halide atoms of zirconocene dichloride, for example, of 90°. The angle formed from the metal atom and the two centroids of the Cp rings in bis-Cp complexes is generally about 120°, although this can be raised or lowered, with the latter effect being more common, through the addition of bridging groups between the rings. Metallocenes useful for polymerization generally have d^0 electronic configurations, and are thus diamagnetic. Complexes containing Cp rings alone are usually weakly colored, often yellow–gold, but the fusion of an aromatic ring to the Cp ring results in a much stronger coloration, presumably because of L–M (π–d^*) transitions.

The molecular orbitals involved in bonds between the Cp_2M fragment and the remaining, nonring ligands are shown in Figure 1, adapted from Lauher and Hoffmann (6). In d^0 systems such as Cp_2ZrCl_2, the electrons filling these orbitals are derived solely from the non-Cp ligands. Alteration of the metallocene geometry, or in the electronic properties of any of the ligands will obviously change the energies of the molecular orbitals, with consequences for metal–alkyl reactivity. Because of the lack of metal-based electron density, however, Group IVB metallocenes are not strongly influenced by acceptor orbitals on non-Cp ligands such as the π^* orbitals of ethylene or CO.

Chemical Reactivity. Group IVB metallocenes are moderately air-stable compounds unless (*1*) there is a highly basic carbanion attached, either in the form of a highly alkylated Cp ring or a polycyclic C_5-containing ligand, or (*2*) there is an alkyl group attached directly to the metal; in the latter case the compound is extremely water- and oxygen-sensitive, and often decomposes upon heating or exposure to strong light. The hydrolysis products of Group IVB metallocene dichlorides are generally HCl and zirconia, as well as a mixture of organic compounds.

Preparation. Group IVB metallocenes and Lanthanocenes are conventionally prepared by ligand exchange between lithium or Grignard reagents and metal chlorides (eqs. 1a and 1b). Often the metal chlorides are present as etherate complexes; such complexes need to be prepared carefully, as the reaction is unusually exothermic.

$$m\ \mathrm{Cp'Li} + \mathrm{MX}_n \longrightarrow \mathrm{Cp'}_m\mathrm{MX}_{(n-m)} + m\ \mathrm{LiX} \tag{1a}$$

$$m\ \mathrm{Cp'MgX} + \mathrm{MX'}_n \longrightarrow \mathrm{Cp'}_m\mathrm{MX'}_{(n-m)} + m\ \mathrm{MgXX'}$$

[X,X′ = halide; M = transition metal; Cp′ = (substituted) cyclopentadienyl] (1b)

Milder preparatory schemes include the reaction of silyl or stannyl cyclopentadienides with metal halides, as shown in equation 2. (For the application of this

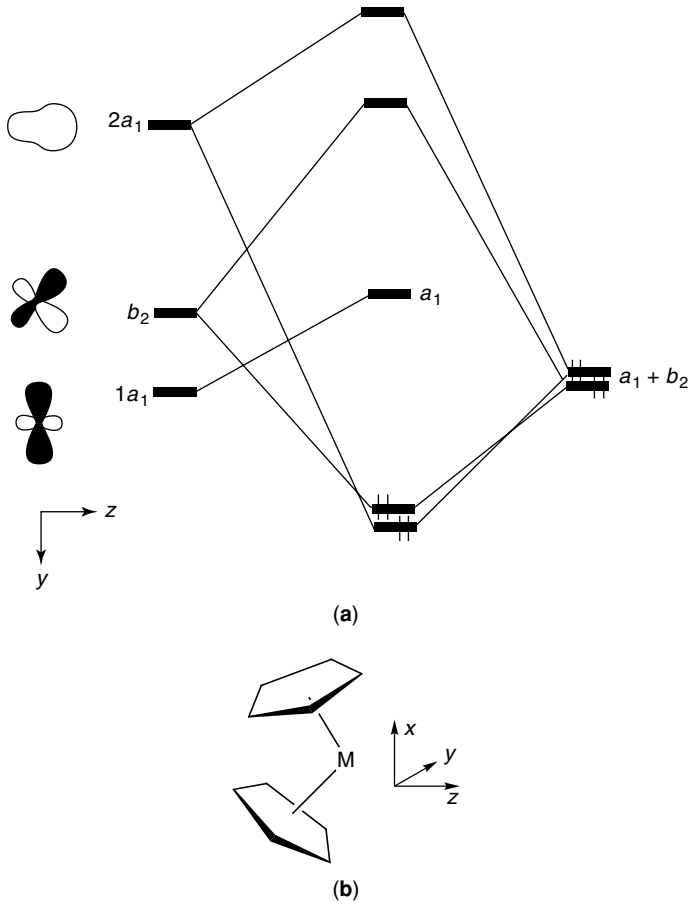

Fig. 1. (**a**) Orbitals responsible for metal–hydride bonding in Cp_2TiH_2. reaction to bridging ligands, see Ref. 7.) This method is especially well suited to the preparation of titanocenes, as the use of a strongly reducing metal alkyl such as LiCp is avoided. Another route to metallocenes involves the reaction of the neutral mono- or bis-Cp ligand with a metal tetraamide (eq. 3). This pathway has been demonstrated by Jordan (8) to allow the preparation of racemic bis(indenyl) zirconium compounds in high selectivity. Aluminum complexes of bis(indene) ligands will also undergo transmetallation reactions with zirconium tetraamides in high yield (9).

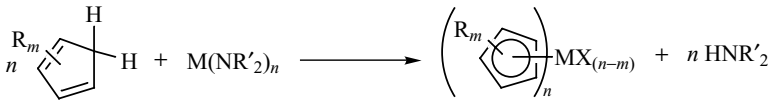
(2)



[X = halide; M = transition metal; E = Si, Ge, Sn] (3)

Toxicity. There is little known of the effects on living organisms of metallocene precursors beyond those of the parent compounds Cp_2MCl_2 (M = Ti, Zr). Titanocene dichloride has been reported (10) to be a potentially useful anticancer agent, while the zirconium analogue has been identified as a mutagen in at least one toxicological report (11). Prudence dictates that extreme care should be exercised with metallocenes, particularly those with polycyclic aromatic groups.

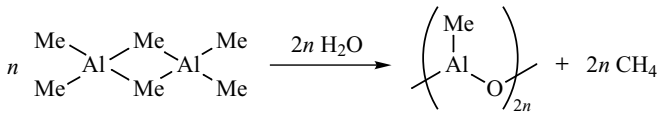
Cocatalysts for Polymerization

Aluminoxanes.

Health and Safety Considerations. Solutions of MAO are generally nonpyrophoric because of the low volatility of toluene. However, if toluene is removed, a finely divided white powder remains that is extremely air- and water-reactive, and will often spontaneously burst into flame. Contact of MAO or its solutions with water usually results in an immediate explosion, but caution must be maintained even after the initial reaction, because, similar to other aluminum alkyl reagents, MAO often forms a crust of alumina when hydrolyzed quickly. This crust tends to protect the remaining alkyl, and disturbing it without care may cause a second violent reaction.

Similar safety considerations apply to modified MAO, although when solvent has been removed these materials are often glasses or viscous oils. Modified MAO solutions in light alkanes such as isopentane may form dangerous mixtures with air because of the volatility of the solvent and the presence of an intrinsic source of ignition.

Methylaluminoxane. Methylaluminoxane (MAO) is prepared from the controlled hydrolysis (eq. 4) of trimethylaluminum (TMA), usually in toluene.



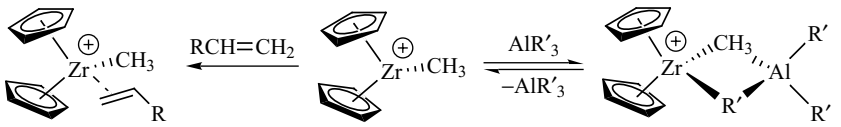
(4)

This is an extremely exothermic reaction and poses great hazards, as large amounts of heat and gas must be safely removed. Early workers employed hydrated inorganic salts as a controllable method for addition of water, but it appears that this procedure is not practiced commercially. The patent literature suggests that the main suppliers of MAO (Albemarle, Akzo Nobel, and Witco) add water directly, either by use of moist nitrogen or a marginally wet aromatic solvent. The precautions necessary for the synthesis of MAO add to the cost of this material, which suffers as well from the expense of TMA, which cannot be made by the normal routes available for the higher trialkylaluminum compounds, such as the

addition of olefin to AlH_3. MAO solutions normally have methyl/Al ratios greater than 1, reflecting the fact that some TMA (about 30 mol% on an Al basis) must be present for the solution to be stable. NMR analysis suggests that much of the excess methyl content, at least, is present as TMA [as opposed to $((CH_3)_2Al)_2O$), although it may be complexed to the MAO.

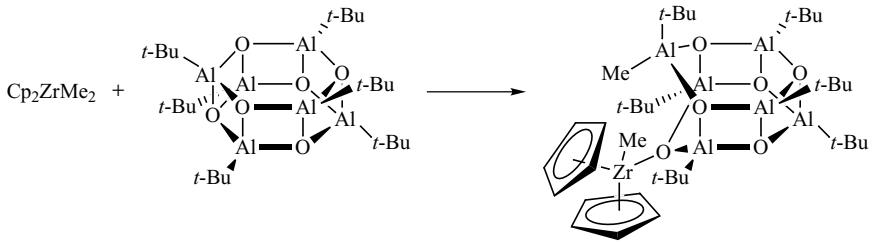
The function of the excess TMA is the focus of considerable controversy. To it have been ascribed the roles of alkylating agent, ionizing agent, chain-transfer agent, and deactivator. TMA can be removed, at least partially, by vacuum distillation, leaving a toluene-soluble material, which remains a competent activator for metallocene polymerization.

As noted above, the initial high activity metallocene catalysts involved zirconocenes and titanocenes mixed with methylaluminoxane. MAO is a poorly understood mixture of oligomers (generally with degree of polymerization of about 20), despite years of study. It can accurately be characterized by its proton NMR spectra, its methyl content, and its average molecular weight, but proposed structures for specific MAO oligomers or subunits remain highly speculative. As will be discussed in greater detail, the two actions of MAO are alkylation and activation by Lewis acid methyl anion abstraction. The key to the activity of MAO-activated metallocenes is the degree to which the anion formed from this process is relatively inert and well separated from the metallocene cation, which has only 14 valence electrons and tends to form bridging complexes such as shown in equation 5 and 1a with ordinary aluminum alkyls.



(5)

While the origin of the ability of MAO to effectively abstract methide and remain loosely associated with the metallocene is not well understood, the most convincing proposal comes from the work of Barron, in which structural studies of analogous oligomeric *t*-butylaluminoxanes (12) and their exchange reactions with $Cp_2Zr(CH_3)_2$ have led to the concept of "latent Lewis acidity," which can be paraphrased as a potential for the drum-like subunit of the structure of the aluminoxane to reversibly open up a highly electrophilic tricoordinate aluminum atom for methide abstraction, resulting in an anion of high stability and bulk, factors that militate for a weak ion–pair interaction (eq. 6).



(6)

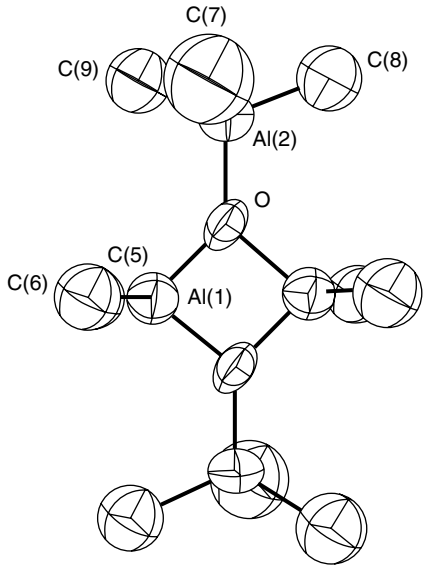


Fig. 2. Structure of $[Me_3)Al(OAlMe_2)]_2$ dianion. Reproduced from Ref. 13 by permission of The Royal Society of Chemistry.

The two crystal structures that come closest to shedding light on the actual form of MAO are shown in Figures 2 and 3, structures for a dianion of a MAO oligomer (13) and of a *t*-butylaluminoxane hexamer (14).

In practice, it has been found that MAO must be used at fairly high atomic ratio of Al to transition metal, conventionally between 300 and 10,000, although this is not necessarily the case when immobilized systems are used. For example,

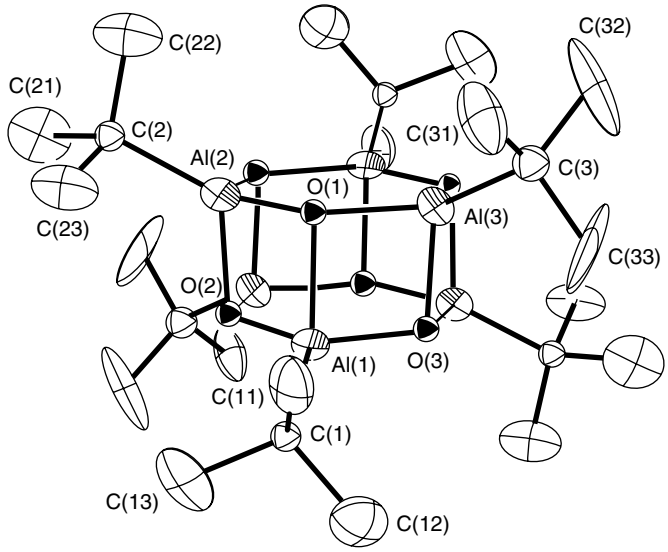

Fig. 3. Crystal structure of $(Al(t\text{-}Bu)O)_6$. Reprinted with permission from Ref. 14. Copyright (1993) American Chemical Society.

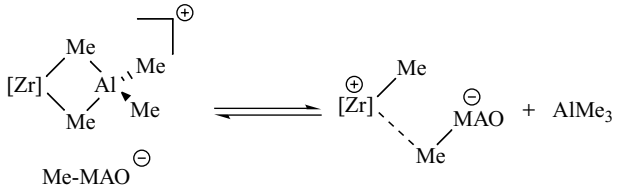
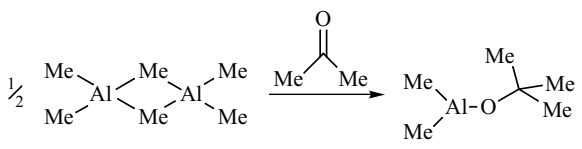


Scheme 1.

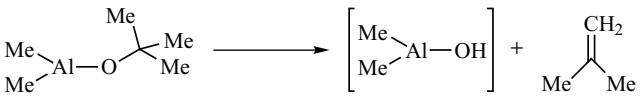
most of the silica-supported metallocene/MAO catalysts reported in the patent literature employ Al/Zr ratios of between 100 and 300. The high ratios required have led to speculation that there exists a particular oligomer or family of oligomers that perform the bulk of the activation. Experiments done by Sishta and co-workers have shown (15) that a very low Al/Zr ratio—perhaps representing the reaction of one molecule of MAO per metallocene—is sufficient to produce NMR spectra similar to those for much higher ratios. This result hints that the additional MAO is required either for scavenging of poisons, reactivation of metallocene in a dormant state, or agglomeration of MAO oligomers following activation of the metallocene, leading to larger anions and hence looser ion pairs. Recent NMR experiments led by Brintzinger have suggested that the large MAO counterion contains 150–200 aluminum atoms, and have given weight to the theory that the main effect of increasing Al/Zr ratio is to shift the equilibrium between coordinatively saturated zirconocene–trimethylaluminum dimers and ion pairs with more accessible open sites (Scheme 1) in favor of the latter (16).

Modified Methylaluminoxane. The fact that MAO is only soluble in aromatic solvents can present problems in handling; often a highly pyrophoric solid precipitates when these solutions are mixed with other reagents. For this reason, as well as to limit the consumption of expensive TMA, much effort was expended in making MAO soluble in aliphatic solvents, principally by replacing some of the methyl groups with higher alkyl substituents. The most commercially successful reagents, known as modified methylaluminoxanes, contain up to 30 mol% of isobutyl substitution. These complexes are made either by direct hydrolysis of a mixture of TMA and higher aluminum alkyl compound, or by a number of more exotic processes, and are extremely soluble in hexane or isopentane. Catalysts prepared from modified MAO are of comparable activity to those activated by MAO.

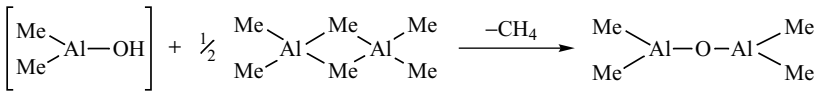
A nonhydrolytic method of making MAO has been described (17); it apparently results in an aluminoxane much reduced in residual TMA, which harms certain catalysts, yet of similar shelf life to conventional MAO. The procedure uses a carbonyl compound as the initial oxygen source (eq. 7a, 7b 7c), then calls for alkoxide ligand fragmentation and secondary hydrolysis to make the final product.



(7a)



(7b)



(7c)

Discrete Activators. MAO is a troublesome activator for several reasons. More expensive on a molar basis than cocatalysts such as $Al(C_2H_5)_3$ used by Ziegler–Natta catalysts, MAO seemed until recently to require a very large molar ratio to transition metal, preventing metallocenes from competing with conventional catalysts on a cost basis. From an academic perspective, MAO, an ill-defined mixture, hinders the detailed analysis of active-site structure. Not surprisingly, many attempts have been made over the years to replace MAO, the most successful of which have given us discrete activators based on perfluorinated aryl groups.

There are three popular modes by which these cocatalysts ionize the metallocene (which must be alkylated by a different agent such as triisobutylaluminum): Lewis acid extraction of the alkylide group by a neutral Lewis acid (eq. 8) or by a carbocation (eq. 9) and protonolysis of the alkylide group (eq. 10). (Ionization may also occur through direct reaction of the alkylated metallocene by a strong oxidant such as $[Cp_2Fe^+][B(C_6F_5)_4^-]$ (18).)

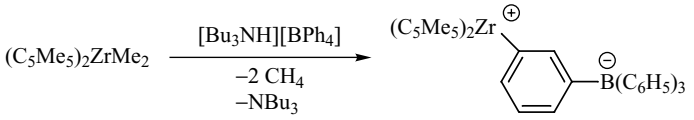
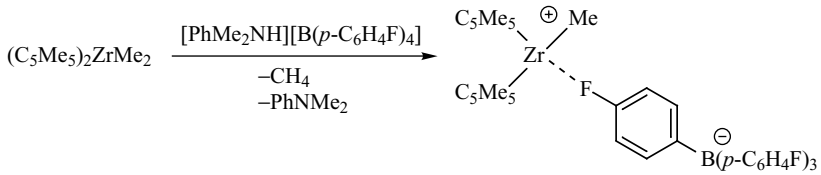
(10)

The first pathway, extensively studied by Marks and co-workers, is a rapidly reversible ionization (19). The second two routes, actually discovered prior to reaction 8 by scientists at Exxon and Fina, are technically irreversible, as one of the by-products is a kinetically unreactive alkane. (For protonation, see Ref. 20 and for methyl transfer, see Ref. 21.) In practice, more than one equivalent of discrete activator is usually employed. While the source of this requirement is still unknown, candidates include reactions with the trialkylaluminum species (present in excess as alkylating agents) that destroy the special activating power of the borane in equation 8 or the inertness of the anions in equations 9 and 10. Another possible culprit is the formation of dormant alkyl-bridged metallocene dimers (22). In equation 10, one of the by-products is a trisubstituted amine that might be expected to trap the coordinatively unsaturated cation formed in this reaction. (*N*,*N*-Dimethylaniline is shown, but is not exclusively used; tri-*n*-butylamine is another common component of the activator.) However, it does not appear to diminish catalytic activity. Variations on the structure of $B(C_6F_5)_n^-$ have been explored, including aluminum substitution for boron (23), silylation of the arene (24), and the use of larger perfluoroaryl substitutuents (24,25). Not surprisingly, activity rises with the size of the counterion. Use of the nonperfluorinated aryl groups phenyl (26), *p*-fluorophenyl (27), and 3,5-bis(trifluoromethyl)phenyl gives a zwitterionic catalyst (eq. 11), a fluorine-bridged ion pair (eq. 12), and a weakly active titanocene catalyst at low temperature (28), respectively. (This counterion has been used extensively by Brookhart and co-workers, especially for the activation of single-site cyclopentadienylcobalt polymerization catalysts; see Ref. 29.) In equation 12, activity appears to be high only for the metallocene $(C_5(CH_3)_5)_2Zr(CH_3)_2$, whose steric congestion is probably responsible for preventing decomposition.



(11)



(12)

Other noncoordinating anions have been discovered that enable high activity polymerization. Among these are the metallacarboranes $[(C_2B_9H_{11})_2M]^-$ (M = Fe, Co, Ni), where catalyst ionization is by protic abstraction by an ammonium ion (30).

Commercially, Dow appears to have implemented activation by well-defined cocatalyst for its Insite solution-phase metallocene process. Aside from historical priority, one reason for the persistent use of MAO is that the perfluorinated boron compounds are difficult to prepare, thus raising their expense. (One of the intermediates, $(C_6F_5)Li$, must be handled at very low temperature to prevent violent decomposition.) Another is that, unlike the MAO systems, catalysts activated by discrete activators have no large excess of alkylaluminum to scavenge poisons from the reaction medium, while common scavengers may hinder activity by consuming the expensive activator.

Other Methods of Activation. Despite some early claims (31), the evidence for metallocene activation by simple trialkylaluminum compounds has not accumulated. Activation by alternate aluminoxanes such as isobutylaluminoxane (IBAO) has also been attested (32). The fact that these much cheaper methods have not consigned MAO to the ash-heap of history speaks, perhaps, of some limitations in these alternatives.

Some support materials can be rendered Lewis acidic enough to ionize dialkyl metallocenes. Marks and co-workers have reported (33) that alumina dried at very high temperatures can react at least to some small degree with both thorium- and zirconium-based metallocene dimethyl species to yield active catalysts for polyethylene. The resulting cationic metal center is believed to remain coordinated to the surface through an Al–O–M Lewis acid/base linkage, at least prior to exposure to ethylene. Hybrid surface/cocatalyst systems based on aluminum alkyl-treated clays have been developed (34) in which the solid substrate appears to play some role in promoting polymerization activity far beyond that expected for non–methyl aluminoxane- or trialkylaluminum-activated catalysts.

Forms of Catalyst Delivery

Porous Silica Supports. While single-site catalysts continue to be studied in solution polymerizations, especially in academic laboratories, the adaptation of metallocene technology to existing industrial processes has generally entailed the immobilization of the homogeneous catalyst on a solid surface of well-controlled morphology and porosity. Generally speaking, the support favored is amorphous silica containing fairly high pore volume (>1 cm^3/g) and average particle diameter of about 50 μm. Early on it was discovered that the extremely high atomic ratios of MAO to zirconium that had been needed to obtain high activity in solution polymerization were unnecessary when the catalyst was supported. (Excellent activities based on supported metallocene/MAO catalysts with Al/Zr <100 are reported in Ref. 35.) This has greatly facilitated the commercialization of metallocenes. Supporting the catalyst can have consequences for the reactivity pattern of the metallocene (36), indicating that the aluminoxane, when covalently bound to the silica surface through one or more Si–O–Al groups (each formed from the silanolysis of an Al—Me bond), displays different ion–pairing dynamics with

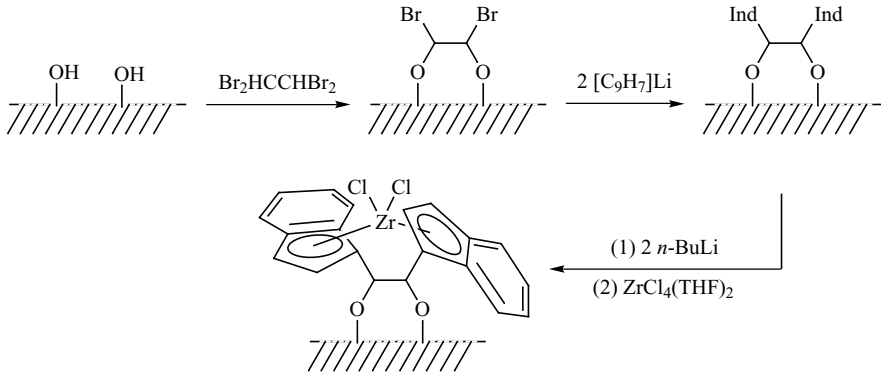


Fig. 4. Overview of bridge-anchored ansa-metallocene synthesis (Ref. 43).

the metallocene relative to the solution cocatalyst. Industrial research has yielded numerous examples of polymerization supports beyond silica, including alumina, zeolites, clays, and organic polymers. Metallocene catalysts have been covalently bound to polymer either through prior attachment of part of the ligand to a polymeric substrate (37), or through the incorporation of a pendent unsaturated group on the ligand itself into the growing polymer (38). In both cases, excellent particle morphology was claimed.

Alternate Modes of Catalyst Physisorption. Other forms of catalyst delivery to the reactor have been implemented. Catalyst solution has been injected directly into fluidized-bed gas-phase reactors (39), evidently creating a mist of *in situ* spray-dried catalyst. Spray-dried catalyst has been prepared *ex situ* as well, in an attempt to better control the morphology of the particles (40). Solid catalytically active materials have also resulted from precipitation of MAO by aliphatic solvent (41) and through a low conversion polymerization (prepolymerization) prior to introduction to the large-scale polymerization medium (42).

Supports as Part of Ligand Set. Solid supports bear functional groups that have been utilized as part of the ligand framework of metallocenes. Soga and co-workers covalently bound bridged metallocenes to silica through reaction of the surface silanols with reactive carbon halide or silicon halide bonds on the ligand bridge. The overview of the synthesis for one catalyst precursor is shown in Figure 4, with the indenyl rings in pseudo-racemic orientation because the high isotacticity of the polypropylene produced suggests a structural analogy to *rac*-Et$(Ind)_2ZrCl_2$. Activities were reported to be greatly superior to the homogeneous analogues (43).

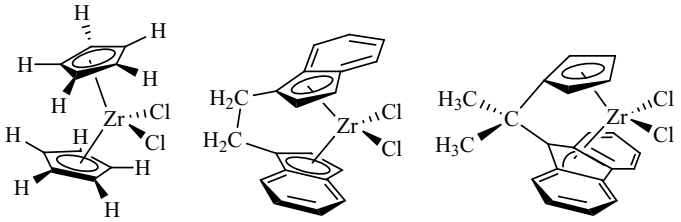
Families of Metallocene Catalysts

In this section, we will briefly examine the salient features of the basic classes of metallocene catalysts. Polymerization activity comparisons and the mechanisms that govern polymerization will be treated in subsequent sections.

Group IVB Metallocenes.

Bis(cyclopentadienyl) Complexes. Representatives of the three most-intensively studied subfamilies of bis(Cp) metallocenes are **1**, **2**, and **3**. The parent

zirconocene (**1**) was the first to be exploited, and soon substitution of the Cp rings with alkyl groups and replacement of the Cp rings with indenyl and fluorenyl ligands was undertaken. Unbridged metallocenes of this sort exhibit a suite of characteristics that have caused their application in the commercial arena to be intense, but limited in scope. High activities are common to this family, and because of the relative ease of precatalyst synthesis, they are well suited to large-scale production of commodity grades of polyethylene. Facile chain transfer in the presence of α-olefin, however, renders these metallocenes nearly useless for making very low density copolymers of ethylene. With rare exception (covered in section Mixed Tacticity Polyolefins), they cannot polymerize α-olefins such as propylene with any degree of stereospecificity.

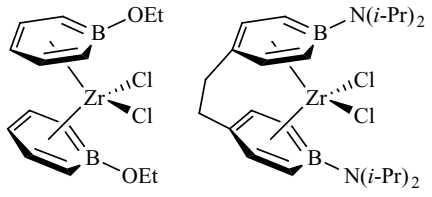


1 **2** **3**

Comparative studies of unbridged metallocene catalysts have indicated that, in general, alkylation of the Cp ring(s) causes an increase in polymerization activity, although substitution of all five carbons can lead to very low activities, as steric congestion prevents monomer approach. Bis(indenyl) and bis(fluorenyl)zirconium complexes have received far less attention, and in the latter case, this is almost certainly due to the greater lability of the fluorenyl–metal interaction.

Aside from the ubiquitous *n*-alkyl, halide, and alkoxide groups, metallocenes also bear carboxylate, trifluoromethanesulfonate (44), thiolate (45), and other more exotic moieties in addition to the Cp groups. It is commonly believed that these ligands are completely exchanged for alkyl groups originating on the aluminoxane in the case of MAO activation; however, this supposition does not imply that the groups have no effect on olefin polymerization as part of the counterion complex.

Monoanionic analogues of the cyclopentadienyl group have been explored. The bis(boratabenzene) complexes of Zr(IV) as in **4** have been shown by Bazan (46) to be catalysts for the oligomerization of ethylene to olefins, with the groups attached to boron influencing selectivity to α-olefin. Tethering the two C_5B rings (see structure **5**) tends to give polymer (47).



4 **5**

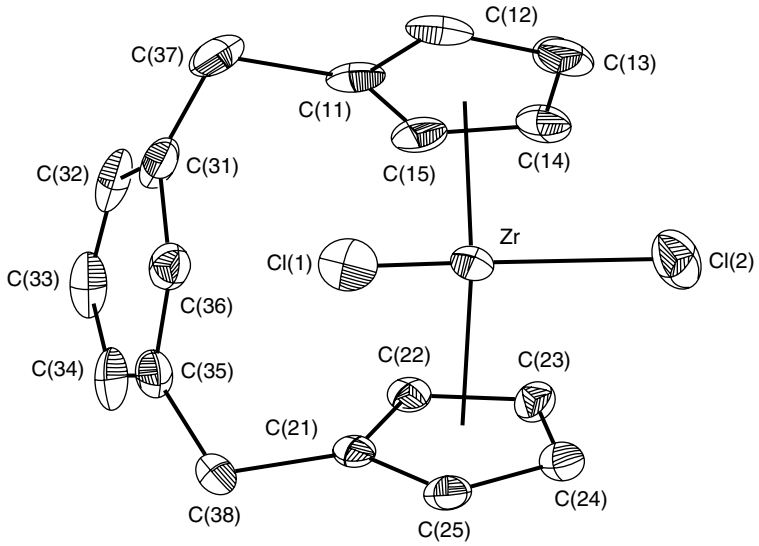


Fig. 5. Crystal structure of 1,3-bis(cyclopentadienylmethyl)benzenezirconium dichloride. Reproduced from Ref. 50 by permission of The Royal Society of Chemistry.

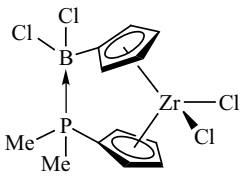
Bridged Metallocenes. The addition of a linkage between the two Cp rings has enabled the precise manipulation of the steric environment encountered by reactive molecules such as α-olefins, and the development of metallocenes for stereoregular olefin polymerization has proceeded from this advance (*vide infra*). The first and most widely employed bridges are $-[CR_2]_n-$ ($n = 1, 2$) and $-SiR_2-$ (R = methyl, phenyl), which are easily incorporated into ligands by reaction of two equivalents of Cp^- with α,ω-dibromoalkanes and dichlorosilanes, respectively. Increasing the bridge length generally increases the centroid–metal–centroid (Cp—M—Cp) angle, which can change polymerization characteristics. For example, the Cp—M—Cp angle rises in the series $(CH_2)_n(C_5H_4)_2TiCl_2$: 121° ($n = 1$); 128° ($n = 2$); 133° ($n = 3$) (48). The $-CH_2CH_2-$ and $-Si(CH_3)_2-$ bridges, by far the most popular bridging moieties, give rise to similar Cp—M—Cp angles, but the ethylene bridge allows a wide range of relative motion between the two halves of the ligand (49), which may lead to decreased molecular weight and stereocontrol in olefin polymerization relative to the more rigid silylene-bridged analogues. Increases in bridge length beyond that of 1,3-propanediyl generally lead to severe distortion, in which the bridge is rotated toward the wedge containing the nonchelating ligands, as in Figure 5 (50).

Bridging linkers also include R_2E (E = Ge, Sn) (51), as well as RB (52).

The Buchwald and Bercaw groups have reported (53,54) complexes in which two bridges tie the Cp rings together. The substituents on the Cp rings change the selectivity of olefin polymerization, as discussed in under Mixed Tacticity Polyobefins.

The bridging linkage need not be strictly covalent. In **6**, a bridged bis(cyclopentadienyl)zirconocene is depicted in which the two Cp's are connected via a Lewis acid–Lewis base interaction between P and B atoms attached to the

rings. A racemoid bis(indenyl) version gives highly isotactic PP at low temperatures, indicating the bridge is quite robust under polymerization conditions (55).

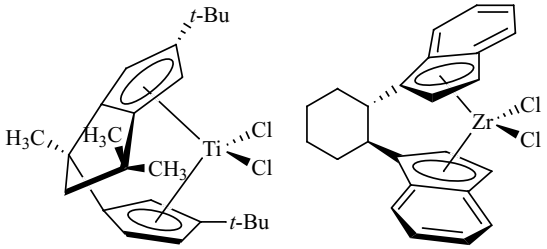


6

Bridges containing heteroatoms such as nitrogen that can bind directly to the transition metal have also been explored (56).

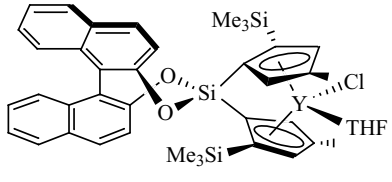
Siloxide (57) and amide (58) groups have been appended to Cp rings. Lewis acids such as Al atoms in MAO may reversibly coordinate to the heteroatom in these systems, leading to two distinct types of catalyst site and a bimodal distribution of polymer MW (59).

One of the perceived deficiencies of the early ethylene-bridged metallocenes in propylene polymerization was the relative lack of rigidity of the bridge. Several attempts have been made in recent years to make highly rigid bridged metallocenes, for example by use of cyclic groups in the bridge, as in **7** (60). Other uses of bulky bridges are to provide chiral centers, as in **8** (61), or to prevent the formation of mesoid isomers during synthesis due to bridge–ring repulsions, as in **9** (62).



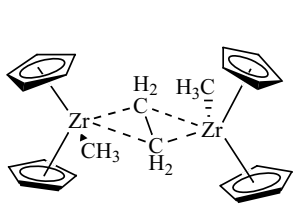
7

8

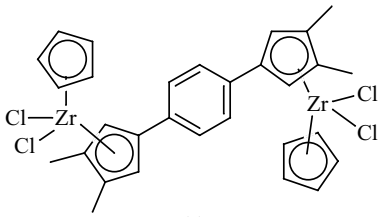


9

Polynuclear metallocene complexes may be produced through linking groups in which the alkyl group provides the bridge **10** (63). Other links may be through the Cp ring substituents, either indirectly, with a ferrocenyl bridge (64), or more directly through hydrocarbon-only linkages as in **11** (65).



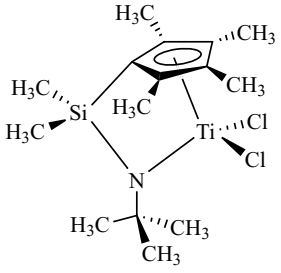
10



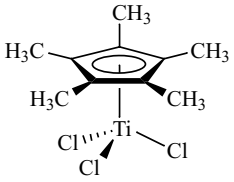
11

The aim of many of these investigations has been to facilitate cooperative behavior among the two or more catalytically active centers by forcing them to remain in proximity to each other. In some cases, positive enhancements in copolymerization have been observed (66).

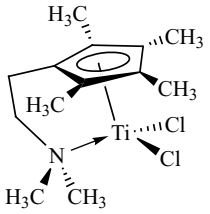
Mono(cyclopentadienyl) Complexes. Metallocenes bearing a single cyclopentadienyl ring are not as widely used in polymerization as their bis-Cp cousins, but they display a distinct reactivity that makes them particularly suited to certain polymerizations. As with the bis-Cp metallocenes, they appear as both bridged and unbridged varieties, with structures **12** and **13** portraying the most prominent members of these respective families. The most successful of the mono-Cp catalyst precursors are titanocenes, which are distinguished from zirconocenes in having stable Ti(III) structures, such as **14**.



12



13



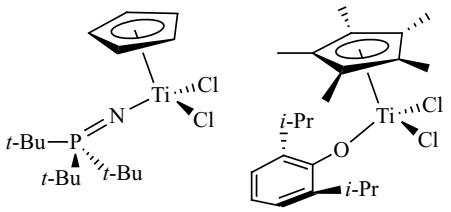
14

Mono-Cp complexes are generally prepared by the same routes as are the bis-Cp versions (see under preparation), but in addition they may be synthesized via comproportionation ($Cp'_2MX_2 + MX_4 = 2\ Cp'MX_3$; X = halide) (67) or by reaction of Cp salts with titanium compounds having only one substituent that is readily exchanged (68), such as $ClTi(OR)_3$.

Unbridged Complexes. Unbridged mono-Cp titanium complexes have been explored for polyethylene, but have found more consistent application in the area of polystyrene. In the latter case, reduction to Ti(III) appears to be necessary prior to entry into the polymerization cycle (69). Unbridged mono-Cp zirconocenes have been much scarcer in the polymerization literature. In many instances, the remaining substituents on the zirconium atom are divided into those ligands that are believed to exchange with aluminum alkyl groups and those assumed not to do so. The sole Cp ligand is thereby combined with a Cp analogue in a pseudo–bis-Cp metallocene–type active site arrangement, with catalytic performance typically intermediate between bis-Cp and bis-pseudo-Cp analogues. Cp

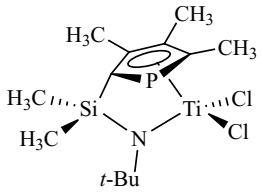
analogues include benzamidinate (70), tris(pyrazolyl)borate (71), and the chelating alkoxide (2-pyridyl)dimethylmethoxide (72). In the case of titanocenes, the strategy of mixing one Cp with a pseudo–Cp analogue has often led to the discovery of systems that far outperform typical bis- or mono-Cp catalysts, especially in the polymerization of ethylene and other α-olefins. These complexes are generally distinguished by significant steric bulk and a heteroatom with the potential for binding to titanium through multiple bonds. Two interesting examples from thisr subfamily are the phosphinimide complex **15** reported by Stefan and co-workers (73) and the phenoxide complex **16** described by researchers Sumitomo at (74). In both cases, activities are fairly good for ethylene/α-olefin copolymerization, and the levels of incorporated comonomer are high as well.

Recently, Baird and co-workers have reported (75) examples of polymerizations by a simple mono-Cp titanium complex, $(C_5(CH_3)_5)Ti(CH_3)_3$ activated with a Lewis acid ($B(C_6F_5)_3$) that not only copolymerizes ethylene and α-olefins but also induces polymerization of monomers normally associated with cationic polymerization such as isobutylene and vinyl ethers. Shaffer and Ashbaugh found (76) that for isobutylene and α-methylstyrene, the metal complex is an initiator rather than a catalyst (if it even participates at all), but that a transition from cationic to coordination polymerization occurs in styrene polymerization as temperature is raised. Even if it merely functions as an initiator, however, these investigations have revealed new polymerization systems based on anions such as $[RB(C_6F_5)_3]^-$ (R = alkyl, C_6F_5) that are less prone to side reactions tending to limit the MW and degree of polymerization of monomers like isobutylene at moderate temperatures ($T > -80^\circ C$).



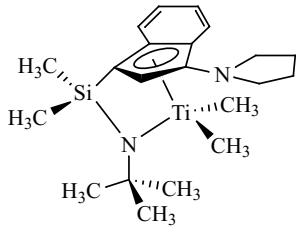
15 **16**

Bridged Complexes. The best-known bridged mono-Cp metallocene is the so-called constrained-geometry catalyst precursor **12**, a titanocene with a fairly bulky $C_5(CH_3)_4$ moiety on one side and a large amido group on the other. Despite this bulk, the short bridging unit, which enforces a Cp-centroid—Ti—N bite angle of 107.6° (77) (hence the sobriquet "constrained geometry"), ensures easy access of monomers to the active center. The ligand was first disclosed by Bercaw and co-workers in its complex with scandium (data published in—not first discloure—Ref. 78), a molecule with limited ethylene polymerization activity. Soon thereafter, patent applications from workers at Dow Chemical (79) and Exxon Chemical (80) appeared, claiming high activities for olefin polymerization using **12**. A heteroatomic analogue of **12** and **17** has also been found (81) to have good polymerization behavior.

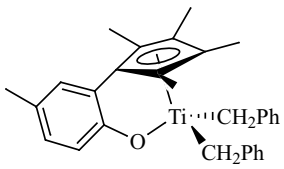


17

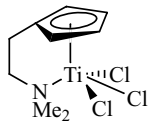
The bridged amido–Cp titanocenes such as **12** have risen to prominence presumably for the following features: (*1*) polymerization kinetics well suited to solution-phase reaction at high temperatures ($T > 120^{\circ}C$), the environment of Dow's commercial reactor; (*2*) high comonomer-incorporation ability, which makes production of amorphous polyethylenes practical; and (*3*) ability to generate long-chain branches that result in superior melt processability for LLDPE (see under Long-Chain Branching). Analogous complexes feature substituted indenyl or fluorenyl groups in place of the $C_5(CH_3)_4$ unit, as well as bulky alkyl or cycloalkyl substituents besides t-butyl on the nitrogen atom; any advantages in activity or performance appear to be offset by the complexity and expense of catalyst synthesis. A marked exception to this general trend is the heteroatom-substituted complex **18**, which shows (82) activities for ethylene–1-octene copolymerization far greater than those of complex **12**. The zirconium analogue of **12** and its relatives do not seem to share the high comonomer response of their titanium versions and are consequently much less widely employed. Also, titanium- and zirconium-based compounds with a single carbon atom bridging group show lower activity than does **12** (83).



18



19

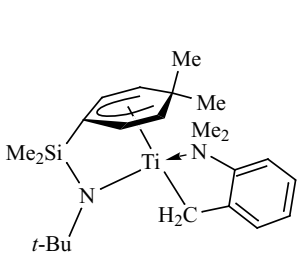


20

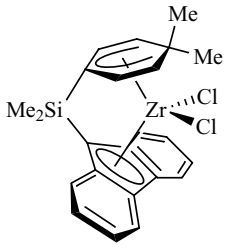
Other bridged metallocenes bearing one Cp ring have been described recently. One structure, **19**, reported by Marks and co-workers (84), has a direct Cp—phenoxide linkage. A series of Ti(IV) complexes, of which **20** (85) is an example, were developed by Chien and co-workers, bearing donor atoms that, based on NMR spectroscopic and polymerization data, coordinate to titanium prior to and upon activation by MAO. Compound **14** shown above also includes a Lewis basic

nitrogen bound to titanium, but in this case the bond appears in the precursor and the oxidation state of titanium is +3. Precursor **14**, developed by DSM under the name Lovacat (86), also produces rubbery ethylene–propylene copolymers, indicating that the reactivity of higher α-olefins in titanium-based copolymerizations with ethylene is similar in catalysts derived from Ti(III) and Ti(IV) precursors. Whether the oxidation state of complexes like **12** as well as **14** is also less than +4 in the active state has not been resolved.

Complexes with Open Pentadienyl Ligands. Open-chain analogues of the Cp ligand have only received limited attention. Compounds **21** (87) and **22** (88) have been featured in patent examples as moderately active polyethylene catalysts after activation by $[Cp_2Fe][B(C_6F_5)_4]$ and MAO, respectively.

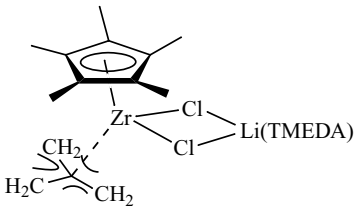


21

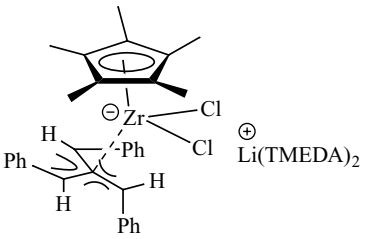


22

Complexes with Dianionic Ligands. In the search for metallocenes that do not require ionization, several workers have targeted the synthesis of Group IV complexes in which a dianionic ligand replaces a monoanionic Cp′ of bis-Cp′ metallocenes. Bazan has found good activity for TMM **23** (trimethylenemethane dianion) and TBM **24**, (tribenzylidenemethane dianion) complexes of zirconium (89).



23

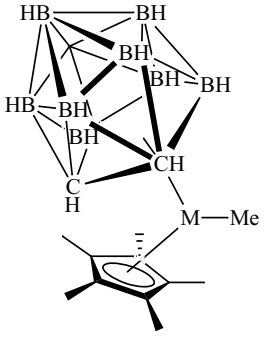


24

(The degree of association of Li with the Zr–Cl functionality appears to be dictated by the size of the dianionic substituent.) Although MAO is required for high productivity, similar activity from an unstable solution of the prealkylated neutral complex $(C_5(CH_3)_5)$(TBM)$ZrCH_3$ led the authors to propose that a similar neutral species is indeed the propagating site.

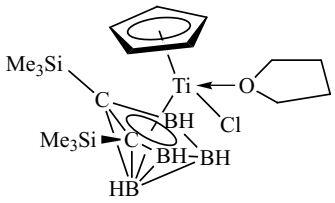
Carboranes were some of the first dianionic ligands to replace Cp in metallocenes. The unstable monomeric complexes **25a–c** were examined by Jordan and co-workers for ethylene activity. While **25b** and **25c** have fair activity for ethylene polymerization (~7 g/mmol(Zr)/h/atm for **25b**) (90), the titanium

analogue only dimerizes ethylene to 1-butene (91). The dianionic carborane (2,3-$(Si(CH_3)_3)_2$-2,3-$C_2B_4H_4$) has been used opposite Cp in complex **26** (92).

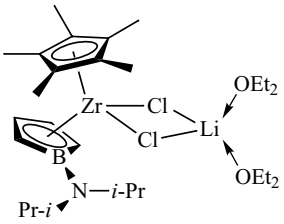


a: M = Ti
b: M = Zr
c: M = Hf

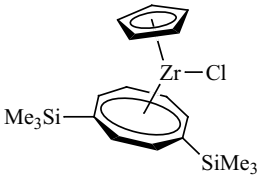
25



26



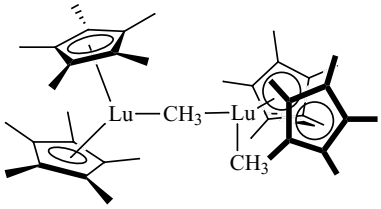
27



28

Quan and co-workers (93) have synthesized the aminoborollide complex **27**, bearing yet another dianionic Cp analogue. The cyclooctatetraene dianion complex **28** has shown fair polymerization activity with MAO (94).

Group IIIB and f-Block Metallocenes. The need for expensive cocatalysts has always hampered the development of metallocene catalysts for olefin polymerization. It was recognized early on that substitution of the Group IVB metal with a lanthanide or Group IIIB element in the +3, d^0 state would represent a cocatalyst-free analogue of the Kaminsky system. Active catalysts are indeed obtained from bis-Cp lanthanocenes and yttrium- and scandium-based congeners. The lutetium dimer **29** has an activity of >7 kg/mmol(Lu)/h/atm for ethylene polymerization in cyclohexane (95). (This remarkable compound can also break the C–H bonds of alkanes.)

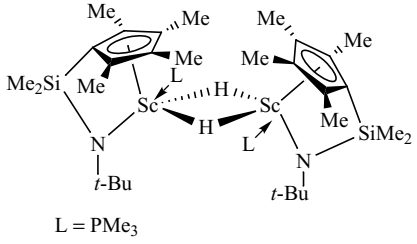


29

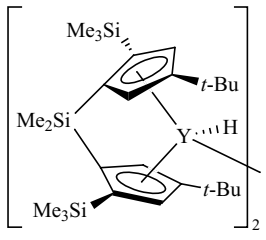
Because of their larger ionic radii, lanthanide (hereafter taken to include Y and Sc) atoms are usually bound to heavily substituted cyclopentadienyl groups such as $C_5(CH_3)_5$. Although ionization of the lanthanocene is unnecessary, preparation of the appropriate metal hydride or metal alkyl that can initiate polymerization is a matter of considerable art. Lanthanide alkyl complexes with β-hydrogens tend to decompose, while hydride and chloride species readily dimerize or form "-ate" complexes with lithium salts. In fact, not only the Cp-ligands but also the metal-bound alkyl substituent are often required to be large (such as $-CH(Si(CH_3)_3)_2$) (96), or the complex is further coordinated by a Lewis base molecule such as THF.

Lanthanocenes are even more reactive toward polar impurities than are Group IVB metallocene catalysts, which makes commercial use an even more daunting prospect. Another feature that limits the applicability of lanthanocenes is that the catalysts generally show high selectivity for ethylene insertion over larger olefins. Polyethylene produced by these catalysts generally is of very high density and MW. Larger olefins can be homooligomerized, but at rather low rates.

The scandium complex **30** disclosed by Shapiro and co-workers (97), which represents the first application of the bridging amido–Cp ligand in metallocene chemistry, is unusual in its moderate ability to polymerize larger olefins such as 1-pentene. A yttrium analogue initiates polymerization of *t*-butyl acrylate and acrylonitrile at room temperature and below (98). In the bis-Cp systems, a bridging group seems to improve reactivity toward α-olefins (99). The yttrocene dimer **31** produces highly isotactic polypropylene ($P_{mmmm} = 97\%$) (100).



30



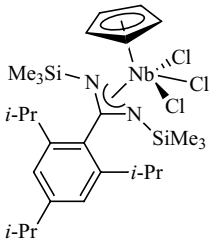
31

Although actinide complexes usually disqualify themselves from industrial utility by their radioactivity, the thorocene $(C_5(CH_3)_5)_2Th(CH_3)_2$ displays high activity for ethylene polymerization after activation (101). Like zirconocenes, this family of metallocenes tends to remain on the +4 manifold, and thus requires ionization by an appropriate cocatalyst (in this case, a highly Lewis acidic surface such as dehydroxylated alumina or $MgCl_2$) before it is active.

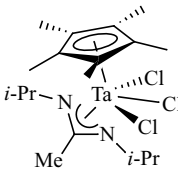
By their highly Lewis acidic nature, lanthanocenes are particularly suited to the polymerization of polar monomers such as acrylates and lactones (for a review, see Ref. 102). The lack of significant chain-transfer and -termination paths allows the production of block copolymers, including the case in which acrylate polymerization follows that of ethylene (103).

Group VB and VIB Metallocenes. Cyclopentadienylniobium and -tantalum compounds bearing amidinate ligands as in **32** (104) and **33** (105) have been occasionally used as ethylene polymerization precursors, usually with

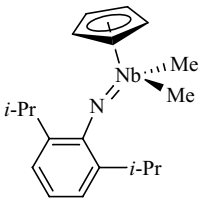
MAO as activator. Generally, the turnover rates for these systems are only moderate, with that for **33** being on the high side at 470 g(PE)/mmol(Ta)/h/atm. Activities for **34** and the vanadium complex CpV(*N*-*p*-tolyl)Cl_2 were 0.2 and 8.3 g(PE)/mmol(M)/h/atm, respectively (106). Molybdenum- and tungsten-based systems are similarly mediocre catalysts (106).



32

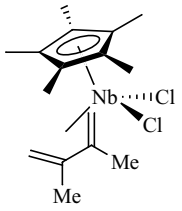


33

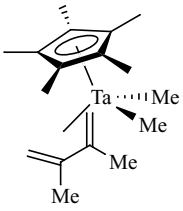


34

The mono-Cp butadiene complexes **35** and **36** have been found to polymerize ethylene at moderate rates as well (35.23 and 5.69 g/mmol(M)/h/atm, respectively, at 20°C, with 500 eq. MAO) (107). At low temperatures, the polymerizations appear to be living in nature (see under Living Polymerization).

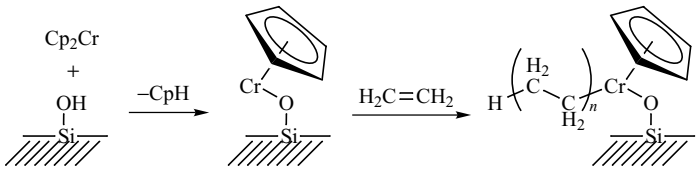


35



36

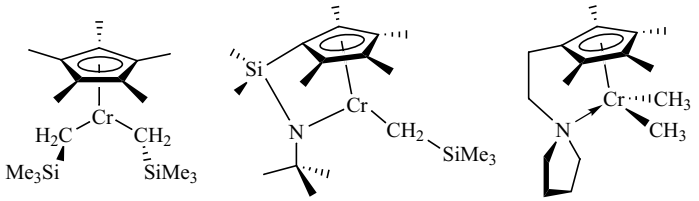
Cyclopentadienylchromium Compounds. Chromocene, a paramagnetic and somewhat labile metallocene, forms a polyethylene catalyst after chemisorption on silica (108). The reaction generates an equivalent of C_5H_6, and the propagating site has been proposed (109) to be as shown in equation 13. The characteristics of this ill-characterized catalyst are facile chain transfer to H_2, poor comonomer incorporation, and fairly broad molecular weight distribution (MWD). This catalyst is still in commercial use.



(13)

Theopold and co-workers have prepared unsupported mono-Cp ethylene polymerization catalysts by use of very bulky cyclopentadienyl and alkyl ligands on chromium; these catalysts do not require an activator. Precursors having both

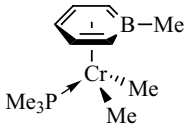
unbridged **37** (110) and bridged **38** (111) ligand sets yield polyethylene with broad MWDs, indicating a considerable breadth in active-site structures.



37 **38** **39**

Poor propylene incorporation by **38** is reported, although dimerization to 2-methyl-1-pentene was observed. Complexes such as **39** bearing electron-pair donor atoms, described by Döhring and co-workers (112), are active catalysts for ethylene polymerization (activity for **39**: 10.5 kg(PE)/mmol(Cr); conditions: 21°C, 2 atm ethylene, 100 eq. MAO); polymerization of propylene and higher olefins is approximately two orders of magnitude slower. Activities of up to 15 kg(PE)/mmol(Cr)/h/100 psi(C_2H_4) have been recorded for analogous unbridged mono-Cp chromium compounds such as $(C_5(CH_3)_5)Cr(CH_3)_2$(pyridine) supported on metal oxides and activated by isobutylaluminoxane (113). A noteworthy aspect of this system is that the MWD of the polymer produced is relatively narrow (2) $< M_w/M_n < 3$).

Another interesting catalyst system is the boratabenzene complex **40** from the Bazan group (114). This precursor, after activation by MAO, $B(C_6F_5)_3$, or $[(C_6H_5)_3C][B(C_6F_5)_4]$, polymerizes ethylene with activities comparable to Cp_2ZrCl_2.



40

General Trends in Metallocene Polymerization

Although activity comparisons are fraught with perils, as the conditions of polymerization, including catalyst concentration, purity of monomers, reaction time, etc., greatly influence the lifetime and polymerization rates of catalysts, a few conclusions may be drawn from selected surveys. In Table 1, Kaminsky and co-workers compare (115) the activities of metallocenes with different metals and cocatalysts.

Under identical conditions, metallocenes based on Hf are approximately an order of magnitude less active than their zirconocene analogues, and titanocenes are likewise of low activity. (There are inportant exceptions to this rule: *rac*-$C_2H_5(Ind)_2$ $HfCl_2$ has been shown to have activity comparable to *rac*-$C_2H_5(Ind)_2ZrCl_2$; see Ref. (116).) Of the aluminoxanes, MAO is by far the

Table 1. Ethylene Polymerization Activities for Aluminoxane-Activated Unsubstituted Metallocenes 115

Cp_2HfCl_2	0.03	70	65	490	MAO

[a]Units: g(PE)/g(M)/h/bar.

best activator. On the basis of periodic trends, the metal–carbon bond strength for the L_nM(polymer) cation should be greater for M = Hf, and this may explain the sluggishness of the third-row systems. A similar argument could be used to account for the much lower rates of chain transfer (in the absence of added H_2) in hafnocenes. In comparing the behavior of hafnocenes and zirconocenes, it is important to determine the level of Zr impurity in the Hf starting material (about 1 mol% in unenriched samples). This is normally carried through the synthesis and can lead to non–single-site behavior because of the much higher activity of the zirconium analogue (117).

Bridged metallocenes tend to incorporate larger olefins more readily than their unbridged counterparts. This probably has less to do with accessibility of the monomer than with electronic effects, although the fact that large-amplitude motions are restrained in the ansa-metallocenes cannot be ignored.

Electron-withdrawing substituents seem to cause polymerization activity to diminish, if steric effects are accounted for (118,119).

Effects of Additives on Polymerization

Compared with the effort spent in optimizing metallocene catalyst performance through modification of the ligand framework, tuning catalyst properties through the addition of catalyst modifiers has been far less popular. However, catalyst behavior is strongly influenced by the presence of certain agents, either directly (at the transition metal) or indirectly (by modifying the cocatalyst/anion). There are some reports of synergistic effects from mixed MAO/discrete activator cocatalyst systems (120). Modification of the MAO cocatalyst with Lewis bases such as $Si(OC_2H_5)_4$, hindered phenols, and bulky amines is described in an Exxon patent application (121), in which the catalyst derived from $(CH_3)(C_6H_5)Si(C_5(CH_3)_4)(N\text{-}t\text{-}C_4H_9)TiCl_2$ + MAO shows enhanced comonomer incorporation and altered chain-transfer rates in the presence of these agents. The seemingly simple catalysts based on Cp_2ZrCl_2 seem to show distinct two-site behavior depending on the cocatalyst, in which the degree of association between the ions apparently dictates fundamental kinetic parameters such as monomer selectivity (122).

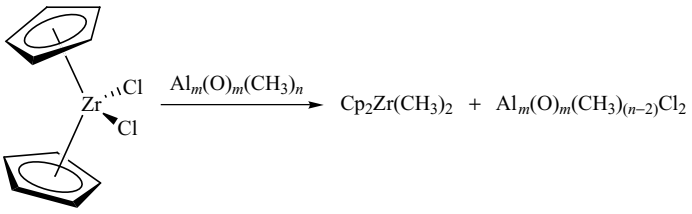
In commercial reactor operation, one would like the ability to either reversibly or irreversibly deactivate the catalyst, depending on the type of reactor

upset. Benzyl chloride and CO_2 have been claimed to be useful for the reversible deactivation of metallocenes, with MAO added to reactivate the catalyst (123). Mobil workers have discovered that CO_2, among other agents, can change the MW-response of MAO-activated metallocenes (124).

Polymerization Using Metallocenes

Most of the experimental and computational work on metallocene polymerization has dealt with the classic bis-Cp zirconocene family, and therefore this section will focus on this area. However, many of the reactions delineated here can be expected to occur in polymerizations involving other early transition metal (early-TM) based catalysts.

Activation. The paths shown in equation 14 are generally accepted to be that by which a metallocene precursor is transformed into a catalytic site in aluminoxane-cocatalyzed polymerization, while equations 8–10 portray the three mechanisms for activation using Lewis and Brønsted acids.

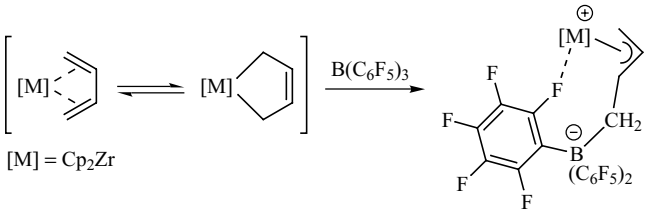


$$Cp_2Zr(CH_3)_2 + Al_m(O)_m(CH_3)_{(n-2)}Cl_2 \longrightarrow Cp_2Zr(CH_3)^+ + Al_m(O)_m(CH_3)_{(n-1)}Cl_2^- \quad (14)$$

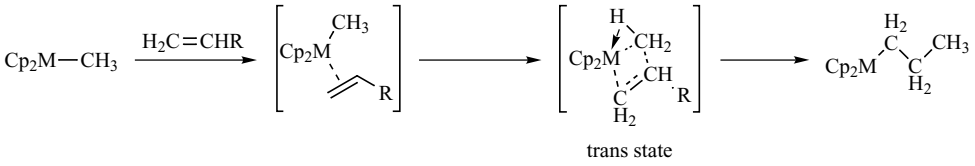
The first step in equation 14 involves the exchange of the halide groups attached to the metal atom with the alkyl groups bound to one or more aluminum atoms. In equations 8–10, it is assumed that the metallocene is introduced into the reactor as a dialkyl complex, or that it has been converted into such form by a halide-exchange process involving an alkylating agent in the polymerization environment.

The next step in both MAO-activated and MAO-free systems is believed to involve the transfer of an alkylide group to a Lewis acid (eqs. 8 and 9) or a proton (eq. 10), which creates an electron-deficient (14 e^-) metal center with a site for the potential coordination of an olefin. The nature of the counterion strongly affects the ability of the site to polymerize olefins, and indeed may change the active-site geometry enough to drastically change the selectivity of polymerization as well as the chain-transfer rate. Cation–anion interactions have been reviewed by Bochmann (125). The reactivity of anion-free cationic metallocenes has been probed by ion-cyclotron resonance (ICR) spectroscopy (126).

One variation on the ionization of dialkyl metallocenes is shown in equation 15, in which a butadiene complex, which may be predominantly M(IV) or M(II) in nature, reacts with a Lewis acid to form a Zwitterion that is able to further polymerize olefins, as shown by Erker and co-workers (127).



(15)



(16)

The approach and insertion of an olefin molecule may or may not pass through a local minimum or coordination complex (first in brackets in eq. 16); recent theoretical work (128) indicates that the well, if it indeed exists, is very shallow. The insertion of the new molecule into the growing chain is represented in equation 13 as a structure intermediate between reactants and products. The mechanism for this apparently concerted reaction does not involve the participation of metal-based electrons, and can be considered to be a Lewis acid–assisted anionic attack of the zirconium alkyl (ie, the polymer chain) upon one end of a carbon–carbon double bond. The concept of this reaction pre-dates metallocene study, and is merely a variant of the Cossee–Arlman mechanism (129) routinely invoked in Ziegler–Natta polymerization. Computational studies indicate (130) that an α-agostic interaction (131) provides much needed stabilization during the process of insertion.

A major consequence of this pathway, also known as migratory insertion, is that the growing chain sweeps from one side to another with every addition of monomer. This is a generalization, for some authors have explained the loss of stereoselection in metallocene polymerizations of propylene, for example, at low monomer concentrations to the action of a "windshield wiper" isomerization, in which the polymer chain and open coordination site switch places without the benefit of monomer insertion. At low insertion rates, this site inversion phenomenon may become competitive with insertion and thus render ineffective any substituent influences which differ between the two faces of the catalyst site. With appropriate ligand design, different or enantiomeric steric environments may be created for the two sides of the active site. This makes possible stereoselective polymerization of propylene and higher α-olefins, as will be seen below.

The use of discrete activators was instrumental in elucidating the structure and electronic nature of the active site for Group IVB metallocenes. A number of Lewis base–stabilized metallocene cations such as **41** (132), **42** (133), and **43** (134) were studied, chiefly by the Jordan group at the University of Iowa. Reactivity is not completely shut down by the base, although polymerizations are sluggish. Remarkably, agostic species such as **42** and **43**, which are believed to be important in chain transfer and propagation, respectively, can be characterized in such systems.

43

Deactivation. One of the factors that complicates the quantification of active-site concentration (135) is the fact that metallocene cations are subject to equilibria between catalytically active and inactive forms. In situations in which intramolecular coordination of an arene group can occur, this process competes with monomer coordination in styrene (136) and possibly olefin polymerization. Another dormant state invoked to explain catalyst decay is the dimeric structure $[Cp_2Zr(CH_3)(\mu\text{-}CH_3)Zr(CH_3)Cp_2]^+$ in which a methyl group bridges two metallocene fragments. This has been characterized by NMR for the reaction of $Cp_2Zr(^{13}CH_3)_2$ with MAO and other cocatalysts (136).

Ethylene–α-Olefin Copolymerization. Linear low density polyethylene (LLDPE), engineered to match the flexibility of polyethylene made by free-radical processes (LDPE), contains short-chain branches, which reduce the crystallinity of the resin. The short-chain branches result from incorporation of α-olefins such as 1-butene, 1-hexene, or 1-octene (known collectively as *comonomers*) when added to the reactive mixture. Traditional catalysts such as $MgCl_2/TiCl_3/AlR_3$ incorporate these comonomers in a manner that is very inhomogeneous, that is, there is considerable breadth in the distribution of comonomer content both within individual chains and from chain to chain. The first form of inhomogeneity is often referred to as *blockiness*, and is best estimated by examination of the monomer sequence distribution as determined by ^{13}C NMR spectroscopy. The second, intermolecular type of inhomogeneity shows up in extraction experiments, and is particularly well suited to TREF chromatography (temperature rising elution fractionation chromatography, which separates polymer fractions on the basis of solubility as solvent temperature rises.) The single-site nature of metallocenes gives rise to extremely narrow intra- and intermolecular distributions of short-chain branching.

Figures 6 and 7 compare the sequence distributions and TREF chromatograms respectively for Ziegler–Natta- and metallocene-catalyzed ethylene–1-hexene copolymerizations. The lack of blockiness in the metallocene resin in Figure 6 is demonstrated by the low levels of homopolymer triads, whereas intermolecular compositional homogeneity is shown by the narrow peak for the metallocene resin in Figure 7. It should be noted that while the narrow intermolecular distribution of comonomer content is a direct consequence of the single-site nature of the catalyst, the absence of blockiness is a reflection of the relative magnitudes of the rate constants for insertion for the two monomers and does not speak to catalyst site diversity. The kinetics of insertion will be treated in the following section.

Exceptions to the rule of narrow intermolecular distribution of comonomer can and do occur. These often result from the activity of catalytic sites of different structure (ie, loss of single-site nature) or, less often, from mass-transfer

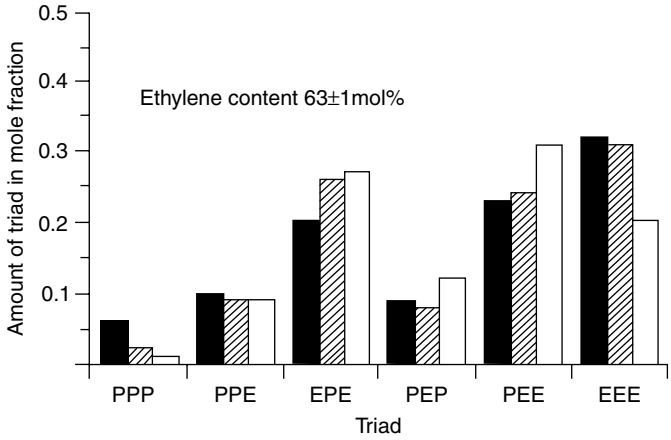

Fig. 6. A comparison of the triad distributions for three ethylene-propylene copolymers of similar propylene contents made by three different catalysts: $MgCl_2/TiCl_4/AlEt_3$ (black); $VOCl_3/Et_2AlCl$ (hatched); and Cp_2ZrCl_2 (white). Reprinted with permission from Ref. 138.

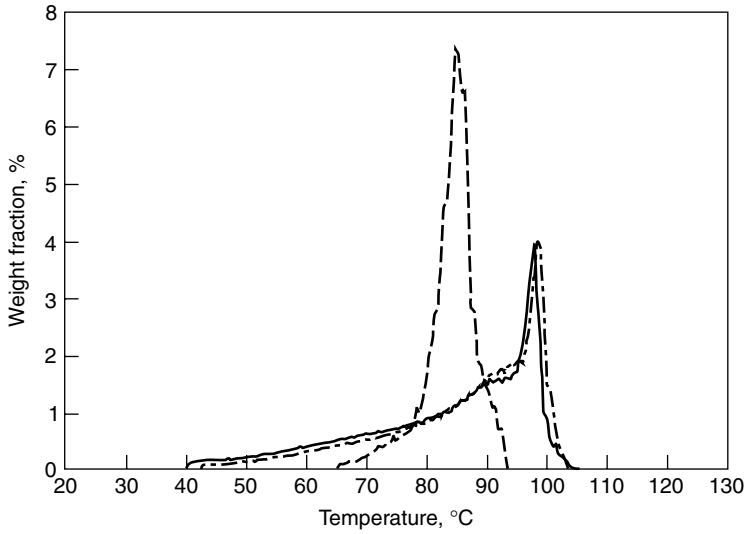

Fig. 7. TREF chromatograms for metallocene (dashed line; density = 0.922 g/mL) and Ziegler–Natta (solid and dot-dashed lines; densities = 0.921 and 0.930 g/mL, resp.) catalyzed ethylene-1-hexene copolymers. Reprinted from Ref. 139. Copyright (1994), with permission from Elsevier Science.

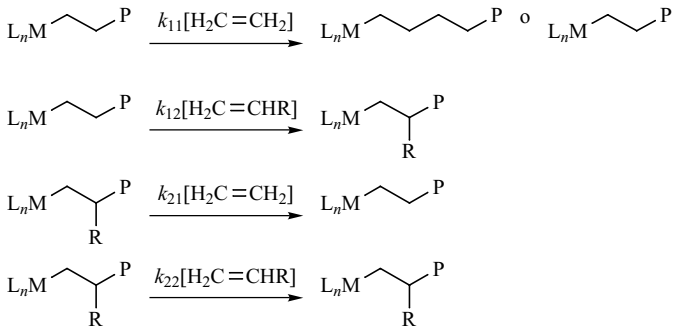
limitations that may occur between gas and catalyst solution, between gas and growing polymer particle, or between solution and polymer particle, depending on the process employed. Diffusional limitations only effect the distribution of comonomer content if there is a considerable gradient in the relative or absolute concentration of monomer(s) across a nonnegligible fraction of the diameter of the growing particle or volume of solution. Other potential sources of heterogeneity



Scheme 2.

include distributions of reactor residence time and heat history, imposed either by the reactor design or by a wide range of catalyst particle sizes. Reports on the control of comonomer content heterogeneity have been few.

The relative rates of olefin insertion reactions lead to models for the reactivity of the catalyst site, and the complexity of any chosen model arises principally from the degree to which the last monomers to be inserted affect the rate of subsequent insertion. If the last inserted monomer is assumed to have no effect, then one obtains two rate constants for insertion: one for reaction with ethylene and one for reaction with α-olefin. The next level of discrimination, also called First-Order Markov theory, posits that the last-inserted monomer influences the rate of insertion of the next unit, yielding four rate constants (Scheme 2). Higher-level treatments lead to many more rate constants in obvious extension. Metallocene copolymerizations display the tell-tale signs of First-Order (or higher) Markov behavior. This is necessary, for example, to explain the tendency for ethylene–α-olefin copolymerizations to alternate between ethylene and comonomer insertions beyond the proportion predicted by a random distribution. While First-Order copolymerization has been the basis of many studies of metallocene-based copolymerization, some researchers, most notably Fink (140), have argued for Second-Order Markov kinetics. A persuasive and statistically meaningful fit of copolymer unit sequence data to a model with eight parameters is difficult to achieve, however; so this level of treatment is unlikely to be generally applied.

At the first-order level, the preference of the metallocene for one monomer over the other is quantified by the two reactivity ratios, r_1 ($= k_{11}/k_{12}$) and r_2 ($= k_{22}/k_{21}$). Since ethylene is invariably more reactive than any other monomer, $r_1 > 1$ and $r_2 < 1$. Study of the First-Order Markov constants (Table 2) reveals important correlations with metallocene and comonomer structure. As is to be expected, the larger the comonomer, the higher the r_1 value, indicating a steric hindrance to its insertion. Bridged metallocenes, such as structure **2**, give catalysts with much lower r_1 values than do unbridged metallocenes. In general, metallocenes copolymerize monomers with a tendency toward alternation of monomers, as indicated by a value for $r_1 r_2$ less than 1.

Herfert and co-workers resolved the copolymerization reactivity ratios for two bridged metallocenes at the second-Order Markov level (140), as shown in Table 3. The data demonstrate bridged metallocenes are somewhat sensitive to

the size of the comonomer, but that this effect is ligand-dependent. There is also a trend toward a greater degree of alternation of monomers as comonomer size rises, probably due to increased steric repulsion preventing consecutive α-olefin insertion.

In the case of terpolymerization of ethylene with two dissimilar α-olefins, an apparent competition between the larger monomers causes the increase in monomer concentration of one to cause a reduction in the incorporation of the other (150).

Within the best-described family of catalysts, the bis-Cp zirconocenes, steric congestion tends to reduce the ability to insert the bulkier α-olefin, as might be expected. Burger and co-workers have proposed (151) a two-parameter methodology for quantifying the steric resistance to monomer coordination. These parameters, denoted the coordination gap *aperture angle* and the coordination gap *obliquity angle* are demonstrated in Figure 8 for the bridged metallocene *rac*-$(CH_3)_2Si(3\text{-}C_6H_5Cp)_2ZrCl_2$. Electronic effects often dominate over steric effects, especially when polycyclic aromatic groups such as fluorenyl

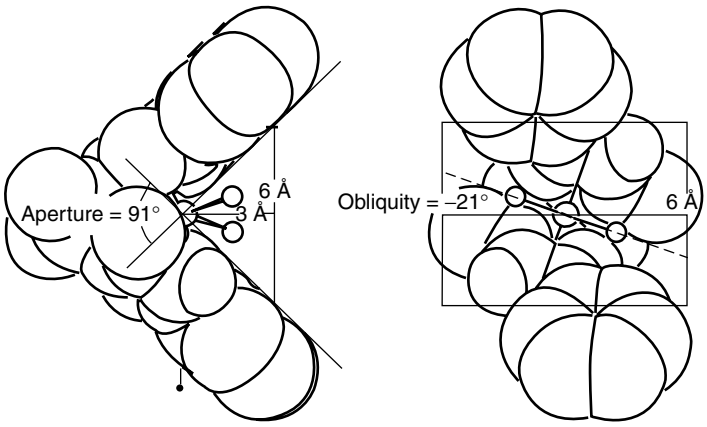

Fig. 8. Aperture and obliquity angles as defined in Ref. 151. Reprinted with permission of Wiley-VCH and the authors.

and benz[*e*]indenyl groups are considered. For example, in ethylene–1-octene copolymerization, *rac*-$(CH_3)_2$Si(benz[*e*]indenyl)$_2ZrCl_2$/MAO incorporates more comonomer than does *rac*-$(CH_3)_2$Si(Ind)$_2ZrCl_2$/MAO, despite the greater bulk of the benzannelated ligand (152).

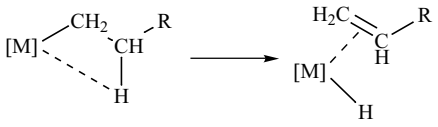
The reader will note that the regiochemistry for the insertion of olefins in Scheme 2 and elsewhere is presumed to be that which causes carbon 1 of the α-olefin to be bound to the metal; this is denoted 1,2-insertion, while the case in which the monomer inserts with opposite arrangement is known as 2,1-insertion or regioerror. While chain-end studies have shown 1,2-insertion to be the dominant regiochemistry, misinsertion may exert an influence upon the rates of chain transfer or ultimate polymer properties out of proportion to its frequency. Regiochemical inversion seems to be rather prevalent in polypropylene produced by mono-Cp titanocene catalysts (153).

As is often the case with polyethylene catalysts, both single-site and otherwise, polymerization rates rise rapidly as the level of comonomer rises. This phenomenon, often called the comonomer boost, has generated some contention among researchers, as it is unclear whether the effect represents a rate enhancement for insertion based on the donor effect of comonomer, or whether it derives from a physical effect, such as a lowering of the mass-transport barrier between the reservoir of monomer and the catalyst site. The two causes are difficult to separate, but at least part of the effect is diffusional: transport of small molecules through polyethylene is believed to occur solely through amorphous regions, and so any reduction in bulk crystallinity, such as through the inclusion of short-chain branching, should dramatically increase the diffusion rate.

Chain Termination. In this section, we will cover how polymer chain growth ends and a new chain begins. This process, alternately called chain transfer or chain termination, leads to a distribution of molecular weights. These two terms, often used interchangeably in olefin polymerization, mean rather different things in other areas of polymerization, in which the reactivity of a polymer chain

end (eg, a radical) can either be transferred (eg by hydrogen atom migration) to a new monomer or be quenched or terminated by reaction with a sacrificial agent (eg, a radical trap). An ideal single-site catalyst will produce a distribution of chain lengths conforming to the Schulz–Flory model and this leads to the ratio between weight-averaged and number-averaged molecular weights, or polydispersity index (PDI), being equal to two. The PDI tends to the limiting value of 2.0 so long as (*1*) the rate of chain transfer is sufficiently large relative to the rate of initiation (activation), and (*2*) there are no reactions that lead to branched polymer, eg, diolefins or reactive polymer chain ends. In practice, the distribution in MW is also subject to complications similar to those that affect the comonomer distribution (see above), inevitably resulting in larger values for the PDI. Now we will take a closer look at the processes involved in chain transfer, and will divide them into two categories: those that are induced by the action of chain-transfer agents and those that occur in their absence.

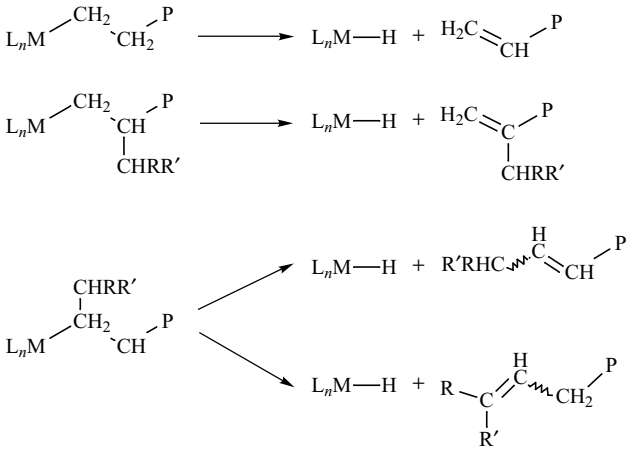
Endogenous Chain Termination. Two processes are now claimed to represent the vast majority of chain-transfer events that happen without the intervention of chain-transfer agents. The first, known as β-hydride elimination and shown in equation 17, is a mechanism of considerable lineage in organometallic chemistry.



(17)

Here, the extrusion of a growing polymer chain is effected by the transfer to the metal atom of an equivalent of H^- from the carbon atom β to this metal. Theoreticians lean toward the existence of a discrete intermediate along this reaction coordinate, often designated the *agostic* complex, in which electron density is donated by the C—H bond undergoing the process of breaking. Agostic-type nonclassical bonding arrangements have been observed experimentally in special cases, but have been invoked for many aspects of early-TM polymerization, including the process of monomer insertion. The strength, estimated to lie in the range of 8–15 kcal/mol, of the agostic interaction is a testament to the electrophilicity of this electron-poor, cationic metal center. The reaction is completed by the dissociation of a polymer chain with an unsaturated chain end.

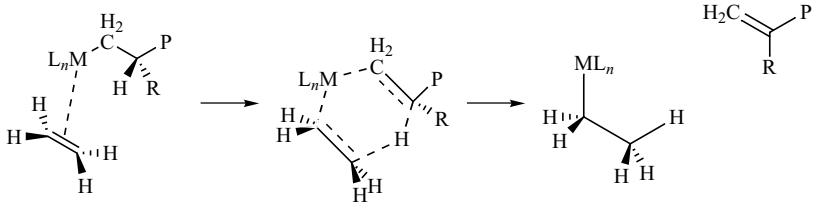
In copolymerizations, the double bond formed by β-hydride elimination may signify the nature of the last-inserted monomer. As shown in Scheme 3, the type of unsaturated group reflects whether the monomer was ethylene or comonomer (in this case, 1-hexene). In fact, the regiochemistry of the last insertion may also be given by the placement of the double bond. In normal insertion, followed by elimination, a pendent methylene group is observed, while regiomisinsertion will generate an internal olefinic group, whose regiochemistry is dictated by whether the hydrogen that is transferred to metal originates on C_1 or C_3 of the original α-olefin (This generalized discussion ignores isomerization reactions which may occur prior to chain release, and also does not treat the formation of trisubstituted olefinic chain ends, which have been reported.)



Scheme 3.

(In this Scheme, wavy lines indicate both E and Z isomers are possible, but in practice, only the trans isomer derived from path (a) is observed.) The correspondence between unsaturation structure and last-inserted monomer does break down: in certain documented cases (154), chain-end isomerization leads to a preponderance of *trans*-CH_3—CH=CH—CH_2P chain-termini from ethylene homopolymerization.

Another type of chain-transfer reaction that has gained believers in recent years is the reaction that we will call chain transfer to monomer (in this case, ethylene) (155) (eq. 18). Chain transfer here superficially resembles β-hydride elimination, in that the same olefinically terminated chains are formed from the same monomers, but in this case the β-hydride is transferred directly from the chain to another monomer molecule. The reader will note that this process is the conflation of β-hydride elimination followed by insertion of monomer into the new M—H bond, and indeed it is difficult to distinguish between these mechanisms by labelling studies, for example. Unlike β-hydride elimination, however, chain transfer to monomer is a first-order process in monomer concentration, and if one assumes a rate for monomer insertion that is also first order in monomer concentration, then the number-average MW should be unaffected by monomer concentration in the case of chain transfer to monomer, while it should rise in proportion to monomer concertration in the case of β-hydride elimination.

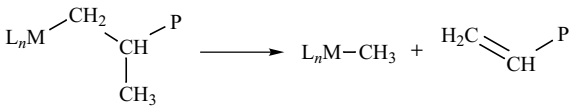


(18)

Some new work on ethylene homopolymerization indicates that this mechanism may dominate, at least under certain conditions (156). In fact, in the case

of "certain meso-bridged zirconocenes," ethyl branching occurs, and it is believed to derive from the reinsertion of a vinyl-terminated polymer chain after chain transfer to ethylene (157). However, it appears certain that β-hydride elimination is a large component of chain transfer in the presence of comonomer. Generally, the MW of metallocene copolymers falls sharply as comonomer content rises. This is attributed to the higher reactivity of the β-hydride group attached to a tertiary as opposed to a secondary carbon atom. There is ample evidence that the MW of copolymers rises as the overall monomer concentrations rise, even with the ratio of monomer concentrations held fixed and the comonomer content of the polymer remaining nearly constant. The most parsimonious explanation for this phenomenon is the existence of a unimolecular chain transfer process involving loss of a chain containing comonomer as the last inserted unit.

A process that has been noted in lanthanide metallocene polymerizations of α-olefins as well as in the polymerization of propylene by the highly sterically congested metallocene $(C_5(CH_3)_5)ZrCl_2$/MAO (158) is that shown below (eq. 19), in which an alkyl group attached to the β-carbon of the polymer chain is transferred to metal, resulting in the loss of a vinyl-terminated chain.

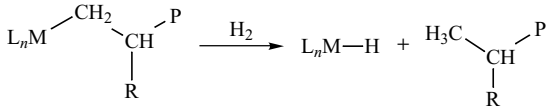


(19)

Transfer of side-chain substituents larger than methyl is unknown.

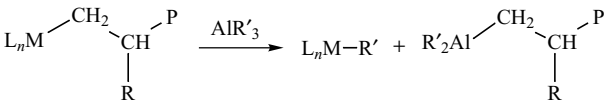
Endogenous chain-transfer rates commonly increase with temperature. The empirical activation energy found for H-transfer termination is about 34 kcal/mol estimated from relative barrier to *trans*-vinylene termination over propagation in Ref. 159.

Exogenous Chain Termination. Industrial Ziegler–Natta processes routinely use chain-transfer agents, predominantly hydrogen, for MW control. This reaction (eq. 17), as well as others, such as chain transfer to a metal alkyl compound such as diethylzinc or triisobutylaluminum, works well for metallocenes also. This type of chain transfer liberates a molecule with a saturated chain end. Hydrogen has also been reported to alter overall metallocene activity, either upwards or downwards. The phenomenon of rate acceleration by H_2 may be related to the reactivation of dormant catalyst sites that contain sterically demanding metal–polymer environments, eg following 2,1-insertion of propylene (160).

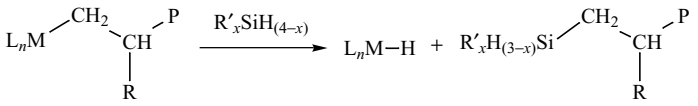


(20)

Other chain-transfer processes that have been observed are chain transfer to aluminum (eq. 21) and to silicon (eq. 22).

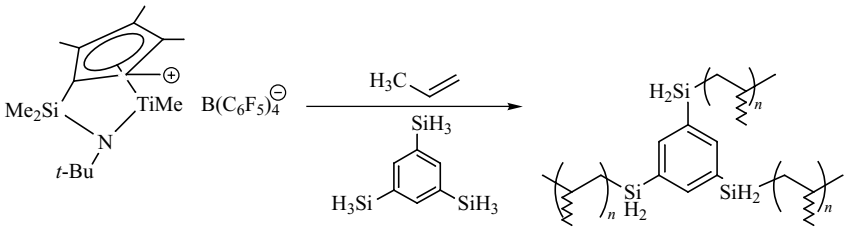


(21)



(22)

In an elegant adaptation of the latter reaction, Koo and Marks found (161) that 1,3,5-trisilylbenzene can lead to long-chain–branched copolymers through successive chain-transfer events (eq. 23).



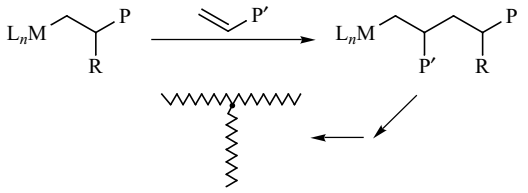
(23)

This technique was also applied to the production of block copolymers of dissimilar subunits, using silyl-capped polymer chains as chain-transfer agents. Both mechanisms for chain extension using silanes could in principle be mirrored in similar reactions with polyfunctional alkylaluminum or boron compounds, but the ensuing C—(Al/B) linkages would be vulnerable to hydrolysis, although oxidation of a borane-terminated polyethylene sample can lead to a growth point for methacrylate polymerization, yielding a diblock copolymer (162).

Living Polymerization. Polymerization in the absence of both chain transfer and termination, or living polymerization, has value to the study of metallocene reactivity, but little potential beyond very specialized applications. If initiation of polymerization is rapid on the timescale of the polymerization run, PDIs will approach 1.0, the limiting value representing monodispersity. Several examples of metallocene-based living olefin polymerization catalysts have appeared in the literature (105,163).

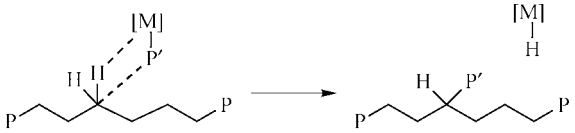
Long-Chain Branching. Processing metallocene polyethylene can be difficult, especially if extrusion equipment optimized for high pressure–low density LDPE is used. Not only is the polymer melt of relatively high viscosity for a desired application because of the narrow molecular weight distribution, it does not undergo shear thinning to the same extent as LDPE because of the lack of long-chain branches, which tend to reduce a polymer's radius of gyration. During the investigation of metallocene polymerization using catalysts with very low r_1 values for copolymerization, generally bridged bis(indenyl)zirconocenes, researchers noted rheological behavior indicative of long-chain branching (LCB) in polymer melts

and solutions. The mechanism for LCB formation in metallocene systems has been postulated as in equation 24, where reincorporation of a vinyl-terminated chain end from a dissociated polymer molecule, followed by further monomer insertion and finally chain loss, yields a polymer with three branches radiating from a methine carbon. (For the branches to have rheological impact, it is believed that they should be about the entanglement length of linear polyethylene, or about 3 kD.)



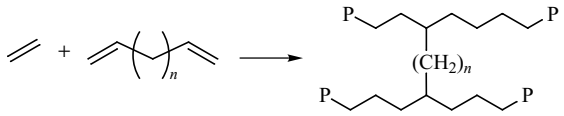
(24)

Reinking and co-workers have raised the possibility that at least some of the LCB seen in metallocene-based polymers may arise from an unusual aliphatic C—H activation of dissociated ("dead") polymer molecules (eq. 25) (As part of a study of non-metallocene vanadium catalysts, see Ref. 164). In this study, a bridged bis(indenyl) zirconocene was found to incorporate ethylene units into the heptane solvent, while an unbridged version, $(n\text{-}C_4H_9Cp)_2ZrCl_2$, did not.



[M] = *rac*-$Me_2Si(Ind)_2Zr^+$ (25)

The reactions in both (equations 24 and 25 lead to long-chain branches of the Y-type, with three arms of appreciable length. The higher the level of LCB by these routes, the more one obtains polymer molecules of a bushy or dendritic structure (Fig. 9**a**). Cyclic structures cannot result from equation 24, a fact that reduces significantly the danger of passing into a cross-linked or gelled condition. Cross-linking is much more difficult to avoid when LCB is engendered by the copolymerization of an α,ω-diene such as 1,9-decadiene with ethylene (eq. 26),



(26)

which results in an H-type or four-armed polymer node (Fig. 9**b**).

Because gelled or networked polyolefins are almost completely infusible and insoluble, even small amounts can adversely affect the appearance and mechanical performance of a fabricated article.

Side Reactions. Many of the reactions of metallocenes that occur as minor pathways during polymerization demonstrate the extreme electrophilicity of the metal cation, in that fairly unreactive bonds may be broken. Generally, the

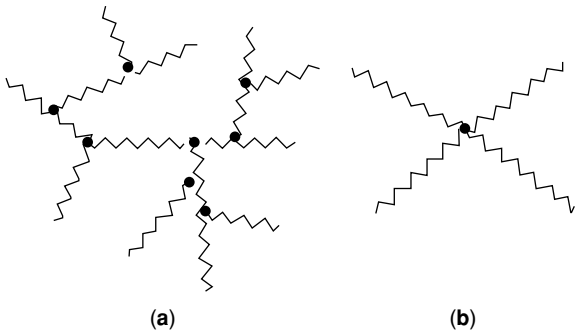


Fig. 9. Schematics of (**a**) a dendritic polymer (left) and (**b**) a four-armed star polymer.

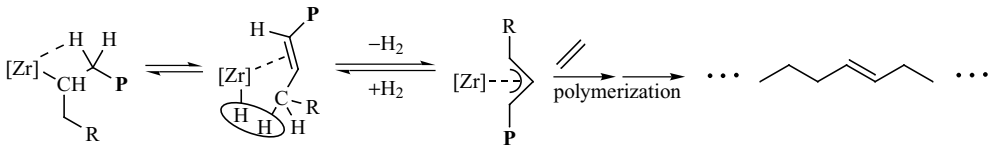
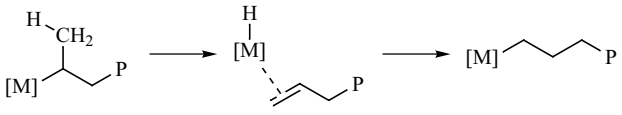
occasion for such a process is the formation of a species that has a low rate of monomer insertion, thus increasing the likelihood of lower-probability reactions. One interesting reaction that may influence the rate of chain transfer in batch polymerizations is shown in equation 27). In the first step of this process, detected by NMR (165) and by ion-cyclotron resonance (166), activation of one of the allylic C—H bonds causes the extrusion of one molecule of H_2 and the formation of an allyl–Zr cation. This structure has been considered inactive for further propagation, yet there is evidence (167) that return to the polymerization cycle can occur, either through the reverse of the allylic-activation process or through the direct insertion of ethylene into the Zr–allyl bond, leading to unsaturation in the polymer backbone.



$[Zr] \equiv Ph_2C(Cp)(Flu)Zr^+$

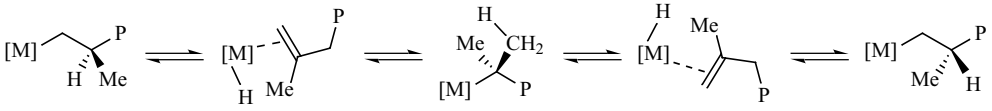
(27)

Researchers have also noted that metallocene catalysts can exchange Zr—C and C—H bonds during propagation, leading to 1,3-enchainment of propylene, for example, following regiomisinsertion (eq. 28) (168).



(28)

A number of very similar paths have been proposed (169) for the rearrangement of polyethylene chains attached to $(C_5(CH_3)_5)_2Zr^+$, another system in which propagation is sterically hindered (albeit by the ligand in this case). Interestingly,



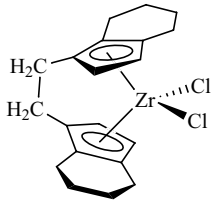
Scheme 4.

both of the previous two mechanisms require the existence, though transient, of a metal–olefin complex.

In the isotactic polymerization of propylene mediated by bridged metallocenes, certain errors in polymer microstructure have been conclusively found (170) to result from an elimination–reincorporation mechanism involving insertion of a 1,2-disubstituted unsaturated polymer chain end as in Scheme 4.

Although the metal–Cp linkage is usually assumed to be inviolable in most mechanistic treatments of metallocene polymerization, there is evidence that this assumption is flawed. The rac/meso ratios of certain bridged bis(indenyl) metallocenes have been shown to equilibrate in the presence of light (171), LiCl, or MeLi (172). These processes require the rupture of the M–Cp bond to one half of the ligand, the rotation of the dissociated C_5 ring, and its reassociation with the metal. Titanocenes and Group III metals appear to be more susceptible than zirconocenes to this process (although it is claimed to occur for the latter as well). Whether this reaction is important to polymerization has not been investigated, but it could affect catalyst quality, especially in isotactic polypropylene production.

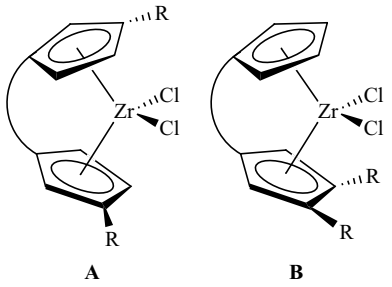
Stereoselective Polymerization. In the early 1980s, Ewen (173) and Kaminsky (174,175) independently examined the polymerization behavior of metallocenes *rac*-Et(Ind)$_2$TiCl$_2$ and *rac*-Et(4,5,6,7-IndH$_4$)$_2$ZrCl$_2$ (**44**) each with two indenyl fragments linked by a dimethylene bridge.



44

It was found that polypropylene made by such complexes (cocatalyzed by MAO) tended to be isotactic, as opposed to the atactic polypropylene that had been hitherto made by metallocenes such as Cp_2ZrCl_2. The strong relationship between ligand structure and polymer tacticity is considered to be the most secure proof of the migratory insertion mechanism for polymerization. The lure of homogeneous stereoselective olefin polymerization is responsible for much of the diversity of ligand structures within the bis(Cp) family.

Since metallocenes with ligands that protrude into the coordination zone in a fashion represented in Scheme 5 by complex A give rise to isospecific polymerization and those of structure B lead to syndiospecific polymerization, researchers generally assumed that the interactions causing stereoselection were

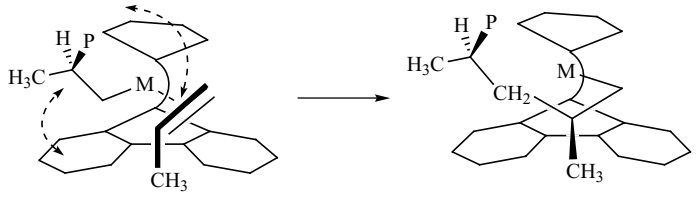


Scheme 5.

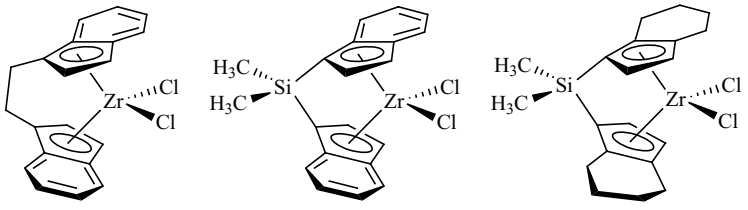
those directly between ligand and incoming monomer. Catalyst sites, therefore, of approximately C_2 symmetry (A) would then choose the same face of the prochiral monomer regardless of which side of the catalytic site the monomer approached. Sites with approximate C_s symmetry (B) would cause a selection of alternately re or si faces of the incoming monomer as the polymer chain switcheds sides. Bercaw has recently produced evidence (54) that the steric interactions that favor monomer face alternation in complexes of type B are those between the growing chain and the incoming monomer. (A similar mechanism for stereoregulation had earlier been proposed by Guerra and co-workers (176) for complexes of C_2 symmetry on the basis of molecular mechanics models.)

In this mechanism (Scheme 6), the directing effect of the ligand structure is upon the orientation of the polymer chain (lower dotted curve in Scheme), which then in turn dictates the preferred orientation of the incoming olefin. This leads to the somewhat counterintuitive conclusion that the methyl group in propylene is actually positioned toward the large fluorenyl side of the ligand in all insertions for Cp–fluorenyl complexes. While polymer–monomer interactions were advanced by Brintzinger and co-workers (177) as factors partially responsible for stereoselection in isospecific polymerization some years earlier, it is only in the case of syndiospecific polymerization that the hypotheses predict different monomer orientations with respect to the ligand. Combined *ab initio* and molecular mechanics calculations (178) had also led to the conclusion that the polymer chain controls the orientation of monomer in isospecific polymerization by $(CH_3)_2Si(1,3\text{-}(CH_3)_2Cp)Zr(P)^+$.

Isotactic Polypropylene. The bis(indenyl) metallocenes that are most often associated with isotactic polypropylene (iPP) and other isotactic polyolefins are shown in structures **45**–**49**.



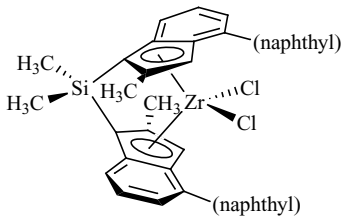
Scheme 6.



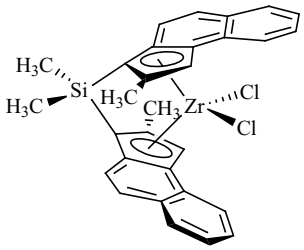
45

46

47



48



49

Synthesis of the complexes usually requires the separation (normally by fractional crystallization) of the racemic isomer pair from the meso isomer, since the latter leads only to atactic polymerization of propylene. The syntheses explored by Jordan, described above in the section Preparation, tend to raise the overall yield of racemic metallocene.

The resolution of the enantiomers of bridged bis(indenyl) metallocene dichlorides has been accomplished by the replacement of both halides by one enantiomer of binaphthol, followed by chromatography (179). Direct synthesis of enantiomerically pure precursors via chiral epoxides has been reported (180). Polymerization of α-olefins using such precursors does not lead to the production of appreciably chiral polymer due to the *de facto* mirror plane which exists in an isotactic poly(α-olefin) of reasonably high degree of polymerization (Fig. 10).

The quest for iPP of commercially acceptable melting point (MP) has led to preparation of bis(indene) ligands with increasingly elaborate substitution patterns. MP appears to correlate positively with the run length of isotactic dyads (stereoselective enchainment) as well as negatively with the level of regiomisinsertions. Substitution with small alkyl groups at the 2-position of the indene causes the iPP to be much reduced in regioerrors, while increasing bulk at the

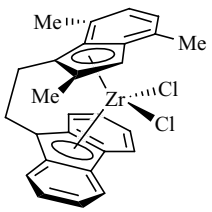
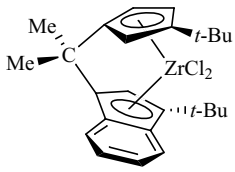
4-position has the effect of suppressing stereoerrors. Table 4 details the effects of alkyl placement on indenyl ligands upon polypropylene properties, while Mise and co-workers (181) have collected data on a large number of bis(Cp) complexes.

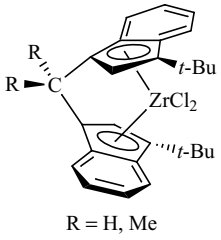
Recent work in the area of isospecific olefin polymerization has challenged the mindset that C_2-symmetry is necessary for high isotacticity. For example, compound **50** gives P_{mmmm} between 80 and 91% (183). Another assumption which has been overturned is that, in the bridged indenyl systems, substitution at the 3-position defeats the stereocontrol enforced by the fused benzene ring. Complexes **51** (184) and **52** (185) give some of the highest-melting iPP produced by metallocenes (up to 162°C; R = H).



50



51



52

Regioerrors have also been linked to elevated chain-transfer rates (186). Ligand modification with the objective of altering the *electronic* environment of the propagating center has not been pursued systematically, although the inductive effects of substituents may influence the stereoselectivity: Lee and co-workers have shown electron-withdrawing groups to suppress stereoerrors in propylene polymerization by *rac*-$C_2H_4(Ind')_2ZrCl_2$/MAO (Ind′ = substituted indenyl) (119).

Isotactic polymers of 1-olefins higher/larger than propylene has been accomplished with metallocenes, as would be expected from the enhanced ability of these catalysts to incorporate large comonomers in ethylene–olefin copolymerization.

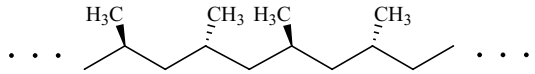


Fig. 11. Syndiotactic polypropylene.

Syndiotactic Polypropylene. Syndiotactic polypropylene (sPP) is a crystalline homopolymer with alternating stereochemistry at each successive methine carbon in the chain (Fig. 11).

Compared with iPP, sPP has lower modulus and melting point, making it less useful for applications demanding strength. It does, however, appear to be superior to iPP in such properties as clarity and flexibility (187,188). Although catalysts such as VCl_4 had been shown to produce sPP at low temperature, metallocenes with C_s symmetry such as **3** were the first catalysts to make sPP under practical conditions with high activity (189). The performance of some complexes in this family is shown in Table 5. Note the effects of bridge substituents on polymer MW (190).

Mixed Tacticity Polyolefins. The Waymouth group at Stanford has recently unveiled (193) a catalyst family for the production of elastomeric polypropylene, in which blocks of isotactic polymer are linked by segments of essentially atactic material, resulting in a product with geographically separate crystalline and amorphous domains, which is imbued with high flexibility and recovery. The underlying mechanism has been said to be as shown in Scheme 7, where an unbridged complex oscillates between racemoid and mesoid conformers on a timescale intermediate between that for monomer insertion and that for production of a single polymer molecule.

However, recent microstructural investigations have led Busico and others to advance an alternate mechanism (194), in which two enantiomeric racemoid catalysts interconvert (Scheme 8) at a rate nearly equal to monomer insertion.

In any case, the relative amounts of isotactic and atactic sequences depend on temperature, monomer concentration, transition-metal identity (Zr or Hf) as well as upon the size of the 2-indenyl substituent. Chien (195) and Collins (196) have also described metallocenes **53** and **54**, respectively) which produce elastomeric polypropylene.

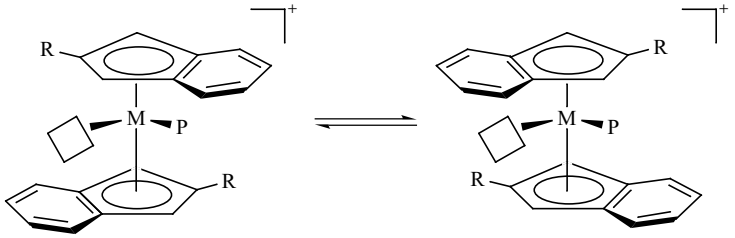
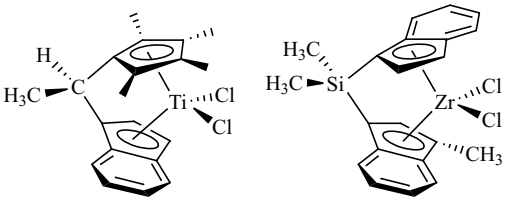


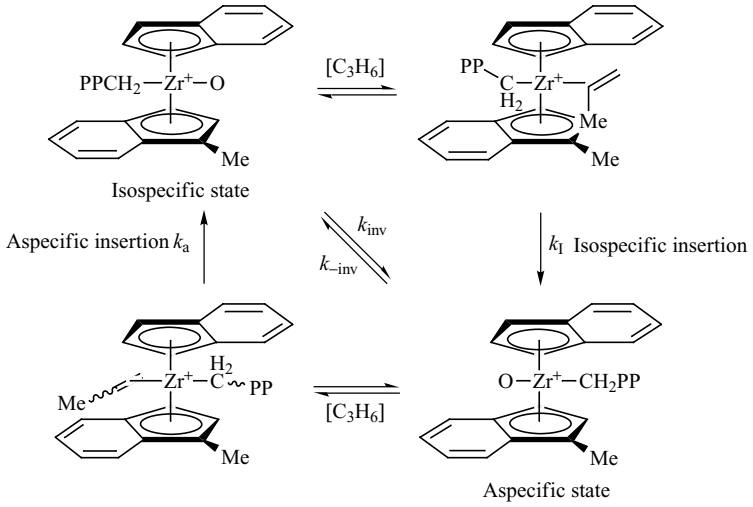
Scheme 8.



53 **54**

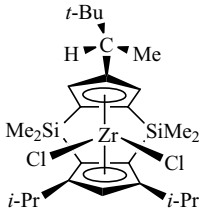
In both of these cases the metallocenes have a highly asymmetric character. The authors postulate a different kind of oscillation for the origin of the blockiness: a competition between migratory insertion and polymer chain migration without insertion. This is shown graphically for Collins' system in Scheme 9.

Isotactic sequences are here due to successive insertions upon the same side of the catalyst (rather than from alternate sides as is believed to occur in C_2-symmetric systems), which are made possible by "windshield-wiper" motions of the chain relative to the catalyst. The dibridged catalyst **55** switches from being predominantly syndiospecific to being moderately isospecific as temperature is raised and propylene concentration is lowered, probably due to a similar phenomenon (54). The fact that the catalyst with the chiral substituent projecting



Scheme 9. (Reprinted with permission from Ref. 196. Copyright 1998 American Chemical Society.)

into the wedge (as shown in **55**) suppresses the strong syndiospecificity evident in the system with this substituent replaced by H is further evidence of a missed-insertion mechanism, since one side becomes significantly more crowded than the other.



55

A subtle modification of the ligand sphere in Cp–fluorenyl complexes, as in structure **56**, changes the stereospecificity of the catalyst enough so that hemiisotactic polypropylene, rather than sPP, is produced (197). Apparently, the added substituent on the Cp ring is enough to remove any enantiofacial selectivity from one side of the site, but not enough to completely suppress monomer coordination to one side, as in Scheme 9. This material, shown in Figure 12, can be thought of as a syndio-isotactic stereoblock polymer.

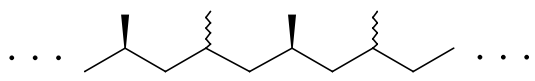


Fig. 12. Hemiisotactic polypropylene. (Wavy lines indicate methine units of indeterminate chirality.)

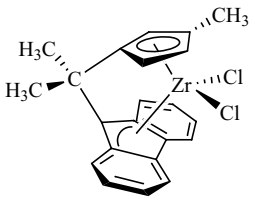


56

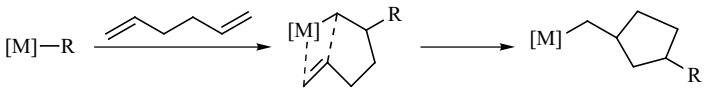
Catalysts such as **56** also lead to alternating isotactic ethylene–propylene copolymers through a similar mechanism (198), since conditions can be arranged such that ethylene incorporates predominantly on the more hindered catalyst side.

Other Monomers.

Dienes. Dienes tend to reduce the polymerization activity of metallocenes, and it is generally difficult to incorporate more than a few mole pernts into polyethylene. Monomers having two C=C bonds can be incorporated into one or two chains depending on the reactivity of the two unsaturated fragments. If conjugated, the diene can be incorporated via 1,2- or 1,4-insertion, leaving one double bond either in the polymer backbone or on a side chain. Conjugated dienes are particularly potent catalyst poisons for bis-Cp metallocenes, although there are occasional reports (199,200) of copolymerization with ethylene. Mono-Cp titanium complexes, by contrast, are fairly competent for the homopolymerization of 1,3-butadiene or isoprene (201). Incorporation of butadiene leads in some cases to the presence of *trans*-vinylidene groups and *trans*-1,2-cyclohexanediyl structures (202) and in others to *trans*-1,2-cyclopentanediyl and 1,2-cyclopropanediyl groups. (203). The oxidation state of titanium in the catalyst is (again) not known, but the ability of the $[C(C_6H_5)_3][B(C_6F_5)_4]$ activator to give high activity for polybutadiene (1240 g(BR)/mmol(Ti)/h at 30°C, giving about 80% cis and 15% vinyl microstructure) is suggestive of Ti(IV) character (204).

As mentioned in the section Long-Chain Branching, the presence of low levels of α,ω-dienes in the reaction mixture for ethylene polymerization can lead to polyethylene with LCB or cross-linked PE.

An interesting type of polymerization—cyclopolymerization—occurs with certain bridged metallocenes exposed to short α,ω-dienes such as 1,5-hexadiene (205,206). The homopolymerization, shown by (equation 29, involves the initial 1,2-insertion of the first vinylic group followed by the 1,2-insertion of the second, leading to cyclic groups.



(29)

The microstructure, shown in Figure 13 for the *trans*-isotactic polymer, is defined by two types of stereoselection, intra- and inter-ring, since the two types of insertions in equation 29 differ chemically.

The structure of the metallocene influences the stereochemistry of acyclic insertion, with isospecific metallocenes tending to select the same enantioface for the

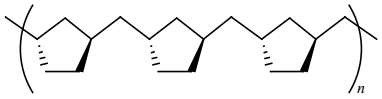


Fig. 13. Trans-isotactic poly(methylene-1,3-cyclopentylene).

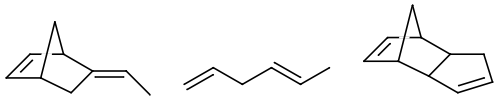
nonring insertion; aspecific and isospecific catalysts both favor trans insertion for the ring-closing step. One intriguing property of polymer with a structure such as shown in Figure 13 is that the polymer has no mirror plane (unlike poly(α-olefins) as discussed in section Isotactic Polypsopylene), and hence can be optically active even at high MW. This was demonstrated by using a single enantiomer of the bridged racemic metallocene ethylenebis(η^5-4,5,6,7-tetrahydroindenyl)zirconium dichloride, itself selected by reaction with a single enantiomer of 1,1-bi-2-naphthol.

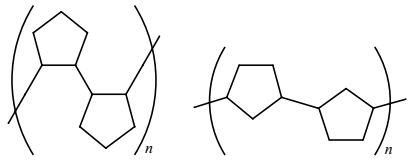
The most industrially relevant family of dienes used in metallocene polymerizations is represented by **57**, **58**, and **59** (ethylidene norbornene, 1,4-hexadiene, and dicyclopentadiene, respectively).



57 **58** **59**

These dienes, along with ethylene and propylene, are used to make EPDM, a sulfur-vulcanizable elastomer. Generally, EPDM contains 25–60 wt% propylene and 1–5 wt% diene, and is completely amorphous. Metallocene catalysts have inherent advantages in EPDM polymerization, the most important of which are the ability to incorporate large amounts of α-olefin with ease and the avoidance of long ethylene sequences that lead to crystallinity. Catalysts that appear to have found commercial application in EPDM include mono-Cp catalysts such **12** (207) and **14** (208).

Cycloolefins. The ability of metallocenes to controllably insert previously recalcitrant monomers is further evidenced by the homo- and copolymerization of cycloolefins such as cyclopentene. Initially, enchainment of cyclopentene was assumed (209) to proceed in normal 1,2-fashion, as shown in Figure 14**a**, and indeed this appears to hold true in copolymerizations with ethylene. However, later work (210) on homopolymers showed that isomerization following 1,2-incorporation is obligatory, presumably due to steric considerations, yielding 1,3-inserted units (Fig. 14**b**)



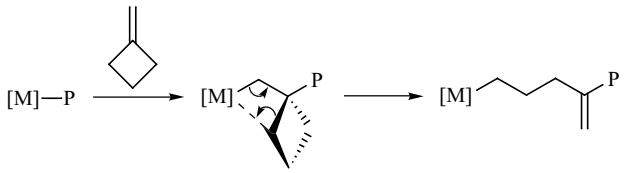
(**a**) (**b**)

Fig. 14. Polycyclopentene regiochemistries.

Polar Comonomers. Heteroatom-containing monomers have the potential to allow polyolefins to ameliorate deficiencies in key product areas such as printability and water permeability. Despite the well-deserved reputation of metallocenes for sensitivity to polar functional groups, Waymouth and co-workers have polymerized α-olefins bearing protected hydroxyl or dialkylamino groups on the terminal carbon, albeit at fairly low rates (211). The very bulky metallocene $(C_5(CH_3)_2)_2Zr(CH_3)_2$ combined with the discrete activator $[C_6H_5(CH_3)_2NH][B(C_6F_5)_4]$ displayed the highest activities for poly (5-(*N*,*N*-diisopropylamino)-1-pentene), apparently due to the inability of the nitrogen atom to coordinate to either transition metal or cocatalyst (212). Copolymerization of ethylene and 4-allylanisole followed by deprotection led to the preparation of polyethylene-bearing phenol groups (213). Incorporation of polymer stabilizers such as vinylic hindered amines (214) via copolymerization could potentially defeat the phase separation and blooming, which often compromise the activity of blended-in stabilizers.

Isobutylene. Unlike conventional Ziegler–Natta and most metallocene catalysts, the compound $(CH_3)_2Si(C_5(CH_3)_4)(NR)Ti(CH_3)_2$ (R = cyclododecyl; activators = MAO or discrete ion pair) can copolymerize isobutene with ethylene, as has been shown by an Exxon group (215). The isobutene units tend to be isolated, eliminating a carbocationic addition mechanism.

Methylenecycloalkanes. Strained cycloalkanes with exo-methylene groups have been homopolymerized as well as copolymerized with ethylene by catalysts such as $[(C_5(CH_3)_5)_2Zr(CH_3)]^+[(CH_3)B(C_6F_5)_3]^-$ and analogous Group IIIB and lanthanide metallocenes via the C—C bond migration mechanism shown in equation 30 (216).



(30)

Styrene (as Random Comonomer with Ethylene). Both bis- and mono-Cp Group IVB metallocenes copolymerize ethylene and styrene (217). The catalysts are believed to be M(IV) in nature. The sequential enchainment of two styrene units is generally disfavored (an exception being the isopropyl-bridged metallocenes, as reported in Ref. 218, even at styrene levels approaching 50 mol% in the polymer, leading to nearly alternating ES copolymers. These copolymers have properties that vary from thermoplastics to elastomers to crystalline or glassy solids, depending on the level of styrene incorporation (218) (see Fig. 15).

Although the alternating ES copolymers are generally atactic, crystalline ($T_m = 145^\circ C$) isotactic *alt*-ES (Fig. 16) results from copolymerization at $-25^\circ C$ in the presence of *rac*-$Et(Ind)_2ZrCl_2$ (**2**) activated by MAO.

Mixed Metallocene Catalysts. By combining two or more metallocenes in the (co)polymerization of olefins, polymers of broadened MW distribution or comonomer distribution may be obtained. In certain cases, it seems the polymer

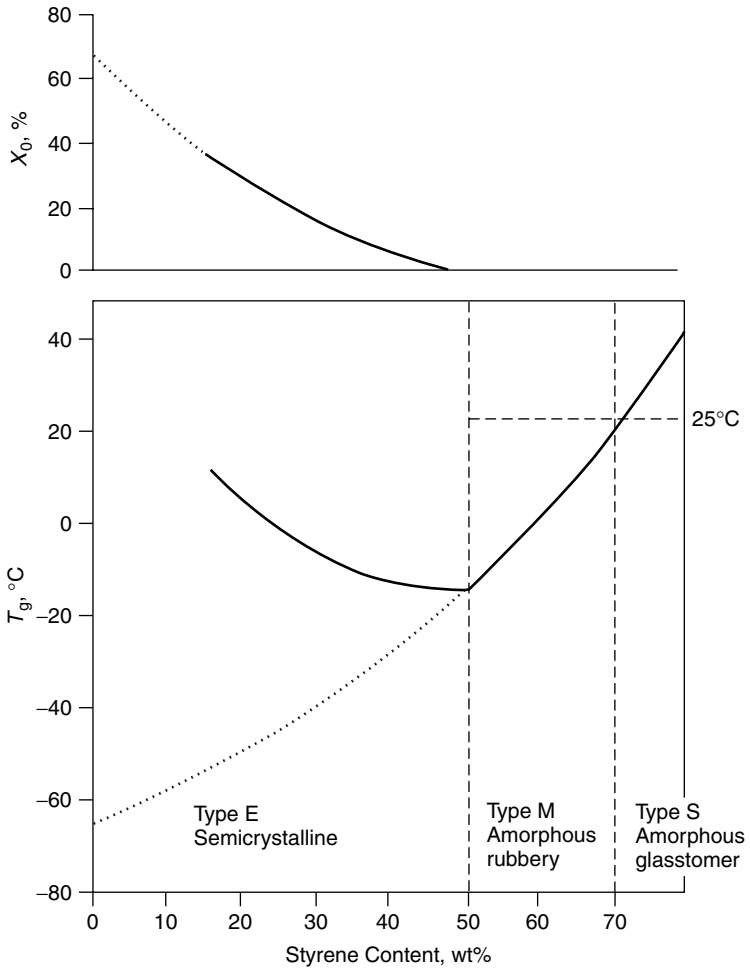


Fig. 15. Characteristics of ethylene–styrene copolymers made by INSITE technology. From 218. Copyright © (1998). This material is used by permission of Wiley-Liss, Inc., a subsidiary of John Wiley & Sons, Inc.

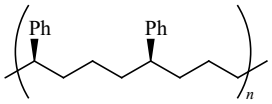

Fig. 16. Isotactic alternating ethylene–styrene copolymer.

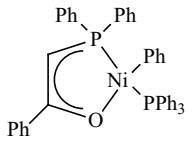
chains produced by one metallocene can serve as a comonomer for a second, thus making LCB-containing polymer possible in cases where the two catalysts may not be competent to produce it by themselves.

In a variation of this concept, metallocene catalysts can function in the presence of olefin oligomerization catalysts, whether the latter be metallocenes

themselves, as in the case of Bazan's bis(boratabenzene)zirconium catalyst (219), or entirely different types of catalyst, as with the nickel-based single-component catalyst **60** (220).



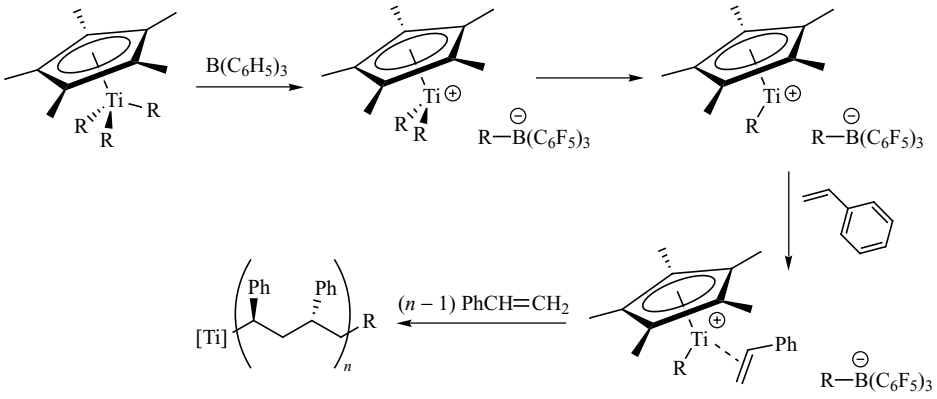
60

Polymerization of Monomers Other Than Alkenes

In this section we survey the use of metallocenes as catalyst precursors for polymerizations in which the predominant monomer is not ethylene or any α-olefin. The subject of metallocenes as initiators for the cationic polymerization of vinyl monomers is dealt with elsewhere. Except for styrene, true random copolymers of the monomers in this section with alkenes are not produced because the mechanisms for polymerization of the non-olefins differ greatly from that operating in Sinn–Kaminsky catalysis.

Styrene. Mono-Cp complexes of titanium are especially useful in the syndiotactic polymerization of styrene (first reported in Ref. 221, a material with high melting point ($\sim$278°C) and other useful features such as a rapid crystallization rate (222). The catalysts are believed (223) to be cationic Ti(III) monoalkyl species, which then undergo predominantly 2,1-insertions (Scheme 10). This is true even in the case of systems in which the activator is the fluorinated borane $B(C_6F_5)_3$. The mechanism of reduction is unclear, but appears to be accelerated in the presence of styrene.

Catalyst activities can be as high as 38 kg(PS)/mmol(Ti)/mol(styrene)/h in laboratory polymerizations, with syndiospecificities close to 99% (for the system

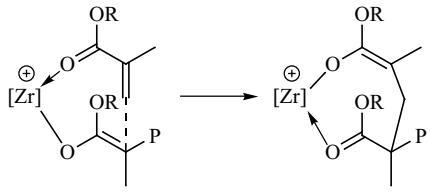


R = Me, CH_2SiMe_3; [Ti] = $(C_5Me_5)Ti^+$

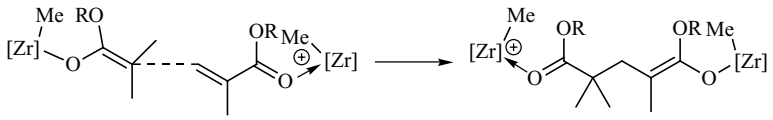
Scheme 10.

$C_5(CH_3)_5Ti(OCH_2CH_2)_3N$, see Ref. 224). Solvent effects indicate that competition of aromatic solvent with monomer for the open coordination site affects activity (225).

Methyl Methacrylate. The quasi–living polymerization of methyl methacrylate can be achieved using lanthanide (226) and Group IVB metallocene complexes, with the latter requiring organozinc, organoaluminum, or borate salt activators. At the heart of the chemistry is a metal-assisted Michael addition, which can occur either through intra- (eq. 31) or intermolecular (eq. 32) C—C bond formation, the latter being more properly described as group-transfer polymerization.



(31)

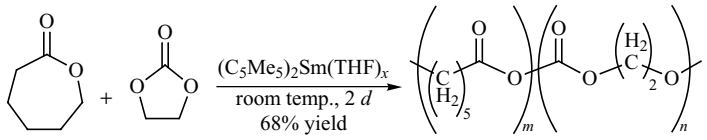


[Zr] = Cp_2Zr; R = Me, *t*-Bu.

(32)

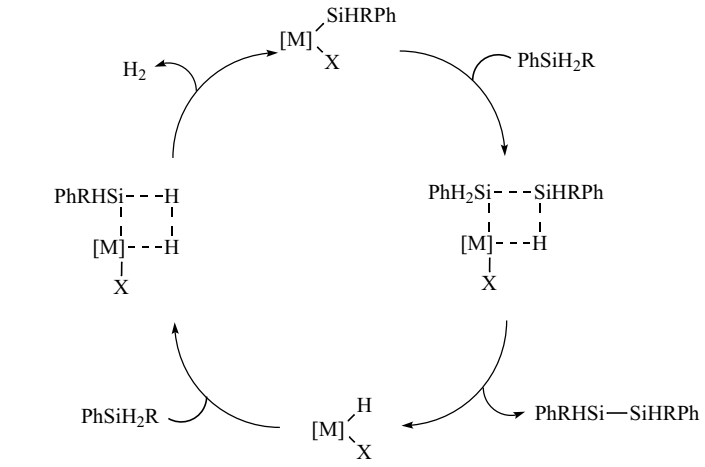
In both cases, propagation requires the facile decomplexation of the polymer chain carboxylate and its replacement by that of the monomer. Isotactic PMMA results when a racemic bridged bis(indenyl) (227) or amidocyclopentadienyl half-sandwich complex is employed (228); enantiomorphic site control indicates that path (eq. 31) dominates in that case.

Lactones. Esters *cyclo*-$(CH_2)_nCO_2$ (n = 4, 5) have been shown by Yamashita and co-workers to be efficiently polymerized by the lanthanocenes $(C_5(CH_3)_5)_2Sm((CH_3))(THF)$ and $[Cp_2Yb(CH_3)]_2$ (229). Recent work of Evans and co-workers has revealed that the highly reactive, divalent pentamethylsamarocene, optionally solvated by THF, which can effectively polymerize ε-caprolactone by ring-opening (230), also copolymerizes ethylene carbonate and ε-caprolactone (eq. 33) (231). Even when present at levels up to 23 mol% in the copolymer, the carbonate units appear to be isolated, indicating a low level of blockiness.



1 : 1 $m/(m + n) = 0.8$

(33)



[M] = (Cp)(C_5Me_5)Hf; X = Cl; R = H or polymer chain.

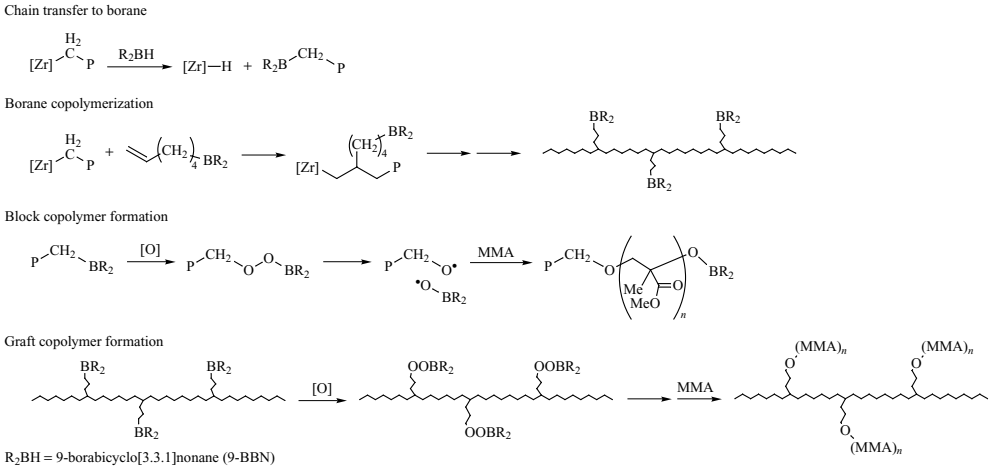
Scheme 11.

Silanes. Group IVB metallocenes catalyze the stepwise polymerization (dehydrocoupling) of primary silanes, yielding H—(SiHR)$_n$—H and n H_2 (232). The mechanism appears to be strictly metathetical for such molecules as (Cp)($C_5(CH_3)_5$)Hf(X) (R = H, alkyl; X = H, alkyl, chloride), wherein the entire process takes place on the neutral manifold (Scheme 11) (233).

A different pathway, probably involving the coupling of free silyl radicals, appears to operate in polymerizations catalyzed by Group IVB complexes (eg, Cp_2ZrCl_2) activated by noncoordinating ionizing agents such as $[(C_6H_5)_3C][B(C_6F_5)_{4-n}(n\text{-}C_4H_9)_n]$ ($n = 0$–2) following pretreatment with n-C_4H_9Li (234).

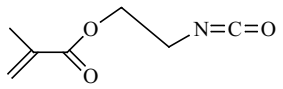
Graft and Block Copolymerization of Olefins with Non-Olefins. The compositional homogeneity and relatively narrow molecular weight distribution that are typical for metallocene copolymers present an opportunity for the functionalization of the majority of polyolefin chains with chains composed of non-olefinic units. In these cases, the secondary polymerizations are mediated by catalysts or initiators that are unrelated to the polyolefin catalyst. The reactive groups at which anionic or free-radical polymerization can begin are either derived from chain-transfer events during metallocene polymerization or from olefinic comonomers. It is often necessary to chemically transform the end groups or side chains prior to the polymerization of the non-olefin. The potential advantages of this strategy, which has been thoroughly reviewed by Chung (235), lie in the compatibilization of polyolefins and other polymers (ie, homopolymers of the non-olefin blocks). Both graft and block copolymers of ethylene with methyl methacrylate can be made through the oxidation of borane side-chain or terminal groups, respectively, as shown in Scheme 12.

Miscellaneous. Patten and Novak have described (236) the polymerization of isocyanates using $CpTiCl_2(OCH_2CF_3)$ as a single-component catalyst. Unlike non-metallocene titanium catalysts, this species is active for the



Scheme 12.

polymerization of isocyanates with functional side chains such as **61**. Acrylonitrile (237) has been polymerized by lanthanocenes.

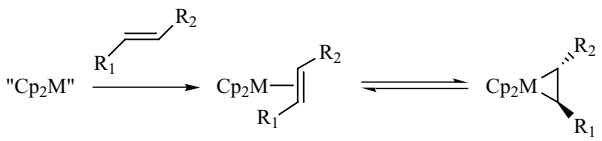


61

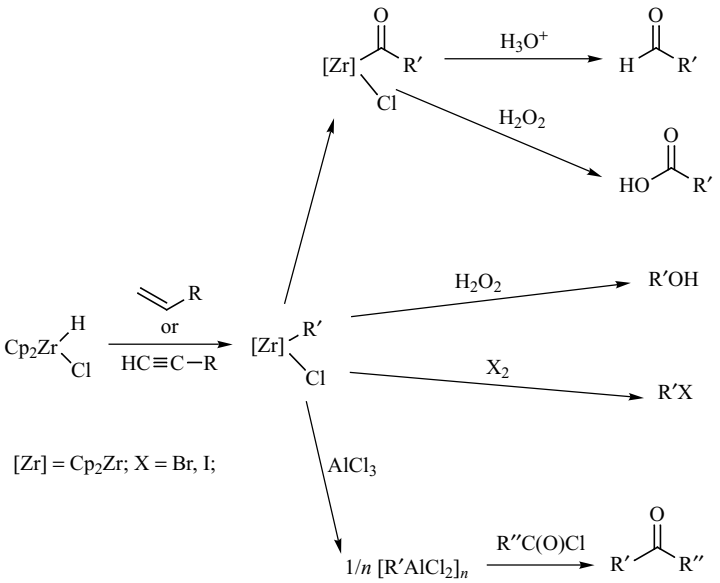
Reactions of Metallocenes Not Involving Polymerization

Transformations of small molecules using Group IVB metallocenes are important in organic chemistry, and it is impossible to give more than the most superficial treatment here. Noncatalytic chemistry will be covered only briefly.

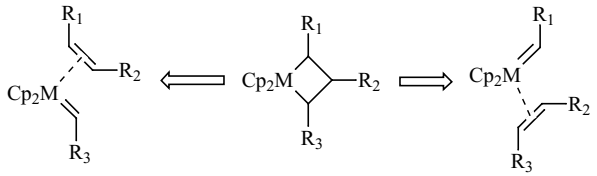
A common theme in many reactions is the generation of an equivalent of Cp_2M through the reduction of a tetravalent precursor metallocene with a metal alkyl such as *n*-butyllithium. The chemistry of olefin complexes of Cp_2M is characterized by a facile interconversion between formally M(II) and M(IV) manifolds, as shown in equation 34. Another central motif of metallocene chemistry, especially that of titanocenes, is the accessibility of pathways connecting metallacycles and metal alkylidene complexes, eg in alkene metathesis (eq. 35).



(34)



Scheme 13.



(35)

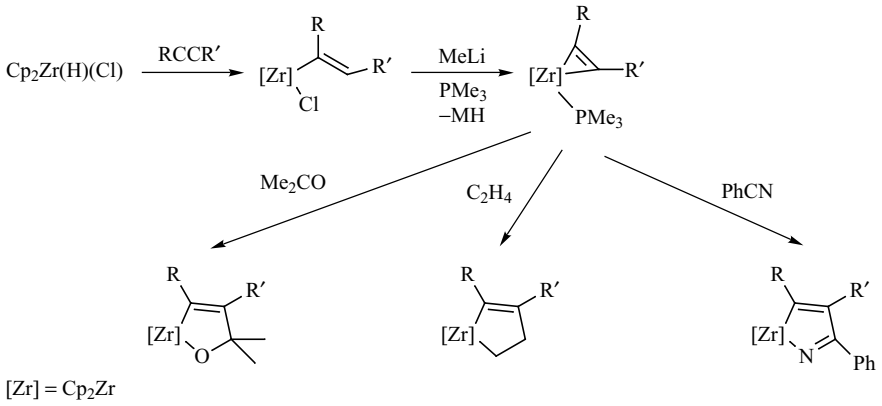
Stoichiometric Reactions.

Hydrozirconation. Of great use in preparative organic chemistry is the addition of the zirconium–hydride bond to alkenes and alkynes. Not only are the alkylzirconium species thus formed useful in themselves, giving rise to a diverse set of organic compounds depending on reagent used to destroy the Zr—C bond (238), they can undergo transmetallation reactions with chloroaluminum compounds with retention of stereochemistry to yield more reactive alkylaluminum moieties (239) (Scheme 13).

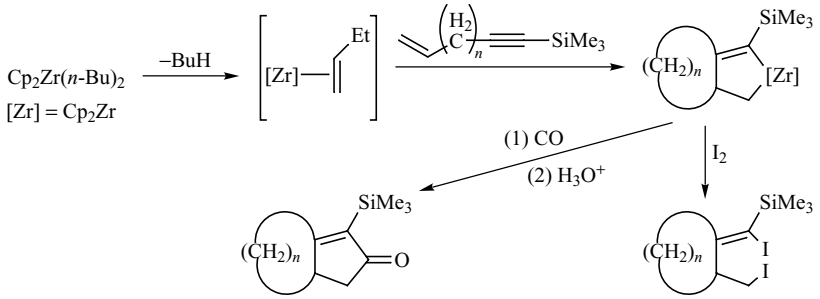
Coupling of Alkenes and Alkynes. The highly reactive [Cp_2Zr] fragment, generated through trapping of an alkyne complex with Lewis base (240), forms metallacycles with alkenes, alkynes, ketones, aldehydes, and nitriles (selected reactions shown in Scheme 14).

Another means of generating zirconocene, via the decomposition of dialkyl zirconocenes (241) can be used to produce bicyclic organic compounds from the cyclization reaction followed by carbonylation (Scheme 15).

In both cases, acyclic final products can be obtained through quenching reactions such as aqueous workup or addition of elemental halogen. Alkene

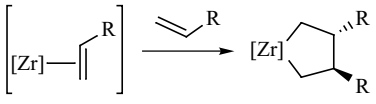


Scheme 14.



Scheme 15.

complexes of zirconocene will also form carbon–carbon bonds with alkenes to give *trans*-3,4-dialkylzirconacyclopentanes (eq. 36) with selectivity >98%; these can be reacted further, eg with CO or HCl to give cyclic and acyclic products, respectively (242).



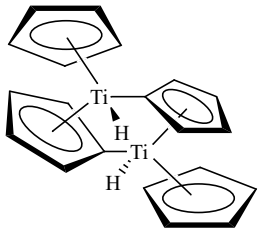
(36)

Metallocene complexes of *o*-benzyne will also add to alkenes or alkynes, yielding 1-metallaindans and 1-metallaindenes, respectively (243). The zirconacyclopentadienes formed from the dimerization of alkynes are convenient synthons for phospholes, siloles, and germoles (244).

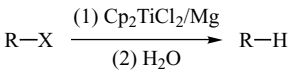
Addition of styrenes to olefins leads to 2-aryl-4-alkylzirconacyclopentanes.

Reductions. Bromo- or chlorohydrocarbons may be efficiently dehalogenated by titanocene dichloride in the presence of metallic magnesium (eq. 37) (245). The source of the hydrogen for the reaction appears to be the

Cp rings of the titanocene, by way of the titanocene dimer, which has the structure **62**.

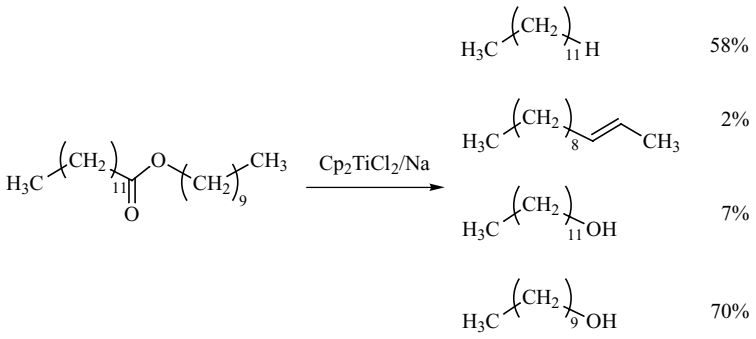


62



(37)

Noncatalytic metathesis of the carbenoid group of $Cp_2Ti{=}CH_2$ with organic carbonyl oxygen atoms leads to formation of the corresponding exo-methylene organic molecule. In this way, cyclohexanone is transformed into methylenecyclohexane and benzaldehyde into styrene (246). The oxophilicity of titanium is again called into service in the conversion of oxiranes, aldehydes, and esters (eq. 38) into the corresponding alkanes by sodium-reduced titanocene dichloride (247).

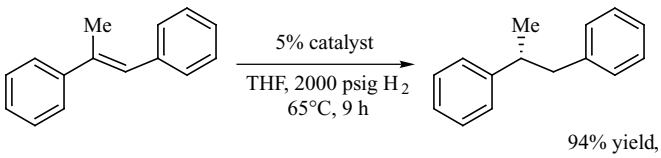


(38)

Titanocene has also been reported to reduce alkyl nitriles to alkanes (248).

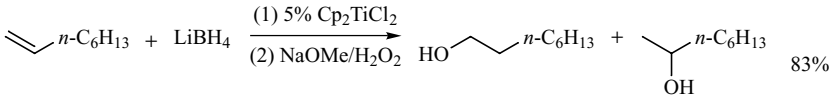
Catalytic Reactions.

Hydrogenations. Olefins can be reduced to alkanes with good enantioselectivity with either neutral Ti(III) (249) (eq. 39) or cationic Zr(IV) (250) metallocenes bearing chiral bis(indenyl) ligands. Unbridged titanocenes and zirconocenes with bulky chiral substituents attached to the Cp rings asymmetrically hydrogenate 1,1-disubstituted olefins, though with somewhat lower e.e.'s (251).



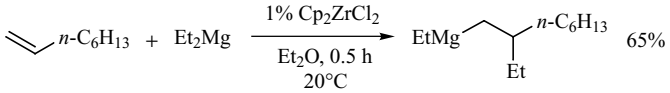
(39)

Assisted Metallations of Unsaturated Hydrocarbons. Titanocenes and zirconocenes catalyze the addition of M—R (M = B, Mg, Al; R = H, alkyl) bonds across C=C double bonds. The hydroboration of olefins (eq. 40) is believed to involve the species $Cp_2Ti(BH_4)_2$ (252).



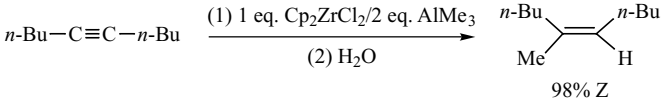
(40)

The carbomagnesation of olefins (eq. 41) is selective for terminal vinyl double bonds (253).



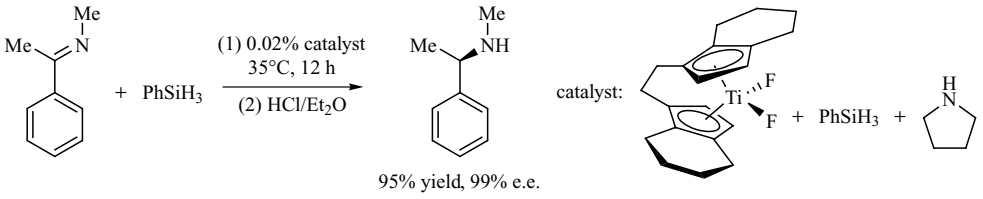
(41)

Alkynes may be converted to the corresponding substituted vinylalanes by the action of zirconocene dichloride and trimethylaluminum (Eq. 42) (254). The regioselectivity for Z-addition of the Al—R bond is generally >95%, but drops significantly if R is larger than the methyl group.



(42)

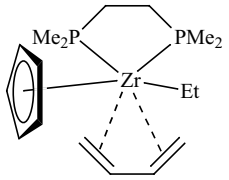
Titanocene difluorides also catalyze the hydrosilation of imines, presumably through the formation of the trivalent titanocene hydride $Cp'_2Ti—H$. This reaction can be made enantioselective, as shown in (equation 43) (255).



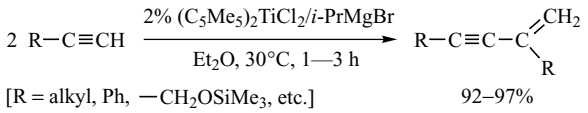
(43)

Alkene and Alkyne Dimerization and Trimerization. The low-valent mono-Cp zirconium compound $CpZrMe(DMPE)_2$ (DMPE = 1,2-bis(dimethylphosphino)ethane) catalyzes the dimerization of ethylene to 1-butene at low frequency (3 t.o./d), a process wherein the 1,3-butadiene complex **64** is presumed to be the catalyst (256). The clean dimerization of olefins using the Cp_2ZrCl_2/MAO (Al/Zr = 1) catalyst has recently been reported (257). Recently,

the monocyclopentadienyl titanium compound $[(\eta^5\text{-}C_5H_4C(CH_3)_2C_6H_5]TiCl_3$ has been shown to generate 1-hexene from ethylene with fairly high selectivity (258).



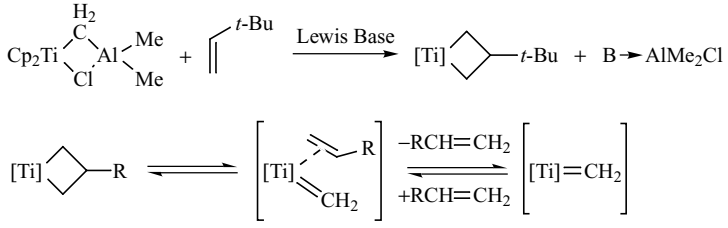
63



(44)

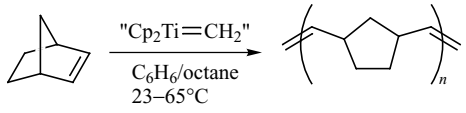
The highly regioselective head–tail dimerization of alkynes has been accomplished using a Grignard-reduced titanocene dichloride (eq. 45) (259).

Metatheses. Alkene metathesis can be catalyzed by the dinuclear metallacycle $Cp_2Ti(\mu\text{-}CH_2)(\mu\text{-}Cl)AlR_2$ (Tebbe's reagent) (260). Grubbs and co-workers have postulated (261) that the reaction proceeds first by the formation of a metallacyclobutane, followed by C—C bond cleavage to give a carbene–olefin complex that can exchange olefin through a dissociative process (Eq. 45).



(45)

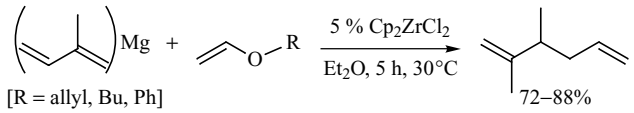
Titanacyclobutanes can serve as catalysts for the living ring-opening metathesis polymerization (ROMP) of cycloolefins through analogous metathesis chemistry (262) (Eq. 46). The driving force for polymerization is relief of ring strain.



(46)

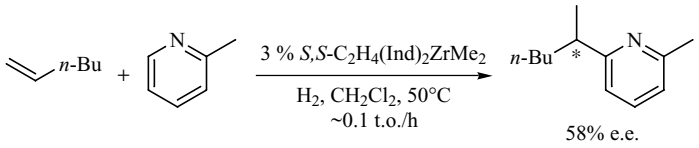
Olefin metathesis reactions involving Groups V and VIB metallocenes have also been thoroughly examined (263).

Allyl Coupling Reactions. Zirconocenes assist in the attack of allylmagnesium species on allyl alkyl ethers (eq. 44) and other activated allylic compounds (264).



(47)

Alkylation. Use of the chiral metallocene *rac*-Et(Ind)$_2$Zr(CH$_3$)$_5$, activated with the protic salt [HN(C$_9$H$_5$)$_3$][B(C$_6$H$_5$)$_4$], couples 1-hexene and 2-picoline with some enantioselectivity (eq. 48), but at about one-tenth the turnover frequency of the analogous Cp$_2$Zr(CH$_3$)$_5$-derived catalyst (265).



(48)

Commercial Overview

Patenting Activity. A large volume of patents has resulted from the globally intensive search for profitable application of metallocenes. Starting modestly in the mid-1980s, the rate of patenting activity rose rapidly through the early 1990s and has only recently begun to stabilize.

Four companies have historically led in the number of awarded patents, Exxon Chemical, Hoechst Aktiengesellschaft and its successors (Targor, Elenac), Mitsui Petrochemical, and Dow Chemical, as evinced by Figure 17. Other companies have tried to stake out smaller, more focused domains of intellectual property, with Fina (syndiotactic polypropylene), Idemitsu Kosan (syndiotactic polystyrene), and Ticona (cycloolefin copolymers) being notable examples. The vicissitudes of the struggles over patent rights are such that nothing can be said regarding the ultimate strength of any particular portfolio. However, the search for freedom to operate in the field of metallocenes has been a large factor in determining the direction and emphasis of research at many companies. The effects of mergers and patent litigation on the climate for metallocene implementation has been recently summarized (266).

Polyethylene. The polyethylene market is rather conservative and price-sensitive, especially in the commodity grades, so it is not surprising that metallocene resins, which are more expensive than the Ziegler–Natta materials they aim to replace, have made only small inroads here. The most promising area of market penetration is in specialty grades, especially in the very low density regime ($d < 0.910$ g/cc), where the absence of oligomers and high-melting crystallinity make for a clear, flexible product with low tackiness and odor. These products are well-suited for food packaging and cable insulation, and are beginning to find their way into markets hitherto dominated by plasticized PVC. Much of the emphasis in metallocene research for polyethylene applications has been directed toward adapting the polymer architecture so that the user may process the molten resin in existing equipment. This is facilitated by use of catalysts that

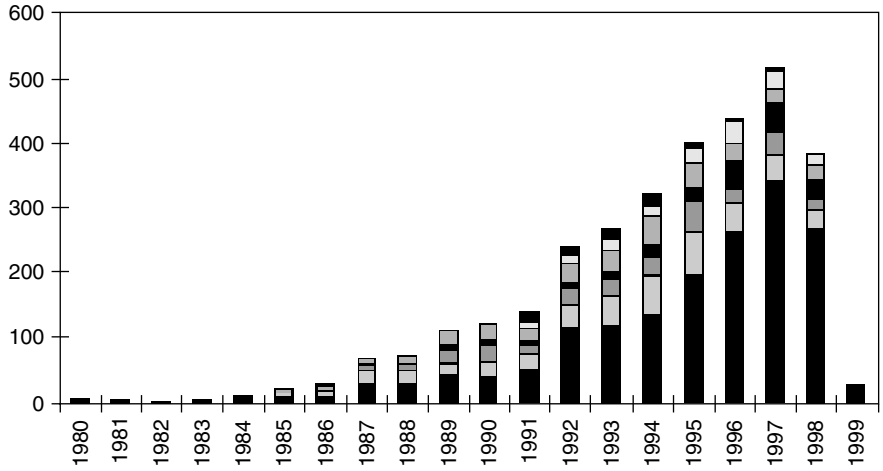


Fig. 17. Patenting activity by company in metallocene-based olefin polymerization (approximately all unique published applications by priority date as of May 2000). ■ Phillips, ■ BASF, ■ Hoechst, ■ Dow, ■ Mitsui, ■ Exxon, ■ Others.

give long-chain branched PE or by use of mixed catalyst systems to yield a polymer with broadened MW distribution.

Metallocene catalysts have been successfully adapted to all commercial polyethylene processes. Recently, companies have begun to join forces to avoid patent disputes as well as to accelerate the pace of commercialization. Joint ventures between Exxon and Union Carbide (Univation Technologies) and between Dow and BP were formed to leverage popular process technologies (variants of fluidized-bed gas-phase reactor systems) to expand the market for metallocene catalysts and products. The Dow–Union Carbide merger of 2001 could greatly influence the rate of technology dissemination.

Polypropylene. Metallocene iPP, as with metallocene PE, has made the least headway in the commodity resin market, where the catalyst technology based on $Mg_xTi_yCl_z$ and selectivity control agents already achieves the high isotacticity (>98%) and activity (<2 ppm Ti) metallocene catalysts have struggled to attain. The areas in which metallocene catalysts have inherent advantages are in (*1*) nonwoven fiber applications, because of the low melt-viscosity associated with narrow MW distribution resins, and (*2*) random copolymers with ethylene or butene, because of the low tendency to form long ethylene blocks. Metallocene iPP is also beginning to displace polystyrene in injection-molding applications.

Fina and Mitsui Toatsu have combined development efforts in syndiotactic polypropylene, but it is not clear where this material will have the greatest impact.

Elastomers. Ethylene–propylene elastomers (EPR) as well as ethylene–styrene elastomers (Index) have been commercialized using Dow's constrained-geometry technology, with the former material being produced and marketed out of the joint venture DuPont–Dow Elastomers. The low levels of crystallinity possible with single-site catalysts make the advantages of metallocenes over Ziegler catalysts much more apparent than in crystalline resins. Market acceptance of these rubbers, along with the very low-density ethylene–1-octene

copolymers made by Dex Plastomers (Exxon/DSM joint venture) and by Dow (Affinity grades), has been swift.

Cycloolefin (co)Polymers. Many metallocenes can incorporate bulky cycloolefins into polyethylene, but only a few companies, notably Hoechst and its successor Ticona, have attempted to sell the resulting materials. These glassy, amorphous copolymers have high rigidity, chemical resistance, and clarity, which predisposes them to be useful in optical applications and in pharmaceutical containers.

Polystyrene. Dow and Idemitsu have worked together to bring syndiotactic polystyrene (Questra) to market, where it has certain advantages over existing PS products, chiefly due to its crystallinity, such as high heat-distortion temperature.

Because of its popularity among both industrial and academic chemists, metallocene technology has been the subject of numerous reviews, some of which have been cited in earlier sections. An excellent listing of metallocene catalyst activities sorted by monomer system and catalyst structure has been collected by Gupta and co-workers (267); the review of Möhring and Coville (268) also stands out for its comparison of metallocene activities, and also thoroughly covers non-ethylene polymerizations. Reddy and Sivaram have produced an overview (269) that is especially strong in the area of aluminoxane structure and function. The constrained-geometry catalyst family has been reviewed by McKnight and Waymouth (270). A fine overview of the state of metallocenes in industry has been put together by Maier (271). A very good general reference for metallocene chemistry including stoichiometric reactions and Cp-equivalents has recently issued (272). Useful collections of articles on the subject of metallocene polymerization occasionally appear in review journals (273).

MICROCELLULAR PLASTICS

Introduction

Microcellular plastics (MCPs), which were first invented at the Massachusetts Institute of Technology in 1979, refer to any polymeric materials that have closed cells of very small diameters, typically smaller than 50 μm. The cell density can be made to vary a great deal depending on the final application of a given MCP. MCPs can have as many as 10^{15} bubbles/cm^3 when the bubble diameter is 0.1 μm, 10^{12} bubbles/cm^3 for 1-μ- and 10^9 for 10-μ- diameter cells. They can be created in thermoplastics, thermosetting plastics, and elastomers. Figure 1 shows the microstructure of a typical MCP. See Reference 1 for a detailed historical account as well as a detailed review of MCPs.

The original impetus for the invention of MCPs was to create a plastic consuming less material without sacrificing mechanical properties, especially toughness. The saving of material was achieved by creating voids, and toughness was a result of making the diameter of the bubble smaller than a critical size. The central idea was to replace some of the polymers with a large number of very small bubbles that are smaller than the preexisting flaws in polymers. Small bubbles can blunt the crack tips and act as crazing—initiation sites, thus making the material tougher.

The basic processing method for all MCPs is the use of thermodynamic instability phenomena. A large amount of gas, typically CO_2 or N_2, is dissolved in the plastics under high pressure at the processing temperature so as to create a driving force for phase separation when the pressure is suddenly lowered.

Depending on the magnitude of the driving force, various nucleation sites are activated. The number of nucleation sites increases nearly exponentially with the amount of gas dissolved, when the polymer is supersaturated with the dissolved

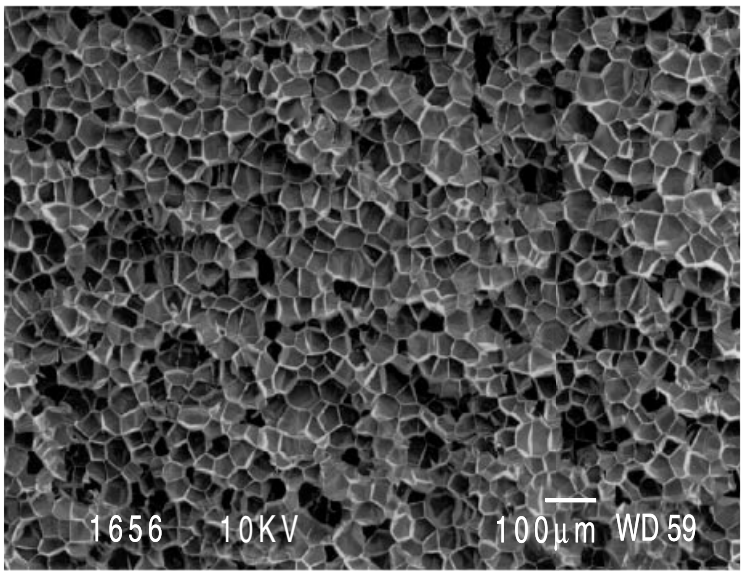

Fig. 1. Microstructure of microcellular plastics. This particular micrograph shows an average cell size of about 30 μm.

gas—relative to its equilibrium concentration at the pressure of 0.1 MPa (1 bar) and the operating temperature. Microcells form for the following reasons: the amount of gas dissolved must be shared equally by an extremely large number of nucleated sites, since the cells nucleate nearly simultaneously, preventing the preferential diffusion of the gas to the sites that have nucleated first. Because the driving force is so large, homogeneous nucleation dominates even when there are second-phase particles that would be the preferred heterogeneous nucleation sites because of its low activation energy.

MCPs have unique processing characteristics. The processing temperature is substantially less than the conventional processes because the viscosity of plastics is substantially reduced owing to the presence of gas between polymeric molecules. The throughput rate of a given extruder can also be greater because of the low viscosity. The cycle time of injection-molding machines is also reduced because the processing temperature is lower and the phase separation of gas from polymer instantaneously increases the rigidity of plastics. Furthermore, there is no shrinkage of the injection-molded part because it (shrinkage) is compensated by the internal expansion in the microcells, creating parts with minimal residual stress and warpage. Sometimes, depending on the color of the plastic and the smoothness of the molded surface, swirl marks may appear, which can be hidden through painting or texturing.

Certain properties of MCPs, such as modulus and strength, follow the rule of mixture, whereas such properties as toughness and coefficient of thermal expansion do not. When the cell size is less than a few micrometers, the toughness of certain MCPs should be equal to or better than the plastic without the cells. Small cells also lower the thermal conductivity when they are smaller than a critical size.

Many industrial firms worldwide are now making microcellular products through extrusion and injection molding (under license from Trexel, Inc.). Trexel, as the sole licensee of MITs has developed the MIT technology further for commercial applications. The trade name is MuCell. It is very likely that the number of new applications that use the microcellular technology will continue to increase at a rapid rate in the years to come.

MCP technology is in some ways in the early stages of research and development, notwithstanding its relatively long history. It has raised many interesting scientific and technological issues that can be the basis for thought-provoking ideas and research. Many academic institutions worldwide are conducting their research in the field of MCPs, which should further generate new ideas and applications. Many industrial firms are developing new applications for injection—molding and extrusion processes.

Design of MCPs

MCPs were designed to satisfy the following three functional requirements (FRs) based on axiomatic design (1,2):

(1) FR1 = Reduce plastics consumption
(2) FR2 = Maintain the toughness of plastics
(3) FR3 = Make 3-D parts

To satisfy these FRs, the concept of MCP was created by envisioning plastics with tiny bubbles (see Reference 1 for an historical account). Then the design parameters (DPs) of MCPs are the following:

(1) DP1 = Total volume of cells (ie, bubbles), V
(2) DP2 = Diameter of cells, d
(3) DP3 = Die or mold

The design equation that relates the FRs to the DPs of microcellular plastics may be written as

$$\begin{Bmatrix} FR1 \\ FR2 \\ FR3 \end{Bmatrix} = \begin{bmatrix} X & X & 0 \\ 0 & X & 0 \\ 0 & 0 & X \end{bmatrix} \begin{Bmatrix} DP1 \\ DP2 \\ DP3 \end{Bmatrix} \quad (1)$$

Equation 1 indicates that the design of an MCP is a decoupled one. It indicates that the bubble size must be determined first before setting the total volume of the bubbles.

In an ideal MCP, where spherical bubbles are packed in a body-centered cubic structure, the bubble size can be directly related to the bubble density. In a 1-cm cube of foamed material, the number of cells is inversely proportional to the cube of the bubble diameter. Therefore, an MCP with 10-μm bubbles has approximately 10^9 bubbles/cm^3 of unfoamed material, whereas MCPs with 1-μm

and 0.1-μm bubbles have approximately 10^{12} and 10^{15} bubbles/cm^3 of unfoamed material, respectively.

Since the volume taken by spherical bubbles in an ideal, closely packed hexagonal or cubic structure is approximately 74%, the plastic occupying the interstitial space takes up 26% of the volume. Therefore, the cell density of an ideal closely packed spherical MCP is equal to (1/cell size)^3 times 1/0.26. For an MCP with 1-μm cell diameter, the bubble density is 3.85×10^{12} cells/cm^3 of the solid plastic. The overall density of foam can decrease further when these cells expand, thinning the wall diameter and reducing the interstitial materials between the cells.

Design of MCP-Processing Techniques

Dissolution of Gases in Polymers. The basic physics of gas dissolution in polymers is as follows (3):

(1) The plastic must be supersaturated with sufficient gas (such as N_2 and CO_2) to nucleate simultaneously a large number of cells.
(2) The temperature of the plastic must be set so as to control the flow of plastics during processing.
(3) A gas with a suitable solubility and diffusivity for the plastic must be selected.
(4) Homogeneous nucleation must dominate the nucleation process to create a large number of microcells even when heterogeneous nucleation sites are available by providing sufficient driving force with a sufficient amount of dissolved gas.

The processing technique consists of forming a polymer/gas solution and then suddenly inducing a thermodynamic instability by either lowering the pressure or raising the temperature to change the solubility S. The solubility is a function of two thermodynamic properties such as temperature and pressure:

$$S = S(p, T) = H(p, T) \tag{2}$$

where H is known as Henry's law constant. At low pressures and low concentrations, H is constant. At high pressures, H depends on both pressure and temperature. The temperature dependence follows the Arrhenius-type rate equation. At low pressures, the gas solubility is low but Henry's constant is high. At higher pressures, the gas solubility is high, but the rate of the weight increase with pressure decreases with pressure.

The solubility of gas in polymers decreases with an increase in temperature. The solubility of N_2 is considerably less than that of CO_2. Since the amount of gas that can be dissolved is a function of the saturation pressure and since the gas diffusion rate is the rate-limiting process, we can use supercritical CO_2 to enhance the solubility and diffusion rate. CO_2 is supercritical at pressures and temperatures greater than 7.4 MPa and 31.1°C.

With dissolution of a large number of gas molecules in polymers, the glass-transition temperature and viscosity decrease with the increase in gas concentration. The change in the glass-transition temperature is quite substantial at high gas concentrations. These changes affect the processibility of polymers.

The change in the solubility can be expressed as

$$\Delta S = \frac{\partial S}{\partial p}\,\Delta p + \frac{\partial S}{\partial T}\,\Delta T \tag{3}$$

The $\P S/\P p$ term of equation 3 is positive, whereas the $\P S/\P T$ term is negative. Therefore, to decrease the solubility and to induce the thermodynamic instability, either the pressure must be decreased (ie, $\Delta p < 0$) or the temperature must be increased (ie, $\Delta T > 0$). Furthermore, regardless of whether the process is continuous or batch-type, the thermodynamic instability must be induced quickly so that the cells will nucleate simultaneously before significant diffusion of gas has taken place. Therefore, the higher the temperature of the polymer, the quicker the nucleation has to occur since the diffusion of the gas occurs faster at higher temperatures. Such simultaneous cell nucleation will assure a uniform cell-size distribution. The following two dimensionless numbers must be less than 1 for this to happen:

$$\frac{\text{Characteristic nucleation time}}{\text{Characteristic diffusion time}} \ll 1$$

$$\frac{\alpha}{\frac{dN}{dt}\mathrm{d}_c} \ll 1 \tag{4}$$

$$\frac{\text{Characteristic gas diffusion distance}}{\text{Characteristic spacing between stable nuclei}} \ll 1$$

$$2\rho_c^{1/3}(\alpha t_D)^{1/2} \ll 1 \tag{5}$$

The number of cells nucleated is a function of the supersaturation level relative to the equilibrium concentration at ambient pressure at the processing temperature. The higher the supersaturation level, the greater is the number of cells nucleated. Furthermore, since the amount of dissolved gas that fills the nucleated cells is finite, and since all the cells are nucleated almost simultaneously, the gas distributes more or less evenly among all these cells—a condition for making MCPs. The final bubble size is then determined by the total amount of gas per bubble, and by the flow characteristics of the polymer at the nucleation temperature.

To create a continuous process, processes and associated equipment to perform the following functions in extrusion and injection molding have been designed.

(1) Rapid dissolution of gas into molten flowing polymer to form a polymer/gas solution
(2) Nucleation of a large number of cells

(3) Control of the cell size
(4) Control of the geometry of the final product

To produce the MCP at an acceptable production rate through a continuous process, we must dissolve the gas in polymers quickly despite the slow diffusion rate. The diffusivity increases with temperature by an Arrhenius relationship:

$$\Delta = \Delta_0 \exp(-\Delta G/kT) \tag{6}$$

where δG is the activation energy, k is the Boltzmann's constant, and T is the absolute temperature. The time for gas diffusion is proportional to the thickness of the plastic ℓ as

$$t \propto \frac{\ell^2}{\alpha} \tag{7}$$

The diffusivity of CO_2 and N_2 are nearly the same and it takes a long time to diffuse gas into a polymer at room temperature. For example, the diffusivity of CO_2 in most thermoplastics at room temperature is in the range of 5×10^{-8} cm^2/s and the diffusion time is approximately 14 h when ℓ is 0.5 mm. The diffusivity at 200°C is 3–4 orders of magnitude greater than that at room temperature. Even at high temperatures, the diffusion rate is still the rate-limiting step in continuous processes.

To accelerate the diffusion rate and shorten the time for the formation of gas/polymer solutions, we must raise the temperature and shorten the diffusion distance. This is done by deforming the two-phase mixture of polymer and gas through shear distortion to decrease the diffusion path. This type of deformation occurs in an extruder under laminar-flow conditions. The bubbles are stretched by the shear field of the two-phase mixture and eventually break up to minimize the surface energy when a critical Weber number is reached (4). The disintegrated bubble size is calculated to be about 1 mm and the initial striation thickness after bubble disintegration is calculated to be about twice the bubble diameter (5). This striation thickness decreases with further shear, and the gas diffusion occurs faster as a result of the increase in the surface area and the decrease in striation thickness. The striation thickness in an extruder is estimated to decrease to about 100 μm. At this thickness, the diffusion time is about 1 min in PET, from 10 to 20 s in polystyrene (PS), poly(vinyl chloride) (PVC), and high density polyethylene (HDPE), and in the range of a few seconds in low density polyethylene (LDPE).

Nucleation. The key idea in the formation of an MCP is the nucleation of an extremely large number of bubbles (cells). Although cells can nucleate either homogeneously or heterogeneously, the driving force is so high owing to such a large amount of supersaturation of the gas in the polymer that both the homogeneous and the heterogeneous nucleation sites are expected to be nucleated. This can be seen from micrographs, which show that cells are nucleated both at and away from the heterogeneous sites.

For nucleation to occur, a finite energy barrier has to be overcome. The energy barrier depends on two competing factors: (*1*) the energy available in the gas diffused into the embryo of the cell and (*2*) the surface energy that must be supplied

Table 1. Potential Activation Sites for Cells and Rough Estimates of Potential Cell Density

Activation Sites	Cell density, cells/cm^3
Solid–polymer interface	10^5 to 10^6
Nonpolar polymer–polar polymer interface	—
High strain region	10^9
Free volume	10^9
Crystalline–amorphous interface in a polymer	10^{12}
Interface between crystallites	10^{18}
Morphological defects in a polymer	—
Polar groups of polymers	10^{22}

to form the surface of the cell. There is a critical cell size beyond which the cell becomes stable and grows, and below which the cell embryo collapses. Typically the cell nucleation rate is expressed as

$$\frac{dN}{dt} = N_0 f \, e^{\frac{-\Delta G}{kT}} \tag{8}$$

where N is the number of cells, N_0 is the number of available sites for nucleation, f is the frequency of atomic or molecular lattice vibration, ΔG is the activation energy barrier, k is the Boltzmann constant, T is the absolute temperature.

A variety of different nucleation sites may be nucleated when the driving force is very large, the most prominent of which are the free-volume sites. Also, in the case of semicrystalline polymers, the interfaces between the amorphous region and the crystalline region could be the nucleation sites. Depending on the gas supersaturation level, all or part of these nucleation sites will be activated. Table 1 shows the potential activation sites and the expected cell density when these sites become activated.

The activation energy associated with each one of these potential activation sites is expected to be substantially different, probably increasing with the available sites. The activation energy may be represented in terms of its probability density function as shown in Figure 2.

The activation energy also changes when the gas is dissolved. As a result, the change in the probability density of activation energy due to the dissolved gas may be schematically represented as shown in Figure 3 at a specific gas concentration.

The number of the available sites, N_0, is also affected by the gas dissolved since the gas changes the intermolecular forces, as indirectly evidenced by the change in the viscosity and melting point of the polymer/gas solution (see Fig. 4). N_0 is a function of both the original activation energy ΔG and the amount of the gas dissolved. Although there is no definite data available, the N_0 is expected to increase with higher activation energy since it appears that there are more activation sites at these higher level activation energies. This change in the available sites may be represented schematically as shown in Figure 5.

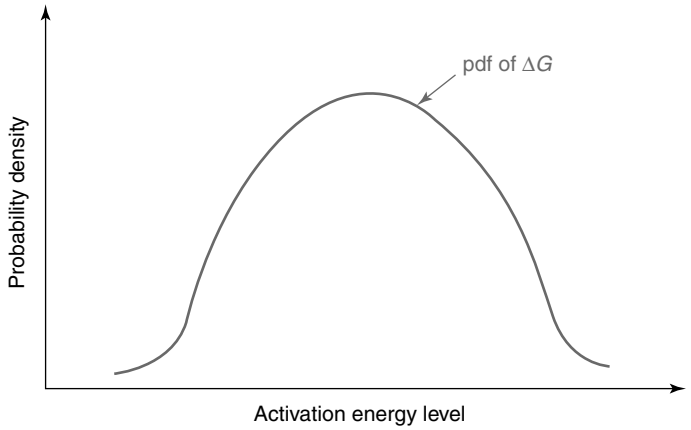

Fig. 2. Probability distribution of ΔG. Note that as the amount of dissolved gas increases, the sites with high activation energy is expected to be activated.

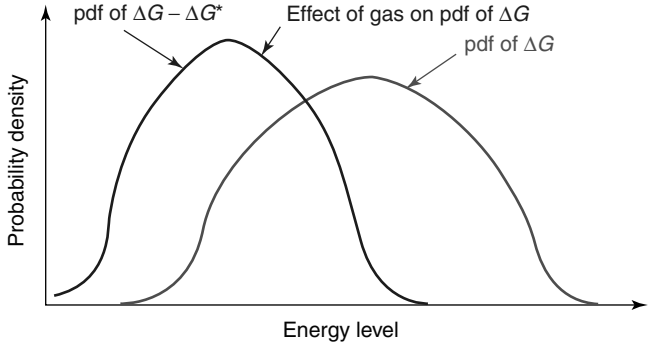

Fig. 3. Schematic representation of the effect of the dissolved gas on the probability density of activation energy.

Cell Growth. Immediately after the cells are nucleated, the pressure in the bubble is equal to the saturation pressure. Therefore, the cells expand if the polymer matrix is soft enough to undergo viscoelastic–plastic deformation. A cell expands until the final pressure inside the cell is equal to the pressure required to be in equilibrium with the surface forces and the stress in the viscoelastic cell wall.

Unlike in conventional foaming, in the case of MCPs, there are so many cells nucleated and the diffusion length is so short that the diffusion of the gas to the cell growth stops relatively quickly.

In practice, the temperature of the surface of the extrudate changes as a result of heat transfer, and thus, the expansion of the cells is constrained by the outer stiff layer. Also some of the gases from the cells near the surface escape, reducing the cells tendency to expand.

Cell Density and Cell Size. The cell density is a function of both the pressure drop and the pressure drop rate. During the cell nucleation stage, there

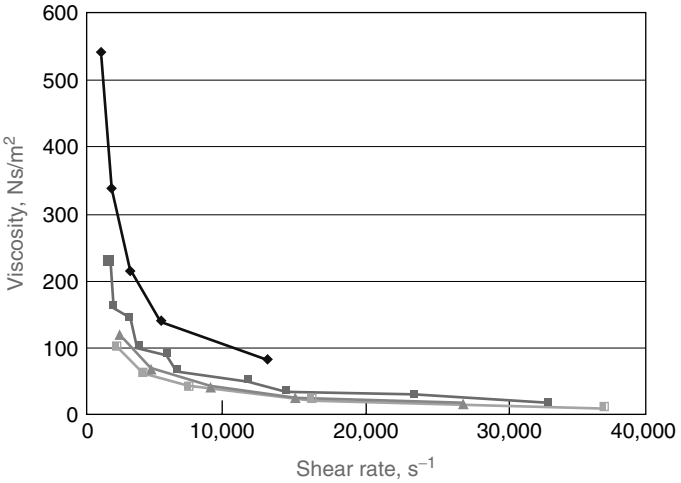

Fig. 4. Viscosity of ABS as a function of CO_2 concentration and shear rate at 370 F (Courtesy of Trexel, Inc.). Note that the relative viscosity change is most pronounced at low shear rates.

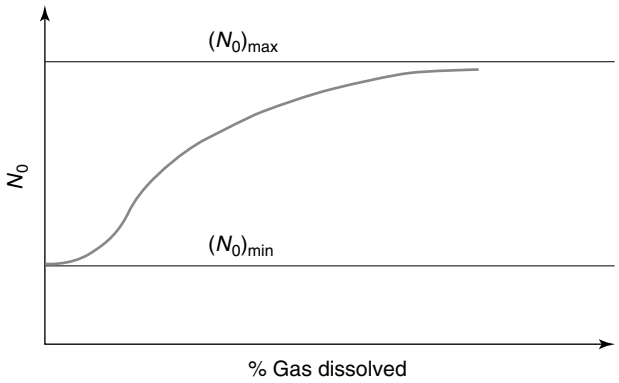

Fig. 5. Number of available sites for cell nucleation as a function of the gas dissolved. It is conjectured that $(N_0)_{max}$ is greater as the activation energy increases.

is a competition for gas between cell nucleation and cell growth if the cells do not nucleate simultaneously. When some cells nucleate before others, the gas in the solution will preferentially diffuse to the nucleated cells to lower the free energy of the system. As the gas diffuses to these cells, low gas concentration regions where nucleation cannot occur are generated adjacent to the stable nuclei. As the solution pressure drops further, the system will either both nucleate additional microcells and expand the existing cells by gas diffusion or only expand the existing cells. Therefore, when the pressure drop occurs rapidly, the gas-depleted region where nucleation cannot occur will be smaller and a more uniform cell distribution will result. It has been determined experimentally that a drop rate of 2 GPa/s is the minimum pressure drop rate required for MCP processing. Two dimensionless groups given in equations 4 and 5 give the condition for simultaneous nucleation

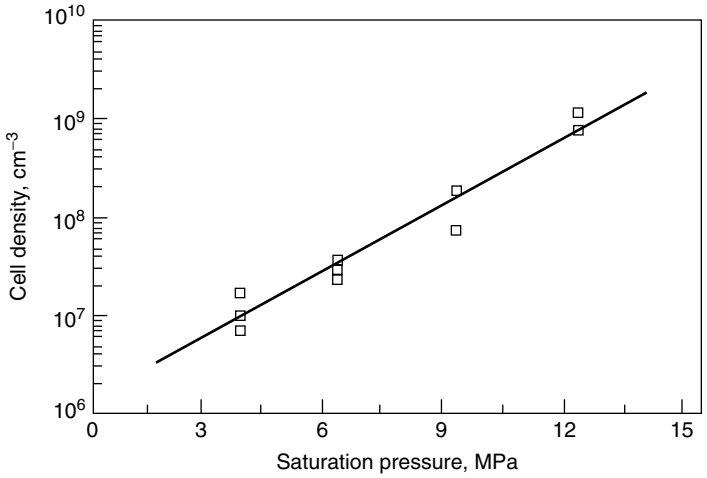

Fig. 6. Cell nucleation density as a function of N_2 pressure in polystyrene (6). To convert MPa to psi multiply by 145.

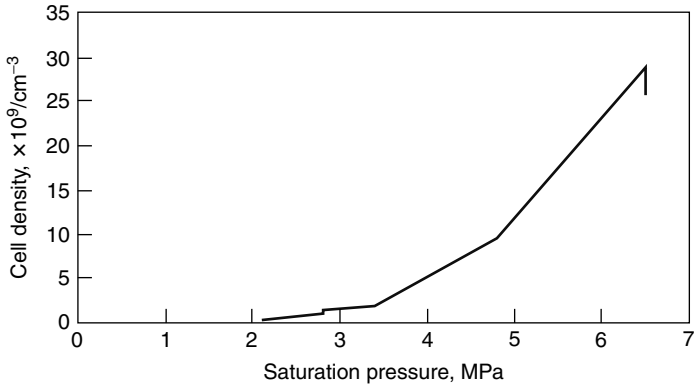

Fig. 7. Cell density as a function of N_2 pressure in polycarbonate (7).

of cells. Figures 6 and 7 show examples of the cell nucleation density as a function of the gas pressure.

Equipment and Die Design

The role of the extruder (or the plasticating unit of an injection-molding machine) is to melt the plastic, create a single-phase polymer/gas solution, and pump the solution through a die or inject it into a mold. To achieve these functions, high pressure CO_2 or N_2 gas is introduced into the extruder barrel by metering the exact amount of CO_2 or N_2 at pressures greater than 2000 psi. The flow rate of CO_2 into the extruder can be controlled using a special metering pump. The gas forms a large bubble in the extruder since the flow of the gas is briefly interrupted whenever the screw-flight wipes over the barrel.

Then to diffuse the gas in the bubble quickly in the molten plastic, the polymer–gas interfacial area is increased and the striation thickness of polymers between the gas bubbles is decreased. This is done by elongating the bubble in the barrel through the shear deformation of the two-phase mixture of the polymer and gas.

The approximate residency time required for diffusion and solution formation in the extruder is estimated to be as follows: <100 s for PET and <10 s for polystyrene at typical operating temperatures.

To design the process, the FRs and DPs are selected as

(1) FR1 = Reduce the amount of plastic used
(2) FR2 = Increase the toughness of the plastic product
(3) FR3 = Make 3-D geometrical shape
(4) DP1 = Microcellular plastics (uniform cell distribution in large numbers)
(5) DP2 = Diameter of microcells
(6) DP3 = Die shape

The process variables (PVs) for the process described that can satisfy the DPs given are

(1) PV1 = Supersaturation of the plastic with a large amount of gas and sudden pressure change (dp/dt)
(2) PV2 = Temperature of the molten polymer to control the expansion of cells at the die
(3) PV3 = Cross-sectional dimensions

The design equation for the extrusion process may be written as

$$\begin{Bmatrix} DP1 \\ DP2 \\ DP3 \end{Bmatrix} = \begin{bmatrix} X & 0 & 0 \\ X & X & 0 \\ 0 & 0 & X \end{bmatrix} \begin{Bmatrix} PV1 \\ PV2 \\ PV3 \end{Bmatrix} \tag{9}$$

Equation 9 shows that the process design is also a decoupled design. Therefore, each design satisfies the Independence Axiom. However, for concurrent engineering to be possible, the product of the product and process design matrices must also be diagonal or triangular. Because FRi = Aij DPj and DPj = Bjk PVk, FRi = Cjk PVk, where Cjk = Aij Bjk. However, the process design matrix with elements given by Cjk is neither diagonal nor triangular. This means that the foam density and toughness of the plastic part cannot be independently controlled by means of the PVs chosen unless the tolerances on the density variation or the toughness variation are large enough to change one of the two design matrices. Experiments support this conclusion.

DP1 and PV1 can be further decomposed as

(1) DP11 = Large number of nucleated cells
(2) DP12 = Uniform-sized cells

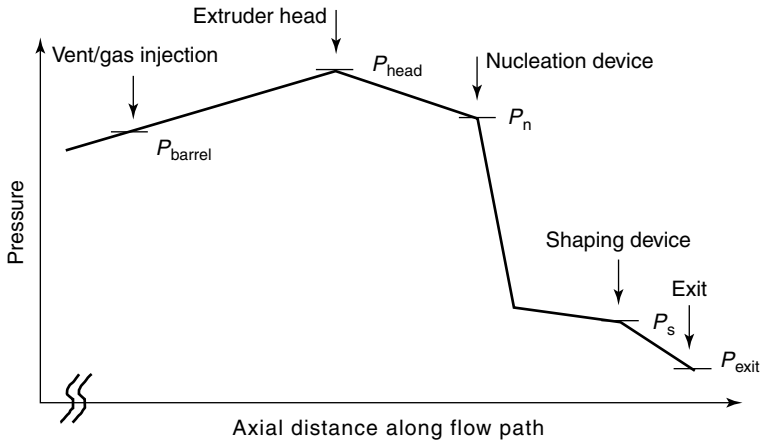

Fig. 8. Representative pressure profile along the polymer flow field in the extruder and die (8).

(3) PV11 = The level of supersaturation of CO_2
(4) PV12 = Rapid pressure drop dp/dt

The design matrix for this design may be represented as

$$\begin{Bmatrix} DP11 \\ DP12 \end{Bmatrix} = \begin{bmatrix} X & x \\ X & X \end{bmatrix} = \begin{Bmatrix} PV11 \\ PV12 \end{Bmatrix} \tag{10}$$

Equation 10 states that DP11 and DP12 are coupled slightly in that if the pressure drop rate is really slow, we cannot get a large number of cells and uniform-sized cells. In most cases, the effect of dp/dt on the number of cells is negligible. A typical pressure profile in a single-screw extruder is shown in Figure 8.

The role of the plasticating section of the injection-molding machine or the extruder is to melt the plastic and dissolve the gas in the polymer. The extruder must be under high pressure to maintain a single-phase solution. The cell density is primarily controlled by the amount of the dissolved gas and also partly by the pressure drop rate.

The die must be designed to control the pressure drop rate, which controls the uniformity of cell size. The desired pressure drop rate is greater than 1 GP/s. It also removes the thermal energy from the molded part. The die also creates 3-D shapes in the case of injection molding or the profile in the case of extrusion. It can be seen that the die design is as important as the extruder or the injection-molding design.

The highest-level FRs and DPs are given as

(1) FR1 = Control cell size
(2) FR2 = Control the number of cells
(3) FR3 = Control the geometry of the extrudate
(4) DP1 = P_i^*

(5) DP2 = dp/dt
(6) DP3 = Die shape & Accessories (Die & Acc.)

The design equation is given by

$$\begin{Bmatrix} \text{Cellsize} \\ \text{Celldensity} \\ \text{Geometry} \end{Bmatrix} = \begin{bmatrix} X & x & 0 \\ X & X & 0 \\ x & 0 & X \end{bmatrix} \begin{Bmatrix} P_i \\ dp/dt \\ \text{Die \&Acc.} \end{Bmatrix} \tag{11}$$

The corresponding PVs are chosen as

(1) PV1 = Extruder RPM
(2) PV2 = Die lip length
(3) PV3 = Means of controlling the profile

The design equation for the process is given by

$$\begin{Bmatrix} P_i \\ dp/dt \\ \text{Die \&Acc.} \end{Bmatrix} = \begin{bmatrix} X & x & 0 \\ X & X & 0 \\ 0 & 0 & X \end{bmatrix} \begin{Bmatrix} \Omega \\ L \\ \text{Profile} \end{Bmatrix} \tag{12}$$

The die design is illustrated in Figure 9. Cell nucleation and cell growth in a parallel die have been simulated (9). The results show that most of the cell nucleation occurs near the middle of the die lip and cell growth occurs within 2/4 die length once the cell nucleation begins.

Advantages of Injection Molding with MCPs

The injection pressure of injection-molding process decreases substantially because of the presence of dissolved gas, which lowers the viscosity. The cycle time is also substantially reduced because of the elimination of the "hold and pack" time and also because of about 25% reduction in cooling time. Table 2 presents a comparison of the injection-molding process with and without the dissolved gas (see INJECTION MOLDING).

Figure 10 shows an extruded MCP part made of PVC and Figure 11 shows an injection-molded printer chassis for inkjet printers made of glass-filled

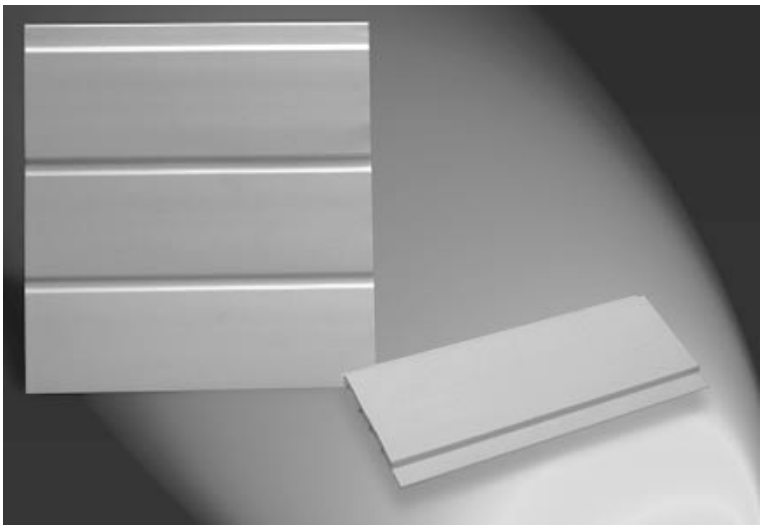

Fig. 10. Extruded commercial product of microcellular plastics (Courtesy of Trexel, Inc.).

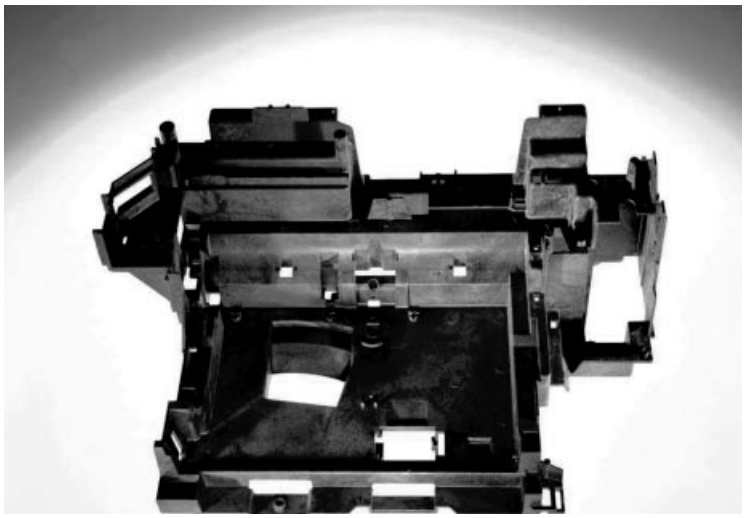

Fig. 11. Injection-molded printer chassis made of microcellular plastics (Courtesy of Trexel, Inc.).

engineering plastic (PPO/HIPS). The chassis made of MCPs has 50 % less warpage, 25% reduction in cycle time, and 8% weight reduction. The microcellular plastic also had higher toughness: 9.0 ft lb vs 6.7 ft lb by drop weight test, and 9.7 kJ/m^2 vs 7.3 kJ/m^2 by notched Izod impact test.

There are a large number of advantages of using MCPs:

(1) Reduction of material consumption (between 5 and 30%)
(2) Faster cycle time
(3) Higher productivity
(4) Greater toughness in some plastics
(5) Low residual stress
(6) Dimensional accuracy
(7) Dimensional stability
(8) Reduction in warping of injection-molded parts
(9) Appearance (no visible cells)
(10) Thin sections
(11) No sink marks
(12) Low temperature process
(13) Low pressure process
(14) Large number of cavities or smaller machines
(15) Most polymers
(16) Use of non-hydrocarbon solvents (CO_2 and N_2)
(17) No additives for nucleation
(18) No reactive components such as viscosity modifiers
(19) No special equipment other than gas supply system

Performance and Applications of MCPs

Some MCPs also exhibit better physical properties. Many MCPs are tougher and have a longer fatigue life. Also the specific mechanical strength is much better than conventional large-cell foamed plastics. MCPs can have densities as low as 0.03 g/cm^3. At such low densities, the thermal insulation properties of MCPs are excellent because of the small cell size.

Since the cell size is extremely small, the cells cannot be seen by the naked eye. Therefore, the foamed plastic resembles a solid plastic, having a good physical appearance. At conventional cell sizes, they are opaque, without the need to introduce pigments such as titanium dioxide.

MCPs save money for manufacturers owing to the use of less material and faster cycle time. Since about 70% of the cost of foamed plastic goods is the material cost and since up to 50% weight reduction is possible for some applications, the cost of plastic parts can be reduced by as much as 35%.

MCPs are environmentally acceptable since they are processed using CO_2 or N_2 instead of hydrocarbons or fluorinated materials. Since smaller amounts of plastics are used in a given product, there is less material to recycle or dispose. Furthermore, less raw material and energy are used to make the same plastic article.

MCPs find many applications in housing and construction, sporting goods, vehicles, electrical and electronic products, chemical and biochemical applications, and the textile and apparel industry. They can be used in siding, pipes, electrical wire, automotive seats and other parts, airplane parts, filters, shoe soles, office equipment housing, artificial paper, food containers, polishing cloth, thermal insulation around pipes, and other uses as well.

MCPs are processed at lower processing temperatures, since the glass-transition and melting temperatures and the viscosity of plastics decrease with increase in dissolved gas. As the gas is formed in the bubble during the nucleation and cell-growth phase, the viscosity and the melting temperature of plastics increases, reverting back to the original state. Therefore, MCPs "solidify" much more quickly—by almost a factor of two—and therefore, injection-molded MCP parts can be taken out of the mold quickly.

Process Research Issues

There are many research issues generated by MCPs. The following is a partial list:

(1) Molecular mechanism of the role of dissolved gas in affecting viscosity
(2) Crystallization process
(3) Solidification process during the phase separation of a gas/polymer solution
(4) Two-phase flow of a gas bubble/polymer mixture at the solid surface–polymer interface
(5) Modeling of the cell nucleation and growth in a die or a mold

Materials Research Issues

There are many research issues related to materials that can advance the field further as briefly listed below:

(1) Mechanical behavior of MCP parts and materials
(2) Effect of gas on morphology
(3) Fracture behavior of MCPs
(4) Fatigue behavior of MCPs

Conclusions

Because of their advantages in performance, cost, and processing MCP show great promise in changing the polymer-processing industry. A great deal is known about MCPs and their processing techniques, but the field is still full of research and development opportunities to satisfy the diverse requirements of the polymer-processing field.

MICROEMULSION POLYMERIZATION

Introduction

The pioneering work on microemulsions was established in the late 1940s (1,2). Extensive studies on this unique colloidal system were carried out after the 1974 oil crisis. This then led to great interest in free-radical polymerization in vinyl monomer containing microemulsion. Microemulsion polymerization involves the propagation reaction of free radicals with vinyl monomer in very fine oil (or water) droplets dispersed in the continuous aqueous (or oily) phase. Unlike the classical emulsion, the transparent or translucent reaction system comprising microemulsion droplets is thermodynamically stable in nature and these tiny droplets (1–10 nm in diameter) exhibit an extremely large oil–water interfacial area ($\sim 10^5$ m^2/dm^3). Relatively stable polymer particles ($\sim$10 nm in diameter)

Encyclopedia of Polymer Science and Technology. Copyright John Wiley & Sons, Inc. All rights reserved.

consisting of only a few polymer chains per particle are produced and, therefore, the resultant polymer molecular weight is very high ($10^6 - 10^7$ g/mol) (3–7). This cannot be achieved readily by conventional emulsion polymerization (8,9) or miniemulsion polymerization (10). In addition, the particle nucleation and growth mechanisms and kinetics associated with microemulsion polymerization are quite different from those of emulsion and miniemulsion polymerization systems (see HETEROPHASE POLYMERIZATION). Research interests in microemulsion polymerization techniques have grown rapidly since the 1980s because of their potential applications in the preparation of fine latex particles, ultrahigh molecular weight water-soluble polymers (flocculants), novel porous materials, polymeric supports for binding metal ions, conducting polymers, colloidal particles containing various functional groups for the biomedical field, and transparent colloidal systems for photochemical and other chemical reactions (5).

Formation and Microstructure of Microemulsion

Considering a colloidal system at constant temperature, volume, and composition, the change of Helmholtz free energy (dF) for any process undergoing the expansion of the oil–water interfacial area ($dA > 0$) can be expressed as

$$\mathrm{d}F/\mathrm{d}A = \sigma - W_{\mathrm{des}} \tag{1}$$

where σ is the oil–water interfacial tension and W_{des} is the work of desorption of surfactant per unit interfacial area. W_{des} is the resultant of various components such as changes of entropy and surface charge density and molecular interactions between constituents of the interfacial film. When W_{des} is sufficiently large and σ is extremely small ($\sim 10^{-3}$ mN/m or lower), dF/dA becomes negative and, therefore, dF is smaller than zero. Under the circumstances, a spontaneous reduction in the average droplet size down to $10^0 - 10^1$ nm is achieved, thereby leading to a thermodynamically stable colloidal system (microemulsion). For example, a gradual transition from the milky oil-in-water (O/W) emulsion to the transparent microemulsion and then to the lamellar gel phase can be observed visually when 1-pentanol (C_5OH, approx. 0.4 g each time) is added successively to the mixture comprising 100 g of water, 11 g of sodium dodecyl sulfate (SDS), and 5.92 g of styrene (ST) only with mild mixing at room temperature. Incorporation of amphipathic cosurfactant (C_5OH) into the adsorbed layer of anionic surfactant (SDS) around oil (ST) droplets greatly decreases the electrostatic repulsion force between two surfactant molecules, minimizes σ, and reduces the persistence length of the interfacial film (ie, enhances the flexibility of the interfacial membrane). All these synergistic factors promote the spontaneous formation of a transparent one-phase microemulsion product that exhibits excellent fluidity. It should be noted that cosurfactant is not a must in the preparation of microemulsion.

Figure 1 shows a schematic representation of the pseudo three-component phase diagram of a surfactant/cosurfactant–oil–water system. Depending on formulas, fine oil droplets dispersed in the continuous aqueous phase [O/W (or direct) microemulsion] or fine water droplets dispersed in the continuous oily

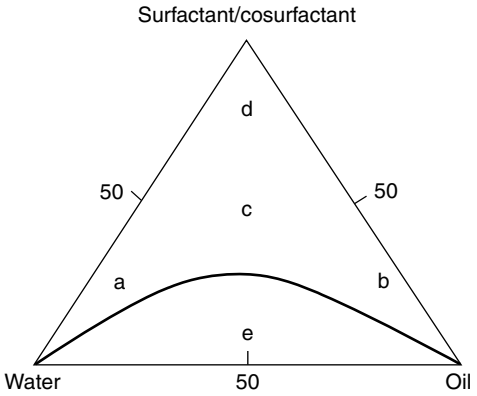

Fig. 1. A schematic representation of the pseudo three-phase diagram of surfactant/cosurfactant–oil–water systems: (**a**) oil-in-water microemulsion; (**b**) water-in-oil microemulsion; (**c**) bicontinuous structure; (**d**) lamellar structure; and (**e**) conventional two-phase emulsion.

phase [W/O (or inverse) microemulsion] are obtained. The intermediate region between the O/W microemulsion phase and W/O microemulsion phase is characterized by a bicontinuous structure in which the aqueous and oily microdomains are interconnected with each other (11,12). Such a middle phase was verified by the literature data (13). It was shown that the oil–water interfacial layer in the bicontinuous structure has a zero-mean curvature (ie, it is flat on the average) and this sponge-like structure is completely disordered. Such a structural aspect of microemulsion allows the monomer to be incorporated into different phases in the polymerization system [eg, the dispersed phase (microemulsion droplets), the continuous phase, or the bicontinuous phase]. This then makes it practical to design and prepare versatile microemulsion polymers for a variety of applications. The information on the initial condition of the reaction system (eg, the type of microemulsion, the dimension of microemulsion droplets, the physical properties of the oil–water interfacial film, the distance between two droplets, and the viscosity of microemulsion) is required in order to gain a better understanding of the subsequent polymerization kinetics and mechanisms. For more detailed information on this subject, please refer to References 3–5,14, and 15.

Microemulsion Polymerization Mechanisms and Kinetics

Significant research efforts have been devoted to the free-radical polymerization of hydrophobic monomers [eg, ST, methyl methacrylate (MMA), and butyl acrylate (BA)] in O/W microemulsions. The anionic surfactant SDS in combination with a short-chain alcohol (eg, C_5OH) as the cosurfactant is the most popular stabilization package. However, as more polymer forms with the progress of polymerization, the increase of free energy as a result of the conformational limitation and/or incompatibility between polymer and cosurfactant results in the instability or turbidity of microemulsion polymer (16). When a cationic surfactant,

dodecyltrimethylammonium bromide (DTAB), was used to stabilize the ST microemulsion polymerization, eventually no cosurfactant was required to form a satisfactory microemulsion product (17). It should be noted that the amount of monomer that can be solubilized within microemulsion droplets is generally quite low, whereas the levels of surfactant and cosurfactant required to stabilize the colloidal system are very high in O/W microemulsion products. For example, the weight percentage of ST does not exceed a few percent, which is much smaller than that of surfactant/cosurfactant (approx. 15% total) used in microemulsion polymerization. The acrylic monomer BA can partition into the oil–water interfacial layer to some extent. Therefore, it promotes the formation of microemulsion in the absence of a typical cosurfactant such as C_5OH (18).

The most widely investigated hydrophilic monomer in the W/O microemulsion polymerization is acrylamide (AM). In this case, AM is usually dissolved in water [50/50 (w/w)] immediately before the preparation of microemulsion because AM is in powder form. Thus, the resultant polymer particles are swollen with water and dispersed in the continuous organic medium. These polymer products are widely used for the flocculation of colloidal dispersions, sewage treatment, coatings, adhesives, and enhanced oil recovery (see ACRYLAMIDE POLYMERS). Just like the hydrophobic monomer BA, AM also tends to migrate toward the oil–water interfacial layer and it acts as a reactive cosurfactant in the formation of the W/O microemulsion using toluene as the continuous medium (19,20). Sodium bis(2-ethylhexyl) sulfosuccinate (AOT) is the anionic surfactant of choice. The polymerization can be initiated by thermal initiators, photochemical initiators, or γ-radiolysis. The W/O microemulsion polymerization system also suffers from the drawback that a very high ratio of surfactant to monomer (the ratio of surfactant to monomer = 2.5–25) is generally required to stabilize this colloidal system. The basic formulas, characteristics, and kinetic parameters of some representative O/W and W/O microemulsion polymerization systems can be found in References 3–7 and 4 and 5, respectively.

Candau and co-workers (19,21) proposed a mechanistic model for particle nucleation and growth in the W/O microemulsion polymerization system comprising AOT, AM/water, and toluene. They observed that the diameter of the resultant latex particles (d_p = 20–40 nm) is much larger than that of initial microemulsion droplets (d_m = 6 nm), that is, the final number of latex particles (N_p) is approximately two to three orders of magnitude smaller than the number of microemulsion droplets initially present in the polymerization system (N_m). Furthermore, on the average, only one polymer chain per particle was obtained. Based on these results, it was postulated that latex particles are nucleated continuously throughout the polymerization. This is not the case for the conventional emulsion polymerization in which the nucleation of latex particles stops at about 10–20% conversion (9). The growth of latex particles was attributed to the very limited fraction of initial microemulsion droplets that can be transformed successfully into latex particles. The remaining droplets only serve as a reservoir to supply particle nuclei with monomer and surfactant during the polymerization. The transport of monomer molecules from microemulsion droplets to latex particles can be achieved either by molecular diffusion through the continuous organic phase or by the mutual collision between one droplet and one latex particle. Monomer-swollen micelles (ie, microemulsion droplets) are present throughout the polymerization because of the

very high level of surfactant used to stabilize the colloidal system. The probability for primary radicals generated in the continuous organic phase to enter these micelles with a very large oil–water interfacial area is much higher in comparison with latex particles. Thus, the nucleation of latex particles is carried into the latter stage of polymerization and each latex particle is capable of capturing only one free radical during its lifetime on the average. This particle nucleation mechanism was verified experimentally (20). It was shown that N_p increases linearly with monomer conversion. On the other hand, d_p remains relatively constant with the progress of polymerization. Such reaction mechanisms with some minor modifications may also be adequate for the qualitative description of the nucleation and growth of latex particles in the O/W microemulsion polymerization.

The O/W microemulsion polymerization system such as SDS/C_5OH–ST/water has been investigated extensively in the last decade. Representative studies conducted by Guo and co-workers (22–25) are chosen for discussion hereinafter. Sodium persulfate (SPS) and 2,2′-azobis(2-methyl butyronitrile) (AMBN) were used as the water-soluble and oil-soluble initiators, respectively, in their experiments. The rate of polymerization (R_p) first increases to a maximum with the progress of the reaction (Region I, ranging from 0 to 20–25% conversion for polymerizations initiated by SPS and ranging from 0 to 10–15% conversion for polymerizations initiated by AMBN) and then decreases toward the end of the reaction (Region II). A schematic representation of R_p versus conversion (X) profile for the O/W microemulsion polymerization is shown in Figure 2a. For comparison, a typical R_p versus X profile for the conventional emulsion polymerization is also included in Figure 2b. It should be noted that the constant R_p period, often observed in conventional emulsion polymerization, is absent from microemulsion polymerization (Fig. 2). Furthermore, the gel effect [ie, the rapidly increased X with time (t) owing to the greatly retarded bimolecular termination reaction] is not experienced in the latter stage of microemulsion polymerization. This is simply because the resultant latex particles are not large enough (d_p = 20–30 nm) to accommodate more than one free radical therein.

Guo and co-workers (22–25) also showed that the nucleation of latex particles occurs throughout the polymerization. Microemulsion droplets (ie, monomer-swollen micelles, d_m = 4 nm) are primary loci for the nucleation of latex particles. However, the nucleation of particle nuclei in the continuous aqueous phase [homogeneous nucleation (8,9)] and limited flocculation of these particle nuclei cannot be completely ruled out. The molecular weight of polymer obtained is very large ($1 \times 10^6 - 2 \times 10^6$ g/mol) because of the predominant chain transfer of polymeric radicals to monomer inside the growing latex particles. The resultant monomeric radicals may desorb out of the very small latex particles, thereby leading to a value of the average number of free radicals per particle (n) smaller than 0.5. These monomeric radicals in the continuous aqueous phase may also be reabsorbed by latex particles. A mechanistic model was developed to simulate the reaction kinetics of the ST microemulsion polymerization. The entry rate coefficient of free radicals into microemulsion droplets estimated by this model is 7×10^5 cm^3/(mol · s), which is several orders of magnitude smaller than that of radicals into the monomer-swollen polymer particles. This is most likely due to the condensed interfacial layer of SDS and C_5OH on the microemulsion droplet surface, which acts as a physical barrier to the incoming radicals. As a

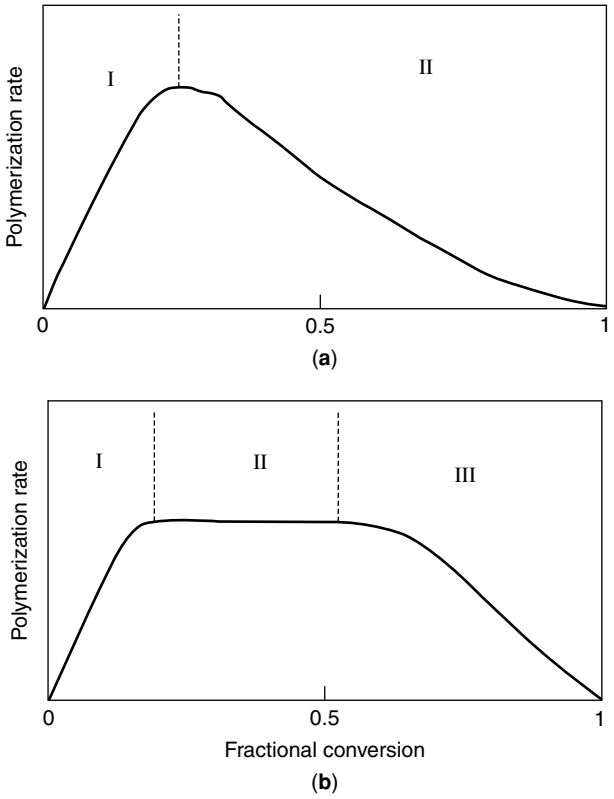

Fig. 2. A schematic representation of the rate of polymerization versus conversion profile: (**a**) oil-in-water microemulsion polymerization and (**b**) conventional emulsion polymerization.

result, only a small fraction ($\sim 10^{-3}$) of microemulsion droplets initially present in the reaction system can be successfully converted into latex particles. A satisfactory agreement between the experimental data and model predictions was achieved. However, the extremely small entry rate coefficient of free radicals into microemulsion droplets was thought to be physically unreasonable because this would lead to the greatly enhanced bimolecular termination rate in Guo's model (26).

Morgan and co-workers (26) derived the following compact equation for predicting microemulsion polymerization kinetics.

$$\ln(1 - X) = -fk_d[\mathrm{SPS}]_0 k_p[\mathrm{ST}]_{d,0} t^2 / [\mathrm{ST}]_0 \qquad (2)$$

The parameter f is the initiator efficiency factor, k_d is the initiator decomposition rate constant, k_p is the propagation reaction rate constant, and $[\mathrm{ST}]_{d,0}$ and $[\mathrm{ST}]_0$ are the initial monomer concentrations in microemulsion droplets and in the polymerization system, respectively. This kinetic model was based on the assumption that (*1*) all the free radicals generated in the continuous aqueous

phase enter microemulsion droplets (ie, particle nucleation loci) and initiate the polymerization therein, (*2*) the bimolecular termination reaction in the aqueous phase is negligible, (*3*) the entry of radicals into latex particles is insignificant, and (*4*) the growing polymeric radical in a latex particle is primarily terminated by the chain-transfer reaction. According to equation 2, plotting the $\ln(1 - X)$ versus t^2 data should result in a straight line with a slope of $(-fk_d[SPS]_0k_p[ST]_{d,0}/[ST]_0)$. This simple model predicts the behavior of the *n*-hexyl methacrylate (C_6MA) microemulsion polymerization reasonably well. In fact, it is the only existing model that can predict the course of microemulsion polymerization depicted schematically in Figure 2a. The general validity of this kinetic model was assessed by several sets of experimental data obtained from the ST microemulsion polymerization, and the poor performance of equation 2 in the high conversion region was often observed (27–30). Such a discrepancy between the experimental data and model predictions was attributed to the bimolecular termination and diffusion-controlled propagation reactions (28).

The technique of pyrene fluorescence intensity measurements was proposed to study the particle nucleation mechanisms involved in the O/W microemulsion polymerization (31). The experimental data showed that microemulsion droplets are the major particle nucleation loci for the polymerization system with the more hydrophobic ST as the monomer. This is followed by the flocculation of latex particles with the remaining droplets. In contrast, the polymer reactions taking place initially in the continuous aqueous phase (homogeneous nucleation) plays an important role in the MMA microemulsion polymerization.

The feasibility of using a water-insoluble dye to investigate the particle nucleation mechanisms in the ST microemulsion polymerization has been evaluated (30). The parameters chosen for this study include the cosurfactant type (C_iOH, $i = 4, 5, 6$), the SPS concentration, and the initiator type [the oil-soluble 2,2′-azobisisobutyronitrile (AIBN) versus water-soluble SPS]. Most of the dye molecules are solubilized within microemulsion droplets immediately before the start of polymerization. Dye molecules can be incorporated into latex particles only when free radicals enter these droplets and successfully convert them into particle nuclei. Primary particles nucleated in the continuous aqueous phase (homogeneous nucleation) should not contain any dye because the transport of dye molecules from droplets or latex particles, across the continuous aqueous phase, and then into latex particles originating from homogeneous nucleation is prohibited because of the very low water solubility of dye. Thus, the weight percentage of dye ultimately incorporated into final latex particles (P_{dye}) serves as an indicator for the extent of nucleation in microemulsion droplets. The dye content (P_{dye}) increases with increasing alkyl chain length of alcohols. Based on these experimental data, it was postulated that the importance of homogeneous nucleation in decreasing order is $C_4OH > C_5OH > C_6OH$. Guo and co-workers (22) showed that N_p increases with an increase in the persulfate initiator concentration. This trend was attributed to the enhanced flux of free radicals into microemulsion droplets. It was suggested in Reference 30 that the increase of the SPS concentration not only promotes the capture of radicals by microemulsion droplets but also increases the probability for oligomeric radicals to precipitate out of the aqueous phase and then form particle nuclei. The latter effect may override the former, thereby leading to the decreased P_{dye} with the SPS concentration.

Chern and Wu (30) also investigated the influence of the oil-soluble initiator AIBN on the particle nucleation and growth mechanisms in the ST microemulsion polymerization. Considering the limiting case that the particle nucleation process is controlled predominantly by the formation of AIBN radicals in the monomer phase, the value of P_{dye} should be much larger compared to the ST microemulsion polymerization initiated by SPS. However, this is not the case because the bimolecular termination reaction between two neighboring AIBN radicals produced in pair in the very small microemulsion droplets is significant. It was then postulated that the particle nucleation process involves (*1*) the desorption of one radical out of the microemulsion droplet containing two AIBN radicals, followed by the propagation reaction between the remaining AIBN radical and monomer, (*2*) the entry of one radical into the microemulsion droplet containing two AIBN radicals, followed by the bimolecular termination reaction and the subsequent propagation reaction between the survivor and monomer, or (*3*) the entry of one radical into the microemulsion droplet containing no radicals, followed by the propagation reaction between this radical and monomer therein. For the microemulsion polymerization initiated by AIBN, the particle nucleation process is characterized by a very low efficiency for the initiation reaction. Under the circumstances, a much higher AIBN concentration is required to give a value of P_{dye} comparable to that of the SPS-initiated polymerization.

Kaler and co-workers (26,28,32–36) have contributed a series of papers dealing with the effects of a number of kinetic parameters (eg, the monomer partitioning, bimolecular termination reaction, and diffusion limitation to the propagation reaction) on the reaction kinetics, latex particle size distribution, and polymer molecular weight distribution in various O/W microemulsion polymerization systems. Analytical expressions based on a mechanistic model were developed to predict the polymer particle size and molecular weight distributions (32). These computer simulations were verified by the experimental data obtained from quasielastic light scattering (QLS) and gel-permeation chromatography (GPC) (32) and online small-angle neutron scattering (SANS) (33). The results obtained from SANS also showed that the C_6MA monomer does not swell polymer particles during microemulsion polymerization (33). Mixed cationic surfactants of dodecyltrimethylammonium bromide and didodecyldimethylammonium bromide were used to stabilize this colloidal system. A model based on the latex particle comprising a polymer core surrounded by a monomer-rich shell is consistent with the kinetic data, and SANS measurements provided that the concentration of monomer in the shell is equal to that in the core of the C_6MA-swollen micelles.

The SANS technique was further adopted to study the partitioning of monomer between microemulsion droplets and polymer particles for various monomers (ST, *n*-butyl methacrylate, *t*-butyl methacrylate, and C_6MA) (34). It was found that, during microemulsion polymerization, the partitioning of monomer is strongly dependent on the composition of microemulsion, especially on the distance to the phase boundary in the pseudo three-phase diagram of the surfactant/cosurfactant–oil–water system. For example, the monomer partitioning is linear in nature and the concentration of monomer in polymer particles is quite low if the initial microemulsion composition is far away from the phase boundary. In contrast, the monomer partitioning is essentially nonlinear and the

concentration of monomer in polymer particles is much higher if the initial microemulsion composition is quite close to the phase boundary. The experimental data could be interpreted reasonably well by modeling the monomer partitioning behavior as a competition between the Flory-Huggins bulk polymer free energy and the Helfrich curvature elastic energy of the surfactant monolayer. The failure of equation 2 was then attributed to a combined effect of the nonlinear monomer partitioning, bimolecular termination reaction, and, in some cases, diffusion limitation to the propagation reaction (35). It is also very interesting to note that the weight-average molecular weight of polystyrene close to 1.5×10^7 g/mol, about one order of magnitude greater than that controlled by chain transfer to monomer ($\sim 2 \times 10^6$ g/mol), was obtained by the technique of GPC coupled with a multiangle laser light scattering detector and a differential refractive index detector (36). This was attributed to the diffusion-controlled desorption of monomeric radicals out of latex particles in combination with chain transfer to polymer. Although the results obtained from these studies made significant progress in this field, further research is still required to gain a better understanding of microemulsion polymerization mechanisms and kinetics.

In addition to the commercially available water-soluble polymers for the treatment of wastewater (37,38), the incorporation of various functional groups (eg, —OH, —COOH, and $-SO_3H$) onto microemulsion polymer particle surfaces for biomedical applications certainly deserves more attention (39). These functionalized latex particles with a diameter of 20–30 nm exhibit an extremely large particle surface area and they are especially effective for the adsorption of proteins, immobilization of enzymes and antibodies, and controlled drug delivery.

Polymerization in the Continuous or Bicontinuous Phases of Microemulsion. In an attempt to prepare hydrophobic polymers used to encapsulate water-soluble materials, W/O microemulsion polymerization systems were evaluated in the 1980s. For example, the influence of polymerization within the continuous organic phase (ST and acrylic monomers such as methyl methacrylate and methyl acrylate) on the regions of stable W/O microemulsion systems was investigated (16,40–42). It was observed that the formation of polymer results in serious phase separation during the reaction. Therefore, a much smaller region of stable microemulsion can be obtained in comparison with the counterpart in the absence of polymer. These results imply that a recipe adequate to the preparation of satisfactory microemulsion does not guarantee the successful transformation of this microemulsion into a unique polymer product. The factors responsible for this instability problem include changes in the molecular conformation (the entropy effect) and interactions among constituents (eg, monomer, polymer, and cosurfactant).

Porous polymeric materials can be prepared by the polymerization of ST in Winsor I, II, and III microemulsions (43,44). It was found that the porosity of polymer achieved by polymerization in the bicontinuous phase is higher than that in the continuous phase of the O/W or W/O microemulsion. This was attributed to the interconnected microdomains in the bicontinuous phase. In fact, the microstructure of polymer achieved is closely related to the nature of microemulsion (45–49). For example, porous polymer with a closed-cell structure (ie, the discrete

water pores are distributed throughout the polymer matrix) is produced when the polymerization of the W/O microemulsion takes place. In contrast, polymerization in the bicontinuous phase results in porous polymer with an open-cell structure in which water channels are interconnected throughout the polymer matrix. These results strongly indicate that the morphology of the resultant porous polymer retains the initial structure of microemulsion to some extent. Nevertheless, the dimension of the resultant porous microdomains ($\sim 10^3$ nm) is much larger than that of the initial structure of microemulsion ($<10^2$ nm) as a consequence of phase separation with the progress of polymerization. A recent breakthrough showed that it is possible to produce polymer with a pore size of 50–70 nm, which is on the order of that of the precursor microemulsion (50). The potential applications of such a polymerization technique for preparing novel polymeric materials include microfiltration, separation membranes, polymer blends with a unique microstructural morphology, and porous microcarriers for the culture of living cells and enzymes (5). Some other interesting ideas about the preparation of novel materials include the conductive composite film (51) and microporous silica gel (52).

MISCIBILITY

Introduction

The phase behavior of polymers, whether in solution or in mixtures with other polymeric components, differs considerably from that of small molecules. This difference is a direct consequence of the large size of polymer molecules. For mixtures of small molecules the driving force for miscibility is a result of the large gain in entropy that takes place on mixing, but this is not the case for polymers. The entropy of mixing is particularly small for polymer/polymer mixtures and, as a result, one-phase systems are obtained only in a limited number of cases.

Here, the term miscibility is used to describe a mixture containing two or more components that form a one-phase (solid or liquid) system. Whereas this definition is unequivocal as it corresponds to a precise thermodynamic description of the system, in practice for polymers the experimental determination of miscibility may be rather ambiguous. This is because the latter depends on the specific experimental technique adopted and, for example, while a system may appear one-phase if examined at sufficiently large length scales, it may not correspond to true miscibility at the molecular level.

One of the primary tasks in the past few decades in polymer science has been to control the structure and properties of multicomponent systems. Since the properties of multicomponent systems depend on their structure, the control and design of these structures is fundamental to produce novel properties. Phase separation and spinodal decomposition are used to design multiphase structures. To understand the fundamentals of these phenomena it is necessary to understand thermodynamics, phase transitions, (qv) and critical phenomena in polymer blends (qv) and be able to evaluate quantitatively the degree of miscibility between the polymeric blend components.

Thermodynamics of Solutions of Small Molecules

The necessary condition for two substances to mix is that the Gibbs free energy of the solution, G_{12}, is lower than the sum of the Gibbs free energies of the separate constituents, G_1 and G_2. In other words, for a homogeneous solution to form, the Gibbs free energy of mixing, $\Delta G_m = G_{12} - (G_1 + G_2)$, should be less than 0. Therefore miscibility is governed by the Gibbs free energy of mixing ΔG_m, which is related to enthalpic ΔH_m and entropic ΔS_m components through the relationship

$$\Delta G_m = \Delta H_m - T\Delta S_m \quad (1)$$

It follows that the necessary condition for a mixture of two components to be miscible at a temperature T is that ($G_m < 0$ (it will be noted later that this is a necessary though not sufficient condition for thermodynamic miscibility).

Since ΔS_m is related to the number of "distinguishable" arrangements available to a system, it is a positive quantity; mixing always increases the disorder of the system. This is particularly evident for low molecular weight materials, where the large entropic change occurring on mixing provides the driving force to miscibility. For such systems, ΔG_m becomes more negative with increasing temperature and this favors miscibility.

The first term on the right-hand side of equation 1, ΔH_m, provides a measure of the extent of interactions between molecules. ΔH_m is negative if there are attractive interactions between the components, as this decreases ΔG_m. Obviously, ΔG_m increases if ΔH_m is positive (repulsive interactions). For an ideal solution $\Delta H_m = 0$ and this condition is satisfied when the intermolecular forces between both like and unlike molecules (ie the two components) are similar.

For an ideal mixture of small molecules, consisting of n_1 moles of component 1 and n_2 moles of component 2, the lattice model (Fig. 1a) can be used to determine the entropy of mixing. This is based on various assumptions: (*1*) solvent and solute molecules are identical in size and shape and each occupies a lattice site; (*2*) mixing is a random process since all possible arrangements are equi-energetic (ie $\Delta H_m = 0$); (*3*) no volume changes take place on mixing. By using this simplified model, it is possible to determine the number of possible "distinguishable" arrangements and therefore the entropy change for an ideal solution

$$\frac{\Delta S_m}{nR} = -[x_1 \ln x_1 + x_2 \ln x_2] \quad (2)$$

where x_1 and x_2 are the mole fractions of the two components, n is the total number of moles ($n = n_1 + n_2$), and R is the gas constant. Since the model assumes that the heat of mixing is zero (*athermal mixing*), the free energy of mixing of an ideal solution is simply

$$\frac{\Delta G_m}{nRT} = [x_1 \ln x_1 + x_2 \ln x_2] \quad (3)$$

For the ideal solution, mixing is a spontaneous process that is entropically driven.

Real solutions may deviate from ideality, particularly since the condition of athermal mixing is not usually encountered. The model can be modified to

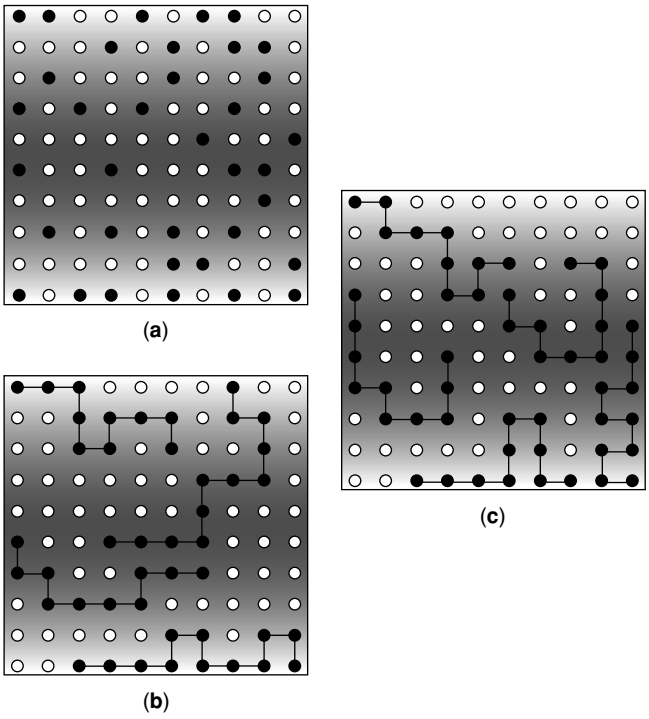

Fig. 1. Schematic representation of the lattice model for the determination of the combinatorial entropy of mixing: (**a**) mixture of small molecules; (**b**) polymer chain in a solvent; and (**c**) polymer/polymer mixture.

account for intermolecular interactions, which, within the lattice model, are of the first-neighbour-type. For a binary system, three kinds of interactions need to be considered: [1, 1], [2, 2], and [1, 2] contacts; and so the process of dissolution is given by

$$\frac{1}{2}[1,1]+\frac{1}{2}[2,2]\rightarrow[1,2] \tag{4}$$

A contact exchange energy, ΔW, can be defined as

$$\Delta W_{12}=\varepsilon_{12}-\frac{\varepsilon_{11}}{2}-\frac{\varepsilon_{22}}{2} \tag{5}$$

from the pair interaction energies ε.

In absence of special attractive forces such as those due to hydrogen bonding and complex formation, and assuming random mixing, the enthalpic term can be expressed as the product between the number of [1, 2] contacts in solution and ΔW_{12}

$$\Delta H_{\mathrm{m}}=nzN_{\mathrm{A}}\Delta W_{12}x_1x_2 \tag{6}$$

where z is the lattice coordination number and N_{A} is Avogadro's number. Equation 6 is often written in terms of the van Laar dimensionless segment–segment

interaction parameter χ_{12}:

$$\chi_{12} = \frac{z\,\Delta W_{12}}{kT} \tag{7}$$

and so

$$\Delta H_m = RT\,\chi_{12} x_1 x_2 \tag{8}$$

The modification introduced above leads to the free energy of mixing of a *regular solution*

$$\frac{\Delta G_m}{nRT} = [x_1 \ln x_1 + x_2 \ln x_2] + \chi_{12} x_1 x_2 \tag{9}$$

This equation, ie the van Laar model of solvent mixtures, can be considered the predecessor of the Flory–Huggins theory but, as explained later, it can be applied only to mixtures of small molecules.

As the temperature is decreased the interaction parameter becomes larger. This affects the free energy of mixing (ΔG_m) versus composition curves as shown in Figure 2. For χ_{12} values less than 2, ΔG_m is negative and the composition dependence is negative, while for $\chi_{12} > 2.0$ the curve changes shape. In this case, for compositions between the two points A and D, the system can lower the free energy by separating into two phases. As the temperature decreases, the interaction parameter becomes increasingly positive and this leads to positive ΔG_m values, which make the system immiscible.

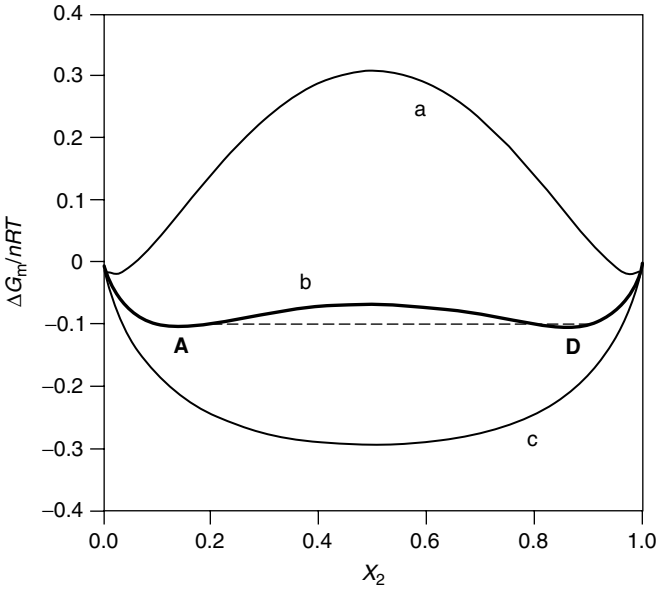

Fig. 2. Composition dependence of the free energy of mixing calculated for a regular solution. Different values of the interaction parameter χ_{12} have been used to generate the curves a ($\chi_{12} = 4$), b ($\chi_{12} = 2.3$), and c ($\chi_{12} = 1.6$).

The interaction parameter χ_{12} is often associated with *Hildebrand's solubility parameter* δ_i, which is in turn related to the *cohesive energy density (CED)* through the relationship (1)

$$\delta_i = \sqrt{CED_i} = \sqrt{\frac{\Delta E_i^{\text{vap}}}{V_i^{\text{o}}}} \tag{10}$$

where $\Delta E_i{}^{\text{vap}}$ is the energy of vaporization of component i. The relationship between χ_{12} and δ_i is given by

$$\chi_{12} = V_{\text{m}}(\delta_1 - \delta_2)^2 / RT \tag{11}$$

V_{m} being the molar volume. As expressed in terms of the solubility parameter, the interaction parameter χ_{12} is necessarily a positive quantity. In practice, negative χ_{12} can be obtained when, because of specific interaction, [1, 2] contacts are favored compared to contacts between like molecules. Thus the solubility parameter concept is only applicable to systems involving dispersive interactions and fails for those involving hydrogen bonds, donor–acceptor interactions, etc.

Thermodynamics of Polymer Solutions

Polymer solutions show deviations from the ideal behavior described in the previous section. In addition to intermolecular polymer–solvent interactions that make $\Delta H_{\text{m}} \neq 0$, chain connectivity causes ΔS_{m} to deviate from the ideal case (eq. 3). When dealing with polymer solutions where one of the components is much larger than the other, significant changes need to be introduced in the treatment of binary liquid–liquid mixtures (2).

The lattice model is still applicable and so are some of the assumptions made for simple liquids. As shown in Figure 1b, in order to position a polymer chain in the lattice, it can be divided into a number of segments, each equal in size to a solvent molecule and therefore each occupying a lattice site. Positioning of these subunits cannot be considered a random event; because of chain connectivity, two consecutive segments in the chain have to be placed in adjacent sites. The schematic diagram of Figure 1b clearly indicates that, for polymer solutions, one expects a reduction of the entropy of mixing compared to solutions of small molecules.

The calculation of the entropy of mixing, ΔS_{m}, of polymers in solution was carried out by Flory (3) and Huggins (4) in 1942. The Flory–Huggins (FH) theory, based on the rigid lattice model developed for solutions of small molecules, leads to the following expression for the free energy of mixing:

$$\frac{\Delta G_{\text{m}}}{RT} = [n_1 \ln \varphi_1 + n_2 \ln \varphi_2] + n_1 \varphi_2 \chi_{12} \tag{12}$$

where n_i represents the number of moles of component i. The FH equation can be written in alternative forms, and, particularly useful, is the expression in terms

of φ_1 and φ_2, the volume fractions of solvent and polymer:

$$\frac{\Delta G_m}{RT} = \frac{V}{V_R}\left[\varphi_1 \ln \varphi_1 + \frac{\varphi_2}{r_2} \ln \varphi_2 + \varphi_1\varphi_2\chi_{12}\right] \quad (13)$$

where $r_2(=V_2/V_1)$ are the number of segments per chain molecule, that is, the degree of polymerization of the polymer, V is the total molar volume of the two components, and V_R is a reference segment volume.

The above equation is similar to that derived in the previous section, the only difference being the replacement of mole fractions with volume fractions. This substitution makes it possible to account for the larger volume occupied by a polymer chain compared to a solvent molecule, while the use of mole fraction rests on the assumption that solute and solvent molecules have equal size.

It follows from equation 13 that, for polymer solutions, the entropy of mixing does not only depend on composition but also on the degree of polymerization of the chains, and it decreases as r_2 (the number of interconnected units) increases. Since r_2 is large, this reflects the reduction of the combinatorial entropy of mixing that arises from the constraints imposed by chain connectivity.

As shown in Figure 3, the free energy versus composition curve becomes highly asymmetric and gets skewed toward the dilute solution end of the composition range. Similar to the case of the regular solution, the temperature dependence of the interaction parameter causes changes in the free energy versus composition curves.

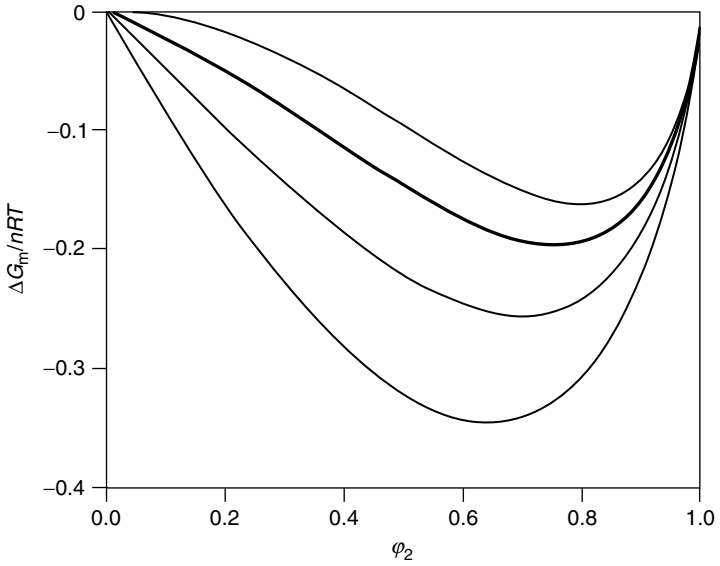

Fig. 3. Composition dependence of the free energy of mixing determined for a polymer ($r = 10^3$) in solution. The different curves have been generated using different values of the interaction parameter (in order of decreasing ΔG_m: $\chi_{12} = 1, 0.8, 0.5, 0.1$).

Phase Equilibria

It has been noted that as temperature decreases the interaction parameter increases; the interactions between molecules are increasingly less favorable to mixing and, at a given stage, a situation will be reached where the system will tend to phase separate into two different phases. Phase separation and limited solubility play a crucial role in situations of practical interest and therefore it is of great importance to establish the phase behavior of a mixture. For this purpose it is instructive to analze the free energy versus composition curves shown in Figure 2. For curve c, ΔG_m is always negative and the mixture cannot separate into two phases since this would lead to an increase in ΔG_m: the system is completely miscible in the whole composition range. On the contrary, for curve a, ΔG_m is always positive and the system is completely immiscible.

The situation represented by curve b is more complex. In this case, ΔG_m is always negative but there is a change of curvature in the middle of the composition range (between A and D). For clarity, this situation is reproduced in Figure 4, where a series of free energy versus composition curves are plotted, which correspond to different temperatures and therefore different values of the interaction parameter. With decreasing temperature, ΔG_m shows a local negative curvature between points A and D. Thus, for compositions between points A and D, the system can lower its free energy by separating into two phases of compositions φ_A and

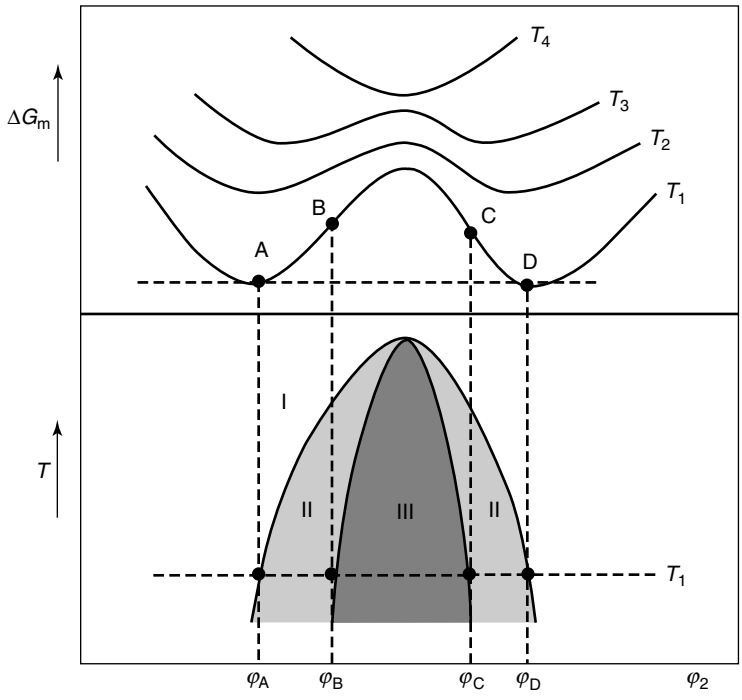

Fig. 4. Schematic representation of free energy of mixing versus composition curves at different temperatures $T_1 < T_2 < T_3 < T_4$ and corresponding phase diagram. In the lower section, I refers to the one-phase region while II and III are the metastable and unstable regions of the phase diagram, respectively.

φ_D that correspond to free energy minima. This implies that there is a miscibility gap between these two compositions. As shown in Figure 4, for $T = T_1$, a common line can be drawn to the free energy curve that is tangent to two points, called *binodal points*, A and D. In the region between points A and D, the free energy along the tangent line, ie the free energy of the two separate phases, lies below the curve that represents the free energy of the single-phase system. It follows that the phase-separated system is more stable, at this temperature and within this composition range, compared to the homogeneous phase. For this condition to be achieved, the ΔG_m versus composition curve needs to show two inflexion points, here indicated as φ_B and φ_C, where the curvature changes sign.

The conditions for miscibility can be found by differentiating the FH equation and by defining the minima and inflexion points. The first derivative, with respect to the number of solvent molecules, leads to the change in chemical potential:

$$\frac{\partial \Delta G_m}{\partial n_1} = RT\left[\ln(1-\varphi_2) + \left(1-\frac{1}{r_2}\right)\varphi_2 + \chi_{12}\varphi_2^2\right] \tag{14}$$

Maxima and minima can be derived by setting the above equation equal to zero. The binodal curve coincides with the set of points where the first derivative of the Gibbs free energy with respect to composition is zero.

The spinodal curve corresponds to the inflection points φ_B and φ_C where the relationship $\partial^2 \Delta G_m / \partial \varphi^2 = 0$ holds. From equation 14, this corresponds to

$$\frac{\partial^2 \Delta G_m}{\partial n_1^2} = \frac{-1}{(1-\varphi_2)} + \left(1-\frac{1}{r_2}\right) + 2\chi_{12}\varphi_2 \tag{15}$$

The binodal and spinodal points can be defined from the conditions above for different temperatures and this leads to the determination of the binodal and spinodal curves plotted in Figure 4. At the critical point, the two curves coincide; this condition is met when the following relationship is satisfied:

$$\frac{\partial^3 \Delta G_m}{\partial n_1^3} = \frac{1}{(1-\varphi_{2c})^2} + 2\chi_{12c} \tag{16}$$

Using equations 15 and 16, the following relationships are obtained:

$$\varphi_{2c} = \frac{1}{1+\sqrt{r}} \tag{17}$$

$$\chi_{12c} = 0.5 + r^{-1/2} + 0.5r^{-1} \tag{18}$$

A phase diagram relative to a polymer solution that phase separates on heating is shown in Figure 4. The solid line in this figure is called the *binodal* and it separates the stable from the metastable regions of the phase diagram. The dashed line is the *spinodal* curve, which separates the metastable and unstable regions. The spinodal touches the binodal at the critical point, T_C, which for a polymer solution is defined by equations 17 and 18.

For compositions between φ_B and φ_C, we have $\partial^2 \Delta G_m / \partial \varphi^2 < 0$, and because any small concentration fluctuations lower the free energy, the system tends to phase separate into two phases of compositions φ_A and φ_D. In this case, phase separation takes place spontaneously by a process called spinodal decomposition. Between φ_A and φ_B and φ_C and φ_D phase separation proceeds by nucleation and growth if there is a fluctuation in concentration large enough to overcome the potential barrier to demixing.

It follows from all the above considerations that for miscibility to be achieved, the following thermodynamic condition needs to be satisfied:

$$\left[\frac{\partial^2 \Delta G_m}{\partial \varphi_2^2}\right]_{T,p} > 0 \tag{19}$$

The temperature marking the upper limit of phase separation, defined by equations 17 and 18, is the so-called upper critical solution temperature (UCST). The UCST represents the maximum temperature (and composition) at which a system exists as two-phase. The phase diagram for polymer solution is molecular-weight–dependent and it becomes increasingly asymmetric with increasing molecular weight. The effect of chain length on the coexistence curve is illustrated in Figure 5. The critical point moves towards more dilute polymer solutions with increasing molecular weight. In the limit of infinite molecular weight, ie for $r \to 8$, the interaction parameter approaches 0.5 and $\varphi_{2c} \to 0$. On the contrary, for

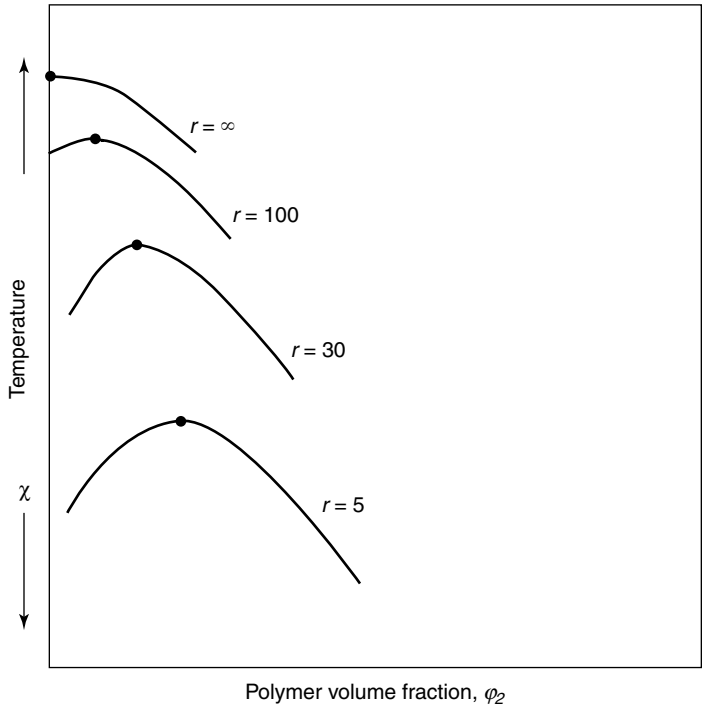

Fig. 5. Schematic diagram illustrating changes in the location of the coexistence curve as a function of molecular weight: with increasing r, and therefore M, the critical points move toward more dilute solutions, and it is located at higher temperatures.

$r = 1$, $\chi_{12c} = 2$ and $\varphi_{2c} = 0.5$ (result for regular solution). These results indicate that a high molecular weight polymer is less soluble than a low molecular weight sample, and this observation forms the basis for the fractionation of a polymer sample, by lowering the temperature of a thetsolution or by lowering the thermodynamic quality of the solvent, progressively.

Comparison between experimental results and theory has indicated that the experimental coexistence curve is always wider than the one predicted on the basis of the FH theory. This discrepancy between theory and experiment is a result of neglecting the composition dependence of the interaction parameter. When the latter is taken into account, accurate predictions of the coexistence curves can be made.

Phase Diagrams. The phase diagrams reported so far in Figures 2, 3, and 5 refer to UCS behavior. These types of phase equilibria are those predicted on the basis of the Flory–Huggins theory and are observed experimentally for solutions of small molecules as well as polymer solutions. This situation implies that mixing is favored by heating and that it is accompanied by a decrease of the interaction parameter, while cooling may lead to a two-phase system.

Experimentally, polymer solutions as well as mixtures of small molecules may show a wide range of phase behavior. A schematic representation of possible phase diagrams for binary mixtures of small molecules and polymers in solution is given in Figure 6. For some systems, eg water/triethylamine solutions, miscibility decreases with increasing temperature, phase separation taking place above a

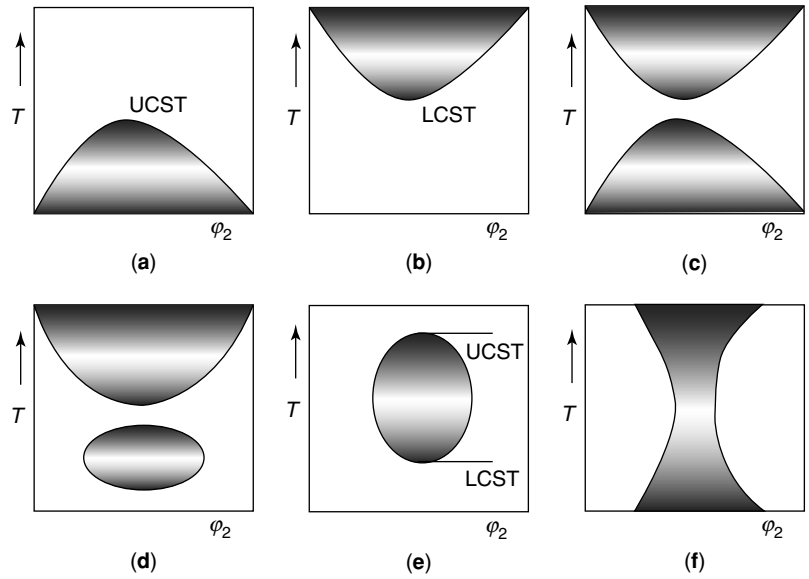

Fig. 6. Schematic representation of possible phase diagrams for binary mixtures; the shaded areas indicate two phase regions: (**a**) upper critical solution temperature behavior (UCST); (**b**) lower critical solution temperature behavior (LCST); (**c**) combination of LCST and UCST, mostly observed in nonpolar polymer solutions; (**d**) phase diagram showing upper, lower, and quasilower critical phase boundaries; (**e**) immiscibility loop; and (**f**) hourglass-shaped phase boundary obtained by convergence of upper and lower critical boundaries.

given temperature. This behavior is schematically shown in Figure 6b; it is referred to as lower critical solution (LCS) behavior and it is characterized by a corresponding lower critical solution temperature (LCST). Other systems, such as nicotine in water, exhibit both UCST and LCST, forming closed loops of miscibility as schematically shown in Figure 6e. An interesting behavior was observed for mixtures of poly(ethylene oxide)/water as this system exhibits both LCST and closed loops. Polymer solutions can show coexisting LCST and UCST as indicated in Figure 6c; the range of temperature separating UCST and LCST is a measure of solvent quality. As the solvent becomes poorer, the gap between the two phase boundaries becomes smaller, until these coalesce leading to the phase diagram of Figure 6f.

The separation of polymer/polymer or polymer/solvent systems into two phases as temperature increases is an established characteristic feature of polymeric systems that is not predicted by the Flory–Huggins theory. LCS phase diagrams are typical of polymer/solvent and polymer/polymer systems that involve specific interactions among the constituents. However, LCST behavior can also be observed in nonpolar systems.

As originally defined by the Flory–Huggins theory, the interaction parameter is independent of concentration and inversely dependent on temperature. This feature reproduces the UCS behavior experimentally observed in some systems. To account for the existence of a LCST, it is necessary to introduce a free-volume component (5–7) that accounts for the difference in size between polymer and solvent molecules. In this approach, a flexible expandable lattice is introduced, which can be envisaged to arise from the different rates of expansion of the polymer and the solvent, with increasing temperature.

Thermodynamics of Polymer Blends

The mixing together of two or more polymers is an established method used to arrive at new property combinations without having to synthesize new structures with the desired characteristics (8–10). The Flory–Huggins (FH) model originally developed for polymer solutions can be extended to polymer/polymer mixtures by introducing the concept of a reference segment volume V_R that is approximated to the smallest polymer repeat unit. For a binary polymer mixture, the combinatorial entropy of mixing ΔS_m can be expressed as (2)

$$\frac{\Delta S_m}{R} = -\left(\frac{V}{V_R}\right)\left[\frac{\varphi_1}{r_1}\ln\varphi_1 + \frac{\varphi_2}{r_2}\ln\varphi_2\right] \tag{20}$$

where r_i represents the number of segments per chain molecule (ie the degree of polymerization) of component i relative to the reference volume V_R, φ_i is the corresponding volume fraction, and V is the total molar volume of the two components.

For a binary mixture of two polymers, the Gibbs free energy of mixing can be obtained from equation 20, leading to an expression similar to equation 13

$$\frac{\Delta G_m}{RT} = \left(\frac{V}{V_R}\right)\left[\frac{\varphi_1}{r_1}\ln\varphi_1 + \frac{\varphi_2}{r_2}\ln\varphi_2 + \varphi_1\varphi_2\chi_{12}\right] \tag{21}$$

Equation 21 shows that the combinatorial entropy of mixing, which is usually the driving force for miscibility in mixtures of small molecules, is very small when r_i is large, ie for high molecular weight polymers. This situation is also schematically shown in Figure 1c where, because of requirements of chain connectivity, the number of possible arrangements are greatly reduced for a binary polymer mixture compared to a mixture of small molecules and polymer solutions. The large size of polymer molecules affects dramatically their thermodynamic behavior; when two high molar mass polymers are mixed, the entropic contribution ΔS_m is very small and any small interaction between the components that is unfavorable to mixing makes ΔG_m positive. In the early days of polymer blending, this observation together with the fact that the van Laar enthalpy of mixing (the third term in eq. 21) is usually endothermic or positive led to the pessimistic view that polymer materials should be largely immiscible.

This has been partly disproved by experiments and, despite the unfavorable entropic term, a number of polymer pairs were found to be miscible. Miscibility is achieved if $\Delta H_m \approx 0$, ie for systems with very similar chemical structures or when specific interactions such as dipole–dipole or hydrogen bonding are introduced among the blend components. In the latter case, $\Delta H_m \leq 0$ and ΔG_m is also negative.

The dependence of ΔG_m on composition φ_i and χ_{12} for a binary blend consisting of two polymers of equal molar mass can be determined from equation 21, and it is similar to that reported for polymer solutions. As temperature increases, the specific interactions between the two components weaken owing to molecular motion and the mixture phase separates. A large number of polymer blends show LCS behavior represented in Figure 6b. However, a UCST may still be observed in some polymeric binary systems, particularly low molecular weight nonpolar mixtures. In this case, even if the entropic term is small it is still larger than ΔH_m, and ΔS_m governs the miscibility.

The critical value of the interaction parameter can be estimated from equation 21, by differentiation:

$$\chi_{12} = 0.5\left[\frac{1}{\sqrt{r_1}} + \frac{1}{\sqrt{r_1}}\right]^2 \tag{22}$$

The critical value above which the two polymers phase separate can be determined from equation 22 for various mixtures with $r_1 = r_2$, and χ_{12} can be compared to the corresponding difference in solubility parameters, as shown in Table 1. The tolerated difference between the solubility parameters for miscibility to be achieved decreases with r_1 and, for high molecular weight polymers to mix, the solubility parameter must be very close. For example, polystyrene ($[\delta = 18.4$ $(J/cm^3)^{0.5}]$ and poly(α-methyl styrene) $[\delta = 18.1$ $(J/cm^3)^{0.5}]$ are predicted to be miscible up to $M_n \sim 60000$ while for miscibility to be achieved between poly(methyl methacrylate) $[\delta = 19.0$ $(J/cm^3)^{0.5}]$ and poly(methyl acrylate) $[\delta = 19.6$ $(J/cm^3)^{0.5}]$ M_n needs to be lower than 13000. Miscibility is expected to be strongly molecular/weight–dependent, as illustrated for polystyrene/poly(α-methyl styrene) blends in References 11 and 12.

Specific Interactions. In order to enhance miscibility between two polymers, the enthalpic term has to be made negative by introducing specific interactions between the two components. A wide range of miscible polymer pairs

have been reported in the literature in which favorable intermolecular interactions such as hydrogen bonds, dipole–dipole, and ion–dipole interactions or charge-transfer complexation exist among the components (13). These interactions may either exist because of the presence of specific chemical groups in the polymer chain or may be introduced by design through copolymerization or other appropriate chemical reactions. For example, it has been demonstrated that when hexafluoro dimethyl carbinol groups are introduced into the phenyl rings of polystyrene (14), miscible blends can be obtained with a number of polymers containing proton acceptor groups, eg poly(vinyl acetate), poly(alkyl methacrylate)s, which are immiscible with polystyrene.

Examples of chemical groups that may lead to miscible polymer pairs are given in Tables 2 and 3. A polymer containing groups listed in column 1 may be miscible with a polymer containing groups listed in Table 2. For example, polystyrene forms miscible blends with poly(vinyl methylether) and this is attributed to interaction between the π-electrons of the phenyl rings and the lone pairs of the ether oxygens (15,16). Similarly, it is believed that a hydrogen bonding interaction exists between the carbonyl units of poly(methyl methacrylate) or poly(ε-caprolactone) and the α-hydrogen of poly(vinyl chloride) (C—O. . . . . H—C—Cl) (17,18).

In addition, it has been shown that by introducing groups capable of ion–ion, ion–dipole, and dipole–dipole interactions, it is possible to achieve miscibility between otherwise immiscible polymer pairs. For example, although polystyrene and poly(ethyl acrylate) are immiscible polymers, miscibility can be achieved by

Table 2. Examples of Interacting Groups Capable of Enhancing Blend Miscibility

Interacting Groups			
Polymer 1	Polymer 2	Strength	Examples
		Weak	PVC/polycaprolactone
		Moderate	Poly(styrene sulphonate)/poly(vinyl pyridine)
		Weak	Polystyrene/poly(2,6-dimethyl phenylene oxide)
		Strong	Poly(acrylic acid)/poly(vinyl methyl ether) or poly(ethylene oxide)

Table 3. Examples of Groups Used of Modify Polymers to Introduce Specific Intermolecular Interactions

introducing styrene sulphonic acid units in the PS chains and ethylacrylate can be copolymerized with small quantities of 4-vinyl pyridine (19). This system is now one-phase through the effect of coulombic attractions between the two copolymers (20–22).

Ion–dipole interactions are also exploited to achieve miscibility; the immiscibility between poly(ethylene oxide) and PS can be overcome by incorporating up to 10 mol% of the lithium salt of methacrylic acid into the PS chain. Weaker interactions arise from the use of donor–acceptor groups to form intermolecular charge-transfer complexes (23–25), and examples of groups that have been used for this purpose are given in Table 3.

Intramolecular Repulsive Interactions. Miscible blends can also be achieved in absence of specific interactions, by exploiting the so-called intramolecular repulsive effect. This is observed in mixtures where at least one of the components is a statistical copolymer; miscibility is restricted to a "miscibility window," that is, it takes place within a well-defined range of copolymer composition. For example, poly(styrene-*co*-acrylonitrile) (SAN) and poly(methyl methacrylate) form miscible blends for copolymer compositions in the range 9–39% acrylonitrile (26,27). Miscibility in these systems is not a result of specific interactions but it is due to the intramolecular repulsive effect (28) between the two monomer units in the copolymer such that, by mixing with a third component, these unfavorable contacts are minimized. The same situation is encountered in binary mixtures of two copolymers (29).

In general, for a binary mixture of two statistical copolymers poly(A-*co*-B) and poly(C-*co*-D), the interaction parameter is (30):

$$\chi_{\text{blend}} = xy\chi_{AC} + y(1-x)\chi_{BC} + x(1-y)\chi_{AD} + (1-x)(1-y)\chi_{BD} - x(1-x)\chi_{AB} - y(1-y)\chi_{CD} \quad (23)$$

where x is the volume fraction of monomer A in poly(A-*co*-B) and y is the volume fraction of monomer C in poly(C-*co*-D), and χ_{ij} are the interaction parameters for each of the segment–segment interactions in the mixture.

For the case of a copolymer A poly(C-*co*-D) and a homopolymer A, equation 23 simplifies to

$$\chi_{\text{blend}} = y\chi_{\text{AC}} + y(1-y)\chi_{\text{AD}} - y(1-y)\chi_{\text{CD}} \tag{24}$$

Equation 24 indicates that miscibility can be obtained by a suitable combination of χ_{ij} values that are unfavorable to mixing; in particular a large positive χ_{CD} value leads to a negative χ_{blend}, which favors the appearance of a "miscibility window."

By using experimental values of the binary interaction parameters it is possible to calculate miscibility maps and therefore predict the phase behavior of polymer/copolymer, copolymer/copolymer, and more complex blends. A list of segment–segment interaction parameters and corresponding interaction energy densities, B_{ij}, where

$$B_{ij} = \frac{\chi_{ij}RT}{V_{\text{R}}} \tag{25}$$

is given in Table 4. These were all determined experimentally or calculated with respect to one initial reference value for the styrene–methyl methacrylate interaction parameter of $\chi = 0.03$, obtained from the light-scattering results of Fukuda and co-workers (31). These consequently comprise a self-consistent set and while they may differ from values quoted in the literature by other workers, they predict phase behavior quite accurately. The other literature values may have been established using different reference points and should not be used in conjunction with this set.

Shortcomings and Extensions of the Flory–Huggins Theory

One of the limitations of the Flory–Huggins theory is that it assumes that all segments have the same size and shape and no volume change takes place on mixing. The theory is therefore unsuccessful in describing the phase behavior of high molecular weight polymer mixtures since it cannot reproduce the LCST that is experimentally observed for many polymer/polymer and polymer/solvent systems. Various factors have been suggested as giving rise to an LCST: (*1*) free-volume dissimilarities between the components that may become unfavorable to mixing at high temperature, (*2*) nonrandom mixing; and (*3*) a temperature-dependent heat of mixing due to the dissociation, upon heating, of the specific intermolecular interactions. Models have been formulated that account for volume changes upon mixing, and the equation-of-state approach has proved to successfully reproduce the LCST behavior.

In addition, in its original formulation, the interaction parameter was assumed to be independent of composition and inversely temperature-dependent. Experimental investigations using small-angle neutron scattering (SANS) (32) have shown that χ is not only temperature-dependent but it also varies with blend

α-Methylstyrene	Acrylonitrile	22.3	0.90
α-Methylstyrene	Ethylene	5.0	0.20
α-Methylstyrene	Chloroethylene	1.1	0.04
m-Nitrostyrene	Vinyl methyl ether	2.8	0.11
Acrylonitrile	Vinyl chloride	12.2	0.49
Vinyl chloride	Ethylene	3.3	0.13
Vinyl chloride	Chloroethylene	1.0	0.04
Ethylene	Chloroethylene	9.6	0.39

[a]All values are scaled to the original reference point "styrene-methyl methacrylate".

[b]All χ_{ij} values have been determined considering $V_R = 100$ cm^3/mol. In addition, since all χ_{ij} and B_{ij} values were derived from miscibility maps expressed in volume fractions, they should be used to predict phase diagrams in the same units.

composition, molecular weight, and chain architecture. Moreover, the temperature dependence may differ from that predicted by the FH model. Usually, χ_{12} values experimentally measured are complex functions of various parameters, and in this respect they differ considerably from the original Flory–Huggins parameter.

Recent studies have shown that structural differences among components, eg differences in tacticity, affect phase behavior (33–35). The inability of the Flory–Huggins theory to account for these experimental observations is mainly a result of neglecting the particular molecular structure of the polymer chains. Extensive studies have been undertaken in order to be able to link polymer phase behavior to molecular structure (36). The polymer reference interaction site model (PRISM) represents one of the successful approaches in understanding the relationship between molecular structure, local packing and thermodynamics.

MODELING OF POLYMER PROCESSING AND PROPERTIES.

See Volume 3.

MOLECULAR MODELING

Introduction

Computational chemistry has been practiced since the earliest days of digital computing. Initially restricted to a small class of problems in the hands of a few specialists, the methods are now widely adopted by every type of scientist and engineer. Because the field is so broad, only a portion of it can be covered in this article. But before restricting the scope, it is essential to define our subject in comprehensive terms. We take computational science to be the application of a machine executable algorithm to the solution of either a single or a coupled set of equations that are devised to provide a description of matter. At one extreme of description are the elementary particles—electrons and nuclei—that require the methods of quantum mechanics. At the other limit, there are continuum models that generally assert the piecewise continuity of materials and which usually rely upon "engineering" or constituitive equations, quantified with material parameters frequently determined by experiment. Molecular modeling is everything in between, ie, from atoms up to coarse-grained collections of atoms that can be treated as discrete entities.

The earliest models of molecules were constructed of wire, wood, or plastic. The most famous of these, the Corey–Pauling–Koltun (CPK) models, were commercially available in plastic and consisted of a large variety of atom types representative of average atoms with, say, sp, sp^2, and sp^3 hybridization. The models were helpful because they enabled one to see the three-dimensional relations between atoms more accurately than could be portrayed on the printed page. The extent of the utility of the models was just that they helped to convey molecular architecture. With the advent of high speed graphical computing, physical models have been replaced with computerized pictures that enable one to visualize and move molecules in many different ways.

Encyclopedia of Polymer Science and Technology. Copyright John Wiley & Sons, Inc. All rights reserved.

Many of the earliest uses of computational graphics were in biochemistry. The ability to visualize large enzyme molecules was a boon to both structural biochemistry and the pharmaceutical industry, and the applications of computational chemistry to drug discovery led to the formation of several successful commercial ventures into scientific software. Molecular modeling continues to flourish in the life sciences, where the broader use of computers is developing in ways that are pertinent to current problems in drug design, genetics, proteomics, and other newly emerging disciplines. However, our purpose here is not to discuss the life sciences—we are focussed on the material properties of polymers.

For polymers, the advantage of a digital display over unwieldy physical models is that one may both view the model and simultaneously measure distances, bond angles, and dihedral (torsion) angles, for example, from the atomic coordinates that are stored in the machine, regardless of the size of the model. Furthermore, the types of information that can be displayed graphically, quantities such as quantum mechanical wave functions for molecules of all kinds, and the agility with which these can be manipulated make the computer displays tremendously more powerful than tangible models.

However, molecular modeling is much more than pictures. In defining modeling as the use of a computer to solve complicated theoretical models, we access methods that are capable of providing useful information related to the observable properties of materials, and not just the individual molecules that comprise them. While graphics provides valuable insights into chemical behavior that informs "chemical intuition," this aspect of modeling is now being supplemented by extremely potent quantitative information, of immediate engineering utility, that can be extracted from the mathematical models.

The boundary between theory and modeling can be sharply drawn: a theorist creates a mathematical description, whereas the modeler solves it numerically. A single individual may do both things, but they are different activities. The distinction between experiment and modeling is likewise sharply drawn: an experiment involves real materials, whereas modeling only requires an algorithmic reduction of a mathematical description.

Modeling is the third leg of the scientific tripod, the other two legs being experiment and theory. A theory that cannot be evaluated may be beautiful to contemplate, but it will likely not have very much practical value. Similarly, an experiment that simply generates data in the absence of some understanding of the meaning of the data is not apt to be very useful. In many respects, modeling is the bridge between data and theory, in that it provides a means to analyze data in terms of theory, thereby helping one to understand the data, and it renders the complexities of theory into simply comprehensible quantities that can be related to observations.

When applied to polymers, molecular modeling has to grapple with complexities that go beyond experiences with small molecules. The notion of a pure chemical substance is usually not applicable to polymers. The high molecular compounds that might be interesting for applications may have a distribution of molecular weights, tacticity, sequence, and may contain residual catalysts. They may be partially crystalline, glassy, or a cross-linked melt. In practice, polymers may be formulated with fillers, colorants, stabilizers, or plasticizers, and may be used as films, foams, adhesives, structural materials, fibers, gels, or elastomers.

Thus, the problems of interest to the polymer scientist or engineer involve much more than the behavior of individual molecules, or even of a single, "pure" material. Furthermore, there is a vast range of dynamical and mechanical behavior that is very challenging to describe by any method.

Many properties of interest will succumb to brute-force theoretical and modeling methods. For example, a molecular dynamics method that utilizes an accurate description of the potential energies of molecules and their interactions and which is executed within an appropriate statistical mechanical ensemble is capable, in principle, of solving for any "classical" (as opposed to quantum) problem. However, the computer resources necessary to get to the size and/or time domain where the property of interest manifests itself with this level of description might not yet exist. The certitude of this claim throughout the history of computational chemistry has generated a consistent and substantial effort to utilize the fastest and largest computers available for the problems of molecular modeling.

Fortunately, computers have advanced at an astounding rate since the invention of the integrated circuit. Moore's law, which states that the density of logic elements on chips doubles every 18 months, is expected to hold until about 2012. This leads to the prediction that laptop machines with CPU speeds operating in the range of 10–20 GHz will be available at that time. With the general reduction in the prices of integrated circuits, we expect that inexpensive teraflop personal computers, built with 50 processors operating at 20 GHz each, will be commonplace when silicon-based machines reach their asymptotic chip density. Beyond this, even greater computational power will be available for research problems, and so we are assured that the hardware will continue to add to our capacity to make discoveries and gain new insights. Yet even today, research is underway on the next generation of computers that will employ altogether different technology—perhaps utilizing photons that are switched with polymers!

However, rather than waiting for future developments, scientists and engineers have applied themselves to inventing a multitude of clever ways to negotiate the many different length and timescales that are manifest in the properties of polymers. This article is an attempt to portray a cross section of the methods that have been developed for this multitude of purposes, as well as to describe some of the outstanding results that have been obtained to date.

We have chosen to structure this article primarily around computational methods, as the type of problem that can be solved generally depends on the simulation tool that is available. Before addressing these methods, it is necessary to agree on the types of properties that are accessible to calculation. As alluded above, a complete description of typical polymer is beyond us, so modelers are usually working with the same sorts of idealizations as might apply to a small molecule system. In fact, modeling begins with small molecules, as it is necessary to build up a description of the forces between molecules by first investigating the more tractable systems, for which quantum methods can be conjoined to other simulation methods to provide a detailed description. These are our first concerns, before elaborating the methods. Finally, a selection of representative results that have been obtained is presented.

In preparing this article we have relied upon a great deal of original scientific literature, and our numerous citations will make clear which journals have been

receptive to modeling research. A few general interest journals have a relatively high concentration of polymer modeling papers:

(1) *Journal of Chemical Physics* (Americal Institute of Physics)
(2) *Macromolecules* (American Chemical Society)
(3) *Journal of Physical Chemistry B* (American Chemical Society)

Several journals specialize in the publication of molecular modeling papers:

(1) *Journal of Computational Chemistry* (Wiley), started in 1980
(2) *Molecular Simulation* (Gordon and Breach), started in 1987
(3) *Journal of Molecular Modeling* (electronic, Springer), started in 1995
(4) *Computational and Theoretical Polymer Science* (Elsevier), started in 1991 (discontinued in late 2001 by Elsevier; the journal *Polymer* has accepted responsibility for coverage previously provided by *CTPS*)
(5) *Macromolecular Theory and Simulation* (Wiley-VCH), started in 1992

As is clear from the titles, the latter two are dedicated to polymers. Monographs on modeling, many devoted to polymers, have also been published:

(1) *Statistical Mechanics of Chain Molecules* (1)
(2) *Computer Simulation of Liquids* (2)
(3) *Molecular Modeling of Polymer Structures and Properties* (3)
(4) *Monte Carlo and Molecular Dynamics Simulations in Polymer Science* (4)
(5) *Atomistic Modeling of Physical Properties* (5)
(6) *Computational Modeling of Polymers* (6)
(7) *Conformational Theory of Large Molecules: The Rotational Isomeric State Model in Macromolecular Systems* (7)
(8) *Rotational Isomeric State Models in Macromolecular Systems* (8)
(9) *Computer Simulation of Polymers* (9)
(10) *Interdisciplinary Workshop on Molecular Modeling of Polymers: Wild Dunes*, Isle of Palms, South Carolina (10)

Undoubtedly, the reader will find topics of interest in all of these resources, despite the fact that we are unable to adequately cover many of them owing to the limited scope of this article. We have not taken it upon ourselves to review every significant paper on polymer modeling that has been published. To do so would have been a very much larger task than could be managed within the scope of this Encyclopedia article. Instead, we have attempted to present a balanced view of the major trends in this enterprise, and by so doing we have found it necessary to omit some work. We have undoubtedly overlooked others. However, we are assured that the significance of our omissions will become apparent to the diligent researcher who traces the literature back through the references that we have provided. We apologize in advance to those whose contributions we have been unable to represent in this survey.

Objectives of Modeling

The point at which we start this discussion is somewhat arbitrary, but for our purposes the start of molecular modeling for polymer applications began with the the work of Flory's group at Stanford in the 1960s (1). The rotational isomeric state (RIS) models that were developed at that time were built on the theory invented by Volkenstein (11) and Birshtein and Ptitsyn (12), but it was Flory who polished up the theory and made it systematic and generally accessible. There were certainly very notable efforts to model the properties of single molecules prior to that time, exemplified in the work of Wall and co-workers (13), Teramoto and co-workers (14), and Verdier and Stockmayer (15). (This history is briefly reviewed in Section 17 of the monograph by Yamakawa (16).) These pioneering efforts utilized generic lattice models of chains; there was no systematic application of a theory to a wide range of different "real" molecular architectures preceding RIS theory. Flory's efforts were the first to use experimental data on small molecules to come to an understanding of rotational potentials in polymers and to assess the interplay between molecular structure, force fields, and chain configuration statistics.

As an end in itself, the configuration statistics of a molecule tells one relatively little about the material properties of the polymer. (However, it is precisely those properties of individual molecules that are of unquestioned historical significance in the characterization of polymers by investigation and interpretation of their dilute solution properties.) Most importantly, the methods that were developed within the RIS setting presaged more direct attacks on property prediction methods, as will be seen as our story unfolds.

The *elementary* properties that one would like to be able to calculate or predict with computations include the equation of state, $V(T, P)$, where V is the volume, T the absolute temperature, and the pressure. (For present purposes, the extensive thermodynamic variables are understood to be for any quantity of substance under consideration, and so apply equally well to small molecules as to polymers.) The temperature and volume dependence of energy, $E(V, T)$, are also of interest. While one would like to determine the free energy of a pure substance, $G(P, T)$, this is usually not possible because of the difficulties that will be addressed later.

The *next level* of problems of equilibrium thermodynamics involve more complex properties, such as the tensorial mechanical properties described by compliance and stiffness tensors, as well as those entailing interactions between two or more phases. The latter properties include surface tension as well as phase separation and equilibria. There is great interest in using simulations to probe polymer behavior and properties in environments that are not readily accessible to measurement, such as those encountered in the confined spaces between filler particles.

Several transport properties can be evaluated from equilibrium simulations with use of linear response theory, which relates correlation functions of spontaneously fluctuating molecular properties to phenomenological transport coefficients. These relations can be used to evaluate diffusion coefficients, thermal conductivities, viscosities, IR spectra, and so on. However, most of these properties are evaluated more directly using appropriately devised techniques of nonequilibrium molecular dynamics. Particularly challenging for polymers is the direct

calculation of the viscoelastic properties (the storage and loss moduli), simply because the usual time or frequency span of interest is so large. However, even these problems, at least in narrow time windows, are being effectively investigated today.

Finally, there are the problems related to the ultimate properties of polymers. These include environmental degradation (such as oxidation and photolysis), fracture, and other phenomena that involve bond breakage. All of these phenomena ultimately require a quantum mechanical description of transition states, which places the larger portion of this literature outside the scope of this review. However, there are some semiclassical descriptions that are being employed for these problems, and they are discussed here.

Models and Force Fields

The ability of a simulation to yield specific, rather than generic, information about a system is highly dependent on the quality of the potential energy function that is used to describe the interactions between the smallest entities in the simulation. These smallest units may be atoms, united atoms, beads, or other coarse-grained objects depending on the nature of the simulation. Most modelers who use coarser descriptions than united atoms are primarily interested in generic or global properties, and fairly crude estimates of the potentials suffice for these studies. Models in this category include the finitely extendable nonlinear elastic (FENE) descriptions of bond stretching (17), simple harmonic springs (18,19), square-well potentials for nonbond interactions (20), hard-core repulsions (18,21), and similar model parameterizations. Our primary focus in this section is on atomic and united atom descriptions; other methods are discussed in other sections. A general review with an extensive bibliography, encompassing a wide range of different materials and associated potentials, has appeared recently (22).

It is clear that a coarse-grained model for a polymer requires a compatible force field. As noted above, many of the potentials developed for this purpose have been intended for use in simulating generic properties, eg, the MW dependence of center of mass diffusion, and so have not been used for more detailed work. Efforts to generate more accurate force fields for calculation of thermodynamic properties with these types of models include the work of Boyd and co-workers (23,24) as well as that of Reith and co-workers (25).

General-purpose united atom force fields have also been developed, and one of the most widely cited of these is the OPLS force field of Jorgensen (26). The primary parameterization done in this work was on alkanes, including branched species; the nonbond parameters were fixed with Monte Carlo simulations on liquids. One advantage of a united atom model is that heat capacities for systems containing hydrogen can be computed with some reliability, at least at modest temperatures because the hydrogens are absent and cannot contribute to the equipartition of energy in the simulation (cf. seq.). It is of interest that the well depths for the dispersion interaction term for branched carbon atoms in the alkanes (26) are considerably shallower than for methyl and methylene carbons. This is also seen in the NERD force field (27), and has recently become apparent in an all-atom force field (28).

Just as there is a range of detail that can be invested in a computational model, there is a range of accuracy that is expected from potential energy functions (force fields). One of the more extensively used modeling packages is CHARMM, which comes equipped with a force field that has been developed largely for biological molecules (29). The aim of a general-purpose force field, such as the DREIDING force field of Goddard and co-workers (30) or the universal force field (UFF) of Rappé and co-workers (31–33) is to cover as much of the Periodic Table as possible. This wide scope is accomplished with use of general rules, such as average bond lengths for compounds containing X—Y bonds, or average angles for X—Y—Z bond angles, etc, where X, Y, and Z are any atoms. Data of all kinds have been used for these parameterizations, including quantum-calculated equilibrium structures as well as experimental diffraction studies of crystals and gases. These types of force fields are routinely used to get rapid estimates of structures, for which they are admirably suited. The geometry of an exotic molecule that has never before been synthesized might be amenable to description with DREIDING or UFF when other classes of force fields might not be able to give results, simply because the exotic has not been parameterized.

The disadvantage of these generic force fields is that they are usually not sufficiently accurate to predict condensed phase properties reliably. For example, "fair agreement" between experiment and UFF is a prediction of a bond length within 0.008 nm (33). (The accuracy for main groups elements with UFF is usually better than this.) This is a 4% error for a bond length of 0.2 nm, which translates into ca. 12% error in the density! The point is that a 4% error in the structure of an isolated molecule is barely perceptible to the eye, yet when physical properties of condensed phases are predicted for this structure, unfortunately large errors may be encountered.

The functions that are used for the broad coverage force fields are usually simple quadratic functions in the deviations from equilibrium bond lengths and bond angles. The higher accuracy force fields, such as MM3 (34) or CFF (35), make use of more complicated functions. The function used in CFF is

$$
\begin{aligned}
E_{\text{pot}} = {} & \sum_{\text{bonds}\, j} \sum_{s=2}^{nb} k_{js}\left(b_j - b_j^0\right)^s + \sum_{\text{angles}\, l} \sum_{t=2}^{n\alpha} h_{lt}\left(\theta_l - \theta_l^0\right)^t \\
& + \sum_{\text{dihedrals}\, k} \sum_{r=1}^{nt} V_r\left[1 - \cos\left(r\phi - \phi_r^0\right)\right] + \sum_{oop\, i} K_i \chi_i^2 + \sum_{\text{bond pairs}} F_{jk}^b\left(b_j - b_j^0\right)\left(b_k - b_k^0\right) \\
& + \sum_{\text{angle pairs}} F_{mn}^{\theta}\left(\theta_m - \theta_m^0\right)\left(\theta_n - \theta_n^0\right) + \sum_{\substack{\text{bond + angle} \\ \text{pairs}\langle i,l\rangle}} F_{il}^{b\theta}\left(b_i - b_i^0\right)\left(\theta_l - \theta_l^0\right) \\
& + \sum_{\substack{\text{bond + dihedral} \\ \text{pairs}\langle j,l\rangle}} \left(b_j - b_j^0\right) \sum_{k=1}^{m} V_k \cos(k\phi_l) + \sum_{\substack{\text{angle + dihedral} \\ \text{pairs}\langle j,l\rangle}} \left(\theta_j - \theta_j^0\right) \sum_{k=1}^{m} V_k \cos(k\phi_l) \\
& + \sum\sum\sum K_{lkk'} \cos(\phi_l)\left(\theta_k - \theta_k^0\right)\left(\theta_{k'} - \theta_{k'}^0\right) + \sum_{i>j} \frac{q_i q_j}{r_{ij}} + \sum_{i>j} \left(\frac{A_{ij}}{r_{ij}^n} - \frac{B_{ij}}{r_{ij}^6}\right)
\end{aligned}
\tag{1}
$$

Values with the superscript zero are reference values. The sums in each of the bonded terms (first four lines of the equation) run over all bonds, angles, etc,

in the molecules of the simulation, while the nonbond terms in the last line run over all pairs of atoms, both intermolecular and intramolecular. The nonbonded interactions within a molecule are usually included only for atoms separated by three or more bonds. In these types of force fields, a truncated Taylor's series approximation is used to describe the "real" function for the various atomic displacements, with the number of retained terms (usually no more than three or four) being determined by the required accuracy of the representation.

The first four terms of the above equation are "diagonal" in the sense that they do not cross-couple different displacements as do the next six terms. Terms of the latter category are required to describe the perturbation of one displacement by a neighbor. The force constants that appear as the coefficients of the displacement terms are carefully chosen to give good frequencies, and the cross-terms are added to give even better IR frequencies. The fourth term describes an out-of-plane (oop) bending degree of freedom (χ).

The nonbond interactions are summed over all partial atomic charges in pairs (separated by three or more bonds) taken as point monopoles in the Coulombic term. The dipole-induced dipole (London dispersion) interaction between polarizable atoms is contained in the last term, with the atomic overlap repulsion being included here (for algebraic convenience) as the 9th or 12th power. (CFF uses the 9th power, whereas the traditional Lennard–Jones choice is the 12th.)

The parameterization of a molecule with a function such as equation 1 usually proceeds in stages. First of all, it is assumed that the mathematical description of a chemical functional group is transferable from one molecule to another. In this approximation, there is only one ester group with aliphatic substituents, for example, but this group *may be different* from an ester with aromatic substituents. Any distinction that might be drawn between these two types of ester groups is decided on consideration of the desired level of accuracy. Each group consists of a number of *atom-types*. In principle, every symmetry-unique atom in a molecule is a different type of atom, requiring a unique set of parameters. However, at the level of accuracy that can be achieved today, it is not necessary to tune the force field to the level of individual atoms in each unique molecule. Functional groups, defined at the level that they are understood in organic chemistry, are sufficiently fine units for virtually all force field parameterizations. This is essential for polymers, as a parameterization of the repeat unit in a chain will suffice to describe the entire chain, with the exception of end groups. And they can be handled with similar methods even though they are different from the mid-chain units.

Even with atom typing and group parameterizations, a high accuracy potential energy function for even a relatively small molecule (say a typical solvent molecule) may require hundreds of parameters. The labor involved in generating these parameters is enormous if done by hand, which is what Allinger and co-workers have done in parameterizing MM3 and its predecessors (34,36–49). The labor can be automated to a considerable extent by making use of quantum mechanical (QM) calculations, in which the energies, gradients, and hessians of molecules containing a given functional group are calculated (35,50–61). This gives equilibrium values of bond lengths, bond angles, etc, as well as force constants. The plentiful QM data is parameterized by least-squares methods with a function such as equation 1, with the parameters being generated more or less automatically. Partial atomic charges are usually found by fitting the electrostatic

potential derived from QM to a point charge model, from which bond dipole parameters are constructed.

The QM calculations at any selected level of approximation are generally susceptible to systematic errors, but empirical corrections for these inaccuracies can be applied. Finally, the London dispersion interaction term is fit by performing simulations on a condensed phase to get the correct crystal structure, or in the case of liquids, the correct mass and cohesive energy densities. The dihedral terms in equation 1 are of considerable importance for polymer conformations and their transitions, and require careful treatment because of the coupling between nonbond and torsion terms (59). Even with some automation, the construction of a widely representative force field is a major undertaking.

The all-atom version of OPLS (62) is a diagonal force field, with parameters adapted largely from AMBER (63). Heats of vaporization for a range of organic liquids from alkanes to amides are predicted within about 2% with this force field, and densities are given to within 3%. The pressure dependence has apparently not been thoroughly investigated, but heat capacities are in good agreement with experiment. The latter are calculated from fluctuations in the energy during MC simulations of the condensed phase, which gives the intermolecular contribution. The intramolecular term, which might entail the hydrogen equipartition problem, is taken from experiment or a quantum statistics calculation. This is a practical solution to the heat capacity problem for small molecules, but it is not applicable to polymers. The quality of several different potentials for water, undoubtedly the most difficult small molecule to model correctly, was reviewed many years ago by Jorgensen and co-workers (64). This work is essential reading for anyone wanting to perform simulations on aqueous polymer solutions.

The GROMOS and GROMACS packages (65–67) from The Netherlands contains an MD engine that is supported by the GROMOS force field developed largely by van Gunsteren and Berendsen. This is best described as a diagonal force field with a 6–12 Lennard–Jones term. The GROMOS force field has been extended to a variety of molecules, such as cyclodextrins (68).

A force field that focusses on intramolecular interactions, and particularly on the force constants that determine vibrational frequencies, is the spectroscopically determined force field of Krimm and co-workers (50–52). They advocate very high level quantum calculations to fix the geometries, force constants, and electrostatic terms while using OPLS nonbond Lennard–Jones parameters. The recent focus of this work has been on highly polar molecules, as are discussed later. While this force field reproduces gas-phase IR data very accurately, it does not appear to have been tested on condensed phases.

A number of researches have developed special purpose force fields to enable simulations on specific polymers. Representative examples of both united-atom and all-atom parameterizations are:

(1) alkanes by Rigby and Roe (69)
(2) polymethylene by Boyd (23,70)
(3) polyisobutylene by Boyd and Pant (24)
(4) poly(ethylene oxide) and monatomic ions by Jaffe, Smith, and Yoon (71–73)
(5) poly(propylene oxide) by Ahlström, and co-workers (74)

(6) 1,4-polybutadiene by Smith and Paul (75)
(7) polytetrafluoroethylene by Holt and Farmer (60) and Chang and co-workers (76)
(8) poly(vinylidene fluoride) and trifluoroethylene by Abe and co-workers (77)
(9) poly(ethylene terephthalate) and related esters by Hedenqvist, Bharadwaj, and Boyd (78,79)
(10) polyimides by Young and co-workers (80)

In work of this type there is no implication that the "boutique" force field has applicability beyond its intended purpose, although there are clearly opportunities for transferring parameters for groups developed for one system to another molecule having the same or similar group (78,79). A closely related category of special purpose force fields is those derived from commercial or broad-coverage force fields by modification. The work by Ennari and co-workers (81) is illustrative of this method to develop new functionality from a springboard of established results.

The next phase in the development of high accuracy force fields will likely involve a treatment of polarizability. It is well documented that molecular polarization, as evidenced in depolarized scattering, strain birefringence, or the Kerr effect (1), is highly dependent on the molecular environment (82). The shell model (22), a highly successful potential function for the treatment of inorganic solids and used for poly(vinylidene fluoride) by Karawawa and Goddard (83) and Carbeck and co-workers (84), has polarizability as its primary focus. In this model, atoms are represented with positive cores and negative shell charges (or with positive shell charges for highly polarizable cations) with harmonic springs holding the shell charge to the center. An alternative to the shell model is provided by bond polarizibility tensors (85). This approach hews closely to the principles of the RIS model (1), but has not achieved widespread popularity.

Polarization of the kind envisioned here results when the dipolar molecules surrounding a given molecule, group, or atom induce a dipole moment in the object, the magnitude of which depends on magnitude of the electric field generated by the neighbors. The induced moment then reacts back on the neighbors, resulting in a self-consistent readjustment of the orientations and magnitudes of all the dipoles in the system. Obviously, this effect is more important the larger are the permanent dipoles and the atomic numbers, ie, polarizabilities, of the elements involved. Unfortunately, the parameterization of atomic and molecular polarizability is apt to be a substantial undertaking, as current methods are not highly accurate (86). The recent promising work of Krimm and co-workers (52) utilized very high level quantum calculations to determine the electrostatic potential of water and formaldehyde, which provided the data required to fit a variable atomic charges/atomic dipole model for the molecules, including bimolecular clusters. However, as this study shows, very extensive calculations are required to generate data of sufficient quality to enable accurate fitting of model parameters. That is, the more deeply one delves into refinements in force fields, the greater are the demands on the theoretical methods and the more difficult it is to find pertinent and accurate experimental data. There is a need to come to a better

understanding of many-body effects in general, and this will require a significant basic research program.

There is a pressing need for reactive force fields (87–90) that are capable of modeling both simple polymerizations and degradation reactions. Ab initio quantum methods can be coupled with dynamics to study chemical reactions, as they are in the Car–Parinello method (91), but the overhead of the QM calculation restricts these types of simulations to relatively short timescales. The use of semiempirical QM methods with MD has also been advocated (92), and this technique has spanned up to 200 ps with C_{60}. However, to induce chemistry on this timescale requires the use of very energetic initial states. There is a great need to develop less rigorous, but nonetheless useful and generally correct, descriptions of slow reactions for use in polymer lifetime simulations. Descriptions of this kind must get the chemistry right, but at a faster than natural rate that can be subsequently scaled to physical time.

Construction Methods

Placing Molecules in Containers. The construction of individual polymer molecules with use of graphical software is simply done by linking together specified number of atoms or groups by applying appropriate operations to the fundamental coordinate data structures of the units. Chemical bonding rules, with average bond lengths and bond angles selected from a general-purpose table of values for representative atoms, atom pairs, and atom triplets, are used together with elementary translations and rotations of coordinates so as to place atoms in more or less correct chemical relation to one another. On assignment of a potential energy to the molecule, an energy minimization may be performed using standard techniques to adjust the geometry of the molecule to adopt a low energy conformation if that is desired.

The construction of a condensed phase that is representative of a bulk amorphous material consisting of one or more molecules that have been built as described above requires that the molecules be packed in a container so as to enforce a predetermined density on the system. If the system is monoatomic, ie, is a nobel gas, the atoms are inserted one at a time in the box with evaluation of the energy at each attempted insertion. Those trials with too great an energy according to some criterion, most preferably the Metropolis Monte Carlo criterion (93) to be discussed, are discarded. Successive attempts to place atoms in the box are continued until the required density has been achieved. Of course, in this simple case it may be preferable to start with an easily constructed crystalline array and then randomize it by the molecular dynamics or Monte Carlo techniques to be described.

For molecular modeling of condensed polymeric phases (polymer melts and glasses), an important consideration is the generation of a well-relaxed molecular model at the density and temperature of interest. Unlike simple molecules whose structure can be prepared by simply starting from a known crystal structure and melting it, chain connectivity (ie, various intrachain constraints such as bond lengths, bond angles, and chain conformations) makes generation of well relaxed structures of condensed polymeric phases a nontrivial problem. Over the

last two decades of the twentieth century, several approaches were presented in the literature to tackle this problem; a brief summary of these methods along with the key results obtained in each study is presented in this section.

The early studies of molecular modeling of polymers attempted to generate structures of condensed polymeric phases in a manner analogous to that used for preparing structures of simple liquids, ie, starting from a regular, ordered (crystalline) structure and then melting this structure using either molecular dynamics or Monte Carlo methods to obtain a structure of polymer melt. This was the approach followed by Boyd (23) in the simulation of liquid *n*-tetracosane. However, such an approach encounters major difficulties when applied to polymers with larger monomeric units or for chains having complicated architecture, as mentioned above.

Another class of methods for generating structures of condensed polymeric phases consists of methods that grow the polymer chains in a bond-by-bond fashion in the simulation box. This approach was followed in one of the first molecular modeling studies of alkanes (which provided an initial approximation to polymers) at realistic experimental density reported by Vacatello and co-workers (94). In that work, an initial configuration of the chains was generated by starting with just one methylene group for each of the *n*-tricosane (C_{30}) chains. In the initial stages of the simulation, the chains were grown to their full length by a modification of the slithering snake move: upon addition of a new methylene group to one end of the chain, a methylene group from the other end was not removed if the chain was shorter than the required length. Another variant of the chain growth method, called the "Phantom Chain Growth" method, was presented by McKechnie and co-workers (95). In this method, an initial configuration of chains is produced without accounting for the excluded volume effects (long-range nonbond interactions). Such a procedure generates the correct conformational statistics of the chains but leads to severe interatomic overlaps, which are removed in the subsequent relaxation stage using molecular dynamics simulations (to be described) in which the short-range nonbonded interactions were modified. The method was successfully applied to polyethylene by these authors.

In general, because of their higher density and very long relaxation times, direct generation of structures of glassy polymers is a more difficult task than generating structures of polymer melts above T_g. Several approaches have been presented for generating structures of these materials. Theodorou and Suter (96) presented the first application of molecular modeling to a polymer glass—atactic polypropylene. For the generation of these models, a two-step approach was employed: Generation of a "reasonable" initial guess structure by growing the polymer chain bond-by-bond in the simulation box followed by minimization of the energy of the structure. An important consideration in generating an atomistically detailed model of this system at the experimental density and temperature of interest was that the conformational statistics of the chains in the bulk model should be similar to those for unperturbed chains. This was achieved by selecting the location of the new bond during the chain growth process from candidate positions determined by the rotational isomeric states of the chain as given by the RIS model. The energy minimization strategy involved a gradual increase in the magnitude of the nonbonded interactions between various atoms. This construction procedure was repeated several times to generate a small but

representative sample of structures drawn from the ensemble of amorphous glassy structures.

Suter and co-workers have also applied this technique for generating structures to glassy poly(vinyl chloride) (97), polycarbonate (98,99) and polystyrene (100). It was found, however, that when this technique was applied to polycarbonate and polystyrene, the initial structures generated had severe interatomic overlaps, and required tedious relaxation strategies involving 25 and 41 minimization stages respectively, in which the nonbonded interactions were gradually increased from their initial weakened values to full strength.

As described above, when the technique developed by Theodorou and Suter (96) is applied to polymers containing large or rigid monomer units, the resulting guess structures are highly strained and have large interatomic overlaps that require cumbersome relaxation strategies involving several stages of energy minimization. These problems can be removed to a large extent by combining this technique with the ideas of a "scanning method" as described by Meirovitch (101,102). In this approach, rather than considering the energy change associated with the addition of just one new bond at a time as in the original Theodorou and Suter method, the state of the current bond is selected by considering energies associated with several possible continuations of the chain over a specified number of future bonds. This technique facilitates the construction of amorphous and liquid crystalline phases of polymers containing large and/or rigid monomer units, and can also handle constructions of films confined by surfaces. Such an implementation of bond "look-ahead" (ie, accounting for several future extensions of the chain) is available in the Amorphous Cell package commercially distributed by Accelrys (103) (see Fig. 1).

Another class of methods for generating structures of condensed polymeric phases involves "polymerization" of the required number of monomers that are already placed in the simulation box. Rigby and Roe (69) used this approach in their study of polyethylene in the liquid and glassy state. They first placed centers of the required number of methylene groups randomly in the simulation box. Spatially close groups were then bonded to each other to form the initial configurations of the chains. The structure thus generated was relaxed using molecular dynamics with weakened potentials for all of the intrachain, bonded interactions, and full strength Lennard–Jones interactions for all of the nonbonded interactions. As the system relaxed, the force constants for the intrachain interactions were gradually increased toward their actual values. The approach used by Rigby and Roe (69) for generating configurations of condensed polymeric phases was extended by Khare and co-workers (104) to generate structures of glassy atactic polystyrene at realistic density. In that work, polystyrene chains were generated by "polymerization" of the required number of styrene monomers that were randomly distributed in the simulation box. The initial configuration thus obtained was relaxed using a combination of molecular mechanics and molecular dynamics simulations.

Kotelyanskii and co-workers (105) have presented an alternate approach for efficient building of large amorphous polymer structures. In this approach, a coarse-grained representation of the polymer structure is first created by generating trajectories for self-avoiding walks on a fully occupied lattice. The atomically detailed chains are then generated by placing the chain backbones along these trajectories and adding other atoms required to account for the specific chemical

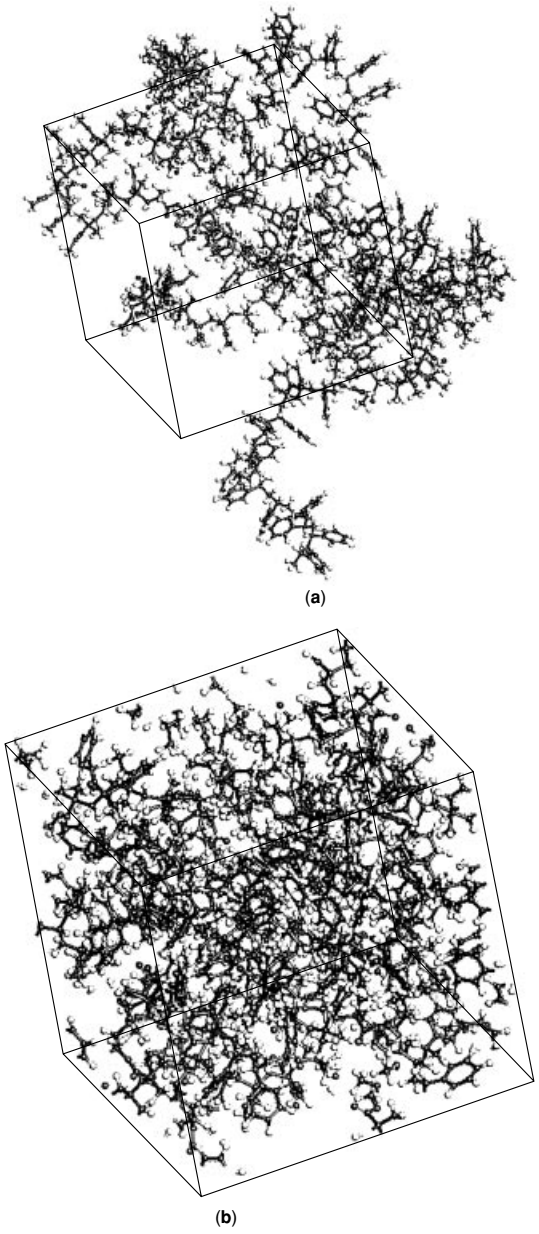

Fig. 1. A molecular model of a condensed phase polymer blend. The example shown is used to study a mixture containing atactic polystyrene 40-mer (2 chains) and atactic poly(methyl methacrylate) 40-mer (2 chains). Figure 1a shows the cell with the molecules configured as they are in space; the parts of the molecules lying outside the cell occupy adjacent cells in the periodic structure. To convey the space filling nature of the construction, Figure 1b shows the same molecules packed in the cell. The model system was constructed using the Amorphous Cell module in the *Materials Studio* software package distributed by Accelrys (103). The amorphous cell system was constructed at a density of 1.12 g/cm^3 at 300 K and the subsequent 80 ps of *NPT* dynamics at the same temperature and zero pressure equilibrated the system to a density of 1.057 g/cm^3.

structure of the polymer of interest. By proper choice of the two parameters (mapping between physical length and bond length on the lattice, and the number of atomistic monomers assigned to one lattice site) involved in this procedure, chain configurations obeying Gaussian statistics can be generated. Unlike other methods that require multistage energy minimization of the initial structures, the structure generated using this approach could be relaxed in a single minimization stage. The authors demonstrated the validity of this technique by applying it to atactic polystyrene to generate structures containing chain lengths of up to 364 repeat units. The X-ray scattering intensities calculated from these structures compared favorably with experimental data. A closely similar method of mapping chains onto lattices so as to make use of rapid Monte Carlo methods for equilibration has been developed by Mattice and co-workers (106,107).

Suter and co-workers (108,109) have more recently developed a slightly different technique for efficient generation of condensed polymer phases. In this method (108), the task of packing the required number of polymer chains at a given density in the simulation box is treated as a geometrical optimization problem. Using a "cost function" that accounts for interatomic overlaps, the geometrical packing problem is solved by approximating the nonbonded interactions between atoms with hard sphere potentials and accounting for the distribution of the torsional angle values given by the RIS model. The initial guess structures thus obtained are then relaxed using a combination of energy minimization and molecular dynamics and a "full" force field. Chain conformations (torsional angle distributions) in structures of glassy polystyrene obtained by this method (109) were found to be in much better agreement with the RIS model predictions than those obtained in the structures generated by Rapold and co-workers (100) using the traditional method.

Periodic Boundary Conditions. The representation of a condensed phase with a computer model requires careful attention to the boundary conditions. Obviously, any simulation is done with a relatively small number of particles (atoms, united atoms, beads, blobs, etc), and falls far short of a macroscopic amount of material. If one were to simply treat this collection of, say, a few thousand atoms as an isolated system, the surface/volume ratio would be quite large, and the properties that were determined would not be representative of the bulk material. The way around this problem is to use periodic boundary conditions, which is tantamount to making an infinite crystal of the model, regardless of whether the "unit cell" has symmetry or not.

In one of the earliest published studies of molecular modeling of condensed polymeric materials, Weber and Helfand (110) used molecular dynamics to simulate a polyethylene melt comprised of infinite length polyethylene chains. In this work, an infinitely long polyethylene chain was simulated by imposing an extra condition on the usual periodic boundary conditions: a random walk polyethylene chain containing appropriate fractions of the trans and gauche states was generated and it was required that the 200th carbon center be bonded to the periodic image of the first carbon center. This technique has not been used subsequently because of other limitations it imposes.

In implementing the boundary conditions for a periodic system, a distinction is made between a "parent" molecule and an "image." A parent molecule belongs to the parent cell if the first atom of the molecule was placed in the cell, regardless

of what happens to the molecule subsequently. For example, during a molecular dynamics simulation, a parent molecule may wander outside the parent cell. Also, this distinction is necessary because it is quite probable that a growing polymer will meander outside the parent cell as it is constructed. This is owing to the fact that the mean-squared diameter of a random coil exceeds the diameter of the domain having the same mass as the chain but the density of the bulk.

The parent cell and its contents are imagined to extend to infinity in all directions. The additional cells and molecules are "images" of the parent. The intramolecular energy of the cell consists of the energy of the parent molecules alone, whereas the intermolecular energy of the cell is calculated for all of the parent molecules interacting with all of the molecules, both parents and images, in the simulation (2). A more complete description of how this is done brings us to the next topic.

Simulation Methods

Molecular Dynamics. The technique of molecular dynamics (MD) is perhaps the most commonly used technique for classical simulations of polymeric materials. MD involves propagating the time evolution of a system of atoms using Newton's equations of motion. The force field for the system, $V(\{\mathbf{x}\})$, constructed using one of the force fields described above, is a function of the $3N$ coordinates, the set $\{\mathbf{x}\}$, of the particles (atoms, united atoms, beads, blobs, etc) in the system. The force f_j on the jth particle is given by the derivative $f_j = -\partial V(\{\mathbf{x}\})/\partial x_j$, and Newton's equation of motion for this degree of freedom is

$$m_j\left(d^2x_j/dt^2\right) = f \tag{2}$$

where m_j is the mass of the jth particle and, of course, t is the time. The forces exerted by the interacting atoms on each other are evaluated from the potential energy at each step in the numerical integration of this set of coupled equations. Given the right-hand side of equation 2, the differential on the left is approximated by a finite difference, and the state of the system is advanced by incrementing the time by an amount Δt, the magnitude of which is at the discretion of the modeler. After each integration step (also known as a "time step"), a new set of spatial positions and velocities is obtained for the particles, and by repeating this process several hundreds, thousands, or even millions of steps, the spatial and time evolution of the system is generated.

A number of different numerical integration methods have been proposed for solving the equations of motion [Verlet (111), leap-frog, Gear predictor-corrector, etc (2)]. Most atomistic simulators prefer the velocity Verlet algorithm, as this integrator preserves the volume element in phase space (112). The solution of a set of differential equations depends on initial conditions, and possibly also on boundary conditions. The method that is chosen for this part of the problem is usually couched in terms of the statistical mechanical ensemble that is used. The microcanonical ensemble holds constant the number of particles, N, the volume of the container, V, and the energy, E, written in shorthand notation as NVE. Of course, integration of the equation of motion within the NVE ensemble requires

specifying the initial state and energy of the system, which includes both potential and kinetic contributions. The kinetic component might be constructed by assigning velocities to the particles of the system with random numbers drawn from a Maxwell distribution defined at a temperature T. Since the total energy is an integration constant of Newton's equations of motion, an accurate integrator will hold the energy constant. Therefore, by monitoring the energy during the simulation, one can determine whether or not the integrator is performing properly.

Other ensembles, notably *NVT* (canonical), *NPE*, and *NPT*, are also used routinely. Since energy is constantly flowing back and forth from potential to kinetic terms in any MD simulation, it is necessary to regularly readjust the kinetic energy in the ensembles that hold the temperature constant. This is required because the temperature is defined by the classical statistical mechanical equation

$$kT = \langle m_i (\mathrm{d}x_i/\mathrm{d}t)^2 \rangle_i \tag{3}$$

where the average, indicated by the angle brackets, is taken over all the particles in the system, and where k is Boltzmann's constant. Thus, to hold the temperature constant, it is necessary to hold the kinetic energy constant. A number of algorithms have been described in the literature for simulations at constant *NVT* (113–116). Somewhat more elaborate techniques are required to hold the pressure constant. In the latter, the pressure of the system is calculated from the virial theorem

$$PV = NkT + \frac{1}{3}\sum_{j=1}^{3N} x_j f_j \tag{4}$$

The *NPT* algorithms of Andersen (113) and Berendsen and co-workers (116) are popular for simulations in this ensemble.

For reasons of numerical stability, the time step used for the numerical integration is determined by the frequency of the fastest oscillating mode in the system, and must be made even shorter for some applications, eg, close to the critical point of a fluid. Most often, the fastest mode is the vibration of hydrogen atoms in the system, and to handle these degrees of freedom requires using a time step of 1 fs or smaller. Clearly, such a small time step places severe restrictions on the total time duration that can be simulated and hence the timescales of the processes that can be investigated using MD. With this in mind, algorithms have been developed for performing MD with bond and angle constraints, eg, SHAKE (117,118) and RATTLE (119), constructed so as to suppress vibrations of the fastest modes in the system. These algorithms permit the use of a much larger time step, but we hasten to point out that in condensed phase simulations the intermolecular collisions ultimately control the size of the time step. The techniques of multiple time steps also offer an alternative for speeding up the simulations by separating out the motion of the faster modes in the system from the slower modes (120). However, this method has not achieved widespread popularity.

Brownian Dynamics. The technique of molecular dynamics simulations described above explicitly accounts for the motion of all of the atoms contained in the system and thus provides a detailed description of the dynamics of the

entire system. For some applications, there exists a large separation in length and timescales of motion of the different components of the system. Furthermore, detailed knowledge of dynamics of only a part of the system is of interest, the case in point being the dynamics of a long-chain polymer immersed in a solvent. The technique of Brownian dynamics (or Langevin dynamics) provides an efficient simulation approach in such a case (2). In a Brownian dynamics simulation, only some of the molecules in the system are treated explicitly, and the remaining components, most often just the solvent, are treated as a continuum. Typically, the polymer chain is modeled explicitly, whereas the effects of the motion of the solvent molecules are accounted for in an average fashion via a combination of frictional and random forces. The basic equation of motion in a Brownian dynamics simulation is

$$m_i \mathrm{d}^2 x_i / \mathrm{d}t^2 = -m\zeta \, \mathrm{d}x_i/\mathrm{d}t + f_i(t) + R_i(t) \tag{5}$$

where the first term on the right represents the frictional force, with ζ being the friction coefficient, the second term represents intermolecular forces between the particles that are being treated explicitly, and the third term represents the random forces. The random forces are chosen from a Gaussian distribution with variance related to the friction coefficient by

$$\langle R_i(t) R_i(t') \rangle = 2m_i kT\zeta \delta(t - t') \tag{6}$$

where $\delta(t)$ is the Dirac delta function. Because the solvent is treated as a continuum, fast modes of motion associated with solvent degrees of freedom are suppressed. This enables larger time steps to be used, which proves most useful for the investigation of long timescale, diffusive processes. Brownian dynamics was one of the very first dynamical methods to be applied to polymer problems, and it continues to find prominent applications that are appropriate for its range of validity.

Nonbond Energy Evaluation. The evaluation of the intramolecular energy of a system from the potential energy is a straightforward sum over all the molecules in the simulation, taken one at a time. The intermolecular energy requires more thought.

The trusted technique for determining the total energy of a crystal is Ewald summation (2). This method is used for amorphous systems as well, except that it is very slow. The boxes used for simulating amorphous systems usually contain thousands of atoms rather than the handful of atoms in the unit cell of a crystal, and this slows down the method tremendously. The routine application of Ewald summation to determine the energies of these large systems is very wasteful of computer time, and many modelers prefer to use faster methods of provable accuracy for amorphous phases.

The pair correlation function $g(r)$ in a monoatomic fluid is different from unity only within a range of about five atomic diameters from an atom at the origin. Roughly the same statement applies to the atom–atom pair correlation functions in polyatomic systems. This observation is put to use in simulations by algorithms that perform discrete sums over atom pairs out to a cutoff distance r_0 from a given atom and replace the remainder of the interactions out to infinity

by an integral with $g(r) = 1$ for $r > r_0$. The latter contribution generates the so-called tail correction. The Lennard–Jones term is the only one to survive this surgery in either an amorphous system or one with high symmetry. This happens for a nonelectrolyte, even if there are dipoles in the system, because the dipolar interactions are generally so weak that orientational correlations are lost very quickly with increasing distance of separation. The result is that the long-range electrostatic contribution averages to zero in either an amorphous system or in a crystal with high symmetry. The prudent modeler will verify that these conditions apply to the system of interest, and will demonstrate that various cutoff distances or Ewald summations give consistent results.

The treatment of charges with cutoffs has to be handled with care also. This is generally done with use of charge groups, which are neutral collections of atoms that travel together. Each charge group has an identified switching atom, usually selected to be near the center of the group. If the switching atom is inside the cutoff, all atoms in the charge group are included in the discrete sum, whereas if the switching atom is outside, all atoms in the group are excluded from the sum. This procedure avoids splitting dipoles, which could create a spurious electrostatic component to the interaction energy of the system.

Clearly, the considerations that need to be applied to electrolytes are somewhat different. However, Debye–Hückel screening for all except the most dilute electrolytes helps to limit the range over which discrete sums of Coulomb terms have to be carried out for amorphous systems, and the cell multipole method can be used to compute the longer range contributions (121). Sometimes it is useful to use cutoffs to propagate the MD simulation, and then use Ewald summations to intermittently evaluate the energy to test that the cutoff procedure is sufficiently accurate.

In general, a great deal of careful thought goes into the calculation of the nonbond interaction energy in molecular modeling, as this step, requiring as many as $O(N^2)$ operations, is the most costly of computer time. The tricks just discussed change one of the factors of N in this order of magnitude estimate to just the number of atoms that are near neighbors to a given atom, which speeds up calculations considerably. However, there is still a necessity to periodically perform the $O(N^2)$ steps that are required to build the neighbor lists for each of the atoms in the cell.

Classical Mechanics vs. Quantum Mechanics. The problems to MD that are posed by the equipartition theorem of classical statistical mechanics are best described in the context of the crystalline phase; polymer crystals have been of interest to modelers as a route to an understanding of the relations between phonon spectra, quantum corrections, and related issues. The vibrational modes of models of united atom polyethylene (PE) particles and crystals have been examined from time-averaged Hessian matrices, using eigenvalue methods to extract the phonon spectra (122). More conventional approaches to the study of PE crystals have been reviewed by Rutledge and co-workers (123), who show that quantum corrections to vibrational modes are very important. When doing a classical simulation with an all-atom force field, the equipartition of energy results in too much energy going into high frequency motions of hydrogen atoms. The result is that MD simulations on explicit atom systems containing light elements give too large heat capacities.

Methods to apply quantum corrections for this inadequacy of classical mechanics when applied to crystals, as well as other phases, have been explored (124–127), but there is not yet general agreement on how best to calculate thermodynamic properties for these types of systems. The practical solution of Berens and co-workers (124) entails "... calculating the velocity spectrum $S(\nu)$ from molecular dynamics and then integrating $S(\nu)$ over all frequencies with a weighting function which is the difference between the quantum and classical harmonic weighting functions for the thermodynamic variable of interest." However, as the statement avers, anharmonic contributions to the vibrational modes will not be captured correctly; this relatively minor shortcoming was addressed by Hardy and co-workers (128).

Molecular Mechanics. The term molecular mechanics (mm) refers to subjecting a model structure to energy minimization. If this is done for a crystal, the structure that is obtained is uniquely defined by the symmetry group. Such is not the case for an amorphous system. Instead, when the energy of a random system is minimized, the system falls into the nearest local energy minimum, and the structure that is obtained is but one member of an ensemble of a large number of similar structures. In a typical application of molecular mechanics to amorphous polymers, a molecular model of an amorphous phase of the polymer of interest is prepared at the experimental density and temperature of interest. The model is then minimized with respect to potential energy using a force field while holding the volume constant. In this minimized structure, the thermal motion of atoms is accounted for only in an average fashion via the volume available to atoms at the specified density. The minimized structure thus provides a 0 K representation of the polymer of interest at the experimental density—a state of suspended animation. One application of such a model to an amorphous system was the calculation of the vibrational spectrum of bulk isotactic poly(methyl methacrylate)(PMMA) from the Hessian matrix for the minimized system (129).

Another use of a calculation of this kind is to perform averages over configurations when the property of interest is primarily determined by energetic, rather than entropic, terms. A collection of several structures is built and minimized, and calculation of the property of interest is obtained as a simple arithmetic average of the value of the property for the individual structures. More sophisticated averages can also be constructed (130).

As discussed in the earlier section on Construction Methods, the technique of molecular mechanics has been used for investigating structural properties of glassy states of various polymers (70,96–100,131). In spite of the approximations mentioned above, ie, the absence of thermal motion of the atoms, these studies showed that the structural properties, such as X-ray scattering structure factors, radial distribution functions, etc, of the glasses can be very well represented by the simulated structures.

In addition to these methods, Boyd and Pant (70,131) presented a molecular mechanics method for generation of polymer glasses starting from a well-equilibrated polymer melt structure. Recognizing that densification is a key feature during vitrification of a polymer melt, they developed an energy minimization method in which periodic box dimensions were treated as variables, thus allowing the system density to change during the process of glass formation. Using this technique, the authors subjected a well-equilibrated PE (*n*-tetracosane) melt

configuration to energy minimization to generate the desired polyethylene glass structures. It was found that the specific volume of the system decreased by about 10% in going from the melt to the glassy state. The structures thus generated were considered to be polymer glasses at 0 K temperature. The calculated mechanical properties, eg, shear modulus, of these glasses showed reasonable agreement with the experimental values.

In addition to the investigation of static, equilibrium properties, the techniques of molecular mechanics have also been used for the investigation of dynamic properties of the polymeric materials. A number of dynamical processes, such as conformational transitions and penetrant molecule diffusion in a glassy polymer, occur on longer timescales than can be readily accessed with MD. Some of these processes can be studied using transition state theory with the help of molecular mechanics techniques (132). An intrinsic assumption in transition state theory is that the process of interest occurs on a much longer timescale than other processes in the system (typically those associated with random thermal motion or vibrations). In other words, the process of interest should have activation energy that is much larger than the thermal energy kT. In this approach, a reaction coordinate (a reaction path connecting the transition state with the stable configurations on either side) is first defined on the potential energy surface for the process of interest. Evaluation of the energy of interaction of, say, a diffusing molecule with the stationary polymer at grid points serves to identify energetically favorable neighborhoods where the diffusant is mechanically stable as well as the lowest energy paths that can be traversed in traveling from one neighborhood to the next. The point of highest energy on the path determines the transition state, which suffices to estimate the diffusion coefficient.

Monte Carlo. The method of MD simulations described above is a general, deterministic technique for the investigation of material properties. However, when applied to polymeric systems, MD simulations can probe only limited volume of the accessible phase space for these systems because of the long relaxation times involved. As a result of this, MD is generally restricted to relatively short timescale behavior, and is not a very efficient method for sampling configuration space. The technique of Monte Carlo (MC) simulations provides a solution to this problem; if cleverly designed, these can be used for efficiently sampling the phase space accessible to the material of interest. The disadvantage of MC is that it is not a true dynamical method, and so cannot directly provide time-dependent phenomena.

MC simulation is a stochastic simulation technique. The basis of the method lies in the evaluation of integrals by stochastic methods (2). A typical ensemble average in statistical mechanics involves a multidimensional integral over the configuration space. It is not possible to evaluate such an integral numerically by the traditional methods of numerical quadrature, but Monte Carlo methods provide an efficient approach for calculating these quantities. A typical MC simulation proceeds as follows: starting with an initial configuration of the system, the configuration is changed by applying a perturbation to the system (known as a "Monte Carlo move"). This "move" or the new configuration is then either accepted or rejected according to a probability chosen from a prescription. The key to devising an efficient MC algorithm resides in developing a prescription such that the sampling of the quantity of interest (the integrand) is concentrated in the region of phase space that makes important contributions to the integral.

The fundamental idea of the MC method was clearly described in the seminal paper by Metropolis and co-workers (93). In this method, static structures are evolved from one to another by moving one or more atoms to new locations. A move is accepted unconditionally if the new configuration, the nth, has a lower energy (E_n) than its predecessor (E_{n-1}), and is accepted with probability if $\sigma = \exp[-\beta(E_n - E_{n-1})]$ if $E_n - E_{n-1} \geq 0$. This condition is enforced by comparing the Boltzmann factor σ with a random number x lying in [0,1]. If $\sigma \leq x$ the new configuration is accepted; if it is rejected the preceding configuration is counted again before generating another move. A sequence of moves will thus generate a family of configurations that occur with probability equivalent to a canonical ensemble for the family. If information is available on the number of states of equal energy, these entropic factors are included in the acceptance criterion (133).

A well-constructed MC method is generally more efficient for equilibrating systems than is MD. However, there is no temporal causality in MC simulations, so they cannot be used directly for dynamical (transport) properties. Nonetheless, several authors map properties between MC and MD, and thereby establish an equivalent time step corresponding to an MC step (134,135). It will usually be the case that the equivalent time step will be system and property dependent, and may be different for different properties depending on the nature of the allowed moves. Furthermore, a wide variety of MC methods abounds. One of these mixes large MC steps with MD to alleviate the bad overlaps (136,137). The types of moves that one chooses, and the number of atoms to be moved in each step is arbitrary; there are no general rules that guide the choice of these parameters. MC moves are not difficult to construct and implement for simple models, for example, moving beads between neighboring 2-D lattice sites for isolated chains (138). Another example of a model allowing simple moves is the RMMC method of Honeycutt (139). Since the model that is being solved satisfies essentially the same conditions as RIS, a move in the algorithm makes a large change of a single torsion angle selected at random along the backbone of the chain. (This is a "pivot algorithm" (140), which was invented by Lal (141) for the excluded volume problem.) Even though the ends of chains swing through wide arcs when this is done, the absence of interactions between topologically remote neighbors permits a substantial acceptance of moves, so that the method is very effective in generating allowable configurations for chains *in vacuo* (or without explicit solvent). Other types of moves in torsion space have been developed (142), but the applications have been largely restricted to isolated molecule simulations. MC studies of the limited extensibility of isolated polyethylene chains have been used to infer important limitations to the enhancement of physical properties from processing (143), showing that very important conclusions can be drawn from more facile simulations than are required for a complete description of the condensed phase.

For simple fluids, eg, water, the MC moves consist of translation or rotation of individual molecules. These types of MC models are doomed to fail for a condensed phase, as the large motions almost certainly lead to unacceptably large overlap energies. For more realistic models of condensed phases, a considerable research effort may be required to determine the moves that yield an acceptable acceptance ratio (relative number of successful to unsuccessful moves). For polymer melts the moves have to be cautiously constructed, and may involve small atomic displacements (126,127,134), concerted (crankshaft) rotations (15,135,144), or cutting and

gluing (145,146), of which the so-called slithering snake moves (23,24,133,147,148) are an example.

In some of the early MC work on polymers, the move termed "reptation" (now preferably called "slithering snake" so as to avoid confusion with the de Gennes/Edward reptation concept) was widely used. A typical slithering snake move involves deleting a backbone atom (together with attached atoms) from one end of a polymeric chain and adding it to the other end of the chain. The move thus results in a serpent-like motion of the chain where the chain appears to move along its contour. Such a cut/splice move was used by Vacatello and co-workers (94) and by Boyd (23) in their MC simulations of polyethylene. The slithering snake move works well for short chains (containing up to about 20–30 carbon atoms), but for long-chain polymers it alone is inefficient in relaxing the internal parts of the chain and hence new moves need to be devised for such systems.

Continuum Configuration Bias. A major breakthrough in this regard was made by the development of the Continuum Configuration Bias (CCB) move (149–151). The CCB move consists of cutting a segment of any length from one end of a chain and regrowing it to yield a different configuration. During this regrowth process, several potential positions for each bond that is being added are considered and one of these is chosen using a prescription that favors (or biases) the lower energy configurations. The bias thus introduced in the process is removed subsequently in the probability that is used for accepting or rejecting this new configuration (or the MC move). Using such CCB moves, de Pablo and co-workers (151) simulated a system containing polyethylene chains consisting of 60 segments each. These authors showed that the simulated density–temperature behavior of this system was in reasonable agreement with the experimental data.

Monte Carlo Moves for Long-Chain Polymers. The CCB move, though efficient, also operates on one end of the chain. For systems containing very long chain polymers, the CCB move is not very efficient in relaxing the internal parts of the chain. Motivated by this, several new MC moves have been proposed in recent years for efficient relaxation of the condensed phase consisting of long-chain polymers in an MC simulation. Prominent amongst these are the "end-bridging" and the "concerted rotation" moves devised by Theodorou and co-workers (145, 152). The end-bridging move involves attaching a chain end to an internal segment of another chain by a trimer bridge, and in the process creating a new chain end on the second chain by removing a trimer segment adjacent to the newly formed bridge (145). The move thus alters the chain connectivity and leads to large jumps in the configurational space of the bulk polymer. The "concerted rotation" or the "intramolecular rebridging" moves involve selecting an internal part of the chain (consisting of five segments) and changing its internal conformation while leaving the rest of the chain unchanged (145,153). Recent work carried out by Mavrantzas and co-workers (152) has demonstrated that a combination of these moves can be used to efficiently equilibrate a polyethylene melt consisting of chains of lengths up to 500 methylene units, modeled in atomic detail, which is a feat not possible with any other MC or MD simulation. Recently, a few additional methods have been developed for enabling efficient equilibration of internal parts of the chain (and also simulation of cyclic molecules). Some examples include the "Self-Adapting Fixed-End-Point Configurational-Bias Monte Carlo" method developed by Wick

and Siepmann (154) and the "Rebridging Configurational-Bias" method developed by Chen and Escobedo (155).

Sadanobu and Goddard (156) have used a Continuous Configuration Boltzmann Biased Monte Carlo calculation of the free energy of two "independent" united atom C_{100} chains from very dilute vapor up to about 70% of physical density. While these are longer chains than are typically attainable with CCB methods, the densities of the Sadanobu and Goddard systems are generally lower.

Jorgensen and Tirado-Rives (157) have also used a united atom model for hexane to compare the rates of convergence to equilibrium of MC and MD methods. They conclude that the two methods give the same results, but that the MD is some 1.6–3.8 times slower than the MC. This result is consistent with the widespread use of MC to equilibrate polymer systems; if MC were not more efficient there would be little reason to use it. Of course, the disadvantage of MC is that dynamical processes such as diffusion cannot be evaluated without calibration relative to an absolute method such as MD. And this only for the case of "dynamical MC." For other types of MC algorithms, especially those in which cutting and splicing moves are invoked, the possibility of calibrating dynamical properties seems to be forfeited altogether.

Gibbs Ensemble Methods. The investigation of phase equilibria of polymeric systems by molecular simulation was made possible by the development of the technique of Gibbs ensemble simulation by Panagiotopoulos (158,159). In the Gibbs ensemble simulation method, the two coexisting phases are simulated simultaneously in separate simulation boxes. An *NVT* Gibbs ensemble simulation is carried out as follows: The phases in the individual boxes are equilibrated in a fashion analogous to the usual MC simulation by carrying out several types of equilibration moves (molecule translation, rotation, hybrid MC move, etc) and accepting or rejecting these according to a Metropolis criterion. In addition, mechanical equilibrium, ie, constant pressure, is maintained between the two boxes by implementing a volume swap move in which the volume of one of the boxes is changed by a certain amount accompanied by an equal and opposite change in the volume of the other box. Finally, various molecular species in the two simulation boxes are maintained at the same chemical potential by implementing a particle swap move, ie, a randomly chosen molecule is removed from one of the boxes and is inserted at a random location in the other box. Thus, the coexisting phases will be at the same temperature, pressure and all of the molecular species will have equal chemical potential in both of the boxes.

Such an *NVT* Gibbs ensemble method has become a popular tool for investigating the pure component vapor–liquid equilibrium of simple molecules and polymeric species. The technique has been used for simulating the vapor–liquid equilibria of simple gases such as nitrogen (160). The *NPT* variant of this technique has been widely used for the simulation of vapor–liquid and liquid–liquid mixture equilibria. The applications of this technique can be found in studies of the vapor–liquid mixture equilibria of methane, ethane, and carbon dioxide (161) as well as of nitrogen and butane mixtures (160).

As usual, a problem arises when the Gibbs ensemble technique is applied to a system consisting of polymeric molecules. In particular, when a chain molecule is removed from one box and an attempt is made to insert it into the other box (the "particle swap" move described above), the new configuration almost always

precipitates large interatomic overlaps, and the move will almost never get accepted. The problem can be overcome by combining Gibbs ensemble simulations with the CCB Monte Carlo method described above (162). Thus, instead of selecting a random conformation for the chain molecule being inserted in the other box, its internal conformation is chosen using the prescription given by the CCB method which favors low energy conformations, which in turn, increases the probability of acceptance of such a move. Such an approach has been widely used in the literature in recent years and has proved to be successful in predicting the phase equilibria of a wide array of low to medium molecular weight chemical species.

Histogram Reweighting. A conventional simulation yields values of various properties at the thermodynamic state at which the simulation was carried out. The technique of histogram reweighting (163,164) provides a methodology for extrapolating these results to other thermodynamic states that are in the vicinity of the state point at which the original simulation was run. In this method, the data, eg, distribution of values of various properties such as energy, obtained from a simulation are stored in histograms, and statistical mechanical relations are used to extrapolate these results to other thermodynamic states. The actual procedure involves reweighting of the stored histograms. Thus, by carrying out a selected number of simulations, thermodynamic properties over a range of state parameters can be obtained. This approach has been used by Panagiotopoulos and co-workers (165) to simulate the phase equilibria of lattice polymers and by Conrad and de Pablo (166) for simulating the phase equilibria of water. Histogram reweighting grand canonical MC simulations were used by Errington and Panagiotopoulos (167,168) for developing model parameters in their potential model for *n*-alkanes, benzene, and cyclohexane. It is to be expected that the technique of histogram reweighting, in combination with other simulation methods, will be used widely in future applications of molecular modeling to polymeric materials.

Parallel Tempering. As has been emphasized repeatedly, polymers present two problems to a molecular modeler: the long timescales associated with various relaxation processes and the algorithmic difficulties in efficiently carrying out configurational changes. Efficient sampling of the configuration space is thus always one of the main obstacles in the molecular modeling of polymeric materials. The technique of "parallel tempering" (169,170) provides a way for overcoming some of these sampling problems. In this method, several replicas of the system that do not interact with each other are simulated simultaneously by either MD or MC at different state points, eg, at different temperatures. The key step in this approach consists of an MC move where an attempt is made to swap the replicas at two different state points. Such an attempt is then either accepted or rejected using a criterion analogous to that used for accepting or rejecting a move in a conventional MC simulation. Bedrov and Smith (171) have demonstrated that parallel tempering provides a huge speedup over conventional MD simulations for the conformational relaxation of polymer melts. The reasons for this fast relaxation are twofold: each replica relaxes at a faster rate by virtue of having visited a state point where relaxation is fast (typically, a high temperature), and secondly, the calculated averages at each state point converge faster by having received contributions from several uncorrelated replicas of the system (171). Yan and de Pablo (172,173) have further extended this approach by combining the expanded

ensemble simulations with multidimensional parallel tempering, which they call "hyperparallel tempering." These authors showed that the hyperparallel tempering method provides a large speedup for the determination of the phase equilibria of very long chains modeled on a lattice (173). It is expected that these methods will also be used increasingly in the coming years for tackling problems in polymer science and engineering.

Bond Fluctuation and Other Lattice Methods. The bond fluctuation method (BFM) (174) and related lattice methods (175) have enjoyed considerable popularity because they are quite effective for equilibrating polymers. It is often the case that polymers, just as with small molecule systems, come to a state during an MD run in which the energy and volume appear to be relatively constant (within the usual fluctuations), but yet the chain configuration distribution function has not reached equilibrium. The only way to determine whether the latter condition is satisfied is to perform a sufficiently large simulation so that the population of chain configurations yields mean square values, eg, radius of gyration or end-to-end distance, that are consistent with either experimental values ("unperturbed" dimensions from neutron scattering, for example) or an RIS/RMMC calculation. The primary advantage of the BFM is that equilibration in this sense is relatively easy to achieve. However, the price that one pays for global equilibration of the chain configurations is essential loss of chemical information. As a result, the method has been primarily used for problems involving the generic physics of polymers. The several different MC techniques have been reviewed by Leontidis and co-workers (134).

A simple cubic lattice is used in BFM simulations, with statistical segments of the polymer occupying 2^d lattice sites in a d-dimensional simulation. The chains have great flexibility, in that the bonds that connect neighboring segments are allowed considerable bending and stretching freedom. However, the bond lengths are limited so as to prevent crossings. This is economically achieved by the multiple contiguous site occupancy for the elementary units of the chain and by limiting the length of bonds: Chains are prevented from crossing one another because the bonds restrict the spacings between the occupied sites so that neighboring sites cannot pass. As is usual in any lattice method, a significant fraction of unoccupied sites (approximately 50%) is required to allow movement.

The Binder group especially has treated a number of physical properties with the BFM method (4,176–178). It is not uncommon for these simulations to cover seven decades in "time," which enables one to explore slow relaxation processes such as those encountered in polymers close to the glass temperature. Here, as in all MC methods, an equivalence between MC moves and a time interval is either assumed or established by comparison with MD or experiment. Several different types of MC moves can be used with the BFM model, including both slithering snake and random hopping. Scaling laws, glass transitions, molecular diffusion, and entanglements are susceptible to investigation with the model.

Other Generic Models. The lattice methods that have been briefly considered are but one example of what we are calling "generic methods." These methods lose atomic detail through a coarse-graining procedure or ad hoc parameterization. The traditional Rouse spring-bead model is an example of this type of model. Clearly, a description of this kind is useful only to the extent that the properties one seeks to describe are generic. Thus, the Rouse model has been extremely

useful in understanding the universal aspects of the dilute solution viscoelastic behavior of flexible polymers (179).

Another model of wide applicability is the Ising lattice model. The RIS theory is an Ising model in one dimension; the model has been applied to other types of problems in spaces of two and higher dimensions. A recent 2-D model was developed to gain an understanding of the distribution of surfactant molecules in immiscible fluid systems (180).

One of the most successful recent applications of a generic model to a complex polymer problem is in the area of the microphase separation behavior of block copolymers. A highly successful self-consistent field theory describing the equilibrium phases and phase diagram of diblock copolymers was devised by Matsen and Schick (181), and this was extended to ABA triblocks by Matsen (182). Drolet and Fredrickson (183,184) have devised a modeling method to generate phase-separated patterns from a self-consistent field theory that does not require the assumption of a space group as required in the Matsen–Schick method. While the published work (183,184) reports two-dimensional (2-D) simulations only, the method shows promise of being very powerful in designing block copolymer architectures.

Many mean field or self-consistent field theories that use the computer for evaluation of functions fall outside our definition of modeling. The Drolet–Fredrickson method is at the borderline of our definition of a simulation method: it qualifies as a modeling method because it uses a random starting point based on underlying coupled fields (playing the role of concatenated particles) and evolves into a regular structure whose pattern may (conceivably) depend on the initial stucture in a way that cannot be anticipated from the initial data of the problem. Having said that, a dynamics method is required for these systems if one wants to study the time-evolution of the structures from, say, the homogeneous melt to the phase separated state.

Mesoscopic methods that link together a dynamical method, such as Langevin or Brownian dynamics, with the mean-field description of the free energy have been developed for this purpose. The sizes of the domains that are formed in microphase-separated block copolymers are comparable to the lengths of the homopolymer blocks, which implies that any finer detail than is contained in a coarse-grained or mean-field model will be computationally impossible if an attempt is made to model more than a few separate domains. A desire for detail notwithstanding, if the domains are amorphous, a description of their properties at the level of a coarse-grained model is sufficient with respect to the phase separation problem. Techniques that operate at this level of description include MesoDyn (185–187), Langevin methods (188–190), dissipative particle dynamics (DPD) (191–194), and a variety of coarse-grained MD and lattice methods (20, 144,148,195–197). The power of these methods resides in their ability to handle length and timescales that are appropriate to the problems that they are designed to address. In making this observation, it should also be clear that coarse-grained models will not necessarily yield all thermodynamic and/or transport properties with equal fidelity (198). The same is true of atomistic force fields, which reaffirms the wisdom of checking the results of any modeling study with many different properties if accuracy of quantitative predictions is an issue. General approaches to multiple length and timescale problems have been reviewed (199).

The study of the block copolymer morphologies has been intense, and highly sophisticated models have been developed to describe their large-scale structure. In particular, domain distortions have been treated with higher order Ginzburg–Landau models (200). Furthermore, MesoDyn (186) and DPD (192,201) can be used to study these systems under shear flows; different morphologies have very different viscosities, and can be interconverted under shear. The development of structure in block copolymer systems is paralleled by phase separation in binary mixtures with chemical reactions (202), which exemplifies the universality of phase ordering. However, the reacting systems apparently do not order to the extent that polymeric systems do.

A problem area that is not so amenable to mesoscale methods is polymer crystallization. This has proven to be one of the most difficult computational challenges in all of polymer science because the pertinent phenomena operate simultaneously over a wide range of length scales. The polymer crystallizes into a particular space group because of atomic detail, and the mechanical properties of the crystallites are determined by, and can only be calculated reliably with, atomic force fields with all atoms represented (126,127). Yet the size of the crystallites or spherulites is so large as to require mesoscopic methods for comprehension. But a crystalline polymer is almost never 100% crystalline. The interphases between crystalline and amorphous domains, with the possibilities for adjacent or nonadjacent reentry and tie-chain distributions, are critical to the properties of semicrystalline polymers. Only recently have models been developed (203) to rigorously address this problem area.

The crystallization of isolated polyethylene chains was first reported by Kavassalis and Sundararajan (204) using MD with the Nosé–Hoover thermostat. More recently, single polyethylene chains driven by Langevin dynamics have been used by Muthukumar and co-workers (205,206) to model the early stages of nucleation and growth of crystals in solution. But even simpler models of chains will form ordered domains, and hence they have been explored as a means to understand some of the aspects of crystallization (122,138). A lattice model has been used in conjunction with an MC technique to model crystallization in short polyethylene-like chains (207). The crystallite–amorphous interface is found to be rough, and to have a relatively low concentration of regular folds for even this lattice model.

An interesting block stacking algorithm based on the Sadler–Gilmer model of crystallization was developed by Goldbeck-Wood (208,209), with a variation on the algorithm being described by Doye and Frenkel (210,211). One starts with a uniform wall of blocks from which blocks are removed and restacked one at a time by kinetic MC moves with free energy terms that are determined by the number of contacts with neighbors. Chain connectivity is emulated by restricting the location of movable blocks to terminal stems or to "sliding diffusion" (209) in the interior of the crystallite model. Good agreement with experiment is claimed for a number of polymers (208).

The aggregation of polymers and surfactants has been studied with DPD (212). This algorithm provides an alternative to Langevin or Brownian dynamics, and can even be used with Widom insertion (212). The ad hoc potential that is used in DPD is not unlike a soft ellipsoidal model for polymer molecules (213,214), which suggests that DPD could be extended to polymer melts. Along these lines a

"blob" model that incorporates an algorithm to check for and manipulate uncrossability has been developed very recently (215). It is shown that the incorporation of entanglements by means of the algorithm has a significant effect on the dynamics of the system.

A method that has some similarity to DPD has been developed by Yuan and Doi (216). While restricted to two dimensions in the published work, the extension to three dimensions should be relatively straightforward if computationally demanding. They model a two-phase viscous fluid by means of a Voronoi tesselation, with discretized versions of continuum hydrodynamics serving as the equations of motion that motivate the centers and vertices of the tesselation polygons. Simulations under shear show that the dispersed phase elongates under flow, with the deformation of droplet size equilibrating at strains (not strain rates) of between 5 and 10. A refinement of this model was presented by Okuzono and co-workers (217), in which the continuum hydrodynamic equations are augmented with a Cahn–Hilliard theory for the interfacial structure. Two-dimensional simulations showed the coalescence and break-up of droplets. These simulations have not been extended to polymeric fluids, except insofar as they can be modeled as high viscosity Newtonian fluids.

Orientational orderings of liquid crystal domains, including dislocations and grain boundaries, are most often modeled on a lattice where a simple potential depending only on the mutual orientations of site vectors (218,219) is needed to generate interesting structures.

Theories for polymer networks have their basis in treatments of gelation and rubber elasticity (220). Cross-linked systems can be investigated with coarse-grained and atomistic MD methods (221–225). However, these methods cannot capture the effects of long-range connectivity, which are better analyzed with very coarse-grained MC methods (226–234). There are theoretical methods that compete with simulations (235–237), but these methods are usually not concerned with spatial correlations to the same extent as simulation methods. The Grest–Kremer group (225) has devoted considerable effort to understanding the role of entanglements, constraints, and cross-links on the mechanical properties of model elastomers. In these simulations, FENE chains interacting with a purely repulsive potential were subjected to step strains, following which the stress relaxation was monitored. The results were analyzed with theory to separate the entanglement and cross-link contributions to the stress. An even coarser ad hoc model was used by Masubuchi and co-workers (238) to model reptation in an entangled melt. Mechanical models of elastomers are also subject to investigations with modeling (239). The review by Burkhart (240) contains an extensive survey of modeling results on rubbery polymers.

A dynamical cross-linking simulation using the bond fluctuation model has been developed by Gilra and co-workers (241,242). They find a strong dependence of network properties on equilibration times, leading them to conclude that a 20% excess of cross-linker results in optimum properties. This conclusion is different from the assertion that balanced stoichiometry yields the best networks, as obtained both with statistical methods as well as the static MC method (226). As the authors point out, this may reflect slow relaxation of network systems beyond the gel point. The more "perfect" the network, the slower it will appear to relax because there are fewer fast-moving defect structures.

Group Additivity Methods. It is frequently desirable to rapidly explore or estimate the properties of materials in advance of more elaborate experimental or modeling studies. Group additivity, or QSPR (quantitative structure property relation), methods are widely used for this purpose. The standard reference for this material is the book of van Krevelen (243), which makes use of common atomic groups, eg, esters, aldehydes, methylenes, etc, and tabulated properties assigned to each. A related treatment is the "group interaction model" of Porter (244). The comprehensive method advocated by Bicerano (245) utilizes connectivity indices (derived from graph theoretical concepts) rather than atomic groups to encode structural information. The advantage of this method is that predictions can be made for molecules having novel structures that have not been synthesized, making it particularly useful for estimating the properties of polymers falling outside the norm.

More recent extensions of QSPR methods to more complex phenomena, such as the viscosity of dispersions (246) or diffusion of gases through polymers (247), have been developed. These works should be consulted for more penetrating bibliographies of literature in this field.

Applications

Modeling in the Service of Theory. There are many examples of recent "analytical" theories that have been developed, tested, or validated with MD or MC simulations. If simulations are used to validate theory, one might ask why make theories at all? The reasons are that (*1*) a good theory implies a level of understanding of the problem that the scientist or engineer aspires to, (*2*) evaluation of a theoretical equation, even if done with a computer, usually gives answers faster than a simulation, but most importantly (*3*) there are length and timescale problems that cannot be reached with straightforward MD or MC, and which require fresh theoretical approaches for their solution. The use of simulations to test and develop theories is especially helpful in those cases where the theory is difficult to compare with experiment or when the theory requires mathematical approximations whose validity is difficult to assess by other methods.

Baschnagel and co-workers (176,248) have emphasized this aspect of modeling in their study of the Gibbs–Di Marzio (249,250) and other theories of the glass transition. Simulations led to the resolution of the negative entropy anomaly in this theory by showing that a higher order approximation to the configurational entropy of the chains is needed.

Theories of the excluded volume expansion factor for polymers have a long history, and as discussed elsewhere, this problem led to some of the earliest applications of computer models to polymers. More recently, Krishnaswamy and Fixman have used simulations to verify a theoretical treatment of the expansion factor for polyelectrolytes (251).

The structure of a diblock copolymer confined between surfaces has important consequences for the properties of filled block copolymer systems. Because filled polymers are very complex heterogeneous materials (perhaps anisotropic as well), it is desirable to have a theoretical description of the properties of the

separate phases to put into higher level theories. The behavior of the polymer in this kind of environment is difficult to determine by experiment, but is quite amenable to lattice simulations (252–254) which are used to validate both density functional theories as well as simpler phenomenological theories.

Polymer miscibility—with solvents, other polymers, or in block copolymers—can be treated with integral equation methods such as PRISM (255–257) or density functional theory (252,258). Theories of this kind inevitably required approximations that are difficult to assess by independent methods, with the variety of closure relations having been developed in integral equation theories (259) illustrating the case in point. Molecular modeling can provide the detailed molecular-level information, such as pair correlation functions, that is needed to assess the validity of these types of theories (260,261).

A MC study (262) of two different types of relatively short chains on a lattice, with solvent molecules represented as vacancies, was used to explore phase separation of the UCST type; the conclusion was that the Freed–Dudowicz lattice theory (263,264) gives good agreement with simulations. A similar lattice model was used to investigate the behavior of chains tethered to a surface, with the MC results being compared with numerical self-consistent field theory (135). The essential identity of density profiles obtained by the two methods was taken to validate the self-consistent field theory.

The role of positional fluctuations in polymer networks is central to some theories of elasticity, and has been investigated with an MC method based on a modified bond-fluctuation model (265). The simple model used in the simulations gave results close to those calculated from theory for a Bethe lattice (also known as a Cayley tree). More extensive results bearing on the role of fluctuations in polymer networks have been reported by Grest and co-workers (225). They find that entanglements limit fluctuations, giving behavior similar to the description provided by the tube model.

Filled Polymers. Filled polymers are difficult to model directly for much the same reasons as semicrystalline polymers. The behavior of these systems develops over a wide range of length scales, which generally requires the modeler to select a scale that is believed to be the most appropriate for the phenomena of interest, and this scale determines the nature of the model. The influence of filler particles on chain configuration statistics has an impact on rubber elasticity, and so an MC calculation with the RIS model is appropriate for these investigations (266). Some MD work with a model of large spherical particles together with 1,4-*cis*-polybutadiene has been reported (267), but the simulations were done without periodic boundary conditions, resulting in the collapse of the chains.

Nanoscopic particles, dispersed in a block copolymer, have dimensions that are appropriate for Brownian dynamics simulations (268). Clay composites have a range of length scales, but if the gallery spacing between the layers is not large, MD methods can be used (269) with periodicity in the directions parallel to the clay platelets. However, continuum mechanical models need to be invoked for the description of exfoliated clay systems (270). These materials have so much interfacial area that adhesion properties are very important (271). Traditional continuum bounds methods (130) usually ignore the interphases on the grounds that they comprise a very small volume fraction of the total material, and so are not expected to be very accurate for exfoliated clay systems.

In the work of Wang and Teraoka (272), a lattice model was used to determine the partitioning of chains between bulk solution and a confined slit. They found that a "blob" description fit the simulation data well as the concentration of chains in the slit increased. For dilute chains, the end-to-end distance is the right correlation length to use in determining the partitioning of chains into a slit, but as the concentration increases the interaction between backbone segments is screened, and the configurational entropy becomes sensitive to more localized length scales. Block copolymer morphology in confined geometries was investigated by Wang and co-workers (273).

Fiber-reinforced systems have been modeled with use of an MC method to place parallel fibers into a polymer matrix, with a finite element algorithm (FEA) then being used to compute elastic properties (274). A generic meshing algorithm for use in FEA studies of nanoparticle reinforcement of polymers has been developed (275) and applied to the calculation of mechanical properties of whisker and platelet filled systems. The method should be applicable to void-containing low dielectric materials of such great utility in the semiconductor industry.

Disordered systems of rods have also been modeled with MC (276), and the Onsager–Flory transition to an anisotropic phase was observed. Chain configurations and surface energies of individual polymeric nanofibers have been investigated with Mattice's 2nnd lattice method (277). In short, methods exist to treat, say, cord-reinforced tires from atoms up to FEA on the whole tire.

An exception to difficult-to-model filled systems is provided by the norbornene-POSS polymers studied by Bharadwaj and co-workers (278). POSS is polyhedral oligomeric silsequioxane—groups that are pendant from the poly(norbornene) chains of the model. This can be viewed as a filled system, but one in which the filler is nanoscopic and chemically bonded to the chains. The simulations were done to determine T_g, density, thermal expansion, solubility parameter, POSS mobilities, and elastic moduli in a wide-ranging study. They conclude that the "ponderous nature of the POSS moieties" is largely responsible for the reinforcing effect.

Chemical Reactivity. An adequate coverage of molecular modeling applied to the chemical reactivity of polymers, which includes polymerization, chemical modification, and degradation (qv), could only be achieved in a separate article. For present purposes, it suffices to recommend a few recent studies that will provide gateways to the larger literature on these important topics. This excursion will not lead us to stray from molecular modeling for very long, because a thorough treatment of chemical reactivity requires primary attention to QM methods, and that would indeed divert us.

Zirconocene catalysts provide an unprecedented level of control over polyolefin structure, and this suffices to generate a high level of commercial interest in the substances. The structural variation within this group of catalysts is very wide, which has made them an attractive target for modeling. From the early work of Castonguay and Rappé (279) to more recent studies (280,281) the mechanism for the stereochemical control of the reaction has been thoroughly investigated with quantum chemical methods. Complementary theoretical work to determine rates of polymerization with use of transition state theory has also been presented (282). Zeigler–Natta catalysts also continue to be of interest (283).

One important class of modification reactions on polymers is those that induce cross-linking. Studies of the kinetics of end-linking reactions with a generic polymer model using proximity bonding have been conducted by Grest and co-workers (284) with the aim of relating stoichiometry to the relative rates of formation of network defects. A proximity bonding algorithm was also exploited by Doherty and co-workers (285) to study the structure of methacrylate networks. Jones and co-workers (286) have investigated cross-linking reactions, but with a greater emphasis on an atomistic understanding of radical stability and bonding probabilities for various groups. An interesting study of the technologically important imidization reaction of polyamic acids that combined quantum chemical calculations with MD was carried out by Young and co-workers (287). The further development of a general-purpose reactive force field, such as that initiated by Rappé and co-workers (87), would be a welcome addition to studies in these important areas of polymer science and engineering.

Information at the atomistic level of detail is required to understand the mechanisms of degradation of polymers. The work of Nyden (89,90) on thermal degradation aims at this level of detail. Statistical models, using more abstract representations of elementary reactions, have also been developed (288). In general, relatively little attention has been given to degradation reactions—they are difficult to study because they are slow and often nonspecific, requiring open-ended exploration of possibilities. At the very least, methods to sort through a manifold of potential reactions and identify the most probable under a given set of conditions would be a boon. Work in this direction for surface, catalyzed reactions (289) is well advanced.

Bond-Fluctuation Model Results. The BFM model has been applied to 2-D single-chain thermodynamics, appropriate for the description of strongly adsorbed polymer on a surface (19). Here it is claimed that formation of a 2-D glass depends on the choice of bond vectors. This is reminiscent of a phenomenon seen in the collapse transition of a single short chain (290), where fine details of the model cause "freezing out" of geometrical isomers. Perhaps these differences in the "effective" models are a reflection of the subtleties of molecular motions that determine the onset of the glass transition.

The disadvantage of the BFM is that very little chemical detail can be invested in it. Having extracted all the information that can be gleaned from a BFM simulation, there is nothing to be gained from its repetition. Other lattice methods promise more in this regard, one of which is the mapping/reverse mapping protocol of Mattice (106,107,175). Here a chemically detailed model is mapped onto a "2nnd" lattice formed by omitting every second site from a diamond lattice. Chains with relatively simple backbones can be coarse-grained and placed on this lattice with fidelity, meaning that the RIS-generated configurations of both the atomistic chain and the lattice chain can be made to coincide. Even when applied at physical densities, the coarse-grained lattice is only sparsely occupied, which facilitates the single-bead moves that are used to evolve the system. Finally, the atomistic chain can be recovered by reversing the mapping, thus allowing MD simulations to be run on the equilibrated systems to recover properties that depend on both global structure and local atomic detail. A similar lattice is used by Pakula and co-workers (291) in their cooperative motion algorithm. This algorithm has been used to simulate quite complex structures, including catenanes.

Isolated Chains and Chain Collapse. The RIS model continues to be of considerable utility in modeling, both because single-chain behavior is of interest for a number of applications, and because the unperturbed chain dimensions that one computes with RIS are needed to assess the approach to equilibrium in condensed phase simulations. It is therefore important to appreciate some of the underlying physics of RIS theory.

A practical measure of the difference between RIS weights, which are properly viewed as Boltzmann factors for potentials of mean force (PMF), and explicit potentials is contained in the work of Smith and co-workers (292). They reproduce local torsional populations obtained from direct MD of poly(ethylene oxide) chains in water by means of a standard RIS model (which can be described as a single gas-phase phantom chain) by adjustment of the RIS weights. Their results indicate that the PMFs are highly dependent on composition for some bonds and not for others, thus indicating subtleties in the influence of environment on the apparent potentials. This example shows why it is necessary to parameterize an RIS model with real data; we are still far from being able to quantify the perturbation of intramolecular potentials by neighboring molecules. However, MD simulation in the condensed phase gives these effects directly without additional effort, provided one can equilibrate the chain configurations (which is all-important for the attempted analysis) in a reasonable amount of computer time.

Isolated chain RIS calculations have been used to interpret the high strain behavior of elastomer (293), and they are reported to resolve discrepancies between Gaussian chain statistics and experiment stress-optical coefficients (294) for PE networks. RIS chains show larger correlations between bond vectors and the principal strain axis than do random Gaussian chains. Results such as this suggest that isolated chain simulations still have a role to play in the analysis of polymer properties, even though they do not convey the complexity of intermolecular interactions that are revealed condensed phase simulations, as mentioned above. In cases where rapid and comprehensive averages over configurations are desirable, and when care is taken in interpreting the results, single-chain vacuum calculations are appropriate.

Another example of single-chain dynamics is contained in the work of Srinivas and co-workers (295) who used Brownian dynamics with a spring-bead model to investigate the rate of collapse of a linear chain to a compact globular configuration. Their particular interest was in using simulations to gain an understanding of appropriate rate constants for Forster energy transfer between dye molecule donors and acceptors attached to linear chains. Dye-modified polymers are of considerable interest for experimentally probing configuration statistics and conformational transitions.

A clever method to equilibrate a model of a collapsed chain has been advocated by Paul and Müller (296). They allow the chain segments of their BFM to move in four dimensions. Any configuration in which all "atoms" of the model lie on a single three-dimensional (3-D) plane constitutes an allowable configuration of the 3-D system. As the authors describe, this is akin to allowing adsorption–desorption moves in the equilibration of molecules on a 2-D surface. The only disadvantage of an algorithm such as this is that it is restricted to simplified models, such as lattice models, for otherwise one gets involved in very

difficult questions as to the meaning of, say, quantum-derived force fields for four-dimensional space.

Interfaces. The study of polymer interfaces, including models of surface-adsorbed or bonded molecules, is of interest in problems of barrier diffusion, coatings (qv), adhesion (qv), and patterning. MC methods, both on-lattice (107,144,297,298) and off-lattice (299–301), have been utilized for these applications. Mattice and co-workers (106,302) have used the 2nnd lattice to study diffusion of centers of mass of C_{44} and C_{100} alkanes. They have also shown that chain ends will migrate to the surface of a free-standing film if the end group interaction with the mid-chain segments is not favorable. This suggests that there may be situations involving the adhesion of two polymer surfaces in which the properties of one or more of the surfaces has unanticipated properties owing to the segregation of minority constituents. Similar results have been obtained for free space simulations using both explicit atom and united atom models of C_{13} by Chang and co-workers (303).

Torres and co-workers (304) studied the dependence of T_g on film thickness, and found both increases and decreases in the apparent T_g of thin films, depending on whether the film is free or deposited on an attractive substrate. Kranbuehl and co-workers (305) found that T_g decreases with confinement by noninteracting surfaces consisting of planes (one dimensional, 1-D), tubes (2-D), and spheres (3-D). Perhaps the surface-to volume ratio, and the influence of free volume at the constraint surface, creates additional freedom of motion for the chains in these types of confinement. Consistent with this view is the observation that when chains are attracted to a surface, and thereby immobilized, the T_g increases (304). Similar conclusions were reached by Aoyagi and co-workers (306) in a spring-bead model simulation of confined chains.

The adsorption of FENE-model chains on a structureless surface was studied by Milchev and Binder (307). The energetics was such that the polymer segments preferred to interact with themselves rather than with the surface, resulting in polymer droplet formation. By careful analysis of the fluctuations in the position of the free surface of the droplets, the authors were able to evaluate the polymer–vacuum interfacial tension. It would be of considerable interest to extend this method to more accurate force field descriptions of a variety of polymers.

Diffusion. Diffusion processes in polymers have been extensively studied by simulation since about 1990. Not only is diffusion one of the more accessible transport properties to compute, it is also a property of considerable practical importance for barrier polymers and separation membranes.

Statistical mechanics provides two routes for evaluating diffusion coefficients using MD. The first approach involves monitoring the mean-squared displacement $\langle r^2 \rangle$ of the diffusing species as a function of time. More precisely stated, the Einstein relation

$$D = \lim_{t \to \infty} \left\langle (\mathrm{r}_t - \mathrm{r}_0)^2 \right\rangle / 6t \tag{7}$$

holds in the diffusive regime. Here $\mathbf{r}_t$ is the position of the diffusing particle at time t, and D is the diffusion coefficient. The angle brackets denote an average over an ensemble of systems. If the slope of a plot of $\langle r^2 \rangle = \langle (\mathbf{r}_t - \mathbf{r}_0)^2 \rangle$ with time is constant, the Einstein formula gives the diffusion coefficient of interest.

The second approach consists of monitoring the velocity autocorrelation function of the diffusing species and then using the Green–Kubo formula to evaluate the diffusion coefficient (259). This method is not as direct as monitoring the displacement directly. Furthermore, it is generally observed that correlation function methods are subject to uncertainty arising from statistical noise and slow convergence. Because of this, almost all of the MD simulation studies of penetrant diffusion in polymers have calculated diffusion coefficients by the evaluation of $\langle r^2 \rangle$ for the diffusing species.

As we have seen, computational resources currently available enable routine MD simulations of amorphous polymers to be carried out up to times of the order of a few nanoseconds. This short timescale places restrictions on the properties of polymeric materials that can be studied using direct MD simulation. The process of diffusion of small penetrants (eg, gases such as oxygen, nitrogen, methane etc) in amorphous polymers above T_g frequently has timescales shorter than the simulation timescales and is amenable to investigation by molecular dynamics simulation. Slower diffusion, as occurs in glasses, requires techniques such as transition state theory. A review of the simulation of diffusion in polymers using the methods of molecular dynamics and Transition State Theory (described in the section on molecular mechanics) has been presented by Gusev and co-workers (308).

Most of the simulations of diffusion in amorphous polymers have been carried out with systems containing up to several hundred heavy (nonhydrogen) atoms which translates to systems containing a few hundred monomer units for the hydrocarbon polymers typically studied. When the mean-squared displacement of the penetrant is monitored as a function of time for these systems, three distinct regimes can be identified. These are the initial, short-time ballistic regime, followed by a regime (referred to as anomalous diffusion) in which $\langle r^2 \rangle$ is proportional to t^n where $n < 1$. Finally, at long times, a regime of "true" diffusion can be identified where $\langle r^2 \rangle$ is proportional to t. Furthermore, it is observed that for most systems, the onset of the "true" diffusion regime is found to occur when $\langle r^2 \rangle$ is roughly equal to the square of the simulation box length. These observations motivated Cuthbert and co-workers (309) to investigate the system size dependence of the diffusion coefficient calculated by molecular simulations. Diffusivities of gases (of different sizes corresponding to helium, argon, and carbon dioxide) in amorphous polypropylene structures containing 125, 729, and 2197 monomers each were calculated in this work using MD simulation. The main conclusion of the study was that for the simulation system sizes investigated, the calculated diffusion coefficients were independent of the system size. This observation was rationalized based on the dynamics of the polymer matrix. It was shown that in the time required for the penetrant molecule to travel a distance corresponding to the box dimension, which is approximately the time required for the $\langle r^2 \rangle$ vs. time plot to show "true" diffusive behavior, the polymer matrix itself undergoes structural changes significant enough such that the local environment in the current position of the penetrant is quite different from what it was when the penetrant was in the vicinity of the periodic image of the current location.

The early MD simulations of penetrant diffusion in polymers focussed on diffusion of simple gases, eg, oxygen, through polyethylene-like polymers (24,310–316). These early studies showed that the simulated values of diffusion coefficients

were about an order of magnitude higher than the corresponding experimental values. Rather than achieving a quantitative prediction of the diffusion coefficients, the focus of these studies was on the investigation of the mechanism of diffusion and the effects of a number of factors such as the chain length (312) and free volume distribution (313).

The early work of Trohalaki and co-workers (317) on the diffusion of CO_2 in PE showed that both chain segment and gas molecule diffusion could be followed, and the activation energy for diffusion determined. Similar studies were conducted by Boyd and Pant on united atom models of PE and polyisobutylene (PIB) (24,131). They showed that the too-rapid diffusion predicted by the earlier simulations was a result of unsatisfactory force field parameters. Most importantly, they showed that the polymer density is the critical factor in determining the diffusion coefficient of small molecules. They found that the activation energy for diffusion of methane through PIB is about 20% larger than is that for PE over the temperature range from 250 to 600 K. In addition to PE and PIB, Boyd and co-workers have also studied the diffusion coefficients of methane in amorphous atactic polypropylene (318) and atactic polystyrene (319) using MD. The work was later extended to polyesters (79) at high temperatures (from ca. 425 to 625 K) by Bharadwaj and Boyd, who provide a good discussion of the cage effect and its disappearance with increasing temperature. Thus, free volume plays a very important role in diffusion, even though the diffusion process appears to have an Arrhenius temperature dependence. Much the same conclusion was reached by von Meerwall and co-workers (320,321) in an experimental study of alkane diffusion.

MD study of diffusion of simple gases (hydrogen, oxygen and methane) in amorphous polypropylene carried out by Müller-Plathe (322) also confirmed the hopping motion to be the primary mechanism of penetrant diffusion. However, the simulated diffusivities were found to be about an order of magnitude higher than the experimental values, in accord with other studies reported at the time. Later work carried out by Müller-Plathe and co-workers (323) also demonstrated (as was found by Pant and Boyd) that the over-prediction of the experimental diffusion coefficients by simulations was a result of the united atom force field used in the earlier simulations. Using an all-atom force field, these authors showed that the diffusivity of oxygen in polyisobutylene can be predicted to within a factor 2 using MD simulation. In a subsequent contribution (324) these authors investigated the diffusion coefficients of three gases (helium, hydrogen, and oxygen) in amorphous PIB using an all-atom force field. In this work, both equilibrium and nonequilibrium MD simulation methods were used for the purposes of evaluating the diffusion coefficient. The diffusivities calculated using the equilibrium MD simulations by monitoring the mean-squared displacements and using the Einstein relation were found to be larger than the experimental values by factors of 2–5. The diffusion coefficients obtained by nonequilibrium MD (where a constant external force was imposed on each of the penetrant molecules to encourage diffusion) were found to be even larger than the equilibrium MD values by a factor of about 2. The study concluded that there was little advantage in using nonequilibrium MD, as implemented in that work, instead of usual equilibrium MD for the evaluation of the diffusion coefficients.

Although most of the penetrant diffusion studies in polymers have been carried out on hydrocarbon polymers (polyethylene, polypropylene, and

polyisobutylene), diffusion of penetrants in polydimethylsiloxane (PDMS) has also received some attention in the literature. In an early investigation carried out by Sok and co-workers (325), diffusion of helium and methane in PDMS was studied using MD. Diffusion was found to occur by the mechanism of hopping between the holes, with the calculated diffusion coefficient of helium being about twice the experimental value. The calculated diffusion coefficient of methane showed excellent agreement with the experimental value. Tamai and co-workers (326) also reported an investigation of diffusion of methane, water, and ethanol in PDMS using MD. The calculated diffusion coefficient was smaller than the experimental value by a factor of about 4. [These authors showed that if the diffusivity was calculated based on a short MD run as was the case in the work reported by Sok and co-workers (325), the value so obtained, though derived from the anomalous diffusion regime, showed very good agreement with the experimental data.] Both water and ethanol were shown to form aggregates in the polymer matrix, which lowered the diffusivity by a factor of 50 compared with the values calculated in the absence of aggregation (by using only one penetrant molecule in the system). The calculated diffusivity under nonaggregating conditions was shown to agree quite well with the experimental data that was obtained in the presence of penetrant clusters. This observation led the authors to hypothesize that when a large amount of penetrant is used in the experiments, the penetrant first clusters in available holes in the polymer matrix and remains virtually immobile there, while the remaining molecules diffuse through the matrix as nonaggregated, isolated molecules.

Diffusion coefficients of a variety of penetrants (such as methane, methanol, ethanol, benzaldehyde, acetophenone, benzoic acid, fluocinolone acetonide, etc) in PE, PDMS, poly(methyl methacrylate-*co*-hydroxyethyl methacrylate), and ethyl and benzyl esters of hyaluronic acid were calculated by Li and co-workers (327) using molecular dynamics. The main conclusions of their study were that the values of the diffusion coefficient predicted by the simulations showed reasonable agreement with the experimental data for systems containing hydrophobic penetrants and hydrophobic polymers. However, these numbers showed large disagreement when either the penetrant or the polymer was hydrophilic. This might be ascribed to force field inadequacies. The diffusion of both O_2 and H_2O in aqueous solutions of polyvinylpyrrolidinone at a variety of concentrations was studied by Eichinger and co-workers (328).

Because of the long timescales associated with the diffusion of medium to large molecular weight species (molecular weight > 100) in amorphous polymers, investigations of diffusion of these molecules in polymers are scarce. An investigation of the diffusion of benzene molecules in a benzene–polystyrene system containing up to 84 wt% polystyrene was presented by Müller-Plathe (329). The problem of slower diffusion of these larger molecules (compared with the timescales of typical MD simulations) can be alleviated to some extent by carrying out the simulations at relatively high temperatures (higher than 450 K). Such an approach was used by Nath and co-workers (330) in their study of diffusion of hindered amine light stabilizer molecules in amorphous polyethylene. By fitting their high temperature diffusion data with the Williams–Landel–Ferry (WLF) equation (331), they showed that their simulation results were consistent with experimental data obtained at a lower temperature. Hahn and co-workers (332) investigated diffusion

of phenol in bisphenol-A–polycarbonate at temperatures in the range 500 to 640 K. These authors found that the diffusion coefficient showed Arrhenius behavior with the mechanism changing from a hopping diffusion at lower temperatures to continuous diffusion at higher temperatures.

The diffusion of polymer chains across an interface, as will occur in the welding of polymers, has been investigated by a variety of techniques as discussed above (see Ref. 333, for example). Jang and Mattice (334) have used the mapping/reverse-mapping technique with the dynamics being driven by the "dynamic MC" method executed on the 2nnd lattice to study the healing of an interface between films of melt PE (actually $C_{99}H_{200}$). They find three regimes following initial contact of relaxed films: (*1*) density repair at the interface, (*2*) redistribution of chain ends, and (*3*) intermixing of molecules from the two sides. The chain end redistribution is an interesting aspect of this simulation. It occurs because the initial polymer–vacuum interfaces are relatively rich in chain ends, as noted above. During equilibration, the ends will diffuse to locations that eliminate this initial bias. It is not clear that this is describable as reptation.

Although most of the work on diffusion through polymers has focussed on diffusion through amorphous polymer structures containing linear chains, some studies of diffusion in other types of polymer matrices have also appeared in the literature. An example is an investigation of gas diffusion through polymer networks reported by Sonnenburg and co-workers (335). These authors employed an idealized model of the polymer network made up of freely jointed chains joined with each other by tetravalent junctions and whose beads interacted with each other by a purely repulsive Lennard–Jones potential. The dependence of the diffusion coefficient of a simple penetrant on the temperature, the network packing fraction, and on the penetrant size was determined in this MD work.

The process of penetrant diffusion in rubbery and glassy polymers can be studied using the transition state theory. Initial attempts in this direction were made by Suter and co-workers (132,336). In the first instance (132), the motion of the penetrant molecules was considered to be completely uncoupled from that of the atoms of the polymer matrix. Values of diffusion coefficient thus calculated showed reasonable agreement with experiment only for the smallest penetrant (He) studied, while for all other penetrants considered (H_2, Ar, O_2, and N_2), the calculated diffusivity values were at least 3–4 orders of magnitude lower than the experimental values. In subsequent work (336), the approach was improved by assuming that the penetrant motion is coupled with the thermal or vibrational motion of the polymer atoms (but not with structural relaxations of the polymer). The thermal motion of the polymer matrix was accounted for by using a "smearing parameter" which could be calculated based on displacements of the host atoms evaluated from a MD simulation. The values of diffusion coefficients calculated for penetrants of various sizes such as Ar, N_2, O_2, H_2, and He agreed within an order of magnitude with the experimental data for diffusion in both rubbery and glassy polymers.

This approach proposed by Gusev and Suter (336) was further improved upon by Theodorou and co-workers (337,338), who explicitly accounted for the motion of the polymer atoms during the penetrant diffusion process. In this work, a geometric analysis of the glassy polypropylene structures was first carried out to obtain initial estimates of the local minima where penetrant molecules will

reside most of the time; transition states for the motion of the penetrant molecules between adjacent minima were also located. These guesses for transition states were then refined using a rigorous calculation on a multidimensional potential energy surface of the system. In addition to the penetrant molecule, the atoms of the polymer matrix in the vicinity of the penetrant were also considered to be mobile (or considered to constitute "flexible" degrees of freedom in the transition state formalism) in this procedure. It was found that in all about 350 atoms of the glassy polypropylene matrix moved cooperatively with the diffusing methane molecule. Such explicit incorporation of polymer degrees of freedom during the calculation led to much lower, and more realistic, energy barriers for the transition state than those found in the work of Gusev and Suter described above. Once the transition state was located, the reaction path connecting it with the local minima on either side was determined. Finally, a harmonic approximation to the potential energy surface at the minima and transition state was used to calculate the rate constant for the transition of the penetrant molecule from one energy minimum to another by means of the standard transition state theory formula.

Gray-Weale and co-workers (339) used the geometric data collected by Greenfield and Theodorou (337) to develop a somewhat approximate treatment of the diffusion in polymers in the spirit of transition state theory. In that work, rather than considering the motion of the penetrant molecule in a sea of polymer atoms, the polymer matrix was treated as a continuum. The activation energy for the transition state was then calculated by considering the energy required for deforming the polymer matrix to open up the channels for penetrant motion from one minimum to another. The predictions of this model were in semiquantitative agreement with experimental data.

Diffusion of O_2 through a thin film of PE was simulated by the Doi group (340) using a single configuration of 60 PE molecules of 100 united atoms. The Rigby-Roe potential for PE induced crystalline order at 300 K, which melted out at 500 K. The trajectories of individual O_2 molecules were followed in the simulation, which enabled the authors to conclude that the apparent increase in O_2 concentration as the temperature was lowered to 180 K was due to surface adsorption. (The obvious warning is that when performing simulations on small systems, do not be misled by a large surface-to-volume ratio.) By simulating the surface directly, the authors were able to follow all events of the encounter between gas-phase molecules and a polymer surface, with subsequent diffusion into the surface. Such studies should be quite useful in the analysis of barrier properties of films.

The influence of the glass transition on diffusion has been considered by several groups (319,341). Paul and co-workers (341) focus on anomalous diffusion, and show that this short-time behavior is related to the freezing-in of isolated packets of free volume. Their BFM included a preference for chain stiffness, and they showed that diffusing molecules tend to move parallel to the director of the nematic phase; that is, diffusants find it easier to move in the direction of the chain backbone (within the tube!) than perpendicular to it.

Fried and Goyal (342) studied the permeability of poly[1-(trimethylsilyl)-1-propyne] to several gases, and found good agreement with experiment. An insertion method was used to determine the solubility of He, O_2, N_2, CH_4, and CO_2 in the polymer, and diffusion coefficients were obtained from the Einstein relation. The DREIDING force field was used for the simulations. This polymer is

interesting in that it is highly permeable, which facilitates the thorough study carried out by Fried and Goyal.

Park and co-workers (343) used MD with a simple Lennard–Jones model of alkanes hosting a large spherical particle to show that this system could mimic the MW behavior of measured diffusion coefficients of methyl yellow in a range of *n*-alkanes and *n*-alcohols. In these simulations, no effort was made to analyze the results in terms of changes in the melting temperatures of the model alkanes. (The MW dependencies of the experimental diffusion coefficients extrapolated to 45°C have breaks at *n*-docosane and *n*-hexadecan-1-ol, both of which have melting temperatures at about 45°C! This work may be a new method to measure melting temperatures, which is not trivial owing to the dependence of phase transitions on the force field.)

It will be interesting to see how the interplay between Vogel–Fulcher behavior, free volume "adjustments," and Arrhenius activation resolve themselves as MD simulations extend to longer times and to more accurate descriptions of potentials. It seems to be a general rule that "stationary" random systems, of which a glassy polymer is an example, have frozen-in heterogeneities that are all important in determining properties. While intuition suggests that random systems should be "uniform," this seems not to be the case.

Ionic diffusion is important in battery and fuel cell applications as well as other areas, and it too has been the subject of simulation studies. Ennari and co-workers (81,344,345) produced a clever means to model proton diffusion in aqueous systems containing poly(ethylene oxide) (PEO) with sulfonic acid groups, and found the results to be in reasonable agreement with experiment. The diffusion of Li^+ in dry PEO melts has been simulated by Borodin and Smith (346). They find that the system slows down because of complexation of the cation by the O atoms of the PEO chains. The lifetimes of the complexes are relatively short, between 100 and 200 ps. At the concentrations of ions used in the simulations, the Li^+ and I^- form fairly tight ion pairs, which causes the two to diffuse at about the same rate.

Viscoelasticity. Direct MD simulations of the long-time dynamics of models of polyethylene using both united atom and explicit atom potentials were reported by Paul and co-workers (347) and Harmandaris and co-workers (348). In this work, relatively long (C_{100} in the former and C_{24}–C_{156} in the latter) alkanes were simulated for several nanoseconds with MD. It was shown that the chain dynamics, including the monomer friction coefficient, autocorrelation function of the end-to-end vector, and several other properties are well described by the Rouse model. These chain lengths are below the entanglement molecular weight, so that reptation was not expected. Importantly, the Rouse modes were shown to depart from simulations as the wavelength of the excitation decreased, ie, when atomic detail begans to invalidate the Rouse model.

An understanding of the influence of polydispersity on chain dynamics in the melt was achieved by Baschnagel and co-workers (177) in a simulation using BFM. These "dynamic Monte Carlo" simulations showed that long chains move more rapidly in the presence of short chains, and the short ones move more slowly in the presence of the long ones. The net effect is that the dynamics of a polydisperse melt is close to Rouse theory predictions, ie, the chains act as if they are not entangled! An indirect approach to reptation dynamics was described by Byutner

and Smith (349). They used direct MD simulations on relatively short polybutadiene with random microstructure (350) to evaluate a few molecular parameters (Rouse relaxation time, chain dimensions, and bulk density), which were then fed into various theories of viscoelasticity (qv) to estimate the storage and loss moduli of high polymer (see VISCOELASTICITY). Good agreement with experiment was obtained with the parameter set from simulations when used with Milner–McLeish theory (351). This hybrid approach to viscoelasticity is apt to be the only practical method to get to the very broad timescales typical of bulk polymer dynamics. However, as a comparison of these two results suggests, there are details that need to be considered very carefully. In particular, departures from Rouse dynamics have been seen in the same polybutadiene system (352), which is taken as a signal of the importance of intermolecular correlations. Smith and co-workers (350) have shown that it is important to get good representations for rotational potentials and chain microstructure for this polymer when attempting quantitative comparisons with NMR relaxation time experimental data. United atom potentials seem to make the torsional modes too "slippery" relative to all-atom potentials. That is, torsional motions of the backbone are subject to forces similar to those that create the ratcheted motion of methyl groups (see below), and explicit hydrogens are responsible for each.

Brownian dynamics has been used to study the behavior of dilute solutions of dendrimers in shear flow by Lyulin and co-workers (353). In this work they showed that the onset of shear-thinning depends on the number of generations, the details of the structure of the rod-bead model, and the strength of the hydrodynamic interaction. The SHAKE algorithm was used to impose the constraint of fixed bond lengths. Bond and torsion angles were free of constraints. One of the most interesting aspects of this work is the different shear behavior shown by dendrimers and linear chains—linear chains first expand, ie, the radius of gyration increases, and then contract with increasing shear rate, whereas dendrimers expand monotonically. This interplay between segment density, topology, and shear rate should provide fertile ground for both future simulations and practical applications.

Local Chain Motions. Continuing in the dynamical vein, high frequency methyl group librations in glassy polymers can be directly studied with MD (354). The distribution of potential barriers to rotation seen in simulations on polyisoprene at 150 K is very nicely correlated with inelastic neutron scattering. Methyl rotations in poly(vinyl methyl ether) and PMMA have also been studied by the Davies group (355,356) which has enabled them to conclude that packing effects are just as important, if not more so, than monomer structure in determining the barriers to rotation.

Short-range conformational transitions, such as backbone torsional motion or side-chain rotations as mentioned above, are often considered to play a major role in a number of subglass relaxations exhibited by polymeric materials as well as for diffusion of penetrants. As might be expected, these conformational transitions, especially of groups larger than the methyl group, usually occur on timescales too long to be captured by conventional MD in the glass, but they can be studied using molecular mechanics with the help of transition state theory. Suter and co-workers have applied this technique to the investigation of the phenyl ring flip motions in polycarbonate (99) and polystyrene glasses (100). In this study of the ring rotation process, the reaction coordinate in the transition state theory

formalism was defined simply to consist of only the ring torsion angle. The torsion angle of interest was "driven" through 180 degrees in steps of 5–10 degrees, and after each such change the energy of the system was minimized. The energy profiles obtained using this approach were used in conjunction with the transition state theory rate expression to determine the rate of the process of interest (the entropic contributions to the free energy barrier were assumed to be negligible).

It is to be expected that in a condensed polymeric phase such as a glassy polymer, even a local conformational change of a chain requires the cooperative motion of the neighboring chains. The approach followed by Suter and co-workers, as described above, focusses only on the change in the torsional angle of interest, and consequently ignores the cooperative nature of the motion between the ring torsion angle and the neighboring torsion angles. Khare and Paulaitis (357) explicitly accounted for this cooperative motion by considering a multidimensional reaction coordinate that included the two neighboring backbone torsion angles in addition to the phenyl ring torsion angle in their investigation of the phenyl ring flip motion in glassy polystyrene. Their work clearly demonstrated the cooperative nature of the process. The cooperativity of these local motions was also found for phenyl group ring flips in a polyimide (358).

The approach proposed by Khare and Paulaitis (357) seeks a middle ground between the extremes of considering only one dihedral angle as the reaction coordinate and considering a reaction coordinate made up of all of the degrees of freedom (all of the atoms or internal coordinates) in the system. It is to be noted that a priori selection of the degrees of freedom that are to be included in the multidimensional reaction coordinate is a difficult task and a judicious choice of these requires a detailed knowledge of the physics of the process being studied.

The dynamics of polymers depends on more than these selected examples of rotations/librations. Simulations to detect backbone rotations in polyisoprene, both above and below T_g, have been reported (359–361); similar results were found for 1,4-polybutadiene by Furuya and co-workers (362). It is found that backbone rotations are correlated, with neighboring bonds undergoing rotations of contrary handedness, thereby preserving the overall contours of the chains. Similar behavior is observed in amorphous PE below the glass temperature (363). [Obviously, the nature of the cooperativity of rotations is highly dependent on monomer architecture as well as temperature and density. Zuiniga and co-workers (364) did not find as many correlated rotations in PE, but their simulations were done *in vacuo*, for which the rotational transition behavior is very different from the bulk.] Below T_g, the bonds that have some rotational/librational freedom are localized in "hot-spots" (361), while other bonds do not experience any significant torsional motion on a 20-ns timescale. Similar results, indicating increasing heterogeneity of local motions with decreasing temperature, have also been obtained by Smith and co-workers (365) on 1,4-polybutadiene. This is an aspect of the heterogeneity of systems with frozen-in disorder, and is probably not an artifact of the algorithmic construction of cells. Another interesting aspect of polymer dynamics is emphasized in the work of Fukuda and Kikuchi (361). Their correlation functions are very slowly decaying unless the temperature is well above T_g. This phenomenon, ie, the further slowing of already slow motions as temperature is reduced, is typical for polymeric simulations, and is a major obstruction to the analysis of polymer dynamics. However, it is a problem that yields up more information the faster

is the computer that can be applied to it. For this reason, extension of existing methods to slower mode problems will continue to be of interest for many years to come.

The density dependence of backbone torsions in a united atom model of PE in the melt at 400 K has been investigated by Karatasos and co-workers (366–368). They found that second-neighbor torsional coupling (with relaxation times around 10 ps) increases with density, as the above results suggest. But most importantly, there appears to be a second reorientation process with much longer relaxation times that appears with increasing density and which is seen most clearly with longer chains. This motion "... can be thought to originate from an effective "*pipe*" formed from the surrounding chains constraining the relaxation of the chain axis, even after the correlation of the torsional angles is lost. This effect is not to be confused with the "*tube*" model associated with chain reptation" (367). It will be interesting to see if this is just the next slower process in a long sequence of different types of motion in polymeric systems [which is implied by the general viscoelastic behavior of bulk polymers (331)]. Longer simulations will determine if yet slower processes will be found.

The density and temperature dependence of some of the slow relaxations in PE were studied by Bharadwaj and Boyd (369) using *NVT* simulations with a relatively simple united atom model of the polymer. Runs of six nanoseconds for each of several conditions were performed, resulting in a comprehensive view of how relaxation processes depend on ρ and T. One insight provided by this work is that reorientation motion of the chains seems to require barrier crossings rather than free-volume "adjustments." This result suggests that there is a need for analysis tools that are capable of cross-correlating different types of motions with structural or packing aspects of amorphous polymers so as to unravel the complex interplay of phenomena that determine the dominant motions in these systems.

These results reinforce once again the need to go to longer and longer timescales to capture slowly relaxing modes of motion in polymeric systems. Depending on the property of interest, failure to account for the slow relaxation can sometimes bedevil the analysis of properties.

Glasses and Glass Transitions. One of the earliest investigations of polymer glasses, which utilized alkane models of polyethylene in both liquid and glassy states, was presented by Rigby and Roe (69,370–372) (see AMORPHOUS POLYMERS). By carrying out MD simulations over a range of temperatures, these authors showed that the simulated system behaved like the experimentally observed polymeric systems in the vicinity of the glass transition (qv). The authors presented a detailed investigation of various conformational (eg, distribution of torsional angles), structural (eg, radial distribution function, orientation correlation function, free-volume distribution), and dynamic (eg, conformational transitions, segmental self-diffusion coefficients) properties of polyethylene chains containing up to 50 monomeric units in both liquid and glassy states.

Simulating the kinetic transition of a polymeric system from the melt to the glass has been a modeling target for many years (69,131,176,248,370–379). Any of the techniques that have been discussed for performing either "dynamic MC" or MD is capable of yielding densities that exhibit the characteristic knee at T_g. Simulations, just as in the real world, give T_g's that depend on the rate of

cooling (248,380), molecular weight (69,248), and pressure (376). Obviously, the value that is obtained for T_g is very much dependent on the force field that is used, as switching off the torsion potential in a simple united atom model reduces the apparent T_g significantly (69,378). Results of the Mainz group (248) show that the Vogel–Fulcher law is well obeyed by diffusion coefficients obtained from "dynamic MC", but caution that interpretation of the apparent reference temperature resulting from the fit is subject to considerable uncertainty given the limited scope of the modeling data. This statement is generally true—the correspondence between simulated T_g's and experiments is open for discussion. The proper equilibration of polymer models, especially if one is interested in the MW dependence of T_g, is very important. Given the slow relaxation of large random coils, determination of the temperature dependence of density should be systematically explored for a variety of MWs, but this is rarely done. Given the sensitivity of the apparent T_g to the factors mentioned, especially the force field, agreement between simulations and experiment may at times be fortuitous.

The FENE model with short chains of ten beads interacting with a truncated Lennard–Jones potential has been used for an MD investigation (381,382) of mode coupling theory just above the predicted critical temperature, which in turn is above the T_g. It is too early to say whether this theory will prove to be of practical use for polymer science, but simulations of this kind are probing deeply into the nature of the glass transition, which can only help to illuminate the physics of this important transition.

A generic FENE model has also been used to study crazing in glassy polymers (383), with the resulting pictures looking very much like what one sees in micrographs. Earlier work with a 2-D lattice model of a cross-linked system exhibited much the same phenomena (384).

The influence of surface bonding on the glass transition has been studied with BFM (385). The adhesive strength of thermosetting resins is especially challenging to model, but progress is being made in this area by Stevens (386,387). A modified Grest–Kremer model with multifunctional units and breakable bonds has been used to construct a densely cross-linked system confined between parallel planes of atoms. The model was subjected to both normal and shear stresses by moving the surfaces, with strains up to the point of fracture. Both yield and plastic behavior as well as fracture are seen in the simulations. The pull-off from a bonded surface is dependent on the fraction of bonds to the surface, and the overall yield strain is determined by the minimum path from surface to surface. Viscoelastic contributions, as might become apparent upon varying strain rates, have not yet been extensively considered.

Crystalline Polymers. The thermodynamic properties of perfect crystals treated in the harmonic approximation constitute an important textbook example of the success of quantum statistical mechanics. Early examples of applications to polymers are found in the work of Tadakoro and colleagues (388–391). (see SEMICRYSTALLINE POLYMERS). This theory and elaborations thereof continue to be of considerable interest, especially because the free energy can today be calculated as a function of strain from first principles with the use of a high quality force field. Lacks and Rutledge (392) have described a method in which the Gibbs free energy is minimized as a function of applied strain. They perform molecular mechanics (MM) with fixed stress and cell parameters to locate the local energy minimum

while preserving the space group; this is repeated for a variety of different cell parameters. For each of these, the Hessian matrix for the unit cell is computed either analytically or numerically to obtain the harmonic force constants, and from these the phonon frequencies are obtained. Standard Debye theory gives the free energy, which is then minimized with respect to the cell parameters so as to obtain the strain, while the temperature dependence of the cell parameters yields the thermal expansion coefficient. (The reader will recall that thermal expansion is a manifestation of anharmonicity. The method of Lacks and Rutledge neatly solves this problem while retaining the simplicity of the harmonic approximation for the calculation of other thermodynamic properties.) This theory has been used successfully for several polymers.

Modeling is also useful for the determination of crystal structures, as the inversion of an X-ray diffraction pattern generally requires the construction of an atomic model of the system. This has been true since the earliest days of crystallography, when it was seen that a forward Fourier synthesis of the diffraction pattern was required to determine the phases of scattered rays (393,394). The prodigious calculations required for this analysis were a natural for computers, and some of the earliest chemical uses of computers were for this purpose. Continuing in this vein, molecular models and simulation have vastly improved the ability to solve very difficult structures. The work on poly(vinyl alcohol) (PVOH) (395–397) is illustrative of what can be done. Two competing structures for PVOH, one due to Bunn and the other to Sakaruda (see references in Ref. 397) were resolved in favor of the Bunn model. Assender and Windle (396) showed that a model incorporating water into the PVOH crystal reproduced the changes in relative intensities of two peaks seen in the experimental data. The Blackwell group (397) emphasized the importance of using MD, rather than simple MM, to understand subtle relations between cell dimensions and hydrogen bonding, thereby accounting for changes seen in the diffraction patterns for different tacticities.

A somewhat different situation is encountered in the structure of random copolymers of *p*-hydroxybenzoic acid and 2-hydroxy-6-naphthoic acid. These polymers do not crystallize in the traditional sense, yet they exhibit diffraction patterns that mimic those of partially crystalline polymers. Modeling (398,399) has been a crucial aid to understanding the relation between the conformational and translational disorder in these liquid crystalline polymers, despite some differences in the types of modeling done and interpretation thereof. Similar types of polyesters were investigated both experimentally and with modeling by Oda and Rutledge (400). Their interest was in understanding the influence of processing conditions on the molecular orientation, and MC modeling was used to produce a molecular level understanding of the noncrystalline domains.

Polyesters containing ethylene moities, namely polyethylene-biphenylate (PEBB) and naphthalate (EN) copolymers, were analyzed by Wendling and co-workers (401) in an effort to comprehend their crystal/amorphous structures. They found that minority repeat units were excluded from the crystalline phase of the majority comonomer when the concentrations of the two are very dissimilar, whereas the two comonomers are able to cocrystallize by segregation when their compositions are more nearly equal.

Techniques to determine the interplay between random copolymer statistics and crystallite stability in a situation where two comonomers (hydroxybutyrate

and hydroxyvalerate) can co-crystallize have been described by Wendling and Suter (402). The thermodynamic integration method was used for these simulations. The technique utilizes a mapping, $H(\lambda) = (1-\lambda)H_A + \lambda H_B$, between two Hamiltonians for species A, H_A, and B, H_B. If the two species are sufficiently close to one another in structure, the transformation of the system from A to B can be performed by gradually changing λ, allowing for equilibration of the hybrid system at each increment in the coupling parameter. While this thermodynamic integration method is fraught with hazards when applied carelessly, it is extremely potent when used judiciously, as it provides a means to evaluate the free energy change that accompanies the transformation of the system. [Two other methods are capable of yielding the free energy for a crystalline material such as this: normal mode analysis (123) and the Gibbs ensemble method (159).]

Phase transitions between crystalline polymorphs can also be approached with modeling. Sorensen and co-workers (403) calculated energies and free energies of PE as well as the hexagonal and orthorhombic forms of poly(oxymethylene) using their ab initio method (404) for predicting crystal structures of helical polymers. Good agreement with experimental structures was obtained with use of a "boutique" force field. Free energies were calculated from phonon dispersion curves with use of statistical mechanics in the usual way, and they found the energies of the two polymorphs to be equal within the uncertainty of the calculation. This work was one of the first to show how a phase transition could be calculated from first principles.

The use of modeling to estimate the elastic constants for the crystalline phases of semicrystalline polymers is becoming a reliable strategy to determine properties that are very difficult to estimate directly from experiment. A representative example of these types of simulations is the study of silk by Sinsawat and co-workers (405), who find reasonable agreement between the Young's modulus in the chain direction with the values determined experimentally. Earlier work by Klunzinger and Eby (406) showed that one could obtain reasonable values for the anisotropy of the thermal expansion coefficient of PE represented with the DREIDING force field by direct determination of the temperature dependence of cell dimensions obtained from MD simulations using the Parinello–Rahman algorithm (407).

The topic of chain folds at lamella surfaces has been controversial for decades. Very recently, molecular modeling has become sufficiently versatile to aid in understanding the complex interplay between crystal and amorphous densities, chain stiffness, and crystallite proximity effects. The simulations of Rutledge and co-workers (203,408,409) on a freely rotating united atom PE model with truncated Lennard–Jones interactions demonstrate that the lowest energy crystal face in a semicrystalline PE is the {201} face, in excellent agreement with experiment. (These authors review the extensive older literature on this problem as well as some of the controversies.) The most striking feature of this result is that this face has very few adjacent reentrant folds, in contrast to the {001} face. The method used to equilibrate these systems included four different types of MC moves: end-rotation, slithering snake, intrachain concerted rotations, and end-bridging. Further studies of this kind, with different polymers, would be welcome.

MC methods can be used with full atomistic descriptions, and these have been particularly useful for crystalline (127) and liquid crystalline (410) polymers. The

MC moves that can be made in these types of systems include rigid body rotations and translations besides the local displacements of atoms, and these larger moves greatly facilitate the exploration of the anisotropic domains in phase space. Moves of this type cannot be used for the amorphous phase, as rigid body rotations, for example, will most likely precipitate very energetic overlaps with neighboring molecules as has been discussed above.

Equation of State. A number of modeling studies of amorphous polymers have included *PVT* behavior, either as an end in itself, as a means to validate the potential functions, or to investigate other aspects of polymer behavior (411). Polymer melts and glasses that have been studied in some detail include polyethylene (23,370,412), poly(dimethylsiloxane) (413), poly(ethylene oxide) (414), and poly(ethylene terephthalate) (78). Dendrimers having a variety of generations have been compared with linear chains in the respect of their equation of state by means of a tangent hard sphere model by Lue (415).

Electrical Properties. The piezoelectricity of the technologically important polymer of vinylidene fluoride (PVDF) has been the subject of modeling for several decades (see PIEZOELECTRIC POLYMERS). An early example of the use of molecular mechanics to aid in the calculation of the mechanical and electrical properties of this polymer is found in the work of Tadokoro and co-workers (390,391). Subsequent investigation of PVDF by Karasawa and Goddard (83) focussed on the prediction of alternative crystal structures with use of the shell model to capture polarization effects. The latter phenomenon was further explored by Carbeck and co-workers (84), who used the shell model to show that the induced moment because of neighboring dipoles in the crystal increases the dipole per repeat unit by about 50% over its value in the isolated molecule.

Young and co-workers (80) studied the poling of a model polyimide film by using the "amorphous cell" technique, with the electric field being generated by an array of fixed charges. They relaxed the system at 2000 K under a poling field of 700 MV/m—harsh conditions that are feasible in the computer but physically unrealistic. However, this treatment enabled them to relax a very stiff polymer in a reasonable length of time (ca. 200 ps) and examine its polarization. They claim excellent agreement with experiment.

The calculation of dielectric permittivity is of considerable interest for a variety of reasons, most especially for electronic applications. Heinz and co-workers (416) tested several different techniques for determining the dielectric constant of liquid water, and determined that none is clearly better than the simplest route of evaluating the dipole moment autocorrelation function. The relations $\mathbf{P} = \chi_e \mathbf{E}$ and $\varepsilon = 1 + 4\pi\chi_e$ between the induced polarization $\mathbf{P}$, electric field strength $\mathbf{E}$, electric susceptibility χ_e, and dielectric constant ε, for an isotropic medium (417) can also be employed to determine the dielectric constant by application of an external field. An external field may be readily incorporated into an MD engine by adding a force term of the form $\mathbf{F} = q\mathbf{E}$, where q is the partial atomic charge on an atom, and by monitoring the induced polarization.

The use of quantum methods for large crystalline systems (418) may have appeal for the analysis of conductive polymers.

Polyelectrolytes. Multiple chain polyelectrolytes (qv) have been simulated by Limbach and Holm (419). They used a FENE model having beads that interact with both a truncated LJ potential and an electrostatic potential. Counte-

rions were observed to condense on the chains, but such that the segments in the center of the chain are more highly screened than are those at the chain ends. The mutual repulsion of backbone segments causes the chains to extend themselves, but if the solvent quality is poor, they collapse locally into a pearl necklace configuration. A range of polyelectrolyte properties has been studied by a combination of theory and simulation by Shew and Yethiraj (420–422).

Nanoscopic Systems. The considerable current interest in nanoscale particles and devices will appear to be familiar territory to polymer scientists and engineers, as this domain entails length scales that are commonly encountered with polymeric systems. United atom models for up to 60,000 atom models of PE droplets have been simulated with MD methods (423). The design of purposeful devices, eg, motors, at this length scale has been initiated (424). Furthermore, as semiconductor devices shrink in size, it is foreseen that the ultimate length scales will be in the nanometer range. The modeling territory that has been explored in working on polymer problems will be of considerable importance as these fields advance.

Mechanical Properties. In addition to structural properties, mechanical properties of glassy polymers can also be studied using the methods of molecular mechanics (131,425). In this application, a glass structure at a local energy minimum (and also mechanical equilibrium) is subjected to small deformations. The first and second derivatives (slopes and curvatures) of the potential energy can be evaluated numerically and related to the elastic constants of the polymer. Note that this approach assumes that the entropic contributions to the elastic response are negligible, an assumption shown to be valid for typical polymer glasses by Theodorou and Suter (425). The elastic constants of glassy atactic polypropylene calculated (425) using this approach showed very good agreement with experimental values. Subsequent to this work, Matheson (426,427) mustered more extensive experimental data on the pressure and temperature dependence of the bulk modulus to show that the entropic contribution is not always negligible for glassy polymers, and is certainly not negligible in the melt.

Pervaporation. In addition to the simulation of the penetrant diffusion in the polymeric matrices, the technique of molecular dynamics has also been applied for investigating the process of pervaporation separation using polymeric membranes (428). In this study, the process of separation of a 90:10 wt% water–ethanol mixture by a PDMS membrane and separation of a 90:10 wt% ethanol–water mixture by a PVA membrane was investigated by simulating systems containing the respective polymer matrices in direct contact with the respective liquid mixtures. The authors showed that within one nanosecond of MD simulation the liquid molecules were found to be absorbed in the polymer matrices. Furthermore, consistent with the experimental observations, an enrichment of ethanol in the PDMS matrix and an enrichment of water in the PVA matrix were observed.

Viscosity. The molecular modeling techniques used for determining the other transport coefficients, viscosity and thermal conductivity, in addition to diffusivity that was discussed above, fall into two categories. In the first category, the coefficients are calculated from Green–Kubo relations, with the required correlation functions being evaluated with equilibrium simulations at the desired state point. Indeed, this was the approach followed traditionally. However, the calculation of correlation functions is known to yield large statistical uncertainties. This

has led to the development of alternate techniques for evaluation of the transport coefficients. There is now a preference for using direct simulations of the phenomena that define the quantities. Perhaps the most popular of these is the "homogeneous shear" (often described as nonequilibrium molecular dynamics or NEMD in short) technique used for the calculation of viscosity (429). In a homogeneous shear simulation, a velocity gradient is set up in the simulated system by modifying the equations of motion and using "sliding brick" periodic boundary conditions. The viscosity of the fluid is then determined by measuring the appropriate component of the stress tensor, ie, the momentum flux. The results of homogeneous shear simulations are generally extrapolated to low shear rates to obtain the zero shear rheological properties, eg, zero shear viscosity. The technique has been applied to study the rheology of low to medium molecular weight *n*-alkanes (430–437) and branched alkanes (434–437). In addition, it was shown that the performance of the simulations for predicting the temperature and pressure dependence of viscosity for *n*-alkanes was comparable to that of empirical correlations based on experimental data (434). In addition to hydrocarbons, the technique has also been applied for investigating the viscosity of other small organic molecules such as *iso*-amyl alcohol and *n*-butyl acetate (438).

Shear Flow of Confined Fluids. The homogeneous shear simulation technique described above employs periodic boundary conditions in all three dimensions thus effectively simulating a small region in the bulk fluid. For many applications (eg, investigation of wall-slip behavior in polymer processing or understanding the results obtained by the Surface Forces Apparatus experiments), interfacial rheology plays an important role in the phenomena of interest and thus the surfaces confining the sheared fluid need to be considered explicitly in the simulation (see RHEOLOGY). Such processes can be studied using a simulation technique that closely mimics the setup of an experimental rheometer (or the Surface Forces Apparatus): the fluid of interest is confined to a film between two surfaces, and shear is imparted on the fluid by actual motion of these confining surfaces. Such an approach has been used to investigate the steady shear rheological behavior of molecularly thin films of simple fluids (439,440) as well as polymers that were modeled using both coarse grained bead-spring models (441–445) and more realistic united atom models (446–449). Recently, viscoelastic properties of thin films of simple and polymeric fluids were investigated by extending this approach to study oscillatory shear flow of the confined fluids (450,451).

Phase Transitions.

Traditional Methods. The Flory–Huggins χ parameter, in combination with the combinatorial entropy of mixing, controls liquid–liquid phase separation in polymer solutions and blends. Owing to the technical importance of polymer solutions for analytical work and the commercial importance of blend compatibility, there is considerable interest in finding methods to evaluate the χ parameter with theory or simulations. The initial view of the interactions between the components of a mixture led to the formulation of the interaction parameter χ as the energy change on forming unlike pair contacts (220). This led to the early development of algorithms that would report energies of interaction between molecules as the molecules were brought from "infinity" to a random configuration of minimum energy. With sampling of the contact configurations with an MC procedure, the energy change on forming unlike contacts could be evaluated (452).

On the next simplest level, solubility is predicted with use of regular solution theory. The computation of solubility parameters, δ, can be done reliably for small molecules, oligomers, and polymers, and the heat of mixing ΔE_M, estimated from (453)

$$\Delta E_M = \varphi_1 \varphi_2 V(\delta_1 - \delta_2)^2 \tag{8}$$

where the ϕ_i are the volume fractions of the two components and V is the mixture volume. This is the approach taken by Patnaik and Pachter (454) in one part of their study of the miscibility and properties of several different liquid crystal formers in poly(methyl methacrylate).

Perhaps the simplest phase transition for a polymeric system is the collapse of a single chain. There is much current interest in collapse transitions in relation to the protein folding problem (455). These simulations are often done with Brownian dynamics, and may include electrolyte effects. Low dimensional simulations (456) are of use in helping to understand this problem, particularly because theories of 1-D systems, which can be compared with simulations, are much easier to construct than for 2-D and 3-D.

Balazs and co-workers (17), in a study of comb polymers having hydrophobic and hydrophilic groups, observed the collapse of single chains in simple models of oil/water mixtures. The comb-like chains were modeled with FENE springs and a simple LJ potential with cutoff; combs with hydrophobic backbones and hydrophilic teeth as well as the converse were investigated. Surfactant behavior could be ascribed to the polymer by investigation of the spatial correlations between oil and chain segments. These early calculations presaged the results that would be obtained with DPD.

Honeycutt (457) showed that PRISM is capable of correctly predicting the influence of tacticity on phase separation in blend of poly(vinyl chloride) and poly(methyl methacrylate). In this work, the potentials for united atoms were taken to be independent of tacticity, but the chain statistics conveyed in the RIS models were tacticity dependent. This is not always the case. Direct simulations to obtain pair correlation functions that are pertinent to a phase separating system were performed with the 2nnd-lattice mapping/reverse-mapping technique by Akten and Mattice (458), who showed that the positive heat of mixing in polyethylene–polypropylene blends was the result of intermolecular potentials, and not chain statistics. It has long been theorized that these two polymers are incompatible (459), in agreement with experiment.

In the early work of Rigby and Roe (370) it was shown that a united atom model of PE would spontaneously pass from an isotropic to a nematic phase on lowering the temperature. More recently, the same model potential has been applied by Koyama and co-workers (460), who found a T_g at about 230 K, with significant ordering of the chains occurring between 300 and 330 K. The latter is taken to indicate incipient crystallization. The work on a polymer film by Ito and co-workers (340) used the same model, and found a crystalline structure below and at 300 K. Thus, if the simulation times are sufficiently long relative to the relaxation time of the modeled chains, it is possible to observe at least the onset of crystallization in a condensed phase. The timescale for crystallization in thin films may be shorter than in the bulk; Ito and co-workers (340) have shown that their PE film forms

crystallites with a grain boundary within a reasonable simulation time. Perhaps the tendency of chains to run parallel to the surfaces induces increased order, thereby enhancing the rate of nucleation. MC simulations on a lattice model of a thin film are reported to show similar behavior, (461), but here the speed advantage of MC allows greater exploration of the configuration space of the system.

Holt and Farmer studied the helix reversals in polytetrafluoroethylene crystals that are imputed in the "very rich phase behavior" of the polymer (462). They find that diffusive pairs of reversals that bracket relatively short-chain segments are readily formed, and increase in occurrence with increasing temperature. Another fluoropolymer of perennial interest is polyvinylidene fluoride. The ferroelectric phase transition of copolymers of vinylidene fluoride (VDF) and trifluorethylene (TrFE) was studied by Abe and Tashiro (463), who found that the introduction of TrFE leads to a decrease in the transition temperature. The transition is brought about by a disordering of the rotational states that is promoted by a density reduction that accompanies an increase in the TrFE content. This despite the fact that the TrFE monomer has higher rotational barriers than does the VDF repeat unit. This is an interesting example, but not an isolated one, where modeling correctly senses and balances some apparently contradictory trends in behavior.

Gibbs Ensemble Methods. As has become increasingly apparent with newer modeling techniques, especially those based on the Gibbs ensemble method, the entropic contributions to χ are often of considerable importance for quantitative work (464–467). While noncombinatorial contributions to χ have long been observed in experiments and with equation of state theories, it is only very recently that modeling methods have been able to discern this part of the interaction parameter. The Gibbs ensemble method has been used by de Pablo and co-workers (468) to investigate the pure component vapor–liquid equilibria of n-alkanes (469), branched alkanes (27), α-olefins (470), and mixture equilibria of alkanes (27,471) and alkenes (470). Siepmann and co-workers have used this methodology to investigate the pure component vapor–liquid equilibria of linear alkanes (472–474), branched alkanes (475), alkenes and alkylbenzenes (476), and alcohols (477) and the mixture equilibria of alkanes (474), alkenes and alkanes (154), and alcohols and alkanes (477). Fuchs and co-workers have investigated the pure component vapor–liquid equilibria of linear alkanes (478), cyclic alkanes (479), and sulfides and thiols (480) and mixture equilibria of linear alkanes (478). The approach has also been used to study the vapor–liquid phase equilibria of mixtures of alkanes and perfluoroalkanes with carbon dioxide (481).

In the Gibbs ensemble–CCB method used in most of the simulations reported above, the particle swap move still consists of inserting the entire chain into the other phase. Although the selection of a favorable chain conformation by the CCB method does help, the approach still becomes inefficient for chains longer than about 20 united atoms or for dense systems. This difficulty has led to the development of the expanded Gibbs ensemble, which enables simulation of phase equilibria of very long-chain molecules. In the Expanded Gibbs ensemble simulation technique as developed by Escobedo and de Pablo (482), instead of transferring an entire chain molecule from one box to another, the chain molecule is transferred in parts. Thus, during the course of the simulation, a chain molecule is chosen at random, and a part of it, made up of one or more united atoms, is removed from one box and added to the other box. Thus, parts of the selected chain

molecule exist simultaneously in both simulation boxes. In subsequent simulation steps, attempts are made to transfer the remainder of the molecule a part at a time, and this process is continued until the chain molecule as a whole occupies either of the boxes. After this, another chain molecule in the system is selected at random, and once again is subjected to the same procedure of transferring it in parts. The approach has been used by de Pablo and co-workers to investigate the pure component vapor–liquid equilibria of n-alkanes (469)and α-olefins (470), and the mixture equilibria of the two (470).

Widom's Test Particle Insertion Method. The solubility of small molecules at infinite dilution can be estimated based on the knowledge of the chemical potential of these molecules. Widom's test particle insertion method (483) provides a technique for calculating this quantity. The residual chemical potential (the difference between the chemical potentials of the fluid and the ideal gas at the same temperature and density) of a fluid is given by

$$\mu^r = -kT \ln\langle \exp(-U/kT)\rangle \tag{9}$$

where U is the energy of interaction between the test particle or molecule and the host matrix, and kT is Boltzmann's constant times the absolute temperature, as usual. The brackets denote an average over the fluidic host matrix containing N particles in a canonical ensemble. In application, a set of configurations of the host matrix is first generated from a simulation in a canonical ensemble using either MD or MC methods. The host matrix configurations are then frozen and the test molecule is inserted at a random location, and its interaction energy with the matrix is evaluated. The average in the above expression is calculated by repeating this process many times over (ie, by inserting the test molecule in several randomly chosen locations in the host matrix). The efficiency of the procedure can be improved by combining it with the "excluded volume map sampling" technique (484), which biases the insertion process such that the locations in the system where host matrix atoms are present are avoided. This approach has been used for obtaining the excess chemical potentials of methane, water, and ethanol in PE and PDMS (485) and for obtaining the chemical potentials of a series of penetrants (water, methane, argon, oxygen, etc) in amorphous PE (486).

As is to be expected with long chains, an insertion of a polymeric test molecule into a condensed phase will almost always result in interatomic overlaps with the host matrix atoms. Such an insertion will be rejected and will not contribute to the average denoted in the above expression. A modification of the technique thus has been proposed for polymers, where instead of inserting the entire polymer chain in the host matrix, only one segment is added to a preexisting chain (487). Kumar and co-workers (487) showed that this procedure yields the incremental residual chemical potential between a chain of length and $n+1$. The total chemical potential of a chain of length N can then be obtained by a simple, sequential sum of the incremental segmental potentials of all chains of lengths 1 through N. Furthermore, these authors also demonstrated that for simple bead-spring model chains, the incremental segmental chemical potential becomes independent of the chain length for chains longer than 5–10 beads, thus reducing the need for the number of simulations required for evaluating the sum of the incremental segmental chemical potentials for all of the longer chain lengths. This approach was used by Sheng and co-workers (488) to evaluate the chemical potentials of

bead-spring model chains of lengths up to 100. The vapor–liquid coexistence curves for these model systems were evaluated by devising an iterative procedure where coexisting vapor and liquid densities were found by requiring that the pressure and chemical potentials of the coexisting phases be equal.

Another approach for alleviating the problems encountered with polymer chain insertion in a condensed phase involves combining the Widom insertion process with the CCB chain growth method described earlier (489). Thus, instead of choosing a random conformation for the chain that is being inserted in the host matrix, positions of the first two segments of the chain are chosen at random, and then the rest of the chain is grown using the CCB method. This approach was used for evaluating the chemical potentials of alkanes as long as *n*-decane up to densities of 0.6 g/cc, using united atom models for these systems (489).

Even when the "test particle" being inserted is a small molecule, the straightforward Widom insertion process becomes impractical if the host matrix has a high density or if the chemical species in the system exhibit strong or long-range interactions. For studying such systems, Knopp and co-workers (490) proposed a modification that combines the Widom test particle insertion process with the technique of "thermodynamic integration." Suter and co-workers demonstrated the validity of such an approach by applying it to study the sorption behavior of water in polyamides (490,491), polycarbonate, and poly(vinyl alcohol) (492).

Outlook

Two major themes weave through the application of simulations to polymers. On the one hand there are efforts to extend the range of phenomena, as well as the time and length scales that are comprehensible, so as to gain an understanding of the universal phenomena that make polymers behave as they do. The other trend focusses on improvement in the accuracy of the description of the molecular structure and intermolecular interactions, so as to provide ever more accurate material properties predictions. We anticipate that both approaches will continue to be practiced side-by-side. The range of phenomena, relaxation times, and length scales is far from being exhausted. Simultaneously, there is a need to continue to improve accuracy so as to augment or even replace experiments where appropriate. Computer simulation is now firmly planted in the research enterprise as indispensably as are theory and experiment, and with each new and faster computer chip, we will see new polymer problems being solved.

MORPHOLOGY

Introduction

Polymer morphology, literally the study of organization within solid polymers, seeks to read the messages from the specimen's history contained in its physical form and hence gain understanding of the physical processes involved in its creation. In crystalline polymers the morphological record is not only extremely rich, because long molecules are largely immobile and remain where they were placed, but it has also provided the most effective means of establishing the fundamental patterns of behavior of long molecules and the increasingly important materials they compose, paving the way for quantification by appropriate techniques.

Historically, synthetic polymers are essentially twentieth-century materials, coming into prominent use in the second half with the introduction of polyethylene and polypropylene. The earliest textural model, the fringed-micelle, was an interpretation of wide-angle X-ray scattering (WAXS) patterns containing evidence of both small crystalline and disordered (amorphous) regions (1). According to this, long molecules were partly entangled and meandered from one kind of region to the other with mechanical and other properties dependent on the *degree of crystallinity*, ie the proportion of crystalline phase. The scale of the fringed micelle was believed, on the basis of the small widths of WAXS reflections, to be of the order of 10 nm, a dimension well below what it was then possible to see. Only with the advent of the transmission electron microscope (TEM) did such resolution become feasible but then it became clear that organic materials were vulnerable to damage by the imaging electrons, which mostly destroyed crystals, thereby tending to distort the physical record and adding little to knowledge until the discovery of polymer single crystals in 1957.

Single lamellar crystals were the second element of polymer texture to be identified, the first being spherulites, whose presence in polyethylene was reported in 1945 (2). Study with the polarizing microscope established that molecules lay tangentially to polyethylene spherulites and nearly so to those of polyamides and polyesters, systems with hydrogen bonding. Spherulites and their presumed substructure of fringed micelles were hard to reconcile (3), a difficulty that disappeared with the discovery of polyethylene single crystals and the inference of their internal molecular chainfolding. This is where modern polymer morphology started and much that was new and important was achieved within a few years. At the same time, the problem of radiation damage remained a serious obstacle to the study of melt-crystallized polymers for 20 years more and, until it was resolved, textural models were adopted from the limited information available and, unfortunately, have not always been substantiated, requiring radical revision when actual textures were eventually made visible.

Nowadays, polymer morphologies can be observed routinely, at least in the major polymers, to lamellar levels and, in combination with the complementary techniques of small-angle X-ray scattering (SAXS), WAXS, differential scanning calorimetry (DSC), ^{13}C nuclear magnetic resonance (NMR), neutron and Raman scattering among others, have served to lay firm foundations for the understanding of crystallization and texture-dependent properties not just in the materials studied but across all polymers. The central, but not the only, element in this understanding is the lamella.

Polymer Lamellae

The Inference of Chainfolding. The introduction of linear polyethylene in the late 1950s led quickly to the discovery that it could crystallize with a lamellar habit, visible in the optical microscope. First, surface steps were seen (4), then three individuals, Till (5), Fischer (6), and Keller (7) found that on cooling dilute solutions ($\sim$0.01%) in xylene, separate lamellar crystals precipitated. Their appearance closely matched that of *n*-alkane lamellae in which molecules are transverse to lamellae. Electron diffraction showed that this was also true of polyethylene lamellae that, given that molecular lengths were not significantly reduced by crystallization, led Keller to propose that molecules were chainfolded within lamellae (7). This inference has proved correct and chainfolded lamellae have now been shown to be a general feature of synthetic crystalline polymers including those grown from the melt.

The inference says nothing, however, about surface condition, whether folding is tight, occurring within four or so main-chain carbon atoms in polyethylene, or loose, extending over many more. Although there may be complete folding in isolated lamellae, in bulk material a proportion of molecules in adjacent lamellae must pass from one lamella to the next—*tie molecules*—and not fold back at a lamellar surface; otherwise mechanical integrity would be lost and eg the toughness associated with long polyethylene molecules be replaced by the waxy behavior of solid paraffins. Knowledge of the precise nature of fold surfaces still continues to be refined as more techniques are introduced and experiments performed and is currently a central theme of research. This reflects the fact that fold surfaces

are a major manifestation of the long molecular nature of polymeric solids in contrast to lamellar interiors whose crystal structures follow the same principles as in nonpolymeric materials.

Chainfolded Lamellae from Solution. Much of our basic knowledge of polymer lamellae and their properties was established relatively early from the study of monolayer or bilayer crystals grown from solution and examined on a supporting carbon substrate (8). It is possible to study these systems with diffraction imaging in a TEM for a short while until crystallinity is lost, then subsequently as residual amorphous pseudomorphs, which, when on a carbon substrate, retain the shapes of the original although they distort when embedded in a soft matrix such as gelatine. It was some 20 years before melt-crystallized textures could be examined in similar detail and, at the time, they were either assumed by some (9) to be basically similar although less well organized than lamellae grown from dilute solution or, by others (10), to be intrinsically different because the conditions for ordering from the melt were not present. In fact, most of the essential features shown by solution-grown lamellae do carry over at least in some degree to those grown from the melt although these are generally more disordered.

Crystal Habits. The habits of solution-grown polymer crystals are many and varied, with slow growth from the most dilute solutions giving the simplest objects. As usual, much is known about linear polyethylene (11) not only because this was the first system to be investigated and shows a profusion of informative detail but also because this is the closest approach to the ideal linear chain whose properties underlie those of all linear polymers. The basic habit of polyethylene lamellae is the lozenge, bounded by four {110} faces. At higher temperatures, $>$ $\sim$80°C from 0.01% solution in xylene, these are truncated by two {100} faces whose relative size increases with temperature. For crystallization from other solvents at higher temperatures, the truncating faces become the largest and may become slightly curved (12). Curved faces are not uncommon in other systems, but planar facets are the norm for most polyolefines. They even persist, albeit with very narrow widths $\sim$0.1 μm, for very rapid growth when dendrites form because diffusion limits the supply of material to the growth front (11,13).

The lozenge habit characteristic of orthorhombic polyethylene is paralleled by hexagons of polyoxymethylene (14) and i-polystyrene (15), squares of i-poly(4-methylpentene-1) (16), and, very unusually, triangles of poly(L-hydroxyproline) (17), in each case corresponding to the symmetry of the chain packing or subcell.

Twins occur, especially for lower molecular masses. For example, objects with six arms are common for {110} twinning in low mass polyethylene because (110) and $(1\bar{1}0)$ faces are inclined at 67.5°, close to 60° (18). Moreover, laths are prone to develop with such a twin boundary along its center line (11,19) because of the accelerated growth provided by the notch at its tip, which aids molecular attachment. More exotic, three-dimensional twins are shown by α-polypropylene in "quadrites" (20) and by interpenetrating layers in polyethylene (21).

Sectorization. The long lengths of polymer chains and chainfolding in particular are not directly reflected in the lateral habits of polymer lamellae. The first feature that does show their influence is sectorization, revealed by diffraction contrast, internal microstructure, or surface texture, possibly augmented by decoration with gold (22) or evaporated polyethylene (23). This is the division of a lamella into discrete regions bounded by a growth face, a phenomenon that is both

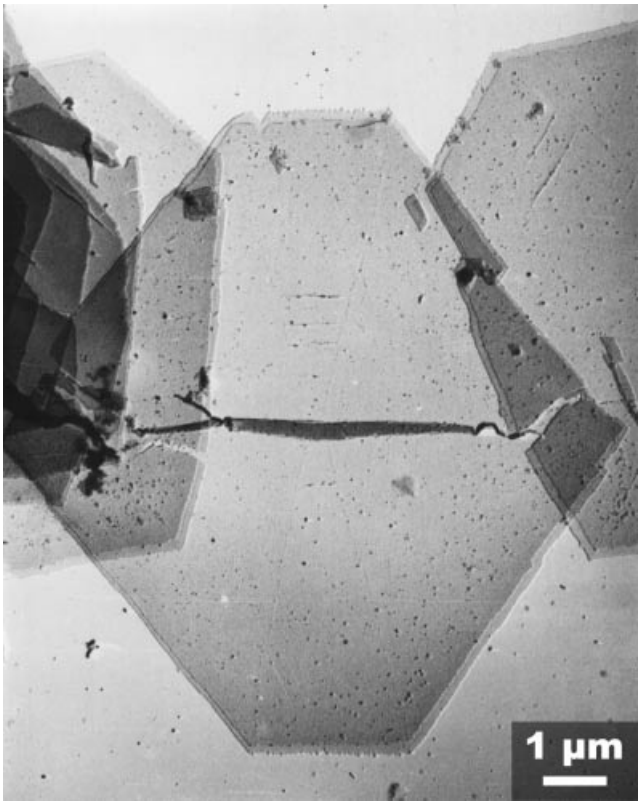

Fig. 1. A truncated lozenge of linear polyethylene, crystallized from 0.01% solution in xylene, with boundaries delineating its six sectors and a step at the outer edge where the crystallization temperature was reduced from 90 to 76°C. From Ref. 18.

a consequence and confirmation of chainfolding along the growth face; it would not occur if, for example, molecules prefolded into blocks before adding to a lamella.

Sectorization arises because such folding transforms a long molecule into a pleated sheet, which can extend across several successive lattice planes (24), but essentially lies along the relevant growth surface, denoted the *fold plane*. In so doing it breaks the symmetry of, and slightly distorts, the subcell lattice, ie the repetitive unit of chain packing within the lamella, excluding the surfaces. The fold plane in a given sector differs from nominally equivalent ones along which there is no folding and so transforms a single lamella into a multiple twin according to the respective fold planes. A four-sided polyethylene lozenge bounded by four {110} growth surfaces is, accordingly, a fourfold twin with four equivalent sectors in each of which one of the two nominally equivalent {110} surfaces will be parallel to the fold plane, the other not. When, at higher growth temperatures, lozenges become six-sided with truncating {100} surfaces, then there are six corresponding sectors (Fig. 1). The two new ones, denoted {100} sectors, are twinned with respect to each other but different in character to the four twinned {110} sectors because of the different fold plane with, for example, a lower melting point (25).

The size of a sector is governed by that of its growth face and can be very small, eg in dendritic growth, when individual facets, each of which has its own microsector attached, may be as little as 20 nm wide (13).

Nonplanar Geometries. One consequence of sectorization is to make lamellae nonplanar (18). This happens in two distinct ways, the first of which is a consequence of subcell distortion. Folding along the growth face makes nominally equivalent planes in the subcell become unequal, adopting slightly different spacings. For the three systems on which measurements have been made: polyoxymethylene, isotactic poly(4-methylpentene-1) (26), and low mass polyethylene (13), with, respectively, hexagonal, tetragonal, and orthorhombic subcells and all with chains normal to lamellae, the difference in spacing between otherwise equivalent planes only one of which is the fold plane is ~0.001 nm. In consequence, transverse axes of the subcell no longer meet precisely at 60° or 90°. Joining six or four such sectors, as appropriate, without dislocations (as is observed) gives, therefore, a lamella that is not strictly planar but slightly dished into a cone of semiangle ~89° rather than a planar sheet, as confirmed by direct observation (14). This deviation from planarity is sufficiently small to allow all sectors to be seen simultaneously in diffraction contrast from one principal reflection after a lamella has been flattened on a substrate prior to examination. In consequence, it is possible to make measurements of the small spacing difference of the same plane as it crosses a sector boundary, possible using bilayers and moiré patterns. Flattening also produces characteristic streaking normal to the growth face in each sector where slight local shearing in the fold plane has created the necessary additional surface (14).

Such small effects are probably universal in sectored polymer lamellae to which chains are normal. But they are overshadowed by much greater nonplanarity when chains are substantially inclined to lamellar normals, most notably in polyethylene of typical molecular weights. Then the diffraction pattern, eg for a single polyethylene lamella, is not generally single crystalline, as was initially assumed (7), but a composite with different reflections contributed by different sectors (27), according to the particular fold plane—showing that, in a flattened crystal, the molecular direction changes from sector to sector. In complementary dark-field images, only sectors with the same fold plane may appear in bright contrast.

These effects are a consequence of the collapse of what, in suspension, are highly nonplanar lamellae (27–29). The nonplanarity can take several forms but arises because molecular inclination to lamellar normals increases the surface area per end group or fold and so reduces surface congestion, as is common for the alkane subcell. The simplest polyethylene geometries are hollow pyramids that form, at higher temperatures, with {312} fold surfaces in {110} sectors and a common *c*-axis (30). The adoption of $\{31\ell\}$ planes is thought to reflect the asymmetric shape of sharp folds, both within and normal to the fold plane.

There are two other principal nonplanar habits of polyethylene lamellae: chair and ridged crystals. Chair crystals (30) form simultaneously with, and are related to, hollow pyramids; their shape may be described as resulting from a hollow pyramid divided in two along the short diagonal, the two halves rotated 180° around their long diagonal and then constrained to rejoin. The proportion of chair to hollow pyramidal crystals appears to vary with crystallization conditions.

It was first measured (30) to be equal, but later figures (31) have been as low as 10%; no more precise information is available.

At lower crystallization temperatures ($<\sim 80^{\circ}$C in xylene), hollow pyramidal crystals are replaced initially by ridged crystals, then by dendrites, which occur when growth is limited by diffusion, here of material to the growth interface (28). In the ridged crystals, each {110} sector contains alternating {314} facets that are in phase across the long but not the short diagonal. Intermediate forms such as half hollow pyramidal/half ridged or ridged lamellae with a central hollow pyramidal portion have also been found (30). As was suggested at the time, these changes in habit suggest that lamellae begin to form flat, with nonplanarity developing later. This has recently been demonstrated explicitly to be the case in melt-crystallized systems, for which it has major implications. New light has been shed on the significance of these various forms by recent work on melt crystallization (to be discussed later).

Although preparation for TEM involves drying lamellar suspensions when surface tension forces cause collapse on a rigid substrate, the nonplanar habits can be observed directly in the optical microscope, especially with dark-field imaging, while lamellae are floating in suspension or preserved, at least in part, if collapse can be limited, eg by sedimentation on glycerine or drying within gelatine (30).

Different nonplanar habits collapse in different ways. Hollow pyramids may occasionally fold in two along their short diagonal, revealing sectors in their original shape (11). More often they collapse by laying {110} sectors flat on the substrate, leaving a central triangular pleat of characteristic shape in which the excess material is located (27,32). In so doing, changes of slope at sector boundaries disappear, leaving a line along each visible boundary to outline the separate sectors (Fig. 1). In this collapsed form the two {200} sectors are thinner (33) than the other four and may show lines along the *b*-axis, suggesting that shear in {200} planes, parallel to *c*, may also have occurred. Ridged lamellae tend rather to collapse mostly by shear in {310} planes, parallel to *c*, creating a flat lamella, but this is often combined with some rotation of facets revealed by differential sector contrast in dark-field images.

Lamellar Thickness. The thinness of polymer lamellae is very important to crystalline polymers because of the many surfaces it creates that directly affect important properties such as melting point, chemical reactivity, and mechanical behavior among others. The actual thickness is primarily a physical property relating to crystallization rather than one depending on the chemistry of the molecular chain but is affected by chemistry, such as hydrogen bonding, in appropriate circumstances whose requirements limit the thickness to particular, rather than continuous, values. It increases with crystallization temperature (34) [sometimes, as in i-polystyrene, from a constant value at lower temperatures (35)] apparently without limit but as the crystallization rate slows at higher temperatures the higher thicknesses become increasingly unattainable in reasonable times.

Lamellae form because this is the fastest way for long molecules to crystallize. The actual thickness is determined at the growing edge, where a decrease of temperature will leave a sharp step for growth from solution (Fig. 1) but not from the melt (36), for which, with higher temperatures, there is subsequent thickening. This points to secondary nucleation at the growing edge as the determining process. If the lamellar thickness remains close to that of the secondary nucleus,

ℓ, then an expression for lamellar thickness as a function of temperature may be obtained as follows.

The fold surfaces add free energy to the system but crystallization is possible if this can be permanently offset by the free energy of crystallization of fold stems in lamellar interiors. The former quantity is $2\sigma_e/\ell$ per unit volume, where σ_e is the surface free energy per unit area, while the latter is per unit volume, $\Delta_g \approx \Delta h \Delta T/T_m{}^0$, with Δh, the enthalpy of fusion per unit volume; $\Delta T = T_m{}^0 - T_c$, the supercooling below $T_m{}^0$, the equilibrium melting temperature (of an infinitely thick crystal); and T_c, the crystallization temperature. The value of σ_e is $\sim$100 mJ·m^{-2}, an order of magnitude more than for side surfaces, and includes the work of chainfolding. Crystallization becomes possible once $\Delta g > 2\sigma_e/\ell$ requiring that

$$\ell > 2\sigma_e T_m^0 / \Delta h \Delta T$$

or, as usually expressed,

$$\ell = 2\sigma_e T_m^0 / \Delta h \Delta T + \delta\ell$$

with $\sigma\ell$ a small positive length. This expression identifies supercooling rather than temperature as the pertinent variable, which experiments using different solvents have confirmed to be the case (37).

Growth rates initially increase with supercooling when thermodynamics is the controlling factor—it is always faster for chains to fold at a shorter interval, provided they produce stable lamellae—but are liable to pass through a maximum and then decrease when transport becomes dominant (38).

Once formed, the presence of the extensive basal fold surfaces makes lamellae metastable with respect to an increase of thickness and a correspondingly lower melting point. It is readily shown (18) that the melting point, T_m, of a lamella, thickness ℓ, is given by

$$T_m = T_m^0[1 - 2\sigma_e/(\Delta h \cdot \ell)]$$

The second term in brackets gives the depression in melting point caused by lamellar thinness, which is considerable, amounting to $\sim$10–20 K in typical circumstances. The spread of melting points typical of a crystalline polymer is at least partly attributable to the spread of lamellar thicknesses it contains. It is also possible for the reduced melting point of a thin lamella to fall below the crystallization temperature of a thicker one. In this circumstance, gradual heating, such as happens in a DSC scan, is liable to transform the initial lamellar population into a thicker one during the course of the scan (39). Whether this is occurring can be checked by carrying out scan at different heating rates; a sufficiently fast one will record the original population while slower ones will allow a progressive transformation into a higher-melting population (40).

Because a thicker layer is more stable than a thinner one, it is always thermodynamically advantageous for a lamella to thicken irreversibly. If the lamellar thickness equals that of the secondary nucleus, ie $\delta\ell = 0$, then a lamella will melt at its crystallization temperature, as substitution into the two previous equations

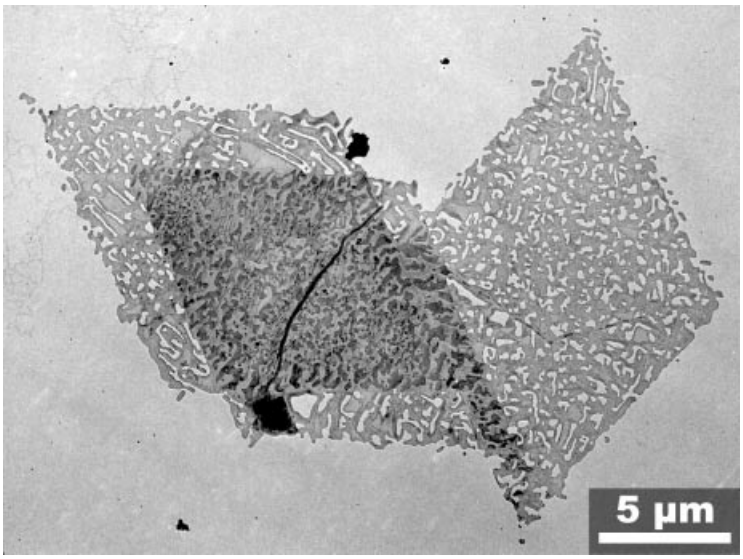

Fig. 2. Solution-grown lozenges of linear polyethylene heated, on a carbon substrate, until they had begun to thicken. Note that holes are confined to single layers; there are none where layers overlay. From Ref. 18.

verifies. That it does not, but at a greater figure, shows that the actual thickness exceeds that of the nucleus. In part this is required to obtain a positive crystallization flux but, in melt-crystallized materials, the discrepancy is so large as to indicate that a process of substantial isothermal lamellar thickening, ~3 for polyethylene (41), has occurred during crystallization. Two mechanisms are possible, partly melting then recrystallizing a sample as above (18) or solid-state thickening without melting (42); both have been identified unambiguously as cited.

Early experiments on solution-grown lamellae revealed not only the earlier melting of the {100} sectors in polyethylene lamellae (25) [which Atomic Force Microscopy (AFM) has confirmed (33) to be thinner than {110} sectors in collapsed, and presumably as-grown, crystals] but also the presence of holes (43) in lamellae that had been heated in contact with a carbon film (Fig. 2). While providing clear evidence of lamellar thickening, the presence of holes is a response to the carbon film, which restrains lateral contraction; holes do not appear on thickened upper layers of the same sample that are not so restrained.

These early and rapid successes in confirming the presence of chainfolding and demonstrating its consequences for solution-grown material brought much speculation as to the situation in melt-crystallized systems when molecules must compete to crystallize rather than add in the comparatively unrestricted circumstances of very dilute solutions. The presence of significant chainfolding in bulk melt-crystallized polyethylene was not finally confirmed until 1979 when analysis of neutron scattering data required that the probability of a molecule folding and reentering a polyethylene lamella at an adjacent lattice site was ≥ 0.67 (44). In the meantime, two morphological routes had been explored to shed light on systems that had still not been studied systematically by TEM.

One was study of polyethylene crystallized from increasingly concentrated solutions (45) to concentrations ~70%, whose principal demonstration was that the same, pseudospherulitic objects so formed had different appearances in different projections. What appeared as a well-faceted crystal in one projection appeared sheaf-like, as in an immature spherulite, in another at right angles while the view from the third Cartesian direction was of separated parallel multilamellar units. Such objects are termed axialites because, to a first approximation, they are formed of lamellae splaying about a common axis. The major difference from melt-grown spherulitic systems is that splaying, of the longer axis, makes *a* radial in solution-grown systems but *b* in melt-grown systems.

The second system was the crystallization of polyethylene under high pressures, ~0.5 GPa. The attraction of this system was that it gives exceptionally thick lamellae, sometimes exceeding 1 μm, which are readily observed in fracture surfaces (46). This behavior results from crystallization of a second polyethylene phase (47), which is hexagonally ordered normal to chains but disordered along them (48). The low heat of fusion brings, as with poly(tetrafluoroethylene) (PTFE), (49,50) a greater lamellar thickness, which then demonstrably increases isothermally. The precise thicknesses are lower in thinner samples (51) but increase with molecular length and crystallization time. They normally exceed 80 nm for polyethylene of 20,000 molecular mass while, for normal homopolymers—commonly attaining thicknesses visible in the optical microscope and sometimes much more—280 μm has been reported (52). Many of the features subsequently found for polymeric crystallization from the melt in general were first demonstrated in this system. They include fractional crystallization and kinetic competition between alternative modes of crystallization (53).

Melt-Crystallized Lamellae. Until the mid-to-late 1970s, radiation damage effectively restricted the examination of the internal lamellar organization of melt-crystallized polymers with TEM to the study of merely their fracture surfaces by replication. Although much was seen of interest in many systems (8), the method is open to criticism because it may not be representative of the material: the fracturing crack may select particular locations, such as concentrations of low mass polymer or follow particular paths through a sample in preference to others. The latter is the case for polyethylene for which {200} surfaces are fractured preferentially (36). These planes contain *b*, the growth direction, so that the view down *b* which is important and diagnostic, is rarely present.

This situation changed with the introduction of two new specimen preparation techniques, chlorosulfonation (54) and permanganic etching (55,56). The first is ostensibly a staining technique for polyethylene, that introduces electron-dense atoms at fold surfaces—chlorine, sulfur and, if uranyl acetate is added, uranium—producing strong contrast of black surfaces and white interiors when lamellae are viewed edge-on. Such images are remarkably stable in the electron beam but in the staining process samples lose much or all of their crystallinity (57) and give lower thicknesses than in fracture surfaces of the same sample (58). This is, nevertheless, a popular technique because it provides a clear measure of the lamellar thickness but it does not show other perspectives well, nor is it useful for other polymers.

Permanganic etching, on the other hand, is able to reveal lamellar textures well in all polyolefines plus a number of other polymers including aromatic

polyamides and poly(etheretherketone) (PEEK). Solutions of potassium permanganate in strong acids, sulfuric and/or phosphoric, selected according to the particular sample, will remove material preferentially from any surface—external, fracture, or cut—of these polymers by selective oxidation, leaving a topography of lamellar textures exposed, which may then be examined by TEM following replication or directly in the scanning electron microscope (SEM) at lower resolution.

The technique was first applied to polyethylene and i-polypropylene revealing itself to be sensitive to crystallinity, lamellar orientation, crystal structure, and crystal defects (55). Thus it penetrates between lamellae; attacks lamellar side surfaces more than their fold surfaces, α- more than β-i-polypropylene; and removes dislocation cores preferentially. As with chlorosulfonation, it allows systematic study of samples by cutting them open where desired. But it can also reveal the particular character of external or fracture surfaces, neither of which is usually random.

Both these two quite different preparative techniques gave the same new information for polyethylene, engendering confidence in its objectivity. Similar features have recurred as the use of permanganic etching has been extended to other polymers. The principal findings are, first, that high crystallinity polymers are full of lamellae; second, that lamellae are not all equivalent; and third, that in polyethylene, lamellae have different profiles, viewed down b, the growth axis, at low and high crystallization temperatures (59).

The first of these removed any lingering doubts that crystalline polymers are lamellar solids. The second lies at the heart of spherulitic growth, which is not only characteristic of melt-grown polymers but is responsible, in large measure, for their intrinsic spatial variation of properties. Inspection of quenched growth fronts shows that spherulites advance by the propagation of individual lead or *dominant* lamellae that branch and diverge. The space between dominant lamellae is, except in very low crystallinity materials, filled in later by *subsidiary* or *infilling* lamellae. This mode of growth tends to give dominant and subsidiary lamellae different properties for two reasons. On the one hand, fractional crystallization—which selective extraction (60) confirms to be widespread, especially at lower supercoolings—places shorter and/or more branched molecules in later-crystallizing polyethylene lamellae (61), with less tactic species similarly located in i-polypropylene. On the other hand, their different orientations, with dominant lamellae being essentially radial but subsidiary lamellae inclined to the radius at angles of 20° and more, makes their mechanical response differ as different deformation modes come into play. The dominant/subsidiary structure is characteristic of polymer spherulites throughout their temperature range of formation (62).

The conditions under which the different profiles of dominant lamellae occur are as follows (59). At crystallization temperatures $\geq\sim 127^\circ$C, melt-crystallized lamellae of linear polymer have {201} fold surfaces, the same basal surface typical of n-alkanes, allowing folds more surface area in a subcell with a comparatively small cross-sectional area per fold stem. Their profile viewed down b, the growth direction, has lamellar normals inclined at $\sim 35^\circ$ to c, indicating {201} surfaces. For higher mass materials, lamellae are planar, but for molecular masses of $\sim$30,000, {201} inclinations alternate in ridged lamellae (Fig. 3a). At immediately lower temperatures, the corresponding profile of dominant lamellae differs: it is then

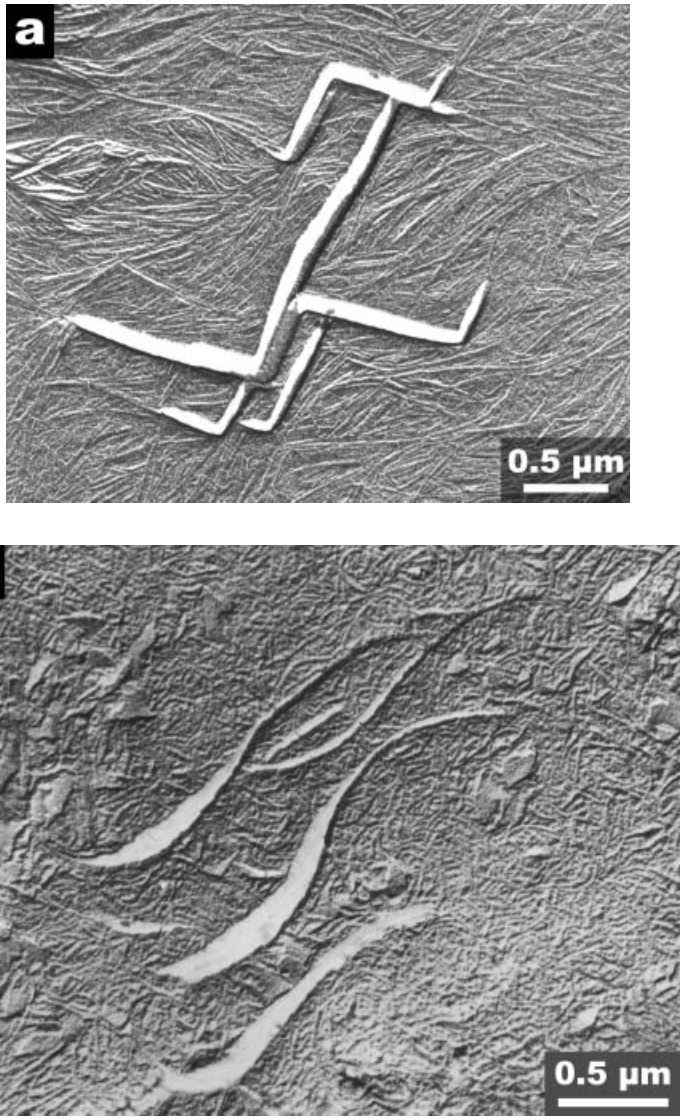

Fig. 3. Profiles of dominant lamellae of linear polyethylene viewed down the growth direction *b*. (**a**) For slower growth, at temperatures $\geq$127°C, lamellae grow with {201} facets. (**b**) For faster growth, at lower temperatures, dominant lamellae display S- or C-profiles. From Ref. 18.

S- or C-shaped (Fig. 3b), with the normal to the center of the S-profile also inclined at a maximum $\sim$35° to *c*, a figure that tends to reduce for lower temperatures and branched polymer. The change coincides with the onset of banding in spherulites, with a consistent orientation of the S-profile for a given sense of twist, an observation that is pertinent to the long-sought explanation of banding in spherulites (to be discussed later). It also coincides, more or less, with a discontinuity in kinetics interpreted as due to a change in growth regime (63). Accordingly, above $\sim$127°C,

depending slightly on molecular mass, regime I would correspond to a single nucleus per characteristic length of growth face while below this figure, regime II would have multiple nuclei active on the growth face.

The reason for the adoption of different profiles becomes clear when the chain inclination to the fold surface is monitored during growth. This is possible when a highly oriented (and so high melting) polyethylene fibre is used as a linear nucleus to form a row structure from a quiescent melt. By examining appropriate sections parallel to the fibre axis (exposed by suitable times of etching down from the outer surface) and looking down b, the inclination can be determined from the nucleus to the outer edge of the row. The change from {201}to S-profiled fold surfaces occurs at a critical growth rate that is characteristic of a given material and decreases for longer and/or more-branched molecules (64,65). The corresponding time to add a single 5-nm-thick molecular layer to the crystal is $\sim 10^{-1}$ s for linear polyethylene of 100,000 molecular mass. For slower growth, {201} surfaces occur and nucleate as such in contrast to faster growth, when lamellae nucleate with {001} surfaces and subsequently transform, behind the growth front, adopting S-profiles and thickening isothermally (65). For slower growth a molecule is able to achieve inclined fold packing as it adds to the crystal, but not for faster growth when improvements in fold packing must be accomplished within the constraints of a surrounding lamella. When a region of inclined packing is produced in the central, ie oldest portion of a lamella, this leads automatically to an S-profile in cross-section (66) (as discussed further below).

The lateral habits of melt-grown polyethylene lamellae are similar to those found for growth from solution at high temperatures in various solvents, ie becoming not only increasingly elongated along b for higher-temperature growth but also displaying increasingly curved side surfaces (67). The {110} surfaces remain planar but become progressively smaller until, for regime I at $\sim 130^{\circ}$C, they are barely detectable and are claimed to be only $\sim$100 nm wide (68). The lateral shape then has been described as elliptic (in the botanical sense) or lenticular, with macroscopically curved side surfaces (Fig. 4a). Theoretical analysis (69,70) explains the macroscopic curvature in terms of a succession of incomplete {200} surface growth strips according to the relative rates of lateral growth and strip completion.

Individual elliptic lamellae are often divided into two sectors along their major axes, especially for long crystallization times at the highest temperatures, corresponding to a single ridge in cross section (71). For lower masses ($\sim$30,000) the ridging becomes multiple (Fig. 4b), with alternate {201} facets extending along the crystal (61,66,71). The quite different habit of lamellae grown in regime II (Fig. 4c), in which no indications of sectorization have been reported, not only has the wider {110} facets expected of lower temperatures but also displays an S-profile, especially in its central, older regions.

The axis of the S-profile is not along b but inclined to it at $\sim 20^{\circ}$, thereby introducing an asymmetry pertinent to the propagation of banded growth that is achieved through isochiral arrays of screw dislocations systematically positioned to one side of the outward axis of the S-profile (66). It is to be expected that the axis of the S-profile will not be aligned along b because of the lack of crystallographic symmetry in fold placement; but to account for the large angle between them it has been suggested that the elastic energy of the nucleating S-profile needs to be

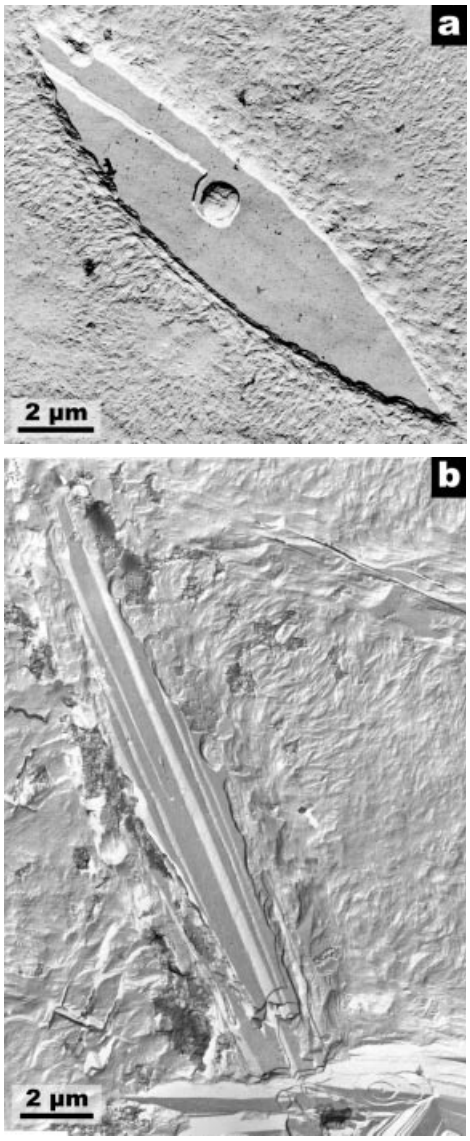

Fig. 4. Melt-crystallized polyethylene lamellae: (**a**) linear polymer crystallized at 130°C as a "planar" crystal in which successive layers spiraling around the central (etched-out) giant screw dislocation are not in contact; (**b**) ridging along *b* in a 17,000 mass fraction of linear polymer crystallized at 129°C; (**c**) an ethyl-branched copolymer crystallized at 123°C showing a central S-profile, asymmetrically placed screw dislocations and new layers diverging therefrom. From Ref. 66.

considered. Once the axis of the S-profile is so inclined then the associated shear stresses as the S-profile progresses lead naturally to the development of isochiral screw dislocations to one side, where the stress is highest.

As for solution growth, the lateral habits of melt-grown crystals reflect both the underlying crystal structure and the kinetics of growth. Thus i-polystyrene

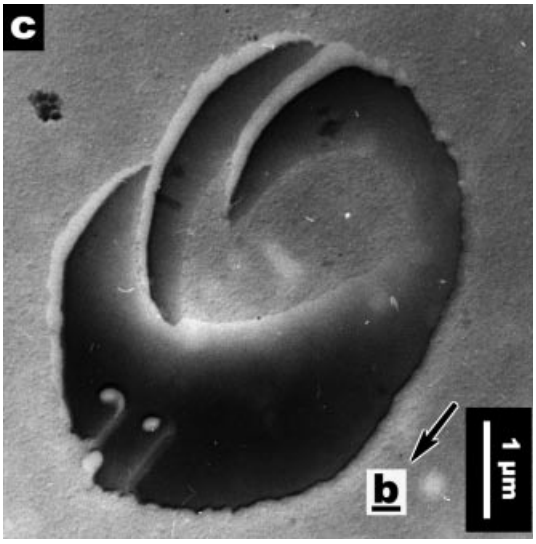

Fig. 4. (Continued)

forms hexagonal lamellae (72) [with sectors revealed by streaks normal to the surface (73) as for collapse of slightly nonplanar solution-grown crystals (14)]. Square lamellae occur for tetragonal i-poly(4-methylpentene-1) (62) and laths elongated along a^* for the monoclinic or α-form of i-polypropylene (74,75). Lamellae are circular for the high pressure hexagonal form of polyethylene when formed from the homopolymer but develop a modulated envelope when grown from a 5:95 blend with branched polymer, probably reflecting difficulties in transport of material as for dendritic growth (76).

Lamellar Surfaces

Polymer lamellae differ from those of oligomers and low mass materials primarily in their fold surfaces, which are a direct consequence of the long molecular length. Although at first, folds were treated as sharp and equivalent to end groups in oligomeric lamellae, with similar packing requirements leading to surfaces of low crystallographic index, the actual circumstances are more complicated. As melt-crystallized polyethylene shows clearly, surfaces form in two ways, depending on whether or not fold packing has time to order as molecules attach to the growing lamella. This is the case for slower growth at low supercoolings, but under normal conditions surfaces form as {001} and subsequently reorganize to inclined states (65). The implication is that surface packing requirements are overridden in rapid growth by the crystallization of fold stems, leaving the initial surfaces rather disorganized. This is true even for monodisperse n-alkanes in which rapid growth on quenching leaves methyl end groups in a disorganized surface (77). On the other hand, for slower growth, surface packing considerations may predominate over lattice distortion as has been explicitly demonstrated in monodisperse alkanes (78,79).

Once formed, polymer lamellae are metastable with respect to thickening and improved fold surface packing, both of which can be accomplished, at sufficiently high temperatures, using the strong longitudinal molecular vibrations. Thickening is accomplished both by an increased height of the growth edge and by incorporation of new material behind the growth front (64). But although the adoption of tighter folding should be relatively unhindered and fold placements should not be greatly altered in this process, the extent to which inclined fold packing can be adopted in an existing lamella is much constrained, hence the S-profiles (66).

The different nonplanar habits of solution-grown polyethylene lamellae (28) may well be open to a similar interpretation, given that the change from hollow pyramidal and chair crystals to ridged lamellae occurs at a similar critical growth rate to that for melt growth. The suggestion at the time (30) that inclined surfaces formed initially as {001} can refer only to the primary nucleus; the {312} inclination, once adopted, is then maintained in both hollow pyramidal and chair crystals. (This contrasts with melt-crystallized row structures for which only secondary nucleation is involved.) If the analogy applies, ridged lamellae with their {314} facets (30) would result from conversion from a rapidly grown lamella initially with {001} surfaces. There are known to be differences in the nature of the corresponding fold surfaces (11).

One of the consequences of surfaces transforming from an initially rough state is that the surface energies, σ_e, for crystallization will be higher than those measured subsequently in eg melting experiments. While fold adjustment at fixed inclination has long been recognized in principle (80), for which a 10% increase has been estimated, the change of inclination now observed is a more drastic change so that fold surface energies for crystallization may be considerably higher than this figure and so far appreciated. In consequence, claims made for the role of metastable phases in crystallization (81) may well be invalid.

Lamellar surfaces provide channels through which gases and liquids may penetrate; it has been shown that they are the preferential site of certain chemical reactions (82,83). Not only is the local density necessarily less at the surface, because of the van der Waals' force as opposed to covalent bonding, but this is supplemented by a degree of disorder, as SAXS data confirm (84). In part this will reflect loose and nonadjacent-reentry folding plus uncrystallized cilia. But the morphology of row structures suggests that there is also a finite separation, less than lamellar thicknesses, between lamellae growing in close-packed array (85). In terms of contemporary understanding, this is likely to be a consequence of cilia pressure during growth by which lamellae are kept apart, with the intervening space occupied by uncrystallized material. There is also evidence from swelling that solvent can penetrate fold surface regions reversibly (86). In sum the several strands of evidence support the concept of an "amorphous" region proximate to lamellar surfaces, which is the model used to interpret SAXS data (84).

Polymer Spherulites

Spherulites, literally little spheres, are a form of higher level ordering readily seen with a polarizing optical microscope (Fig. 5). They are characteristic of

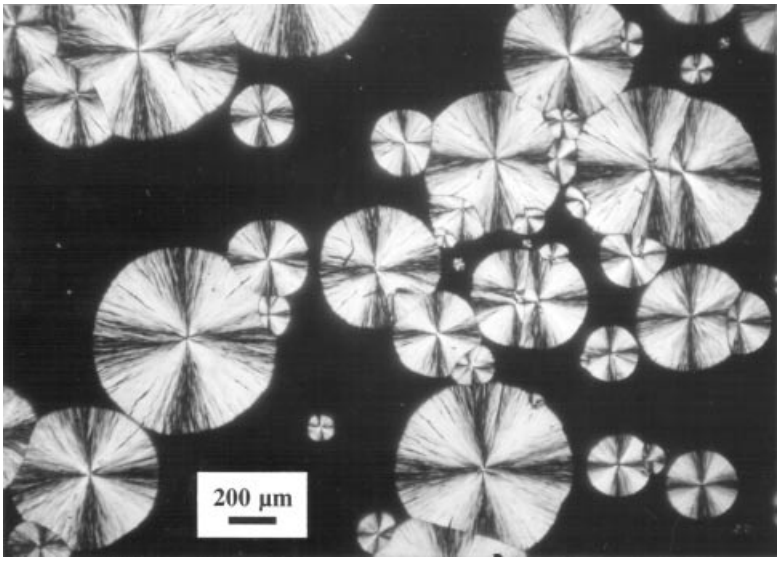

Fig. 5. Spherulites of the α-form of i-polypropylene viewed between crossed polars while crystallizing from the melt at 130°C. From Ref. 85.

melt-crystallized polymers, although their size and internal structure are highly variable depending upon primary nucleation, crystallization conditions, and the molecular constitution of the polymer, allowing the physical texture to be used by a skilled investigator to inform on these same factors. Primary nucleation controls the size and is almost always heterogeneous, ie of extraneous material such as catalyst particles. Homogeneous nucleation has only been demonstrated in systems subdivided into small spheres to isolate heterogeneous nuclei (88,89). Small spherulite size is often desired in commercial material to provide uniform properties but i-polypropylene in its normal α-form is difficult to nucleate and so often contains large spherulites. Most of the illustrations of spherulites in the literature tend to be of specially prepared specimens, often crystallized in thin films to accentuate relevant detail; sections cut from actual specimens may not be so clear or striking in appearance in part because the birefringence contrast of a section, particularly of banded spherulites, varies with distance from the spherulite center (90,91).

Figure 6 shows that the lamellar structure of polymer spherulites is built on a framework of individual dominant lamellae that branch repetitively and then diverge. The reasons for this are discussed below, but this construction leads, on a macroscopic level, to a typical succession of forms before the growing spherulite reaches maturity with a circular envelope and all radii crystallographically equivalent. Starting from an individual lamella, the progression is first to multilayer axialites in which the longest, ie fastest growing, lamellae splay most, presenting a sheaf-like appearance down the principal axis of splay, a lamellar habit at right angles to this and arrays of parallel but separate lamellae down the third Cartesian axis (45,93). When the diverging units eventually meet they enclose an inner area known as an eye or Popoff's leaves (94), which crystallizes separately, usually inward from its boundaries. How far development proceeds in an individual

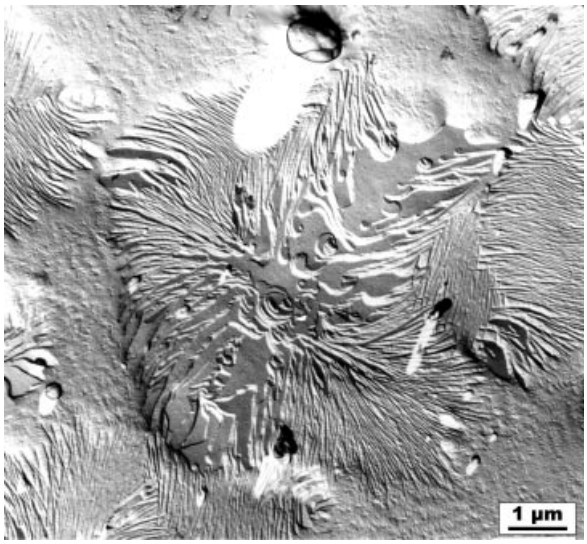

Fig. 6. Lamellar texture of a developing spherulite of linear low density polyethylene grown at 124°C. From Ref. 82.

case before impingement depends upon the nucleation density. The ideal spherical envelope may not have been attained before this occurs and, in particular cases, (95), may always preserve the legacy of its development to great distances. The boundaries between intersecting spheres are hyperboloids whose shape can be used to infer the respective times of nucleation; simultaneous nucleation gives a plane perpendicular to and bisecting the line of centers.

While spherulites grow from effectively point nuclei, other nucleation conditions are often encountered. Row structures result from linear nuclei, commonly fibres, on which growth is epitaxial, giving a cylinder whose radius is the same crystallographic axis as that of the spherulite. Transcrystallization is a consequence of nucleation on a surface to which this same direction is normal. In α-i-polypropylene the isothermal growth rates of all three have been measured to be the same (96). Once nucleated, similar growth processes ensue, unless segregation is significant when different diffusion conditions apply for the different geometries.

Spherulites and their formation are important because they are a major determinant of polymeric properties. Their size may cause significant light scattering, making products appear cloudy while interspherulitic boundaries may be weak, particularly in lower mass materials, and contribute to actual or potential brittleness. Moreover, spatial variability is inherent because diverging dominant lamellae are liable to behave differently from intervening regions. If these are crystalline, the infilling lamellae will probably be inclined to the dominants and contain later-crystallizing molecular species that, in the case of polyethylene, are liable to be shorter (61) and/or more branched (97), with intrinsically different behavior, including lower melting points.

Spherulitic Growth. The dominant/subsidiary lamellar organization within spherulites was not established until the early 1980s, notwithstanding

earlier results from fracture surfaces (8) and stained poly(isoprene) (98) showing that dominant lamellae advanced separately into the melt. There were claims to the contrary that this was restricted to higher growth temperatures (regime I) whereas lamellae were grouped into "fibres" at lower temperatures (99). This view derived in large measure from early attempts to open up the dense textures of spherulites for easier examination by blending, eg atactic with isotactic polypropylene (100). Although for high concentrations of the atactic component the isotactic material does then form multilamellar "fibres," systematic TEM shows that this is a consequence of blending and is not a typical behavior of homopolymer spherulites whose texture is established, over a wide temperature range, by individual dominant lamellae advancing into the melt (95).

The essential problem, concerning spherulitic growth, is to explain how and why a single lamellar precursor develops into a mature object whose radii are, to the resolution of the optical microscope, the same crystallographically, eg b in polyethylene and a^* in α i-polypropylene. The early proposal (101) that this was a problem of morphological instability and cellulation brought about by the segregation of species rejected at the growth front, has been shown not to be the case by the demonstration that, when cellulation does occur, in circumstances of high segregation of species that lower the local growth rate, this sets in only after spherulitic growth is well established (102,103). In other words it is a rather rare event, and an effect, not the cause, of spherulitic growth.

Although characteristic of melt-crystallized polymers, spherulitic growth is met with more widely, generally in viscous, often impure, inorganic systems for example (101,104). This has naturally led to the expectation that its explanation would not be specifically polymeric. What has now been shown in much detail is that there are specific features contributing to spherulitic growth in polymers, that are, however, of sufficient generality to be readily extended to apply to nonpolymeric systems. They are that lamellae diverge because they are pushed apart near their origins and/or that they form with rough surfaces, which do not pack parallel. The first of these was suggested initially from observations of the early stages of growth in which planar lamellae branch at rather regular angles (105–107) reinforced by the fact that successive layers of a spiral terrace (forming around a giant screw dislocation) are not in contact (71). Detailed confirmation, together with evidence for the second mechanism, has come from study of the monodisperse long n-alkanes discussed below.

The geometry of growth cited above, of what are very flexible lamellae, indicates that they grow undeformed after diverging near their origin. The angles of divergence are typically $\sim 20^\circ$ but increase with supercooling, ie for thinner lamellae (62). This requires a mesoscopically short-range repulsive force effective in the immediate neighborhood of a branch point. It was first suggested that, for polymers, this is due to the pressure of transient cilia, ie the uncrystallized portions of molecules partly attached to the growth face (105–107). They must (temporarily) occupy space adjacent to fold surfaces and will resist any competition for it with a rubbery modulus causing adjacent lamellae to diverge unless, exceptionally, they are incorporated within it (87). In another system with similar embryonic geometry, ice growing from a glycerine solution, the agent responsible for the force has been suggested to be osmotic pressure (108).

Monodisperse Long *n*-alkanes. The synthesis of monodisperse long *n*-alkanes, initially by Whiting (109) and then developed by Brooke and co-workers (110), has brought model materials, oligomeric to polyethylene, whose study has shed much light on how linear molecules crystallize. As expected, the methyl end groups tend to locate in basal surfaces giving lamellae of quantized thicknesses $\sim L \cos \theta/n$, where L is the molecular length; θ, the inclination of the c axis to lamellar normals ($\sim 35^\circ$); and n-1, the number of folds (111). This is not an invariable outcome, however, but merely the most ordered state. Unexpectedly the growth rate was found to pass through a minimum when the mode of crystallization changes from one quantized thickness to another, eg extended-chain to once-folded, attesting to the interference, at the growth surface, of one molecular conformer with the other (112).

In relation to spherulites, the first proposal tested was that, to the approximation that fold stems add as integral units, transient cilia and, therefore, spherulites would be present in once-folded growth when only one stem was attached to a lamella but not in extended-chain growth. This exactly matches the behavior of n-$C_{294}H_{590}$ in the region of the changeover between these two forms (113,114). On the other hand, lamellae do begin increasingly to diverge at higher supercoolings in this and other *n*-alkanes even when only extended-chain growth occurs, showing that a more detailed view of the attachment process is appropriate. The deviation of adjacent dominant lamellae is linear in supercooling over the narrow range possible to study, as will be cilium length, when taken to be the excess of molecular length over that of the secondary nucleus, but the plot of deviation against supercooling has a finite intercept at zero supercooling when, by this definition, cilium length must be zero (115). This points to a second factor contributing to lamellar divergence, which has been suggested to be (initially) rough surfaces, which do not pack parallel (116). This novel concept is supported both by SAXS on monodisperse *n*-alkanes and by contemporary work on the formation and reorganization of fold surfaces in polyethylene.

SAXS data show that the quantized thicknesses are not established immediately but that the long period passes through a nonintegrally folded (NIF) form, in which surfaces will not be well defined (77). There are also new infrared data showing that {001} surfaces of solution-crystallized deuterated *n*-alkanes are inherently disordered (117). Similarly, linear nucleation has shown that for most crystallization conditions, polyethylene fold surfaces form as {001} in a stressed condition from which they subsequently transform to S-profiles, with banding (65). Monodisperse n-$C_{294}H_{590}$ also forms banded spherulites of the once-folded form when quenched (113), signifying that, in this condition, its basal surfaces are stressed.

Banded Spherulites. Banded growth (Fig. 7a) is not a general feature of spherulites or rows but occurs in certain systems, seemingly those in which chains tend to be inclined to lamellar normals, these include various polyesters, poly(vinylidene fluoride) and polyethylene. Various strands of evidence on the last two systems have recently come together to provide a rudimentary account and an explanation of what has been a persistent puzzle. Although in some instances rhythmic growth patterns do occur (118), the concentric or spiraling extinction ring patterns are almost, if not always, due to a spiraling of the crystal axes around the maintained growth direction (90,91,118,120). Extinction

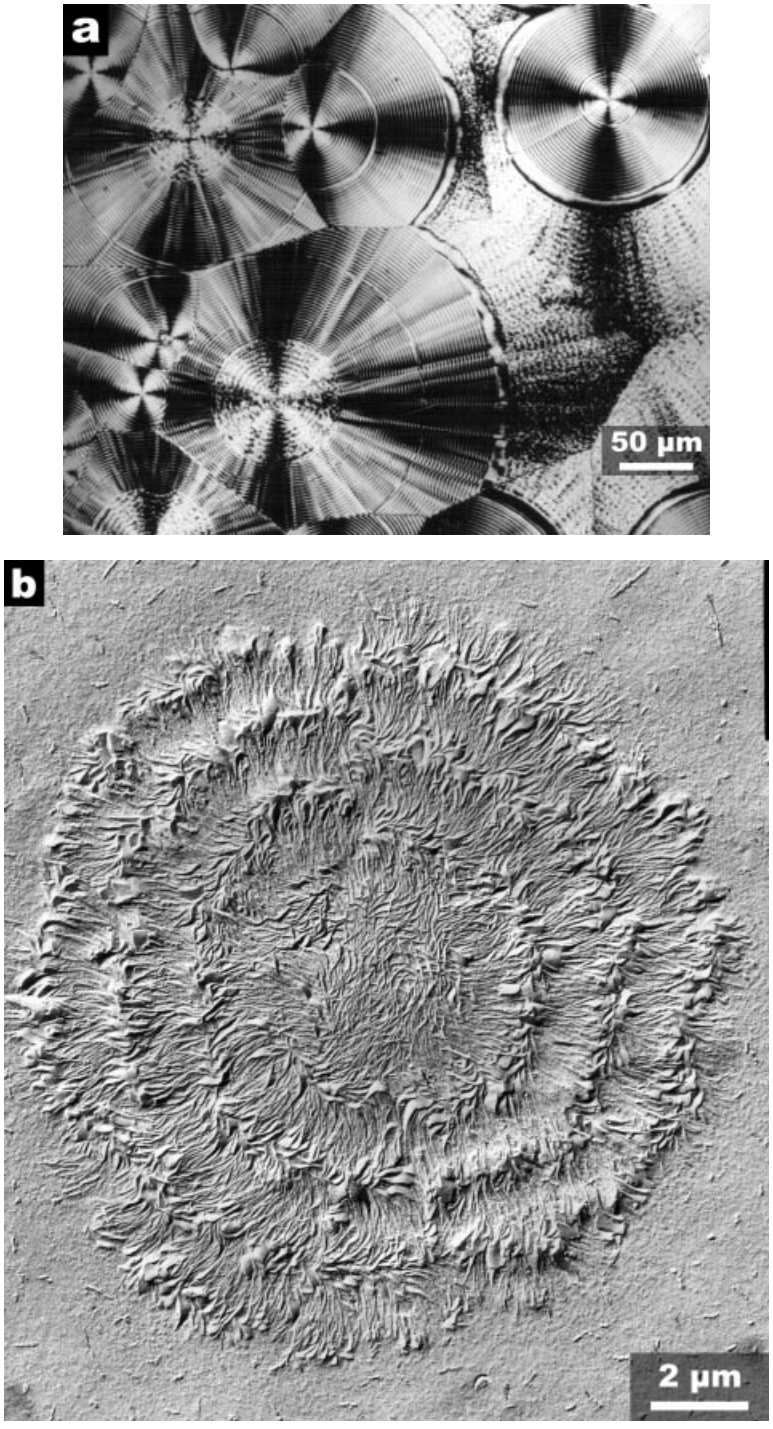

Fig. 7. (**a**) Banded spherulites of poly(trimethylene glutarate) viewed between crossed polars in a polarizing microscope. From Ref. 118.. (**b**) lamellar texture in a banded spherulite of butyl-branched linear low density polyethylene crystallized at 124°C. From Ref. 119.

(blackness) occurs whenever an optic axis is parallel to the viewing direction. For optic axes tangential to a spherulite, a uniaxial system will extinguish once per 180° turn but a biaxial system twice as each axis comes into position in turn.

The optical properties of banded spherulites were explained just as polymer single crystals were discovered but the relationship between the two has only recently been made clear. The average twist spirals uniformly around the spherulite radius, with an associated lamellar rotation (Fig. 7b) but packing considerations rule out uniformly twisted radial lamellae. The link between S-profiled dominant lamellae and twisting in polyethylene, with the concave surfaces advancing with increasing radius, came with the application of permanganic etching (121), but details of precise lamellar morphologies have only recently been published (66,122).

The unambiguous demonstration (6) that, in polyethylene, S-profiles develop after lamellae have formed with {001} surfaces and behind the growth front points to relief of (fold) surface stress as the driving force behind twisting. This will be greater in systems for which the preferred packing is inclined than for those where chains remain normal to lamellae. In polyethylene the asymmetry is introduced by the axis of the S-profile not being parallel to b, the growth axis. It is maintained via a series of isochiral giant screw dislocations positioned systematically to one side, created by the asymmetric shear stress generated by the change of fold surface inclination (66).

The fold surface stress thus described is built in during growth that occurs too rapidly for surfaces to have ordered. There is another situation in which initially ordered fold surfaces become stressed at a later stage when banded growth ensues. This occurs for slow growth of linear low density polyethylene once isothermal thickening brings initially excluded branches into surface regions (123).

Morphology and Mechanical Properties

Morphology affects mechanical properties in two ways. First, the macroscopic property falls below that of the crystal lattice, by some three orders of magnitude for Young's modulus, partly because of disorientation but more significantly because of the interruption of covalent bond sequences by fold surfaces. Second, boundaries and defects such as cracks, crazes, voids and dislocations can cause or influence yield, deformation, and fracture. A recent review of the effect of morphology on mechanical properties has been published recently (124).

Advanced Materials. The first major contributor to enhanced mechanical properties, orientation of chain axes and their covalent bonds, may be achieved by stretching or extrusion of the melt, from solution or gel states, or of solid polymer. But even in highly oriented fibres, the longitudinal Young's modulus is still well below the ideal value (of ∼300 GPa for polyethylene). To approach such figures, fold surfaces need to be reduced in number and/or strengthened with taut tie molecules. Some degree of folding is, however, helpful in retaining toughness, which would be absent for fully extended molecules (125). Various routes have been found to produce tough high modulus polyethylenes commercially, typically in the form of fibres some tens of nanometers in diameter (126–128). Different materials have different internal structures but all possess a transverse texture

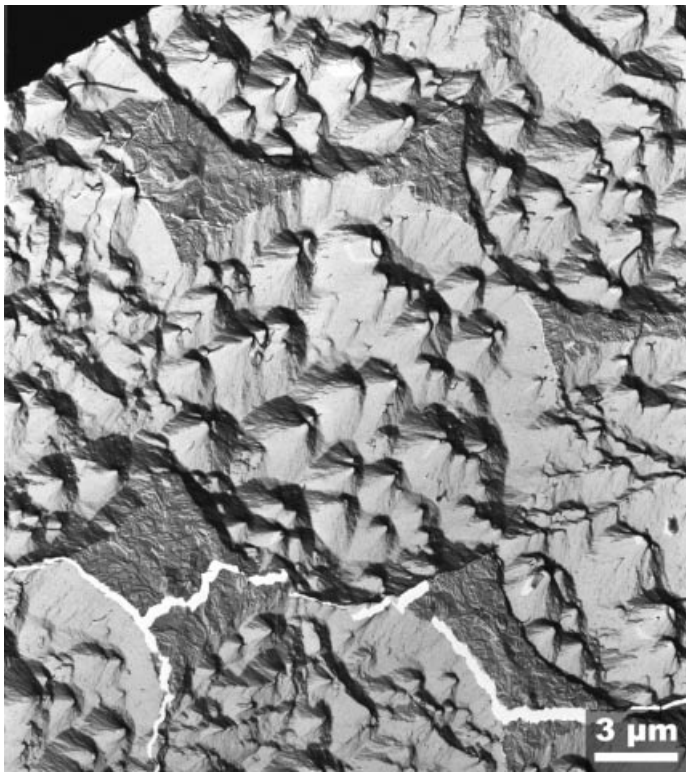

Fig. 8. A uniaxial compaction of high modulus, melt-spun polyethylene fibers seen in transverse section. The interstices between the individual fibres have been filled by material melting from the surfaces and then recrystallizing epitaxially thereon. Replica of etched surface viewed by TEM. From Ref. 132.

of higher melting internal walls from which lower melting lamellae have grown outwards as in transcrystalline growth (129). In longitudinal section, this can give the appearance of parallel shish-kebabs but there is no cylindrical symmetry (130).

Macroscopic samples with similarly good mechanical properties can be manufactured by hot compaction to make self-composites. For example (Fig. 8), an array of high modulus fibres held parallel in a matched mould and heated until just sufficient material melts from the surface to fill the gaps between fibres produces a uniaxial material retaining 90% of the fibre modulus but with good transverse strength, due to epitaxial bonding (131,132). Exceptional impact strengths are achieved by two-dimensional self-composites of polypropylene, made from compacted cloths (133).

Tensile Deformation. Following the discovery of polymer single crystals there was much interest in exploring their deformation behavior; for example, polyethylene monolayers stretched on an extensible substrate reveal a wide variety of transverse deformation modes (134). The influence of folds and the fold plane are evident in the different responses to cracks: those parallel to the fold plane are generally clean in contrast to those normal to it, which are bridged by

drawn threads (135). Detailed study (136) has widened this distinction and shown how local deformation modes of slip favor those in which slip occurs parallel to the fold plane. Such studies tend not to reveal deformation along the chain, whereas with melt-crystallized polyethylene chain slip has been identified as a major mode of lamellar deformation (137). By this, adjacent portions of a lamella can be displaced by shear in the chain direction until folds stop further slip unless covalent bonds are broken (124).

The deformation of spherulitic materials is considerably more complicated. Interspherulitic boundaries are a potential source of weakness, being liable to crack in lower mass material when there is insufficient crack blunting by tie molecules (138). Voids may form where three spherulites meet because of a dearth of material to compensate for the shrinkage in the final stages of crystallization (139,140) For spherulites themselves, there is an initial elastic response (to ∼30% strain) recoverable over many hours or a few days, followed by permanent, inhomogeneous changes with active modes involving various combinations of slip, twinning, and phase changes as identified for solution-grown lamellae (141). Which modes operate in given circumstances is strongly dependent on the orientation of lamellae and their chain axes to the applied stress. Figure 9 shows the different responses of lamellae in a polyethylene spherulite according to their inclination. Under tension or shear, lamellae rotate, disrupt, and/or fragment; under

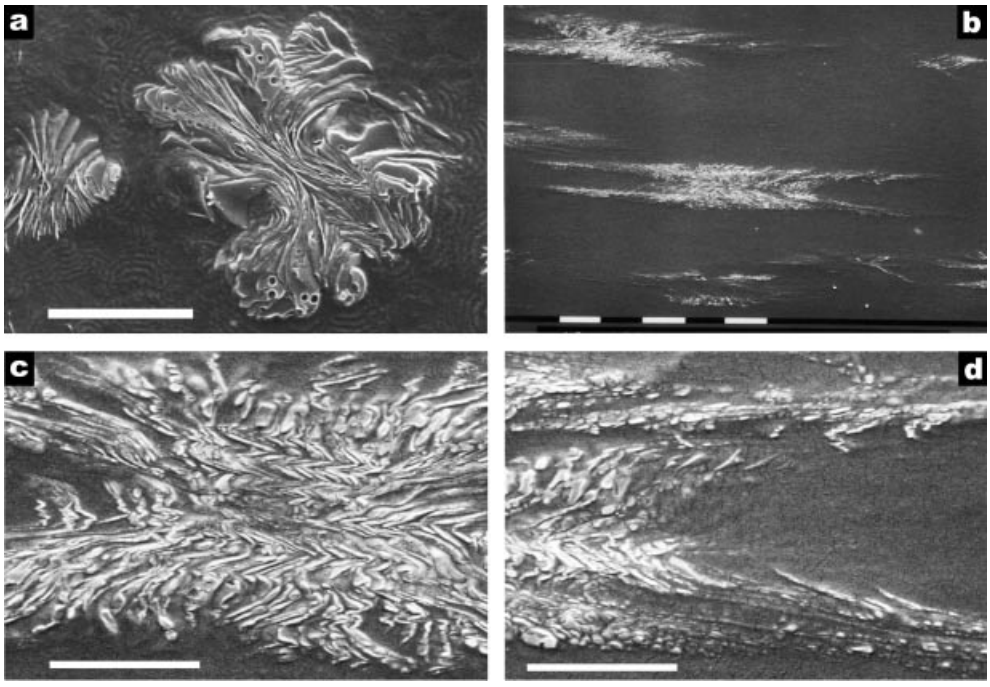

Fig. 9. Immature spherulites in a 5% blend of linear polyethylene in branched polymer: (**a**) undeformed; (**b**) drawn horizontally 4.5× at 75°C; (**c**) detail revealing zigzags of rotated lamellae in phase parallel to the draw direction; (**d**) detail of the extremity of an object as in (**b**), showing how individual lamellae have become disrupted giving an interrupted appearance. SEM images; bar = 10 μm. From Ref. 124.

compression they buckle and then kink cooperatively where the stress is highest (142).

Such situations are complex and it is rarely, if at all, possible to gain sufficient information for a thorough analysis. However, for long it was thought that no memory of the original morphologies remained in the fibrous structures produced at high draw ratios (143). Recent work has shown that this is not so. The earlier conclusion was reached from X-ray and microscopic examination perpendicular to the orientation axis, whereas it has now been shown, by looking down this direction, that traces of the original morphology do survive at high draw ratios ~50 (144,145).

Underlying all mechanical behavior is an important, central, aspect of morphology that lies beyond the scope of current capabilities to resolve. It is an entangled molecular network, transient in thermoplastic polymers, that sustains the applied stress and drives the slow elastic recovery of deformed spherulites, and without which materials would fail. Its extension leads to the extended nuclei for shish–kebabs and/or walls within fibres. One system in which it is suggested where entanglements are located is "overdrawn" fibres of polyethylene or i-polypropylene. These show a series morphology called Pisa structure with alternating draw ratios (146). Crazing and/or fibrillation occur for regions of higher draw ratio but where there is no discernible texture in the intervening regions, of lesser draw ratio, is the possible location of the entanglements.

In summary, polymer morphology in its twin aims of exposing and interpreting the nature of organization in macromolecular systems is essential to advance knowledge and understanding of these complex materials. It is a primary process to be followed, once the pattern of organization has been established, by complementary means to quantify and refine the underlying concepts.

NOMENCLATURE

Overview

Nomenclature, as used in this article, refers to the naming of polymeric materials. The nomenclature of scientific communication is emphasized, although there is generally little reason for differences between scientific and other, eg, commercial, usages.

Since the publication of the first edition of this Encyclopedia, the International Union of Pure and Applied Chemistry (IUPAC) established the Commission on Macromolecular Nomenclature, which was, for the duration of its existence, the leading nomenclature body in the field of polymers. Between its inception in 1968 and the end of 2001, when the IUPAC underwent a major reorganization to a project-driven organization, the Commission promulgated a series of definitions and recommendations that established polymer nomenclature on a much more systematic basis than had previously been the case. The Commission developed a set of definitions for many of the basic terms dealing with polymer molecules, assemblies of polymer molecules, polymer solutions, polymer crystals, polymer melts and solids, polymerization reactions, etc. It also extended existing nomenclature to more complicated cases, such as double-strand (ladder and spiro) polymers. Completion of this work was accomplished by the early 1990s. Table 1 lists the Commission publications on polymer nomenclature.

Polymer naming and terminology became largely systematized and, following the IUPAC practice in other fields of chemistry, a compendium of polymer nomenclature recommendations was published in 1991 (30).

For 2002 and subsequent years, the IUPAC Macromolecular Division established the Subcommittee on Macromolecular Terminology, which has already embarked on the projects listed in Table 2.

Title	Comment	Ref.
Definitions of Terms Relating to Degradation, Aging, and Related Chemical Transformations of Polymers (1996)		23
Source-Based Nomenclature for Non-Linear Macromolecules and Macromolecular Assemblies (1997)		24
Definitions of Terms Relating to the Non-Ultimate Mechanical Properties of Polymers (1998)		25
Definitions of Basic Terms Relating to Low-Molar-Mass and Polymer Liquid Crystals (2001)		26
Generic Source-Based Nomenclature for Polymers (2001)		27
Definitions Relating to Stereochemically Asymmetric Polymerizations (2002)		28
Nomenclature of Regular Single-Strand Organic Polymers (2002)		29

The International Standardization Organization (ISO), primarily through its Technical Committee TC/61 Plastics, and various national nomenclature bodies (such as that of the American Chemical Society) are also helping to shape the field.

Chemical Abstracts Service (CAS) is also an authority on polymer nomenclature. CAS publishes *Chemical Abstracts*, which is available both in printed format and electronically via STN® International, Scientific and Technical Information Network. The *Chemical Abstracts* Registry file provides many examples of CAS polymer nomenclature principles, which are published as Section 222 of Appendix IV in every edition of the *CA Index Guide* (33).

Basic Definitions. No nomenclature document was more fundamental to polymer science than the one which set forth definitions of basic terms. First published by the IUPAC Commission in 1974 (5), this document defined 53 terms, including polymer, constitutional unit, monomer, polymerization, regular polymer, tactic polymer, block polymer, graft polymer, monomeric unit, degree of polymerization, addition polymerization, condensation polymerization, homopolymer, copolymer, bipolymer, terpolymer, copolymerization, and many others. Both structure-based and process-based definitions were given. In 1996, these recommendations were revised, enlarged, and updated (22). The new glossary, which provides a total of 135 terms, deals with three major groups of terms relating to molecules and molecular structure, substances, and reactions. These definitions are essential to any systematic polymer nomenclature and the reader is strongly encouraged to consult the full document.

The Principle of Source-Based Nomenclature. Traditionally, polymers have been named by attaching the prefix "poly" to the name of the real

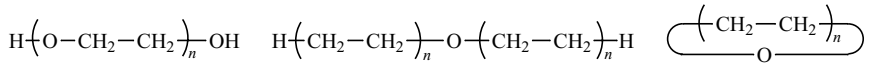
Title	Anticipated Completion Date
Compendium of Macromolecular Terminology and Nomenclature (The Purple Book), 2nd Edition	2003
Definitions of Terms Relating to Reactions of Polymers and Functional Polymers	2003
Glossary of Class Names of Polymers Based on Their Chemical Structure and Molecular Architecture	2003
Guide to Macromolecular Terminology and Nomenclature	2003
Kinetics, Thermodynamics, and Mechanisms of Polymerizations	2003
Terminology and Nomenclature of Macromolecules with Cyclic Structures	2003
Terminology of Polymers with Ionizable Groups and Polymers Containing Ions	2003
Terminology Related to Multi-Phase Polymer Composites and Blends	2003
Terminology and Structure-Based Nomenclature of Dendritic and Hyperbranched Polymers	2003
Nomenclature for Chemically Modified Polymers	2004 or 2005
Nomenclature for Macromolecular Rotaxanes	2004 or 2005
Terminology Used in Sol–Gel Processing of Advanced Ceramics and Inorganic–Organic Polymeric Substances	2005

[a]An italicized title indicates a book; the other items listed will be published as recommendations in *Pure and Applied Chemistry*.

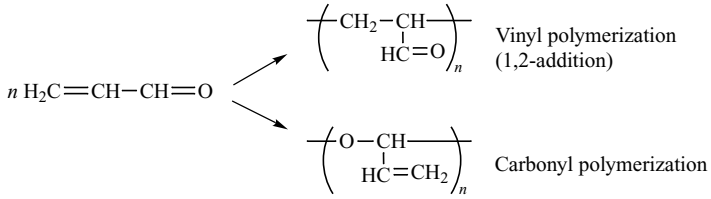
or assumed monomer (the "source") from which it is derived. Thus, polystyrene is the polymer made from styrene. When the name of the monomer comprises two or more words, parentheses should be used (7), as in poly(vinyl acetate), poly(methyl methacrylate), etc. Failure to use parentheses can lead to ambiguity: polychlorostyrene can be the name of either a polychlorinated (monomeric) styrene or of a polymer derived from chlorostyrene; polyethylene oxide can refer to either the polymer **1**, the polymer **2**, or the macrocycle **3**.



1 **2** **3**

These problems are easily overcome with parentheses: names such as poly(chloro)styrene, poly(chlorostyrene), and poly(ethylene oxide) clearly indicate the part of the name to which the prefix "poly" refers. The omission of parentheses is, unfortunately, still common in the literature.

The principal deficiency of source-based nomenclature is that the chemical structure of the monomeric unit in a polymer is not identical with that of the monomer (eg, —CHX—CH_2— versus CHX=CH_2); thus, a "polymonomer" name is actually a misnomer. The structure of the constitutional repeating unit may also not be implied in this scheme; for example, the name polyacrolein does not indicate whether the vinyl or the aldehyde group has polymerized.



Depending on the polymerization conditions, different types of polymerization can take place with many other monomers. Furthermore, a name such as poly(vinyl alcohol) refers to a hypothetical source, since this polymer is obtained by hydrolysis of poly(vinyl acetate).

Despite these serious deficiencies, source-based nomenclature is still firmly entrenched in industrial literature and, to a lesser extent, in scientific communication. It originated at a time when polymer science was less developed and the structure of most polymers was ill-defined. The significant advances made during the last 50 years on the structure determination of polymers is gradually shifting the emphasis of polymer nomenclature away from starting materials and toward the structure of the macromolecules.

The Principle of Structure-Based Nomenclature. Structure-based nomenclature is based on a method of naming the sequence of constitutional or structural units that represent the ideal, and sometimes the actual, repeating pattern of the structure of a typical macromolecule in a polymer. The name has no direct relation to the structure of the (co)monomer(s) used to synthesize the polymer. Details are given below in both the IUPAC Nomenclature and Chemical Abstracts Nomenclature sections entitled "Structure-Based Nomenclature."

IUPAC Nomenclature

Source-Based Nomenclature.

Homopolymers. Although source-based names are usually simpler and less rigorous than structure-based names, historically the Commission has not systematically recommended source-based names for homopolymers because it considered that the more rigorous structure-based names were more appropriate for scientific communications (27). This rationale was based upon two specific points.

(1) A homopolymer that can be represented by a source-based name can usually be given a completely unambiguous structure-based representation, and such a representation should therefore be ideally accompanied by a structure-based name. A source-based name was therefore deemed redundant.

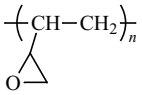
(2) There are cases in which the simplicity of source-based nomenclature leads to ambiguous names for homopolymers. Two examples illustrate this point.
   a. A source-based name such as poly(buta-1,3-diene) or polybutadiene does not indicate whether the structure is 1,2-, or 1,4-; its structure is a result of 1,2- or 1,4-polymerization.
   b. The polyacrylaldehyde example cited above.

Despite the Commission's long-standing position, the scientific community has continued to use source-based nomenclature for homopolymers such as polystyrene and poly(vinyl acetate) because of their simplicity, convenience, and obvious relationship with the monomers from which the homopolymers were prepared. The Commission therefore decided to recommend source-based nomenclature as an alternative official nomenclature for homopolymers in a 2001 publication (27). Consequently, both source-based and structure-based names are now available for most polymers. The names of monomers in the source-based names may be trivial or semi-systematic, if well established by usage, not necessarily only those retained in the 1993 *A Guide to IUPAC Nomenclature of Organic Compounds* (31).

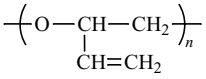
The broad principle is to write the source-based name of a homopolymer by combining the prefix "poly" with the name of the monomer. When the latter consists of more than one word, or any ambiguity is anticipated, the name of the monomer is parenthesized.

The same publication (27) recommended generic source-based nomenclature, which comprises the optional addition of a polymer class name to the source-based name of the polymer. The addition is recommended only to avoid ambiguity or to add clarification.

Example: the source-based name poly(vinyloxirane) is ambiguous; ambiguity about the structure is removed by writing either polyalkylene:vinyloxirane to accompany the structure-based representation



or polyether:vinyloxirane to accompany the structure-based representation



Copolymers. *Copolymers* are polymers that are derived from more than one species of monomer (22). Similarly to homopolymers, source-based nomenclature has been applied to copolymers (14). The principal problem in this scheme is to define the kind of arrangement in which various types of monomeric units are related to each other. Seven types of separate arrangements have been defined, which are shown in Table 3, where A, B, and C represent the names of monomers. The monomer names are linked through an italicized qualifier used as either a connective (infix), such as "*-co-*," to form the name of the copolymer, as in poly(styrene-*co*-acrylonitrile), or a prefix, such as "co". The order of citation of the monomers is arbitrary.

An equally acceptable alternative scheme, shown in the last column of Table 3, utilizes the prefix "copoly" followed by citation of the names of the monomers used, separated from each other by a solidus (oblique stroke). Parentheses are also needed. For example, copoly(styrene/butadiene) denotes an unspecified copolymer of styrene and butadiene. The other connectives of Table 3

Table 3. IUPAC Nomenclature of Copolymers[a]

Type	Arrangement of monomeric units	Representation	Connective	Example	
				Name	Alternative name
Unspecified	Unknown or unspecified	(A-*co*-B)	*-co-*	Poly[styrene-*co*-(methyl methacrylate)]	Copoly(styrene/methyl methacrylate)
Statistical	Obeys known statistical laws	(A-*stat*-B-*stat*-C)	*-stat-*	Poly(styrene-*stat*-acrylonitrile-*stat*-butadiene)	*stat*-Copoly(styrene/acrylonitrile/butadiene)
Random	Obeys Bernoullian statistics	(A-*ran*-B)	*-ran-*	Poly[ethylene-*ran*-(vinyl acetate)]	*ran*-Copoly(ethylene/vinyl acetate)
Alternating	Alternating sequence	$(AB)_n$	*-alt-*	Poly[(ethylene glycol)-*alt*-(terephthalic acid)]	*alt*-Copoly(ethylene glycol)/(terephthalic acid)
Periodic	Periodic with respect to at least three monomeric units	$(ABC)_n$ $(ABB)_n$ $(AABB)_n$ $(ABAC)_n$	*-per-*	Poly[formaldehyde-*per*-(ethylene oxide)-*per*-(ethylene oxide)]	*per*-Copoly(formaldehyde/ethylene oxide/ethylene oxide)
Block	Linear arrangement of blocks	—AAAAA—BBBBB—	*-block-*[b]	Polystyrene-*block*-polybutadiene	*block*-Copoly(styrene/butadiene)
Graft	Polymeric side chain different from main chain[c]	—AAAAAAAAAAAA— | B B B B B |	*-graft-*[d]	Polybutadiene-*graft*-polystyrene	*graft*-Copoly(butadiene/styrene)

[a] Main system described in IUPAC document 14; an alternative scheme is described in the text.
[b] The connective *-b-* has also been used.
[c] Main chain (or backbone) is specified first in the name.
[d] The connective *-g-* has also been used.

Table 4. Examples of the IUPAC Nomenclature Formats for Copolymers

Description	Nomenclature formats
A block copolymer containing 75 mass% of polybutadiene and 25 mass% of polystyrene	Polybutadiene-*block*-polystyrene (0.75:0.25 *w*) or *block*-copoly (butadiene/styrene) (75:25 mass%)
A graft copolymer, comprising a polyisoprene backbone grafted with isoprene and acrylonitrile units in an unspecified arrangement that contains 85 mol% of isoprene units and 15 mol% of acrylonitrile units	Polyisoprene-*graft*-poly(isoprene-*co*-acrylonitrile) (0.85:0.15 *x*) or *graft*-copoly[isoprene/(isoprene; acrylonitrile)] (85:15 mol%)
A graft copolymer comprising 75 mass% of polybutadiene with a relative molecular mass of 90 000 as the backbone, and 25 mass% of polystyrene in grafted chains with a relative molecular mass of 30 000	Polybutadiene-*graft*-polystyrene (75:25 mass%; 90 000:30 000 M_r)
A graft copolymer in which the polybutadiene backbone has a degree of polymerization (DP) of 1700 and the polystyrene grafts have an unknown DP	*graft*-Copoly(butadiene/styrene) (1700:*a* DP)

are placed *before* such names to provide additional structural information, as in *ran*-copoly(ethylene/vinyl acetate) or *alt*-copoly(styrene/maleic anhydride). It is unnecessary to use parentheses to enclose names of monomers comprising more than one word, eg, vinyl acetate, maleic anhydride, methyl acrylate; the names of the polymers, as written here, are unambiguous.

The names of copolymers, derived either from the main scheme or the alternative, can be further modified to indicate various structural features. For example, the chemical nature of end groups can be specified as α-X-ω-Y-poly(A-*alt*-B), as in α-butyl-ω-carboxy-*block*-copoly(styrene/butadiene).

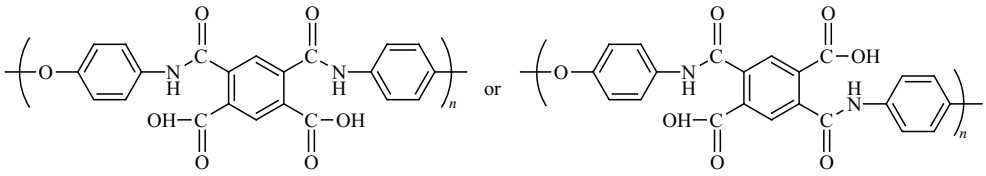
Subscripts placed immediately after the formula of the monomeric unit or the block designate the degree of polymerization or repetition. On the other hand, mass and mole fractions and relative molecular masses, which in most cases are average quantities, are expressed by placing corresponding figures after the complete name of the copolymer. The order of citation is as for the monomeric species in the name. Unknown quantities are designated by *a*, *b*, etc. Table 4 gives some examples.

The complete document (14) should be consulted for names of more complex copolymers, eg, those having a multiplicity of grafts or having chains radiating from a central atom.

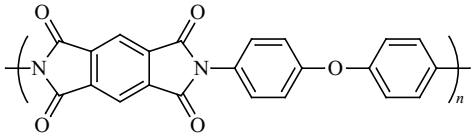
The utility of generic source-based nomenclature (27) can also be illustrated for source-based names of copolymers. As for homopolymers, the addition of a polymer class name is recommended only to avoid ambiguity or to add clarification.

Example: the source-based name poly[(benzene-1,2:4,5-tetracarboxylic dianhydride-*alt*-4,4′-oxydianiline] is ambiguous; ambiguity about the structure is removed by writing poly(amide-acid):[(benzene-1,2:4,5-tetracarboxylic

dianhydride)-*alt*-4,4′-oxydianiline] to accompany the structure-based representation



and polyimide:[(benzene-1,2:4,5-tetracarboxylic dianhydride)-*alt*-4,4′-oxydianiline] to accompany the structure-based representation



In 1997 the principles of source-based nomenclature for regular copolymers were extended to nonlinear macromolecules and macromolecular assemblies (24), which are classified according to the following terms: cyclic; branched (long- and short-branched); micronetwork; network; blend; semi-interpenetrating polymer network; interpenetrating polymer network; and polymer–polymer complex. The range of italicized qualifiers, listed as connectives in Table 3 for regular copolymers, was extended by addition of new qualifiers such as "blend," "comb," "star," or "net." Table 5 lists the new qualifiers, together with examples of their use. Quantitative characteristics of a macromolecule or an assembly of macromolecules, such as mass and mole fractions or percentages as well as the degrees of polymerization and molar masses, may be expressed by placing corresponding figures after the complete name. The complete document (24) should be consulted for details and more examples.

Structure-Based Nomenclature.

Regular Single-Strand Organic Polymers. For organic polymers that are regular (ie, have only one species of constitutional repeating unit in a single sequential arrangement) and comprise only single strands, the IUPAC has promulgated a structure-based system of naming polymers (29). Originally devised by the Nomenclature Committee of the American Chemical Society Polymer Division (34), the system consists of naming a polymer as "poly(constitutional repeating unit)," wherein the repeating unit is named as a bivalent organic group according to the usual nomenclature rules for organic chemistry. It is important to note that in structure-based nomenclature, the name of the constitutional repeating unit has no direct relationship to the source from which the unit was prepared. The name is simply that of the identifiable constitutional repeating unit in the polymer, and locants for unsaturation, substituents, etc, are dictated by the *structure* of the unit.

The steps involved in naming the constitutional repeating unit (CRU) are (*1*) identification of the unit (taking into account the kinds of atoms in the main chain and the location of substituents); (*2*) orientation of the unit; and (*3*) naming of the

Table 5. IUPAC Source-based Nomenclature for Non-linear Macromolecules and Macromolecular Assemblies

Macromolecule or assembly	Italicized qualifier	Examples	Comments
Cyclic	*cyclo*	*cyclo*-Poly(dimethylsiloxane)	
		cyclo-Poly(styrene-*stat*-α-methylstyrene)	
Branched, unspecified	*branch*	*branch*-Polystyrene-*v*-divinylbenzene	Polystyrene cross-linked with divinylbenzene, insufficient to cause a network to form
Short-chain-branched	*sh-branch*	*sh-branch*-Polyethylene	
Long-chain-branched	*l-branch*	*l-branch*-Poly(ethyl acrylate)-*v*-(ethylene dimethacrylate)	
Branched with branch points of functionality *f*	*f-branch* (*f* is given a numerical value)		
Comb(like)	*comb*	*comb*-Poly(styrene-*stat*-acrylonitrile)	Both the main chains and side chains are statistical copolymer chains of styrene and acrylonitrile
		Polystyrene-*comb*-polyacrylonitrile[a]	Main chains of styrene homopolymer; side chains of acrylonitrile homopolymer[b]
		Polystyrene-*comb*-[polyacrylonitrile; poly(methyl methacrylate)][a]	
Star	*star*	*star*-(polyA; polyB; polyC)	A variegated star copolymer molecule consisting of arm(s) of polyA, arm(s) of polyB, and arm(s) of polyC
		star-(polyA-*block*-polyB-*block*-polyC)	Star copolymer molecule, each arm of which consists of the same block copolymer chain
		star-[Polystyrene-*block*-poly(methyl methacrylate)]	Each arm of the star macromolecule is a block copolymer chain, with a polystyrene block attached to the central unit

Table 5. (Continued)

Macromolecule or assembly	Italicized qualifier	Examples	Comments
Star with f arms	f-star (f is given a numerical value)	4-*star*-Polystyrene	
		3-*star*-Polystyrene-*v*-methyltrichlorosilane	
		star-(Polyacrylonitrile; polystyrene) (M_r 100 000:20 000)	Star macromolecule consisting of arms of polyacrylonitrile of a total $M_r = 100\,000$ and arms of polystyrene of a total $M_r = 20\,000$
		6-*star*-(Polyacrylonitrile (f 3); polystyrene (f 3)) (M_r (arm) 50 000:10 000)	A six-armed star macromolecule consisting of three arms of polyacrylonitrile, each of $M_r = 50\,000$, and three arms of polystyrene, each of $M_r = 10\,000$
Network	*net*	*net*-Polybutadiene	
		net-Poly(phenol-*co*-formaldehyde)	
		net-Polybutadiene-*v*-sulfur	Polybutadiene vulcanized with sulfur
		net-Polystyrene-*v*-divinylbenzene	Polystyrene cross-linked with divinylbenzene to form a network
		net-Poly[(hexane-1,6-diyl diisocyanate)-*alt*-glycerol]	
		net-Poly[styrene-*alt*-(maleic anhydride)]-*v*-(ethylene glycol)	Alternating copolymer of styrene and maleic anhydride cross-linked with ethylene glycol to form a network
		Poly[(ethylene glycol)-*alt*-(maleic anhydride)]-*net*-oligostyrene	Unsaturated polyester cured with styrene
		Poly(methyl methacrylate)-*net*-poly(ethylene oxide)	
		[Poly(butyl vinyl ether)-*v*-(2-vinyloxyethyl methacrylate)]-*net*-[poly-(methyl methacrylate)-*v*-(2-vinyloxyethyl methacrylate)]	Poly(butyl vinyl ether) and poly(methyl methacrylate) chains cross-linked mutually with 2-vinyloxyethyl methacrylate to form a network

Micronetwork	μ-*net*	μ-*net*-Poly[styrene-*stat*-(vinyl cinnamate)]	Cross-linked copolymeric micronetwork
Polymer blend	*blend*	Polystyrene-*blend*-poly(2,6-dimethylphenol)	
		(*net*-Polystyrene)-*blend*-(*net*-polybutadiene)	Blend of two networks
Interpenetrating polymer network (IPN)	*ipn*	(*net*-Polybutadiene)-*ipn*-(*net*-polystyrene)	IPN of two networks
		[*net*-Poly(styrene-*stat*-butadiene)]-*ipn*-[*net*-poly(ethyl acrylate)]	IPN of two networks
Semi-interpenetrating polymer network (SIPN)	*sipn*	(*net*-Polystyrene)-*sipn*-poly(vinyl chloride)	SIPN of a polystyrene network and a linear poly(vinyl chloride)
Polymer–polymer complex	*compl*	Poly(acrylic acid)-*compl*-poly(4-vinylpyridine)	Complex of two species of linear macromolecules
		Poly[(methyl methacrylate)-*stat*-(methacrylic acid)]-*compl*-poly(*N*-vinyl-2-pyrrolidone)	Complex of statistical copolymer and homopolymer molecules

[a] In naming nonlinear copolymer molecules having linear subchains of two or more types, the italicized connective for the skeletal structure is placed between the source-based names of the types of constituent linear subchains. In the case of branched and comb-like macromolecules, the linear chain named before the connective is that which forms the main chain, whereas that (those) named after the connective forms (form) the side chain(s). The names of different species of side chain are separated by semicolons. In the case of variegated star macromolecules the prefix is placed before the name of the macromolecule with the different species of arms separated by semicolons.

[b] Equivalent to polystyrene-*graft*-polyacrylonitrile; *-graft-* is recommended for these cases. However, *comb* as a prefix cannot be replaced by *graft*.

unit. The CRUs are named systematically according to the IUPAC-recommended nomenclature of organic compounds (31). Examples of names for some common polymers are given in Table 6. Note that in this system, parentheses, brackets, braces, or a combination of these, are always used to enclose the CRU. For organic names, the IUPAC uses parentheses for the innermost set, then brackets, then braces, and thus {[(. . .)]}. If further nesting is required, this cycle is repeated: ({[(. . .)]}), [({[(. . .)]})], {[({[(. . .)]})]}, etc.

Structure-based nomenclature can be utilized to name polymers of great complexity, provided only that they be regular and single-stranded. Among these are polymers the constitutional repeating units of which consist, themselves, of a series of smaller subunits, polymers with hetero atoms or heterocyclic ring systems in the main chain, and polymers with substituents on acyclic or cyclic subunits of constitutional repeating units. It should be noted that structure-based nomenclature is also applicable to copolymers having a regular structure, regardless of the starting materials used, eg, poly(oxyethyleneoxyterephthaloyl) for poly(ethylene terephthalate) (14).

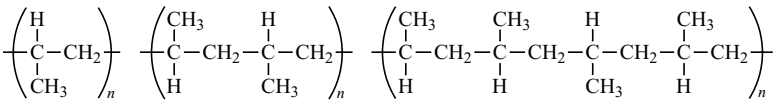
The basic principles of structure-based nomenclature have been extended beyond regular, single-strand organic polymers (29) to single-strand and quasi-single-strand inorganic and coordination polymers (12), double-strand (ladder and spiro) polymers (18), irregular single-strand organic polymers (19), and other complex systems. Work in this field is continuing.

Structure-based nomenclature has gained wide acceptance in the scientific literature, eg, in Chemical Abstracts, because it overcomes many of the deficiencies of source-based nomenclature.

Inorganic and Coordination Polymers. The nomenclature of regular single-strand inorganic and coordination polymers (12) is governed by the same fundamental principles as those for single-strand organic polymers. The name of such a polymer is that of the smallest constitutional repeating unit prefixed by the terms "poly," "*catena*" (for linear chains) or other structural indicator, and designations for end groups. The structural units are named by the nomenclature rules for inorganic and coordination chemistry. Table 7 lists some examples.

Stereochemical Definitions and Notations. Structure-based nomenclature of regular polymers (10) can denote stereochemical features if the repeating unit used is the configurational base unit, ie, a constitutional repeating unit having one or more sites of defined stereoisomerism in the main chain of a polymer molecule (22). Structure-based names are then derived in the usual fashion. The various stereochemical features that are possible in a polymer must be defined.

The pioneering work of Natta and co-workers introduced the concept of *tacticity*, ie, the orderliness of the succession of configurational repeating units in the main chain of a polymer. For example, in polypropene (polypropylene), possible steric arrangements are (shown in Fischer projections displayed horizontally) as follows:



Isotactic Syndiotactic Atactic

Table 6. Examples of Structure-based and Source-based Names for some Common Polymers[a]

Structure	Structure-based name	Source-based or trivial name
	Poly(methylene)	Polyethylene
	Poly(1-methylethylene)	Polypropene; polypropylene
	Poly(1,1-dimethylethylene)	Polyisobutylene
	Poly(1-methylbut-1-ene-1,4-diyl)	Polyisoprene
	Poly(1-phenylethylene)	Polystyrene
	Poly(1-chloroethylene)	Poly(vinyl chloride)
	Poly(1-cyanoethylene)	Polyacrylonitrile
	Poly(1-acetoxyethylene)	Poly(vinyl acetate)
	Poly(1,1-difluoroethylene)	Poly(vinylidene fluoride)
	Poly(difluoromethylene)	Polytetrafluoroethylene
	Poly[(2-propyl-1,3-dioxane-4,6-diyl)methylene]	Poly(vinyl butyral)
	Poly[1-(methoxycarbonyl)-1-methylethylene]	Poly(methyl methacrylate)
	Poly(oxyethylene)	Poly(ethylene oxide)
	Poly(oxy-1,4-phenylene)	Poly(phenylene oxide)
	Poly(oxyethylene-oxyterephthaloyl)	Poly(ethylene terephthalate)
	Poly(iminoadipoyliminohexane-1,6-diyl)	Poly[hexamethylenediamine-*alt*-(adipic acid)] or poly(hexamethylene adipamide)
	Poly[(2,5-dioxotetrahydrofuran-3,4-diyl)-(1-phenylethylene)]	Poly(maleic anhydride-*alt*-styrene)

[a]Ref. 29.

Table 7. Examples of Inorganic and Coordination Polymers[a]

Name	Structure
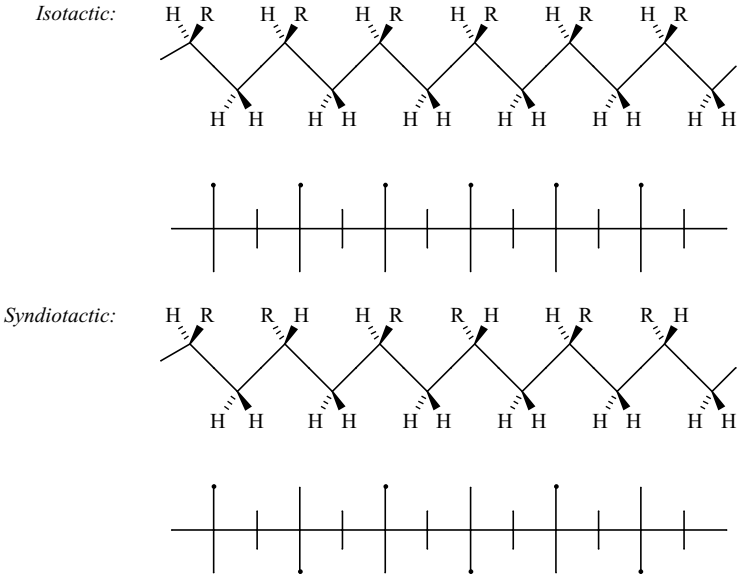
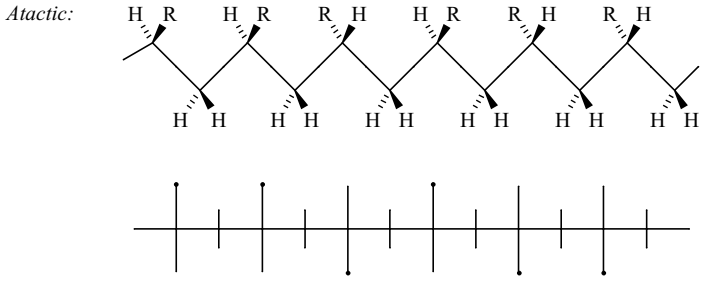
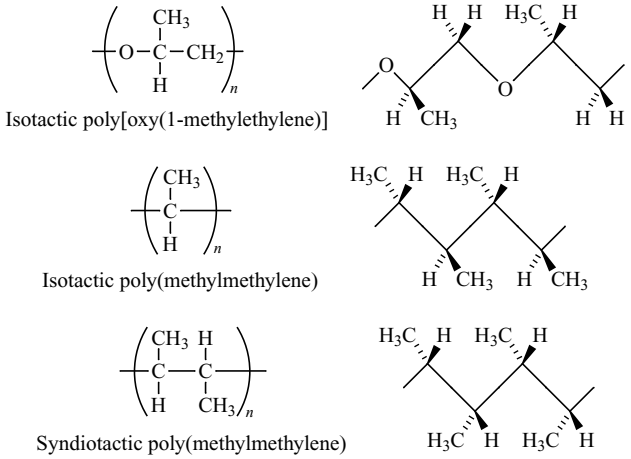
catena-Poly[dimethyltin]	catena-Poly[titanium-tri-μ-chloro]	catena-Poly[nitrogen-μ-thio]	catena-Poly[silver-μ-(cyano-*N*:*C*)]	catena-Poly[(diphenylsilicon)-μ-oxo]	α-Ammine-ω-(amminedichlorozinc)-*catena*-poly[(amminechlorozinc)-μ-chloro]	
[a] If named according to the rules for linear organic polymers (29), the polymers on lines 1 and 5 would be oriented and named poly(dimethylstannanediyl) and poly[oxy(diphenylsilanediyl)] respectively.

An isotactic polymer has only one species of configurational base unit in a single sequential arrangement and a syndiotactic polymer shows an alternation of configurational base units that are enantiomeric, whereas in an atactic polymer the molecules have equal numbers of the possible configurational base units in a random sequence distribution. This can be generalized as follows:





Further examples of tactic polymers are



The published IUPAC document (10) should be consulted for more information.

Regular Double-Strand (Ladder and Spiro) Organic Polymers. Structure-based and source-based nomenclature rules have been extended to regular double-strand (ladder and spiro) organic polymers (18). A *double-strand polymer* is defined as a polymer, the molecules of which are formed by an uninterrupted sequence of rings with adjacent rings having one atom in common (spiro polymer) or two or more atoms in common (ladder polymer).

The structure-based nomenclature rests upon the selection of a preferred CRU (22,29) of which the polymer is a multiple; the name of the polymer is the name of this repeating unit prefixed by "poly." The unit itself is named wherever possible according to the established principles of organic nomenclature (31). For double-strand polymers, this unit usually is a tetravalent group denoting attachment to four atoms. Since some of these attachments may be double bonds, the unit may be hexavalent or octavalent. Table 8 lists some examples.

As in linear, single-strand polymers, substituents that are clearly part of the constitutional repeating unit are denoted by means of prefixes affixed to the name of the subunit to which they are bound.

End groups are specified by prefixes cited in front of the name of the polymer. The ends designated by α and α' are those attached to the left side of the

Table 8. Examples of Structure-Based Nomenclature for Regular Double-Strand (Ladder and Spiro) Organic Polymers

Name	Structure
Poly(buta-1,3-diene-1,4:3,2-tetrayl)	Poly(naphthalene-2,3:6,7-tetrayl-6,7-dimethylene)	Poly[(7,12-dihydro-7,12-dioxobenzo[*a*]anthracene-3,4:9,10-tetrayl)-9,10-dicarbonyl]	Poly(cyclohexane-1,1:4,4-tetrayl-4,4-dimethylene)	
constitutional repeating unit as drawn; the end groups attached to the right side are designated by ω and ω′. End groups are named by the nomenclature rules for organic compounds (31). The designations and names of the end groups proceed in a clockwise direction starting from the lower left: α,α′,ω,ω′. Table 9 lists two examples with substituents (lines 1 and 2) and one with both substituents and end groups (line 3).

Source-based nomenclature identifies the starting monomer(s) from which the double-strand polymer is prepared with addition of an appropriate prefix "*ladder-*" or "*spiro.-*" Examples are

(1) *ladder*-poly(1,4-diphenyldiacetylene)
(2) *ladder*-poly(2,5-dichloro-3,6-dihydroxy-*p*-benzoquinone)
(3) *ladder*-poly[(pyromellitic dianhydride)-*alt*-(1,2,5,6-tetraaminoanthraquinone)]
(4) *spiro*-poly[dispiro[3.1.3.1]decane-2,8-bis(carbonyl chloride)]

The rules are complex, and the published IUPAC document (18) should be consulted for more information.

Irregular Single-Strand Organic Polymers. *Irregular single-strand organic polymers* are single-strand organic polymers that can be described by the repetition of more than one type of constitutional unit or that comprise

Table 9. Examples of Nomenclature for Regular Double-Strand (Ladder and Spiro) Organic Polymers with Substituents and End Groups

Name	Structure
Poly[(1,4-dimethyl-7-azabicyclo[2.2.1]heptane-2,3:5,6-tetrayl)-5,6-dicarbonyl]	Poly(2,4-dimethyl-1,3,5-trioxa-2,4-disilapentane-1,5:4,2-tetrayl)[a]	α,α′-dihydro-ω,ω′-dihydroxypoly(2,4-diphenyl-1,3,5-trioxa-2,4-disilapentane-1,5:4,2-tetrayl)[a]	
[a]The CRU is named using replacement nomenclature ('a' nomenclature) (18,31).

constitutional units not all connected identically with respect to directional sense. A new system (19) names irregular polymers for which the source-based system is inadequate, eg, polymers that have undergone partial chemical modification, homopolymers having both head-to-tail and head-to-head arrangements of monomeric units, and polymers derived from a single monomer that can provide more than one kind of monomeric unit.

The new system also provides a structure-based alternative to source-based nomenclature for copolymers. Irregular polymers, oligomers, or blocks are named by placing the prefix "poly" before the structure-based names of the constitutional units; the latter are collectively enclosed in parentheses, with the names of the component constitutional units separated by solidi (oblique strokes).

Block copolymers are named by using dashes (double-length hyphens) for the bonding of blocks with each other and with junction units. With graft and star polymers, the grafts or the arms, respectively, are considered to be substituents to the main chain, and the structure is named in the same way as a regular or irregular polymer. Table 10 lists some examples.

The published IUPAC document (19) should be consulted for more information.

Table 10. Examples of Nomenclature for Irregular Single-Strand Organic Polymers

Characteristics	Name	Structure[a]
A statistical copolymer comprising units derived from 1-phenylethene and l-chloroethene joined head-to-tail	Poly(l-chloroethylene/l-phenylethylene)	An irregular polymer derived from l-chloroethene, the units of which are linked both head-to-tail and head-to-head	Poly(l-chloroethylene/2-chloroethylene)	A modified (chlorinated) poly(methylene)	Poly(chloromethylene/dichloromethylene/methylene)	A modified (partially hydrolyzed) head-to-tail poly(1-acetoxyethylene)	Poly(1-acetoxyethylene/1-hydroxyethylene)	A triblock copolymer consisting of a sequence of three blocks joined directly or through unspecified junction units	Poly(oxy-1,4-phenylene)–poly(2-cyanoethylene)–poly(ethyleneoxy)	A diblock copolymer in which the blocks are joined by a specific junction unit	Poly(ethyleneoxy)–dimethylsilanediyl–poly(1-chloroethylene)	A graft copolymer with many of one type of graft unit	Poly[methylene/poly(2-phenylethylene)methylene]	A poly(oxyphenylene) with a poly(2-chloroethylene) block grafted through a carbonyloxy group (a junction unit) to the 2-position in some of the rings	Poly{oxy-l,4-phenylene/oxy-2-[poly(2-chloroethylene)carbonyloxy]-l,4-phenylene}	A four-armed star polymer comprising silane substituted with different polymer blocks	Bis[poly(but-2-ene-1,4-diyl)][poly(1-phenylethylene)][poly(2-phenylethylene)]silane	
[a]The dashes at each end of the formulas on lines 1, 2, 3, 4, 7, and 8 are drawn fully inside the enclosing marks, because they do not necessarily denote terminal chemical bonds of the macromolecules.

Chemical Abstracts Nomenclature

Chemical Abstracts Service is the publisher of *Chemical Abstracts* and corresponding products and services, which are available in the following formats: printed, microform, online databases, CD-ROM, World Wide Web. Polymers selected for inclusion in the CAS Chemical Registry System and the *CA Chemical Substance Indexes* are indexed in two ways:

(1) in terms of the component monomer(s) from which they are prepared
(2) in terms of the structural representation of the polymer formed

CAS has published its own set of principles governing how each type of polymer is registered and named (33). Specific polymers are named on the basis of the monomers from which they are formed and/or on the basis of their structure, as represented by a structural repeating unit (SRU). Since original documents sometimes provide insufficient structural information to allow generation of the SRU name, the method most frequently used for describing polymeric substances is by citation of the component monomers. However, a few commercial polymers, including poly(ethylene terephthalate) (PET), nylon-6,6, and nylon-6, each of which has a large number of index entries, are exceptions; they are indexed *only* at the SRU-based systematic polymer name.

CAS chemical nomenclature is in general agreement with the IUPAC recommendations. However, there is one important difference. For any given chemical substance, the IUPAC nomenclature guidelines always lead to an unambiguous name, but not necessarily to only one name. In most communications about chemical substances, this approach causes few problems, but where a formal, rigidly controlled index is needed, such as the *CA Chemical Substance Indexes*, it is insufficiently rigorous. CA Index names must be unique, unambiguous, completely reproducible, and written in a way that brings together alphabetically all structurally related substances (33). CAS recognizes that a unique name is required for indexing purposes and for substance identification, but it is not expected that the highly structured CA Index names would be used in normal communications among authors or lecturers, or in industry and in the primary publications.

The more fully systematic IUPAC rules were adapted for the highly ordered alphabetical CA indexes. Most common names and special rules for some classes of substances were discontinued in 1972. Names used in the previous CA indexes as well as trivial names used in the literature have been retained as cross-references in the *CA Index Guide* and in the CAS database, and are available for polymer searching and retrieval. For each identifiable substance, a rigid order of precedence of chemical functions and compound classes is followed to determine first the preferred *index heading parent*, and then a single preferred name.

Systematic names of chemical substances in the indexes are arranged in inverted format as follows. The *index heading parent* (usually the basic skeleton name with a locant and suffix that denotes the principal function), a comma, any *substituents*, and any *modification* (derivative of the principal function). Table 11 lists some common monomers, with both common names and CA Index names.

Table 11. Examples of Common Monomers with Common Names and CA Index Names

Common name	CA Index name
Acrylamide	2-Propenamide
Acrylic acid	2-Propenoic acid
Acrylonitrile	2-Propenenitrile
Adipic acid	Hexanedioic acid
p-Aminobenzoic acid	Benzoic acid, 4-amino-
Bisphenol A	Phenol, 4,4′-(1-methylethylidene)bis-
Butadiene	1,3-Butadiene
Butylene glycol	1,4-Butanediol
ε-Caprolactam	2*H*-Azepine-2-one, hexahydro-
ε-Caprolactone	2-Oxepanone
Dimethyl terephthalate	1,4-Benzenedicarboxylic acid, dimethyl ester
Ethylene	Ethene
Ethylene glycol	1,2-Ethanediol
Ethylene oxide	Oxirane
Fumaric acid	2-Butenedioic acid (2*E*)-[a]
Glycolic acid	Acetic acid, hydroxy-
Hexafluoropropylene	1-Propene, 1,1,2,3,3,3-hexafluoro-
Hexamethylenediamine	1,6-Hexanediamine
Hydroquinone	1,4-Benzenediol
p-Hydroxybenzoic acid	Benzoic acid, 4-hydroxy-
Isobutylene	1-Propene, 2-methyl-
Isophthalic acid	1,3-Benzenedicarboxylic acid
Isoprene	1,3-Butadiene, 2-methyl-
Lactic acid	Propanoic acid, 2-hydroxy-
Maleic acid	2-Butenedioic acid (2*Z*)-[a]
Maleic anhydride	2,5-Furandione
Melamine	1,3,5-Triazine-2,4,6-triamine
Methacrylic acid	2-Propenoic acid, 2-methyl-
Methyl acrylate	2-Propenoic acid, methyl ester
Methyl methacrylate	2-Propenoic acid, 2-methyl-, methyl ester
4,4′-Methylenedianiline	Benzenamine, 4,4′-methylenebis-
Methylenedi-*p*-phenylene diisocyanate	Benzene, 1,1′-methylenebis[4-isocyanato-
4,4′-Oxydianiline	Benzenamine, 4,4′-oxybis-
m-Phenylenediamine	1,3-Benzenediamine
p-Phenylenediamine	1,4-Benzenediamine
Phthalic anhydride	1,3-Isobenzofurandione
Propylene	1-Propene
Propylene oxide	Oxirane, methyl-
Pyromellitic dianhydride	1*H*,3*H*-Benzo[1,2-*c*:4,5-*c*′]difuran-1,3,5,7-tetrone
Styrene	Benzene, ethenyl-
Terephthalic acid	1,4-Benzenedicarboxylic acid
2,4-Toluene diisocyanate	Benzene, 2,4-diisocyanato-1-methyl-
Vinyl acetate	Acetic acid ethenyl ester[a]
Vinyl alcohol	Ethenol
Vinyl chloride	Ethene, chloro-
Vinyl fluoride	Ethene, fluoro-
Vinylidene chloride	Ethene, 1,1-dichloro-
Vinylidene fluoride	Ethene, 1,1-difluoro-

[a]No typical comma between the parts of the name is present, because of a special formatting rule for large, subdivided index headings.

Table 12. Examples of Multiplying and Substituent Groups with Common Names and CA Equivalents

Common name	CA equivalent	Common name	CA equivalent
Adipoyl	1,6-Dioxo-1,6-hexanediyl	Allyl	2-Propenyl
sec-Butyl	1-Methylpropyl	*tert*-Butyl	1,1-Dimethylethyl
Ethylene	1,2-Ethanediyl	Hexamethylene	1,6-Hexanediyl
Isobutyl	2-Methylpropyl	Isophthaloyl	Carbonyl-1,3-phenylenecarbonyl
Isopropyl	1-Methylethyl	*p*-Phenylene	1,4-Phenylene
Succinyl	1,4-Dioxo-1,4-butanediyl	Terephthaloyl	Carbonyl-1,4-phenylenecarbonyl
Vinyl	Ethenyl	Vinylene	1,2-Ethenediyl

Table 13. Examples of Common Names and Their CA Index Name Equivalents

Common name	CA index name	Molecular formula
Poly(*p*-aminobenzoic acid)	Benzoic acid, 4-amino-, homopolymer	$(C_7H_7NO_2)_x$
Poly(methyl methacrylate)	2-Propenoic acid, 2-methyl-, methyl ester, homopolymer	$(C_5H_8O_2)_x$
Polystyrene	Benzene, ethenyl-, homopolymer	$(C_8H_8)_x$
Poly(vinylidene fluoride)	Ethene, 1,1-difluoro-, homopolymer	$(C_2H_2F_2)_x$

Similarly, many commonly named multiplying and substituent groups have their systematic equivalents in CA indexes. Table 12 lists some examples.

Source-Based Nomenclature.

Homopolymers. The CA Index name is written by citation of the name of the monomer, and the term *homopolymer* is cited in the *modification*. Table 13 lists some examples.

Copolymers. The CA Index name is written by citation of the name of the senior comonomer, in inverted format, followed by a comma. The modification contains the expression "polymer with B, C, D, . . . and Z", where B, C, D, . . . and Z are the names of the other comonomers, alphabetized, and in uninverted format, and also stereochemical and structural terms such as *isotactic, syndiotactic, alternating, block*, or *graft* whenever applicable. The senior comonomer is chosen by a set of principles that include a strict order of precedence of chemical functions and compound classes (33). The format is A, Polymer with B, C, D, . . . and Z in which A, B, C, D,. . . and Z are the comonomers.

Before 2002, for most records, in addition to the CA Index names, systematic Index names were generated for each comonomer. Thus, for a copolymer containing n comonomers, a total of $(n-1)$ additional Index names, each beginning with the name of a different comonomer in the copolymer, were created. This practice was discontinued in 2002. Examples are

(1) CA Index name: 1-Propene, polymer with ethene

(2) Other CA names: Ethene, polymer with 1-propene

Table 14. Examples of Post-Treated Polymers

Post-Treated polymer[a]	CA Index name
Acrylic acid–methyl methacrylate copolymer esterified to an unknown degree to methyl acrylate	2-Propenoic acid, 2-methyl-, methyl ester, polymer with 2-propenoic acid, methyl ester[b]
Acrylic acid–styrene copolymer esterified to an unknown degree to methyl acrylate	2-Propenoic acid, polymer with ethenylbenzene, methyl ester
Ethylene–methacrylic acid copolymer neutralized to an unknown degree to sodium methacrylate	2-Propenoic acid, 2-methyl-, polymer with ethene, sodium salt[c]
Isophthalic acid–ethylene glycol copolymer post-treated to form the diallyl ester	1,3-Benzenedicarboxylic acid, polymer with 1,2-ethanediol, di-2-propenyl ester

[a]The degree of modification (esterification for lines 1 and 2, neutralization for line 3) is not part of the chemical record.

[b]Notice the difference in word order between the CA Index name of this modified copolymer and that of the unmodified methyl acrylate–methyl methacrylate copolymer, in which the second comonomer name is written in uninverted format: 2-propenoic acid, 2-methyl-, methyl ester, polymer with methyl 2-propenoate.

[c]Notice the difference in word order between the CA Index name of this modified copolymer and that of the unmodified ethylene–sodium methacrylate copolymer: 2-propenoic acid, 2-methyl-, sodium salt, polymer with ethene.

(3) CA Index name: 2-Propenoic acid, 2-methyl-, polymer with ethene, 1-propene and 2-propenoic acid

(4) Other CA names: 1-Propene, polymer with ethene, 2-methyl-2-propenoic acid and 2-propenoic acid 2-Propenoic acid, polymer with ethene, 2-methyl-2-propenoic acid and 1-propene

(5) Ethene, polymer with 2-methyl-2-propenoic acid, 1-propene and 2-propenoic acid

The CA Index name of a post-treated (modified) polymer is written by citation of the name of the polymer, inverted as described above; the *modification* segment of the name indicates how the polymer was post-treated. Post-treated polymers fall into two subcategories.

For esters, ethers, and salts of homopolymers and copolymers, this information is associated with the CA Index name and is part of a unique CAS Registry record. Table 14 lists some examples.

For other types of post-treated homopolymers and copolymers, such as those that have been aminated, chlorinated, hydrolyzed, etc, this type of information is present in the Index entry only when associated with a specific document. CAS Registry numbers are not assigned to such post-treated polymers except for use in certain regulatory inventories, such as those mandated by the Toxic Substances Control Act. Table 15 lists some examples.

Telomers are named as copolymers with the term "telomer with" cited in the *modification* under either the monomer (taxogen) or the chain-transfer agent (telogen), depending on which is the senior component. Table 16 lists some examples.

There is no provision for structuring and naming end groups in source-based representations, except for ester-terminated polymers (see Table 14) and mixed polyalkylene glycols (see below).

Table 15. Examples of Post-Treated Polymers (Halogenated or Chlorosulfonated to an Unknown Degree)

Post-Treated polymer	CA Index entry
Post-brominated polystyrene	Benzene, ethenyl-, homopolymer, brominated
Post-chlorosulfonated polyethylene (chlorosulfonation introduces both —Cl and —SO_2Cl groups)	Ethene, homopolymer, chlorinated, chlorosulfonated

Table 16. Examples of Telomers

Telomer	CA index name	Molecular formula structure representation
Vinylpyrrolidone homopolymer terminated with 3-mercaptopropionic acid	Propanoic acid, 3-mercapto-, telomer with 1-ethenyl-2-pyrrolidinone	$(C_6H_9NO)_x \cdot C_3H_6O_2S$ Acrylic acid–vinyl chloride copolymer terminated with carbon tetrachloride	2-Propenoic acid, telomer with chloroethene and tetrachloromethane	$(C_3H_4O_2 \cdot C_2H_3Cl)_x \cdot CCl_4$ $(H_2C{=}CH{-}CO_2H \cdot H_2C{=}CH{-}Cl)_x \cdot CCl_4$

Structure-Based Nomenclature. When the regular structure of a polymer is well documented, or can be confidently assumed, in addition to the main entry with a source-based name, a *supplementary* entry is made for the SRU and its accompanying systematic structure-based name.

Assumptions are made for

(1) polyamides formed from a diamine and a dibasic acid, ester, or dihalide; from an amino acid, ester, or halide; from a lactam;
(2) polycarbonates formed from a dihydric alcohol or phenol and carbonic acid, ester, or dihalide;
(3) polyesters formed from a dihydric alcohol or phenol and a dibasic acid, anhydride, ester, or dihalide; from a hydroxy acid, ester, or halide; from a lactone;
(4) polyurethanes formed from a diisocyanate and a dihydric alcohol or phenol.

The SRU is named by citation of one or more multivalent radicals of regular substitutive nomenclature. The CAS SRU is equivalent to the IUPAC CRU. CAS and the IUPAC are virtually in perfect agreement with regard to the guidelines for identification and orientation of repeating units; the guidelines are given above in the IUPAC section entitled “Structure-Based Nomenclature.”

Table 17. Examples of Structure-Based Representations

Common name	CA Index name	Molecular formula structure representation
Poly(ethylene terephthalate)	Poly(oxy-1,2-ethanediyloxycarbonyl-1,4-phenylenecarbonyl)	$(C_{10}H_8O_4)_n$ (see Table 6 for structure)
Nylon-6,6	Poly[imino(1,6-dioxo-1,6-hexanediyl)imino-1,6-hexanediyl]	$(C_{12}H_{22}N_2O_2)_n$ (see Table 6 for structure)
Nylon-6	Poly[imino(1-oxo-1,6-hexanediyl)]	$(C_6H_{11}NO)_n$ Poly(*p*-phenylene oxide)	Poly(oxy-1,4-phenylene)	$(C_6H_4O)_n$ Poly(*p*-phenylene sulfone)	Poly(sulfonyl-1,4-phenylene)	$(C_6H_4O_2S)_n$ 
Table 18. Examples of Poly(alkylene glycols)

Common name	CA Index name[a]	Molecular formula structure representation
Polyethylene glycol	Poly(oxy-1,2-ethanediyl), (α-hydro-ω-hydroxy-	$(C_2H_4O)_nH_2O$ Polyethylene glycol monomethyl ether	Poly(oxy-1,2-ethanediyl), α-methyl-ω-hydroxy-	$(C_2H_4O)_nCH_4O$ Polybutylene glycol diacetate	Poly(oxy-1,4-butanediyl), α-acetyl-ω-(acetyloxy)-	$(C_4H_8O)_nC4H_6O_3$ 
[a]End-group citation order is governed by a set of rules (33), not by alphabetization.

The CA Index name of a structure-based representation is written by citation of the name of the SRU, parenthesized, and preceded by the prefix "poly." Table 17 lists some examples.

Poly(alkylene glycols) and their ethers and esters are indexed as SRUs; end groups, when known, are added as *substituents* after the name of the repeating unit. Table 18 lists some examples.

Because the fragment sequences are unknown, mixed glycols such as polyethylene–polypropylene glycol or polyethylene–polytetramethylene glycol are

Table 19. List of Abbreviations and Acronyms for Polymers

Abbreviation	Polymer
ABS[a]	Poly(acrylonitrile/butadiene/styrene)
AEPDS[a]	Poly[acrylonitrile/(ethylene/propylene/diene)/styrene] (generic)
AMMA[a]	Poly[acrylonitrile/(methyl methacrylate)]
ASA[a]	Poly(acrylonitrile/styrene/acrylate)
CA[a]	Cellulose acetate
CAB[a]	Cellulose acetate butyrate
CAP[a]	Cellulose acetate propionate
CF[a]	Poly(cresol/formaldehyde)
CMC[a]	Carboxymethylcellulose
CN[a]	Cellulose nitrate
CP[a]	Cellulose propionate
CPE[b]	Chlorinated polyethylene
E/P[a]	Poly(ethylene/propene)
EC[a]	Ethylcellulose
EEAK[a]	Poly(ethylene/ethyl acrylate)
EP[a]	Epoxide resin; epoxy (generic)
EVAC[a]	Poly(ethylene/vinyl acetate)
FEP[a]	Poly[perfluoro(ethylene/propene)]; poly(tetrafluoroethylene/hexafluoropropene)
MF[a]	Melamine/formaldehyde resin
MP[a]	Melamine/phenol resin
PA[a]	Polyamide (generic)
PAC[b]	Polyacrylonitrile
PAN[a, c]	Polyacrylonitrile
PAPI; PMPPI[b]	Polymethylenepolyphenylene isocyanate
PBAK[a]	Poly(butyl acrylate)
PB[a]	Poly(1-butene)
PBI[b]	Polybenzimidazole (generic)
PBT[a]	Poly(butylene terephthalate)
PC[b]	Polyacrylonitrile
PC[a, b, c]	Polycarbonate
PCF[b]	Poly(chlorotrifluoroethylene)
PCO[b]	Polycarbonate
PCTFE[a, c]	Poly(chlorotrifluoroethylene)
PDAP[a]	Poly(diallyl phthalate)
PDMS[b]	Poly(dimethylsiloxane)
PE[a, b, c]	Polyethylene
PE[b]	Polyester (generic)
PEA[b]	Poly(ethyl acrylate)
PEC[b]	Chlorinated polyethylene
PE-C[b]	Chlorinated polyethylene
PEEK[a, b, e]	Polyetheretherketone
PEG[b]	Poly(ethylene glycol)
PEKK[b, f]	Polyetherketoneketone
PEO[b, c]	Poly(ethylene oxide)
PEOX[a, b]	Poly(ethylene oxide)
PET[a, b]	Poly(ethylene terephthalate)

Table 19. (Continued)

Abbreviation	Polymer
PETP[b, c]	Poly(ethylene terephthalate)
PF[a]	Phenol/formaldehyde resin
PFA[a, b]	Perfluoroalkoxy resins[g] (generic)
PIB[a, b, c]	Polyisobutene; polyisobutylene
PMMA[a, b, c]	Poly(methyl methacrylate)
PMP[a, b]	Poly(4-methyl-1-pentene)
POM[a, b, c]	Poly(oxymethylene); polyformaldehyde; polyacetal
POP[b]	Poly(oxy-1,4-phenylene); poly(1,4-phenylene oxide)
PP[a, b, c]	Polypropene; polypropylene
PPO®[b]	Poly(oxy-1,4-phenylene); poly(1,4-phenylene oxide)
PPS[a, b]	Poly(sulfanediyl-1,4-phenylene); poly(thio-1,4-phenylene); poly(1,4-phenylene sulfide)
PS[a, b, c]	Polystyrene
PTFE[a, b, c]	Poly(tetrafluoroethylene)
PTMEG[b]	Poly(tetramethylene ether glycol); poly(tetrahydrofuran)
PU[b]	Polyurethane (generic)
PUA[a]	Polyurea (generic)
PUR[a, b]	Polyurethane (generic)
PVA[b]	Poly(vinyl acetate)
PVA[b]	Poly(vinyl alcohol)
PVAC[a, b, c]	Poly(vinyl acetate)
PVAL[a, b, c]	Poly(vinyl alcohol)
PVB[a]	Poly(vinyl butyral)[h]
PVC[a, b, c]	Poly(vinyl chloride)
PVDC[a, b, c]	Poly(vinylidene dichloride)
PVDF[a, b, c]	Poly(vinylidene difluoride)
PVF[a, b, c]	Poly(vinyl fluoride)
PVFM[a]	Poly(vinyl formal)[i]
PVK[a]	Poly(vinylcarbazole); poly(*N*-vinylcarbazole)
PVME[b]	Poly(vinyl methyl ether)
PVOH[b]	Poly(vinyl alcohol)
PVP[a, b]	Poly(vinylpyrrolidinone); poly(*N*-vinylpyrrolidone)
SB[a]	Poly(styrene/butadiene)
SMS[a, b]	Poly(styrene/α-methylstyrene)
SI[a]	Silicone (generic)
SIS[b]	Poly(styrene/isoprene/styrene)
UF[a]	Urea/formaldehyde resin
UP[a]	Unsaturated polyester (generic)
VC/E[b]	Poly[(vinyl chloride)/ethylene]
VCE[a]	Poly[(vinyl chloride)/ethylene]
VC/E/VAC[b]	Poly[(vinyl chloride)/ethylene/(vinyl acetate)]
VCEVAC[a]	Poly[(vinyl chloride)/ethylene/(vinyl acetate)]
VC/E/MA[b]	Poly[(vinyl chloride)/ethylene/(methyl acrylate)]
VCEMAK[a]	Poly[(vinyl chloride)/ethylene/(methyl acrylate)]
VC/MA[b]	Poly[(vinyl chloride)/(methyl acrylate)]
VCMAK[a]	Poly[(vinyl chloride)/(methyl acrylate)]
VC/MMA[b]	Poly[(vinyl chloride)/(methyl methacrylate)]
VCMMA[a]	Poly[(vinyl chloride)/(methyl methacrylate)]

Table 19. (Continued)

Abbreviation	Polymer
VC/VAC[b]	Poly[(vinyl chloride)/(vinyl acetate)]
VCVAC[a]	Poly[(vinyl chloride)/(vinyl acetate)]
VCVDC[a]	Poly[(vinyl chloride)/(vinylidene chloride)]

[a]Ref. 44.
[b]Ref. 46.
[c]Ref. 7.
[d]"PC" usually means poly[oxycarbonyloxy-1,4-phenylene(dimethylmethylene)-1,4-phenylene], but it can also mean "polycarbonates" in a generic sense.
[e]Structure-based name poly(oxy-1,4-phenyleneoxy-1,4-phenylenecarbonyl-1,4-phenylene).
[f]Structure-based name poly(oxy-1,4-phenylenecarbonyl-1,4-phenylenecarbonyl-1,4-phenylene).
[g]Copolymers of tetrafluoroethylene with perfluorinated alkyl vinyl ethers.
[h]Predominantly poly(vinyl acetate) hydrolyzed to poly(vinyl alcohol) and then cyclized by reaction with butanal (butyraldehyde). Depending upon the degree of hydrolysis, some residual monomeric units of vinyl acetate may be present. See Table 6 for idealized, completely cyclized polymer.
[i]Predominantly poly(vinyl acetate) hydrolyzed to poly(vinyl alcohol) and then cyclized by reaction with formaldehyde. Depending upon the degree of hydrolysis, some residual monomeric units of vinyl acetate may be present.

structured and named as copolymers of the respective monomers:

(1) CA Index name: Oxirane, methyl-, polymer with oxirane
(2) CA Index name: Furan, tetrahydro-, polymer with oxirane

Ethers (end-groups) of such mixed polyalkylene glycols are named analogously to the post-treated (modified) polymers:

(1) CA Index name: Oxetane, polymer with methyloxirane, dipropyl ether

Wiley's *Polymer Handbook* (4th ed.) contains a comprehensive chapter on "Chemical Abstracts Registry Numbers and Online Dabase Searching for Polymer Literature" (35), which contains examples of CA Index names for over 500 homopolymers and copolymers.

Trade Names and Abbreviations

Because the systematic names of polymers can be cumbersome, trade names and abbreviations are frequently used as a shortcut in industrial literature and oral communication. For example, the simple generic name nylon-6,6, in which the first number refers to the number of carbon atoms of the diamine component and the second number to that of the diacid component used to form the polyamide, appears often in the literature in lieu of systematic names such as poly(iminoadipoyliminohexane-1,6-diyl) (structure-based name) or poly[hexamethylenediamine-*alt*-(adipic acid)] (source-based name). Useful compilations of trade names for polymers can be found in references (36–43) and (47–53).

Perhaps the most widely used shortcut is the use of abbreviations for common industrial polymeric materials. The IUPAC recognizes that there may be

advantages in some cases to the use of abbreviations, but urges that each abbreviation be fully defined the first time it appears in the text and that no abbreviation be used in titles of publications. Because of the inherent difficulties in assigning systematic and unique abbreviations to polymeric structures, only a short list has the IUPAC's official sanction (7). This list, published in 1987, will be updated in 2003. ISO published a more extensive list in 2001 (44), and in the mid-1980s the American Chemical Society's Polymer Nomenclature Committee compiled a master-list of all known abbreviations in the polymer field (45). The *Polymer Handbook* (46) contains an extensive list. A selection of abbreviations and acronyms from these sources is reproduced in Table 19.

OPTICAL PROPERTIES

Introduction

Three phenomena take place when light interacts with polymeric materials: absorption, scattering, and transmission through the bulk of the material. In the case of absorption it is possible that emission may take place of some or all of the absorbed energy. In the case of scattering, the light vector changes direction. This change may happen either with a change in energy (inelastic scattering) or without (elastic scattering). The scattered intensity depends on the refractive index variation. In the case of transmission the light propagates through the material and its state of polarization may change.

Polymers have many important optical properties, such as refractivity, reflection, scattering, absorption, clarity, haze, birefringence, stress–optical coefficient, optical configuration parameter, yellowness index, light transmission, gloss, color, and surface texture among others (1).

One application related to polymer rheology is stress field visualization. It relies on birefringence techniques to examine the spatial and temporal evolutions of stress in a polymer melt (see Fig. 1) (2). In this particular example the picture shows the isochromatic fringe patterns of a high density polyethylene melt in the entrance region in capillary flow experiment at 200°C. Techniques such as the application of birefringence to polymer flow problems are very useful in understanding polymer processing.

Extensional flow and structure–property relationships may also be studied by birefringence. A particularly interesting application from transient flow is presented in Figure 2, where phenomena such as overshoot and ringing are observed (3). In this example we see results for 1.5% polyethylene oxide solution for three different velocity gradients. Birefringence detects the presence of an overshoot,

whose magnitude increases with the velocity gradient while the time needed to attain the maximum has decreased. Phenomena such as those are observed after start-up of an extensional flow in a four-roll mill at various strain rates. Theories of polymer rheology can be improved with the insight provided by such experiments.

Market applications based on optical properties of polymers are countless. Polymer optical lenses, CDs, DVDs, and packaging applications for the medical, electronic, food, and cosmetic markets are just a small sampling where optical properties of polymers play a dominant role.

Emerging high technology areas such as optical computing, optoelectronics, and fiber optics are some others. Transitioning from traditional copper wire to fiber-optic cables for faster information transfer, light switches of very high speed, or intensity modulators up to 40 GHz are areas of immense interest in today's market. Altering the frequency of light from red to blue for laser applications and the associated increase of the density of data stored on an optical disk because of the shorter wavelength of blue light has recently been accomplished. Polymers can play a vital role in developing new electrooptical devices, optical waveguides, display screens, optical integrated circuits, amplifiers, attenuators, and photonic switching systems.

Applications in the biomedical area are also very important. Contact lenses, transparent medical tubing, and films for packaging are just few examples. There is literally no area of our life that has not been positively affected by the usefulness of the optical properties of polymers.

Basic Definitions and Computational Prediction of Fundamental Optical Properties of Polymers

Reliable prediction of optical properties allows a better, clearer understanding of the underlying structure–property relationships. This in turn opens new avenues for designing new polymers with desired optical properties. One may rely on

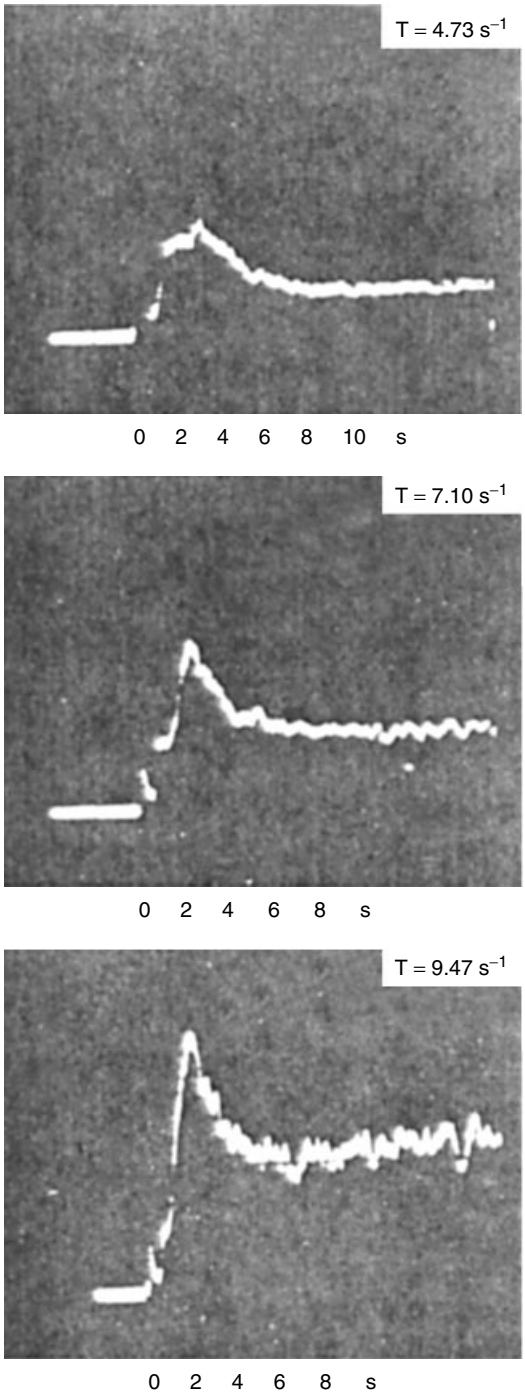

Fig. 2. Overshoot and ringing as observed through flow–birefringence experiments. In this example we see results for 1.5% polyethylene oxide solution for three different velocity gradients. (From Ref. 3).

ab initio (from first principles) and semiempirical models to study polymer fragments and monomers (4). Monte Carlo, molecular dynamics, and QSPR (quantitative structure–property relationships) are also being extensively used to study single chains and multichain polymer systems in bulk and in solution (5). Here we very briefly review the theory and qualitatively look at some of the available methods for predicting optical properties.

Optical Polarizability and Its Anisotropy. The polarizability, α, the constant of proportionality between the induced dipole moment, μ', and the intensity of the applied electric field, E, is of primary importance and is given by (6)

$$\mu' = \mu + \alpha E + \frac{1}{2}\beta E^2 + \frac{1}{6}\gamma E^3 + \cdots \tag{1}$$

where μ is the permanent dipole moment and the parameters β and γ in the nonlinear terms are the hyperpolarizabilities (see also under Nonlinear Optical Properties). Qualitatively, polarizability is the "ease" of the displacement of the electrons around the nuclei because of the presence of the field.

Application of perturbation theory allows the calculation of the electronic polarizability according to

$$\alpha = \frac{2}{3}\sum_n \frac{|\langle 0|\mu|n\rangle|^2}{E_n - E_0} \tag{2}$$

where the numerator is proportional to the square of the electric transition dipole moment μ from the ground (eg 0) to the excited (eg n) states. Dynamic polarizabilities far from an absorption band may be calculated from

$$\alpha(\omega) = \frac{2}{3\hbar}\sum_n \frac{\omega_{n0}|\langle 0|\mu|n\rangle|^2}{\omega_{n0}^2 - \omega^2} \tag{3}$$

where $\hbar = h/2\pi h$ being the Planck's constant and ω the frequency.

It is common to divide the polarizability by $4\pi\varepsilon_0$ to obtain what is called the polarizability volume, which typically has units of $\mathring{A}^3$. According to equation 1, if the two vector quantities μ and E are not of the same direction, then α must be a tensor. Generally for a molecule one may write the polarizability tensor as (7)

$$\alpha = \begin{bmatrix} \alpha_{xx} & \alpha_{xy} & \alpha_{xz} \\ \alpha_{yx} & \alpha_{yy} & \alpha_{yz} \\ \alpha_{zx} & \alpha_{zx} & \alpha_{zz} \end{bmatrix} \tag{4}$$

from which through diagonalization one obtains

$$\alpha = \begin{bmatrix} \alpha_X & 0 & 0 \\ 0 & \alpha_Y & 0 \\ 0 & 0 & \alpha_Z \end{bmatrix} \tag{5}$$

where X, Y, and Z are now the principal axes of the molecule. In the case of spherical symmetry, $\alpha_X = \alpha_Y = \alpha_Z$. Carbon tetrachloride, an optically isotropic

solvent used routinely in depolarized Rayleigh scattering experiments, is a typical molecule with spherical symmetry. For cylindrical symmetry, it holds that $\alpha_Y = \alpha_Z$. This will be true, for example, for the bonds of a polymer chain that is being treated in the freely jointed chain limit.

The anisotropic part of the polarizability tensor is defined as

$$\hat{\alpha} = \alpha - \frac{1}{3}\,\mathrm{Tr}(\hat{\alpha}\hat{\alpha})E_3 \tag{6}$$

where E_3 is the identity matrix of order 3. The quantity $\frac{1}{3}\,\mathrm{Tr}(\hat{\alpha}\hat{\alpha})$ is equal to the mean polarizability.

In some cases it is convenient to employ the following two relationships:

$$\alpha_{||} = \alpha_X - \frac{\alpha_Y + \alpha_Z}{2} \tag{7}$$

and

$$\alpha_{\perp} = \alpha_Y - \alpha_Z \tag{8}$$

where the symbols $\alpha_{||}$ and $\alpha_{\perp}$ denote the longitudinal and transverse anisotropies of the polarizability, respectively.

***Ab Initio* and Semiempirical Approximations and Models.** The general formulas of *ab initio* methods can be used for calculations directly and without approximation, only if the set of wave functions and eigenenergies is known with sufficient accuracy. This is true only in the case of the very simplest atoms and molecules. The "from first principles" approach is to calculate the wave functions by solving the Schrödinger equation exactly. For large molecules, such as polymer fragments and chains, it is currently impossible to produce a set of exact wave functions or to obtain sufficient spectroscopic data. Therefore various assumptions are introduced to alleviate the complexity of the calculations; semiempirical models contain such assumptions—which are beyond the scope of this chapter. However one may rely on semiempirical quantum-mechanical methods to predict (at least qualitatively) properties of polymer chain fragments.

Linear optical properties such as linear polarizabilities can be calculated relying on the theory mentioned above. For nonlinear optical properties there are several approximate methods available too. Some of the most basic ones are given below in a qualitative manner. For further reading a number of excellent books on the subject is suggested (8–10).

Resonant Case. The greatest simplification of the general formulas for the susceptibilities (see under Nonlinear Properties) can be made in the case when the nonlinear process under study is resonantly enhanced. In this case one aims to extract the significant resonant terms from the full expression for susceptibility, $\chi^{(n)}$, and then piece together the contributions from all the other levels into a negligible term. The resonant contribution may then be calculated using the best available wave functions for the resonant levels. One could also choose to use experimental data for the selected transition frequencies and oscillator strengths. In the case when one pair of levels provides the dominant resonant contribution, a two-level model is appropriate.

Resonant Two-Level Atom Systems. The description of resonant optical processes is greatly simplified by focusing on the dominant resonant transition. The model is based on a concept of an ensemble consisting of many two-level atoms that are identical and noninteracting. By "two-level," one refers to two energy eigenstates that are used to describe the atom. An alternative approach is to consider the eigenstates of the system and the optical field taken together (often called "dressed" atoms approach).

Unsoeld Approximation and Charge Models. In the case when all the combinations of optical frequencies involved are far removed from molecular resonances the hyperpolarizabilities do not depend on the details of the energy structure but only on the chemical bonding. The hyperpolarizabilities depend on the detailed distribution of charges in the ground state *only*, together with statistical averages of the frequencies and oscillator strengths of transitions to the excited states.

For saturated molecules in which the electrons are localized in bonds, the moments can be estimated using the vector sum of the polarizabilities of the individual bonds, and the interaction between bonds is neglected (bond additivity scheme).

Sum Over States (SOS). This method computes molecular orbitals, from which values for transition frequencies may be calculated. First the electronic ground state of the molecular system is determined, after which one may apply either the Hartree–Fock–Roothan method or the LCAO (linear combination of atomic orbitals) approximation. Then one accounts for correlations by configuration interaction calculations to form the lowest-energy excited states and transition dipole moments of the molecule. Finally transition frequencies and dipole moments are employed along with the formulas for the hyperpolarizabilities. The SOS method needs as input, energies and transition moments for excited states. It yields $\beta(\omega)$ directly (eq. 1); identification of contributing excited states is important.

Finite-Field Method. This method relies on deriving the various terms in the power series for the static-induced molecular dipole moment in terms of derivatives with respect to the local field. Therefore, if the molecular dipole moment can be calculated as a function of local electric field E then β_{ijk} is obtained from the second derivative of this function at $E = 0$.

The Local Field

The role of local field is very important in determining optical properties of polymers, both in solution and in the bulk (11). It becomes particularly critical in measurements where polarized light is involved. It is therefore reasonable to include a short description in this chapter.

In a vacuum the electric field E is defined in terms of the force experienced by an infinitesimal test charge that can be placed at any point in space. However this cannot be done within systems like a polymer melt or a polymer solution, since, by definition, the space where we would like to measure the field is already occupied by either a polymer fragment or a solvent molecule.

Typically, the standard definition of E at a point in a polymer system proceeds analogously to the procedure in vacuum except that one first creates a needle-shaped cavity oriented along the field direction. This definition has its own limitations: the shape of the cavity in which E is defined will probably be different from that of the definition; real charges will probably not have an appropriately shaped cavity around them. The actual field must be modified by allowance of the real shape of the molecule to which the charge belongs. The definition neglects the fields due to the other charges that belong to the molecule under consideration. E is defined in the absence of the other charges that belong to the molecule. Even if the interaction of these charges is already taken into account in the quantum-mechanical calculation of the molecular states in vacuum, there are contributions mediated through material outside the cavity that must be included.

Lorenz–Lorentz theory addressed the issue by extending the approach of Clausius–Mossotti to optical frequency fields (12,13). This extension relies on a spherical cavity (compare with the need for a needle-shaped cavity) and takes into account the effect of other charges. The only thorny issue is that a spherical cavity is not the best choice for anisotropic molecules. Nevertheless, the Lorenz–Lorentz approach has been widely used in studying optical properties of polymers (14). The expression of the local field is given by

$$L = \frac{n^2 + 2}{3} E \tag{9}$$

Using the molecular shape as a guide to develop the anisotropic cavity field may be a more realistic way of dealing with the issue. Boundary conditions could be a needle-shaped cavity and a disk-shaped one.

For polarized measurements the relationship between refractive index and absorbance is critical. Directional absorbance changes lead to birefringence, which in turn will affect strongly the nature of polarized light. The Kramers–Kronig relations come into play for cases like this one (15). They relate the complete electromagnetic absorption spectrum of a material to its refractive index at all frequencies and vice versa. A form of the relation is

$$\Delta n = \frac{2.303Cc}{2\pi^2} P \int_0^\infty \frac{\varepsilon(\nu')d\nu}{\nu'^2 - \nu^2} \tag{10}$$

Δn is the contribution to the refractive index due to the solute whose concentration is C (mol/L), c is the speed of light, and $\varepsilon(\nu')$ is the molar extinction coefficient. Δn is the difference between the refractive indexes of the solution and the solvent. Δn is essentially the isotropic contribution to the refractive index by the solute whose absorption spectrum determines $\varepsilon(\nu')$. It should not be confused with birefringence, which uses the same symbol (see under Birefringence). A common application of the Kramers–Kronig relation appears in light scattering, especially when one is interested in the effects of scattering on absorbance measurements.

Refractive Index

According to the ISO definition (16), refractive index is the ratio of electromagnetic radiation *in vacuo* to the phase velocity of electromagnetic radiation of a specified frequency in the medium. The refractive index is always greater than unity and it is dimensionless. For anisotropic materials the state of polarization of the light and its direction must be defined relative to a reference axis in the sample.

The two experimental methods recommended by ISO-489 are the Abbe refractometer technique and the Becke line technique. The latter is more useful with powdered or granulated transparent material or even with small flakes of material taken from a larger sample. ASTM D542 method includes only the Abbe method and it is widely used for the characterization of refractive index of polymers.

The refractive index decreases with increasing wavelength. The term *dispersion curve* refers to the graphical representation of that dependence (Fig. 3) (17).

One may estimate the refractive index in terms of the molar refraction R, which quantifies the intrinsic refractive power of the structural units constituting the polymer. According to Refs. 18 and 19 the molar refraction R_{LL} is given as

$$n = \sqrt{\frac{(V + 2R_{LL})}{(V - R_{LL})}} \tag{11}$$

According to another definition, by Gladstone, molar refraction R_{GD} is given by

$$n = 1 + \frac{R_{GD}}{V} \tag{12}$$

The value of n increases with the refractive power of the polymer. There is no simple correlation between high mass density and high refractive index for all polymers. For example, the densities of many polymers containing aromatic rings are not especially high, but these polymers usually have high refractive indexes.

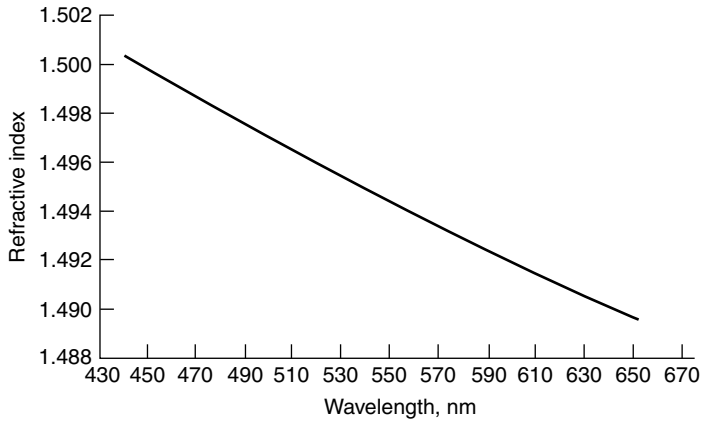

Fig. 3. Dispersion curve for an acrylic cast sheet (From Ref. 17).

Both the intrinsic refractivity and the density are key physical factors determining the refractive index.

Both R_{LL} and R_{GD} have relatively little dependence on temperature and crystallinity. On the other hand the molar volume V changes drastically with both of those properties. In particular, volume increases with temperature while it decreases with increasing crystallinity. As a result the refractive index decreases with increasing temperature and increases with crystallinity. The refractive index undergoes a change at the glass-transition temperature.

The temperature dependence of n is quite similar for all polymers. An empirical rule for glassy polymers (21) is that n decreases by about 1×10^{-4} to 2×10^{-4} per degree Kelvin increase of temperature. For isotropic amorphous polymers above T_g that value changes to about 3×10^{-4} to 5×10^{-4} per degree Kelvin, at typical temperatures. Since n can never be less than unity the rate of decrease with increasing temperature above T_g eventually levels off and asymptotically approaches zero. However, most polymers will degrade long before reaching temperatures high enough to for such a phenomenon be observed. Therefore the empirical rule mentioned above is valid for (moderate) temperatures of practical interest.

Typically one aims to predict the refractive index of the amorphous limit for a semicrystalline polymer. After that the effect of crystallinity may be calculated by using either R_{LL} or R_{GD} combined with an estimate of the change in volume due to crystallization. A large collection of refractive index data on polymers may be found in *Physical Properties of Polymers Handbook* by the American Institute of Physics (22). A representative albeit necessarily short list is given below in Table 1.

Bicerano, in his book *Prediction of Polymer Properties*, proposes the following predictive equation for the refractive index at room temperature (23):

$$n = 1.885312 + 0.024558(17^0\chi^v - 20^0\chi - 12^1\chi^v - 9N_{rot} + N_{ref})/N \qquad (13)$$

χ^0, $^0\chi^v$, and $^1\chi^v$ are the connectivity indexes; N_{rot} and N_{ref} are correction factors that account for crystallinity and for contributions of certain atoms such as F, Si, and ring structures.

The graphical representation of the correlation is given in Figure 4.

Specific Refractive Index Increments. The rate of change of refractive index n of a dilute solution with changing polymer concentration C plays an

Table 1. Refractive Indexes for Some Polymers

Polymer	Refractive index	Temperature, °C
Nylon 6,6	1.566	See Ref. 22

Polyethylene (0.914 g/cc)	1.5050	25
Poly(tetrafluoroethylene)	1.555	20

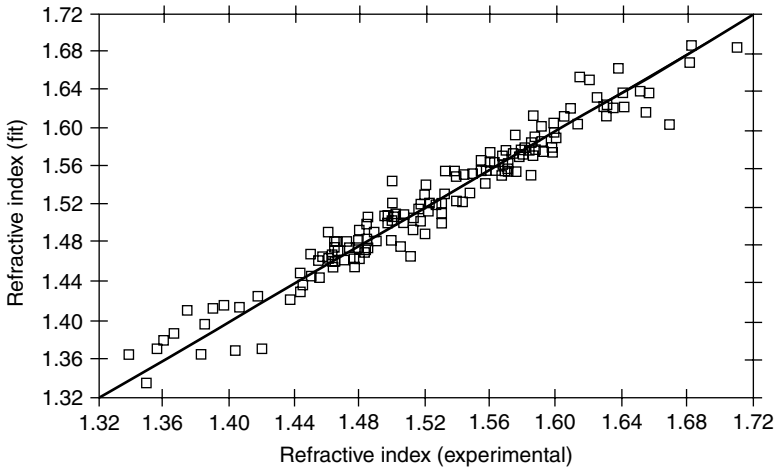

Fig. 4. Refractive index correlation for a series of polymers. Standard deviation: 0.0157; correlation Coefficient: 0.9770. The line denotes $y = x$. (From Ref. 23). □, $n(298\ \mathrm{K}) \approx 1.885312 + 0.024558(17.0\chi \mathrm{v} - 20.0\chi - 12.1\chi \mathrm{v} - 9N_{\mathrm{rot}} + N_{\mathrm{ref}})/N$.

important role in the extraction of information from light-scattering experiments, in particular for the determination of weight-average molecular weights (see Fig. 5). That change depends on the polymer, solvent, and temperature (20).

$$\frac{dn}{dC} \approx \frac{(n_{\mathrm{polymer}} - n_{\mathrm{solvent}})}{\rho_{\mathrm{polymer}}} \tag{14}$$

The correlation outlined above relies on values of refractive index and of density for the amorphous phase. All results are for room temperature.

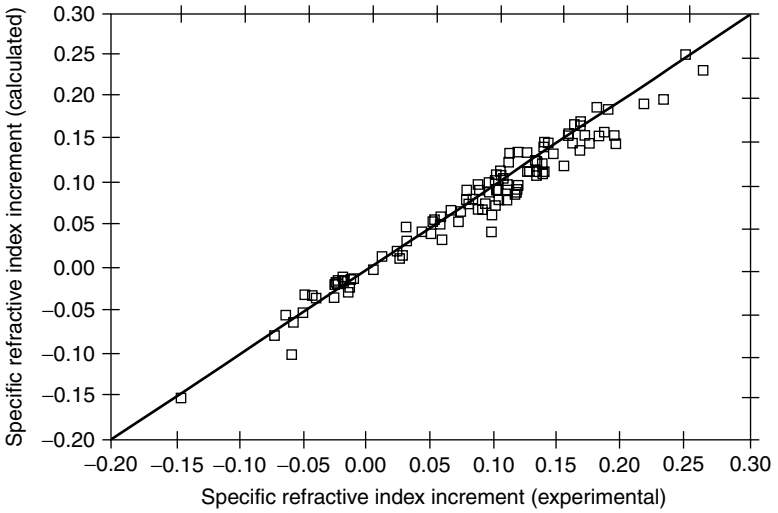

Fig. 5. Correlation for specific refractive index increments for a series of polymers. Standard deviation: 0.0158; Correlation coefficient: 0.9796. The line denotes $y = x$. (From Ref. 23).

Refractive Index Fluctuations in Glassy Polymers. Fluctuations in the refractive index within the bulk of a polymer can arise because of various optical inhomogeneities. Those fluctuations may be described by a radial correlation function, defined as

$$\gamma(r) = \frac{\langle \eta_i \eta_j \rangle_r}{\langle \eta^2 \rangle_{\text{av}}} \tag{15}$$

where η_j and η_i are the refractive indexes at positions i and j respectively, being at a distance r from each other. The brackets denote averages at all pairs of points at distance r apart.

At $r = 0$ the correlation function approaches unity. A common expression is

$$\gamma(r) = \exp(-r/a) \tag{16}$$

constant α being the correlation length. For PMMA, for example, α is at 100–200 nm.

Fluctuation in the refractive index will affect the intensity of the scattered light. According to Debye–Bueche (24) the scattered intensity at an angle θ to the incident beam has intensity I, given by

$$I \sim \langle \eta^2 \rangle_{\text{av}} \int_0^\infty \gamma(r) r^2 \frac{\sin Sr}{Sr} dr \tag{17}$$

with

$$S = 4\pi/\lambda \sin(\theta/2) \tag{18}$$

For PMMA the root mean square refractive index fluctuation is around 2×10^{-4}. The larger the fluctuations, the larger is the scattering intensity. This is critical for applications such as fiber optics, where transmission distances are critical.

Refractive Index and Orientation Fluctuations in Semicrystalline Polymers. The crystals of semicrystalline polymers are optically anisotropic. The simplest spherulite-based model for predicting light scattering is a sphere of radius r with a different polarizability in the radial direction α_r than in the tangential direction α_t (25). Assuming vertically polarized incident light, the intensities of the two scattered components (vertical and horizontal) are

$$I_{\text{VV}} \sim \cos^4 \mu_A (\alpha_t - \alpha_r)^2 + \cdots \tag{19}$$

$$I_{\text{HV}} \sim \sin^2 \mu_A \cos^2 \mu_A (\alpha_t - \alpha_r)^2 \tag{20}$$

where μ_A is the azimuthal angle in the scattering pattern. The HV component will have a maximum intensity in the θ direction at

$$\sin\left(\frac{\theta_m}{2}\right) = \frac{1.025}{\pi}\left(\frac{\lambda}{r}\right) \tag{21}$$

Therefore the scattering maximum moves to larger θ values as the mean spherulite radius decreases. For unpolarized incident light the scattering pattern becomes axially symmetric, with intensity independent of the angle μ_A.

There is always a concern when one tries to optimize properties such as transparency and toughness, because the requirements for those two in terms of particle size conflict with each other. For example, rubber-toughened ABS is opaque because the particle size of the rubber particles is kept at 1 μm in order to optimize toughness.

Another example is that of isotactic PP film produced on a cast film line. Its optical properties can change considerably by changing line conditions such as die temperature and chill roll temperature. Line speed affects cooling time and is therefore important too in affecting optical properties. All those conditions affect the development of the crystalline structure of the film, which in turn is related to its optical properties. Random copolymers of PP will have better optical properties than homopolymers, because of their inherently lower crystallinity.

Particulate Scattering from Isolated Irregularities. A model that addresses the issue of particulate scattering on the surface is the following: if the scattering centers are sufficiently separated from each other, the total scattering is the sum of those calculated individually from each particle. Mie light-scattering theory (26,27) uses spherical particles of diameter d and relative refractive index n (which is the ratio of the refractive index of the sphere to that of the matrix) (28).

The scattering efficiency factor K is defined as the total scattered energy divided by the energy incident on the surface of the particle. The size of the sphere will affect the values of K (Fig. 6). In general there are three regions of interest:

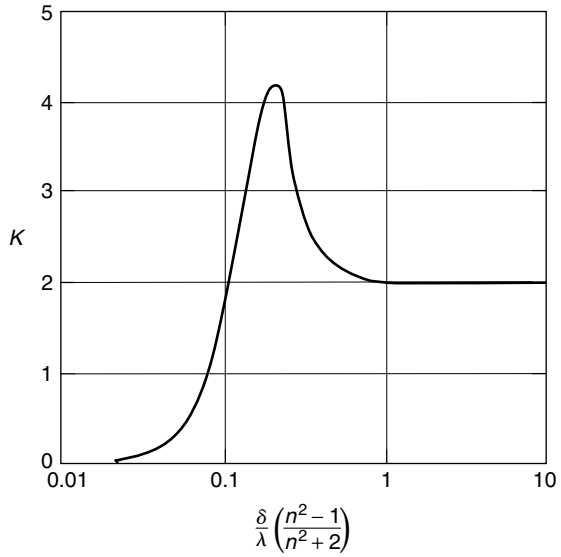

Fig. 6. Scattering coefficient K for a single sphere of relative refractive index n versus the ratio of the sphere diameter to the wavelength of the light (From Ref. 26).

When the particle diameter is less than 10% of the wavelength of light, Rayleigh scattering is observed, in which the efficiency factor is given by

$$K = \frac{8}{3}\pi^4 \left(\frac{d}{\lambda}\right)^4 \left(\frac{n^2-1}{n^2+2}\right)^2 \tag{22}$$

When the diameter is of the same order of magnitude as the wavelength of light, a peak in the value of K is observed. When the diameter is larger the scattering efficiency is around 2.

Internal Absorption. Internal absorption causes the transmitted intensity I to fall exponentially as the path length L increases through the polymer:

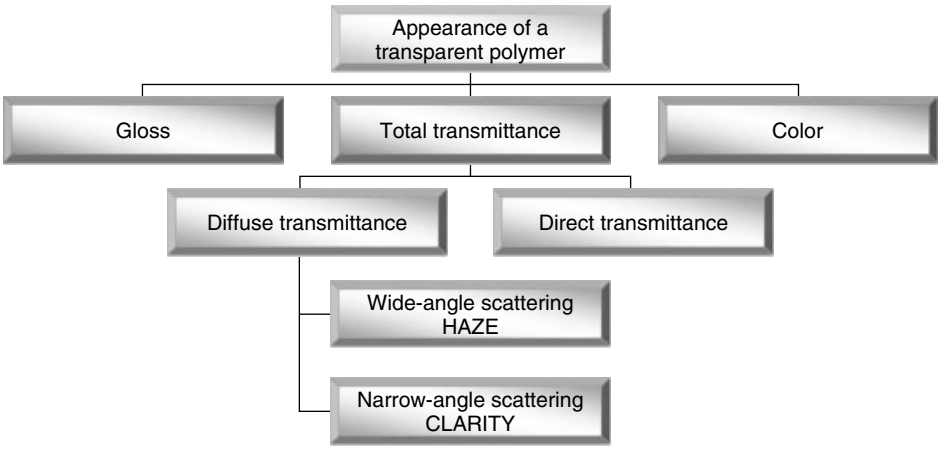
$$I = (1-R)^2 I_0 e^{-AL} \tag{23}$$

I_0 is the incident intensity and A is the attenuation coefficient. All polymers absorb strongly in the UV region.

Transmission and Haze

The degree of optical transparency of a polymeric material is determined by its luminous transmittance, haze, and clarity. Total luminous transmittance is the ratio of the transmitted luminous flux to the incident luminous flux. Regular transmittance is the ratio of undiffused transmitted flux to incident flux. Typically it encompasses the flux that deviates from the incident beam no more than 2.5°.

A breakdown of the factors affecting the appearance of a transparent polymer appears in the chart below:



The term "haze" is used to describe the slightly cloudy appearance of film material resulting from the forward scattering of light. ASTM D1003 defines *haze* as the "percentage of transmitted light which in passing through the specimen deviates from the incident beam by forward scattering." For the purposes of this method only light flux deviating more than 2.5° on the average is considered to be haze.

Haze can be caused from a variety of sources found at the surface or in the bulk of the material. Some of them could be impurities, voids, bubbles, and filler particles. Regions of different refractive indexes brought about by crystallization can also be a cause of haze. Surface roughness could also be a reason for haze. For example, abrasion and/or weathering will affect haze by altering the surface of a polymer sample.

Haze characterizes the loss of contrast that results when objects are viewed through a scattering medium. The deterioration of contrast is due mainly to light scattered forward at large angles to the undeviated transmitted beam and is usually expressed through the forward-scattered fraction.

It is important to distinguish between surface and bulk scattering; for testing purposes the former is minimized by wetting the surface with a liquid of similar refractive index. That way the two effects (surface vs bulk) can be decoupled. The "milk-like" appearance of translucent polymer samples viewed from the side on which light is incident is due to back scattering.

It is customary to calculate the total luminous transmittance of the sample, T_t, as well as Haze, H. The ASTM method uses the following equations:

$$T_1 = 100\left(\frac{T_2}{T_1}\right) \tag{24}$$

and

$$H = 100\left[\left(\frac{T_4}{T_2}\right) - \left(\frac{T_3}{T_1}\right)\right] \tag{25}$$

The various transmittances are defined as follows (29):

Measurement	Position A	Position B
T1	No sample	White standard
T2	Sample	White standard
T3	No sample	Light trap
T4	Sample	Light trap

A simple hazemeter schematic is shown in Figure 7.

ISO CD14872, on the determination of haze of transparent material, specifies instrumentation similar but not identical to ASTM. While both methods require four measurements each, the sphere geometry employed is different.

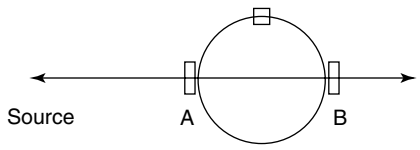


Fig. 7. Simple hazemeter (From Ref. 29).

Polymer morphology and its response to processing parameters will affect haze values. For example, polypropylene homopolymers have higher haze than random copolymers, with ethylene. The haze values of PP copolymers, in cast film operations, will be affected by such parameters as die temperature, chill roll temperature, line output, and sample thickness.

Transparency and Clarity

Transparency is a property that depends mainly upon the optical homogeneity of the polymer both in the bulk and at the surface. The variation of the refractive index in the material has the following effects:

(1) It produces changes in the phase and the amplitude of the light wave.
(2) It removes from the incident wave part of its energy through scatter within a certain solid angle.

The first effect is responsible for the aberration of the image formed by the optical system, for example, films, sheets, or optical lens. Typically, loss of clarity is associated with the confusion in the image plane of two distinct points in the object plane.

The second effect is responsible for the deterioration of contrast of the formed image. The two effects are closely interrelated and together constitute the two different aspects of what is typically termed as transparency.

Consider a monochromatic parallel beam of unpolarized flux ϕ incident perpendicularly on a polymer film immersed in a liquid of matching refractive index. A certain amount of the flux, ϕ_{sc}, will be scattered in all directions; another part, ϕ_{ab}, will be absorbed by the material. The remainder, ϕ_{under}, will be transmitted without any deviation (Fig. 8) (30):

$$\phi_{under} = \phi - \phi_{ab} - \phi_{sc} \tag{26}$$

The specular transmittance T is defined as

$$T = \phi_{under}/\phi \tag{27}$$

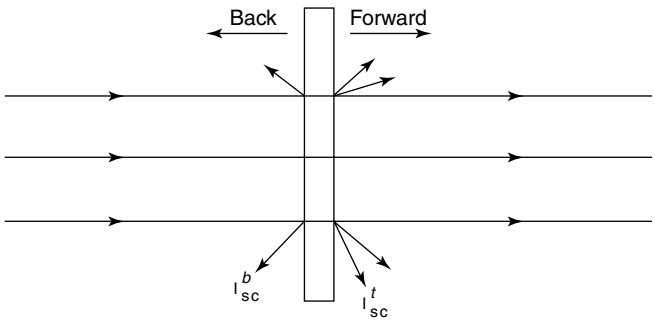

Fig. 8. Transmission of light through a sheet (From Ref. 30).

T is a function of the wavelength of the incident light and of the thickness of the sample. Immersion of the sample in a liquid of matching refractive index avoids having to take into account the reflective losses at the incident and emerging surfaces.

For materials of fairly high transparency, the relationship between specular transmittance and sample thickness Z is given by

$$T = \exp\{(-\sigma + \mathrm{K})Z\} \tag{28}$$

An expression based on the extinction index n'' is

$$(\sigma + \mathrm{K}) = (4\pi/\lambda)n'' \tag{29}$$

The sum $\sigma + K$ is equivalent to the attenuation factor α:

$$\alpha \simeq 54.6(n''/\lambda) \tag{30}$$

σ is known as the scattering coefficient and is a measure of the amount of scattered light. K is the absorption coefficient and represents the amount of light absorbed. Both quantities have units of m^{-1}. Typically, for polymers, K is fairly small when compared to σ. Therefore the attenuation coefficient may be taken to be equal to the scattering coefficient, which leads to the following expression for the total flux transmitted, ϕ_T:

$$\phi_\mathrm{T} = \phi_\mathrm{under} + \phi_\mathrm{sc} \tag{31}$$

Clarity is the ability of the sample to transmit the fine details of an object viewed through it. Maximum clarity is therefore achieved by minimizing the size of scattering centers as it is strongly related to the angular distribution of the scattering intensity. It is also affected by the distance between the object viewed and the sample (31).

Fresnel's law allows calculation of the maximum transparency τ_i of a plastic material.

$$\tau_i = 1 - R_0 \tag{32}$$

with

$$R_0 = \frac{(n-1)^2}{(n+1)^2} \tag{33}$$

Maximum transparency of a polymer can range between 98% (for a refractive index of 1.33) and 92.8% (for a refractive index of 1.73). However none of these values can be achieved in practice because there is always absorption and/or scattering of light by the sample.

For example, poly(methyl methacrylate) (PMMA), one of the most transparent plastics, never exceeds a transparency of around 93% for wavelengths between

430 and 1100 nm. In theory however PMMA could achieve a transparency of 96.1%. PMMA's transparency decreases above 1150 nm and below 380 nm.

Transparent polymers have values of τ_i higher than 90%. On the other hand polymers with τ_i less than 90% appear clear as only thin films. These are called translucent or contact-clear because films look clear when in contact with an object but hazy when viewed alone.

Clarity is negatively affected by light absorption and scattering. As we saw earlier, loss of contrast by forward scattering causes haze. The combined loss by scattering (both forward and backward) causes a "milk-like" appearance.

Local fluctuations of refractive index and/or orientation of anisotropic volume elements cause a polymer to be opaque. The various volume elements must be at least equal to the wavelength of the incident light. The clarity of the material can thus be increased considerably if elements such as microdomains are decreased. For example, spherulites are more homogeneous optically than lamellar structures of similar diameter.

Adjustment of refractive indexes of phases within a polymer blend can somewhat improve the clarity of the polymer. For example, ABS-modified PVC has a milky/yellowish appearance if the ABS is dispersed in PVC. The blend looks bluish milky if PVC is dispersed in ABS. If the dispersed materials have core-shell morphology then one can get transparent material if the mean refractive index of the core-shell particles matches that of the matrix.

Processing conditions strongly influence the morphology of polymers, thus affecting their transparency. For example, for injection/blow-molded PET, nonspherulitic structure and a limited range of crystal orientations can be achieved by (*1*) imparting crystallization at a low temperature upon heating from a glassy or partially disordered state, (*2*) cooling the preforms very rapidly so they are glassy, and (*3*) subsequent reheating to 100°C, so very small crystals form. Biaxial stretching before the occurrence of crystallization results in the desired microstructure.

Minimization of the refractive index difference between the crystalline and amorphous phases will also yield in higher transparency of articles. For example, poly(4-methyl-1-pentene) will yield transparent injection-molded products because of the small difference in refractive index for the two phases.

The hiding power of a polymer surface is related to inhomogeneities (such as fillers or more than one phase) that cause strong reflections.

$$R_{0,h} = \frac{(n_1 - n_2)^2}{(n_1 + n_2)^2} \tag{34}$$

The refractive index of the polymer is given by n_1 and that of the inhomogeneity (eg filler) by n_2.

The hiding power of a polymer is also affected by light scattering. High filler concentrations lead to multiple scattering, which reduces the hiding power through reduction of the relative scattering intensity. If one wishes to increase the hiding power one must look into increasing the backward scattering. Increasing the size of the filler particles would be one way to accomplish that. Typically though, one finds that the hiding power reaches a maximum at certain filler size and then it decreases.

ASTM D-1746 correlates see-through clarity with regular transmittance. However the correlation is not very strong for highly diffusing materials. There is no method widely accepted for this property. The work of Webber is often cited as a popular approach (32).

Reflection and Gloss

Reflectivity is defined as the ratio of the intensity of reflected to incident light. Both of those depend on the angles of incidence, alpha (α), and refraction, beta (β):

$$R = \frac{I_r}{I_0} = \frac{1}{2}\left[\frac{\sin^2(\alpha-\beta)}{\sin^2(\alpha+\beta)} + \frac{\tan^2(\alpha-\beta)}{\tan^2(\alpha+\beta)}\right] \tag{35}$$

Gloss is the ratio of the reflectivity of a sample to the reflectivity of a standard. The gloss increases with increasing refractive index and with sample of incidence. In the polymer film industry, three different angles are employed: 20°, 45°, and 60°. A test at an angle of 85° may also be performed in certain cases.

Gloss decreases when the sample has a rough surface because of the scattering. Optical inhomogeneities just below the surface also affect the values of gloss in a negative way.

Differences in local gloss on a surface cause "glitter" as a result of high directed light reflections. For example, polymer fibers show glitter if their cross sections are triangular or trilobal.

Gloss can also be defined as the degree to which a surface simulates a perfect reflecting material in its capacity to reflect light. Specular gloss is the term used for the proportion of light reflected in the mirror direction. The typical standard for gloss is optically flat, black glass. However, the assigned values of gloss depend on the refractive index of the glass employed, so comparisons between tests must take that into account.

According to ASTM D523 an angle of 60° is recommended for general use, 20° for high gloss materials, and 85° for low gloss materials. ASTM D2457 suggests measurements at 20°, 45°, and 60°.

Polymer surface morphology will affect the value of gloss. Processing parameters as well as mold finish (for various molding operations) or chill roll finish (in cast film operations) will also affect gloss values. Typically, rubber-modified polyolefins have a lower gloss than highly crystalline polyolefins.

Birefringence

Birefringence is the optical phenomenon in which a polymer sample exhibits different refractive indexes for light with plane polarization in two perpendicular directions. In other words an unequal retardation of orthogonal components is observed. Crystalline phases in a polymer are birefringent. Birefringence may also be induced in the unordered phase by applying an orientation field, be that mechanical or electromagnetic. Orientation birefringence is a result of physical

ordering of optically anisotropic elements along some preferential dimension. For uniaxially oriented samples there will be two refraction indexes $n_{\parallel}$ and $n_{\perp}$ corresponding to the polarization of light parallel and perpendicular to the sample symmetry axis. In a Cartesian coordinate system the birefringence for uniaxial symmetry will be given as

$$\Delta n = n_{\parallel} - n_{\perp} \tag{36}$$

Its individual components, along the axis, are given by

$$\Delta n_x = \Delta n_y \quad \text{and} \quad \Delta n_z = 0 \tag{37}$$

A macroscopic, quantitative way to analyze birefringence is through Jones (33–40) and Mueller (41) calculus and the Poincaré sphere (42). Those tools are widely used in the optical industry and references on them abound. Another active field of birefringence applications is the combination of the technique with polymer rheology, called flow–birefringence (43,44).

Birefringence of the Single-Chain and the Rotational Isomeric State (RIS) Model

The optical behavior of a single isolated chain is central in building optical molecular theories for polymers. Application of the RIS model to strain-birefringence is a well-known technique that has been around for the last 30 years. We focus on the mechanics of calculating the optical configuration parameter of a chain. The optical-configuration parameter is central to the structure–property optical relationships in polymers. This will help us to better understand the behavior of polymer networks later on. Flory and Nagai have shown how to evaluate the optical-configuration parameter in terms of the RIS model, thereby obtaining the following equation (7,45,46):

$$\Delta\alpha_s = \frac{3}{2}\sum \frac{\langle r^T \hat{a}_i r\rangle_0}{\langle r^2\rangle_0} \tag{38}$$

where $\boldsymbol{r}^{\mathrm{T}}$ is the transpose (ie, the row form) of the end-to-end vector $\boldsymbol{r}$ and $\hat{\boldsymbol{a}}_{\mathrm{i}}$ is the traceless tensor representing the anisotropy of the polarizability of bond i defined by

$$\hat{a}_i = a_i - \bar{a}_i \mathrm{E}_3 \tag{39}$$

where $\boldsymbol{a}_i$ is the polarizability tensor, $\bar{\boldsymbol{a}}_i$ is the mean polarizability, and $\boldsymbol{E}_3$ is the identity matrix of order 3. The angle brackets denote averages over the free unperturbed chain.

Application of the RIS model transforms the sum to a serial matrix multiplication scheme as follows:

$$\sum_{i=1}^{n} \langle r^{\mathrm{T}} \alpha_i r \rangle_0 = 2Z^{-1} J^* \left(\prod_{i=1}^{n} \mathrm{Q}_i \right) J \tag{40}$$

The configuration partition function is denoted by Z. The matrix $\boldsymbol{Q}_i$ is the generator matrix, for the quantity $\langle \boldsymbol{r}^{\mathrm{T}} \alpha_i \boldsymbol{r} \rangle_0$ is a rather large expression. The interested reader is encouraged to consult Flory's work on the subject (7).

Matrix $\boldsymbol{T}_i$ transforms a vector from its representation in local coordinate system $i + 1$ into its representation in local coordinate system i. The row and column operators $\boldsymbol{J}$ and $\boldsymbol{J}*$ in equation 40 are given by the first and last columns, respectively, of the matrix $\boldsymbol{Q}_i$.

Birefringence of Semicrystalline Polymers. For semicrystalline polymers the birefringence is the sum of the following terms:

$$\Delta n = v_{\mathrm{c}} \Delta n_{\mathrm{c}} + (1 - v_{\mathrm{c}}) \Delta n_{\mathrm{a}} + \Delta n_{\mathrm{f}} \tag{41}$$

v_{c} is the volume-fraction crystallinity determined from density measurements, Δn_{c} is the contribution to birefringence from the crystalline phase, Δn_{a} the contribution of the amorphous phase, and Δn_{f} the contribution from the boundaries between the two phases. An alternative expression, using the degree of crystallinity χ_{c}, as it is determined from X-ray diffraction, is

$$\Delta n = \chi_{\mathrm{c}} \Delta n_{\mathrm{c}} + (1 - \chi_{\mathrm{c}}) \Delta n_{\mathrm{a}} + \Delta n_{\mathrm{f}} \tag{42}$$

The value of Δn_{f} depends on the shape of the boundary between the phases as well as the difference in the average refractive indexes of the two phases. If that difference is small enough one could neglect its contribution. One way to determine its value is to swell the oriented polymer in solvents of varying refractive index. The solvent should swell the amorphous phase only and alter its refractive index. Thus the refractive index difference between the crystalline and the swollen amorphous phase may be altered (47).

Deformation birefringence arises as a result of an external deformation applied to the polymer sample. It could result from chain-packing changes or even bond-angle or bond-length deformations. Applying an external deformation is one way to make a normally optically isotropic sample optically anisotropic.

Deformation birefringence of a semicrystalline polymer is given by

$$\Delta n = v_{\mathrm{c}} \Delta n_{\mathrm{c}}^0 f_{\mathrm{c}} + (1 - v_{\mathrm{c}}) \Delta n_{\mathrm{a}}^0 f_{\mathrm{a}} + \Delta n_{\mathrm{f}} \tag{43}$$

$\Delta n_{\mathrm{c}}{}^0$ is the intrinsic birefringence of a crystalline phase, where the axis of the crystal is most nearly parallel to the chain axis.

The strain-induced birefringence in the amorphous region of a semicrystalline polymer disappears at the glass-transition temperature, as the chains assume isotropic configurations.

The deformation birefringence for graft or block copolymers is

$$\Delta n = v_{\mathrm{A}} \Delta n_{\mathrm{A}}^0 f_{\mathrm{A}} + v_{\mathrm{B}} \Delta n_{\mathrm{B}}^0 f_{\mathrm{B}} + \Delta n_{\mathrm{f}} \tag{44}$$

The volume fractions of the individual components A and B are denoted by ν_A and ν_B. Their respective orientation functions are denoted by f_A and f_B.

Birefringence of Polymer Networks. Elastomeric polymer networks deserve special mention because their cross-linked structure gives them unique physical properties, unlike those of other polymers. Covalently bonded networks are insoluble in any solvent, even in those that dissolve their precursor polymers. Optical techniques such as strain-induced birefringence allow the development of structure–property relationships as well as the study of their optical properties. Here we review some of the classical theories as well as some of the latest developments in the field.

The Theory of Kuhn and Grün. The theory of birefringence of deformed elastomeric networks was developed by Kuhn and Grün and by Treloar on the basis of the same procedure as that used for the development of the classical theories of rubber-like elasticity (48,49). The pioneering theory of Kuhn and Grün is based on the affine network model: that is, upon the application of a macroscopic deformation the components of the end-to-end vector for each network chain are assumed to change in the same ratio as that of the corresponding dimensions of the macroscopic sample.

Kuhn and Grün proceeded to calculate the length of the deformed chain vector and its angular coordinates in terms of the original length and orientation and the macroscopic elongation of the sample. Their assumptions allow the calculation of the contribution of a given chain to the total polarizability referred parallel to the principal axes of strain. Integration over all network chains allows the determination of the total polarizability for the network.

The chain model adopted by Kuhn and Grün is not based on the detailed chemical structure of the chain repeat units. Instead, the chain is composed of anisotropic statistical segments that become oriented as the network is deformed. Each segment is free to assume any orientation without any correlation to the orientation of the neighboring segments. The chain is considered to follow Gaussian statistics. Each link is assigned two polarizability components for light polarized parallel (symbol: $\alpha_\parallel$) and perpendicular (symbol: $\alpha_\perp$) to the segment axis. The difference in the refractive indexes is in general given by

$$n_i - n_j = \Delta n_0 \Psi_{i\,j} \quad \text{i, j} = 1, 2, \text{ or } 3 \tag{45}$$

where Ψ_{ij} is an orientation function depending on the angles θ and ϕ. The angle between the axis of the segment and the 3-direction is denoted by θ. The angle between the projection of the segment on the 1,2-plane and the 3-axis is denoted by ϕ. The Hermans orientation function is then given by

$$f = \frac{3\langle \cos^2\theta \rangle - 1}{2} \tag{46}$$

where $\langle \cos^2\theta \rangle$ is over the orientation of all segments.

On the basis of this model Kuhn and Grün develop the following expression for the stress–optical coefficient C for the case of uniaxial elongation:

$$C = \frac{\Delta n}{\tau}\frac{2\pi}{45kT}\frac{(\bar{n}^2+2)}{\bar{n}}\Delta\alpha_s \tag{47}$$

where Δn is the birefringence of the uniaxially stretched sample subjected to a stress τ (per unit area in the stretched state), k is Boltzmann constant, T is the absolute temperature, and $\bar{n}$ is the average refractive index of the network. The stress–optical coefficient is essentially the proportionality constant between the birefringence and the difference between the true stresses along the same axes. It is predicted to be independent of the degree of cross-linking and proportional to the anisotropy of the statistical segment. Experimentally it is found that this conclusion captures only part of the actual physics of the network. The anisotropy of the statistical segment $\Delta\alpha_s$ is given by

$$\Delta\alpha_s = (\beta_1 - \beta_2)_s \tag{48}$$

where β_1 and β_2 are the polarizabilities parallel and perpendicular, respectively, to the axis of the segment.

One crucial assumption here is that the local field on a segment is given by the Lorentz–Lorenz equation, which implies that the environment of a segment is optically isotropic (see also under Local Field). The treatment also involves the assumption of tensor additivity of polarizabilities of noninteracting segments (Valence Optical Scheme).

The anisotropy of a segment may be related to the anisotropy of the constituent bonds, again assuming polarizability additivity, by using

$$\Delta\alpha_s = \sum\left\{(\beta_1 - \beta_2)_i\left[3\cos^2\theta_i - 1\right]/2\right\} \tag{49}$$

where β_{1i} and β_{2i} are the polarizabilities of the ith bond along and perpendicular to the bond axis respectively, and θ_i is the angle between the bond axis and the segment axis.

According to the theory the orientation of the statistical links is predicted to be proportional to the stress difference, $\tau_i - \tau_j$

$$\Psi_{ij} = \frac{1}{5}\frac{\nu_c}{\nu_L}\left(\alpha_i^2 - \alpha_j^2\right) = \frac{\tau_i - \tau_j}{5\nu_L kT} \tag{50}$$

where ν_c is the number of network chains per unit volume and ν_L is the number of statistical segments per unit volume.

Birefringence of Phantom Networks. This theory is the basis for all theories that deal with birefringence of elastomeric polymer networks. It is based on the phantom network model of rubber-like elasticity. This model considers the network to consist of "phantom" (ie, non-interacting) chains. Consider the instantaneous end-to-end distance r for the ith network chain at equilibrium and at fixed strain. For a perfect (ie, no-defects) phantom network the birefringence induced

because of a deformation is defined as (50)

$$\Delta n = \left(\frac{2\pi}{27}\right)\left(\frac{\nu}{V}\right)\left[\frac{(n^2+2)^2}{n}\Gamma_2\right]\left[\Lambda_x^2 - \frac{\left(\Lambda_y^2+\Lambda_y^2\right)}{2}\right] \tag{51}$$

$\Lambda_t{}^2$s are the components of the molecular deformation tensor, which is given by

$$\Lambda_t^2 = \left[1-\frac{2}{\varphi}\right]\lambda_t^2 + \frac{2}{\varphi} \quad t = x, y, z \tag{52}$$

where $\lambda_t{}^2$ are the components of the macroscopic deformation tensor.

As we saw previously the quantity Γ_2 is defined as

$$\Gamma_2 = \frac{9}{10}\sum_i \frac{\langle r^{\mathrm{T}}\hat{a}_i r\rangle_0}{\langle r^2\rangle_0} \tag{53}$$

The summation is over all the units forming the chain. $\hat{\boldsymbol{a}}_i$ is the anisotropic part of the polarizability tensor for the unit with index i. $\boldsymbol{r}^{\mathrm{T}}$ is the transpose vector of the end-to-end vector $\boldsymbol{r}$, and the subscript 0 signifies that the average is over all configurations of the free chain. It is assumed that the polarizability tensor for the chain with a given configuration is obtained as the sum of the polarizability tensors of the groups forming the chain.

The connection between the polarizability tensor and the parameter Γ_2 given by

$$\left[\alpha_{xx} - \frac{(a_{yy}+a_{zz})}{2}\right]_r = \Gamma_2\frac{x^2 - [(y^2+z^2)/2]}{\langle r^2\rangle_0} \tag{54}$$

and $\langle r^2\rangle_0$ is the mean square end-to-end distance of a free chain. a_{xx}, a_{yy}, and a_{zz} are the x, y, and z components of the tensor $\hat{a}_{\mathrm{i}}$ for the chain averaged over all configurations. The subscript r on the left side of equation 54 signifies that the averaging is for the chain with fixed ends.

Combining equations 51 and 52, we obtain for the birefringence of a phantom network,

$$\Delta n_{\mathrm{ph}} = \left(\frac{\xi}{V}\right)kTC\left[\lambda_x^2 - \frac{\left(\lambda_y^2+\lambda_z^2\right)}{2}\right] \tag{55}$$

Focusing on the birefringence along the two principal axes x and y (typical for uniaxial deformation experiments), we obtain

$$\Delta n_{xy} = \left(\frac{2\pi\nu}{27V}\right)\left(1-\frac{2}{\varphi}\right)\left[\frac{(n^2+2)^2\Gamma_2}{n}\right]\left(\lambda_x^2 - \lambda_y^2\right) \tag{56}$$

For the development of equation 56 we have used the expression for the quantity C, the stress–optical coefficient, which is given by (compare to eq. 47)

$$C = \frac{2\pi}{27kT}\frac{(n^2+2)^2}{n}\Gamma_2 \tag{57}$$

and n is the mean refractive index of the network.

The Real Network. The total birefringence for a real network is the linear combination of the contributions resulting from the phantom network and the contributions arising from the constraints (51).

$$\Delta n_{xy} = \Delta n_{xy,\mathrm{ph}} + \Delta n_{xy,\mathrm{c}} \tag{58}$$

Flory has defined a reduced birefringence in a way similar to the reduced stress:

$$[\Delta n_{xy}] = [\Delta n_{xy,\mathrm{ph}}]\left[1 + \frac{\Delta n_{xy,\mathrm{c}}}{\Delta n_{xy,\mathrm{ph}}}\right] \tag{59}$$

where

$$[\Delta n] = \Delta n\left(\frac{V}{V_0}\right)^{1/3}(\alpha^2 - \alpha^{-1})^{-1} \tag{60}$$

The contribution from topological constraints is based on the various theories of rubberlike elasticity (52).

Birefringence Measurements. Birefringence measurements rely on placing a birefringent object between crossed polarizers (53,54). The basic concept is depicted in Figure 9.

Placing the sample at 45° to the plane of light polarization causes the object to stand out on a dark background. The two components of the polarized light A and B correspond to the principal planes of the sample. These two components travel the sample at different speeds, thus causing the emerging beams A1 and B1 to be out of phase. Each of those components reaches the analyzer, where they may be resolved into components parallel and perpendicular to the analyzer direction. One can see the interference results since they cause bright colors (typically called interference patterns). A photosensor may also be used to help quantify the results. Advances in technology of photoelastic modulators (PEM) and digitizing image software are helping in the design of new instruments that measure birefringence.

Nonlinear Optical Properties of Polymers

All the properties dealt with up until now involve linear interactions between light and polymer. Interaction of light with polymers in the nonlinear region involves second- and third-order effects as well as the phenomenon of photorefractivity (55,56). An optical nonlinear optical (NLO) polymer is one that, in response to an externally applied electric field, can either vary the speed of incoming light or alter its frequency. Varying the speed of light involves a change in the refractive

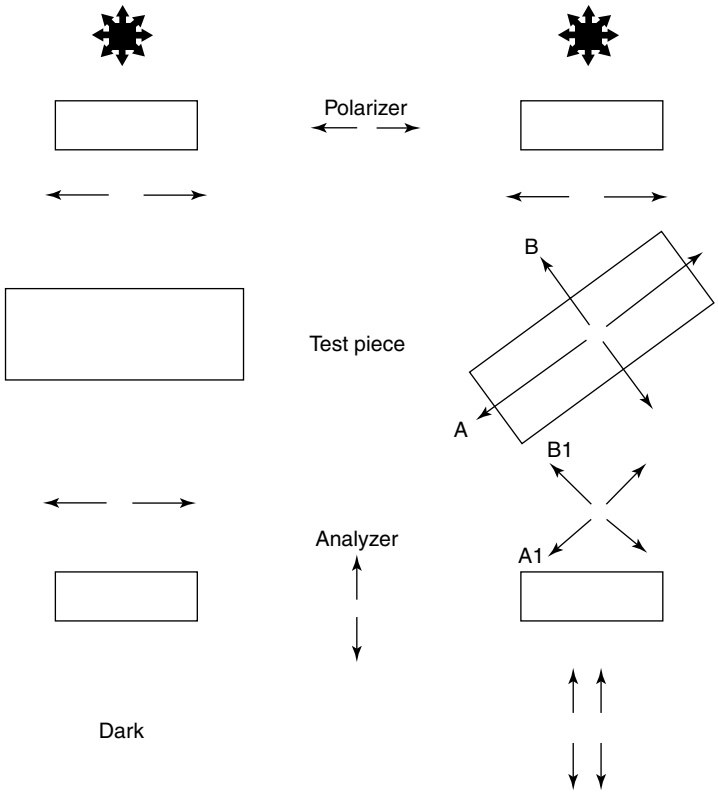

Fig. 9. Basis for birefringence setup (From Ref. 54).

index of the material. An optically nonlinear polymer has two components: the polymer itself and an optically nonlinear molecule (chromophore), which is either chemically attached to the polymer or dissolved in it.

The induced polarization P of a polymer is given by

$$P = \chi^{(1)}E + \chi^{(2)}EE + \chi^{(3)}EEE + \cdots \tag{61}$$

Linear optical phenomena involve the first-order susceptibility $\chi^{(1)}$, and in that case only the first term in the equation above is important. Higher order susceptibilitites are involved in nonlinear optical phenomena. Susceptibilities are a function of wavelength.

An equivalent equation but at the molecular level is the following:

$$\Delta\mu = \alpha E + \beta EE + \gamma EEE + \cdots \tag{62}$$

which gives the change in dipole moment μ when the field E is applied. Molecular polarizability is given by the term α. We saw equation 62 in a similar form earlier as equation 1. Higher order polarizabilities (hyperpolarizabilitites) are given by β (second-order), γ (third-order), etc.

In order for the polymer–chromophore system to be optically nonlinear the chromophores must be aligned so that on average they are all pointing in the same direction within the polymer. This alignment is achieved through a process called poling. The polymer is placed in a strong electric field and its temperature is raised above its T_g. Above this temperature the chromophores become mobile and can orient themselves in the external field. After orientation the polymer is cooled back down to room temperature and the orientational ordering is "frozen in."

Polymer NLOs are easily formed into thin films for guiding light in the optical equivalent of integrated circuits. These can potentially be operated at very high data rates, much higher than those possible for inorganic systems. However, inorganic systems don't need poling to achieve non-linearity. In polymer systems orientation degradation occurs as a result of thermal noise. Cross-linking has been considered as one method to stabilize the orientation of the chromophores. Another method is the use of high T_g polymer matrices.

The area of applications of nonlinear optics has not matured yet and the opportunities for creative work, both theoretical and experimental, abound. Here we have only covered some very introductory concepts.

PHENOLIC RESINS

Introduction

Phenolic resins are a large family of polymers and oligomers, composed of a wide variety of structures based on the reaction products of phenols with formaldehyde. Phenolic resins are employed in a wide range of applications, from commodity construction materials to high technology applications in electronics and aerospace. Generally, but not exclusively, thermosetting in nature, phenolic resins provide numerous challenges in the areas of synthesis, characterization, production, product development, and quality control.

As a family of resins originally developed in the early twentieth century, the nature and potential of phenolic resins have been explored thoroughly to produce an extensive body of technical literature (1–9). A symposium sponsored by the American Chemical Society commemorated 75 years of phenolic resin chemistry in 1983 (10), and in 1987 the Phenolic Molding Division of the Society of the Plastics Industry (SPI) sponsored a conference on phenolics in the twenty-first century (1). Exciting new developments continue as new systems are developed for carbon–carbon composites, aramid honeycombs, and new derivative chemistries such as cyanate esters and benzoxazines. New U.S. patents with phenolic resins in the claims are growing at about 150 patents per year.

Phenolic resins are prepared by the reaction of phenol or substituted phenol with an aldehyde, especially formaldehyde, in the presence of an acidic or basic catalyst. Their thermosetting character and the exotherm associated with the reaction presented technical barriers to commercialization. In 1900, the first U.S. patent was granted for a phenolic resin, using the resin in cast form as a substitute for hard rubber (11).

Work on the first commercially viable product was initiated by Baekeland in 1905. Using phenol and formaldehyde as starting materials, he established not only the differences between acid- and alkali-catalyzed products, but also the importance of excess phenol or formaldehyde made in producing intermediates.

Encyclopedia of Polymer Science and Technology. Copyright John Wiley & Sons, Inc. All rights reserved.

However, producing the resin was only part of the challenge. Baekeland also developed the technology to convert the reactive resins, which had a severe tendency to foam and cure to a brittle product, into useful molded articles by adding wood or mineral fibers and molding under heat and pressure. The final molded parts were tough, temperature resistant, and had a low void content (12). The first commercial phenolic resin plant was Bakelite GmbH, started in Germany in 1910; in the same year, the General Bakelite Co. was founded in the United States.

Early phenolic resins consisted of self-curing, resole-type products made with excess formaldehyde, and novolaks, which are thermoplastic in nature and require a hardener. The early products produced by General Bakelite were used in molded parts, insulating varnishes, laminated sheets, and industrial coatings. These areas still remain important applications, but have been joined by numerous others such as wood bonding, fiber bonding, and plywood adhesives. The number of producers in 2001 is approximately 15 in the United States and over 50 worldwide. Overall the number of producers is declining as the industry continues to undergo consolidation.

Monomers

Phenol. This is the monomer or raw material used in the largest quantity to make phenolic resins (Table 1). As a solid having a low melting point, phenol, C_6H_5OH, is usually stored, handled in liquid form at 50–60°C, and stored under nitrogen blanket to prevent the formation of pink quinones. Iron contamination results in a black color.

The most widely used process for the production of phenol is the cumene process developed and licensed in the United States by Honeywell (formerly AlliedSignal). Benzene is alkylated with propylene to produce cumene (isopropylbenzene), which is oxidized by air over a catalyst to produce cumene hydroperoxide (CHP). With acid catalysis, CHP undergoes controlled decomposition to produce phenol and acetone; α-methylstyrene and acetophenone are the by-products (13). Other commercial processes for making phenol include the Raschig process, using chlorobenzene as the starting material, and the toluene process, via a benzoic acid intermediate. In the United States, ~35–40% of the phenol produced is used for phenolic resins.

Table 2. Substituted Phenols Used for Phenolic Resins

Substituted phenol	Resin application
Cresol (*o*-, *m*-, *p*-)	Coatings, epoxy hardeners
p-*t*-Butylphenol	Coatings, adhesives
p-Octylphenol	Carbonless paper, coatings
p-Nonylphenol	Carbonless paper, coatings
p-Phenylphenol	Carbonless paper
Bisphenol A	Low color molding compounds, coatings
Resorcinol	Adhesives
Cashew nutshell liquid	Friction particles

Substituted Phenols. Phenol itself is used in the largest volume, but substituted phenols are used for specialty resins (Table 2). Substituted phenols are typically alkylated phenols made from phenol and a corresponding α-olefin with acid catalysts (14). Acidic catalysis is frequently in the form of an ion-exchange resin (IER) and the reaction proceeds preferentially in the para position. For example, in the production of *t*-butylphenol using isobutylene, the product is >95% para-substituted. The incorporation of alkyl phenols such as cresol into the resin reduces reactivity, hardness, cross-link density, and color formation, but increases solubility in nonpolar solvents, flexibility, and compatibility with natural oils.

Formaldehyde. In one form or another, formaldehyde is used almost exclusively in the production of phenolic resins, regardless of the type of phenol (Table 3). It is frequently produced near the site of the resin plant by either of two common processes using methanol (qv) as the raw material. In the silver catalyst process, the reaction takes place at 600–650°C and produces water and hydrogen as by-products. The more common metal oxide process operates at 300–400°C. The gaseous formaldehyde is absorbed in water, and the final product is a formalin solution containing 36–50% formaldehyde. Of the various chemical forms of formaldehyde, the aqueous form is preferred for making phenolic resins, even though at least half of this form is water. The water serves to moderate the reaction and is readily removed in processing equipment (15).

Aqueous Formaldehyde. Water solutions of formaldehyde consist mainly of telomers of methylene glycol having <100 ppm of the formaldehyde as CH_2O (5). Alcohols form hemiformals with aqueous formaldehyde according to the following, where $n = 1, 2, 3$, etc.

$$ROH + HOCH_2OH \rightleftharpoons ROCH_2OH + H_2O$$

$$RO(CH_2O)_nH + HOCH_2OH \rightleftharpoons RO(CH_2O)_{n+1}H + H_2O$$

However, a second mole of alcohol or hemiformal does not add at the ordinary pH of such solutions. The equilibrium constant for hemiformal formation depends on the nature of the R group of the alcohol. Using NMR spectroscopy, a group of alcohols including phenol has been examined in solution with formaldehyde (16,17). The spectra indicated the degree of hemiformal formation in the

Table 3. Forms of Formaldehyde

		Resin preparation	
Type	Chemical formula	Advantages	Disadvantages
Gaseous	CH_2O		Unstable
Formalin			
36%	$HO(CH_2O)_nH$[a]	Easy handling, moderate, reactivity, stable at RT	High water content
50%	$HO(CH_2O)_nH$[b]	Increased capacity	Elevated temperature storage, formic acid formation
Paraformaldehyde	$HO(CH_2O)_nH$[c]	Increased capacity, water-free	Dangerously high reactivity, solids handling
Trioxane	$(CH_2O)_3$	Water-free	Catalyst requirements, high cost
Hexamethylenetetramine	$(CH_2)_6N_4$	Autocatalytic	Amine incorporation

[a] $n \approx 2$.
[b] $n \approx 3$.
[c] $n = 20$–100.

order of methanol > benzyl alcohol > phenol. Hemiformal formation provides the mechanism of stabilization; methanol is much more effective than phenol in this regard.

The large value for the hemiformal formation constant of methanol and its low molecular weight explains the high efficiency of methanol in stabilizing formalin solutions. Phenol, on the other hand, is inefficient, and phenol hemiformals are only formed by careful removal of water (18).

Other Aldehydes. The higher aldehydes react with phenol in much the same manner as formaldehyde, although at much lower rates. Examples include acetaldehyde, CH_3CHO; paraldehyde, $(CH_3CHO)_3$; glyoxal, OCH—CHO; and furfural. The reaction is usually kept on the acid side to minimize aldol formation. Furfural resins, however, are prepared with alkaline catalysts because furfural self-condenses under acid conditions to form a gel.

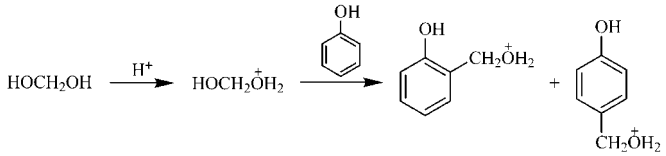
Hexamethylenetetramine. Hexa, a complex molecule with an adamantane-type structure, is prepared from formaldehyde and ammonia, and can be considered a latent source of formaldehyde. When used either as a catalyst or as a curative, hexa contributes formaldehyde-residue-type units as well as benzylamines. Hexa [100-97-0] is an infusible powder that decomposes and sublimes above 275°C. It is highly soluble in water, up to ca 45 wt% with a small negative temperature solubility coefficient. The aqueous solutions are mildly alkaline at pH 8–8.5 and reasonably stable to reverse hydrolysis.

Other Reactants. Other reactants are used in smaller amounts to provide phenolic resins that have specific properties, especially coatings applications. Aniline had been incorporated into both resoles and novolaks but this practice has been generally discontinued because of the toxicity of aromatic amines. Other materials include rosin (abietic acid), dicyclopentadiene, unsaturated oils such as tung oil and linseed oil, and polyvalent cations for cross-linking.

Polymerization

Phenolic resins are prepared with strong acid or alkaline catalysts. Occasionally, weak or Lewis acids, such as zinc acetate, are used for specialty resins.

Strong-Acid Catalysts, Novolak Resins. Phenolic novolaks are thermoplastic resins having a molecular weight of 500–5000 and a glass-transition temperature T_g of 45–70°C. The phenol–formaldehyde reactions are carried to their energetic completion, allowing isolation of the resin; formaldehyde–phenol molar ratios are between 0.5:1 and 0.8:1. Methylene glycol [463-57-0] (**1**) is converted to the corresponding hydrated carbonium ion **2**, which adds to the ortho and para positions of phenol with the elimination of water to form the corresponding ortho (**3**) and para (**4**) benzylic ions. The benzylic carbonium ions are in equilibrium with the corresponding benzylic alcohols, observed by NMR as transient species in the formation of novolak resins (16).



1 **2** **3** **4**

In the next step the hydrated benzylic carbonium ions **3** and **4** react with free ortho and para positions on phenols to form methylene-linked bisphenols, 2,2′(**5**), 2,4′(**6**), and 4,4′(**7**).

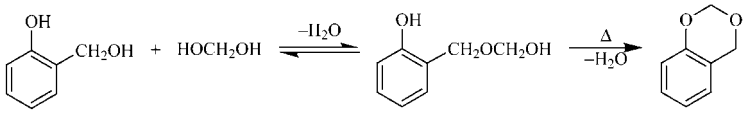
[a]High ortho.

Continued reaction leads to the formation of novolak polymers having a molecular weight of up to 5000. Acid-catalyzed resins contain 50–75% 2,4′ linkages (**6**). The reaction rate is proportional to catalyst, formaldehyde, and phenol concentrations, and inversely proportional to the concentration of water. The rate of formation of the benzyl alcohol intermediate is 5–10 times lower than the rate to form the methylene-linked bisphenol (**3**). At typical molecular weights of 500–1000, novolak molecules are essentially linear because of the much lower reactivity of doubly-reacted phenolic units. In higher molecular weight polymers, the low concentration of end groups and unreacted phenol causes branching. Above 1000 molecular weight, branching has been observed by ^{13}C NMR; about 20% branching has been predicted in computer simulations (14,19,20). In the curing process, end groups are more reactive than the backbone groups. Thus a branched resin having a higher content of end groups than a corresponding linear equivalent may gel sooner and cure faster because of the higher resin functionality. The properties of an acid-catalyzed phenolic resin are shown in Table 4.

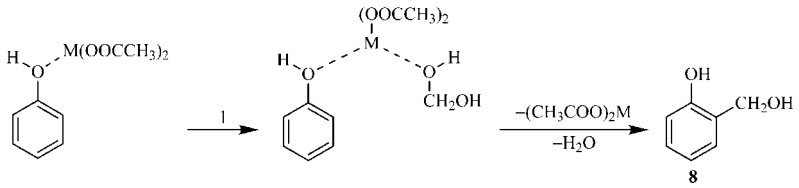
The typical acid catalysts used for novolak resins are sulfuric acid, sulfonic acid, oxalic acid, or occasionally phosphoric acid. Hydrochloric acid, although once widely used, has been abandoned because of the possible formation of toxic chloromethyl ether by-products. The type of acid catalyst used and reaction conditions affect resin structure and properties. For example, oxalic acid, used for resins chosen for electrical applications, decomposes into volatile by-products at elevated processing temperatures. Oxalic acid catalyzed novolaks contain small amounts (1–2% of the original formaldehyde) of benzodioxanes formed by the cyclization and dehydration of the benzyl alcohol hemiformal intermediates.



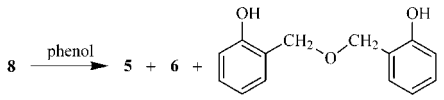
Benzodioxane is reasonably stable at neutral pH, but may decompose when the resin is cured, serving as a source of labile formaldehyde. Benzodioxanes are not found in sulfuric or sulfonic acid catalyzed resins, since the stronger acid readily catalyzes the second step in the reaction sequence.

Neutral Catalysts, High Ortho Novolaks. In the range of pH 4–7, formaldehyde substitution of the phenolic ring is possible, using divalent metal catalysts containing Zn, Mg, Mn, Cd, Co, Pb, Cu, and Ni; certain aluminum salts are also effective. Organic carboxylates are required as anions in order to obtain sufficient solubility of the catalyst in the reaction medium, as well as to provide a weak base. Acetates are most convenient and economical. Although lead acetate is highly effective because of its excellent solubility properties, it has been largely eliminated because of lead toxicity. Zinc and calcium salts are probably the most widely used catalysts (21).

Novolaks produced from these catalysts exhibit a high content of 2,2′-methylene units. The mechanism proposed for the ortho-directing effect involves chelation of the phenolic unit with the metal ion.



8



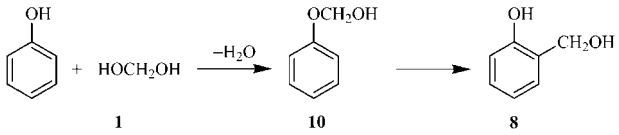
9

Zinc acetate catalyst produces essentially 100% *o*-methylol phenol (**8**) in the first step. The second step gives an approximately equal quantity of 2,2′- (5, 45%) and 2,4%-diphenylmethylene (6, 45%) bridges, indicating little chelate-directing influence. In addition, a small quantity (10%) of methylene ether units (**9**) (dibenzyl ether) is observed at moderate reaction temperature.

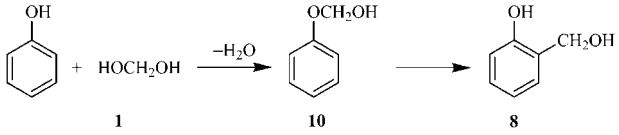
High ortho novolaks have faster cure rates with hexa. Typical properties of a zinc acetate catalyzed high ortho novolak are also shown in Table 4. The gel time with hexa is one-third of that with a strong acid catalyzed novolak.

Alkaline Catalysts, Resoles. Resole-type phenolic resins are produced with a molar ratio of formaldehyde to phenol of 1.2:1 to 3.0:1. For substituted phenols, the ratio is usually 1.2:1 to 1.8:1. Common alkaline catalysts are NaOH, $Ca(OH)_2$, and $Ba(OH)_2$. While novolak resins and strong acid catalysis result in a limited number of structures and properties, resoles cover a much wider spectrum. Resoles may be solids or liquids, water-soluble or -insoluble, alkaline or neutral, slowly curing or highly reactive. In the first step, the phenolate anion is formed by delocalization of the negative charge to the ortho and para positions. Alkaline catalysts are also effective in the polymerization–depolymerization of methylene

glycol. The mechanism of the formaldehyde addition to the phenolate is still not completely understood. The most likely mechanism involves the contribution of phenol hemiformals (**10**) (5).



Rate studies show that base-catalyzed reactions are second order and depend on the phenolate and methylene glycol concentrations. The most likely path involves a nucleophilic displacement by the phenoxide on **1**, with the hydroxyl as the leaving group. In alkaline media, the methylolated quinone intermediate is readily converted to the phenoxide by hydrogen-ion abstraction (22).



The ratio of ortho-to-para substitution depends on the nature of the cation and the pH. Para substitution is favored by K^+ and Na^+ ions and higher pH, whereas ortho substitution is favored at lower pH and by divalent cations, such as Ba^{2+}, Ca^{2+}, and Mg^{2+} (23).

Several extensive kinetic studies on the polymethylolation of phenol have been reported (22,24,25). For the reaction scheme shown in Fig. 1, seven different rate constants must be determined. Despite different solution concentration, temperatures, and methods of analysis, comparing reaction rates (26–28) from each study using an NaOH catalyst gave fairly close agreement that rate constants increase with methylol substitution. In fact, dimethylol-substituted phenols react with formaldehyde two to four times faster than phenol. As a result, unreacted phenol remains high in resole resins (5–15%) even though the formaldehyde/phenol ratio is as high as 3:1.

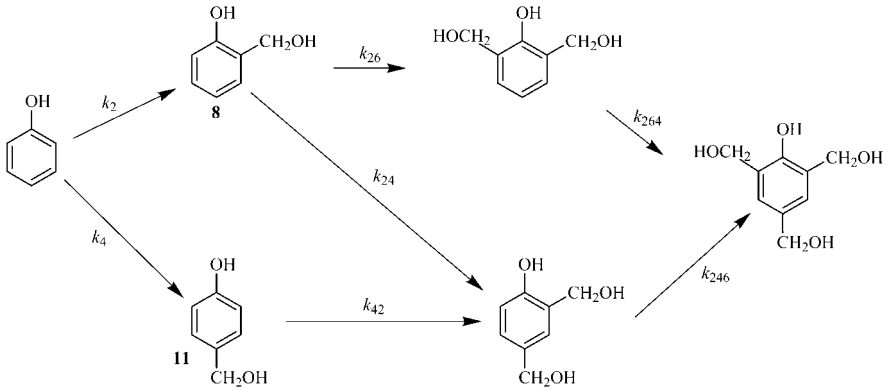


Fig. 1. Possible pathways and rate constants for the methylolation of phenol.

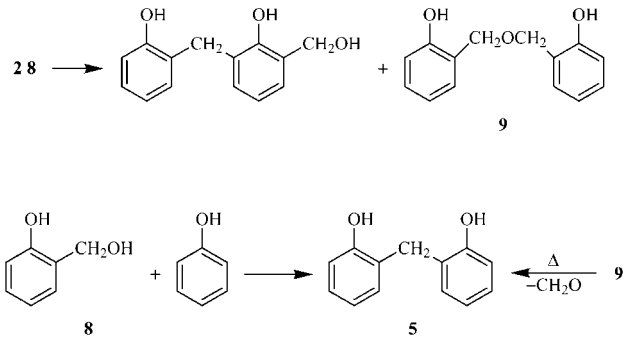
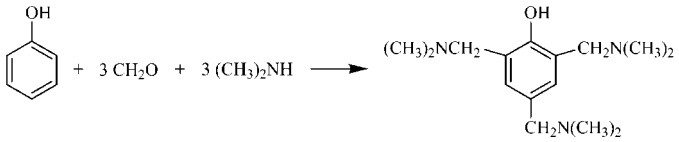
The rate studies show that k_{264} is by far the fastest reaction (by a factor of 4–6) than k_2 or k_4, with k_{24} the second fastest (by a factor of 2–4) (22,25).

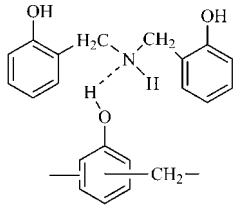
Although monomeric methylolated phenols are used in certain applications, such as in fiber bonding, higher molecular weight resins are usually desirable. Molecular weight is increased by further condensation of the methylol groups, sometimes after the initial pH has been reduced. Dibenzyl ether (**9**) and diphenylmethylene formation are shown in the following. The formation of diphenylmethylene bridges is favored above 150°C and under strongly alkaline conditions; dibenzyl ether formation is favored at lower temperatures and near neutral pH.



Special resoles are obtained with amine catalysts, which affect chemical and physical properties because amine is incorporated into the resin. For example, the reaction of phenol, formaldehyde, and dimethylamine is essentially quantitative (29).



In practice, ammonia is most frequently used. With hexa, the initial reaction steps differ, but the final resole resins are identical, provided they contain the same number of nitrogen and CH_2 groups. Most nitrogen from ammonia or hexa is incorporated as dibenzylamine with primary, tertiary, and cyclic amine structures as minor products.



The physical properties of a resole resin prepared with hexa catalyst are shown in Table 5. Compared to the resin catalyzed with NaOH, this resin has higher molecular weight, less free phenol, lower water solubility, and a higher T_g.

Benzoxazine	0	2

[a] 6 pph.

This increase in T_g is higher than that expected if only phenol and formaldehyde were used, and is a result of the hydrogen-bonding interaction between the backbone amine units and the phenolic hydroxyls. Taking advantage of this effect, hexa and ammonia have been frequently used to produce solid, grindable, and water-insoluble resoles for molding compounds.

The methylene-isomer distributions of NaOH and hexa-catalyzed resoles are shown in Table 6. The distribution of amine structures is

$$\text{secondary} > \text{primary} \approx \text{tertiary}$$

and most benzylamines are ortho in the phenol ring from early steps in the reaction sequence.

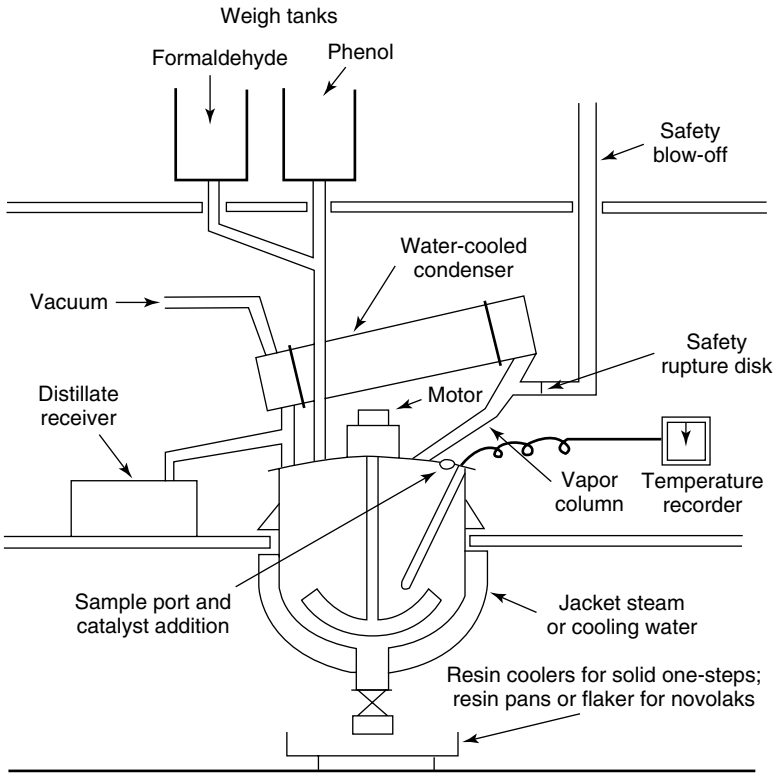

Fig. 2. Typical phenolic resin production unit.

Manufacture

The final state of a phenolic resin varies dramatically from thermoplastic to thermoset and from solid to liquid, and includes solutions and dispersions. With a bulk process, resole resins, in neat or concentrated form, must be produced in small batches ($\approx$ 2–10 m^3) in order to maintain control of the reaction and obtain a uniform product. On the other hand, if the product contains a large amount of water, such as liquid plywood adhesives, large reactors (20 m^3) can be used. Melt-stable products such as novolaks can be prepared in large batches (20–40 m^3) if the exotherms can be controlled. Some reactors are reportedly as large as 60 m^3 (Ref. 9, p. 83).

Batch processes for most phenolic resins employ the equipment shown in Fig. 2. Liquid reactants are metered into the stirred reaction vessel through weigh tanks, whereas solid reactants such as bisphenol A and $Ba(OH)_2$ present handling problems. Facilities are provided to carry out the reaction under vacuum or an inert gas.

Materials of Construction. Compatibility of the materials of construction and the process chemicals is extremely important. The reactors are usually made of stainless steel alloys. Copper is avoided because of the possible presence

of amines. Glass-lined reactors are occasionally used for nonalkaline resins. Because the use of HCl has been largely discontinued, material requirements are less stringent. The reactor contains a bottom discharge, which for solid heat-reactive resins must be large. Solid resole resins are discharged for rapid cooling in order to quench the thermosetting reactions. Resin coolers are made up of vertical plates with internally circulating water. The product can also be discharged to a large cooled surface. Discharges to belt and drum flakers are highly automated; however they can only be used for less-reactive resins.

Novolak resins can be stored molten in heated holding tanks under nitrogen. Because novolaks are used mainly in pulverized form with hexa and additives, a process that includes belt flaking and feeding directly into the blending and pulverizing system is preferred. Liquid and solution resole resins are cooled in the reactor by using jacket cooling and vacuum refluxing. Discharged products are filtered and pumped to refrigerated intermediate holding areas or packaged for shipping. The stability of liquid resole products varies greatly from product to product and depends on the storage temperature. The viscosity of a liquid resole resin increases but the water miscibility decreases as time and temperature increase. Generally, resoles, both liquids and solids, must be refrigerated.

Novolak Resins. In a conventional novolak process, molten phenol is placed into the reactor, followed by a precise amount of acid catalyst. The formaldehyde solution is added at a temperature near 90°C and a formaldehyde-to-phenol molar ratio of 0.75:1 to 0.85:1. For safety reasons, slow continuous or stepwise addition of formaldehyde is preferred over adding the entire charge at once. Reaction enthalpy has been reported to be above 80 kJ/mol (19 kcal/mol) (30,31). The heat of reaction is removed by refluxing the water combined with the formaldehyde or by using a small amount of a volatile solvent such as toluene. Toluene and xylene are used for azeotropic distillation. Following decantation, the toluene or xylene is returned to the reactor.

The reaction is completed after 6–8 h at 95°C; volatiles, water, and some free phenol are removed by vacuum stripping up to 140–170°C. For resins requiring phenol in only trace amounts, such as epoxy hardeners, steam distillation or steam stripping may be used. Both water and free phenol affect the cure and final resin properties, which are monitored in routine quality control testing by gas chromatography (GC). Oxalic acid (1–2 parts per 100 parts phenol) does not require neutralization because it decomposes to CO, CO_2, and water; furthermore, it produces milder reactions and low color. Sulfuric and sulfonic acids are strong catalysts and require neutralization with lime; 0.1 parts of sulfuric acid per 100 parts of phenol are used. A continuous process for novolak resin production has been described (32,33). An alternative process for making novolaks without acid catalysis has also been reported (34,35), which uses a peroxidase enzyme to polymerize phenols in an aqueous solution. The enzyme can be derived from soybeans or horseradish.

High Ortho Novolaks. The process for high ortho novolaks is similar to the one used for those catalyzed by strong acid. Zinc acetate is used at concentrations higher than the acids, typically 2% or more. The formaldehyde/phenol ratio is similar (0.75–0.85) but yields are 5–10% lower than those produced with strong acids, and reaction times are longer. Problems with gel particles and bulk gelation occur more frequently because small amounts of reactive dibenzyl ether

groups are present. Overall, the process is more expensive because of higher raw material costs, lower yields, and longer cycle times.

Another process employs a pH maintained at 4–7 and a catalyst that combines a divalent metal cation and an acid. Water is removed continuously by azeotropic distillation and xylene is recycled. The low water content increases the reaction rate. The dibenzyl ether groups are decomposed by the acid; the yield of 2,2′-methylene can be as high as 97% (36).

Resoles. Like the novolak processes, a typical resole process consists of reaction, dehydration, and finishing. Phenol and formaldehyde solution are added all at once to the reactor at a molar ratio of formaldehyde to phenol of 1.2–3.0:1. Catalyst is added and the pH is checked and adjusted if necessary. The catalyst concentration can range from 1 to 5% for NaOH, 3 to 6% for $Ba(OH)_2$, and 6 to 12% for hexa. A reaction temperature of 80–95°C is used with vacuum-reflux control. The high concentration of water and lower enthalpy compared to novolaks allows better exotherm control. In the reaction phase, the temperature is held at 80–90°C and vacuum-refluxing lasts from 1 to 3 h as determined in the development phase. Solid resins and certain liquid resins are dehydrated as quickly as possible to prevent overreacting or gelation. The endpoint is found by monitoring the gel time, which decreases as the reaction progresses. Automation includes on-line viscosity measurement, GC, and gel-permeation chromatography (GPC).

Phenolic Dispersions. These systems are predominantly resin-in-water systems in which the resin exists as discrete particles. Particle size ranges from 0.1 to 2 μm for stable dispersions and up to 100 μm for dispersions requiring constant agitation. Some of the earliest nonaqueous dispersions were developed for coatings applications. These systems consist of an oil-modified phenolic resin complexed with a metal oxide and a weak solvent.

In the postdispersion process, the solid phenolic resin is added to a mixture of water, cosolvent, and dispersant at high shear mixing, possibly with heating. The cosolvent, frequently an alcohol or glycol ether, and heat soften the resin and permit small particles to form. On cooling, the resin particles, stabilized by dispersant and perhaps thickener, harden and resist settling and agglomeration. Both resole and novolak resins have been made by this process (26).

The *in situ* process is simpler because it requires less material handling (37); however, this process has been used only for resole resins. When phenol is used, the reaction system is initially one-phase; alkylated phenols and bisphenol A present special problems. As the reaction with formaldehyde progresses at 80–100°C, the resin becomes water-insoluble and phase separation takes place. Catalysts such as hexa produce an early phase separation, whereas NaOH-based resins retain water solubility to a higher molecular weight. If the reaction medium contains a protective colloid at phase separation, a resin-in-water dispersion forms. Alternatively, the protective colloid can be added later in the reaction sequence, in which case the reaction mass may temporarily be a water-in-resin dispersion. The protective colloid serves to assist particle formation and stabilizes the final particles against coalescence. Some examples of protective colloids are poly(vinyl alcohol), gum arabic, and hydroxyethylcellulose.

For products intended to remain stable dispersions for an extended period, a particle size of 2 μm or less is desirable. A thickening agent is usually added after the reaction has been completed and the mixture is cooled in order to prevent

settling and agglomeration. Examples of thickeners are guar gum, xanthan gum, and hydroxyethylcellulose. The final products are generally between 40 and 50% solids, with a viscosity of 1500–5000 mPa·s (=cP).

Resole dispersions intended for isolation as discrete particles (27) can be used as flatting agents in coatings (28). Particles larger than 1000 μm are used in friction-element compositions. A-stage, thermosetting phenolic particles have been isolated from dispersion (27,38). With a hexa catalyst (6–12 parts) and a formaldehyde/phenol ratio of 1.5:1, the reaction is carried out at 50% solids for $\approx$90 min at 85°C. Poly(vinyl alcohol) and gum arabic are the preferred protective colloids. The particles (20–80 μm) are isolated from the mixture by filtration and, in the patent examples, by fluid-bed drying. These A-stage products (gel time at 150°C, 50–100 s) are suitable in applications where pulverized phenolic resins are being used, as well as in applications that take advantage of their spherical nature. One patent describes a sinter-resistant product for wood-bonding applications (39). In another patented process, both the production of particulate novolak resins and the aqueous dispersions of these resins are described (40).

Spray-Dried Resins. Spray drying produces resins in particulate form. Spray-drying a resole solution containing a blowing agent (41) produces phenolic microballoons. Spray drying also produces A-stage resins (42). The resins, prepared with a high NaOH content, are spray dried to give a final particle size of 40–60 μm. The particles are hygroscopic because of the high caustic content, but are sinter-resistant when kept dry. The principal application for this type of product is believed to be wood binding, especially for waferboard applications.

Cyanate Ester Resins. Cyanate ester resins, sometimes called triazines or cyanurates after the cured structure that they produce, are derived from phenols and phenolic resins. Specifically the starting phenols are reacted with cyanogen chloride, ClCN, and base to give the resins. In the cure step the cyanate groups trimerize to form triazine rings when heated in the range 180–250°C. Performance is generally intermediate between aromatic amine cured epoxides and toughened bismaleimides. Glass transition temperature T_g is about 250°C and the heat distortion temperature is about 250°C dry and 175°C wet. Electrical properties are excellent due to very low residual chlorine content. Principal applications are printed wiring boards and structural composites (Fig. 3) (43).

Benzoxazine Resins. Benzoxazine resins are prepared by the reaction of phenol, formaldehyde, and an amine. In one particular example a benzoxazine is prepared from bisphenol A, formaldehyde, and aniline to give 2,2′-bis(3-phenyl-4-dihydro-1,3,2-benzoxazine) propane. When heated to about 200°C the methylene bond to oxygen breaks and reforms onto the available ortho positions of adjacent moieties to give dibenzylamine structures. Resin formulations have been developed and formulated, in some cases with epoxy and phenolic resins to give ternary systems with T_g as high as 170°C (Fig. 4) (43–46).

Cure

A typical resin has an initial molecular weight of 150 to perhaps 1500. For systems of unsubstituted phenols, the final cross-link density is 150–300 amu

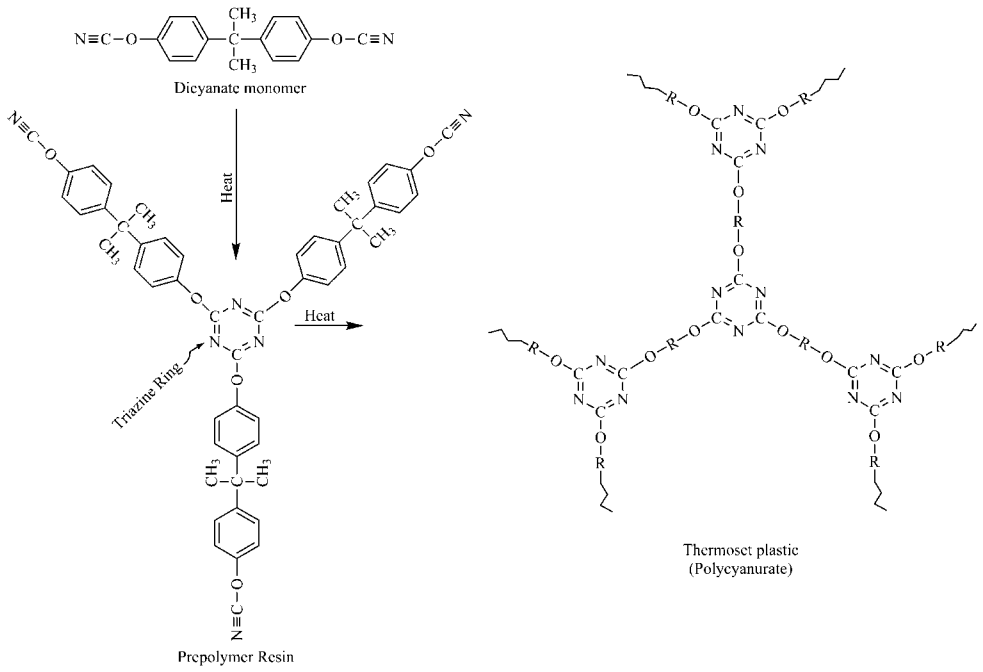

Fig. 3. Curing via cyclotrimerization; R = bisphenol unit. From Ref. 43.

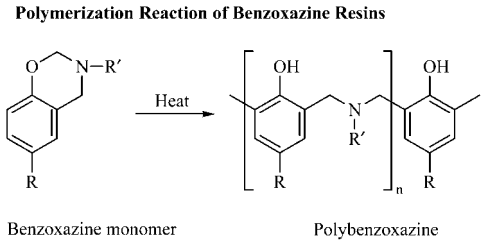

Fig. 4. Polymerization reaction of benzoxazine resins.

per cross-link. In other words, 25–75% of the ring-joining reactions occur during the cure phase.

Resoles. The advancement and cure of resole resins follow reaction steps similar to those used for resin preparation; the pH is 9 or higher and reaction temperature should not exceed 180°C. Methylol groups condense with other methylols to give dibenzyl ethers and react at the ortho and para positions on the phenol to give diphenylmethylenes. In addition, dibenzyl ethers eliminate formaldehyde to give diphenylmethanes.

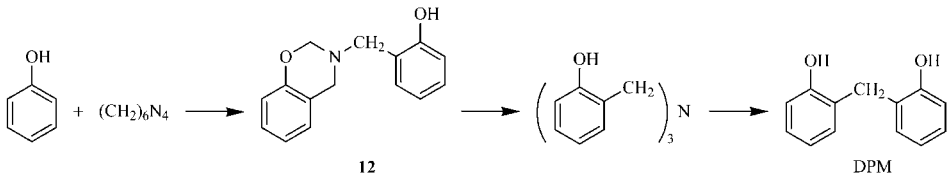
In some resole applications, such as foam and foundry binders, a rapid cure of a liquid resin is obtained at room temperature (RT) with strong acid. The reactions proceed in the same manner as those of novolak resin formation. Methylol groups react at ortho and para phenolic hydrogen to give diphenylmethane units (47).

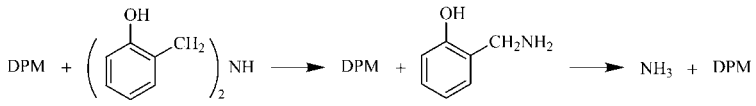
At pH 4–6, the cure is slower than it is at pH 8 and higher, and much slower than at pH 1–3. Reactions at pH 4–6 resemble those on the more alkaline side,

but with a substantial increase in side products. This is partly the result of the low rates of the main reactions and partly the result of stable intermediates at this pH range.

Some resoles contain latent acid catalysts, which on heating generate moderately strong acids. Examples include aryl phosphites such as diphenyl hydrogen phosphite and ammonium sulfate (48,49). The use of latent acid catalysis broadens the range of applications of phenolic resins to include areas such as liquid composite molding and pultrusion. Also resoles, which can contain so-called free formaldehyde, can be formulated with formaldehyde scavengers in form of amines such as melamine.

Novolaks. Novolak resins are typically cured with 5–15% hexa as the cross-linking agent. The reaction mechanism and reactive intermediates have been studied by classical chemical techniques (3,4) and the results showed that as much as 75% of nitrogen is chemically bound. More recent studies of resin cure (50–53) have made use of TGA, DTA, GC, IR, and NMR (16). They confirm that the cure begins with the formation of benzoxazine (**12**), progresses through a benzyl amine intermediate, and finally forms (hydroxy)diphenylmethanes (DPM).





In the reaction of phenol and bisphenol F with hexa, NMR spectra show the transient appearance of benzoxazine intermediates; after 2 h at 103°C, all the benzoxazine decomposed to the diphenylmethylene and benzylamine intermediates (16).

The cure of novolaks with hexa has been studied with differential scanning calorimetry (DSC) and torsional braid analysis (TBA) (54); both a high ortho novolak and a conventional acid catalyzed system were included. The DSC showed an exothermic peak indicating a novolak–hexa reaction ≈20°C higher than the gelation peak observed in TBA. Activation energies were also calculated.

The resin rich in 2,2′-methylene exhibited the lowest activation energy, gel temperature, and DSC exotherm. The high concentration of the slightly acidic 2,2′-diphenylmethane end groups may account for the higher reactivity. These end groups should react with hexa to form benzoxazine intermediates first, which then decompose to react with vacant positions throughout the novolak molecule.

An isothermal method for studying the cure of phenolics employs dynamic mechanical analysis (DMA) (Table 7). The problems associated with programmed

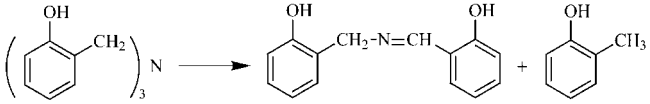
Table 7. Isothermal DMA Results

Sample	Rate, min^{-1}		Activation energy, kJ/mol[a]
	At 150°C	At 185°C	
Hexa-catalyzed resole	0.22	1.00	71.1
Novolak			
6% hexa	0.07	0.09	8.8
12% hexa	0.12	0.19	18.8

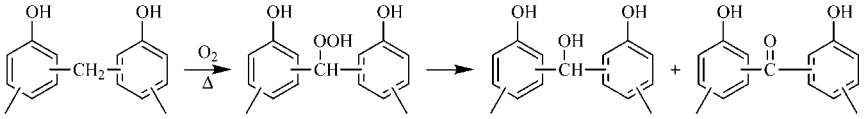
[a]To convert kJ to kcal, divide by 4.184.

heating rates are avoided and mathematical treatment of the results is simplified. Although a more complex treatment is possible, a simple first-order dependence of modulus with time and an Arrhenius-type temperature dependence are sufficient. The rate studies of Table 7 indicate that doubling the amount of hexa doubles the rate at which the modulus approaches its long-term value. The novolak – 12% hexa cures substantially slower than the resole. In addition, they differ in temperature dependence of cure rates; the resole has an activation energy approximately four times greater than that of the novolak – 12% hexa (55).

Decomposition of Cured Resoles and Novolaks. Above 250°C, cured phenolic resins begin to decompose. For example, dibenzyl ethers such as **9** disproportionate to aldehydes (salicylaldehyde) and cresols (*o*-cresol). The aldehyde group is rapidly oxidized to the corresponding carboxylic acid. In an analogous reaction in hexa-cured novolaks, tribenzylamines decompose into cresols and azomethines, which cause yellowing.



Substantial decomposition of phenolic resins begins above 300°C. In the presence of oxygen, the methylene bridging group is converted to a hydroperoxide, which, in turn, yields alcohols and ketones on decomposition.



The ketone is especially susceptible to random chain scission. Decomposition continues up to ≈600°C; the by-products are mostly water, CO, CO_2, and phenols. The first stage of decomposition produces a porous structure having minimal shrinkage. The second stage begins near 600°C and is accompanied by shrinkage and substantial evolution of CO_2, H_2O, methane, and aromatics. The resulting polyaromatic chars represent ≈60% of the original resin when the atmosphere is inert, but this may be substantially less in the presence of air. The char ignites in air above 900°C.

The controlled decomposition of phenolic resins, in an inert atmosphere, is a method used to make carbon–carbon composites. In this case the resin is combined with other forms of carbon, such as carbon fibers, coke, and synthetic graphite, and cured under heat and pressure. Further heating to about 900°C converts the resin to a glassy form of carbon that can serve as a binder for the other carbon forms. The carbon yield from the phenolic resins can be in the range of 60–70% of the initial weight (see under CARBON–CARBON COMPOSITES).

Analysis and Characterization

The principal techniques for determining the microstructure of phenolic resins include mass spectroscopy (MS), proton and ^{13}C NMR spectroscopy, as well as GC, LC, and GPC. The softening and curing processes of phenolic resins are effectively studied by using thermal and mechanical techniques, such as TGA, DSC, and DMA. Infrared (IR) and electron spectroscopy are also employed. Recently matrix-assisted laser desorption-ionization mass spectrometry (MALDI-MS) has been used for the determination of molecular weight and end-group analysis (see MASS SPECTROMETRY). MALDI-MS is a soft ionization technique that has been applied to the determination of mass of large biomolecules and synthetics resins. The approach is useful for molecular weight determination and end-group analysis. Both novolaks and resoles have been studied and individual fragments with *m/z* up to about 2000 specifically identified. For resoles the technique is even able to resolve the various hemiformal structures that can occur. (Ref. 9, p. 92; 56–58).

Spectroscopy. Infrared spectroscopy (59) permits structural definition, eg, it resolves the 2,2′- from the 2,4′-methylene units in novolak resins. However, the broad bands and severely overlapping peaks present problems. For uncured resins, NMR rather than IR spectroscopy has become the technique of choice for microstructural information. However, Fourier transform infrared (FTIR) gives useful information on curing phenolics (60). Nevertheless, IR spectroscopy continues to be used as one of the detectors in the analysis of phenolics by GPC. (see VIBRATIONAL SPECTROSCOPY)

A great wealth of microstructural information is provided by Fourier transform ^{13}C NMR. Using the much greater chemical-shift range of this technique, detailed structural information is provided for both the aliphatic and the aromatic carbons (Table 8). Current techniques provide highly reliable quantitative data and relative peak areas (19,61–65) and make possible a quantitative measure of the numbers of branch points and end groups. Branching can cause early gelation in a novolak resin, and end groups usually have greater reactivity in the thermosetting reaction than do the backbone units. Another important advantage of ^{13}C NMR is the parametric predictability of the chemical-shift values. As a result, unknown peaks can be assigned to a hypothetical structure with reasonable certainty. At the same time, the process can be reversed and a computer can provide detailed structural analysis. ^{13}C NMR has been applied to cured phenolic resins (63). (see NUCLEAR MAGNETIC RESONANCE).

Chromatography. Gel-permeation chromatography (GPC) is an invaluable technique for determining the molecular size distribution of polymers. Phenolic resins, which have molecular weight components ranging from 100 to rarely

more than 5000, require special column arrangements to optimize resolution. By using proper instrument calibration, it is possible to obtain number-average (M_n) and weight-average (M_w) molecular weight as well as quantitative information on free monomer and certain other low molecular weight species (66–68) (see CHROMATOGRAPHY, SEC).

Many resole resins exist as phenolate salts in solution. Because these ionic species are sparingly soluble in carrier solvents such as tetrahydrofuran, careful neutralization and filtration are required. Although GPC is an excellent technique for examining medium and high molecular weight fractions, GC and high performance LC are more effective for analyzing low molecular weight species.

Gas chromatography (GC) has been used extensively to analyze phenolic resins for unreacted phenol monomer as well as certain two- and three-ring constituents in both novolak and resole resins (69). It is also used in monitoring the production processes of the monomers, eg, when phenol is alkylated with isobutylene to produce butylphenol. Usually, the phenolic hydroxyl must be derivatized before analysis to provide a more volatile compound. The GC analysis of complex systems, such as resoles, provides distinct resolution of over 20 one- and two-ring compounds having various degrees of methylolation. In some cases, hemiformals may be detected if they have been properly capped (61).

The combined techniques of GC/MS are highly effective in identifying the composition of various GC peaks. The individual peaks enter a mass spectrometer

in which they are analyzed for parent ion and fragmentation patterns, and the individual components of certain resoles are completely resolved.

High performance liquid chromatography (HPLC) is extremely effective in separating individual resin components up to a molecular weight of 1000 according to size and polarity. Dilute-solution conditions and low temperatures preserve the structure of unstable components. The resins are usually not derivatized. Gradient solvent elution gives excellent peak separation (69,70). In one study, resoles catalyzed by sodium and barium hydroxide were compared, and the components were separated up to and including methylolated four-ring compounds (61). Resole components resolved by GC and HPLC techniques are shown in Table 9. Like GC, HPLC is most effective when combined with other analytical tools, such as mass and UV spectroscopy. By using preparative-scale HPLC, individual peaks can be analyzed by proton and ^{13}C NMR spectroscopy.

Thermal Analysis. The main thermal analysis techniques applied to phenolic resins are TGA and DSC. In TGA, the sample weight is monitored microanalytically with time and temperature in air or nitrogen. When applied to resins and molding compounds, the scans indicate cure and decomposition temperatures accompanied by a measurable loss in weight. Resoles and novolaks lose from 5 to 20% of their weight on curing at 100–200°C. Weight loss provides information on shrinkage, void formation, and density change of composites.

Phenolic resins give a high char yield on combustion and TGA provides a measure of the expected yield. Typical values are between 40 and 65% in nitrogen. Decomposition begins at 350°C and continues up to 600°C. Autoignition temperature in air is above 900°C. Thermogravimetric analyses have played an important part in the development of carbon–carbon and carbon–graphite-fiber composites

containing phenolic resins. These composites are used in aircraft brake linings and carbon-pipe applications. In DSC and DTA, heat flow and sample temperature are compared to a reference material. Glass-transition temperature T_g is determined by DSC. The T_g of liquid resoles is below RT, that of friable novolaks is in the range of 50–75°C, and that of lightly cross-linked phenolics is between 150 and 225°C.

Cure kinetics of thermosets are usually determined by DSC (71,72). However, for phenolic resins, the information is limited to the early stages of the cure because of the volatiles associated with the process. For pressurized DSC cells, the upper limit on temperature is ≈170°C. Differential scanning calorimetry is also used to measure the kinetics and reaction enthalpies of liquid resins in coatings, adhesives, laminations, and foam. Software packages that interpret DSC scans in terms of the cure kinetics are supplied by instrument manufacturers.

Dynamic Mechanical Analysis. In DMA, a vibrating or oscillating sample is heated at a programmed rate or held isothermally at elevated temperature. The frequency and damping characteristics of the sample are monitored with time. A change such as gelation or passage through the T_g causes abrupt changes in the fundamental oscillation frequency of the sample and the damping ability of the specimen. The oscillation frequency can be related to the storage modulus of the sample, whereas the damping contains information related to the loss modulus.

Softening and cure are examined with the help of a torsional pendulum modified with a braid (73), which supports thermosets such as phenolics and epoxies that change from a liquid to a solid on curing. Another method uses vibrating arms coupled to a scrim-supported sample to measure storage and loss moduli as a function of time and temperature. An isothermal analytical method for phenolic resins provides data regarding rate constants and activation energies and allows prediction of cure characteristics under conditions of commercial use (55).

DSC and DMA scans of a novolac cure are shown in Figures 5a and 5b (74). The sample is a glassy solid initially and the DMA shows the distinctive T_g at 65°C followed by the appearance of a liquid state. From 110 to 125°C, the resin is a liquid and the chemical curing reactions begin, and it is followed by gelation at 140°C. Further reaction continues until 200°C, when a highly cross-linked, infusible solid is obtained. As the sample is cooled to RT, a slight increase in storage modulus is observed. The peak in the damping curve indicates the T_g of the cross-linked system at about 185°C.

Dynamic mechanical analysis provides a useful technique to study the cure kinetics and high temperature mechanical properties of phenolic resins. The volatile components of the resin do not affect the scan or limit the temperature range of the experiment. However, uncured samples must be supported by a braid, a scrim, or paper. This does not influence the kinetic results and can be corrected in the calculations of dynamic mechanical properties (qv). Recent DMA work on phenolic resins has been used to optimize the performance of structural adhesives for engineered wood products and determine the effect of moisture in wood product on cure behavior and bond strength (75–77).

Control Tests. Numerous chemical and physical tests are used in the manufacture of phenolic resins to ensure correct properties of the finished resins,

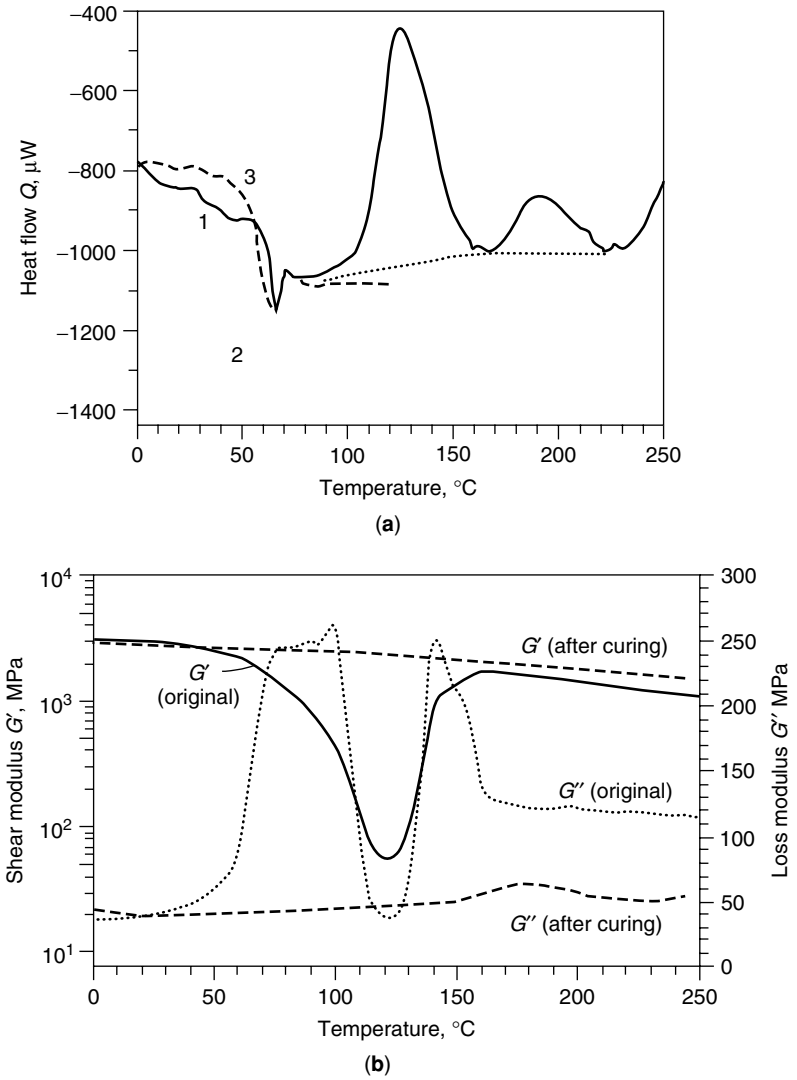

Fig. 5. DSC and DMA of novolac resin. (**a**) DSC Measurement of (1) original PF resin, (2) cured PF resin, and (3) novolac. (**b**) Torsion pendulum measurement of original and cured PF. To convert MPa to psi, multiply by 145. From Ref. 74.

including the following: refractive index is used to estimate the dehydration during manufacture and is proportional to the solids content; viscosity is used to determine molecular weight and solids content; nonvolatiles content is roughly proportional to polymer content; miscibility with water depends on the extent of reaction in resoles; specific gravity is measured for liquid resins and varnishes; melting point of novolaks and solid resoles affects application performance; gel times determine the reactivity of the resins; resin flow is a measure of melt viscosity and molecular weight; particle size affects performance and efficiency; and flash point and autoignition temperature provide flammability-characteristic measurements

required by government agencies regulating safety and shipping. ASTM D4706-93 (1998) describes the standard test method for qualitative determination of methylol group in phenolic resins.

Health, Safety, and Environmental Factors

The factors contributing to the health and safety of phenolic resin manufacturing and use are those primarily related to phenol (qv) and formaldehyde (qv). Unreacted phenol in a resin can range from ~5% for liquid resoles used in impregnation processes to well below 1% for novolaks intended for use as epoxy hardeners. Free formaldehyde can be <1% in liquid adhesives. Novolaks are usually free of formaldehyde. The toxicity of the resins is significantly lower than that of the phenol and formaldehyde starting materials. No detrimental toxicological effects have been reported for cured phenolic resins, which can be used in direct contact with food as in can coatings.

Uncured resins are skin sensitizers and contact should be avoided, as well as breathing the vapor, mist, or dust. Novolak-based pulverized products generally contain hexamethylenetetramine, which may cause rashes and dermatitis. Phenolic molding compounds and pulverized phenolic adhesives must be controlled as potentially explosive dusts. In addition, they contain irritating or toxic additives. ASTM test method D4639-86 (1996) describes the method for volative content in phenolic resins.

Phenol. Phenol is highly irritating to the skin, eyes, and mucous membranes in humans after acute inhalation or dermal exposures. Phenol is considered to be quite toxic to humans via oral exposure, with blood changes, liver and kidney damage, and cardiac toxicity reported. Chronic inhalation exposure to phenol in humans has been associated with gastrointestinal irritation, liver injury, and muscular effects. No data are available on the developmental or reproductive effects of phenol on humans. EPA has classified phenol as a Group D, not classifiable as to human carcinogenicity. The NIOSH threshold limit value (TLV) and Occupational Safety and Health Administration (OSHA) permissible exposure limit for phenol is 19 mg/m^3 (78). The health and environmental risks of phenol and alkylated phenols, such as cresols and butylphenols, have been reviewed (79).

Formaldehyde. Acute and chronic inhalation exposure to formaldehyde in humans can result in eye, nose, and throat irritation and respiratory symptoms. Reproductive effects have been reported in women workers exposed to formaldehyde. Limited human studies have reported an association between formaldehyde exposure and lung and nasopharyngeal cancer. The EPA has classified formaldehyde as a Group B1, probable human carcinogen of medium carcinogenic hazard. The OSHA has set its permissible exposure limit (PEL) at 4.5 mg/m^3 and the American Conference of Governmental and Industrial Hygienists have set the TLV at 1.5 mg/m^3 (80).

Wastewater. Phenol is a toxic pollutant to the waterways and has an acute toxicity (~5 mg/L) to fish. Chlorination of water gives chlorophenols, which impart objectionable odor and taste at 0.01 mg/L. Biochemical degradation is most frequently used to treat wastewater containing phenol. Primary activated sludge, along with secondary biological treatment, reduces phenol content to below

0.1 mg/L (81). ASTM D1783-01 describes the standard test methods for phenolic compounds in water.

Flammability. Phenolics have inherently low flammability and relatively low smoke generation. For this reason they are widely used in mass transit, tunnel building, and mining. Fiber-glass reinforced phenolic composites are capable of attaining the 1990 U.S. Federal Aviation Administration (FAA) regulations for total heat release and peak heat release for aircraft interior facings (1,82). They are also used as "fire restricting material" on cruise ships, high speed ferries, and commercial submarines. The self-ignition temperature is about 600°C and limiting oxygen index (LOI) is in the range 40–49%. (83).

Recycling. Thermosets are inherently more difficult to recycle than thermoplastics, and thermosetting phenolics are no exception. However, research in this area has been reported, and molded parts have been pulverized and incorporated at 10–15% in new molding powders. Both German and Japanese groups had instituted this type of practice in 1992 (84,85) (see RECYCLING).

A number of alternatives will have to be developed in order to effectively utilize cured phenolic material (86). One approach is the "thermoset recycling pyramid," a preferred order of execution that includes

(1) Tier 1: Reintroduction of the used material into the original material at relatively low levels (∼10%) in the raw material mix (this approach is used widely to recycle SMC and BMC thermoset polyesters)
(2) Tier 2: Reuse of the material in a lower performance thermoset product at relatively high levels (40–50%)
(3) Tier 3: Reuse of the product in alternative materials such as asphalt, roofing materials, concrete, and other construction products
(4) Tier 4: Pyrolysis of the material to generate raw material feed stocks and incineration for energy recovery. Phenolic molding compounds can yield a caloric value of 14,000–23,000 kJ/kg, depending on the type of filler.

Plenco and other companies have been working with the SPI's Phenolic Division to produce a "Recycling Blueprint" shown in Figure 6 below (87).

Biomass and Biochemical Processes. Phenolic resins have been produced from biomass and using biochemical processes in various ways. In Japan biomass from wood waste or waste from the food industry is treated with phenols and strong acid catalysis and heat to produce phenolic resins (88). Research at the National Renewable Energy Laboratory has shown that ablative fast pyrolysis can be used to convert a wide variety of biomass feedstocks into a liquid oil. The phenolic rich component can be extracted from this oil and used as a low cost replacement for synthetic phenol in phenolic resins (89). In another approach, soybean peroxidase enzymes have been used to prepare resins from phenolic moieties without the use of formaldehyde (90).

Economic Aspects. In 2000, worldwide consumption of phenolic resins exceeded 4×10^6 t; slightly less than half of the total volume was produced in the United States (91). The largest-volume application is in plywood adhesives, an area that accounts for ≈49% of U.S. consumption (Table 10). All wood bonding applications account for about two-third of phenolic resin use. During the early

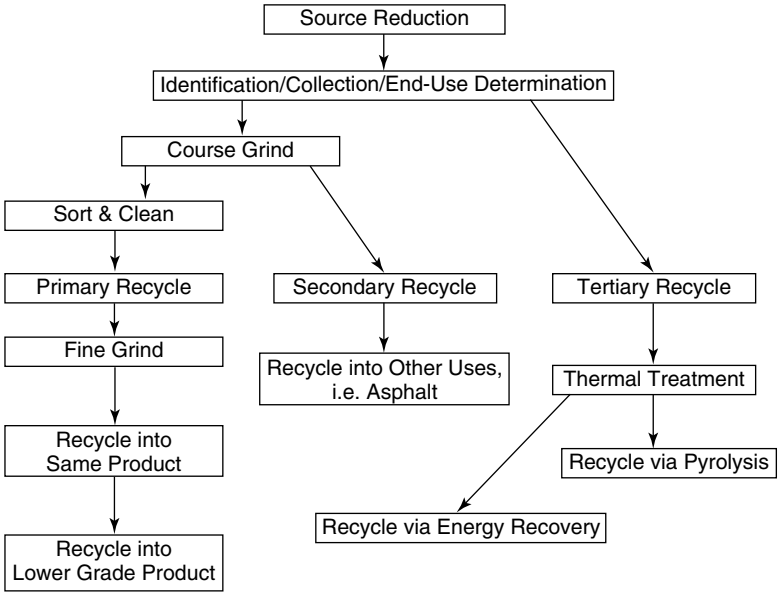

Fig. 6. SPI Blueprint for the reclamation of molded phenolics.

1980s, the volume of this application more than doubled as mills converted from urea–formaldehyde (UF) to phenol–formaldehyde adhesives because of the release of formaldehyde from UF products.

As a mature industry, U.S. production and application of phenolic resins have paralleled the growth in the GNP and the housing industry. The consumption of phenolic resins for coatings and molding powders has continued its decrease. The driving force behind coatings has been the need to reduce the volatile organics content (VOC) and the growth in alternative coatings such as waterborne, powder, and radiation-cured coatings. In the area of molding powders, numerous new engineering thermoplastics and alloys having superior properties have been introduced since the 1970s; however, phenolic molding powders continue to be used extensively in electrical, electronic, and machinery and underhood parts applications.

U.S. phenolic resin manufacturers include Ashland, Borden Chemical, Cytec Fiberite, Durez, FiberCote Industries, H.B. Fuller, P.D. George, Georgia-Pacific,

International Paper, Lockport Thermosets, Maruzen America, Plastics Engineering, Resinoid, Sumitomo America, TriQuest, and Vantico (92).

Prices of phenolic resins vary substantially depending on the application. In 2001, the price of general-purpose and semisolids was $1.50–1.80/kg, whereas epoxy-hardener grades can exceed $2.20/kg. Because raw materials of phenolic resins are derived from crude oil and natural gas, the prices of phenolic resins depend on the prices of these resources.

Applications

Coatings. For coatings applications, phenolic resins are grouped into four classes, depending on heat reactivity and the type of phenol. Substituted phenols are more compatible with oil and hydrocarbons, whereas heat-reactive resins require polar solvents. Depending on its nature, the resin can be used alone or as a modifying resin that acts as an adhesion promoter, a chemical cross-linker, or a hardening agent. In these cases the primary resin may be an alkyd, polyester, or epoxy (93).

Unsubstituted heat-reactive resins are designed for baked-on coatings and are usually not oil-soluble. They require strong solvents and although most are not water-miscible, their low molecular weight, high formaldehyde content promotes water miscibility. These resins are available as solids, viscous liquids, and solutions. Resins prepared with an alkaline catalyst and a slight excess of formaldehyde over phenol are heat-reactive, but not as much as resole resins designed for fiber bonding and paper impregnation. Recommended cure conditions are 30 min and 150°C.

Heat-reactive resins are more compatible than oil-soluble resins with other polar-coating resins, such as amino, epoxy, and poly(vinyl butyral). They are used in interior-can and drum linings, metal primers, and pipe coatings. The coatings have excellent resistance to solvents, acids, and salts. They can be used over a wide range of temperatures, up to 370°C for short periods of dry heat, and continuously at 150°C. Strong alkalies should be avoided.

The maximum recommended film thickness is 25 μm. At greater thicknesses, volatiles from the curing reaction, mainly water and some formaldehyde and phenol, can cause defects. These coatings have excellent electrical insulation properties, ie, up to 20 V/μm, because of low moisture absorption and low conductance. The coatings are hard with low flexibility, depending on curing conditions and film thickness.

Phenolic baking coatings can be used for metal, ceramic, and plastic surfaces. Applications include equipment for heating and air conditioning, chemical processing, petroleum refining, and water treatment. Some types are used in oil-well pipes and marine environments (94). Certain coatings can be used in food and beverage processing, subject to regulations.

The largest use of novolak resins in coatings is as a hardener for epoxy resins. The epoxy is frequently based on bisphenol A or epoxidized novolaks. Basic catalysts such as benzyldimethylamine are required for moderate baking conditions, such as 2 h at 180°C. The phenolic/epoxy ratio is adjusted to be stoichiometrically equivalent in order to give a highly cross-linked coating that has moderate

flexibility and excellent resistance to chemicals, heat, and moisture. Powder coating of pipes continues to be a growing application, especially when corrosion resistance is required. In solution form, the epoxy–phenolic systems are used as metal primers and in pipe coating.

Substituted heat-reactive resins are most widely used in contact-adhesive applications and, to a lesser extent, in coatings (95,96); *p*-butylphenol, cresol, and nonylphenol are most frequently used. The alkyl group increases compatibility with oleoresinous varnishes and alkyds. In combination with these resins, phenolics reduce water sensitivity. Common applications include baked-on and electrical insulation varnishes, and as modifiers for baking alkyds, rosin, and ester gum systems. Substituted heat-reactive resins are not used for air-dry coatings because of their soft, tacky nature in the uncured state; substituted nonheat-reactive phenolics are the modifying resin of choice in this case.

Substituted nonheat-reactive resins do not form a film and are not reactive by themselves, but are excellent modifier resins for oleoresinous varnishes and alkyds. Their high T_g and molecular weight provide initial hardness and reduce tack; oxygen-initiated cross-linking reactions take place with the unsaturated oils.

Early phenolic resin drying-oil varnishes were cooked in order to incorporate the phenolic resin into the formula. These resins have been replaced by cold-cut resins that reduce atmospheric emission by permitting direct incorporation of the phenolic after the oleoresinous varnish has been prepared. High solids systems enable coatings to meet the VOC standards required by regulatory agencies. Newer phenolic varnishes, developed in the 1980s, may contain as high as 80% nonvolatile solids (97).

Oleoresinous phenolic varnishes are excellent coatings that dry in 2–4 h and show exterior durability, corrosion resistance (especially when aluminum-modified), compatibility, solubility, and good package stability. Recoatability and intercoat adhesion are also excellent. The films are sensitive, however, to strong solvents and concentrated acids and alkalies. Unlike systems containing cross-linking phenolics, films containing these resins remain flexible.

Phenolics that are not heat-reactive may be incorporated into both air-dried and baked oleoresinous coatings. Applications vary widely and include clear and pigmented exterior varnishes, aluminum-maintenance paints, zinc-rich primers, can coatings, insulation varnishes, and concrete paints. As modifiers in a great variety of applications, they enhance the performance of oleoresinous and alkyd coatings.

Dispersions. In phenolic resin dispersions, the continuous phase is water or a nonpolar hydrocarbon solvent. The resin exists as droplets that have particle sizes of 1–20 μm and are dispersed in the continuous phase. Aqueous dispersions are prepared either *in situ* during the preparation of the resin itself or by high shear mixing (26,37).

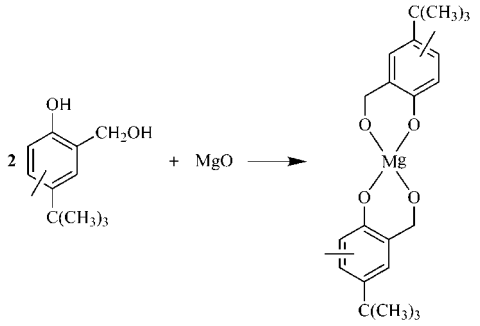
Aqueous dispersions are alternatives to solutions of liquid and solid resins. They are usually offered in 50% solids and may contain thickeners and cosolvents as stabilizers and to promote coalescence. Both heat-reactive (resole) and nonheat-reactive (novolak) systems exist that contain unsubstituted or substituted phenols or mixtures. A related technology produces large, stable particles that can be isolated as discrete particles (52). In aqueous dispersion, the resin structure is

designed to produce a hydrophobic polymer, which is stabilized in water by an interfacial agent.

Aqueous dispersions are used in fiber bonding, paper coating, friction and abrasive applications, and laminates and wood bonding. Phenolic dispersions improve the strength of latex-contact adhesive applications. Epoxy-modified phenolic dispersions are prepared by dispersion of the phenolic epoxy resin. The systems are used for baked primer applications and bonding requirements. Minimum baking conditions are 20 min at 150°C (26).

Adhesives. Contact adhesives are blends of rubber, phenolic resin, and additives supplied in solvent or aqueous dispersion form; they are typically applied to both surfaces to be joined (98). Evaporation of the solvent leaves an adhesive film that forms a strong, peel-resistant bond. Contact adhesives are used widely in the furniture and construction industries and also in the automotive and footwear industries. The phenolic resins promote adhesion and act as tackifiers, usually at a concentration of 20–40%. In solvent-based contact adhesives, neoprene is preferred, whereas nitrile is used in specialty applications. The type and grade of phenolic resin selected control tack time, bond strength, and durability.

Neoprene–phenolic contact adhesives, known for their high green strength and peel values, contain a resole-type resin prepared from 4-*t*-butylphenol. The alkyl group increases compatibility and reduces cross-linking. This resin reacts or complexes with the metal oxide, eg, MgO, contained in the formulation, and increases the cohesive strength of the adhesive. In fact, the reactivity with MgO is frequently measured to determine the effectiveness of heat-reactive phenolics in the formulation.



Phenolic resins substantially increase open time and peel strength of the formulation (98). For example, higher methylol and methylene ether contents of the resin improves peel strength and elevated temperature resistance. Adhesive properties are also influenced by the molecular weight distribution of the phenolic; low molecular weight reduces adhesion (99).

Waterborne contact adhesives contain an elastomer in latex form, usually an acrylic or neoprene-based latex, and a heat-reactive, cross-linkable phenolic resin in the form of an aqueous dispersion. The phenolic resin improves metal adhesion, green strength, and peel strength at elevated temperature. A typical formulation contains three parts latex and one part phenolic dispersion (dry weight bases). Although metal oxides may be added, reaction of the oxide with the phenolic resin does not occur readily.

Bonding properties of water-based contact adhesives are similar to those of solvent-based systems, but are free of flammability hazards. However, drying times are longer and the bond is sensitive to moisture.

Carbonless Copy Paper. In carbonless copy paper, also referred to as pressure-sensitive record sheet, an acid-sensitive dye precursor, such as crystal violet lactone or *N*-benzoylleucomethylene blue, is microencapsulated with a high boiling solvent or oil within a cross-linked gelatin (94,100,101) or in synthetic mononuclear microcapsules. Microcapsules that have a starch binder are coated onto the back of the top sheet. This is referred to as a coated-back (CB) sheet. The sheet intended to receive the image is treated on the front (coated-front (CF)) with an acid. When the top sheet is mechanically impacted, the dye capsules rupture and the dye solution is transferred to the receiving sheet where the acid developer activates the dye.

The original acid–clay developers have been largely replaced by phenolic compounds, such as para-substituted phenolic novolaks. The alkyl group on the phenolic ring is typically butyl, octyl, nonyl, or phenyl. The acidity is higher than that of a typical unsubstituted novolak because of the high concentration of 2,2′-methylene bridges.

Color intensity and permanence are improved by metal carboxylate salts, especially zinc salts (100), which catalyze the dye development and stabilize the dye in its colored form. The substituted novolak resin, along with extender and binder, can be applied to the receiving sheet as a solution or aqueous dispersion. Aqueous dispersions are probably the most widely used; they are manufactured by the resin supplier or the user from the base resin.

A typical coating composition for the CF component is shown in Table 11. It is dried in a high velocity air oven at 93°C.

Molding Compounds. Molding compounds were among the earliest applications for solid phenolic resins. Molding neat phenolic resin was almost impossible and the strength, especially on impact, was poor without reinforcement. Combining the resin, usually a novolak, with hexa, wood-flour, or asbestos reinforcement, as well as pigments and additives, gave a moldable thermoset. The molded articles exhibit high temperature, flame, and chemical resistance, retention of modulus at elevated temperature, and hardness. Systems that have good electrical properties can be formulated at low cost. Resins can be compounded with a choice of fillers for a variety of applications.

ASTM D4617-96 is the specification that covers phenolic molding compounds. The general-purpose compounds, having good strength and electrical properties,

are used in electrical appliances, automotive ignitions, and handles. Impact-resistant grades contain longer glass and textile fibers and rubber modifiers. Applications include pump housing and switches. Heat resistance is improved by incorporating mineral and glass fillers. Electrical-grade compounds contain mica and fiber glass fillers, and are used in specialty switches and cases. Graphite filler reduces the coefficient of thermal expansion. Although phenolic molding compounds compete with a wide variety of thermoset and thermoplastic compounds, they continue to be the preferred material in numerous applications, such as reinforced phenolic pistons in automotive disk brakes and transmission torque converters. Table 12 lists several applications for molded phenolic parts.

Phenolic molding materials are prepared by first blending the pulverized raw materials. In a compounding operation, the blend is passed through heated rolls to form a sheet as the resin melts. The compounded mixture remains on heated rolls until the desired flow and viscosity are reached. At this point, it is discharged as a thin sheet and allowed to cool. The product is then granulated and packaged. Alternatively, a Banbury-type mixer can be used for the initial mixing; the mix is then fed to a roll mill for finishing and sheeting. Compounding extruders are also used and through a continuous process provide a pelletized product.

Phenolic resins used in molding materials are predominantly novolaks with hexa as the curing agent. Oxalic acid catalyzed novolaks and high ortho resins are used. Resole resins may be used in place of hexa as the curing agent in certain electrical applications in which the NH_3 generated from the hexa can adversely affect metals such as copper and silver. Typically, the compound contains 40–50 wt% resin binder, 40–45% filler, and 5–10% pigment and additive. Fillers and reinforcements include wood flour, nutshell flour, cellulose fiber, mica (qv), wollastonite, mineral wool, mineral flour, glass fiber, organic fiber, carbon fiber, clay, and talc. Additives and pigments are magnesium oxide, graphite, molybdenum

sulfide, stearates, calcium carbonate, carbon black, nigrosine, lime, fluoropolymers, and salicylic acid.

Molding materials are fabricated into articles by compression, transfer, and injection molding processes. For compression molding, the powder is poured into the mold cavity or a preform heated prior to molding. Temperature ranges from 140 to 190°C and pressures from 13.8 to 55.5 MPa (2000–8000 psi). Because the material is more fluid in the mold, transfer molding is suitable for molding around inserts or for intricate shapes. In injection molding, cross-linking in the barrel and sprues must be avoided.

Abrasives. Abrasive materials are either bonded or coated. Bonded phenolic abrasives have superior strength and shock resistance compared to sintered ceramic compositions. The higher stability permits higher rotational speeds for resin-binder wheels; however, temperatures are lower than with ceramic wheels.

Synthetic aluminum oxide and silicon carbide are the principal inorganic abrasive materials. They are used in grit sizes from 44 or finer to 1680 μm (12–325 mesh). The coarser grit sizes are used for rough work when wheels are as large as 60 cm in diameter and 7.5-cm thick. These wheels are mounted in swinging-frame grinders and used to remove surface imperfections from stainless steel billets. Finer grit (250 μm (60 mesh)) may be used in 45-cm-dia cutoff wheels mounted in automatic grinders. These wheels can slice through a solid 2.5-cm steel bar in 4 s, leaving a clean, shiny cut surface.

In the usual method of manufacture, the grit is first wetted with a low viscosity liquid resole phenolic resin or furfural, using 1–3 wt% of the grit. A dry mixture of phenolic resin and fillers is added and the combination of wet grit and powder is tumbled until each grit particle is coated. The mix is temporarily dry and free-flowing. The powdered phenolic resin varies from 6 to 10% of the weight of the grit. The quantity and type of filler (alumina, cryolite, iron oxide, silicate) depend on the intended use of the wheel, whose grinding characteristics are affected by the filler. The free-flowing grit resin mix is placed into the mold and pressed at RT for 1–2 min at 13.8–34.5 MPa (2000–5000 psi). The dense form is removed and cured for 12–24 h; temperatures are increased gradually to 185°C for 8–12 h. Pressing temperatures may be increased for high density structures.

Heat resistance is an important characteristic of the bond. The strength of typical abrasive structures is tested at RT and at 300°C. Flexural strengths are between 24.1 and 34.4 MPa (3500–5000 psi). An unmodified phenolic resin bond loses about one-third of its RT strength at 298°C. Novolak phenolic resins are used almost exclusively because these offer heat resistance and because the moisture given off during the cure of resole resins results in undesirable porosity. Some novolaks modified with epoxy or poly(vinyl butyral) resin are used for softer grinding action.

Coated abrasives, such as sheets, disks, and drums, are used for polishing and finishing. Here, too, the abrasives, such as aluminum oxide and silicon carbide, have replaced the flint and garnet of common sandpaper. These industrial coated abrasives are manufactured from cloth or tough paper base. First, a coat of medium viscosity liquid resole resin is laid down on a continuous web of the backing. The web passes wet-side-down over a pan of grit, which adheres to it electrostatically and remains embedded in the resin layer. Altering the strength of the applied electrostatic field and the speed of the web can control the amount of grit deposited,

which varies from an open to a closed dense mass of abrasive. The uncured coated sheet is partially dried in a low temperature oven at 60°C, and a second, thinner coating of lower viscosity liquid resole resin is applied as a top to anchor the grit thoroughly. The coated web is taken off in rolls to be cured at 107–120°C for 3–4 h.

The resins should dry quickly and cure well at low temperatures. They usually are made at a high pH with high ratios of formaldehyde to phenol and held to fairly low molecular weight. Typical viscosities are 15,000 mPa·s (=cP) at 75% solids content for a first coat and 1000 mPa·s (=cP) at 50% solids for the top resin. For dense backing materials, such as fiber disks, a typical resin has a viscosity of 50,000 mPa·s (=cP) at 80% solids and is cured at 148°C. New opportunities are arising for coated abrasive belts in high pressure grinding. High strength backing has been developed and zirconia media are available for grinding.

Friction Materials. Phenolic friction materials are made from molding compounds developed to meet the extraordinary demands required by friction elements in the transportation industries. Friction materials are used for brake linings, clutch facings, and transmission bands. A moderately high coefficient of friction, which is temperature-independent, is needed. In addition, the material must be high in strength, low in wear and abrasion, and resistant to moisture and hydraulic fluids.

In the 1980s, significant changes occurred in automotive brake elements. Reformation of friction elements eliminated asbestos and increased employment of disk brakes. These developments required binder resins that have higher temperature performance without affecting the coefficient of friction and wear. Alternatives to asbestos include mineral, carbon, aramid, and metal fibers, especially iron. Semimetallic linings contain as much as 70% iron fibers. Other inorganic fillers include barites, alumina, lime, magnesia, and clay. Graphite and molybdenum disulfide are used to reduce scoring.

The resins can be a novolak–hexa or a resole–novolak blend. In some applications liquid resoles are used. Addition of alkylated phenol, oil, or cashew nutshell liquid (CNSL) reduces hardness and increases abrasion resistance. Modification by rubber improves the coefficient of friction and reduces brake fading.

Many friction material formulations contain 5–15 wt% of friction particles, the granulated cross-linked products of the reaction of CNSL, a phenol substituted at the meta position with a C_{15}, unsaturated side chain, and formaldehyde. Friction particles range in size from 50 to 500 μm. They reduce frictional wear and increase pedal softness (103).

Manufacture of friction elements includes the impregnation of fabrics and subsequent lamination, the wet-dough process, and the dry-mix process. Elements from the last two are prepared by compression-molding the formulation for up to an hour at 150–175°C. Thick brake elements require a carefully controlled heating-and-cooling cycle to minimize stresses created by expansion and contraction.

Foundry Resins. In the foundry industry, phenolic resins are used as the binder for sand in the manufacture of shell molds and cores. The two mating halves are joined by clamps or a bonding agent to form a shell mold into which the molten metal is poured for castings. The shell is formed by depositing a resin–sand mix on a hot metal pattern plate. After a certain period the pattern is inverted and

the excess resin–sand is removed. The sand particles are bonded by an oven cure, and the shell is ejected from the pattern plate.

Iron is the preferred metal for casting; steel and nonferrous metals are used in smaller amounts. Most castings are made in green sand molds, ie, uncured molds of sand, clay, and water. However, the use of shell moldings is growing, because such moldings permit reproducibility of castings with close dimensional accuracy. In addition, the simplicity of equipment procedures reduces costs.

The shell-molding process, introduced in the United States in 1948, is an important market for phenolic resins. In the original process, dry sand and powdered resin (6–8%) are blended. However, because of the high binder content and the difficulty in obtaining a uniform mix, precoating methods were developed.

Both cold- and warm-coating processes employ solutions of phenolic resins. The principal process used for foundry resins is the hot-coating process. It is the fastest, least expensive, and safest process, and it requires no volatile removal. The sand is heated to 135–170°C in a muller, and solid novolak resin in flake form is added, which melts quickly and coats the sand. A lubricant may be added at this point. After 1 min of mulling, the batch is cooled by adding water, which evaporates rapidly.

Hexa, which is not supplied with the resin, is usually added either with the water as a solution or just before or immediately after the water addition. By quenching the mix with water, the resin-coated sand is cooled to a point where there is no significant reaction with the curing agent. Any reaction between the resin and the hexa in the muller affects the bonding properties of the coated sand. As the batch cools and begins to break up, more lubricant may be added, which remains on the outside of the coated grains where it is most effective.

The total cycle time for most production batches is 2.5–3.5 min, considerably shorter than the cold- or warm-coating processes. Although a few available units have large capacity per batch, high production rates are possible because of the short cycle. While one batch is being mulled, sand for the next batch can be heated. The typical flake phenolic is an intermediate melting-point novolak containing 4% lubricant.

Laminates. Laminate manufacture involves the impregnation of a web with a liquid phenolic resin in a dip-coating operation. Solvent type, resin concentration, and viscosity determine the degree of fiber penetration. The treated web is dried in an oven and the resin cures, sometimes to the B-stage (semicured). Final resin content is between 30 and 70%. The dry sheet is cut and stacked, ready for lamination. In the curing step, multilayers of laminate are stacked or laid up in a press and cured at 150–175°C for several hours. The resins are generally low molecular weight resoles, which have been neutralized with the salt removed. Common carrier solvents for the varnish include acetone, alcohol, and toluene. Alkylated phenols such as cresols improve flexibility and moisture resistance in the fused products.

Industrial laminates are composed of two or more webs in sheet form that have been impregnated with a thermosetting resin and molded under heat and pressure. The web is usually made of cellulose paper, cotton fabric, glass cloth, glass mat, asbestos paper, wood veneer, and similar materials. Laminates are manufactured in sheets, rods, tubes, and special shapes, which can be machined by

common methods to produce parts for a wide range of uses. An important example is in printed-circuit applications, which require varnishes that impart electrical properties, punchability, machinability, and hot-solder and solvent resistance to the laminate. General-purpose laminates are used in gears, spacers, cams, ball-bearing retainer rings, and other structural parts requiring machinability as well as moisture, oil, and impact resistance.

A decorative laminate is composed of layers of resin-impregnated paper, which have been molded together under heat and pressure to form a solid homogeneous sheet. The component parts are composed of corestock impregnated with phenolic, print, and overlay. The corestock confers body and strength. The print sheet provides the design characteristic; it is impregnated with melamine resin, as is the overlay sheet that imparts abrasion protection to the print sheet. Approximately seven sheets of phenolic-impregnated corestock are covered with one print sheet, which, in turn, is covered with one overlay sheet. This combination is molded against polished steel plates to obtain the desired finish, usually satin or gloss.

The type of varnish used in the process depends on the kraft paper manufacturer and basis weight of the papers; the machine, temperature, and control (scraper bars, squeeze rolls) used; the method of cutting the paper to size; the laminate being produced (post-forming or regular); and the press-cure cycle.

Air and Oil Filters. Liquid resole resins are used to coat and penetrate the cellulose fibers of filters and separators in order to increase strength and stiffness and protect against attack by the environment. The type of phenolic to be used depends on both the final property requirements and the papermaking process.

Air and oil filters are made by a dry-web process in which the filter paper is dried over heated metal drums. The paper is saturated with the phenolic resin solution, either off- or on-line, and dried in an oven advancing the resin to the B-stage (semicured). The sheet, containing 20–30% resin, is rolled and shipped to the filter-unit manufacturer, where the sheet is convoluted and the filter assembled and cured to the C-stage (fully cured).

The resins used in air and oil filters are moderate-to-low molecular weight, catalyzed by caustic in one step; 10–20% alcohol is added; solids content is in the range of 50–60%. These resins are designed to penetrate the sheet thoroughly, yet not to affect the porosity of the paper. In the B-stage, the resin must have sufficient flexibility to permit pleating; the C-stage should have stiffness and resistance to hot oil.

Wood Bonding. This application requires large volumes of phenolic resins (5–25% by weight) for plywood, particle board, waferboard, and fiberboard. Initially, phenolic resins were used mainly for exterior applications, whereas UF was used for interiors. However, the concern over formaldehyde emission has caused the replacement of UF by phenol–formaldehyde adhesives.

Different phenolic resins are used for different types of wood; for example, plywood adhesives contain alkaline-catalyzed liquid resole resins. Extension with a filler reduces cost, minimizes absorption, and increases bond strength. These resins have an alkaline content of 5–7% and are low in free phenol and formaldehyde. Because many resins have a high water content and limited storage stability, they are frequently made at or near the mill producing the plywood product. The

plywood veneers are dried, coated with resin, stacked for pressing, and cured at 140–150°C.

Particle board and wood chip products have evolved from efforts to make profitable use of the large volumes of sawdust generated annually. These products are used for floor underlayment and decorative laminates. Most particle board had been produced with UF adhesive for interior use; resin demand per board is high due to the high surface area requiring bonding. Nevertheless, substantial quantities of phenol–formaldehyde-bonded particle board are produced for water-resistant and low formaldehyde applications.

The phenolic resins used for particle board are NaOH-catalyzed resoles of low viscosity and high water miscibility, similar to the liquid resole adhesives used in plywood manufacture. The higher resin and caustic content of the board frequently necessitates the addition of hydrophobic agents such as wax emulsions to increase the barrier properties of the board. The adhesive is applied to the particles in thin streams using high agitation to maximize material usage. Boards are cured in presses for 5–10 min at 150–185°C.

Waferboard, a more recent wood construction product, competes more with plywood than with particle board. Waferboard and strand board are bonded with solid, rather than liquid, phenolic resins. Both pulverized and spray-dried, rapid-curing resins have been successfully applied. Wafers are dried, dusted with powdered resin and wax, and formed on a caul plate. A top caul plate is added and the wafers are bonded in a press at ≈180°C for 5–10 min. Physical properties such as flexural strength, modulus, and internal bond are similar to those of a plywood of equivalent thickness.

Fiberboard or hardboard is made of low grade wood and wood waste. In the wet production process, a sheet is produced on a papermaking machine, such as a fourdrinier. A liquid resole is usually added to the beater section and precipitated onto the wood fibers by adjusting the pH. The moderately dry felt is further dried and cured in an off-line press.

Fiber Bonding. In fiber bonding, the resin is used as a binder in such products as thermal insulation batting, acoustic padding, and cushioning materials. All these materials consist of long fibers (glass or mineral fiber, cotton, polyester) laid down in a randomly oriented, loosely packed array to form a mat. They are bonded with resin to preserve the special insulating or cushioning quality of the mat.

In the dry-bonded process, fibers are reclaimed from woven textile scraps and powdered resin. Automotive acoustical padding (cotton and synthetic organic fiber) and thermal insulation batting (glass fiber) are made by this process. Inorganic and/or organic fibers are picked open to allow distribution of the phenolic resin among individual fibers. The fiber–resin mixture is formed into a blanket by cross-lapping a series of webs or by being blown into a chamber for deposition. The blanket is oven-cured to fuse the resin. Oven temperatures, dwell times, molding temperatures, and cycle times vary, depending on the type of fiber and curing characteristics of the resin.

The wet-bonded process uses virgin fiber spun from molten glass and liquid water miscible resin. High grade, thermal insulation batting is made by this process. The most common wet-bonded process for manufacturing glass or rock-wool, thermal insulation batting employs steam- or air-blowing. A stream of molten glass falls from the melting furnace into a rapidly spinning platinum

cylinder. Centrifugal force causes the glass to be extruded through many small holes in the cylinder wall. At the outside, the fibers are attenuated (drawn) by the action of a jet flame from burners located around the spinning cylinder. Spray nozzles located just below this unit apply liquid binder resin to the fibers, which are sucked onto a moving screen to form a continuous mat. The mat is conveyed through a forced hot-air curing oven similar to that used in the dry-bonded process. Curing is followed by cool-down, trimming, slitting, and roll-up.

Fiber bonding resins are marketed in the form of finely pulverized powders of novolak/hexa mixtures or resoles and water-miscible liquids. Resole resins are the standard for the fiber bonding industry. They have excellent curing properties and low content of solvent extractables after curing. Bond strength to the fiber is high and resin usage is low. Solid resole resins must be stored cool to reduce sintering and aging.

Novolak-based resins are primarily used for organic fibers. They require a cross-linking reagent, usually hexa, for cure. Bond strength is good, producing bonded mats that have high tensile strengths. The storage stability is also good, so that refrigeration is rarely required. A typical binder mix produced by the customer consists of phenolic resin, urea, hydrocarbon oil or wax emulsion, ammonium sulfate, and occasionally a silane adhesion promoter; it is diluted with water to 5–10% solids content. The urea acts as a scavenger for the free formaldehyde (5–8%) invariably present, both as an inexpensive extender and, owing to its high nitrogen content, as an antismoldering agent. The oil or wax emulsion acts as a fiber lubricant and dust suppressant, the ammonium sulfate as a cure accelerator, and the silane as an adhesion promoter. The large volume of water in the binder mix cools the newly spun fibers, thus preventing premature resin cure, ie, before the mat has been formed and compressed to the proper thickness. All water-miscible resins must be stored under refrigeration.

Composites. There has been substantial progress in improving the processability of phenolics in composite materials (104–106) to the point where a variety of materials are available for pultrusion, filament winding, and resin-transfer molding (see COMPOSITES, FABRICATION). More complicated composite systems are based on aramid and graphite fibers.

Epoxy resins are usually superior to phenolics because of better adhesion, lower shrinkage on curing, and a much lower volatile content. Nevertheless, there are many specific applications for phenolic resins, including formable laminates and sheet-molding compounds having low flammability and smoke generation. These systems are suitable for aircraft interiors. Another area is in binders for carbon–carbon composites for applications such as in ablative coatings of reentry vehicle and aircraft brakes. The high char yield and the strength and porosity of the char are important in these applications. Finally, phenolic novolaks are effective curing agents for epoxies, and epoxidized novolaks are being used in applications requiring high functionality and high cross-link density.

Glass-Reinforced Composites. These composites are prepared from SMC and by liquid injection molding, (LIM). Phenolic resins are usually not amenable to LIM because of the volatiles generated. However, a resin suitable to LIM has been prepared (107). The properties of the 60% glass-mat-reinforced product obtained from this resin were compared to conventional isophthalic polyester and vinyl ester sheet-molding compounds at equivalent glass loading; the mechanical

Table 13. Mechanical Properties of Composites[a]

Matrix resin	Flexural strength,[b] MPa[c]	Elongation, %	Notched Izod, J/m[d]	UL-94
Phenolic	228	2	1868	V0
Polyester	276	1.75	960	Burns
Vinyl ester	310	2	1227	Burns

[a]Glass content, 60%.
[b]For all three matrix resins, the flexural modulus is 12 GPa (1.7×10^6 psi).
[c]To convert MPa to psi, multiply by 145.
[d]To convert J/m to ft·lbf/in., divide by 53.38.

properties are shown in Table 13 (108,109). The phenolic resin systems have slightly lower strength values but measurably higher impact resistance. In addition, the phenolic glass composite has a UL-94 V0 rating, whereas the polyester SMC burns.

A patent describes the glass-reinforced pultrusion of phenolic resin composites (110). In pultrusion, bundles of continuous fiber are wetted with resin and shaped and cured through a series of heated dies. A sulfonic acid accelerates the cure rate, which must be high. The mechanical properties are reported to be equivalent to those obtained from conventional unsaturated polyesters, but the heat-distortion temperature and flammability resistance are superior. An acid-free phenolic pultrusion system has been announced that can produce large panels for buildings, ships, aircraft, and mine ducts. The system involves an injection-type die rather than conventional dip tanks, and up to 70% glass loadings can be attained (111).

Phenolic sheet-molding compound is seeing increased use in interior and exterior applications in mass transit. The trains in service on the English Channel tunnel have several panels made from phenolic SMC, which had to meet the strict European safety standards for fire and smoke generation.

Phenolic resin prepregs on glass fibers are prepared from alcohol solution and occasionally from aqueous solutions. The glass web is dipped in a tank containing resin solution; the resin content in the web is controlled by metering rolls. The wet web is dried in a horizontal or vertical oven arrangement and cured to B-stage of the resin. The dry web is cut, stacked, and stored under refrigeration until used in a laminate. Depending on the application, the prepreg can be rigid, similar to the epoxy-type prepregs used in laminated circuit boards, or soft and flexible, which provides the tack and drape required to conform to a shaped article. Autoclave molding is essential for shaped articles to reduce void formation by trapped air and volatiles. Examples of shaped articles include interior parts of commercial airplanes such as the composite duct assembly, based on wrapped phenolic – fiber glass, being used on the Boeing 737. Although not equal to epoxy-prepreg systems in strength, phenolic resins provide superior flammability resistance and lower smoke toxicity, because antimony and halogens are absent.

Carbon-Fiber Composites. Cured laminates of phenolic resins and carbon-fiber reinforcement provide superior flammability resistance and thermal resistance compared to unsaturated polyester and epoxy. Table 14 shows the dependence of flexural strength and modulus on phenolic–carbon-fiber composites at 30–40% phenolic resin (112). These composites also exhibit long-term elevated temperature stability up to 230°C.

Table 14. Strength Properties of Phenolic–Carbon-Fiber Composites

	Resin, %		
	Phenolic		
Property	40	35	Epoxy novolak, 27

Flexural strength, MPa[a]	183	126	110
Flexural modulus, GPa[b]	15.8	6.3	6.4

[a] To convert MPa to psi, multiply by 145.
[b] To convert GPa to psi, multiply by 145,000.

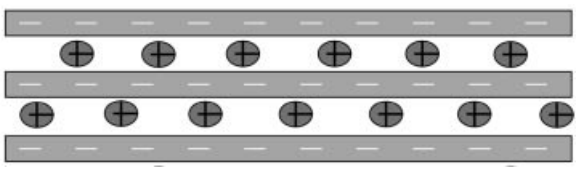
Carbon–Carbon Composites. Above 300°C, even such polymers as phenolics and polyimides are not stable as binders for carbon-fiber composites. Carbon–carbon composites are used at elevated temperatures and are prepared by impregnating the fibers with pitch or synthetic resin, followed by carbonization, further impregnation, and pyrolysis (112).

Carbon–carbon composites are used in high temperature service for aerospace and aircraft applications as well as for corrosion-resistant industrial pipes and housings. Applications include rocket nozzles and cases, aircraft brakes, and satellite structures. Carbonized phenolic resin with graphite fiber functioned effectively as the ablative shield in orbital reentry vehicles for many years (113).

Phenolic and furfuryl alcohol resins have a high char strength and penetrate into the fibrous core of the fiber structure. The phenolic resins are low viscosity resoles; some have been neutralized and have the salt removed. An autoclave is used to apply the vacuum and pressure required for good impregnation and sufficient heat for a resin cure, eg, at 180°C. The slow pyrolysis of the part follows; temperatures of 1000–1800°C are recommended for the best properties. On occasion, temperatures above 1800°C are used and constant weight is possible even up to 2760°C (114). A new process for carbon–carbon composite has been developed for engine components using phenolic resin and PAN fiber to produce near netshape parts (115,116).

Nanocomposites. Work conducted at Toyota in nylon-6 nanocomposites has generated several commercial products and stimulated substantial interest in a variety of polymer/nanoclay systems (see NANOCOMPOSITES, POLYMER-CLAY). The melt intercalation and curing behavior of phenolic resin were investigated using layered silicates such as montmorillonite and alkyl ammonium modified layered silicates. It was found by X-ray diffraction that the uncured phenolic was effectively intercalated. Depending on the surface treatment, the resulting interaction between organic modifier and phenolic resin played an important role in determining the stable nauostructure and the final morphology of the layered silicate composite (117,118).

The diagram below shows a representation of a polymer–clay, nanocomposite (qv).



Liquid-Injection Molding. In LIM, monomers and oligomers are injected into a mold cavity where a rapid polymerization takes place to produce a thermoset article. Advantages of these processes are low cost, low pressure requirement, and flexibility in mold configuration. Conventional systems, such as isocyanate with polyol, release little or no volatiles. The generation of substantial volatiles in the mold is obviously undesirable and has represented a significant obstacle to the development of a phenolic-based LIM system. A phenolic LIM system based on an anhydrous high ortho liquid resole has been reported (119,120). Formaldehyde is present in the form of both methylol and phenolic hemiformals. A formaldehyde/phenol ratio of ≈1.5–1.0 is used at a pH of 4–7. Divalent salts catalyze the reaction at 80–90°C for 5–8 h and the water is removed by an azeotropic solvent. Uncatalyzed resoles have excellent storage stability.

An important aspect of this procedure is the use of latent acid catalysts, such as phenyl hydrogen maleate, phenyl trifluoracetate, and butadiene sulfone. These catalysts reduce the peak exotherm from over 200°C to 130–160°C. The resin catalyst mixture has a working life of up to several days at RT. The elevated temperature of molding these latent catalysts generates the corresponding acids, namely, maleic, trifluoracetic, and phenolsulfonic, which catalyze the resole reaction. Typically, a cycle time of 1–2 min is required for a mold temperature of ∼150°C.

The water liberated during the cure has no apparent effect on the composite properties. Glass-filled composites prepared in this manner retain mechanical properties at elevated temperatures as well as solvent and flammability resistance (108,109). Phenolic–graphite-fiber composites that exhibit superior mechanical properties have also been prepared by this process.

Foam. Phenolic resin foam is a cured system composed of open and closed cells with an overall density of 0.16–0.80 g/cm^3. Principal applications are in the areas of insulation and sponge-like floral foam. The resins are aqueous resoles catalyzed by NaOH at a formaldehyde/phenol ratio of ≈2:1. Free phenol and formaldehyde content should be low, although urea may be used as a formaldehyde scavenger.

The foam is prepared by adjusting the water content of the resin and adding a surfactant (eg, an ethoxylated nonionic), a blowing agent (eg, pentane, methylene chloride, or chlorofluorocarbon), and a catalyst (eg, toluenesulfonic acid or phenolsulfonic acid). The sulfonic acid catalyzes the reaction, while the exotherm causes the blowing agent, emulsified in the resin, to evaporate and expand the foam (121). The surfactant controls the cell size as well as the ratio of open-to-closed cell units. Both batch and continuous processes are employed. In the continuous process, the machinery is similar to that used for continuous polyurethane foam.

The properties of the foam depend mainly on density and the cell character. For insulation, a high content of closed cells, along with an encapsulated fluorocarbon blowing agent, is desired. The foam must have sufficient strength and be able to resist smoldering, ie, a glowing combustion characteristic of early foams. Smoldering is controlled by additives and foam structure. For floral foam, lower density and an open-cell structure having low toughness are desirable. Floral foam usually contains a wetting agent in the formulation to ensure the rapid uptake of water.

An all-phenolic sandwich structure for aircraft interior applications has been developed using syntactic and expandable semisyntactic phenolic foam. The

parts have outstanding fire behavior and are moldable to complex sandwich cores (117,118).

When smoldering is eliminated, phenolic foams exhibit excellent flammability resistance. Their LOI is 32–36%, and their smoke density is lower than that of polyisocyanurate foam of similar density. High thermal insulation K values have been obtained on foams of small cell size containing fluorocarbon blowing agents. Phenolic foams are used for building products and warehouse insulation and ASTM C1126-00 is the standard for faced or unfaced rigid cellular phenolic thermal insulation.

Honeycombs. Honeycomb structures usually involve resin-treated papers and fiberglass, sometimes with a core filler and surface skins bonded to the honeycomb. Uses can be in aircraft interior panels as well as more demanding parts. Phenolic resin-impregnated aramid paper honeycomb cores have been developed for fighter aircraft applications. These new honeycomb structures provide greater structural strength than other honecomb products currently available. One particular part application is the inlet cowl, which incorporates a complex structure, core machining, and core forming (122).

Spheres. Hollow spherical fillers have become extremely useful for the plastics industry and others. A wide range of hollow spherical fillers are currently available, including inorganic hollow spheres made from glass, carbon, fly ash, alumina, and zirconia; and organic hollow spheres made from epoxy, polystyrene, UF, and phenol–formaldehyde. Although phenol–formaldehyde hollow spheres are not the largest volume product, they serve in some important applications and show potential for future use.

In an early process by Sohio, a variety of compositions were produced by dissolving a film-forming polymer in a solvent (or water), adding a blowing agent, and spray drying the resulting solution under carefully controlled conditions. The use of spray drying to produce discrete, uniform hollow spheres, organic or inorganic, requires high skills in formulation, process control, and engineering. Some of the organic materials described include phenolic resins, poly(vinyl alcohol), polystyrene, methylcellulose, and protein. In the case of the phenolic resins, water-miscible resoles were used; water was the solvent and ammonium carbonate – ammonium nitrate or dinitrosopentamethylenetetramine was the blowing agent. Hollow phenolic spheres in sizes of 5–50-μm dia were obtained. The principal intended use was as a floating cap on petroleum naphtha and crude oil to retard evaporation.

Emerson & Cumming, Inc., eventually bought the rights to the Sohio process and produced a variety of microspheres. Union Carbide was licensed to produce the phenolic microspheres offered under the name Phenolic Microballoons (Table 15). When Phenolic Microballoons are introduced into a crude-oil storage tank, they form a fluid seal that rises and falls with the level of the oil. A continuous vapor-barrier seal is formed, which reduces evaporational losses up to 90%. Tests have been conducted under various mechanical and weather conditions and with crude oils of varying vapor pressure.

Phenolic Microballoons applications in plastics take advantage of low density, porosity, and surface-to-volume ratio to produce lightweight parts. Probably the most notable example is the syntactic foam.

Table 15. Physical Properties of Phenolic Microballoons

Property	Value
Average particle size, μm	43
Typical particle range, μm	20–120
Liquid displacement density, g/cm^3	0.15–0.35
Bulk density, g/cm^3	0.07–0.15
Toluene flotation, %	~90

While a conventional foam uses a blowing agent to form a cellular structure as the resin sets, syntactic foams are made by incorporating hollow spheres into liquid resins, especially epoxy resins in the case of Phenolic Microballoons, although urethanes and polyesters are also used. Having a continuous polymer phase and taking advantage of the high compressive strength of the spheres, syntactic foams can be made much stronger than conventional foams. In addition, they are being formed in place. As a result, syntactic foams have become widely used as a modeling, styling, and structural core material in automotive, marine, and aerospace applications.

A mixture of Phenolic Microballoons and resin binder has a putty-like consistency. It can be molded to shape, trowelled onto surfaces, or pressed into a core. Curing gives a high strength, low density (0.144 g/cm^3) foam free of voids and dense areas, and without a brittle skin. Syntactic foams are used in widely diverse applications, including boat flotation aids; structural parts in aircraft, submarines, and missiles; structural cores for wall panels; and ablative heat shields for reentry vehicles and rocket test engines.

Microballoons have been used for gap filling, where the spheres dampen sound or vibration in the structure. In the medical area, microballoons have been evaluated as a skin replacement for burn victims and phantom tissue for radiation studies. An important application is in nitroglycerin-based explosives, in which microballoons permit a controlled sequential detonation not possible with glass spheres.

In the 1990s, carbon microbeads have been produced by a proprietary process using phenolic resin. Potential applications are lubricants, adhesives, and conductive fillers for plastics, rubbers, and coatings (123).

Fibers. The principal type of phenolic fiber is the novoloid fiber (124). The term novoloid designates a content of at least 85 wt% of a cross-linked novolak. Novoloid fibers are sold under the trademark Kynol, and Nippon Kynol and American Kynol are exclusive licensees. Novoloid fibers are made by acid-catalyzed cross-linking of melt-spun novolak resin to form a fully cross-linked amorphous network. The fibers are infusible and insoluble, and possess physical and chemical properties that distinguish them from other fibers. Applications include a variety of flame- and chemical-resistant textiles and papers as well as composites, gaskets, and friction materials. In addition, they are precursors for carbon fibers.

The fibers are prepared from a high molecular weight novolak resin. Uncured fibers are prepared by melt-spinning the novolak. These fibers are then immersed in aqueous formaldehyde solution containing an acidic catalyst. As heat is applied, curing commences and the novolak resin is transformed into a cross-linked

network through the formation of methylene and dibenzyl ether linkages. The final cross-linked structure is free of molecular orientation, and the density of cross-linking is low. The fiber contains ≈5 wt% unreacted methylol groups, which can be utilized in the formation of novoloid-fiber composites, or be reduced by heating the cured fiber to 180°C.

Optimum mechanical properties of the fibers are developed provided the precursor novolak filaments are less than 25 μm in diameter to ensure sufficient diffusion of the formaldehyde and catalyst into the fiber. The individual fibers are generally elliptical in cross section. Diameters range from 14 to 33 μm (0.2–1.0 tex or 2–10 den) and fiber lengths are 1–100 mm. Tensile strength is 0.11–0.15 N/tex (1.3–1.8 g/den) and elongation is in the 30–60% range. Elastic recovery is as high as 96%.

The LOI of novoloid materials varies with the particular structure (fiber, felt, fabric) being evaluated; it is generally in the 30–34% range. By comparison, aramid fiber has a LOI of 28–31 and wool of 24. When exposed to flame, novoloid materials do not melt but gradually char until completely carbonized. The high strength of the phenolic char results in the fiber retaining its original fiber structure, and the char effectively absorbs heat from the materials. When novoloid products are exposed to flame, the products of combustion are principally H_2O, CO_2, and carbon char. Smoke emission is minimal, less than that of any other organic fiber.

Applications for novoloid fibers include a variety of flame-resistant protective clothing, safety accessories, and flame barriers for upholstered furniture. As an asbestos replacement, novoloid fibers have been used in gasketing, packings, brake linings, and clutch facings. In electrical applications, novoloid fibers and papers can be used as flameproof coatings and as wrapping tapes in wire and cable applications.

The novoloid molecular structure includes methylol groups, which are available for cross-linking with reactive sites in the matrix material. The ability of the fibers to react with matrix resins yields synergistic improvements in the properties of the composite. Novoloid fibers have been incorporated into composites with thermoplastic resins such as polypropylene, PVC, and polyamide polyesters. Thermosetting resins include phenolics, epoxies, and melamines. In certain elastomers, the methylol reactivity can be used to upgrade the high temperature performance, for example, in chlorinated polyethylene. A process has been announced that produces carbonized Kynol fiber having extremely high surface area (125).

POLY(*p*-PHENYLENEVINYLENE)

Introduction

Poly(*p*-phenylenevinylene) (PPV) and its derivatives are polymers that have been widely studied because of their potential applications in optoelectronic devices. PPV is a conjugated polymer, with a backbone consisting of alternating single and double bonds. Many conjugated polymers are known and exhibit remarkably high electrical conductivities when oxidatively or reductively doped (1) (see ELECTRICALLY ACTIVE POLYMERS). Much of the early research on PPV focused on the relatively disappointing properties of the doped material; however, interest in this material was reawakened in 1990 when Friend and co-workers in Cambridge discovered that films of undoped PPV could be used as the emitting layer in organic electroluminescent (EL) devices (2). This discovery stimulated intense research in the area, including many fundamental studies into the properties of PPV and its derivatives, as well as extensive academic and industrial interest on the applications of the materials (see LIGHT-EMITTING DIODES).

This article seeks to provide an overview of the methods by which PPV and some of its derivatives may be prepared, the physical and electronic properties of these materials, and the applications that are being explored. The reader who seeks a deeper and more detailed understanding of this fascinating material is referred to several excellent and comprehensive reviews that have been published on the synthesis, properties, and applications of PPV (3–7).

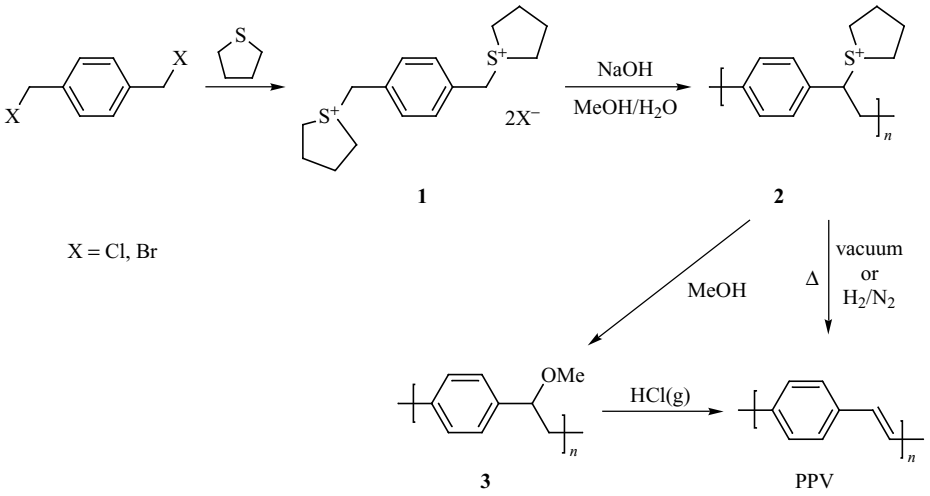
Methods of Preparation

Unsubstituted PPV. Many methods have been devised to prepare PPV for fundamental and applied studies. Because of its rigid conjugated backbone,

Encyclopedia of Polymer Science and Technology. Copyright John Wiley & Sons, Inc. All rights reserved.

unsubstituted PPV and even short oligomers are insoluble and intractable materials. An important consideration in all preparative routes that seek to prepare high molecular weight material, therefore, is the solubility of the growing polymer chain. One of the most successful approaches to high molecular weight (10,000–100,000) PPV is the Wessling or sulfonium precursor route, which proceeds via a soluble precursor polymer that is subsequently thermally converted to fully conjugated PPV. Other methods are available but generally produce low molecular weight material.

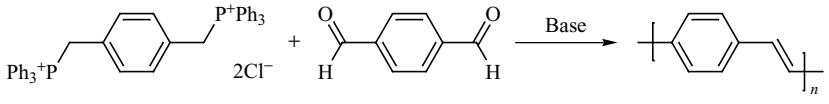
Sulfonium Precursor Route. In this route, polymerization of the bis sulfonium salt **1** with base yields a soluble polyelectrolyte **2** (8,9). This intermediate may then be purified, processed, and finally thermally converted to PPV. Both the nature of the sulfide used in the sulfonium salt and the counterion affect the conditions required in the preparation, as well as the molecular weight and structure of the resulting polymer (9,10). When dodecylbenzenesulfonate is used as a counterion, conversion to PPV is achieved in 3 min at only 115°C (11). A modified sulfonium precursor route has also been developed, in which the soluble methoxy-substituted polymer **3** is converted to PPV in the presence of HCl gas (12).



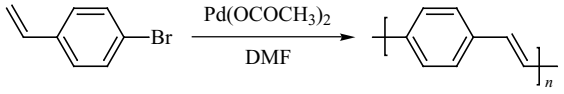
The mechanism of the polymerization has been the subject of some debate in the literature, with both radical and anionic mechanisms proposed. The presence of oxygen during the polymerization results in lower molecular weight polymer consistent with a radical mechanism (8). A *p*-xylylene or *p*-benzoquinodimethane intermediate is postulated and has been observed spectroscopically. Other studies have suggested that this intermediate polymerizes via an anionic mechanism (13, 14). Despite these conflicting results, the polymerization is typically carried out in the absence of oxygen, and the thermal conversion step done either in vacuum or under an inert or forming gas atmosphere.

Other Routes. Other synthetic routes to PPV include the Wittig reaction (eq. 1) (15), Pd-catalyzed Heck reaction (eq. 2) (16), and McMurry coupling (eq. 3) (17). Reaction of α,α'-dichloro-*p*-xylene with potassium *tert*-butoxide yields PPV

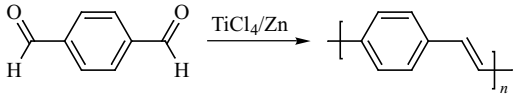
(eq. 4); this procedure was discovered by Gilch and Wheelwright and is referred to as the Gilch route (18). All of these methods yield PPV directly from soluble monomers, and thus produce primarily low molecular weight oligomers.



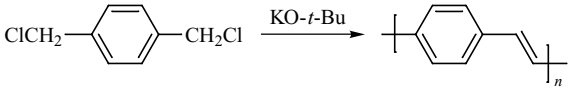
(1)



(2)

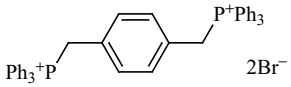


(3)

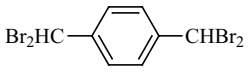


(4)

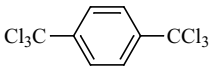
Electropolymerization is a convenient method for the preparation of insoluble conjugated polymers such as PPV because it yields thin films directly on an electrode surface. Such a film may then be directly utilized in an application requiring a conducting contact, such as electroluminescence. Several methods have been reported for the electrochemical preparation of PPV films. Electrochemical reduction of **4**,**5**,**6** has been shown to yield PPV films on metal and indium tin oxide (ITO) electrodes (19–21). Another direct route to thin-films is chemical vapor deposition (CVD) from precursors such as **7** or **8** (22,23).



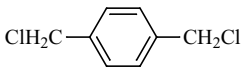
4



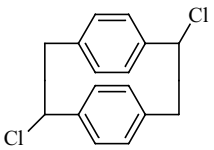
5



6



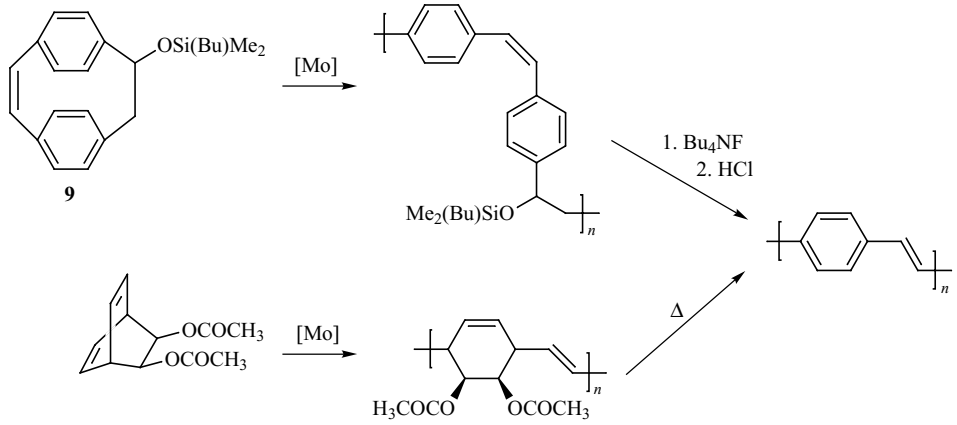
7



8

Ring-opening metathesis polymerization (ROMP) has been used to prepare unsubstituted PPV via a soluble precursor. Substituted paracyclophan-1-ene (**9**) (24) and norbornadiene derivatives (**10**) (25) have been used as monomers, with

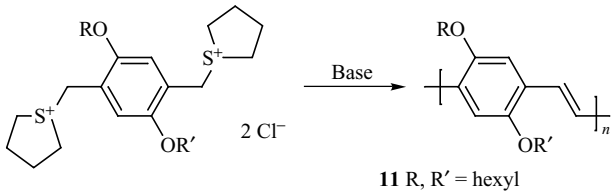
$Mo(NAr)(CHC(CH_3)_2C_6H_5)[OCCH_3(CF_3)_2]_2$ (Ar = 2,6-diisopropylphenyl) used as the catalyst in the polymerization. This route proceeds via a living polymerization and consequently yields a relatively narrow molecular weight distribution.



9 **10**

Substituted PPV. In order to increase the solubility and processibility of PPV in the conjugated form, substituents such as alkoxy or phenyl groups have been added to the backbone structure. In addition to enhancing the solubility, these substituents also change the electronic properties of the polymer via both inductive and conjugative effects. An additional benefit of soluble derivatives of PPV is that techniques for polymer characterization that require soluble material may be brought to bear on, and provide direct information about, molecular weights and higher-order structure.

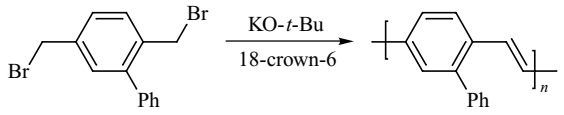
Sulfonium Precursor Route. The Wessling route has also been used to produce soluble derivatives from monomers containing solubilizing substituents on the phenyl ring. For example, dialkoxy-substituted monomers yield **11**, which is soluble in organic solvents such as chloroform and chlorobenzene (26), as well as poly[2-(2-ethylhexyl)oxy-5-methoxy-*p*-phenylene)vinylene], or MEH–PPV (**12**) (eq. 5) (27). The branched side chains in MEH–PPV improve the solubility of this derivative over unbranched analogs, and this polymer is one of the most popular for use in electroluminescence applications.



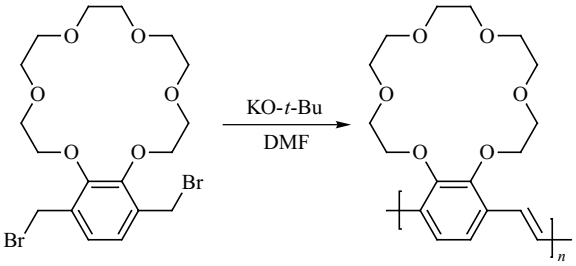
11 R, R′ = hexyl
12 R = methyl, R′ = 2-ethylhexyl (MEH-PPV) (5)

Other Routes. Substituted PPV derivatives have also been prepared by several other routes. In cases where the resulting polymers are soluble, these methods are often successful in preparing high molecular weight material. The Gilch route has been used to prepare phenyl and crown ether substituted polymers

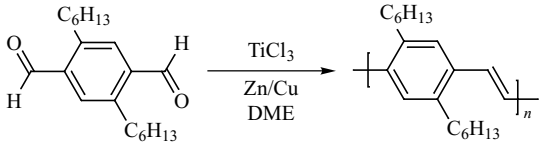
(**13** and **14**) (eqs. 5 and 6) (28,29), and McMurry coupling has been used to yield a dihexyl-substituted polymer (**15**) that is soluble in a range of organic solvents (eq. 7) (30).



13 (6)

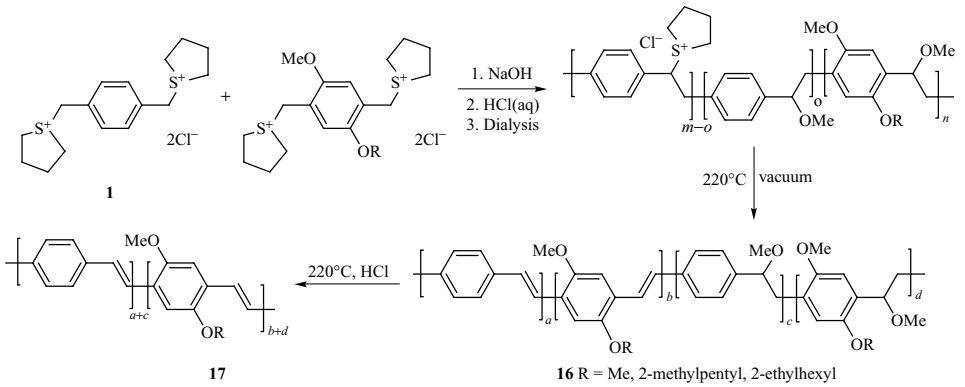


14 (7)



15 (8)

Copolymers. A number of studies have focused on the preparation of copolymers containing fully conjugated backbones, as well as those containing both conjugated and nonconjugated blocks. This work has been motivated by the desire to prepare materials having a range of electronic properties that can easily be tuned by variations in the proportion and nature of the monomers used in the copolymer synthesis. In addition, local variations in the π–π^* energy gap can be introduced in this way, which has been shown to result in dramatic improvements in the performance of these copolymers in electroluminescent devices.

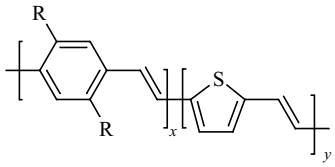


1

16 R = Me, 2-methylpentyl, 2-ethylhexyl

17

The sulfonium precursor route has been used to prepare copolymers by using various proportions of different monomers in the synthesis. This method has yielded both partially conjugated (**16**) and fully conjugated polymers (**17**) (31,32), as well as copolymers containing other aromatic groups in the backbone in addition to phenylenevinylene moieties such as in copolymer **18** (33).



18 R = H, OMe Cl

The Wittig reaction has also been successfully used to prepare soluble copolymers with substituents such as alkoxy groups on the backbone (**19**) (34), as well as copolymers containing flexible, nonconjugated spacers (**20** and **21**) (35,36). Heck chemistry has been applied to prepare copolymers such as **22** (37).

Composites and Blends. The mechanical and optoelectronic properties of PPV and its derivatives may be optimized for specific applications through the use of polymer blends (qv) and Composite materials (qv). Blends of MEH–PPV and polyethylene have been used to significantly enhance the degree to which the conjugated polymer chains are aligned upon stretching (38). The density of entanglements in gels of polyethylene is much lower than in spin-cast polymer solutions, and this effect remains after removal of the solvent. This allows tensile drawing of such blends to large draw ratios (>200), which causes the conjugated polymers to align to a degree normally expected in single crystals. Charge transport through blends can also be controlled by using a host polymer with specific properties. Blue emitters have been prepared from blends of poly(*p*-phenylphenylenevinylene) (PPPV) in poly(9-vinylcarbazole) (PVK), a hole-transporting polymer (28). In addition to enhancing the processibility of the PPPV, the PVK blue-shifts the electroluminescence, enhances hole-transport, and increases the probability of radiative recombination because of the dilution effect.

Composites of PPV with silica (SiO_2) and vanadium oxide (V_2O_5) have been prepared for use in nonlinear optical applications (39–41). These composites are prepared via sol–gel processing methods, and allow the superior nonlinear optical properties of the conjugated polymers to be combined with the very low optical losses found in inorganic glasses. In homogeneous nanocomposites of PPV with SiO_2, inter- and intrachain disorder in the polymer chains is disrupted when the silica interparticle separation is comparable to the coherence distance in the polymer. This influences the absorption and emission spectra, and results in reduced electronic conductivity (42). Composites of PPV with gold-coated silica nanoparticles showed enhanced stability to photo-oxidation, an effect attributed to an electronic interaction of the metal particles with the triplet excitons in PPV (43). Composite films of insulating SiO_2, TiO_2, and Al_2O_3 nanoparticles with MEH–PPV were prepared and result in more efficient charge injection and transport in electroluminescent devices formed from them, as well as enhanced emission intensities (44,45). Photovoltaic and time-resolved microwave conductivity measurements were also used to study nanocrystalline TiO_2/PPV composites, showing that excitons generated in the polymer are dissociated at the polymer/TiO_2 interface, with the electrons transferred to the nanocrystals (46). Indium arsenide-zinc selenide nanocrystals have been blended with MEH–PPV, giving materials emitting in the near-IR region (1–1.3 μm). External efficiencies of devices made from these composites were ∼0.5% (47).

Composites of PPV in films of the polyelectrolyte Nafion have been synthesized by electrostatically binding the dicationic monomer to the film, followed by treatment with base and thermal conversion (48). Ordered nanocomposites of PPV have been synthesized from mixtures of polymerizable lyotropic liquid crystals with PPV precursors (49). Photopolymerization of the host results in a hexagonal architecture, which can be fabricated into fibers and thin-films. A significant enhancement in photoluminescence of the composite relative to PPV was found.

Properties

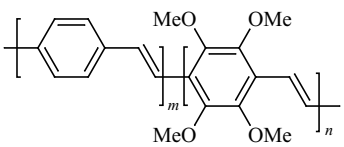
Absorption and Emission. Films of PPV show three absorption bands, with maxima at 6.12, 5.06, and 3.09 eV respectively (50). The two higher-energy bands are attributed to localized molecular states, while the lower-energy band is due to a delocalized electronic excitation. The emission spectrum of PPV upon excitation at 355 nm is resolved into three lines with a spacing of 0.16 eV because of vibronic coupling (51). Migration of the excited state to the longest conjugation length segments in the polymer appears to occur prior to radiative decay, since smearing out of the vibrational fine structure is expected if emission from a distribution of sites within the polymer occurs. The photoluminescence efficiency varies between 5 and 25%, depending on the synthetic route used and the conversion conditions (52).

Two descriptions of the excited state have been applied to organic semiconductors, the exciton and the band model. The appropriate model depends on the extent of coupling between sites, with strong coupling yielding uncorrelated electrons and holes, while weak coupling favors correlated electron–hole

pairs (excitons). Time-resolved fluorescence and polarized fluorescence experiments suggest that the exciton model is appropriate in PPV (53). Rothberg and co-workers have examined the relative effects of interchain vs. intrachain excitations in MEH–PPV by comparing excited-state lifetimes and quantum yields in films to dilute solutions (54). They observed significantly lower quantum yields for emission in the films, and attributed this to the formation of nonemissive interchain excitons, which are not formed in dilute solution. They have also concluded that film morphology can play a significant role in the photophysical behavior of PPV (55). The presence of trace oxygen in the conversion of precursor polymer to PPV reduces the photoluminescence of the resulting material (56). This was shown to be correlated to the formation of carbonyl groups in the polymer backbone, and can be prevented by carrying out the conversion in a reducing atmosphere.

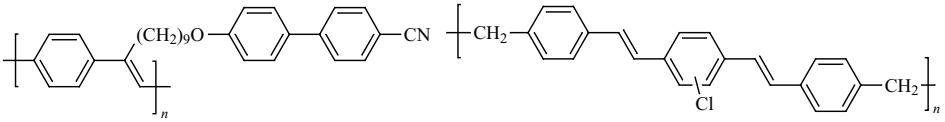
Photoconductivity. The first measurements of photoconductivity in PPV were carried out in the early (57). A later study revealed low dark conductivities for PPV films ($<10^{-15}$ S/cm), but significant photoconductivity upon irradiation at 440 nm. Significant conductivity was also found upon irradiation of the film in the near-IR region, despite insignificant optical absorption in this region. This was attributed to a charge-transfer mechanism involving trace oxygen (58). Oriented films of PPV showed enhancements in the photoconductivity with light polarized parallel to the direction in which the films were stretched (59). Transient photoconductivity measurements have also been used to address the question of the nature of the charge carriers in MEH–PPV films. The exciton model predicts a strong dependence of photoconductivity on temperature, and this is indeed observed for films greater than 120 nm in thickness. For thinner samples, both steady-state and fast time-resolved photoconductivity measurements demonstrate that photoconductivity is independent of temperature. These results are inconsistent with the exciton model (60).

Doping and Electrical Conductivity. Pristine PPV films are insulators at room temperature; however, exposure to oxygen causes an increase in conductivity to 10^{-11} S/cm—an effect attributed to reversible doping, with the oxygen acting as an electron acceptor (61). Irreversible doping of PPV films with strong oxidants such as $FeCl_3$ or H_2SO_4 produces black films with very high conductivities relative to the pristine material (62). Films doped with sulfuric acid showed conductivities of $\sim 10^4$ S/cm that were only weakly temperature-dependent, indicative of metallic behavior. The conductivity of films doped with $FeCl_3$ was slightly lower (10^3 S/cm) and decreased with temperature. The doped films are stable in oxygen, but are moisture-sensitive. Copolymers of PPV derivatives containing electron-donating groups, such as poly(1,4-phenylenevinylene-*co*-2,3,5,6-tetramethoxy-1,4-phenylenevinylene) (**23**), can also be doped with weaker oxidants such as I_2 to give materials with conductivities as high as 7×10^{-2} S/cm (63).



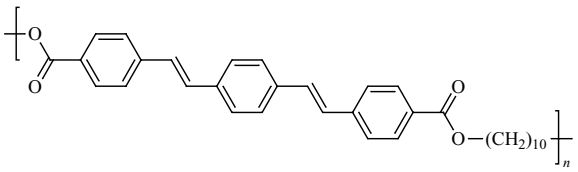
23

Microstructure and Liquid Crystallinity. The degree of structural order in PPV films depends greatly on the method of preparation. The degree of broadening in electron diffraction patterns has been used to assess the extent of ordering in different PPV samples (64). High resolution transmission electron microscopy revealed crystalline regions approximately 7 nm in size in oriented PPV films, and these crystallites are retained upon doping the films with H_2SO_4 (65). Substituents also have an effect on the structural order of PPV derivatives. Methoxy substituents allow chains to interlock and form a more ordered three-dimensional structure, while methyl groups cause the backbone to distort because of repulsive interactions between the backbone and side groups, resulting in a more disordered material (66). X-ray diffraction studies on MEH–PPV films cast from different solvents have shown that the chain orientation is anisotropic, and the aromatic rings are oriented predominantly parallel to the film plane (67). The crystallinity of films cast from THF is highest, and the crystalline domains largest, compared with films prepared from other solvents.



24

25

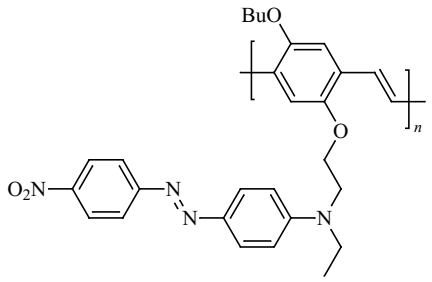


26

Liquid crystallinity has been observed in derivatives of PPV bearing mesogenic substituents, as well as in copolymers containing phenylenevinylene segments in the main chain. Copolymers in which some of the phenyl rings have alkoxy side chains (**22**) exhibit a nematic liquid crystalline phase, which has been characterized by polarized microscopy and differential scanning calorimetry (36). The temperature range between the melting point and the nematic–isotropic phase transition was found to depend on the length of the alkoxy group. A PPV derivative (**24**) bearing the well-known cyanobiphenyl mesogen as a side chain has both nematic and smectic mesophases (68). This polymer was oriented by rubbing a film with a Teflon stick, and a significant degree of orientation observed by polarized UV/vis and IR spectroscopies. Several examples of main-chain liquid crystalline polymers containing phenylenevinylene moieties bridged by saturated linkers are known. The thermotropic polymer **25** was prepared using a Wittig procedure, and was found to melt anisotropically (69). A related main-chain polymer (**26**) has a mesophase that exists between 218 and 275°C (70).

Nonlinear Optical Properties. For many optical signal processing applications, it is desirable for materials to have large optical nonlinearities and fast response times. For example, third-order nonlinear optical properties (qv) result in laser-pulse–induced refractive index changes that occur on the femtosecond

timescale. These changes could potentially be exploited in fast optical switches. Conjugated polymers are expected to be good candidates for such applications because of the delocalization of charge in the polymer backbone (71).



27

PPV has many of the characteristics desired in an NLO material, including good transparency, high π-electron density, and optical quality films that may be oriented and ordered. PPV has a third-order nonlinear optical susceptibility ($\chi^{(3)}$) of 7.8×10^{-12} esu (72), while $\chi^{(3)}$ for a substituted derivative, poly(2,5-dimethoxy-*p*-phenylenevinylene), is 5.4×10^{-11} esu at 1.85 μm (73). The higher value for the dimethoxy-substituted derivative may be due to more extended conjugation in this material. An alternative strategy that has been investigated is to introduce an NLO-active moiety pendent to a PPV backbone. For example, Disperse Red 1 has been tethered in this way (**27**), and the resulting polymer has a $\chi^{(3)}$ value of 2.5×10^{-12} esu (74).

Applications

Photovoltaics. Heterojunctions between conjugated polymers and films of electron acceptors behave as rectifying *p*–*n* junctions and may be used in photovoltaic devices. Such junctions have been prepared by vacuum evaporation of *n*-type buckminsterfullerene (C_{60}) onto spin-cast films of *p*-type MEH–PPV on ITO/glass substrates (Fig. 1) (75). These devices behave as rectifiers in the dark, and pass a photocurrent upon illumination with visible light. The open circuit voltage (V_{oc}) saturates at 0.53 V, with a fill factor of 0.48 and a power conversion efficiency of 0.04%. Photovoltaic devices made from blends of PPV with a processible methanofullerene showed power efficiencies of 0.25% under white light (76). The Cambridge group has also reported photovoltaic devices in which a heterojunction between bis(phenethylimido)perylene and PPV is sandwiched between ITO and Al. These devices had a somewhat greater fill factor (0.6) and V_{oc} approaching 1 V, with a quantum yield of 6% (electrons per incident photon) (77). A related approach involves using a blend of MEH–PPV and bis(phenethylimido)perylene, giving a fill factor of 0.27 at an open circuit voltage of 0.58 V; however improvements to these devices are limited by the poor solubility of the bis(phenethylimido)perylene (78).

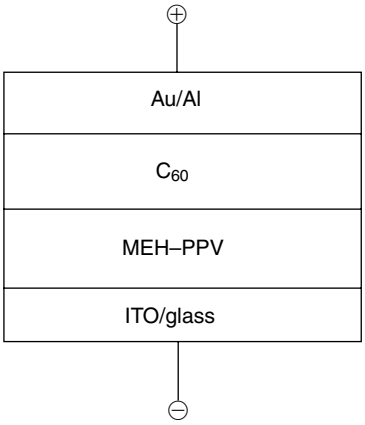


Fig. 1. Schematic of a MEH–PPV-based photovoltaic cell.

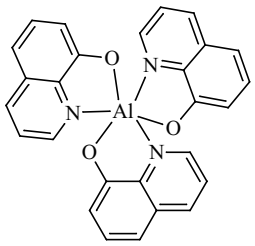
Photovoltaic cells have also been constructed from light-emitting electrochemical cells (LECs, see below) (79). In these devices, a phase-separated blend of MEH–PPV and cyano-PPV is used along with a solid electrolyte consisting of a mixture of polyethylene oxide (PEO) and $LiCF_3SO_3$. Sandwich photovoltaic cells using Al and ITO as the electrode contacts were doped using a prebias of 3 V, resulting in a V_{oc} of 1.0 V and a power conversion efficiency of 0.1%, assuming a fill factor of 0.25. The built-in potential is determined by the chemical potential difference between the *p*-doped and *n*-doped layers, rather than the work function of the electrodes, thus air-stable electrodes can be used in these cells.

Optical Memory. The permanent storage of data in films of PPV derivatives has been accomplished by irradiating films of the sulfonium precursor polymers with either a Xe arc lamp or Ar ion laser (488 nm) (80). Subsequent heating of the films resulted in the formation of colored, conjugated films only in regions that were not irradiated. Photochemical scission of the polymer chains leaves a water-soluble residue, which is readily removed by rinsing the heat-treated films with water. This process may also be used for the lithographic patterning of PPV films onto substrates.

Light-Emitting Devices. In the late 1980s Tang and VanSlyke reported electroluminescent devices that utilized thin films of 8-hydroxyquinoline aluminum (Alq_3) as the emitting material (81). They distinguished these devices from those based on conventional inorganic semiconductors by calling them "organic," despite the fact that the emissive compound is actually an inorganic coordination complex. The devices consisted of a layer of a hole-transporting aromatic amine on an ITO electrode, 60 nm of the luminescent Alq_3 and a Mg/Ag electrode. The devices behaved like rectifiers, and emitted light with a peak intensity at 550 nm, with a forward bias of as little as 2.5 V. In a subsequent publication, Tang and VanSlyke showed that doping of the Alq_3 layer with other highly fluorescent molecules, such as coumarin 540, increases the electroluminescence efficiency and allows tuning of the color from blue-green to orange-red (82).



Alq_3

In 1990, the discovery that PPV could be utilized as the emitter in an electroluminescent device was reported by Friend and co-workers at the Cavendish Laboratory in Cambridge (2). The devices consisted of a PPV film, prepared using the sulfonium precursor route, sandwiched between an ITO and an Al electrode, and emitted green-yellow light under forward bias of 14 V, with a quantum efficiency of up to 0.05%. Shortly after this initial publication, Braun and Heeger demonstrated that MEH–PPV could also be used to fabricate EL devices in which the polymer was directly cast in the conjugated form from solution. They used both indium and calcium cathodes, and observed visible light at 4-V forward bias with the calcium cathode, with an efficiency of 1%.

Device Operation. Single-layer devices consist of an electroluminescent layer sandwiched between an electron-injecting cathode (usually a low work function material such as Ca or Al) and a hole-injecting anode (most commonly the transparent conductor ITO on glass).

The operation of the device under forward bias may be understood using a simple band diagram (Fig. 2**a**). The anode and cathode materials are chosen to provide low barriers to electron and hole injection by matching the valence and

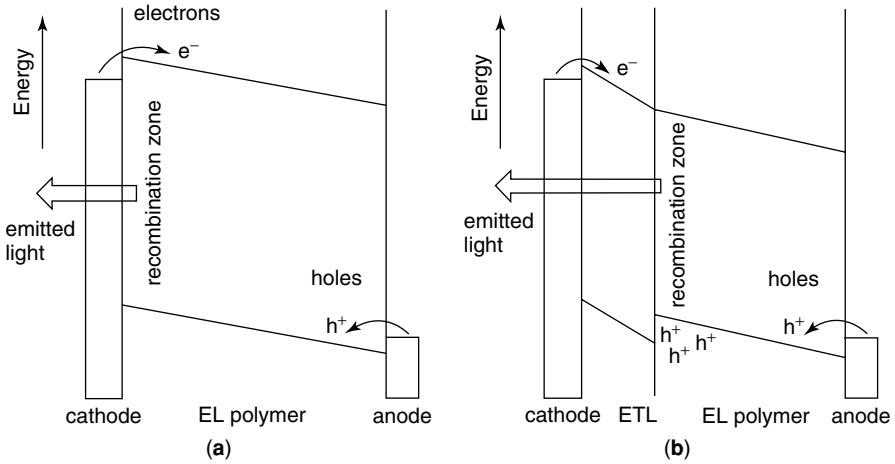


Fig. 2. Band diagram for (**a**) single-layer and (**b**) two-layer polymer EL devices (ETL = electron transporting layer).

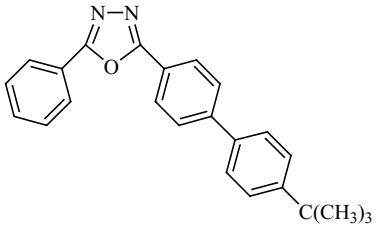
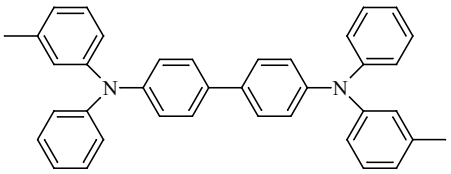
conduction band energies of the polymer to the electrode work functions. A disadvantage of the single-layer device configuration is that charge recombination often occurs close to the cathode, since most EL polymers are better hole conductors than they are electron conductors. The metal electrodes are able to quench excitons in close proximity, thus reducing the EL efficiency.

An approach that has been used successfully to move the emitting zone away from the electrodes is the construction of two-layer cells in which recombination occurs at the interface between the two organic layers (Fig. 2**b**). Here, the material in the layer adjacent to the cathode is selected to have a high electron mobility but a lower hole mobility than the EL polymer that is located adjacent to the anode. Thus, electrons and holes are readily injected into the adjacent layers contacting the respective electrodes and accumulate at the interface between the two layers. A number of materials have been exploited for use as the electron-transporting layer (ETL), including 2-(4-biphenylyl)-5-(4-*tert*-butylphenyl)-1,3,4-oxadiazole (butyl PBD) **28** (83). Two-layer devices constructed with PPV as the emitting layer and butyl PBD dispersed in poly(methylmethacrylate) (PMMA) as the ETL showed a tenfold improvement in efficiency relative to analogous single-layer devices constructed using only PPV. Polymers containing oxadiazole moieties pendent to the backbone, as well as in the main chain, have been synthesized and tested as ETLs, and also act to improve external quantum efficiencies in two-layer devices (84). The EL efficiency was found to be temperature-independent in these devices, suggesting that charge injection from both electrodes is well-balanced. Multiwalled carbon nanotubes have been used as the ETL in devices, leading to an increase in brightness (85).

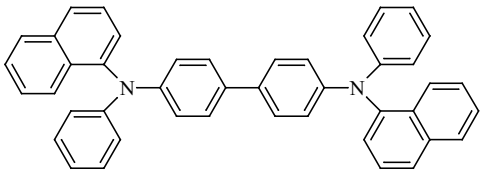


28

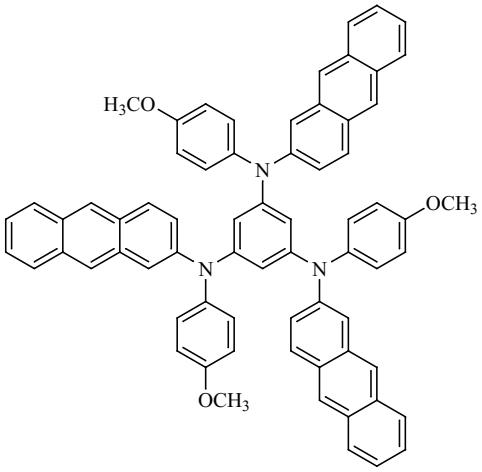
Hole injection from the anode can be improved via the use of a hole-transporting layer, which functions by improving hole injection into the electroluminescent layer and maximizing recombination of injected charges. Optimally, these materials should possess high glass-transition temperatures (T_g) and low ionization potentials. A large variety of triaryl amines have been investigated for use as hole-transport materials, including *N,N′*-diphenyl-*N,N′*-di-*m*-tolyl-1,1′-biphenyl-4,4′-diamine (TPD) (**29**) (86), *N,N′*-1-naphthyl-*N,N′*-diphenyl-1,1′-biphenyl-4,4′-diamine (NPD) **30** (87), 1,3,5-tris(2′-anthracyl-4″-methoxyphenylamino)benzene (**31**) (88), and the atropisomeric *cis*- and *trans*-5,11-dihydro-5,11-di-1-napthylindolo[3,2-*b*]carbazole (**32**) (89).



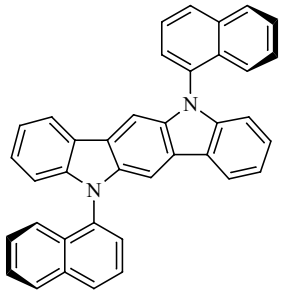
29



30



31



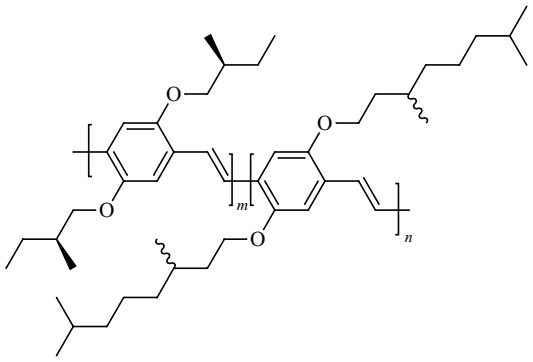
trans-**32**

The brightness of EL polymer based devices varies depending on the device configuration and polymer used. Uniax Corporation has reported ITO/PANI–CSA/MEH–PPV/Ca (PANI–CSA = polyaniline–camphor sulfonic acid) devices with a brightness as high as 10,000 cd/m^2 for bias voltages >5 V, over twice the brightness of a fluorescent lamp (90). Device brightness can be increased by using short drive pulses, which permit high current operation (91). Luminous efficiencies as high as 0.8 cd/A could be achieved in this way using current densities of 1 kA/cm^2 in single-layer PPV-based devices. Poly(3,4-ethylenedioxythiophene) (PEDOT) doped with polystyrene sulfonic acid (PSS) has also been investigated as a polymeric anode, and has been shown to result in increases in efficiency, brightness, and lifetime for devices based on MEH–PPV (92). When PPV is thermally converted with a PEDOT/PSS overlayer a large surface area interface results because of interpenetration of the two layers, possibly contributing to the improvement in quantum efficiency measured for these devices (93).

An application for which polymer-based EL devices may be uniquely suited is as flexible emitting materials. Such devices were first reported in 1992 by workers at Uniax, using a thin layer of PANI–CSA on flexible poly(ethylene terephthalate) (PET) as the anode, an MEH–PPV film as the emitter and vacuum-deposited Ca as the cathode (94). The PANI–CSA film is light green in color; however the absorption is low in the region of the spectrum where MEH–PPV emits (500–700 nm), so emission is readily observed through the anode.

Doped silicon has also been used as a hole-injecting electrode material (95). Devices consisted of an MEH–PPV film on a thin SiO_2 layer atop a heavily *p*- or

n-doped Si substrate. The top contact was a semitransparent Ca or Au electrode, and light emission was observed through this layer. The insulating SiO_2 layer allows the electrode Fermi level to be matched to the conduction band of the polymer, thus permitting the devices to operate in reverse bias with a high work function cathode material such as Au. The Cambridge group has also investigated the effect of separating the polymer layer from the Al cathode with a thin SiO_2 layer. This results in an increase in PL quantum efficiency since the emission zone is brought away from the metal interface (96).



33

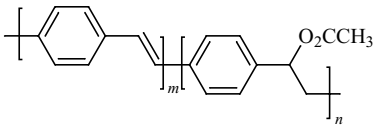
Circularly polarized electroluminescence (CPEL) has been obtained from a single-layer device in which the emitter is a PPV derivative with chiral pendent groups (**33**) (97). The CPEL is due to the inherent chirality of the polymer, since polymers containing racemic side groups did not show any effect; however aggregation of the polymer chains in the solid state is believed to enhance the magnitude of the effect.

The external efficiencies of electroluminescent devices based on PPV derivatives are typically between 0.2 and 4% (4), comparable to the efficiencies of inorganic EL devices. In addition to the use of electron- and hole-transporting layers to enhance efficiencies, other strategies have also been used. Son and co-workers reported polymers in which cis linkages were intentionally introduced into the PPV backbone (98). These defects prevent the polymer chains from packing efficiently in the solid state, thus producing amorphous PPV films. Both single- and two-layer devices prepared from this material had significantly higher efficiencies than comparable devices fabricated using PPV synthesized in the conventional fashion (high trans content). This improvement in efficiency may result from better chain separation in the amorphous material.

Degradation of polymer EL devices leading to limited lifetimes is a serious problem, particularly for commercial applications that typically demand lifetimes of $>10{,}000$ h. The low work function metals used as cathode materials (Al, Ca, In) are all air- and moisture-sensitive to varying degrees. Encapsulation to prevent intrusion of air and water is necessary for practical devices. The polymer layer has also been shown to be susceptible to degradation by singlet oxygen, which can form from oxygen impurities in the film by energy transfer from a nonradiative exciton in the polymer (99). Strict removal of oxygen in the film preparation process thus

results in longer device lifetimes. Oxidation of MEH–PPV has been shown to result in reduced fluorescence because of the formation of carbonyl groups, along with reduced carrier mobility as a consequence of chain scission. Localized shorts also form in these devices, which are initially isolated by melting of the cathode; however these eventually coalesce, causing device failure (100).

Although most studies have been carried out on PPV prepared using solution processing, EL devices have also been prepared from PPV prepared by chemical vapor deposition (101). The advantage of this approach is that many of the side reactions that typically occur during solution processing are eliminated, and this method is also compatible with existing methods for processing of inorganic LEDs. Single-layer devices prepared in this way had turn-on voltages as low as 4.5 V, with a brightness of 20 cd/m^3.



34

Modifications of the PPV structure have also been demonstrated to have an effect on the performance of EL devices (102). A PPV copolymer bearing acetate side groups (**34**), which disrupt the conjugation in the backbone, has been used to fabricate encapsulated single-layer devices with Al cathodes and ITO anodes, which operated continuously in air without degradation for 12,000 h. The devices were encapsulated by gluing a glass slide over the top of the device with epoxy resin.

For many display applications it is useful to pattern the emitting area of a device. Several successful approaches have been developed in this vein, including inkjet printing and solvent-assisted micromolding. In the inkjet approach, a conventional printer was modified to spray a solution of PEDOT onto defined areas of an ITO electrode (103). The whole area was then coated with an MEH–PPV film and a Ca cathode deposited to complete the device. Emission occurs only in the areas defined by the PEDOT layer because of the enhanced charge injection from this polymer relative to the ITO layer. Typical pixel sizes ranged from 180 to 400 μm, and the density of the dots could be used to control the brightness of emission from a given area. Solvent-assisted micromolding involves wetting a polydimethylsiloxane mold with methanol and allowing a solution of PPV precursor polymer to wick into the recessed regions of the mold (104). The mold is initially prepared by casting and curing a prepolymer against a lithographically prepared relief structure. When the methanol evaporates, the mold is removed, leaving the PPV precursor polymer patterned on the surface. Curing yields PPV, and devices are completed by deposition of Ca or Al. Emitting features as small as 800 nm can be prepared using this method. Inkjet patterning has also been used to produce a three-color (red–green–blue) display, using PPV derivatives and molecular dopants to achieve the various colors (105).

Color Range and Tuning. Variations in polymer structure allow tuning of the emission color over the entire visible spectrum. Polymers in which the

conjugation is broken because of the presence of the methoxy groups (as in **16**) show blue-shifted electroluminescence relative to unsubstituted PPV, with an emission maximum at 508 nm (106). Blue emission was also obtained from a copolymer containing short methoxy-substituted phenylenevinylene segments (**35**) (107). Single-layer devices containing this polymer sandwiched between Al and ITO have a maximum in the EL spectrum at 465 nm. A PPV derivative with Si groups in the backbone (**36**) emits blue light in both single- and two-layer device configurations (108). Green light was obtained from multilayer devices with poly(2-methyloctylsilyl-1,4-phenylenevinylene) (DMOS-PPV) (**37**) as the emitter combined with an electron-conducting and hole-blocking layer of either butyl PBD or a polymeric oxadiazole derivative (109). A low bandgap, cyano-substituted thienylene phenylenevinylene copolymer **38** was shown to emit in the near-IR region. The maximum in the EL spectrum is at 740 nm, and emission tails down to 1000 nm (110).

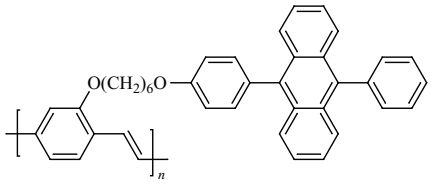
38



39

Several groups have developed polymer LEDs that emit light over a broad wavelength range, resulting in white light. Photoluminescence from polymer **39** arises from both the pendent diphenylanthracene units and the polymer backbone, thus covering much of the visible spectrum (111). However, electroluminescence from single-layer devices containing this polymer is significantly red-shifted relative to the photoluminescence, emitting green–red light apparently only from the main chain. Another approach that has produced white electroluminescence involves CdSe/PPV multilayer structures (112). These structures were prepared by alternate absorption of PPV precursor polymer and negatively charged CdSe

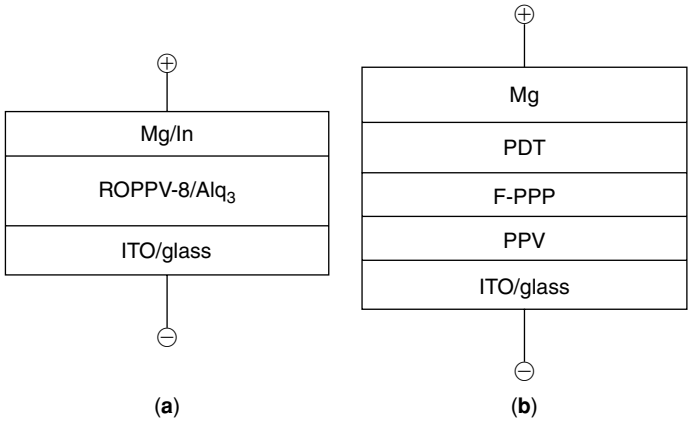


Fig. 3. Schematics of tunable color light-emitting devices.

particles onto an ITO substrate. In these devices, electroluminescence arises exclusively through charge recombination on the CdSe particles, and has a maximum intensity at 650 nm. The PPV is believed to act only to transport charge, thus significantly reducing the turn-on voltage in these devices compared with those using insulating poly(allylaminehydrochloride) as the host.

Polymer-based light-emitting devices in which the emission color may be tuned by varying the bias voltage have been fabricated. In one approach, the emitting layer consists of a mixture of poly(2,5-dioctyl-*p*-phenylenevinylene) (ROPPV-8) and Alq_3 sandwiched between a Mg/In cathode and an ITO anode (Fig. 3**a**) (113). The electroluminescence from this device varies from orange to greenish yellow as the bias voltage is increased from 15 to 22 V. Increasing the voltage increases the proportion of the emitted light arising from the Alq_3. Devices in which ROPPV-8 and Alq_3 are in separate layers emit only from the polymer layer regardless of applied voltage. Another approach uses a three-layer device, consisting of PPV, perfluoropropylated poly(*p*-phenylene) (F-PPP), and poly(3-dodecylthiophene) (PDT) (Fig. 3**b**) (114). The F-PPP acts as an electron-blocking layer, confining emission only to the side of the device to which a negative bias is applied. Thus, green light is emitted when the negative bias is on the PPV side, and red light is emitted when it is applied to the PDT side. Doping a PPV derivative with a dinuclear ruthenium complex, that acts both as electron-transfer mediator and triplet emitter, gives a material that exhibits reversible, voltage-dependent switching from red to green emission. Under forward bias, the excited state of the ruthenium complex is populated, giving red light, while under reverse bias, the lowest singlet state of the polymer is generated, giving green emission (115).

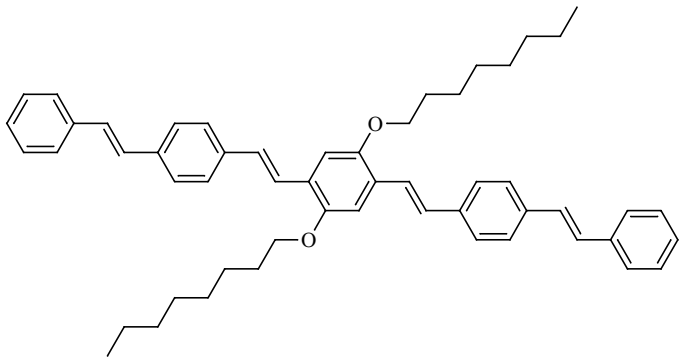
Self-Assembled Devices. Rubner and co-workers at MIT have developed a self-assembly approach to constructing PPV-containing heterostructures for use in EL devices (116). The heterostructures are built up by alternately dipping a substrate in solutions of the sulfonium PPV precursor polymer and anionic polyelectrolytes such as the sodium salts of poly(styrenesulfonate) (PSS) or poly(methacrylic acid) (PMA). The layers are then heated to convert the PPV to the fully conjugated form. This method allows for very precise control of thickness,

as well as manipulation of the nature of the surface (cationic or anionic) in contact with the anode and cathode. Device efficiency is very sensitive to the chemical nature of the interface, and the PMA/Al interface consistently yielded efficiencies greater by a factor of 2 relative to devices with a PPV/Al interface.

Light-Emitting Electrochemical Cells. Recently, Heeger and co-workers have developed light-emitting devices in which a blend of a semiconducting, luminescent polymer with a solid-state electrolyte is used in the emitting layer (117). These devices function as solid-state electrochemical cells, and charge injection results in the formation of a *p–i–n* junction through electrochemical doping. Many of the requirements in conventional polymer LEDs, such as a match between the electrode work function and the polymer valence and conduction bands, are circumvented in such light-emitting electrochemical cells (LECs).

Polymer LECs have been demonstrated to function in a dynamic-junction mode, in which ions move under the external bias to create the junction. These devices degrade when the drive voltage is beyond the window of electrochemical stability. When polyethylene oxide (PEO) is used as the ion-transport medium, the devices can operate in a frozen-junction mode at 100 K. In this mode, response times are comparable to those of polymer LEDs. An improvement on this approach allows the frozen junction to function at room temperature (118). In these single-layer devices a PPV derivative such as poly(2-butyl-5-{2-ethyl(hexyl)}-1,2-phenylenevinylene) was blended with an electrolyte containing a crown ether and lithium triflate. The devices were activated by applying a small voltage while heating to 60–80°C, creating the *p–i–n* junction, and functioned at room temperature with a turn-on voltage of 2.1 V and an external EL efficiency of 2–3%.

Stimulated Emission and Lasers. In 1996, Friend and co-workers demonstrated optically driven lasing from thin films of PPV sandwiched between a distributed Bragg reflector and an Ag mirror (119). Excitation was with a Nd:YAG laser, frequency-tripled to 355 nm. Emission occurs in three cavity modes, equally distributed at low excitation energy; but the 545-nm emission dominates at higher excitation energy, indicating that the device is lasing. The same year the Santa Barbara group reported laser emission from solutions and films of MEH–PPV and TiO_2 nanocrystals. The nanoparticles multiply scatter photons in the composite material, resulting in the scattering length exceeding the gain length (120). Stimulated emission has also been observed from crystalline films of an oligomer of phenylene vinylene substituted with octyloxy groups (**40**) (121).



40

Future Considerations

The last 10 years have seen an explosion of research interest in PPV and its derivatives, driven by the potential of these materials as emitters in EL devices. Companies such as Philips, Uniax (DuPont Displays), Cambridge Display Technology, and Covion are engaged in bringing low information content display applications (cell phone and alphanumeric displays) based on organic emitters to market, and in late 1999 Pioneer Electronics had already begun selling a monochrome display for use in vehicles. Higher-information content applications, such as computer and television displays may be developed in the near future.

Although many of the problems that are of concern for optoelectronic applications of organic materials have been overcome, there are still many challenges ahead in the field. Many of the polymers that have been made recently have not yet been investigated in detail, and more work is needed to optimize these materials for specific applications. Fundamental questions also remain, such as the exact nature of the charge carriers in PPV films, and further studies on the photophysical behavior of these polymers are required.

Perhaps the most exciting prospect that has arisen from the intense research activity on PPV is the realization that organic materials and polymers can be used in real world optoelectronic applications. This will hopefully stimulate efforts to make and study more novel materials and to find new applications for them. In particular, any integration of conventional and molecular electronics will require many advances. The success of PPV and other organic EL materials has demonstrated that research in this field is a worthwhile enterprise, and the development of entirely new classes of materials with as yet unknown properties may be on the horizon.

POLYANHYDRIDES

Introduction

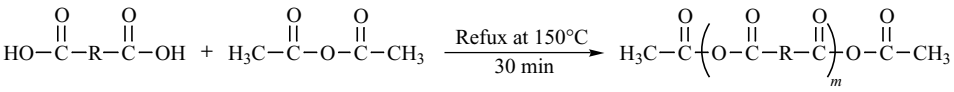
The first report on the formation of polyanhydrides appeared in 1909 (1) and the detailed synthesis of a range of polyanhydrides was reported in 1930s (2,3). Polyanhydrides derived from aromatic diacids were hydrolytically stable and had excellent film- and fiber-forming properties (4). A large number of aromatic polyanhydrides were studied and characterized. They had glass-transition temperatures in the range of 50–100°C, appeared as opaque porcelain-like solids, and were resistant to hydrolysis even upon exposure to an alkaline solution (4). The mechanical properties of aromatic polyanhydrides were exemplified by the measurements carried out on stretched fibres of poly(di-(*p*-carboxyphenoxy)-1,3-propane) annealed at 110°C under constant load. The fibres showed a tensile strength of 40 kg/mm^2 with an elongation of 17.2% and a Young's modulus of 505 kg/m^2 (4). Concurrently, various types of heterocyclic polyanhydrides were synthesized from five-member ring heterocyclic diacids with acetic anhydride at 200–300°C under vacuum and nitrogen atmosphere, which had melting points in the range 70–190°C (5,6). It is thus clear that all the early research efforts were devoted to enhancing the stability of polyanhydrides against hydrolysis to get a good fiber- and film-forming polymer. Unfortunately, polyanhydrides were not commercially successful textile materials due to their unstable nature against hydrolysis, especially for aliphatic polyanhydrides. In contrast, their hydrolytic instability make them potentially useful for biomedical and pharmaceutical applications, where the hydrolytic instability of a polymer is a desired feature rather than a weakness. Langer and co-workers (7) were the first researchers to exploit the hydrolytically labile nature of polyanhydrides for controlled drug delivery through a medical device. This article will mainly focus on summarizing the synthesis and characterization of polyanhydrides used for pharmaceutical and medical device applications.

Encyclopedia of Polymer Science and Technology. Copyright John Wiley & Sons, Inc. All rights reserved.

The main advantage of using polyanhydrides for medical applications is that they gradually degrade into nontoxic, small molecular weight products after their intended use in drug delivery, obviating the need for retrieval (see BIODEGRADABLE POLYMERS, MEDICAL APPLICATIONS). A large number of polyanhydrides synthesized to date have been found biocompatible (8) and have excellent controlled release characteristics (9,10). The control over drug release kinetics and matrix degradation rate can be achieved through manipulation of the polymer compositions (11). Among the most useful diacid monomers for making polyanhydrides used in pharmaceutical applications are sebacic acid (SA), 1,3-bis(*p*-carboxyphenoxy)propane (CPP), and erucic acid dimmer (EAD). The copolymers poly(CPP-SA) and poly(EAD-SA) have been used in the clinic for the delivery of the anticancer agent *N*,*N*-bis(2-chloroethyl)-*N*-nitrosourea (BCNU) and the antibiotic gentamicin sulfate and in the United States, Food and Drug Administration (FDA) approved BCNU-poly(CPP-SA) as treatment for brain tumors (12).

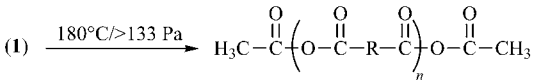
Synthesis

Polyanhydrides have been synthesized by various techniques such as melt polycondensation, ring-opening polymerization, interfacial polycondensation, dehydrochlorination, and dehydrative coupling (13,14). The most widely used technique for polyanhydride synthesis is melt polycondensation, which occurs in two steps. In the first step, dicarboxylic acid monomers react with excess acetic anhydride to form acetyl-terminated anhydride prepolymers (**1**) with a degree of polymerization (DP) ranging from 1 to 20 (eq. 1).



(1)

The activated monomers are then polymerized at an elevated temperature (if necessary) under vacuum to yield polyanhydrides with DP ranging from 100 to over 1000 (eq. 2).



(2)

Purification of the prepolymers, using methods such as recrystallization, is a crucial step to increase the molecular weight (M_w) of polymers (15). It is important to carefully monitor the kinetics of the prepolymer reaction to prevent the formation of high molecular weight oligomers, which may have high T_m and are difficult to purify. In general, the melt polycondensation commences readily under low pressure and is completed in several hours at grams to kilograms scale. In comparison to the preparation of polyesters, in general, polycondensation of polyanhydrides proceeds more rapidly (11,16), for example, ester polycondensation completes in 12–24 h while polyanhydride takes less than 2 h to complete the reaction, depending on the molecular weight required. This reaction to form anhydrides is weakly

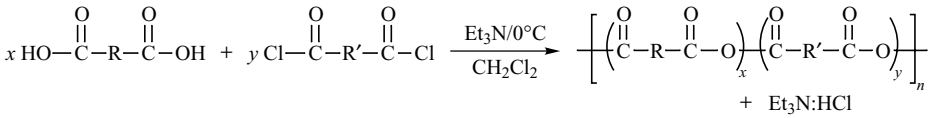
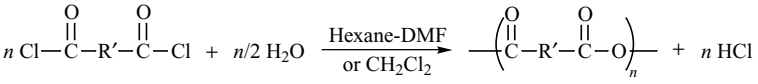
exothermic (17), and hence, the equilibrium constant decreases with an increase in temperature. All the things being equal, a low polymerization temperature should afford a higher molecular weight. Excessive heating at 180°C appears to cause decarboxylation or decarbonylation (18). However, prolonged distillation of the initial reaction mixture, up to 72 h, improves the molecular weight. The condensation reaction of diacetyl mixed anhydrides of aromatic and aliphatic diacids is carried out in the temperature range of 150–200°C (19). In addition to acetic anhydride, a variety of catalysts have been included in the synthesis of polyanhydrides. Particularly, coordination catalysts facilitate the anhydride interchange in the polymerization and enhance the nucleophilicity of the carbonyl carbon (20). Table 1 shows the highest molecular weight obtained by using coordination catalysts in the synthesis of polyanhydride copolymer of bis(carboxyphenoxy)propane and sebacic acid (CPP-SA) (13). Except calcium carbonate, which is a naturally occurring material, the use of most catalysts for the production of medical grade polymers is undesirable because of their potential toxicity (15). Ring-opening polymerization (ROP) can also be used for the synthesis of polyanhydrides used for medical applications. For example, adipic acid polyanhydrides were prepared from cyclic adipic anhydride (oxepane-2,7-dione) by using cationic (e.g., $AlCl_3$ and $BF_3{\cdot}(C_2H_5)_2O$), anionic (e.g., $CH_3COO^-K^+$ and NaH), and coordination-type (e.g., stannous-2-ethylhexanoate and dibutyltinoxide) catalysts (21).

Because melt polycondensation often requires a high temperature, it is not suitable for making heat sensitive polymers. A variety of solution polymerizations at ambient temperature have been reported (18,22). Polyanhydride formation can be effected at room temperature by a dehydrochlorination between a diacid chloride and a dicarboxylic acid (eq. 3).



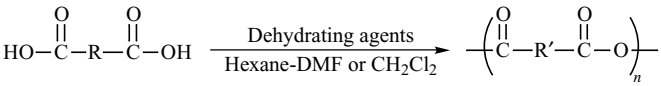
(3)

In an attempt to prepare copolyanhydrides of regular structures, polycondensation was conducted in organic solvent pairs such as pyridine–benzene and pyridine–ether. A polycondensation was reported between an acylchloride and a carboxylic acid in a single solvent system in the presence of an acid acceptor such as triethylamine (18). The polymerization took place on contact of the two monomers and was essentially complete within an hour as monitored by gel permeation chromatography (GPC). The DP was in the range of 20–30 as determined by vapor pressure osmometry. Comparable M_w and yields were obtained for polymerization conducted in solvents such as dichloromethane, chloroform, benzene, and diethyl ether (18). The DP was influenced by the order of addition. Adding the diacid solution dropwise to the diacid chloride solution consistently produced higher M_w polymers and yields as compared to the reverse order of addition (22). Adding the acyl chloride in a single portion, however, yields satisfactory results, suggesting that the rate of dehydrochlorination is comparable to the rate of acid chloride–amine complexation. The inconvenience of this homogeneous Schotten–Baumann condensation in solution is outweighed by the need to obtain the highly purified diacid chloride monomer. The formation of polyanhydrides by this method can be effected by using diacid chlorides, which upon controlled hydrolysis with a half equivalent of water form the acid that condense to anhydride bonds (eq. 4).



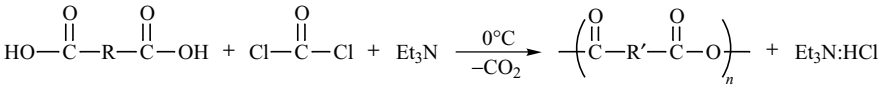
(4)

Low molecular weight polyanhydrides were prepared from the reaction of diacid with dehydrating agents such as *N*,*N*-bis[2-oxo-3-oxazolidinyl]phosphoramidoyl chloride and phenyl-*N*-phenylphosphonamidoyl chloride (18) or by direct condensation at elevated temperature under vacuum and acid catalysis (eq. 5).



(5)

A one-step polymerization using diacyl chloride, phosgene, or diphosgene as coupling agents was also developed (eq. 6).



(6)

The results of polymerization between sebacic acid and fumaric acid, using either phosgene or diphosgene as coupling agents with various acid acceptors, were reported (22). Although phosgene and diphosgene are equally efficient, diphosgene as a liquid is preferred because of its ease of handling and lower vapor toxicity. The polymers have similar M_w when the same type of amine base was used. For example, the heterogeneous acid acceptor poly(4-vinylpyridine)(PVP) produced satisfactory results, whereas a nonamine heterogeneous base (e.g., K_2CO_3) yielded a lower M_w. This effect may be explained by the observation that pyridine forms a 1:1 complex with acid chlorides prior to their reaction with hydroxyl-bearing molecules. In the same way, the amines formed a soluble intermediate complex of acid–amine that improved the interaction with the coupling agent under homogeneous conditions. Although PVP is insoluble in the reaction medium, it swells and forms a similar acid-PVP complex. Carbonates, however, form a heterogeneous mixture with the acid and presumably react more slowly with the coupling agents to form the polymer (22).

Polyanhydride Structure

Since the introduction of polyanhydrides in the regime of polymers, hundreds of polyanhydride structures have been reported for the past century (23). A representative list of polyanhydrides is shown in Table 2. On the basis of their monomers, polyanhydrides can be categorized as the following types:

Aliphatic Polyanhydrides. Aliphatic polyanhydrides of saturated diacid monomers are crystalline, melt at temperatures below 100°C, and are soluble in chlorinated hydrocarbons. They degrade and are eliminated from the body within weeks (11).

Unsaturated Polyanhydrides. A series of unsaturated polyanhydrides were prepared by melt or solution polymerization of fumaric acid (FA), acetylenedicarboxylic acid (ACDA), and 4,4′-stilbenedicarboxylic acid (STDA). The double bonds remain intact throughout the polymerization process as noted by IR spectroscopy and were available for a secondary reaction to form a cross-linked matrix (27). The unsaturated homopolymers were crystalline and insoluble in common organic solvents, whereas copolymers with aliphatic diacids were less crystalline and soluble in chlorinated hydrocarbon solvents (27). Branched and crosslinked polyanhydrides were synthesized in the polymerization reaction of diacid monomers with tri- or polycarboxylic acid branching monomers (48). The molecular weights of the branched polymers were significantly higher (250,000 Da) than those of the respective linear polymers (80,000 Da). The specific viscosities of the branched polymers were lower than those of linear polyanhydrides with similar molecular weights. Except for the difference in molecular weights, there were no noticeable changes in the physicochemical or thermal properties of the branched polymers as compared to the linear polymers.

Table 2. Representative Polyanhydride Structures

Polymer type	General structure	Examples	Melting point, °C	Ref.
Aliphatic polyanhydrides	 R = Aliphatic chain and X and n are the number of its unit	 $x = 8$, PSA; 4, PAA	50–90	(24–26)
Unsaturated polyanhydrides	 R' is unsaturated and remain intact during polymerization	 Poly(STDA)  Poly(FA)  Poly(ACDA)	>200	(27,28)

Table 2. (Continued)

Polymer type	General structure	Examples	Melting point, °C	Ref.
Aromatic polyanhydrides	 Homopolymers	 Poly(TA) Poly(ITA)  $X = 3$, poly(CPP); 6, poly(CPH)	>200	(4,29,30)
	 Copolymers	 Poly(TA-ITA)	<100	
Aliphatic–aromatic polyanhydrides	 R and Ar are aliphatic and aromatic moieties respectively	 poly((*p*-carboxyphenoxy)alkanoic anhydride)	50–120	(19,31, 32)
	 R and Ar are aliphatic and aromatic moieties respectively	 poly(CPP-SA)	50–240	(29)

Poly(ester anhydride) and poly(ether anhydride)	 R' and R are aliphatic or aromatic moiety	 R = $(CH_2)_{2-8}$; {$(CH_2)_2$—O—(CH_2—CH_2—O)$_2$—$(CH_2)_2$}	98–176	(16,33–35)
Fatty acid based polyanhydrides	 Z = —COO, —NH, CH_2, —$CONH_2$ R, R_1, R_2, R_3, R_4 are saturated or unsaturated alkyl groups. *l*, *m*, and *n* are the number, may be same or different	 Copolymer of recinoleic acid and sebacic acid anhydride	20–90	(36–39)
Amino acid based polyanhydrides	 R" is amino acid moiety	 R = $(CH_2)_3$; {$(CH_2)_2$—O—$(CH_2)_2$}	58–170	(40–43)
Blends	Blends of two or more polyanhydrides or one polyanhydride with other like polyesters, polycarbonates, etc.	PSA-blend-PLA, poly[bis(glycine ethyl ester) phosphazene]-blend-(PSA or PSTP)		(44–47)

Aromatic Polyanhydrides. Aromatic homopolyanhydrides are insoluble in common organic solvents and melt at temperatures above 200°C (29). These properties limit the use of purely aromatic polyanhydrides, since they cannot be fabricated into films or microspheres using solvent or melt techniques. Fully aromatic polymers that are soluble in chlorinated hydrocarbons and melted at temperatures below 100°C were obtained by copolymerization of aromatic diacids such as isophthalic acid (IPA), terephthalic acid (TA), 1,3-bis(carboxyphenoxy)propane (CPP), or 1,3-bis(carboxyphenoxy)hexane (CPH).

Aliphatic-Aromatic Polyanhydrides. Polyanhydrides of diacid monomers containing aliphatic and aromatic moieties, such as poly-((*p*-carboxyphenoxy)alkanoic anhydride), were synthesized by either melt or solution polymerization, with molecular weights reaching up to 44,600 Da (19). The polymers of carboxyphenoxy alkanoic acid having methylene groups ($n = 3$, 5, and 7) were soluble in chlorinated hydrocarbon solvents and melted at temperatures below 100°C. These polymers displayed a zero-order hydrolytic degradation profile for 2–10 weeks. The length of the alkanoic chain positively correlates to the degradation time (19).

Poly(ester-Anhydrides) and Poly(ether-anhydrides). 4,4′-alkane- and oxa-alkanedioxydibenzoic acids were used for the synthesis of polyanhydrides. These polyanhydrides melted at a temperature range of 98–176°C and had M_w up to 12,900. Di- and triblock copolymers of poly(caprolactone) (PCL), poly(lactic acid) (PLA), and poly(hydroxybutyrate) (PHB) have been prepared from carboxylic acid terminated low M_w prepolymers copolymerized with SA prepolymers by melt condensation (49). Similarly, di-, tri-, and brush copolymers of poly(ethylene glycol) (PEG) with poly(sebacic anhydride) (PSA) have been prepared by melt copolymerization of carboxylic acid terminated PEG (50).

Fatty Acid Based Polyanhydrides. These polyanhydrides were synthesized from dimer and trimer unsaturated fatty acids (36,37,51). The dimers of oleic acid and eurecic acid are liquid oils containing two carboxylic acids, which are available for polymerization; correspondingly, the homopolymers are viscous liquids. Copolymerization with increasing amounts of SA forms solid polymers with increased melting points. The polymers are soluble in tetrahydrofuran, 2-butanone, and acetone. Polyanhydrides synthesized from nonlinear hydrophobic fatty acid esters based on ricinoleic acid, maleic acid, and SA, possessed desired physicochemical properties such as low melting point and hydrophobicity, and good flexibility (52) in addition to biocompatibility (53) and biodegradability (54).

Amino Acid Based Polyanhydrides. Amino acid based polymers were synthesized from dicarboxylic acids prepared by amidation of the amino group of an amino acid with a cyclic anhydride, or by the amide coupling of two amino acids with a diacid chloride (55). Low molecular weight polymers from methylene bis(*p*-carboxybenzamide) were synthesized by melt condensation (56). A series of amido-containing polyanhydrides based on *p*-aminobenzoic acid were synthesized by melt condensation (56). These polymers melted from 58 to 177°C and had molecular weights from 2500 to 12,400 Da. The homopolymers of all *N*-trimellitylimido acids containing amino acids were rigid and brittle with M_w below 10,000 Da (57). Higher molecular weight polymers were obtained by incorporation of flexible segments, ie, copolymers with aliphatic diacids, in the polymer backbone. Copolymers of *N*-trimellitylimido-glycine or aminodecanoic acid with either sebacic acid

(SA) or 1,6-bis(*p*-carboxyphenoxy)hexane (CPH) were prepared in defined ratios. High molecular weight copolymers (>100,000 Da.) were generally obtained with an increasing content of the SA or CPH comonomer relative to the trimellitylimidoglycine.

Blends. Blending, or mixing, appropriate polymers can alter the physical and mechanical properties of polyanhydrides. Blends of poly(trimethylene carbonate) (PTMC) with poly(adipic anhydride) (PAA) were found biocompatible in both *in vitro* and *in vivo* experiments (44). Blends were prepared by dissolving each polymer in methylene chloride followed by separately mixing in varying proportions using solvent-mixing technique (45). The results indicate that the blend may be a promising candidate for controlled drug delivery (44,46) and varying the proportion of PTMC and PAA can control the erosion rate of the polymer blend. Low molecular weight polyesters such as PLA, PHB, and PCL are miscible with polyanhydrides, whereas high molecular weight polyesters (M_w > 10,000 Da) are not compatible with polyanhydrides. Uniform blends of PCL with 10–90% by weight of poly(dodecanedioic anhydride) (PDD) were prepared by melt mixing at 120°C and exhibited good mechanical strength. Hydrolysis studies indicated that the anhydride component degraded and was released from the blend composition without affecting the PCL degradation (45).

Properties

Thermal. Because crystallinity is an important factor in controlling polymer erosion, the effect of polymer composition on crystallinity was studied (40,41). Almost all polyanhydrides show some degree of crystallinity as manifested by their crystalline melting points. Polymers based on SA, CPP, CPH, and FA were particularly investigated. Homopolyanhydrides of aromatic and aliphatic diacids, for example, poly(CPP) and poly(FA), were crystalline (>50% crystallinity) (29), whereas the copolymers possess a less degree of crystallinity, which increases by enhancing the mole ratio of either aliphatic or aromatic diacid monomers (29). The heat of fusion (H_f) values for poly(CPP-SA) demonstrated a sharp decrease from 36.6 to 2.0 cal/g as CPP is gradually added upto 40%, while an increase in H_f value was observed upto 26.5 cal/g on further addition of CPP (58). The trend of decreasing crystallinity, as one monomer is added, was noted using X-ray diffraction or differential scanning colorimeter (DSC) methods. The decrease in crystallinity is a direct result of the random presence of other units in the polymer chain. A detailed analysis of the copolymers of SA with the aromatic and unsaturated monomers, CPP, CPH, FA, and trimellitic-amino acid derivative, showed that copolymers with high ratios of SA and CPP, TMA-gly, or CPH were crystalline while copolymers with equal ratios of SA and CPP or CPH were amorphous (40). In contrasts, the poly(FA-SA) series displayed high crystallinity regardless of comonomer ratio (27).

The melting points of a large number of polymers have been determined and are shown in Table 2. Aliphatic polyanhydrides generally melt at lower temperatures than do aromatic polyanhydrides. The melting point of aromatic–aliphatic copolymers is proportional to the aromatic content in the copolymer. Introduction of fatty acids in copolymers also lowers the melting point of the bulk polymer.

Inclusion of an aromatic amide linkage in the backbone is found to increase the transition temperatures (55). The formation of intermolecular hydrogen bonds is believed to cause this high crystallinity. Poly(anhydrides-*co*-amide) also have high thermal stability (55).

Mechanical. Polyanhydrides show poor mechanical properties in comparison with other polymers such as polyesters. Mechanical properties of various polyanhydrides and their copolyanhydrides were tested as transparent and flexible films made by melt compression and solvent casting. It was observed that increasing the CPP content in copolymer composition increases the tensile strength as well as elongation of various polyanhydrides tested (13). Despite the low molecular weight ($M_n = 6400$) of poly(CPP-SA) (60:40), it has a higher tensile strength of 981 MPa (100 kgf/cm^2) than it has in the 20:80 composition ($M_n = 18{,}900$), 441 MPa (45 kgf/cm^2). Decreasing the M_n of films of the same CPP content (60%) from 12,100 to 6,400 results in lower tensile strength. The elongation at break of these films ranges from 17 to 23%.

Table 3 shows the mechanical properties of fatty acid based polyanhydrides. Films of fatty acid polyanhydrides were transparent and flexible with a tensile strength of 4–19 MPa and elongation at break in the range of 77–115%. The terpolymer of (fatty acid trimer (FAT)-CPP-SA) in a 1:1:1 weight ratio formed the strongest film. Figure 1 shows the stress–strain curve for polyanhydrides derived from natural fatty acids (54). The polymer had a tensile strength of 2.5–3.2 MPa and yield stress at break around 20% in comparison to poly(EAD-SA) (1:1) and PSA, which had tensile strengths of 5.7 and 7.2 MPa and yield stress at break of 10 and 1.5%, respectively. Thus, introduction of nonlinear fatty acid structures in polyanhydrides provides hydrophobicity and flexibility to the polymers.

Stability. The stability of polyanhydrides in solid state and dry chloroform solution was studied (20). Aromatic polymers such as poly(CPP) and

Table 3. Physical Properties of Fatty Acid Polyanhydrides[a]

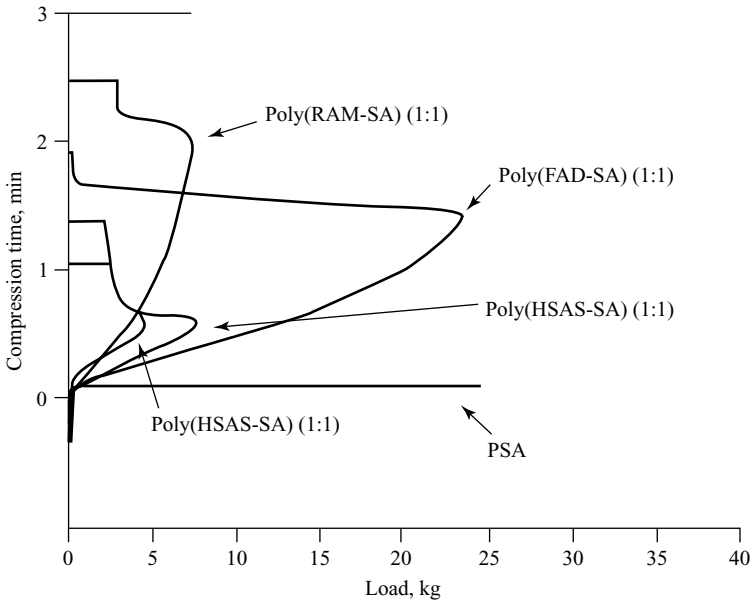

Fig. 1. Stress–strain curves for ricinoleic acid derived polymers (38).

poly(1,1-bis(*p*-carboxyphenoxy) methane) maintained their original molecular weight for at least 1 year in the solid state. In contrast, aliphatic polyanhydrides, such as PSA, showed decreased molecular weight over time. The decrease in molecular weight shows a first-order kinetics, with activation energies of 7.5 Kcal/(mol·K). The decrease in molecular weight was explained by an internal anhydride interchange mechanism, as revealed from elemental and spectral analyses. This mechanism was supported by the fact that the decrease in molecular weight was reversible and heating the depolymerized polymer at 180°C for 20 min yielded the original high molecular weight polymers. However, under similar conditions the hydrolyzed polymer did not increase in molecular weight (20). In many cases, it was observed that the stability of polymers in the solid state or in organic solution did not correlate with its hydrolytic stability (20). A similar decrease in molecular weight as function of time was also observed among the aliphatic–aromatic copolyanhydrides and imide-containing polyanhydrides (19,57).

Gamma-irradiation technique is typically used to sterilize polyanhydrides (59). Aliphatic and aromatic homo- and copolymers were irradiated at 2.5 Mrad dose and the change in properties was monitored before and after irradiation. Properties such as molecular weight, melting temperature, and heat of fusion remained the same, and ^{1}H NMR and FT-IR spectra of the polymer were also similar before and after irradiation (60,61). Using the same concept, these studies were extended for saturated and unsaturated polyanhydrides (28). Ricinoleic acid based copolymers with SA and poly(CPP:SA) were irradiated under dry ice and at room temperature while poly(FA:SA) was irradiated only at room temperature. Saturated polyanhydrides are stable enough during irradiation; however, the presence of double bonds conjugated to an anhydride bond creates an unstable structure

and leads to the formation of free radicals (28). These free radical polyanhydrides degrade into less conjugated polyanhydrides. The outcome of this process is self-depolymerization via inter- and/or intramolecular anhydride interchange to form polymers with lowered molecular weight. In general, polymers with high melting points and crystallinity give the highest yield of room temperature observable radicals. These endogenous free radicals were used to study processes of water penetration and polymer degradation *in vivo* (59). The detection of gamma sterilization induced free radicals *in vivo* using EPR could be of significance because changes in the mobility of the radicals can be used to study drug release kinetics in a non-invasive and continuous fashion, without introducing paramagnetic species (61).

***In Vitro* Degradation and Drug Release.** Degradation of polyanhydride matrices depends on many factors including the (*1*) chemical nature and hydrophobicity of the monomers; (*2*) shape, geometry, and surface area of the implants; (*3*) porosity; (*4*) level of drug loading in the polymer matrix; and the (*5*) pH of the media (polymers degrade faster in alkaline media (Fig. 2)) and drug solubility. As the degradation of polyanhydrides follows erosion and pH plays an important role in the solubility of its monomers in the medium (63), degradation of the polymer becomes faster on increasing the pH of the medium (Fig. 2) and porosity increases gradually on its surface as well as in bulk (63). Notably, the porosity of the implant can be changed by change in method of fabrication. For example, a compression-molded device will degrade faster than an injection-molded device (64,65) due to a higher porosity in the polymer mass. A large number of examples on the degradation behavior of various types of polyanhydrides exists, but the clinically tested polyanhydrides such as poly(CPP-SA), poly(FA-SA), and poly(EAD-SA) have been most scrutinized. In general, during the initial 10–24 h of incubation in aqueous medium, the molecular weight dropped rapidly with no loss in wafer mass (66). This incubation period was followed by a fast decrease in wafer mass, accompanied with a small decrease in polymer molecular weight. The period of extensive mass loss starts when the number-average molecular weight (M_n) of polymer approaches 2000 (DP $\sim$ 10 units) regardless of the initial molecular weight of the polymer. For example, SA, a slightly water-soluble comonomer, is released from the wafer over a 1-week time frame, leaving the less soluble comonomer, CPP

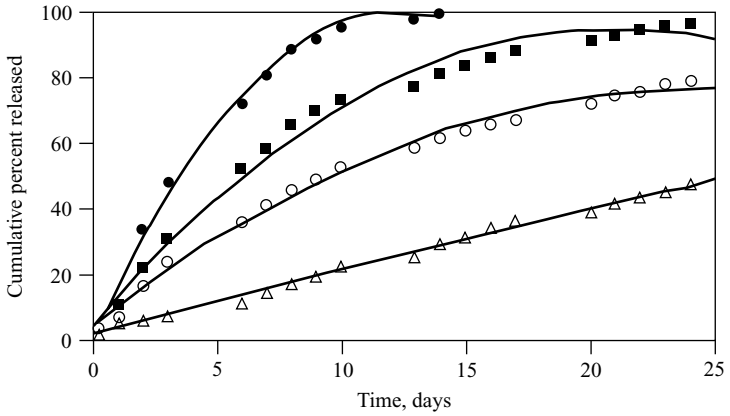

Fig. 3. Bupivacaine release from various poly(EAD-SA) compositions. Bupivacaine was released from polymer slabs in phosphate buffer (pH 7.4) at 37°C and determined by HPLC (36). ●, 10% FAD; ■, 20% FAD; ○, 30% FAD; △, 80% FAD.

or EAD, which is slower to solublize (66). Increasing the content of SA in the copolymer increases the hydrophilicity of the copolymer, which results in a higher erosion rate and hence higher drug release rate. The water uptake depends on the hydrophobicity of the polymer and therefore, the hydrophobic polymers that prevent water uptake have slower erosion rates and lower drug release rates. Because of this property, one can alter the hydrophobicity of the polymer by altering the structure and/or the content of the copolymer, and consequently alter the drug release rate. Increase of methotrexate (MTX) release upon increasing SA content in the fatty acid terminated polyanhydrides was reported recently (67). In the poly(CPP-SA) and poly(EAD-SA) series of copolymers, a 10-fold increase in bupivacaine release rate was achieved by alteration of the ratio of the monomers, and thus, both polymers can be used to deliver drugs over a wide range of release rates (Fig. 3).

Thus, there is no correlation between the drug release rate and polymer degradation expressed as percent decrease in the molecular weight, which might appear to be contradictory (68). On closer examination, it appears that drug dispersed in the polymer matrix is released when the eroding polymer brings the drug into contact with the solution. Drug release depends on the rate of erosion expressed as volume of the matrix dissolved per unit time, times the drug load rather than the rate of polymer degradation. The implication is that drug release should correlate with mass loss, which is a more appropriate indicator of the erosion rate than the decrease in molecular weight. Another feature of surface erosion is that the molecular weight of the polymer may decrease at the surface while the interior of the device still retains its initial molecular weight. Furthermore, lower molecular weight fragments so formed may not diffuse out or dissolve into the release medium. Therefore, it is not the decrease in molecular weight but the subsequent mass loss to the diffusion and erosion of molecular weight fragments which should correlate with drug release. This phenomenon also explains why drug release from these polymer devices was independent of the initial molecular weight of the copolymer (68).

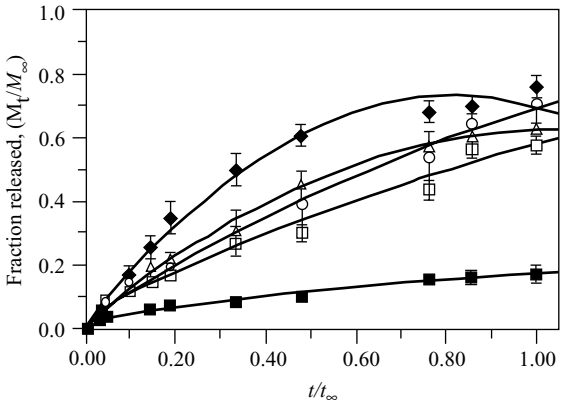

Fig. 4. *In vitro* release of ciprofloxacin from ricinoleic acid derived polymers. Release time (t_∞) was 460 h and the total drug load (M_∞) was 10 mg (38). □, SA; ●, RAM; ○, HSAM; (▲), HSAS; ■, FAD.

Recently, Stephans and co-workers (62) investigated the *in vitro* release behavior of gentamicin sulfate from a poly(EAD-SA) matrix and found that drug release rate was faster in a water than in a phosphate buffer of pH 7.4. Sulfate release was monitored along with drug release and the results indicated that an exchange of ions occurred during the *in vitro* drug release at pH 7.4. It was subsequently demonstrated that gentamicin could form an insoluble salt with EAD. This salt formation explains the slower drug release in pH 7.4 phosphate buffer. The release of indomethacin from poly(CPP-SA) and poly(EAD-SA) was studied and was found to be independent of drug loading (69). Moreover, more hydrophobic components reduce the water penetration into the polymers and this reduces the drug release rate. Figure 4 is one example of *in vitro* ciprofloxacin release with copolymers of various fatty acids components. A simple model that takes into account the following kinetic steps, namely, the spontaneous degradation of polymer to crystallized monomer, the creation of pores, the dissolution of monomers inside the pores, and the final release of monomer via diffusion through the pore network, was put forth by Gopferich and Langer to explain this unusual release behavior (69,70). Erosion was then simulated using a Monte-Carlo method that describes these morphological changes during erosion.

Characterization

Polyanhydrides have been characterized with regard to their chemical composition, structure, crystallinity and thermal properties, mechanical properties, thermodynamic properties, and hydrolytic stability. A representative set of analysis data has been summarized for the polyanhydrides poly(EAD-SA) and poly(CPP-SA) (Table 4). ^{1}H NMR spectroscopy indicates the degree of randomness that suggests whether the polyanhydrides is either a random or a block copolymer; the average length of sequence (L_n); and the frequency of occurrence of specific comonomers sequences (58). The anhydride bond presents characteristic peaks in

the IR and Raman spectra. In general, the carbonyl of aliphatic polymers absorbs at 1740 and 1810 cm^{-1}, and aromatic polymers at 1720 and 1810 cm^{-1} (72). The presence of carboxylic groups in the polymers can be determined from the presence of a peak at 1700 cm^{-1}. Thus, the degradation of polyanhydrides is determined from the ratio of the subsequent peaks at 1810 and 1700 cm^{-1}.

Fourier-Transform Raman Spectroscopy (FTRS) was used to characterize an homologous series of aliphatic poly(anhydrides), poly(carboxyphenoxy)alkanes, and copolymers of CPP and SA (72). All anhydrides show two diagnostic carbonyl bands, the aliphatic polymers have the carbonyl pairing at 1803/1739 cm^{-1}, and the aromatic polymers have the band pair at 1764 and 1712 cm^{-1} (72). FTRS was used to study the hydrolytic degradation of PSA rods exposed to water for 15 days. The carbonyl anhydride band pair (1803/1739 cm^{-1}) diminished in intensity from Day 0 to 15, with the emergence of the complimentary acid carbonyl band (1640 cm^{-1}) which increased in intensity over the same period. Similarly, the increase in the intensity of the C—C deformation at 907 cm^{-1} with hydrolysis reflects the increased freedom of the methylene chain in the low molecular weight oligomers.

The molecular weights of polyanhydrides were determined by viscosity measurements and GPC (58). The weight-average molecular weight (M_w) of polyanhydrides ranges from 5,000 to 300,000 with a polydispersity of 2–15 that increases with increased M_w. The intrinsic viscosity [η] increases with the increase in M_w. The Mark–Houwink relationship for poly(CPP-SA) was calculated from the viscosity data and the M_w values as determined by universal calibration of the GPC data using polystyrene standards.

$$[\eta]^{23^\circ C}_{CH_3Cl} = 3.88 \times 10^{-7} M_w^{0.658}$$

Crystallinity was determined by X-ray diffraction, a combination of X-ray and DSC, and data generated from ^1H NMR spectroscopy and Flory's equilibrium theory (40).

The morphology of polyanhydrides was studied by scanning electron microscope (SEM) to elucidate the mechanism of polymer degradation and drug release from polyanhydrides. The surface chemical structure of aliphatic polyanhydride films was examined using time-of-flight secondary ion mass spectroscopy (ToF-SIMS) and X-ray photoelectron spectroscopy (XPS) (24,76). The main peak at 285 eV corresponds to C—H. The peak at 289.5 eV arises from O—C=O. The XPS data confirmed the purity of the surface, and the experimental surface elemental ratios were in good agreement with the known stoichiometry of the examined polyanhydrides. The ToF-SIMS spectra of the polyanhydrides reflected the polymer structure. The SIMS data confirms a systematic fragmentation, in both negative- and positive-ion SIMS spectra, occurring throughout the entire series of the polyanhydrides examined. Radical cations were observed in the positive-ion spectra. The ion at *m/z* 71, which may arise from the fragmentation of the anhydride unit, CH_2=CHCOO—, was seen for all polyanhydrides. The combined use of ToF-SIMS and XPS provides a detailed insight into the interfacial chemical structure of polyanhydrides. Atomic force microscopy (AFM) was used to follow the degradation of poly(SA) and its blends with poly(lactide) (73,77). AFM was suitable to visualize polymer degradation without the need to dry the samples.

Biocompatibility and Elimination

Several tests to evaluate new biomedical materials were used to assess the safety of polyanhydrides (53,78). In these studies, poly(bis(*p*-carboxy-phenoxy)propane anhydride) poly(CPP) and its copolymers with SA were tested. Neither mutagenicity and cytotoxicity nor teratogenicity was associated with the polymers or their degradation products, as evaluated by mutation assays. The tissue response of these polyanhydrides was studied by subcutaneous implantation in rats and in the cornea of rabbits. The polymers did not provoke inflammatory responses in the tissues over a 6- week implantation period. Histological evaluation indicated relatively minimal tissue irritation with no evidence of local or systemic toxicity (53). Systemic response to the polymer was evaluated by monitoring of blood chemistry and hematological values, and by comprehensive examination of organ tissues. Both methods revealed no significant response to the polymer. Recently, biocompatibility of ricinoleic acid based polymer was tested in rats and compared to Vicryl (Ethicon) surgical suture and sham surgery (37). No abnormal gross pathological finding was observed at the implantation site after 3, 7, and 21 days of implantation. Blood chemistry and blood counting levels were similar for treated and untreated rats. The polymer was degraded into ricinoleic acid with constant release of incorporated drug while the inflammatory response after subcutaneous implantation was minimal to mild and comparable with clinically used Vicryl absorbable sutures.

CPP-SA copolymer was designed to deliver an anticancer agent directly into the brain for the treatment of brain neoplasm and *in vivo* safety evaluations and brain biocompatibility were assessed in rats (79), rabbits (8), and monkeys (80). In the rat brain study, the tissue reaction of the polymer (P(CPP-SA) (20:80)) was compared to the reaction observed with two standard materials used in surgery, which have been extensively studied, Gelfoam (absorbable gelatin sponge; Becton Dickenson) and Surgicel (oxidized cellulose absorbable hemostat; Ethicon). Histological evaluation of the tissue demonstrated a small rim of necrosis around the implant, and a mild to marked cellular inflammatory reaction limited to the area immediately adjacent to the implantation site. The pathological response associated with poly(CPP-SA) copolymer was slightly more pronounced than with Surgicel at the earlier time points, but noticeably less marked than with Surgicel at the later times. The reaction to Gelfoam was essentially equivalent to that observed in control rats. In a similar brain biocompatibility study carried out in monkeys, no tissue abnormalities were noted either in computerized tomography and magnetic resonance imaging. Furthermore, no abnormalities were observed either in the blood chemistry or hematology evaluations (81). There appeared to be no adverse systemic effects caused by the implants as determined by histological evaluation of tissues. Overall, no unexpected or untoward reaction to the treatment was observed. Copolymers of SA with several aliphatic comonomers such as EAD, FA, and IPA were also tested subcutaneously and in the rat brain and were found to be biocompatible as well (82). The hydrolysis and elimination processes of polyanhydrides have been studied using a series of polyanhydrides derived from different linear aliphatic diacids (83). These polymers degrade into their monomer or oligomers units at about the same rate but differ in the water solubility of their degradation products. Polymers based on natural diacids of

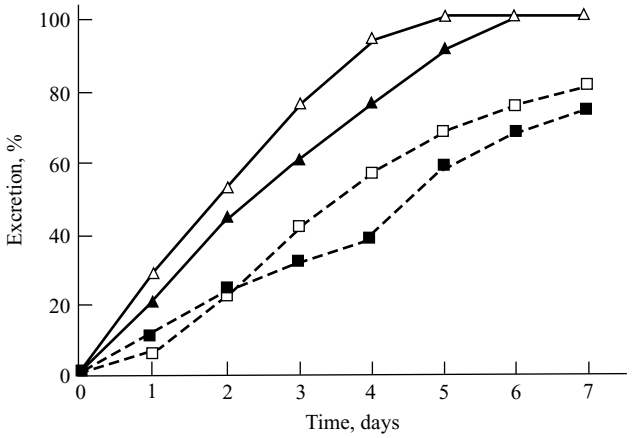

Fig. 5. *In vivo* and *In vitro* degradation of poly(CPP-SA) (20:80). The radioactive excretion data were used to determine the *in vivo* of SA and BCNU. *In vitro* hydrolysis was evaluated on compression-molded wafer in 0.1 *M* phosphate buffer, pH 7.4, at 37°C. SA and BCNU concentrations were determined by HPLC. △, BCNU, *in vitro*; ▲, SA, *in vitro*; □, SA, *in vivo*; ■, BCNU, *in vivo* (84).

the general structure —(OOC—$(CH_2)_x$—CO)— (where x is between 4 and 12) were implanted subcutaneously in rats and the elimination of the polymers from the implantation site was studied (83). The *in vitro* hydrolysis of this polymer series was studied by monitoring the mass loss, release of monomer degradation products, and the changes in content of anhydride bonds as a function of time. Both *in vitro* and *in vivo*, the rate of polymer elimination was a function of monomer solubility. The elimination time for polymers based on soluble monomers ($x = 4$–8) was 7–14 days, while the polymers based on monomers with lower solubility ($x = 10$–12) were eliminated only after 8 weeks. All polymers were found to be biocompatible and useful as carriers of drugs.

The elimination of poly(CPP-SA)-based implant (Gliadel (Guilford Pharmaceuticals)), which has been approved for the treatment of brain cancer, was studied in rabbit and rat brains using radioactive polymer and drug (Fig. 5) (84,85). The implant is composed of BCNU dispersed in a copolyanhydride matrix of 1,3-(*p*-carboxy)phenoxypropane (CPP) and sebacic acid (SA). Four groups of rabbits were implanted with wafers loaded with BCNU, one in a ^{14}C-SA-labeled polymer, another in a ^{14}C-CPP-labeled polymer, and two groups with ^{14}C-BCNU in a nonlabeled polymer, in which one group was for BCNU disposition study and the other was for residual drug study. In the rabbits implanted with the 14C-SA-labeled polymer, approximately 10% of the radioactivity was found in the urine and 2% in the feces, and about 10% remained in the device after 7 days of implantation. In contrast, only 4% of the radioactivity associated with the ^{14}C-CPP-labeled polymer was found in urine and feces during this period. However, a drastic increase in the CPP excretion was found after 9 days, and at 21 days, during this period, 64% of the implanted ^{14}C-CPP was recovered in the urine and feces, and 29% was still in the recovered wafers. Studies with radiolabeled BCNU in rabbit brain revealed that approximately 50% of the BCNU in the wafers was released in

3 days, and over 95% was released after 6 days in the rabbit brain. Excretion of this polymer after implantation in the rat brain using radiolabeled polymers showed that over 70% of the SA comonomer was excreted in 7 days, with about 40% of the SA metabolized to CO_2 (85). The elimination of poly(EAD-SA) rods loaded with 0, 10, and 20 wt% of gentamicin sulfate after implantation in the femoral muscle and bone of dogs was studied as part of the preclinical studies for Septacin-bone implant (86). Most of the polymer implant was gradually eliminated from bone and muscle within 4–8 weeks post implantation, with elimination from bone being faster leading to new bone formation in the implant site without any polymer entrapment. The elimination rate was dependent mainly on the amount of polymer implanted. Gentamicin was released for a period of about 3 weeks, with no residual drug detected in the polymer remnants 8 weeks postimplantation. In all experiments, no local or systemic toxicity was observed.

Fabrication of Delivery Systems

Polymers having low melting point and good solubility in common organic solvents such as methylene chloride, allow for the easy dispersion of a drug into their matrix. For example, drugs can be incorporated into a slab either by melt mixing the drug into the melted polymer, or by solvent casting (87). Polymer slabs loaded with drug can also be prepared by compression molding a powder containing the drug (88). Similarly, one can injection mold the drug-polymer formulation into beads or rods (89). Polymer films can be prepared by solvent casting the polymer solution containing the drug onto Teflon-coated dish (67). Microsphere-based delivery systems can be formulated by the common techniques including solvent removal, hot-melt encapsulation, and spray drying (90–92). However, it is essential that all processes be performed under anhydrous conditions to minimize hydrolysis of the polymer (see CONTROLLED RELEASE TECHNOLOGY).

Production and World Market

Polyanhydrides are not commercially available. One polyanhydride composition, poly(CPP-SA) (20:80), is manufactured at Guilford Pharmaceuticals in Baltimore on a kilogram scale, as part of the Gliadel implant for the treatment of brain tumors. Poly(dimer eurecic acid-co-sebacic acid) was developed for large scale production by Abbott Lab (Chicago) for the fabrication of the Septacin implant for prevention of bone infections. The Septacin product was manufactured by injection molding of the polymer–drug composition. The development of this product was stopped for marketing reasons. Samples of polyanhydrides may be obtained by a request from the corresponding author.

Pharmaceutical Applications

Polyanhydrides have been investigated as a candidate for controlled release devices of drugs for treating eye disorders (93), chemotherapeutic agents (94,95),

local anesthetics (88,96), anticoagulants (97), neuroactive drugs (98), and anticancer agents (99). Polyanhydrides were loaded with carmustine and implanted in the brains of rats, rabbits, and monkeys and studied. These were found to be biocompatible and efficacious against brain tumors (100,101). Based on the foundation of these laboratory studies, phases I and II were completed, which showed that treatment was well tolerated in all patients and did not appear to produce systematic side effects (81). Phase III human clinical trails demonstrated that the site-specific delivery of BCNU (carmustine) from a poly(CPP-SA) (20:80) wafer (Gliadel) in patients with recurring brain cancer (glioblastoma multiforme) significantly prolongs patients' survival (100). On the basis of result of a 4–5-years-long clinical trial, FDA has given the approval for a new treatment of brain tumors (94). Gliadel subsequently has been approved in Canada, South America, Israel, South Korea, and Europe for brain tumor treatment. Masters and co-workers (102,103) have used a polyanhydride cylinder for the delivery of local anesthetics in close proximity to the sciatic nerve to produce a neuronal block for several days. The use of polyanhydrides in oral delivery of insulin and plasmid DNA has been investigated (104). In the past 5 years, investigations have expanded to newer polymers and other drugs such as 4-hydroperoxy cyclophosphamide, cisplatin, carboplatin, and paclitaxel, and several alkaloid drugs in an effort to develop a better system for treating brain tumors (80,105–107). Carboplatin incorporated in poly(EAD-SA), prepared by mixing the drug in the melted polymer, has been evaluated for the treatment of brain tumors in laboratory animals, and has shown promising results (107). Poly(CPP-SA) has also been used to develop a delivery system for gentamicin sulfate for the treatment of osteomyelitis (105,108). A sustained release of gentamicin sulfate over a period of few weeks was obtained both *in vivo* and *in vitro* using this system. This delivery device was used in human clinical trials in the United States. The effect of long-term glutamic acid stimulation of trigeminals motoneurons, using poly(EAD-SA) microspheres, has also been explored. This study was undertaken to determine the role of glutamate in possible growth disorders of the craniofacial skeleton. Pronounced skeletal changes in the snout region were observed in rats that received glutamate, indicating a sustained release of glutamic acid *in vivo* can affect the development of skeletal tissue in growing rats (109). Recently, the use of polyanhydrides for the delivery of heparin and treatment of osteomyelitis has been reported (62,67).

Outlook

Polyanhydrides, especially the copolymers of aliphatic and aromatic anhydrides, are a versatile class of biodegradable polymers. The desired physicochemical properties of these polymers can be obtained by carefully adjusting the composition of the monomers and molecular weight of the final polymer. Polyanhydrides degrade gradually into nontoxic monomers after their intended uses. Another attractive feature of polyanhydrides is the erosion-dominated degradation mechanism, and accompanied controlled release of drugs from the matrices. Gliadel is the only regional drug therapy approved by FDA for treating brain cancer in the past 20 years. Given their structural and physicochemical versatility, polyanhydrides are

likely finding more applications in other novel drug delivery systems, medical devices, and tissue engineering products.

The advantages and disadvantages of these polymers are the hydrolytic instability of the anhydride bond. The main advantages of this class of polymers are as follows:

(1) prepared from easily available, low cost resources and generally regarded as safe dicarboxylic acid building blocks, many of them are body constituents or metabolites
(2) prepared in a one-step synthesis with no need for purification steps to yield, well-defined polymer structure with controlled molecular weight
(3) can be manipulated to release bioactive agents at a predictable rate for periods of weeks, as a function of polymer composition
(4) processable by low temperature injection-molding or extrusion for mass production, versatile properties, obtained by appropriate monomer selection, composition, surface area, and additives
(5) degrade to their respective diacids and completely eliminate from the body within a period of weeks to months
(6) sterilized by gamma-irradiation without any effect on polymer properties

Apart from these advantages, the main disadvantages of these polymers are their short-term degradation and release period, and the need for special storage conditions (refrigeration, dry conditions). Thus, these polymers are most suitable for short-term (days to weeks) controlled delivery of bioactive agents in the form of solid implants or injectable microspheres.

POLYARYLATES

Introduction

Polyarylate resins are heat-resistant thermoplastics with excellent toughness, uv stability, flexural recovery, dimensional stability, and electrical properties.

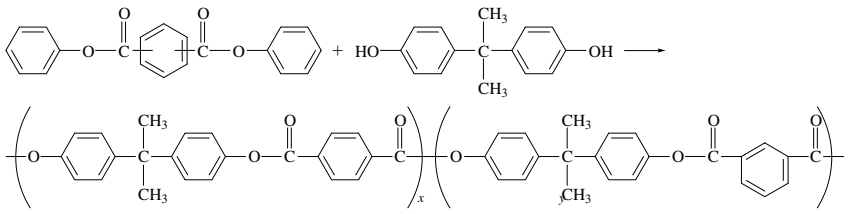
Polyarylate polymer properties can be tailored by compositional variation, alloying with other high performance thermoplastics, and reinforcement. This flexibility renders polyarylate one of the more versatile high temperature polymers for current and emerging markets served by engineering thermoplastics.

Chemistry

Polyarylate polymers are aromatic polyesters derived from aromatic dicarboxylic acids and diphenols. In contrast to liquid crystalline aromatic polyester (derived from dicarboxylic hydroxy acids), polyarylates exhibit amorphous character on molding; T_g is ca 198°C. Polyarylates present a competitive cost/performance profile in the context of amorphous engineering thermoplastics, delivering an excellent balance of mechanical properties, particularly practical heat resistance which substantially exceeds that of polycarbonates (qv).

The preferred aromatic diphenol based on current commercial offerings is bisphenol A; the aromatic dicarboxylic acid is proportioned between isophthalic acid and terephthalic acid (eq. (1)). The election of a particular isophthalic acid/terephthalic acid ratio is influenced by both the commercial manufacturing process and market orientation (1). The ratio of x, y in the product of equation (1) is close to one for U-Polymer, produced by Unitika, the only current commercial polyarylate.

Encyclopedia of Polymer Science and Technology. Copyright John Wiley & Sons, Inc. All rights reserved.



(1)

Diphenols are scarcely reactive towards aromatic diacids (2) and only low molecular weight polymers can be achieved through their direct reaction. To increase the reactivity and promote the polycondensation, at least one of the monomers has to be properly activated. Thus, two processes have been conceived for polyarylate synthesis: interfacial polycondensation (preferred over the solution process) between diacyl chlorides and alkali metal diphenate, and the high temperature metal-catalyzed melt polycondensation between either diphenol acetates and aromatic diacids, or diphenols and diacid diphenyl esters.

Properties

Polyarylates deliver excellent thermal performance with heat-deflection temperatures ranging from 154 to 174°C at 1.82 MPa (264 psi) and a UL thermal index of 130°C. In addition, a very low coefficient of thermal expansion [5.0–6.2 $\times$ 10^{-6} mm/(mm·°C) (60–130°C)] allows for superior performance in polyarylate/metal assemblies. The inherent uv resistance of polyarylate polymers results in excellent retention of mechanical properties under prolonged weathering conditions. As a coating or laminate, polyarylate provides a uv barrier for other performance plastics.

Mechanical properties compare favorably with other high performance amorphous and semicrystalline thermoplastics, where strength and toughness requirements are rigorous (Table 1). The flexural recovery (resilience) of polyarylate is excellent over a wide temperature range, which suggests applications where snap-fit action is required.

Polyarylate resins exhibit good combustion resistance in terms of low flame spread, a high oxygen index, and low smoke generation.

Unmodified polyarylates exhibit sufficient fire-retardant characteristics for many applications, whereas more stringent combustion requirements can be achieved with the proper selection of additives. The electrical properties of polyarylate polymers are reasonably constant over a broad temperature range and present a competitive profile for high performance electrical applications.

The amorphous character of polyarylates renders this class of polymer susceptible to stress-cracking tendencies in solvents such as ketones, aromatic hydrocarbons, esters, and chlorinated hydrocarbons. In applications where chemical resistance is critical, alloying polyarylate with other high performance materials can often meet the requirement.

Polyarylates are transparent and range in color from light yellow to amber. The transparent character can be maintained in alloying with other reactive

Table 1. Properties of Polyarylates

polyesters while mechanical properties can be tailored to end-use applications. Additional property modification is achieved by targeting mechanically compatible blends.

Processing

Polyarylates can be processed by most conventional melt processes, including injection molding, extrusion, blow molding, and thermoforming. Processing characteristics are similar to that of polycarbonate with the exception that higher melt temperatures are required.

Injection molding is the processing technique that is most widely employed, and resins are available that fill complex mold designs. Recommended melt temperatures range from 260 to 382°C depending on the composition, and mold temperatures can range from 65 to 149°C. Additionally, extrusion and blow-molding grades offer good melt strength combined with high throughput rates that are essential for blow molding, profile extrusions, and thermoforming operations.

Successful processing of polyarylates requires moisture levels below 0.02%, which is similar to requirements for other polyesters (ie, PET). All polyarylates are unstable in the presence of moisture at the processing temperatures described earlier; unsatisfactory part properties result from processing poorly dried resin.

Applications

Polyarylates are presently used in a wide variety of end-use applications and also show potential for future applications. Presently, polyarylates find use in the automotive, safety, electrical and electronics, and exterior construction and lighting areas.

Automotive. Properties of polyarylates, such as high heat resistance, dimensional stability, and capability for high gloss surface metallization of parts, allow these resins to be used in headlight housings and brake light reflectors. For exterior trim parts such as mirror housings, window trim, and door handles, the good uv resistance and weatherability of polyarylate eliminate the need for painting. In brackets and fasteners, the resin's creep resistance and dimensional stability are advantageous. Polyarylate alloys are being evaluated for use in body panel applications.

Safety Equipment. Polyarylates are used in fire helmets and fire shields because of their inherent resistance to hot and cold temperatures, impact and flammability resistance, colorability, and transparency. Polyarylates can also be used in other safety-related applications such as mining light covers and lenses for traffic signals.

Electrical and Electronic. Polyarylates provide the excellent temperature resistance and flame retardancy needed for electrical connectors, relay housings, coil bobbins, and switch and fuse covers.

Exterior Applications. Because of the excellent uv resistance of polyarylates, end use is found in such outdoor applications as glazing, skylights, and transparent panels. Polyarylates can be used alone or in multilayer constructions with other polymers. Properties such as transparency, impact and heat resistance, and low haze levels after long-term exposure have suited this resin for use in globes and other lighting components.

Producers

Currently, Unitika Corp. Ltd. is the only producer of this material in the world. The trade name of Unitika's polyarylate is U-Polymer. Polyarylate is marketed in North America by Toyota Tsusho America, Inc. World production is about 1000 t/year.

POLYCARBONATES

Introduction

Polycarbonates are an unusual and extremely useful class of high heat polymers known for their toughness and clarity. The vast majority of polycarbonates are based on bisphenol A (BPA), and sold under the trade names Lexan (GE), Makrolon (Bayer), Caliber (Dow), Panlite (Teijin), and Iupilon (Mitsubishi). Many other producers and suppliers are available. BPA polycarbonates have glass-transition temperatures (T_g) in the range of 140–155°C and are widely regarded for their optical clarity and exceptional impact resistance and ductility at or below room temperature. Other properties such as modulus, dielectric strength, and tensile strength are comparable to other amorphous thermoplastics at similar temperatures below their respective T_gs. However, while most amorphous polymers are stiff and brittle below their T_gs, polycarbonates retain their ductility. Polycarbonates are prepared commercially by two completely different processes: Schotten–Baumann reaction of phosgene (qv) and an aromatic diol in an amine-catalyzed interfacial condensation reaction, or via base-catalyzed transesterification of a bisphenol with a monomeric carbonate such as diphenyl carbonate. Each process has its own inherent advantages and disadvantages. Many important products are also based on polycarbonate in blends with other materials, copolymers, branched resins, flame-retardant compositions, foams, and other materials. Polycarbonates are produced by more than a dozen companies, with global manufacture currently just over 2 million tons annually. Polycarbonate is also the object of both industrial and academic research because of its widespread utility and unusual properties. Research on polycarbonates has steadily increased over the past two decades, with over 5000 publications on the topic since 1995 and nearly 20,000 patents having appeared globally (more than 8000 since 1995). the number of patent holders, including Teijin Chemicals, Teijin Limited, Sekisui Chemical, Asahi Chemical, Idemitsu Petrochemical, Toray Ind., and Mitsubishi Gas Chemical Co. Other companies with significant patent portfolios include General Electric, Bayer AG, and Dow Chemical. Polycarbonate has been the subject of three monographs, one of them published in 2000 (1,2).

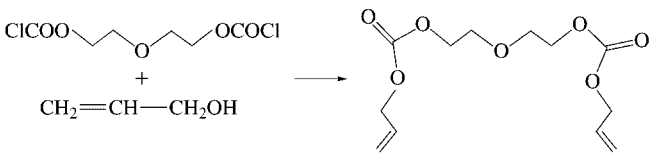
Historical Development

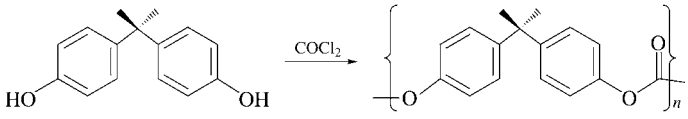
The first polycarbonates were prepared by Einhorn in the late 1890s via reaction of hydroquinone or resorcinol with phosgene, using pyridine as solvent (3). Attempts to prepare the polycarbonate of catechol led only to the cyclic five-membered carbonate. A few years later, the same materials were prepared by Bischoff via solventless transesterification using diphenyl carbonate (4). The hydroquinone polymer is brittle, crystalline, insoluble in most solvents, and melted at >280°C. The polymer from resorcinol is glassy and brittle, although it crystallizes from solution and melts at about 190–200°C. Both of these polymers were apparently of low molecular weight and owing to difficulties of processing and characterization, were not developed further. In fact, no research on polycarbonates appeared in the literature for about 30 years after their initial discovery. In the early 1930s, the preparation of *aliphatic* carbonates was studied during the investigation of the preparation and properties of polyesters (5). Because the reactions of aliphatic alcohols and phosgene proceed more slowly than those of phenols, two other methods were used to prepare the aliphatic polycarbonates: direct transesterification reactions and ring-opening polymerization of low molecular weight cyclic polycarbonates prepared by a distillative transesterification–depolymerization. Further work was carried out in the 1940s. 1,6-Hexanediol polycarbonates were prepared via transesterification using dibutyl carbonate (6). The aliphatic polycarbonates had low melting points and did not prove interesting commercially. In 1941, the Pittsburgh Plate Glass Co. (PPG) introduced a liquid casting resin designated as CR-39 (7). This material, formally a polycarbonate, was a cross-linked thermoset resin prepared by a peroxide-initiated radical polymerization of the bisallyl carbonate of diethylene glycol. The starting material was prepared from allyl alcohol and diethylene glycol bischloroformate (eq. (1)). Once polymerized, CR-39 was a colorless, transparent, scratch-resistant plastic which was used in optical applications. These materials differ markedly from the current thermoplastic polycarbonates. Although its nature and chemical makeup are completely different from modern polycarbonates, CR-39 was the first commercially available polycarbonate.



(1)

A reexamination of aromatic polycarbonate chemistry was carried out about 50 years after the first polycarbonates of resorcinol and hydroquinone were

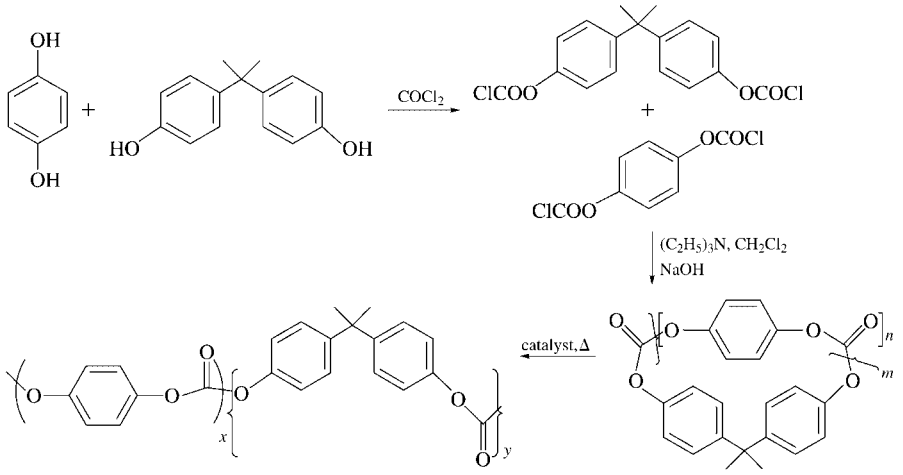
discovered. In independent investigations by Schnell at Bayer AG and by Fox at General Electric, it was discovered that the polycarbonates of BPA could be prepared (eq. (2)). Unlike the aliphatic polycarbonates prepared earlier, which were either liquids or low melting solids, the aromatic polycarbonates were tough, amorphous solids having elevated T_gs. Owing to the unusual properties of the BPA polycarbonate, ie, toughness, transparency, and thermal stability, each company began development programs. Bayer AG, the first to report the properties of a series of polycarbonates (8), had patents issuing as early as 1954 (9). Commercial production of polycarbonate by Bayer AG began in Germany in 1958 and in the United States in 1960. General Electric (GE) started U.S. commercial production in 1960. After a period of litigation, U.S. patents were issued to Bayer AG, which claimed an interfacial process for preparation of polycarbonates, and had multiple claims to various polycarbonates (10). The basic GE patent claimed the transesterification process and the polycarbonate product so formed (11). Since that time extensive research has been carried out on polycarbonates. Several manufacturers have developed many niches of new products, blends, or processes for the production of these materials. Although GE and Bayer AG remain the principal producers, at least 50 companies have patented some aspect of polycarbonate chemistry. Over a dozen producers exist worldwide.



(2)

Solubility and Solvent Resistance. The majority of polycarbonates are prepared in methylene chloride solution. Other chlorinated solvents such as chloroform, *cis*-1,2-dichloroethylene, *sym*-tetrachloroethane, and methylene chloride are also good solvents for polycarbonates. The polymer is soluble in chlorobenzene or *o*-dichlorobenzene when warm, but crystallization may occur at lower temperatures. Methylene chloride is most commonly used because of the high solubility of the polymer (350 g/L at 25°C) and also because this solvent has low flammability and toxicity. Nonhalogenated solvents include tetrahydrofuran, dioxane, pyridine, and cresols. Hydrocarbons and aliphatic alcohols, esters, or ketones do not dissolve polycarbonates. Acetone promotes rapid crystallization of the normally amorphous polymer and causes catastrophic failure of stressed polycarbonate parts. In general, polycarbonate resins have fair chemical resistance to aqueous solutions of acids or bases, as well as to fats and oils, although prolonged exposure to high or low pH conditions can lead to loss of molecular weight. Chemical attack by amines or ammonium hydroxide occurs readily, and aliphatic and aromatic hydrocarbons promote crazing of stressed molded samples. For these reasons, care must be exercised in the choice of solvents for painting and coating operations. For sheet applications, polycarbonate is commonly coated with a silicone-silicate or acrylate hardcoat, which provides abrasion resistance as well as increased solvent resistance. Coated films are also available. Certain blends and copolymers of polycarbonate demonstrate dramatically improved solvent resistance. The blend of polycarbonate and poly(butylene terephthalate), eg, Xenoy

(GE) or Makroblend (Bayer), combines the toughness of polycarbonate with the solvent resistance of the semicrystalline polyester and is used in automotive applications. Hydroquinone polycarbonates were reinvestigated in the late 1980s (12). Several binary and ternary copolycarbonates were prepared using monomers such as hydroquinone, biphenol, and substituted hydroquinones. However, no thermal transitions other than the T_g were noted, and the copolymer with hydroquinone had a very low molecular weight ($\eta_{inh} = 0.09–0.10$). Difficulty in preparation of hydroquinone polycarbonates, owing to the insolubility of the oligomers, had been noted in the 1950s (13). Copolycarbonates of BPA and hydroquinone can be prepared via the intermediacy of oligomeric cocyclics (eq. (3)) (14). Although hydroquinone linear oligomers having degrees of polymerization greater than 2 are insoluble in CH_2Cl_2, the cyclic analogues remain soluble when randomly cyclized with BPA. Polymerization of the hydroquinone–BPA cocyclics via anionically initiated, ring-opening polymerization leads to high molecular weight semicrystalline polymers. Using this methodology, hydroquinone can be incorporated into the polycarbonate in levels up to 60%. The copolycarbonates show dramatically increased solvent resistance and are insoluble in all common polycarbonate solvents such as methylene chloride or tetrahydrofuran. Furthermore, when molded bars of the polycarbonate are exposed to gasoline while under stress, impact properties are retained, whereas standard polycarbonate grades fail.



Hydroguinone HQ – BPA copolycarbonate (3)

BPA polycarbonate has excellent resistance to hydrolysis. Prolonged contact with water at 60°C or moderate-term (months) contact at 100°C has little effect on polycarbonate, but extended contact can eventually lead to embrittlement. For example, exposure of polycarbonate film to steam at 101 kPa (1 atm) at 100 and 150°C showed failure of the film after 700 and 200 h, respectively (15). Additives can accelerate the degradation by catalyzing hydrolysis. Although acids have little effect, aqueous base can lead to etching. Hydrolysis occurs at the surface. The hydrolytic stability can be attributed to the low water solubility in the resin (~0.3%), which leads to essentially no swelling, and to the high glass-transition temperature of

the resin. Heating at elevated temperatures (eg, during molding), however, can lead to degradation owing to hydrolysis. Drying of all grades of polycarbonate is recommended prior to molding so as to avoid hydrolysis to lower molecular weight materials. Hydrolysis of polycarbonate has been extensively studied (16).

Molecular Weight and Viscosity. BPA polycarbonates are commercially available in a wide range of molecular weights. As the molecular weight increases, melt and solution viscosities increase proportionally. Molecular weights may be determined or inferred by several means, including gel-permeation chromatography (gpc), light-scattering size-exclusion chromatography, measurement of intrinsic or inherent viscosity, and measurements of melt viscosity and flow. Correlation of intrinsic viscosity (IV), or inherent viscosity [η_{inh}], with weight-average molecular weight (M_w) has been carried out on carefully characterized polycarbonate samples (17). The following relationship exists when [η_{inh}] is in mL/g.

$$[\eta] = (41.2 \times 10^{-3})\left(M_w^{0.69}\right)$$

For chemical studies, the chromatographic methods or solution viscosities are methods of preference, but for practical applications, melt flow is most important. Standard injection-molding grades of polycarbonate have intrinsic viscosities in the range of 0.50–0.55 dL/g in chloroform at 30°C, with M_w of 35,000–70,000 and number-average molecular weight (M_n) of 15,000–24,000, as determined by gpc using polystyrene standards, or M_w of 18,000–30,000 as determined by light scattering. The polydispersity ratio (M_w/M_n) of polycarbonate is about 2.3–2.7. The range of molecular weights and viscosities available is shown in Table 1.

The mechanical properties of polycarbonate, eg, tensile strength, impact resistance, flexural strength, elongation, etc, improve dramatically with increasing polymer intrinsic viscosity up to a value of about 0.45 dL/g (Table 2). After that point, only slight increases in mechanical properties are seen with increasing molecular weight, but melt viscosity continues to climb. At IV values greater than

0.6 dL/g, the melt viscosity becomes so high that processing is very difficult. Because some compromise between polymers having high molecular weight and good mechanical properties must balance the processibility of the resin, newer formulations having increased melt flow are being marketed. Lexan SP copolyestercarbonates (GE), for example, demonstrate enhanced flow rates as measured by melt-flow index (10–22 g/min) compared to standard grades of resin (6–16 g/min), yet retain excellent impact resistance, eg, notched Izod of 642–910 J/m (12–17 ft·lb/in.). A variety of strategies have been used for improvement in the melt flow of polycarbonate, usually sacrificing thermal resistance (ie, lower T_g), while maintaining good impact strength. Ultrahigh molecular weight polycarbonates can be prepared via ring-opening polymerization of cyclic aromatic oligomeric carbonates. These materials, which are not commercially available, can lead to polycarbonates having IV > 1.0 dL/g and molecular weights of 300,000–500,000 (18).

Spectroscopy and Analysis. Polycarbonates have a strong C=O stretching band at 1770 cm^{-1}, and strong C—O stretching bands at 1220 and 1235 cm^{-1}, distinguishing them from polyesters. The amount of phenol end groups can be determined from the O—H absorption at 3595 cm^{-1}. Proton nmr spectroscopy shows a symmetrical A_2B_2 aromatic pattern at 7.16 and 7.24 ppm, and absorption for the *gem*-dimethyl at 1.68 ppm, relative to $(CH_3)_4Si$. The ^{13}C nmr shows seven distinct absorptions: 152.1, attributable to C=O; 148.9; 148.2; 127.9; 120.3; 42.5; and 30.9. X-ray spectroscopy shows a weak absorption at 725 cm^{-1}, related to crystallinity, and a band at 917 cm^{-1}, independent of crystallinity. Differential scanning calorimetry reveals a T_g at around 154°C, shifting somewhat with molecular weight or level of branching. End group and impurity analysis is best revealed by hydrolysis of the polycarbonate using KOH-methanol in tetrahydrofuran under nitrogen, followed by reversed-phase hplc analysis or by spectroscopic techniques. Trace levels of impurities, such as methylene chloride, amine, chloride, and sodium, are determined by standard analytical techniques, eg, atomic absorption or titration.

Structure and Crystallinity. The mechanical–optical properties of polycarbonates are those common to amorphous polymers. The polymer may be

crystallized to some degree by prolonged heating at elevated temperature (8 days at 180°C) (19) or by immersion in acetone. Recently, an extensive amount of work has appeared on solid-state polymerization of polycarbonate oligomers. The oligomers or low molecular weight polycarbonate can be crystallized by a variety of methods, typically treatment with an antisolvent vapor. Amorphous powder appears to dissolve partially in acetone, initially becoming sticky, then hardening and becoming much less soluble as it crystallizes. Enhanced crystallization of polycarbonate can also be caused by the presence of sodium phenoxide end groups (20). Film or fibers derived from low molecular weight polymer tend to embrittle on immersion in acetone; those based on higher molecular weight polymer (>0.60 dL/g) become opaque, dilated, and elastomeric. When a dilated sample is stretched and dried, it retains orientation and is crystalline, exhibiting enhanced tensile strength. The tensile heat-distortion temperature of the crystalline file is increased by about 20°C, and the gas permeability and resistance to solvent attack is increased.

Thermotropic polycarbonates have been prepared from mixtures of 4,4-dihydroxybiphenyl and various diphenols (12). Nematic melts were found for copolycarbonates prepared from methylhydroquinone, chlorohydroquinone, 4,4-dihydroxydiphenyl ether, and 4,4-dihydroxybenzophenone. Slightly crystalline polycarbonates have been prepared from mixtures of hydroquinone and BPA (14) [$T_g = 154°C$, $T_m = 313°C$, $\Delta H = 11.0$ J/g (2.63 cal/g)], and a highly crystalline, high heat polycarbonate has been prepared from methylhydroquinone (21) [$T_g = 155°C$, $T_m = 289°C$, $\Delta H = 31.0$ J/g (7.41 cal/g)]. While the former (hydroquinone–BPA) copolymer has only been prepared via cyclic oligomers, the methylhydroquinone polycarbonate can be prepared via a melt process.

Experimental and theoretical studies on the structure of BPA polycarbonates have been the object of considerable interest since the work of Williams and Flory in the late 1960s (22). Because of the low conformational barriers to rotation, phenyl ring-flipping and cis–trans isomerization about the carbonate group have been invoked as mechanisms for energy absorption, providing polycarbonates with low temperature impact strength. Crystal structures of diphenyl carbonate, described in detail, have been published (23,24). The crystal structures of a model carbonate (the bisphenyl carbonate of BPA) has also appeared (25). All of the published structures indicate that the thermodynamically preferred backbone conformation about the carbonate functionality is a trans–trans conformation. In this form, the dihedral angles of the aromatic rings with the carbonyl oxygen, C—O—C(=O)—O (174.8° and 176.5°), are nearly eclipsed, and as a consequence, the planes of the carbonyl groups are skewed from the planes of the aromatic rings by 59.1° and 53.2°. A cis–trans relationship about the carbonyl group was first seen in a complex of the bisphenyl carbonate of BPA with two molecules of a thiopyrilium salt (26). The cyclic dimer carbonate of BPA also shows only a cis–trans relationship of aromatic rings about the carbonyl (24). The crystal structure of the cyclic tetramer has also been described (24), showing two distinct types of aromatic conformations about the carbonyl. Several mathematical (27) and physical (28) methods have been used to analyze the conformational features of BPA polycarbonate. Estimations of the energy differences between conformations have been investigated by a variety of techniques, including ab initio calculations, (29) nmr spectroscopy, (30) and infrared spectroscopy (31). Molecular

simulation studies on the conformation of cyclic oligomers have also appeared (32).

Glass-Transition Temperature and Melt Behavior. The T_g of BPA polycarbonate is around 150°C, which is unusually high compared to other thermoplastics such as polystyrene (100°C), poly(ethylene terephthalate) (69°C), nylon-6,6 (45°C), or polyethylene (−45°C). The high T_g can be attributed to the bulky structure of the polymer, which restricts conformational changes, and to the fact that the monomer has a higher molecular weight than the monomer of most polymers. The high T_g is important for the utility of polycarbonate in many applications because, as the point which marks the onset of molecular mobility, it determines many of the polymer's properties such as dimensional stability, resistance to creep, modulus, and ultimate use temperature. Polycarbonates of different structures may have significantly higher or lower T_gs (see Table 3).

BPA polycarbonate becomes plastic at temperatures of around 220°C. The viscosity decreases as the temperature increases, exhibiting Newtonian behavior, with the melt viscosity essentially independent of the shear rate. At the normal injection-molding temperature of 270–315°C, the melt viscosity drops from 1100 to 360 Pa·s (11,000–3600 poise), which is about five times the viscosity of poly(ethylene terephthalate) of similar molecular weight over the same temperature range. Because the viscosity of polycarbonate can only be reduced by increasing the temperature, the ultimate limit on molecular weight is controlled by the processing conditions and the thermal stability of the polymer. Branched polycarbonates can be prepared by incorporation of small amounts of tri- or tetrafunctional phenols or carboxylic acids. The rheological properties of the branched resin are different from those of the linear resins. The branched resins demonstrate non-Newtonian behavior, and viscosity depends on shear rate. The melt viscosity of branched resins decreases with increasing shear, allowing extrusion at lower temperatures of materials with exceptional melt strength for blow-molding applications (Fig. 1). Polycarbonate melt rheology has recently been summarized in a review (55).

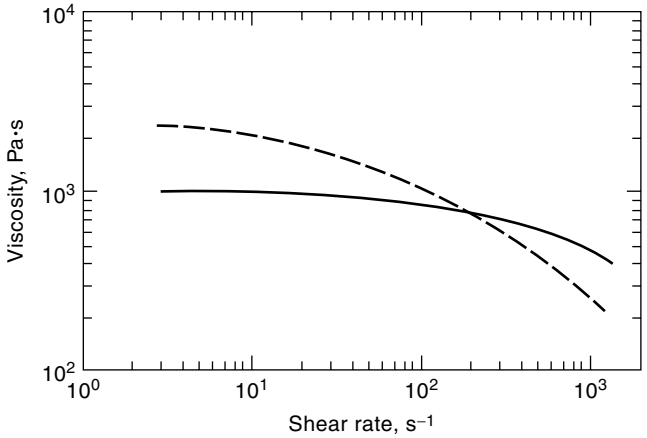

Fig. 1. Melt viscosity as a function of shear rate for (—) linear BPA polycarbonate and (- - -) branched polycarbonate. To convert Pa·s to Poise, multiply by 10.

Thermal, Flame-Retardant, and Hydrolytic Behavior. BPA polycarbonate exhibits excellent thermal stability, especially in the absence of oxygen and water. The dry polymer may be heated to 320°C for several hours, or for short times to as high as 330–350°C with only minimal degradation. At these high temperatures, thermal-oxidative degradation leads to slight yellowing, requiring color stabilization. Low levels (usually <5000 ppm) of stabilizers (phosphites, phosphonites, phosphines, epoxide compounds, and organosilicon compounds) are usually added during processing. At temperatures above 400°C, rapid decomposition and cracking occur. BPA polycarbonate has an oxygen index of 26 according to ASTM D2863-70, indicating that under test conditions, an atmosphere of 26% oxygen is required to sustain combustion. Owing to thermal-oxidative stability, polycarbonate has some inherent flame-resistant properties and can be classified as V-2 according to UL94 of the Underwriters Laboratory. Several polycarbonate grades include additives to increase the flame-retardant properties, and to decrease smoke. Flame-retardant agents include brominated oligomers or polymer from tetrabromo-BPA, alkali metal salts, usually alkali sulfonates, and polytetrafluoroethylene (PTFE). The flame-retardant grades are classed as V-0 according to UL94 testing procedures, using a wall thickness of 3.2 mm. Recently, several so-called Eco-FR grades have appeared, which contain no halogenated or phosphorus additives, yet which still retain the V-0 rating.

Because of the low solubility of water in the resin, BPA polycarbonates are inherently resistant to aqueous acid and base, although strong nucleophilic bases can catalyze hydrolysis. Prolonged contact with water at 100°C can lead to reduced impact strength as a result of microcrack formation. In autoclave testing under steam pressure, water can be forced into the resin, forming pockets that eventually lead to haze, microcracks, and loss of properties. The formation of water-filled pockets has been confirmed experimentally (56). Although many additives have a deleterious effect on hydrolytic stability by acting as hydrolysis catalysts, some stabilizers, especially epoxides, can increase the hydrolytic stability. Polycarbonates should always be dried prior to melt processing because even the low levels of water present in the resin at equilibrium can lead to partial hydrolysis and lowering of the molecular weight of the molded parts. The equilibrium water content at 60% relative humidity is 0.26 wt% at ambient temperature, and 0.9 wt% at 100°C in water.

Optical Properties. Polycarbonate is a transparent, nearly colorless polymer, making it attractive as a glass replacement. Visible light transmission is about 90%, and haze is only 1–2% in typical commercial products. Absorption in the uv regions accounted for by the aromatic structure reaches a maximum at around 255 nm. Polycarbonate has a high refractive index (1.588) and a lower density than glass (1.52 g/mL), making it an attractive material for eyewear. Exposure of non-uv stabilized polycarbonate to strong uv or outdoor sunlight conditions can lead to photoyellowing of the survace. uv screens can be combined with hard coats to protect the surface of polycarbonate and also to provide resistance to chemical attack in sheet products used for glazing applications. Polycarbonate eyewear is usually available with a scratch-resistant coating.

Special polycarbonate grades have been developed for the rapidly growing optical information storage markets. Compact discs (CDs) utilize the transparency, low birefringence, mechanical and dynamic stability, and good heat-distortion

properties of polycarbonate. Polycarbonate prepared by the melt technique can be made especially free of contamination and with a controlled low molecular weight, and is the preferred substrate. The use of *p*-alkyl phenols with branched alkyl groups containing eight or nine carbon atoms result in extremely high melt flow polycarbonates having sustained impact strength. A number of other agents for increasing melt flow have also been patented. Typically, polycarbonate as molded is highly anisotropic and exhibits birefringence. Although the birefringence can be minimized using the appropriate processing conditions, only modification of the backbone can be used to reduce birefringence to zero. Use of the high flow resins leads to lower birefringence in the molded parts and also decreases the molding cycle times to only a few seconds. New polycarbonates with inherently lower birefringence have also been studied recently. A number of polymers with the phenyl rings out of the plane of the polycarbonate backbone are effective at reducing birefringence; the spirobiindane bisphenol (SBI) is a notable example. A copolymer of BPA with SBI can lead to zero orientational birefringence. This work has been reviewed (57,58).

Mechanical Properties. Mechanical and other properties of BPA polycarbonate are listed in Table 2. The room temperature modulus and tensile strength are similar to those of other amorphous thermoplastics, but the impact strength and ductility are unusually high. While most amorphous polymers are glass-like and brittle below their T_gs, polycarbonate remains ductile to about -10°C. The stress–strain curve in uniaxial tension (Fig. 2) is typical of ductile materials, having an initial Hookean region, followed by shear-induced yielding and plastic deformation. Breakage occurs at about 120% elongation. The area under the stress-strain curve is a measure of energy absorption per unit volume, and is about 65 J/m^3 (15.5 cal/m^3). That value is about 8.5 times higher than the energy

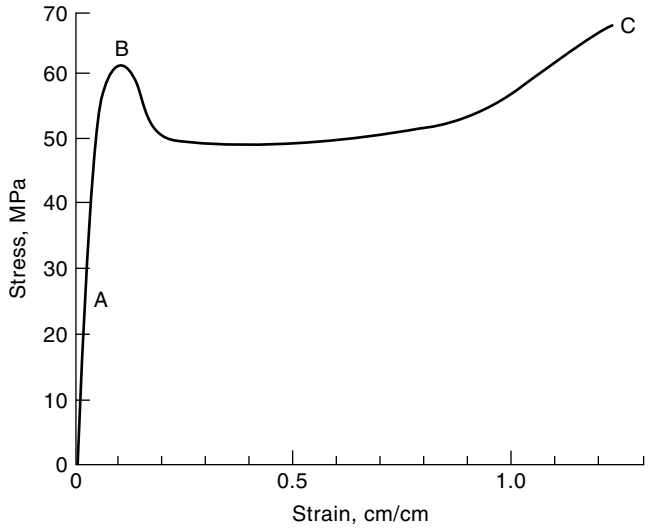

Fig. 2. Stress–strain curve for standard polycarbonate resin at 23°C where the points A, B, and C correspond to the proportional limit (27.6 MPa), the yield point (62 MPa), and the ultimate strength (65.5 MPa), respectively. To convert MPa to psi, multiply by 145.

absorption of cast aluminum, and 60% that of carbon steel, placing polycarbonate in an ideal position for use as a metal replacement. Weight savings as a metal replacement are substantial because polycarbonate is only 44% as dense as aluminum and one-sixth as dense as steel.

Impact strength can be measured by a variety of methods including notched Izod, tensile impact, and falling dart impact. The notched Izod test is most widely used to measure the toughness of a resin. This test involves measuring the energy absorption under impact conditions on a sample in which a notch has been cut to serve as a stress concentrator. Polycarbonates are among the highest rated engineering polymers for impact resistance and are the toughest transparent materials known. Under high strain rate conditions (impact), polycarbonates are sensitive to the nature of the stress concentrator, and different results can be obtained depending on how the notch is cut and on the thickness of the sample. At room temperature, decreasing the radius of the notch tip from 0.038 to 0.020 mm reduces the notched impact strength from 960 to 130 J/m (230–31 cal/m). A similar transition is noted when samples are tested over a range of temperatures, showing a transition from ductile to brittle behavior at temperatures around -20°C. As the thickness of the specimen is increased from 3.18 to 6.35 mm, a similar transition occurs, with brittle failure of thicker samples. The critical thickness phenomenon as well as the low temperature embrittlement can be alleviated by use of copolymers or blends.

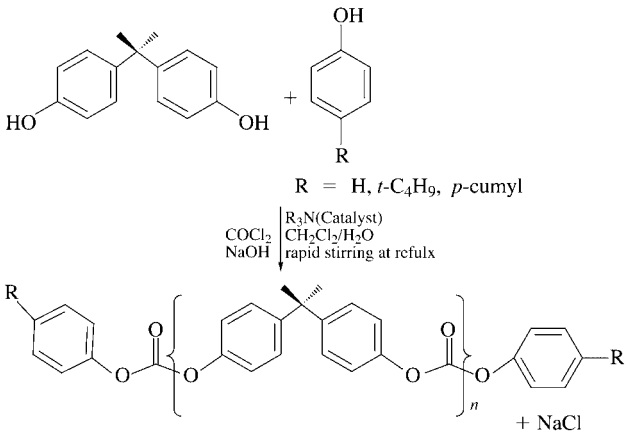
Glass-reinforced polycarbonates are sold as high modulus materials having properties approaching those of metals while retaining the basic plastic attributes of low cost processing, dielectric character, resistance to corrosion, light weight, and inherent color. As the level of glass is increased, tensile and flexural strength and modulus increase to almost double their original values. Compressive strength increases by about 65%. Fatigue endurance increases dramatically to 7 times the value of the neat resin; deformation under load drops to 0.1% under 27 MPa (6800 psi) at 23°C. Both the coefficient of thermal expansion and mold shrinkage drop in glass-reinforced resins. As expected for a stiffer resin, the impact properties drop as well, to a notched Izod impact value of 133 J/m (32 cal/m). Properties of a 40% glass-reinforced resin are compared to a standard injection-molding resin in Table 2.

Preparation

The historical direct reaction route, which utilized phosgenation of a solution of BPA in pyridine proved inefficient commercially because of the need for massive pyridine recycle. Calcium hydroxide was used as an HCl scavenger for a brief period of time, but again, recycle was an issue. Although both solution and melt processes were piloted through the early and mid 1960s, the industry settled on an amine-catalyzed interfacial phosgenation process. In this process, the BPA is phosgenated in a solvent such as CH_2Cl_2 using a tertiary amine catalyst, while maintaining pH via the addition of NaOH. The by-product NaCl is then recycled back to chlorine (used to make phosgene in combination with carbon monoxide) and NaOH. The melt transesterification process simply involves base-catalyzed reaction of BPA with diphenyl carbonate. After sporadic work on the melt process

over many years, GE Plastics first commercialized this technology in a joint venture with Mitsui Petrochemical Industries, now called GE Plastics Japan. The small plant (35,000 ton/year) validated the technology and led to large-scale commercialization of the melt process in a full-scale plant (150,000 ton/year) in Cartagena, Spain.

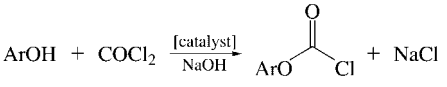
Interfacial Polymerization. Most BPA polycarbonates are produced by an interfacial polymerization process utilizing phosgene. The interfacial process for polycarbonate preparation involves stirring a slurry or solution of BPA and 1–5% of a chain stopper such as phenol, *p*-*t*-butylphenol, or *p*-cumylphenol in a mixture of methylene chloride and water, while adding phosgene in the presence of a small amount (0.1–3%) of a tertiary amine catalyst (eq. (4)). Sodium hydroxide solution is added concurrently to maintain the appropriate reaction pH (typically 10–12). Efficient mixing is important to ensure contact between the four phases present [solid BPA, gaseous phosgene, methylene chloride (into which the polymer dissolves), and the aqueous phase (in which the by-product sodium chloride becomes concentrated)]. Phosgene addition is continued until the presence of free phenolic groups can no longer be detected. Interfacial reactions are often overphosgenated to ensure complete reaction, and the excess phosgene becomes hydrolyzed, forming sometimes significant amounts of sodium carbonate. When the reaction is complete, and after the brine phase has been separated, the methylene chloride solution of polymer is washed first with acid to remove residual base and amine and then with water. Many variations of this basic interfacial process have been patented including continuous or semicontinuous processes, various workup procedures, many types of catalysts (including phase transfer catalysts and bifunctional catalysts), methods which rely on the intermediacy of bischloroformate oligomers, and various schemes to control the formation of low molecular weight oligomeric species or cyclics.



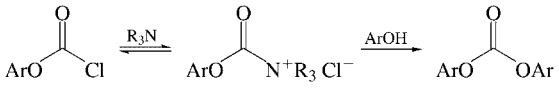
(4)

Studies on the mechanism of interfacial polycarbonate formation are complicated by its interfacial nature, involving four phases. In addition, effects such

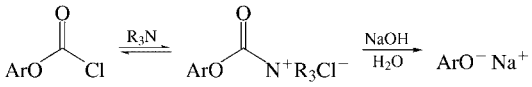
as stirring rate, interfacial volume, and acid–base equilibria of BPA with NaOH are involved. Although some authors still believe that the tertiary amine acts solely as a base (59) (and hence as a phase-transfer agent, with $R_3N\text{-}H^+$ as the cationic species), other experimental kinetic evidence supports the importance of formation and reaction of acyl ammonium salts as intermediates (60). Assuming that acyl ammonium salts are formed, the sequence of reactions shown in equations 567 would occur. In the first step, the bisphenol reacts with phosgene to form a chloroformate (eq. (5), Ar = aryl group). Although this reaction can proceed in the absence of a catalyst, it is accelerated both by phase transfer and by nucleophilic catalysts. The reaction occurs quickly enough to compete effectively with phosgene hydrolysis, even at the reaction pH of 10–12. Reaction of a chloroformate functionality with a phenol to form a carbonate functionality requires a catalyst to proceed effectively (eq. (6)). In the absence of a catalyst, the reaction takes several hours, even at high pH (60). Tertiary amines provide a substantial rate acceleration, but phase-transfer catalysts [such as $(C_4H_9)_4NOH$ or $(C_4H_9)_3NCH_3OH$] are also very effective (61). The amines function by nucleophilic catalysis, forming an acyl ammonium salt in an equilibrium reaction with chloroformate, which is more susceptible toward attack by a phenol. The effects of tertiary amines on the formation and reactions of aryl chloroformates using model compounds have been studied (60). These studies, which used stop flow ftir techniques to measure kinetics, clearly showed that very slight changes in the nature of the tertiary amine structure can lead to dramatic changes in both the rate at which equilibrium is achieved and the position of equilibrium; both the rate and position of equilibrium can be affected by a factor of 4000–5000, simply by changing the amine from triethylamine to diethylmethylamine. Other investigators have shown that those changes effectively account for dramatic changes in product formation (62). Less hindered amines such as methyldiethylamine afford very fast reactions but significant hydrolysis of chloroformate, while more hindered amines, such as tributyl amine afford less hydrolysis, but also slower rates. Phase-transfer catalysts cannot involve intermediacy of an acyl ammonium salt, yet also provide fast rates. These catalysts function by solubilizing the phenoxide anion, making reaction in the organic phase more facile. Phase-transfer catalysts also provide the advantage that hydrolysis of both phosgene and chloroformates is greatly reduced. In highly phosgene-efficient cases, however, a small amount of tertiary amine is required to catalyze chloroformate hydrolysis (63). It is believed that the main route to hydrolysis, a largely undesired reaction, is via the acyl ammonium salt which, as it becomes less lipophilic, enters the water-rich interfacial region. Normally, polycarbonate reactions are overphosgenated to ensure complete conversion of bisphenol to product, forming slight stoichiometric excesses of chloroformate. Some hydrolysis of the chloroformate so formed is then necessary to complete the reaction, by converting the chloroformate to a phenoxide so that condensation to a carbonate can occur (eq. (7)). The use of bifunctional catalysts containing both a tertiary amine and a quaternary ammonium salt on the same molecule for polycarbonate synthesis has recently been patented (64). A side reaction that can also occur during interfacial phosgenation is the formation of urethanes. Under conditions of long reaction time or high amine level, acyl ammonium salts undergo a first-order reaction to form dialkyl urethanes (eq. (8)) (65).



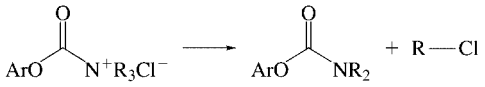
(5)



(6)



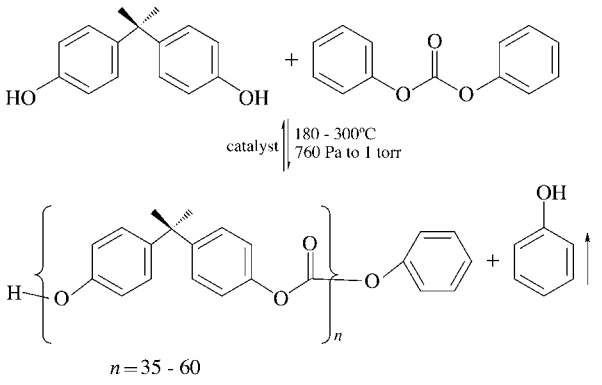
(7)



(8)

Methods for isolation of the product polycarbonate remain trade secrets. Feasible methods for polymer isolation include antisolvent precipitation, removal of solvent in boiling water, spray drying, and melt devolatilization using a wiped film evaporator or similar equipment. Regardless of the technique, the polymer must be dried, to avoid hydrolysis, and essentially be devoid of methylene chloride. Most polycarbonate, whether isolated as pellets or powder, is extruded at which point stabilizers, additives, and colors may be formulated.

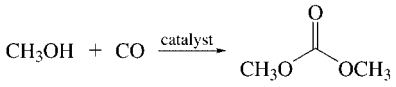
Transesterification or Melt Process. There has recently been much renewed interest in the transesterification process for the preparation of polycarbonate because of the desire to transition technology to environmentally friendly processes. Three hundred and fifty patents on the melt process have appeared since 1995. The transesterification or melt process utilizes no solvent during polymerization, producing neat polymer directly, and so chlorinated solvents may be entirely eliminated. GE Plastics operates two melt polycarbonate plants, one in Chiba, Japan, and the other in Cartagena, Spain. The melt polymerization process involves the base-catalyzed transesterification reaction of a bisphenol with a source of carbonate functionality, such as diphenyl carbonate. During the reaction, the by-product phenol is removed, and polycarbonate forms directly. In the first stage of the reaction, diphenyl carbonate and BPA are combined with small amounts (usually <0.01 mol%) of basic catalysts (Na, Li, K, tetraalkylammonium, or tatraalkylphosphonium hydroxides or carbonates) in a melt reactor. Phenol is liberated in an equilibrium reaction, as shown in equation (9). As the raw materials pass through the stages of reaction, the reaction temperature is increased and higher vacuum is provided to facilitate removal of the phenol, driving the equilibrium toward polycarbonate. In the later stages of reaction, the polymer melt becomes very viscous and specialized equipment such as wiped film evaporators, helicone reactors, or multiple vacuum-vented extruders are necessary to expedite mass transfer of by-product phenol via good surface renewal of the melt.



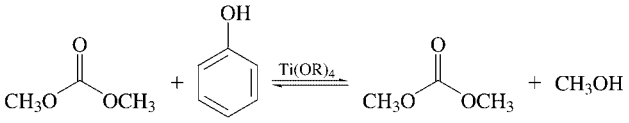
(9)

The polymer is exposed to an extensive heat history in the melt process. Early work on transesterification technology was troubled by thermal-oxidative reactions of the polymer, especially in the presence of basic catalysts (8–11). Early polycarbonates prepared by Fox and others via the melt process had noticeable brown colors. More recent work on catalyst systems, more reactive carbonates, and modified processes have improved the process to the point where formation of color and product decomposition can be effectively suppressed. Polymers with color at least as good as interfacially prepared materials can now be prepared commercially. One of the key requirements for the transesterification process is the use of clean starting materials. Methods for the purification of both BPA and diphenyl carbonate have been developed and patented. Activated carbonates that form high molecular weight polycarbonate at equilibrium in solution at or below room temperature have also been reported, although they are chiefly only of academic interest (66,67).

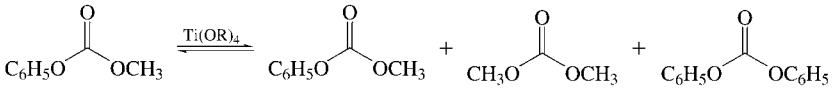
Initially, diphenyl carbonate to be used for the transesterification process was prepared by reaction with phosgene. The phosgenation can be carried out in CH_2Cl_2, or in water, which avoids the use of organic solvents in the polycarbonate process altogether (68). More recently, other methods for the preparation of diphenyl carbonate have been developed, which avoid the use of phosgene. GE Plastics uses a process commercialized by Enichem for the preparation of diphenyl carbonate, utilizing a two-step process. In the first step (eq. (10)), methanol is carbonylated using carbon monoxide in the presence of a catalyst to produce dimethyl carbonate. Reaction of dimethyl carbonate and phenol under specific transesterification conditions produces diphenyl carbonate. The by-product is methanol, which can be recycled. Because the transesterification reaction from dimethyl to diphenyl carbonate is a thermodynamically unfavorable equilibrium process, the reaction is normally carried out in two stages: first, formation of a mixed carbonate (eq. (11)), then disproportionation to dimethyl carbonate and diphenyl carbonate (eq. (12)). An alternative method for formation of diphenyl carbonate is the direct carbonylation of phenol, using palladium catalysts (69). Although this latter chemistry works well for formation of diphenyl carbonate, it has not proved efficient enough for the formation of high molecular weight polycarbonate directly from BPA.



(10)



(11)



(12)

Preparation of polycarbonate via the melt process offers several processing advantages, including elimination of solvents and phosgene. The principal *product* advantage of melt-prepared polycarbonate is the fact that as an equilibrium product, the resin is stable. No changes in polydispersivity, oligomers, etc will be seen upon further processing (unless monomers are introduced). Additionally, the equilibrium levels of low molecular weight species (cyclic and linear oligomers, diaryl carbonates formed from chain stopper) are much lower than typically found in interfacially prepared polymer, and hence the polydispersivity (M_w/M_n) is narrower. Other impurities are also minimized, since there are no sources for contaminants such as solvent, amine, or NaCl to enter the process. One other major difference from interfacially prepared polycarbonate is the fact that the polymer is typically *not* completely end-capped; some level of phenol-terminated polymer will usually be present, which should be recognized in subsequent formulations.

Recent patent literature from Asahi describes novel polymerization processes that involve equipment with no moving parts, where the molten prepolymer is allowed to fall through holes and descend either freely or along a wire as a molten strand (70). The molten polymer from the bottom of the reactor is recycled to the top to reach the desired molecular weights. The setup provides a method to overcome mass transfer resistances and allows for removal of phenol from the system. Another process which has been an area of patent activity from GE and Asahi is in the area of solid-state polymerization of polycarbonate, wherein the prepolymer is converted to flakes/powder/particles and crystallized. The solids are then polymerized at a lower temperature than in conventional melt polymerization. Both methods seem to be in the development stage.

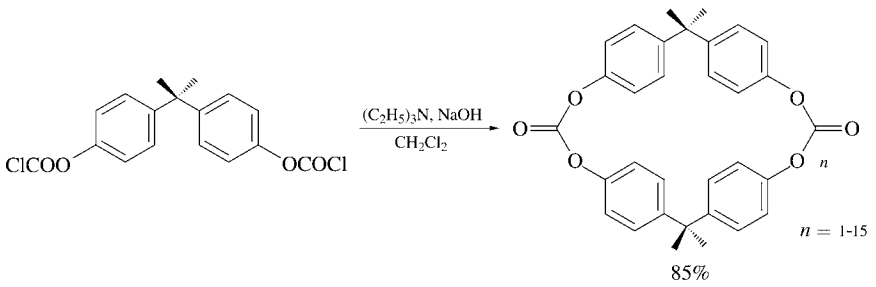
A spinoff of the melt process is "redistribution" technology, patented by GE (71). In the redistribution process, high molecular weight polycarbonate is extruded in the presence of a transesterification catalyst and, optionally, other monomeric or oligomeric materials. At the extrusion temperature, equilibrium transesterification occurs, leading to products similar to melt-prepared polycarbonate, even though the polymer may have originally been prepared by interfacial phosgenation. This technique is very useful for lowering the amounts of oligomers

in interfacial resin, and for forming very low M_w polycarbonate or branched polycarbonates.

Other polymerization techniques. An analogue of the transesterification process has also been demonstrated, using the diacetate of BPA (72). Transesterification of the diacetate with dimethyl carbonate using a titanate catalyst produces polycarbonate with methyl acetate as the by-product. Removal of the methyl acetate from the equilibrium drives the reaction to completion. Because of the problem of recycling methyl acetate back to BPA-diacetate, the process has not been commercialized.

Another technique for the preparation of polycarbonates which can lead to many novel applications is the ring-opening polymerization of cyclic oligomers. Although discrete cyclic oligomers of BPA and other bisphenols were isolated in the early 1960s, exploitation of this chemistry was not possible, owing to the difficulty of their preparation and purification (73). Furthermore, the cyclic tetramer of BPA, the most easily isolated, in about 25% yield, was a high melting, crystalline solid with a melting point of about 375°C, making melt polymerization difficult.

A newer process for the preparation of mixtures of cyclic oligomers has recently been discovered (18,62). This process utilizes a triethylamine-catalyzed hydrolysis and condensation of BPA bischloroformate in a pseudo-dilution reaction. This reaction efficiently provides 85–95% of a mixture of cyclic oligomers having a degree of polymerization of 2 to about 12, with good productivity [10–20% solids reactions (eq. (13))]. Three important features distinguish this work from the previous preparation of cyclic tetramer. First, the reaction is extremely selective toward formation of cyclic oligomers: less than 0.01% linear oligomers are formed. Because any linear oligomers which might be present would reincorporate into the polymer via chain-transfer reactions during ring-opening polymerization, their presence would limit ultimate molecular weight and so it is important to limit their level. Second, a *mixture* of cyclics is formed. The fact that a broad mixture of cyclics is formed results in depression of the melting point of the cyclics, allowing a clear melt to form at 200–210°C from BPA carbonate cyclic oligomers. The melting point can be depressed further by the incorporation of long-chain bisphenols (74). Lastly, the reaction can be carried out at concentrations similar to conventional polycarbonate processes, rather than under very high dilution (eg, $<0.01\,M$) conditions, allowing good productivity in large-scale equipment.



(13)

Melt polymerization of the cyclic oligomers can be achieved at 200–300°C, and solution polymerization is possible at ambient temperature (75). The ring-opening polymerization is driven almost entirely by entropy, in a reaction with

almost no exotherm, leading to the highest molecuar weight polycarbonates achievable by any process. Because the viscosity of the cyclic oligomers is about 10^5 times lower than the ultimate polymer, a variety of processing techniques become possible, including pultrusion, resin-transfer molding, and other techniques for the fabrication of fiber-reinforced composites. The use of cyclic oligomer technology also makes it possible to prepare polycarbonates that had been unattainable by other means, eg, hydroquinone–BPA copolymers. Although scaling to hundreds of kilograms has been carried out, this technology has not yet been commercialized.

Solid-state polymerization of BPA-polycarbonate oligomers has received much recent attention, with over 160 patents since 1995 (76,77). Typically, one prepares oligomeric or low molecuar weight polycarbonate (η_{inh} = 0.2–0.3 dL/g, $T_g \sim$ 120–135°C) via a melt process. After isolation of the oligomer, and enhancing crystallization by various techniques, additional basic catalyst is blended. Using solid-state polymerization techniques, the solid is then heated above its T_g, but below the melting point of crystalline polycarbonate, using a variety of techniques to remove by-product phenol. Vacuum and nitrogen purge conditions have been demonstrated, as well as methods involving supercritical or liquid carbon dioxide (78). After prolonged heating, the molecular weight increases to a useful range (η_{inh} = 0.44–0.8 dL/g). The polycarbonate is then processed as usual, losing the crystallinity and leading to an amorphous product, as in conventional melt processes. Despite many patents, the process has not yet been commercialized.

Processing. Polycarbonates may be fabricated by all conventional thermoplastic processing operations, of which injection molding is the most common. Recommended operating conditions are stock temperatures of 275–325°C and molding pressures of 69–138 MPa (10,000–20,000 psi). Thorough predrying is necessary to prevent hydrolysis of the polymer by dissolved water at the high processing temperatures. Inadequate drying may lead to surface-streaked parts and loss of molecular weight. Extrusion produced film, sheet and stock shapes, and higher molecular weights than those used for injection molding are preferred. Temperatures for extrusion vary between 285 and 315°C.

Structural foam molding is also a valuable commercial technique. The molding compound is charged with an inert gas under pressure and at the same time thermally plasticized in an extruder. Nitrogen gas may be pumped into the melt, or the molding compound may contain a chemical blowing agent that decomposes with gas generation at the plasticizing temperature. The pressurized plasticized melt is injected into a low pressure mold with a volume change taking place, causing the polymer to expand and fill the mold cavity. Very large parts having relatively low clamping pressures can be produced with this process.

Injection blow molding of polycarbonates produces an assortment of containers, from 20-L water bottles and 0.25-L milk bottles to outdoor lighting protective globes. The polymer normally contains a small amount of polyfunctional monomer that serves as a branching agent. Low level branching enhances the melt strength, as well as inducing non-Newtonian flow behavior (sensitivity of melt viscosity to shear).

Conventional thermoforming of sheet and film is applicable to the production of skylights, radomes, signs, curved windshields, body parts for automobiles,

skimobiles, boats, etc. Because BPA-polycarbonate is malleable, it can be cold-formed like metal, and may be cold-rolled, stamped, or forged.

Production. Production of polycarbonate has steadily increased since the first commercial scale plants were built in the early 1960s. Current annual capacities are edging close to the 4.5 billion pound mark. Demand forecasts continue to be in the 8–12% range, with the Far East showing the greatest growth potential. A number of joint ventures have been announced over the last few years, namely Dow/Sumitomo, Asahi/Chi Mei, Idemitsu/Formosa, to name a few. Plants have also opened in several countries and several more have been announced. Production of polycarbonate is approaching a fairly even split between the Americas, Europe, and Asia. Polycarbonate enjoys a comfortable niche between high priced specialty polymers and lower priced commodity resins.

GE Plastics is the largest polycarbonate producer, accounting for approximately 44% of the worldwide capacity (2 billion pounds). Bayer AG has a worldwide capacity of about 900 million pounds. Dow and the Dow/Sumitomo joint venture account for about 500 million pounds of annual capacity. Other producers include Mitsubishi and associated joint ventures (475 million pounds), Teijin (200 million pounds), and Idemitsu (100 million pounds). Capacity announcements have been made for the near future by Teijin (in Singapore; about 150 million pounds), Asahi/Chi Mei (in Taiwan; about 100 million pounds), Idemitsu/Formosa (100 million pounds), and General Electric (in Spain and in the United States). Normal grades of polycarbonate sold in 2000 for $1.40–$1.50/lb ($3–$3.30/kg). Many specialty grades demanded significantly higher prices. Over the last few years, growth of optical quality polycarbonate has been extremely strong.

Health and Safety Factors

BPA polycarbonate is an amorphous solid, supplied as extruded pellets averaging 2.5 mm in diameter and 3.2 mm long, or as a powder. Polycarbonate is considered a slight or nonexistent fire hazard. The ignition temperatures are quite high; flash ignition is at 449°C and autoignition is at 632°C, according to ASTM D1929. Odor and volatiles are negligible. Processing fumes, which include water, carbon dioxide, diphenyl carbonate, methylene chloride, and phenol are not formed in levels considered to be hazardous. Nonetheless, good housekeeping and industrial hygiene techniques should be followed. Polycarbonate has very low acute oral and dermal toxicity, is not a primary skin irritant, and does not cause systemic or local sensitization. In a finely divided form, polycarbonate is a mile eye irritant, consistent with the abrasive nature of the ground resin particle. Polycarbonate does not degrade during storage, and no heating or cooling requirements are necessary. For transportation purposes, polycarbonate is not classified as a hazardous material by U.S. Department of Transportation code, Title 49.

Uses

Extreme toughness, transparency, low color, resistance to burning, and maintenance of engineering properties over a wide thermal range are the outstanding properties of polycarbonate that make it useful for a variety of aplications. Glazing

and sheet are the largest markets for polycarbonate resins. About 80,000 t are used in these markets annually in the United States, nd 150,000 t worldwide. Clarity and an impact resistance 250 times greater than glass and 30 times greater than acrylic sheet makes polycarbonate the natural choice for window replacement in areas where breakage is common. Windows in airplanes, trains, and schools commonly use polycarbonate. Exotic applications include military use, for example in high speed aircraft canopies, where tests have shown polycarbonate to withstand impact with fowl at Mach 2. Polycarbonate is also used for security applications as laminates with glass or other materials. Polycarbonate offers unsurpassed projectile-stopping capability, as the material softens upon impact with a bullet, absorbing the projectile's energy. A large volume in laminated products also exists. The soft inner layer may be a urethane, acrylic, or siloxane–polycarbonate copolymer.

Automotive applications account for about 150,000 t of worldwide consumption annually, with applications for various components including headlamp assemblies, interior instrument panels, bumpers, etc. Many automotive applications use blends of polycarbonate with acrylonitrile–butadiene–styrene (ABS) or with poly(butylene terephthalate) (PBT). A large effort is currently under way to commercialize automotive window glazing from coated polycarbonate. Both large and small appliances also account for large markets for polycarbonate. Consumption is about 75,000 t annually. Polycarbonate is attractive to use in light appliances, including houseware items and power tools, because of its heat resistance and good electrical properties, combined with superior impact resistance and the ability to produce a wide variety of colors.

Packaging is a growing segment of the polycarbonate market, accounting for about 30,000 t of consumption annually. Polycarbonate has been the preferred choice for large returnable, refillable 20-L water bottles because of its light weight and impact resistance. GE Plastics has also introduced returnable, refillable 0.25-L milk bottles for use in schools. These bottles, which can be refilled 50–100 times, are attractive alternatives to nonreusable paper milk cartons in communities that are concerned about waste.

Electrical, electronic, and technical applications use polycarbonates for a variety of purposes. The worldwide market is about 160,000 t annually. Because of excellent electrical properties (dielectric strength, volume resistivity) and resistance to heat and humidity, polycarbonate is used for electrical connectors, telephone network devices, outlet boxes, etc. Polycarbonate had been popular for use in computer and business machine housings, but the use of neat resin was largely supplanted by blends of polycarbonate with ABS. However, new, highly colored and special effect resins (translucents, flip-flop colors, speckles, etc) have recaptured a significant portion of that market. A total of 25,000–30,000 t of resin is used annually. Polycarbonate also has many technical uses in instrument panels and devices, especially for membrane switches and insulators. Optical quality polycarbonate is the only suitable material for the compact disc market. Since their introduction in 1983, compact discs have shown explosive growth in the consumption of polycarbonate, with utility for audio, video, and computer applications, reaching about 25,000 t of annual production.

Medical and health-care related applications consume about 30,000 t of polycarbonate annually. Polycarbonate is popular because of its clarity, impact

strength, and low level of extractable impurities. Special grades have been developed to maintain clarity and resistance to yellowing upon gamma radiation sterilization processes. Leisure and safety applications are many and varied, accounting for about 30,000 t of consumption annually. The largest markets are for protective headgear such as football and motorcycle helmets, and safety helmets for firefighters and construction workers. Protective eyewear also uses polycarbonate because of its clarity and impact resistance.

Other Polycarbonates, Blends, and Copolymers

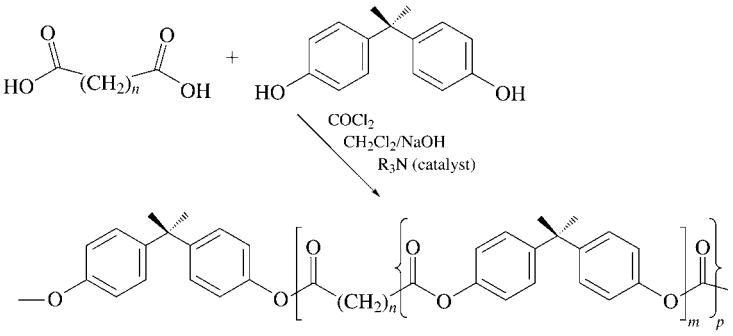
During the early development of polycarbonates, many bisphenols were investigated for potentially useful products. Some of these monomers and polymers are listed in Table 3. Despite this intensive research, however, no homopolycarbonates other than that of BPA have been produced commercially in any significant volume. Copolymers and blends, on the other hand, have been quite successful. Copolymer research constitutes a large portion of polycarbonate patents, with nearly 6000 patents since 1995. An excellent review of many types of polycarbonate homo- and copolymers arranged according to utility has recently appeared (79). Blends of polycarbonate with ABS and with PBT, in particular, have shown significant growth since the mid-1980s.

Copolymers. The copolymer of tetrabromo-BPA and BPA was one of the first commercially successful copolymers (80). Low levels of the brominated comonomer lead to increased flame resistance (V-0 rating by UL-94), while having little effect on other properties. The homopolymer of tetrabromo-BPA can also be prepared (81,82), but only the oligomeric version has been commercialized. The polycarbonate of bis-4-hydroxyphenyl-1,1-dichloroethylene, prepared from chloral and phenol, followed by dehydrohalogenation, was investigated as another inherently flame-resistant polymer that retained good impact properties (83).

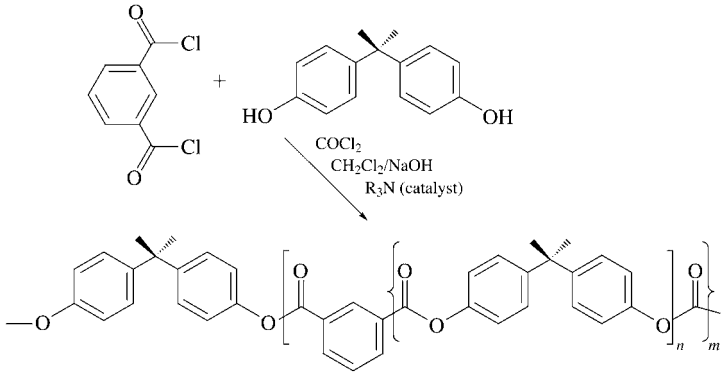
For utility in compact discs and other laser-readable and especially in read–write data storage systems, polycarbonates of low birefringence are advantageous. Birefringence can be reduced by using bulky polarizable side groups, or eliminated entirely in structures such as the spirobiindane bisphenol (84) (SBI) shown in Table 3. Efforts to reduce the birefringence of polycarbonate by modifying the bisphenol have been reviewed (57,58). Numerous alkyl-substituted bisphenols have also been used (85). Aliphatic groups do not contribute to birefringence, and also lead to less water absorption in the polymer. Birefringence can also be reduced by eliminated molded-in stresses via the use of high flow resins. Many techniques for achieving high flow polycarbonates have been reported, including incorporation of aliphatic diesters into the backbone, modification of the bisphenol with aliphatic groups, and changing the polymer end groups. Incorporation of aliphatic diacids to form aliphatic ester carbonates can provide nearly twice the melt flow with little sacrifice in ductility.

Polyester carbonates can be prepared by the copolymerization of BPA with diacyl chlorides such as iso- or terephthaloyl chloride (eq. (14)) (86). These polymers have been commercialized by Bayer AG, GE, Dow Chemical, and Mitsubishi Chemical, Ltd. Melt processes to prepare these materials have also been demonstrated. In some cases, a diacid can be used directly because reaction with phosgene

converts it into an acid chloride prior to reaction with the bisphenol. The polyester carbonates prepared using aromatic diacids are useful as high heat materials. Although the polyarylate esters are crystalline as homopolymers, copolymerization as copolyestercarbonates allows formation of amorphous resins, which have impact strength similar to BPA polycarbonate, with the glass-transition temperature elevated to about 190°C. Incorporation of aliphatic esters into polycarbonate leads to elastomeric materials or copolymers with depressed T_g, but with dramatically increased melt flow (eq. (15)) (35). Some of these block copolymers also have improved low temperature impact strength and higher stress-crack resistance than neat BPA polycarbonate.



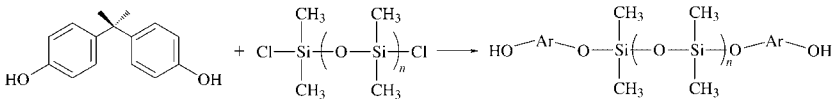
(14)



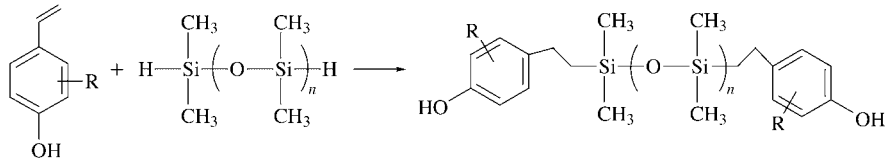
(15)

A variety of methods have been developed for the preparation of polydimethylsiloxane-*co*-BPA polycarbonates (87). These polymers differ greatly from conventional polycarbonate in that they have very low glass-transition temperatures ($T_g = -123$°C), and yet have excellent thermal stability and good weathering properties. Phosgenation of silanol-terminated siloxane oligomers in the presence of BPA, or reaction of BPA sodium salt with chlorosilane-stopped siloxane oligomers, followed by phosgenation with BPA are two of the described procedures (eqs. (16) and (17)) (88). Hydrosilation methods are also used (89). Use of cyclic oligomers for the preparation of these copolymers has also been described

(90). These materials display a wide range of properties, depending on the block length of the individual polymers and on the weight level of silicone present. Some of the block copolymers having low levels of silicone have outstanding low temperature impact strength; those having higher levels of silicone are thermoplastic elastomers. The enhanced ductility at low temperature was reported in the 1970s; incorporating 25% silicone into BPA polycarbonate lowers the ductile-brittle transition temperature from $\sim -15^{\circ}$C to -110°C (91).



(16)



(17)

In 1991, Bayer reported the preparation of a family of polycarbonates (Apec) using a monomer based on the condensation of a hydrogenated isophorone with phenol (74,92). Because the bulky structure leads to rigidity derived from hindered rotational freedom, the polycarbonate retains the low temperature loss modulus of BPA polycarbonate, which affords low temperature impact strength, yet has a high glass-transition temperature. The homopolymer has a T_g of 239°C, and copolymers with BPA provide intermediate glass-transition temperatures. A variety of other monomers also provide high heat polycarbonates, but often at the expense of limited ductility (78).

Blends. The concept of blending two or more commercially available materials to create a new material having properties different from either starting material has generated a great deal of interest over the past few decades. One of the fastest growing market segments within the polycarbonate industry is this arena of blends. Polycarbonate blends are used to tailor performance and price to specific markets. Despite its strengths, polycarbonate suffers from shortcomings with regard to flow characteristics and solvent resistance. The two principal blends are produced to improve those characteristics. Polycarbonate–ABS blends (GE, Cycoloy; Bayer, Bayblend; Dow, Pulse; and Monsanto, Triax 2000) have improved flow and lower cost, and polycarbonate-polyesters which use either PBT or PET (GE, Xenoy, Bayer, Makroblend; Dow, Śabre, and Hoechst Celanese, Vandar) utilize semicrystalline polymers to improve chemical resistance, especially for automotive applications.

Fundamental studies of blends of polycarbonate with ABS indicate that the presence of ABS greatly decreases the melt viscosity in the blend, enhancing processibility. Even as little as 20% ABS provides a decrease in melt viscosity by a factor of 4–5 (93). A synergistic improvement of the notched impact strength at low temperature is also seen for polycarbonate–ABS blends (Fig. 3). About

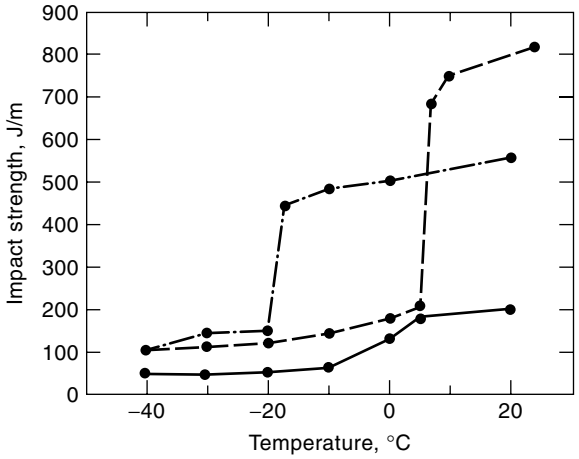


Fig. 3. Dependence of Izod impact strength on temperature for (- - -) polycarbonate, (—) ABS, and (-·-) polycarbonate–ABS blends. To convert J/m to ft·lbf/in., divide by 53.38.

35,000 t of these blends are produced annually, and significant growth in the market has been seen, with a yearly growth rate of 12–13%. More than half of the blends produced are used in the automotive market, mostly on instrument panels. The other large use for polycarbonate blends is in office and business machines, such as computer and printer housings.

Polycarbonate–polyester blends were introduced in 1980 and have steadily increased sales to a volume of about 70,000 t. This blend, which is used on exterior parts for the automotive industry, accounting for 85% of the volume, combines the toughness and impact strength of the polycarbonate with the crystallinity and inherent solvent resistance of PBT, PET, and other polyesters. Although not quite miscible, polycarbonate and PBT form a fine-grained blend, which upon analysis shows the T_g of the polycarbonate and the T_m of the polyester.

Other blends of polycarbonate have limited markets so far. The most significant blends are with polyurethane, polyetherimides, acrylate–styrene–acrylonitrile (ASA), acrylonitrile–ethylene–styrene (AES), and styrene–maleic anhydride (SMA).

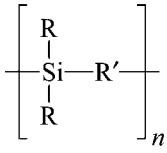
POLYCARBOSILANES

Introduction

Polycarbosilanes (**1**) have a polymeric backbone composed of silicon atoms and difunctional organic groups that connect the silicon atoms (1–4).



1

The side groups R can be alkyl, aryl, or alkoxy groups, and hydrogen or halogen atoms. The bridging group R′ can vary widely from methylene to alkenylene, alkynylene, arylene, and a combination of these groups. Because of this structural variation, polycarbosilanes can exhibit various interesting properties that neither polysiloxanes nor the usual hydrocarbon polymers can achieve. Polycarbosilanes generally have a very flexible and chemically stable backbone derived from Si—C bonds. Applications to ceramic precursors, conductive polymers, heat-resistant materials, and side-chain liquid crystalline polymers have been widely investigated. Methods commonly applied to prepare polycarbosilanes are ring-opening polymerization (ROP) of silacarbocycles, cross-condensation of dihalosilanes with difunctional organometallic compounds, and self-condensation of difunctional silicon compounds.

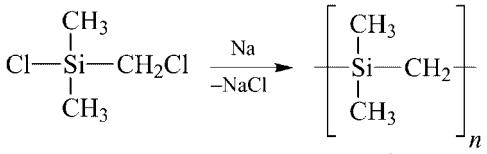
Table 1. T_g's of Poly(silylenemethylene)s and Related Hydrocarbon Polymers

Polymers	T_g, °C
$[Si(CH_3)_2CH_2]_n$	−87
$[Si(CH_3)(CH_2CH_3)CH_2]_n$	−78
$[Si(CH_3)(n\text{-}C_4H_9)CH_2]_n$	−63
$[Si(CH_3)(n\text{-}C_6H_{13})CH_2]_n$	−71
$[SiH(CH_3)CH_2]_n$	−112
$[SiH(n\text{-}C_6H_{13})CH_2]_n$	−91
$[SiH(C_6H_5)CH_2]_n$	−37
$[CH(CH_3)CH_2]_n$	−10 to −20
$[CH(n\text{-}C_6H_{13})CH_2]_n$	−65
$[CH(C_6H_5)CH_2]_n$	100

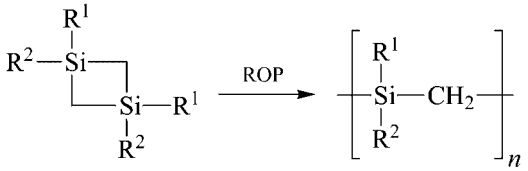
Poly(silylenemethylene)s

Poly(silylenemethylene)s, $(SiR_2(CH_2))_n$, polymers composed of alternating SiR_2 and CH_2, are the simplest and the most extensively investigated polycarbosilanes. They can be regarded as the carbon analogues of polysiloxanes. They have been known for almost half a century, but keen interest has been paid since Yajima discovered that poly(silylenemethylene)s can be SiC ceramic precursors in 1975 (5–7). Poly(silylenemethylene)s have quite low glass-transition temperatures (T_g) owing to the relatively long Si—C backbone bonds, as shown in Table 1. A direct comparison of T_g's between asymmetrically substituted poly(silylenemethylene)s and the corresponding carbon analogues revealed the high flexibility of the poly(silylenemethylene)s (8,9). Poly(1,1-dimethylsilylenemethylene) (**2**) was first synthesized by reaction of $ClCH_2Si(CH_3)_2Cl$ with sodium metal (eq. 1) (10), but the molecular weight of the polymer was relatively low ($M_w = 850$).



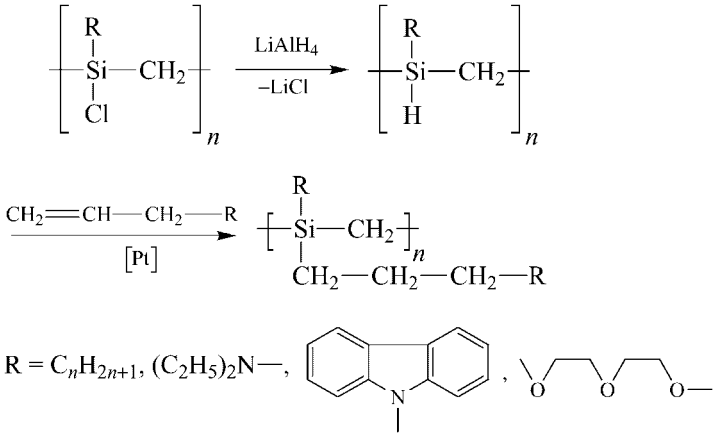
2 (1)

Higher molecular weight poly(silylenemethylene)s (**3**) can be prepared by ROP of 1,3-disilacyclobutanes (eq. 2).



$R^1, R^2 = H, CH_3, (CH_2)_nCH_3, C_6H_5, Cl, OCH_2CH_3$ **3** (2)

Heating of 1,1,3,3-tetramethyl-1,3-disilacyclobutane to 300°C gave poly(dimethylsilylenemethylene) (M_w = 15,000) (11). On the other hand, platinum-catalyzed ROP of 1,1,3,3-tetramethyl-1,3-disilacyclobutane was reported in 1965 (12). Later, several researchers investigated other transition-metal-catalyzed ROP of 1,3-disilacyclobutane derivatives (13–19). Platinum-catalyzed ROP of 1,1,3,3-tetrachloro-1,3-disilacyclobutane (20,21) and 1,1,3,3-tetraalkoxy-1,3-disilacyclobutane has been reported (22). The platinum-catalyzed ROP is thought to be the most efficient and convenient way so far to obtain high molecular weight poly(silylenemethylene)s. Successive transformations of preformed polymers containing Si–X (X = H, Cl, OR) groups have been used to prepare a wide range of functionalized poly(silylenemethylene)s (eq. 3) (23–25).

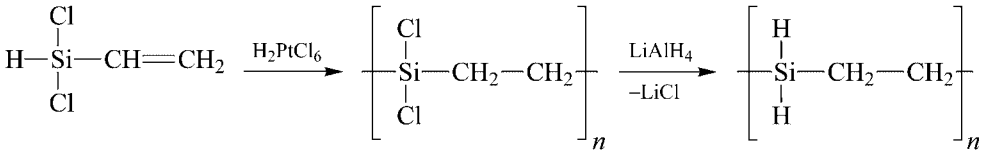


(3)

Polymers with mesogenic groups on silicon atoms have also been synthesized (26).

Poly(silyleneethylene)s

Poly(silyleneethylene)s, composed of alternating SiR_2 and $(CH_2)_2$, are synthesized by a catalytic hydrosilation of $HSi(CH_3)_2CH{=}CH_2$ (27,28). There are naturally copolymers of $-(Si(CH_3)_2{-}CH_2CH_2)-$ and $-(Si(CH_3)_2{-}CH(CH_3))-$, owing to α- and β-addition. More efficient synthesis of this series of polymers is attained by hydrosilation of $HSiCl_2CH{=}CH_2$ (29–31). In this case, the obtained poly(dichlorosilyleneethylene) (**4**) can be transformed into poly(dihydrosilyleneethylene) (**5**) by treatment with $LiAlH_4$ (eq. 4), which can be converted to SiC ceramics in high yield.

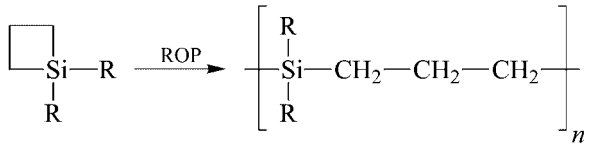


4 **5**

(4)

Poly(silylenetrimethylene)s

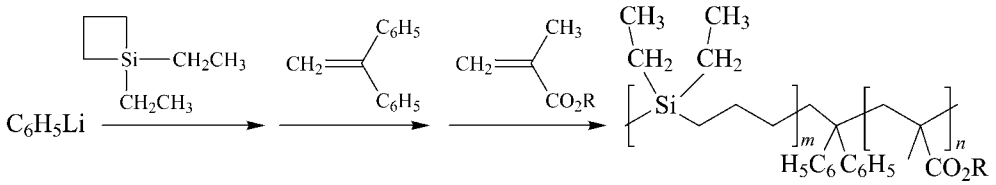
Poly(silylenetrimethylene)s (**6**), consisting of a —Si—$(CH_2)_3$— backbone, are most easily synthesized by the ROP of silacyclobutanes (eq. 5).



R = H, CH_3, CH_2CH_3, —*n*-C_3H_7, —CH═CH_2, C_6H_5, OCH_3, Cl **6**

(5)

Thermal ROP of 1-methylsilacyclobutane proceeds at 50°C (32), but those of 1,1-dimethylsilacyclobutane and 1-chloro-1-methylsilacyclobutane need high temperatures like 150–200°C (33) and 230°C (34), respectively. Platinum-catalyzed ROP of silacyclobutanes has also been reported (12,35). Other transition-metal-catalyzed ROPs have also been investigated (36). Very efficient Pt catalysts for the ROP of 1,1-dimethylsilacyclobutane has been recently reported (37). Polymers with oligooxyethylene pendant groups (38) or liquid crystalline mesogenic groups (26,39) are synthesized by utilizing the Pt-catalyzed polymerization. Anionic ROP of silacyclobutanes, which was first reported (40,41) in 1964, is also a powerful method for the preparation of poly(silylenetrimethylene)s (42,43). Recently, butyllithium-induced anionic polymerization of vinyl- (44) or hydride-substituted (45) silacyclobutanes was accomplished in THF at −78°C in the presence of hexamethylphosphoramide (HMPA). The produced poly(hydrosilylenetrimethylene) can be transformed to other poly(silylenetrimethylene)s having various pendant groups by hydrosilation with olefinic compounds such as allyl cyanide and allyl pentafluorobenzene (46). Organolithium-induced living anionic polymerization of 1,1-dialkylsilacyclobutanes was reported (47–51). This method is very attractive because it is applicable for synthesis of various block copolymers (eq. 6) (52,53).



R = CH_3, *t*-C_4H_9, $CH_2CH_2OSi(CH_3)_2$*t*-C_4H_9

(6)

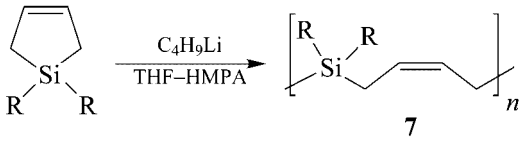
Self-assembly of amphiphilic block copolymers can be a new research area for applications of polycarbosilanes (54–56). An alternative route to prepare poly(silylenetrimethylene)s is hydrosilation of allylsilane derivatives bearing a Si—H group. $[C_6H_5SiCl(CH_2)_3]_n$ was synthesized by self-hydrosilation of allylchlorophenylsilane with Karstedt's catalyst (57). The synthesis of

poly(silylenetrimethylene) was reported, with a high degree of stereoregularity. Poly(methylphenylsilylenetrimethylene) rich in isotacticity was obtained by polyaddition of optically active allylmethylphenylsilane using platinum catalyst (58).

Other Polycarbosilanes with One Silicon and Three Carbons in the Repeating Unit. Various polymers consisting of one silicon and three carbons in the repeating backbone unit can be prepared by ROP of silacyclobutane derivatives. For instance, poly(silylenemethylene-1,2-phenylene), $(Si(CH_3)_2CH_2\text{-}o\text{-}C_6H_4)_n$, can be synthesized from 1,1-dimethyl-2,3-benzosilacyclobutene (59,60). Poly(silylene-2-propenylene), $(Si(CH_3)_2CH_2CH{=}CH)_n$ was synthesized from 1,1-dimethylsilacyclobutene (61). Poly(silylene-2-methylenetrimethylene), $(Si(CH_3)_2CH_2(C{=}CH_2)CH_2)_n$, was obtained from 1,1-dimethyl-3-methylenesilacyclobutane (62). Self-hydrosilation of propargylsilane also provides poly(silylene-2-propenylene). Optically active poly(methylphenylsilylene-2-propenylene) was synthesized by stereoselective polyaddition of (*R*)-methylphenylpropargylsilane using platinum catalyst (63).

Poly(silylene-2-butenylene)s

Poly(silylene-2-butenylene)s, $(SiR_2CH_2CH{=}CHCH_2)_n$ (**7**), can be readily prepared by butyllithium-induced anionic ROP of silacyclopent-3-ene derivatives in THF at −78°C in the presence of HMPA (eq. 7) (64).



7

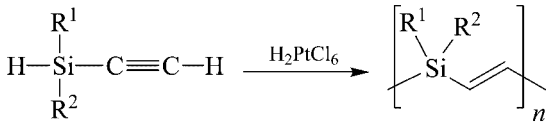
$R = CH_3, C_6H_5, H, —CH{=}CH_2$ (7)

The polymerization proceeds with high stereoselectivity to provide polymers having Z geometry around C=C double bonds with relatively narrow molecular weight distributions. Vinyl (65) groups and hydride (66) on the silicon atom are tolerant to the polymerization conditions and functional polymers bearing various pendant groups such as oligooxyethylene (67) or liquid crystalline mesogenic group (68) can be prepared. Another method to prepare poly(silylene-2-butenylene)s is acyclic diene metathesis (ADMET) polymerization of diallylsilanes, $(CH_2{=}CHCH_2)_2SiRR'$ (where R, R′ = CH_3 or Cl) catalyzed by tungsten carbene complex, $[\{(CF_3)_2CH_3CO\}_2(N\text{-}2,6\text{-}C_6H_3\text{-}(i\text{-}(C_3H_7)_2)Pr_2)W{=}CHC(CH_3)_2R]$ (where R = CH_3 or C_6H_5) (69,70).

Poly(silylenevinylene)s

In 1962, it was reported that platinum-catalyzed condensation of methylphenylsilane and diethynylmethylphenylsilane gave low molecular weight

poly(methylphenylsilylenevinylene) $(SiCH_3C_6H_5CH{=}CH_2)_n$ (71). High molecular weight poly(silylenevinylene)s, $(SiR^2CH{=}CH_2)_n$ (**8**), can be prepared by platinum-catalyzed hydrosilation of dialkyl-substituted ethynylsilane. For instance, poly(dimethylsilylenevinylene) (M_w = 30,380), poly(diethylsilylenevinylene) (M_w = 110,700), and poly(methylphenylsilylenevinylene) (M_w = 11,400) can be synthesized by hydrosilation of the corresponding dialkylethynylsilane, $HSiR^1R^2C{\equiv}CH$ (eq. 8) (72).



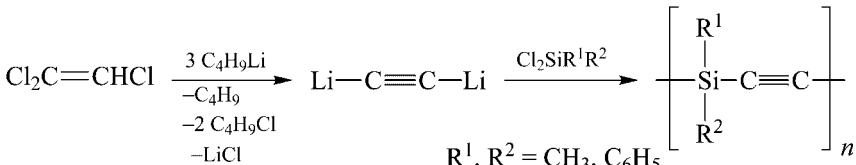
8

$R^1, R^2 = CH_3, CH_2CH_3, C_6H_5$ (8)

Melt-spun fibers from these polymers are thermally converted to SiC fibers in good ceramic yield. Another way to synthesize poly(silylenevinylene) is ruthenium- or rhodium-catalyzed polycondensation of dimethyldivinylsilane (73).

Poly(silylenealkynylene)s

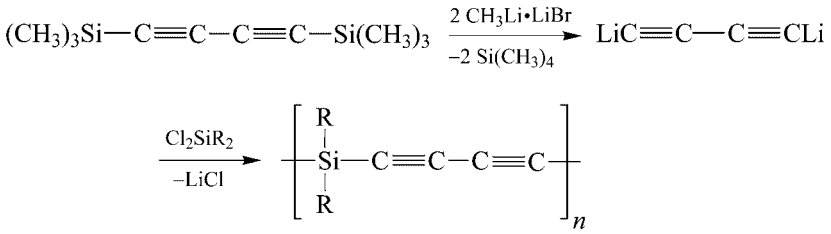
Because silicon is able to conjugate electronically with adjacent alkyne π bonds, poly(silylenealkynylene)s, $(SiR_2C{\equiv}C)_n$ (**9**), can be expected to exhibit conducting or nonlinear optical properties. A very efficient method to synthesize poly(silyleneethynylene) has been reported. Dilithium acetylide prepared from trichloroethylene and butyllithium was treated with Cl_2SiR_2 to give high molecular weight polymers (M_w = 30,000, when R = C_6H_5; M_w = 20,000, when R = C_6H_5, CH_3) (eq. 9) (74).



$R^1, R^2 = CH_3, C_6H_5$

9 (9)

However, these polymers were found to be very poor conductors, even after doping with iodine. Another type of acetylenic polymer, poly(silylenediethynylene), $(SiR_2C{\equiv}C{-}C{\equiv}C)_n$ (**10**), can be synthesized by condensation of $Cl_2SiR^1R^2$ (R^1, R^2 = CH_3, C_2H_5, or C_6H_5) and 1,4-dilithio-1,3-butadiyne prepared from 1,4-bistrimethylsilylbut-1,3-diyne and methyllithium (eq. 10) (75).

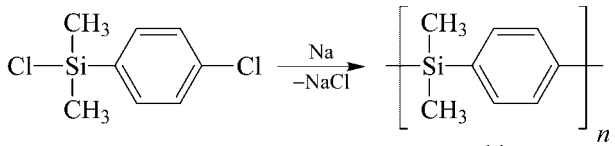


R = CH_3, CH_2CH_3, C_6H_5 **10** (10)

These polymers exhibit conductivity (10^{-5} – 10^{-3} S·cm^{-1}) after oxidation with $FeCl_3$, which is in the range of semiconductors. Application of polymer **10** as SiC ceramic precursors has also been investigated (76).

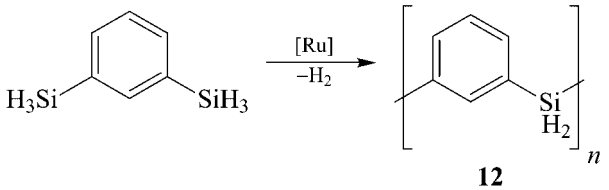
Poly(silylenearylene)s

Poly(dimethylsilylene-*p*-phenylene), $(Si(CH_3)_2\text{-}p\text{-}C_6H_4)_n$ (**11**), is successfully synthesized via condensation of *p*-chlorophenyldimethylchlorosilane and sodium (eq. 11).



11 (11)

The polymer showed significantly high thermal stability and was not decomposed even at 400°C (77). It was reported that poly(silylenephenylene)s can be synthesized from the reaction of dichloromethylsilane or dichlorophenylsilane with *p*- and *m*-dilithiobenzene (78). An efficient method to prepare poly(silylene-*m*-phenylene) (**12**)(M_w = 4000–20,000), that is, a ruthenium-catalyzed desilylative condensation of *m*-bis(trihydrosilyl)benzene (eq. 12), was reported (79).

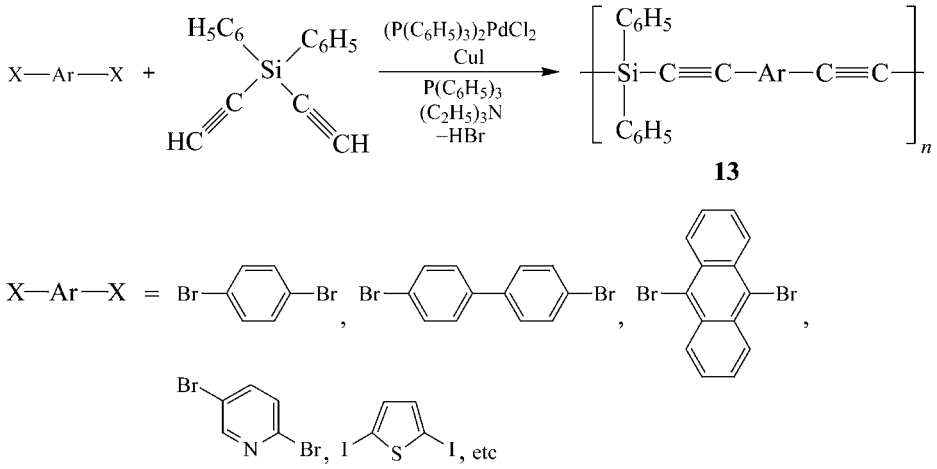


12 (12)

The synthesis and the high heat-resistant property of poly{[bis (ethynylphenyl)silylene]phenylene} have also been reported (80). Poly [(diethoxysilylene)phenylene] was first synthesized by a reaction of (3-bromophenyl)triethoxysilane with magnesium. Then the polymer was treated with (trimethylsilylethynyl)phenyllithium, followed by deprotection of the trimethylsilyl groups.

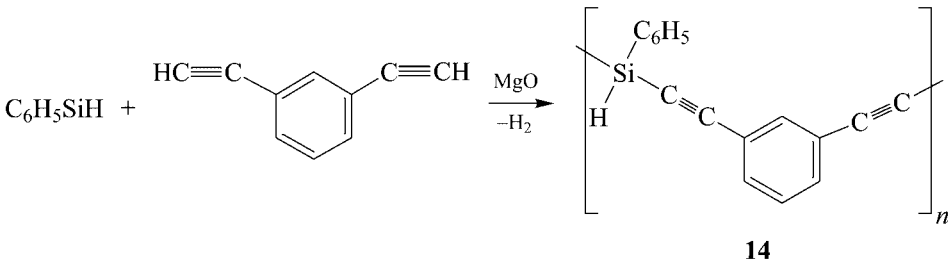
Poly(silylenealkenylenearylene)s. Poly(dimethylsilyenephenyleneviny lene)s were synthesized by chloroplatinic acid catalyzed self-hydrosilation of *o*-, *m*-, and *p*-(dimethylsilyl)phenylacetylene (81). These polymers are interesting as not only ceramic precursors but also blue-light-emitting materials. Poly(methylphenylsilyelenephenylenevinylene) and poly (diphenylsilyelenephenylenevinylene) were also prepared by chloroplatinic acid-catalyzed hydrosilation of methylphenylsilane or diphenylsilane with 1,4-diethynylbenzene (82). These polymers had both β- and α-hydrosilation addition structures in the vinylene moieties.

Poly(silylenealkynylenearylene)s. The first poly(silylenealkynylene arylene) to be reported was poly(dimethylsilyleneethynylene-*p*-phenyleneethynylene), $(Si(CH_3)_2C{\equiv}CC_6H_4C{\equiv}C)_n$, which was prepared by polycondensation of the disodium salts of *p*-diethynylbenzene with dimethyldichlorosilane (83). A more efficient method was reported, which is a palladium-catalyzed polycondensation of dihaloaromatics and diethynyldiphenylsilanes (eq. 13).



(13)

This polymerization can be applied to a wide range of condensations between diethynyldiphenylsilane and aromatic halides including pyridine and thiophene derivatives (**13**) (84). It was reported that dehydrogenative coupling of phenylsilane with *m*-diethynylbenzene in the presence of MgO to provide poly(silylene-*m*-diethynylenephenylene) (**14**) (eq. 14) (85,86).

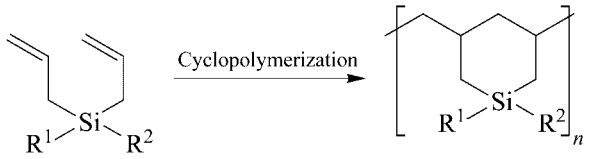


(14)

This polymer exhibited significantly high heat-resistant and burn-resistant properties, which is due to cross-linking of the polymer backbone through Si—H and C≡C bonds (85,86).

Poly(methylene(silacylohexanylene))s

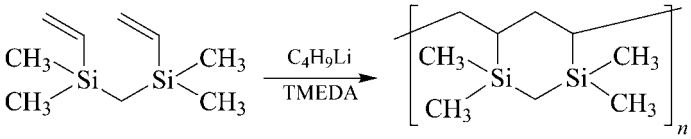
Polycarbosilanes with silicon-containing six-membered rings in the backbone can be synthesized by cyclopolymerization of organosilicon monomers bearing two olefinic substituents. Poly(methylene-(1-sila-3,5-cyclohexanylene))s (**15**) are obtained by cyclopolymerization of dialkyldiallylsilanes. Coordination polymerization by Ziegler-type catalysts (87–89), cationic polymerization by $AlBr_3$ (90–92), and radical polymerization induced by AIBN (93) have been reported (eq. 15).



R^1, R^2 = CH_3, C_6H_5

15 (15)

Cyclopolymerization of another type of organosilicon monomer has been reported. Poly(methylene-4,6-disila-1,3-cyclohexanylene) (**16**) was prepared by an anionic polymerization of bis(dimethylvinylsilyl)methane in the presence of tetramethylethylenediamine (TMEDA) (eq. 16).

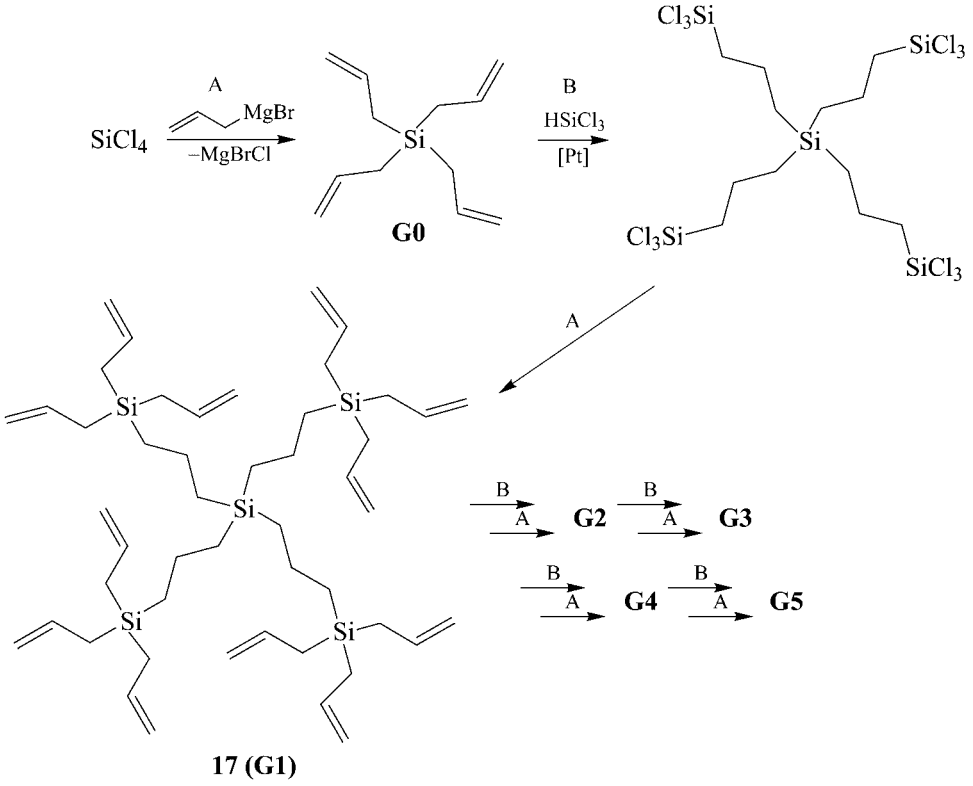


16 (16)

The polymerization can be controlled well to provide a sufficiently high molecular weight polymer (M_w = 12,400) having a six-membered ring structure in a very high yield (94,95).

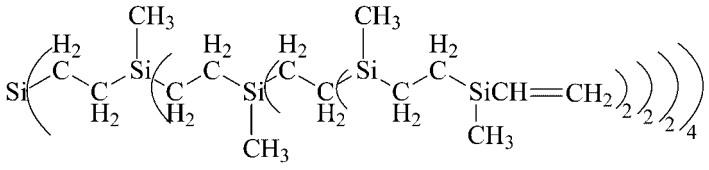
Carbosilane Dendrimers

In 1992, the synthesis of a carbosilane dendrimer was reported (96). Starting from tetrachlorosilane, allylations of Si—Cl groups by allyl Grignard reagents and hydrosilations of the allyl groups with trichlorosilane were alternately repeated to give a dendrimer composed of silylenetrimethylene units up to the fifth generation (**G5**) (eq. 17) (96).

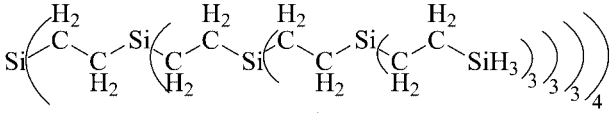


(17)

Other carbosilane dendrimers composed of silyleneethylene units, such as **18** and **19**, can be synthesized analogously by applying vinylations of Si—Cl groups instead of the allylations (97,98).



18



19

Many researchers employed these dendrimers as frameworks to attach other functional groups. For instance, dendrimers with mesogenic cholesteryl (99), perfluoroalkyl (100,101), hydroxyl, dimethylamino, sodium sulfonate,

trimethylammonium groups (102), palladium complexes (103–105), iron/gold clusters (106), and cyclopentadienyltitanium complexes (107) were synthesized.

POLYELECTROLYTES

Introduction

Polyelectrolytes are polymers that develop substantial charge when dissolved or swollen in a highly polar solvent such as water. These polymers are also commonly termed *polyions* because their charge arises from many ionized functional groups positioned along the chain contour. Electrostatic interactions between the ionized groups, as well as the presence of small electrolyte ions in the nearby solution, convey to polyelectrolyte systems a host of properties distinct from those displayed by neutral polymer systems. Unfortunately, describing and modeling these properties has proven difficult, and many key properties remain poorly understood. Industrial applications and academic interests focus on polyelectrolyte behavior in solutions, gels, adsorbed layers, and grafted brushes. Polyelectrolytes frequently form complexes with cosolutes such as multivalent ions, surfactants, other polymers, or small colloidal particles.

Even in water, which possesses a high dielectric constant, electrostatic forces strongly oppose the dissociation and physical separation of unlike charges. Thus, a diffuse cloud of small counterions closely surrounds a dissolved polyelectrolyte chain, and this cloud accumulates sufficient charge to compensate for the polyelectrolyte's fixed charge. Ions within the diffuse cloud dynamically exchange with small ions present as added or ambient low molecular weight electrolyte in the surrounding solution, but this exchange does not affect the net excess of countercharge the cloud accumulates. The size of the diffuse cloud reflects a balance between electrostatic energy, favoring the cloud's collapse onto the oppositely charged chain, and entropy, favoring the cloud's unbounded expansion. Counterions in the diffuse cloud, as well as other small ions of an added electrolyte, screen electrostatic interactions, a phenomenon reducing the length scales over which

Encyclopedia of Polymer Science and Technology. Copyright John Wiley & Sons, Inc. All rights reserved.

electrostatic interactions remain important. Adding electrolyte to a polyelectrolyte solution contracts the counterion cloud, and at sufficiently high electrolyte concentrations, the cloud's shrinkage onto the chain transforms many polyelectrolyte properties to those of a neutral polymer. Conversely, with no added electrolyte and thus only liberated counterions present, a special condition termed *salt free*, distinctive polyelectrolyte behaviors are strongly magnified.

Borrowing from the terminology of simple electrolytes, if the extent of dissociation of a polyelectrolyte's ionic groups depends on solution conditions, particularly pH or concentration, the polyelectrolyte is labeled "weak." On the other hand, if a polyelectrolyte's charge is relatively insensitive to solution conditions, the polyelectrolyte is labeled "strong." Weak and strong classifications can be ambiguous. Polyampholytes simultaneously contain both positive and negative charge units. These molecules may display an *isoelectric point*, a pH or solution condition at which the magnitudes of positive and negative charge are equal. Many proteins, for example, behave as weak polyanions at high pH, weak polycations at low pH, and neutral at some well-defined intermediate pH.

The electrostatic interactions of polyelectrolytes with nearby small ions have frequently been addressed using theoretical methods and approximations adapted from studies of colloids or simple electrolytes. However, polyelectrolytes introduce new and complicating features, most notably, molecular flexibility/orientation, chain entanglement, and a necessity for modeling electrostatic interactions consistently over a large range of length scales. Additional theoretical difficulties may include specific ion interactions, hydrogen bonding of water, unknown values of the local dielectric constant, and ordered placement of charges along the backbone.

Polyelectrolytes sometimes are categorized according to the solubility of their uncharged backbone. Polyelectrolyte species that would not dissolve in the absence of charge are termed *hydrophobic*, while those that would are termed *hydrophilic*. The distinction is only conceptual, as even if possible, removal of charge will normally modify nonelectrostatic interactions that affect polyelectrolyte solubility. Amphiphilic polyelectrolytes or "polysoaps" contain, in addition to charged chain sequences, well-defined hydrophobic units either in the backbone or attached as branches. *Ionomers* are charged polymers possessing along their backbones only a low density of charged units, with the fraction of these units typically less than about 15% on a mole basis. The remaining units are nonpolar and water-insoluble, and so ionomers do not dissolve readily in high dielectric constant solvents, and in more suitable lower dielectric constant solvents, the ionizable units interact mainly through dipole–dipole rather than direct electrostatic forces. Ionomers as a class are therefore distinct from polyelectrolytes.

Although DNA is perhaps the best-known biological polyelectrolyte, many additional examples are found among common proteins and polysaccharides. Polyelectrolytes are produced synthetically by polymerization of charged monomers or by chemical functionalization of both natural and synthetic neutral polymers. An increasing number of neutral polymers have been observed to behave much as polyelectrolytes as a result of association in solution with charged cosolutes such as surfactants and small ions. Such materials may be termed *pseudopolyelectrolytes*.

Outside of natural systems, where polyelectrolytes perform an enormous number of biological functions, polyelectrolytes are mostly employed to modify

solution rheology, control the aggregation of colloidal particles, or alter the nature of surfaces by adsorption. However, the number of applications for synthetic polyelectrolytes is large and growing, and no single use or class of uses dominates.

Examples of Polyelectrolyte

A vast number of chemical structures have been reported for polyelectrolytes. Table 1 illustrates a few of the more important and commonly encountered polyelectrolyte chemical structures. Although the table divides polyelectrolytes according to chemical origin, the division can be arbitrary. For example, poly(glutamic acid) can be prepared by either traditional organic synthesis or biosynthesis in genetically modified bacteria. Poly(styrene sulfonate) is an example of a synthetic polymer made equally by polymerization of charged monomer, styrene sulfonate, or by modification of neutral polymer, sulfonation of polystyrene. The ionic groups that endow polyelectrolytes with charge are no different than those found in small organic molecules bearing charge. The list of anionic groups includes sulfate, phosphate, sulfonate, and carboxyl, while that of cationic groups includes protonated ammonium, quaternized ammonium, sulfonium, and phosphonium. Polyelectrolytes in solid form are frequently available as either the salt or the acid/base, and the two forms can usually be interchanged after dissolution in solution by appropriate methods of ion exchange or dialysis. When dissolved in an aqueous environment containing small ions, the form of the starting material is irrelevant, as the system properties depend only upon the mixture of small ions present and not their source. The multivalent salts of a polyelectrolyte are often sparingly soluble or insoluble.

Basic Description of a Polyelectrolyte System

The Polyelectrolyte Chain. The presence of covalently attached ionic groups fundamentally distinguishes polyelectrolytes from neutral polymers, and so a description of polyelectrolyte properties begins with parameterization of polyelectrolyte charge. The projected number of elementary charges of magnitude e (1.602×10^{-19} C) per unit backbone length defines a polyelectrolyte's linear charge density. The inverse of this quantity, given the symbol b, represents the average axial spacing between charges. Important assumptions are implicit in the capturing of polyelectrolyte charge in b. First, charge units that are physically positioned at some radial distance from the backbone on side groups or ordered about the backbone as a helix are treated as equivalent to hypothetical charge units positioned along the chain axis. Second, the discrete axial spacing of charges present in the real chemical structure is smeared along the chain contour, eliminating local charge correlations. Finally, the radial mispositioning of charge implicit in specification of b supposes that the dielectric properties of the backbone are irrelevant to the polymer's electrostatic properties. The combined impact of all of these assumptions is unclear; at best, b should be understood to describe polyelectrolyte charge and its effects at large enough length scales so that local structural detail is unimportant. When local detail cannot be ignored, other measures of charge

Table 1. Typical Polyelectrolytes

Name	Repeat Unit
Poly(glutamic acid)	Poly(vinyl sulfate)	Poly(acrylamide-*co*-acrylic acid)	Natural polyelectrolytes	
Hyaluronic acid	Chitosan	Carboxymethyl cellulose	DNA (single stranded)	
are needed. For example, to understand some behaviors of DNA, one might characterize the polymer's charge via a surface charge density rather than a linear charge density, or even further, via the helical placement of phosphate groups relative to a finite dielectric constant backbone. More complex polyelectrolyte charge descriptions require additional and often unavailable molecular details.

Even in the absence of charge, the characterization of an ordinary flexible polymer chain requires at least three physical parameters, chosen as the persistence length l_p (measuring chain stiffness), contour length L (measuring chain length), and excluded volume strength ν (measuring segmental interactions or solvent quality). The same quantities or their equivalents are also necessary to characterize a linear, flexible polyelectrolyte chain. Thus, the most basic polyelectrolyte chain description incorporates four parameters: b, L, l_p, and ν. Different and/or additional parameters will appear in the description of structurally complex polyelectrolytes such as globular proteins and dendrimers.

The Electrolyte Environment. The electrolyte environment also needs to be described to characterize a polyelectrolyte system. Polyelectrolytes dissolved or swollen in a solvent are bathed in a dielectric medium that typically includes, in addition to other polymer chains and liberated counterions, some level of added or ambient low molar mass electrolyte. A full system description therefore includes information about the solvent medium and any added electrolyte.

The interaction of thermally equilibrated charges across a medium of dielectric constant ε introduces to electrolyte solutions a fundamental length scale l_b, the Bjerrum length. This length characterizes the distance over which two bare charges of magnitude e experience an electrostatic interaction energy equal to the medium's thermal energy kT, ie,

$$l_b = \frac{e^2}{4\pi\varepsilon\varepsilon_0 kT} \tag{1}$$

where ε_0 is the permittivity of vacuum (8.854×10^{-12} $(A^2 \cdot S^4)/(kg \cdot m^3)$). (SI units will be employed here, although most of the polyelectrolyte literature uses CGS units.) At 25°C, l_b in water ($\varepsilon = 78$) is about 0.71 nm.

The introduction of counterions and added electrolyte introduces yet another length scale to electrolyte solutions, one that manifests the enhanced decay of electrostatic interactions in the presence of screening charges. When electrostatic effects are treated within the standard Poisson–Boltzmann approximation, the Debye length κ^{-1} governs the screening length of electrostatic interactions by these ions:

$$\kappa^{-1} = \left(\frac{\varepsilon\varepsilon_0 kT}{\sum_i c_{0,i} (ez_i)^2} \right)^{1/2} \tag{2}$$

where $c_{0,i}$ is the bulk concentration (number per volume) of the ith ion species of valence z_i. Relating the denominator of the term in parentheses to the ionic strength I (expressed in moles per volume) through

$$I = \frac{1}{2N_a} \sum_i c_{0,i} (z_i)^2 \tag{3}$$

where N_a is Avogadro's number, the expression for κ^{-1} can be rewritten as

$$\kappa^{-1} = \left(\frac{\varepsilon\varepsilon_0 kT}{2N_a e^2 I}\right)^{1/2} = \left(8\pi N_a I l_b\right)^{-1/2} \tag{4}$$

In water at 25°C, the last formula simplifies to $\kappa^{-1} = 0.304 I^{-1/2}$ nm when I is expressed in mole per liter (M). When $I = 1.0\,M$, for example, κ^{-1} is about 0.3 nm, and when $I = 0.001\,M$, κ^{-1} is about 10 nm. The largest experimentally obtainable values of κ^{-1} are in the range of tens to hundreds of nanometers, values characteristic of dilute, essentially salt-free polyelectrolyte solutions. For these extreme cases, I is dominated by the bulk concentration of counterions dissociated as the polymer dissolves. How this concentration can be estimated is discussed later; for highly charged polyelectrolytes, not all dissociated counterions contribute to I.

The basic description of the solvent medium thus provides two additional length scales, l_b and κ^{-1}, the former characterizing the spatial attenuation of electrostatic interactions according to the medium's dielectric constant and the latter characterizing the spatial attenuation of electrostatic interactions according to the medium's concentration of thermally equilibrated small ions. The Poisson–Boltzmann equation provides a consistent, albeit approximate, framework for describing the role of electrostatic interactions within a polyelectrolyte–solvent system, incorporating effects associated with both l_b and κ^{-1}. The diffuse counterion cloud described by the Poisson–Boltzmann equation is often termed the *Gouy–Chapman layer*. Some models for charged surfaces and polymers suppose that beneath the Gouy–Chapman layer lies an immobilized layer of adsorbed ions termed the *Stern layer*. Electrostatic models that address the electrolyte solution but ignore the nature of the charged substrate cannot predict the presence or properties of a Stern layer. The Poisson–Boltzmann equation suffers from numerous well-known deficiencies, and the full nonlinear equation can be difficult to solve analytically. The linearized version of the Poisson–Boltzmann equation, obtained via the Debye–Hückel approximation, is much easier to analyze and offers much qualitative, if not quantitative, insight into polyelectrolyte phenomena. Nevertheless, the Debye–Hückel approximation imposes a severe constraint, requiring that the electrostatic potential ψ be everywhere small compared to kT/e, a questionable condition for most polyelectrolyte systems. At typical polyelectrolyte charge densities, ψ is much in excess of kT/e near the chain backbone.

In the Debye–Hückel approximation, the electrostatic interaction energy of two point charges of magnitude e separated by distance r across a dielectric medium containing equilibrated small ions is expressed as

$$U(r) = kT\,\frac{l_b}{r}\,\exp(-\kappa r) \tag{5}$$

This simple Debye–Hückel or Yukawa potential captures the essence of electrostatic interactions in many polyelectrolyte systems, and as the outcome of a linear analysis, provides discrete interaction terms that can be directly summed to obtain the net electrostatic energy associated with the multiple charges of a polyelectrolyte system. When rigor beyond the Debye–Hückel approximation is mandatory, electrostatic energies must be evaluated through the full

Poisson–Boltzmann equation, more sophisticated analytical alternatives, or computer simulation. Both Debye–Hückel and Poisson–Boltzmann approaches offer a mean-field description of electrostatic screening by small (point-like), thermally equilibrated ions; such descriptions fail to address the spatial correlations in placement of these ions that may be important in real polyelectrolyte systems.

The various properties characterizing a polyelectrolyte chain and its surrounding solution combine to form a set of dimensionless parameters. Most importantly, the combination of b and l_b leads to the dimensionless charge density parameter ξ:

$$\xi = \frac{l_b}{b} = \frac{e^2}{4\pi\varepsilon\varepsilon_0 kTb} \tag{6}$$

In the study of polyelectrolytes, ξ plays a crucial role, as it provides the simplest well-defined physical property that can distinguish one polyelectrolyte from another or from a neutral polymer. Most polyelectrolytes possess a substantial charge density, a condition associated with ξ of order unity or greater. For a polyelectrolyte with a vinyl backbone and one charge per monomer unit, b is about 0.25 nm, and the value of ξ in water at room temperature is about 2.84; for DNA at the same solution conditions, b is about 0.17 nm (two phosphate charges per base pair step of 0.34 nm), and the value of ξ is about 4.2.

Counterion Condensation

In a variety of contexts, highly charged polyelectrolytes behave as if their net charge, or equivalently their average effective charge density, is less than the value determined by the number of ionizable units in the chain's chemical structure. Such behaviors imply that for energetic reasons some fraction of the counterions resides near or at the polyelectrolyte's "surface" where this opposite charge compensates for some of the charge associated with the chain's covalently attached ionic units. The hypothesized "condensation" of oppositely charged small ions reduces the polyelectrolyte's "apparent" or "effective" charge even when the polyelectrolyte's charge moieties are known to dissociate at the specified bulk solution conditions. Because the binding of condensed counterions arises from electrostatic forces in the solution phase, the condensed counterions do not form a classical Stern layer.

Although similar ideas were presented earlier and less rigorously (1–10), Oosawa (11,12) and Manning (13–16) independently formalized counterion condensation in the 1960s. Manning subsequently clarified and extended the original proposition to such a degree that the phenomenon is now frequently referenced as *Manning condensation* (17–24). Counterion condensation in its simplest form balances the entropy and electrostatic energy of small counterions located near a line or thin cylinder representation for a polyelectrolyte chain. Such descriptions for the local conformation of a polyelectrolyte chain have a long history (2,25); unfortunately, these geometric representations often muddy the extrapolation of theoretical predictions to flexible polyelectrolytes (26). Manning's first theoretical treatment of counterion condensation assumed that the polyelectrolyte's fixed

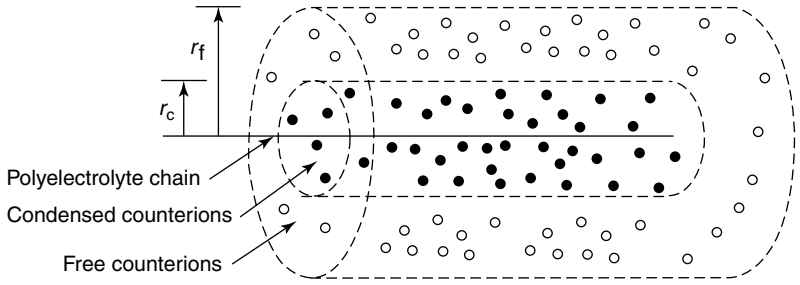

Fig. 1. Sketch of the two-phase model for counterion distributions near a line charge representation of a polyelectrolyte chain. Condensed (darkened circles) and free (open circles) ions occupy distinct regions bounded by r_c and r_f, respectively.

charge was smeared along the backbone (13–15), while later he developed an analogous treatment that assumed the charge was present as discrete point charges (19); the two treatments, both treating the chain as a line charge, produce nearly the same results.

Counterions released into solvent from a line charge sample a larger volume than before release, and therefore their entropy rises. However, entropy enhancement comes at a cost, as the further in outlying space the counterions explore the greater is their electrostatic energy. The condensation model splits counterions into two populations or states, those that are *condensed* and those that are *uncondensed* or *free*. The condensed ions possess only the freedom to move along and near the chain backbone while the free ions can move in a more or less unconstrained fashion within the solvent domain away from the backbone. Figure 1 provides a schematic of the postulated counterion populations near a line charge. The key issues for counterion condensation theories are the fraction of free ions and the extent to which condensed ions are localized. Some authors have found it useful to define two subpopulations of condensed ions (27): *site-bound condensed ions* are those in direct contact with a fixed charged group of the polyelectrolyte (no intervening water molecules) and *territorially-bound* condensed ions are those nonspecifically attached to the polyelectrolyte backbone, perhaps with their hydration layers intact. Only territorially bound condensed ions are able to wander readily along the chain's contour. Univalent condensed counterions are nearly always envisaged as territorially bound.

For univalent polyelectrolyte charge units and univalent counterions, Oosawa (12) argued that the concentrations of condensed and free counterions are related by an appropriate Boltzmann factor:

$$n_c = n_f \exp\left[\frac{-e\Delta\psi}{kT}\right] \tag{7}$$

where $\Delta\psi$ is the electrostatic potential difference between the regions containing the condensed and free ions (the potentials in both regions are assumed constant), and n_c and n_f are the respective (uniform) counterion concentrations (number per volume) in these regions. The bare charge density of the line charge is given

by e/b, but with condensation, the effective linear charge density is reduced to $\beta e/b$, where β is the fraction of free counterions. The electrostatic potential field near an infinitely long line charge in a dielectric (unscreened) medium decays logarithmically with radial distance from the line. Letting the outer radius of the region containing condensed ions be denoted r_c and the outer radius of the region containing free ions be denoted r_f, $\Delta\psi$ is estimated to be

$$\Delta\psi = -\frac{\beta e}{2\pi\varepsilon\varepsilon_0 b}\ln\left(\frac{r_f}{r_c}\right) = -\frac{\beta e}{4\pi\varepsilon\varepsilon_0 b}\ln\left(\frac{V_f+V_c}{V_c}\right) \tag{8}$$

where V_c and V_f are the volumes of the regions containing condensed and free counterions, respectively. Equations 7 and 8 can be combined to eliminate $\Delta\psi$:

$$\ln\frac{n_c}{n_f} = -\frac{e\Delta\psi}{kT} = \frac{\beta e^2}{4\pi\varepsilon\varepsilon_0 kTb}\ln\left(\frac{V_f+V_c}{V_c}\right) = \beta\xi\ln\left(\frac{V_f+V_c}{V_c}\right) \tag{9}$$

Counting the condensed and free ions located in volumes V_c and V_f,

$$\ln\left(\frac{1-\beta}{\beta}\right) = \ln\left(\frac{n_c V_c}{n_f V_c}\right) = \ln\frac{n_c}{n_f} + \ln\frac{V_c}{V_f} \tag{10}$$

Designating ϕ as the volume fraction of space containing only condensed ions, the two previous equations can be combined into an expression relating φ and β:

$$\ln\frac{1-\beta}{\beta} = \ln\frac{\varphi}{1-\varphi} - \beta\xi\ln\varphi \tag{11}$$

In the limit $\varphi \to 0$, the space occupied by condensed ions is small, and Oosawa demonstrated the existence of two types of solutions for this expression. When $\xi \leq 1$, a solution exists for $\beta \to 1$, and when $\xi > 1$, a solution exists for $\beta = 1/\xi$. The second statement establishes the presence of condensed counterions on a highly charged polyelectrolyte modeled in this fashion.

Counterion condensation offers the following quantitative predictions for effective polyelectrolyte charge: when $\xi < 1$, no ions condense and the effective charge density parameter ξ_{eff}, defined as the product $\beta\xi$, and the bare charge density parameter ξ are equal; when $\xi > 1$, sufficient counterions will condense onto the polyelectrolyte to lower its effective charge density parameter ξ_{eff} to unity. The condition $\xi_c = 1$ is viewed as the critical condition for the onset of counterion condensation for a polyelectrolyte in the presence of univalent counterions. The same trends apply to higher valence counterions except that the onset of counterion condensation is lowered to $\xi_c = |z_i|^{-1}$, and for $\xi > \xi_c$, $\beta = 1/|z_i|\xi$. Figure 2 sketches these predictions.

Although reaching the same predictions for the fraction of condensed counterions, Manning's derivations of counterion condensation are superior to the one just given (Oosawa's) in the sense that Manning's derivations allow ψ in the region of free ions to be screened in the Debye–Hückel approximation according to

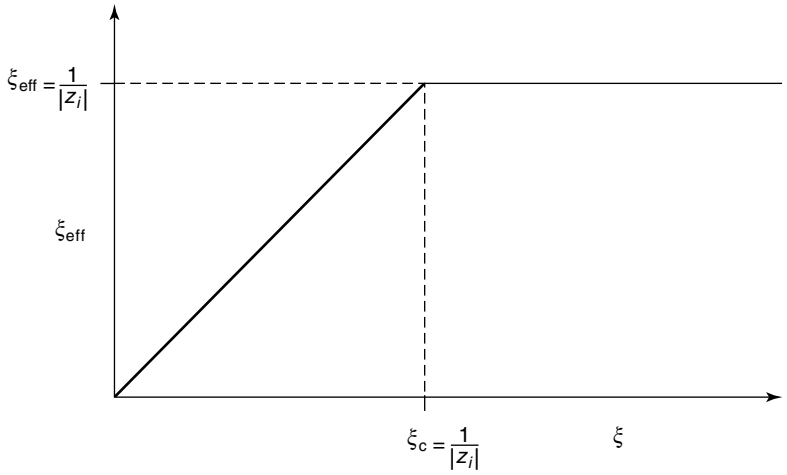

Fig. 2. Relationship of the effective linear charge density ξ_{eff} to the fixed linear charge density ξ as predicted by counterion condensation. The onset point of condensation ξ_c and the value of ξ_{eff} for $\xi > \xi_c$ both depend on the counterion valence z_i.

the value of κ^{-1}. Uncondensed ions accordingly contribute to screening, being included in the calculation of κ^{-1}, while condensed ions do not. Indeed, in a salt-free solution, only uncondensed ions create electrostatic screening, and accounting for counterion condensation, κ^{-1} is given as

$$\kappa^{-1} = \begin{cases} \left(4\pi N_a l_b f c_p\right)^{-1/2}, & \xi < 1 \\ \left(4\pi N_a b f c_p\right)^{-1/2}, & \xi > 1 \end{cases} \tag{12}$$

where c_p is the concentration (mole/volume) of polymer repeat units, and f is the fraction of these repeat units that bear charge; f equals unity for a polyelectrolyte homopolymer and less than unity for a copolymer possessing both charged and neutral repeat units. When I is small but nonzero and fc_p is large, κ^{-1} manifests contributions from both added electrolyte and dissociated counterions. Manning argued that the phenomenon of counterion condensation, although rigorously derived as a limiting law (all components infinitely dilute), satisfactorily describes polyelectrolyte solutions up to ordinary electrolyte concentrations.

Counterion condensation has detractors (28–34), who point to flaws in the concept's derivation, such as artificial subdivision of the counterions into two populations, inappropriate extrapolation of the Debye–Hückel approximation to regions of high electrostatic potential, and inconsistent treatment of counterions. The full nonlinear Poisson–Boltzmann equation offers a more rigorous way to interpret electrostatic phenomena in electrolyte solutions, but the physical picture obtained through this equation is different in some ways from the one suggested by condensation (21,34,35). In particular, a Poisson–Boltzmann analysis does not readily identify distinct populations of condensed and free counterions but rather a smoothly varying Gouy–Chapman layer. Nevertheless, Poisson–Boltzmann-based

analyses do find that in salt-free solutions there is a fraction of counterions equal to $1-\beta$ that cannot be fully diluted away from the chain at infinite chain dilution; the volume occupied by this trapped fraction is predicted by the Poisson–Boltzmann equation to be rather large, a feature inconsistent with the physical picture on which condensation is based (32). Zimm has pointed out that by applying this dilution criterion to identify condensed ions in salt-free solutions, all counterions are condensed on plane, none on a sphere, and some on a cylinder (36). Many experimental and theoretical studies support the general picture, if not the details, of the original counterion condensation concept (26,37–50).

Subdivision of counterions into condensed and uncondensed populations according to the Manning/Oosawa depiction is not unique. For example, a hypothetical "thermodynamically bound" counterion population can be defined to account for the deviations of polyelectrolyte solutions from thermodynamic ideality (35); this population is not equal to the condensed population. One can also use different definitions of *condensed*. The inflection point in the radial ion distribution, the Bjerrum length, and the radial distance over which the electrostatic interaction energy decays to kT have all been employed as alternative criteria for defining a condensed fraction (50).

According to a nonlinear Poisson–Boltzmann analysis, the initial radial decay of ψ from a cylindrical chain segment is much steeper than predicted by a Debye–Hückel analysis; see Figure 3 (28). The steep decay lessens at large distance, and ψ eventually adopts an asymptotic functional form compatible with a Debye–Hückel approximation. However, to superimpose across this distant region the predictions of the Poisson–Boltzmann analysis onto those formulated

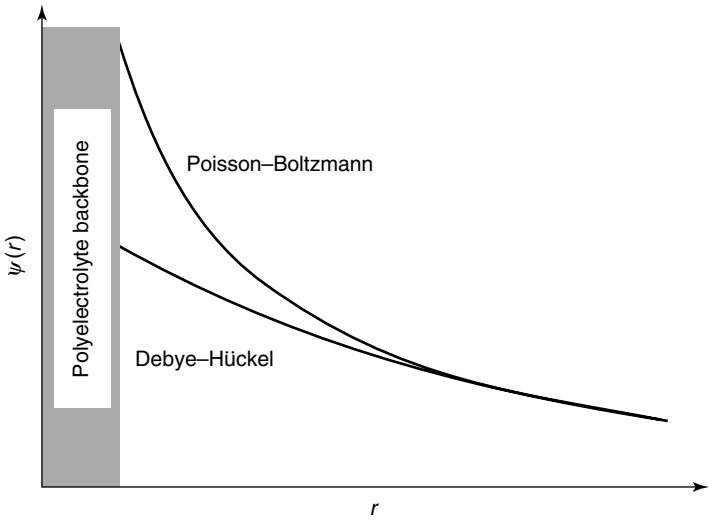

Fig. 3. Schematic plots of the decay of the electrostatic potential $\psi(r)$ near a polyelectrolyte chain of unspecified chain radius. The potential decay predicted by a nonlinear Poisson–Boltzmann analysis can be superimposed onto one predicted by a linearized Debye–Hückel approximation in the far field region if the surface potential of the Debye–Hückel is appropriately adjusted. However, in this case there remains strong deviation between the two approaches in the region nearer the chain.

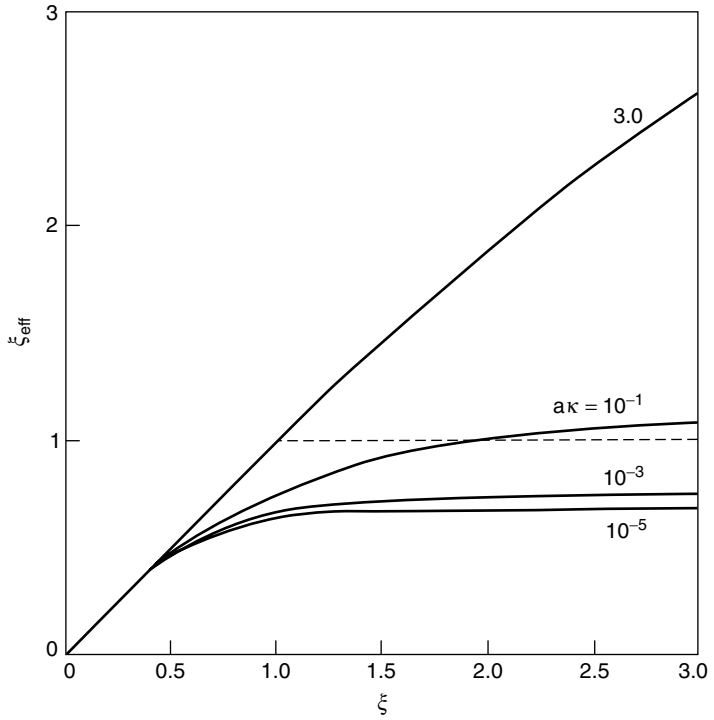

Fig. 4. Effective linear charge density ξ_{eff} of a charged cylinder derived by superimposing the far field (large r) Poisson–Boltzmann potential field onto the potential field predicted by use of the Debye–Hückel approximation. The solid lines correspond to different values of $a\kappa$, where a is the cylinder radius and κ^{-1} is the Debye length; the electrolyte is monovalent. For comparison, the counterion condensation prediction for ξ_{eff} is shown as a dotted line. Adapted from Ref. 51.

within the Debye–Hückel approximation, the linear charge density in the Debye–Hückel calculated must be reduced from the linear charge density in the Poisson–Boltzmann analysis. This reduced Debye–Hückel linear charge density can be interpreted, from the perspective of a distant observer, as defining the polyelectrolyte's "effective" or renormalized linear charge density (29,51); the same renormalization approach can be extended to other highly charged solutes (52). Figure 4 compares the effective linear charge density, as determined for a charged cylinder of radius a, to the effective linear charge density predicted by the Manning line charge model with counterion condensation. The two approaches agree in only the most qualitative manner, notably for $\xi \ll 1$. In this limit, where $\xi_{\text{eff}} = \xi$ according to both approaches, the Debye–Hückel approximation is valid throughout the entire solvent domain surrounding the polyelectrolyte. For $\xi \geq 1$, the effective linear charge and associated Debye–Hückel predictions apply only to phenomena associated with distant portions of the potential field.

Despite the nonrigorous theoretical status of counterion condensation, many of its predictions find direct support in experiment. As will be seen, properties such as osmotic pressure, ion activity coefficients, and counterion diffusion coefficient

can readily be understood if condensation is assumed. However, the same properties can almost always be successfully interpreted without the assumption of counterion condensation, perhaps after the greater analytical difficulty of a Poisson–Boltzmann analysis. Unfortunately, experiments designed to detect condensed counterions or to measure ξ_{eff} have led to ambiguous results. The status of counterion condensation in nondilute solutions remains an active area of research (48).

Single Chain Conformation in Dilute Solution

As reflected in size measures such as the mean radius of gyration R_g or mean-square end-to-end distance $\langle R^2 \rangle^{1/2}$, an isolated polyelectrolyte chain in dilute solution expands relative to an analogous neutral chain because of electrostatic repulsions between its similarly charged chain segments. Low molar mass electrolyte and counterions screen these repulsions, and in consequence, a flexible polyelectrolyte chain contracts as electrolyte is added (assuming the electrolyte does not contain ions that specifically bind to the chain, affecting the chain's charge in an unexpected way). At high enough electrolyte concentrations, the suppression of segment–segment repulsions suffices, at least for some polyelectrolytes, to transform a good solvent into one of marginal or poor quality. In the latter instance, precipitation or coacervation of the polymer may ensue, a process referred to as "salting out." Higher valence ions more effectively screen electrostatic repulsions and induce this phase separation at lower salt concentrations. Across the I range where flexible polyelectrolytes are normally used, 0.001–1.0 M, changes in chain conformation are significant, leading to variations of R_g of up to an order of magnitude. Polyelectrolyte expansion has immediate significance to numerous solution properties such as viscosity and diffusion coefficient.

Even the earliest discussions of polyelectrolyte conformation recognized that long-range electrostatic repulsions could induce chain stiffening and coil swelling (see CONFORMATIONS AND CONFIGURATION). In 1951, for example, Katchalsky wrote "...at low degrees of ionization the molecules are more or less hypercoiled rigid spheres ...they open up with increasing ionization and assume the form of kinked threads at about 10% ionization and, finally, at high degrees of ionization, stretch to rodlike filaments" (53). In a solution containing little added electrolyte, many investigators initially expected a conformational crossover, from electrostatically stiffened rod to electrostatically swollen Flory-like coil, when chain length exceeds κ^{-1} (2,54–57). Later investigations showed that polyelectrolyte size and conformation in solution present subtle complexities. Although there have been important recent theoretical contributions by Odijk, Skolnick, and Fixman (OSF) (58–63), Joanny and Barrat (64,65) and Muthukumar and co-workers (66–68), the quantitative matching of experimental data to theoretical predictions remains inconclusive except in a few limiting cases.

OSF Model. Extending two-parameter theories for neutral polymers to polyelectrolytes, the OSF approach envisages that electrostatic forces within a polyelectrolyte chain operate at two well separated length scales (51,58–63). At the short or segmental level, as sketched in Figure 5a, electrostatic repulsions between neighboring backbone charges increase l_p, stiffening the chain locally, while at the large or coil size level, as sketched in Figure 5b, electrostatic repulsions between

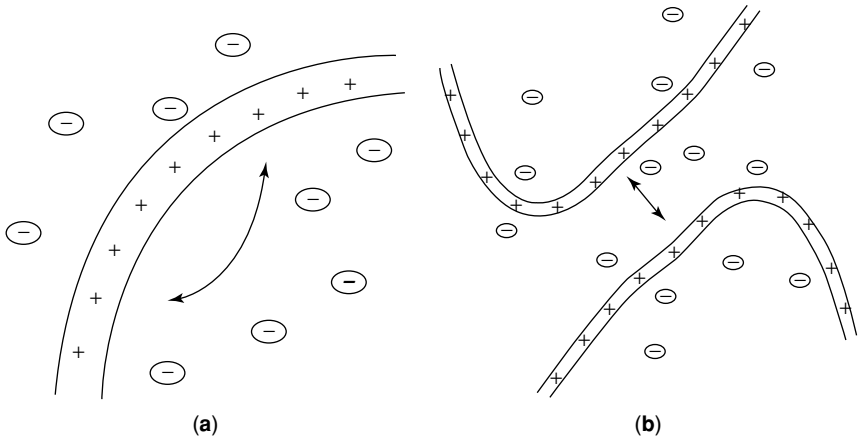

Fig. 5. Sketches illustrating the decomposition of electrostatic interactions into local and global impacts. In part **a**, repulsive forces between neighboring fixed charges on the chain cause backbone stiffening. In part **b**, repulsive forces between distant fixed charges on the chain backbone cause coil swelling. The presence of screening electrolyte ions reduces the magnitude of the repulsive forces.

segments widely separated along the backbone increase excluded volume, swelling the chain globally.

To model the first of these effects the OSF approach splits l_p into two contributions, one assigned from the equivalent neutral chain, defining the bare or intrinsic persistence length l_0, and one defined by electrostatic interactions, defining the electrostatic persistence length l_e,

$$l_p = l_0 + l_e \tag{13}$$

The value of l_0 is external to the OSF model while the value of l_e is determined by evaluating how local electrostatic interactions raise the bending energy of an extended chain segment of length L_s. The model defines the curvature of this segment through a function $\theta(s)$, where s is contour coordinate spanning $-L_s/2 < s < L_s/2$, and $\cos\,\theta(s)$ is given by the product $\boldsymbol{t}(s)\cdot\boldsymbol{t}(0)$, where $\boldsymbol{t}(s)$ is a unit vector tangent to the segment at position s. Allowing only small departures of the chain configuration from rod-like and imposing the Debye–Hückel approximation, the OSF treatment balances thermal fluctuations, intrinsic bending rigidity, and screened electrostatic interactions. At large s, the flexibility of the curve is captured in the mean-squared angle $\langle\theta(s)^2\rangle$:

$$\langle\theta(s)^2\rangle = \frac{s}{l_0 + l_e} \tag{14}$$

where

$$l_e = \frac{l_b}{4b^2\kappa^2} \tag{15}$$

The Debye–Hückel approximation strictly limits the OSF analysis to $\xi \ll 1$, but the analysis can reasonably be extended to more highly charged polyelectrolytes by invoking counterion condensation and substituting l_b for b. Then, for $\xi > 1$,

$$l_e = \frac{1}{4 l_b \kappa^2} \tag{16}$$

If the fluctuations in $\theta(s)$ are too great, ie, if the chain is too flexible, the perturbation approach of OSF fails. This breakdown occurs when $l_0 < b^2/l_b$. Consequently, the OSF model rigorously applies only to intrinsically stiff and highly charged polyelectrolytes such as DNA ($l_0 \approx 50$ nm). The original OSF calculation predicts l_e decays in inverse proportion to κ^2. Le Bret (69) and Fixman (70) improved the OSF model by evaluating electrostatics of a bendable chain segment within the broader framework of the Poisson–Boltzmann equation, finding that the decay of l_e at large I follows roughly κ^{-1} rather than κ^{-2}.

In addition to the local electrostatic stiffening manifested in l_e, the OSF approach considers how long range electrostatic repulsions impact excluded volume. Fixman and Skolnick (63) and Odijk and Houwaart (60) independently calculated an electrostatic contribution to excluded volume by adding a term to the binary cluster integral β_c associated with screened interaction between two charged, cylindrical chain segments. They both found that the electrostatic contribution to β_c is proportional to l_e^2/κ. From β_c, the expansion coefficient α, expressing the ratio of swollen chain size to unswollen chain size in the theta state, can be evaluated via the same expressions applied for neutral polymers.

Variational Models. Variational models address the conformations of inherently flexible polymers better than the OSF model. In the variational approach, a polyelectrolyte chain is postulated to conform to a simple flexible chain model that constrains how the conformation can rearrange; the overall free energy of the model is then minimized with respect to model parameters such as persistence length and chain size to obtain a mean-field chain description (71). The final result hinges on the choice of an appropriate chain model. Early studies assumed that a polyelectrolyte's segment distribution remains Gaussian or spherical as the molecule expands or contracts from a hypothetical uncharged theta state. Using these depictions, the free energy was expressed as a sum of terms arising from entropic elasticity and electrostatic segment–segment repulsions, the latter most often modeled using the Debye–Hückel potential.

More recently, Barrat and Joanny depicted a weakly charged, flexible polyelectrolyte as a semiflexible string of electrostatic subunits or "blobs" (64,65). Each blob is associated with a chain segment of sufficient length to balance electrostatic and elastic energies. Within a blob, the local chain statistics are unperturbed by electrostatic repulsions, but over larger length scales, blobs interact electrostatically, and the chain becomes extended if these interactions are strong. At values of κ^{-1} appropriate to salt-free solutions, the blobs arrange linearly in space to reduce electrostatic energy, and Barrat and Joanny argued that the chain radius R obeys the scaling relationship

$$R \sim l_b^{1/3} N \tag{17}$$

where the symbol $\sim$ implies proportionality. At small κ^{-1}, which imposes electrostatic screening between blobs, their variational calculation leads to the following relationships for l_p and R:

$$l_p \approx \kappa^{-1} \tag{18}$$

and

$$R \sim N^{3/5} \kappa^{-2/5} \tag{19}$$

In this instance, l_p can be termed only an "apparent" electrostatic persistence length since the variational procedure self-consistently calculates l_p and R. Muthukumar and co-workers approached the conformation of a flexible polyelectrolyte slightly differently, employing a variational procedure that combines the Debye–Hückel approximation with the Edward's path integral formalism (66–68). A similar formula was found for R in the limits of large and small κ^{-1} along with a crossover formula appropriate for intermediate κ^{-1}. At small values of κ^{-1}, the approach of Muthukumar and co-workers (66–68) can be rearranged to show an apparent persistence length

$$l_p \sim \kappa^{-4/5} \tag{20}$$

with a different dependence on κ^{-1} than predicted by Barrat and Joanny (64,65).

The large κ^{-1} result of both groups corresponds to an intuitive picture that a polyelectrolyte chain unravels into an extended linear conformation when electrostatic repulsions between segments are strong enough. Although unraveled, the chain retains local conformational freedom and remains less than fully stretched ($R \ll L$). The large κ^{-1} formula given above was first suggested in 1948 by Katchalsky and co-workers (54,72) and Hermans and Overbeek (56) and later clarified by de Gennes and co-workers (73) and Pfeuty (57). Similarly, the low κ^{-1} formula result shows that strongly screened electrostatic repulsions between segments can be interpreted as an increase in the chain's excluded volume (67,74). Indeed, using variational procedures, Hermans and Overbeek (56) and Flory (55) half a century ago derived the same small κ^{-1} formula for R; Richmond (74) and Pfeuty (57) more recently reported derivations.

Electrostatic stiffening dictates the persistence length of an inherently flexible polyelectrolyte, and so both the Joanny and Barrat as well as the Muthukumar values of l_p can legitimately be compared to the OSF value of l_e. Note the different dependences of the quantities on κ. Li and Witten criticized variational approaches (75), arguing that short wavelength bending modes should not alter the OSF formula for l_p except to the extent there may be weak logarithmic corrections. Other variational approaches have been described, leading to somewhat different formulas for l_p and R (76–81). Dobrynin and co-workers recently developed a scaling theory for the dilute and semidilute solution conformations of hydrophobic polyelectrolytes, those that dissolve solely because of their charges; these polyelectrolytes were predicted to decompose into a necklace-like shape of compact beads separated by narrow strings (82–84). Simulation results relevant to polyelectrolyte conformation are discussed in a later section.

The same electrostatic forces that influence chain conformation in dilute solution affect the thermodynamic interactions between chains, and these alterations are most directly reflected in the magnitude of the second virial coefficient A_2. As expected, when repulsive interactions are heightened, A_2 in polyelectrolyte solutions is large and positive. The magnitude of A_2 falls sharply upon increasing addition of electrolyte. Values of A_2 derived via an OSF-type model for polyelectrolyte conformation compare well to experimental data for both stiff and flexible polyelectrolytes when two closely approaching polyelectrolyte chains are allowed to reduce their mutual overlap by flattening (85,86).

Numerous scattering methods, along with diffusion, viscosity, birefringence, spectroscopy, and microscopy methods, have been employed to measure the structure of polyelectrolyte chains in dilute solution. A discussion of these methods is not attempted here. Most methods are employed in the same way as for neutral polymers. Neutron scattering makes accessible measurements of polyelectrolyte chain structure in nondilute solutions (87).

Figure 6 displays experimental measurements of l_e for two well-characterized samples of the inherently flexible cationic polyelectrolyte poly(2-vinyl-pyridiniumbenzyl bromide) (80). Data for l_e vs concentration c_s of an added 1:1 electrolyte are compared to predictions of the OSF model and a numerically evaluated variational model that yields l_p slightly dependent on chain length. Clearly, none of the proffered models offer quantitative agreement with experimental data. As noted by several investigators (88–90), the OSF model overpredicts the drop of l_p as electrolyte is added to a flexible polyelectrolyte solution. For

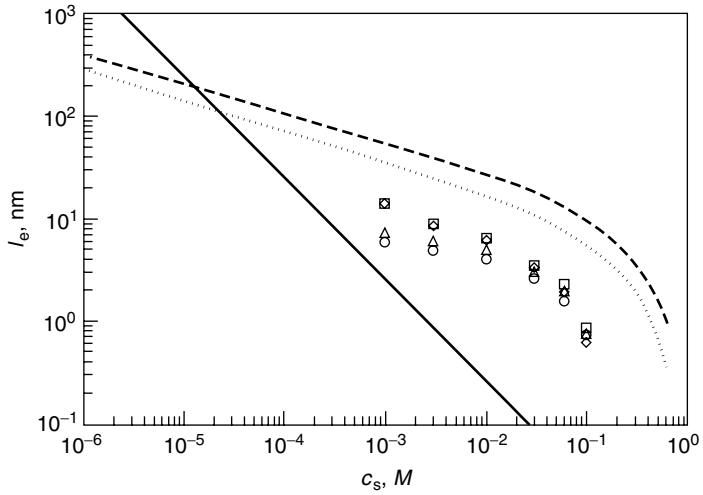

Fig. 6. Experimental data and theoretical predictions of the influence of added monovalent electrolyte at concentration c_s on the electrostatic persistence length l_e of poly(2-vinyl-pyridiniumbenzyl bromide). The data were obtained for chains of length L equal to 885 nm (circles from dynamic light scattering and diamonds from static light scattering) and 2240 nm (triangles from dynamic light scattering and squares from static light scattering), although no systematic influence on L is noted. The solid line represents the OSF theory for both chain lengths, and the dotted ($L = 885$ nm) and dashed ($L = 2240$ nm) curves provide l_e predictions from a variational calculation. Adapted from Ref. 80.

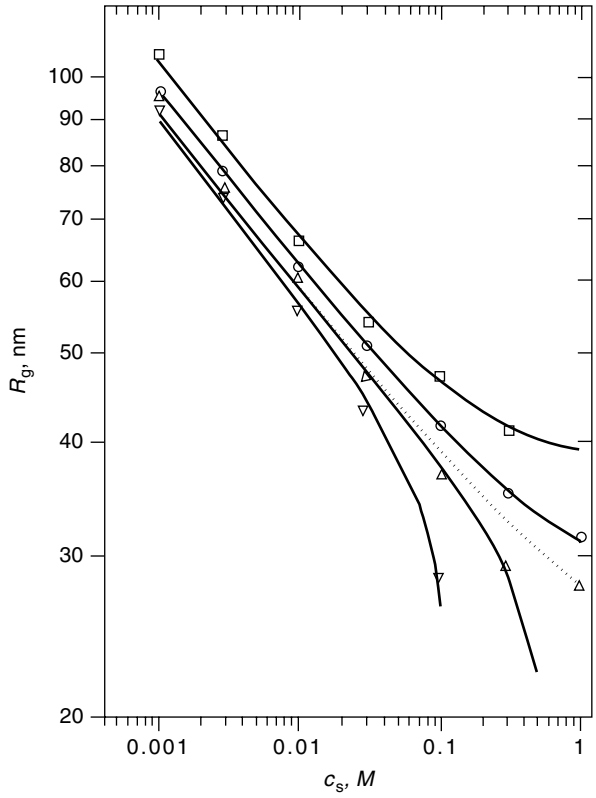

Fig. 7. Dependence of radius of gyration R_g on added electrolyte concentration c_s for 55–58% ethyl quaternized poly(2-vinyl pyridine) of chain length $L = 1000$ nm. Different symbols correspond to different counterions: F^- (squares), Cl^- (circles), Br^- (upward triangles), and I^- (downward triangles); the co-ion in each case is Na^+. The curves are fits to a theory described in the original reference. Adapted from Ref. 67.

low values of I, data for flexible polyelectrolytes approximately follow $l_p \sim \kappa^{-1}$ rather than $l_p \sim \kappa^{-2}$, a feature successfully captured in many variational calculations. Comparison of theoretical and experimental values of l_p for an inherently stiff polyelectrolyte is presented later; in this instance, the OSF model provides an excellent theoretical description.

The dependence of R_g on c_s is shown in Figure 7 for a high M sample of poly(2-vinyl-pyridiniumethyl bromide) (67). During a 3-orders-of-magnitude increase of c_s, R_g drops by approximately a factor of 4. The drop is sensitive to counterion identity, especially when c_s exceeds 0.1 M. The same investigation found that co-ion identity was unimportant to R_g over the same c_s range. Variational models that allow for hydrophobicity of segments and variable fractions of condensed counterions were reported to capture these trends well (67). Other investigators (89,91,92), however, were able to explain similar trends successfully through the OSF model, and still others reported trends inexplicable through any of the existing models (93); so the correct approach for flexible polymers remains uncertain.

Structure of Semidilute and Concentrated Polyelectrolyte Solutions

The properties of a single polyelectrolyte chain can be readily examined only in dilute solution, where on average, individual polymer molecules are widely separated. Most technological applications employ polyelectrolytes in semidilute or concentrated solutions, environments in which the polyelectrolyte coils overlap and perhaps entangle with one another. Unfortunately, many of the properties of semidilute and concentrated polyelectrolyte solutions are not well understood. The crossover from dilute to semidilute occurs at a value of c termed the critical overlap concentration c^*. As with neutral polymer solutions, the crossover is not abrupt, and so c^* is properly interpreted as a mean value characterizing a broad c range. The overlapping of polyelectrolyte chains at c larger than c^* causes solution thermodynamic properties to lose their dependence on polyelectrolyte molecular weight M, and instead, these properties depend on the solution's correlation length ξ_s, effectively the average mesh size of the fluctuating network formed by overlapping chains (94). At c^*, $\xi_s \approx R$, and above c^*, $\xi_s < R$. In semidilute or concentrated polyelectrolyte solutions, interactions between segments along the chain backbone separated by distances greater than ξ_s are screened by the presence of interposing segments attached to other chains.

Closely packed but nonoverlapped chains fully occupy a polymer solution at c^*, and so the concentration of segments inside any one chain domain approximately matches the solution's bulk segment concentration. The value of c^* thus can be estimated as the ratio of M to the average volume pervaded by a chain in dilute solution. Ignoring unimportant order unity geometric prefactors,

$$c^* \approx \frac{M}{N_a R^3} \tag{21}$$

The strong dependence of R on added electrolyte concentration implies that c^* for polyelectrolytes can vary greatly with solution conditions. Especially for salt-free polyelectrolyte systems, electrostatically driven chain swelling can strongly lower c^* from values expected for a neutral polymer. Dilute, salt-free polyelectrolyte systems are for this reason rarely examined. Dautzenberg (95) provided a model calculation of c^* for sodium poly(styrene sulfonate) of degree polymerization 10^4 dissolved in water without any added low molar mass electrolyte; using versions of equations 17 and 21 with added prefactors (73), he found $c^* \approx 6 \times 10^{-7}$ g/cm^3. However, applying the OSF model (58) in a similar calculation for a solution containing a relatively modest level of added monovalent electrolyte, $I = 0.01\ M$, he obtained $c^* \approx 6 \times 10^{--4}$ g/cm^3, an enhancement of c^* by 3 orders of magnitude.

As the previous section illustrated, different theories provide different values of R, making a theoretical assessment of c^* problematic. Substituting measured value of M and R into equation 21 offers the best way to determine c^*. Although flexible polyelectrolyte coils overlap above c^*, these coils are not necessarily entangled. As demonstrated by Boris and Colby (96) through measurements of the c dependence of viscosity, the polyelectrolyte concentration c_e required for onset of entanglement may be substantially higher than c^*.

To understand how chain–chain interactions affect polyelectrolyte solution properties at concentrations above c^*, many investigators have developed "cell" models that assign to each polyelectrolyte chain a nonoverlapping, concentration-dependent volume (7,25,41,97). Most often, the chains are regarded as infinitely long thin cylinders or lines spread uniformly in space but mutually aligned. Each chain then lies on the centerline of a cylindrical volume that possesses an outer radius inversely proportional to $c^{-1/2}$. For one common model, the Poisson–Boltzmann cell model, the potential field and ion distributions are solved within a single cell by assuming that radial gradients vanish at the volume's outer radial surface. From these distributions, both thermodynamic and dynamic properties of the polyelectrolyte and its surrounding electrolyte ions can be solved without further consideration of neighboring chains. Although providing insights and qualitative trends, cell models have a major drawback in their assumption that polyelectrolytes assemble into identical, space-filling cells. Such ordered structures are rarely, if ever, found in real polyelectrolyte solutions.

The understanding of structure in dilute, semidilute, and concentrated polyelectrolyte solutions remains incomplete. For polyelectrolyte systems that do not develop long-range order (ie, form mesophases) Odijk (98), Pfeuty (57), and de Gennes and co-workers (73,99) first proposed theoretical models for electrostatically induced solution structure, and others subsequently built upon their works (77,83,100–106). Dobrynin and co-workers developed a generalized scaling formalism for predicting thermodynamic and transport properties of both dilute and semidilute solutions of flexible polyelectrolytes (83). Rather complicated state diagrams distinguishing a variety of solution regimes (up to 10) were proposed by these investigators and others (49,65,77,84,107,108). The complexity of such diagrams arises from the interplay of intrinsic chain stiffness, electrostatic chain stiffness, chain entanglement, screening by electrolyte, intrinsic backbone hydophobicity, concentration of dissociated counterions, etc, as temperature, polymer concentration, and electrolyte concentration vary. At the current time, experimental methods have not caught up with theory, and the proposed state diagrams have not been confirmed.

Electrostatic repulsions in nearly salt-free solutions create sufficient order for the appearance of a well-defined peak in the low angle scattered intensity (107–114). In a plot of scattered intensity versus scattering vector q, Figure 8 displays how these peaks vary with c (114). Analogous peaks do not occur for flexible neutral polymers. When polyelectrolyte chains are dilute (but for c not too far below c^*), the angular position of the peaks is associated with the average distance d between physically separated chains; d is measured and predicted to be proportional to $c^{-1/3}$ (73,107,115). The spacing arises from the electrostatically induced liquid-like order in chain locations created when the electrostatic energy imposed through neighboring chains exceeds any given chain's thermal energy. When the polyelectrolyte chains are semidilute, the scattering peak's angular position reflects the value of ξ_s; ξ_s is measured and predicted to be proportional to $c^{-1/2}$ (57,73,99,101,107,110,111,113,115,116). In the so-called isotropic model, the scattering peak for a semidilute polyelectrolyte solution is attributed to the presence of a correlation hole of size κ^{-1} about each chain segment.

Considerable experimental evidence points to the presence of attractive electrostatic interactions between like-charged polyelectrolytes in simple electrolyte

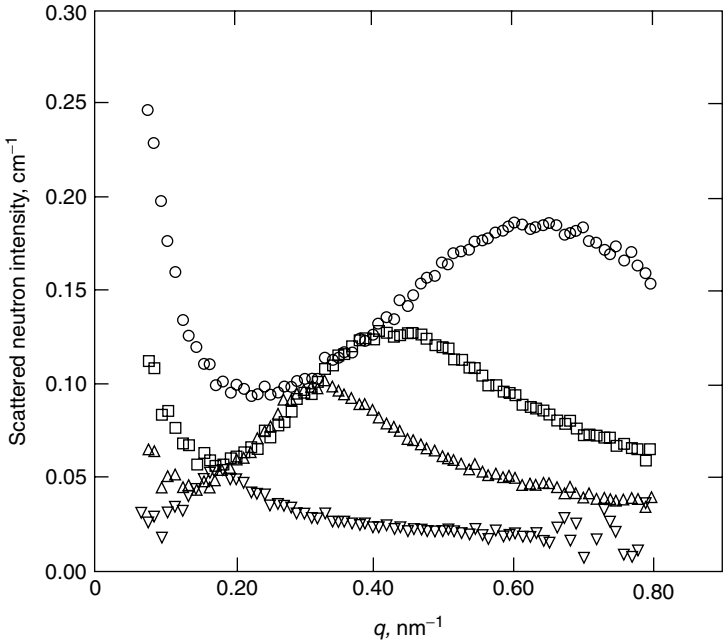

Fig. 8. Small-angle neutron scattered intensity plotted versus scattering vector q for salt-free deuterium oxide solutions of poly(2-vinyl pyridine), which possessed a molecular weight $M = 281{,}000$ g/mol prior to 45% methyl quaternization. Four different polymer concentrations were examined: 22 g/L (circles), 8.8 g/L (squares), 4.5 g/L (upward triangles), and 2.2 g/L (downward triangles). Adapted from Ref. 114.

solutions (114,117,123). One type of evidence is an upturn in scattered intensity in the low q range, as demonstrated in Figure 8. Attractive interactions would explain the aggregates or ordered domains that are often reported in semidilute and concentrated polyelectrolyte solutions. Because attractive interactions are not consistent with standard mean-field formalisms (Poisson–Boltzmann, Debye–Hückel) for electrostatic interactions, numerous efforts have been undertaken to augment these formalisms so as to admit such interactions (11,33,104,124–134). No consensus has yet been reached about the validity of extended formalisms. Indeed, the existence of attractive interactions between polyelectrolytes in a solvent containing only monovalent electrolyte ions remains a subject of debate. Experimental evidence for attractive electrostatic interactions in a solvent containing multivalent electrolyte ions, however, is overwhelming. For the multivalent case, attractions have been explained through coupled fluctuations in ion density (11,12,124) or short-range correlated order in condensed ions (132). Several theories predict that in more concentrated polyelectrolyte systems attractive electrostatic interactions might derive from potentials of mean force even when the pairwise interaction potentials are purely repulsive (104,133).

Understanding of structure in polyelectrolyte solutions at c well above c^* is poor, with many predictions but little experimental support for additional transitions as c increases (65,108). Characteristic features in rheology and scattering

data reveal transitions associated with the onset of chain entanglement and the crossover from semidilute to concentrated (96,108). Even under salt-free conditions, electrostatic interactions in concentrated solutions will be screened heavily by liberated counterions, leading to structure and properties comparable to a swollen neutral polymer solution. Experimentally, preparing concentrated, homogeneous polyelectrolyte solutions is usually difficult.

Solubility and Phase Behavior of Polyelectrolyte Solutions

Polyelectrolyte solutions can display a complex phase diagram strongly affected by the type and concentration of any added electrolyte (135–141). Figure 9 plots the phase behavior of sodium poly(vinyl sulfonate) in aqueous solutions varying in the concentration of added sodium chloride (135); the ordinate of the plot is the cloud point temperature T_p, indicating the first appearance of cloudiness as the solution is cooled. In this monovalent electrolyte, the polymer roughly obeys a standard, Flory–Huggins-type phase behavior, as indicated by the presence of

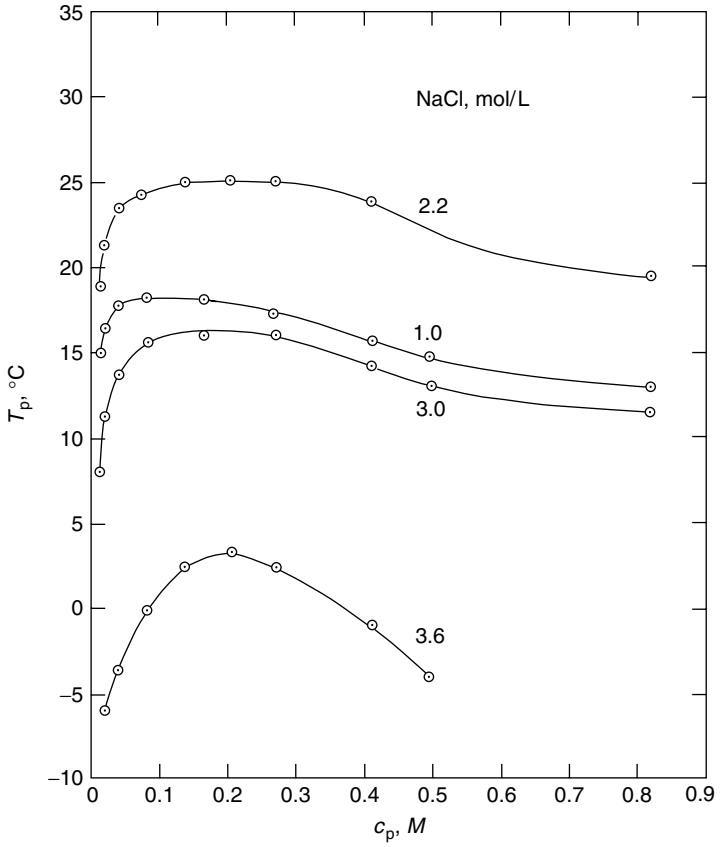

Fig. 9. Phase separation temperatures T_p plotted versus the concentration c_p of sodium poly(vinyl sulfate) at constant concentrations of NaCl. Adapted from Ref. 135.

an upper critical solution temperature at all electrolyte concentrations. A closer examination reveals less expected trends, such as an increase and subsequent decrease of the critical temperature with increasing electrolyte concentration. The rise of the critical temperature with increasing electrolyte concentration can be rationalized in terms of weakened electrostatic repulsions between polyelectrolyte chains when the electrolyte concentration is high. As electrostatic repulsions weaken, the core attractive segment–segment interactions of the uncharged polymer begin to dominate and polyelectrolyte insolubility eventually ensues (ie, salting out). In the absence of charge, most polyelectrolytes are hydrophobic, and so this sort of insolubility is expected but not always observed. The resolubilization or "salting in" of this polymer at higher sodium chloride concentration is more difficult to explain, although such resolubilization is not rare. Resolubilization may reflect specific chemical interactions of electrolyte ions with polyelectrolyte or development of a dense counterion layer near the backbone that overcompensates the polyelectrolyte's fixed charge. Computer simulations of ion distributions near polyelectrolytes often observe spontaneous overcharging at high electrolyte concentrations due to short-range correlations in ion placement.

Reliable theories that accurately correlate or predict polyelectrolyte phase diagrams are lacking. Letting electrostatic excluded volume between chain segments be modeled at the level of the Debye–Hückel approximation, a modified or effective Flory–Huggins parameter χ_{eff} can be determined via the random phase approximation (141):

$$\chi_{\text{eff}} = \chi_0 - \frac{\pi l_b f^2}{2\kappa^2 l_0^3} \tag{22}$$

where χ_0 is the interaction parameter in the absence of electrostatic interactions, a large and positive quantity for a polyelectrolyte with a hydrophobic backbone. The negative sign of the second term, which accounts for the added excluded volume derived from electrostatic interactions, confirms the tendency of repulsive forces among chain segments to heighten solubility. Substituting χ_{eff} into the standard Flory–Huggins model, shifts in the phase envelope of the type noted in Figure 9 at low electrolyte concentration can be qualitatively predicted. However, the same approach does not predict the observed change of phase envelope shape or the salting-in effect found at higher electrolyte concentrations. The Flory–Huggins model tacitly assumes the presence of only short-range forces, and so discrepancies arising from use of the model in the presence of long-range forces are not surprising.

Relatively few complete polyelectrolyte phase diagrams have been determined, and thus the universality of experimental trends remains uncertain. Even neutral water-soluble polymers display diverse phase diagrams, exhibiting in many instances a lower critical solution temperature due to entropy changes of solvent associated with hydrogen bonding; similar phenomena might be expected of polyelectrolytes. By plotting c_s vs c_p at fixed temperature, Ikegami and Imai identified two types of solubility behavior in polyelectrolyte solutions containing added electrolyte (137). In the first type, values of c_s required for phase separation are nearly independent of c_p (H-type). In the second, values of c_s at the onset of phase separation increase linearly with c_p (L-type). Subsequently, Axelos and

co-workers found that some systems exhibit intermediate behavior, the phase separation onset displaying a minimum on a c_s vs c_p plot (I-type) (138). More vexing, Prabhu and co-workers observed H-type behavior at low c_p and L-type behavior at high c_p (141), while Eisenberg and Ram Mohan reported still more complex trends (135). The phase-separated region can be characterized by the appearance of a transparent, polymer-poor liquid phase in equilibrium with a polymer-rich phase variously possessing the character of a solid precipitate, liquid, dispersion of microgel aggregates, or uniformly dense gel.

Trends in polyelectrolyte phase behavior and solubility are more complicated when solutions contain multivalent counterions. For poly(styrene sulfonate), Delsanti and co-workers demonstrated that both salting out and salting in occur for a wide range of added multivalent electrolyte types (139). The two-phase region they observed at intermediate concentrations of multivalent ion widened as valence increased and narrowed (and even vanished) as the concentration of a second, added monovalent electrolyte increased. Many investigators have discussed the possibility that multivalent counterions have an ability to form inter- and/or intramolecular ionic bridges or cross-links between polymer segments (95,136,142–144). However, phase separation requires an attractive force between chains, and the origin of this attraction remains mysterious. In addition, factors such as the intrinsic solubility of the analogous small electrolyte species, as defined by the chemical identity of the fixed charged unit and the multivalent counterion, are obviously also relevant (142). The solubility of polyelectrolytes, regarded as the maximum polyelectrolyte concentration before a gel or precipitate first forms, is nearly always lowered substantially in the presence of a substantial concentration of multivalent counterion.

Certain polyelectrolyte interactions induced by multivalent ions appear special. An important example is the condensation of dilute DNA chains by multivalent ions such as manganese, cobalt hexamine, and oligomeric polyamines (spermidine, spermine) (144–148). In this context, *condensation* refers to the compaction of a swollen DNA coil into a dense globule or toroid. The same multivalent ions cause DNA solutions to gel when DNA concentrations are high. Although some argue that periodic ordering of multivalent counterions in the space between aligned chains drives DNA to condense, others maintain that correlated ion fluctuations in this region cause condensation (11,128,130,149). A second special polyelectrolyte interaction is that between polyelectrolytes and oppositely charged organic dyes, which can either stack along the backbone or occupy preferred chain binding sites (150). A large photochromic shift in the dye's adsorption spectra often arises from stacking. Lastly, oppositely charged surfactants induce polyelectrolyte precipitation when the net surfactant charge approximately matches the net polyelectrolyte charge. Polyelectrolyte complexations resulting from these special interactions appear fundamentally different than the more universal electrolyte effects discussed here.

Thermodynamic and Transport Properties of Polyelectrolyte Solutions

Viscosity. At low c, the solution viscosity η can follow remarkably different trends for a polyelectrolyte than for a neutral polymer. With a neutral polymer,

the c dependence of specific viscosity η_s, defined as

$$\eta_s = \frac{\eta - \eta_0}{\eta_0} \tag{23}$$

where η_0 is the solvent viscosity, obeys the standard Huggins formula

$$\frac{\eta_s}{c} = [\eta] + k_H[\eta]^2 c \tag{24}$$

where $[\eta]$ is the intrinsic viscosity and k_H is the Huggins coefficient. The contribution to η_s/c due to isolated polymer chains is captured in $[\eta]$, while the contribution due to binary chain–chain interactions is captured in k_H. Contributions from higher order chain–chain interactions are neglected in the Huggins formula but can safely be ignored when c is below c^*. Molecular theories show that for neutral chains $[\eta]$ is proportional to the average hydrodynamic volume V_h pervaded by a single chain divided by the chain's molecular weight M, ie, $[\eta] \sim V_h/M$ (151). Further, V_h is proportional to the cube of the chain's hydrodynamic radius: $V_h \sim {R_h}^3$. Finally, R_h can often be expressed as a power law in M, ie, $R_h \sim M^\nu$, when M is sufficiently large. Putting these statements together, $[\eta]$ can generally be connected to M as $[\eta] \sim M^{3\nu-1}$. At large M, the excluded volume parameter ν provides an indication of chain conformation: for a dense spherical globule, $\nu = 1/3$; for a flexible chain in a theta solvent, $\nu = 1/2$; for a flexible chain in a good solvent, $\nu \approx 3/5$; and for a rod-like chain, $\nu = 1$.

At high concentrations c_s of added electrolyte, electrostatic interactions between polyelectrolyte chain segments are heavily screened, and polyelectrolyte solutions behave similarly to neutral polymer solutions, with the c dependence of η_s/c in accord with the Huggins formula. At somewhat smaller values of c_s, the expansion of polyelectrolyte chains by intramolecular electrostatic repulsions is reflected in elevated values of $[\eta]$, but again, η_s/c follows the Huggins formula. When there is little or no added electrolyte, the situation becomes more complex. As shown in Figure 10, plots of η_s/c vs c for solutions of poly(styrene sulfonate) containing low concentrations of sodium chloride display a pronounced maximum. The presence of the maximum is inconsistent with the Huggins formula. As shown in the same figure, varying c_s causes the position of the maximum to move in a way that maintains rough equality between the concentrations of liberated counterions and added electrolyte.

To model the anomalous behavior of η_s/c at low c_s, Fuoss and Strauss (154–157) long ago proposed an empirical relationship to replace the Huggins formula:

$$\frac{\eta_s}{c} = \frac{A}{1 + Bc^{1/2}} \tag{25}$$

where A and B are constants. Diluting a polyelectrolyte solution with solvent aliquots containing a low but constant value of c_s reduces I because polyelectrolyte solutions at lower c contain correspondingly fewer counterions. Configuration-based models for trends in η_s/c attribute the anomalous polyelectrolyte viscosity behavior to electrostatically driven chain expansion as I changes (157–162). In

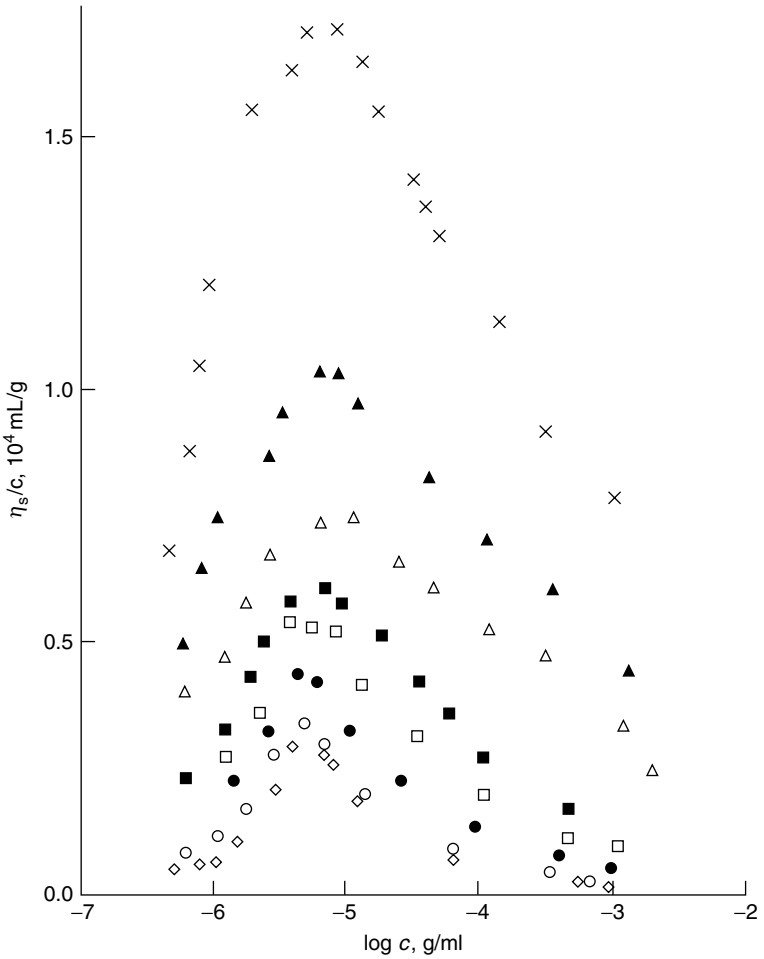

Fig. 10. Molecular weight M dependence of reduced viscosity η_s/c plotted against polymer concentration c_p for sodium poly(styrene sulfonate) in nearly salt-free solution. M, g/mol: × 690,000; ▲ 345,000; △ 212,000; ■ 177,000; □ 138,000; ● 88,000; ○ 31,000; ◇ 16,000. Adapted from Ref. 152, which uses data from Ref. 153.

the limit of infinitely small c, some have suggested that chains in salt-free solution become rod-like (157–159). This expectation is supported by the observed proportionality of A with the second power of M (163), a feature consistent with a solution containing rods. Also, the configuration-based models suggest that the maximum in η_s/c can be eliminated by adding sufficient electrolyte ions during dilution to compensate for the loss of liberated counterions, a procedure termed *isoionic dilution*. Indeed, the maximum disappears when isoionic dilution is followed (164,165). This last observation is important, as measurements of $[\eta]$ are important for polyelectrolyte characterization, and isoionic dilution appears the only method that can provide reliable values of $[\eta]$ at low c_s.

The Fuoss–Strauss formula has obvious flaws, perhaps most significantly, it does not predict the observed maximum in plots of η_s/c vs c. Strong evidence also

suggests that polyelectrolytes in salt-free solution do not fully extend at low c and that electrostatic interactions between chains influence η significantly (166–168). Other configuration-based models have subsequently appeared, incorporating increasingly sophisticated molecular dynamics to explain the drop of η_s/c at finite c (73,83,100,103,162). Many of these models recognize that in the region where η_s/c drops, c lies near or above c^*, and so an accounting of configurational constraints associated with chain–chain interactions may be needed.

Competing, nonconfiguration-based models for polyelectrolyte viscosity also have appeared, motivated largely, but not entirely, by observations that rigid, charged colloids also display a maximum in plots of η_s/c vs c (169–176). In the colloidal systems, the maximum is attributed to the impact on viscosity of long-ranged interparticle electrostatic interactions, a phenomenon sometimes termed the *secondary electroviscous effect*, which can be assessed at various levels of approximation by mode-coupling theories (177). From this perspective, the linear Huggins equation fails at low c_s because the primary interactions between chains are electrostatic, not hydrodynamic as this equation assumes; the interpretation is also consistent with the appearance and c dependence of the small-angle scattering peak observed for dilute polyelectrolytes under the same solution conditions. Transforming the mode-coupling principles to polyelectrolytes, Rabin and co-workers (153,170–172) proposed a phenomenological equation:

$$\frac{\eta_s}{c} = \frac{Ac}{\kappa^3} \tag{26}$$

where A is a constant proportional to the product $R_h l_b^2$. In this equation, a maximum in η_s/c derives from the c dependence of κ^{-1}. At low c, most electrostatic screening is by added or ambient electrolyte, but at high c, most electrostatic screening is by liberated counterions; the maximum in η_s/c occurs in the crossover region where both contributions are almost equal. For c below the maximum, the invariance of κ^{-1} implies that meaningful extrapolations to obtain $[\eta]$ are possible although perhaps difficult. For c above the maximum, a decay of η_s/c proportional to $c^{-1/2}$ is found, consistent with the Fuoss–Strauss formula. The location of the maximum itself is independent of M, consistent with experiment. Although lacking in rigor, the preceding formula accounts for most observed trends. The formula may fail to predict the impact of chain topology on η_s/c in the low c regime (161,178). Newer conformational models that do not rely on the secondary electroviscous effect can also rationalize a peak in η_s/c under certain conditions (160,162).

The dependence of $[\eta]$ on c_s has been correlated with various theoretical and phenomenological expressions, of which two are shown below (76,164,179,180):

$$[\eta] = [\eta]_\infty + Bc_s^{-1/2} \tag{27}$$

$$[\eta] = [\eta]^0 \left(\frac{c_s}{c_s^0}\right)^{-m} \tag{28}$$

where $[\eta]_\infty$ is the asymptotic value of $[\eta]$ at high c_s, and $[\eta]^0$ is the value of $[\eta]$ at an arbitrary reference value of c_s designated $c_s{}^0$. The constant B incorporates

nonelectrostatic contributions to excluded volume and chain stiffness. Values of the parameter m measured by experiment vary between 0.06 and 0.6, with higher values associated with more flexible polyelectrolytes (152). The two expressions obviously can lead to significantly different dependences of $[\eta]$ on c_s. At large enough M, relationships between $[\eta]$ and M for polyelectrolytes follow the standard Mark–Houwink formula

$$[\eta] = kM^a \tag{29}$$

which introduces the semiempirical Mark–Houwink coefficients k and a ($=3\nu-1$). At lower values of M, the complex conformational trends of polyelectrolytes make a simple scaling formula of this type less useful. As per the previous discussion, for characterization purposes, $[\eta]$ should be measured at high c_s, if possible, or alternatively by isoionic dilution at low c_s. Many values of k and a have been tabulated for polyelectrolytes (181), facilitating the determination of M by measurements of $[\eta]$; experimental methods and analysis are exactly as for neutral polymers. At large M, extreme care in the experiment may be needed to avoid artifacts due to shear-thinning of η; such shear-thinning is a larger problem for polyelectrolytes than neutral polymers, especially when c_s is small (165,168).

Little effort has been expended for polyelectrolytes to measure rheological properties other than η at values of c near and below c^*. Several measurements of the storage and loss modulus for dilute flexible polyelectrolyte solutions have been interpreted in terms of shifts in the longest chain relaxation time as the polyelectrolyte expands and contracts (182,183). The c dependence of η reflects the onset of chain entanglement well above c^* through a sharp upward transition in slope (96,184). In the semidilute but unentangled region, measured linear viscoelastic properties can be interpreted via a modified Rouse theory, and at the higher concentrations associated with chain entanglement, these properties can be interpreted via a modified reptation theory (184). Conditions that govern polyelectrolyte entanglement, however, are not understood.

Titration. Polyelectrolytes that dissociate as polyvalent weak acids or bases in an aqueous medium can be titrated with strong acid or base for the purpose of characterizing or varying the charge density. For a low molecular weight monoprotic acid, the degree of dissociation α closely follows the classic Henderson–Hasselbalch equation

$$pK_a = pH + \log\frac{1-\alpha}{\alpha} \tag{30}$$

where pK_a is the negative logarithm of the acid equilibrium constant K_a. This equation predicts that α rises sharply from zero to unity over a narrow pH window straddling the value of the acid's pK_a. Titration curves for diprotic acid and triprotic acid are not so simple, and thus complex trends are not be unexpected for polyelectrolytes, which possess a much greater number of dissociating sites. Indeed, α for polyelectrolytes typically varies across a large range of pH, and unlike low molecular weight acids or bases, depends strongly on I. With such interfering features, assigning a unique pK_a to a polyelectrolyte becomes problematical, and the well-defined pK_a of the low molecular weight acid or base corresponding to the repeat unit has little direct relevance.

Complexities arise in polyelectrolyte titration for a simple reason: the charge density of the chain changes during titration, altering the attractive electrostatic interactions between charged chain and oppositely charged titrant ion (185). For instance, if the fully ionized form of a polyelectrolyte such as poly(acrylic acid) is titrated with H^+, the strong attraction of the negatively charged polymer for H^+ at high pH weakens as more H^+ ions associate with the chain. Indeed, because the fully ionized chain is so negatively charged, H^+ associates with the polymer at pH values much above those at which H^+ associates with a hypothetical, isolated repeat unit. Although the pK_a of acrylic acid is 4.25, poly(acrylic acid) at pH 6.0 is about 20% protonated; by comparison, at the same pH acrylic acid is essentially unprotonated.

Extending the Henderson–Hasselbalch equation for a polyelectrolyte containing weak acid units, the negative logarithm pK_{app} of an apparent polyelectrolyte dissociation constant K_{app} can be determined from titration measurements using the following definition (186):

$$pK_{app} = pH + \log\frac{1-\alpha}{\alpha} \tag{31}$$

The value of K_{app} lies below the intrinsic dissociation constant K_a of an isolated acidic repeat unit, and as described above, typically decreases with increasing α because of enhanced electrostatic attractions between H^+ and negatively charged polyelectrolyte. A relationship between pK_{app} and pK_a was derived by Overbeek and others (53,185,187,188) through introduction of $dG_{el}/d\alpha$, the electrostatic contribution to the free energy change associated with transfer of a proton from infinity to the charged chain backbone:

$$pK_{app} = pK_a + 0.4343\left(dG_{el}/d\alpha\right)/RT \tag{32}$$

If all ions dissociated independently, $dG_{el}/d\alpha$ would be zero, while in the Debye–Hückel approximation, $dG_{el}/d\alpha$ is linear in α. In the preponderance of cases, $dG_{el}/d\alpha$ increases with α, the rate of the rise lessened at larger I (189,190); the variation of $dG_{el}/d\alpha$ with I in these situations mainly reflects the screening of electrostatic interactions between protons and the chain. A few polyelectrolytes display different behavior, pK_{app} showing a maximum followed by a minimum as α increases (186). A sharp conformational change such as helix-to-coil transition typically underlies a nonmonotonic dependence of pK_{app} on α.

Deriving a theoretical expression for pK_{app} requires evaluation of an electrostatic model for the polyelectrolyte chain, a procedure with significant uncertainties and much analytical and/or computational difficulty. Consequently, two empirical approaches are often employed to treat experimental data. In the first, one considers a modified Henderson–Hasselbalch equation, as for example, the form shown below which includes a single empirical parameter n (187,191):

$$pK_{app} = pH + n\log\frac{1-\alpha}{\alpha} \tag{33}$$

Values of pK_{app} and n obtained by fitting experimental titration data can reasonably correlate such data accurately over a range of α near 0.5, but the

fitted values vary strongly with c_s. Other modifications that also introduce fitting parameters to the Henderson-Hasselbalch equation have been proposed (192). The second approach represents titration data as the difference

$$\Delta pK(\alpha) = pK_{app} - pK_a \tag{34}$$

with the constant pK_a determined by extrapolation to $\alpha = 0$ (189). The function $\Delta pK(\alpha)$ is sometime replaced by $\Delta G_{el}(\alpha)$, obtained by integrating equation 32 (186):

$$G_{el}(\alpha) = 2.303RT\int_0^\alpha \Delta pK(\alpha)\ d\alpha \tag{35}$$

The second approach represents titration data in the form of a constant (pK_a) and a function [either $\Delta pK(\alpha)$ or $G_{el}(\alpha)$] rather than by two or more constants, as done in the first approach. Multiplying $G_{el}(\alpha)$ by the number of charges on the chain provides the total electrostatic contribution to the chain's free energy.

Viewing titration as a chain-charging process, one can derive a formula relating $\Delta pK(\alpha)$ to the electrostatic potential $\psi_s(\alpha)$ at chain sites where protons are bound (38,186,190):

$$\Delta pK(\alpha) = 0.4343\frac{e\psi_s(\alpha)}{kT} \tag{36}$$

Under the assumption that free energy changes during titration are purely electrostatic, this formula allows titration data to be assessed against electrostatic chain models that predict $\psi_s(\alpha)$. However, to interpret a polyelectrolyte's titration curve quantitatively requires a full understanding of how the chain's overall free energy varies upon association with protons, and this understanding may incorporate nonelectrostatic factors such as the local spacing of charge groups, chain flexibility and local conformation, and counterion hydrophobicity and size. A counterion condensation model incorporating some of these effects has been proposed by Manning (38,193).

Nonelectrostatic factors do not affect the end points of a titration, and thus when performed properly, titrations provide unequivocal information concerning the number of fixed charges on a polyelectrolyte just as they do for low molecular weight compounds.

Osmotic Pressure. The osmotic pressure π is a fundamental thermodynamic property that measures the activity of solvent in solution after the solution is equilibrated across a solute-impermeable membrane against a reservoir of pure solvent. For a neutral polymer solution, π can be expanded in c according to the well-known formula

$$\frac{\pi}{c} = RT\left(\frac{1}{M_n} + A_2c + \cdots\right) \tag{37}$$

where M_n is the polymer's number-average molecular weight, and A_2 is the second virial coefficient, reflecting nonideal chain mixing when its value is nonzero. With

nonideal mixing, chain locations in solution are correlated by either attractive or repulsive chain–chain interactions. Extrapolated to $c = 0$ or evaluated at theta conditions where $A_2 = 0$, measurements of π frame an absolute method for determining an unknown polymer's average molecular weight. Equally important, these measurements provide a means to evaluate A_2, and thus solvent quality, if π is obtained as a function of c at constant M_n.

For a polyelectrolyte solution, the situation is entirely different, as each dissociated counterion can contribute nearly as much to π as the polymer itself. If each chain dissolved in a salt-free solution dissociates Z^* monovalent counterions, the value of π can be written as, in the limit of ideal mixing (an inappropriate approximation),

$$\frac{\pi}{c} = \frac{RT}{M_n}\left(1 + Z^*\right) \tag{38}$$

In the usual case, with $Z^* \gg 1$ and $Z^* \sim M_n$, measurements of π extrapolated to zero c do not offer a way to measure M_n, as even a small variation or uncertainty in Z^* will obscure the polyelectrolyte chains' contribution to π. In general, Z^* is less than Z, the total number of fixed charges on the chain, owing to effects such as counterion condensation that reduce counterion activity. The reduction of π as a consequence of reduced counterion activity defines the osmotic coefficient ϕ_o (95,194):

$$\frac{\pi}{c} = \frac{RT}{M_n}\phi_o\left(1 + Z\right) \tag{39}$$

The same concepts apply to a polyelectrolyte solution containing added electrolyte. In the presence of a monovalent electrolyte at concentration c_s,

$$\pi = \phi_o RT\left[\left(1 + Z\right)c_m + 2c_s\right] \tag{40}$$

where c and M_n from the previous expression have been replaced by c_m, the molar concentration of polymer molecules. When the first term exceeds the second for a highly charged polyelectrolyte, experimentally determined values of ϕ_o are much less than unity (as small as 0.1), indicating that solutions at low electrolyte levels or high polymer concentration are strongly nonideal.

Although their theories differ, Lifson and Katchalsky (97) and later Manning (13) presented identical predictions for ϕ_o in dilute, salt-free polyelectrolyte solutions. Extrapolating ϕ_o to its value at zero c_p, experimental values consistent with their limiting theoretical predictions were obtained for both univalent and divalent counterions, as shown in Figure 11 (195–198). Experimentally, when M is large, values of ϕ_o depend little, if at all, on M. Low values of ϕ_o demonstrate that highly charged polyelectrolytes strongly suppress the activity of counterions, a finding in accord with counterion condensation, or more generally, the strong electrostatic interaction of counterions with polyelectrolyte chains. Experimentally, values of ϕ_o in salt-free solution slightly increase with c_p (195–198), as qualitatively captured by the Poisson–Boltzmann cell model of Lifson and Katchalsky (97). However, this and other simple electrostatic models cannot predict observed

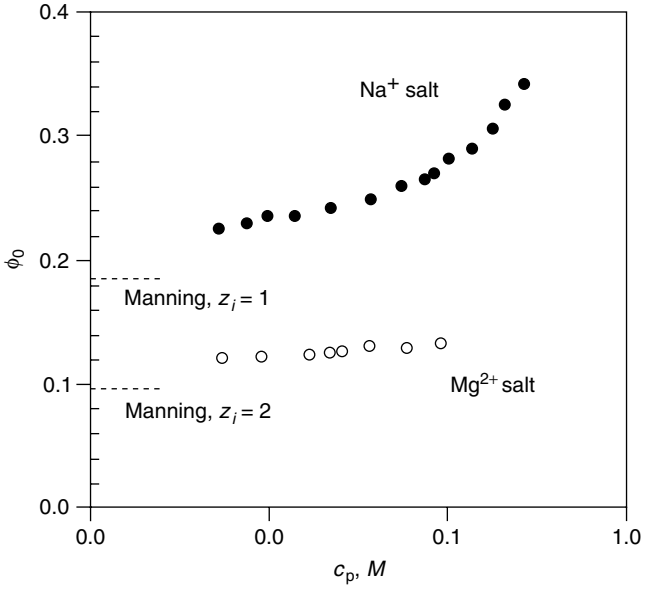

Fig. 11. Osmotic coefficients ϕ_o of poly(styrene sulfonate) with $M = 40{,}000$ g/mol plotted against polymer concentration c_p for salt-free solutions. Darkened and opened circles are for the Na^+ and Mg^{2+} salts of the polymer, respectively. The parameter z_i is the counterion valence. Data are from Refs. 195 and 196.

changes in ϕ_o when ε varies, a finding arguing for the presence of additional interactions between polyelectrolyte and counterion, such as ion pairing (199). Also, experimental data indicate that small counterions associate with polyelectrolytes to a greater extent than larger ones, a feature not explainable through a mean-field ion cloud description.

The osmotic pressures of polyelectrolyte solutions are most often measured in the presence of a membrane permeable to solvent and small ions but not to polyelectrolyte. The chemical potentials of the added electrolyte and solvent on each side of the membrane in this instance match, a condition defining Donnan equilibrium (200). Assuming ideal chain mixing, the quantity measured here is the Donnan osmotic pressure π_d, which can be equated to the difference of the osmotic pressures π and π', as defined above, between the inner (polymer-containing) and outer (polymer-free) compartments equilibrated in the presence of the electrolyte across the membrane:

$$\pi_d = RT\{\phi_o[(1+Z)c_m + 2c_s] - \phi_o' 2c_s'\} \tag{41}$$

where unprimed and primed quantities are evaluated at conditions of the inner and outer compartments, respectively. The need for electroneutrality establishes that $c'_s \neq c_s$, a feature referred to as the Donnan effect. Balancing the appropriate chemical potentials and imposing electroneutrality, the expression for π_d can be rearranged to a simpler form (95,200)

$$\frac{\pi_{\mathrm{d}}}{c} = RT\left(\frac{1}{M_{\mathrm{n}}} + \mathrm{A}_2^{\mathrm{d}}c + \cdots\right) \tag{42}$$

of similar appearance to the expression for the osmotic pressure π of a neutral polymer solution. The quantity $A^{\mathrm{d}}{}_2$ is the Donnan second virial coefficient (200):

$$A_2^{\mathrm{d}} = \frac{\phi_{\mathrm{o}}^2 Z^2}{4M_{\mathrm{n}}^2 c_{\mathrm{s}}} \tag{43}$$

The major contribution to $A_2{}^{\mathrm{d}}$ is the mismatch between c'_{s} and c_{s}, and as one consequence, $A_2{}^{\mathrm{d}}$ is independent of M_{n} (remembering that $\mathrm{Z} \sim M_{\mathrm{n}}$). The asymmetric distribution of small ions is such that the added electrolyte ion bearing the same charge as the polyelectrolyte is concentrated in the outer compartment while the converse is true for the added electrolyte ion of opposite charge.

The value of π for a polyelectrolyte solution will generally manifest nonideal chain mixing as well as the Donnan effect. Because of intermolecular electrostatic repulsions, A_2 is nearly always positive and large for polyelectrolytes. When $A_2 \neq 0$, an approximate expression corresponding to equation 37 for a polyelectrolyte solution in Donnan equilibrium can be written as (33,37)

$$\frac{\pi}{c} = RT\left(\frac{1}{M_{\mathrm{n}}} + A_2 c + A_2^{\mathrm{d}} c + \cdots\right) \tag{44}$$

Values of $A_2{}^{\mathrm{d}}$ are experimentally found to exceed substantially those of A_2 (95).

Equation 44 demonstrates that membrane osmometry can be employed to determine M_{n} for polyelectrolytes much as the method does for neutral polymers. The experiment works best when c_{s} is high and M_{n} is low, conditions that enhance the first term of equation 42. Although polyelectrolyte molecular weights of up to 10^5 g/mol have been successfully determined by membrane osmometry (95), the application of membrane osmometry for the measurement of polyelectrolyte molecular weight remains rare. More often, researchers exploit the technique to understand the interactions of electrolyte ions with polyelectrolyte chains. Recent attention has focused on measurements of π at values of c above c^*, and investigators have shown that polyelectrolytes in the presence of added salt behave similarly to neutral polymers at these concentrations (201). Without salt, experimental trends are more complex; however, when sufficiently concentrated in polyelectrolyte, solution behavior typical of neutral polymers is again observed (202).

Diffusion. The translational diffusion coefficient D is the most commonly measured transport property of polymer solutions, but as there are several distinct types of diffusion, care must be taken to interpret D properly. For $c \ll c^*$, Brownian motion of isolated chains in a homogeneous solvent defines the dilute solution diffusion coefficient D_0. As c increases toward c^* and above, chain–chain interactions modify the friction felt during chain motion. Under these conditions, the tracer- or self-diffusion coefficient D_{tr} is measured by tracking the path of a single chain in a macroscopically uniform mixture of chains and solvent. To distinguish the test chain from neighbors so that its path can be identified, the chain

must be labeled in a way that does not modify its motion. Chain–chain interactions typically increase friction and cause D_{tr} to fall with increasing c. The Brownian motion of highly diluted chains in a gel or similar medium defines a different type of tracer diffusion experiment, one in which labeling may not be necessary to follow chain motion. When diffusion is driven by a gradient of solute concentration (more properly, solute chemical potential), the situation envisaged by Fick's law of diffusion, a diffusion experiment yields the cooperative- or mutual-diffusion coefficient D_m. In a polyelectrolyte solution, D_m must be measured in the presence of a spatial gradient only in the polyelectrolyte component, holding the chemical potentials of other components everywhere uniform. Hypothetically, one might imagine the mutual diffusion of polyelectrolyte being measured by contacting two baths of different c that had previously been brought into Donnan equilibrium (8). As does D_{tr}, D_m in a sufficiently dilute solution superimposes on D_0, but unlike D_{tr}, D_m usually increases with c.

The value of D_{tr} can be obtained from the expression governing a solute's thermally driven root-mean-square displacement $\langle r^2 \rangle$ in time interval t. In three dimensions,

$$D_{tr} = \frac{\langle r^2 \rangle}{6t} = \frac{kT}{f_{tr}} \tag{45}$$

The second half of the equality defines f_{tr}, the tracer- or self-friction coefficient. Unlike D_{tr}, which reflects only solute friction, D_m manifests both solute friction and solute thermodynamics. For a binary system of neutral polymer and solvent, the following formulas apply:

$$D_m = \frac{c_m}{N_a f_m} \left(\frac{\partial \mu_p}{\partial c_m} \right)_{T,\mu_0} = \frac{1}{N_a f_m} \left(\frac{\partial \pi}{\partial c_m} \right)_{T,\mu_0} \tag{46}$$

where μ_p and μ_0 are the polymer and solvent chemical potentials, respectively, and f_m is the solute's mutual friction coefficient. For $c < c^*$, f_m and f_{tr} both vary nearly linearly with c, obeying expressions of the type

$$f_{m,}\, f_{tr} = f_0 \left(1 + k_p c\right) \tag{47}$$

where f_0 is the friction coefficient of an isolated chain with its ion cloud, and k_p is a positive coefficient.

Assuming sufficient added electrolyte in the asymptotic limit of small c, no distinction is made between D_0, D_{tr}, and D_m. In this limit, inserting f_0 for a sphere of radius R into the expression for D_0, the Stokes–Einstein formula is obtained:

$$D_0 = \frac{kT}{f_0} = \frac{kT}{6\pi \eta_0 R} \tag{48}$$

Often, the results of diffusion experiments in dilute solution are reported in terms of the hydrodynamic radius R_h, defined through the Stokes–Einstein expression by solving for R after D_0 is measured. The reporting of R_h is common even when solute shape is far from spherical.

At large values of I, D_m is found by experiment to obey

$$D_m = D_0\left(1 + k_D c\right) \tag{49}$$

where k_D is sometimes called the virial coefficient of diffusion. This form that can be theoretically rationalized by combining equations 43, 44, 46, and 47 and then expanding for small c (8,37,203),

$$D_m = D_0\left[1 + \left(2A_2M_n + \frac{\phi_0^2 Z^2}{2M_n c_s} - k_p\right)c + \cdots\right] \tag{50}$$

The first and third terms in parentheses are usually smaller than the second, and so k_D is expected to be approximately proportional to ${c_s}^{-1}$, as indeed is observed experimentally (37,92,203–206). The primary c_s influence on D_m at large I is through D_0; increasing c_s causes polyelectrolyte coils to contract, raising D_0 (91,92,206). The strong dependence of D_0 on c_s is shown for poly(styrene sulfonate) in Figure 12 (92). Equation 50 remains suspect, since polyelectrolyte solutions at large I contain at least two additional components, the counterions and the coions, not considered in equation 46, one of the relationships on which equation 50 is based. Polyelectrolyte motions are strongly influenced by nearby ions because the polyelectrolyte and the ions move within a common electrostatic field.

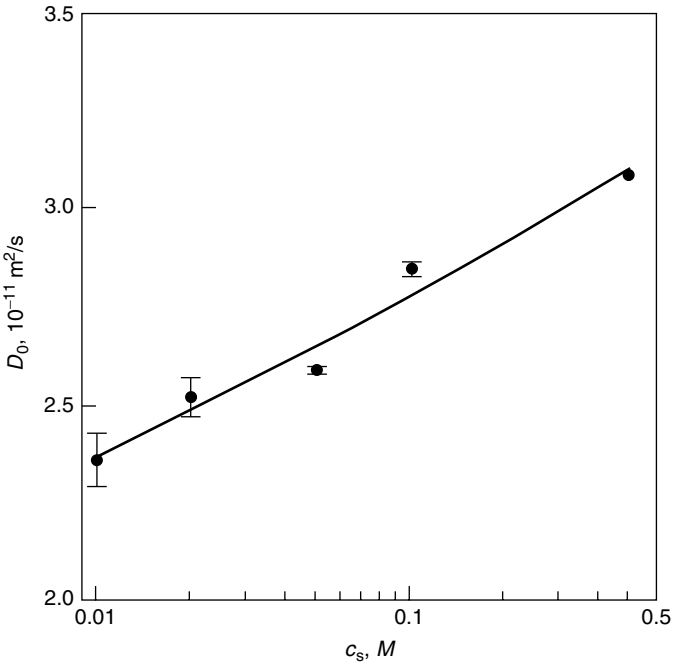

Fig. 12. Dilute solution diffusion coefficient D_0 of sodium poly(styrene sulfonate) as a function of added concentration c_s of NaCl. The polymer molecular weight M is 77,400 g/mol. Adapted from Ref. 92.

Fluctuations in ion density near a polyelectrolyte impose fluctuating electrostatic forces on the chain that can affect the chain's diffusion. As described by Sedlák (207), polyelectrolyte diffusion in dilute solution is "fast diffusion" because counterions cause more rapid motion in a polyelectrolyte than would be noted in an equivalent neutral chain. Several investigators have modified equation 50 to include this Nernst–Hartley-type diffusion in a consistent manner (203,206). Tivant and co-workers suggested that in a monovalent electrolyte solution at large I the enhancement of D_m by polyelectrolyte–electrolyte coupling should be expressed as (208)

$$D_m \cong D_0 \left[1 + \left(1 - \frac{2D_0}{D_1 + D_2} \right) \frac{\phi_0^2 Z^2}{2M_n c_s} c + \cdots \right] \tag{51}$$

where D_1 and D_2 are the diffusion coefficients of the counterion and co-ion, respectively. The factor in parentheses is typically close to unity at large I, allowing polyelectrolyte mutual diffusion to mimic roughly neutral polymer diffusion, albeit with the thermodynamic contribution to diffusion dominated by the Donnan effect. For small ion motions infinitely fast compared to polymer motions, equation 50 is recovered from equation 51.

At low I, the understanding of polyelectrolyte diffusion remains unsettled. Most diffusion experiments in polyelectrolyte solutions are conducted by dynamic light scattering, a method sensitive to the relaxation of the microscopic concentration fluctuations that spontaneously occur in a macroscopically homogeneous polyelectrolyte solution. The relaxation of these fluctuations is governed by mutual diffusion of polymer chains. The light scattering method can detect whether the relaxation is by a single diffusive process, and thereby monomodal, or by multiple diffusive process, and thereby multimodal. Schurr and co-workers (204) first discovered that when c is high and I is low, multimodal relaxation can occur over widely separated time scales. When two distinct diffusive modes are detected, the one that decays more rapidly is termed the *fast* mode and its effective diffusion coefficient designated D_f, while the second, less rapid mode is termed the *slow* mode and its effective diffusion coefficient designated D_s. Schurr referred to the region of solution conditions corresponding to monomodal behavior as the "ordinary phase" and that corresponding to multimodal behavior as the "extraordinary phase" (204). Equation 51 captures trends in diffusion for the ordinary phase when c is low. Figure 13 shows the emergence of two diffusive modes as a function of c.

By dynamic light scattering, a sharp shift in the intensity of scattered light and the appearance of two (or more) diffusive modes mark the onset of the extraordinary phase as c_p increases at constant c_s (118,120,204,209–215). Various empirical criteria for locating the boundary between ordinary and extraordinary phases have been proposed, the most successful establishing a threshold dependent on the ratio of c_p to c_s; the extraordinary phase normally appears when these two concentrations are roughly similar (112,118,210). However, the proposed criteria are not robust or universal (207,215,216). The fast mode originates in the electrostatic coupling of polyelectrolyte and counterions, as just described for the ordinary phase under conditions of low c and large c_s. The rapid diffusive motions of the small counterions are moderated by the slower polyelectrolyte, and

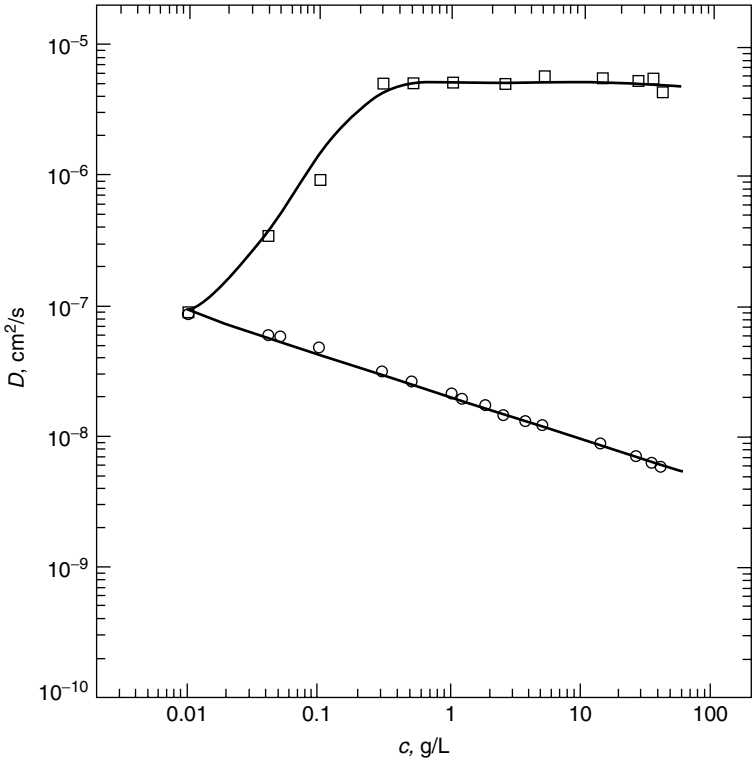

Fig. 13. Dependence of the fast (squares) and slow (circles) diffusion coefficients D of salt-free solutions of poly(styrene sulfonate) varying in polymer concentration c_p. The polymer molecular weight M is 100,000 g/mol. Adapted from Ref. 209.

simultaneously, the slow diffusive motions of the polyelectrolyte are enhanced by the faster counterions. A generalized version of equation 51 successfully explains the observed independence of D_f on M and c_p when M is large and $c_p/c_s \gg 1$. The same equation also successfully predicts values for D_f of the order 10^{-6} cm^2/s, a magnitude more typical for small molecule diffusion than for polymer diffusion. Values of Z needed to match experiment with theory, however, are often not much greater than unity, orders of magnitude smaller than the actual or effective (condensed) charge of the polyelectrolyte being studied (210,212,216,217).

The physics underlying the slow mode remain unclear, although many ideas have been suggested, such as the presence of an ordered phase, temporal aggregates, self-diffusion, or undissolved polymer (120,209,211–213,218). The structures responsible for D_s are larger than individual polymer chains, a feature taken by some to manifest the presence of attractive forces between chains. Others argue that filtration or long equilibration eliminates the slow mode, and thus its origins must be sought in kinetic rather than thermodynamic factors (207,219–221).

Techniques such as forced Rayleigh scattering, pulsed gradient NMR, and fluorescence recovery after photobleaching have recently made information concerning self-diffusion available for polyelectrolyte across the range of solution concentrations. The complex diffusion dynamics uncovered for D_m by dynamic

light scattering are not reflected in D_{tr}. As electrolyte levels rise from 0 to 1.0 M in a semidilute polyelectrolyte solution, D_{tr} usually increases by roughly a factor of about 2, reflecting alterations in coil size. Likewise, D_{tr} decreases with M and c across this range in a manner analogous to the trends expected of an unentangled polymer melt (180,212,222,223).

In polyelectrolyte systems, diffusion coefficients for species other than the polyelectrolyte may be important, especially those of counterions. In a salt-free solution, the counterion diffusion coefficient D_c at low c is depressed by the presence of polyelectrolytes, demonstrating that inherently faster counterion motions are attenuated by electrostatic interactions with slower moving polyelectrolyte. Manning developed a counterion condensation theory describing this attenuation for a salt-free solution in the limit of small c; he predicted that the ratio of D_c in the polyelectrolyte's presence to D_c in the polyelectrolyte's absence equals $0.866/|z_i|\xi$ (14). Experiments verify the predicted ξ dependence (42), but unexpectedly, the ratio also depends on c (224–226). The ratio falls rapidly from unity at low c to a broad minimum and then rises slightly to achieve a broad maximum. The maximum has been explained via a cylindrical cell model that shows increasing c electrostatically favors a shifting of the counterion distribution toward spaces between polyelectrolyte chains, a factor increasing D_c (226). However, beyond a c threshold, the density of chains become so great that counterion diffusion is physically obstructed, a factor then decreasing D_c. These shifts all occur at semidilute polymer concentrations. If the polyelectrolyte–electrolyte coupling ideas that explain D_f are correct, then D_c and D_f must be related, as recently theoretically demonstrated by Sasaki and Schipper (227).

Electrophoresis. As charged molecules, polyelectrolytes in solution migrate toward regions of lower electrostatic potential when an external electric field is applied. This electrophoretic migration can be monitored either in free solution (228) or in the presence of a separation medium imposing molecular-level geometric hindrances (229); the hindrances reduce the rate of migration compared to that in free solution. Gels, neutral polymer solutions, and other porous materials can act as effective separation media, with hindrances tailored to attenuate the migration of polyelectrolytes best according to chain size. A variety of experimental methods allow migration rates to be measured. Recently, the number of accessible medium types has expanded greatly owing to the development of capillary electrophoresis, a method allowing measurements of polyelectrolyte electrophoresis in a variety of both fluid-like and solid-like environments. The ratio of steady-state drift velocity v to the electric field strength E defines the electrophoretic mobility μ, the polyelectrolyte property measured by electrophoresis:

$$\mu = \frac{v}{E} \tag{52}$$

To distinguish results for a free solution experiment, one conducted without a separation medium, the mobility in free solution is usually written as μ_0. When the value of E is low enough to avoid field-induced distortion of the polyelectrolyte's configuration, μ is independent of E. Measurements of μ have long been a cornerstone of polyelectrolyte characterization, especially for polyelectrolytes of biological origin.

A uniform, externally applied electric field imposes four types of forces on a polyelectrolyte in free solution (228,230–232). First, the field acts directly on the fixed charge of the polyelectrolyte, producing on the chain a direct electric force F_e of magnitude EZe. Second, the field acts directly on the local excess of counterions, and since the charge of the counterion cloud is equal and opposite to that of the polyelectrolyte, produces on these ions an opposite, spatially distributed force of magnitude $-EZe$. However, because of the physical separation of counterions from polyelectrolyte, the force experienced by each ion is transmitted to the polyelectrolyte through intervening solvent only as a velocity disturbance. During the transmission, the disturbances are attenuated by viscous dissipation. Thus, the polyelectrolyte chain experiences the electric forces on counterions only vicariously, as dampened hydrodynamic forces distributed along the chain backbone. The magnitude of the overall transmitted force F_c, termed the retardation force, can be significantly less than $-EZe$. Indeed, F_c depends strongly on the spatial disposition of the counterions and thereby on κ^{-1}. When κ^{-1} is large, F_c is much reduced because the velocity disturbances propagate a long distance through solvent before impact on the chain. Third, the viscous character of the solvent resists chain translation, creating a drag force of magnitude F_d. This force is calculated as the product of v with the chain friction coefficient ζ: $F_d = -\zeta v$. Fourth, the field can distort and polarize the counterion cloud surrounding the polyelectrolyte, modifying two of the forces already described. With polarization, the force transmitted to the chain from counterions no longer can be calculated using the equilibrium structure of the counterion cloud, and the local dipole field associated with polarization reduces the electric force on the chain's fixed charges. Together, the two corrections comprise the relaxation force F_r. Summing forces on the chain at steady state (228),

$$F_e + F_c + F_d + F_r = 0 \tag{53}$$

While F_e is positive, F_c, F_d, and F_r are negative, ie, directed against the polyelectrolyte's migration. Interpreting μ_0 for a charged colloidal particle or a small electrolyte ion requires the same force balance (230).

Complications for polyelectrolytes arise from the complex architecture of the chain, poor understanding of the electrostatic interactions between counterions and polyelectrolyte, and chain flexibility. Notwithstanding complications, several observed trends in μ_0 for polyelectrolytes can readily be explained in terms of the force balance just described. For instance, irrespective of I, as seen in Figure 14, μ_0 is independent of M for high M polyelectrolytes (228,233). This trend has often been incorrectly rationalized by balancing F_e and F_d, assuming that both are proportional to M. Forcing the equality immediately leads to

$$\mu_0 = \frac{Ze}{f_0} \tag{54}$$

which is recognized as the standard Einstein formula for electrophoretic mobility of a small ion. With $Z \sim M$, constancy of μ_0 mandates that $f_0 \sim M$. However, f_0 is not proportional to M for polyelectrolytes of any conformation, as polyelectrolytes never behave as "free-draining" objects, an assumption of the Einstein formula.

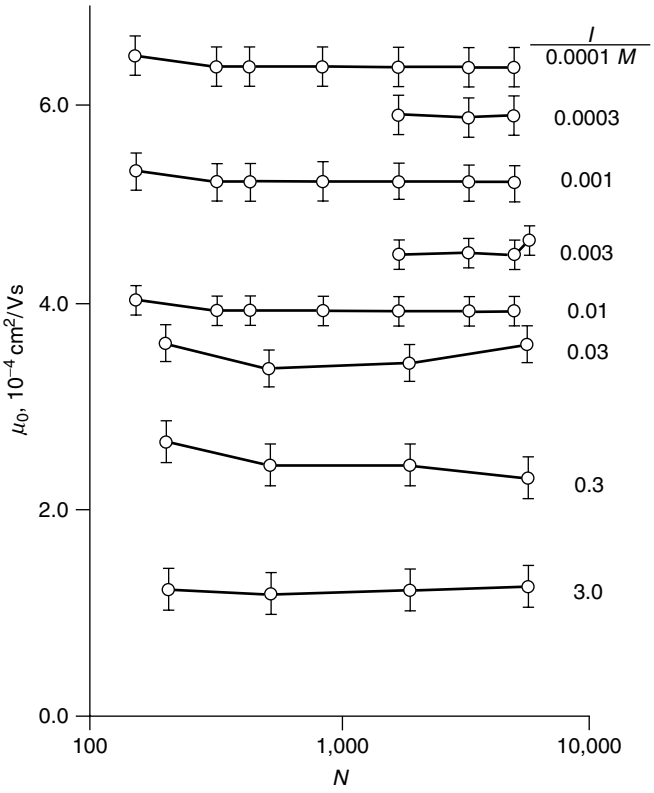

Fig. 14. Dependence of the free solution electrophoretic mobility μ_0 on degree of polymerization N for poly(styrene sulfonate) chains dissolved in NaCl solutions of varying ionic strength I. Adapted from Ref. 228.

The independence of μ on M more properly can be traced to the screening by counterions of long-ranged hydrodynamic interactions that ordinarily exist between distant chain segments. This screening has roots in F_c. The velocity disturbance propagated through solvent due to electric force acting on one chain segment is always accompanied by a comparable disturbance transmitted through solvent due to the force acting on a nearby counterion. At distances large compared to κ^{-1}, the two disturbances cancel, and for this reason, the polyelectrolyte gains apparent free-draining character. The same polyelectrolyte will not display free-draining character in a diffusion experiment (ie, D_0 will not be proportional to M^{-1}), and Z inferred by application of equation 54 to actual data is much too small (234).

A second important experimental trend interpretable through the force balance of equation 53 is the dependence of μ_0 on I at fixed M (228). As displayed in Figure 14, μ_0 drops significantly with increasing I. Again, the explanation lies in F_c. As I increases, κ^{-1} becomes smaller, and the hydrodynamic coupling of counterions to polyelectrolyte is enhanced, reducing μ_0 as F_c grows. Still another important trend, one not yet fully understood, is the dependence of μ_0 on ξ (43,46,235). Figure 15 shows that at low ξ, $\mu_0 \sim \xi$, but at high ξ, $\mu_0 \approx$ constant. One explanation for the loss of ξ dependence at high ξ is counterion condensation,

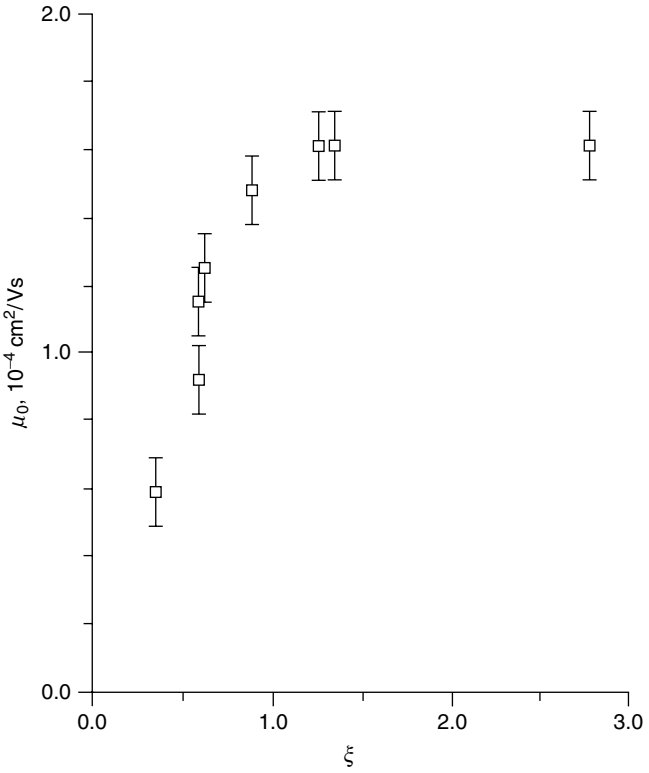

Fig. 15. Dependence of the free solution electrophoretic mobility μ_0 on dimensionless charge density ξ for equal M copolymers of acrylic acid and acrylamide. The charge density is controlled by varying copolymer composition while holding the pH high enough (pH 10.5 phosphate electrolyte) to ionize the acrylic acid units fully. From Ref. 46.

but nonlinear effects associated with F_r frame a plausible alternative explanation that remains to be explored fully.

In a separation medium such as a gel, the dependence of F_d on M is affected by the polyelectrolyte's configurational interactions with the medium, and consequently, μ becomes M dependent. Various sorts of interactions have been proposed, ranging from sieving to reptation to entropic barriers transport (229,236,237). Which type of interaction dominates depends on the heterogeneity and pore size of the medium, the size and flexibility of the polyelectrolyte, and the magnitude of the electric field. In recent years, characterization of polyelectrolytes by the traditional method of gel electrophoresis has slowly been supplanted by various capillary electrophoresis techniques, including many that exploit nongel separation media (229). In the future, characterizations may be performed in microfluidic, chip-based devices that allow precise tailoring of a patterned separation medium.

Electric and Magnetic Birefringences. In addition to causing polyelectrolyte migration, external fields can also make polyelectrolyte solutions become optically birefringent due to partial or even complete chain orientation (238,239). The birefringence Δn of a transparent medium measures how the refractive index n varies with respect to the polarization plane of propagated light. The difference

in n between light polarized parallel and perpendicular to an external alignment field defines Δn. If Δn is positive, n in the field direction is greater than n in the direction perpendicular to the field. For a polymer solution, finite values of Δn manifest preferential alignment of anisotropic chain segments. For many polyelectrolytes such as poly(styrene sulfonate), the optical polarizability of chain segments is larger perpendicular to the backbone than parallel to the backbone; in this case, the alignment of chains with respect to an electric field produces negative Δn.

Held for sufficient time in a steady field, polymer chains reach a saturating level of segmental orientation associated with their stationary birefringence Δn_s. For low magnitudes of E, Δn_s rises as the square of E, the ratio $\Delta n_s/E^2$ defining the Kerr constant K. At high enough E, Δn_s reaches an E-independent plateau corresponding to complete segment alignment. Achieving any level of segmental alignment implies the presence of permanent or induced dipoles that impose torque on the chain as the field is applied. For most polyelectrolytes, which possess no permanent dipole, the polarization of the counterion cloud by the electric field is responsible for providing the necessary induced dipole.

Several theories for the longitudinal polarizability of a counterion cloud surrounding a charged cylinder or rod have been developed, each employing a different treatment of the counterions (16,240,241). All results indicate that the polarizability of such a cylinder or rod increases approximately as the second or third power of length, a trend consistent with experiments performed on flexible polyelectrolytes under salt-free conditions (242). Worm-like chain theories, incorporating the average polarizability and optical anisotropy per segment as independent parameters, find that K/c_p in a sufficiently dilute solution has a significant dependence on l_p, and this fact allows l_p to be calculated from measurements of K/c_p (243–245). Analogously, l_p can be determined by a magnetic field alignment experiment using the measured value of CM, the Cotton–Mouton constant, which plays an analogous role to K (245–247). Figure 16 shows values of l_p as a function I for DNA examined by magnetic birefringence; data from other methods are plotted alongside, as are predictions made by the OSF model for various values of l_0. The agreement between theory and experiment and between data sets appears good.

Transient electric birefringence, the study of polyelectrolyte solutions by birefringence as a pulsed or oscillating electric field is applied, offers a powerful tool for examining both polyelectrolyte chain dynamics and structure (248–251). An external electric field can be manipulated and Δn measured over times scales short compared to those associated with chain reorientation and deformation. Thus, chain conformation can be inferred from the build up and decay of Δn as a time-dependent electric field of prescribed magnitude is abruptly applied and then removed. The field free Δn decay curves are typically fitted as a sum of exponentials, the largest of which is assigned to the longest conformational relaxation time τ_1 of the chains. According to the extended Zimm theory, the longest relaxation time of an isolated chain in a good solvent obeys

$$\tau_1 = \left(\frac{6^{3/2}}{2.38}\right)\frac{\Phi_0\eta_0}{N_a kT}R_g^3 \tag{55}$$

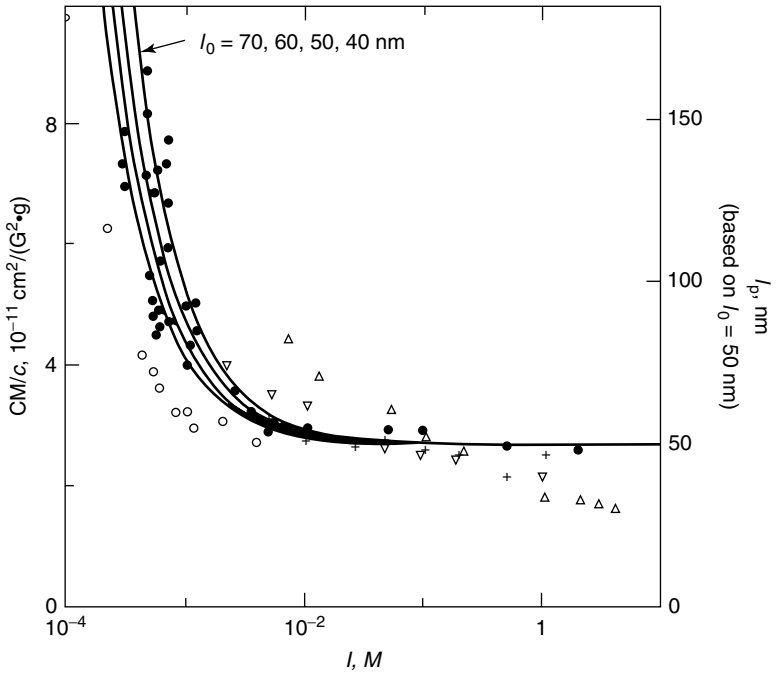

Fig. 16. Comparison of experimental values of the Cotton-Mouton constant CM (darkened circles) with theoretical (lines) and independently measured values (open symbols) of the persistence length l_p. The left and right axes have been shifted so that measured values of CM can be referenced against l_p. Theory curves are for the OSF model with l_0 between 50 and 70 nm, and l_e values from independent measurements were adjusted to the plotted l_p values by adding 50 nm. Adapted from Ref. 247.

where Φ_0 is a constant draining parameter of value 1.81×10^{23}. Values calculated by this formula agree with remarkable precision to those measured for flexible polyelectrolytes by transient electric birefringence (250). In addition, as c increases the observed values of τ_1 grow in predictable fashion (249). Figure 17 shows a sharp upward turn in τ_1 as c exceeds c^*. The presence of polydispersity, field-induced chain aggregation, or high levels of added electrolyte sometimes make electric birefringence measurements difficult.

Electric and magnetic birefringences are but two examples from a class of experimental methods that probe molecular structure and dynamics while external fields are applied to a homogeneous polyelectrolyte solution. Another important member of this class, one that remains poorly understood, is dielectric relaxation, which for a polyelectrolyte measures polarization of the counterion cloud as a function of frequency (45,252,253). Multiple relaxations are noted, including a low frequency mode associated with polarization of free ions over the whole length of the chain and a faster mode variously associated with polarization of condensed ions over a single segment, motion of counterions perpendicular to a segment, segmental reorientation, or motion of counterions over the screening length.

Conductivity. Polyelectrolyte solutions contain a variety of ionic species, including the polyelectrolyte itself, which move electrophoretically toward either

anode or cathode when an electric field is applied, and as a consequence of these motions, the solutions carry current. The specific conductance χ, characterizing the current-carrying ability of a solution, is defined as the reciprocal of the specific resistance; the specific resistance is the resistance in ohms across 1 cm of solution that has a cross section of 1 cm^2; the units of χ are $ohm^{-1} \cdot cm^{-1}$. In the discussion that follows, any contribution to χ from pure solvent is ignored; experimentally, any solvent contribution can simply be subtracted from the solution measurement. The equivalent conductance Λ for a polyelectrolyte solution is calculated from χ by multiplying by $1000/c_p$:

$$\Lambda = \frac{1000\chi}{c_p} \tag{56}$$

The factor 1000 allows c_p to be expressed in molar units so that Λ has the standard units of $cm^2/(\Omega \cdot mol)$.

The equivalent conductance of a polyelectrolyte solution is conventionally apportioned to the various ionic species present. If the solution is salt-free, the apportioning suggests the following empirical equation:

$$\Lambda = f_c \left(\bar{\Lambda}_p + \Lambda_c^0 \right) \tag{57}$$

where f_c is an interaction parameter dependent in part on the fraction of dissociated counterions, and $\bar{\Lambda}_p$ and $\Lambda_c{}^0$ are the equivalent conductances of polyelectrolyte and counterion, respectively (the latter defined at infinite dilution in absence of polyelectrolyte). The same type of apportioning can be more rigorously written as

$$\Lambda = F \frac{Z^*}{Z} (\mu_0 + \mu_c) \tag{58}$$

where F is the Faraday constant, representing a mole of elementary charges e, and μ_0 and μ_c are the mobilities of polymer and counterion, respectively, evaluated together in solution; the parameters Z^* and Z have the same meanings as before, representing the number of counterions released upon dissolution and the number of ionized sites on the chain, respectively. Relating f_c and Z^*/Z is not without ambiguity, clouding interpretations of the meaning of f_c and $\bar{\Lambda}_p$. The value of f_c relates to the fraction of uncondensed ions β within the counterion condensation model but also incorporates how these ions electrostatically interact with the chain.

Manning determined values of f_c and $\bar{\Lambda}_p$ for a line charge model with counterion condensation (18). Above ξ_c,

$$f_c = \frac{0.866}{|z_i|\xi} \tag{59}$$

The right-hand side is recognized as equivalent to the formula Manning presented for the attenuation of D_c in the presence of polyelectrolyte. The reduction of f_c below β demonstrates that polyelectrolytes suppress uncondensed counterion motions, but in this instance, in the context of counterion electrophoretic mobility and not counterion diffusion constant. Likewise, the value of $\bar{\Lambda}_p$ predicted by Manning reflects the influence of counterions on polyelectrolyte mobility. His model for Λ assumes that condensed counterions migrate rigidly with the polyelectrolyte line charge to which they have condensed.

Measurements of Λ in salt-free or nearly salt-free polyelectrolyte solutions reveal complex and seemingly nonuniversal trends (254–258). If Λ is measured as a function of c_p, a maximum is sometimes seen at very small values of c_p, and the maximum is usually followed at higher c_p by a broad minimum. For c_p below the minimum, M strongly affects Λ, but above the minimum, little impact of M on Λ is noted. At high M, the initial maximum may disappear. A schematic of typical behavior is presented in Figure 18. Wandrey correlated the position of the maximum with $c_p \sim c_s$ and the height of the maximum with $L \sim \kappa^{-1}$ but why these conditions lead to a maximum in Λ is unclear (257). The decrease of Λ after the

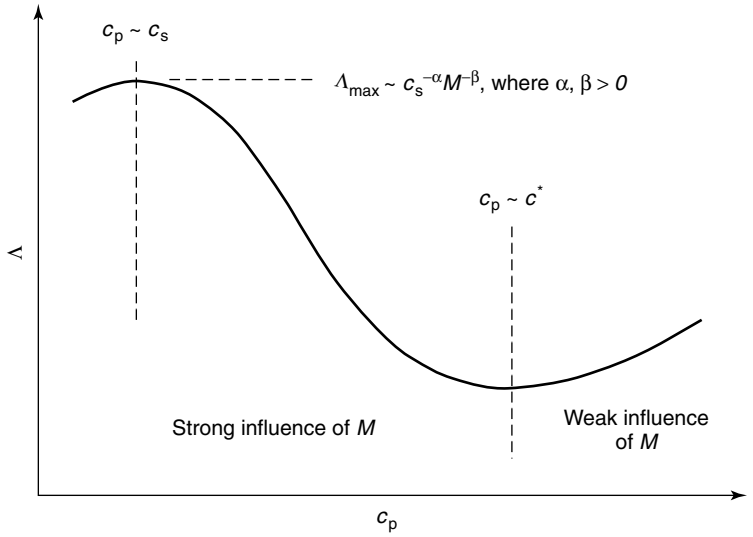

Fig. 18. Schematic depiction of the variation of polyelectrolyte equivalent conductance Λ with polyelectrolyte concentration c_p for salt-free solutions. Adapted in part from Ref. 257.

maximum can be explained through the continuous strengthening of electrostatic coupling between polyelectrolyte and counterions as κ^{-1} falls with increasing c_p; electrophoretic mobilities of both polyectrolyte and counterion decrease in consequence. To fit Λ data across the dilute polymer regime via the Manning model, Wandrey found it necessary to adjust f_c to smaller values at higher c_p. This trend can be rationalized as a shift toward more condensed counterions when κ^{-1} drops below the polyelectrolyte's molecular size. Shaaban and co-workers had earlier reached much the same rationalization (258). The need to vary f_c reflects that Λ falls too steeply with c_p for fitting to the unmodified (constant f_c) Manning model. Colby and co-workers considered the c range over which Λ decreases as semidilute in polyelectrolyte and thus developed a model for Λ based on a different description for the polyelectrolyte's mobility (259). The alternative model also does not capture well the steep drop of Λ with c. Interestingly, the growth of Λ above the broad minimum was explained by Colby and co-workers as possibly due to an increase in f_c with rising c_p, exactly opposite to the argument used by Wandrey to explain behavior at lower c_p. No rigorous theoretical model has yet predicted either the maximum or the minimum in Λ, but one might speculate that both trends in Λ for salt-free solutions might be connected to somewhat analogous anomalous trends in D_c or counterion activity (260).

With added electrolyte, the polyelectrolyte conductance can be derived from the measured solution conductance by subtracting the measured conductance of a polyelectrolyte-free solution containing the same level of added electrolyte. The polyelectrolyte equivalent conductance is then defined exactly as before, substituting the corrected polyelectrolyte conductance into equation 56. Trends in Λ vs c_p in this case do not match those of a salt-free solution, demonstrating that electrostatic interactions disallow additivity laws; in this case, additivity would suppose that the solution conductivity is simply the sum of independent conductances of

each component. Kowblansky and Ander proposed a modified additivity relationship, accounting for the impact of polyelectrolyte on electrolyte conductance, and this relationship correlates Λ reasonably well (261). At constant c_s, Λ usually grows or decreases more or less linearly with c_p in the dilute regime, allowing orderly extrapolation of Λ to Λ_0, the limiting equivalent conductance at zero c_p. Values of Λ_0 decrease with decreasing c_s, as might be expected in light of the previous discussion of how μ_0 varies with I.

Polyelectrolyte Gels

The placement of fixed charges in a swellable polymer network can endow the network with a variety of useful properties, perhaps the most important of which is a discontinuous swelling transition (262). For example, the volume of a polyelectrolyte gel may abruptly expand by several hundred times as the electrolyte concentration of a bathing solution decreases below a critical value (263). This property underlies the "superabsorbency" of many polyelectrolyte gels. A discontinuous swelling transition can be understood in terms of concepts already discussed, with attention focused on counterions and their impact on osmotic pressure.

The volume change of a polyelectrolyte gel is usually expressed in terms of the swelling ratio α, defined as the charged gel's volume V divided by the gel's volume V_0 when the constituent network strands adopt electrostatically unperturbed random walk configurations. At equilibrium, the charged gel adopts the value of α that minimizes the gel's total free energy $G(\alpha)$. Although slightly different forms have been proposed, expressions for $G(\alpha)$ generally assume separate additive contributions from network elasticity $G_{\text{elasticity}}$, which disfavors swelling, thermodynamics of polymer–solvent mixing G_{mixing}, which either favors or disfavors swelling depending on temperature, and counterion osmotic pressure G_{osmotic}, which favors swelling (263–266). Writing $G(\alpha)$ as a sum,

$$G(\alpha) = G_{\text{elasticity}} + G_{\text{mixing}} + G_{\text{osmotic}} \tag{60}$$

Sometimes included is another term accounting for electrostatic repulsions between the fixed charges of the network, but this term in most instances is small enough to be neglected. The first two terms explain the equilibrium swelling of neutral polymer networks. The elasticity term arises from the stretching of network strands as the gel expands. Such stretching can be analyzed by approximating network strands as Gaussian, or more accurately, via configurational models limiting strand extensibility. The mixing of solvent with network strands allows these strands to sample a larger range of conformations, which raises their entropy. The same mixing, however, increases solvent-segment contact, which nearly always raises enthalpy. The overall balance of entropy and enthalpy represented in the first two terms of equation 60 is captured in the standard Flory–Huggins theory for neutral polymer gels.

The most distinctive features of polyelectrolyte gels come from the third term, G_{osmotic}. Because the gel's fixed charges cannot escape the network, polyelectrolyte gels establish Donnan equilibrium with a bathing solution containing

only electrolyte and solvent. As noted earlier, the Donnan effect is a mismatch in c_s established across the boundary between two compartments held in Donnan equilibrium. The mismatch here can be traced to electroneutrality, which requires a sufficient number of counterions in the network to neutralize the fixed charges held there. The excess counterions inside the gel can be considered to apply a pressure at the gel–solution interface that causes the gel to swell. Ions in the external electrolyte solution apply an opposing pressure that causes the gel to shrink. The difference in the two pressures equals the Donnan osmotic pressure discussed earlier. Polyelectrolyte gels swell until their elastic modulus counters the Donnan osmotic pressure. The latter falls as the concentration of electrolyte ions in the external solution rises and at a critical concentration becomes too small to stabilize the swollen state of the gel against elastic contractile forces. For univalent fixed charges and monovalent electrolyte, the critical electrolyte concentration approximately matches the concentration of fixed charges in the swollen network (265). Above the critical electrolyte concentration, the gel shrinks, as only the first two terms of the expression for G remain important. The abrupt shrinkage with addition of electrolyte corresponds to a first-order phase transition if the reduced temperature is low enough.

Figure 19 displays the volume changes observed for *N*-isopropylacrylamide gels containing a small fraction of charged sodium acrylate units. Uncross-linked poly(*N*-isopropylacrylamide) solutions display a lower critical solution temperature slightly above room temperature. Upon heating, the cross-linked copolymer gel displays a discontinuous volume change as temperature is raised above 33°C, in some instances, with the gel shrinking by a factor of nearly 100. The presence of the charged units increases the transition temperature and expands the magnitude of the discontinuous volume change. Without the charged repeat units,

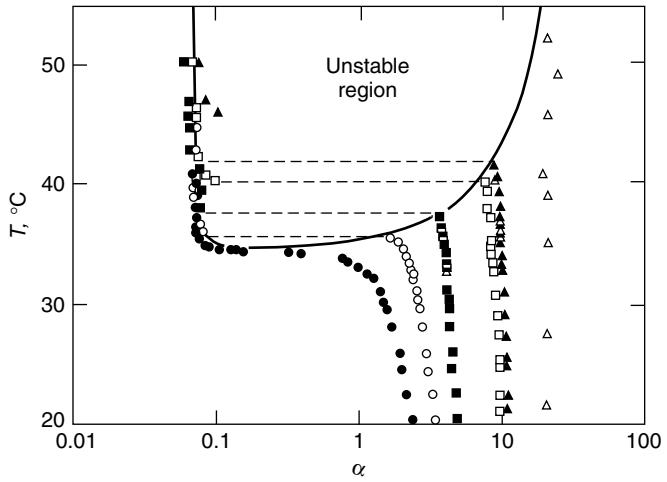

Fig. 19. Temperature T dependence of the degree of coil swelling α for copolymer gels of *N*-isopropylacrylamide and sodium acrylate in water. The total monomer concentration of gels at preparation was 700 mM, and the different plot symbols provide the concentration at preparation of sodium acrylate: ● 0 mM; ○ 8 mM; ■ 32 mM; □ 50 mM; ▲ 70 mM; △ 128 mM. Adapted from Ref. 263.

the volume change is continuous. Barrat and co-workers (266) and Rubinstein and co-workers (267) recently discussed many of the scattering, relaxation, and mechanical properties of swollen polyelectrolyte gels.

Polyelectrolyte Adsorption

The Adsorption (qv) of polyelectrolytes from solution onto solid, liquid, or gas interfaces defines a vast field, one that encompasses innumerable phenomena and many technologies. To simplify, only the grossest and most common issues are introduced here (268–270). Figure 20 displays pictorially how flexible polyelectrolyte homopolymers interact with a flat, charged surface (269). The left-hand side of this cartoon indicates behavior at low c_s, a condition typically dominated

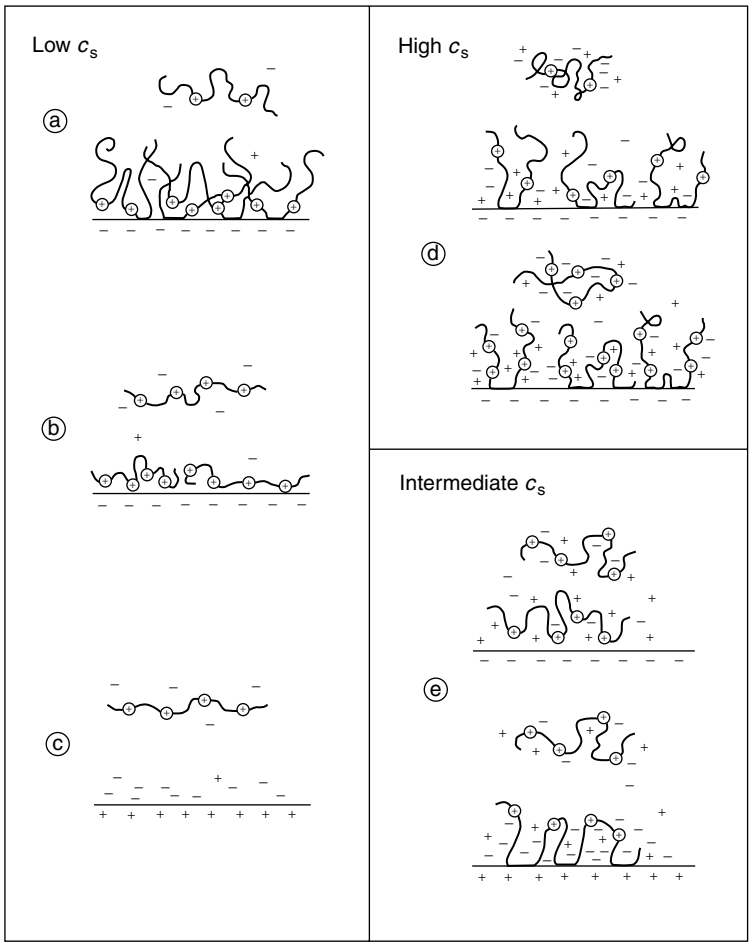

Fig. 20. Pictorial representations of polyelectrolyte adsorption under various conditions of surface charge density, polymer charge density, and ionic strength. The text discusses the specific conditions relevant to sketches **a-e**. Reprinted from Ref. 270.

by electrostatic interactions, while the right-hand side illustrates behavior at high c_s, a condition requiring additional consideration of the segment–surface interaction energy χ_s and possibly the segment–solvent interaction energy χ. Diagram **a** represents the adsorption of a lightly charged electrolyte from dilute solution onto an oppositely charged surface. In this instance, there is compensation by polyelectrolyte of surface charge, the adsorbed amount is high, and the adsorbed layer is thick (thickness $\sim R_g$). When the polyelectrolyte is more highly charged, as sketched in diagram **b**, there is again charge compensation, but the adsorbed amount is lower and the adsorbed layer is much thinner (thickness $\ll R_g$). The trend reflects the increased electrostatic attraction between polyelectrolyte and surface charges, resulting in a larger fraction of polyelectrolyte segments in contact with the surface. Diagram **c** shows that polyelectrolytes typically do not adsorb onto similarly charged surfaces when c_s is low; electrostatic repulsions cannot be overcome by even a large positive segment–surface contact energy.

Turning to the right-hand side of the figure, the top portion of diagram **d** shows adsorption at high c_s for a lightly charged polyelectrolyte attracted to an oppositely charged surface by a positive segment–surface interaction energy. The bottom portion of the same diagram shows the analogous situation for a more strongly charged polyelectrolyte. The strong screening of electrostatic interactions makes features in the two cases similar, including adsorbed amounts and layer thicknesses. Electrostatic interactions are essentially irrelevant. The bottom of the right-hand side, diagram **e**, describes behavior at intermediate c_s. Either electrostatics (top portion) or segment–surface interaction energy (bottom portion) can dominate. In the latter case, a polyelectrolyte adsorbs to a similarly charged surface with its fixed charges positioned as far away from the surface as is possible.

Sufficiently large χ_s can drive polyelectrolytes to adsorb on uncharged surfaces. Factors that enhance electrostatic repulsions within and between chains will oppose adsorption, as these interactions grow in step with the enhancement of segment concentration within an adsorbed layer. The adsorbed amount thus increases with c_s and decreases with ξ. Many studies show that polyelectrolyte adsorption is irreversible, just as with neutral polymers (*irreversible* implying undetectable desorption into polymer-free solvent) and that adsorbed layers equilibrate slowly, over time scales much longer than would be ordinary with neutral polymers (269,271). Because relaxation within layers is so slow, metastable states may persist over all practical time scales, with properties reflecting not just current conditions but the entire layer history.

To create polyelectrolyte brushes, which share many properties with adsorbed layers, chains are terminally attached to a surface through the hydrophobic association of a neutral end block or the covalent linkage of an end functionality (272–276). Many natural polymers are *polyampholytes*, polymers that can adsorb to a charged surface through segments of opposite charge even when the net charge interaction appears repulsive (277). Another adsorption phenomenon, of recent discovery and not yet fully understood, is *layer-by-layer* polyelectrolyte deposition (278–285). The *layer-by-layer* method capitalizes on the overcompensation of charge noted when polyelectrolytes are exposed to oppositely charged surfaces. Thus, a surface with inherently negative charge, such as a silicon oxide in contact with water, will adsorb sufficient cationic polyelectrolyte to become positively charged. This positive charge, in turn, can be overcompensated by adsorption of

an anionic polyelectrolyte. The process continues through alternating, sequential exposures of the surface to solutions of anionic and cationic polyelectrolyte. The final film may consist of hundreds of interpenetrated but identifiable polyelectrolyte layers; desirable properties included high uniformity, good stability in aqueous environments, and precise control of final layer thickness.

Adsorption or attachment of polyelectrolytes to dispersed colloidal particles underlies a number of technologies requiring particle stabilization or destabilization. Among these are paper manufacturing, paint formulation, mineral separation, water purification, and wastewater treatment. Stabilization prevents attractive interparticle forces, particularly short-range van der Waals forces, from causing particle aggregation, while destabilization, by exploiting new or enhanced attractive interparticle forces, accomplishes the opposite. Although terminologies and definitions vary, the aggregation of colloidal particles by added agents is usually termed *flocculation*. Permanent particle aggregates are called *flocs*, which typically possess a fractal structure that incorporates a considerable solvent fraction. By increasing effective particle size, flocculation plays an important role in solid–liquid separation processes such as filtration, flotation, and sedimentation.

Combining steric (ie configurational), osmotic, and electrostatic contributions, adsorbed/attached polyelectrolytes can modify interparticle forces in complex ways (286–291). Stabilization typically ensues when polyelectrolytes are irreversibly adsorbed/attached to particle surfaces at high density and in such a way that the chains extend significantly into the solution phase. High molecular weight polyelectrolyte brushes at large grafting density offer perhaps the most effective stabilization, but the same outcome often may be achieved more simply, for example, by the charge reversal created when polyelectrolytes adsorb to saturation on lightly charged particles. It is important for stabilization that the thickness of the adsorbed/attached polyelectrolyte layer exceeds the distance to the primary minimum of the van der Waals attraction. The irreversibility of polyelectrolyte stabilization contrasts with the reversibility of similar stabilization by surfactants.

Two distinct mechanisms have been identified for particle flocculation by added polyelectrolyte, *bridging* and *charge neutralization*. Bridging is effective when a high molecular weight, lightly charged polyelectrolyte is introduced to a dense dispersion of particles onto which the polymer adsorbs. The polyelectrolyte chains are long enough and the interparticle distances small enough for chains to link two or more particles. A loose polyelectrolyte layer structure favors bridging, as does a low adsorbed amount that leaves free a large fraction of the particle surface area. With a high adsorbed amount, the surface areas needed for bridging contacts become sparse, and stabilization arises rather than flocculation. Charge neutralization is effective when a polyelectrolyte of low molecular weight and high charge density is introduced to a dispersion of oppositely charged particles. The chains adsorb as a thin layer to an adsorbed amount that effectively compensates for the particle charge. The electrostatic stabilization of the bare particles is lost, causing flocculation. Since additional adsorption can recover electrostatic stabilization, charge neutralization is observed over a narrow window of polyelectrolyte concentration. In one variant of charge neutralization, termed the “electrostatic patch” mechanism, the point of charge compensation is achieved when the adsorbed polyelectrolyte has not yet fully covered the particle surface. The resulting

heterogeneity of surface charge induces attractive particle forces above those expected with uniform coverage. Bridging produces mechanically stronger flocs than charge neutralization.

Polyelectrolyte Complexes

Polyelectrolyte complexation forms a field as vast as polyelectrolyte adsorption, and so again, only the most salient features are mentioned. Complexes spontaneously form when polyelectrolytes are added to systems containing certain multivalent counterions (144,145,147), organic dyes with ionic groups (150), charged surfactants (292–295), oppositely charged polyelectrolytes (95,296–299), charged dendrimers (300,301), and charged colloids (95); the latter was discussed in the previous section. In addition to the systems listed, there are many examples of polyelectrolytes forming complexes with species such as neutral polymers, neutral surfactants, monovalent counterions, as well as proteins, viruses, and other biological structures.

Cooperative interactions among chain segments distinguish polyelectrolyte complexes from the complexes formed by low molecular weight compounds (302). As polyelectrolyte molecular weight decreases, the cooperativity is lost, and eventually complexation itself may disappear. Direct charge–charge interactions between polyelectrolyte "host" and oppositely charged "guest" drive polyelectrolyte complexations but so too does the entropy gain associated with the release of small counterions. Host–guest complexes characterized by 1:1 charge ratio are common. Most of these stoichiometric complexes are effectively insoluble, although at extremely low concentration solubility may be recovered. Nonstoichiometric complexes, on the other hand, are usually soluble or at least dispersible as charged aggregates or assemblies.

While polyelectrolyte charge density and solution ionic strength play a role in the final properties of soluble complexes, their greatest impacts are felt during complex formation and dissociation. Newly formed complexes are rarely ordered, and if mobilities of components are low, will remain disordered forever (302). There seems to be no universal approach for describing kinetic processes within a complex or predicting whether order will eventually appear. Complexes with smaller, less charged, and more mobile species, such as counterions, organic dyes, and surfactants, more often organize into well-defined structures, while polyelectrolyte–polyelectrolyte complexes usually possess a permanent "scrambled egg" morphology (95). Complexation at higher concentrations leads to structures reminiscent of thermoreversible gels. Such systems can frequently be disrupted or dissociated by altering parameters such as ionic strength so as to weaken electrostatic interactions.

Two complex types are given special attention. When charged surfactants are added to a solution of oppositely charged polyelectrolyte, the surfactant molecules begin to form micelles at a well-defined surfactant concentration that can be several orders of magnitude below the usual critical micelle concentration; this new concentration threshold is usually termed the *critical aggregation concentration*. The micelles formed under this condition may bind to the polyelectrolyte chains to form soluble complexes that have been described as possessing the "necklace

of beads" morphology (303–307); in other instances, spherical or cylindrical surfactant micelles apparently cluster into larger, dense aggregates surrounded or interpenetrated by polyelectrolyte (307). Bound micelles are smaller than free micelles formed above the critical micelle concentration in the absence of polyelectrolyte.

The thermodynamic factors governing the local organization of polyelectrolyte–surfactant complexes remain uncertain, but some have speculated that the polyelectrolyte chains stabilize smaller micelles by adsorbing to their surfaces. Stabilization clearly combines both electrostatic and hydrophobic interactions, making the outcome of complexation dependent on the chemistry of both polymer and surfactant. As the surfactant concentration increases, reaching a level at which enough micelles bind on the polyelectrolyte to raise the complex stoichiometry to approximately 1:1, solubility is lost and an ordered polymer–micelle precipitate appears (294); the unique solid-state structures so-formed are being intensely investigated for applications ranging from nonwetting coatings to drug delivery. Only as more surfactant is added to the phase-separated mixture do free surfactant micelles begin to appear. In some instances, even greater levels of added surfactant can resolubilize the precipitated complex. All of these behaviors depend strongly on ionic strength.

Polyelectrolytes form insoluble, stoichiometric (1:1 charge ratio) complexes when mixed with oppositely charged polyelectrolytes (95), especially if the mixing is performed under salt-free conditions at polymer concentrations that are neither extremely low nor high. The complex formation is fast and nearly molecular weight independent beyond the oligomer range. Soluble, nonstoichiometric complexes can be formed in two ways, by mixing oppositely charged polyelectrolytes of highly different molecular weights at nonstoichiometric mixing ratios (296) or by mixing oppositely charged polyelectrolytes at very low polymer concentrations (298). As opposed to polyelectrolyte–surfactant complexes, polyelectrolyte–polyelectrolyte complexes have little, if any, order, a feature probably reflecting the low mobility of their constituent chains. The driving forces for complexation is principally counterion release into a polyelectrolyte-depleted solution phase, a release that raises the entropy of the complexed system. Dependent on levels of added electrolyte, polyelectrolyte–polyelectrolyte complexes can undergo swelling, flocculation, and dissolution. When mixed at high polymer concentrations, oppositely charged polyelectrolytes may form an optically clear, one-phase system.

Polyelectrolyte Simulations

Serious difficulties abound in formulating analytical theories able to describe polyelelectrolyte phenomena, and so it is unsurprising that molecular simulation of these phenomena has seen much activity and development over the past decade. Unfortunately, few consensus judgments have as yet emerged about the relevance of simulation results to the properties of real polyelectrolytes. This situation will certainly change in the near future. A major issue in simulating polyelectrolytes is the long-range nature of electrostatic interactions. For a salt-free system containing a single flexible N-unit chain bearing a charge on each unit, the calculation of the electrostatic energy for each chain configuration requires

a computation time proportional to N^2. Thermally equilibrating this chain so as to explore configuration space fully requires the same step be repeated N^2 times. Thus, the total computation time for a simulation of equilibrium chain structure is proportional to N^4. A comparable calculation involving only short-range interactions, such as would be needed for the same chain without its charges, would entail a computation time proportional only to N^3. Various schemes have been devised to make polyelectrolyte simulations more computationally tractable, and each makes debatable physical approximations. Simulations attacking three general problems have been reported: the structure of the ion cloud near a polyelectrolyte segment (308–318), the overall configurational properties of a single flexible chain (311,312,317–331), and the structure of a system containing many polyelectrolyte chains (317,318,326,328,329,331).

Le Bret and Zimm (308), and later Vlachy and Haymet (309), Valleau (311), Christos and Carnie (312), and Stevens and Plimpton (317) examined ion distributions near polyelectrolyte segments by applying Monte Carlo or molecular dynamics methods that explicitly account for finite counterion size, treat electrostatic interactions at the level of full (not screened) Coulombic potentials, and represent water as a dielectric continuum. These constraints define the "primitive" model, which allows local correlations to develop in the placement of small ions. Two effects create such correlations, excluded volume (finite ion size) and electrostatics; mean field models (Poisson–Boltzmann, counterion condensation) incorporate neither of these effects. Within some simulations, limited structural or even molecular detail has been given the polyelectrolyte segment (332). In fewer cases, the standard primitive model was modified to account for the spatial variation of the dielectric constant near the chain backbone, recognizing that the high electric fields developed in this region can polarize the solvent (313,333). Adding even greater sophistication, Siebel and co-workers (334), Gordon and Goldman (335), Forester and McDonald (336), and Beveridge and Jayaram (337) performed simulations of ion distributions that replace the dielectric continuum of the primitive model with explicit solvent molecules. Many of these investigators specifically formulated simulation appropriate to DNA by assuming cylindrical or helical descriptions of the polyelectrolyte, while others formulated simulations appropriate to more flexible polyelectrolytes.

Le Bret and Zimm (308), modeling DNA as a dielectric cylinder within the primitive model, noted significant deviations from Poisson–Boltzmann predictions when either multivalent counterions or an large excess of positive and negative small ions are present. Also, they found strikingly large counterion concentrations, exceeding 1 M, at the model DNA surface, reminiscent of the oft-hypothesized condensed counterions. Others confirmed the findings (337), and in most instances, reported that the high counterion surface concentration persists as the bulk electrolyte concentration is varied, as predicted by counterion condensation but not Poisson–Boltzmann theory. Several investigations observed by simulation that screening of charges for flexible polyelectrolytes is much stronger than predicted by the Debye–Hückel approximation because counterions preferentially place themselves so as to heighten screening effects (311,312). Vlachy and Haymet deduced that the Poisson–Boltzmann equation retains semiquantitative utility for monovalent added electrolyte up to concentrations of $\sim$ 1 M. In the presence of divalent ions, the same investigators observed a cloud of counterions

clustered close to the chain of sufficient density to invert overall charge, another effect not predictable by Poisson–Boltzmann theory (309). More recently, the same overcompensation was reported for monovalent electrolyte at high concentration (316). Simulation studies have offered limited support for the classical counterion condensation depiction but interpretation of this concept within the context of simulation models is not unambiguous. Gonzales-Tovar and co-workers evaluated ion distributions through the hypernetted chain approximation, an analytical screening formalism of greater accuracy than the Poisson–Boltzmann equation, and identified several failings of counterion condensation (338) that others have identified through simulation.

Numerous simulations assessing the configurational properties of a single polyelectrolyte chain bathed in salt-free or electrolyte-containing solutions have been reported. Except for intrinsically stiff chains, nearly all studies have indicated that the OSF model overestimates the local stiffness of a highly charged, flexible polyelectrolyte as well as the dependence of this stiffness on electrolyte concentration. With intrinsically stiff chains, the OSF model appears to be quantitative. Molecular dynamics simulations by Stevens and Kremer suggested that the local structure of a flexible polyelectrolyte under salt-free conditions is not worm-like (326,327). Rather, these authors concluded that local counterions fluctuations cause the stiff (but not rod-like) chain segments to kink. Similarly, Micka and Kremer argued from simulation results that l_p is an inadequate measure by which to describe the conformation of a polyelectrolyte chain (330). Most simulations focused on polyelectrolyte coil size have assumed a priori a screening formula for electrostatic interactions between chain segments; commonly, screening has been applied using the form predicted by Debye–Hückel linearization. Irrespective of formalism, trends reported for the molecular weight dependence of coil size in the presence of electrolyte are reasonably consistent, although dispute persists about the precise dependence on c_s and whether simulated trends reflect asymptotic high M behavior (318,321,323,331,339). Under salt-free conditions, several simulations showed that polyelectrolyte chains are extended by repulsive segment–segment interactions such that $R \sim M$, but nonetheless, R_g remains less, by perhaps an order of magnitude, than it would be for a totally extended, rod-like configuration (311,326).

Simulation studies of polyelectrolyte–polyelectrolyte interactions appropriate to nondilute polyelectrolyte solutions are in their infancy. Stevens and coworkers performed a multiple chain, explicit counterion simulation demonstrating an extended-to-coiled conformational transition during passage from dilute to semidilute in a salt-free solution; this contraction unexpectedly began at c significantly below c^* (317,326). The same investigators found that simulated osmotic pressures during the c to c^* transition are reasonably consistent with experimental data but not with simulation results relying on Debye–Hückel linearization (328). For systems below coil overlap, Chu and Mak discovered by molecular dynamics simulation the presence of inter- and intrachain attractions that strengthen with increasing polymer concentration and Bjerrum length (318).

Many simulations of dynamic phenomena such as adsorption, electrophoretic motion, complexation, dilute solution viscosity, and electric birefringence have also been reported for polyelectrolytes, often for the purpose of gaining insight into experimental situations too complex for analytical theory. These

application-specific simulations usually apply polyelectrolyte models that ignore properties such as excluded volume, high charge density, or solvent viscosity. Such simulations guide physical understanding but normally do not offer any quantitative predictions other than scaling laws.

POLYESTERS, THERMOPLASTIC

Introduction

Polyesters enter our lives in a most ubiquitous manner as textiles, carpets, tire cords, medical accessories, seat belts, automotive and electronic items, photographic film, magnetic tape for audio and video recording, packaging materials, bottles, and so on. Their utility is illustrated by the vast range of their applications. This article describes the properties, synthesis, manufacture, and raw materials for the two most widely used thermoplastic polyesters: poly(ethylene terephthalate) (PET) [25038-59-9] and poly(butylene terephthalate) (PBT) [26062-94-2]. In order of volume, PET comes first by virtue of its enormous market tonnage in polyester fibers and films, as well as the resin for blow-molded bottles, containers, and food packaging.

Polyesters are linear polymeric molecules containing in-chain ester groups, formally derived by condensation of a diacid with a diol. The earliest commercial polyesters were the alkyd resins (qv), nonlinear polymers developed for surface coatings shortly after World War I. It was not until the 1930s that the classic studies of Carothers examined main-chain polyesters in a rigorous and systematic fashion (1). Although he studied a wide range of polyesters, made both from aliphatic diacids and diols (AA-BB) type and from ω-hydroxyacids (ABAB type), for various reasons, Carothers did *not* pursue polyesters derived from aromatic diacids and alkylene diols. All his aliphatic polymers were low melting ($<100^{\circ}$C) and were easily soluble in common organic (dry cleaning) solvents. They had little utility as textile fibers, which largely explains why Carothers turned his attention to polyamides. The first successful synthesis of satisfactory high molecular weight poly(ethylene terephthalate), 2GT, was made in England in 1942, during the early days of World War II. The inventors were J. Rex

Encyclopedia of Polymer Science and Technology. Copyright John Wiley & Sons, Inc. All rights reserved.

Whinfield and W. Dickson, working at the Calico Printers' Association (2,3). Other polymers pioneered by these workers included poly(1,3-propylene terephthalate), 3GT, poly(1,4-butylene terephthalate), 4GT, and the polyester from ethylene glycol and 1,2-*bis*(4-carboxyphenoxy)ethane, known as CPE-2G or "Fiber-O" (4). Of these materials, PET was selected for development as a melt-spinnable synthetic fiber, but commercialization was impossible until after the end of World War II. Eventually, when the various national economies were back on a peacetime footing, PET polymer and fibers derived from it were put into production. The whole market-driving force for polyester at this time was in the form of synthetic fibers. In the United Kingdom, the new material was manufactured by Imperial Chemical Industries Ltd. under the trade name Terylene, while DuPont introduced it to the United States in 1953 as Dacron (see POLYESTERS, FIBERS).

In the early 1950s, additional poly(alkylene terephthalate)s were examined in both United States and Europe for synthetic fiber applications. One of these, poly(1,4-butylene terephthalate), 4GT or PBT, had (and still has) some very attractive *fiber* properties. Notably, it was white and resisted photooxidative yellowing much better than nylon. It accepted disperse dyes much more readily than PET. It had excellent resilience and elastic recovery. All these features made it attractive for such fiber end uses as women's wear, hosiery, and carpet fiber. However, the twin criteria of pleat-retention and crease-resistance in apparel fabrics were commercially important at the time (it was an era when accordion pleats were highly fashionable in women's wear) and PET was superior on these counts. Only later was it realized that PBT polymer was highly suited to injection-molded applications. Not only was it highly crystalline, it had a *high rate of crystallization*, so that parts could be molded in a fully crystallized state and therefore free from distortion or warping. Unlike nylon, it had a low moisture uptake and was much more dimensionally stable to changes in atmospheric humidity. Molding-grade PBT resins were introduced in 1970 by Celanese Corp. as Celanex and others followed.

In contrast, PET was not successful as a molding resin because of its low rate of crystallization in a cold mold. The mold has to be heated to 130–140°C, well above the PET glass–rubber transition temperature (T_g) to obtain adequate crystallization rates. Satisfactory moldings were still not obtained because of uncontrollable crystal morphology. During the late 1960s, fast-crystallizing grades of PET were developed which had uniform morphology because of the presence of specific nucleating agents (5–7). Akzo and DuPont were early entrants in the field with their Arnite and Rynite range of PET resins; other manufacturers followed and PET molding resins are now widely used, particularly in the auto industry. However, the biggest single market for moldable PET today is in blow-molded bottles, which exceeds every other single end use for PET polymer except polyester fibers. In 1990, the annual world production of PET fibers (8) was about 9 million tons; according to Table 2 (see later) the annual production of PET bottle resin in 2000 was 1.4 million ton and growing rapidly. It is worth noting that poly(ethylene-2,6-naphthalenedicarboxylate) (PEN) was another important polyester also synthesized first by ICI workers in 1948 (9) (see POLY(ETHYLENE NAPHTHANOATE).

Manufacture of Raw Materials and Monomers

PET and PBT are both made from terephthalic acid and its dimethyl ester. Terephthalic acid (TA) is made by air-oxidation of *p*-xylene [106-42-3] in acetic acid under moderate pressure in the presence of catalysts such as divalent cobalt and manganese bromides (10). *p*-Xylene is the highest melting of three isomeric dimethylbenzenes and is separated by fractional crystallization from the C_8-aromatic fraction (including ethylbenzene) during petroleum refining (11). Alternatively it may be separated by selective adsorption on a zeolite bed combined with an isomerization process (12). For PET fiber production, very pure TA is required and in the early days, when the oxidation of *p*-xylene was achieved with 50% aqueous nitric acid under pressure, the process left some highly undesirable by-products such as nitroaromatics and carbazoles in the crude TA. Because of the great insolubility of TA, it was not easily purified by recrystallization and so it was converted to its dimethyl ester (dimethyl terephthalate, DMT), and the DMT in turn purified by redistillation under reduced pressure and a final recrystallization. PET was made by the reaction of DMT with excess ethylene glycol in the presence of catalysts to promote ester-interchange and polymerization. When the direct air-oxidation process of *p*-xylene became the process of choice, the DMT purification route was still used as an interim process, even though major undesirable impurities had been eliminated by the new oxidation route.

During the 1967–1972 period, pure TA became available in large quantities (13) because of the improvements in the process and purification of TA. Harmful incomplete oxidation products in crude TA such as *p*-toluic acid and 4-carboxybenzaldehyde (4-CBA) were eliminated by recrystallization from water under pressure with concomitant hydrogenation. Under these conditions, *p*-toluic acid is highly water-soluble and 4-CBA is hydrogenated to toluic acid (14). The availability of pure TA caused a major change in production methods for PET. Direct esterification (DE) processes using pure TA superseded the former ester-interchange (EI) process based on DMT. Interestingly, in recent years DMT has made something of a comeback, ostensibly because of the recycling of waste PET. Production of pure DMT derived from the methanolysis and glycolysis of PET waste is carried out on a significant scale (15,16). Manufacture of TA from *p*-xylene has undergone a constant process of improvement over the years and innumerable patents have been filed on small improvements, new oxidation catalysts, etc. A very recent article describes an experimental "Green Chemistry" *p*-xylene oxidation process using hydrogen peroxide and a manganese dibromide catalyst in supercritical water as a solvent. Under these conditions, the TA remains in solution (17).

Turning now to the diol components, ethylene glycol (ethane-1,2-diol) is made from ethylene in essence by direct air-oxidation to ethylene oxide and ring opening with water to give the 1,2-diol (18). Butane-1,4-diol is still made by the old Reppe process. Acetylene reacts with formaldehyde in the presence of a catalyst to give 2-butyne-1,4-diol, which is hydrogenated to butanediol. The ethynylation step depends on a special cuprous acetylide-bismuth salt catalyst, which minimizes side reactions (19). The hydrogenation step is best done in two stages over special catalysts (20). Another butanediol route starts from butadiene. In a process due to Mitsubishi Chemical Industries, butadiene reacts with acetic acid and

oxygen in the presence of a palladium catalyst to give 1,4-diacetoxy-2-butene (21), and the latter is hydrogenated over a special catalyst (22) and finally hydrolyzed to 1,4-butanediol. It is not known whether this process is in commercial use at the time of writing. Although Reppe plants still operate, the process has been replaced in newer plants by a route based on hydroformylation of allyl alcohol (from propylene oxide) over a rhodium catalyst (23) to give 4-hydroxybutyraldehyde. This is reduced to butanediol using a two-stage hydrogenation route (24) to minimize side reactions. The ethynylation route is still an important one but new plants use the Arco hydroformylation process, which was purchased by Lyondell.

Polymerization Processes

Thermoplastic polyesters are step-growth polymers which need to be made to high molecular weight (12,000–50,000) to be useful (25). The first stage is an esterification or ester-exchange stage where the diacid or its dimethyl ester reacts with the appropriate diol to give the bis(hydroxyalkyl)ester and some linear oligomers. Water or methanol is evolved at this stage and is removed by fractional distillation, often under reduced pressure at the conclusion of the cycle. For EI, weakly basic metallic salt catalysts are used: the list is extremely long, and many recipes are proprietary, but such salts as calcium, zinc and manganese acetates, tin compounds, and titanium alkoxides have been widely used (26–28). Certain EI-catalysts have the undesirable effect of promoting thermal degradation at high temperatures (29) encountered during the latter stages of high polymerization. A McClafferty rearrangement of the ester unit is often deemed responsible. To overcome this, EI-catalysts are sequestered at the end of ester-interchange by adding phosphorus compounds such as triphenyl phosphite, triphenyl phosphate, or polyphosphoric acid in stoichiometric amounts (30). Again, such recipes are often proprietary. Titanium and tin compounds [eg $Ti(OR)_4$ or R_2SnO] act as powerful universal catalysts for both EI and polymerization reactions and are left unchanged. They are not suitable for 2G-derived polyesters because of formation of a yellow color, although recipes are under development in Japan which claim to obviate this problem. For PBT, ester-exchange using DMT and a titanium alkoxide catalyst is the route of choice, since butanediol cyclizes to tetrahydrofuran (THF) in the presence of acids (31). Nevertheless, the direct polycondensation of butanediol with terephthalic acid using special reaction catalysts and conditions to minimize THF formation has been described (32–35).

Batch polymerization is usually done in an autoclave fitted with a powerful mechanical stirrer to handle the viscous melt, under high vacuum at a temperature above the melting point of the final polymer. During this critical stage, it is very important to eliminate oxygen and blanket the process with inert gas, nitrogen, or argon. During the polycondensation stage, the linear oligomers and the bis-hydroxyalkylterephthalate esters undergo a succession of ester-exchange reactions, eliminating the diol, which is removed under high vacuum, and thus increasing the molecular weight steadily. A polymerization catalyst is needed, whether the initial process is EI-based or DE-based. As already mentioned, tin

and titanium catalysts are suitable for both ester-interchange and polymerization, but for PET, antimony trioxide is the usual polymerization catalyst (36). It only becomes active at high temperatures and thus can be added at the start of the reaction along with the other catalysts. More recently, there has been a move away from heavy metals like antimony, particularly in Europe, where they are viewed with increasing disfavor on environmental grounds. Even in the United States, problems can arise with heavy metal contaminants (which include antimony) in waste glycolysis still-bottoms. These cannot be landfilled for environmental reasons and their safe disposal causes added expense. A less toxic metal would clearly be advantageous. However, alternatives are not universally satisfactory. Titanium alkoxides cause unacceptable yellowing of PET, apparently because of reaction with vinyl ester chain ends. This cannot occur with PBT. Germanium compounds, either as the dioxide, tetraalkoxide, or glycoloxide, are good catalysts, nontoxic, and give very white polymers. However, they are usually considered to be too expensive because of the relative scarcity of germanium. Another problem is loss of germanium by volatilization. The use of a germanium/titanium mixed catalyst is disclosed in a patent relating to PET bottles (37). Antimony trioxide is a robust polymerization catalyst, but in PET it is susceptible to reduction to antimony metal, which can cause an undesirable gray-blue color in the polymer.

As the polymer molecular weight increases, so does the melt viscosity, and the power input to the stirrer drive is monitored by a wattmeter so that an end point can be determined for each batch. When the desired melt viscosity is reached, the molten polymer is discharged through a bottom valve, often under positive pressure of the blanketing gas, and extruded as a ribbon or as strands, which are water-quenched and chopped continuously by a set of mechanical knives. Large amounts of PET are also made by continuous polymerization processes. PBT is made by both batch and continuous polymerization processes (38–40).

The polymer is then dried thoroughly and stored for subsequent processing. Whenever a polyester is made by melt polycondensation, a small amount of cyclic oligomer is formed which is in equilibrium with the polymer. This can be extracted with solvents from solid polymer but when the extracted polymer is remelted, more oligomer forms until the equilibrium is reestablished. The level of such oligomers is about 1.4–1.8% by weight for both PET and PBT. Thus it is impossible to completely remove cyclic oligomers from any melt-processed polyesters. In the case of PET, the main oligomer is a cyclic trimer (41,42) while in the case of PBT, the oligomers comprise roughly an equal mixture of cyclic dimer and trimer, together with much smaller amounts of higher oligomers (43). The presence of such oligomers usually does little harm, but under certain conditions they can exude to the surface. This is a problem with polyester *fibers* with their high surface/volume ratio. For example cyclic trimer can interfere with the fiber dyeing process. It is also a nuisance in bottle production as the trimer coats the preform injection molds.

It is often necessary to make polymer of much higher molecular weight than would be practicable in the melt, either by reason of excessively high melt viscosity or because degradation reactions would begin to overtake the rate of polymerization and limit molecular weight. For this reason, solid-state polymerization (SSP) is frequently used. Dried polymer chip of moderate molecular weight is heated at a temperature roughly 20°C below its softening point, either in a high vacuum or

in a stream of hot inert gas in a device which agitates the solid. Typical devices might be a twin-cone rotary vacuum drier or a fluidized-bed unit. There are many types of commercial SSP units available.

One very important practical consideration with PET is that the polymer chips must be fully crystallized by careful annealing before the solid-phase polymerization process begins. Usually the polymer has been water-quenched before cutting and will be largely amorphous. If not precrystallized, the chips may sinter together on attempted solid-phase polymerization. The difficulties caused by several tons of polymer setting to a solid mass can well be imagined! It is possible by careful annealing to raise the T_m of the PET considerably above the usual figure (44), thus allowing the solid-phase polymerization to take place at higher temperatures and shorter reaction times. Various agitation devices (45) and polymer chip treatments (46) have been described to prevent sticking. An integrated crystallizing and solid-state polymerization process has been described (47) in the patent literature.

In the solid-state process, the volatile by-products of the polycondensation reaction (traces of water, methanol, excess diol, etc) escape by vapor diffusion through the solid chip and are rapidly removed from the chip surface instead of being limited by viscous diffusion through a bulk melt. Esters of aliphatic diols and aromatic diacids begin to decompose thermally even in an inert atmosphere at around 250°C (48). In the polymer melt, local mechanical heating caused by viscous shear during agitation can cause thermal degradation. SSP eliminates this and the molecular weight rises within a few hours to the desired figure.

During the polymerization reaction, various by-products are formed. In the case of PBT, the major one is THF formed by dehydration of butanediol or by internal cyclization of the C_4-ester units. This is a harmless by-product, as far as the polymerization is concerned, since it is nonreactive under polymerization conditions and quickly volatilizes away. However, its formation is commercially undesirable because it constitutes an air pollution problem as a volatile organic emission, and represents the loss of valuable starting material (butanediol). PET, by contrast, has two major troublesome by-products. One is the generation of diethylene glycol (DEG) units in the chain by dehydration of 2-hydroxyethyl ester chain ends to form an ether link. This process cannot be entirely prevented, although addition of alkalis can reduce it, and it is further mitigated by restricting those time/temperature combinations that tend to favor DEG formation. DEG content is related to the change in softening point (ΔT_m) by the empirical relation (49)

$$\Delta T_m = (-2.2)m(^\circ C)$$

where m is the molar % concentration of DEG.

In addition to depressing melting point, DEG units adversely affect the crystallinity of the polymer, reduce the strength of both fibers and oriented films, and increase the susceptibility of the polymer to chemical attack and aqueous hydrolysis.

The other major by-product is acetaldehyde, which is produced by thermal degradation of the PET unit. Random oxygen–alkyl scission of ester units leaves a vinyl ester end and a carboxyl-ended chain. The vinyl ester reacts with a polymer

end-group to form a new polymer link and expels acetaldehyde, the tautomer of vinyl alcohol (50). The vinyl ester end can also thermally polymerize to give chain-branched and cross-linked products and gel-particles, and further thermal degradation of these polyvinyl units gives rise to colored polyenes (51,52). Although acetaldehyde is highly volatile, its presence is particularly objectionable in PET bottle resin used for soda bottles. Its presence may not exceed 3 ppm in the final container if used for potable substances, as it imparts an off-taste to popular cola drinks (53). Every time PET is melted during its processing, more acetaldehyde is generated. One reason for bottle resin undergoing a final solid-phase polymerization before stretch blow molding is to remove the last traces of acetaldehyde.

Physical Properties of PET

The full crystal structure of PET has been established by x-ray diffraction (54–57). It forms triclinic crystals with one polymer chain per unit cell. The original cell parameters were established in 1954 (54) and numerous groups have reexamined it over the years. One difficulty is determining when crystallinity is fully developed. One researcher (57) annealed PET at up to 290°C for 2 years.

Cell parameters are $a = 0.444$ nm; $b = 0.591$ nm; $c = 1.067$ nm; $\alpha = 100°$; $\beta = 117°$; $\gamma = 112°$; density = 1.52 g/cm^3

Thermochemical data depends on the degree of crystallinity in the polymer, and a very highly annealed polymer sample can have $T_m = 280°C$, much higher than the usual value of 260–265°C (58). The heat of fusion (59) is about 140 J/g, (33.5 cal/g). The glass–rubber transition temperature (T_g) depends on both the method of measurement and the state of the polymer. A solid chip sample as measured by differential scanning calorimetry (dsc) gives a value around 78°C (60) but a highly oriented and crystalline-drawn fiber measured by the dynamic loss method will give values as high as 120°C (61). The specific gravity of undrawn amorphous PET is 1.33, whereas crystalline-drawn fiber has a value of 1.39 (62).

As a step-growth polymer made under equilibration conditions, PET has a molecular weight distribution very close to the theoretical value of 2.0. The Mark–Houwink equation relates the intrinsic solution viscosity $[\eta]$ to the molecular weight as $[\eta] = KM_v^{\alpha}$, where M_v is the viscosity average molecular weight and K and α are the Mark–Houwink coefficients determined experimentally for individual solvents. The usual solvents historically used for PET are 60/40 w/w phenol/tetrachlorethane (P/TCE) and 2-chlorophenol (OCP). Neither solvent system is entirely satisfactory and better results have been obtained using either hexafluoroisopropyl alcohol (HFIP) or a 50/50 v/v mixture of HFIP and pentafluorophenol (PFP) at 25°C (63). Although expensive, these acidic fluorinated solvents readily dissolve even highly crystalline samples of PET at moderate temperatures, *thus avoiding the degradation problems commonly encountered with the older solvents at high temperatures*. Thus the results are more likely to be reliable, since degradation under normal conditions is minimal. The Mark–Houwink coefficients for PET for a range of solvent systems are shown in Table 1.

PET is a strong, stiff polymer. High tenacity tire-cord fibers with a tensile strength (tenacity) of up to 0.9 N/tex (10 g/den) and a tensile modulus of 11 N/tex

Table 1. Mark–Houwink Coefficients for PET in Various Solvents at 25°C

Solvent	K, 10^{-4} dL/g	α
OCP	6.31	0.658
P/TCE	7.44	0.648
HFIP	5.20	0.723
PFP/HFIP	4.50	0.705

(125 g/den) are readily obtained. Normal (ie apparel) textile fibers usually have tenacity around 0.5 N/tex (5.6 g/den) with a modulus of 7 N/tex (80 g/den). The tensile modulus of PET is significantly higher than that of either PBT (4GT) or PPT (3GT) polyester fibers.

Applications of PET

The applications of PET are almost too numerous to mention and new uses appear constantly. Historically, PET was first commercialized in the early 1950s as a *fiber-forming* polymer. Staple (noncontinuous) fiber for blending with wool (qv) and cotton (qv) for increased fabric performance was the first product and as such was highly successful. Later, continuous filament yarn, frequently bulked mechanically, for knitwear and especially for women's apparel was introduced. The high T_g and low moisture regain (0.4%) gave excellent wash-wear fabric properties with significantly reduced tendencies to wrinkle. Industrial high strength fibers were then developed, notably tire cords for automobile tires. These were usually made from high intrinsic viscosity (IV) polymer (ca 0.75) and spun as continuous filament yarn. When automobile seat belts became the norm, they were also made from polyester because, unlike nylon, it had a high modulus and low tendency to stretch. The whole topic of polyester fibers is a very large one and for a more comprehensive treatment, see Ref. 64 and Polyesters, Fibers.

Another market where PET proved of great value was in the form of *polyester films*, which were made by extrusion through a slit die, followed by a biaxial drawing process. They are used for photographic film backing and for magnetic audiotape and videotape substrates. Another market is drafting film. In all of these outlets the high strength and high modulus of PET, particularly for biaxially drawn films, give the desired dimensional stability and low stretch. For further details of film fabrication and processing, see Ref. 65 and films, manufacture; films, orientation.

One of the largest uses of PET resin and certainly the most dramatic in growth during the last 20 years is the stretch blow-molded *PET bottle*; annual consumption runs into billions of units in United States alone with corresponding rapid expansion on a worldwide scale. The advantages of a thermoplastic bottle are self-evident: it is light-weight, shatterproof, and recyclable. The early market driver was weight, which reduced transportation costs compared with glass during a severe energy shortage. Improved product safety associated with shatter-proof plastic bottles was another factor: recycling did not become a factor until later.

The major technical problem facing any thermoplastic bottle manufacturer is the permeability of the plastic bottle wall to oxygen and carbon dioxide, which affect the shelf-life of the contents. The average 2-L soda bottle maintains an internal pressure of CO_2 of ca 520 kPa (75 psi). To stop the product going "flat," carbon dioxide pressure must be retained during storage before unsealing for several weeks. Likewise, oxygen must not diffuse in through the bottle walls to oxidize the contents, spoiling the flavor of the product. PET is semipermeable to such gases. At one time, attempts were made to coat PET with impermeable layers but safety, cost, and recycling difficulties defeated them, although more recent processes appear promising.

The basic enabling invention in 1973 was the stretch blow-molded PET bottle process (66,67). In this process, the polymer bottle wall is subjected to a rapid biaxial drawing, which greatly increases the molecular orientation of the bottle wall. Not only does this increase the mechanical strength of the bottle but it also reduces the permeability of the walls (68). Blow-molding thermoplastic hollow articles is a highly specialized process and for more details the reader should consult a specialist publication (69). However, the process will be outlined so that the reasons for certain polymer properties will become apparent. A typical process is the two-stage blow-molding process. A bottle "preform" is molded by a conventional injection-molding process with thick walls and the neck with screw-cap threads in place. This preform is amorphous and clear. Multiple cavity dies are used to increase productivity. In the second stage, the preforms are heated in a mold to a carefully controlled temperature above the glass–rubber transition temperature, typically to 90–100°C. The inside of the mold cavity is the size and shape of the finished bottle. The preform is subjected to a combined axial and radial stretching process. A hollow metal mandrel passes into the preform and partially elongates it in the axial direction while dry air at about 345–690 kPa (50–100 psi) blows the walls of the softened preform outward to fill the mold, giving radial stretching. The mold opens to allow the bottle to cool. This combined process results in both radial and axial drawing of the bottle walls, which causes strain-induced crystallization and gives a container superior strength, clarity, and no environmental stress-cracking.

The usual 2-L bottle preforms weigh about 50 g and the final blown bottle has a wall thickness of about 0.38 mm (0.015) in. (70). In view of the enormous number of bottles produced annually, the processes are constantly being modified to raise throughput rates and are all highly automated. Several large machinery manufacturers (eg Cincinnati-Milacron, Sidel) specialize in building the complex blow-molding equipment. Typical cycle times for the actual blow molding are 3–6 s. This process had one serious drawback in the early days—it gave a bottle with a hemispherical base, which is clearly not capable of standing upright. A flat base could not be fully oriented, so gases would permeate out through it. For several years, PET soda-bottles were fitted with separate flat-bottomed basecaps, usually molded from high density polyethylene (HDPE) and secured with a hot-melt adhesive. This meant extra cost because of extra material and processing steps and interfered with recycling. The invention by the Continental Group of the so-called petaloid base bottles with a five- or six-lobed pattern base was a major advance: it made possible a one-piece, fully biaxially oriented bottle which could stand up by itself (71).

PET Bottle Resin. Stretch blow-molding is a mechanically severe operation with very high deformation rates. The consumer wants a glass-clear bottle: any opacity caused by strain-induced crystallization is highly undesirable. PET bottle resins are usually made to high molecular weight ($M_n = 22{,}000$–$40{,}000$; IV 0.75–0.90 dL/g) so as to withstand the severe blow-molding operation. Such an intrinsic viscosity is too high for melt-polymerization, and solid-stage polymerization is required. The process has been reviewed (72). PET bottle resin is made in a continuous melt-polymerization plant either by direct esterification using TA/glycol, or by EI using purified DMT, often recovered from recycled PET bottles. The process to be described is a direct esterification process. Firstly, the acid and glycol are thoroughly mixed to a paste and catalyst and stabilizers are added. The paste is pumped to the esterifiers where water is driven off. The molten mixture of low polymer and oligomers passes through various polymerization stages: a prepolymerizer, an intermediate polymerizer, and finally the melt arrives at the high polymerizer or finishing stage where the final IV is about 0.65 dL/g. During the various successive stages, the melt grows increasingly viscous and high vacuum is applied at the finisher to complete the reaction. The agitators used in the polymerizers are designed to disengage volatiles without high shear-rates and to obviate dead spots where polymer melt could stagnate and undergo degradation. A series of DuPont patents (73–75) describes a process whereby no vacuum is needed to build molecular weight to the desired level. By use of specially designed mechanical agitators and an ingenious reactor design, which continually generates thin films of polymer melt, a brisk stream of inert gas (nitrogen or CO_2) is sufficient to cause efficient disengagement of the excess glycol and thus drive the reaction to the desired IV. The entrained glycol can be recovered from the exit gas stream and the inert gas recycled. Clearly, the absence of vacuum equipment reduces capital costs and, it is claimed, the process can be operated both batchwise and continuously and is suitable for several commercial polyesters including PET, PEN, and PBT.

Returning to the original process description, at the exit from the high polymerizer, the molten polymer is extruded into a water-bath and continuously diced to small chips about 2.5–3.5 mm across. The chips are dried and passed to the crystallizers where they are annealed in the solid state above T_g, gradually rising to a temperature close to the point of maximum crystallization rate (approx. 40–160°C). They are slowly agitated to prevent them from sintering together as they move to the solid-state polymerizer. During the crystallization stage, the chip density increases from 1.33 to about 1.37 g/cm^3. Finally the chips pass into the solid-phasing towers. Here they descend slowly under gravity in a plug-flow mode through a long hot zone under a countercurrent flow of inert gas to sweep away the volatile by-products. The speed of descent is controlled so that an optimum time/temperature profile is maintained for the desired final IV. The scale of operation is impressive: typical melt-continuous polymerizers run at 10 tons/h, which implies a capacity of approximately 70 million kg/year; a large manufacturer may have several such units and each one provides enough polymer for well over one billion 2-L soda bottles. Newer plant capacities are even more remarkable: a new plant in South Carolina has a capacity of 182 million kg/year *in a single line*.

The number-average molecular weight for typical bottle resin is between 24,000 and 31,000 Da/molecule. One of the most objectionable by-products of

PET polymerization is acetaldehyde, which affects the taste of cola drinks at concentrations as low as 60 ppb. The specification for acetaldehyde in the final product must not exceed 3 μg of acetaldehyde per liter of headspace. The bulk of the acetaldehyde produced in the polymerization process is removed during the final solid-phase polymerization stage. Since blow molding is carried out well below 200°C, only minute amounts of fresh aldehyde are formed by thermal degradation at the last stage. Originally, bottle preforms weighed 60–70 g but this has now been reduced to about 50 g. The lighter weight bottles have thinner walls so that during biaxial drawing, excessive strain-crystallization (opacity) becomes a problem. Most manufacturers (76,77) have introduced copolymers of PET containing minor amounts (2–5 mol%) of such comonomers as isophthalic acid (PET-A) or cyclohexanedimethanol (PET-G) to reduce the polymer melting point by about 4–12°C with a lower tendency to crystallize. Polyesters hydrolyze very rapidly at 280°C in the melt. Rigorous polymer-drying to a chip moisture content below 50 ppm moisture is necessary before the injection molding of bottle preforms. (PET stored under ambient conditions can easily have a moisture content of 2000 ppm). Melt-dyed polymers using FDA-approved dyes are used to mold preforms for colored bottles where the customer requires them.

In recent years, more and more potables have been packed in PET bottles—one of the most rapidly growing areas, first in Europe but now in the United States as well, is bottled drinking water, both noncarbonated and name brand spa waters. Interestingly, for such potables, acetaldehyde must be even more stringently excluded than for cola drinks. A major market prize would be a bottle sufficiently impermeable to oxygen for packaging beer and wine without spoiling the flavor. This is a much more difficult task than packaging carbonated soft drinks. Numerous designs and bottle coatings have been explored but recycling must not be impaired. Plasma-coating of PET bottles with inorganic materials such as silica and glass to bring about a fivefold reduction in oxygen permeability has been disclosed (78,79). Sidel Corp. (80) has gained FDA approval for a process which plasma-coats amorphous carbon on the insides of 600-mL PET beer bottles at a rate of 10,000 bottles/h. The bottles, which are amber-colored, are said to be fully recyclable.

Other PET Packaging Products. In addition to blow-molded bottles, a packaging market has appeared in recent years for other types of PET polymer. One is amorphous PET (APET) which uses a comonomer (isophthalic acid is one) to minimize crystallinity. Such polymers are used in clear bubble and blister packs for a variety of pharmaceutical products and medical devices (81). Food packaging is also a rapidly growing market for APET and clear heat-sealable thermoformed packages are widely used. By use of blowing agents, foamed PET with a specific gravity of as little as 0.05 g/cm^3 can be made. Markets include baking trays and the very light foams can be used in food packaging. PET bottle resin is the feedstock and the foams can be recycled. One ingenious process uses the hydrocarbon heptane at 249°C as a PET blowing agent (82). These products are largely spin-offs from the vast and rapidly growing bottle resin process and provide new opportunities and markets for resin manufacturers. PET is regarded as a premium packaging material and its recyclability is both a market and an environmental advantage (83).

PET Molding Resins. It is difficult to establish accurately the world market size for PET as a molding resin. The total tonnage is small compared with the vast amounts used for fibers and bottle resin. However Table 2 shows estimates for 1999–2000 consumption of nonfiber PET and PBT resin, broken down into end uses in several major world markets. The bulk of the U.S. market for PET molding resin is the auto industry. Its T_m and heat distortion temperature are higher than the corresponding values for PBT, and its low moisture uptake and dimensional stability with respect to changes in humidity make it superior to nylon. Both PET and PBT engineering resins have good resistance to chemicals and being crystalline, do not suffer from the solvent stress-cracking problems that plague amorphous materials such as polycarbonate. Polyesters are only attacked by powerful acidic or phenolic solvents, hot strong aqueous alkali, and certain bases such as hydrazine.

In the unfilled state, PET is not a good molding resin and all commercial grades are filled with either chopped glass strand (typically 3–4 mm long) or mineral fillers (usually mica) or a mixture of the two. Various proprietary nucleating agents added are often sodium salts of various organic carboxylic acids (see Ref. 5). Some manufacturers supply fire-retardant (FR) polymer grades as well. Such formulations often involve a synergistic mixture of an aryl halide with antimony oxide. One difficulty with flame-retardant PET polymer is that recipes which contain antimony trioxide can suffer severe polymer degradation at molding temperatures around 280–290°C. As has been discussed earlier, antimony trioxide is a polymerization catalyst and can also act as prodegradant at high temperatures. This is a less serious problem with FR grades of PBT because of lower processing temperatures (240–250°C). To mitigate the effect on PET, pentavalent antimony compounds such as sodium antimonate is used in some FR formulations. The halogenated species is often a ring-brominated polystyrene (85–90). These materials

are approved for Underwriters Laboratory V-0 classification and are nonfugitive and less likely to be environmentally harmful than are small molecule additives like decabromodiphenyl oxide. In Europe there has recently been a move to eliminate organohalogen compounds from FR formulations for environmental reasons. As a result, organophosphorus derivatives such as triarylphosphine oxides are being introduced (91).

Since the early 1990s in the United States, there has been pressure on manufacturers from the automotive industry, led notably by the Ford Motor Co., to use at least 25 wt% of post consumer recycled (PCR) material in their resins rather than 100% virgin polymer. In the case of PET, this is readily achievable, because of the large volume of recovered PET bottle polymer chip now available in the United States and in Europe. A recent article (82) states that during 1998–1999, 273,000 t of PET waste was recycled in the United States. Some suppliers use 100% recycled polymer in their compounded PET resins. The PCR recovery process and subsequent melt-compounding and reformulation reduce the initial IV of the original resin from around 0.75–0.85 dL/g to values around 0.62–0.65 dL/g, but this is still in the range of virgin melt-polymerized resin (as opposed to SSP resin). In the automobile industry, components are often pigmented black, so that differences in feedstock PCR chip color are minimized.

Initially, PET moldings were used in small components, typically electrical connectors and covers for fuses, etc (see Figs. 1 and 2). This is still the case, even

Fig. 1. Electrical automotive connectors molded from CelanexR PBT, Grote & Hartmann (Germany). Courtesy of Ticona, A business of Celanese AG.

more so with the growing complexity of the modern automobile with its numerous on-board electronics, but recently the trend has been to use PET moldings more and more for non-load-bearing structural parts, such as radiator grille supports and headlamp mountings (Fig. 4). Glass/mineral filled PET moldings do not have

Fig. 4. Automotive, electroplatable grill-opening retainer molded from ImpetR PET, Mercury Sable. Courtesy of Ticona, A business of Celanese AG.

a smooth enough surface for exterior body-parts. However, they are very suitable for internal structural components. This trend is part of the drive to reduce automobile weight to improve gas-mileage or boost the range and performance of electric cars. Some moldings are dimensionally quite large, weighing well over 5 kg per shot. Improvements in mold design and better understanding of melt-flow behavior in molds, brought about by increasing use of computer-aided design and flow-simulation programs, have helped to make these large moldings possible on a routine production basis. Figures 5 and 6 show an experimental concept car where the bulk of the body/chassis pan is molded in a PET formulation. As stated, PET

does not crystallize well in the unoriented state even in a hot mold unless nucleating agents and/or plasticizers (qv) are added. Commercial PET molding-grade polymers are nearly always filled. Typical compounded polymer properties are shown in Table 3.

Economic Aspects of PET

The total world market for nonfiber PET polymer is still growing because of the demand for bottle resin. This grew worldwide from 1993 to 2000 at about 15%/year, although overproduction led to a falling-off recently. A published article (93) stated that the global consumption of PET grew at 19% during 1992 to a world total of 1,719,000 ton (3.79 billion lbs). Adding up the bottle resin figures from Table 1 given an estimated total of 3,121,000 ton, a 181% increase in 7 years. The world total devoted to beverage bottles is astonishing, but it is significant that Europe had by the year 2000 almost caught up with the United States in total bottle resin tonnage. There are interesting regional variations, notably the strong demand for packaging for mineral waters in Europe and the large hot-fill market in Japan. Looking ahead, the future growth of PET looks to be assured, its balance of properties and ability to be recycled being extremely favorable factors. New outlets for PET packaging are constantly appearing.

One significant trend in recent years has been the complete disappearance of some well-known major producers of PET polymer and the emergence of new ones. In the late 1990s, several major chemical companies sold off commodity chemical and polymer businesses to concentrate on other more profitable market areas such as pharmaceuticals and life-sciences. In 1998–1999, Hoechst Celanese split into Celanese AG and Aventis, a pharmaceutical company. It sold its large PET interests to the Koch-Saba group, now called Kosa, and headquartered in Houston, Tex. Celanese's remaining engineering polymer interests were taken over by its subsidiary Ticona. During 1998–2000, Shell gave up its polymer business and sold some 300,000 ton of PET capacity to the Mossi & Ghisolfi Group of Milan, Italy (94). ICI sold its PET plants in Europe to DuPont, and Dow in 1996 became a major PET manufacturer by acquiring 270,000 ton of plant capacity. Dow is also in the process of buying Union Carbide. Allied-Signal became Honeywell and were then almost acquired by GE until (2001) the European Union prevented the sale on antitrust grounds. Table 4 shows major world manufacturers of PET resin in late 1998, a situation that has now changed again with the removal of Shell and Hoechst Celanese as PET producers.

Table 4. Major World PET Producers[a]

Manufacturer	Nameplate capacity, 10^3 t

Commercial PET Engineering Resins. The first company to introduce nucleated PET molding resins was Akzo Plastics BV with their Arnite® range, later acquired by DSM NV. DuPont introduced their Rynite® fast-crystallizing materials in 1978, followed by other manufacturers. The present North American market is still dominated by DuPont, but there are other notable suppliers like Honeywell (Allied-Signal) with Petra® and Ticona with Impet®. Eastman also markets PET injection-molding grades under the tradename Thermx. In Europe the situation with PET is confined primarily to two suppliers, DSM NV and DuPont, while in Japan the main suppliers are Teijin, Toray, and Toyobo. The market prices for PET molding resins at the time of writing in the United States are \$2.90–3.15/kg for 30% glass-filled PET, \$3.26–3.41/kg for 55% glass-filled PET, and \$3.23–3.45/kg for 30% glass-filled FR grade PET (95). These compare with a current commodity price for PET bottle resin of \$1.36–1.50/kg (see ENGINEERING THERMOPLASTICS).

Safety and Environmental Factors

PET. PET polymer is safe and poses no threat to animals or humans. PET fibers have been in use for nearly 50 years and PET has U.S. Food and Drug Administration (FDA) approval for use as a food-packaging material. PET fibers have been used in internal arterial prostheses. The only significant hazard in handling PET resins is the dust hazard associated with mineral or glass fillers during chip grinding or compounding operations. Appropriate protective equipment must be worn. All extruders or machinery handling molten polymer should be properly ventilated to remove harmful fumes from the decomposition of molten polymer. Molten PET can cause serious contact thermal burns: it has a high heat capacity and sticks to the flesh. Adequate protection must always be worn when handling hot polymer.

PBT. PBT resins are not harmful or hazardous when handled at room temperature under normal conditions according to their Materials Safety Data Sheets. No problem with contact with the pellets has been encountered under normal conditions. Glass fines can however cause skin irritation, and if glass-filled resins are being ground or reground, due precautions must be taken. Inhalation of dust must be guarded against, as is true for grinding any glass-filled resin. During the molding, the temperature must not exceed 520°F and never over 550°F as decomposition with the evolution of harmful vapors can occur. As with all thermoplastics, adequate ventilation must be provided around injection-molding machines.

PBT Molding Resins

Poly(butylene terephthalate) is historically the oldest of the crystalline thermoplastic polyester molding resins, having been introduced by Celanese Corp. in 1970 under the trade name Celanex. General Electric Co. then brought out their own version Valox®, and today there are numerous suppliers including BASF, Bayer AG, and DSM. Celanese have recently become Ticona. In Japan,

the major manufacturers are Polyplastics, Toray, Teijin, and Mitsubishi (see ENGINEERING THERMOPLASTICS). As already explained, unlike PET, PBT has the ability to crystallize very rapidly (like nylon-6,6) even in a cold mold. It gives tough, distortion-free moldings without special additives or nucleants. Although the unmodified polymer has very good flow properties, and is used in electrical connectors and fiber-optical cable buffer tubes, it performs even better if reinforced with inorganic fillers, notably ∼3 mm (1/8 in) chopped glass fiber. Additional mineral fillers are incorporated for special applications where high heat-deflection temperature and stiffness are important. These mineral fillers include mica, talc, wollastonite, and even barium sulfate, the latter for special applications such as countertops.

The filled grades of PBT are tougher, stiffer, and stronger materials and they have improved notched Izod impact strength, since unfilled PBT is notch-sensitive (96,97). Even when unfilled, the plastic has good strength, rigidity and toughness, low creep, minimal moisture absorbance, and does not undergo dimensional changes with changes in humidity. It is characterized by excellent electrical and dielectric properties and a high surface finish. It has found wide acceptance in a variety of end uses where precision molding and a high quality finish are required. Typical are the electrical and electronic markets where it is widely used in such parts as connectors, plugs, switches, typewriter and computer keyboard components, printed circuit boards, and small electric motor components. PBT is widely used in the automotive industry for electrical components such as distributor caps, coil-formers, rotors, windshield wiper arms, headlight mountings, and other fittings. In the auto market, "under the hood" components have to maintain their dimensional stability at elevated temperatures as well as resist various automotive fluids. Other uses for PBT are home appliances, such as food mixers, hair dryers, coffee makers, toasters, and camera parts. PBT is used in industrial machinery, for example in molded conveyor-belt links and in medical devices such as nasal sprays and nebulizers. An appreciable quantity is used in polymer alloys and blends with other polymers. PBT is marketed in both standard and flame-retardant grades, the latter being essential in the United States to meet Underwriters' Laboratory 94V-0 standards in thin-walled sections.

Properties of PBT

Physical Properties. Unlike PET, the polymer PBT exists in two polymorphs, the α and β forms, which have distinctly different crystal structures. The two forms are interconvertible under mechanical stress (98–100). Both crystal forms are triclinic and the crystal parameters are shown in Table 5.

The change in the two forms mainly involves the c lattice dimension, which lengthens from 1.174 to 1.300 nm. It is believed that the relaxed α-form has a gauche–trans-gauche conformation of the three C—C bonds in the C_4-glycol unit, and the extended β-form exists in an all-trans form (62). The melting point of PBT is 222–224°C, depending on the degree of crystallization and annealing conditions. The heat of fusion is about 140 J/g (101) and the T_g is usually quoted at about 45°C, although this depends on the physical nature of the sample (102). PBT crystallizes

Table 5. Crystal Parameters for the Two Forms of PBT

Cell parameter	α form (unstretched)	β form (stretched)
a, nm	0.482	0.469
b, nm	0.593	0.580
c, nm	1.174 (1.165)[a]	1.300
α, degrees	100 (98.9)[a]	102
β, degrees	115.5 (116.6)[a]	120.5
γ, degrees	111	105
Volume, nm^3	0.260	0.267
density, g/cc	1.41	1.37

Table 6. Mark–Houwink Parameters for PBT

Solvent	K, dL/g	α
P/TCE (at 30°C)	1.17×10^{-4}	0.87
OCP (at 25°C)	6.62×10^{-5}	0.915

very readily from the melt and it is difficult to obtain a truly amorphous sample. Its crystallization kinetics are thus not easy to determine (103). The density of the annealed crystalline unfilled polymer is 1.33 g/cm^3 whereas the amorphous material has a value of 1.26 g/cm^3 (104). Like PET, PBT is made to various molecular weights, the M_n values being in the 20,000–50,000 range. Intrinsic viscosities are usually measured in *o*-chlorophenol (OCP) or a phenol/tetrachlorethane mixture. The Mark–Houwink parameters are shown in Table 6 (105,106).

Flame-retardant grades of PBT usually consist of synergistic mixtures of antimony trioxide with various halogenated (brominated) aromatic compounds. A typical recipe for PBT might be 10 wt% decabromodiphenyl oxide and 5 wt% antimony oxide. Recently the trend has been to use polymeric or oligomeric brominated additives. A typical additive is an end-capped polycarbonate derived from tetrabromobisphenol-A [94334-64-2]; another is a mixture of epoxy oligomers derived from the diglycidyl ether of tetrabromobisphenol-A [68928-70-1]. The brominated polystyrenes (*loc. cit.*) have only limited usefulness in PBT as they have a low melt compatibility (107).

Chemical Properties. PBT is highly crystalline and does not suffer from solvent stress corrosion cracking as do amorphous materials. It is resistant at room temperature to most common chemicals and solvents, lubricants, greases, and automotive fluids. Ketones will attack it at elevated temperatures. Parts made from PBT are dishwasher-safe, but will not withstand repeated steam autoclaving. PBT is attacked by aqueous alkali and other strong bases and by dilute acids, particularly at elevated temperatures. PBT has very good resistance to weathering, and black pigmented grades with uv-stabilizers have excellent outdoor stability. Like all polyesters, PBT is susceptible to hydrolytic attack by moisture in the melt. Injection-molding screw temperatures are usually about 250°C and IV drop is rapid unless the polymer chip is dried to below 50 ppm moisture content and kept dry. Inadequate drying is the cause of most molding

Table 7. Mechanical Properties of PBT[a]

problems. As the PBT melt is quite fluid, drooling from nozzles is sometimes a problem.

Mechanical Properties. Properties of typical grades of PBT, either as unfilled neat resin or glass-fiber filled, and FR grades are set out in Table 7. This table also includes impact-modified grades which incorporate dispersions of elastomeric particles inside the semicrystalline polyester matrix. These dispersions act as effective toughening agents which greatly improve impact properties. The mechanisms are not fully understood in all cases. The subject has been discussed in detail (109), and the particular case of impact-modified polyesters such as PBT has also been discussed (110,111).

Economic Aspects of PBT

According to information published between 1999 and 2000 the market for PBT in the United States and Canada increased from 67,000 to 71,000 t (147.6–156.6 million lbs), as shown in Table 2. The European and Japanese markets also use large amounts of PBT. The main outlets are electrical, electronic, and automotive components. The major manufacturers of PBT in North America, Europe, and Japan are shown in Table 8.

A more detailed analysis of end uses for PBT in North America, Europe, and Japan are shown in Table 9.

The future prospects for economic growth for PBT look good. It is still displacing thermosets from some markets and its versatility, excellent flow properties, and ease of molding will assure it a prominent place in the world for years to

POLYIMIDES

Introduction

Polyimides are a class of high performance, highly versatile resins that can be tailored for application through the use of chemistry, processing, molecular weight control, and reaction conditions. Polyimides display excellent thermal, mechanical, and physical properties that place them in a general use category as material systems that can compete with other structural materials, mechanical fasteners, higher voltage connectors, and chemically resistant parts. As the requirements for lighter weight, broader temperature performance, increased strength, durability, and inertness continue to drive technology, polyimides will play an increasing role in the innovations of the future.

The first reported synthesis of an aromatic polyimide was in 1908 (1). However, much of the credit for the development and commercialization of polyimide products goes to DuPont, who benchmarked this endeavor in the 1960s with the release of Kapton H film, Vespel molded parts, and Pyre-ML wire varnish (2). This effort inspired other researchers in academia, industry, and government laboratories to pursue the chemistry, fabrication, and applications of polyimides not envisioned several decades ago. There are several excellent books that address the extensive topic of polyimides (3–6). This article provides an overview of the field of polyimides from synthesis and basic kinetic behavior to fabrication and articles of manufacture.

Polyimide Synthesis

The synthetic approach to the formation of polyimides is divided into three groups. The first group involves the synthesis of the polyimide by increasing the molecular

Encyclopedia of Polymer Science and Technology. Copyright John Wiley & Sons, Inc. All rights reserved.

weight of the monomer(s) through the formation of the imide ring via the amic acid/ester route. The second approach involves increasing the molecular weight of a precursor already containing the imide ring. The last method involves the conversion of a polymer into a polyimide.

Polyimides via Imide Ring Formation. The two-step approach is the most general approach used in the synthesis of linear polyimides (7–9). The first step involves the treatment of a diamine with either a dianhydride (the most popular), a tetracarboxylic acid, a diester diacid, a diester diacid-chloride or a trimellitic anhydride chloride (TAC) as in the case of polyamide-imides (Amoco's Torlon) (10,11). These reaction schemes are generally carried out in a high boiling polar protic (phenolic) or aprotic (NMP, DMAc, DMF, etc) solvent at low to moderate temperatures, resulting in the formation of the polyamic acid (or polyamide acid), amic ester, amic acid ester, etc via nucleophilic attack by the amine on the carbonyl carbon (12). Next the formation of the imide ring is brought about through thermal treatment, chemical dehydration, or both by a second nucleophilic attack, occurring at the adjacent carbonyl carbon, by the amide nitrogen, followed by the elimination of a condensate (typically water or alcohol). Removal of this condensate forces the equilibrium toward the right, driving the polymerization to completion (Le Chatelier's principle), thus forming the imide ring (8,13). Alternatively, a "one-step" method or direct conversion is used where a diamine and a dianhydride are placed in a solvent and heated to a temperature where the amic acid moiety formed dehydrates rapidly to the resulting imide. Thus, the polyimide is formed in "one step" (14).

Polyamic Acid Formation. To successfully carry out this synthetic approach, the following requirements must be met: chemical purity; the proper type and percent solids of reaction medium (facilitating solubility of the resulting polyamic acid); reaction temperature; and a method allowing for the removal of any by-products of polymerization (heat, condensates, etc) (13,15). Most commonly, a bifunctional compound is treated with a diamine to afford the amic acid, followed by imide ring formation during the final polymerization step. The routes to achieving a high molecular weight polyimide starting from the monomers via the polyamic acid are shown in Figure 1 (16). When a diamine (**1**) is treated with either a dianhydride (**2**), or a tetraacid or diacid-ester (**3**), alternative routes may occur depending on the reaction kinetics, where k_1 and k_3 are desirable and k_2 and k_4 are not. Table 1 summarizes the approximate kinetic "k_x" values. The pathway to k_4 depends on the amount of water or alcohol in the reaction medium; the reactivity (electrophilicity) of the dianhydride or tetraacid/diacid-ester; and the

Table 1. Typical Rate Constants for Polyamic Acid Synthesis[a]

Reaction	Rate constants
Propagation (k_1)	0.5–6.01 $mol^{-1} \cdot s^{-1}$
Depolymerization (k_2)	10^{-5}–10^{-6} s^{-1}
Imidization (k_5)	10^{-8}–10^{-9} s^{-1}
Anhydride hydrolysis (k_4)	0.1–0.41 $mol^{-1} \cdot s^{-1}$
Amine hydrolysis ($-k_3$)	0–10^{-6} s^{-1}

[a]Refs. 5,17, and 18.

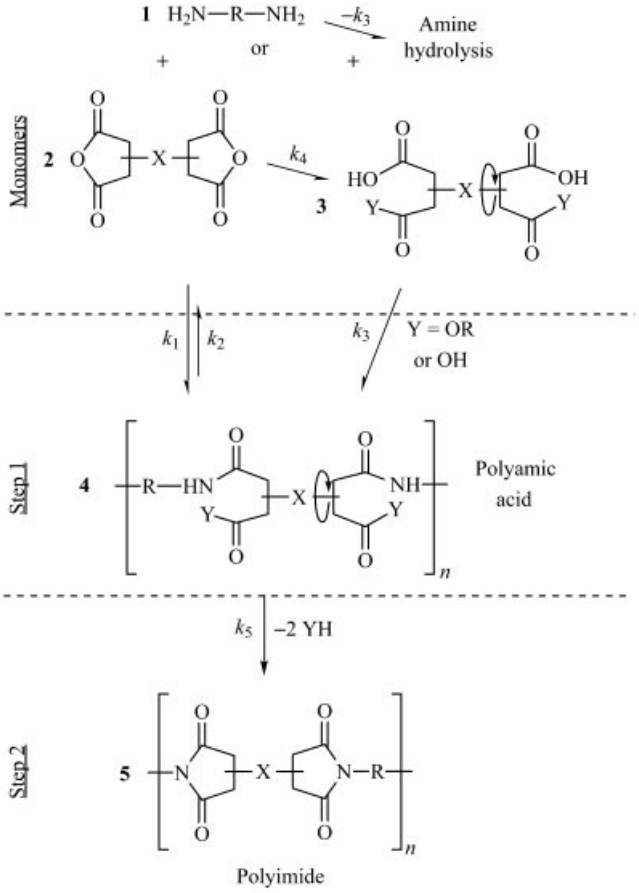

Fig. 1. Reaction Scheme for thermal imidization via polyamic acid/ester.

nucleophilicity of the diamine (Table 2). Steric hindrance and isomerization; polarity and autocatalytic effects of the solvent; and the time/temperature profile during the polyamic acid formation also affect the pathway to k_4 (17,18,20). Conversion of the anhydride moiety, k_4, has the effect of introducing another chemical functionality with a different reactivity that can affect both k_1 and k_3 via resonance. As shown on the reaction coordinate (Fig. 2), the effect of k_2 competes with k_1 and k_3 when the reaction temperature is raised and the thermal dehydration (k_5 conversion) to imide is occurring. Once the imide ring is formed, depolymerization is severely limited through removal of the condensate by-product. The choice of diamine and dianhydride affects the rate of polyamic acid formation both sterically, and through the electronic interactions of the monomers (affinity and basicity). PMDA is the dianhydride with the highest E_a value in Table 2. Any diamine that is treated with PMDA should polymerize faster than if it is treated with a dianhydride having a lower affinity. However, once one of the anhydride units of PMDA has reacted, the second anhydride moiety will display a lower reactivity because the former anhydride group has less electronic withdrawing ability since it ceases to exist with the progress of the reaction. This effect on other dianhydrides is less

Table 2. Electron Affinity and Basicity Values of Several Common Dianhydrides and Diamines Used in the Synthesis of Polyimides[a]

Dianhydride	Abbreviated name	E_a, eV	Diamine	Abbreviated name	pK_a (H_2O)
	PMDA	1.9		pDA	6.08

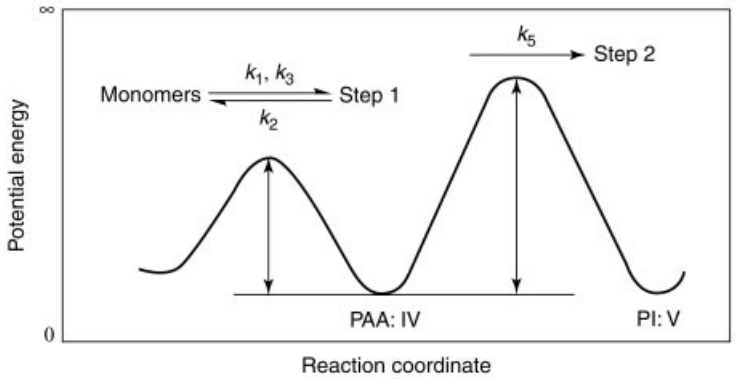

Fig. 2. Qualitative reaction coordinate diagram for polyimde synthesis via polyamic acid. From Ref. 21.

pronounced as the anhydride groups are separated by additional moieties that decrease the impact of the reacted anhydrides (20). A similar trend is seen with diamines. The more basic the amine, the faster it can react with a moiety that is susceptible to nucleophilic attack. Additionally, depending on type, the larger the number of chemical groups separating the amines, the less of an effect the conversion of one amine will have on the reactivity of the other (22).

Solvent effects depend on several factors, including the polarity of the medium, the percent solids, and the solubility of the reactants. As the polarity of the medium changes with conversion to polyamic acid, the viscosity and potential autocatalytic effects (kinetic conversion to polyamic acid) are observed (23). These effects are caused by the increasing molecular weight of the polyamic acid, which results in the buildup of carboxylic acid. The hydroxyl portion of the amic acid can form additional hydrogen bonds to adjacent polyamic acid groups, artificially increasing the observed viscosity (13). These additional carboxyl acid protons can assist nucleophilic attack (on the carbonyl carbon) via coordination with the anhydride carbonyl oxygen, increasing the step growth kinetics to polyamic acid formation. An accurate kinetic profile has been difficult to obtain as a result of the solvent effects and the changing reaction medium. Some investigators claim that irreversible second-order kinetics is followed, while others have observed reversible autocatalytic kinetics when THF is the solvent. Typically, polymerizations carried out in amide solvents (polar aprotic) do not display autocatalytic behavior (23,24). These solvent molecules closely associate with the hydroxyl protons, effectively isolating them from interacting with other anhydrides and amic acids. The reaction rate generally increases as the solvents become more polar and more basic (25,26). A model compound study showed that the acylation rate increased in the order THF < acetonitrile < DMAc < *m*-cresol. The polar protic solvent *m*-cresol was claimed to increase the rate because it functions as an acidic catalyst (23,24). Similar observations were noted when acids (benzoic acid) were introduced into a polyamic acid medium employing an amide solvent. THF, not being very basic, does not associate with the polyamic acid and some reversal occurs. This "retro" reaction (k_2) occurs when a proton is transferred from a carboxylic acid to an amide nitrogen (or any other basic species), followed by the subsequent attack of the carboxylate oxygen on the adjacent carbonyl carbon to re-form the anhydride or the rare isoimide (25,27). This reverse reaction can be prevented by replacing the hydroxyl proton of the polyamic acid with amine salts or esters, causing a marked decrease in conversion to monomeric species (28–30).

The effects of adventitious water on both the starting anhydride and polyamic acids have been shown to decrease their molecular weight over time via conversion to diacid and hydrolytic cleavage, respectively (16,31–33). This drop in molecular weight appears to be more dramatic the more dilute the solution, which is caused by the apparent increase in water content as the percent polyamic acid decreases. Additionally, the conversion from polyamic acid to monomer moieties is unimolecular, whereas the reverse reaction is bimolecular, shifting the equilibrium to the left toward the reactants (8). Evidence has indicated that further imidization of the polyamic acid occurs upon standing over time, having the effect of releasing water into the solution, resulting in further hydrolysis of the polyamic acid (16,34).

Lastly, monomer addition (sequence and rate) has been shown to affect both thermodynamic equilibrium, and the resulting molecular weight of the

polyamic acid. This condition is due to the difference in solubility of the monomers (dianhydride and diamine) in the polymerization solvent (8,16). As the dianhydride slowly dissolves in a medium containing the faster dissolving diamine, it maintains stoichiometric balance with the diamine, setting the condition for an infinite degree of polymerization. This "pseudo-interfacial" polymerization generates high molecular weight polyamic acid until one of the monomers is consumed. Thus, near the completion of the reaction, the medium contains a wide bimodal distribution. As the unreacted or excess monomer has time to come in contact with the high molecular weight polyamic acid, thermodynamic equilibrium (k_1/k_2) occurs and the molecular weights redistribute toward a unimodal distribution (35–37).

Polyimide Formation via the Polyamic Acid. The three methods to form the polyimide from the polyamic acid are thermal, chemical, and a combination of both. The thermal conversion of polyamic acid to polyimide requires the removal of the condensate produced during cyclodehydration (Fig. 1). This is achieved by elevated temperatures and, whenever possible, the addition of a solvent that facilitates azeotropic removal of the condensate. A typical solution for the thermal conversion reaction setup contains approximately 30% solids polyamic acid in NMP and 10% solids xylenes (azeotrope to remove water), and the reaction temperature is maintained at about 165°C for several hours, with water distilling out rapidly early in the reaction (8,38,39). Thermal conversion of polyamic acid in solution is fairly straightforward and becomes complex only when the resulting polyimide precipitates out of solution prior to complete imidization. The kinetics are more complex when the polyamic acid is isolated as a powder, spun as fiber, or cast as a film prior to imidization (40). Generally, the azeotropic cosolvent is not present in these "solid state" preforms, and the effects of the advancing T_g, solvent evaporation rate, percent solids, steric effects, side reactions, cure temperature, and surface-to-volume ratio of the polymeric preform affect the overall kinetics (9,41–43). Thus, attempts to follow the imidization rates using spectroscopy have been confusing as these factors are difficult to account for. One reaction that does not occur during thermal imidization is cross-linking between diamide groups (21,44,45). This is not surprising since there are soluble polyimides cited in the literature, and no spectral evidence exists that support this mechanism. However, thermal aging above 350°C for a period of time may result in cross-linking, but this is most likely due to a free-radical mechanism (thermal degradation) and is influenced by film thickness and the casting surface (46–48). Two pathways of thermally induced imidization are loss of proton on the carboxylic acid group after cyclization (the amide nitrogen initiates the attack on the adjacent carbonyl carbon) or removal of the proton on the carboxylic acid prior to or during ring closure. Since the conjugate base of the amide is more nucleophilic than the amide itself, ring closure should be faster in the latter case (9). When thermal imidization occurs in the presence of an amide solvent, the conversion to polyimide proceeds more readily because the loss of amic acid proton is facilitated through solvent hydrogen bonding. In some cases, the thermal imidization occurs in two steps (9,41). The first step is the rapid conversion to imide above 150°C, and the second step is a slower process during the latter stages of imidization. The following scenario can explain this. During the early stages of imidization, more solvent is present to assist ring closure and the T_g of the polymer is low (9). As the thermal conversion continues, the T_g is increased and the solvent content decreases (41). Chain mobility and

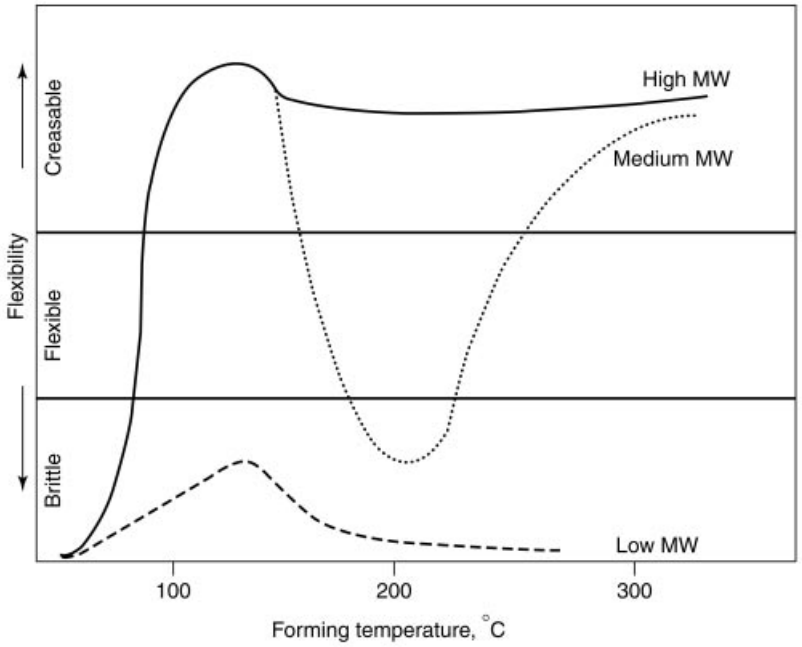

Fig. 3. Qualitative physical properties vs. molecular weight for thermally formed polyimide films (16).

solubility is decreased with increasing conversion, especially if the growing polyimide is semicrystalline. Additionally, as the amount of solvent decreases, the amount of solvent–polymer complexation, which normally facilitates the rate of ring closure, also decreases (9). This two-step rate effect is seen for fibers (high surface area) and cast films where solvent is lost during the processing. It has been shown that thicker films cure at faster initial rates as these films retain the solvent longer, due to extended migration/evaporation time, allowing the chains more mobility to undergo conversion (49). However, the effects of the surface imidizing faster (skinning) than the bulk must be taken into account for thermal convection curing (16). Dry polyamic acid powders with the highest surface-to-volume ratio imidize the slowest. The resulting molecular weight of the polyimide depends, in part, on the molecular weight of the polyamic acid (16). Although the kinetics follow Figure 2, the resulting physical properties of the polyimide films are displayed in Figure 3. Three molecular weight divisions are plotted as a function of temperature versus qualitative physical properties, demonstrating the effect of the polyamic acid molecular weight on the polyimide during conversion. This effect can be rationalized knowing that the amount of chain scission is independent of molecular weight, resulting in a more dramatic effect on lower molecular weight polyamic acids. The lower molecular weight polyamic acids can be reduced to monomers, where these units may be thermally unstable and susceptible to oxidation. When this occurs, the adulterated monomers upset the stoichiometric balance resulting in low molecular weight polyimide. Higher molecular weight polyamic acids are less likely to be converted down to monomeric levels, and the

oligomers will repolymerize to form medium or high molecular weight polyimide as stoichiometry is maintained.

Chemical imidization is not widely used because it employs additional reagents. However, it has the advantage of low temperature imidization and can be used to directly form fine polyimide molding powder (16,50). A typical chemical imidization reaction employs a 20–30% solids polyamic acid in an amide solvent with a slight molar excess of acetic anhydride and a molar equivalent of a triamine (triethyl amine, pyridine, or β-picoline) (51–54). The percent conversion for chemical imidization is a function of polyimide solubility. If the polymer crystallizes and/or precipitates from the reaction medium, imidization will be incomplete (16,50). Those systems that remain soluble must undergo thermal treatment to convert any isoimide, and remove residual solvent. The mechanistic routes of chemical imidization are shown in Figure 4, and involve the use of a triamine

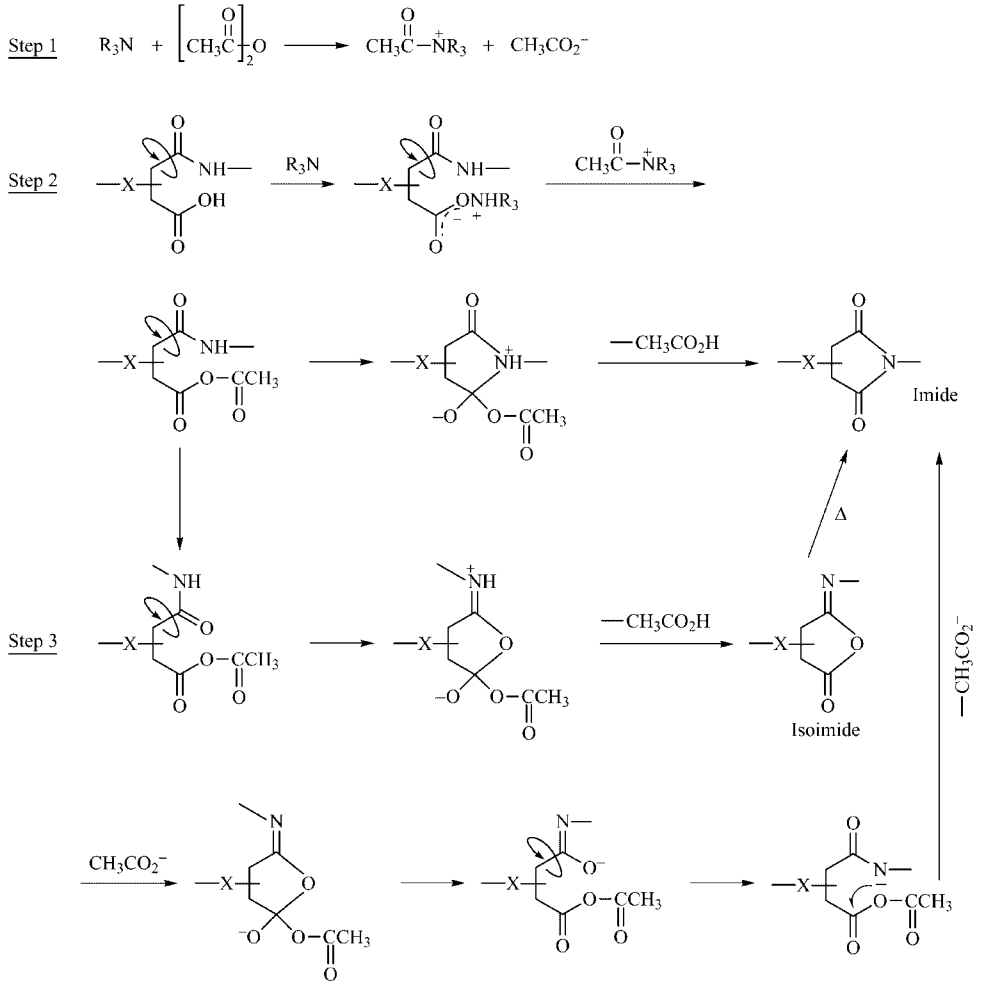

Fig. 4. Reaction Scheme for chemical imidization via polyamic acid.

to form the amine salt from acetic anhydride (step 1) and the amine salt of the polyamic acid (step 2). Next, the salt is replaced with the acetyl group (from the dianhydride salt) to form a mixed anhydride. The acetate group from the mixed anhydride group leaves as the amide nitrogen attacks the carboxylic acid carbonyl. The acetate group picks up the amide proton to form acetic acid resulting in the formation of the imide ring. If the polyamic acid is not in the proper conformation (ie the amide group may be rotated out of position) the carbonyl oxygen may attack the mixed anhydride to form the corresponding isoimide (step 3). The isoimide is readily converted to the imide thermally or by the presence of acetate ions that attack the ester carbonyl carbon, closely following the later stages of step 2. The important step is the conversion of the polyamic acid's hydroxyl group into a better leaving group, the acetate (55,56).

One system that takes advantage of both the chemical and thermal imidization is the gel casting of PMDA–ODA. This system starts as polyamic acid in NMP or DMAc to which is added β-picoline and acetic anhydride. This mixture starts to imidize and forms a gel as it is coated onto a rotating heated drum. The swollen gel film has mechanical integrity that allows it to be stripped off the drum and gripped by a tenter frame. Final conversion and solvent removal is achieved thermally (infrared and convection) while the film is undergoing mechanical orientation (57).

One-Step Formation of Polyimides. Polyimides that are soluble in high boiling organic solvents can be directly converted from their corresponding monomers. This is done by mixing a diamine and a dianhydride into a solvent above 180°C. Typically, solvents such as *m*-cresol with catalytic isoquinoline, nitrobenzene, or NMP are used depending on the polyimide formed (14,58,59). This system is useful for diamines and dianhydrides having low reactivity and those that are sterically hindered, such as perylenic dianhydrides (60,61). The conversion of monomer to polyimide proceeds rapidly with the intermediate polyamic acid being short-lived to the point that it is virtually undetectable. The degree of imidization is nearly 100% (62,63).

Synthesis of Polyimides Using Imide-Containing Monomers. Two methods may be employed to form a polyimide when the imide ring is intact. The first method uses a high yield organic reaction where imide-containing monomers polymerize via a different mechanism (aromatic nucleophilic displacement). The second approach involves thermosetting imide oligomers.

Polyimides via Aromatic Nucleophilic Displacement. Aromatic nucleophilic displacement is used in the synthesis of polyarylene ethers. Halogenated bisimides are polymerized with bisphenolates and activated A–B phthalimides to form polyetherimides (64–67). The reaction proceeds through the Meisenheimer-type transition lowering the activation energy of the displacement reaction. Table 3 shows the relative rates of displacement on substituted phthalimides with phenoxide (eq. 1), and it is worth noting that the displaced nitro group may affect the growing polyimide if not handled properly (66–68). A related synthetic method has been employed specifically for both bisphenols and halogenated diimides or the halogen containing A–B phenolated phthalimide monomers. Bisphenol or the *N*-phenol unit of the fluorinated phthalimide is converted to its corresponding trimethylsylated analogue. Polymerization of these sylated monomers

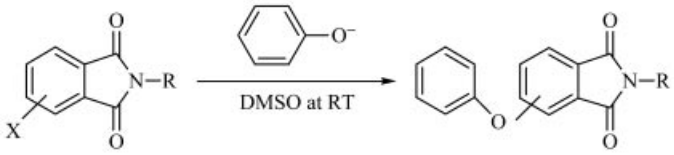
into polyimides is achieved in the melt at high temperature using cesium fluoride as a catalyst (69).



(1)

Polyimides via Addition Reactions. A second approach involves using maleimide-terminated monomers (bismaleimides or BMIs) in equal molar ratios with a dinucleophile, such as a diamine, or a diene like dibenzocyclobutane (BCB) and substituted dicyclopentadienes to form the corresponding linear polyaspartimides via Michael-type addition or the polyimides via a Diels–Alder [4 + 2] cycloaddition (Table 4) (104–115). Linear polyimides can be synthesized directly from the A–B maleimidobenzocyclobutane monomers (116). These reactions proceed without volatile evolution, but undergo thermally initiated retrograde reactions that lead to change in physical properties, chemical cross-linking, and aromatization of the cyclohexene ring (BCBs). Reactions involving BMIs with dicyclopentadieneones also proceed by a cycloaddition mechanism (114,115). This has the same advantage inherent to all Diels–Alder reactions in that no volatiles are generated. However, with these pentadieneone dieneophiles, CO is eliminated forming a cyclohexadiene moiety. The cyclohexadiene can undergo further addition reactions or aromatize with the abstraction of two hydrogen atoms, depending on the reaction conditions and the added stability of any pendent substituents (114,115). This type of chemistry can be used to create photosensitive polyimides for imaging. The last approach utilizes free-radical polymerization of substituted maleimides to afford ethylenic-type imide polymers (117,118). Maleimide groups are copolymerized with styrene and other maleimides to afford copolyimides. Polymerization of these systems is typically carried out with AIBN in polar solvents such as THF (119). These types of polyimides can be used for a variety of applications depending on the selection of the N-substituent.

Thermosetting systems involve the placement of reactive moieties on the imide containing molecule (1 part), and these oligomers can be blended with other reactive oligomers (2+ part) to provide additional benefits (Table 4). These

Table 4. Chemical Groups Used for Functionalizing or Reacting with Polyimides[a]

Reactive group	Onset cure temp., °C	Comments on long-term stability at 177°C
—O C≡N (Cyanate)	200–230	Poor thermal stability
 (Benzocyclobutene)	200–250	Coreacts with maleimide, poor long-term stability
—OCF═CF_2 (Trifluorovinylether)	250	Small processing window, unknown thermal stability
—C≡CH (Ethynyl)	200	Small processing window, unknown thermal stability
 (Phenylethynyl)	320–370	Excellent thermal stability
 (Nadimide)	300–350	Cyclopentadiene evolution, low toughness
 (Maleimide) (Chloromaleimide) (Methylmalimide)	200–230	Poor thermal stability
200–230	Poor thermal stability	
220–250	Poor thermal stability	
340–370	Unknown thermal stability

systems contain maleimide, norbornene (nadic), vinyl and allylic, acetylenic, phenylethynyl, or other types of unsaturated groups that react to cross-link the polyimide (70–99). When bismaleimides are used alone or in excess with a difunctional (at least) nucleophilic monomer, the resulting system is thermosetting, with chain extension (via Michael-type addition) occurring prior to the thermal

cross-linking of the maleimide functionality (via Michael addition) (120–124). Although the cross-linking of the maleimide group is thermally initiated, it is catalyzed with both free radicals and bases (72,73,118). Typical synthesis involves 30% (or more) total solids diamine and two equivalents of maleic anhydride in acetone at ambient temperature. After the bismaleamic acid precipitates (several hours), triethyl amine (approximately 0.5 equiv) is slowly added to the mixture until dissolution occurs. Acetic anhydride (slightly over 1 equiv) is added and the mixture is heated at reflux for several hours and the crude product is isolated by water precipitation. The intermediate maleamic acid is susceptible to isomerization during cyclodehydration, resulting in the production of the less desirable acetanilide (72,115). Metal acetate catalysts have been known to increase the yields of BMI (125). However, it has been the author's experience that these catalysts tend to be difficult to remove and provide marginal benefit. Blends of BMIs with aromatic allyls and phenylpropenyl oligomers, such as a bisallylphenol, have been used as thermosetting systems that undergo a complex reaction involving ene addition followed by Diels–Alder addition, respectively (90,91,93,95,98,99,126,127). The nadic group has been extensively explored for creating polyimide thermosetting resins including the "PMR" materials. These nadic-terminated oligomers are formed from nadic anhydride (NA), a diamine, and a dianhydride (87,88,128–133). These systems (like their aromatic counterparts) do not exhibit the same behavior as maleamic acid does during imidization as structural conformation remains in place. Unfortunately, the nadimides generate cyclopentadiene at the elevated temperatures required to cure them. Hence, these systems must be cured under pressure to avoid volatilization of the cyclopentadiene, which copolymerizes with itself, other nadic moieties, and the resulting maleimide (134–136). In an attempt to create a high temperature thermosetting imide system that can be handled as a room temperature liquid, the PMR approach was developed (polymerization of monomeric reactants). Here, the dianhydride and NA are treated with molar equivalents of an aliphatic alcohol and allowed to form the liquid diacid-ester isomers. The diamine and the diacid-esters are then dissolved in methanol, and the liquid system is solution cast or coated onto a preform to create a prepreg that is dried and cured under pressure to form a composite part. The advantage of this system is that the monomers remain intact at or below room temperature (89,137–139). The molar ratios of the diacid-methylester of BTDA, 4,4′-methylenedianiline (MDA), and the acid-methylester of NA of 2.087:3.087:2 are used to make a 1500 g/mol imidized reactive oligomer referred to as PMR-15. Acetylenic groups on polyimides are used to induce thermal cross-linking (76,140). The actual chemical structures developed during the acetylenic cross-linking can vary, as the reactivity of these groups is high enough to allow attack on chemical moieties other than acetylenic units (141). National Starch's Thermid IP-600 is an acetylene-terminated thermoset that has enhanced solubility, as it is an isoimide that thermally converts to imide when cured (142,143). The highest temperature matrix resin/structural adhesives were those based on phenylacetylene (phenylethynyl) (94,144,145). NASA's PETI (*p*henylethynyl-*t*erminated *i*mide) series consist of systems that cure at temperatures above 320°C (100–103,146–149).

Polyimides via Polymer Conversion. One method has already been introduced through the chemistry of isoimide synthesis and conversion. If the isoimide is desired directly, a polyamic acid is dissolved in a solvent system that

facilitates removal of the by-product and a molar equivalent of dicyclohexylcarbodiimide "DCC" or similar cyclodehydrating agent. These isoimides are then converted by thermal conversion to the corresponding imide (150). Other methods involve transimidation and treatment of dianhydrides with diisocynates. Transimidation involves the exchange of one imide nitrogen functionality (as the amine) for another. This type of reaction is favored when the attacking amine is more basic than the amine that comprises the imide ring. Because of the lower reactivity of aromatic amines, in comparison to aliphatic amines, this type of reaction offers certain advantages. When the less basic 2-aminopyridine terminates imide oligomers, this amine can be readily exchanged for other aromatic diamines to form a high molecular weight polyimide through proper stoichiometric control (151–154). This scenario allows for the formation of otherwise infusible polyimides, via melt processing techniques, and also permits the incorporation of chemical moieties that are susceptible to hydrolysis via the polyamic acid route. Another conversion route involves the reaction of diisocyanates with dianhydrides to form the polyimide followed by elimination of CO_2 (155–162). There is not a general consensus on the mechanism of this reaction. Some researchers contend that the isocyanate reacts with water to form the amine or alcohol to form the urethanes that react with the dianhydride to form the polyimide (157). Others favor a seven-membered ring formation that liberates CO_2 forming the imide ring (155). Metal salts have catalyzed these imide-forming reactions, and some have been polymerized in the melt (163,164).

Polyimide Structure–Property Relationships

One of the features of polyimides is that the polyimide macromolecules interact with themselves and with each other by either an electronic polarization or charge-transfer mechanisms (165,166). The degree to which these mechanisms play a role depends on the electron affinity of the imide ring (deficiency) and the electron donating ability of the N-substituent (ionization potential) (19). The extent to which these electronic interactions affect the neighboring polymer molecules influences the polyimide's color, glass-transition temperature, crystallinity, mechanical properties, and chemical resistance (167,168). It is apparent that the intrachain electronic polarization affords the yellow to dark orange color that arises in polyimides (167,168). The amount of chromophores present can be controlled to some extent by the selection of the cyclodehydration environment choice of monomers, polymerization conditions, and especially processing methods; and is not related to the presence of unconverted isoimide (167). Generally, the bulk structure–property relationships that apply to most polymers apply to polyimides. The thermal transitions are influenced by the selection of monomers and processing techniques (169–171). Monomers that have kinks, offsets, swivel units, pendent substituents, aliphatic moieties, and bulky units tend to lower the T_g, melt viscosity, and crystallinity and increase the solubility, as these units take up more free volume and introduce a more random structure than their symmetric counterparts (50,172–185). The proper selection of monomers has produced soluble nearly colorless polyimides by the introduction of fluorine-containing monomers (167,168). One interesting and unique polyimide developed by NASA, LaRC-SI,

does not use the standard approaches to develop solubility. This polyimide starts from a mixture of two dianhydrides BPDA and ODPA and a diamine 3,4′-ODA to afford an amorphous high molecular weight polyimide that is soluble in common high boiling amide solvents (38,182,186). What is intriguing is that the two homopolymers, ODPA/3,4′-ODA (LaRC-IA) and BPDA/3,4′-ODA, and the copolymer using ODPA/BPDA/4,4′-ODA are all insoluble and semicrystalline (182).

Aromatic polyimides are highly thermally stable because of their degree of aromaticity and ring structure. Typical decomposition points for polyimides, not subject to thermally initiated retro reactions, are above 450°C in air and above 500°C in nitrogen (187). Endcapping a polyimide with a stable monofunctional unit also enhances thermal stability by protecting chemically active chain ends that are subject to thermal and chemical instability (188,189). As a class, polyimides are resistant to chemical attack and moisture. An exception is the PMDA-containing polyimides that are hydrolyzed under basic conditions (190–192). The effect of degradation of one imide ring, in PMDA, changes the characteristics of the other ring via resonance through the common aromatic ring. This is also the case with monoaromatic diamines like pDA. However, most polyimides are highly resistant to caustics, acids, organic solvents, specialty fluids, and salts, even at elevated temperatures (38,100,103,175). The electrical properties of polyimides have led to their widespread use as dielectrics, flexible substrates, and wire insulation for the electronics industry (193–198). Although the imide ring is polar and electron deficient, the two dipoles of the carbonyl groups oppose each other and the imide rings along the polyimide backbone also directionally oppose each other. This simulates the bulk effect of a nonpolar polymer. Thus, polyimides make good dielectric materials when combining these properties with their high temperature and chemical stability (196,199–202). As expected, fluorinated polyimides display the best dielectric properties (low dielectric constant) as the fluorine atom imparts low polarizability, water uptake, and surface energy (200–202). Similar comparisons can be made from PTFE systems and their corresponding hydrocarbon analogues. The bulk mechanical properties of aromatic polyimides are among the best for commercial plastics (203). This is due to the interchain interactions of polyimides and their structural integrity imparted by their aromatic character (166,204). Additionally, those polyimides that can undergo melt processing tend to make excellent hot melt adhesives.

Photoimageable Polyimides

There are several ways (see Fig. 5) in which polyimides have been used in applications where "photoimaging" is required to produce a pattern on a substrate (typically silicon, or other materials including polyimide itself) (205). The first method is reactive ion etching (RIE) (includes plasma etching) or photoablation. This method does not require a photosensitive material, only a mask that can withstand the reactive ion gas or photons, and the material to be patterned, which is protected by the mask. In RIE, the reactive ions, generated by an RF field, attack the exposed polyimide to etch out the pattern of the mask. This process can be used with conventional polyimide film and requires few steps, but is not highly accurate and requires a hard (metal, silicon, etc) mask. The other methods

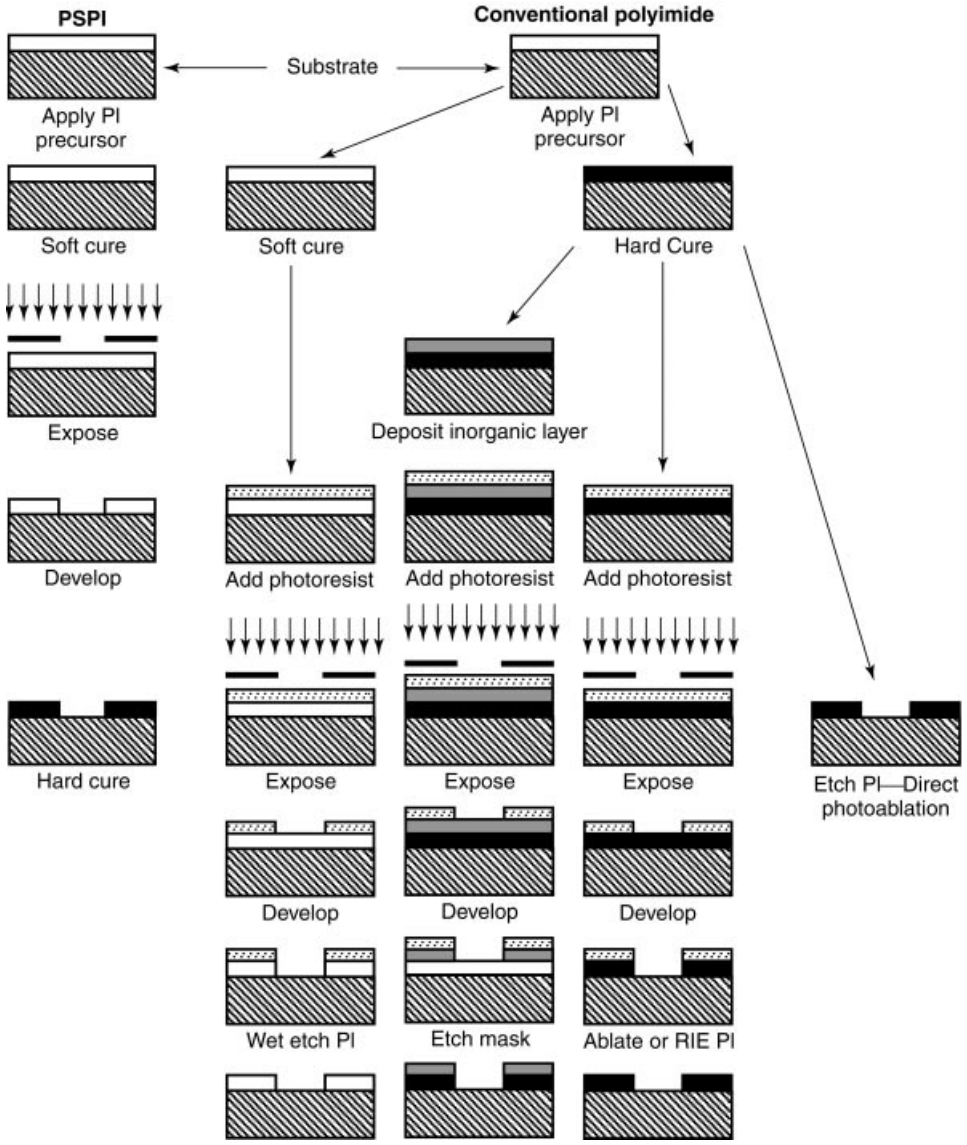

Fig. 5. Chart of various photoimaging processes. Reprinted from Ref. 205 p. 744, by courtesy of Marcel Dekker, Inc.

involving the conventional polyimide, as a dielectric, require an additional photosensitive material as the overcoat. The method is very much the same as using a mask, but higher degrees of accuracy are obtained as the photosensitive material's exposure and development are done with coherent short wavelength light. The combination of step reduction, increased accuracy, and less complexity while maintaining good dielectric, mechanical, and thermal properties have spurred the development of photosensitive polyimides (PSPIs) used with these photoimaging methods (206,207).

Photosensitive polyimides are often used in their soluble polyamic acid form and are of the negative resist type (forms a negative image on exposure). The polyamic acid has photosensitive units either attached to the polymer backbone, in conjugation with the carboxyl unit of the polyamic acid, or incorporated into the polyimide structure. Specific areas of the cast photosensitive film are exposed to light, thereby becoming insoluble, and the masked portions (unexposed areas) are washed away with solvent. The remaining cross-linked (exposed area) is then baked to thermally cure the polyamic acid and remove the photosensitized units. There are several approaches used to create PSPIs, with the more popular being those of the covalent, ionic, and intrinsic types (208). The covalent type was one of the first and still widely used commercial approaches. A photosensitive unit is attached to the carboxyl group of the starting dianhydride prior to polymerization with a diamine (Fig. 1, k_4 followed by k_3). The resulting sensitized polyamic acid is then exposed and the resulting sensitized ester unit photo-cross-links. The exposed film is then developed and baked (Fig. 1, k_5). Such photosensitive units are of the methacrylate or cinamyl variety. The ionic type is similar to the covalent type but instead the premade polyamic acid is sensitized using a tertiary amine having a photoreactive group and a photoinitiator. The interaction of the tertiary amine and the polyamic acid hydroxyls forms a photosensitized salt that is ionically bound to the polyamic acid (similar to Fig. 4, step 2). The ionic PSPI is then exposed, washed, and baked to develop the image. The last type is the intrinsic PSPIs, meaning that they are photosensitive as made. These PSPIs are generally based on BTDA and orthoalkylated diamines. When these intrinsic systems are exposed to a 365 nm wavelength, the hydrogen atoms of these pendent alkyls are abstracted through the excitation (C=O diradical formation) of the benzophenone radicals, inducing cross-linking of the pendent methylene radicals. Overall resolution of PSPIs is controlled by several factors including film thickness, exposure wavelength, and the selectivity of the developer. These drawbacks manifest themselves through pattern distortion, shrinkage, pinhole formation, and thermal stability effects during wafer processing. Most of these developed PSPIs have mechanical properties close to that of a standard polyimide film, demonstrating excellent planarity (surface flatness) and good breakdown voltage resistance.

Applications

Polyimides are manufactured in a variety of forms, finding utility ranging from electronics and medical to structural and adhesive applications. One of the more prevalent forms of polyimides is films. The most popular films are Dupont's Kapton, Ube Industries' Upilex, and GE's Ultem, and Kanekafuji's Apical, to name a few. In film form, some of these materials do not display a T_g, have good radiation resistance, and are used as bagging materials for composites, belts, and wire wrapping. Polyimide films have excellent mechanical properties with elongations from 30 to 120%, and tensile strengths and moduli 170–270 MPa and >3 GPa, respectively. They are coated with acrylics and silicones to make pressure-sensitive tape (209). They are also coated with an adhesive to bond metal foil (copper) on one or both sides, and sold to PCB manufactures for flexible cabling and circuits (examples include DuPont's Pyralux and clad derived from Kaneka's Apical series

of PI films). Metal is also vapor deposited onto polyimide films for applications requiring thin copper (less than 0.5 oz/12 μm) and where the additional adhesive is undesirable. Since these films and clads serve as dielectric materials, they are tested under IPC TM-650 tests and display breakdown voltages above 200 V/μm (5 kV/mil) and 1 MHz dissipation factors of 3.2 on average (198). Another method to create metallic coatings is an *in situ* method involving the introduction of silver organic salts [complexed silver(I) acetates] or other metallic complexes into the polyamic acid; through thermal imidization, the silver metal is reduced and migrates to the surface to form a reflective coating (9,210–213). For years, the electrical and aerospace industry has used polyimides as high performance wire insulation. These coatings are used in combination with other materials and may be either biaxially wrapped onto the wire, solution coated, and dried in multiple passes to form a varnish, or directly extruded over the wire. The polyimide insulation must survive tight radial bends, chaffing, and electrically induced oxidation and carbon tracking (193,214–216). A similar method to that of the wire varnish process is the fabrication of microporous membranes, thin walled tubes, and fibers. Flat or hollow fiber membranes are made by selective solution blending and thermal evaporation techniques and may also consist of rolled multiwalled structures (217–220). Similar methods are also used when creating open cell polyimide foams of varying density (221–225). Thin walled polyimide tubes created from PMDA and BPDA–ODA polyimides cannot be made via melt processing and are created by successive layering and drying to build up thickness and then removal of the internal wire or mandrel (via rapidly applied mechanical strain) that was used to provide the prerequisite form. These polyimide tubes find use as GC columns for chemical separation and as catheter medical tubing (226). The requirement of the preform selected is that it must release cleanly and uniformly from the cured polyimide. Continuous fibers, solution spun and dried from polyamic acid or as the polyimide, present a challenge as the solvent, cyclodehydration, and shrinkage problems associated with curing the fiber result in a technical challenge. Although the properties of these fibers are excellent when the proper draw ratio is used, they have not achieved a high performance niche market able to economically compete with polyesters or polyaramides (215,227,228).

Melt-Processable Polyimides. Polyimides that display a T_g and T_m well below their decomposition or thermosetting temperatures are candidates for melt-processing techniques that include extrusion, injection, and compression molding. Several other factors play into the selection of melt-processable polyimides and include melt viscosity, work time or pot life at temperature, and the ability to carry fillers or blends. Melt viscosity is crucial as it directly relates to molecular weight, affecting the processing temperature (189,229–231). The higher the molecular weight, the higher the temperature and pressure needed to create the part. As the polymer's molecular weight increases, the mechanical properties increase until a critical molecular weight is obtained, where the melt viscosity increases while the mechanical properties start to level out. This "knee" or bend in the mechanical and physical properties versus molecular weight curve is where any further increase in molecular weight increases the complexity of the melt forming without a significant improvement in the overall properties of the neat resin (229–231). The influence of molecular weight and its relationship to melt viscosity are affected by the structure of the polyimide in a fashion similar to the basic structure–property

relationships discussed earlier. Several resin systems developed by GE, NASA Langley, Furon, Mitsui, and others have found utility as thermoplastic molding resins. The T_g for these thermoplastic polyimides are in the range of 210–270°C and are processed 50–150°C above their glass transition temperature (229,230). The molecular weights of these resins range from several thousand to above 25,000 g/mol. These systems display excellent fracture toughness and high modulus and have been extruded, compression molded, machined and polished neat, or filled with graphite, PTFE, and metal and ceramic powders. These thermoplastic polyimides are sold as rod, sheet, and film stock or as final stock parts and composites (232–238).

Thermosetting polyimides solve the molecular weight effect on melt viscosity, but add the additional problems associated with curing exotherms and time/temperature limited processing windows. Thus, a wide processing window from the melt flow of the monomer(s) to the onset cure temperature should be selected. The melt-processable thermosetting systems are typically BMIs, PMRs, or BCB–maleimides, and these can blended with chopped fibers or other fillers, ground, or extruded and pelletized for moldings (239,240). These imide oligomers are then cured into high performance PCB substrates and composite forms. Recently, NASA Langley has developed several PETI-based low viscosity thermosetting resins that can be injection molded or resin infused into carbon fiber performs and then cross-linked at elevated temperatures (241).

Directly Formed Polyimides. There are several polyimides that do not undergo melt flow, but are directly formed into parts requiring performance under extremely harsh conditions (242,243). These direct formed polyimides include DuPont's Vespel (includes the SP product line), Ube's Upimol-S, and Imitec's I-903 and I-772. These polyimides undergo a forming process similar to that of ceramic sintering. The starting fine particle polyimide powder is either hot isostatically pressed (HIPed) or ram extruded and hot formed to generate a polyimide stock shape with a density in the range of 1.4–1.5 g/cm^3. These polyimide powders have also been blended with graphite, PTFE, and boron nitride for dry lubrication. These parts have very low CTE and do not smear under load at elevated temperatures, making them excellent choices for high temperature pressure–velocity requirements. These molded parts have found utility in rotating equipment, silicon wafer and chip processing, machine tooling, and chemical and material processing.

Polyimide Matrix Composites and Adhesives. Polyimides display properties that make the resulting advanced composites excellent choices as primary structural members for aerospace applications (244). The fibers in the composite are the load carrying members and the resin serves to transfer the load to the fibers and hold them in place. The composite is only as good as the resin. Thus, the selected matrix resin must have excellent thermal, chemical, and mechanical toughness, and high compressive strength and adhesive properties. One of the key elements in creating a strong composite is the wetting out of the fibers with the proper amount of resin. This is achieved by two methods, dry and wet (or solution) prepregging (245). The dry-coating method may consist of coating the fibers with fine polyimide powder and melt shearing the powder to form a film about the fibers (246). Another dry process involves melt-infusing a polyimide film into a fiber matrix affording prepreg tape. Solution prepregging involves the coating of the fibers with a solution containing the polymer or reactive monomers and

removing the solvent at a later stage to form the prepreg tape. The resulting prepreg should display tack and drape, ie, tack to allow it to remain in place prior to and during consolidation, and drape to allow it to contour to the tooling surface. These prepregs are then cut into the desired shapes, stacked, and laminated together on a tool in a hot press or autoclave to form the composite part. In order to achieve excellent consolidation, these polyimide laminates must undergo melt flow and adhere (240). Hence, the polyimides must display high adhesive strength under a variety of conditions. Initial Criteria for screening the hot melt aerospace polyimides is the titanium–titanium or aluminum–aluminum lap shear test (ASTM D1002); for the electronic industry, the T-peel and 180° peel tests are used (ASTM D1976 and D3330). Titanium lap shear strengths for polyimide adhesives range from 2000 psi to over 8000 psi under ambient conditions. It is worth noting that surface preparation plays a key role in determining the adhesive strength of the resin system. The polyimide resin systems that have been used for aerospace composite programs include BMIs, PMR-15, DuPont's Avimide series (based on the PMR approach), and NASA's PETI-5 (developed under the HSR program) that exceeds the performance criteria for the High Speed Civil Transport as a structural adhesive and matrix resin for this advanced composites program (240,247,248).

POLYMERIC DRUGS

Introduction

The use of functional polymers in medicine has seen considerable growth during the past two decades (1). Polymers as biomaterials have found applications in such areas as artificial organs, tissue engineering, components of medical devices, and dentistry. A growing aspect of the field is the recognition of polymers as useful therapeutic agents, ie, either polymers that exhibit pharmacological properties themselves, or that can be utilized as carriers for selective and sustained delivery vehicles for small molecule or macromolecular (eg proteins, genetic materials, etc) pharmaceutical agents.

There has been a growing literature pertaining to the use of functional polymers as delivery agents for therapeutics against a variety of disease states. They include delivery of drugs at a sustained rate, targeted delivery of drugs at specific sites (to minimize toxicity and enhance selectivity for certain antitumor agents), as well as macromolecular prodrugs with polymers acting as carrier molecules (2–4). More recently, polymers have been used as nonviral vectors for the delivery of genetic materials for gene therapy (5). There have been significant advancements in the area of polymeric drug delivery systems (including commercial products). Numerous research papers and excellent review articles dealing with this aspect of biomedical polymers have been published over the last two decades (6,7) (see CONTROLLED RELEASE TECHNOLOGY; GENE-DELIVERY POLYMERS).

Although polymers are used extensively as drug delivery agents, *intrinsically* bioactive polymers (polymers as active pharmaceutical ingredients) are a relatively recent development (8). Partly because of their high molecular weight, polymers would appear to offer several advantages over low molecular weight agents as potential therapeutic agents. These benefits may include lower toxicity, greater specificity of action, and enhanced activity due to multiple interactions (polyvalency). Nevertheless, the concept of polymeric drugs has been a subject of considerable skepticism, with medicinal chemists long considering synthetic

Encyclopedia of Polymer Science and Technology. Copyright John Wiley & Sons, Inc. All rights reserved.

polymers uninteresting as a class of potential pharmacophores. Some of the underlying concerns include the issue of polydispersity in molecular weight, and compositional heterogeneity (copolymers in particular) that could complicate process development. The high molecular weight characteristics of polymers make their systemic absorption through oral administration less likely. However, as we show below, these potentially limiting pharmacological characteristics of polymers can in fact be exploited to design and develop therapeutic agents for disease conditions where low molecular weight drugs have either failed or produced inadequate therapeutic profiles (9).

The fact that high molecular weight polymers are not (typically) absorbed from the gastrointestinal (GI) tract may be a decided advantage where it is desirable to deter a therapeutic from systemic exposure. For example, by combining this characteristic with the ability of polymers to selectively bind molecular and macromolecular components in intestinal fluids, it has become possible to develop a powerful new class of therapeutic agents that can selectively bind and remove detrimental species from the GI tract. As with any pharmaceutical, sequestration of each target molecule or pathogen requires a unique strategy and this strategy depends on not only the chemical nature of the target but also the location, concentration, and quantity of the target requiring removal.

Since several books and review articles have been published covering the area of polymeric drug *delivery* systems (2–7), this article has been limited to case studies where polymers act as active drugs. This article focuses on some of the most recent efforts in this regard and concentrates on the development of polymeric drugs for the sequestration of low molecular weight species such as bile acids, phosphate, and iron as well as polyvalent interactions to bind toxins, viruses, and bacteria. Of additional note is the use of polymers for the treatment of autoimmune diseases by inhibiting specific biological antigen binding events, and the use of conjugates of therapeutically active proteins with polymers as hybrid polymeric drugs. The latter approach to novel biopharmaceuticals overcomes possible antigenic properties of the therapeutic proteins in addition to protecting them from degradation by peptidases.

Polymeric Drugs as Specific Molecular Sequestrants

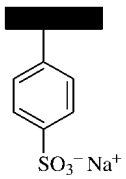
A number of potentially detrimental substances are present in the GI tract. These molecules and pathogens are implicated for various disease conditions. These species can be exogenic, that is, they enter the body with food, drinks, or from the environment or they may be produced endogenously as a result of metabolic processes. Effective removal of these species in a selective manner offers a promising prophylactic and therapeutic approach for the treatment of a number of disease states. Biocompatible polymeric sequestrants represent an ideal class of agents for this purpose. Their nonabsorption through the intestinal wall should offer minimal toxicity, while the incorporation of appropriate functional groups and manipulation of polymer physicochemical characteristics provides opportunities to tailor-make polymers with high selectivity and capacity.

Polymeric Sequestrants for Inorganic Ions. Electrolytes play a key role in regulating distribution of different inorganic anions and cations between

the intracellular and extracellular fluid compartments (homeostasis), and are vital in maintaining myocardial and neurological functions, fluid balance, oxygen delivery, and acid–base balance. Electrolyte imbalance, caused by either excessive ingestion or impaired elimination of an electrolyte from the body, has important physiological effects. Although certain nonrenal tissues (eg, muscle and liver) contribute to maintaining electrolyte balance, the kidney plays the predominant role in maintaining electrolyte balance (10). Therefore, renal impairment is the most common reason for electrolyte imbalance and can lead to critical health conditions. Conceptually, nonabsorbed polymeric sequestrants could be used to bind these excessive ions (implicated in various pathologic conditions) selectively in the GI tract.

Polymeric Potassium Sequestrants: Nonabsorbed Therapy for Hyperkalemia. Since the transmembrane potential is a major regulator of cell function, the ratio of potassium between intra- and extracellular fluids is critically important to all living cells (11). Hyperkalemia (elevated level of serum potassium, usually greater than 5.0 meq/L) can result from burn and crush muscle injuries, acidosis, or through the use of antihypertension drugs (angiotensin converting enzyme inhibitors). A rise in serum potassium can manifest moderate to serious health problems including paresthesias, areflexia, respiratory failure, and bradycardia (12). Since the kidney is responsible for elimination of most excess potassium, patients with impaired renal function are incapable of maintaining potassium homeostatis. Traditional approaches to treat hyperkalemia include use of insulin, glucose, sodium bicarbonate, and calcium chloride. However, these treatments have their own shortcoming. For example, excess calcium could lead to hypercalcemia, that in turn leads to myocardial infarction, kidney stones, and a variety of other conditions.

Use of an insoluble polyanionic resin to sequester excess potassium in the GI tract with elimination in the feces could enable patients to excrete potassium despite impaired kidneys. There are a number of low molecular weight ligands, which complex potassium ions (13). Utilizing this principle, a cation-exchange resin based on sodium polystyrene sulfonate (**1**) was developed to sequester potassium ion in the GI tract. This polymer, marketed under the brand name Kayexalate (Sanofi-Synthelabo) (14), was approved in the United States for the treatment of hyperkalemia in 1975, and is administered orally or rectally. A potential problem with its use is induction of hypernatremia (elevated serum sodium), since the material exchanges 1.0 equiv. of potassium for 1.5 equiv. of sodium. Furthermore, cases of intestinal necrosis have been attributed to Kayexalate (15). The adverse effects associated with Kayexalate may provide an opportunity for developing new generations of potassium sequestering polymers.

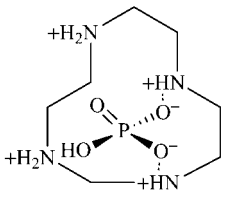


1

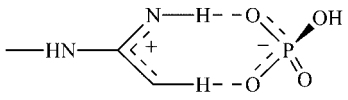
Polymeric Phosphate Sequestrants: Nonabsorbed Therapy for Chronic Renal Failure

Management of hyperphosphatemia (elevated serum phosphate) is a severe issue for patients suffering from chronic and end-stage renal failure (16,17). The major route for the excretion of phosphate in a healthy human is through the kidney, whereas patients with an impaired renal system accumulate phosphate ion through an imbalance in ingestion and excretion. This accumulation of phosphate leads to various pathologies of clinical importance including soft tissue calcification (leading to increased cardiovascular risk) and renal osteomalacia leading to bone pain, reduced bone density, and eventually fracture. The conventional treatment for hyperphosphatemia involves formation of insoluble calcium or aluminum phosphate in the GI tract by the administration of calcium and aluminum salts (18,19). However, since aluminum and calcium salts have the propensity to be absorbed through the GI wall, they can lead to undesirable toxic and metabolic side effects in patients with impaired renal function. Design and development of nonabsorbed cationic polymers as sequestrants for phosphate ions offer an ideal approach to treat hyperphosphatemia in renal failure patients.

The known binding of phosphate by polycationic species has long been a well-studied phenomenon. Polycationic compounds such as macrocyclic oligomeric amines and oligomeric guanidinium compounds (eg, **2** and **3**) have been used as receptors to study molecular recognition events involving phosphate and phosphonate anions as guests (20,21).



2



3

Electrostatic interaction is the primary governing force for this complexation and hydrogen bonding is considered to lend additional binding strength. Utilization of this principle of physical organic chemistry has led, in our hands, to the discovery of a series of nonabsorbed polymeric amine compounds that show affinity toward dietary phosphate (22) and to an effective therapeutic approach to hyperphosphatemia. Amine-functionalized polymer hydrogels (qv) were prepared either by the cross-linking of amine polymers or by the cross-linking polymerization of amine containing vinyl monomers (23–25) (see HYDROGELS). A variety of polymer gels were initially prepared, including materials bearing primary, secondary, and tertiary amine groups, in addition to polymers containing quaternary ammonium and guanidinium groups. Figure 1 illustrates the structural repeat units of a selection of these polymers; the phosphate binding capacities of the materials are summarized in Table 1. From several polymers investigated in detail, polyallylamine cross-linked with epichlorohydrin (**4**) was found to exhibit maximum phosphate

Table 1. Phosphate Binding Properties of Various Amine Functional Polymers at 5 m*M* Phosphate

Polymer type	Phosphate bound to polymer, meq/g
Polyallylamine/epichlorohydrin	3
Polyethyleneimine/acryloyl chloride	1.2
Diethylenetriamine/epichlorohydrin	1.5
Poly(dimethylaminoethylacrylamide)	0.8
Poly(4-trimethylammoniummethyl)styrene chloride	0.7

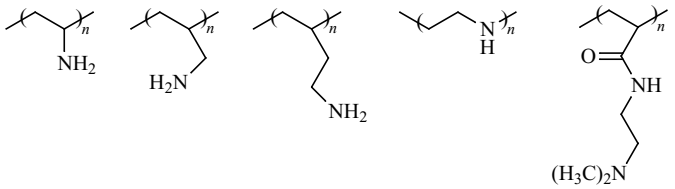


Fig. 1. Structural repeat units of some phosphate-binding polymers.

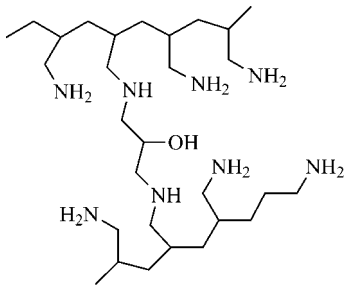
capacity, binding, it is believed, through electrostatic and possibly through hydrogen-bonding interactions.



4

As with low molecular weight receptors for phosphate, the binding strengths and capacities of these polymers were found to depend on the pH of the medium. Since more ammonium groups are present at lower pH, the polymers exhibit higher binding capacity at lower pH. Because of higher concentration of amine groups in a polymer chain, and the divalent (and possibly trivalent) nature of phosphate anions, polymeric amines probably also exhibit stronger affinity over small molecule binders as a result of a chelating effect, although that phenomenon has not been examined in detail. Furthermore, assuring an appropriate spacing between the positive charges of the amine groups in the polymer chain and the backbone are key to the phosphate binding capacities of these polymers (26). Finally, polymers containing primary amines were found to be better phosphate sequestrants than polymers bearing secondary and tertiary amines, while polymers containing quaternary amines were found to be the poorest.

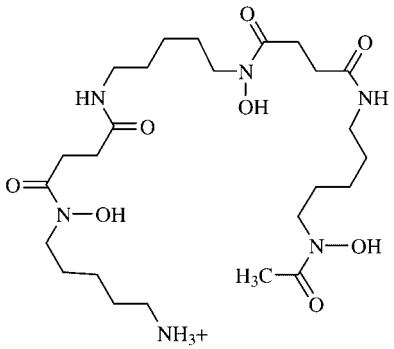
A systematic investigation taking these factors into account suggested that cross-linked polyallylamine gels are the most potent phosphate-binding polymers and possess properties suitable for pharmaceutical applications. This class of polymers exhibited maximum phosphate binding in the pH range encountered in the small intestine, while the polymer gel was found to be nontoxic and is essentially nonabsorbed. It was furthermore very well tolerated in end-stage renal failure patients undergoing hemodialysis (27).

A cross-linked polyallylamine has been developed commercially as a treatment for hyperphosphatemia under the generic name of sevelamer hydrochloride. Approved in the United States by the FDA in 1998, it has been marketed since under the brand name Renagel by Genzyme Corp. Renagel has been found to offer several advantages over and above traditional agents for the management of hyperphosphatemia in renal failure patients (28). It remves the need for exposure to toxic metal ions like aluminum and eliminates the intake of additional calcium, thereby alleviating the possibly serious issue of hypercalcemia. Furthermore, Renagel has been found to reduce serum parathyroid hormone and also reduce total and low density lipoprotein (LDL) cholesterol in hemodialysis patients. Since cardiovascular events are the most common causes of mortality of dialysis patients, Renagel offers a very promising treatment in the management of renal failure, and represents one of the first tailor-made, polymeric drug that exhibits its prophylactic and therapeutic properties through selective adsorption of unwanted dietary components in the GI tract.

Iron-Binding Polymers for the Treatment of Iron Overload Disorders

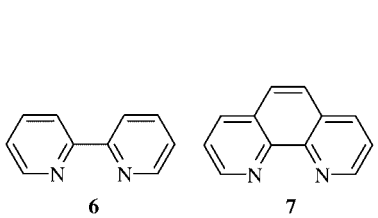
Although iron is essential for the proper functioning of all living cells, it is toxic if present in excess (29). In the presence of molecular oxygen, excess iron can produce oxygen-derived free radicals such as hydroxyl radical. These reactive free radicals interact with many biological molecules, resulting in peroxidative tissue or organ damage that forms the basis for several pathological conditions. Under normal conditions, iron metabolism is highly conserved, with the majority of the iron being recycled within the body. There is no normal iron loss mechanism; iron is not normally present in urine, feces, or bile. Its loss occurs only through bleeding or normal sloughing of epithelial cells. Certain genetic disorders can, however, lead to increased absorption of dietary iron (as in the case of hemochromatosis) or transfusion-induced iron overload (as in the case of β-thalassemia and sickle cell anemia) (30,31).

Although excess iron can be removed by venesection (especially in hemochromatosis patients), removal of iron using an iron chelator is the only effective way to relieve iron overload in patients with β-thalassemia or sickle cell anemia (32). The current standard of care is desferrioxamine (**5**), the only approved iron chelator for this condition in the United States. This drug has several drawbacks including a narrow therapeutic window and, being orally inactive, requiring administration by 8–12 h/day of parenteral infusions (33). Thus, there is a need for the discovery and development of orally active iron chelating agents for the treatment of iron overload.



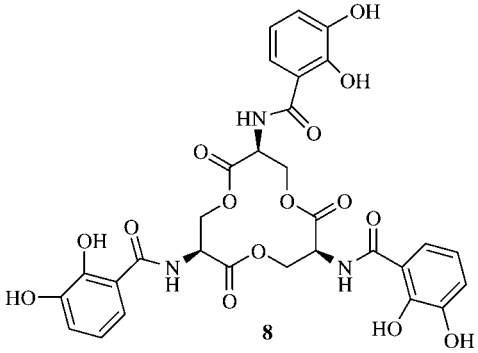
5

Development of nonabsorbed polymeric ligands to selectively sequester and remove dietary iron from the GI tract is an attractive method for the treatment of iron overload. Clinically useful polymeric iron chelators need to possess several features. The polymeric ligand must possess high affinity, capacity, and selectivity toward iron. Furthermore, the chelator should be biocompatible, and should not be absorbed from the GI tract. Design of polymeric chelators has been based on the knowledge of low molecular weight chelators. For clinical applications, the properties of chelators in terms of metal ion selectivity and ligand–metal complex stability is important. Since iron exists in two oxidation states (ferrous, +2, and ferric, +3), chelators can be designed for both the forms. For Fe(II), soft donor atoms [eg, nitrogen-containing ligands such as bipyridine (**6**) and phenanthroline (**7**) can be employed. Although these ligands are selective for Fe(II), they also possess affinity for other biologically important divalent metal ions such as Zn(II) and Cu(II). On the other hand, oxyanions like hydroxamates and catecholates are selective toward Fe(III), and these ligands in general show higher selectivity toward trivalent metal ions over divalent metal ions. Natural iron chelators like siderophores such as enterobactin (**8**) and desferrioxamine (**5**) contain catechol and hydroxamate groups respectively, and are selective for Fe(III) (34).



6

7



8

By considering these criteria, cross-linked polymeric hydrogels containing hydroxamic acid and catechol moieties (**9** and **10**) as well as cross-linked

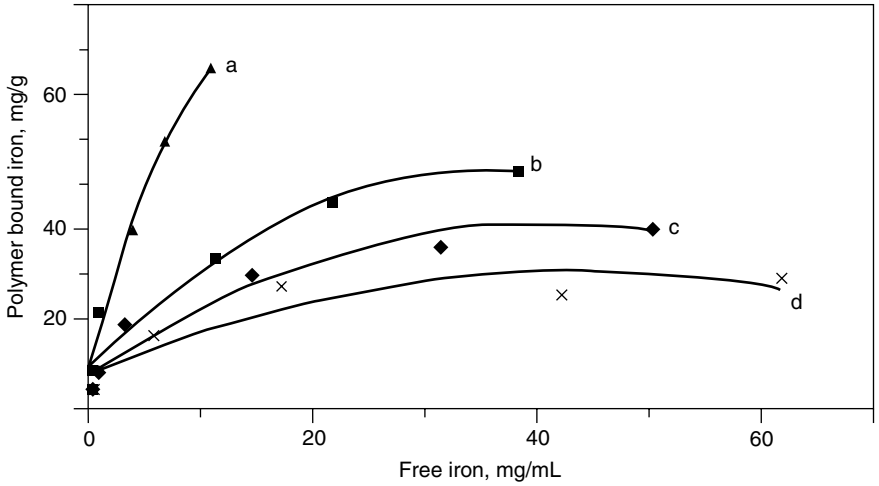


Fig. 2. Iron binding behavior of a poly(hydroxamic acid) hydrogel at different pH values: 8.0 (a), 7.0 (b), 5.7 (c), and 2.3 (d).

polyamines were prepared and were tested for their iron binding properties (35). Under *in vitro* conditions, all of these polymers sequester iron at high pH. At lower pH, the polymers containing hydroxamic acids maintained their iron binding properties, while other polymers showed reduced iron binding. Figure 2 shows the iron binding isotherms for a hydroxamic acid containing hydrogel at different pH values. *In vivo* studies using rodents have shown a decrease in absorption of dietary iron using this polymer (36). However, no human clinical data on the iron chelating polymers is available.

Bile Acid Sequestrants: Polymeric Drugs as Cholesterol-Lowering Agents

Increased plasma total cholesterol and low density lipoprotein cholesterol (LDLc) are established risk factors for antherosclerosis, which is the underlying cause of coronary heart disease and most strokes (37). The reduction of elevated LDLc is one of the most common therapeutic treatments for this disease, with the majority of the individuals at risk requiring only a modest (20–30%) reduction in LDLc level

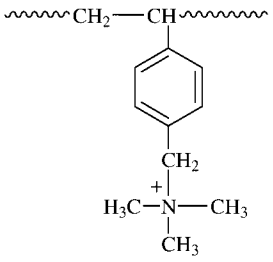
to minimize this serious health risk (38). HMG-CoA reductase inhibitors (more commonly known as statins) are the most widely used drugs for reducing blood levels of LDLc and have been shown to significantly reduce the risk of coronary events and strokes. These findings have led to recent guidelines for expanding the use of cholesterol-lowering drug therapies to more patients (39), with an estimated 36 million people in the United States alone who are candidates for cholesterol-lowering drug therapy.

Despite the success with statins, there is still a need for new therapies to reduce blood LDLc. Statins are, for example, not indicated for pregnant women, for pedriatic use, or for patients with liver disease. Moreover, some patients do not achieve the LDLc goal with statin therapy alone. There are also long-term potential safety issues associated with statins such as liver dysfunction and musculoskeletal symptoms, illustrated by the recent withdrawal of a statin, cerevastatin (Baycol by Bayer), from the market as a result of several cases of rhabdomyolysis (40).

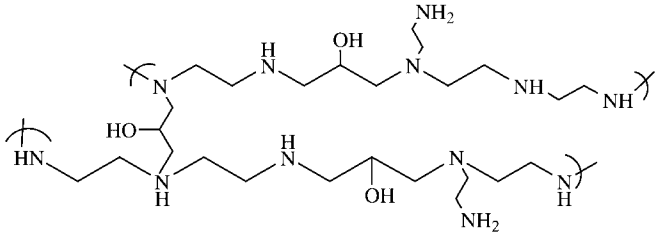
The molecular regulation of cellular cholesterol metabolism was elucidated by Brown and Goldstein (41). Cholesterol is synthesized in the liver by the enzyme HMG-CoA reductase. Subsequently, it is transformed into a bile acid in the liver and secreted to the gall bladder. The statins inhibit HMG-CoA reductase, which is the rate-limiting enzyme in cholesterol biosynthesis. The presence of bile acid in the cholesterol metabolism pathway suggests that another approach to reduce plasma LDLc is through effective removal of the bile acid from the bile pool, resulting in upregulation of bile acid biosynthesis and leading to a corresponding drop in plasma cholesterol levels (42).

Bile acid sequestrants (BAS) are cross-linked polymeric cationic gels that bind anionic bile acids in the GI tract and result in elimination of bile acid from the body (43). The use of these polymeric gels for sequestering bile acids is an established approach for treating elevated cholesterol (44). Being nonabsorbed, these polymeric drugs do not exhibit the systemic side effects that are associated with statins, and the BAS have over 30 years of clinical experience with a good safety record. Until recently, two cationic polymers, namely cholestyramine (**11**) and colestipol (**12**) have been the only approved BAS on the market. Despite the appeal of their safety profiles, these two first-generation BAS have, despite their high *in vitro* capacity, low clinical potency, which has led to reduced patient compliance and hence limited use. For example, the doses required for a 20% cholesterol reduction with cholestyramine and colestipol are typically 16–24 g/day (45). This low clinical efficacy of BAS has been ascribed to competition for bile acids with the active bile acid transporter system of the GI tract (46). It appears that, for a cationic polymer to be a potent BAS, it must have high binding capacity, strong binding strength, and selectivity toward bile acids in the presence of competing desorbing forces of the GI tract. Thus a potent BAS needs to exhibit slow off-rates of bound bile acids from the polymer resin to effectively overcome the active transport of bile acids from the GI tract. The design rules for making BAS of improved potency need to take into consideration the physicochemical features of bile acids (**13**). A typical bile acid possesses an anionic group and a hydrophobic core. Therefore, while electrostatic interaction is the primary force for bile acid binding by cationic polymers, a second attractive force that needs to be considered is the hydrophobic interaction between binder and bile acid. Furthermore,

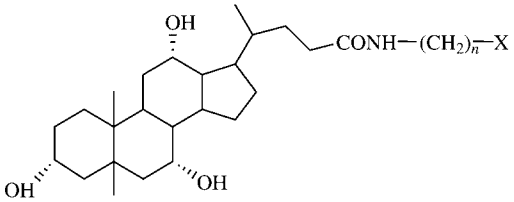
favorable swelling characteristics of these cationic hydrogels in physiological environments are required for attaining high capacity. Thus, a balanced combination of hydrophilicity (high capacity) and hydrophobicity (to slow down the rate of desorption), along with optimum density of cationic groups, would constitute key features of the most potent BAS (47).



11



12



13

a: n = 1, X = COOH
b: n = 2, X = SO_3H

Consideration of these desired features has led to the discovery of a number of BAS over the last decade from our laboratories as well as from other groups (48–52). Figure 3 illustrates structures representative of these new BAS, with common features of these hydrogels being the presence of amine/ammonium groups. Additional structural features of these polymers include the presence of hydrophobic chains. A variety of polymer backbones including vinyl and allyl amine polymers, (meth)acrylates, (meth)acrylamide, styrene, carbohydrates, polyethers, and other condensation polymers have been considered (53,54). While a number of polymers have been synthesized and tested in preliminary *in vitro* and *in vivo* studies, very few have entered preclinical development and clinical trials. Some of these promising BAS include DMP-504 (**14**), colestimide (**15**), SK & F 97426-A (**16**), and colesevelam hydrochloride (**17**). Structural features of these polymers comprise

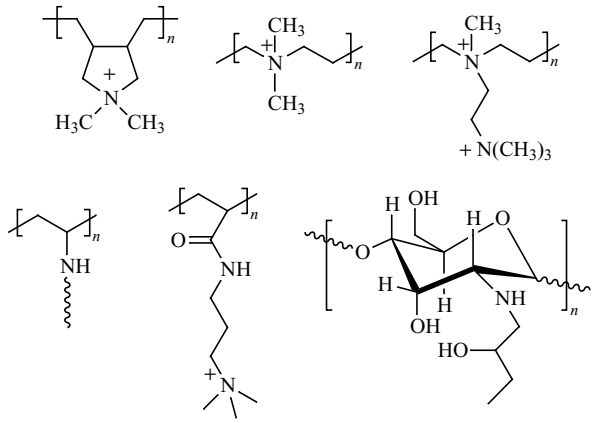


Fig. 3. Chemical structures of some representative bile acid sequestrants.

an optimum combination of charge density, hydrophobic tails, and water swelling properties. From this new generation of BAS that entered clinical trials, only two have been approved for marketing. Colestimide has been approved for marketing in Japan and is sold under the trade name Cholebine (Tokyo Tanabe) while colesevelam hydrochloride has been approved for marketing in the United States and is being sold under the trade name WelChol (Sankyo) (55,56). Both the polymers exhibit lower rates of side effects and better tolerated than previously marketed BAS. These BAS can be used as monotherapy or in combination therapy by coadministration with statins.

Polyvalent Ligands: Polymeric Drugs for the Sequestration of Macromolecular Pathogens

Polyvalent interactions are characterized by the simultaneous binding of multiple ligands on one molecular entity to multiple receptors on another (cells, viruses, proteins, etc). These interactions are widely prevalent in biological systems and they form the initiation steps for a great variety of cellular processes such as cell-surface or receptor-ligand recognition events. Polyvalent interactions can be collectively much stronger than corresponding monovalent interactions. They can provide the basis for mechanisms of both agonizing and antagonizing biological interactions that are fundamentally different from those available in monovalent systems. A schematic illustration of the principle of polyvalent interaction is shown in Figure 4. The theoretical framework of polyvalency and its role in biological processes have been reviewed by Whitesides and co-workers (57).

An appreciation of this important interaction in biological systems has been considered in the design and discovery of a new generation of novel therapeutic agents (58), and is particularly relevant when the interaction between a monovalent ligand and a polyvalent receptor is weak since polyvalency can significantly enhance the binding strength. Thus, a polyvalent inhibitor containing two or more linked ligands can bind at two more receptor sites on a target pathogen, leading to enhanced inhibition and/or sequestration of the target. This concept can obviously be extended further in polymeric systems wherein a collection of similar or different ligands can be covalently linked together to a single polymer chain. The flexibility to choose different polymer architectures (eg, random, alternate, block, graft, hyperbranched, etc), monomer types, and the ease of polymer synthesis and modification enables the synthesis of a wide variety of well-defined polyvalent species with desired features such as controlled ligand density, optimum binding strength/capacity, hydrophilicity/ hydrophobicity, and the incorporation of ancillary groups to enhance binding. Interplay of these features in polyvalent ligands

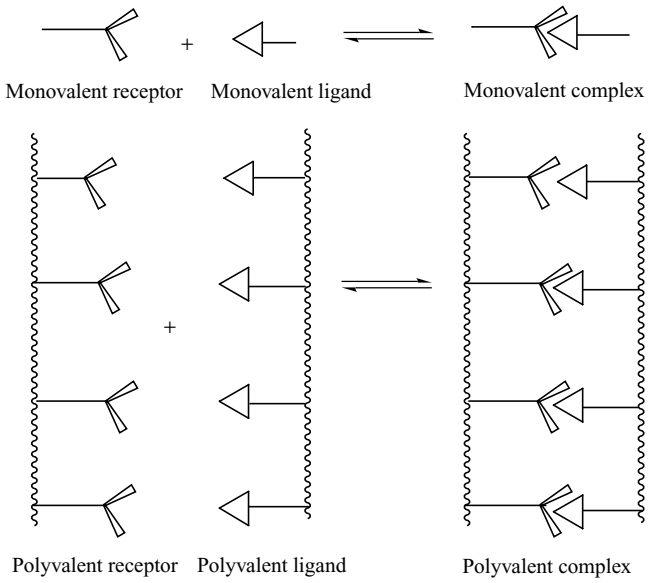

Fig. 4. Ligand–receptor interaction in monovalent (top) and polyvalent (bottom) systems.

can, in principle, lead to therapeutic agents with high potency as well as modulated biodegradability and bioavailability characteristics. This new concept of ligand–substrate interaction has led in recent years to the discovery of a variety of polymeric drugs that have been found to sequester/inhibit toxins, viruses, and bacteria.

Polyvalent Ligands as Sequestrants of Toxins. Toxins, produced by pathogenic microorganisms in the host body can generically be classified under two headings: exotoxins and endotoxins (59,60). *Exotoxins* are generally proteinous materials released by pathogenic species. *Endotoxins* are lipopolysaccharides and consist of polysaccharide segments and glycolipid segments that constitute the outer cell membranes of all Gram-negative bacteria.

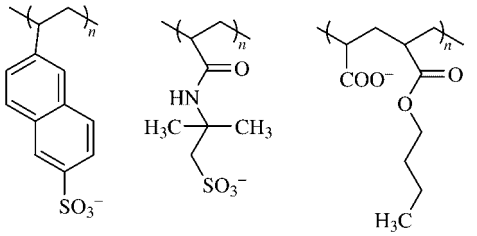
After being secreted by microorganisms, these toxins can travel within the body of the host organism and can cause damage in regions of the body far removed from the infection site. The pathogenic effects of these toxins may include hemolysis, destruction of leucocytes, paralysis, diarrhea, and septic shock (61). Some of the pathogens that produce life-threatening toxins in the GI tract are the food-poisoning organisms *Staphylococcus aureus, Clostridium perfringens*, and *Bacillus cereus*, and the intestinal pathogens *Vibrio cholerae, Escherichia coli*, and *Salmonella enteritidis*. Furthermore, anthrax toxin is produced by *Bacillus anthracis*. In almost all cases, the causative agents responsible for major symptoms of diseases associated with these pathogens are the exotoxins produced by the organisms (62,63).

Clostridium difficile Toxin. Clostridium *difficile* (*C. difficile*) is responsible for large numbers of episodes of diarrhea that arise from antibacterial treatment in nosocomial settings (58). Since normal colonic flora inhibit the growth of *C. difficile*, the outbreak of this disease has been attributed to the disruption of normal

colonic flora by antibiotic treatment, allowing colonization of the gut by *C. difficile* that is ubiquitous in hospital settings. Two high molecular weight proteins (toxins A and B) released by *C. difficile* are primarily responsible for causing the diarrhea (64,65). The traditional approach to treat *C. difficile* associated diarrhea is the use of one of two antibiotics, metronidazole or vancomycin. The use of antibiotics, while effective in eliminating the initial *C. difficile* infection, can allow for repeat infection by *C. difficile* by sterilizing the gut. In many cases, repeated cycles of antibiotic treatment, followed by reinfection by *C. difficile*, leads to long hospital stays and debilitating effects on patients. There are also increasing reports of growing antibiotic resistance to *C. difficile* (66).

Since toxins are responsible for disease symptoms, and recolonization of *C. difficile* results from the inhibition of normal microbial flora growth by antibiotic treatment, selective sequestration and neutralization of these toxins by a polymeric sequestering agent would appear to offer an attractive nonantibiotic therapy for this disease. Being protein-based, *C. difficile* toxins possess multiple binding sites that can effectively interact with polymeric ligands bearing complementary binding sites through simultaneous polyvalent interactions. Anion exchange resins like cholestyramine and colestipol (the BAS described above) were the first group of polymeric ligands to be examined as sequestrants for *C. difficile* toxin. However, the effectiveness of these polymeric ion-exchangers to bind and remove *C. difficile* toxin was found to be modest (67).

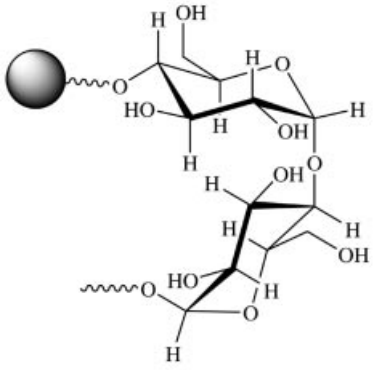
Recent research has led to the discovery of some novel polymeric multivalent ligands as nonantimicrobial sequestrants for binding and neutralization of these toxins. One class of particularly effective materials has proven to be high molecular weight water-soluble anionic polymers (**18–20**) (68,69). In our hands, an anionic polymer, GT 160–246, was found to be very effective in treating this infection in hamsters (70). *In vitro* studies using pulsed ultrafiltration and fluorescence polarization spectroscopy revealed that the binding constants of complexes between this polymer and toxins A and B were 133 nM and 8.7 μM respectively (71). Furthermore, from fluorescence polarization data, it was estimated that one molecule of toxin A interacts with 600–1000 monomer units of GT 160–246, suggesting large polyvalent interactions between the polymer and protein surface. This polymer is currently in human clinical trials.



18 **19** **20**

Polymers bearing pendant oligosaccharide groups have also been investigated as possible sequestrants for *C. difficile* toxins (72,73). This approach is based on the principle that toxin A has shown a lectin-like activity, which allows it to bind to an oligosaccharide receptor on epithelial cells. Furthermore, toxin B has

been found to bind erythrocytes, implying that a carbohydrate receptor may be involved for its binding. After identifying appropriate oligosaccharide sequences, oligosccharide molecules (specific for toxins A and B) were covalently attached to polymer carriers. Compatible spacer arms of appropriate length between polymer backbones and oligosaccharide moieties were utilized to maximize the polymer–toxin interaction (**21**). Specific oligosaccharide sequences that are useful in this context are maltose, cellobiose, isomaltotriose, and chitobiose. Polymeric carriers examined include substituted polystyrene and other olefin backbones. Inorganic carriers such as biogenic silica and kaolinite were also used. These classes of sequestrants [under the trade name SYNSORB (Syn Sorb Biotech, Inc.)] were found to be effective in neutralizing toxins and in controlling diarrhea in animal models. One of these materials progressed to human trials, but was withdrawn after a phase II clinical trial.



21

Anthrax Toxin. Anthrax toxin is produced by *Bacillus anthracis* and is the primary cause for the major symptoms of the disease (74). While the occurrence of anthrax in clinical settings is rare, growing concern over bioterrorism and biological warfare using *B. anthracis* has made development of agents active against anthrax a high priority. Although vaccines against anthrax exist, various factors make mass vaccination difficult. Furthermore, the course of the toxin-induced damage after symptoms are evident makes antibiotic treatment of limited utility. Therefore, development of agents that can sequester anthrax toxin (thereby inhibiting its action) might prove to be a valuable adjunct to antibiotic therapy.

Anthrax toxin consists of a single receptor-binding moiety, termed protective antigen (PA), and two enzymatic moieties, termed edema factor (EF) and lethal factor (LF). Upon release from bacteria as nontoxic monomers, these three proteins combine and undergo a cascade of processes through the formation of a cell-bound heptameric fragment called PA63, finally resulting in attack on macrophages (75). By utilizing phage-display library screening, a dodecameric peptide was identified that binds PA63 and inhibits its interaction with the protease enzyme. By attaching multiple copies of this dodecameric peptide sequence to a polyacrylamide-based polymer backbone, the corresponding polyvalent ligand was obtained. This polymer strongly inhibits ligand binding by PA63, toxin activity in cell culture, and toxicity in an animal intoxication model (76). The efficacy of this polyvalent

ligand in blocking the anthrax toxin *in vivo* suggests that this approach could be useful in developing therapeutically relevant agents for this life-threatening condition.

Polyvalent Ligands as Antiviral Agents. The use of polyvalent ligands to inhibit viral infection is the most extensively studied of all polyvalent interactions. This platform has in fact served as the prototypical system to validate the fundamental concept of polyvalent ligands as a new class of polymeric pharmaceutical agents.

Viral infection is initiated by the attachment of viruses to specific cellular receptors, which is mediated by viral attachment proteins (VAPs) (77). It has been postulated that by inhibiting the receptor-binding epitopes of VAPs with synthetic analogs of cellular receptors, novel antiviral agents can be designed. It has been calculated that many viruses, when binding to cell surfaces, interact with at least 10 (or more) monomeric cellular receptor units that are organized into polymeric cellular receptor units (78). The characteristic feature of such polyvalent cooperative binding is that high avidity of binding may be mediated by multiple low affinity individual contacts. Therefore, by presenting polymeric ligands containing multiple copies of the cellular receptor analogs, competitive inhibitors for viruses can be developed. This design principle has been utilized to develop prototype antiviral agents against viruses such as influenza and rotavirus.

Inhibition of Influenza Virus. Influenza virus A is the primary agent responsible for serious cases of human influenza. The infection of cells by this virus is initiated by attachment of the virus to the cell membrane. The attachment occurs through the interaction of hemagglutinin [a sialic acid (*N*-acetylneuraminic acid) receptor on the virus] with multiple sialic acid groups present on the surface of the mammalian epithelial cell (Fig. 5). This process is called hemagglutination (79). One of the strategies to treat such viral infection is to block the adhesion of the virus to cells by presenting sialic acid derivatives as competitors for cell-surface ligands (80). Although individual viral surface hemagglutinin (HA) binds individual cell-surface sialic acids (SA) weakly, the virus attaches to the cellular surface through multiple interactions between clusters of HA and SA residues. While an individual HA–SA interaction has a KdHA of $\sim 2.5 \times 10^{-3}\ M$, the interaction between the virus and an erythrocyte has a KdHA of $\sim 10^{-12}\ M$. Thus, the polyvalent interaction of the latter system is about a billionfold stronger than the

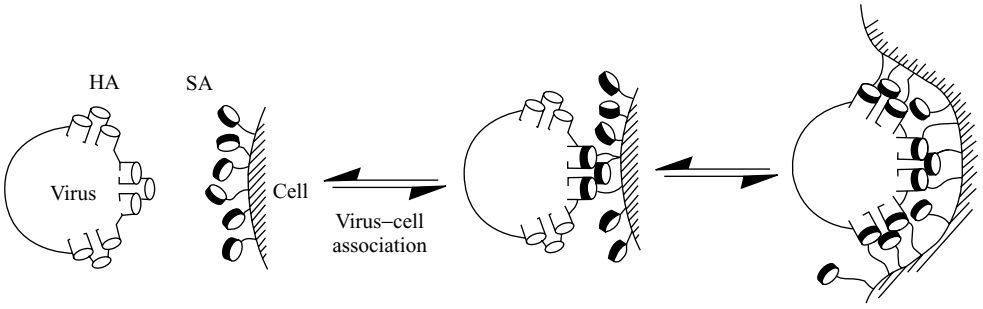


Fig. 5. Attachment of a virus to a host cell by interaction of viral hemagglutinin (HA) with cell-surface sialic acid (SA).

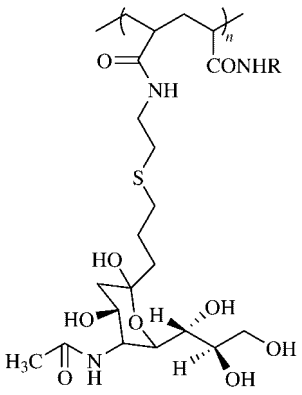
corresponding individual monovalent interaction. In theory, one approach to prevent viral infection may be to design polymeric SA derivatives containing multiple copies of SA. A number of groups have designed and synthesized such polyvalent inhibitors containing side-chain SA groups (81–84). Different kinds of polymer backbones were employed for this purpose (57). The most effective inhibitor among these polymers is a linear polyacrylamide derivative containing, on a side chain, the C-glycoside of SA (**22**). This polymeric ligand prevents hemagglutination at a concentration of 35 p*M*, while the corresponding monomeric α-methylsialoside inhibits hemagglutination at a concentration greater than 2 m*M* (85). A systematic investigation to elucidate the mechanism of this polyvalent interaction between influenza virus and polymeric ligands shows that a balanced combination of several factors including high affinity multiple ligand density, steric stabilization, and entropically driven enhanced binding is believed to contribute to the effectiveness of these polyvalent inhibitors in preventing viral attachment (86).



22

Although a wealth of information is available through *in vitro* studies, *in vivo* assays exhibiting the success of these polyvalent ligands in protecting animals against influenza infection has yet to be demonstrated. The success of this approach to develop antiviral agents for influenza would also depend on their favorable toxicity and activity profile *in vivo*.

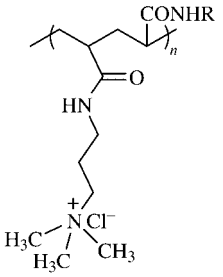
Polyvalent Ligands as Antimicrobial Agents

Emergence of bacterial resistance to a number of antimicrobial agents is becoming a major worldwide health problem. The most significant problem in clinical practice is the increasing occurrence of methicillin-resistant *Staphylococcus aureus* (MRSA) strains (87). The majority of these strains have been found to carry multiple drug resistance factors. At present, the only effective treatment for multiply resistant MRSA infections is vancomycin. However, vancomycin resistance itself is a growing problem (88). This rapid emergence of multidrug-resistant bacterial strains and the potential threat they pose to human life means that development of novel antibacterial agents to overcome these shortcomings is critically important.

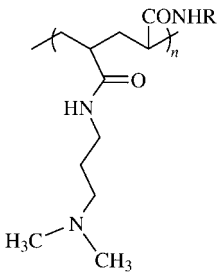
Use of polyvalent ligands as antibacterial agents have been considered to provide several advantages. Cluster effects from polyvalency would result in enhancement of weak nonbonding interaction between the bacterial surface receptors and the polymeric ligand. Furthermore, the use of polyvalent ligands could enhance lysis of the bacterial cell membrane/wall more rapidly.

As with viruses, most bacterial infections are also initiated by adhesion of microorganisms to the mucosal surfaces of host, mediated in part by bacterial protein adhesins (89). These adhesins interact with carbohydrate determinants of host cell glycolipids or glycoproteins. This fact suggests the use of specific polyvalent sugar constructs to competitively block the microbial adhesin and to protect against infection. This concept has been explored in our laboratories through the synthesis of a number of polymers bearing acid-functionalized glycoside moieties. Olefinic monomers containing glycoside moieties and acid functional groups such as *O*-sulfo and *O*-carboxymethyl groups were prepared and converted to various copolymers. These polymers were found to be effective *in vitro* against a number of bacterial targets (90).

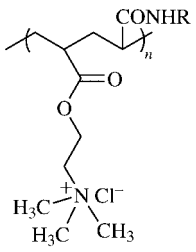
A second approach to design polyvalent ligands as antimicrobial agents based on cationic polymers has also been developed in our laboratories. The mechanism of the antimicrobial action of these polymers is based on cell lysis. These polymers were designed as mimetics of certain cationic amphiphilic peptides containing multiple arginine and lysine residues. These cationic peptides, known as antimicrobial peptides, cause cell lysis through interaction of the positive charges of the peptides with negative phosphate head groups of cell membrane phospholipids (91). A series of amphiphilic cationic polymers were prepared bearing amine and ammonium groups as well as hydrophobic tails. These polymers were found to exhibit an inhibitory effect on a broad spectrum of microbes (92). In particular, some of these polymers (**23–25**) were found be very effective against *Cyptosporadium parvum*, which was, until the advent of protease inhibitors, a primary cause of GI tract infections in individuals with HIV infection (93). Some of these polymers were found to be superior to the commonly prescribed antibiotic, paromomycin.



23



24



25

Synthesis of a multivalent vancomycin derivative exhibiting significantly enhanced antibacterial activity against vancomycin-resistant *enterococci* has been recently reported (94). This work was built upon the finding that dimeric vancomycin showed enhanced affinity toward the L-lysyl-D-alanyl-D-alanine peptidoglycan precursor that is responsible for the growth of the bacterial cell wall (95). A

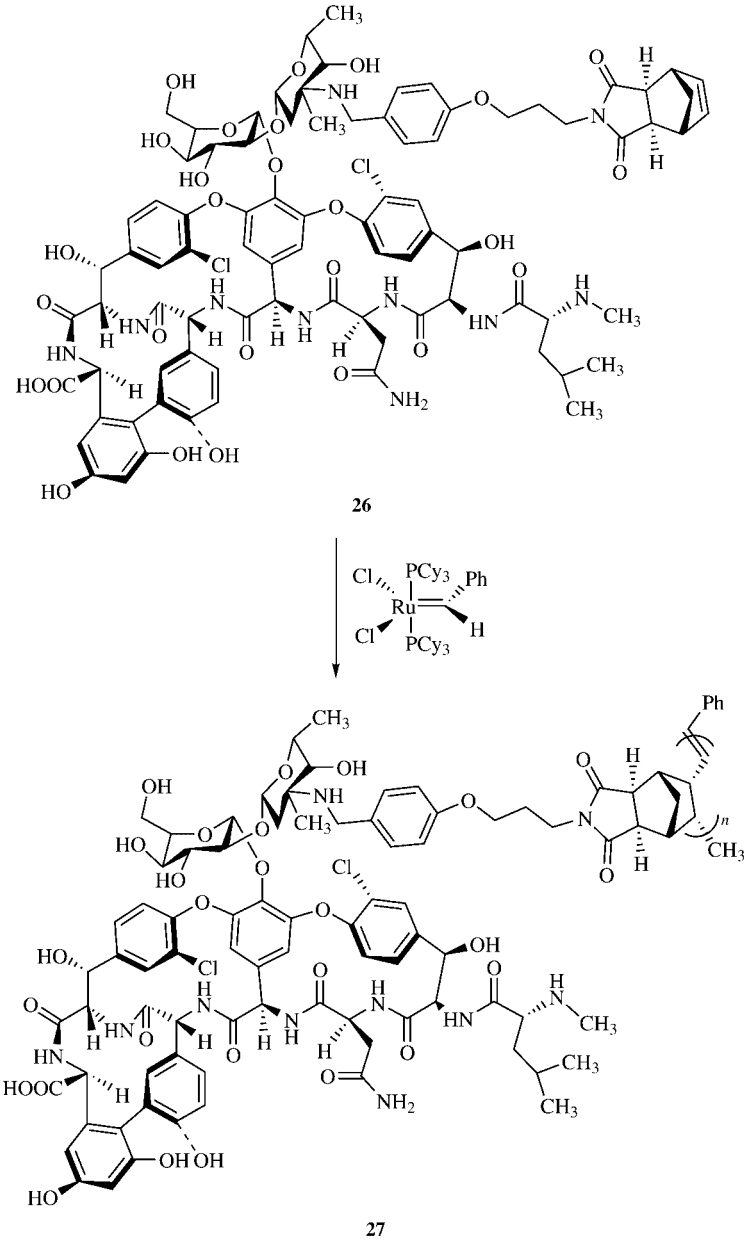


Fig. 6. Synthesis of polymeric vancomycin derivative.

polymeric vancomycin derivative was obtained by ring-opening metathesis polymerization of a functional cyclic olefin monomer containing the vancomycin moiety (Fig. 6). The antimicrobial property of the monomer (**26**) was similar to native vancomycin. Upon incorporation into the polymer backbone, the activity of the corresponding polymeric vancomycin derivative (**27**) was found to have increased

by nearly 60-fold, when tested against *S. aureus* and *S. enterococci*. This result further supports the importance of multivalency in the discovery of novel therapeutic agents.

Polymeric Drugs for the Treatment of Autoimmune Diseases

Simplistically, autoimmune diseases arise when the immune system mistakenly attacks itself. Ordinarily the immune system uses a number of defense mechanisms to prevent the development of autoimmune responses by directing T-cells (defense cells) to distinguish foreign invaders (96). Bypassing of the protection against autoimmunity leads to inflammation in various parts of the human body. Multiple sclerosis (MS) and rheumatoid arthritis (RA) are two of the most common autoimmune diseases.

MS is an autoimmune disease associated with immune activity directed against central nervous system antigens, thus affecting the brain and the spinal cord. Destruction of the regulatory mechanism that guards against autoimmunity leads to inflammation of the central nervous system. This disabling disease affects over 2.5 million people, particularly young adults (97). In general, immunosuppression and immunomodulation have been the mainstays of therapeutics strategies for the treatment of MS. One of the most popular treatments for relapsing–remitting MS is the use of recombinant beta interferon (eg Avonex) (98).

The development of a synthetic amino acid copolymer (glatiramer acetate) as an alternative to beta interferon for the treatment of relapsing-remitting form of MS represents a significant breakthrough in polymeric drug discovery (99). Glatiramer acetate is a random copolymer composed of four L-amino acids (alanine, lysine, glutamic acid, and tyrosine in a molar ratio of 4.2:3.4:1.4:1.0). This copolymer is prepared by the ring-opening random copolymerization of the corresponding *N*-carboxy-α-amino acid anhydrides (100). Systematic *in vitro* (using murine T-cell lines) and *in vivo* (using experimental allergic encephalomyelitis animal models) studies have established the possible mode of action of the polymer to its ability to mimic the myelin basic protein (MBP), one of the major autoantigens implicated in the pathogenesis of MS. MBP is known to sensitize autoreactive T-cells. The autoreactive cells migrate into the central nervous system and mediate the pathogenesis process of MS. The composition of glatiramer acetate is postulated to resemble a portion of MBP. The copolymer therefore competes with MBP for binding with T-cells (through cross-reaction) leading to antigen-specific intervention of the autoimmune process. In human clinical trials, glatiramer acetate demonstrated remarkable decrease in the number of relapses and rate of progression of the disease. Glatiramer acetate has been approved by FDA and European agencies for the treatment of relapsing-remitting form of MS in the United States and Europe, and is marketed under the brand name Copaxone by Teva Pharmaceutical Industries. Copaxone is the first synthetic polymeric drug approved for systemic treatment.

Since Copaxone works by antigen-specific intervention against MS, utility of this class of polymeric drugs can be expanded to treat other autoimmune diseases. Recently, Fridkis-Hareli and co-workers (101) have reported that glatiramer

acetate and other related copolymers (containing three amino acids) compete with type II collagen peptide 261-273, a candidate autoantigen in rheumatoid arthritis (RA) for binding to RA associated T-cells. This suggests the possible utility of these polymers in the treatment of RA and other autoimmune diseases (101).

Hybrid Polymeric Drugs Based on Polymer–Protein Conjugates

Biotechnology has offered the means to develop protein-based human therapeutics by recombinant DNA technology. However, the mode of delivery of these macromolecular drugs is not trivial. Furthermore, these proteins also have propensity to present toxic immunological responses. Design of polymer conjugates of proteins offers an opportunity to improve the therapeutic properties of the latter (102). The advantages of polymer–protein conjugates include reduction or nullification of the antigenicity of protein-based drugs, prolongation of their *in vivo* circulating half life, and enhancing delivery to the target site.

A variety of functional polymers have been used to conjugate therapeutic proteins, with the selection of polymers requiring stringent criteria. The polymers need to be nonantigenic, biocompatible, and intrinsically nondenaturing toward the therapeutic protein. A number of reactive polymers including copolymers of maleic anhydride with divinyl ether and styrene, poly(vinyl alcohol), poly(vinylpyrrolidinone), and poly(ethylene glycol) (PEG) have been utilized for this purpose (103). Amongst various polymers, PEG has been found to be most suitable for this purpose. Conjugation of enzymes using *multifunctional* polymers can lead to inter- and intramolecular cross-links leading to insoluble and/or complex aggregates of proteins. On the other hand, *monofunctional* PEG derivatives are nonantigenic and their conjugates with proteins produce more homogeneous products (104). This property is largely responsible for the success of PEG as the current polymer of choice for preparing polymer–protein hybrid biopharmaceuticals. With regard to architectures of PEG molecules, branched PEG derivatives are generally found to be superior to linear. Protein conjugates prepared using branched PEG were found to be less immunogenic and antigenic, more stable to proteolysis, and enzymatic activities tend to be better preserved. The superior properties of branched PEG are thought to be due to the "umbrella-like" spatial arrangement of polymer chains that protects the protein surfaces (105).

A number of therapeutic proteins such as agents for enzyme-replacement therapy, human growth hormones, and receptor binding proteins have been utilized for to prepare polymer–protein hybrid therapeutics. These polymeric conjugates have shown promising *in vitro* and *in vivo* properties. Most interestingly, some of these conjugates have entered human clinical trials or have already received regulatory approval. Some of these approved products are PEG-INTRON (Schering-Plough) (PEG–recombinant alpha interferon conjugate) for the treatment of hepatitis C, ONCASPAR (PEG–L-asparginase conjugate) for the treatment of acute lymphoblastic leukemia, and ADAGEN (PEG–adenosine deaminase conjugate) as an enzyme-replacement therapy for immune deficiency disease (106–108).

Conclusions and Future Prospects

Although polymeric materials have been developed to produce useful biomaterials and drug delivery systems, polymers acting as inherently therapeutic agents have largely remained unappreciated. In the present article we have attempted to illustrate that, through appropriate consideration of both disease targets and the unique properties of polymers, novel polymeric pharmaceutical products may be developed. These materials have, in many cases, therapeutic properties that cannot be achieved by traditional small molecules. Sequestrants that are confined to the GI tract are a case in point. An appreciation of the polyvalent interactions that drive the initial steps in many biological processes, both benign and pathogenic, also provides a rich source of potential therapeutic applications for polymeric materials. The case studies cited here illustrate that polymeric drugs are not solely an academic curiosity, but have produced novel and valuable therapeutic responses to important diseases.

POLYPHOSPHAZENES

Introduction

Polyphosphazenes (1–9) belong to the class of inorganic polymers (qv). They have a heteroatomic backbone consisting of alternating phosphorus and nitrogen atoms, with two side groups attached to each phosphorus atom (Fig. 1). The side groups can be organic, inorganic, or organometallic. Perhaps the most attractive feature of polyphosphazene chemistry is the very broad range of groups that can be easily incorporated into the macromolecular chain, which opens up unlimited possibilities for derivatization. The number of different polyphosphazenes that have been synthesized will soon approach 1000; no other polymer synthesis has been studied so extensively. The ability to control the macromolecular architecture and to fine-tune properties of the resultant polymer has attracted the attention of many research groups throughout the world. The initial application of polyphosphazenes as high performance elastomers has expanded into solid polymer electrolytes, membranes for gas and liquid separations, optically active polymers, biomaterials, and proton-exchange membranes for fuel cells. Polyphosphazenes are strong competitors for their isoelectronic analogues, polysiloxanes, which are considered the most important of all inorganic polymers with regard to commercial applications (see SILICONES).

History. The history of polyphosphazenes dates back to 1897, when Stokes (8) reported that phosphonitrilic chlorides could be converted by heating into "the rubber-like polyphosphonitrilic chloride." He described it as a "body, or a mixture of bodies, of very high molecular weight, that is highly elastic and insoluble in all neutral solvents, but which swells enormously in benzene". Since then there have been a number of studies devoted to polymerization of phosphonitrilic chlorides. Attempts to carry out the polymerization in organic solvents containing hydrogen

were unsuccessful. Later studies performed in halogenated solvents showed some moderate success: a soluble fraction of 18–50% with a polymerization degree of 300 was reported (11). Any effort to increase the molecular weight of the polymer resulted in formation of cross-linked, insoluble "inorganic rubber". To overcome the problem of cross-linking, Kauth (12) proposed a two-step synthesis. In the first step the monomer was heated for $\frac{1}{2}$ h at 150–200°C, which resulted in a partially polymerized oil that could be dissolved in a suitable solvent. This solution was used to "saturate some material," and the final polymerization was accomplished by an additional heating step. The struggle to obtain a soluble, long-chain polymer continued until the mid-1960s when Allcock and Kugel (13) reported that linear polydichlorophosphazene could be obtained. Optimization of the polymerization conditions and macromolecular substitution of chlorines with organic nucleophiles led to hydrolytically stable polyorganophosphazenes. Since then, interest by the military and polymer industries has led to an enormous growth in polyphosphazene science.

Nomenclature. Of the several naming systems related to phosphorus–nitrogen compounds: phosphonitrile (the oldest one), azaphosphorine, phosphorus-μ-nitrido, nitrilo-phosphoranylidyne, and phosphazene (14), only the last one has been generally accepted and adopted by the macromolecular research community. To comply with IUPAC nomenclature, a polyphosphazene with the common name poly(diphenoxyphosphazene) should be named catena-poly[(diphenoxyphosphorus)-μ-nitrido], if rules for "inorganic and coordination polymers" (15) were applied. If on the other hand, rules for "organic polymers" (16) were used, then the preferred constitutional repeating unit should be reoriented and the polymer should be named poly[nitrilo(diphenoxyphosphoranylidyne)].

Synthesis

There are three general methods to synthesize polyphosphazenes. One is the ring-opening polymerization of hexachlorocyclotriphosphazene, followed by a macromolecular substitution of chlorine atoms with a desired nucleophile or a combination of nucleophiles. As a result, the side groups are bonded to phosphorus through oxygen or nitrogen linkages. This is the primary method for polyphosphazene synthesis. The second method, called a "single-pot synthesis," is based on direct reaction of ammonium and phosphorus salts. The product, poly(dichlorophosphazene), then reacts with an appropriate nucleophile to give a poly(organophosphazene). It is claimed that production costs for this second method are low. The third method is condensation polymerization of phosphoranimines. Here the substituents are

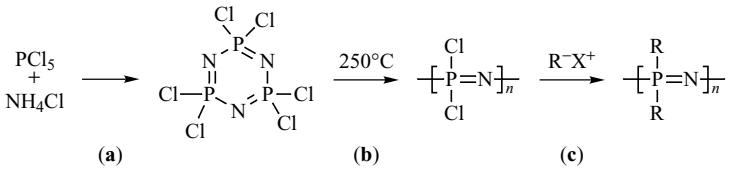

Fig. 2. (**a**) Trimer synthesis, (**b**) the ring-opening polymerization, and (**c**) the macromolecular substitution.

usually attached to phosphorus atoms prior to the polymerization. Very high molecular weights ($M_w = 10^6$) can be reached with ring-opening polymerization but the molecular weight distribution is very broad. Only moderate molecular weights ($M_w = 10^4$–10^5) are accessible via the condensation method; however, polydipersity in this case is usually <2.

Ring-Opening Polymerization. There are two variants of the method: melt polymerization and solution polymerization. The first method was developed by Allcock (13,17,18) and is shown schematically in Figure 2. It starts with the reaction of phosphorus pentachloride and ammonium chloride that leads to hexachlorocyclotriphosphazene. Following a multistep purification involving sublimation, this compound is polymerized by heating at 250°C in an evacuated and sealed glass tube for 24–48 h. After termination of the reaction, the linear poly(dichlorophosphazene) is isolated, by either sublimation or extraction of low molecular weight species, or by dissolution and precipitation. The molecular weight of the polymer is often very high, $M_w \sim 10^6$, but the molecular weight distribution is very broad. In the final step, the polydichlorophosphazene, dissolved in an inert solvent, is added to a suitable nucleophilic reagent. The product, usually polyorganophosphazene, is isolated by multiple precipitations. There are variants of the above method where partially substituted trimer is polymerized (Fig. 3) (19). Here a nucleophilic substitution is carried out on cyclochlorophosphazene and then the substituted trimer undergoes thermal ring-opening polymerization. This approach allows for the preparation of polyphosphazenes with substituents that cannot be incorporated through a classical macromolecular substitution route. There are, however, limitations imposed by both steric and mechanistic factors on the extent of substitution that makes the trimer polymerizable. Unless the substituted ring is highly strained as, for example, in the presence of transannular ferrocenyl (20), polymerization is generally feasible when no more than three nongeminal chlorines in hexachlorocyclophospazene are substituted. Fully methyl- or phenyl-substituted trimers undergo ring–ring equilibration but no polymers are formed (21,22). Ring-opening polymerization of some mixed ring

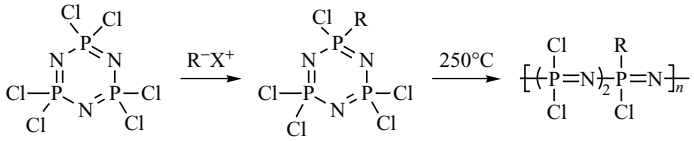

Fig. 3. Trimer substitution and the ring-opening polymerization of the substituted trimer.

systems, eg, $(NPCl_2)_2NSCl$, $(NPCl_2)_2NSOCl$, and $(NPCl_2)_2NSOF$, has been reported (23–25). These polymerizations were carried out at much lower temperatures 90–180°C) than that required for $(NPCl_2)_3$ alone.

The alternative method, solution ring-opening polymerization, was developed by several researchers (26–29), but most of the work is by Magill and co-workers (30). The polymerization of $(NPCl_2)_3$ is carried out in 1,2,4-trichlorobenzene using sulfamic or toluenesulfonic acid as a catalyst and $CaSO_4 \cdot 2H_2O$ as a promoter. The reaction is fast and yields poly(dichlorophosphazene) of high molecular weight with narrow and monomodal molecular weight distribution. From the poly(dichlorophosphazene) precursor, the desired poly(organophosphazene) is obtained by reaction with a suitable nucleophile. This last step is common to both the melt polymerization and the solution polymerization methods.

"Single-Pot" Synthesis. In order to simplify the synthesis of poly(dichlorophosphazene), Allen and co-workers (31,32) developed a method based on "two-step, single-pot" reaction of ammonium sulfate with phosphorus pentachloride (PCl_5). Both reactants are heated until a liquid monomer, *P*-trichloro-*N*-(dichlorophosphoryl)monophosphazene, is formed, which is then bulk-polymerized by further heating under inert atmosphere. After distilling off oxyphosphoryl chloride, the product, poly(dichlorophosphazene), is isolated. The authors claim that the method offers good yields, short reaction time, elimination of halogenated solvents, and leads to a polyphosphazene of high molecular weight and lower polydispersity.

Another method of direct synthesis of poly(dichlorophosphazene) developed by Carriedo and co-workers (33) has been disclosed. NH_4Cl and PCl_5 react in the presence of $CaSO_4 \cdot H_2O$ and NH_2HSO_3 as promoters, leading to polyphosphazenes of molecular weight on the order of 2×10^6. The yields are 30–40% on the basis of PCl_5.

Condensation Polymerization. Several procedures for the condensation polymerization of polyphosphazenes are known. In 1982, De Jaeger and coworkers (34) published an alternate synthetic route to poly(dichlorophosphazene) on the basis of thermal elimination of phosphoryl chloride from a P—N=P precursor. Important advantages of the reaction, as compared to the ring-opening polymerization, were the possibility to control the molecular weight of the polymer and to reduce the amount of cyclic oligomers in the product. The first successful condensation polymerization of substituted polyphosphazene was reported by Neilson and Wisian-Neilson (35–37). The reaction scheme is shown in Figure 4. The sequence begins with the synthesis of a *N*-silylphosphoranimine monomer containing the desired side groups and two leaving groups (trimethylsilyl and trifluoroethoxy). The product is isolated by a fractional distillation with an overall yield of ca 75%. The monomer is then polymerized by heating in a sealed glass

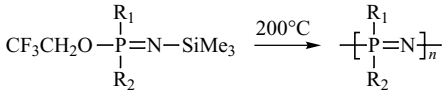

Fig. 4. The thermal condensation polymerization of phosphoranimine.

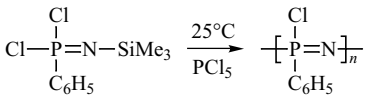

Fig. 5. The "living" cationic condensation polymerization of phosphoranimine.

ampule at 180–200°C for 7–12 days. This method allows for the synthesis of symmetrical and unsymmetrical homopolymers as well as random copolymers, but selection of the monomers is limited to either dialkyl- or alkyl–aryl-substituted. An improvement over the thermal process was proposed by Matyjaszewski's group (38,39). They prepared homo- and copolymers by tetrabutylammonium fluoride (TBAF) catalyzed anionic polymerization of phosphoranimines bearing trifluoroethoxy and alkoxyalkoxy substituents. The conditions of the reactions were relatively mild (100°C for 3–4 h) and it was possible to quantitatively produce linear polyphosphazenes with a narrow molecular weight distribution. The method, however, could be used in a very limited number of cases. The most promising condensation route was reported by Allcock and co-workers (40–43). It was based on PCl_5-induced, room temperature "living" cationic polymerization of *N*-(trimethylsilyl)-phosphoranimine. The reaction scheme is presented in Figure 5. For example, polymerization of *N*-(trimethylsilyl)-trichlorophosphoranimine leads to poly(dichlorophosphazene). Generally, if the monomer contained less then two organic substituents at the phosphorus, then an additional step, namely macromolecular nucleophilic substitution of the remaining chlorines, was necessary. The potential advantage of the method is that it allows for the synthesis of polyphosphazenes with controlled molecular weight and low polydispersity, with sophisticated architectures (eg block copolymers, hybrid organic/phosphazene copolymers, or star-branched polymers).

Polymeric Material Types

Phosphazene Homopolymers. Macromolecular substitution of poly(dichlorophosphazene) with use of a single kind of nucleophile leads to a symmetrical homopolymer. Symmetrical or unsymmetrical phosphazene homopolymers can also be obtained by condensation methods. If the bulkiness of the substituents do not impose any sterical constraints, then the resultant polyphosphazene is a crystalline material. Otherwise, glasses are obtained with a T_g of 150–250°C, as is the case for poly(spirophosphazenes) (44,45).

Copolymers. When two or more nucleophiles are used during the macromolecular substitution of poly(dichlorophosphazene), a mixed substituent system (46), ie a random copolymer, is obtained. There exists numerous data on the preparation and characterization of various random copolymers (47–53). To synthesize a block copolymer (or unsymmetrical homopolymer) condensation polymerization needs to be employed. Matyjaszewski and co-workers (54) synthesized block copolymers bearing various combinations of trifluoroethoxy and alkoxyalkoxy groups, by adding a second phosphoranimine after the first converted completely. Significant differences were found between random and block

copolymers with respect to their thermal properties and morphology. The T(1) transition of the random materials decreased dramatically when the fraction of units bearing alkoxyalkoxy groups increased, while the T(1) of the block copolymer was unaffected by the composition. Also, densities of the random copolymers decreased more rapidly than densities of the block materials when the fraction of the alkoxyalkoxy-bearing units was increased. Allcock and co-workers (55–57) synthesized copolymers with controlled molecular weights through a PCl_5-catalyzed cationic polymerization. First a *N*-(trimethylsilyl)-trichlorophosphoranimine was polymerized into a "living" poly(dichlorophosphazene). Next a second phosphoranimine, eg *N*-(trimethylsilyl)dichlorophenyl phosphoranimine was copolymerized using the "living" terminus. Subsequent replacement of the chlorine atoms with an appropriate side group resulted in a hydrolytically stable copolymer. A similar method was used to prepare a hybrid di- and triblock poly(phosphazene–ethylene oxide) and poly(phosphazene-siloxane) copolymers (58–61). Amphiphilic diblock copolyphosphazene with methoxyethoxyethoxy/methoxyethoxyethoxy and methoxyethoxyethoxy/phenyl units was synthesized by Chang and co-workers (62) and its micellar characterization was examined. The most voluminous literature on polyphosphazene copolymers relates to grafting. Wisian-Neilson and co-workers (63) prepared copolymers of poly(methylphenylphosphazene) with polystyrene, polymethylmethacrylate and with silicone grafts using anionic polymerizations. Chang and co-workers (64) grafted poly(2-methyl-2-oxazoline) onto partially brominated poly[bis(4-methylphenoxy)phosphazene] of low molecular weight ($M_w = 6200$) via cationic polymerization. When a high molecular weight polyphosphazene was used ($M_w > 10^5$), severe gelation resulted and the copolymer was insoluble in available solvents. Gleria and co-workers (65) synthesized several copolymers by thermal or photochemical grafting of various vinyl polymers onto polyphosphazene matrices. The free-radical process was initiated by hydrogen abstraction from a primary, secondary, or tertiary carbon of the alkylphenoxy substituent. Monomers such as maleic anhidride (66), methylmethacrylate (67), *N*,*N*′-dimethyl-acrylamide (68), meth(acrylic) acid (69), styrene (70), and vinyl acetate or alcohol (71,72) were used. Welker and co-workers (73,74) studied radiation-induced grafting onto allylamino-substituted polyphosphazenes and Prange and co-workers (75) prepared graft copolymers from polyphosphazene and polystyrene macromonomers.

An interesting example of a phosphazene random copolymer containing thiophenoxy groups was synthesized by Carriedo and co-workers (76). Although very long reaction times were required and low yields (ca 25%) were observed, it was the first time that a thiophenoxy-substituted poly(phosphazene) was obtained.

Polyphosphazene Blends. Polyphosphazene blends were investigated for thermal stabilization of organic polymers, biochemical applications, and membrane preparation. Poly[bis(carboxylatophenoxy)phosphazene]–polyurethane blends (77) were prepared through reactive mixing of the polyphosphazene with diisocyanate and diol prepolymers, and their flame-retarding potential was analyzed. Chen-Yang and co-workers (78) prepared blends of poly[bis(*p*-chlorophenoxy)phosphazene] and polystyrene, and studied their morphology, thermal properties, and flammability. Partial compatibility was observed when the polyphosphazene content was less than 50%. Ambrosio and co-workers (79) studied degradable polyphosphazene/polyester blends with self-neutralizing potential.

Herrero and Acosta (80) investigated the microstructure of poly(ethylene oxide)–poly[(octafluoropentoxy)(trifluoroethoxy)phosphazene] blends. Limited miscibility of both components was inferred, based on the observed shift of the components' glass-transition temperatures. Wycisk and co-workers (81) prepared membranes from blends of sulfonated poly[bis(3-methylphenoxy)phosphazene] with polyimides, polyacrylonitrile, and Kynar FLEX PVDF. Morphology, electrochemical performance, and methanol permeabilities of the membranes were then evaluated as part of a program to investigate such blends in direct methanol fuel cells. The polymers were immiscible and a domain-type structure was observed. The best compatibility resulted when the tetrabutylammonium or sodium salt of the polyphosphazene was used (82).

Cross-Linked Polyphosphazenes. Many applications require some level of cross-linking to be incorporated into the polymer to obtain an elastomer or to make it stronger, insoluble, or more thermally/chemically stable (83). Three kinds of cross-links are generally distinguished: physical (through crystallites or glassy microdomains), ionic complexes, and finally, covalent cross-links. The most stable are covalent bonds and these are of utmost importance. Two general methods, both of the radical nature, were generally used to induce covalent cross-linking in polyphosphazenes. One was based on incorporating some number of unsaturated functions like vinyl or allyl groups into the polyphosphazenes. This approach was generally adopted for vulcanization of polyphosphazene elastomers (84,85). The second method relied on labile hydrogen abstraction from secondary or tertiary carbons in the side groups (86–89). In Figure 6, an example is presented of photo-cross-linking of poly[(4-ethylphenoxy)(phenoxy)phosphazene] (90). Here, irradiation with UV light of wavelength 340 nm causes excitation of the benzophenone photoinitiator, which then abstracts hydrogen from a benzylic carbon of the polyphosphazene side groups. As a result, a macroradical is formed, where recombination of two macroradicals results in formation of a covalent cross-link. Electron beam irradiation or γ-ray exposure was also used to induce cross-linking of alkylaryloxy- or oligoethoxy-substituted polyphosphazenes (74,91–95). Interesting results were obtained with ionic cross-links. Allcock described the use of poly[bis(carboxylatophenoxy)phosphazene] for a microencapsulation of

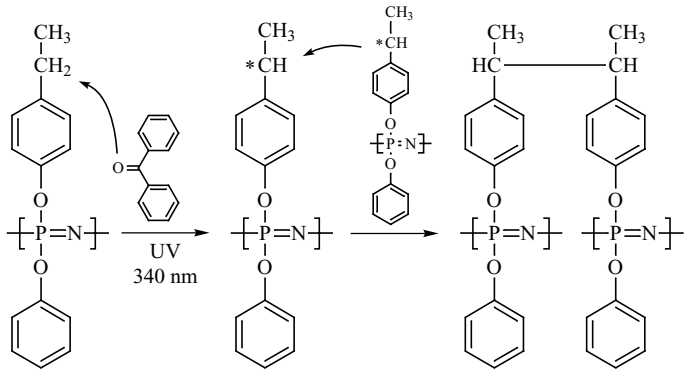

Fig. 6. The photo-cross-linking of poly[(4-ethylphenoxy)(phenoxy)phosphazene] with benzophenone photoinitiator.

mammalian cells (96). Acid–base complexation was also employed for cross-linking (97). In this way a poly[bis(3-methylphenoxy)phosphazene] sodium sulfonate was blended with polybenzimidazole into a membrane. Insoluble films were obtained after conversion of the sulfonate groups into sulfonic acid moieties and heat treatment of the polymer (98). The cross-linking degree and water swelling were controlled by adjusting the polybenzimidazole content.

Functional Polyphosphazenes. Functionalization can be defined as the introduction of chemical groups into the polymer chain that exert a specific function (eg chemical, physical, or biological) (99). Introduction of reactive groups into a polyphosphazene via the general macromolecular substitution route usually requires use of protected reagents, otherwise cross-linking and precipitation of the partially substituted polydichlorophosphazene may result (100,101). Derivatives containing hydroxylic (102–104), amine (105–108), and carboxylic (109) groups were prepared in this way.

Carriedo and co-workers (110,111) developed an interesting method of synthesizing various poly(aryloxyphosphazenes) using K_2CO_3 or Cs_2CO_3 as proton abstractors to substitute for chlorine atoms in poly(dichlorophosphazene). Even if bifunctional nucleophiles were used, no cross-linking was observed when the carbonates were present and the resultant polyphosphazene was soluble. Using this method, novel poly(spirophosphazenes) (112) and the chiral poly(dioxybinaphtylphosphazenes) (45) were synthesized.

A significant amount of research was devoted to post-functionalization of aryloxy- or methyl-substituted polyphosphazenes. In the first case, electrophilic aromatic substitution reactions were used to obtain sulfonated (113–116), carboxylated (117) nitrated (aminated) (118,119) and phosphonated (120,121) products (Fig. 7a). Alternatively, methyl substituents were deprotonated with *n*-BuLi and subsequently treated with a desired nucleophile (Fig. 7b). Using this method, polyphosphazenes bearing carboxylic (122), alcohol (123,124), ester (125), and other (63,126) groups became available. Numerous studies have been devoted

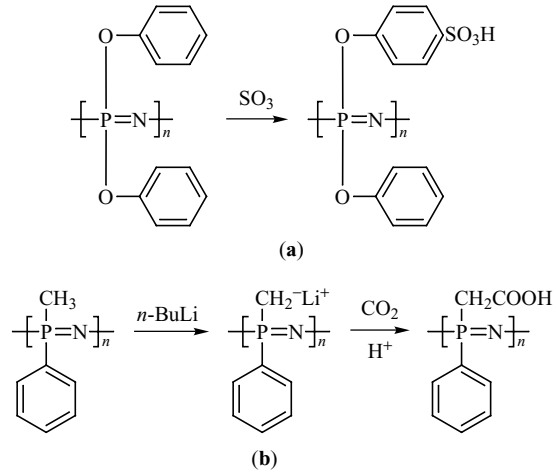

Fig. 7. (**a**) Sulfonation of the phenoxy substituents of the poly[bis(phenoxy)phosphazene] and (**b**) lithiation/carboxylation of the methyl group of poly[(methyl)(phenyl)phosphazene].

to a surface modification of polyphosphazenes (98,100). The most important objectives were balancing hydrophobicity or hydrophilicity, and immobilization of biologically active compounds (113,127–130).

Properties

Polyphosphazenes, owing to their inorganic backbone, are characterized by properties that are not common to organic polymers, namely low temperature flexibility, nonflammability, good thermal stability, and biocompatibility.

Backbone Flexibility. A characteristic feature of all the polyphosphazenes is their high skeletal flexibility, which is reflected in their very low glass-transition temperatures (Fig. 8). The high segmental mobility of the chain was explained by Allcock (4) as originating from cylindrical symmetry of the P—N bond because of broad overlapping of the nitrogen *p*-orbital with any of the five *d*-orbitals of the phosphorus (131). For example, the backbone torsional barrier in poly(difluorophosphazene) was found to be as low as 0.1 kcal per repeat unit (1). Although the formal structure of the polymers comprised a system of alternating single and double bonds, no electron delocalization was evidenced and an "island" pi-bond structure was postulated. Structural studies on poly(dichlorophosphazene) suggested a slight alternation in P—N bond lengths in the polymer backbone with values of 0.144 and 0.168 nm (132).

Crystallinity. Polyphosphazenes with a single substituent that is either small or rigid are semicrystalline. Their melting behavior consists of two first-order transitions, T(1) and T_m, separated by a 150–200°C gap. Optical microscopy showed that the crystalline structure was not lost at T(1), but rather existed as a mesophase until T_m was reached (2). Most fluoroalkoxy and aryloxy derivatives exhibited very high thermal stability with decomposition temperatures of 300–400°C.

Applications

Elastomers. An elastomer is a material that can be stretched repeatedly to a high extent (elongation greater than 200%) and always retracts to its original dimensions when the stress is released. Chain flexibility resulting from a freedom of

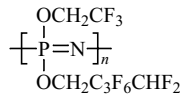

Fig. 9. An example of a typical polyphosphazene elastomer (EYPEL-F).

bond rotation within the polymer backbone is the main prerequisite for achieving elastomeric properties. Polyphosphazenes with low glass-transition temperatures proved to be best suited as high performance elastomers (61,133,134), especially for military applications. Substitution of two different types of fluoroalkoxy side groups on the same chain gave phosphazene polymers that were elastic at temperatures as low as −60°C, nonflammable, and resistant to hydrocarbon solvents, oils, and hydraulic fluids. A representative structure is shown in Figure 9 (135). Several polyphosphazene fluoroelastomers were commercialized under the trade name PNF or EYPEL-F. Polyphosphazenes were also used for toughening of thermosetting resins (136). Polydialkoxyphosphazenes were tested as low temperature greases and sealants (137). These materials proved to have high plasticity over a wide temperature range (−100°C to +100°C) with a decrease in the compressive/tensile modulus as the temperature was lowered.

Solid Polymer Electrolytes. Poly(ethylene oxide) (PEO) doped with a lithium salt has been used as the solid polymer electrolyte in rechargeable lithium batteries. The oxygen atoms in the PEO backbone coordinate metal cations, thus facilitating dissociation of the dissolved salts. However, because of its crystallinity, high conductivity could only be achieved when heated above 65°C. In 1984 Allcock and co-workers (138) found that poly[bis(methoxyethoxyethoxy)phosphazene] (MEEP, Fig. 10) doped with certain lithium and silver salts exhibited a room temperature ionic conductivity that was 2–3 orders higher than that of doped PEO. The repeat unit of MEEP has six oxygen atoms for cation coordination. The side groups are very flexible, which together with the inherent backbone flexibility, contributed to a glass-transition temperature being as low as −84°C. The polymer, however, was totally amorphous, which resulted in problems with its dimensional stability (139). A significant amount of research was directed to overcome this disadvantage. There were reports on cross-linking (140–142), blending with PEO (143,144), composites with silicates (145,146), and synthesis of poly(phosphazene-ethylene oxide) block copolymers (59). A new mechanical stabilization strategy, based on ceramic composites, was invented and developed at the Idaho National Engineering and Environmental Laboratory (147). Polyphosphazenes bearing crown ethers (148), sulfone or sulfoxide (149), or sulfonate (150) groups were also tested as potential Li^+ ion conducting solid polymer electrolytes.

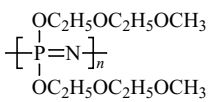

Fig. 10. Poly[bis(methoxyethoxyethoxy)phosphazene] (MEEP), a solid polymer electrolyte that was studied for use in lithium batteries.

Membranes for Gas Separation. Many linear polyphosphazenes have been tested as membranes for gas separation (151). Derivatives with phenoxy, trifluoroethoxy, or *n*-alkoxy were of most interest. Some of the work focused on O_2 and N_2 permeability (152–155) but other gases were also investigated (156–160). The literature data show a wide scatter of measured permeabilities for the same polymers. Most of the confusion can be attributed to the quality of the polymer samples, their thermal history, and experimental factors. Nevertheless, some trends are apparent. In general, low-T_g polyphosphazenes with alkoxy substituents have very high oxygen permeabilities, comparable to those of siloxane polymers, but with better selectivities (151). Also, polyphosphazenes showed a very high permeability for CO_2. Polyphosphazene membranes were applied to the recovery of helium from natural gas (158). Poly[bis(phenoxy)phosphazenes] have been tested in mixed gas separations where SO_2/N_2 separation factors as high as 17.2 were observed at 190°C (161). The effect of trimethylsilyl substituents on the gas transport properties of a series of polyphosphazenes has also been reported (162). When substituted at the para position of the phenoxy side groups, the polymers promoted an increase in selectivity accompanied by a decrease in gas permeability. Alternatively, incorporation of the trimethylsilyl group on the methyl group of poly[(methyl)(phenyl)phosphazene] resulted in an increase of both permeability and selectivity. While searching for chemoselective membranes, Orme and co-workers (163) incorporated three pendant groups into a polyphosphazene chain: 2-(2-methoxyethoxy)ethanol, 4-methoxyphenol, and 2-allylphenol. The first group gave the polymer proper hydrophilic character, the second group provided hydrophobic counterbalance and film-forming abilities, and finally, the third group enabled cross-linking (Fig. 11). The membranes showed some promise for CO_2 separation. The gas permeability of poly(organophosphazenes) was also the subject of theoretical studies and atomistic simulations (164).

Pervaporation. Separation of water–organic and organic–organic solutions by pervaporation is another area for potential applications of polyphosphazene membranes (151). Selectivities as high as 10^4 have been reported for the separation of dichloromethane from water by pervaporation, using a membrane prepared from poly[bis(trifluoroethoxy)phosphazene] (161,165). High selectivities for the separation of toluene and heptane were observed with a similar membrane (166). Pervaporation of water and alcohols was also investigated (167–169).

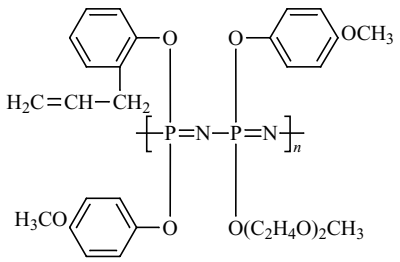

Fig. 11. Polyphosphazene with methoxyethoxyethoxy, 4-methoxyphenoxy and 2-allylphenoxy substituents used by Orme and co-workers (144) for gas separation studies.

Separation of Tritiated Water. Aromatic polyphosphazene membranes were investigated in the separation of tritiated water from normal water, because of their excellent radiological, thermal, and chemical stability (170,171). For these experiments carboxylated poly(diaryloxy)phospohazenes were used. A tritium depletion as high as 33% was reported.

Proton-Exchange Membranes for Fuel Cells. Fuel cells are a promising power source of the future. In current hydrogen/air PEM fuel cells, Nafion perfluorinated membranes are used as the proton-conducting separator of the anode and cathode half-cells. In addition to its high price, Nafion has two serious drawbacks that limit its use: high methanol crossover in direct methanol fuel cells (DMFC) and loss of conductivity (dehydration) at temperatures above 100°C in hydrogen/air fuel cells. Polyphosphazenes are a serious alternative to Nafion. Preliminary studies showed that films from sulfonated and UV-cross-linked poly[bis(3-methylphenoxy)phosphazene] possessed high proton conductivity, low methanol diffusivity, and good thermo-oxidative stability (172–174). Blends of sulfonated polyphosphazene and an inert organic polymer like a polyimide, poly(vinylidene fluoride), or polyacrylonitrile (PAN) were also investigated (175). The polyphosphazene component of the blend was stabilized by UV or e-beam cross-linking. The resultant membranes had conductivities from 0.01 to 0.06 S/cm (in water, 25°C) and an equilibrium water swelling from 20 to 60% (25°C). Direct methanol fuel cell (DMFC) tests were performed using membrane-electrode assemblies (MEA) prepared from SPOP/PAN and SPOP/Kynar FLEX (copolymer of vinylidene fluoride and hexafluoropropylene) blends. With a three-layer composite MEA (a methanol blocking film sandwiched between two high-conductivity membranes), a significant reduction in methanol crossover was observed with a modest decrease in current–voltage behavior, as compared to Nafion 117 (176). Phosphonated polyaryloxyphosphazenes were synthesized by Alcock and co-workers (120,121) and investigated as potential membrane materials for use in direct methanol fuel cells. The membranes cast from *N*,*N*-dimethylformamide were found to have conductivities between 0.01 and 0.1 S/cm and methanol diffusion coefficients (in 3 *M* MeOH) between 0.14×10^{-6} and 0.27×10^{-6} cm^2/s. Phenyl phosphonic acid functionalized poly[aryloxyphosphazenes] were prepared and evaluated as proton-conducting membranes in DMFC tests (177). Sulfonated derivatives of polyphosphazenes were also tested but their methanol barrier properties were found to be less attractive (178). Polyphosphazenes bearing sulfonimide groups were examined in a H_2/O_2 fuel cell at temperatures above 80°C. Less deactivation of the membrane due to dehydration (as compared to Nafion) was observed (179,180), which is a significant finding if these polymers are to be used in high temperature PEM fuel cells.

Biomedical Applications. Biomedical applications were investigated by a number of polyphosphazene research groups (181). The most important studies concerned biocompatibility, biodegradation, enzyme immobilization, and drug delivery (182,183). Polyphosphazene implants and prostheses were also examined. Biocompatibility through appropriate manipulation of surface or bulk chemistry was studied extensively (184). Works on the synthesis and cross-linking of amphiphilic polyphosphazenes (94), heparin immobilization (185–187), and other surface functionalizations (4,101) were reported.

Trypsin and glucose-6-phosphate dehydrogenase were immobilized on surface-aminated poly[bis(phenoxy)phosphazene] and successfully tested in continuous-flow reactors (130). Biodegradable polyphosphazene/poly(lactite-*co*-glycolide) blends were tested for controlled drug delivery using *p*-nitroaniline as a model release agent (188). Other polyphosphazenes that were susceptible to erosion under physiological conditions were also investigated; they contained amino acid ester (189–193), imidazolyl (194,195), glyceryl (104), or glucosyl (103) groups. *In vivo* performance under clinically relevant conditions were planned for poly[(*p*-methylphenoxy)-*co*-(ethylglicinato)phosphazene] matrices (196). Water-soluble methoxyethoxy–aminoaryloxy co-substituted polyphosphazenes were synthesized and tested as carriers for *N*-acetylglycine (106). Synthetic vectors for gene delivery based on polyphosphazenes were also reported (197). Song and co-workers (198,199) investigated the synthesis and antitumor activity of poly(organophosphazene)/diamineplatinum and poly(organophosphazene)/deoxorubicin conjugates. Only the first conjugate exhibited high antitumor activity due to controlled release of diamineplatinum(II). Polyphosphazene membranes and microspheres were investigated for the treatment of periodontal diseases (200). Antibacterial drugs, useful in periodontal tissue regeneration, could be entrapped in the membranes and released at appropriate rates to ensure therapeutic concentrations in the tissue. A hydroxyapatite–polyphosphazene composite was tested as a possible artificial bone-replacement material (201). Peripherial nerve regeneration with a poly[(organo)phosphazene] tubular prosthesis was presented as an alternative to silicone tubes usage (30). In other studies mammalian liver cells were encapsulated using calcium-cross-linked polyphosphazene (96), and polyphosphazene microspheres for insulin delivery were prepared (203) and their release behavior were evaluated. The use of polyphosphazenes as resilient denture liners and maxillofacial prostheses was also reported (204). Water-soluble phosphazene polymers were used to enhance the immunogenicity of HIV-1 secreted viral antigens (205). The system was found to have potential as a new HIV-1 vaccine candidate for human trials.

Flame Retardants. The high phosphorus and nitrogen content of polyphosphazenes make them nonflammable (206). Their properties are characterized by a high oxygen index (2), low smoke emission, noncorrosiveness, and low toxicity of combustion gases. Several polyphosphazenes were tested as coatings, foams, and coverings for electric cables. In flaming combustion, a commercially viable polyphosphazene exhibited a 75% reduction in heat release rate compared to the polyurethane rubber currently used in fire-blocked aircraft seat cushions (207). Cyclic, oligomeric, and polymeric phosphazenes have been investigated as flame-retarding additives and blends for several commodity polymers. For example, flame retardation improvement of polyurethane has been achieved by the use of aziridinyl substituted cyclotriphosphazene (208). The trimer served a dual function as cross-linker and as flame-retardant. Improvement of flame resistancy by incorporation of cyclic phosphazenes into organic polymers was the subject of many studies (209–213). Chen-Yang and co-workers (78) showed that blends of poly[bis(*p*-chlorophenoxy)phosphazene] and polystyrene had thermal stability and flame resistance significantly better than those of a pure polystyrene. Reed and co-workers (214) blended poly[bis(carboxylatophenoxy)-phosphazene] with structural polyurethane using reactive mixing and analyzed the thermal

stabilities of the resultant foams. An increase in flame resistance at loadings equal to or greater than 20 wt% was observed. Chen-Yang described the syntheses of an epoxy resin (215) and polyimides (216) containing flame-retarding cyclophosphazene.

Optical Devices. Of most interest in this application are those studies related to the nonlinear optical effects in polyphosphazene derivatives bearing aromatic azo units (217–219) and the photorefractive effect with polyphosphazenes bearing carbazolyl substituents (220). Possible applications include optical switches, frequency doublers for lasers, holographic data storage, and real-time image processing.

Hybrid Polyphosphazenes

In the last decade a number of hybrid polyphosphazenes containing backbone elements such as carbon, sulfur, or metal, in addition to phosphorus and nitrogen, have been synthesized and studied. Ring-opening polymerization of appropriate cyclic heterophosphazene has led to polymers like polycarbophosphazenes, polythiophosphazenes and polythionylphosphazenes (Fig. 12). Several polycarbophosphazenes have been synthesized (221,222). The general observation is that the polymers have a higher glass-transition temperature than the corresponding polyphosphazenes, which attributed to the lower rotational freedom of the C=N bond as compared to P=N. The first well-characterized examples of polythiophosphazenes, were reported by Dodge and co-workers (223). The polymers were moisture-sensitive and degradation was retarded only when bulky substituents such as o-phenylphenoxy were present. It was found that the S–Cl bond was more reactive than the P–Cl bond, which allowed for a regioselective substitution to yield polythiophosphazenes with different aryloxy substituents at the sulfur and phosphorus atoms. Synthesis of polythionylphosphazenes was reported by Liang and Manners (224). The perchlorinated polymers were moisture-sensitive, but reactions with aryloxy nucleophiles or primary amines converted them into stable poly(aryloxythionylphosphazenes) and poly(aminothionylphosphazenes), respectively (225,226). The substitution with aryloxides was regioselective but, contrary to the situation observed with polythiophosphazenes, only substitution of the P–Cl bonds was observed and the S–Cl bonds were intact. On the other hand, amines

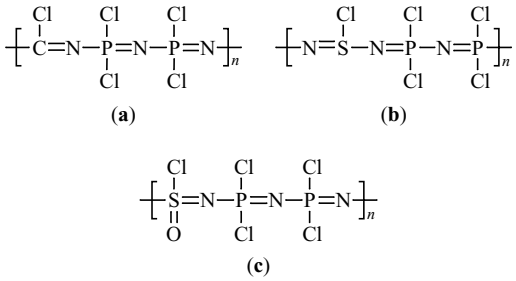

Fig. 12. (**a**) Polycarbophosphazene, (**b**) polythionylphosphazene, and (**c**) polythionylphosphazene, as examples of hybrid polyphosphazenes.

substituted easily at both phosphorus and sulfur atoms. Depending on the type of substituent, the polythionylphosphazenes showed properties typical of elastomers or glasses. Condensation routes to sulfur–nitrogen–phosphorus polymers were also reported (227,228).

Polymers Containing Cyclophosphazenes. Besides linear polyphosphazenes, three other macromolecular structures can be obtained based on the cyclic trimer: organic polymers with cyclophosphazene side groups, cyclolinear polymers, and cyclomatrix materials (Fig. 13). Poly(alkenylcyclophosphazenes) were studied in Allen's group (210). His approach involved the synthesis of cyclophosphazenes with an unsaturated group and subsequent radical copolymerization with various organic monomers, eg styrene or methyl methacrylate (229–232). The polymers consisted of an organic backbone, with the phosphazene rings as side groups. Other approaches involved either incorporation of phosphazene trimers into condensation polymers (233,234) or linkage to preformed organic polymers (213,235). Lately, Allcock presented the synthesis of cyclolinear-phosphazene-containing polymers via ADMET polymerization (236,237). Phosphazene–triazine cyclomatrix polymers were prepared by Mathew and co-workers (238). The group of Kumar and Gupta (239–241) developed several cyclolinear and cyclomatrix derivatives of polyimides. These materials showed good thermo-oxidative stability and a high char yield of 50–60% in air at 800°C.

POLYSILANES

Introduction

Polysilanes or polysilylenes have catenated silicon backbone with two (organic) substituents on each silicon atom. Homopolymers (**1**) consist of single repeating silylene unit (R_2Si), and copolymers consist of two or more silylene units (**2**). Most are random block copolymers as in **2**, though several homopolymers with repeating disilylene ($R^1{}_2Si{-}SiR^2{}_2$) units have also been prepared. Materials prepared from trifunctional monomers are called "networked polysilanes (**3**)" or "ladder polysilanes (**4**)."

Polysilanes bearing no specific chromophore in the side chain are colorless or white solids unless they contain substantial branching points. Most polysilanes are soluble in common organic solvents. But highly crystalline polymers $(CH_3)_2Si$, $(C_2H_5)_2Si$, $(C_6H_5)_2Si$) are insoluble. No specific toxicity has been reported. Polysilanes except those containing Si—H groups are air-stable below 300°C in the dark. Polymers involving halogen or triflate groups are moisture-sensitive and produce Si—O—H or siloxane bond on exposure to moisture. Weight loss begins around 350°C under vacuum or in inert gas. Black residue, mostly SiC, is observed after pyrolysis and this process is industrially used for SiC fiber production. Polysilanes are sensitive toward UV irradiation which induces polymer degradation mainly by Si—Si chain scission in vacuum or oxidation to siloxanes in air. A limited number of polysilanes [$(CH_3)_2Si)_n$, $(CH_3)_2Si)_m(CH_3—Si—C_6H_5)_n$, and $(CH_3—Si—C_6H_5)_n$] are commercially available in reagent quantity (Gelest, Inc., USA). The unique characteristics of polysilanes [strong absorption in UV region (300–400 nm), efficient fluorescence emission, high carrier mobility] originate from delocalized σ-electrons along their backbone, which yield similar physical properties to π-electrons in conjugated carbon polymers (1). The electronic state of polysilanes and ensuing physical characteristics are dependent on the following four factors: molecular weight (Si-catenation number), conformation (dihedral angle of the silicon backbone), substituents on silicon atom, and dimension of the backbone (branching points).

UV Absorption and Chromotropism

Strong absorption in the UV region is one of the most typical characteristics of σ-conjugated polysilanes. The λ_{max} and absorbance (ε) increases with increasing catenation number of silicon, which levels off around $n = 50$ (Fig. 1) (1). Poly(organosilanes) with $n > 50$ show λ_{max} at 300–400 nm (see Table 1). Polysilanes with aromatic substituents generally show longer λ_{max} than poly(alkylsilanes), which is attributed to σ–π conjugation (3). Poly{bis(butylphenyl)silane} shows λ_{max} at 400 nm, the longest absorption among linear polysilanes (1).

Because the silicon backbone is single bond in nature, the potential energy of polysilanes is dependent on the dihedral angle. The potential energy minima of polysilanes have been calculated to be $\omega = 180°$ (anti or trans) and ($\omega = \pm 60°$ (gauche). A more recent calculation (4), however, revealed that potential energy is dependent on the ratio of R^{vdxy}/R^{SiSi} where R^{vdxy} and R^{SiSi} are van der Waals radii of the substituents on silicon atom and $R^{SiSi} = \sim 2.36$ Å (0.236 nm), respectively. $\omega = 60°$ and 180° are the energy minima only for Si_nH_{2n+2}. Polysilanes with $R^{vdxy}/R^{SiSi} = 0.8$–1 have energy minima around $\omega = \pm 165°$ (transoid), $\pm 90°$ (ortho), $\pm 55°$ (gauche). These dihedral angles are found in permethylated oligosilanes in low temperature matrix (5) and Si_4Cl_{10} (11) in crystalline states. $Si_4(C_2H_5)_{10}$ has minima at $\omega = \pm 165°$ (T, transoid), $\pm 145°$, (D, deviant), $\pm 90°$ (O, ortho), $\pm 55°$ (G, gauche), and $\pm 45°$ (C, cisoid) (6).

Conformationally locked tetrasilanes and hexasilanes (7) confirmed that the all-anti conformer shows more intense absorption at the long wavelength than tetrasilanes containing other conformations. The combinations of the above possible dihedral angles make high molecular weight poly(organosilanes) complicated enantiomeric mixtures.

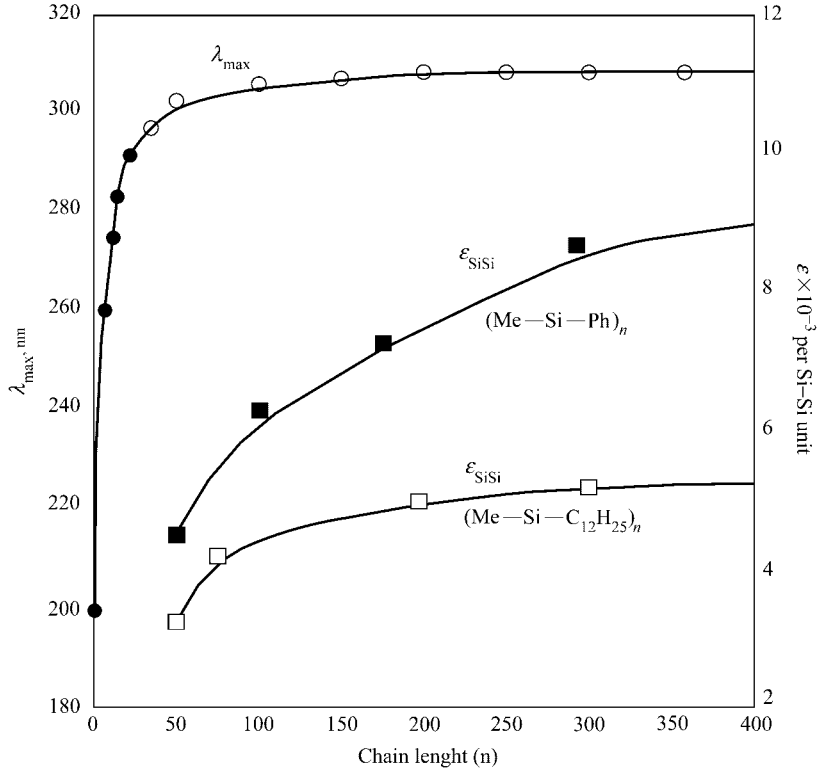

Fig. 1. Absorption wavelength maxima (λ_{max}) and extinction coefficients (ε_{SiSi}) as a function of oligomer chain length of n units $[SiR^1R^2]_n$. Reproduced with permission from Ref. 1, Copyright (1989), America Chemical Society.

UV spectroscopy is a convenient tool to examine the energy state of polysilanes. The silicon backbone of polysilanes is sensitive toward external stimuli and yields interesting chromotropic behavior both in solution and solid state (1,8). Thermochromism in dialkyl-substituted polysilanes has been studied intensively. Depending on the difference of the side-chain length, three types of spectral shift are induced on cooling in solution (Fig. 2) (9): (*1*) Continuous redshift to 320–330 nm is observed for polysilanes with very unbalanced side-chain length (Fig. 2a); (*2*) Continuous redshift to 350 nm with sharp intensification is observed for polysilanes with intermediately balanced side chains (Fig. 2b); (*3*) Discontinuous redshift to 355 nm for polysilanes with balanced long alkyl side chains (Fig. 2c). The absorption at 355 nm was once attributed to the most extended conformer (all-anti) but poly(didecylsilanes) and poly(didodecylsilanes) have recently been found to show absorption at 375 nm in solution (10). No spectral shift or a small hypsochromic shift is found for polysilanes bearing bulky substituents [$(C_6H_5{-}Si{-}CH_3)_n$, C_6H_5-Si-*c*-$C_6H_{11})_n$]. The molecular form of polysilanes in solution is conveniently estimated by the linear relationship $\varepsilon = 1130 \exp(-2.77\alpha)$ [α is the viscosity index in $[\eta] = kM^a$, and ε is the molar absorbance per Si unit] (11). Polysilanes with $\varepsilon = \sim 6000$ ($\alpha = 0.6$–0.7) are globular and those of $\varepsilon = \sim 10{,}000$

[a] Refs. 1 and 2.
[b] All values were measure in THF.

($\alpha = 0.8$–1.0) are in an extended form. Rod-like polysilanes show $\varepsilon = 45{,}000$ ($\alpha = 1.6$ at -75°). The long persistence length of poly(bis(substituted-phenyl)silanes) determined by light scattering (>10 nm) is consistent with the strong absorbance ($\varepsilon > 2.5 \times 10^4$).

The thermochromic behavior of poly(dialkylsilanes) in the solid state is complicated by packing and mutual entanglement of the side groups. A discontinuous spectral shift of poly(dialkylsilanes) $[(R_2Si)_n]$ in the solid state occurs near the thermal phase transition temperature. Three conformations were determined by X-ray studies for uniaxially oriented poly(dialkylsilanes). Absorption maxima, thermochromic transition temperatures, and low temperature conformations of typical poly(dialkylsilanes) are listed in Table 2 (8). The absorptions at 375, 345, and 315 nm in Table 2 are related to all-trans (AT), TGTG′, and 7/3 helix conformations, respectively. Poly(dialkylsilanes) also show liquid crystalline behavior taking hexagonal columnar mesophase (*hcm*) (8,17). The thermochromic transition in the solid state is, however, independent of crystallization (18). Thermochromic behavior of poly(dialkylsilanes) is cooling rate dependent (19). Poly(dibutylsilane) and poly(dipentylsilane) show only a thermochromic blueshift in the solid state. However, they show a discontinuous type of shift either in solution or at high pressure (piezochromism) (20). Complexation with lithium ions

alters thermochromic behavior of [CH_3—Si—$(CH_2)_3$—$(OCH_2CH_2)_3$—OCH_3] (21) and [Oct—Si—$(CH_2)_4$—OCH_2CH_2—OC_2H_5] (ionochromism) (22). Electrochromism is reported only for poly{(3,3,3-trifluoropropyl)-methylsilane-*co*-methylpropylsilane}, which shows a blue shift when an electric field is applied (23).

Photoluminescence

A sharp fluorescence with small Stork shift is another characteristic of polysilanes. Fluorescence quantum yield (Φ) is generally high as summarized in Table 3 for typical polysilanes (1). Fluorescence lifetime is usually less than 1 ns. Temperature-dependent fluorescent spectra of poly(dialkylsilanes) correspond to thermochromic behavior. The fluorescence spectrum is also sensitive to structural defects; polysilanes having branching points (networked polysilanes **3** or ladder polysilanes **4**) show decreased fluorescence emission in the UV region but show an additional broad emission in the visible region (>430 nm) (24). The efficient emission makes polysilanes an emitting material of Light-Emitting Diodes (qv) (LEDs).

Ionization potential of polysilanes is in the range of 5–6 eV as determined by photoelectron spectroscopy (25,26), XPS (27) and xerographic surface analysis (28), which is due to a high HOMO level (29). Polysilanes behave as electron donors and form complexes with TCNE (30) and reduce metal ions (Au^{3+}, Ag^{+}, and Pd^{2+}) (31). The band gap of polysilanes is in the range of 3–4 eV as determined by the absorption edge.

Synthesis

Polysilanes are synthesized by following five methods: (*1*) reductive condensation of dichlorosilanes with alkali or alkali earth metals (Wurtz-type coupling), (*2*)

Table 3. Fluorescence of Polysilanes[a]

	Solution		Solid state	
Polysilane	λ_{max}, nm	Φ, %	λ_{max}, nm	Φ, %

[a]From Ref. 1.

dehydrogenative coupling of hydrosilanes with transition-metal complexes (32), (*3*) anionic polymerization of masked disilenes (33–35), (*4*) ring-opening polymerization (ROP) of strained cyclic oligosilanes (36,37), and (*5*) redistribution polymerization of alkoxylated disilanes with base catalysts (38). Reductive condensation is a practical and general method to prepare a wide variety of polysilanes. The reaction is usually carried out in toluene with sodium. Yield and molecular weight are highly dependent on the dichlorosilane monomer and reaction condition. The reaction is believed to involve silyl anions and/or anion radials (eq. 1) (39). The reaction proceeds only on the surface of sodium (Fig. 3).

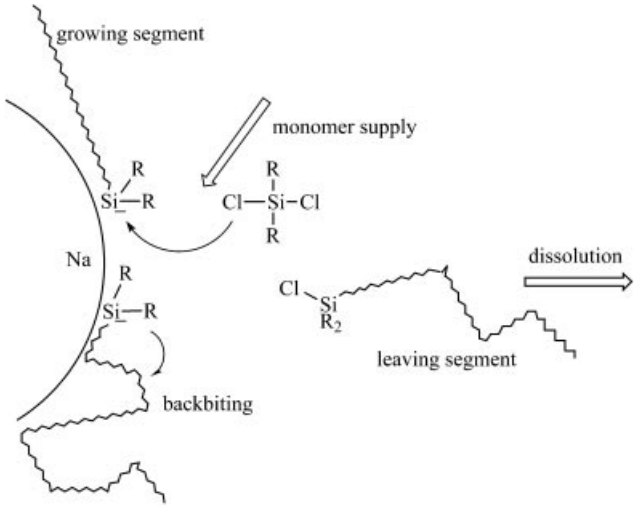

Fig. 3. Diffusion model of Wurtz coupling reaction.

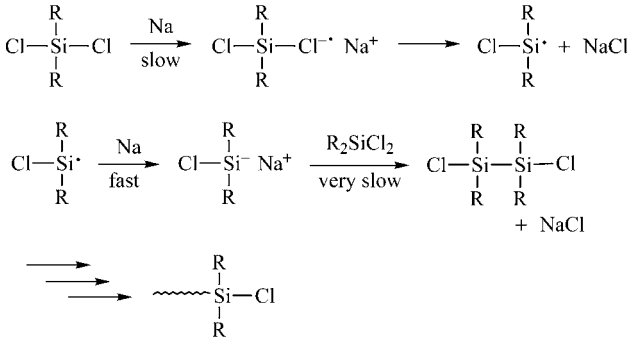

(1)

As a result of the severe reaction conditions (high temperature, alkali metals), the heterogeneous nature of the reaction, as well as a complicated reaction mechanism, polysilanes obtained by this method show polymodal molecular weight distribution. GPC peaks are found around $M_w > 10^6$, $\approx 10^5$, 10^4, and 10^3 and cyclic and linear oligomers ($M_w < 1000$). Reaction at relatively low temperature ($\approx 65^\circ$C) (40), reaction with sodium dispersion into monomer (41), reaction by rapidly adding monomers into sodium dispersion (42), reaction in the presence of sacrificing materials (43), reaction by using benzene as the solvent (44), and reaction under the presence of copper catalysts (42) are effective in obtaining polysilanes with high molecular weight ($M_w > 10^5$). High yield is achieved by the reactions of ultrasound agitation (45), using phase-transfer reagent (46), or using THF, diglyme, or HMPA as the solvent or additive (40). The obtained polysilanes in these high yield synthetic methods usually show monomodal molecular weight distribution. However, the molecular weight is not high ($< 1 \times 10^5$). Polymerization with potassium, Na/K alloy, and KC_8 are applied for less reactive monomers or low temperature polymerization but undesired cyclic and/or linear oligomers are also formed. Electrolysis with Mg electrodes under ultrasound irradiation affords a safe and controllable method but gives low molecular weight polymer ($M_n < 10^4$) (47).

Molecular weight of the product by dehydrogenative polymerization of hydrosilanes is low ($M_n < 10^4$) (48), but the reactive Si—H groups are further converted to diverse functional groups (Fig. 4) (49). Dehydrogenative polymerization

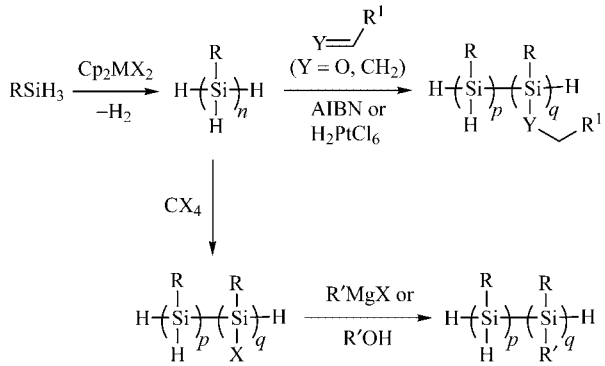

Fig. 4. Conversion of Si—H containing polysilanes.

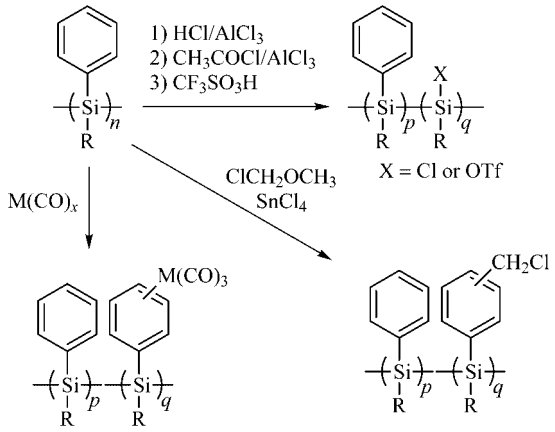

Fig. 5. Functional polysilanes derived from poly(alkylphenylsilane) by one step.

was also achieved under electrolytic conditions using Pt-electrodes (50) and this moderate reaction affords trifluoropropyl-substituted polysilanes (51).

Anionic polymerization of masked disilenes proceeds via a living condition to give polymers having controlled molecular weight (33). Head-to-tail polymers can selectively obtained and polysilanes with functional groups such as diethylamino groups are prepared. However, the masked disilene method is only applicable to the synthesis of non-aromatic-substituted polysilanes.

Ring-opening polymerization of cyclic monomers is initiated either thermally or anionically. Reactive monomers are obtained from $(C_6H_5)_8Si_4$ via dephenylation with HCl or TfOH (see Figs. 5 and 6) and subsequent substitution

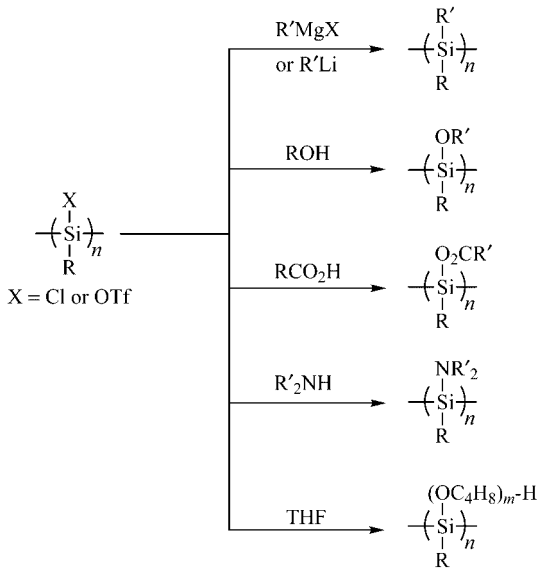

Fig. 6. Functional polysilanes from halogenated- or triflated-polysilanes.

reactions (37). Si_4Cl_8 prepared from $Si_4(C_6H_5)_8$ is found to afford crystalline polymer by thermal ROP (52). The starting monomer and final product can be used as the convenient starting material for polysilanes with functional side groups. ROP of silole-containing cycliopentasilane yields 1,1-silole-*co*-polysilane (53) and ROP of phenylnonomethylcyclopentasilane (54) gives a regular pentad polymer. Base-catalyzed redistribution polymerization of alkoxylated-disilanes is a simple method but offers only networked polymers (55).

Dendritic polysilanes have been prepared by stepwise reactions (56). Copolymerization of dichlorosilane and trichlorosilane yields ladder-type material (57).

Functional Polysilanes

Although severe Wurtz-type coupling reaction conditions destroy most functional groups, some functional polymers have been synthesized. The C=C bonds in the cyclohexenyl group react with HX to afford polysilanes possessing halogen groups (58). Several ethereal group substituted polysilanes (59) and 3,3,3-trifluoropropyl-substituted polysilanes have been prepared by Wurtz coupling at 150°C (60). *N*-carbazoyl-substituted polysilane (61), *p*-aminophenyl-substituted, and *N*-pyrolyl-substituted polysilanes are similarly prepared (62). Polysilanes bearing Si—H groups yield functional polysilanes via H_2PtCl_6-catalyzed hydrosilylation reaction (63) and free-radical reaction (64) or after conversion to Si—Cl groups by reaction with CCl_4, NCS, or $CuCl_2$ (65) (Fig. 4).

Phenyl-substituted polysilanes obtained in high yield are used as the staring material for functional polysilanes. Phenyl groups attached to silicon atoms are selectively replaced by halogen or triflate by $HCl/AlCl_3$ (66), $CH_3COCl/AlCl_3$ (67), or triflic acid (68) (Fig. 5). Functional polysilanes are obtained by the reaction of the halogen- or triflate-substituted polysilanes with nuclepophiles (Fig. 6). The poly(chloromethylphenylalkylsilanes) prepared by $SnCl_4$-catalyzed reaction (69) are useful substrates for diverse functional polysilanes (70) (Fig. 7). Reaction with amines gives polymers having ammonium substituents to prepare LB films (71) (see LANGMUIR–BLODGETT FILMS). Substantial decrease of molecular weight takes place during dephenylation and chloromethylation reactions. Aromatic groups in polysilanes have been studied to prepare arene-type complex with metal carbonyls (Cr, Mo, Mn) (72) but the products are unstable (Fig. 4).

Hybrid-Block Copolymer

Polysilanes are connected with carbon polymers to form A–B and A–B–A type block polymers. Reaction of Li-terminated polystyrene with cyclotetrasilanes (73) or halogen-terminated polysilanes (74), photolysis of polysilanes in carbon monomers (methacrylic monomers) (75), or reaction of halogen-ended polysilanes with poly(ethylene glycol) affords A–B and/or A–B–A type Block Copolymers (qv) (76) (Fig. 8). Comb-like Graft Copolymers (qv) have also been prepared by reaction of triflate-substituted poly(methylphenylsilane) with THF, 2-methyl-2-oxazoline, or isobutyl vinyl ether (77).

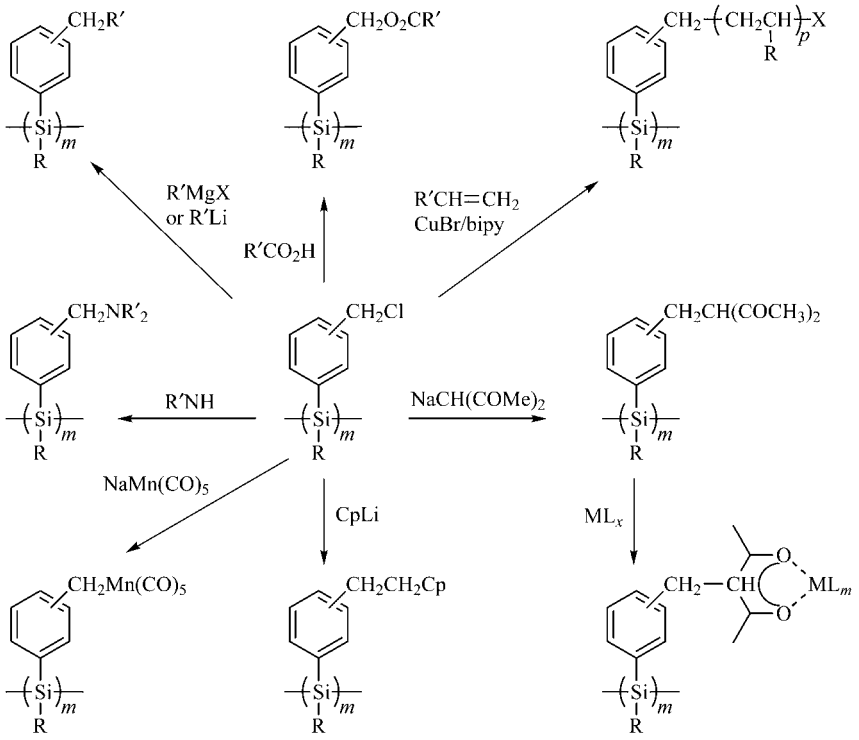

Fig. 7. Functional polysilanes from poly{(chloromethylphenyl)$_m$ethylsilanes}.

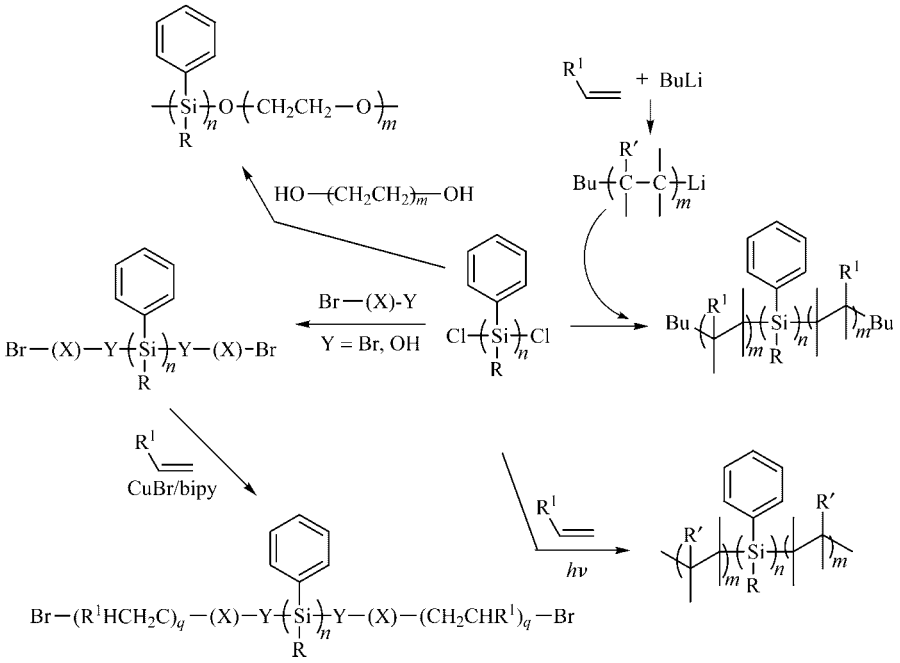

Fig. 8. Block copolymer from α,ω-dichloropoly(methylphenylsilane).

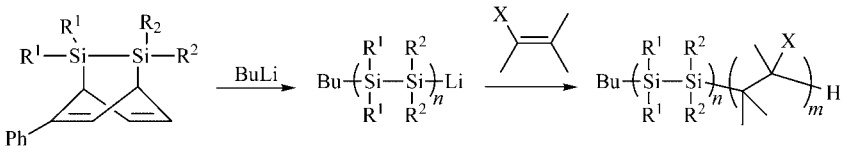
Unquenched product of masked disilene polymerization is used as the initiator of carbon monomers (78) (eq. 2).



(2)

Atom transfer radical polymerization catalyzed by CuBr-bipyridyl is applied to polysilanes with chloromethylated-phenyl groups to prepare comb-like copolymer via the side groups (79) or 4-chloromethylphenylethyl-terminated polysilanes to give A–B–A type polymers (Fig. 8) (80).

Photoreactions

Strong absorption of polysilanes in the UV region makes these materials suitable for application to photo (81) and X-ray lithography (82). Photo-bleaching by UV irradiation indicates scission as the major process for most polysilanes; scission proceeds via silyl radical and/or silylene (R_2Si:) extrusion (Fig. 9) (83).

Dry process with oxygen plasma etching has been studied (84,85). UV-irradiation of polysilanes converts the Si—Si bonds to Si—O—Si bonds selective and efficiently. The resultant siloxane-bonded products are flexible and have different refractive indexes. They interact with polar materials and then are utilized for color filter and microlens production via a sol–gel process (86), depositing metals for electric circuits (87), wave guides, or optical recording (Fig. 10) (88).

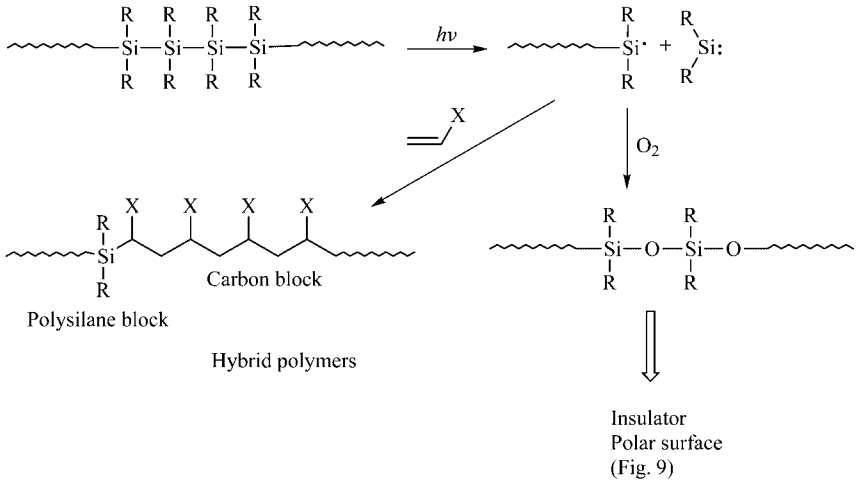


Fig. 9. Photochemical process of polysilanes.

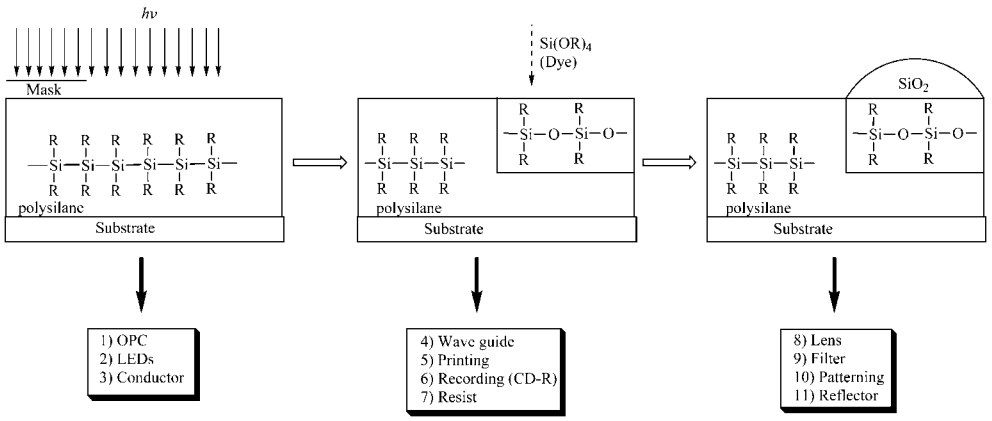

Fig. 10. Possible application of polysilanes.

Carrier Mobility and OPC

Most polysilanes show high photoconductivity, which has stimulated research of applications as organic photoconductors (OPC) in zerography. Carrier generation is, however, poor. Time-of-flight (TOF) studies revealed that holes are almost the sole carrier for most polysilanes (89) and the mobility ($\approx 10^{-4}$ cm^{-2}/V·s) is 2–3 order higher than most carbon polymers ($\approx 10^{-7}$cm^2/V·s) (Table 4).

Table 4. Ionization Potential and Hole Drift Mobility of Polysilanes

Polysilane	$10^{-3}\,M_w$	Ip,eV	μ, cm^2/V·s	Reference
$(CH_3—Si—CH_3)$		5.73		90
$(Bu)_2Si$		5.7	5.3	91
$(Pen)_2Si$		5.9		91
$(Hex)_2Si$		5.8	4.5	91

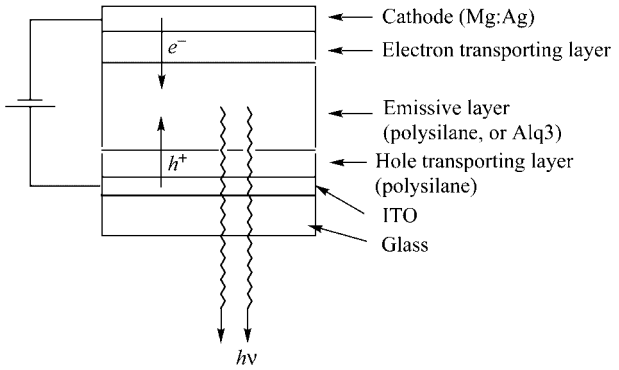

Fig. 11. Structure of LEDs. Polysilanes are used as hole transport layer or emissive layer.

Triarylamino-moieties as the side group or the additives enhance the mobility (93). However, electron mobility is observed only for poly{bis(butylphenyl)silane}, probably because of the localization of electrons along the main chain while holes are delocalized over side groups (94). Because carriers migrate by hopping among σ-conjugated domains (>10–15 Si units), the main-chain orientation (ordering) of the polysilane, in addition to maximizing σ-delocalization by controlling the conformation, is important for higher mobility (95). Ultra-drawing (96), mechanical deposition (97), the LB method (98), rubbing (99), dipping under constant air flow, vacuum deposition (100) as well as well as casting under strong electric field (101), weak electric field (102), or magnetic field (103) have been used to make oriented polysilane films (see FILMS, ORIENTATION).

Electroluminescence

High fluorescence quantum efficiency and high carrier mobility are advantages for the application of polysilanes as the emitting material of (LEDs). Single-layer LEDs by using poly(dimethylsilane) (104), poly(methylphenylsilane) (105), and poly(dialkylsilane) [$(C_4H_9)_2Si$, $(C_5H_{11})_2Si$, $(C_6H_{13})_2Si$] (106) have been reported. External quantum efficiency is, howevder, less than 10^{-4}%. Low efficiency is attributable to the poor efficiency of electron injection. Light is emitted from near polysilane–cathode interface because of low electron mobility. Most polysilane LEDs emit UV light only at low temperature (<200 K) and visible light is dominant in many cases (107). LEDs using carefully prepared poly(methylphenylsilane) (branching point-free) emit almost pure UV light similar to photoluminescence (108). Poly{bis(4-butylphenyl)silane-LEDs show high external quantum efficiency (0.1%) (109). Polysilanes are also used as the hole injection material for multilayer LEDs [anode: TPD:AlQ_3:polysilane:cathode] (110) or mixed with Eu^{3+} complex (111) or ALQ_3 (112) for full-color LEDs (Fig. 11).

Conductivity

Undoped polysilanes are insulating (113) [polysilastyrene ($<10^{-12}$S/cm), $(CH_3{-}Si{-}C_6H_5)_n$; 1×10^{-6} S/cm, $((CH_3)_2N{-}C_6H_4{-}Si{-}CH_3)$; 2×10^{-3} S/cm,

$\{(CH_3{-}Si{-}C_6H_4{-}N(CH_3)_2P)_m(CH_3{-}Si{-}CH_2CH_2{-}C_6H_4{-}NCH_3{}^P)_n\}$; 2×10^{-3} S/cm], ($C_6H_{13}{-}Si{-}C_6H_{13}$; 9×10^{-7} S/cm)]. Doping with a strong oxidant (AsF_5, SbF_5) increases conductivity up to 0.5 S/cm. Polysilanes with amino substituents (*p*-dimethylaminophenyl, pyrolylethyl, bis-pyrolylethyl) become conductive as high as 10^{-2} S/cm^2 on I_2-doping (114). Doped polysilanes are usually moisture- and air-sensitive and polymer degradation occurs.

PROTEIN FOLDING

Introduction

Protein folding is one of the most important processes that are vital for the existence of every living system. The correctly folded state of proteins is essential for the tremendous array of protein functions at all levels of complexity, from the subcellular machinery to organs and macroscopic structural elements. A very incomplete list of protein functions includes their activity as enzymes (biocatalysts), sensors of chemical and physical signals, regulators of expression of the genetic information, structural building blocks (ranging from the microscopic cytoskeleton to the macroscopic fingernails and hair), and mediators of the immunological phenomenon (as antibodies, receptors, and antigen-presenting agents).

As correct protein folding is required for normal cell function, protein *mis*folding has grave consequences. An incorrect folded state of proteins is the hallmark of a large number of diseases of unrelated origin, some of which are the most common diseases in the western society. Such diseases include cystic fibrosis, the most common genetic disease in the Caucasian population, amyloid diseases, including Alzheimer's disease and Type II diabetes, and infectious prion diseases such as bovine spongiform encephalopathy—"the mad cow disease." Since amyloid diseases, are age-related, and the average age of the population will increase significantly in the next decades, the prevalence of such diseases is predicted to increase accordingly.

The "protein-folding problem" is related to the determination of how and why a protein of a given amino acid sequence adopts a certain three-dimensional structure. A recent extension to the problem includes the question of how and why a protein adopts the misfolded or unfolded conformations. This article describes the different hierarchies of protein folding, the classical models and current

understanding of the folding process through defined pathways or funnels, the assistance of molecular chaperons in the folding process, the experimental methodologies that are being used for the study of protein folding, and the attempts and advances in the prediction of secondary and tertiary structures of proteins. Finally, the article will describe recent advancements in the understanding of protein unfolding and misfolding.

Proteins as Polymers

Proteins are generally composed of a linear combination of the 20 naturally occurring L-α-amino acids (see PROTEINS), and are thereby *polyamides*. The polymerization of the amino acids occurs through the formation of an amide linkage between the carboxyl group of given amino acid and the amino group of the next amino acid, with the resultant elimination of a molecule of water. This amide linkage is more commonly called a peptide bond and proteins are polypeptides. The molecular basis for the enormously diverse functions of the proteins is the significant diversity of their building blocks. The chemical nature of the 20 natural amino acids is extremely versatile. The side chain of the amino acids can be either negatively or positively charged, polar, aliphatic (branched or unbranched), or aromatic (substituted or nonsubstituted). It may include various functional groups such as thiol, amine, hydroxyl, carboxyl, phenyl, and amide groups. Furthermore, the properties of this biopolymer are a result of the amino acid sequence, that is, the linear arrangement of the building blocks, rather than the composition of the protein. Two proteins with the very same amino acid composition may be completely different in their folded-state and molecular properties.

Therefore, it is clear that the polymerization of a protein must be directed by a specific molecular plan, rather than a random polymerization process. The information for the polymerization of a linear sequence of a given protein is encoded in the DNA, which is transcribed to a messenger RNA, which is in turn translated into the protein polymer by cellular ribosomes (see POLYNUCLEOTIDES; GENETIC METHODS OF POLYMER SYNTHESIS). A typical length of a protein can range from tens to thousands of building blocks. Shorter polymers composed of amino acids (from 2 to around 40 amino acids long) are usually termed peptides. Some of the peptides are products of cleavage of longer ribosome-translated precursor. Other peptides (usually those shorter than 10 amino acids) may be synthesized by cellular enzymes, each devoted to the synthesis of one specific peptide. In many cases, those short peptides may be composed of amino acids that are different from the 20 naturally occurring amino acids. These peptides may be composed of nonnatural amino acids or D-α-amino acids. Moreover, ribosome-synthesized proteins may have building blocks that are different from the 20 natural amino acids. This is due to post-translational modifications (such as the enzymatic formation of hydroxyproline by the prolyl hydroxylase protein enzyme).

The incredible degree of diversity presented by proteins can be appreciated by the calculation of the number of linear combinations available even for very short proteins. For a very small protein of 50 amino acids, the number of linear combinations of the 20 natural amino acids is about 10^{65}. For a more typical-sized protein of 200 amino acids, the number of linear combinations is more than 10^{260}.

All these calculations are done without taking into account any post-translational modifications. This immense magnitude of structural diversity is the core of the central role of proteins in all living systems.

The Structures of Proteins

The structures of proteins are usually described in four levels of organization: primary, secondary, tertiary, and quaternary. In the context of the protein-folding question the secondary and tertiary structures are the most important.

Primary Structure. This is the linear amino acid sequence of the polypeptide chain as described above. Primary structure is usually denoted by either one- or three-letter conventional codes. Determination of the primary structure of proteins was performed for many years by the N-terminal sequencing that was developed by Frederick Sanger for which he received his first Nobel Prize in Chemistry in 1958. (His second Nobel Prize in 1980 was for the development of DNA-sequencing techniques.) This method is based on the Edman degradation reaction that removes the N-terminal amino acid of the protein chain, leaving a new N-terminus on the chain. The identity of the removed amino acid is then determined by HPLC analysis. In the last few years, there has been an increased tendency to use mass spectrometry techniques to determine the sequence of proteins. These sequencing procedures are based on tandem mass spectrometry (MS/MS) in which proteins, or more commonly protein fragments, are further fragmented in the mass spectrometer by collision with gas molecules. This results in an ensemble of many molecules with defined differences in mass. The high accuracy of the mass spectrometers and the ability to specifically select a precursor ion (through an ion trap or a quadrupole) allow the determination of the amino acid sequence of the chain. Only two amino acids could not be distinguished using conventional MS techniques. These are leucine and isoleucine, which have the same molecular mass. However, recent techniques such as TOF mass spectrometry identify side-chain fragmentations that allow the selective identification of leucine and isoleucine. Mass spectrometry (qv) is also a very powerful method for the determination of post-translational modifications.

The Secondary Structure. The arrangement of the amino acids in a protein into local structural elements is termed secondary structure. The two main structural elements that are seen in proteins are the α-helix and β-sheet structures. The α-helical structure, which was originally suggested by the Nobel Laureate Linus Pauling and Robert Corey (1), could be described as a spring coiled right-handed about an imaginary cylinder. The size of a helix can range from 5 to 50 amino acids. The helical structure has 3.6 residues per turn and the main forces that stabilize the structure are hydrogen bonds between amide hydrogens of peptide bonds and carboxyl oxygens of residues at the next turn of the helix. The β-sheet structure is formed by the stacking of individual β-strands. The β-strands are usually from 5 to 15 residues long and are in a fully extended conformation. This secondary structure is also stabilized by hydrogen-bonding amide hydrogens and carboxyl oxygens of stacked chains. The β-strands can be arranged either in a parallel manner (in each strand the amino acid sequence of the chain is arranged toward the same direction) or in an antiparallel manner, which is more stable

energetically. Other secondary structure elements are β-turns, short turns stabilized by a specific pattern of hydrogen bonds, and loops, which are flexible linkers that connect secondary structure elements.

Tertiary Structure. This is the three-dimensional structure of a protein. The tertiary structure is made up from the interaction of the secondary structure elements to form the overall folding pattern of the polypeptide chain. The tertiary structure of a protein is formally described by the coordinates in space of all (or most) atoms of the protein molecules [see description below of the protein databank (PDB)]. The tertiary structure is usually quite compact and after globular, but can also be elongated or possess other geometries. As with secondary structure elements, in spite of the fact that the number of possible folds (ie, the specific arrangement of secondary structure elements) is almost infinite, there is a basic set of a few thousand unique folds. This observation has a crucial role in our ability to predict the tertiary structure of proteins through fold-recognition methods as described below. The main driving force for formation of three-dimensional structures of proteins appears to be hydrophobic interactions (2–5). The arrangement of the protein in a way that minimizes the energetically unfavorable orientations (ie, hydrophobic moieties on the surface of the protein and hydrophilic moieties buried inside the core) appear to provide an overall structural pattern for the folded state. Interestingly, binary models of proteins, which present the protein as a linear arrangement of hydrophobic and hydrophilic elements, are quite successful in low resolution prediction of the three-dimensional structure of proteins and folding pathways (3–5). However, it is very clear that the fine structure of a protein is a result of much more complex interactions. Even the hydrophobic core could not be regarded purely as an unstructured entity, and there is certainly a core-packing process that may involve more specific interactions (eg, stacking of aromatic residues in a specific orientation within the hydrophobic core). Other elements like salt bridges, disulfide bonds, and hydrogen bonds are also very important in the stabilization of the folded proteins and fine-tuning of the folded state.

Figure 1 shows the primary, secondary, and tertiary structures of the bovine pancreatic trypsin inhibitor (BPTI). This small protein is being widely used as a model for folding studies, because of its small size (58 amino acids), the fact that it contains both α-helical and β-sheet structural elements, and its commercial availability.

Quaternary Structure. This is the spatial arrangement of non–covalently linked protein subunits to form a functional protein assembly. One of the best-known examples of a quaternary structure of protein is the assembly of functional hemoglobin that is made of four non–covalently linked subunits. Extensive discussion of the quaternary structure is beyond the scope of this article.

The Thermodynamic Hypothesis

A guiding principle in the study of protein folding is the "thermodynamic hypothesis" (6), established by Christian A. Anfinsen in the 1950s and early 1960s. The thermodynamic hypothesis suggests that a particular three-dimensional structure of a protein occurs because this molecular arrangement is the most stable

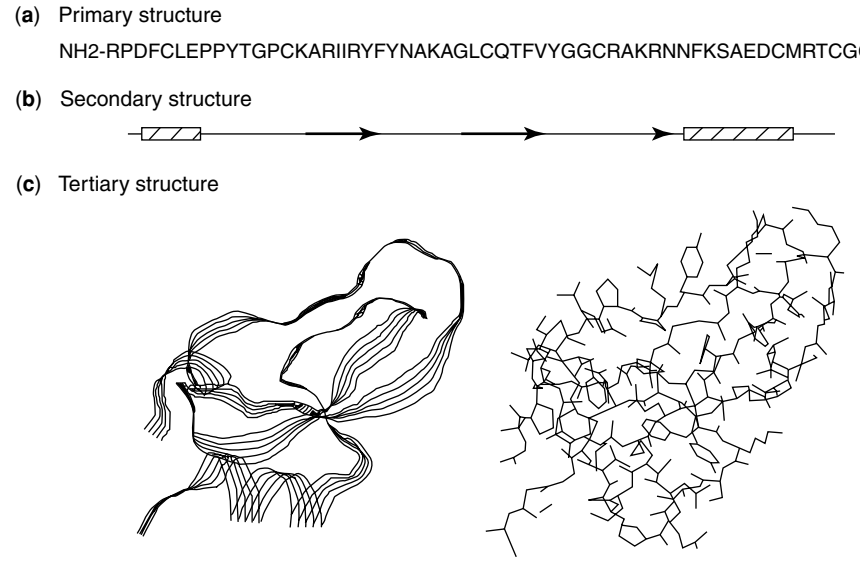

Fig. 1. Levels of structural organization of the BPTI protein. (**a**) Primary structure, the amino acid sequence of protein; (**b**) Secondary structure, α-helices are denoted by shaded boxes and β-strands are denoted by arrows. Secondary structure elements are presented according to their determination as they appear in the file containing the BPTI coordinates (1BPI) as deposited in the protein databank (PDB); (**c**). Tertiary structure, wireframe chemical structure (right), and schematic strand representation (left). The tertiary structures were prepared using rasmol software with BPTI coordinates.

thermodynamically. The development of the hypothesis was based on Anfinsen's experiments with the ribonuclease (Rnase) protein. The RNase is a relatively small protein of 124 amino acids that contains four disulfide bridges. Therefore, there are 105 ($7 \times 5 \times 3 \times 1$) possible combinations for the arrangement of the disulfide bond in the folded protein. However, only one orientation is enzymatically active. Anfinsen reduced the disulfide bridges of RNase and unfolded the protein under extreme chemical conditions using high concentrations of urea. Under these conditions the protein was completely unfolded and could be regarded as a random polymer. However, when the urea was removed, followed by oxidation of the disulfide bridges, the protein spontaneously refolded back into its original form. On the other hand, when the protein was oxidized in the presence of a high concentration of urea (that was only later removed), only about 1% activity was gained. This is consistent with a random formation of various 105 "scrambled" RNase structures, only one of which has enzymatic activity. The Anfinsen hypothesis could be best summarized in his own words from his 1972 Nobel Prize acceptance speech, "The native conformation is determined by the totality of interatomic interactions and hence by the amino acid sequence, in a given environment."

Chaperon-Assisted Protein Folding. The Anfinsen theory was a very clear turning point in our understanding of protein folding and it appears to be valid in the typical time frame of the folding process (milliseconds to seconds) for most studied proteins. However, more recent studies have clearly demonstrated

that in the cellular environment, the folding process may be assisted or may require the help of so-called molecular chaperons (7–9). The chaperons, which are large protein assemblies, are associated with the target protein during part of the folding process. However, once folding is complete (or even before), the correctly folded protein is released from the chaperon assembly into the cellular environment. The physiological role of the molecular chaperons is not fully understood. Chaperons are found in all living organisms including bacteria, but they are mainly expressed under conditions of stress (such as heat shock). It is widely speculated that the main role of these molecular assemblies is to avoid protein aggregation. They also seem to serve as "quality control" machinery under normal growth conditions. Nevertheless, for most cellular proteins the "thermodynamic hypothesis" seems to hold during their initial process of folding upon synthesis by the ribosome.

Levinthal's Paradox

The thermodynamic hypothesis describes the energetic end point of the folding process, but it does not deal with the pathway by which the molecule reaches its global energetic minimum. The rate of protein folding is usually in the order of milliseconds to seconds (10). However, the number of possible orientations of the dihedral angles of the various peptide bonds that compose the protein is astronomical. Assuming 10 possible conformations for each peptide bond in a very short 40 amino acid protein will result in 10^{40} possible conformations. The apparent contradiction between the number of possible configurations and the fast folding rate of proteins is known as "Levinthal's paradox" (11). Levinthal argued that if we consider an average rotation frequency around each bond, one could assume that a protein can sample about 10^{14} structures per second. Therefore, it would take 40 amino acids 10^{26} seconds or about 10^{18} years to examine all the possible conformations. This time scale is much larger than the present age of the universe. The clear conclusion from Levinthal's paradox is that folding cannot occur by sampling the entire conformational space and that there must be another way to reach the folded state of low energy. Indeed, Cyrus Levinthal suggested in the late 1960s, on the basis of his theoretical argument, that there are specific folding pathways.

Folding Pathways

It took several years after Levinthal's and others' theoretical arguments until folding pathways could actually be demonstrated. The very rapid folding reaction, that was proved to be highly instrumental in the conceptual realization of the folding pathways notion, made the observation of folding intermediates quite difficult. The first experimental proof for the existence of specific folding pathways came from experiments done by Thomas Creighton in the mid-1970s (12,13) on the folding of bovine pancreatic trypsin inhibitor (BPTI), the protein that is presented in Figure 1. BPTI has three disulfide bridges, and Creighton was able to trap folding intermediates of BPTI with one or two disulfide bridges formed, by irreversibly blocking all the free thiol groups at different folding stages.

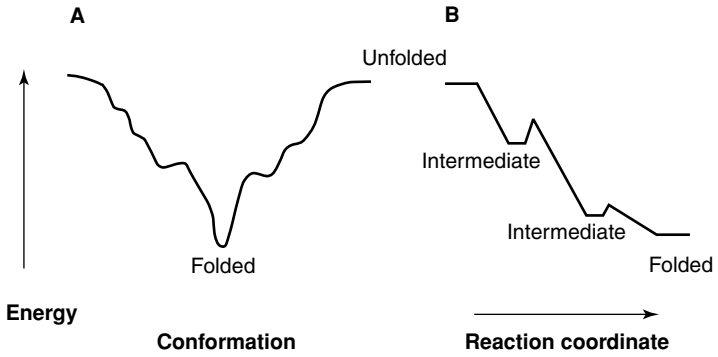

Fig. 2. Energy of folding reaction. **A**. Funnel view of the energetic landscape. The trajectory of the protein along the energy landscape is a probabilistic statistical mechanics function; **B**. A pathway view of the folding process. The folding process is represented as a chemical reaction. The reaction coordinate is deterministic and intermediates along the pathway are well-defined.

Analysis of the nature of the intermediates allowed the construction of a folding pathway of BPTI. Later experiments by Weissman and Kim (14)—using different methodologies—suggested that the nature of the folding intermediate might be different from that originally described. However, there was an agreement on the concept of intermediate species in the pathway from the unfolded to the folded state.

In more recent years, other groups have suggested that the pathway toward the minimum of free energy might be less deterministic than previously assumed (15–20). In this more modern point of view the folding process is seen as a multiplicity of routes down a folding funnel rather than a distinct pathway of discrete intermediates. This view is based on statistical mechanics rather than a chemical reaction view of the folding process (Fig. 2). This approach suggests that different partially folded species are distributed in the energetic landscape of the folding reaction according to the probability of occupation at a finite temperature in a way that is proportional to the Boltzmann factor. According to this view, the molecular dynamics within a folding funnel involves the progressive formation of an ensemble of partially ordered structures. The practical meaning of this approach is that there is no way to clearly know the folded state of a molecule during the folding process. Figure 2 presents a schematic view of the energetic landscape funnel and the folding pathway models.

The funnel approach does not contradict Levinthal's argument that a given protein does not sample the entire energy landscape of its various conformations. However, in spite of sampling only a small part of the energy landscape, the exact path is the result of a probability function rather than a deterministic function. Furthermore, since in a typical experiment of protein folding there is a very large number of molecules, there is no way to predict the exact conformation of each molecule, and they can only be represented as a probability function. Very recent studies that use single-molecule techniques should help further explore the energy landscape of protein folding (21).

Models for the Order of Events in the Folding Process

Regardless of the view of the folding process as discrete steps with defined intermediates or as an energetic funnel, one of the interesting questions that still remains open is the order of events during the folding pathways. The three major hypotheses for the order of events are (*1*) the framework model (22–24), (*2*) the nucleation-growth mechanism (25), and (*3*) the hydrophobic collapse model (3,4).

The framework model suggests that the first stage in the folding reaction involves the formation of elements of secondary structures without any significant compactization. These secondary structure elements are then assembled to form the compact and folded final structure of the protein. The nucleation-growth mechanism suggests that the first stage in the formation of the folded state involves the formation of a small nucleus that is well-folded and compact. This nucleus involves only a small fraction of the protein polypeptide chain. The formation of the nucleus is followed by hierarchical assembly of further structural elements to form the well-ordered three-dimensional structure. The hydrophobic collapse model suggests that the first stage of the folding process involves the rapid collapse of the protein chain into a compact conformation that does not have well-ordered secondary structures. The secondary structure elements then grow in the general framework of the collapsed structure. There is no clear indication which of the models correctly describes the folding mechanism. It may be that different protein molecules are being folded in different ways and/or that the actual sequence of events may be different from or a combination of the three models. The statistical mechanics model also may suggest that all three models are actually different discrete trajectories on the energy landscape and each one of them can occur even at the same folding reaction of an ensemble of protein molecules.

Experimental Methodologies

As described above, the folding reaction is a very rapid event (10). Therefore in order to be able to follow the kinetics of folding and sequence of events there is a need for rapid stopped-flow techniques. The properties that are usually monitored using these techniques are either aromatic residues fluorescence or circular dichroism spectra. The fluorescence of the aromatic residues (especially of tryptophan) is largely dependent on the dielectric constant of its environment. Furthermore, aromatic residues tend to be part of the hydrophobic core of the protein. Therefore, monitoring the change of fluorescence during folding and unfolding reactions allow insight into the reaction mechanism. Circular dichroism (CD) spectra of proteins provide direct information on the secondary structure of proteins. The CD spectrum of a protein in the far-UV region (180–250 nm) shows a clear indication of secondary structure (especially of α-helical structure). Thus it allows the direct observation of the formation of secondary structures. These two techniques can be used not only to study the kinetics of protein folding but also the thermodynamics. By steady-state determination of the fraction of folded protein upon titration with denaturating agent such as urea, the change in free energy (ΔG) of the folding reaction can be calculated.

Fourier-transformed infrared (FTIR) is another excellent method to study protein folding. Unlike the well-known use of FTIR as a method for the identification of functional groups, in terms of protein structure this method allows the determination of secondary structure. The frequency of vibration of the amide I band of the peptide chain (1500–1600 cm^{-1}) heavily depends on the structure of the protein. FTIR has the advantage of being more sensitive for the study of proteins that contain β-sheet elements as compared to CD. Furthermore, since FTIR spectroscopy can be applied to solids also, it allows the structural analysis of aggregated protein deposits. The availability of the rapid step-scan method for FTIR is also very useful for the study of rapid folding reactions (see VIBRATIONAL SPECTROSCOPY).

The Protein Databank (PDB). One of the most instructive tools available for researchers studying both basic and applied aspects of protein folding is the protein databank (PDB) (26,27). Databank data is freely available via the Internet (http://www.pdb.org) and it contains the coordinates of protein structures as determined by X-ray crystallography or nuclear magnetic resonance (NMR) spectroscopy. The rate of structure submission to the PDB has increased steadily over the years (Fig. 3). By the end of 2001 there were nearly 17,000 deposited structures in the PDB. The PDB was established at the Brookhaven National Laboratories (BNL) in the 1970s and maintained there for many years. Several years ago, the maintenance and development of the PDB was transferred to Rutgers, The State University of New Jersey; the San Diego Supercomputer Center at the University of California, San Diego; and the National Institute of Standards and Technology—three members of the Research Collaboratory for Structural Bioinformatics (RCSB).

Prediction of Protein Folding

The importance of the correct protein fold for the understanding of protein activity and design of novel proteins has led to much interest in the possibility of predicting correct protein folds. In spite of the great importance and interest in the prediction of the three-dimensional structure of proteins from the primary structure there are no such algorithms available to date. However, the attempts to predict secondary structures of proteins have been much more (although not fully) successful.

One of the earliest and most pivotal attempts to predict the secondary structure of proteins was made by Peter Chou and Gerald Fasman (28). The Chou–Fasman scale for secondary structure prediction is based on the statistical occurrences of amino acids in different secondary structure elements. Their classification was based on the structures of protein as deposited in the PDB, taking into account the relative occurrence of the different amino acids in various proteins (which can be quite diverse). The various amino acids were classified according to their ability to form or break the two major secondary structures. The categories were strong former (H), former (h), weak former (I), indifferent former (i), breaker (b), and strong breaker (B) of the specific secondary structure elements. Proteins are scanned through a fixed-size window and each area of the polymer is scaled for its tendency to form the various secondary structures. Further developments of the Chou–Fasman method, such as the GOR method (29), improved the prediction potential by taking into account not only the identity of the specific amino acid but

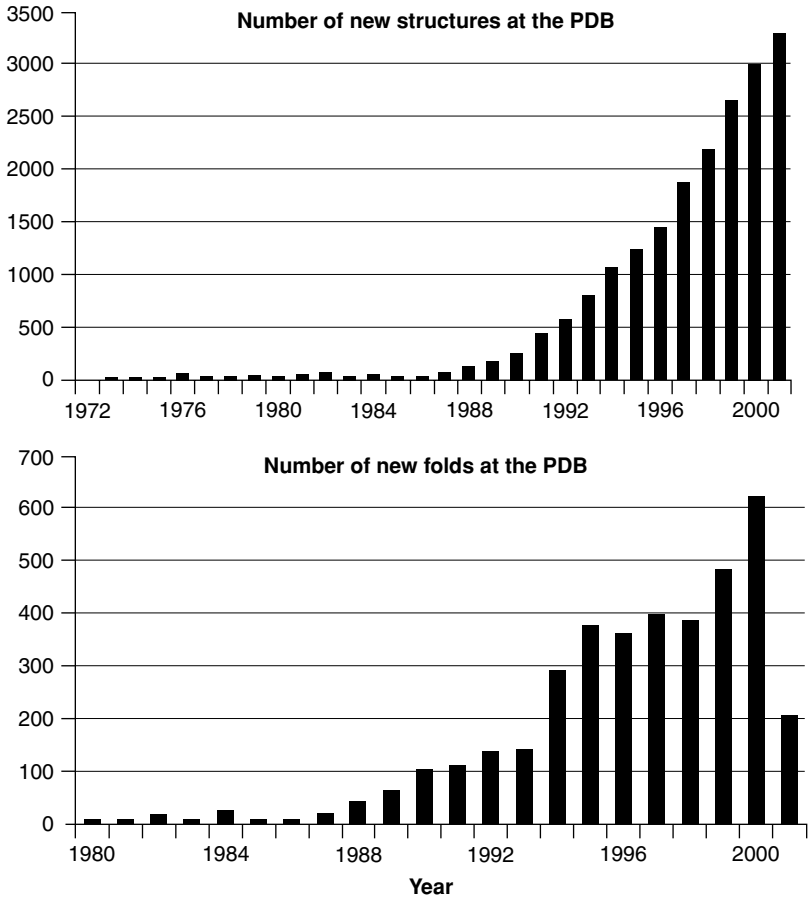

Fig. 3. New structures versus new folds in the PDB. There is a constant increase in the number of new structures submitted to the PDB. The number of new folds shows significantly different behavior, with a sharp decrease in 2001. The data was taken from the official PDB statistics.

also their context (ie, specific secondary structure patterns). Another approach for the prediction of secondary structures is based on neural networks analysis. According to this method, computational neural networks are trained by sequences of known secondary structures. One very successful example of the neural networks method is the development of the secondary structure prediction tool in a mail server called PHD (30).

Prediction of the three-dimensional structures of proteins is much more complex. The success rate of this process is formally determined by the a contest known as the Critical Assessment of Techniques for Protein Structure Prediction (CASP). The CASP contest showed a significant advance in the ability to predict three-dimensional structures of proteins over the years by homology modeling and fold recognition, as described below, but ab initio methods are still not very accurate. One of the major problems is finding a way to distinguish between the global minimum of free energy of a given protein molecule and local energetic minima. Most of the successful models of protein structures are based on homology modeling. Such

methods start by forcing the target sequence into the fold of its closest relative with a known folded state, followed by energy minimization of the structure using force fields. An Automated Comparative Protein Modeling Server, The Swiss Model, is available freely on-line (http://www.expasy.ch/swissmod/SWISS-MODEL.html). More advanced homology-modeling software is available commercially.

Another of the successful methods that is based on a reverse approach relies on protein fold recognition by "threading" (31). This method takes advantage of the fact that the number of folds is limited. Instead of trying to predict the fold of the protein on the basis of the amount of free energy, the method determines whether a given sequence can be fitted to a known fold. As the number of folds (Fig. 3) appears to be finite, it provides a way to look for the structure of new proteins using known folds. Another method for the prediction of three-dimensional structures of proteins is based on the *in silico* assembly of protein structure from shorter structural elements with more defined structures (32).

Protein Unfolding and Misfolding

There is an increased interest in recent years in protein unfolding and misfolding (33–37). For example, there is a clear realization that small but significant parts of protein molecules may be natively unfolded (38). Furthermore, the formation of misfolded protein aggregates is the hallmark of various unrelated diseases and therefore attracts much medical attention. Other research activities are directed toward the search for the physiological significance of the unfolding and misfolding phenomena. Indeed, recent studies have indicated that protein unfolding and misfolding might also have a physiological role. One instance is that of unstable and short-lived proteins, in which their instability is an integral part of a regulatory mechanism, as in the case of Toxin–Anitoxin systems (38). Another recent example is the formation of *curli* amyloid fibril in *Escherichia coli*, which is related to the formation of biofilms (39).

The formation of amyloid fibrils is probably one of the most important cases of protein misfolding. In this self-assembly process, soluble cellular proteins form large and ordered fibrillar structures. This process is also accompanied by a structural transition of the aggregated proteins from their native fold into a predominantly β-sheet secondary structure. The fibrillar structures are well ordered in the long axis direction, and X-ray fiber diffraction shows a clear 0.48-nm reflection on the meridian. Such reflection corresponds to the hydrogen bonding distance between β-strands. This is consistent with the secondary transition toward a β-sheet structure upon amyloid fibril formation as is observed using CD, and FTIR spectroscopy. There is also a correlation between the unfolded and misfolded states of proteins. Two amyloid-forming proteins, the diabetes-related islet amyloid polypeptide (IAPP) and the Parkinson's disease–related α-synuclein polypeptides, have clearly been shown to be natively unfolded.

The "Correctly Folded State" as a Metastable State

The folded state of protein, as determined by X-ray crystallography or NMR and deposited in the PDB, is considered the state of lowest free energy for a given

isolated protein molecule. However, recent studies have raised doubt about the validity of this assumption for concentrated ensembles of proteins in aqueous solution. Many (if not all) proteins may undergo a process of aggregation and misfolding at infinite time (35). For example, as described above, amyloid-related proteins tend to undergo spontaneous aggregation in solution. It is therefore assumed that the nonaggregated state of polypeptides such as IAPP is a kinetically trapped metastable state ["kinetic solubility," as coined by Jarrett and Lansbury (33)]. However, in recent years it has been realized that disease-related proteins are not the only ones to undergo an aggregation process in solution. It has been demonstrated that disease-unrelated proteins also, such as the SH3 domain, myoglobin, and a bacterial cold shock protein, form aggregated structures in solution. Aggregation is also noted in preparations of many protein solutions after long storage. This leads to the suggestion that the aggregated form, and most notably the amyloid form, of proteins may represent a generic form of proteins. Therefore if each protein molecule is not regarded as an independent thermodynamic system, but we consider the ensemble of proteins in aqueous solution as one large thermodynamic system, a solution of aggregation-prone but "correctly folded" proteins represent a system in a transient state that will eventually reach its global free-energy minimum of the aggregated state (35). It appears that many (or perhaps all) proteins will sooner or later undergo the aggregation process. For some proteins this may take minutes or hours and for others it can take months or years. For example, the fibrillation time of the aggregation-prone human calcitonin at physiological pH is 5 min at a concentration of 5 mg/mL, whereas the fibrillation time of non–aggregation-prone salmon calcitonin under the same condition is about 7 months (40), but after this long time it does form aggregated fibrillar structures.

RECYCLING, PLASTICS

Introduction

The unabated growth in the use of plastics in recent years is of considerable concern because of the difficulties involved in waste disposal. Increasingly, plastics are replacing wood, glass, paper, and metal in numerous applications, especially in packaging. Items such as plastic cups, food utensils, and convenience containers such as "clam shells" (sandwich boxes) contribute substantially to the burgeoning municipal solid waste (MSW) stream. As a means of dealing with this waste, the recycling of plastics increased dramatically from about 1990, when the emphasis shifted from landfilling to recycling and energy recovery. To facilitate recycling, ever-revitalized infrastructures are needed for collecting, sorting, cleaning, reprocessing, and manufacturing new products to be marketed to end-users. This article focuses on recycling of thermoplastics in the MSW.

Plastics in MSW: The Americas. In the United States, plastic resin sales and captive use reached 46.2 million tons in 2001, a 4% decrease from 2000, according to the American Plastics Council (1). Resin production rose to 45.9 million tons in 2001, up 4.8% from the previous year. The U.S. plastics industry continues to expand into new markets as plastic products come to replace ones made of wood and metal (Fig. 1). In the United States, some 232 million tons of MSW were generated in 2000, an increase of 0.9 million tons over 1999 (Fig. 2). Of this stream, plastics constitute about 10.7 wt%. Plastic containers and packaging dominate, followed by materials in goods such as automobiles, appliances, electronics, furniture, and carpeting. Plastic resins used in containers and packaging include poly(ethylene terephthalate) (PET; in soft drink bottles with polypropylene [PP] caps), high density polyethylene (HDPE; in milk and water bottles), poly(vinyl

chloride) (PVC; in cooking-oil bottles), low density polyethylene (LDPE) and linear low density polyethylene (LLDPE; for bags, sacks, and wraps), and polystyrene (PS; in cups and containers). Table 1 shows the generation, recovery, and discard amounts for various resin types (see also POLYESTERS, THERMOPLASTIC; Ethylene Polymers; VINYL CHLORIDE POLYMERS; STYRENE POLYMERS).

Although the portion of plastics recovered by recycling in the United States is relatively small—1.34 million tons, or 5.4% of plastics generation in 2000—recovery of certain plastics has been increasing (2). Recently, 40% of discarded PET soft drink bottles and 31.9% of HDPE milk and water bottles were recovered (2). In

Table 1. Total Plastics in MSW (2000) by Resin Type[a]

Resin	Generation, 10^3 ton	Recovery, 10^3 ton	Generation, %	Discards, 10^3 ton
PET	2,490	430		2,060
HDPE	4,830	420		4,410
PVC	1,390			1,390
LDPE/LLDPE	5,740	150		5,590
PP	3,350	10		3,340
PS	2,280			2,280
Other resins	4,630	330		4,300
Total plastics in MSW	*24,710*	*1,340*	*5.4*	*23,370*

[a]Source: Ref. 2.

1960, an estimated 390,000 ton of plastics was discarded; by 1999, that figure had risen to 24.2 million tons. As a portion of MSW generation in the United States, plastics were less than 1% in 1960, increasing to 10.5% in 1999 (2). In Canada, the majority of collected plastic waste is represented by PET (54%) and HDPE (37%), followed by PP (6%) and PVC (3%). Post-consumer plastics recycling in Canada has focused on recycling of plastic packaging, employing manual sorting followed by reprocessing of resin-specific streams (eg, HDPE). In 1998, Canadians recycled almost all collected PET and HDPE waste (3,4). In Latin America, some countries have recently adopted regulations governing the MSW and have started to address recycling infrastructure issues. Brazil has adopted national take-back regulations on batteries and has passed laws regarding electronic scrap and end-of-life vehicles. In Mexico, legislation has been prepared regarding the recycling of lamps and batteries. In 2002, El Salvador, Jamaica, and Argentina considered regulations on batteries and printer cartridges.

Plastics in MSW: Europe, Asia, and the Pacific Rim. Consumption of plastics in Europe is predicted to grow about 4% annually from 24.9 million tons in 1995 to 36.9 million tons in 2006, with PP and PET showing the greatest increase (5). In the United Kingdom in 2000, only 8% of collected plastics was recycled instead of the targeted 15% (6). A related problem in the United Kingdom and elsewhere is the continued growth of the plastic portion in automotive shredded residue (ASR), which recently stood at about 40% of ASR. For Japan, plastics production and waste discharge data have been compiled by the Plastic Waste Management Institute, which reported that resin production in 1999 was 14,570,000 ton; total plastic waste discharge the same year was 9,760,000 ton (7). The breakdown of general waste and industrial waste in Japan in 1999 was 4,860,000 and 4,900,000 ton, respectively. In Australia, total plastic resin consumption in 2000 was 1,530,783 ton, of which 753,000 ton was landfilled and 167,673 ton was recovered (8). Between 1997 and 2000, plastics reprocessing increased by 80%, with packaging materials having the highest recovery (42.1%).

For many Asian countries as well as for Russia and other nations, data are either incomplete, of questionable reliability, or hard to come by. It has been reported that in India, the plastics share of the MSW is about 7% by weight (9). For 2000, the country's total production of plastics was estimated at 3 million tons. Although mechanical recycling (ie, grinding materials) is widely employed in India,

Fig. 3. SPI resin identification code. The seven symbols in the SPI Code can be found at the website http://grn.com/grn/library/symbols.htm (and elsewhere). However, the acronyms below the images are not part of the website images and have been added separately here.

feedstock recycling (ie, chemical depolymerization) is largely untried. In China, consumption of plastic products was estimated in 2000 to be growing about 20% annually (10). Around 50–60% of plastics waste in China is either uncollected or disposed of on land, in rivers, and in the sea. Although the remainder is available to recyclers, the actual rate of recycling has been declining steadily (from 20% to 5% in a recent period). This decrease in recycling of domestic materials is offset by the substantial business devoted to recycling waste imported from abroad, giving rise to allegations of "dumping" by foreigners.

Plastics Coding System and Terminology. In the United States, the Environmental Protection Agency (EPA) advocates Three R's: *Reduce* the amount of waste to be discarded, *Reuse* products or repair what is broken, and *Recycle* as much as possible, including buying products with recycled content. In the mid-1980s the Society of Plastics Industry (SPI) introduced a coding system using numbered triangles that are now found on containers around the world (Fig. 3). By accelerating the sorting of bottles and containers, the code greatly enhances recycling. This system also helps municipalities track plastics in their waste stream.

Terms related to the reprocessing of discarded materials include *recycling* (a process used to recover plastics waste); *recycled* (a reprocessed material containing some quantity of post-consumer plastic waste, usually more than 25 wt%); *reprocessing* (activity involving steps such as sorting, grinding, reextrusion, or remolding into a secondary material for remanufacturing of plastic goods); *recycled content* (the amount of plastics from the post-industrial and/or post-consumer waste stream that is added to a virgin resin); *post-industrial waste* (or preconsumer waste: off-spec parts, plant discards, and the like); and *post-consumer waste* (materials and products discarded after consumer use).

Challenges for Plastics Recycling

Plastics recycling presents numerous technical, economical, and marketing challenges. One such technical issue is the *variability of product composition and color*, because discarded products are made from a wide array of resins and additives. The *contamination* of the waste stream is aggravated by labels, glue, printing, product residue, and similar elements. Most waste streams include *immiscible polymers* (Table 2). Efforts to recover them via conventional melt processing without first sorting them will produce materials with uncontrolled coarse morphology, poor interfacial adhesion, and inferior physical properties (11–13). As is well known, the better the physical properties, the higher the quality of recycled

Table 2. Miscibility Chart for Commonly Used Thermoplastics[a,b]

Plastic type	PET	HDPE	PVC	LDPE	PP	PS	PA	PC
Poly(ethylene terephthalate)	M	IM	IM	IM	IM	IM	IM	IM
High density polyethylene		M	IM	IM	IM	IM	IM	IM

[b]Note: M = miscible; IM = immiscible.

products. Because all six major thermoplastics in the waste stream (PET, HDPE, PVC, LDPE, PP, and PS) are immiscible, they must be sorted before recovery for reuse can occur via melt processing. Also, reprocessing of mixed plastics with *different melting points* causes degradation, leading in turn to deteriorated physical properties. For example, PET and PVC cannot be melt processed together because PVC burns at the temperature where PET melts (270°C). If the same mixture is processed at 170°C—suitable for PVC—PET would remain unmelted, thus preventing the desired mixing.

The *difference in melt flow rates* of the various polymers originally selected for specific fabrication methods causes generation of heterogeneous mixtures (ie, low melt-flow rate plastics are used for blow molding, while high melt-flow rate plastics are needed for injection molding). Remelting mixed plastics usually lowers their properties, except for a few polymer blends such as HDPE/LLDPE or HDPE/PP (with 5–7% PP), which exhibit limited compatibility (14,15). To improve physical properties and processability of mixed plastic waste, an impact modifier and a compatibilizer are needed. Both of these can be added as premade ingredients, but only the compatibilizer can be generated *in situ* during reactive extrusion. The compatibilizer migrates to the interface, reducing the interfacial tension, improving adhesion, and stabilizing the blend morphology from coalescence and agglomeration of the dispersed particles. The most common compatibilizers are block or graft copolymers (ie, styrene–ethylene–butylene–styrene) and functionalized polymers (ie, maleated polyolefins). Although compatibilizers are used sparingly (1–5 wt%), they are expensive.

Although the additives (qv) *in the original product* can affect the physical properties and performance of recycled plastics, the extent of their cross-contamination remains unclear. Moreover, *multiple remelting cycles* cause thermal and oxidative degradation in thermoplastics, resulting in changes in molecular weight, discoloration, and sometimes cross-linking. Because of such adverse effects, 100% recycling cannot be achieved for plastic materials.

Successful recycling requires an *adequate supply* of a reasonably clean feedstock. Items such as PET soft drink bottles or natural HDPE milk bottles are abundant in the United States, where curbside collection and drop-off centers are common, and thus make ideal feedstocks. The collected plastics are sorted, ground, reclaimed as flakes or pellets, and sold to fabricators of new products. In Germany,

where the "Dual" system is operated by Duales System Deutschland GmbH, participants label their packaging with a green dot. Companies using this system are exempt from "take-back" programs. In 1994, the European Community published a directive that resembled the German Packaging Ordinance. Similar legislation known as Producer Responsibility Obligation was introduced in the United Kingdom in 1997. The primary obstacle to increased recycling in all venues, however, remains the imbalance between waste collection and potential end-use; far more plastic material is collected than can be recovered economically.

Economics

Plastics recycling is both an economic and an environmental activity. Possible outcomes of recycling include material recovery (via mechanical or chemical processes), energy recovery via incineration, or as a carbon source for blast furnaces (16). Of these, material recovery is the most ecologically beneficial. This nonpolluting method is applicable to both single and mixed polymeric waste that is generated either during product manufacture or from the MSW.

For plastics recyclers (reprocessors), the high costs of both transportation and processing are harsh economic realities. Because of the fuel and equipment expenses associated with transporting waste over long distances, most plastics recycling is best handled at the local level by municipalities. Sound management of processing costs suggests that energy recovery by incineration, landfilling, cracking plastics waste back into monomers, and use of biodegradable plastics are among the most feasible alternatives. The trend of virgin resin suppliers to become producers of recycled-content resins, which began in the United States and Europe, will continue in the new millennium. Some resin suppliers see this new market as an area for potential growth, especially with refined recycling technologies. For PET and HDPE bottles, for example, the cost of recycling (reprocessing) has been estimated at $100–150/ton, compared with incineration or energy recovery at $100/ton and landfilling at $30–50/ton (17). Waste-to-energy plants are more acceptable than incineration, which can produce undesirable toxic ash or fumes. The economics of post-consumer plastics recycling depends on the margin between product price and the cost of raw materials as well as the size of the recycling (reprocessing) facility. Crude oil prices also play a role in setting the cost of virgin resins.

Since the late 1980s, public awareness of the environmental benefits of recycling has increased, and governmental mandates for recycling have kept pace. Such legal requirements have kept the cost of materials from becoming the sole factor in determining the extent of recycling. These developments, however, do not ensure that recycling will be economically efficient. The cost of collection and separation of plastics remains high in contrast to that for aluminum and paper products. The task is further complicated for those plastics in the MSW that are pigmented in bright colors, contaminated, and/or multilayered. Although such products can be recycled using thermal processes such as pyrolysis, gasification, and hydrogenation (see below), mineral- or glass-filled materials and multilayered structures can be hard to recycle because of their complexity. The divergence among fabrication processes used to make plastic products also contributes to the

difficulty of sorting, cleaning, and reformulating materials cost-effectively. By the early 2000s in the United States and elsewhere, economical plastics recycling was limited to products made from HDPE and PET. Extending recycling to other plastics will require lowering recycling costs while improving physical properties and performance relative to those of virgin resins.

Technologies

Technologies for recycling post-consumer plastics were slow to develop until the 1990s (18). These technologies are usually divided into four categories: *primary* (regrind), *secondary* (mechanical), *tertiary* (feedstock), and *quaternary* (incineration). Each of these technologies has a viable role in recycling plastics while conserving natural resources and avoiding landfills.

In the most straightforward approach, *primary* recycling of regrind occurs in the manufacturing process, where regrind is simply added to virgin resin and the mixture is then reprocessed. *Secondary* recycling uses post-consumer sorted or unsorted plastics waste. When reprocessed, these materials are used in less demanding applications that do not require virgin resins. Manual sorting of plastics waste is still used to separate HDPE and PET. Figure 4 shows the layout of a manual sorting facility, with four people separating HDPE, PET, PP, and PVC. Automated sorting uses the differences in properties such as density, surface energy, low temperature behavior, and melting temperature (19). Frequently used

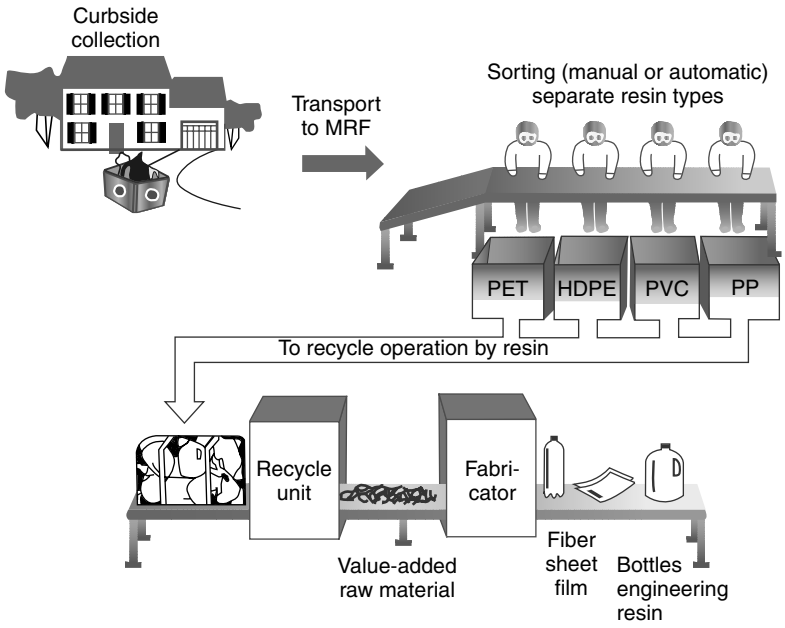

Fig. 4. Layout of a manual bottle-sorting line. Taken from http://www.plasticsrecycling.org/sort.htm.

Table 3. Density of Plastic Materials in the MSW[a]

Plastic material	Density, g/cm^3
PET	1.40
HDPE	0.95
PVC	1.40
LDPE	0.91
PP	0.90
PS	1.05

density separators divide materials into light and heavy fractions on the basis of plastic density (Table 3). Other methods include marking plastic products with one of the seven SPI codes, addition of unique organic markers to the polymer backbone, and solvent separation (selective dissolution) involving a solvent that dissolves one plastic followed by the use of another solvent at room temperature or higher in order to remove another plastic. Mixed plastics can be separated by froth flotation using surfactants.

As the plastics recycling industry matures, manual sorting will be replaced by automated techniques. One such approach has been developed by the Magnetic Separation System Co. (Nashville, Tenn.), which uses X ray, infrared (IR), and other sensors to separate PET and HDPE by type and by color (20). Their most recent automated sorting module, the Alladin, not only sorts plastic resins by type and color but can also create three outputs from one input (21). For example, clear PET, green PET, and blue PET (or PET, colored HDPE, and natural HDPE) could be sorted in one pass with the capacity of 4–6 ton/h. Other sorting methods include the use of solvents, X-ray fluorescence, near-IR, mid-IR, Fourier-transform Raman spectroscopy, and electrostatic sorting (22–25). The triboelectric pen (Tribopen), a compact device that senses the triboelectric charges of different plastics, can sort engineering resins such as polyamide and acrylonitrile–butadiene–styrene (ABS) from commodity plastics such as PP and PE (polyethylene) (26).

Another secondary recycling technology is the novel process called solid-state shear pulverization (S^3P), which does not require sorting of discarded plastics (27–29). The S^3P technology uses a pulverizer made by Berstorff GmbH (Hannover, Germany), that is based on a modified twin-screw extruder with intensive cooling. This mechanochemical process subjects plastics to simultaneous shear and compression, which results in unique changes in chemical structure because of *in situ* compatibilization and physical properties superior to those made by melt processing. Pulverization is accompanied by intimate mixing without melting, resulting in powder of unusual morphology, large surface area, and controlled particle size and distribution (Figs. 5–8).

Tertiary recycling involves thermal treatment of plastics waste resulting in chemical intermediates. Several technologies such as pyrolysis, gasification, and hydrogenation are being practiced (30–32). Pyrolysis converts polymers to a liquid in the absence of oxygen; gasification produces carbon monoxide and hydrogen in a limited-oxygen atmosphere, while during hydrogenation some hydrogen is added

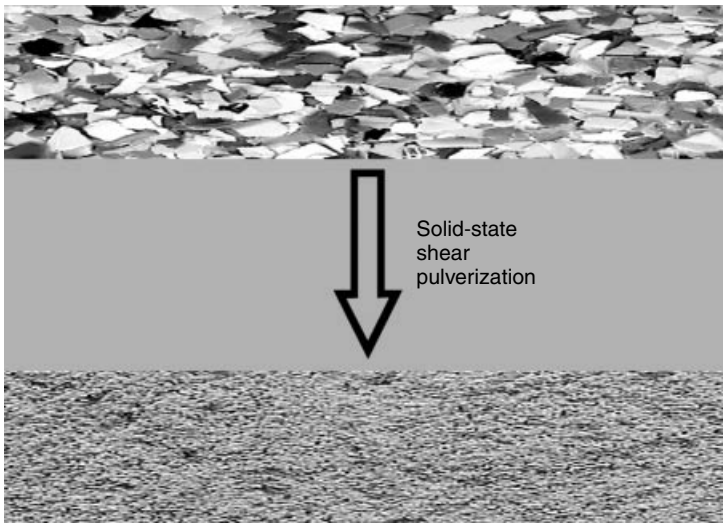

Fig. 8. Representative S^3P powder from corresponding post-consumer flakes.

in the cracking step. Heating plastics such as poly(methyl methacrylate) (PMMA), PS, and acetal homopolymers in the absence of oxygen produces monomers with very high yields (22). These monomers can be isolated, purified, and reused to make new polymers. Thermolysis, when carried out in the absence of air, produces synthetic crude oil. Gasification with controlled amounts of oxygen produces Syngas, which is used as a fuel. Hydrogenation by heat and pressure in an excess of hydrogen produces liquid fuel such as gasoline or diesel. Thermolysis is a versatile process that can handle contaminated medical waste, auto shredded residue, and other complex mixtures. Depolymerization of plastics by solvolysis produces monomers or oligomers (30).

Recycling approaches known as *advanced recycling technologies* (ART) reclaim feedstock value from discarded plastics through depolymerization. ART comprises two groups, depending on whether the depolymerization results in monomer or in hydrocarbon feedstock. The choice of recycling technique is influenced by factors such as the purity of the plastic stream, chemical makeup of the plastics, and the nature of additives. The type of plastic also helps to determine which depolymerization process is appropriate. Polyesters, polycarbonates (qv), polyamides, and polyurethanes (qv) undergo reverse polymerization and they can be converted to their respective monomers for use in making the same virgin resins (18,30). Plastics such as PE, PP, and PVC can be converted into petrochemicals and fuels through pyrolysis. ART processes do not require sorting and are integrated into existing refinery or petrochemical facilities (31).

Quaternary recycling involves waste-to-energy processes. Through combustion, plastics can generate energy amounts comparable to the range between Wyoming coal [22,080 kJ/kg (9600 Btu/lb)] and fuel oil [48,070 kJ/kg (20,900 Btu/lb)]. PE, PS, PET, and PVC yield 23,000, 39,000, 16,100, and 20,700 kJ/kg (10,000, 17,000, 7000, and 9000 Btu/lb) respectively (32). Post-consumer plastics (10–30%) mixed with paper (90–70%) are used as processed engineered fuel in

existing energy plants. Increasingly, automotive shredded residue is being co-combusted with the MSW in Europe and North America. Both environmentalists and citizens afflicted with the "not-in-my-back-yard" (NIMBY) syndrome are concerned about toxic fumes and ash by-products from incineration. Improvements in this process may render it more acceptable; a Japanese incinerator is already functioning alongside a public swimming pool in Tokyo.

Restabilization of Plastics for Recycling. To make recyclate suitable for reprocessing and reuse, it needs to be restabilized because of the partial consumption of the original stabilizers during the "first-life" application. During processing and end-use, plastics undergo an oxidative degradation that results in altered molecular weight by chain scission or by cross-linking, and in deterioration of properties and surface appearance (33). Once restabilized, recycled plastics can be used again despite many years of service. For example, 10- to 13-year-old pigmented HDPE crates that are restabilized with antioxidants (Irganox 1010, phosphite Irganox 168, and light stabilizers Tinuvin 327, including hindered amines Tinuvin 710) make them suitable for the manufacture of new crates (34). Recycled PBT/PC [PBT = poly(butyl terephthalate)] blends and talc-filled PP can be restabilized with Recyloblend 660 (35). Other restablized plastics that are successfully recycled include PP from battery cases, PS from yogurt cups, PVC from window frames, and EPDM/PP [EPDM = ethylene–propylene diene monomer] blends from car bumpers (34).

Single Waste Streams

Single streams consist of PET and HDPE bottles and are the most successfully recycled of all (36). Other types of plastics suffer from either insufficient quantities collected or lacking developed markets and favorable economics. In the United States in 2000, PET and HDPE represented about 50% of plastic bottle recovery, with bottles from PVC, LDPE/LLDPE, PP, and PS accounting for only about 5% (36). One advanced approach converts clear PET bottles into high quality regrind with low residual contamination (37). Labels and glue are removed in a mixture of hot water and steam that softens and separates them. After granulation, PET flakes are washed in a mixture of detergents and caustic soda at an elevated temperature for a few minutes. Possible heavy contaminants (glass, aluminum, sand, and product residue) are separated in a hydrocyclone. Lower density particles (ie, polyolefins) are separated by the sink/float method. Detergents are removed by washing followed by de-watering and drying to reach a moisture content ranging between 20% and 0.5%. The ability of PET to be converted to fiber has made the fiber market the largest U.S. outlet for recovered PET bottles. Other uses for recycled PET include strapping and film/sheet applications. PET can also be recycled by depolymerization to monomers that are used to make virgin PET (38).

HDPE recycling includes granulation, sorting from contaminants (labels, glue, and PP caps), washing, drying, and/or pelletizing. Because of odor retention, recycled HDPE is unsuitable for food packaging but can be used in motor oil bottles, pallets, crates, and plastic lumber (39). Unwashed HDPE can be compounded with fillers or glass fiber and pigments to be extruded only into low value products (14,15,40). LDPE/LLDPE used for packaging are recycled by blending with

Table 4. Physical Properties of 100% Post-Consumer PS[a]

[c]To Convert MPa to psi, multiply by 145.

virgin resins and reused mostly in films (2,3). PP from battery cases and caps, lids, and container packaging is reclaimed by blending with virgin PP. Recycled PP is used in auto parts, appliances, and consumer goods (15). Crystal PS from CD jewel cases and drinking cups is ground, washed, dried, and reprocessed by injection molding to be reused as hangers, trays, picture trays, and similar items (41). Physical properties of 100% post-consumer PS are shown in Table 4. Expanded PS (EPS) from discarded egg cartons, "clam shells" (sandwich boxes), and loose packaging is recycled by blending with virgin EPS at about a 25:75 ratio and reused in the same applications. PVC from wire and cable waste is recycled by a selective dissolution process called Vinyloop (42,43). Recovered pure PVC is used for garden hoses, vinyl wallpaper, and window frames.

Mixed Waste Streams

Polyolefins. One of the most common recycling activities involving mixed waste streams is the conversion of polyolefins to plastic lumber as a replacement for wood or concrete. Compositions of mixed plastics vary from 100% unwashed feedstock to refined, tailor-made mixtures containing mostly polyolefins, foaming and reinforcing agents, pigments, and other additives. The amount and type of polyolefins in these mixtures affect physical properties of the resultant plastic lumber. Higher LDPE content in mixed waste results in a product with low flexural modulus, while a higher PP content leads to a more brittle material, especially at subzero temperatures (44). Plastic lumber containing recycled HDPE, fiberglass, and wood flour exhibits increased stiffness without any significant reduction in tensile strength. The extrusion processes for making plastic lumber resemble those for fabricating thick-wall products such as park benches, railroad ties, and backyard decks. Mechanical recycling of mixed polyolefin waste is limited; products generally have a lower resale value than those from single plastics. Examples include pallets, containers, noise insulation walls, and landscape and garden items (13,45). Feedstock recycling for mixed plastics is gaining acceptance because they permit recovery of hydrocarbon components that are used in the manufacture of new chemicals and plastics.

Engineering Alloys and Blends. Many widely used thermoplastics are engineering alloys and blends created to meet an increasing demand for greater toughness, higher end-use temperature, and improved processability. This

combination of properties cannot be achieved by the use of single polymers but is made possible by alloying or blending of different polymers through the use of impact modifiers, compatibilizing agents, and other ingredients during blending. Modifiers and compatibilizing agents used in producing these blends, however, are sensitive to repetitive thermal history during melt reprocessing.

For example, impact-modified engineering alloys and blends with enhanced toughness are often susceptible to thermal and oxidative degradation because rubber degrades and cross-links, resulting in increased viscosity and processing difficulties. PC/ABS alloys where PC is the matrix require a higher processing temperature than ABS and are more vulnerable to thermal degradation (46). These alloys lose mechanical properties and exhibit increased melt viscosity after five injection molding rounds because of the cross-linking and oxidation of the rubber phase. Polyamide-6,6 (PA-66) and poly(2.6-dimethyl–1.4-phenylene oxide) (PPO) with a graft copolymer such as styrene–maleic anhydride as a compatibilizer and an elastomeric modifier such as styrene–butadiene–styrene block copolymer exhibit good stiffness at high temperature, and solvent resistance (47). Repetitive processing of these alloys at 280°C resulted in a significant loss of impact strength due to degradation. By contrast, reprocessing of a single polymer, PA-66 containing a thermally stable impact modifier, does not show a similar loss of impact strength. PC/PMMA alloy with an impact modifier used in auto lighting components shows a decrease in stiffness after repetitive reprocessing (46). PBT/PC [PBT = poly(butylene terephthalate)] blends exhibit a slight reduction in tensile properties after three reprocessing cycles attributed to a polybutadiene-based modifier. Engineering alloys and blends including PPO/PS, ABS/PC, and PC/PBT are blended with virgin materials and additives for reprocessing and reuse (with a minimum of 25 wt% of recycled material) (48). Thermoplastic polyurethanes (PUs) are recovered by mechanical recycling and are reprocessed by Injection Molding (qv) or Extrusion (qv).

Vehicle Recycling. Recycling of material from vehicles is limited to metals and plastics, with other nonmetallic materials going to landfills (49). After metals are separated, the remaining lighter fraction is called ASR. Of about 4 million tons of ASR produced annually in the United States, more than 1 million tons consist of PU foam and more than 750,000 ton consists of thermoplastics (50). Energy recovery from ASR via incineration is achieved by adding it to the MSW; stack emissions and ash composition show no measurable environmental impact (49). Argonne National Laboratory (Illinois) has developed a unique *froth flotation* process to separate high purity plastics such as ABS, HIPS (high impact polystyrene), and PP from the ASR. The process combines size reduction, two gravity-based separation steps, and a froth-flotation separation step. Froth-flotation recovers equal-density HIPS and ABS particles. When the particles are placed in a special aqueous mixture, HIPS particles float and ABS particles sink. Recovered plastics can be used again for computer parts, office equipment and accessories, and similar products. It has been estimated that this process could recover more than 136,000 ton of high purity plastics annually from scrapped autos and appliances, saving some 92 billion megajoules (87 trillion British thermal units) of energy and avoiding disposal costs of $10–40/ton (50). Another Argonne process separates flexible PU foam from ASR and cleans it to produce high quality foam for reuse.

Auto instrument panels that used to be made from 15 kinds of plastics are now 100% recyclable as a result of redesigning with mutually compatible plastics (51). Thermoplastic olefin elastomer (TOE), forms a skin, and PP foam and mineral-filled plasma-treated PP make up the core. Heat resistant and impact resistance are retained by increasing the amount of TOE and talc in the recyclate. New approaches to vehicle recycling include eco-design, employing design for disassembly (DFD), and design for recycling (DFR) (52). DFR involves designing for end-of-life, using both recycled and recyclable materials, reducing the number of materials, marking parts for material identification, and using compatible materials and DFD (53,54). In 1995, 24 different plastics were used in the average sedan made in the United States, for a total of 143 kg, or 9.3% of the vehicle. PU, PVC, and PP were the most common, followed by PA 66, ABS, and PE. Several of these plastics are recycled for various secondary applications, including reuse in new vehicles.

Electrical/Electronics Products Recycling. Electrical and electronics products such as computers, fans, stereos, TV housings, and vacuum cleaners make up about 1% of the MSW. End-of-life electronics are a fast-growing part of MSW. More than a dozen different resins are used in electrical/electronics products, including ABS, PMMA, polyamides, PC, PP, PS, flame-retardant (FR) HIPS, PU, PVC, blends of PC/ABS, and PET/PBT (55). The six most common resins are PS and HIPS (29%), ABS (14%), PP (12%), PU (9%), PC (8%), and phenol formaldehyde (5%). Several separation technologies are used to recover these polymers. MBA Polymers (Richmond, Calif.) has developed an automated process to recover PP, HIPS, ABS, PPO, FR HIPS, PC, and PVC (Fig. 9). The sorting of plastics from durable parts by plastic type is an important aspect of achieving high quality in recycled materials. Because the parts are made from engineering plastics (qv) with a wide variety of additives, fillers, and pigments, an identification by density is not reliable. Equipment for near-IR (NIR) and mid-IR (MIR) spectroscopy is sometimes used, although with limitations; NIR focuses on determining opacity, separating the mixed stream into clear (PET and PVC), translucent (HDPE and PP), and opaque (all colored materials)materials. Paints and coatings have to be removed for accurate identification; NIR systems cannot identify plastics filled with carbon black. Size reduction of parts involves high speed granulators and rotary grinders that produce particles of different sizes and liberate metal, labels, and other nonplastic materials. After metal and nonplastics removal and sorting, the engineering plastics are repelletized and formulated for manufacture of new parts and reuse in similar applications. About 7000 kJ/kg (3000 Btu/lb) are used to recover plastics with the MBA process, and no "raw material" energy is consumed. Using recovered plastic instead of additional virgin resin results in energy savings of 39,000 kJ/kg (17,000 Btu/lb) of raw material, or more than 85% of the energy needed to make virgin resin in the first place.

Carpet Recycling. By the beginning of the century, about 4.7 million tons of residential carpets were disposed of annually in the United States, with less than 5% being reused or recycled (56). Scrap carpet is bulky and difficult to collect. Efforts are underway in the United States to reduce landfilled carpets by 40% by 2012. Carpeting is a complex product consisting of 40–60 wt% of yarn from PA-6, PA-66, PET, and PP, 4–6% of primary backing made from woven PP, 38–52 wt% of adhesive made from styrene–butadiene latex with calcium carbonate as a filler,

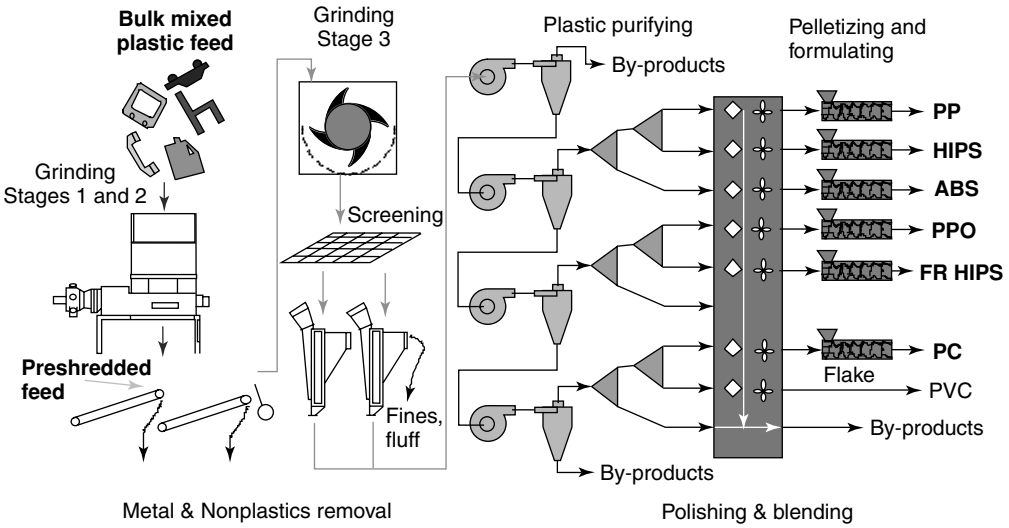

Fig. 9. Simple process flow diagram for recycling plastics from durable goods. Courtesy of MBA Polymers, Inc., Richmond, Calif.

and 3–5 wt% of secondary backing made from PP or jute (57). Carpets removed for disposal are often contaminated with dust and stains. In one method, carpets are chopped into small pieces that are fed into an extruder and then pelletized. The pellets are blended with virgin PP or LDPE for use in plastic lumber. Monsanto's patented process recycles PA-66 carpet without separation by using reactive extrusion and compatibilization (58). The resultant material is suitable for injection molding and extrusion. Yet another process produces interlocking floor tiles from vinyl-backed carpet with all the fibers of the carpet intact (59). The U.S. market for resilient flooring is about 1.5 billion square feet per year, representing a major outlet for recycled carpet.

Plastic Film Recycling

In contrast to the relative simplicity of recycling commodity resins, recycling plastic film has numerous facets, including the efficient consolidation of materials and the sorting and removal of contaminants. A significant aspect is the high volume-to-weight ratio of films, which translates into increased transportation cost. Films are more difficult to sort because most do not have identification codes. Some films like the pallet wrap contain plasticizers that make them tacky, and need to be handled separately from other films to prevent sticking. Different additives such as antislip agents and lubricants are used to manufacture films, and thus sorting is necessary. Agricultural film in the form of bags and shrink wrap can be hard to collect and to transport because of their bulk. A film used outdoors for a long time may be partially degraded, limiting its recyclability by melt extrusion. The S^3P technology discussed earlier allows recycling of densified agricultural film into

blown film without significant loss of physical properties. In Western Europe, the infrastructure for collecting and recycling PE film is more advanced than in the United States and Japan.

Biodegradable Plastics

Biodegradable plastics, designed to decompose through the action of living microorganisms, are an alternative to conventional plastics when recovery or recycling are impractical or not economically feasible. Biodegradable polymers, medical applications (qv) are of two types: naturally occurring and synthesized (64,65). The first group includes polysaccharides (qv) (starch, thermoplastic (qv); cellulose (qv)), protein (gelatin (qv); casein), and lignin (qv). Synthetic resins consists of polyalkylene esters, poly(lactic acid) and its copolymers, poly(vinyl alcohol), and others (see POLYLACTIDE; VINYL ALCOHOL POLYMERS). Some biodegradable polymers are commercial products: poly(lactic acid), starch-filled PE, poly(vinyl alcohol), plastics based on starch esters, and blends of starch esters with aliphatic polyesters, starch–poly(ε-caprolactone) blend, and others. Often, their cost prevents wide use of biodegradable plastics. Starch-based polymers are less expensive because starch is available from corn and other crops. Poly(vinyl alcohol) is widely used because of its solubility in water. Poly(lactic acid) is a low cost material used in medical implants and drug delivery. The mechanical properties of poly(lactic acid) are similar to those of PS, except for a lower glass-transition temperature and limited stability to hydrolysis. Like other plastics, biodegradable polymers can be processed by most conventional plastic processing methods such as injection molding and extrusion.

Biodegradable polymers offer unique advantages for the medical market (sutures, pins, implants) and for agriculture (mulch, seeding strips). In the United States, more than 125 million nontoxic biodegradable plastic sutures sutures (qv) are used each year in heart operations. Biodegradable polymers may also replace some hard-to-recycle contaminated products such as silage wrappings, plant pots, seed trays, and empty fertilizer bags containing chemical residue harmful to sewage treatment systems. Ongoing concern for a "green" environment has helped to increase production of biodegradable polymers from corn-derived sugar, beets, soybeans, rice bran, and potato peelings.

Life Cycle Assessment. The relatively new discipline called *life cycle assessment* (LCA) has considerable environmental implications with regard to plastic waste. LCA encompasses every phase from raw materials and resin manufacturers through transportation, processing, usage, recycling, and disposal (66). The life cycle of a plastic product embraces several steps (Fig. 10). Conversion of crude oil into petrochemicals is followed by a synthesis of virgin resins, which are then processed into products. When their useful life ends, products are either recycled or landfilled. By monitoring the qualities of a plastic throughout its life cycle, its performance value can be maintained at the highest possible level. Because only 5% of the consumed resources are transferred into useful products and 95% ends up as waste or by-products, most processes are resource-intensive (67). These may be modified in the future through LCA, which holds promise for emission studies and similar environmental aspects during the life cycle of a product.

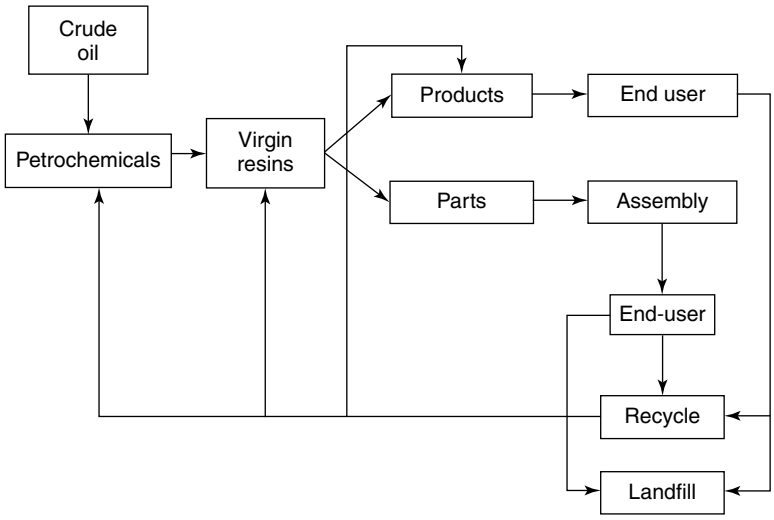

Fig. 10. Life cycle of plastics.

Overall, the reputation of plastics recycling has been a mixed one. On the one hand, many post-consumer products still cannot be recycled economically, and far too much plastic material is landfilled. On the other, emerging technologies and new attitudes are helping to brighten that picture. Increased commitments worldwide to a greener environment are reflected both in enhanced community participation and in stricter governmental regulations, raising expectations for improved plastics recycling in the future.

Other Economic Aspects

Extended Producer Responsibility. First introduced in Sweden in the early 1990s, the concept of Extended Producer Responsibility (EPR) has gained attention in Europe and elsewhere. EPR extends the manufacturer's responsibility regarding environmental impact of their products during the life cycle, recycling, and disposal. EPR was first mandated in Germany in 1991 as the "Green Dot" system. In the United States, EPR is defined more broadly as the shared responsibility of the government, consumers, and industry, rather than of the producer alone. Several American companies have voluntarily implemented EPR concepts: Xerox practices a maximum recovery of office equipment and takes back its products; Kodak takes back single-use cameras, and DuPont takes back and recycles PET film (60).

Eco-Design of Plastic Parts. Eco-design or "green design" of plastic parts involves minimizing the amount of material entering the MSW by reducing part weight and by extending the life of a part through improved performance. Reuse of a plastic for secondary applications is also practiced, along with *closed-loop recycling* (returning recycled plastic back into the same application) (61,62). Designers should choose compatible plastics to eliminate disassembly if possible,

because separation of materials is one of the critical elements in the economics of plastics recycling. Auto makers such as Peugeot (France) have adopted a "mono" material approach for large plastic parts such as bumpers in order to simplify recycling. Bumpers, fixtures, and fittings are made from one grade of PP, in contrast to the PP/EPDM blend usually used. Many manufacturers are still reluctant, however, to use recycled plastics or products with recycled content when designing their products because very little information about physical properties and long-term performance is available (63). Specifications such as size, weight, and wall thickness often constrain the use of recycled plastics. Certain products from recycled materials must be made thicker to compensate for the material's reduced properties.

RIGID-ROD POLYMERS

Introduction

Scientists and technologists have aspired for a long time to produce high strength and high modulus synthetic polymeric fibers. The structural model for such fibers is made of densely packed and perfectly aligned straight polymers as shown in Figure 1. It was proposed many years ago by Staudinger (1) as the structure of polymer crystals. However, the actual development of such a fiber has been relatively slow. Figure 2 shows that the pace remained slow until DuPont revolutionized the field in the early 1970s with the commercial manufacture of an aromatic polyamide fiber under the trade name Kevlar (2–5) (see POLYAMIDES, AROMATIC).

The strongest motivation for exploring high performance fibers was provided by the aerospace industry. It generated needs for novel polymer fiber products with better properties and lower weight to be used in structural composites. Motivated by these needs, the field of high performance polymer fibers developed quickly in the 1970s and 1980s. For a long time, the U.S. Air Force worked to develop the so-called ordered polymers. Synthesis of high temperature resistant aromatic heterocyclic polymer systems began in the 1950s, and proceeded to the synthesis of ladder-like polymers, poly(6,9-dihydro-6,9-dioxobenzimidazo{2,1-*b*:1°,2′-*j*} benzo{1mn}{3,8} phenanthroline-3,12-diyl) (BBB) (**1**) and poly((7-0x0-7,1OH-bez{*de*} imidazo{4′5′:5,6} benzimidazo{2,1-*a*} isoquinoline-3,4:10,11-tetrayl)-10-carbonyl) (BBL) (**2**), in the early 1970s (6,7).

In pursuit of the general goal of producing polymers with better properties, but with easier processability than the ladder polymers, scientists in the Air Force Materials Laboratory successfully synthesized extended chain polymers, including poly((benzo{1,2-*d*:4,5′-d′} bisthiazole-2,6-diyl)-1,4-phenylene) (PBZT) (**3**), poly((benzo{1,2-*d*:4,5′-d′} bisoxazole-2,6-diyl)-1,4-phenylene) (PBZO) (**4**),

poly(*p*-phenylene benzobismidazole) (PBZI or PBI) (**5**), poly(2,5 benzoxazole) (ABPBO) (**6**), poly(2,5 benzothiazole) (ABPBT) (**7**), and poly(2,5 benzimidazole) (ABPBI) (**8**) (shown in Fig. 3), commonly referred to as "rigid-rod polymers" (8,9). In this field, PBO is usually used to represent poly((benzo{1,2-*d*:4,5′-d′} bisoxazole-2,6-diyl)-1,4-phenylene). However, in the previous edition of the Encyclopedia, PBO was used for polybenzoxazole. Therefore, in order to avoid conflict with the current usage, PBZO is applied here as the acronym of poly((benzo{1,2-*d*:4,5′-d′} bisoxazole-2,6-diyl)-1,4-phenylene).

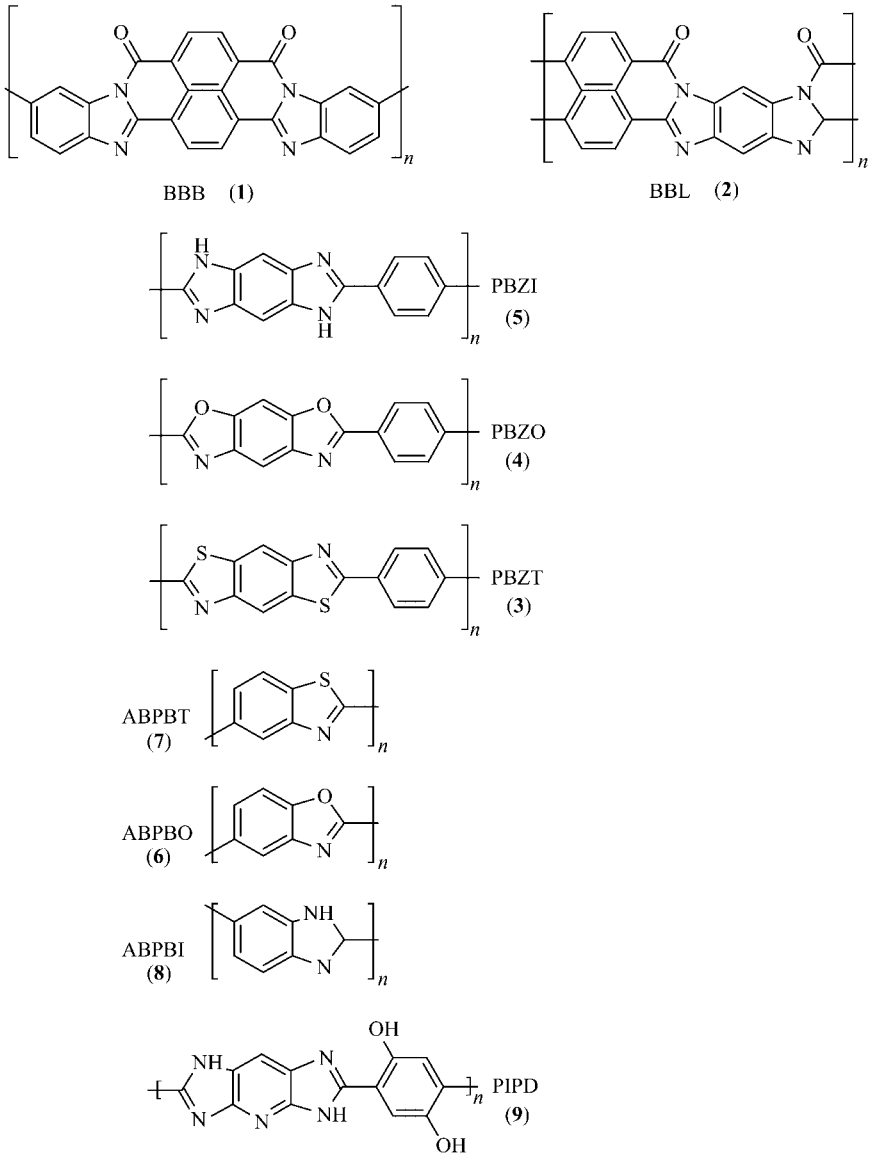

Fig. 3. Molecular structures of component members of PBZT, PBZO, PIPD, and other rigid-rod polymers.

In the 1970s and 1980s, an extensive Air Force-funded development program at SRI International, Celanese (now Hoechst Celanese Co.), DuPont, and several universities led to successful synthesis and fiber spinning from PBZT. In the mid-1980s, Dow Chemical Co. scaled up PBZO synthesis and pursued the commercialization of PBZO fibers and films (10), because they had shown excellent mechanical properties and could be synthesized more cheaply than PBZT (11,12). In 1991, the Toyobo Co. joined Dow in the Development of PBZO fibers. In 1994, Dow

decided to terminate its rigid-rod polymer program, and Toyobo was granted a license for production. In 1998, Toyobo announced success in the commercialization of PBZO fibers as the product Zylon. Recently, Akzo Co. claimed to have manufactured poly(2,6-diimidazo[4,5-b:4′5′-e] pyridinylene-1,4(2,5-dihydroxy)phenylene) (PIPD, also called M5) (**9**) fibers (13), another member of the PBX family, with improved compressive properties.

In addition to new derivatives from the PBZX family (14) and novel rigid-rod polymers such as rigid-rod polyimides (15,16) and aromatic poly(pyridinium salt)s (17), there are several special groups of rigid-rod polymers that have been studied and developed rapidly after the 1980s. Among them are polyphenylenes, poly(phenylene ethynylene), poly(*p*-phenylenevinylene) (qv), polythiophenes, polyanilines, polyquinolines, and some organometallic polymers (18–25) (see ELECTRICALLY CONDUCTIVE POLYMER; METAL–CONTAINING POLYMERS). All these are synthesized with conjugated structures and are primarily applied to optical and/or electrical usage. Recently, this field has become very active and many new rigid-rod polymers and their derivatives have emerged. It is very difficult to cover all the rigid-rod polymers, and in this article, we try to frame the research work and to construct a basic blueprint of these activities. The discussion begins with the properties, structures, syntheses, solution behavior, processing, and applications of the high performance fibers (and films) developed from the PBX family with PBZT and PBZO as the model compounds. Then other rigid-rod polymer systems are concisely reviewed.

Properties of PBZT and PBZO Fibers

The rigid-rod fibers, especially PBZO, display superior tensile properties (Table 1), thermal stability, flame resistance, barrier properties, and low smoke generation as well as low moisture sensitivity. Other good properties are cutting and abrasion resistance, chemical, oxidation, and radiation resistance, as well as a low dissipation factor (26,27). Furthermore, the rigid-rod fibers exhibit potentially useful electrical and nonlinear optical behavior. A shortcoming is the comparatively low axial compressive strength. For example, as shown in Table 1, PBZO (**4**) and PBZT (**3**) fibers exhibit tensile-to-compressive strength ratios around 15–20:1, tensile-to-shear strength ratios, 50:1, and tensile-to-shear modulus ratios, 200:1 (28). However, the newer PIPD fibers, commercialized by Akzo Nobel Co., exhibit improved compressive strength, closer to that of high performance carbon fibers (13).

Tensile Properties. Table 1 shows that the tensile properties of PBZT, PBZO, and PIPD fibers are about 55–60 times higher than that of high tenacity nylon, 25–30 times higher than polyester, 2 times higher than PPTA fibers (Kevlar 49), 4 times higher than glass fibers, and 1.5 times higher than steel. A plot of specific tensile strength and tensile modulus of fibers is given in Figure 4. It shows that PBZT, PBZO, and PIPD fibers are high due to their low density and superior tensile properties. Typical stress–strain curves of PBZT are shown in Figure 5. In general, for the rigid-rod polymer fibers, the tensile elongation at failure is about 1–2%, and heat-treated fibers are nearly linearly elastic.

Tensile properties of rigid-rod fibers, especially tensile strength, generally depend on molecular weight. With increasing molecular weight, tensile strength and

elongation at break of PBZT and PBZO fibers increase (30,31). Of course, defects other than those associated with molecular ends also affect the strength of all polymer fibers. The defects include impurities, voids, surface damage, and misaligned crystals (32,33). When the intrinsic viscosity of PBZO/polyphosphoric acid (PPA) spinning solution reaches about 30 dL/g, the resulting fibers achieve the highest strength and modulus (31). After reaching a certain level, the fiber tensile modulus is independent of molecular weight (31). It is interesting that for different rigid-rod polymer fibers, the tensile molecular deformation process is similar even though these fibers have completely different chemical structures and processing. By monitoring the Raman band of the symmetrical vibrational mode of the *p*-phenylene ring, the tensile molecular deformation of different rigid-rod polymer fibers can be described with a modified series model. The Raman band shift is proportional to tensile stress (rather than tensile strain), and for all different rigid-rod polymer fibers, there is an identical slope of approximately $-4.0\ cm^{-1} \cdot GPa^{-1}$ (31). It was reported that PBZT fibers had two tensile failure modes. In Mode I, fibers with relatively higher average tensile strength exhibited little or no axial fibril splitting. In Mode II, significant splitting was observed with lower tensile strength. These two modes fit the Weibull statistical distribution (32,33).

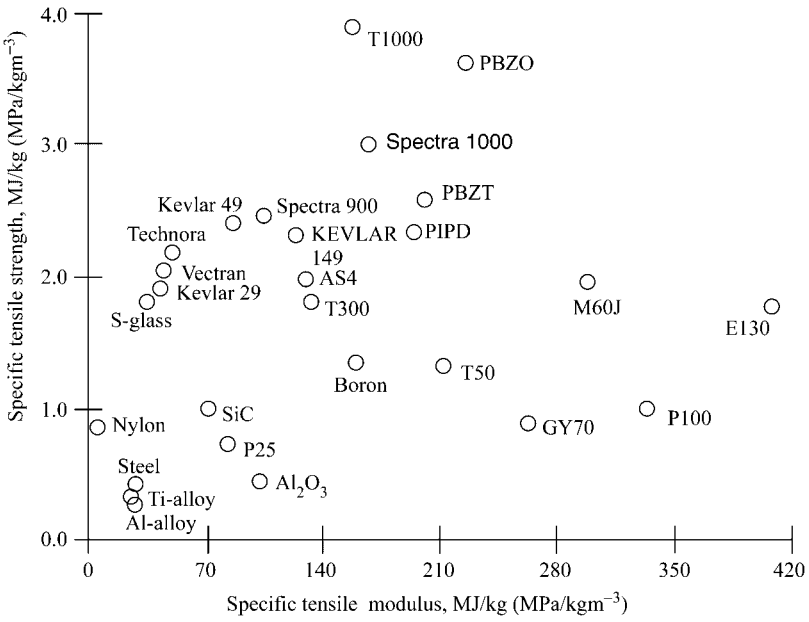

Fig. 4. The specific tensile strength and modulus of various fibers: The unit of specific strength or specific modulus (the fiber tensile strength or modulus divided by its density: Pa/(kg·m^{-3}) is equal to Nm/kg, namely J/kg).

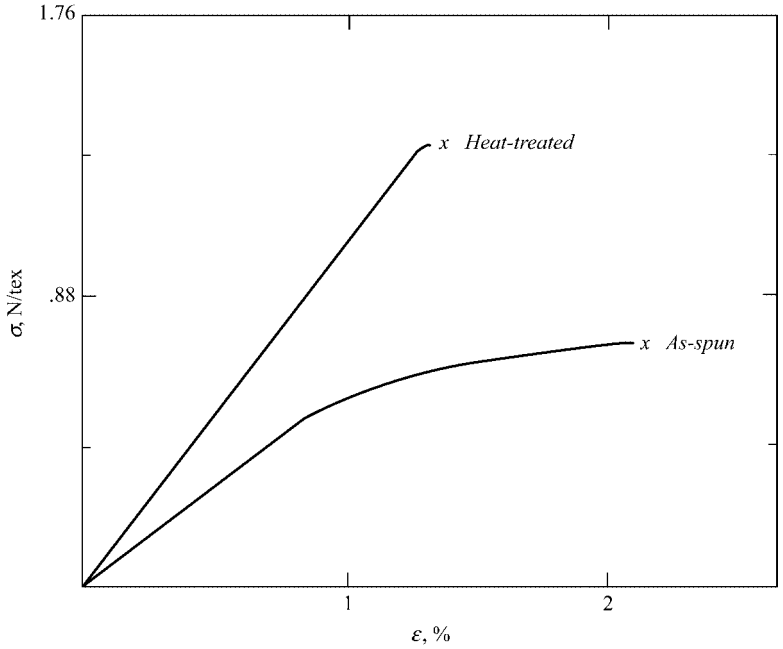

Fig. 5. Typical stress–strain curves of as-spun and heat-treated (HT) PBZT fibers. The unit conversion of fiber tenacity 1 N/tex = 0.102 kg/tex = 11.3 g/d, and the fiber tensile strength in pascal (SI unit) can be obtained as 1 N/tex = $\rho \times 10^9$ Pa = $\rho \times 1$ GPa, where ρ is the fiber density in g/cm^3. Reprinted from Ref. 29, by courtesy of Marcel Dekker, Inc.

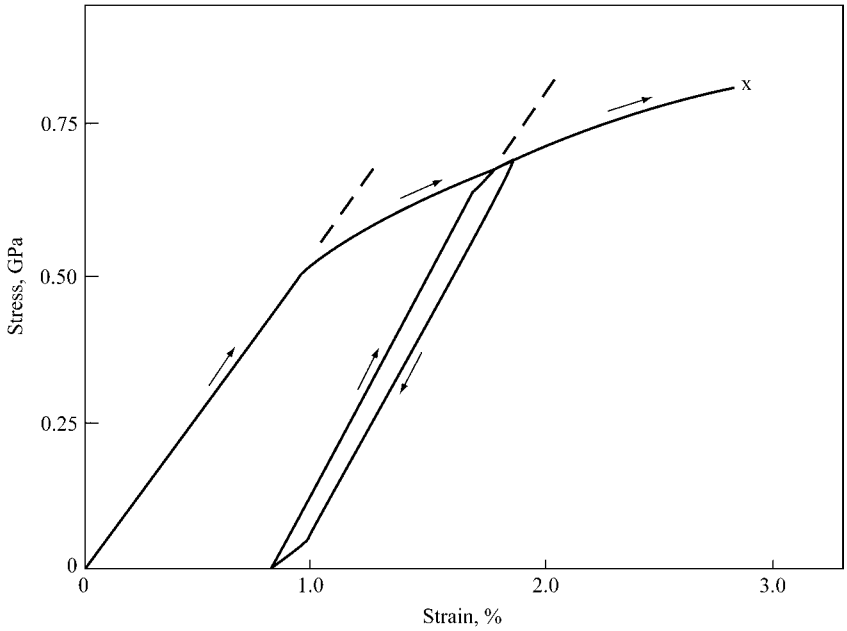

Fig. 6. Cyclic stress–strain behavior of as-spun PBZT fibers. Reprinted from Ref. 34, by courtesy of Marcel Dekker, Inc.

Cyclic stress–strain testing of as-spun (AS) PBZT fibers disclosed a nonlinear elastic–plastic behavior with strain hardening as shown in Figure 6. The tensile modulus of an AS fiber increases with repeated straining after an initial plastic deformation, which was estimated as about 2% (35,36), but the stress–strain curve of a heat-treated (HT) fiber exhibits almost no strain-rate dependence (35–38). The fatigue behavior of PBZT is similar to that of a completely elastic material. If it is perfectly elastic, the dissipation factor (tan δ) is zero. The fatigue lifetime of the HT fibers is about 13 times longer than that of the AS fibers, comparable to that of PPTA (Kevlar) fibers (39). The rigid-rod polymer fibers also have rather small creep and stress relaxation. Their creep and stress relaxation rates are extremely low compared with the conventional nylon and polyester fibers. Presumably this is caused by a combination of rigid chains and high order. Nevertheless, it was reported that the polymer fibers with rigid chains showed remarkable nonlinear dynamic viscoelasticity and poor fatigue behavior compared to those with flexible chains, especially under higher strain rate (40). The nonlinear elasticity of PBZT results from an inherent molecular nonlinear elasticity as well as crystal reorientation under an applied stress (41).

Temperature affects the nonlinear tensile elasticity. In general, the properties of the rigid-rod fibers are temperature-dependent. At 250°C, HT PBZT fiber retains approximately 80% of its room temperature tensile modulus and 70% of its room temperature tensile strength (28,37,42–46). However, fibers heated to 300°C for 65 h in air and then tested at room temperature did not show any loss of their tensile strength and modulus (47). Figure 7 shows both the strength and modulus retentions of PBZO fibers heated to 250°C under N_2 and in the

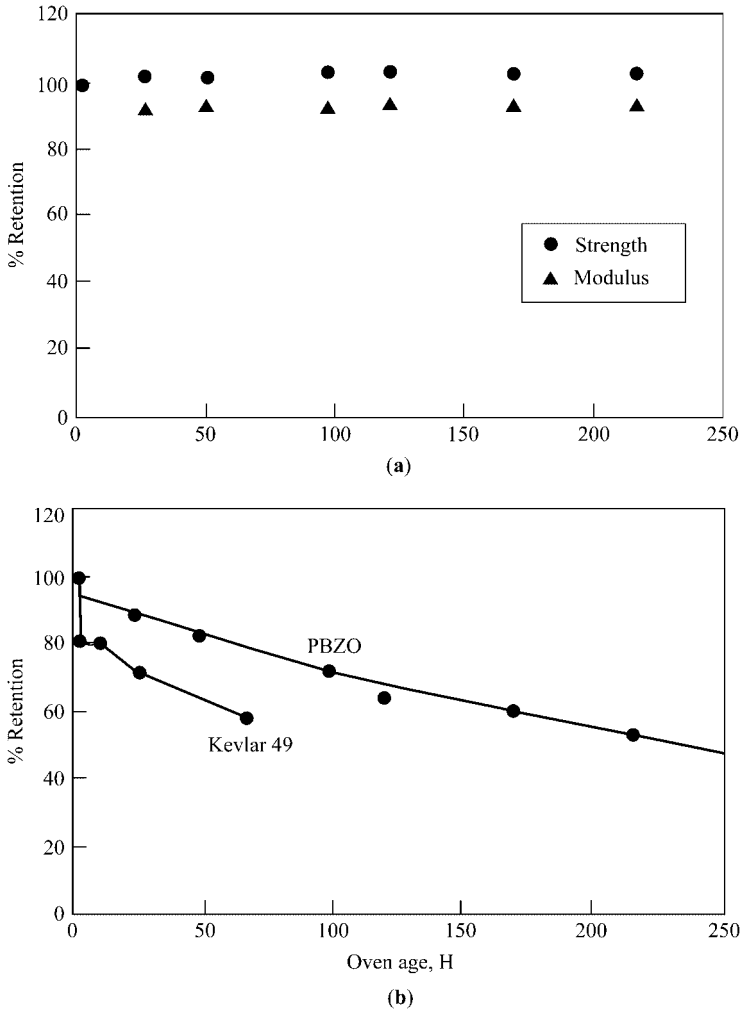

Fig. 7. (**a**) Tensile strength and modulus retention of PBZO fibers at 300°C in N_2. (**b**) Tensile strength retention of PBZO fibers with aging time at 300°C in the air, compared to that of PPTA (Kevlar 49) fibers. Reprinted from Ref. 34, by courtesy of Marcel Dekker, Inc.

air (27). Rigid-rod fibers clearly are more thermally stable than other synthetic polymer fibers (48). Jiang and co-workers reported a correlated relaxation around 300–400°C in both the laser-induced ultrasonic dynamic modulus (1 MHz) and the crystal *a*- and *b*-axis dimensions of PBZT fibers. This phenomenon is attributed to conformational oscillation around the single bond connecting the phenyl rings and bisthiazole moieties (37,49–52). A sharp increase was observed in the calculated X-ray diffraction intensity ratio of (200)/(010) around 300–400°C, which was also explained by the same oscillation using molecular dynamics simulations (50). The increase in the torsion angle was also considered to develop translational molecular motions in the direction parallel to chain axis, which brought about the decrease of the dynamic sonic modulus (53). Nakamae and co-workers recently reported that the static crystal modulus is constant in the range from

room temperature to 400°C (54). This indicates that the molecular motion suggested above is relaxed under a static force at room temperature and higher. Northolt proposed that the strong temperature dependence of the elastic tensile modulus of rigid-rod polymer fibers should be related to the rheological rotational displacement of the crystallites on account of strains in the intercrystallite interlayers (55,56). Based on the study of rigid-chain polymers (polyimides and Kevlar 49), Slutsker argued that the temperature dependence of elastic modulus should be associated with conformational defects in the crystallite lattices (54). The evolution of the conformational defects under load plays a key role in determining the static and dynamic elastic properties of the rigid chain polymer fibers. At low temperature, stretching a rigid chain polymer fiber causes an elastic extension of the covalent bonds and changes in the valence angles in the macromolecular skeleton, namely a true Hookean behavior. However, at high temperature, the fiber tensile elongation leads to a combination of the true elastic stretching and conformational transitions, an additional "non-Hookean" deformation, such as change from cis-conformation to trans-conformation. The conformational transitions are thermally activated and also reversible (57).

Compressive Properties. As listed in Table 1, the axial compressive strength of rigid-rod fibers is comparatively low, while isotropic boron, alumina, silicon carbide, E-glass, and some PAN-based carbon fibers are among the highest compressive strength fibers available. Figure 8 is a typical stress–strain curve of PBZO under tension and compression (47,58). The yield stress in compression is about one-tenth that in tension. However, the PIPD fiber shows improved compressive properties because of the intra- and intermolecular hydrogen bonds in its molecular structure (13). For PBZT fibers, no significant compressive strength dependence on either fiber tensile modulus or diameter was observed (32,33).

There is nonlinearity in compressive behavior for several rigid-rod polymer fibers (41,50,59–66). With increasing compressive stress the modulus decreases. This is the so-called modulus softening (or strain softening) phenomenon. The compressive modulus of PBZT fibers decreases up to 20% as determined with Raman spectroscopy (67), and up to 8% in a microtensile machine test (68–70). Under compression, the fiber birefringence decreases corresponding to crystal disorientation from the fiber axis (41,52,59,62–66). The crystal disorientation has also been observed by X-ray diffraction (65,66), which could contribute to the modulus decrease and even to the fiber compressive failure (52,62–66,71). It was reported that although under tension there was slight strain hardening at high strains, no strain softening behavior was observed during compression for PIPD fibers (72). However, under compression, a PIPD/epoxy composite still exhibits typical nonlinear behavior after yielding (73).

The compressive modulus (E_c) is suggested to be less than the tensile modulus (E_t). Some theoretical estimates predict it to be 70–90% of E_t (60). However, others reported that E_c appears approximately equal to E_t (41,59,62–64,70). The results of compression tests on unidirectional composites of rigid-rod fibers show that E_c is close to E_t (74,75). Improvement in the tensile modulus might not significantly change the compressive strength (76,77). By changing the spinning, coagulating, and drawing conditions, the tensile moduli of PBZO fibers varied from 130 to 210 GPa, but their compressive strengths were always in the range of 200–300 MPa. The small changes in compressive strength were considered within

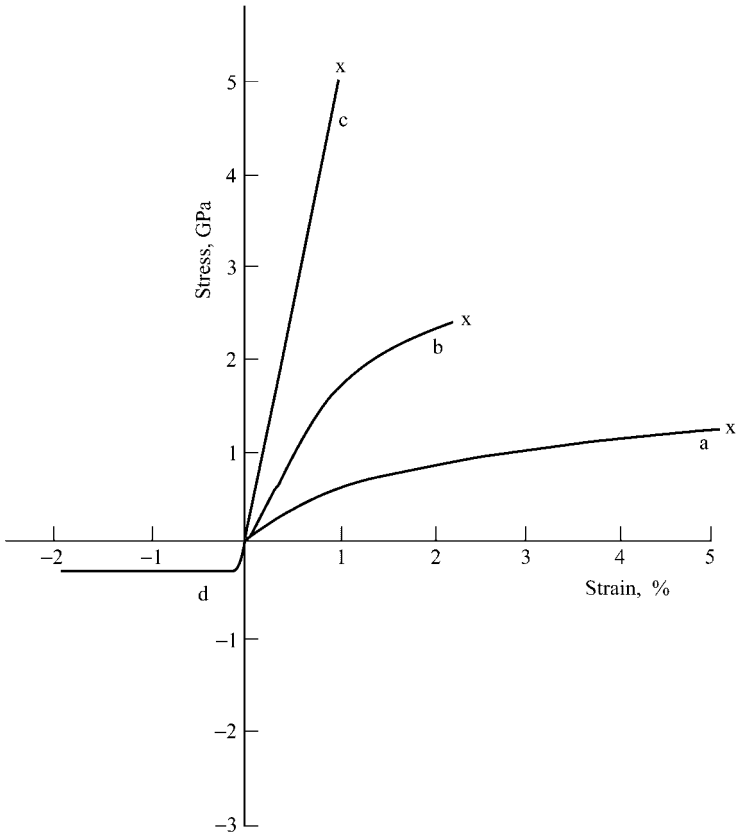

Fig. 8. Typical tensile (**a–c**) and compressive (**d**) stress–strain curves of PBZO fibers. (**a**) as-coagulated (wet), (**b**) as-spun (dried), (**c** and **d**) heat-treated. Reprinted from Ref. 34, by courtesy of Marcel Dekker, Inc.

the experimental error (78). Also, the compressive strengths of fibers made from PBZT and PBZO hardly change with variations in their tensile strengths (from 1.5 to 3.5 GPa). Conversely, the formation of compressive kink bands leads to only a small decrease in tensile strength (76,77,79–82). These results imply that no simple correlation exists between the tensile and compressive properties. For rigid-rod fibers, compressive failure may depend upon different structural factors from those controlling tensile strength. For example, in compression measurements based on bending, the fibrils/nanofibrils can play a role (83).

Based on shear mode buckling instability, a linear relation between compressive strength and torsional modulus of PBZT and ABPBO fibers was suggested, namely $\sigma_c = 0.3G$, where σ_c is the compressive strength and G the torsion modulus (84,85). However, results for a larger set of samples show departures from this relationship (85). For most rigid-rod fibers, the compressive strength is around one third to one fourth of the shear modulus (86). For example, the compressive strength value of PBZT fibers is approximately one fourth of the shear modulus (86). It was also reported that fiber axial compressive strength could be related to transverse tensile strength (87).

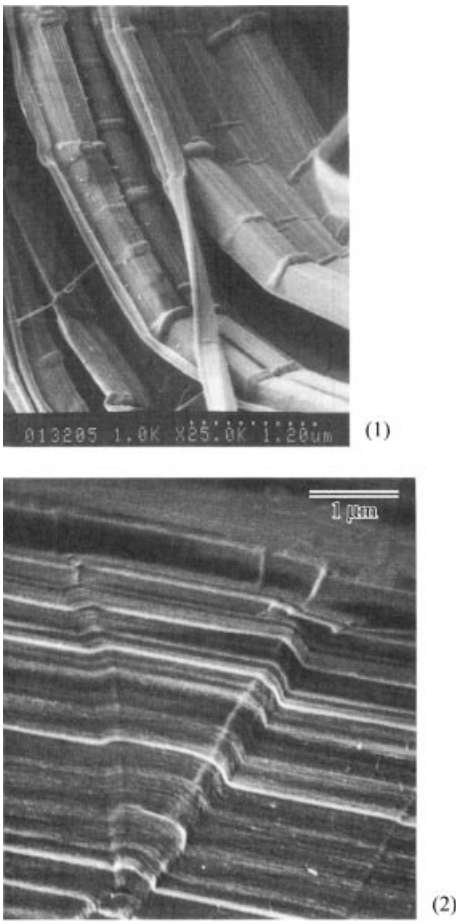

Fig. 9. Kink bands in PBZO fibers. Courtesy of D. Vezie.

For rigid-rod fibers, compressive failure is always associated with kink band formation (seen in Fig. 9) (85). Kinking is considered to be a localized axial deformation (88,89). Kink bands are nucleated locally, probably near the fiber surface. With the increase of compressive stress to a critical point, kink bands propagate and grow in toward the center and/or the other side of the fiber. Different fibers would have different critical strains for the formation of the first kink band (76,77) because of variations in structural order and defects. For PBZT fibers, no kinks are observed by optical microscopy up to 0.1% compressive strain. As the strain increases above 0.1%, kink bands suddenly appear and the number increases rapidly. Most of the new bands occur near the initial band and show some periodicity in kink concentration (90). In a limited range of strain, kink density is proportional to the compressive strain, but over the range (namely at larger strains), the density saturates (90,91). Upon the application of tensile strain after compressive kinking, many kink bands disappear, as observed by optical microscopy (65,66,90). This "reversibility" has also been confirmed by SEM examination (65,66,92). The kink band angle depends upon the fiber structure

and properties (58,93–97). For PBZO fibers, observed by TEM, kink bands are oriented at about $69 \pm 3^\circ$ to the fiber axis, with thickness from 45 nm to 1.8 μm. The thicker bands (1.2–1.8 μm) extend across the fiber with a comparatively uniform thickness. The thinner bands (0.1–0.3 μm) are usually wavy and nonuniform. Cracks and voids can develop in the bands, especially the thicker ones (>0.1 μm). When two bands intersect, a mutual shearing effect occurs, which can lead to the formation of voids. Also, the sheared region can be sheared with another intersection. The shear strain along kink bands is about 0.7%. Buckling may occur in regions of dense kink bands and intersections (98). In the crystals of PBZO fiber, a typical dimension of kinks in the fiber direction is 30–50 nm, shorter than an average PBZO molecule ($\approx$100 nm). The flux of chains through the kink boundary is apparently constant. This indicates that in a kink there is a cooperative local bending/reorientation of the covalently bonded molecules, rather than chain breakage (58,94,95). Computational modeling techniques have been used to study the possible mechanism for the reorientation, wherein compressive buckling might occur using a flipped state requiring a change of a single amide carbon–phenyl torsion angle (93,99).

There are various models for the mechanisms of kinking and compressive failure. Argon pointed out that for composite materials, kink bands form when the compressive stress along the orientation direction makes locally misaligned elements experience a relative shear stress that depends on the misorientation angle ϕ_o (100,101). DeTeresa suggested that for high performance polymer fibers, the kink formation should be determined by an elastic buckling instability in the fibers and that there is a correlation between compressive strength and the longitudinal shear modulus (79–81,83,85,86,102). Huh considered that the compressive strength is not limited by *fiber buckling*, but rather by Euler *fibril buckling* (90). Van der Zwaag argued that kink bands should form before elastic instability occurs, and may, therefore, be attributed to plastic deformation (76,77). Robinson and co-workers thought that compressive failure is related to crystallographic twinning (103), but there are counter-arguments that kinking is caused by slip (104,105). It was noted that for PBZT fibers, kink formation is associated with the $(010)\langle 001\rangle$ crystalline slip systems (91,106–110). Attenburrow and Basset thought that the extended chain deformation facilitates "fine" shear (111). Shigematsu proposed that both uniform *c*-axis shear and intercrystalline slip mechanisms should be involved in forming kink bands (112). However, many unanswered questions still remain. For example, different deformation processes, such as microbuckling, shearing, and bending, can produce kinking. It may be that kink band formation is a posteffect phenomenon and is not directly related to the material compressive strength. Many fibers kink in the mid-section of the compressive stress–strain curve.

Significant research activities have focused on enhancing the compressive properties of rigid-rod fibers (34,113). Most of these efforts have been related to increasing intermolecular interactions to improve the compressive strength (114–120). These efforts can be summarized as follows:

(1) Cross-linking PBZT fiber through post-heat-treatment in order to enhance lateral connectivity and improve the compressive strength (32,121,122);

(2) Cross-linking PBZT through creating free radicals
   a. by thermal elimination and/or irradiative degradation of activated aryl halogen followed by the combination of the aryl/benzyl free radicals (117);
   b. by incorporating a thermally reactive crosslinking fluorine moiety into PBZT (123,124);
(3) Cross-linking benzobisthiazole rigid-rod copolymers via labile methyl or dimethylephenoxy pendent groups (118,125–131);
(4) Cross-linking PBZO fibers with polyphenylene sulfide pendent groups (132);
(5) Making rigid-rod random copolymers of phenyl benzobisthiazole with phenyl benzobisthiazole pendent-*p*-terphenyl to change the packing order (115);
(6) Introducing benzocyclobutene (BCB) cross-linking moieties into PBZT (120, 126,133–136);
(7) Using Lewis acid complexation to change intermolecular interactions and influence compressive properties (137);
(8) Forming two-dimensional PBZT and PBZO films to increase compressive strength (121,138);
(9) Syntheses of tetramethylbiphenyl PBZT-*co*-PBZT systems (139), dihydroxy PBZT and dihydroxy PBZT/PBZT copolymers (140), and monomethyl-pendant-poly (*p*-phenylene benzobisimidazole) (141) to form intermolecular hydrogen bonding.

Unfortunately, so far, all these attempts at introducing stronger intermolecular or interfibrillar interactions in rigid-rod polymer fibers have not been very successful and no significant progress in enhancing compressive behavior has yet been achieved. In a few cases, compressive strengths of over 500 MPa were reported (123,127,141), but many were in the range of 25–400 MPa (78,116,141).

Recently, Sikkema reported a new rigid-rod polymer fiber, PIPD, which exhibits rather high compressive strength (13). Because of the presence of intermolecular hydrogen bonding (N—H···O) and intramolecular hydrogen bonding (O—H···N), PIPD forms either hydrogen-bonded sheets or a bidirectional hydrogen-bonding network. The hydrogen bonding produces a strong interaction between macromolecular chains and results in high shear modulus and compressive properties (13). With the Carr–Parrinello technique based on density functional theory, computer simulation shows that there exist hydrogen-bonding networks in PIPD fibers and the networks lead to an approximately three times stronger interchain interaction, which significantly improves the compressive strength of PIPD compared to PBZO and PBZT (142). For PIPD, a compressive modulus of over 300 GPa and a compressive strength of 1 GPa have been reached. Both of them are considerably higher than the corresponding values of all other rigid-rod polymer fibers and are the best compressive properties that have ever been reported for high performance polymer fibers (13,72,143,144).

There are several other approaches for improving the compressive strength:

(1) Coating a suitable ceramic, metal, or metal compound on the surface of rigid-rod fibers (2,61,67,113), such as immersion of PBZT fibers in molten

aluminum–silicon alloy or vapor-deposition of aluminum on the surface of the fibers (145). After forming a metal or ceramic layer, fiber tensile strength was decreased somewhat. Tensile fracture changed from fibrillar (for failure above 1.9 GPa) to planar (for failure below 1.9 GPa). An oxidized layer formed at the fiber surface, protecting PBZT from degradation. It is possible, therefore, to improve compressive strength of composites by the infiltration of liquid aluminum alloy into the reinforced rigid-rod fibers (143,144). On the basis of the theory of compressive failure caused by microbuckling of fibrils in shear, the critical buckling stress of rigid-rod fibers with stiff external coatings could be modeled (66). Recently it has been reported that coating Kevlar fibers with titanium nitride to a thickness of less than one-half micron by plasma-enhanced chemical vapor deposition technique suppressed the compressing buckling (146,147).

(2) Processing of PBZT/sol–gel and PBZO/sol–gel microcomposite fibers could improve the compressive properties (47,114,148).

(3) Imbedding thermoset polymers into PBZO fiber can enhance the resistance to compressive failure (149–151).

(4) By adding inorganic crystal whiskers (such as SiC and carbon nanotubes) into the spinning dopes to form composite fibers, the compressive properties of rigid-rod fibers could be improved (from 0.22–0.28 GPa for the original fibers to 0.31–0.6 GPa for the SiC-reinforced fibers). The volume percentage of the whiskers is controlled in the range of 1–20%, with sizes being $L =$ 2–20 μm, and $d = 0.1$–1.5 μm (152).

Thermal Properties. Rigid-rod fibers have good thermal stability because of the aromatic or aromatic heterocyclic (delocalized) backbones. PBZT, PBZO, and PIPD fibers in particular have good thermal behavior. Figure 10 shows the

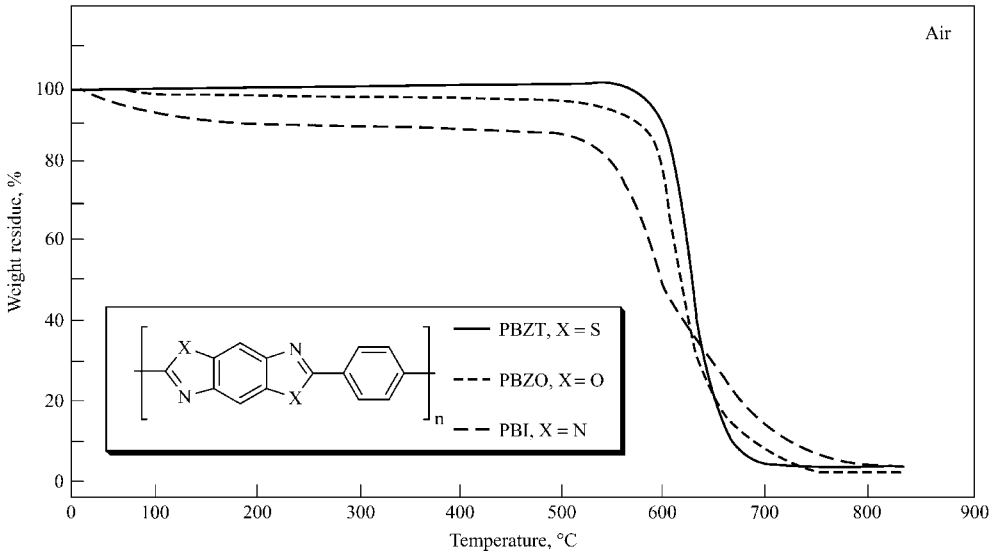

Fig. 10. Thermogravimetric analysis (TGA) diagram of PBX polymers in air. Reprinted from Ref. 34, by courtesy of Marcel Dekker, Inc.

thermogravimetric analysis (TGA) of PBX polymers (153). The thermal degradation of PBZT and PBZO occurs in air at about 600°C, and for PIPD, at around 530°C (13). At 371°C in air for 200 h, the weight retention for PBZO is reported to be 78%, and for PBZT, 70%. These fibers do not melt before decomposition occurs. They do not support combustion, but char at elevated temperature and generate small amounts of smoke while burning (154). The result of a fire fighter coat test (ASTM D4108-87, 2 cal/cm^2, 18-s exposure) demonstrated that the cloth made of aramid fibers formed brittle char while cloth made of the PBZO retained the texture integrity (27). The thermal weight-loss analysis of PBZO in air and helium shows hardly any weight loss up to 700°C in helium, and even at 850°C, 60% weight still remains (155,156). For PBZT, the main gases evolved are H_2S, HCN, and CS_2, which comprise 95% of the total ionization flow (155). The total loss of 28% at 1000°C is consistent with the loss of 1 mol of H_2S, 1 mol of HCN, and 0.25 mol of CS_2 per mole of PBZT repeat (157). For PBZO, oxygen-containing gases are the major released materials. These include CO, CO_2, and H_2O. Huang and So also discussed the mechanism of thermal decomposition for PBZT under elevated temperature (158,159).

The PBX polymer class has small negative axial coefficients of thermal expansion (CTE). For PBZT, the coefficient is approximately -1 to -2.5×10^{-6}/°C (43,160) and extrapolates to -7×10^{-6} at perfect orientation (156), or -2.9×10^{-6}/°C from 20 to 445°C (54). The negative values result from transverse vibration of the molecules as has been shown by molecular dynamics and molecular orbital calculations (52,53,71,161,162). Therefore, the fibers have good thermal dimensional stability. It was observed that under a given tension, the CTEs of PBZO fibers remain nearly the same for all heat cycles (10.8×10^{-6}/K with applied load of 1.2 MPa). The results from wet PBZO at low tension were also similar to those for their dry counterpart (43). Measured by adiabatic calorimetry, the specific heat capacities of PBZO and poly(*p*-phenylene) (PPP) at room temperature are 0.964 and 1.2 J/K·g, respectively, and above 50 K, the heat capacity shows a linear temperature dependence. Although there exists a significant difference between values of the heat capacity of PBZO and PPP, their heat capacity densities (heat capacity per unit volume) are approximately the same (1.5–1.6 J/K·cm^3) (163). Jenkins and co-workers reported a pronounced increase in thermal contraction for monomethyl pendent PBZT, which was observed at the temperatures (at about 350–450°C, varying with different fibers) where the pendent group cleaved, which was accompanied with a decrease in lattice parameters. Thermally induced chemical changes and crosslinking were considered the reasons for the accelerated shrinkage (141).

Optical and Electrical Properties. Nonlinear optics (NLO) is of interest because of its significance in providing novel optical processing approaches and applications in the area of photonics. The PBX polymer class has been recognized as candidates for NLO materials for photonic device applications (140,164–171). Owing to their orientability together with extensive conjugation given by the aromatic heterocyclic moieties, PBX polymers exhibit large third-order NLO response characterized by third-order susceptibility ($\chi^{(3)}$) derived dominantly from the delocalized π electrons (164,172). Table 2 lists the optical properties for PBZO and PBZT (173), and Table 3 exhibits the nonlinear optical third-order susceptibility of PBZT and thiophene-containing PBZT (MPBT) films (138,175,177–179). PBZO, the nonresonant $\chi^{(3)}$ value at 2.4 μm was reported as 8.1×10^{-12} esu and for PBZT, 6.0×10^{-12} esu (measured with third-harmonic generation (THG) spectroscopy) (173). By improving the optical quality of PBZT, a $\chi^{(3)}$ of around $3.3–4.5 \times 10^{-10}$ esu was obtained (measured in a free standing film by degenerate four-wave mixing, as given in Table 3), nearly two orders larger than the former value (154,174,175,180). It has been observed that the magnitude of $\chi^{(3)}$ is essentially the same order for PBZO and PBZT, implying that there is no effect from the heteroatom on the NLO response of the heterocyclic rigid-rod polymers (173). It has also been reported that the NLO coefficient of the *trans*-PBZT monomer is larger (1.5-fold) than that of *cis*-PBZO monomer (174,181). The theoretical calculation disclosed that the geometrical isomerism (*cis vs. trans*) is a dominant factor affecting the NLO properties of the PBX family, compared to the nature of the heteroatom (O vs. S). The fully conjugated trans-isomers provide a better medium for NLO polarization than the partially conjugated cis-isomers (181). Heldmann suggested preparing electrooptical materials of rigid-rod polymers

with rigidly attached chromophores (22). Furthermore, PBZT molecular composites [with nylon-6,6 or poly(trimethyl hexamethyl eneterephthalamide) (PTMHT)] have nearly the same nonresonant third-order NLO coefficient as that of the pure PBZT (182), and molecular composites containing PBZT exhibited an enhanced NLO property (183,184). For PBZT/nylon (Zytel 330) molecular composite, $\chi^{(3)}$ is about 1.2–2.0 $\times$ 10^{-10} esu with an optical loss α of 1.2 $\times$ 10^3 cm^{-1}, compared to the α of 4.7 $\times$ 10^3 cm^{-1} for PBZT (154,175). Martin measured the linear and electroabsorption spectra of the PBZT films spin-coated from a Lewis acid complex, indicating that at least a three-level model must be used to describe their electrooptical behavior (185). The PBZT films showed an optical anisotropy with birefringence as large as 0.5 (186,187). The anisotropy of $\chi^{(3)}$ was also observed in biaxially oriented PBZT films, yielding values from 5.4 to 7.2 $\times$ 10^{-12} esu depending on the orientation degree (172).

Optical waveguide modes at wavelengths of 633 and 1300 nm have been induced in PBZT and PBZT/Mylar films. An in-plane optical loss ($\alpha_{\parallel}$) of 6.3 dB/cm and an out-of-plane optical loss ($\alpha_{\perp}$) of 300 dB/cm (at 700 nm) were determined, which also indicated strong optical anisotropy for PBZT (188). The PBZT thin films exhibit an out-of-plane optical attenuation coefficient (α_0) of 1300 dB/cm at 600-nm wavelength, and the optical loss is mainly due to intrinsic optical absorption of the polymer (169). Optical strength tests show that PBZT has a damage threshold higher than 10 GW/cm^2 with picosecond (ps) and shorter laser pulses (154,164,172,175,189). The threshold of PBZT films reaches 50 GW/cm^2 for ps laser pulses at 1.9 μm (183,184). The bilayer assemblies, consisting of a π-conjugated rigid-rod polymer layer (polybenzobisazoles) and a triarylamine-doped polycarbonate layer, were observed to be good photoconductors (190). Because of the photoinduced electron transfer and exiplex formation occurring at the bilayer interface, the intermolecular exciplexes work as the geminate ion-pairs, resulting in the enhancement of charge photogeneration and photoconductivity (190).

Today, many new conjugated rigid-rod polymers derived from the original rigid-rod molecules also have been synthesized in order to obtain special electrooptical and NLO properties (15,191,192). By way of example, a series of poly(benzobis(imidazole))s have been prepared to investigate the effect of molecular structure on the electrooptical properties (193). By replacing the *p*-phenylene ring in PBZT with a *trans*-divinylene moiety in the polymer backbone repeat unit (PBTDV), there is a 0.4-eV decrease in optical band gap. The longer the *trans*-polyacetylene segment introduced into the PBX mainframe, the lower the optical band gap (174,194).

It is well known that the rigid-rod polymer materials have good dielectric properties. However, it is interesting that because the extended π-conjugated structure provides extensive electron delocalization, the band gap calculated for PBZT in a coplanar conformation is 1.73 eV, which is close to that of polyacetylene (195,196). Therefore, although PBZT has low conductivity (about 10^{-12} S/cm) (197), because of the increase of nonplanarity that results in a significant increase in band gap, the conductivity of electrochemically doped PBZT can reach 20 S/cm (198). Substantial efforts have been made to produce electrical conducting conjugated rigid-rod polymers, including PBZT, PBZO, and their derivatives. PBZT fibers spun from nickel phthalocyanine solutions and followed by chemical

or electrochemical doping exhibited good electrical conductivity. In this fiber, PBZT was used as a component in alloys incorporating the molecular metal nickel phthalocyanine iodide (199). Electrically conducting PBZT fibers were also made by dispersing oxidized phthalocyanines (as synthetic metal phase) into the fibers (200). The experimental results of protonation of *cis*-PBZO in methanesulfonic acid solutions showed a dependence of electrical conductivity upon the *cis*-PBZO concentration (201). Rigid-rod benzobisthiazole, benzobisoxazole, and benzobisimidazole polymers containing 2,2′-bipyridine-5,5′ diyl moieties were synthesized, and displayed thin-film electrical conductivity of around 10^{-8} – 10^{-10} S/cm in the pristine state, and 10^{-4} – 10^{-5} S/cm upon filtration with $AgNO_3$ after $Ag^+ \rightarrow Ag^0$ reduction by $NaBH_4$ (170). By incorporating electroactive triarylamino moieties with insulating rigid-rod PBZT and following with iodine activation, the conductivity of the polymer reached 4.1×10^{-4} S/cm, about 5 orders of magnitude higher than previous reports. However, the activated conductivity did not have good stability (202,203). The longitudinal dc conductivity of lithium-doped sulfonated poly((1,7-dihydrobenzo {1,2-d:4,5-d′}dimidazole-2,6-diyl)-2-(2-sulfo)-*p*-phenylene) (PBI) was measured as high as 8.3×10^{-3} S/cm, but the transverse ac conductivity was lower. The observed conductivity was mainly ionic and no electronic component was detected (202,203).

Electrically conductive PBZT–Ag nanocomposite fibers were spun by two-step methods. First, PBZT fibers were spun with conventional dry-jet wet-spinning technology. Then the wet as-spun fibers were immediately immersed into a silver nitrate aqueous solution (30–70 wt%) at room temperature to allow silver ions to diffuse into the fibers. By means of chemical, thermal, or photo reduction methods, the silver salts in the fiber could be readily reduced to silver metal. The final products (silver-infiltrated fibers) have an optimal DC conductivity of 2.5×10^4 S/cm, about 16 orders greater than that of the pristine fibers (204). Tan synthesized polymers of benzobisthiazole (Bipy-PBZT), benzobisoxazle (Bipy-PBZO), and benzobisimidazole (Bipy-PyBI) containing 2,2′-bipyridine-5,5′diyl moieties. The thin films made out of these polymers displayed an electrical conductivity of 10^{-10} – 10^{-8} in the pristine state, 10^{-5} – 10^{-4} upon infiltration with $AgNO_3$, and 25–42 S/cm after $Ag^+ \rightarrow Ag^0$ reduction by $NaBH_4$ (205). In addition, Bipy-PyBI is the first conjugated rigid-rod polymer reported of this type that exhibits lyotropic behavior without any solubilizing pendents (170).

Du reported that thin films of PBZT, PBZO, and benzimidazobenzophenanthroline (BBL) polymers in the pristine state have an electrical conductivity of about 10^{-12} S/cm at room temperature (205). After high dosage ion implantation with Kr^+ (190 keV energy and 0.12 μA/cm^2 ion flux) on the surface of these polymer films, the conductivity increased by 6–9 orders of magnitude, reaching 10^2 S/cm. Table 4 is a comparison of the electrical conductivities of the pristine films and implanted layers of rigid-rod polymers (206). The ion implantation forms a sp^2-rich and three-dimensional interconnected carbon network on the surface of the polymer films, which exhibits semimetallic behavior (205,207). Wang reported that the conductivity of N^+-implanted poly(benzazole)s is about 0.1–10 S/cm at room temperature, which is significantly higher than that of corresponding pristine polymers. Based on the studies of electron paramagnetic resonance and Raman

vibrational spectroscopy, Wang suggested that the increase in conductivity should be attributed partially to the formation of a graphite laminar structure on the surface by the ion-implantation. This mechanism is significantly different from that of the doping-induced conductivity of polymer materials (208).

Other Properties. Rigid-rod fibers are hydrolytically stable and water has no significant effects on them. In addition, they have rather low moisture retention. The retention of PBZO fibers, after boiling in water, is only 0.5%, which is less than that of PPTA (Kevlar 49) fibers even at shorter desiccation times (43). After being dried at 250–300°C in vacuum, the moisture regain of PBZT fibers is less than 1 wt%, for PBZO fibers, 0.6%, and for PIPD fibers, 2% (13). Furthermore, most solvents have no effect on rigid-rod polymers. Only a few strong protic acids, such as PPA, methanesulfonic acid (MSA), chlorosulfonic acid (CSA), trifluoroacetic acid, and 100% sulfuric acid, can dissolve PBZT and PBZO.

Studies of radiation stability show that rigid-rod fibers are ranked as one of the best to resist electron radiation (46,49). For PBZT fibers, the critical dose (Q) of 100 keV damage is 1.6 C/cm^2, which is 1000 times that for PE (0.002 C/cm^2) (209). Under UV exposure, PBZT fiber can retain its tensile strength. As demonstrated by the GM's tests, for both as-spun and HT fibers there was little or no loss in tensile strength under UV exposure. It seems that the radiation would only disorder the macromolecule packing of PBZO, PBZT, and other rigid-rod fibers, rather than bring about bond scission or reorientation, because of the weak secondary intermolecular forces and the strong highly delocalized covalent bonding along the fiber axis (45).

Morphological Structure

PBZT, PBZO, and PIPD fibers are all spun by air-gap dry-jet wet spinning technology and have a round cross section. Their typical diameter ranges from 10 to 20 μm. A significant skin–core difference has been found for PBZT and PBZO (210,211). For PBZO, the skin thickness is on a scale of 10–100 nm (210). The skin has a relatively ordered structure and high orientation compared to the core

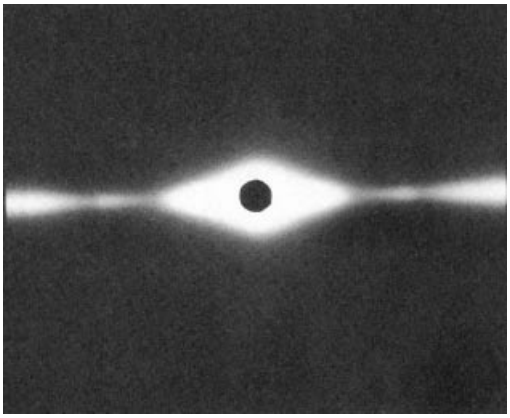

Fig. 11. SAXS photographs of PBZT fibers, showing strong equator scattering and no meridian layers. Reprinted from Ref. 34, by courtesy of Marcel Dekker, Inc.

(212,213). Heat treatment increases the crystallinity of the core (211,213). The magnitude of the skin–core differences is believed to result from the dry-jet wet spinning process involving diffusion of the solvent and fiber coagulation.

PBZT and PBZO fibers, especially the AS fibers, contain voids (44). For PBZT, the fibers spun from MSA have more pronounced voids (5–20% by volume) than fibers spun from PPA. Rates and conditions of coagulation are major factors affecting the porosity (29,44,214). After heat treatment, the SAXS of PBZT (Fig. 11) shows strong equatorial scattering, attributed either to voids elongated along the fiber or to nanofibrils. For PBZO fibers, the average diameter of the capillary-like microvoids is 2–3 nm, elongated in the fiber direction with a length of about 30 nm. Although inside the skin layer, the shape, size and frequency of microvoids are similar to those in the core of PBZO fibers, there is a void-free layer with thickness of approximately 0.2 μm in the surface region (215). Figure 12 presents the PBZO fiber structural models suggested by Martin (58) and Kitagawa (215).

A prominent structural feature found in PBZT and PBZO fibers is the oriented fibrils/nanofibrils. The Hermans–Stein orientation parameters are greater than 0.999. The axial disorder parameters are 0.53% for PBZT and 1.07% for PBZO, lower than that of Kevlar 49 fibers (1.7%) (210). However, local misorientation has been observed. Figure 13 is an image showing 3–4° misorientations between crystallites in PBZO fibers by high resolution electron microscopy (HREM) (94). The fibrils/nanofibrils are predominantly lath-shaped or ribbon-like (44,210). They are entwined and connected via Y-shaped junctions (216). It has also been reported that PBZT exhibits a lamellar appearance morphology (107). Figure 14 shows the fibril/nanofibril structure of PBZO fibers (203). For PBZT the diameter of nanofibrils is about 7–10 nm (216). The fibril dimension of PBZO is about 0.2 μm (210), and nanofibrils are of approximately 10–50 nm (210). Also, there are fibril bundles with diameters of about 5 μm. Some fibrils connect between larger fibril bundles (210). The fibrils/nanofibrils comprise discrete uniaxially oriented crystallites. It should be noted that the observed hierarchical fibril/nanofibril structures could be affected or even induced by the sample preparation techniques.

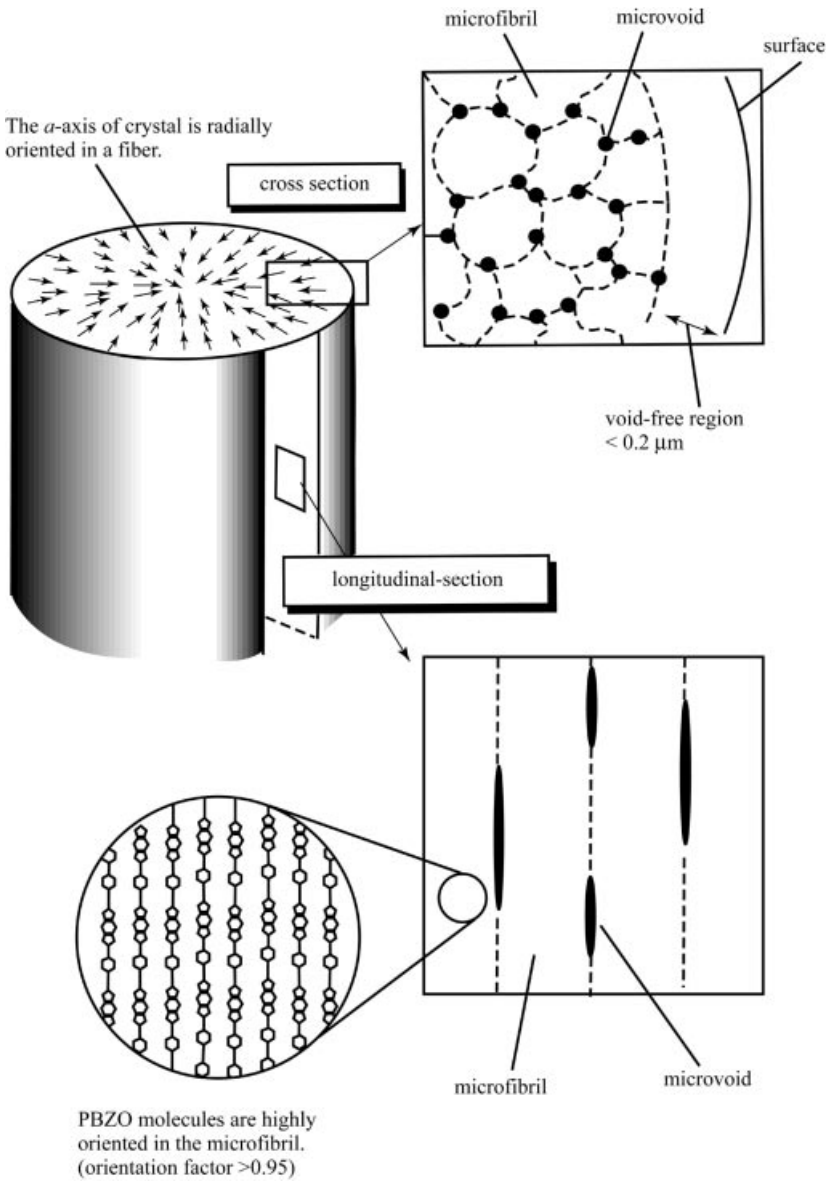

Fig. 12. (Continued).

Another unique characteristic of the rigid-rod fibers is that they are single-phase paracrystalline fibers, which is significantly different from many polymer fibers with a two-phase semicrystalline structure. Table 5 lists refined PBZT, PBZO, and PIPD crystal parameters. All of them have monoclinic crystal unit cells. For PBZT, two molecular chains pass through an oblique unit cell. Figure 15 shows the crystal structural models of PBZT suggested by Takahashi (218) and Fratini (217). In the Takahashi crystal model of PBZT, there is disorder

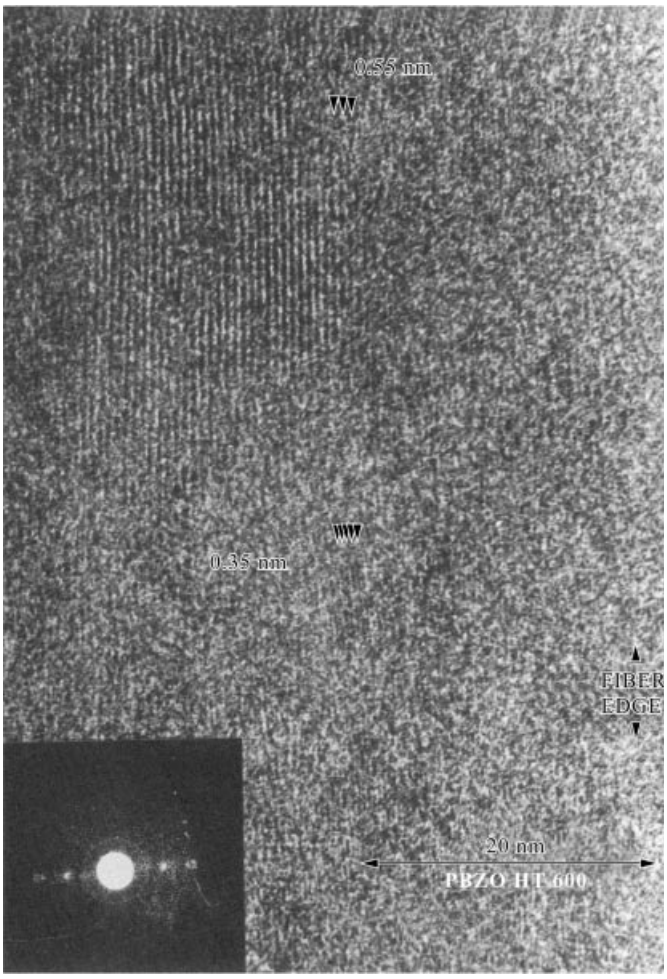

Fig. 13. HREM image of HT 600 PBZO fibers. Reprinted from Ref. 34, by permission of Marcel Dekker, Inc.

with respect to the molecular height. On the *ac* plane the molecular heights are disordered 1/2 and on the *bc* plane are disordered 1/5. Figure 16a is a PBZO crystal structure model suggested by Takahashi (225). For PBZO, two chains are packed in the unit cell and the height of PBZO molecules is disordered by a half of the fiber period, 1.205 nm. The neighboring chains are shifted by $c/4$ along the chain axis and an axial shift of chains is made by $+c/4$ or $-c/4$ randomly along the a-axis (94). Figure 16b gives the PBZO crystal structure proposed by Fratini and by Martin (96,217). In the recent report of the computer simulated modeling of the X-ray data, Tashiro and co-workers suggested that the chains form the layers extending along the (110) planes with the relative heights of neighboring chains in the sheets almost confined to either $+c/4$ or $-c/4$. These sheets are stacked together in b-axis direction with random heights along the chain axis (224).

[a]This torsion angle is close to the calculated values of 27° (219,220), 20° (217), 21° (221), 29° (222), except for 55° (223).

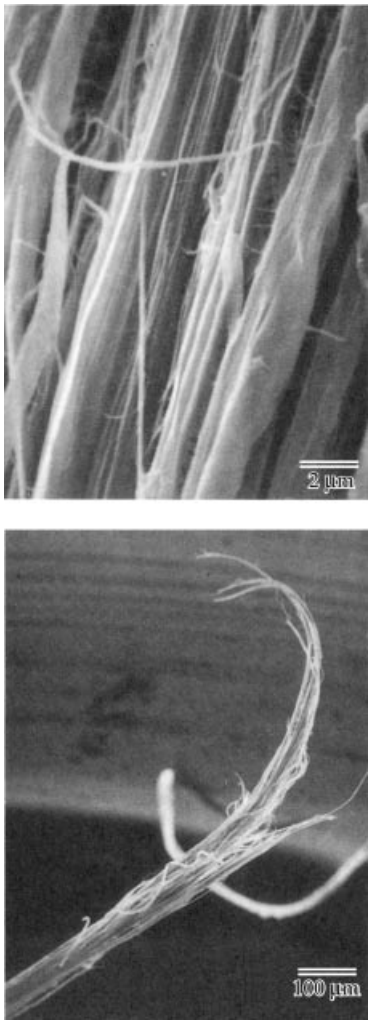

Fig. 14. Fibril/microfibril structure of PBZO fibers Reprinted from Ref. 34, by permission of Marcel Dekker, Inc.

For PIPD, two crystal unit cell models have been suggested, as shown in Figure 17 (142,144). In the monoclinic unit cell structure, the crystal lateral packing is rectangular and the cell contains two polymer chains located at its center and corners (Fig. 17a). As the *a*-axis is not perpendicular to the *c*-axis (chain direction), neighboring chains packed along the diagonals of the projection cell are shifted relative to each other in the *c*-axis direction by 0.2 nm. A distinguishing feature of the PIPD structure is that there are intramolecular (N—H···O) and intermolecular (O—H···N) hydrogen bonds. The intramolecular hydrogen bonds are located between the rigid moieties, contributing to the rigidity of the chains. The intermolecular N-H···O bonds form a bidirectional hydrogen-bonding network in which each polymer chain is linked to its four axially shifted neighbors.

Two crystal cell unit models of PBZT suggested by (**a**) Takahashi and Sul (218) (Reprinted from Ref. 218, Copyright (2000), by permission of John Wiley & Sons, Inc.); and (b) Fratini, the c-axis view of the molecular packing. The a-axis is horizontal (217). (Reprinted from Ref. 34, by permission of Marcel Dekker, Inc.).

Sheet structure may be present in a disorder model (namely a monoclinic model with sheet-like distortions), including sheets running parallel to the $(1\bar{1}0)$ but also sheets running parallel to the (110) planes (144). Computer simulation shows that for PIPD fibers, two possible crystal structures with hydrogen bonding networks may coexist: a sheet-like network for the triclinic structure and a two-dimensional network for the monoclinic structure, and there are negligible energy differences between them (142).

Benzimidazole polymers, such as PBDI, also can form a hydrogen-bonded network since they have two types of nitrogen atoms, one that is protonated as proton donors and the other that possesses the lone electron pair as proton acceptors. The variation in the strength of the hydrogen bonds in PBIs probably results in reversibility of water uptake, since some of the bonds can be more easily broken than others (226). However, PBZT and PBZO are not water-sensitive because they only have lone pair electron nitrogen atoms. In addition, the increased delocalization present in the heterocyclic rings may contribute to the lack of hydrogen bonding to water (226).

Heat-treated PBZO fibers have a three-dimensionally ordered crystal structure with limited long-range order (94,210). The structure exhibits a relatively

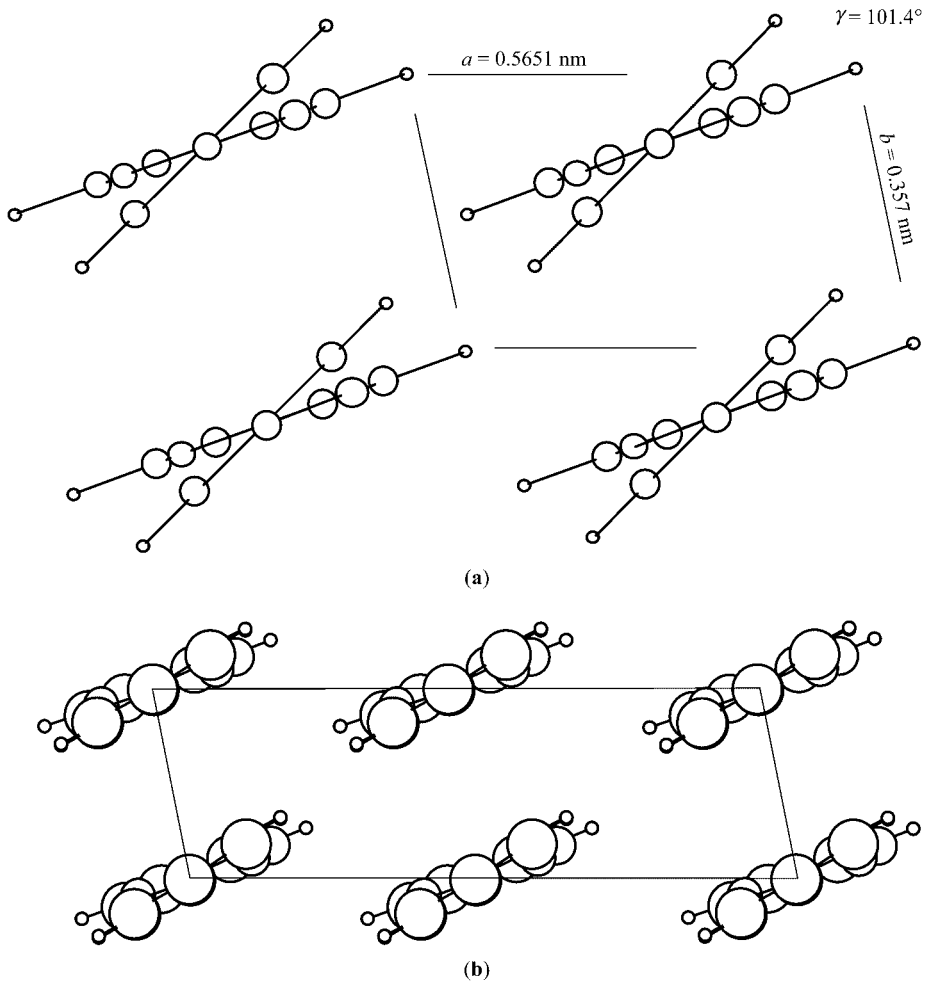

Fig. 16. Two crystal cell unit models of PBZO proposed by (**a**) Takahashi (Reprinted with permission from Ref. 225, Copyright (1999), American Chemical Society); and (**b**) Fratini (217) and Martin (96) (Reprinted from Ref. 34, by permission of Marcel Dekker, Inc.).

small crystal size of 16 nm in the longitudinal and 11 nm in the transverse directions, respectively (215). The average crystallite dimension of 15 nm (axial) $\times$ 50 nm^2 (transverse) for as-spun fibers grows to 20 nm (axial) $\times$ 150 nm^2 (transverse) for HT fibers. The planar molecules have improved registry, thus promoting three-dimensional crystallinity (210). In PBZT, the nonplanar molecules form only two-dimensional crystallites with less long-range periodicity (227) and with rather small crystal lateral size (L_a = 8.6 nm and L_b = 6 nm for HT fibers) (39). The crystallites of the as-spun fibers with a size of 3 nm^3 grow to 20 nm (axial) $\times$ 50 nm^2 (transverse) (39,210). With the synchrotron X-ray source, SAXS of as-spun PBZO fibers shows only an equatorial streak, which is generally attributed to elongated voids or fibrils. Heat-treated PBZO fibers exhibit a four-point pattern (Fig. 18) (228), which is indicative

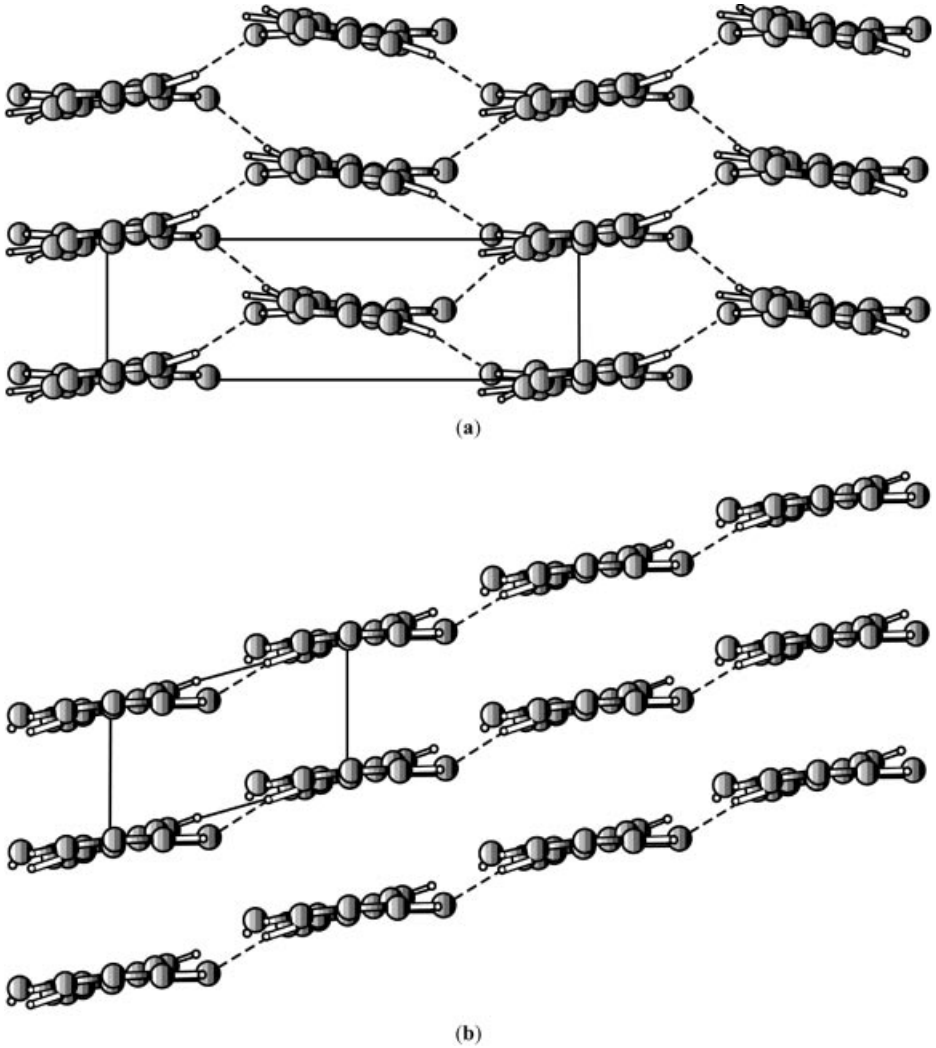

Fig. 17. Two crystal cell unit models of PIPD suggested by Klop and co-workers: (**a**) monoclinic unit cell and (**b**) triclinic unit cell. Both show the hydrogen-bonding network. Reprinted from Refs. 142 and 144, Copyright (1998, 1999 resp.), with permission from Elsevier Science.

of significant periodic density fluctuations along the fiber axis and is not seen in PBZT (Fig. 11) (94,188,210,228,229). It has been suggested that this SAXS pattern results from plate-like ordered regions with a tilt-angle from the fiber axis. For PBZT, because of the noncolinear and noncoplanar backbone, no radial 4-point pattern of SAXS has been observed (188,229). For PBZO, the long period and the radial spacing of the SAXS four-point pattern are 28 and 15 nm respectively (Fig. 18). The spacing keeps constant with varying the temperature of heat treatment. It is interesting that when the incident angle (with regard to the fiber sample) of the X-rays increases from normal (at 0°) to 30°, and then to 60° (by tilting the sample toward the beam), the four-point pattern

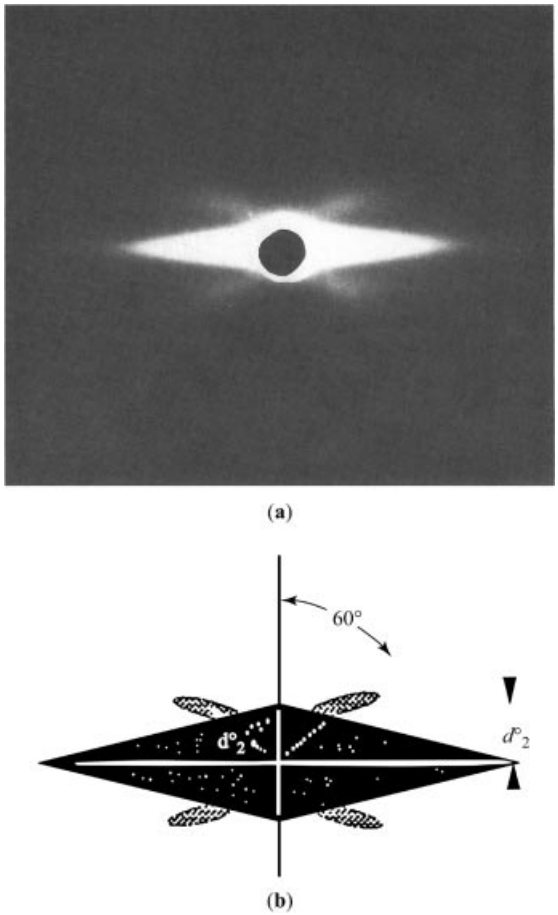

Fig. 18. SAXS pattern of PBZO (**a**) as-spun fibers, (**b**) schematic of HT fibers, exhibiting four-point scattering. Reprinted from Ref. 34, by courtesy of Marcel Dekker, Inc.

gradually changes to a two-point one (228). Figure 19 is a proposed structural model for PBZO to explain this result. In the model, crystal interfaces are at an angle to the fiber axis, giving a rhombohedral shape to the crystals (228). Also, this four-point pattern may result from arrangements of crystals that have a preferential shape. The axial grain boundaries of the crystals may have a tendency to orient at specific angles in regard to the axis. One could consider that the (302) crystal planes, working as axial grain boundaries, might serve an important function in the four-point pattern (94,96). HREM shows that PBZO fiber has large content of grain boundaries. Between adjacent crystal domains there may exist four different types of boundaries. In order of increasing energy, the four are lateral chain invariant, lateral chain rotation, axial chain invariant, and axial chain rotation (96). In addition, for PBZT and PBZO fibers containing small crystallites, there exist many structural defects such as grain boundaries between and dislocations within crystallites (94,95). Table 5 is a comparison of published crystal structural parameters of PBZT and PBZO fibers.

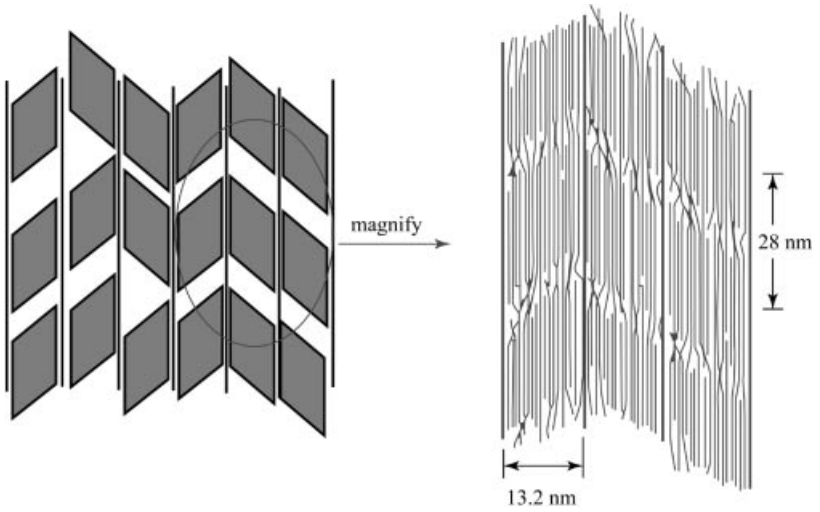

Fig. 19. Suggested structure model for PBZO Reprinted from Ref. 34, by permission of Marcel Dekker, Inc.

Lenhert first measured x-ray axial tensile modulas for PBZT and PBZO fibers with the results of 348, 395 GPa for BPZT as-spun and heat-treated fibers, and 387, 433 GPa for PBZO as-spun and heat-treated fiber, respectively (230). Recently.

Kitagawa also investigated the relation between applied stress and crystal structure of the as-spun (As-) and heat-treated (HM and HM+) PBZO (Zylon) fibers (231–234). The As-fibers have a slightly low tensile crystal modulus (430 GPa) compared to those of the HM and the HM+ (both are 460 GPa) (measured from the meridional X-ray diffraction peak of the PBZO fibers) (231–235). This difference is attributed to structure incompletion. In the rigid-rod polymer fibers, molecular ends, local molecular misorientation, and any inhomogeneities (density fluctuations) can cause the structure incompletion and the internal crystal disorder comes from the existence of density fluctuation along the fiber axis. Under extensional stress, the distribution of meridional diffraction spots becomes wider in the meridian, while the peak profile along the azimuthal direction becomes narrower. Kitagawa suggested that under the stress, the molecular orientation improvement alone should not affect interaction forces between molecules. Since the crystal size does not change but the ordering of periodicity in the crystal lattice decreases, it seems that the extensional stress affects only some local micro-region in the single-phase paracrystalline structure and crystalline disorder is increased (231–235). Davies reported that under axis extension stress, the peak of 1618 cm^{-1} Raman band broadened, which indicated that the stress and strain were distributed over the molecules (235,236).

The single crystalline structure in thin PBZT films has also been investigated (237–239). The PBZT thin films with single crystalline texture were processed from PBZT–MSA solution. In the three-dimensional oriented structure, the crystallographic c-axis is parallel to the shearing direction. The alignment of the a- and b-axes is driven by the self-assembling nature of the PBZT macromolecules

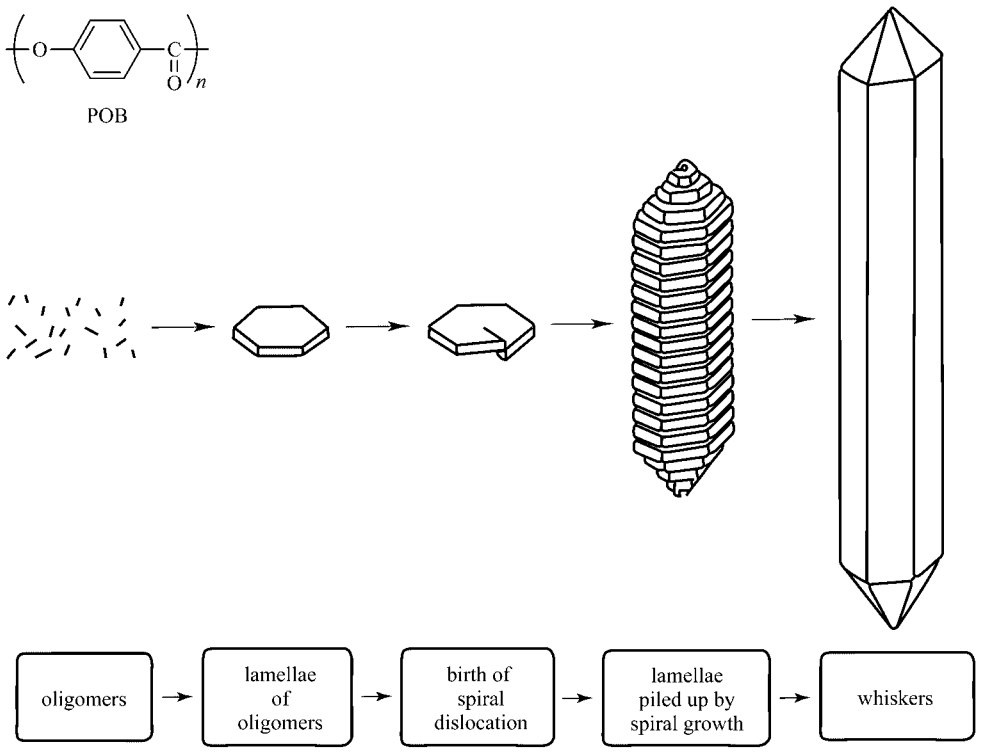

Fig. 20. A schematic diagram of the suggested POB whisker formation procedure. Reprinted from Ref. 247, Copyright (1993), with permission from Elsevier Science.

during the coagulation of the cast films, ie, the b-axis parallel to the transverse direction, and the a-axis perpendicular to the film surface (239,240).

The crystalline perfection of PIPD is similar to that of PBZO. The regular (ie nonrandom) c-axis shift of polymer chains in HT PIPD contrasts with the random $\pm c/4$ shift of polymer chains in PBZO fibers. Hence, the PIPD has a higher three-dimensional order than PBZO. This is a result of the presence of the hydrogen-bonding network, which also leads to good compressive performance (144). The crystal structure of as-spun PIPD fiber is characterized as a two-dimensionally ordered hydrate, which has a rectangular unit cell with $a = 1.685$ nm and $b = 0.338$ nm, containing planar macromolecules at its corners and center. Layers of polymer chains packed face to face are separated by layers of hydrogen-bonded water molecules. Upon heat treatment, the hydrate decomposes and the three-dimensional crystal structure develops. It is noteworthy that there exists some molecular flexibility in PIPD molecules, which is shown by the limited rotation that can exist between dihydroxyphenyl and heterocyclic moieties. The torsion angle between these two moieties may not be zero, but there is apparently some conjugation along the molecules with a closely planar conformation, because of the exhibition of metallic blue color of HT PIPD fibers (144).

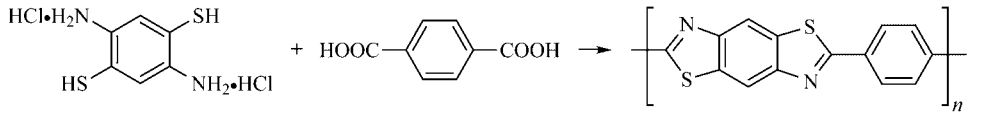
There is another way of preparing extended chain crystals from rigid-rod chain polymers by means of crystallization during polymerization. The products

of this technique are called polymer whiskers. Many aromatic polyesters, such as poly(2-oxy-6-naphthoyl), poly(4′-oxy-biphenylcarbonyl), and poly(4-mercaptobenzoyl), can be used to make whiskers by means of the solid-state polymerization of the monomers and polymerization in solution to grow the crystal whiskers (241–249). Here, poly(oxy-1,4-benzenediylcarbonyl) (POB) is used as a model compound to concisely describe the typical procedure for preparing crystalline whiskers of the infusible rigid-rod polymers (188,238). The chemical structure of POB and the growth of whiskers are shown in Figure 20 (243–249). The process of POB whisker formation can be simply divided into three steps: (*1*) oligomers with low degree of polymerization are formed in a homogeneous polymerization. As soon as the degree of polymerization reaches a critical value, oligomers will crystallize from the solution (such as paraffin) to form lamellae; (*2*) if spiral dislocations can be created in the lamellae, then (*3*) needle-like crystals would be formed with the spiral growth, because of the progress of polymerization by transesterification in the interlamellar regions (as illustrated in Fig. 20). It is interesting that the final products do not have any lamellar structure but exhibit a smooth surface.

The POB whiskers can grow to 30–70 μm in length and 1–2 μm in diameter. The crystal whiskers have an identity period of 1.254 nm, corresponding to two structural residues. The observed density is about 1.50–1.51 g/cm^3, close to the theoretical density of 1.52 g/cm^3. The whiskers show high thermal stability. At about 350°C, the POB whiskers show a reversible first-order solid–solid transition caused by the rotation of 1,4-phenylene ring (250). At about 450°C, there is another phase transition associated with the nematic mesophase (251). The 5% weight loss temperature is at around 524°C (measured by TGA at a heating rate of 10°C per minute, in air). It seems that the whiskers display higher thermal stability than other POB crystals and the transition temperature is roughly correlated with the density of the crystals (243–251). In other words, the more densely the macromolecular chains pack in the whiskers, the higher the thermal stability they have. Since these whiskers have lower density than conventional ceramic whiskers, and excellent thermal and mechanical properties, they can be used as reinforcement materials for sports goods and dental materials, as well as replacement of asbestos (243–249).

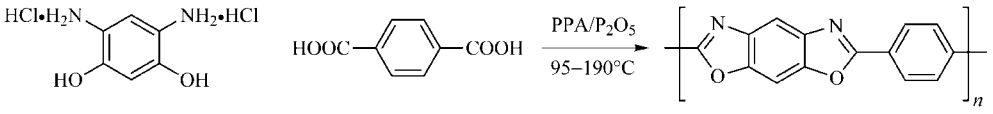
Polymerization Reactions

The morphology and properties of the rigid-rod fibers are closely related to their molecular structure and processing. It is a difficult task to produce a stiff chain polymer by connecting rigid monomer units in a linear style because of the lack of solubility in many conventional solvents and a very high melting point. The synthesis of such a polymer might appear to be a simple condensation polymerization. However, it is difficult, as the long time from scientific discovery to commercialization shows. PBZT and PBZO are prepared by the reaction of terephthalic acid (TA) (**10**) or TA derivatives in PPA with aromatic tetra-amines (252–254). Equations 1 and 2 show the simplified synthetic routes to PBZT and PBZO. The detailed polymerization mechanism has been described elsewhere (254).



11 **10** **3**

(1)

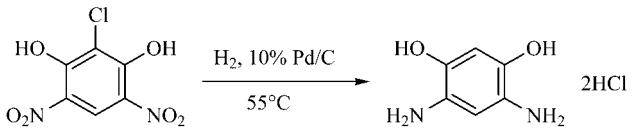


12 **10** **4**

(2)

The synthesis of *trans*-PBZT involves several steps (157,255): (*1*) first, *p*-phenylene diamine (PPD) is converted into bisthiourea with ammonium thiocyanate; (*2*) this compound is cyclized with bromine and then hydrolyzed to the oxidation-susceptible monomeric potassium salt; (*3*) the salt is isolated with HCl under reducing conditions. The bis-HCl salt is easily oxidized so that it should be handled with care. (*4*) The last step is a condensation reaction of 2,5-diamino-1,4-benzenedithiol dihydrochloride (DABDT) (**11**) with TA (**10**) in PPA (eq. 1). To completely remove hydrogen chloride before adding TA, the dehydrochlorination of amino monomers is performed under reduced nitrogen pressure, at 60–80°C (6). The particle sizes of the ultrahigh purity TA should be under 10 μm in order to assure dissolution. In the reaction, PPA has several functions, working as monomer solvent, dehydrating agent, and reaction catalyst. It is favorable to dehydration of PPA and drives polycondensation to completion (256). In order to obtain high molecular weight products, P_2O_5 is added. During the reaction, the phosphorus concentration is monitored and the P_2O_5 concentration is adjusted to about 82–84% (27). In adding the solid P_2O_5, the reaction is carried out with stirring, at 90°C, to completely dissolve the solids to form the mixture of monomers, PPA, and P_2O_5. Then, the mixture is slowly heated above 150°C (generally to 190–200°C) and the reaction kept at that temperature for 8–10 h (6). For *cis*-PBZO, polymerization in PPA is in the same manner as described above, except for using 4,6-diamino-1,3-benzenediol dihydrochloride (DABDO) (**12**) instead of DABDT (257,258). The monomer (4,6-diaminoresorcinol) can be prepared by first nitrating 1,2,3-trichlorobenzene. The second step is to prepare chlorodinitroresorcinol (**13**) through a displacement reaction using sodium hydroxide, followed by reduction to cause hydrogenolysis of the 2-chlorine atom and reduction of the nitro groups from this product (31) (eq. 3). Oxygen and moisture cause a rapid monomer decomposition. Therefore, the purity of the monomers has to be greater than 98.5% to obtain high molecular weight polymers. The procedure of monomer purification has been described (27). To keep the air-sensitive amino monomers away from side reactions, the polymerization is carried out under anhydrous conditions with inert gas protection. In addition, hydrochloride salts or other protective agents are added (6). At conversions of the reaction (eq. 2) in excess of 95%, there is a distinct decrease in the apparent polymerization rate, and the molecular weight distribution tends to broaden with increasing degree of

polymerization but the ratio of M_w/M_n never exceeds 1.8 (259,260). Furthermore, in order to control the molecular weight to the desired range, a monofunctional carboxylic acid (or its equivalent) is added to the polymerization reaction (256). During the reaction, the phosphorus concentration is adjusted so that the final P_2O_5 concentration is around 83% (25).



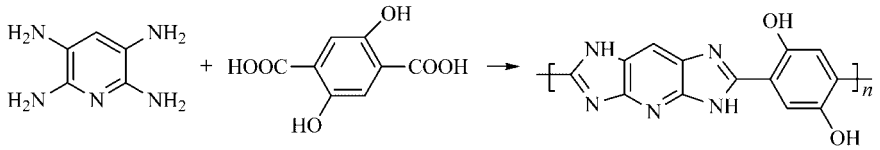
13 **12** (3)

Wolfe suggested that formation of the nematic liquid crystalline phase would increase the rate of polymerization as well as the molar mass of the final products (261). The reason is that ordering the molecules in the nematic domains increases the probability of making the reactive ends of oligomers align together thereby facilitating the reactivity. Ledbetter suggested that increasing shear on the system would also enhance the reactivity (31). The detailed polymerization mechanisms of PBZT and PBZO have been published elsewhere (113).

It has been reported that an alternate way to make the "PBX family" is by polymerizing dinitro difunctional nucleophilic monomers with terephthaloyl chloride, then reducing the nitro groups and cyclizing (262). The benefit of this is the improved oxidative stability of the dinitro monomers, but the disadvantage is the low conversion rate in reduction and cyclization. Recently, Likhatchev suggested a low temperature synthetic route for preparation of ladder poly(aroylenebenzimidazole)s (263). Hattori also reported a new two-step reaction to produce PBZT (264,265).

For PIPD, the synthetic route is different. The first step is to synthesize 2,6-diamino-3,5-dinitropyridine (DADNP) from the nitration of 2,6-diaminopyridine (DAP). With modification of the nitration medium (changing from concentrated sulfuric acid to oleum), degradation during the nitration reaction is stopped (13). Then, through the reduction of DADNP in phosphoric acid under the nitrogen and hydrogen atmosphere, more than 80% of polymer-grade crystals of 2,3,5,6-tetraaminopyridine·3HCl·1H_2O (TAP·3HCl·1H_2O) are prepared. Secondly, more than 90% polymer-grade 2,5-dihydroxyterephthalic acid (DHTA) can be produced by acid-mediated aromatization (in acetic acid refluxing with 30% aqueous H_2O_2 with a sodium iodide catalyst) of diethyl succinoylsuccinate followed by hydrolysis (13,266). Equation 4 is a simple schematic diagram of the synthesis of PIPD monomer and polymerization. Polymerization of the TAP (**14**) and DHTA (**15**) (1:1) complex or TD salt (2,3,5,6-tetraaminopyridinium 2,5-dihydroxyterephthalate) yields high quality PIPD polymers. The important improvement here is to use TAP phosphate (instead of its HCl salt), resulting in a much faster polymerization and eliminating corrosion during processing (13). Compared with PIPD, benzimidazole polymers, especially poly(*p*-phenylene benzobismidazole) (PBDI), are very hard to synthesize to high molecular weight (MW), because their low MW oligomers tend to crystallize out of PPA solution before the condensation polymerization is far advanced. This is due to preferential formation

of a stable hydrogen-bonded network in the presence of the excess water of condensation and this hydrogen network is more energetically favorable than the fully protonated molecular species dissolved in the solvent (226). Contrarily, PIPD can attain high MW via the formation of the TAP·DHTA (1:1) complex, the TD salt, which affords a fast polymerization cycle and eliminates low MW polymer that results when amine is polymerized with acid in PPA medium (13,226). By this route, high molecular weight PIPD polymers can be prepared in a routine of 4–5 h polymerization, with the relative viscosities of the products (0.25g/dL in MSA) greater than 20, even reaching as high as 300 (13).



14 15 (4)

Lyotropic Liquid Crystal Polymer Solutions

It is well known that fibers spun from a lyotropic liquid crystal polymer solution can have good mechanical properties. In 1956, Flory predicted that liquid crystals would be readily formed from a rigid polymer solution at a critical concentration (267). The formation of the liquid crystal solution is dependent upon the solvent, temperature, molar mass, molecular length-to-diameter ratio, and especially, the macromolecular structure, which must be sufficiently rigid. For rigid-rod polymers, by using a suitable solvent, liquid crystals can be obtained, whereas their stiffness does not allow thermally induced liquid crystallinity (thermotropism) below their degradation temperature. However, because of their poor solubility in common solvents compared with flexible polymers, dissolution often requires using aggressive, strong protonating acids, which provide specific interactions (enthalpy), since the entropy change is small (268). Owing to the aromatic and heterocyclic molecular structure, for PBZT and PBZO, the rotation of bonds between the alternating phenylene and heterocyclic groups offers conformational flexibility to some extent. The nearly 180° catenation angle (between the two exocyclic bonds) in the repeat units leads to the overall conformation, which is nearly unaffected by the rotational conformation of the monomeric units. Also, the rotation can be confined by the interaction between the macromolecules. Therefore, they are highly rigid and, as described above, are able to form nematic liquid crystalline solution only in strong protonating acids, such as PPA, MSA, CSA, TFA, and 100% sulfuric acid (259,269,270).

The persistence length of molecules in solution is commonly defined as the average projection of the end-to-end distance of an infinite chain in the direction of the first link. It can be taken as a useful measure of their straightness and rigidity. Generally, the longer the persistence length, the lower the concentration needed for a polymer to form a liquid crystal (271,272). Table 6 lists the persistence lengths of PBZT, PBZO, and a few other polymers. Measured data for PBZT and PBZO agree qualitatively with calculations from molecular dynamics

Table 6. Measured Persistence Length for Various Polymers

Polymer	Experimental persistence length, nm
trans-PBZT	>50 (273)
cis-PBZO	>64 (224,274)
	10–117.5 (224)
PPTA	43.5 (275)
PBA	20–40 (276,277)
	41 (275)
X-500 (poly(amide hydrazide))	20–40 (276,277)
	7.5 (225)
Cellulose	4.2 (278)
PE	0.575 (275)

simulations (161,279). Such results can be subject to uncertainties arising from questions concerning the force fields and sampling all of phase space. Also, there is significant uncertainty in the persistence length measurement for rigid-rod polymers because of difficulty in finding suitable solvents. Another problem is that solvents and salts may change the conformation of the molecules, and thus the molecular rigidity (271,272,280,281). Furthermore, the salts may also change the phase diagram of the rigid-rod polymers. Therefore, the data in Table 6 should be used for relative comparison only.

In recent decades, the properties and structure of rigid-rod polymer concentrated solutions and their liquid-crystal phase formation have been extensively studied (157,259,282–284). To form a liquid crystal phase in MSA for ABPBT, ABPBO, PBZT, and PBZO, the solution concentration should be in the ranges of 13–21%, 15–18%, 5–18%, and 5–14%, respectively. Compared to PBZT and PBZO, the concentration ranges of ABPBT and ABPBO are narrower and higher (261,285). As shown in the phase diagram of the PBZO–H_2SO_4 system (Fig. 21) (286), upon adding the rigid-rod polymer, the viscosity increases but the solution remains isotropic and visually clear. With increasing polymer concentration, the rod-like molecules tend to cluster in bundles of quasi-parallel rods to form "domains." These domains are anisotropic and within them the rods form nematic order. However, there is little, if any, directional correlation among these domains. At this stage, the viscosity keeps increasing with concentration although the solution gradually changes from a single phase to biphasic. At the critical concentration, the solution becomes anisotropic and visually opaque. With further increase in polymer concentration, the viscosity drops sharply. This decrease is the result of the formation of monophase-oriented liquid crystal domains in which the chains align parallel to the flow direction, thus reducing the friction between the neighboring molecules. Temperature and solvent selection have significant effect on the critical concentration. Also it is a function of molar mass and the length-to-diameter ratio. With increasing molar mass and the length-to-diameter ratio of the polymer, the critical concentration tends to decrease. The solution viscosity also depends upon the alignment of the polymer molecules. Thus, external force fields, such as flow, electric, and magnetic fields, which affect the orientation, will influence the viscosity (5,271,272,282,287–290).

For rigid-rod polymers, the relation between intrinsic viscosity and molecular weight is (291):

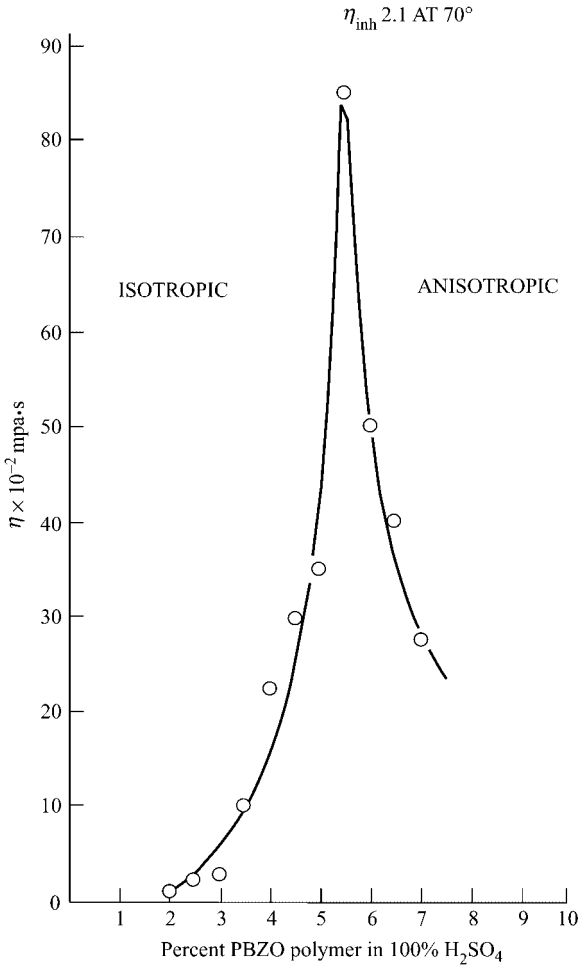


Fig. 21. A typical critical concentration curve for the rigid-rod polymers (PBZO) ($[\eta_{inh}]$: 2.1 dL/g) in 100% H_2SO_4 at 70°C (mPa·s = cP).

$$[\eta] = 5.81 \times 10^{20} \times (d_H)^{0.2} \times (M_n)^{1.8} / (M_1)^2 \quad (5)$$

where $[\eta]$ is intrinsic viscosity, d_H is hydrodynamic diameter of chain element, M_n is molecular weight, and M_1 is the mass per unit length (for PBZT, 2.15×10^9 Da/cm, and for PBZO, 1.83×10^9 Da/cm). A value of 4.86 instead of 5.81 also has been reported (259,261). If d_H is 10^{-7} cm (1 nm), the Mark–Houwink equations in MSA are

$$\text{for } \textit{trans}\text{-PBZT}, [\eta] = 1.65 \times 10^{-7} \times (M_w)^{1.8} \quad (6)$$

$$\text{for } \textit{cis}\text{-PBZO}, [\eta] = 2.77 \times 10^{-7} \times (M_w)^{1.8} \quad (7)$$

Figure 22 is the bilogarithmic plot of $[\eta]$ vs. M_w for PBZT–MSA solution (292). The slope, 1.8, agrees with equation 6. Viscosity measurements of low molecular

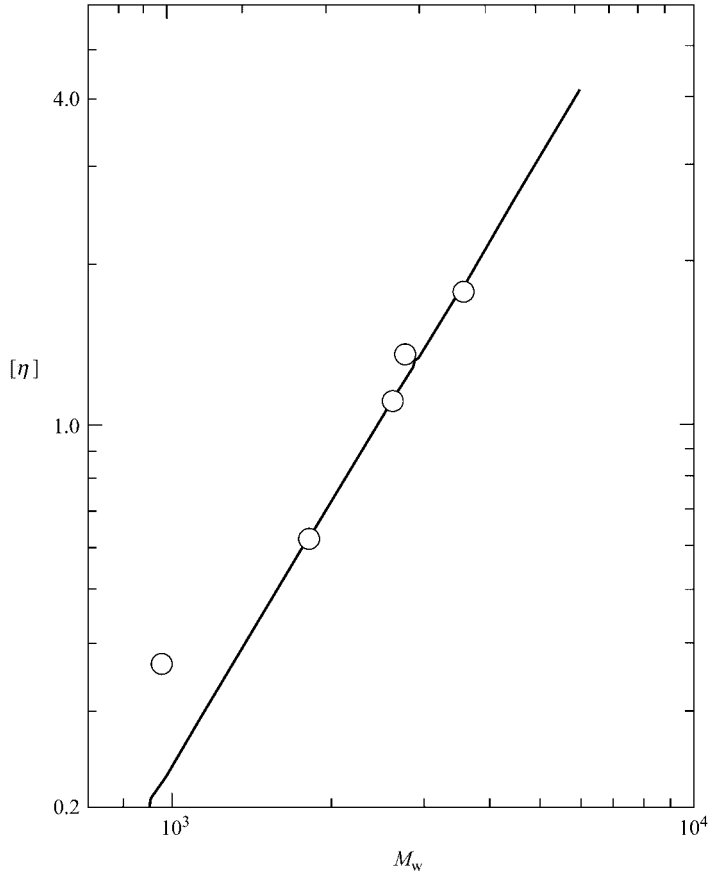

Fig. 22. Bilogarithmic plot of $[\eta]$ vs. M_w for PBZT–MSA solution. Reprinted from Ref. 34, by permission of Marcel Dekker, Inc.

weight PBZO solution in chlorosulfonic acid yield a Mark–Houwink exponent of 1.85 (292). The high Mark–Houwink exponents and persistence lengths both indicate high rigidity. Kwei (293) recently reported that for rigid-rod polymer solutions, in the general expression of the relation between specific viscosity η_{sp}, concentration C, and intrinsic viscosity $[\eta]$

$$\eta_{sp} = C[\eta]\left(1 + k_1 C[\eta] + k_2 (C[\eta])^2 + k_3 (C[\eta])^3 + \cdots\right) \tag{8}$$

the experimental k_1 value is approximately 0.5, which is lower than the theoretical estimation, 0.73–0.77 (294,295). It is possible that the long-range hydrodynamic interaction leads to a higher theoretical value (293).

The rigid-rod model based on the Smoluchowski equation has been proven successful in predicting the rheological behavior of rigid-rod polymers in the nematic phase (259,273,281,293,296–301). The flow birefringence technique has been used to characterize molecular weight, intrinsic viscosity, and optical anisotropy of different rigid-rod polymer solutions (274–276). Based on the rheo-optical flow birefringence data, the Doi–Edwards scaling law, $D_r \propto c^{-2}$ (where

D_r is a concentration-dependent rotational diffusion coefficient and c, the number concentration), holds only at very high concentrations (when $cL^3 > 150$, where L is the length of the rigid rod) for rigid-rod polymer solution. In semidilute solutions (when $cL^2d > 1$, where d is the diameter of the rigid rod), a modified Fixman model can be used to explain the temperature and concentration dependence of the rotational diffusivity (277). For PBZT and PBO, effects resulting from electrostatic interactions and molecular rheology have been studied actively (278,292,302–305). A dilute solution of these rigid-rod polymers in a low ionic strength acid shows high viscosity and small transitional diffusion. These behaviors could be attributed to a pseudo ordering of the solvent introduced by electrostatic repulsion between the protonated macromolecules. For PBZT–MSA, upon flow reversal, at low concentration and shear rate, the shear stress vs. strain shows no overshoot and a positive first normal stress transient. At high concentration and shear rate, damped oscillation in the shear stress (and a negative transient) is followed by oscillations in the first normal stress coefficient. The threshold shear rate dividing response to the flow corresponds to the onset of shear-induced variation in the polydomain texture (258). For PBZT–PPA, the oscillation in shear stress upon flow reversal and step shear persists for long times with very little damping (258). It appears that for PBZT liquid crystalline systems, anisotropic phase transient flow response is closely related to the selected solvent, rod concentration, flow-induced texture, and shear rates (258). With increasing temperature, in the concentrated PBZO– and PBZT–PPA solutions, the viscosity shows an asymmetric "V-shape" change. At high temperature, the viscosity increases markedly and the rigid-rod polymer crystallizes out of solution. This phase separation occurs near or above 230°C. It is argued that this effect is reversible, due to phase separation, not to an anisotropic-to-isotropic transition (306). In multielement systems (such as PBZT/nylon/MSA) the interaction between the rigid rod and coil molecules has a great influence on phase behavior of the systems (307–309). In addition, Fischer observed the belt-structure of PBZT liquid crystals with atomic force microscopy (310). Ding and Wu also studied the formation, transition, and texture of the liquid crystal phase of PBZT (311–313).

WAXD has been used to study the crystal solvate phase in PBZT–PPA and PBZO–PPA solutions (314–317). Upon exposure to moisture, several phases emerge in the liquid crystalline solutions, delineated as crystal solvate phases form I and form II, and the polymer crystalline phase. Form I is observed at low moisture level and ambient temperature. It may be a complex formed by the protonated macromolecules and solvent anions. This form has a three-dimensional structure and melts at around 70°C, a reversible transition. Form II is a crystalline phase observed at higher moisture content. Its behavior is different from that of form I. With increasing temperature, a gradual transition from form II to the crystalline polymer occurs in the temperature range of 250–300°C. This change is irreversible. At about 250°C, a new recrystallization occurs and the crystal spacing is close to that found in the crystalline polymer. In addition, for PBZO–PPA, form II still is a three-dimensional structure, but for PBZT–PPA, it lacks a distinct crystalline order (315–317). It was suggested that the form II of PBZT–PPA is composed of PBZT, PPA, and H_2O molecules with a range of compositions (316,318). During the transformation from form I to form II, thin nanofibrils with width less than 10 nm were formed. The results also indicated that no solvate

structures were formed during spinning and thermally induced crystal solvates which form in PBZO–PPA were not induced by extrusion. On the basis of study of the spinning extrudate and of the crystal solvates, it may be concluded that for rigid-rod fibers, the nanofibrillar/fibrillar morphology is probably determined by structures existing in the liquid crystalline spinning solution (extrudate) before fiber coagulation (316,319–322).

As to rigid-rod polymers, the properties of their dilute solutions have also been extensively studied (259,323,324). For the isotropic PBZT–MSA solution (2.5–8 wt% of PBZT, temperature from 0 to 100°C), the transient behavior from anisotropic to isotropic is qualitatively similar to that of flexible polymers (325). From the PBZT–MSA solution (3%), spherulites and co-crystals could be formed (326). Further, for PBZT–H_2SO_4 dilute solution (0.02–0.1 wt% of PBZT in 86.5–97.0 wt% H_2SO_4), quenching forms fibrillar crystals with the polymer chains parallel to the fibril direction. In addition, heat treatment of the solution can change the fibrils to shish-kebab structure. However, isothermal crystallization forms rod-like crystals (at 85–110°C). Usually the crystals are the same length and from 5 to 20 rod-like crystals align parallel to each other to form groups. Here, the polymer molecules are perpendicular to the rod-like crystals and the width of the crystals is related to the average molecular length, especially for the low molecular weight polymers (327). Shimamura reported that lath-shaped lamella crystals can form in dilute PBZO-concentrated H_2SO_4 solution. Decreasing the crystallization temperature or increasing the chain length changes the crystallites to flat fibrils (328,329).

Rigid-rod polymer–Lewis acid complexes, made by dissolving the polymer in an aprotic polar solvent such as nitromethane containing $AlCl_3$, BCl_3, or $GaCl_3$, have been studied to find new solvents and to improve processability of the rigid-rod polymers. PBZT was taken as a model compound to study this method (128,330–336). The Lewis acid, such as $AlCl_3$ or $GaCl_3$, must be in high molar ratio to obtain a relatively stable complex solution. Such a solution is suitable for film casting, and possibly fiber spinning. However, instability of the PBZT–Lewis acid complex in air is a problem for large-scale processing (335). In addition, Lewis acid coordination complexes of rigid-rod polymers have been used for a variety of applications including nonlinear optical materials (337). In order to increase the thermal plasticity of PBZX compounds in ordinary organic solvents, Reinhardt and others added fluoro-containing groups into the main chains (338–342). It has also been reported that the synthesis of PBZT with sulfur-groups leads to a new group of polyelectrolytes and an improvement of rigid-rod polymer film flexibility (343,344).

Fiber Spinning Process

By using high molecular weight polymers to form liquid crystal spinning solutions, combined with an optimal dry-jet wet spinning process and tension-heat-treatment, high quality rigid-rod polymer fibers can be produced. It has been observed that commonly, the higher the molecular weight of PBZO (with higher intrinsic viscosity (IV) of the spinning dope), the better the fiber mechanical properties, especially tensile strength. As shown in Figure 23, the fiber

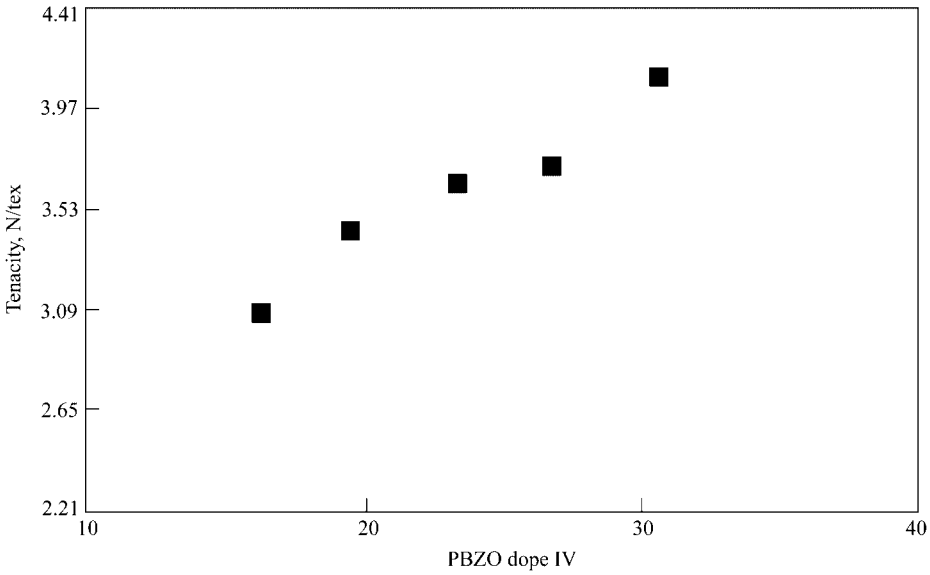

Fig. 23. Effect of dope IV (dL/g) on fiber tenacity (N/tex) of PBZO fibers. The unit conversion of fiber tenacity 1 N/tex = 0.102 kg/tex = 11.3 g/d, and the fiber tensile strength in pascal (SI unit) can be obtained as 1 N/tex = $\rho \times 10^9$ Pa = $\rho \times 1$ GPa, where ρ is the fiber density in g/cm^3. Reprinted from Ref. 34, by courtesy of Marcel Dekker, Inc.

tenacity is improved with the increase of IV (27). However, it is worth noticing that for rigid-rod fiber spinning, a single viscosity coefficient is not sufficient to completely describe the rheology of the dope solution. Because of the complicated rheological behavior of the liquid crystal solutions, there still exist some questions that haven't been answered well (272).

As mentioned above, PBZT and PBZO can be dissolved in only a few solvents. In general, PPA is chosen as the solvent for polymerization and to prepare the liquid-crystal spinning dope. There are several other solvents, such as MSA, 97.5% MSA/2.5% CSA, and 100% H_2SO_4, which can also be used (259,278). The polymer–PPA solutions offer several significant advantages over the solutions from other solvents (35,36): (*1*) Great improvement in process simplicity. After polymerization in PPA, PBZT–PPA or PBZO–PPA solution can be directly used as spinning solution. Therefore, the processes of separating the polymer from its polymerization solvent and then redissolving it into its spinning solvent were eliminated (345). (*2*) With PPA, the spinning dope can have higher viscosity, better spinnability, and higher draw-ratios. Therefore the fibers can have superior properties (35,36,286). In addition, compared to the fibers produced with PBZT–MSA spinning-solution, the fibers made from PBZT–PPA dope have fewer large voids (346).

The polymer concentration in a spinning dope is normally maintained within a factor of 2–3 of the concentration corresponding to the isotropic–anisotropic transition (347). For example, the transition from isotropic to anisotropic solution polymerization of PBZT occurs at 5 wt% (348) so that the polymer concentration in the spinning dope is about 10–15% (29,31). Generally, for both PBZT and PBZO

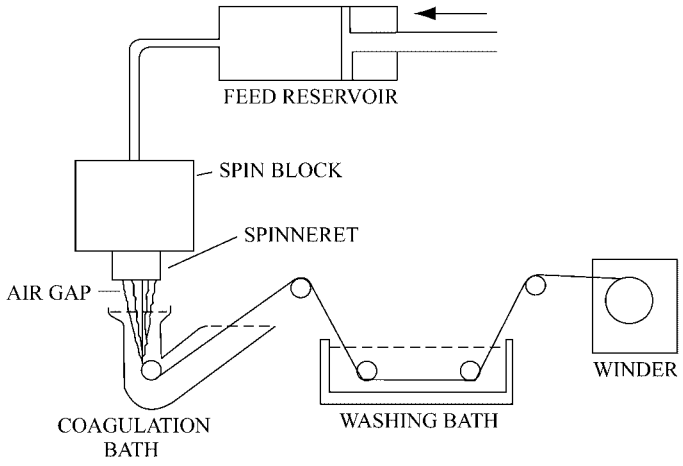

Fig. 24. A schematic chart of dry-jet wet spinning.

in PPA or MSA, 13–15% concentration polymer solutions with M_w over 10,000 are selected to prepare the spinning dopes (258,349).

It has been amply demonstrated that for lyotropic rigid-rod polymer solutions, the dry-jet wet spinning process can produce excellent fibers (29,35,36,44, 286,350). As schematically shown in Figure 24, this technique involves several steps: (*1*) the extrusion of a liquid crystal spinning solution under heat and pressure; (*2*) after passing the spinneret, the stream of the spinning solution goes through an air (or inert gases) gap into a coagulation bath; (*3*) this is followed by the processes of washing, drying, and tensioned heat treatment. The dry-jet wet spinning technique shows several advantages over a conventional wet spinning process: (*1*) owing to the use of a gap, a dope with a considerably higher temperature can be used to extrude the solution into a cold coagulation bath. Normally, the more concentrated the dope, and the higher the molecular weight of the polymer, the higher the achievable spinning rate, which leads to improved fiber mechanical properties and productivity. (*2*) The gap provides a region for extensional flow of the liquid crystalline solution, which allows a higher spin draw ratio (SDR, defined as the ratio of the take-up speed of the fiber to the extrusion speed of the spinning solution), which promotes higher molecular orientation. (*3*) Because of the travel in the air gap, a very thin sheath can be formed on the surface of the spinning solution (and newly formed fiber). Then in the coagulation bath, this sheath has the function of affecting (decelerating) the precipitant diffusion into the fiber, which results in good fiber quality. (*4*) This technique can facilitate a higher output per spinneret (in other words, more spinning dope can be extruded through a spinneret in a given period).

For these fiber-spinning systems, increasing the extrusion rate has only a limited effect upon the molecular orientation. Under constant draw ratio, the orientation parameter has little to do with the capillary die shear rate over the range of 25–5000 s^{-1} (119,319–321). However, the SDR has a significant effect on crystal size and molecular orientation. For PBZO, increasing the SDR increases the axial coherence length and decreases the lateral coherence length. The Hermans–Stein

orientation parameter of the as-spun fibers in the drawing zone increases from 0.9 at an SDR of 3 to 0.95 at an SDR of 20, and then levels off with further increase in SDR (321,349). It has been suggested, after SDR above 10, to adopt an affine deformation model to describe the spin-draw behavior for the PBZO–PPA system (319–321,351). Generally, for PBZT fiber spinning, an SDR greater than 3 is chosen. The commonly used spinning speed ranges from hundreds to thousands of meters per minute.

Several different coagulants, such as cool water, dilute PPA, methanol, and NH_4OH, have been studied for PBX fibers (352). During coagulation, the acid solvent diffuses out of the fiber such that initially about 90% of the solvent is removed (353). At the same time, the highly oriented crystallites in the as-spun fibers are fixed into the fibril/nanofibril network. This network constitutes the basic structure of the final products (47,354). The composition, pH, and temperature are three important parameters of the coagulation bath, which can influence the final structure and properties of the fibers. Generally, slower coagulation rates result in higher tensile strength and modulus, because the slow coagulation assists the formation of co-crystals of the polymer and solvent (216). A low nucleation density of crystal solvates leads to a lamellar structure but a high nucleation density tends to form nanofibrillar structure (47). It has been observed that by changing the composition of the coagulation bath, for example by using iodine/ethanol solution, a measurable variation in PBZT fiber structure and properties results (216,355).

For rigid-rod polymer fibers, the formation process is rather complicated because of the mixing of chemical reactions and physical variations by altering the processing parameters, such as forced external fields (stress and temperature). For example, both chemical quench and thermal quench during the process can change the material concentration and orientation. Owing to the complexity of the process, there exist different arguments about the fiber formation mechanisms. For instance, by means of a TEM study on PBZT fibers, it was proposed that one-dimensional nucleation and growth via axial diffusion during the process should be the mechanism for microstructure formation (356). However, it was argued that this hypothesis could not explain the formation of axial periodicity (10–35 nm). A spinodal decomposition-based clustering model of concentration and orientation rearrangement of macromolecular rods within a transient network has been proposed as the mechanism responsible for the formation of fibrils/nanofibrils, microvoids, and the periodicity (347). In the near future, with the progress in science and technology, as real time *in situ* experimental data become available, new mechanism models and/or modified existing concepts will gradually merge. For example, ribbons recently have been spun through a slit die and coagulated by drastically different conditions in an attempt to elucidate the mechanism by which the nanofibrils are formed (357).

Because of their excellent thermal stability, the subsequent heat treatment of rigid-rod fibers can be run in a wide temperature range. The HT temperature is chosen around 500–700°C and the HT residence time is from a few seconds to several minutes. It has been found that the HT time is closely associated with the HT temperature, and the optimum HT time should be inversly related to the employed temperature (31,358). Tension is necessary for the heat treatment to improve the fiber properties. With tension, during heat treatment chain orientation can be greatly improved, resulting in an increase in tensile properties, especially

Table 7. Changes in Structural and Property Prameters of PBZO Fibers through Heat Treatment at 600°C[a]

Structural or Property Parameters	As-spun PBZO	Heat-treated PBZO
Average lateral crystallite size, nm	7.5	12.6
Average axial crystallite size, nm	16	22
Misorientational angle, deg	6	4
Tensile modulus, GPa[b]	165	317
Tensile strength, GPa[b]	4.3	4.9
Breaking elongation, %	2.8–3.5	1.5–1.7
Density, g/cm^3	1.56	1.56–1.58
Equilibrium moisture, % (at 22°C, 65% RH)	2	<0.5

for modulus (329). For PBZT, the fibers pass through an oven at a temperature of 550–650°C with resident time of 10–30 s, and tension of 140–410 MPa (44) in nitrogen (or air) atmosphere, and for PBZO fibers, 580°C, 10 s, and 480 MPa (69,600 psi) tension in nitrogen (27).

After the tensioned heat-treatment, the fibers have a significant improvement in overall axial orientation, crystal perfection, lateral order, as well as a decreased void content (359). Therefore, fiber tensile modulus has greatly increased, and fiber tensile strength, moderately increased. Taking PBZO as an example, Table 7 lists all these improvements through the tensioned fiber heat treatment: orientation (determined by X-ray azimuthal scans of the equatorial reflections), axial and lateral crystallite sizes (calculated from the equatorial diffraction peaks), tensile strength and modulus (94,210,229). Alternatively it was reported that the heat-treatment temperature has a great influence on the tensile strength but limited effect on the tensile modulus (28). As shown in Figure 25, with the increase in the temperature up to 700°C, the tensile strength is improved, but the modulus remains nearly constant. This could be due to the substantial enhancement of molecular lateral order. However, the applied stress during heat treatment affects both fiber tensile strength and modulus. Figure 26 shows that with the increase of applied stress, tensile strength and modulus both increase (28). Based on these facts, it was suggested that during heat treatment, the development of fiber tensile strength and modulus seems not directly dependent upon the processing parameters, but rather indirectly through the improvement of overall molecular orientation and chain lateral order (28,44).

PIPD and many other lyotropic polymers have also been spun by the dry-jet wet spinning technique (13,46,143,229). The spinning process is similar to that for PBZT and PBZO. The as-polymerized PIPD solution can be directly used to spin the fibers. The molecular weight of PIPD polymers is controlled in the range of 60–150 K. The spinning dope is maintained above 160°C (at 180°C, normally) with a concentration of 18 wt%. The spin-draw ratio can be adjusted from 5 to 15 in accordance with the selection of the spinning orifice diameter in order to manufacture fibers with a diameter in the range of 8–14 μm. Water or dilute phosphoric acid at room temperature is selected as the coagulation bath. After coagulation, the as-spun fibers are fully washed to remove the residual PPA, and

dried at a mild temperature. Subsequently the tension-heat treatment is carried out at a temperature over 400°C for about 20 s in nitrogen atmosphere to produce the final PIPD fiber (13,143,144).

Rigid-rod polymer films, including PBZT and PBZO, have also been produced from their solutions for various applications (114,156,345). Furthermore, scientists have been working to lower the melting points of rigid-rod polymers to enable new melt-spinning processes. Generally, the following approaches exist to lower the melting points: (*1*) appending flexible side-chain groups to the stiff main chains; (*2*) inserting flexible comonomer units into the stiff backbones; (*3*) inclusion of bent units of different sizes. Recently the preparation of new thermotropic liquid crystalline polymer fibers from rigid-rod polymers has been reported (248,360). A transition from solid phase to anisotropic melt phase in the temperature range of 280–450°C has been reported for the thermotropic PBZT with long alkyloxy side chains (C_n-PBZT). Longer side chains give lower transition temperatures. However, these polymers are not stable at high temperatures so that melt processing could not be investigated (248,360). A solid-state coagulation process was suggested to make high quality rigid-rod optical films (361). In this process, the rigid-rod polymer solution is rapidly frozen into a solid mixture and then is coagulated at a cryogenic temperature with a proper coagulate to extract the frozen solvent. PBZT thin films made by this technique had an optical attenuation coefficient (over 250–2500 nm range) of about 1300 dB/cm, significantly lower than

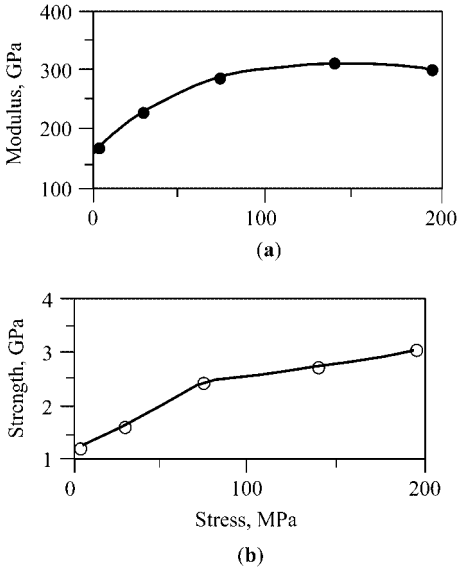

Fig. 26. Effect of applied stress during heat treatment on tensile properties of PBZT fibers: (**a**) tensile modulus, (**b**) tensile strength. To convert GPa to psi, multiply by 145,000. Reprinted from Ref. 34, by permission of Marcel Dekker, Inc.

that (4300 dB/cm) of the thin films prepared by conventional solution coagulation process. The reason for this improvement is that optically isotropic PBZT solution is first frozen into a transparent solid mixture to preserve the molecular dispersion of the polymer in the solvent. Then the solvent is extracted from the frozen mixture without disrupting the molecular distribution of the polymer, and phase aggregation in the final films is minimized (361).

Computer Simulation

Whether from either a practical purpose or from a theoretical viewpoint, it is useful to understand the molecular structure, its geometry, and the properties of a material. In the recent two decades, with the rapid progress in computer techniques, computer modeling has been systematically applied to test theories and to estimate the optimal properties for rigid-rod polymers (362,363). For estimation of the elastic properties of solid materials, computer modeling began by using empirical values for the forces between atoms, not values derived from quantum mechanics. One of the most common methods for calculating material elastic constants is molecular dynamics with the empirical valence field method, which is based on experimental data. Today, advances in computational materials science allow us to choose more accurate calculations to replace the empirical methods (364), but there are still serious limitations in computer techniques (see MOLECULAR MODELLING). The most accurate method, the quantum mechanical, is restricted to a single polymer chain, and nonbonded intermolecular interactions still cannot be explicitly calculated quantum-mechanically because most of

the methods derived from quantum mechanics are still beyond the capability of modern computers. Because of the limitations of computing power and calculation methods, the so-called semiempirical quantum approach has been chosen, which is a compromise, namely, using semiempirical procedures to approximate or simplify the quantum mechanical calculations (362,363).

For rigid-rod polymers, semiempirical quantum mechanical calculations have been applied to estimate the intrinsic axial tensile modulus of molecular chains (99,365–367), as well as strain and temperature dependence (52,71). Comparing PPTA (Kevlar) with typical rigid-rod polymer fibers, such as PBZT and PBZO, it is clear that the rigid rings in PBZT and PBZO are connected essentially coaxially by para-bonds along the chain axis. During axial tensile deformation, the deformation energy is consumed not by rotations, but by deformations of the stiff para-bonds and aromatic rings. Therefore, PBZT and PBZO have very high values of the theoretical chain modulus (368). Comparatively, the experimental tensile moduli of both PBZT and PBZO fibers approach the theoretical values. However, for tensile strength, few fibers exceed 50% of the theoretical values. PBZT and PBZO theoretical fiber tensile strengths are more than 20 GPa (369) and the theoretical strength of a single PBZO molecule is about 60 GPa (367). If the polymer chains in the tested fiber were actually as long as the gauge length, and perfectly oriented parallel to the fiber axis with no flaws, the measured fiber stress at break would equal the theoretical chain estimate. The value of the tensile strength determined primarily by covalent bonds and lateral chain packing density is estimated to be 10–15% of that of the theoretical chain modulus (370,371). Ab initio molecular dynamics has been used to simulate the PIPD crystal structure. The force necessary for the dynamics was calculated from the electronic structure using the Hellmann–Feynman theorem. The calculated chain modulus is in the range of 550–580 GPa, close to the experimental value (510 GPa) (142,143). Note that the current computer simulations of the tensile properties of rigid-rod polymer fibers serve only to establish an achievable upper limit for tensile modulus and show the prospect of future development possible by perfecting the fiber spinning and treatment processes. Liu and Yang did molecular simulation for PBZT molecular arrangements in the crystal structure with quantum mechanics and molecular mechanics, and found that PBZT can hardly form three-dimensionally ordered crystal structure with high regularity (372–374).

Computer simulation has also been used to study the solution properties of rigid-rod polymers (161,279,362). It has been found that the local structure and dynamics of different rigid-rod polymers may be quite different but global motions in dilute and semidilute solutions are expected to be very similar (375). Based on the Broersma and Tirado-de la Torre relations, the translational and rotational coefficients, D_t and D_r, of rigid-rod polymers in dilute (or semidilute) solutions can be written in the forms

$$D_t = (\kappa_B T/3\pi\eta_0 L)(\ln p + \nu) \tag{9}$$

and

$$D_r = \left(3\kappa_B T/\pi\eta_0 L^3\right)(\ln p + \delta) \tag{10}$$

where κ_B is Boltzmann constant, T, the absolute temperature, η_0, the pure solvent viscosity, ν and δ are "end effect" corrections, respectively, L, the length of the rigid-rod (polymer), and $p = L/d$, the length to cross-sectional diameter (d) ratio (376–378). The dimensions of the rigid-rod molecules in dilute solution may be obtained from the measurements of D_r and D_t (375). Teraoka and Hayakawa used a mean-field Green function theory to investigate the dynamics of entangled rigid-rod polymers in solutions, and the translational diffusion coefficient D_t was obtained:

$$D_t/D_{t0} = \left[1 + \gamma^{-\frac{1}{2}}(cL^3)\right]^{-2} \tag{11}$$

and the rotational diffusion coefficient D_r was

$$D_r/D_{r0} = \left[1 + \beta^{-\frac{1}{2}}(cL^3)\right]^{-2} \tag{12}$$
