As mentioned in the section under Normal Forces, van der Waals interactions in different media between SFM probes and apolar polymers have been successfully described using the Lifshitz theory (86). As shown in Figure 22 (left), various polymers can be differentiated clearly in force measurements. For polymers containing polar groups, a correlation of adhesive forces and the cosine of the water contact angle have been predicted and observed (66,85,204). An obvious requirement for reliable force data are flat substrates (205,217,218).

The interaction between hydrophobic tips and protein adherence resistant tri(ethylene glycol)-containing self-assembled monolayers on gold has been studied in electrolyte solution in order to unravel the type of (repulsive) force that is experienced by hydrophobic probes (219). This force is thought to play an important role in the resistance of these films to protein adsorption. In related work, force measurements were utilized to elucidate the factors that govern selective deposition of polyamines on acid and oligoethylene oxide surfaces (220). The data suggested that although PEO derivatives are known as protein-deposition-resistant, certain hydrophobic polyelectrolytes are attracted to the ethylene glycol surface under certain pH conditions.

A particularly powerful approach for the study of surface functional groups in polymers is the so-called method of force titration, introduced originally for monolayer systems (7,66,216,221–223). Force titration refers to the measurement of pull-off forces as a function of pH on polymers comprising ionizable functional groups. For instance, for plasma polymerized allylamine films, the force titration behavior (Fig. 22, right) was found to agree with the presence of primary amino groups in a locally hydrophobic environment based on the observed shift in force pK_a ($\sim$5.7) with respect to solution pK_a ($\sim$10.5) (216).

In addition to forces in the surface normal direction, lateral, ie, friction, forces have been utilized to detect area-selective deposition of polyelectrolytes (224), to

record glass-transition temperatures of various polymers (225–228), to probe the relaxation behavior and viscoelasticity in the surface-near region (229–231), and to obtain information on molecular orientation based on anisotropic friction forces (145,152,155,156,232).

Compositional Mapping by Chemical Force Microscopy. As introduced in the section under Adhesive Forces, CFM is an SFM-based technique, which allows one to determine and map the distribution of chemically distinct functional groups at surfaces. Owing to the small contact area between sample and the (functionalized) tip, this mapping can be performed, depending on the modulus, down to the sub-50-nm level for typical polymers (66). The chemical contrast is achieved by exploiting the spatial or temporal variations of the relevant forces in quantitative measurements of the pull-off and/or friction forces between the tip and selected areas on the surface of interest (compare Fig. 6).

While originally developed for highly ordered monolayers systems (65), this approach is in particular promising for high resolution studies of functional group distributions in surface-treated polymers, such as oxidized polyolefins. In addition to chemically sensitive imaging, the control of tip–sample interactions by means of tip functionalization has been exploited by various authors to improve the imaging forces and thus force contrast (233,234).

The first example for the study of polymer surfaces by adhesion force mapping is the report by Mizes and co-workers, who studied PC with a conventional Si_3N_4 tip (Fig. 23) (64).

Flatness of the polymer surface to be analyzed is a prerequirement since rough surfaces lead to geometrical variations in contact areas, which interfere with the detection of specific interactions, as discussed by various authors (205, 217,218).

van der Vegte and co-workers studied microphase-separated block copolymers using CFM and reported that chemically specific contrast allowed them to differentiate between the two microphases exposed at the surface of microtomed

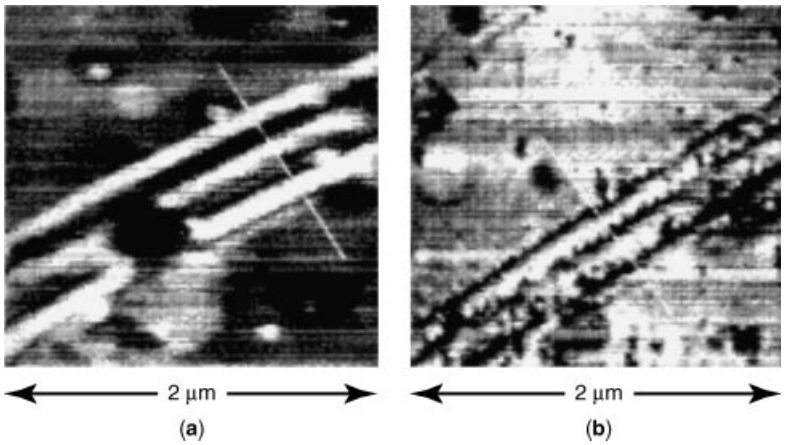

Fig. 23. (**a**) Topography of an undoped PC film. (**b**) Spatial variation in adhesion over approximately the same area. The adhesion ranges from 0.76 to 3.63 mdyn. Reprinted with permission from Ref. 64. Copyright (1991) by the American Institute of Physics.

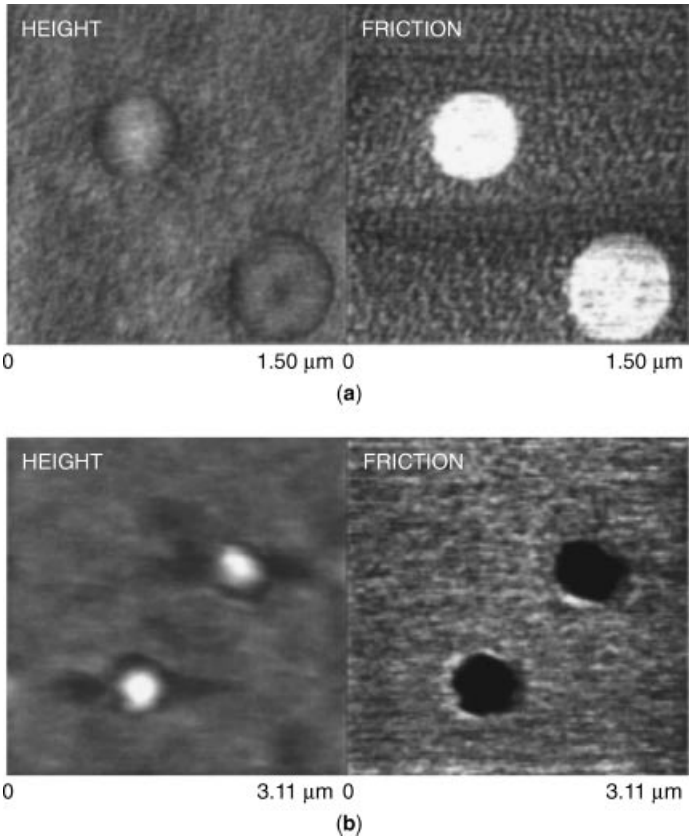

Fig. 24. SFM height (left) and friction (right) images of a spin-cast PS/PMMA polymer blend (PS/PMMA, 1:10 w/w), obtained with (**a**) gold-coated and (**b**) SiO_x tips under perfluorodecalin. Reprinted with permission from Ref. 86. Copyright (1998) American Chemical Society.

films (235). Sinniah and co-workers (236) showed that functionalized SFM tips can be utilized to differentiate polyamide-rich regions from poly(ethylene glycol)-rich regions in a blocky segmented copolymer in water. In this particular case, the friction forces observed with the more hydrophobic methoxy-terminated tips on the polyamide-rich domains exceeded the forces measured on the PEG-rich domains, while for amide-terminated tips, the contrast was significantly reduced.

Feldmann and co-workers studied phase-separated blends of PS and PMMA with gold-coated and silicon oxide coated tips in perfluorodecalin (Fig. 24) (86), where the contrast is dominated by the selectively amplified dispersive van der Waals interactions. The gold-coated tip experiences higher friction forces on the PS compared to PMMA, while the silicon oxide terminated tip shows an inverted contrast.

For the analysis of polar polymer films, the correlation between pull-off forces and surface free energies can be utilized (see section Normal Forces). Ionizable functional groups, such as carboxylic acid groups in oxyfluorinated isotactic PP

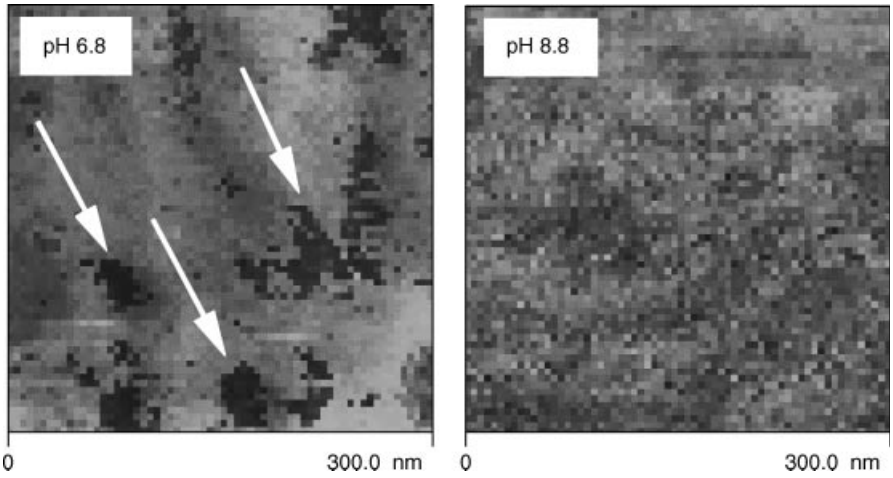

Fig. 25. Pull-off force images of oxyfluorinated isotactic iPP (γ = 39.6 mN/m) at pH 6.8 (left) and pH 8.8 (right). Dark color indicates high adhesion (-0.3 nN for pH 6.8, $\approx$0 nN for pH 8.8), bright color indicates low adhesion (0 nN for pH 6.8 and 8.8). The arrows indicate areas of high pull-off forces, which were attributed to areas with the most hydrophobic character, ie, lower density of polar —COOH and —OH functional groups introduced by the oxyfluorination. Reprinted in part with permission from Ref. 66. Copyright (2000) American Chemical Society.

films (203), have been force-titrated (221,222), and the spatially different response of the films to changes in pH have been used to map the functional group distribution in pull-off force measurements with $<$50 nm resolution (Fig. 25) (66).

Related observations were reported for plasma-polymerized allylamine films on oxidized silicon and for plasma-modified PP (216,223). On the basis of the force titration behavior (Fig. 22, right) the heterogeneous distribution of pull-off forces at pH values close to the force pK_a was related to variations in local hydrophilicity and hence amino group content.

In a pulsed force mode CFM study on poly(ethylene imine), Möhwald and co-workers showed that electrostatic and hydrophobic forces were responsible for the adhesion contrast in this system (237). pH-dependent measurements were thus exploited for chemical imaging. Recently, Vezenov and co-workers presented a systematic study in which the factors contributing to the measured forces in polymers have been discussed in detail (238).

Nysten and co-workers reported on the CFM mapping of the distribution of process stabilizers, UV-light stabilizers and antioxidants in stabilized polypropylene films as a function of aging time (239,240). Differences in the pull-off forces between the additives and PP allowed a submicrometer imaging of the lateral distribution of the additives present on the surface and a clear differentiation between antioxidants and UV-light stabilizers.

CFM using hydroxy- or methyl-terminated tips has also been used to investigate the frictional properties of PS films exhibiting different degrees of oxidation, ranging between 0 and 20 at% by X-ray photoelectron spectroscopy (241,242). A linear increase in the coefficient of friction with increasing surface oxygen level

and water contact angle was observed. The use of chemically modified tips allowed Ton-That and co-workers to differentiate the constituent phases of a PS/PMMA blend in laterally resolved CFM measurements.

Eaton and co-workers reported on force-mapping a phase-separated blend (218,243) of PMMA and poly(dodecyl methacrylate) (PDDMA). Using unmodified silicon nitride probes, the PDDMA-rich domains, which exhibited higher adhesion, could be differentiated from the PMMA-rich domains.

Finally, Nie and co-workers reported an increase in surface energy of mechanically scratched structures on biaxially oriented PP based on adhesion mapping and friction force imaging data using a conventional Si_3N_4 (244).

Surface Mechanical Properties. Phases within heterogeneous polymer systems, such as blends, block copolymers, or particulate-filled systems, can be routinely differentiated owing to image contrast arising from differences in surface mechanical properties (19). In addition, the arrangement of polymer architectures in ultrathin films, such as films formed by block copolymer micelle adsorption (39) or phase-separated blends on chemically structured surfaces (245,246), can be elucidated. For contact mode SFM, friction force measurements, as well as adhesion and indentation mapping, provide materials contrast. In intermittent contact mode, the use of the phase angle shift is particularly useful when differences in compliance exist. Finally, force modulation and pulsed force modes also provide stiffness-based contrast. Since the literature in this area is so abundant, only illustrative examples will be discussed in the following.

Bar and co-workers studied blends of poly(styrene)-*block*-poly(ethene-*co*-but-1-ene)-*block*-poly(styrene) with different PPs and resolved macrophase separation, as well as microphase separation, from size ranges of 15 μm down to 15 nm by intermittent contact mode SFM phase imaging (51). The heights and phase angle shifts determined were found to depend crucially on the operation conditions (169), as also shown in a companion paper (52). Using frequency sweep intermittent contact mode SFM, Bar and co-workers further showed in experiments on PS and PDMS that the phase angle shift obeys a harmonic approximation (53). The underlying features of intermittent contact mode SFM, eg with the sometimes observed tip bistability near the surface (247), and in particular the phase angle shift, have also been addressed in detail by various authors (19,37–41,169,248). The use of active control to tune the quality factor of the oscillating cantilever has been reported to yield optimized stable experimental conditions in the attractive force regime (249).

The elastic and viscoelastic properties of blends of PP and ethylene–propylene (EP) were investigated with the force modulation technique by Nysten and co-workers (250,251). In addition to a mapping of the distribution of the rubbery nodules of EP at the surface, the subsurface distribution of these nodules could be estimated. While the FMM data yielded qualitative data, more recent indentation mapping based on f-d curves allowed Nysten and co-workers to obtain quantitative information of the surface elastic modulus (252).

Tsukruk and co-workers evaluated different classic models of elastic contacts, including Sneddon's, Hertz, and JKR model, to probe the micromechanical properties of elastic polymeric materials (253). A close agreement between absolute values of elastic moduli and bulk data has been observed. With typically available cantilevers with stiffnesses in the range of 0.1–50 N/m, materials moduli

between 1 MPa and several GPa can be probed. The lateral resolution for mapping of moduli has been reported to be better than 100 nm.

van Landingham and co-workers mapped polymer heterogeneity by intermittent contact mode phase imaging and nanoscale indentation measurements for thin film blends of PS and PB (polybutadiene) as a function of annealing time (101). These authors observed that the phase contrast decreased with increasing annealing time because thermal oxidation causes cross-linking in PB, and hence a change in compliance of the PB region. The phases were identified using indentation data (Fig. 9). Similar observations were reported for blends of PMMA and PB (254).

Gracias and Somorjai reported on the determination of the elastic modulus, hardness, and friction of PE and PP using SFM tips with large radii (255). Higher values of modulus and hardness of the polymer surfaces were found to be correlated with the degree of crystallinity of the polymers. The frictional response was dominated by the deformation component of the friction, ie, the yield strength, the elastic modulus, and the pressure dependence of the shear strength.

Du and co-workers (256) analyzed SFM force indentation curves according to the method by Oliver and Pharr (104). For PS and PC thin films, good agreement between theory and experiment required the introduction of a correction factor that accounts for the asymmetry to the SFM indentation (256).

Microphase-separated block copolymer films have been investigated by numerous authors (257,258). van den Berg and co-workers reported on the film structures of poly(styrene-*block* butadiene-*block*-styrene) (SBS) triblock copolymers of PB and PS (259). In particular, the effect of film thickness on the observed morphology was unraveled for this system.

Using FMM SFM, Chen and Thomas investigated the surface and internal fracture surface morphologies of different block copolymers (58). Compared to the height images, the elasticity images were found to exhibit improved contrast and spatial resolution of the respective block copolymer domain structure.

The microphase separation and morphological transitions at the surface of acrylic block copolymers has been studied by Leclere and co-workers, who took advantage of the significant difference in local mechanical properties to obtain clear image contrast (260). The dependence of image contrast has been discussed by Pickering and Vancso, who analyzed the image contrast observed in films of commercial triblock copolymers of PS and isoprene (55). The image contrast was also analyzed by Bar and co-workers in related polymer systems (50–52).

As mentioned above, SFM approaches have also found widespread application in the analysis of block copolymer morphologies found in confinement. Magerle and co-workers showed, on the basis of SFM data and simulations, that the phase behavior at interfaces (261) and in thin films (interphases) (262) can be understood in terms of surface reconstructions analogous to those of classic, inorganic crystals. In Figure 26, thin triblock copolymer films of SBS on silicon are shown, which display a rich variety of morphologies depending on the local film thickness (263).

Owing to the different mechanical properties, filler particles can be in most cases differentiated from the polymeric matrix in SFM. Examples include carbon black or silica-filled rubbers, carbon-black-filled polymer blends or salt-loaded block copolymer micelles. For the latter case, Spatz and co-workers demonstrated

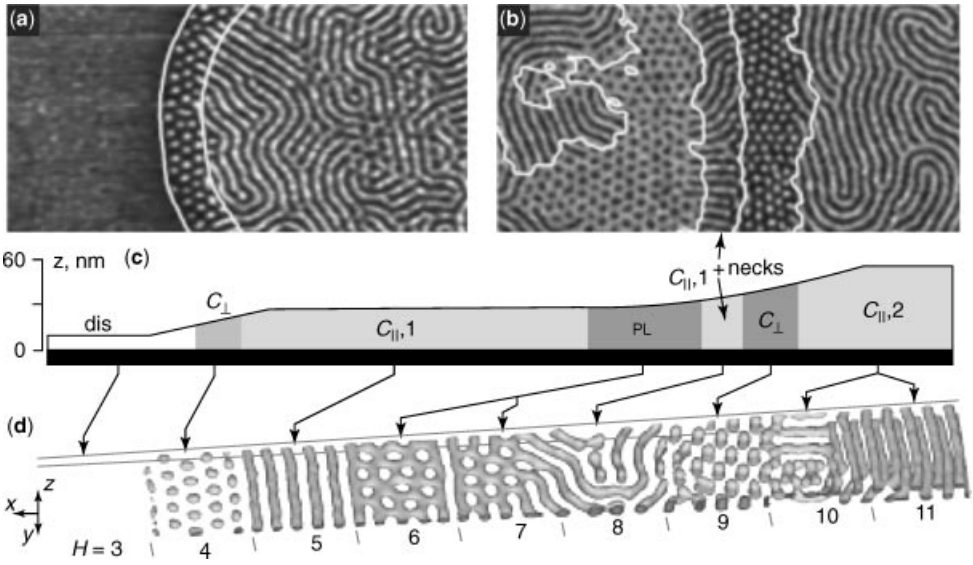

Fig. 26. (**a**,**b**) Intermittent contact mode SFM phase images of thin SBS films on silicon substrates after annealing in chloroform vapor. (**c**) Schematic height profile of the phase images shown in (**a**,**b**). (**d**) MesoDyn computer simulation of a $A_3B_{12}A_3$ block copolymer film in one large simulation box with from left to right increasing film thickness. Reprinted with permission from Ref. 263. Copyright (2002) by the American Physical Society.

that intermittent contact mode can differentiate $HAuCl_4$ loaded and unloaded block copolymer micelles with a mean diameter of 18 nm owing to stiffness differences (39).

The distributions of filler particles in carbon-black- and silica-filled elastomers were detected by intermittent contact mode SFM phase imaging, as well as adhesion mapping by Trifonova and co-workers (264). In the detailed particle size analysis evidence for the observation of primary filler particles was found.

Similarly, Leclere and co-workers utilized FFM to differentiate carbon black from PE and PS in filled blends (265). Carbon black was identified owing to the low friction forces compared to the blend. Ganter and co-workers showed that SFM measurements can provide information about the local distribution of the filler particles, as well as about the morphology of filler modified 1,4-BR/SBR blends (266).

The areas of tribology and lubrication are intimately linked to surface mechanical properties and the analysis thereof. The pioneering work in this area regarding lubrication of computer hard drives with perfluoropolyethers has been carried out by Mate and co-workers (267,268). These authors showed for instance that friction and topography are coupled on nontextured discs, whereas strongly textured discs do not show this effect. It was also shown that perfluoropolyether lubricant films substantially reduce the magnitude and variation of the frictional forces as measured by SFM. On the basis of noncontact mode SFM approaches the disjoining pressure of lubricants on oxidized silicon surfaces was successfully determined (269).

The surface viscoelastic properties of various polymers were studied by Takahara and co-workers (270). The effect of molecular weight on the surface dynamic viscoelastic properties for PS films and the measurement of surface relaxation processes were, for instance, reported (271).

Gladfelter and co-workers probed polymer viscoelastic relaxations with temperature-controlled FFM (272,273). The dependence of the mean value of the friction force on temperature was reported to be correlated to the glass-to-rubber transition and/or secondary relaxation mechanisms in films of PMMA, poly(ethylene terephthalate) (PET), and PS. Viscoelastic mechanical losses were thought to be the dominant contribution to friction, which were found to obey the time–temperature superposition principle. Interestingly, the surface T_g's and values for the activation energy measured for the β-relaxation at the surface were lower than those of the bulk material.

Structure Development and Processes in Real Time

SFM methodologies have been applied predominantly as static imaging and analysis techniques in polymer science and technology. However, recently the potential of the approaches for real-time studies, in particular for the investigation of phase transitions, has been realized. Owing to great importance of an improved fundamental understanding of crystallization and crystallinity in semicrystalline polymers, this section deals with this topic in more detail than the other real-time applications of SFM in the field of polymers.

Polymer Crystallization. In 1997, Miles and co-workers reported on the *in situ* study of polymer crystallization in poly(hydroxy butyrate) at ambient temperatures (274). This work of the Miles group, together with the groundbreaking work of Pearce and Vancso (152,275), who established SFM studies of polymer crystallization at elevated temperatures, initiated a rapid development in this area (276,277). Polymer crystallization can be followed in real time at the nanometer, ie, lamellar, level with this approach, also named hot-stage SFM, and central novel observations were made. The work by the groups of Miles and Vancso established that lamellar growth in spherulites does not proceed with linear growth rates when visualized at the level of individual lamellae. Instead, individual lamellae may remain dormant for some time before growing very rapidly (274–276) (see CRYSTALLIZATION KINETICS).

To date, numerous studies on different polymers have been reported, including poly(hydroxy butyrate) (274,276), PEO (275,277–280), PEO–PMMA blends (281), PE (282–284), poly(ε-caprolactone) (PCL) (285,286), poly(propylene oxide) (287), syndiotactic PP (288), and elastomeric PP (176). As an example, the different stages of development in the hedritic crystallization of PCL are shown in Figure 27.

Although SFM is traditionally an intrinsically slow imaging technique, a wealth of growth rate data has been obtained on the lamellar level. Furthermore, recent developments in the area of high speed SPM (289–291) show that real-time SFM at elevated temperatures possesses the potential to develop into an indispensable microscopic tool for the quantitative investigation of polymer phase transitions and other processes at elevated temperatures and as such may help to develop better theories of, eg, polymer crystallization.

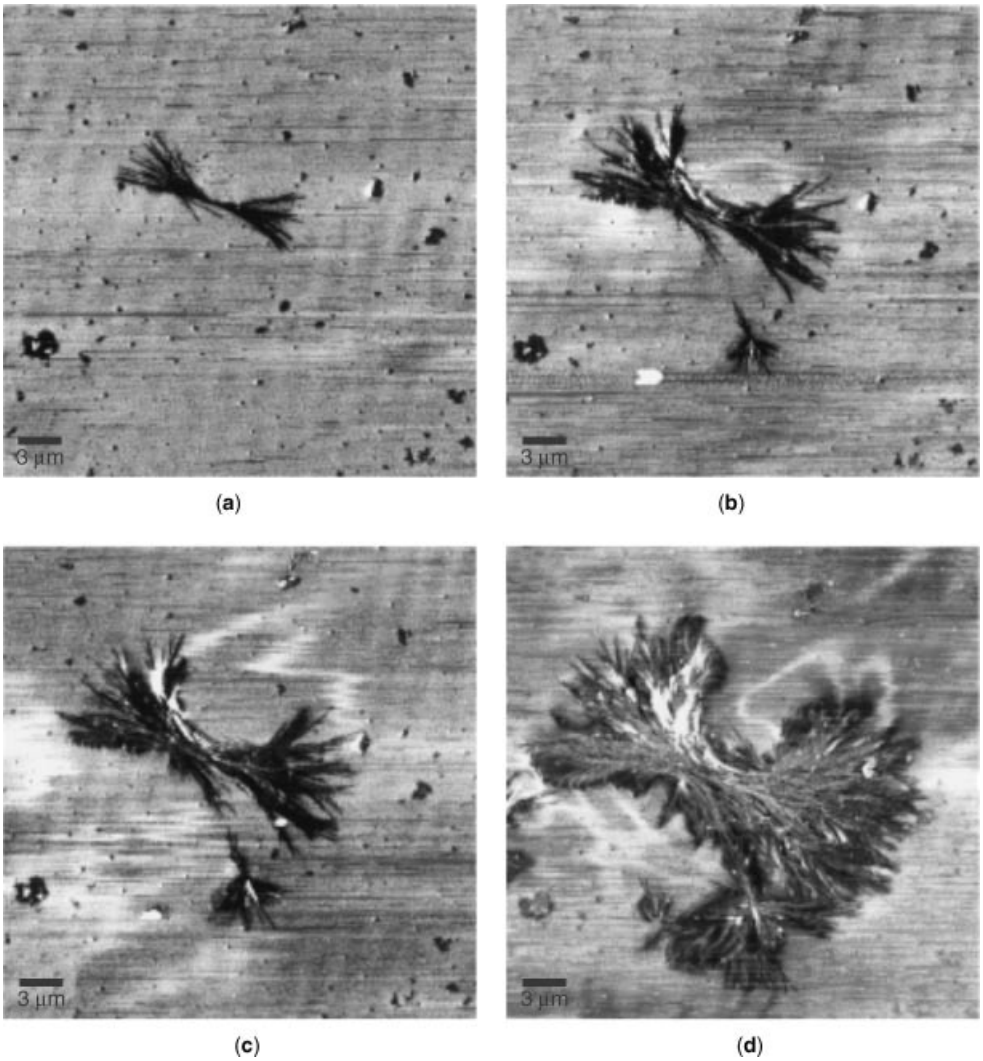

Fig. 27. Four steps in the development of hedrite of PCL as monitored by hot-stage SFM. Reprinted from Ref. 286. Copyright (2000), with permission from Elsevier.

In particular, in the area of nucleation and crystallization of polymers one can anticipate in the near future significant improvements in quantitative real-space investigation on processes occurring at the nanometer level. To date, the nucleation of polymer lamellae from the melt has been observed in some systems (176); however, the limited spatial resolution allowed only to observe the presence and not the shape/precise dimensions of stable, metastable, or unstable nuclei.

The first report of visualization of nuclei in polymer melts by SFM was published by Lei and co-workers (Fig. 28) (292). Subsequently, the observation of stable, unstable, and metastable nuclei has been reported for isotactic PP sequences of stereoblock PP (176).

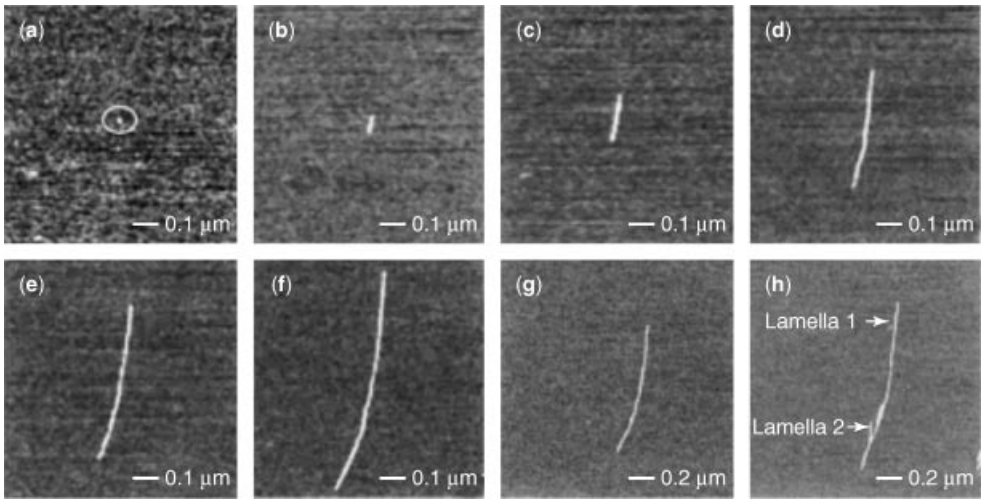

Fig. 28. Nuclei and growing lamellar crystals of poly(bisphenol A octane ether) observed by hot-state SFM. Reprinted in part with permission from Ref. 292. Copyright (2002) American Chemical Society.

Zhou and co-workers investigated the crystallization of individual lamellar crystals of syndiotactic PP from the melt and observed different lamellar thicknesses in different fold sectors (288). In addition, the effect of annealing and the melting behavior was followed in real time.

The crystallization of PEO was also unveiled at the level of individual lamellae in ultrathin films (278–280). It was observed that although lamellar growth rates were retarded in films thinner than 200 nm because of interfacial interactions, SFM provided the same qualitative and quantitative information as typically applied bulk characterization techniques on lamellar growth rates, lamellar thicknesses, and melting points. The Hoffman–Weeks extrapolation, the Gibbs–Thompson equation, and the Hoffman–Lauritzen theory were applied and the results compared favorably to the corresponding bulk data.

The nucleation process of nucleation agents added on purpose to polymer melts, as well as the effects of shear on polymer crystallization, are still not well understood. SFM can provide insight into the underlying processes as shown by Beekmans and co-workers, who investigated the transcrystallization of PCL on PTFE fibers using hot-stage SFM (293), and Hobbs and co-workers who studied the crystallization of sheared PE melts (283,284). In the latter studies, shish-kebab structures, nucleated on oriented backbones, were detected in the melt and could be followed in real time (Fig. 29).

More recently, new developments of hot-stage instrumentation have allowed several groups to study phase transitions in polymers at higher temperatures, thus establishing this approach as generic approach for the investigation of polymers relevant for a wide range of applications (294).

Various Dynamic Processes. The hot-stage approach has also found widespread use in studies on melting and annealing of single lamellae on solid substrates (295), as well as the fundamental mechanisms of melting in

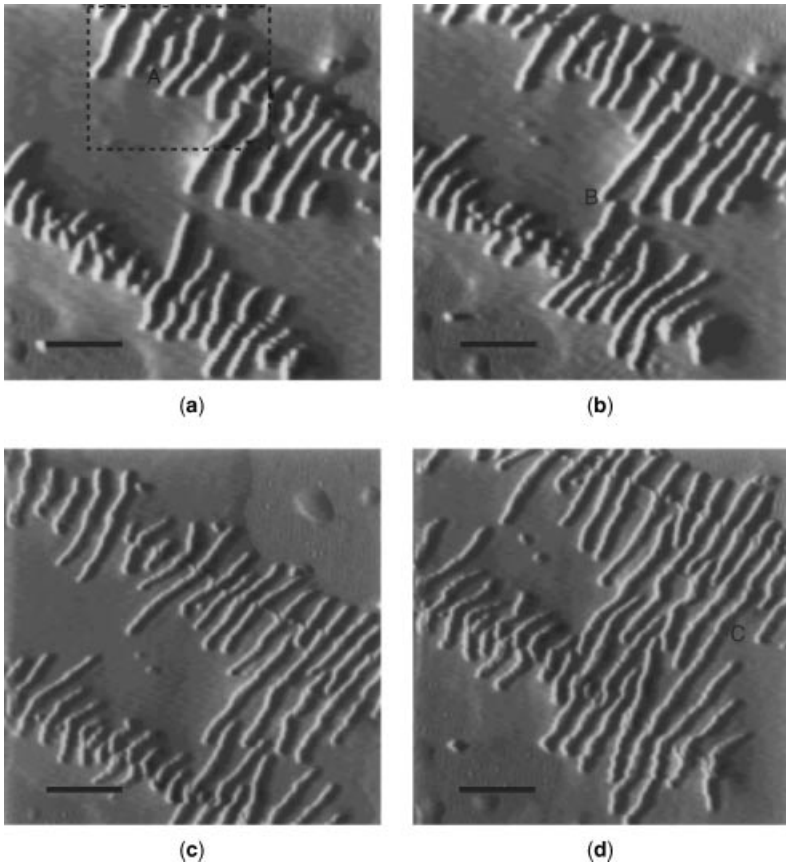

Fig. 29. Crystallization of shish-kebab-type lamellae observed by hot-state SFM in sheared melts of PE. This series of tapping mode SFM amplitude images shows the growth of lamellae from the oriented backbone. (**a**) Taken at 132.5°C; (**b**) taken at 132.3°C; (**c**) taken at 132°C; (**d**) taken at 131°C. The scale bars represent 300 nm. Reprinted with permission from Ref. 283. Copyright (2001) American Chemical Society.

melt-crystallized polymers (296–298). These studies complement the efforts reviewed in the previous section and although the character of the experiments is fundamental, there is a considerable practical significance of the results.

Further examples for real-time studies, which are becoming increasingly more important, target (surface) glass-transition temperatures (225–228), and thermotropic transitions in liquid crystalline polymers both at high and low temperatures (299–301). The analysis of temperature-dependent dynamical–mechanical surface properties has already been mentioned in the section under Surface Mechanical Properties (229–231,270–273).

The surface-glass-transition temperatures found by, eg, SFM approaches in polymers are usually lower than the corresponding values measured in the bulk. This effect has been attributed to an increased mobility of the macromolecules near or at the polymer–air interface. In very thin substrate-supported thin films, interfacial energy effects stemming from the substrate–polymer interface were

found to be important and can in some circumstances lead to an *increase* in T_g. Nealey and co-workers analyzed the dependence of T_g on interfacial energy and film thickness by various methods, including local thermal analysis using SFM-based scanning thermal microscopy (302).

The structure and phase transitions of polydiethylsiloxane were investigated with SFM at temperatures between 300 and 268 K. At room temperature, layers of polydiethylsiloxane are shown to be a mixture in both amorphous and mesomorphic states, while for a temperature of 273 K all material converts into the mesomorphic state (299).

Conformational changes of polymers as a result of stimulation by external stimuli, such as applied potential, changes in solvent or swelling agent, temperature, or irradiation with a suitable wavelength, have been investigated on different length scales in real time. The electrochemically induced response of organometallic polymers was shown to reversibly affect the adhesive properties (208). Ultrathin films composed of chemisorbed poly(ferrocenyl silane) showed fully reversible changes in film thickness, as shown in a recent electrochemical SFM study (303). Very recent work also highlighted the capabilities of SFM to follow the collapse of single polymer chains and the motility of adsorbed macromolecules in real time (121).

Dewetting (304–306) and phase separation phenomena are also amenable to *in situ* real-time SFM studies. As shown by Jacobs and co-workers, the dewetting of PS on an oxidized silicon wafer can be followed *in situ* at elevated temperatures. These observations are useful to develop a better understanding for film stability necessary in many modern applications of polymer ultrathin films in miniaturized electronic and microfluidic device applications.

Finally, SFM has also found widespread application in biology-related polymer science; in particular, the behavior of biopolymers in liquid medium has been studied *in situ*. These studies include the biodegradation of such polymers (307,308) and the crystallization of proteins (309,310).

Outlook: The Future of SFM on Polymers

The examples discussed in this article show that in less than two decades after its invention, SFM has already become an indispensable tool for many materials and polymer scientists for the characterization of polymers. The applications range from conventional surface topography and morphology imaging, mapping of composition and properties to a quantitative estimation of vital surface properties and real-time analysis of important processes.

The immense potential of SFM has been realized in industry, where it finds increasing application in research and development laboratories. It is fair to say that for both bulk and specialty polymers, such as coatings, SFM more than complements the traditional techniques of OM, SEM, and TEM. Despite this success, the standardization of procedures and a clear definition of protocols in the industrial environment are only beginning to emerge. The same is true for establishing routine measurements of various properties in a truly *quantitative* manner.

Together with the mentioned technical developments and improvements of SFM instrumentation (289–291), the anticipated development of new modes and

contrast mechanisms, as well as an improved theoretical understanding of the fundamental physics, the hitherto rapid development will likely continue and fully establish SFM and related approaches as routine technique in polymer science and technology. The expectations, eg, for chemical mapping, localized thermal analysis, and high resolution artifact free imaging are high, considering the recent introduction of functionalized carbon-nanotube probe tips as ultimate probes (311–313) and the progress in the area of scanning thermal microscopy. The many applications of polymers in the biomedical sector, as well as in ultrathin films in miniaturized electronic and microfluidic devices, underline the importance for nanometer-scale metrology and accurate characterization of polymer properties in confinement and constrained geometries. SFM techniques will therefore play an important role in the development of vital future technologies, and hence the impact of SFM can faithfully be expected to further grow in modern polymer science and technology.

Nomenclature

T_g	glass-transition temperature
Δz	cantilever deflection
F	force
k	spring constant
R	tip radius
K	reduced modulus
L	load
$F_{pull-off}$	pull-off force

W_{12}	work of adhesion (surface energy per unit area)
γ	surface free energies
E	Young's modulus
ν	Poisson's number
F_{friction}	friction force
μ	friction coefficient
τ	interfacial shear strength
λ	draw ratio
A	amplitude
$\Delta\phi$	phase angle shift

SCATTERING. See LASER LIGHT SCATTERING.

SCRATCH BEHAVIOR OF POLYMERS

Introduction

Abrasion and wear is a long existing deteriorating phenomenon occurring when two moving surfaces are in intimate contact. Although the history of systematic study of abrasion and wear can be dated back more than 70 years (see Ref. 1, and references therein), the actual processes involved in abrasion and wear are still not clearly understood. It is generally believed that asperity interactions between two surfaces are responsible for such occurrence. Mechanisms involved include adhesion, shearing, fatigue, microcutting, and surface smearing. The resulting damage features will vary with materials properties, compounded by changes with sliding conditions. The situation for polymers is particularly complicated because of their viscoelastic–viscoplastic nature, leading to wear features that alter with the history of wear and time of observation. In addition, those circumstances that result in abrasion and wear often involve multiple asperities, which render studying into the science behind this phenomenon difficult. Since abrasion and wear can be considered as multiple asperities making multiple, repeated scratches on the contact surfaces, a simplified situation where a stylus is used to scratch a polymer surface is often examined to gain insight into this complex process.

Apart from the macroscopic wear behavior that traditional tribology is concerned with, research on micro/nanotribology has gained pace recently to develop crucial understanding of nanoscale surface wear and interfacial mechanical phenomena on a small scale. This trend is driven by both the industrial needs of miniaturization and the desire to understand engineering material-to-material contact damage phenomena based on fundamental science.

Compared to other materials, polymers are more susceptible to scratches and abrasion because they are relatively soft. Yet, polymers and polymer matrix

composites have increasingly been chosen for microelectronic packaging, coatings, aerospace, automotive, food packaging, and biomedical applications because of their adequate strength, lightness, versatility, ease of processing, and low cost. In many cases, they will be subjected to wear or scratch at loads, resulting in surface damages at various scales. Thus, there is a strong need to improve scratch and wear resistance in plastics.

Significant research and developmental efforts have been placed to characterize and improve abrasion and wear resistance of polymers (2–5). However, advances in fundamental knowledge on abrasion and wear are limited mainly because of the complexity of the available test methods, such as the Taber abrasion test. No direct correlation between the applied loading conditions and the observed abrasion damage can be made. As a result, no definitive relationship between material parameters and abrasion resistance can be established.

It is believed that the first step to the understanding of abrasion and wear resistance is to fundamentally understand the scratch behavior of polymers. Since abrasion and wear usually involve repetitive damage on the same location of the polymer surface, it smears the damage mechanisms. As a result, no definitive information can be obtained to identify the exact sequence of events and process(es) leading to the surface damage of the polymer. On the other hand, it is possible to create controlled surface damage on polymers using a single- or multiple-pass scratch process from which the mechanics related to the generation of surface damage is understood and the corresponding surface damage can be characterized to make fundamental correlations between mechanics and materials science of scratch of polymers (6,7).

The objective of this article is to highlight the importance of understanding scratch behavior of polymers by giving readers an up-to-date knowledge in this field of research. The theoretical framework concerning interfacial contacts will be introduced, and the experimental aspects in terms of methodology and quantitative measures summarized. Various factors influence the scratch behavior of polymers in different ways which will be discussed.

Theoretical Background

Even a surface that appears to be flat on a millimeter scale may in fact be rough with micrometer scale asperities on it. Friction and the resulting energy dissipation are thus due to the interaction between the asperities of the different surfaces when they touch each other. It is the real contact area that affects the friction opposing the action of motion and the real area of contact may be therefore a few orders of magnitude smaller than the apparent area of contact. A brief summary on the development of theoretical models for friction is given by Meyer and co-workers (8).

Theory of Contact.

Bowden and Tabor Model. In 1950, Bowden and Tabor (1) presented a simple model for friction on a micrometer scale. They proposed a contact model based on adhesion and shearing that take place at the interfaces of asperity surfaces during translational motion. Based on this model, the energy loss in the friction mechanism is due to plastic deformation of the asperities at the surfaces

on contact. The model assumes that friction F_f is proportional to both the real area of contact, A_R and a mean lateral force per unit area, the so-called shear strength σ. The real area of contact is the area of asperities that are deformed by the normal load and is independent of nominal contact area. Thus, the friction force does not depend on the apparent area of contact. When the normal applied force F_N, is large, F_f takes the form of

$$F_f = \frac{\sigma}{p_m^*} F_N \tag{1}$$

$$A_R = \frac{F_N}{p_m^*} \tag{2}$$

with $p_m{}^*$ being the yield stress of the asperity, which can be smaller than the yield stress of the bulk materials due to the asperity's small size.

Hertzian Model. Hertz described in a general form a contact phenomenon between two spheres of radii R and R', respectively, where the deformation mechanism is totally elastic. $R' \to \infty$, if one of the objects in contact is a plane. Based on his analysis and for symmetry reasons, the area of contact between the sphere and the plane is a circle and its area is

$$A_R = \pi (DR)^{2/3} (F_N)^{2/3} \tag{3}$$

where R is the radius of the sphere, and D is the inverse "plane stress modulus," which is composed of the elastic moduli and Poisson's ratios of both the sphere and the plane. One should note that based on equations 1 and 2, the result in equation 3 suggests $A_R \propto (F_N)^{2/3}$. Assuming the shear strength σ is independent of the load, it leads to a conclusion that $F_f \propto (F_N)^{2/3}$, which contradicts the Amonton's law.

The JKR Model. Since adhesion will surely come into play when the two surfaces are in intimate contact, Johnson and co-workers (9) extended the Hertzian model to include terms due to surface tension γ. The real area of contact is related to normal force by

$$A_R(F_N) = (DR)^{2/3} \left(F_N + 3\pi\gamma R + \sqrt{6\pi\gamma R F_N + (3\pi\gamma R)^2} \right)^{2/3} \tag{4}$$

From equation 4, A_R is finite when F_N is zero and equals

$$A_R(0) = \pi (6\pi D\gamma R^2)^{2/3} \tag{5}$$

Hence, a negative load is required to break the contact. In addition, in the limit of zero surface tension, ie $\gamma \to 0$ and also when the external applied load is large compared to γR, the JKR model coincides asymptotically with the Hertzian model. A comparison at the point of asperities in contact is given in Figure 1.

The Greenwood and Williamson Model. Since a real surface consists of multiple asperities of different heights, a model that takes such a factor into consideration is required. Greenwood and Williamson (10) considered a surface with a random distribution of asperity heights. In this model, every asperity has the same

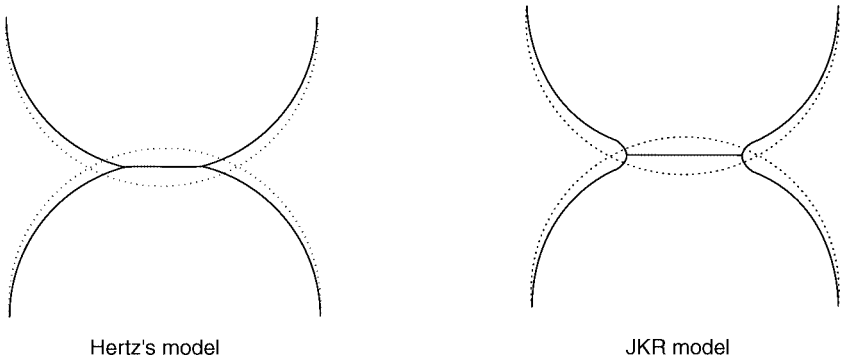

Fig. 1. A comparison of asperities in contact based on the Hertzian model and the JKR model.

radius of curvature β at the summit, and is pressed against a plane (Fig. 2). A probabilistic approach is used to take the height distribution of asperities into account when calculating A_R. The separation between the reference plane in the rough surface and that of the smooth surface is denoted d. We consider the deformation of an asperity with height z; then $w = z - d$ is the "penetration depth" of this asperity. Using Hertz's theory of a total elastic contact, the final form of A_R is related to F_N:

$$A_R = \frac{4\sqrt{\pi}}{3} D F_N \sqrt{\frac{\beta}{\sigma}} \tag{6}$$

Thus, the real contact area is proportional to the load and independent of the nominal contact area.

Theory of Sliding Contact. Based on Hertzian contact model, Hamilton and Goodman (11), which was later elaborated by Hamilton (12), presented the scratch process as a combination of an indentation process and a sliding process. Figure 3 shows the schematic of the scratch process in this model. At the contact surface, where $z = 0$,

$$\sigma_z = \frac{3P}{2\pi a^3}(a^2 - x^2 - y^2)^{1/2} \tag{7}$$

$$\tau_{zx} = \frac{3Q}{2\pi a^3}(a^2 - x^2 - y^2)^{1/2} \qquad x^2 + y^2 \leq a^2 \tag{8}$$

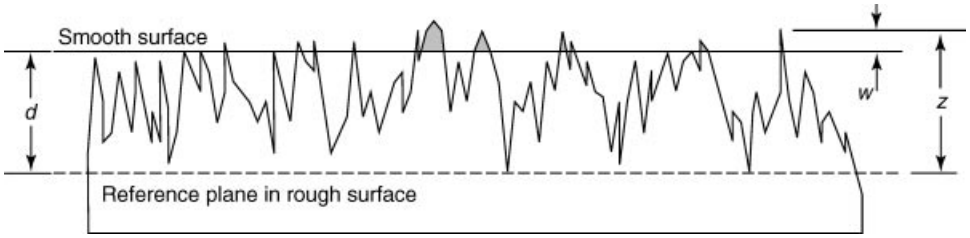

Fig. 2. The Greenwood–Williamson model.

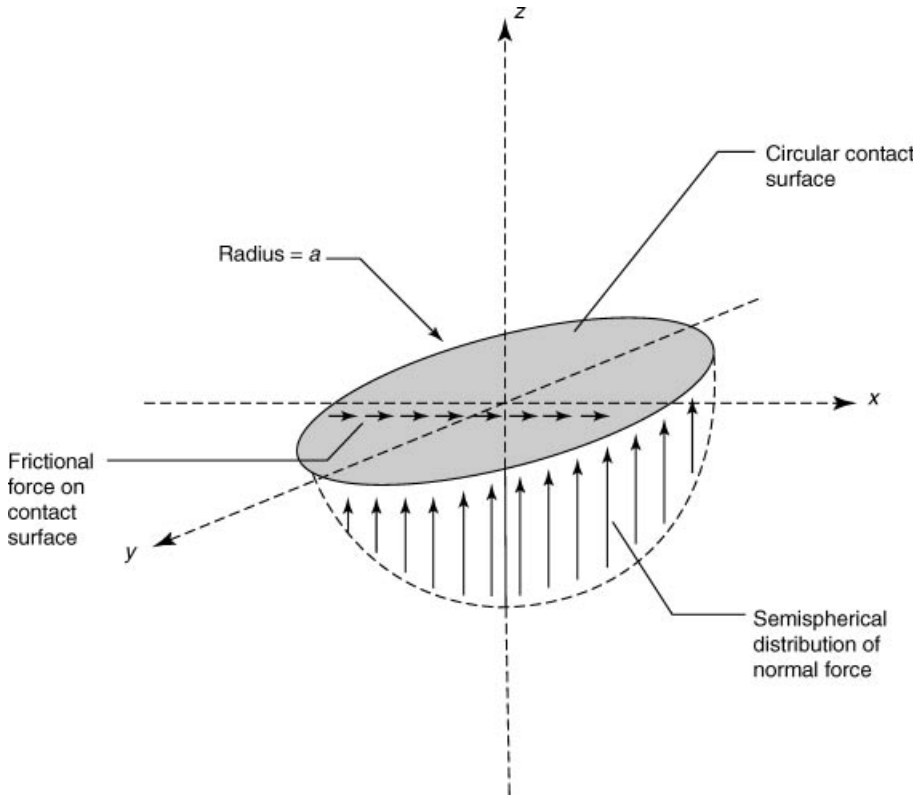

Fig. 3. The Hamilton and Goodman model.

where P and Q are the total normal load in the z-direction and the total frictional force in the x-direction, respectively. Equations 7 and 8 give the normal stress and frictional stress distribution. The maximum tensile stress during the scratch process, which occurs on the circumference of the circle of contact, is

$$\sigma_x = \frac{3P}{2\pi a^3}\left(\frac{1-2v}{3} + \frac{4+v}{8}\pi\mu\right) \tag{9}$$

The existence of friction adds a compressive stress to the front edge of the contact and intensifies the tensile stress at the back edge.

Similarly, Sackfield and Hills (13–15), based on Hertzian contact model, derived mathematical expression for elliptical contacts. In addition, a number of models have been developed recently, mostly based on JRK models (16–18). Furthermore, Ford (19) has derived an analytical model on multiasperity against smooth surface based on a model developed for narrow slider and a single asperity and the Greenwood–Williamson model. All these efforts are exerted, aiming at giving a mechanics-based understanding of the scratch process and potentially help us to correlate scratch conditions, materials properties, and scratch features observed.

Methodology

To assess the scratch behavior of polymers, scratch tests are performed. A compendium of the use of various instruments and methods applied is given in Reference (20). Although different setups have been used for scratch studies, the basic principle relies on the use of a stylus to scratch a surface (2,3,21–43). The stylus can be made of materials ranging from diamond and sapphire, to tool steel, and silicon nitrite for the case of AFM tips. It also comes with a variety of geometries including conical tips with different included angles, spherical tips of different radii, and Berkovich tip. In addition, the observation length scale and controlled experimental parameters are instrument specific.

Individual scratch is often done with a constant loading rate (which includes constant load) and constant scratch rate. The scale of damage of interest varies from macroscopic features to those of nanometer scale. This renders comparisons between studies difficult. The recent concerted industry–university effort (6,7,44) has led to the development of a scratch test method and universal scratch testing equipment to facilitate good scratch test practices and fundamental study of scratch behavior of polymers. Figure 4 presents the scratch tester that was developed. It aims to provide reasonable capability to vary experimental conditions for capturing the essential scratch characteristic of the materials with reliable and reproducible results. One unique feature of the tester is its ability to alter scratch load and velocity at a linear rate. This feature is found to be useful in understanding scratch behavior of polymers, to be presented in later sections.

Since scratches exist on the surface of the materials, different surface morphology evaluation tools and techniques are employed to quantify the severity of scratch damages. The instruments used for such quantification include

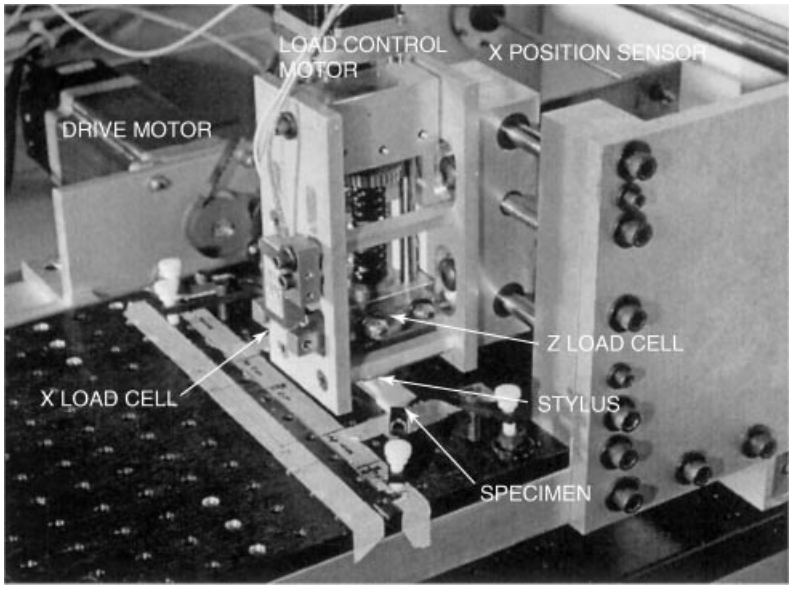

Fig. 4. Custom-made scratch tester in PTC, Texas A&M University.

atomic force microscope (22–24,45–48), optical microscope (22,30,37), scanning electron microscope (38,49), laser confocal microscope (30), Raman spectroscope (39), white-light interferometer (3,22), cross profilometer (50), tribometer (51), ellipsometer (39), and scanner (37,52,53). Each of these equipments examines certain aspects of scratch damages, inter alia scratch surface topology and resulted light reflectivity. With such a wide range of equipments being utilized, a variety of scratch resistance measures were devised.

Scratch Hardness. One of the more commonly used scratch resistance measures is the so-called scratch hardness (10,21,54). This is a concept borrowed from static indentation HARDNESS. Like indentation hardness, scratch hardness is often a measure of force experienced by the sample per unit area. The frequently used definitions for scratch hardness, H_S, and ploughing hardness, H_P, are given in Reference (10):

$$H_S = \frac{\text{Applied Normal Load}}{\text{Apparent Load Bearing Area}} \tag{10}$$

$$H_P = \frac{\text{Tangential Load Measured}}{\text{Apparent Load Bearing Area}} \tag{11}$$

The magnitude of force applied normally and the tangential force exerted on the samples can be measured accurately by force sensors. The definition of contact/load-bearing area is however controversial. When a scratch groove is formed, three kinds of deformation can be differentiated (36): the elastic deformation inside the groove; the elastic deflection of the surface responsible for the vertical displacement of the edge of the contact; and the plastic deformation, which results in the remaining groove, and the pile-up pads. This renders the estimation of true contact area difficult. Figure 5 is a schematic diagram of the scratch process. Assuming that the sample undergoes totally plastic deformation when being scratched, only the front half of the indenter will be supported by the sample. In this case, two definitions of contact area can be devised. First, an apparent scratch contact area, similar to that in the indentation process, is the projected area of the half-cone supported by the sample, as line-shaded in Figure 5**a** and 5**c** for equations 10 and 11, respectively. Second, a true contact area equals to the front half of the indenter curved surface in contact with the sample (line-shaded in Fig. 5**b**).

The issues of defining and measuring contact area become complicated when the viscoelastic–viscoplastic nature of polymer is taken into consideration. As shown in Figure 5**b**, the geometry of the scratch groove that formed during the scratch process (the dash lines) would be different from that of the residual groove that remains after the indenter is removed (the solid lines). Such deviation arises because viscoelastic recovery occurs in polymers (4,55,56). Both the apparent and true contact areas are difficult to define and measure in this case. This is because the materials behind the indenter will recover to support the indenter. Yet the amount of viscoelastic recovery is time-dependent (57,58) and it is not necessary to be isotropic in nature. In addition, if pile-ups exist, materials will be push forward and to the sides of the groove by the indenter to rise above the original sample surface. These materials might provide extra support for the indenter. Moreover,

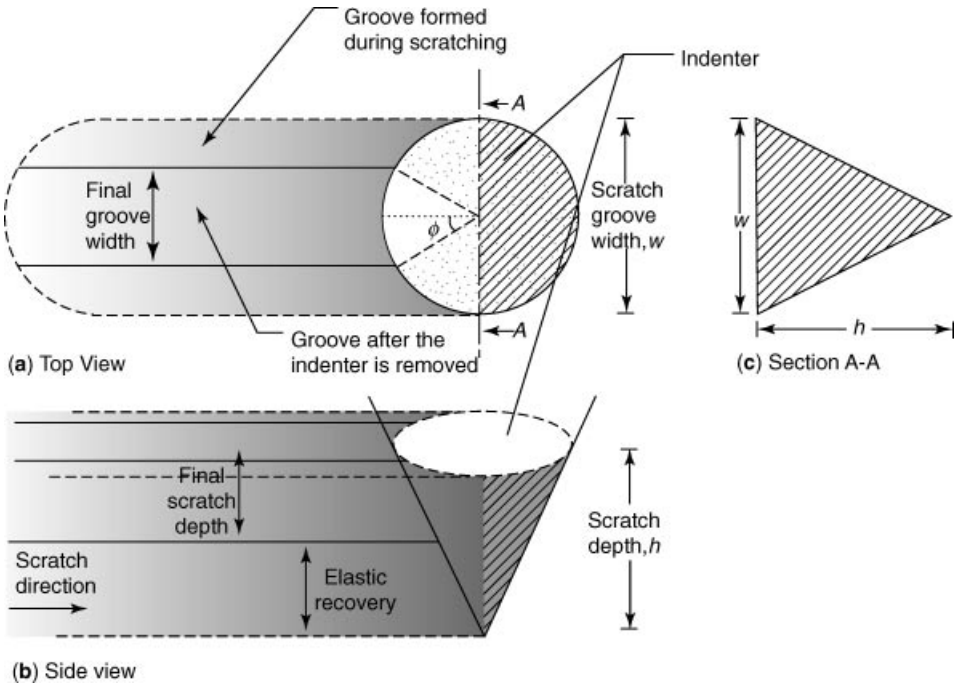

Fig. 5. Schematic diagram showing the scratch process showing difference in groove gemoetry during and after the scratch process.

because of the wide variety of scratch mechanisms that can be involved during the scratch process, the amount of materials supporting the indenter is changing even when the scratch condition is kept constant. These factors contribute to the uncertainties of the actual contact area and render an accurate estimation difficult, subjective, and ambiguous. Under the same line of argument, the use of cross-sectional scratch profiles for surface damage quantification (22,43,52,53,57, 58) suffers from the similar shortcomings mentioned above.

Scratch Visibility. As polymer coatings are frequently used as protective and decorative coatings, another way to quantify scratch resistance and surface damage would be to measure scratch visibility (2,3,28,29,59–62). It has been shown that the use of light reflectivity measure for identification of crack formation and differentiating subtle changes in scratch damage severity is more effective than visual observation by optical or scanning electron microscopy (59). In most cases, a light source is shone on the scratched surface and the reflected light signals are collected and quantified using digital image analyzing software to give a measure of intensity or gloss of the surface. The intensity collected is generally on a per pixel basis. Some types of integration are required in order to find the total intensity/reflectivity of the scratched surface and a comparison to its initial condition.

While some software has generated a measure of gloss or grey scale level, which can be used as a measure of scratch visibility (60,61), others prefer to develop scratch visibility measure after manipulation of data captured by computer.

This is normally done to highlight certain aspects of the scratch properties of the materials. For example, a percentage change of brightness or grey scale is often used for assessing scratch visibility of mineral-filled polyolefin composites (3,5,28,29). This is because the inclusion of mineral fillers might facilitate the light scattering when the sample is being scratched. Such effect of light scattering can be better represented by the manipulated measures than by the raw data generated by the software. In another study (2), by measuring intensity of reflected light using polarized light source and changing the orientation of the scratch with respect to the light source, the importance of different stress whitening mechanisms at a variety of scratch rate was studied. Effort has been made to develop more sophisticated light reflectivity measurements in order to better correlate experimental results with human impression on scratch visibility (62).

Effect of Sliding Conditions

From the equations presented in under Theoretical Background, it can be derived that materials properties, such as modulus and yield strength, and any modifications that might affect them will influence the scratch behavior of polymers. The unique characteristics of polymers make research in polymer scratch particularly challenging. First, as mentioned in the previous section, polymers are viscoelastic–viscoplastic in nature. This makes polymer properties very sensitive to test conditions, especially temperature and strain rate (21,34,56,63,64).

Second, it has been suggested by various authors that the surface properties of polymers might be different from those of the bulk owing to differences in molecular dynamics (66–68). Such differences propagate from the surface over a very short distance. A lower surface glass-transition temperature could result in variation of surface friction with scratching rate and temperature (68–70). Results to date suggest that behaviors of polymers in nanoscale are different from those in the micro- and macroscale. An example is the observation that nanoscale surface coefficient of friction is lower than that of the bulk, owing to the reduction of real area of contact and subsequent effects caused by such reduction when very low loads were being applied to the polymer (24,63–65,71–74). Thus, scratch properties obtained from bulk polymers might not be the same as their nanoscale surface scratch properties.

With these complications in mind, research in this area has blossomed rapidly. Two main foci of research in this area are on (*1*) how external conditions (such as levels of loadings, the use of different indenters, and scratch rate) and (*2*) intrinsic materials properties (such as modulus and crystallinity) affect the tribological behaviors of the polymers. Apart from examining the scratch resistance of polymers, a closely related quantity which is of interest would be changes in coefficient of friction. Studies relating mechanical properties (3–5,9,36,71,75,76), deformation patterns (18,33,63,71,77–81), fabrication process (3,5,35,72,77,82–86) with respect to experimental parameters, such as temperature (18), loading effect (24,71,72,87–96), indenter geometry (21,33,75,82,95,97), and scratch velocity (21,56,57,59,64,65,96,98) have been carried out. In addition, scratch maps for different polymers have been produced (32,33), and various scratch resistance properties estimated (33,37,56,58,59,99).

Scratch Mechanisms. We have considered how external and intrinsic factors influence the scratch resistance of polymers. Here a brief summary on scratch mechanisms is given.

External parameters interact with intrinsic materials properties by varying the stress distribution on the surface and subsurface of the samples. Based on stress distribution, different deformation mechanisms will operate (12). By scratching crystallized poly(ethylene terephthalate), polypropylene, acetate, and gelatin with blunt spherical styli, Ni and Faou (38) identified three possible operating processes when two surfaces are brought into relative motion: (*1*) interfacial slip accompanied with interfacial shear; (*2*) subsurface shear; and (*3*) interfacial shearing and tensile loading in the vicinity of an asperity, which may initiate crack formation (ploughing effect). Associated with these processes are four types of scratch morphologies: (*1*) with deformation bands inside a scratch that are convex with respect to the sliding direction; (*2*) with deformation bands inside a scratch that are concave with respect to the sliding direction; (*3*) with the removal of the top coating; and (*4*) with featureless clear track with shoulders on both sides (Fig. 6).

Type 1 deformation bands (displacement of materials) correspond to ductile materials being squeezed in front of the styli by shear stress (von Mises shear stress being maximum at the surface). Thus, it is a result of surface shear yielding developed by the compressive shear stress in front of the moving stylus. Type 2 concave bands (surface crack) for brittle materials are due to tensile failure arisen by tangential force. Type 3 delamination occurs as coating delaminates under the compressive stress ahead of the stylus and removed under tensile cracking. Thus, the severity depends on tangential force. Type 4 plastic ploughing is due to normal loading and occurs when normal loading and frictional coefficient are low, giving low frictional force. This is due to indentation and friction generated during sliding. This more ductile type of deformation associated with shallower grooves formed at lighter loads might also be the result of lower strain rate experienced

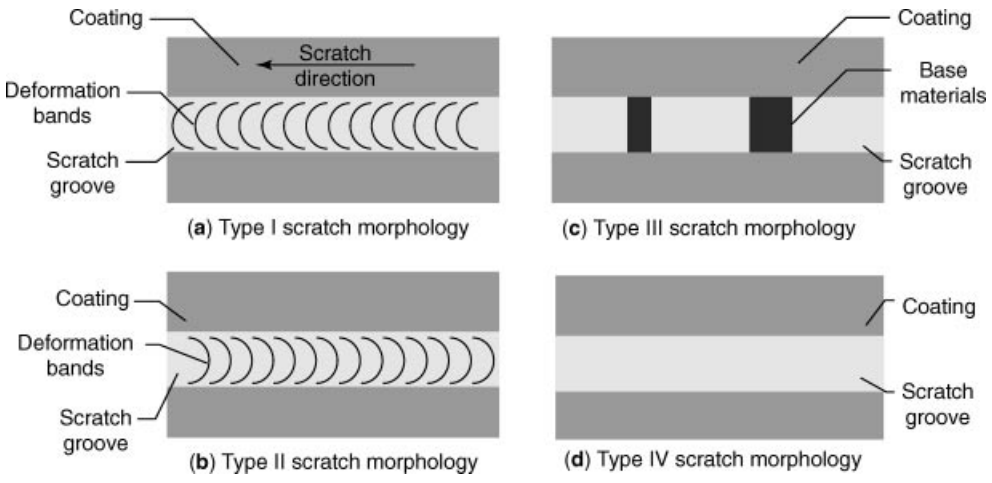

Fig. 6. Schematic diagram shwoing the different types of scratch morphologies.

by the materials because of indenter geometry effect (98). At low normal and tangential force, type 4 prevails. As tangential load increase, we have type 1 and then type 2 domination. In addition, materials properties play an important role in how polymers react to increasing scratch loads. The scratch mechanism governs the measured scratch resistance in terms of amount of materials removed and scratch visibility (58,61,62,100).

Effect of Experimental Conditions.

Magnitude of Loading. One of the most thoroughly studied parameters is the effect of applied load on scratch behavior of polymers (4,32,34,101). An increase in loading will increase severity of scratch damages inflicted on polymer surface (24). In general, the wear rate and the scratch roughness change only slightly when the sample undergoes elastic and plastic deformations. Depending on materials properties, polymers might recover elastically without scratch marks left after being scratched below a critical load owing to its high elasticity and viscoelasticity (96). When the first fracture event occurs there is a sudden increase in both the wear rate and the scratch roughness. This is due to a characteristic change in fracture feature when cracks are involved.

Under a linear load increase condition, abrupt changes in frictional force and coefficient of friction normally indicate the initiation of fracture (78), changes in scratch pattern formed on the scratched surface, and changes in deformation mode of the polymer (54,63,64,71,77–81). Because of the effect of loading on deformation mode, critical loading is often used as an indicator of scratch resistance. There are also situations where the fluctuations in loading curves were associated with stick–slip phenomenon and crack growth (102). In the case of stick–slip motion, both true force and true scratch velocity experienced by the polymer will change with scratch distance (103).

Frictional behavior affects the stress magnitude and distribution when the polymer is being scratched. Thus, it is important to investigate how frictional force and coefficient of friction respond to applied load at various loading scales. According to Amonton's law, the frictional force is proportional to normal load applied. While it is expected for frictional force to increase with applied load, the coefficient of friction, μ, is not constant with normal loadings for both polymeric and nonpolymeric materials when light load is applied to produce nanoscratch (24,63–65,72,74). Thus the general observation of having constant coefficient of friction in macroscale does not apply to nanoscale (63,104). It is the case for polystyrene (63). Its μ first increases with applied load, and then becomes constant for nanofriction. It was found that for the μ increasing regime, a scratch pattern was formed with opening and propagation of cracks. Yet at constant μ regions, wear marks and debris due to buckling are observed. Thus, a change in surface deformation mode exists.

Microfriction in many cases is lower than macrofriction (65,74). This phenomenon is suggested to be due to a reduction in real area of contact and the degree of wear arises from increased hardness and modulus of elasticity with micro/nanoscratch. In addition, the small apparent area of contact reduces the number of particles trapped at the interface, and thus minimizes the "ploughing" contribution to the friction force (73,74).

It should be noted that three types of loads have been utilized for polymer scratch. They are dead load, constant load, and linear-load-increase cases. The

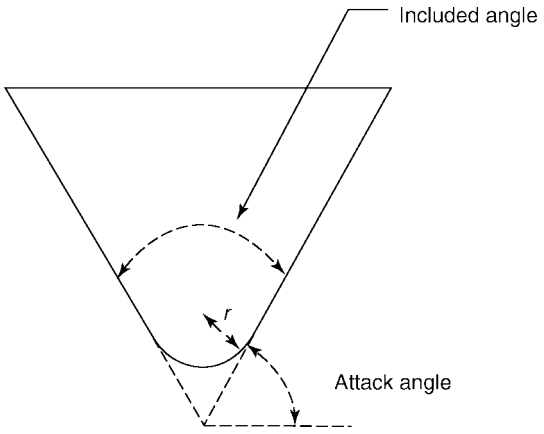

Fig. 7. Schematic diagram showing the gemoetry of a conical indenter.

constant-load and linear-load-increase tests are performed with a good control of the load applied during the scratch test (6). The test results as well as scratch damage exerted are reproducible and reliable. However, the dead-load test, eg, the Ford Five-Finger test, usually leads to jumping and oscillation of the load exerted on the indenter head during scratch. As a result, inconsistency in test results usually ensues.

Effect of Indenter Geometry. An indenter for scratch test can come with various shapes: Vickers, Berkovich, spherical, conical, and wedge-shaped. In the case of conical indenter, two geometric parameters describe the shape of a conical indenter, ie, the included/attack angle and the radius of the tip (Fig. 7). It is observed that different deformation modes are operating at different cone angle regimes. Such changes can be related to changes in contact pressure with a different sharpness of indenter (33). Briscoe and Tabor (102) found that the use of a sharper indenter will give a higher contact pressure with the same applied load. The frictional force increases with increasing contact pressure in a linear fashion for both low and high molecular weight polymers. In addition, an increase in contact pressure might cause a reduction in free volume. This will affect the surface T_g, and thus the general surface property of the polymers (105). Therefore, the indenter geometry influences the stress distribution on the surface of the sample.

In general, deformation becomes more severe as attack angle increases (97). As the attack angle increases, the deformation mode changes from elastic to ironing, ductile ploughing, ductile machining, cracking, and finally to brittle machining. Since the deformation mode changes with the attack angle, it is reasonable to observe that scratch behavior and the coefficient of friction of materials change when the attack angle is altered (21,33,82). Similar effects were observed for changes in tip radius (64,75). The difference between maximum shear stress in front of a stylus and the maximum tensile stress behind is crucial to determine the deformation mechanism during scratching (38).

Based on the relationship between deformation mode and the attack angle, the coefficient of friction during scratch can be estimated (34). However, the quality of fit will be strain-rate-dependent and it is also affected by the classification of deformation mode (82).

Effect of Scratch Velocity and Temperature. Another frequently investigated experimental parameter on the effect of scratch behavior of materials is the scratching rate or the scanning velocity. Since polymers are viscoelastic–viscoplastic in nature, the importance of scratching rate lies in its ability to change the strain and strain rate at the interface of the sample and the indenter and thus alters the deformation mode. The relationship between velocity and coefficient of fiction will depend on the relaxation state of the surface concerned, especially for nanoscratch (21,56,57,63–65). It was shown that rate and temperature interplay to affect nanotribological behavior of polymer films (57).

To explain the scratch rate and temperature dependence of polymer scratch properties, Gauthier and Schirrer (57) proposed a four-volume model, which divides the materials interacting with the tip mainly into two zones. The first zone is the surface and subsurface region in the proximity of the indenter, which is a very thin layer that undergoes extremely high shear strain at a high strain rate and adhesive slipping, with local strain rate equals the tip velocity divided by the width of groove. The second zone is a larger and deeper volume beneath the tip where viscoelastic–viscoplastic yielding occurs. Since the contact area might change with tip speed, an increase in tip speed changes the strain rate (56). Thus, the contact area changes with strain rate. Provided the initial mean strain is no more than a few percent, a transition from viscoplastic scratching to viscoelastic grooving takes place with increasing strain rate. In addition, strain hardening might occur (33). This may further complicate the scratching process.

When temperature is increased, the indenter penetrates deeper into the material and the contact area between the indenter and the specimen increases owing to thermally induced softening of the polymer. This may lead to an increase in the friction force. The increase in temperature may also lead to an increase in the contribution of viscous energy loss to the friction of the polymer, which is strongly dependent on temperature and strain rate (18). Similarly, an increase in scratch velocity that accompanies the high grooving forces will produce a substantial frictional heat exchange at the contact. Such heat may facilitate the permanent displacement of the material (21,98). In addition, scratch behavior correlates with molecular relaxation and surface molecular state of the materials (45,63). When a stick–slip phenomenon is involved in the scratch process, the scratch rate and temperature influence the amplitude, period, and average horizontal force of the process (18). Thus, how the surface and immediate subsurface zone responds to changes in strain and temperature will influence the scratch properties of polymers. This also explains why contradictory results on strain rates and temperature dependence arises with different materials as each of them might respond to such changes differently (38,57,106).

Because of the reason mentioned above, scratch patterns formed were observed to depend on velocity, temperature, and storage modulus (107). Temperature and scratch rate also affect the amount of elastic recovery displayed after scratch is formed (96). In addition, the scratch rate effect might be coupled with cone angle effect to complicate the scratch phenomenon (108).

Effect of Environmental Conditions. Apart from temperature, other environmental factors can also be crucial in terms of affecting coefficient of friction (64),

scratch visibility, and polymer self-healing ability (99). Humidity alters the materials yield stress, thus affecting the mode of deformation the materials undergo (38). Coefficient of friction might increase with increasing humidity because of increasing meniscus force on one hand, and decreases because of the formation of water film, which acts as lubricant, on the other (65).

Effect of Materials Properties

Notwithstanding the importance of experimental parameters, materials characteristics play a crucial role. Modulus and yield strength impact on the size of deformation zone, amount of recovery, and mode of deformation (4,36,109). For example, the deformations shown on polycarbonate and epoxy are different (109,110). Also, depending on modulus and yield strength of polymers, the radius of contact zone, the penetration depth, and plastic zone size will vary (4). In addition, modulus and yield strength will affect the coefficient of friction, scratch hardness, and scratch visibility (3,5,9,35,71,75,76,111). One factor that closely influences the modulus of the polymer is its molecular weight and molecular weight distribution, which may affect polymer ductility and crystallinity, and thus microhardness (112). Therefore, molecular weight and molecular weight distribution will impact on both scratch resistance and deformation (41,113). Similarly, cross-link density will have an effect on scratch phenomena observed (60,109). Treatments on polymer and its fabrication process affect the nanotribological behavior of the polymer film. The effects of surface treatments and fabrication processes, such as plasma treatment (82–85), hydrogen content (86), and use of filler and additive (2,3,5,29,35,77,104) on scratch resistance have been studied. Work looking at how rheology (75) and chain length (111,114) affects scratch resistance of polymers has also been performed.

Processing and fabrication techniques impact on the intrinsic properties of the polymers, and thus influences the polymer scratch properties. Blending, in general, will affect the mechanical properties of polymers and thus the scratch resistance and deformation mode of the blend (35,111). In some cases, certain constituents might preferentially segregate to the surface (35,87). It has been shown that glass-transition temperature on the surface of the blend may vary significantly depending on its composition (115). As the constituents in polymer blend might have very different mechanical properties, scratch deformation mode might change with composition (77).

Fillers are very often added to engineer the mechanical strength of polymers. The use of rigid filler will increase modulus, and thus the polymer will be more prone to tensile cracking, whereas the use of rubber for blending will lower modulus and the scratch depth will increase (4). With the use of different types of rigid fillers, scratch pattern and deformation mechanism might be different (2,3,28,29,104). The role of rigid fillers on scratch resistance of polymer blends will also depend on other additives in the blends, such as rubber modifiers (116), nucleating agent (5), and lubricants (3). If continuous fiber is used as reinforcement, the orientation of fiber will need to be taken into account when assessing polymer scratch resistance (106,117). Lubricants are normally added to reduce surface

friction, and thus have the possibility of reducing severity of scratch damage (5). Yet, its effect on polymer scratch resistance is not necessarily positive because the application of such lubricants might reduce flow resistance of materials and thus increase penetration depth (34). And, the efficiency of lubricants will depend on the scratch rate and cone angle of indenter (34).

Finally, processing condition, such as processing temperature (80,118) and surface treatment (84), will influence the scratch properties of polymers owing to changes in the structure and morphology of polymers. An example would be the existence of skin–core structure in injection-molded samples, giving rise to variation in scratch resistance as scratch depth changes (80). Also, whether the polymer is uniaxially or biaxially stretched will change the polymer scratch properties as a result of alteration of crystallinity (76). In addition, the use of solvent either to swell the polymer surface (35,82) or for film casting (118) influences molecular arrangement on the surface and thus impact on scratch properties of polymers.

Future Work

Scratch damages inflicted on polymer surface have important consequences on the appearance and mechanical performance of the materials. Scratches, in a lot of situations, are precursors of wear and abrasion (119,120). Scratch phenomena impact on the use of polymers in automobiles, microelectronics, food packaging, and coatings. The complexity involved in research of scratch behavior of polymers has been highlighted in this article. Many factors have been considered for their influence on the subject concerned. Very often the factors that affect scratch interact with each other and are difficult to isolate the effect of individual factors. This renders the interpretation of experimental results difficult and thus explains the frequently observed contradictory results in the literature.

While researchers in this field seek to establish the relationships between scratch performance and various controlled parameters, a diversity of techniques and equipment have been used in order to examine phenomena in different scales of interest. This means that it is often difficult, if not impossible, to compare results from different studies. With these challenges in mind, the summary of research findings presented in this article gives at most phenomenological accounts of the scratch behavior of polymers under the influences of a combination of factors, with the correlation among these factors being largely unknown. These studies have provided useful insight in how different polymers respond when they are being scratched. However, in order to better predict polymer scratch properties and design scratch-resistant polymers/parts, a more fundamental understanding of the physics behind the scratch phenomena is required. The general approach toward this goal is described below.

First, in the hope of improving comparability of results among tests on different polymers, a unified testing standard in examining the scratch resistance of polymers has been proposed (44). In addition, a universal scratch test machine is developed (6). The test standard and the scratch machine were introduced to provide a standardized way to investigate scratch behavior of polymers, which is versatile enough to accommodate different testing needs in the

micro- and macroscales. Tests using such machine were carried out with satisfactory results, ensuring good reliability and repeatability, thus generating data that can be compared meaningfully (6,7). One of the distinctive features for these sets of studies is the use of linear load increase test during the course of the experiments. It is shown in our studies that various stages of scratch deformation modes can be observed and correlated to the applied load in a quantitative fashion, and thus useful insight can be gained with such setup.

Second, the more extensive use of finite element analysis (FEA) is encouraged. It is difficult to separate the influence of different factors on surface properties of polymers in real experiments. Using FEA, the effect of individual material and mechanics factor or the correlation between multiple factors can be evaluated with other parameters being held constant in a well-controlled manner. Thus, results obtained from this route can be used to supplement experimental findings. This helps us better understand the impact of individual factors and, more importantly, it also helps to develop scratch deformation theory since a more mechanistic approach rather than a phenomenological approach is applied in FEA.

Finally, in order to better understand the science of scratch phenomenon, we may start off with the simplest case of all, ie, scratch formed by single asperity with shallow scratch groove. Such scratch experiments have been made possible with the invert of atomic force microscopes and depth sensing devices, such as nanoindenter. Two reasons have prompted the rapid growth of result in nanoscratch: First, scratch properties with very shallow scratch depth is expected to be different from those with depth because of the difference in molecular conformation between the surface and the bulk (109). Second, macroscopic scratches and wear might begin with scratches in nanoscale. The observations of nanoscale scratch under single asperity condition can thus suggest mechanisms on formation of surface damage and the subsequent wear properties of polymers.

With all the strategies listed above, we hope that as our understanding on scratch behavior of polymers accumulates, a more complete formulation of theoretical framework on surface deformation and damage phenomena can be developed. Only when such framework relating all relevant materials parameters and mechanics with deformation mechanism is available, can we establish predictive model that is useful for polymer engineering and design of scratch-resistant polymers.

SILICONES

Introduction

Silicones are a class of polymers having the formula $(R_mSi(O)_{4-m/2})_n$, where $m =$ 1–3 and $n \geq 2$. The most common are the polydimethylsiloxanes (PDMS).

Silicones and silanes are the subject of many reviews (1–8). Commercial products include fluids, filled fluids and gums, greases, resins, and rubber (1,2). Various forms of silicones and examples of applications are listed in Table 1.

The designations M, D, T, and Q, respectively, are used for mono-, di-, tri-, and quaternary coordination of oxygen around silicon in silicones. A T group can also be written as $CH_3SiO_{3/2}$; a Q group as SiO_2. When groups other than methyl are present, these groups are indicated with a superscript, eg, D^{Vi} represents a methyl vinyl siloxy group $(CH_3)CHCHSiO$. Resins are often referred to as M_xQ, M_xT, M_xD_y T_zQ, etc. This common shorthand notation for silicones is depicted in Figure 1.

History of Silicones. Although silicon is quite abundant in nature, there are no natural forms of organosilicon. The first covalent compound of silicon, SiF_4, was made in 1771 (9). Berzelius, in 1823, was the first to make amorphous silicon by potassium reduction of SiF_4; he also found that the combination of SiO_2, CuO, and C had greater hardness than SiO_2 alone. In 1896 Morrison made silicon metal by the reaction of SiO_2 and C in an electric arc furnace, a process by which metallurgical-grade silicon has been produced commercially since the 1990s. Ironically, in 1900, Oswalt announced, "elementary silicon has no application or any interesting properties" (10). Six years later, in what would prove to

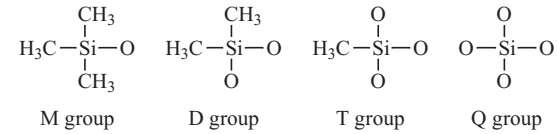
Table 1. Silicone Products and Their Uses

Commercial product	Use
Fluids: heat-stable liquids	Lubricants, water repellents, defoamers, release agents, surfactants
Filled fluids and gums	Valve lubricants, moistureproof sealants for electrical connectors, pressure-sensitive adhesives, personal care products
Grease: fluid and carbon black or soap	Nonflow lubricants, polishes
Resins: cross-linked materials	Electrical insulation, lubricant and paint additives, release formulations, water repellents
Rubbers: fluids or gums and surface-treated fillers; elastic with good tensile strength	Electrical insulation, medical devices, seals, textile coatings, foams

be an important discovery, Vigreaux treated Na_2SiF_6 with copper at 1000°C to give Cu_xSi, a key intermediate in the modern preparation of methylchlorosilanes. Alkoxy silanes were first prepared in the mid-1800s (11,12).

Kipping is considered the father of organosilicon chemistry. He employed Grignard reagents to make compounds of the general class $R_{4-x}SiCl_x$ (13,14). Kipping reportedly remarked that the polymers obtained from the hydrolysis of chlorosilanes were "omnipresent nuisances" (15). In the 1930s Stock made significant contributions by carrying out gas-phase reactions to prepare silicon hydrides and compounds having Si—Si bonds (16).

The beginning of the silicone industry has been well documented (15,17). In 1930 Corning Glass made the first deliberate effort to find a use for silicones, and in 1939 the company began the etherless methyl Grignard process as a method for making methyl silicones. One of the first commercial products, DC 4, was composed of silica in PDMS fluid. It was used in high altitude aircraft applications. Another early product was DC 990A resin, $C_6H_5(C_2H_5)Si(OH)_2$, which when cross-linked



For example:

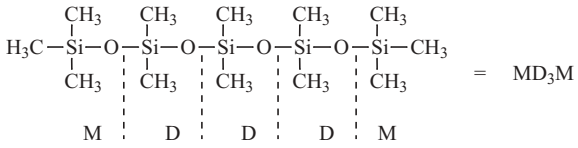


Fig. 1. Widely accepted abbreviations used for silicone groups.

at high temperature had good dielectric strength, low dielectric loss, and good thermal stability.

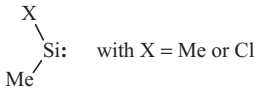
In 1940 Rochow discovered the direct process, also called the methylchlorosilane (MCS) process, in which methyl chloride is passed over a bed of silicon and copper at high temperature (250–300°C) to produce a mixture of methylchlorosilanes, including the industrially important dichlorodimethylsilane [75-78-5], $(CH_3)_2SiCl_2$. Working independently, Müller made a similar discovery in Germany. Consequently, the process is frequently called the Rochow process and sometimes the Rochow–Müller reaction. These discoveries were followed by two key publications describing the work that marked the beginning of the commercial silicone industry (18,19). Production increased rapidly with the need for silicones in World War II. In 1943 the Dow Corning Corp. was formed in Midland, Michigan, as a joint venture between Corning Glass and Dow Chemical. In 1947 GE opened a plant for the manufacture of silicones in Waterford, New York, and in 1949 Union Carbide opened a silicone manufacturing plant in Tonawanda, New York.

Chemistry

The chemistry of silicones has been described in many textbooks (1,20,21).

Direct Process. Passing methyl chloride vapors through a bed of copper and silicon at temperatures near 300°C yields a mixture of methylchlorosilanes. The efficiency of this process is critically dependent on reactor design and chemistry. Optimization of the fluidized-bed reactor is a critical part of the industrial process (22). The rate of methylchlorosilane (MCS) production and selectivity for dichlorodimethylsilane are significantly affected by trace elements in the catalyst bed; very pure copper and silicon give poor rate and selectivity (23–25).

Much of the early work on the direct process was devoted to understanding the structure of the active catalyst. Many reports have suggested that Cu_3Si, or eta-phase, is a key catalytic species in the MCS reaction (9,26–29). Reactions employing Cu_3Si and Cu_5Si have been shown to be good models for the direct process (30). Copper transfer appears to be the first step in the MCS process (31). There is strong evidence to support the intermediacy of a silylene in the Cu-catalyzed direct process (32).



with X = Me or Cl

In a single-crystal study of the surface interaction of Si with various forms of copper as models of the direct process (33), the highest selectivity obtained was for a mixture of 82% Cu and 18% Cu_2O, similar to the selectivity obtained in a fluidized-bed reactor (34). Other surface studies have shown that silicon is efficiently removed from the Cu–Si phase when the ratio of Me to Cl is about 1:1 (35).

In one of the first comprehensive studies on the effect of trace elements on the direct process (34), the importance of zinc and tin and other trace elements as

promoters was recognized. The effects of three promoters and their synergy have been investigated empirically (23). The results show that the reaction rate of the direct process decreases as a function of catalyst bed composition in the following order: SiCuZnSn > aged SiCu > SiCuAlSn > SiCuZn > SiCuAl > fresh SiCu > SiCuZn. The selectivity for the formation of $(CH_3)_2SiCl_2$ also depends on catalyst composition and decreases in the following way: SiCuZnSn > SiCuAlSn SiCuZn > aged SiCu > SiCuSn > SiCuAl > fresh SiCu. This study concluded that zinc functions as a methylating agent. Aluminum and tin are synergistic promotors of rate and selectivity, and it appears that aluminum modifies the alloy properties of CuZnAlSi. Finally, tin and zinc have a synergistic effect. The effect of aluminum on alloying properties has been discussed (36). Aluminum affects reactivity and selectivity while calcium affects only reactivity (37). Additional promoters include phosphorus, which acts as a strong selectivity enhancer (38–40), boron (41), and alkali metal halides (42). Optimization methods have been applied to the complex mixture of promoters used in the direct process (43).

Zinc and tin surface enrichment appears to be essential for high activity and reactivity. Additives that impede silicon and/or zinc surface enrichment have a negative impact on rate. Lead is an example of such a catalyst poison for this reason (44). Considerable fundamental work remains to be done to understand the direct process at the molecular level.

Not surprisingly, the particle size and composition of the silicon used in the direct process are important parameters. Optimum silicon particle size for the fluidized-bed process is above 10 μm. Particles must also have low oxygen content (45). An interesting approach to optimizing the interaction of metal catalysts with the silicon surface is the pregrinding of silicon with at least one of the metals used to catalyze the reaction (46). The elemental composition of the silicon input is critical to its performance in the direct process. Phosphorus can be added as a promoter or may be present as a component of the silicon (47). Significant effort has been made to improve the reactivity of silicon by a water granulation method during the production of silicon (48).

Alternatives to the methyl chloride based direct process have been reviewed (49). Direct-process chemistry has been used to make phenyl and ethyl silicones. For example, chlorobenzene can be used in place of methyl chloride to make phenylchlorosilanes (15). Phenylchlorosilanes can also be produced by the reaction of benzene, $HSiCl_3$, and BCl_3 (17,49). Ethylsilicones have been made primarily in the former Soviet Union, where the direct process is carried out with ethyl chloride in place of methyl chloride (50). Vinyl chloride can also be used in the direct process to produce vinylchlorosilanes (49). Vinylchlorosilanes can also be made by reaction of vinyl chloride with $HSiCl_3$ (51) or by platinum-catalyzed hydrosilylation of acetylene with $HSiCl_3$ (52,53).

Some new direct-process-like reactions have been described. The reaction between methanol and Cu/Si gives $(CH_3O)_3SiH$ (eq. 1), and the reaction of methanol over Si/B gives $(CH_3O)_4Si$ (54–56).

$$3\ CH_3OH + Si \xrightarrow[\text{High boiling solvents}]{250^\circ C} HSi(OCH_3)_3 + H_2 \qquad (1)$$

The reaction of alcohols other than methanol with silicon sources has been examined under direct-process conditions as a method to make alkyl silicates (57). The use of HCl in the MCS reaction gas stream increases CH_3Cl_2SiH without decreasing the total combined yield of $(CH_3)_2SiCl_2$ and CH_3Cl_2SiH; no significant undesirable $SiCl_4$ or $HSiCl_3$ forms (58–60). Similar results are obtained by using hydrogen in place of HCl (61). Hydrogen in the direct process stream enriches SiH monomers, but promoters normally used in the direct process usually retard SiH monomer formation. Zinc is particularly deleterious to CH_3HSiCl_2 formation (62,63). Other forms of the direct process include the reaction of dimethyl ether and methyl halide over Si/Cu to give $(CH_3)_2Si(OCH_3)_2$ (64,65). More recently, the reaction of $(CH_3)_2NH$ and silicon to give $((CH_3)_2N)_3SiH$ has been reported (66).

Methylchlorodisilanes are by-products of the direct-process. Commonly referred to as "residue," these are formed at a level of about 4% of the total $(CH_3)_2SiCl_2$ produced (In 1994 $(CH_3)_2SiCl_2$ production was about 30,000 ton/year). Disilanes are key constituents of the residue, and novel reactions forming Si—Cl bonds have been described (67–69). Commercially, disilanes are redistributed to recover methylchlorosilane monomers (70). Some chemical reactions of direct-process disilanes are shown in Figure 2. Cleavage of Si—Si bonds with HCl has also been described and is practiced industrially (68).

A significant use of direct-process waste can be realized by C_6H_5—Si bond formation via silylative decarbonylation (eq. 2) (74,75). A novel route to C_6H_5—Si bond formation has also been described (eq. 2) (76).

Cleavage reactions:

$$Cl_2CH_3Si{-}SiCl(CH_3)_2 + HCl \xrightarrow{(C_4H_9)_3NHCl} Cl_2CH_3SiH + Cl_2Si(CH_3)_2 \quad \text{(i)}$$

Disproportionation:

$$n\ Cl_2CH_3Si{-}SiCl(CH_3)_2 \xrightarrow{\text{Base catalyst}} n\ CH_3SiCl_3 + \left(\begin{array}{c}|\\ Si\\ |\\ Cl\end{array}\right)_n \quad \text{(ii)}$$

Si—C bond forming reactions:

$$Cl_2CH_3Si{-}SiCl(CH_3)_2 + R{-}C{\equiv}C{-}R \xrightarrow{Pt} Cl_2(CH_3)_2Si{-}RC{=}CR{-}SiCl_2CH_3 \quad \text{(iii)}$$

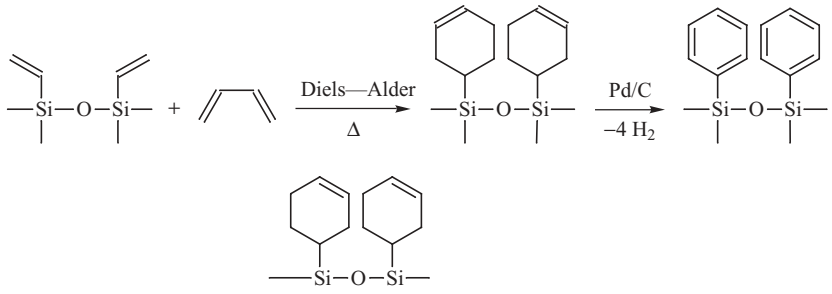
$$Cl(CH_3)_2Si{-}Si(CH_3)_2Cl + H_2C{=}CH_2 \longrightarrow Cl(CH_3)_2Si{-}CH_2CH_2{-}Si(CH_3)_2Cl \quad \text{(iv)}$$

$$ArCOCl + Cl_2CH_3Si{-}SiCl(CH_3)_2 \xrightarrow{Pd} ArSiCl(CH_3)_2 + Cl_3SiCl(CH_3)_2 + CO \quad \text{(v)}$$

Redistribution:

$$Me(Me_2Si)_6Me \xrightarrow{AlCl_3} (Me_3Si)_3SiSiMe_2SiMe_3 \xleftarrow{AlCl_3} Me(Me_3Si)_2SiSiMe(SiMe_3)_2 \quad \text{(vi)}$$

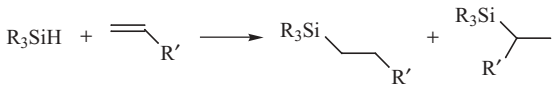
Fig. 2. Chemistry of direct-process residue methylchlorodisilanes. The reactions are discussed in detail in the following references: (i) 71, (ii) 67,68, (iii) 72, (iv) 73, (v) 74,75, and (vi) 69.



(2)

Synthesis of Silicone Monomers and Intermediates.

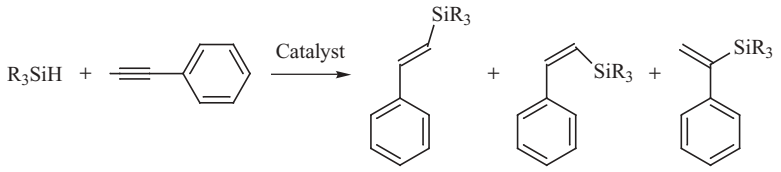
Hydrosilylation Products. In addition to the direct process and Grignard chemistries, a very important reaction for formation of Si—C bonds is the hydrosilylation reaction, which involves the addition of Si—H across an olefinic double bond (eq. 3).



(3)

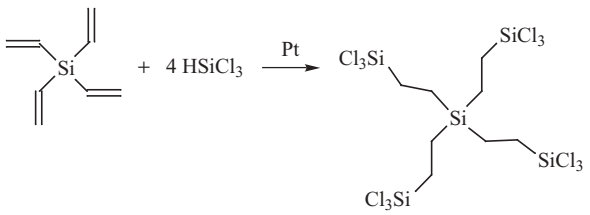
This reaction has been used for the formation of a wide variety of organofunctionalized silicones and for cross-linking silicone polymers by addition cure (77–83).

Recent examples that have utilized the hydrosilylation reaction to prepare very unique organosiloxanes are shown in equations 4 and 5. Equation 4 depicts the hydrosilylation of phenylacetylene to provide beta-vinyl silicones (84,85) and is a convenient route to high refractive index silicones.



(4)

Hydrosilylation reactions have also been used as the key step (86) in the synthesis of dendritic siloxanes (eq. 5).



(5)

Alkoxysilanes. Alkoxysilanes are important intermediates in the manufacture of silicone-based materials. The prevalent method for forming the silyl ether linkage is alcoholysis of Si—Cl bonds (eq. 6. Removal of the concurrently formed HCl is typically accomplished by addition of tertiary amines (87,88). Often NaOR is used instead of the corresponding alcohol to give the less corrosive and more easily removed NaCl as by-product (89,90). Use of alkyl orthoformates represents an alternative to alcohols or metal alkoxides (eq. 7) (91–93).

$$RSiCl_3 + 3\ R'OH \rightarrow RSi(OR')_3 + 3\ HCl \tag{6}$$

$$R_3SiCl + HC(OR')_3 \rightarrow R_3SiOR' + R'Cl + HCOOR' \tag{7}$$

Silyl ethers can also efficiently be prepared starting from Si—H bonds. Silanes containing one or more Si—H functional groups react with alcohols in the presence of a catalyst (eq. 8). Typical catalysts include bases (eg KOH, NaOH, KOR, NaOR, amines), strong acids, metals (colloidal copper), and metal complexes of Fe, Co, Ru, Rh, Pd, Ir, and Pt (94). Recently, a highly efficient catalyst (Ph_3PCuH) was reported to affect alcoholysis of hydrosilanes under mild conditions while also tolerating unsaturated alcohols (95). Tris-pentafluorophenylboron is also a very effective catalyst for silylation of alcohols with hydrosilanes (96).

$$R_{4-n}SiH_n + n\ R'OH \xrightarrow{\text{Catalyst}} R_{4-n}Si(OR')_n + n\ H_2 \tag{8}$$

Alkoxysilanes can also be prepared by exchange of an existing alkoxy group with another one (eq. 9). Generally, alkoxy exchange requires a catalyst such as a mineral or organic acid (97), Lewis acid (alkyl titanate) (98), or strong base.

$$R_{4-n}Si(OR')_n + n\ R''OH \xrightarrow{\text{Catalyst}} R_{4-n}Si(OR'')_n + n\ R'OH \tag{9}$$

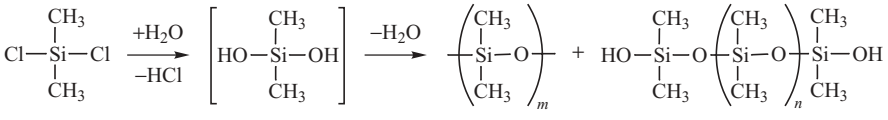
Acetoxysilanes. A very important functional group in silicone chemistry is the acetoxysilane group. It is widely used during the manufacture of single-component moisture-curable room-temperature-vulcanizable sealants. These acetoxy-stopped polymers hydrolyze more readily than the corresponding alkoxy-stopped silicones and release acetic acid during cure. Acetoxy-functionalized silicones are generally prepared by the acylation of a chlorosilane via addition of sodium acetate, acetic anhydride, or acetic acid (99,100).

It is also possible to synthesize acyloxysilanes by reacting triorganohydridosilanes with carboxylic acids (eq. 10) in the presence of strong acids, aluminum, or nickel complexes as catalysts (101).

$$R_3SiH + R'COOH \xrightarrow{\text{Catalyst}} R_3Si{-}O{-}\underset{\underset{O}{\|}}{C}{-}R' + H_2 \tag{10}$$

Polymerization

The manufacture of polydimethylsiloxane polymers is a multistep process. The hydrolysis of the chlorosilanes obtained from the direct process yields a mixture of cyclic and linear silanol-stopped oligomers, referred to as hydrolysate (eq. 11). In some cases, chloro-stopped polymers can also be obtained (102).

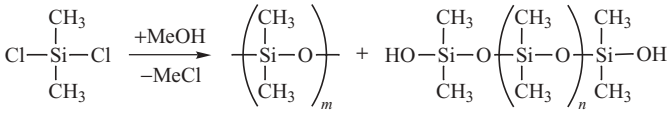


(11)

The ratio of cyclic to linear oligomers, as well as the chain length of the linear siloxanes, is controlled by the conditions of hydrolysis, such as the ratio of chlorosilane to water, temperature, contact time, and solvents (1). Commercially, hydrolysis of dichlorodimethylsilane is carried out by either a batch or continuous process (1,2,103,104). In a typical industrial operation, dichlorodimethylsilane is mixed with 22 wt% azeotropic aqueous hydrochloric acid in a continuous reactor. The resulting mixture of hydrolysate and 32 wt% hydrochloric acid is separated by means of a decanter. After separation, the anhydrous hydrogen chloride is converted by reaction with methanol to methyl chloride, which is then reused in the direct process. The hydrolysate is washed to remove residual acid, then neutralized, dried, and filtered (105). The typical yield of cyclic oligomers is between 35 and 50%. The mixture of cyclic oligomers consists mainly of tetramer and pentamer. Only a small amount of cyclic trimer is formed.

The complete conversion of the dichlorodimethylsilane to only linear oligomers is also possible in a continuous hydrolysis operation (106). In this process, the cyclics are separated from linear oligomers by a stripping process and are mixed again with dichlorodimethylsilane. This mixture undergoes equilibration to chloro-terminated oligomers and is subsequently hydrolyzed. The silanol-stopped linear oligomers are directly used in the manufacture of silicone polymers.

Dichlorodimethylsilane can also be converted into siloxane silanol-stopped oligomers by a methanolysis process (eq. 12).



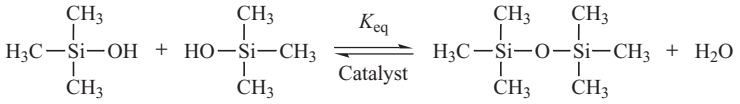
(12)

In contrast to hydrolysis technology, the methanolysis process allows for the one-step synthesis of organosiloxane oligomers and methyl chloride without formation of hydrochloric acid (104,107). The continuous methanolysis can also yield quantitatively linear silanol-stopped oligomers by recycle of the cyclic fraction into the hydrolysis loop.

If the linear fraction of siloxane oligomers is used directly in the manufacture of silicone polymers, extremely pure (greater than 99.99%) dichlorodimethylsilane is required. A high content of trichloromethylsilane can produce significant

amounts of trifunctional units and considerably affect the physical properties of the final products. If such high purity dichlorodimethylsilane is not utilized, an additional step, called cracking, must be included in the production scheme (108). In the cracking process, the hydrolyzate is depolymerized in the presence of strong base or acids to yield cyclic monomers, primarily octamethylcyclotetrasiloxane (D_4) and decamethylcyclopentasiloxane (D_5), which are distilled from the reaction mixture. The trifunctional by-products remain in the pot and are periodically removed.

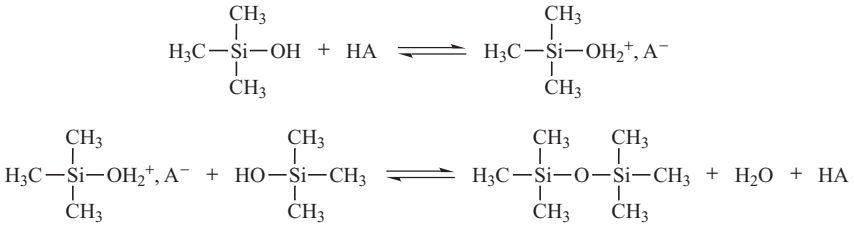
Polycondensation. The linear fraction of hydrolysate, dimethyloligosiloxane-α,ω-diols having a viscosity of 10–100 mPa (=cP), is converted further to silicone fluids and high molecular weight gums by polycondensation of the silanol end groups (eq. 13). Polycondensation is an equilibrium process. In spite of the relatively high equilibrium constant for this reaction ($K_{eq@35^\circ C} = 860 \pm 90$), water removal is required to obtain high molecular weight siloxane polymers (109).



(13)

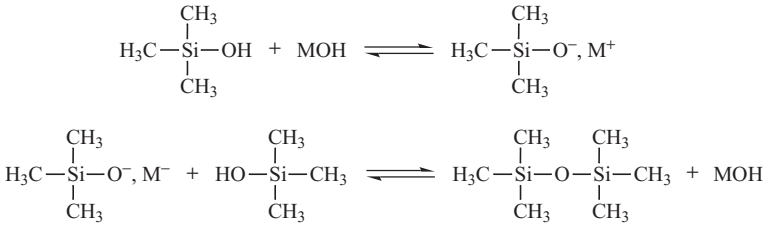
Although the low molecular weight silanols such as trimethylsilanol and dimethylsilanediol undergo condensation thermally, the higher molecular weight oligomers are much more stable and their polycondensation must be catalyzed. Many catalytic systems capable of promoting polycondensation of siloxanediols have been described in patents and open literature (1,110–117). These catalysts include strong acids such as HCl, HBr, H_2SO_4, $HClO_4$, and CF_3SO_3H; phosphonitrilic chlorides such as $(Cl_3\ PN(PCl_2N)_nPCl_3)^+PCl_6^-$; oxygen-containing chlorophosphazenes such as $Cl_3PN(PCl_2N)_nP(OH)Cl_2$; strong bases such as KOH, NaOH, and $(CH_3)_4NOH$; as well as amines, amine salts of carboxylic acids, ion exchange resins, and clays activated with mineral acids. The most selective, efficient and extensively used in industry are phosphonitrilic chlorides (112–114) and oxygen-containing chlorophosphazenes (115–117).

The first mechanistic studies of silanol polycondensation on the monomer level were carried out in the 1950s (118–120). The proposed mechanism of the acid-catalyzed condensation involves the protonation of the silanol group and subsequent nucleophilic substitution at the silicone (eq. 14).



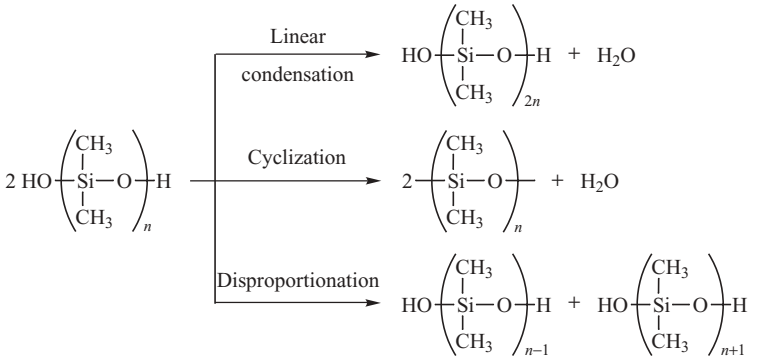
(14)

In the condensation catalyzed by a strong base the rate-determining step is the attack of silanolate anion on the silicon atom in the silanol end group (118,119). Because of the high acidity of silanol (110), the alkali metal base (MtOH) is usually transformed into the silanolate anion (eq. 15).



(15)

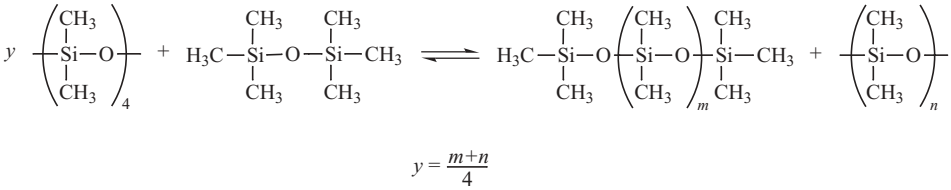
Early studies of the condensation reaction on the monomer level did not give the full picture of this process and only in the 1980s the polycondensation of siloxanols was studied by using oligomeric model compounds (121,122). These studies revealed that in the presence of strong protic acids three processes must be considered: linear condensation, cyclization, and disproportionation (eq. 16). The relative contributions from these processes strongly depend on the reaction conditions, such as type of solvent, substrate, water concentration, and acidity of catalyst (121–124). It was also discovered that in acid–base inert solvents, such as methylene chloride, another silanol group provides the basic assistance required for the condensation process. This phenomenon, called intra–inter catalysis, controls the linear-to-cyclic products ratio, which is constant at a wide range of substrate concentrations (121).



(16)

The behavior of oligosiloxanediols in the presence of strong bases is different. The contribution to the overall process of the disproportionation reaction, involving a migration of the ultimate siloxane unit between siloxane molecules, is much greater and may even completely dominate the polycondensation reaction (125). The reactivity enhancement of the siloxane bond adjacent to the silanolate anion can be understood in terms of $n(0) \rightarrow \sigma*(SiO)$ conjugation.

Ring-Opening Polymerization. Ring-opening polymerization of cyclic oligodiorganosiloxanes is an alternative to the polycondensation method of manufacturing siloxane polymers. Commercially, the polymerization of unstrained D_4 is the most important (1,102,110). In the presence of catalysts such as strong acids or bases, D_4 undergoes equilibrium polymerization, which results in a mixture of high molecular weight polymer and low molecular weight cyclic oligomers (eq. 17). The molecular weight of the polymer is easily controlled by the amount of chainstropper added and can be varied from very low molecular weight to very high molecular weight.



$$y = \frac{m+n}{4}$$

(17)

The position of the equilibrium depends on a number of factors, such as concentration of siloxane units and the nature of substituents on the silicon, but is independent of the starting ratio of linear to cyclics or the polymerization conditions (126,127). For a bulk polymerization of dimethylsiloxane, the equilibrium concentration of cyclic oligomers is approximately 18 wt% (128). The equilibrium mixture of cyclosiloxanes is composed of a continuous population to at least D_{400}, but D_4, D_5, and D_6 make up over 95 wt% of the total cyclic fraction (129).

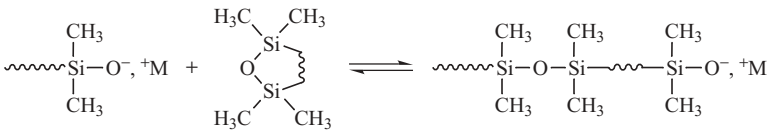
The ring-opening polymerization of D_4 is controlled by entropy, because thermodynamically all bonds in the monomer and polymer are approximately the same (1,110,130). The molar cyclization equilibrium constants of dimethylsiloxane rings have been predicted by the Jacobseon–Stockmayer theory (131). The ring–chain equilibrium for siloxane polymers has been studied in detail and is the subject of several reviews (127,128,132–135). The equilibrium constant for the formation of each cyclic is approximately equal to the equilibrium concentration of this cyclic, $K_n \sim [(SiR_2O)_n]_{eq}$. The total concentration of cyclic oligomers at equilibrium is thus independent of the initial monomer concentration. As a consequence, the amount of linear polymer decreases until the critical dilution point is reached, at which point only cyclic products are formed.

Anionic Polymerization of Cyclic Siloxanes. The anionic polymerization of cyclosiloxanes can be carried out in the presence of a wide variety of strong bases such as hydroxides, alcoholates, or silanolates of alkali metals (1,102,110). Commercially, the most important catalyst is potassium silanolate (98). The activity of the alkali metal hydroxides increases in the following sequence: LiOH < NaOH < KOH < CsOH, which is also the order in which the degree of ionization of their ion pair increases (136). Another important class of catalysts is tetraalkylammonium and tetraalkylphosphonium hydroxides, and silanolates (137–139). These catalysts undergo thermal degradation when the polymer is heated above the catalyst decomposition temperature (typically >150°C), producing volatile

by-products and the neutral, thermally stable polymer. Recently, a new class of super-strong phosphazene bases such as $[(N(CH_3)_2)_3P{=}N{-})_3P{=}N(t\text{-}C_4H_9)]$ have been reported (140–142). The phosphazene bases allow for the synthesis of high molecular weight polysiloxanes, using extremely low catalyst levels with short reaction times and over a wide range of temperatures.

Anionic polymerization is widely used in the silicone industry for the manufacture of silicone polymers. The anionic polymerization of cyclic siloxanes can be conducted in a single-batch reactor or in a continuously stirred reactor (143,144). The viscosity of the polymer and type of end groups are easily controlled by the amount of added water or triorganosilyl chain-terminating groups.

The mechanism of anionic polymerization of cyclosiloxanes has been the subject of several studies (145,146). The first kinetic analysis in this area was carried out in the early 1950s (147). In the general scheme of this process, the propagation/depropagation step involves the nucleophilic attack of the silanolate anion on the silicon, which results in the cleavage of the siloxane bond and formation of the new silanolate active center (eq. 18).



(18)

The kinetics of this process is strongly affected by an association phenomenon. It has been known that the active center is the silanolate ion pair, which is in equilibrium with a dormant ion pair complex (148,149). The polymerization of cyclosiloxanes in the presence of potassium silanolate shows the kinetic order 0.5 with respect to the initiator, which suggests the principal role of dimer complex (150).

The synthesis of new, high performance materials requires the synthesis of well-defined, narrow molecular weight distribution, cyclic-free, homo-, and copolymers. This can be accomplished by the kinetically controlled polymerization of the strained monomers, hexaalkylcyclotrisiloxanes. In the presence of the proper initiator and under the right reaction conditions, the polymerization of hexamethylcyclotrisiloxane (D_3) can proceed as a classical living polymerization. The most frequently used initiator, lithium silanolate, provides fast and quantitative initiation and a propagation that is free of depolymerization or chain-scrambling processes (151–153). However, the rate of D_3 polymerization in the presence of lithium silanolate is slow. To accelerate the polymerization process, a cation-interacting solvent such as tetrahydrofuran (THF) is commonly employed (154,155). Nucleophilic additives such as hexamethylphosphoric triamide (HMPT) or dimethyl sulfoxide (DMSO), as well as chelating agents such as cryptates, can also be used (156–161). These additives interact strongly with the lithium cation and convert the intimate ion pair into a more reactive, separated one.

Cationic Polymerization of Cyclic Siloxanes. The cationic polymerization of cyclic siloxanes is often a preferred method for the synthesis of siloxane polymers. This process, which can be performed at relatively low temperature, can

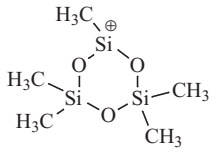
be applied to the synthesis of polysiloxanes having base-sensitive substituents such as Si—H, and the catalyst can be easily deactivated. The first high molecular weight siloxane polymer was prepared by the cationic ring-opening polymerization of D_4 in the presence of sulfuric acid (162). Since that time many catalytic systems have been reported in patents and open literature. These include strong protic acids such as CF_3SO_3H (triflic acid), $HClO_4$, H_2SO_4, aryl- and alkylsulfonic acids, heterogeneous catalysts such as ion-exchange resins, acid-treated graphite, and acid-treated clays, as well as some Lewis acids such as $SnCl_4$ (1,110,163–172). Polymerization in the presence of Lewis acids is a subject of controversy. Strong protic acids such as $HSnCl_5$, the product of the reaction of Lewis acid with water or other protic impurities, are proposed in most cases as the true catalyst (173). However, it has been reported that some nonprotic systems such as ethylboron sesquitriflate (174) and antimony chloride – acid chloride pairs (175) are able to initiate polymerization of cyclotrisiloxane. Also, electron-deficient organosilicone reagents such as trimethylsilyl triflate (176,177) and $Me_3SiH/(C_6H_5)_3C^+B(C_6F_5)_4^-$ (178) have been proven effective as initiators for cationic ring-opening polymerization of cyclosiloxanes.

Despite a long history of commercial application and in-depth studies (110,163,178–184), the mechanism of cationic polymerization of cyclic siloxanes is not as well understood as the anionic process. Several unusual kinetic results have been observed, such as the apparent negative order in the monomer concentration, negative activation energy, or a strong effect of water on the kinetics of polymerization (171,182–185). The proposed complex mechanism of acid-catalyzed polymerization consists of four processes: initiation-ring opening, step growth by homo- and heterofunctional condensation, chain propagation by direct monomer addition, and end group interconversion. Hydrogen bond association plays a crucial role in this process (148,185,186). The cationic ring-opening polymerization initiated by the electrophilic trialkylsilyl species proceeds by the simpler addition mechanism, which involves a single "long-lived" oxonium ion end group (178).

Emulsion Polymerization. Even though siloxane bond formation is an equilibrium process, it is possible to form siloxane polymers by polycondensation or ring-opening polymerization in aqueous emulsions (187–189). D_4 can be converted into high molecular weight polymer by emulsion polymerization in the presence of dodecylbenzenesulfonic acid (DBSA), which acts as both emulsifying surfactant and catalyst (190). It is also possible to obtain high molecular weight polymers by polycondensation of α,ω-dihydroxy-stopped oligosiloxanes in an aqueous emulsion employing DBSA (191) or benzyldimethyldodecylammonium hydroxide (BDDOH) (192) as the surface-active catalyst. The polycondensation involves the reaction of a complex of silanol and two molecules of DBSA with another silanol end group (193). The anionic emulsion polymerization of D_4 in the presence of BDDOH as a surface-active catalyst has been reported (192,194) and a reaction scheme proposed, which involves a quaternary ammonium silanolate as an active species.

Radiation-Induced Polymerization. In 1956 it was discovered that D_3 can be polymerized in the solid state by γ-irradiation (195). Since that time a number of papers have reported radiation-induced polymerization of D_3 and D_4 in the solid state (196,197). The first successful radiation-induced polymerization of cyclic siloxanes in the liquid state (198) and later work (199) showed that the polymerization of cyclic siloxanes induced by γ-irradiation has a cationic nature.

The polymerization is initiated by a cleavage of Si—C bond and formation of silylenium cation.



The γ-irradiation-induced polymerization requires an extremely high purity reaction system. Trace amounts of water can terminate a cationic reaction and inhibit polymerization. Organic bases such as ammonia and trimethylamine also inhibit polymerization. The γ-irradiation-induced polymerization of rigorously dried D_4 exhibits a square-root dependence of the rate on the dose rate as predicted by the Hayashi–Williams equation for completely pure systems (200).

Plasma Polymerization. Plasma polymerization as a method for modifying surfaces of materials has been known for at least 25 years. The need for well-defined, thin polymer films for applications in optics, electronics, or biomedicine stimulated the development of plasma-induced polymerization but to date, relatively few large-scale applications exist. However, in recent years increased awareness of energy consumption and hazardous waste disposal concerns have stimulated the interest in this technique as a method for manufacturing or depositing polymers on various substrates (201). The special interest that has developed in organosilicon monomers may be because many of these monomers are generally volatile, nontoxic, nonflammable, and relatively inexpensive. Also, plasma-polymerized organosilicone films have a natural chemical affinity for adhesion to single-crystal silicon, and the properties of these films can be varied widely by the choice of monomer and polymerization parameters (202). The mechanism of plasma polymerization is still not well understood as of this writing and differs substantially from the conventional ring-opening polymerization of cyclic monomers. The dissociation and ionization of organosilicone monomers by low energy electron impact is the dominant source of radical fragments and a variety of ion–molecules and ion–radicals. In the case of hexamethyldisiloxane, extension of the monomer molecule by one dimethylsiloxane unit and elimination of the trimethylsilylium ion, $(CH_3)_3Si^+$, was proposed as a crucial step in the polymer film formation. The building of Si—C—Si links also plays an important role in the polymerization. Cyclic monomers such as D_4 polymerize via the formation of a network of siloxane chains and rings. The resulting films are usually hard and scratch-resistant but often show considerable stress (203). Such films can be used as corrosion-resistant coatings on metals or as membranes in gas sensor devices (204,205). The plasma polymerization of tetramethyldisiloxane was recently employed to deposit scratch-resistant and antifogging films on transparent polycarbonate substrates (206) and more generally when the formation of silicone films with uniform thickness and without any dust interference was required.

Silicone Network Formation. Silicone rubber has a three-dimensional network structure consisting of cross-linked polydiorganosiloxane chains. Three reaction types are generally employed for the formation of silicone networks (207): peroxide-induced free-radical processes, hydrosilylation addition reactions, and

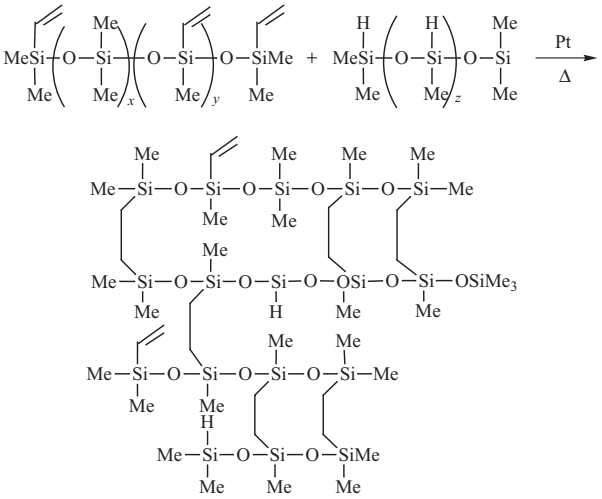
condensation reactions. Silicones have also been cross-linked using radiation to produce free radicals or to induce photoinitiated reactions.

Peroxide Cure. The use of peroxide catalysts at elevated temperatures is one of the most common methods for the preparation of silicone networks (208). Typical peroxides include acyl derivatives such as dibenzoyl (209), bis-*p*-chlorobenzoyl, and bis-2,4-dichlorobenzoylperoxides; arylalkyl derivatives such as dicumyl peroxide; and dialkyl derivatives such as di-*t*-butyl peroxide and 2,5-dimethyl-2,5-di-*t*-butylperoxyhexane. The amount and type of peroxide used determine the cure temperature of the composition as well as its ultimate properties. Diaroyl peroxides can be used with either PDMS or with vinylmethylpolysiloxanes. Bis-2,4-dichlorobenzoyl peroxide has the highest rate of decomposition and the lowest decomposition temperature. Cross-linking by peroxides is initiated by the generation of free radicals via homolytic cleavage of the peroxide at elevated temperatures. The peroxy radicals can abstract hydrogen atoms from methyl groups, forming ethylenic linkages between siloxane chains (210). Model studies have confirmed the formation of $SiCH_2CH_2Si$ as the predominant cross-linking reaction (211).

$$\begin{aligned} \mathrm{ArOOAr} &\longrightarrow 2\,\mathrm{ArO}\cdot \\ \mathrm{ArO}\cdot + \mathrm{CH_3SiR_3} &\longrightarrow \mathrm{ArO} + \cdot\mathrm{CH_2SiR_3} \\ 2\cdot\mathrm{CH_2SiR_3} &\longrightarrow \mathrm{R_3SiCH_2CH_2SiR_3} \end{aligned} \qquad (19)$$

The cross-linking of vinyl containing polydimethylpolysiloxanes can be achieved using alkylaryl or dialkyl peroxides (1,212). A radical can be formed at either the methyl or vinyl site; it is generally agreed that the reaction through the vinyl group is energetically favored. Several mechanisms have been proposed to explain the reaction. One suggestion is that the radical is first formed on a methyl group that can then attack either a methyl group or a vinyl group (213). Another proposal is that the cross-link occurs primarily through the vinyl group (214). The first step is addition of the peroxy radical to the vinyl moiety (215). The resultant radical can then attack either another vinyl group or a methyl group. Termination can occur by coupling or by hydrogen abstraction from adjacent peroxide molecules. Rheometric studies indicate that methylvinylsilicone resins do undergo cross-linking via the methyl groups but at a slower rate than through the vinyl groups (216).

Hydrosilylation. *Hydrosilylation*, the reaction between a silicone hydride group and an olefin to form an alkylenic linkage, is extremely important for the formation of silicone networks (77,83,217–219). Cross-linking and network formation occur by reaction of multifunctional silicon hydride groups with multifunctional silicone olefinic groups. Typically, vinyl groups attached to silicon are employed; however, there are reports of network formation by reaction of multifunctional silicone hydride polymers with hexenyl-terminated siloxanes (220). No by-products aside from Pt residue are produced by this type of curing and no shrinkage is observed. Addition of the hydride to the olefin may be either Markovnikoff or anti-Markovnikoff, depending upon the choice of the silicone–olefin group and catalyst. With silicon-bound vinyl groups, the reaction produces 95% of the β-addition product.



(20)

Hydrosilylation is generally catalyzed by Group 8–10 (VIII) metal complexes or supported metal catalysts. Platinum complexes are the most widely used, although rhodium(I) complexes have also been reported (83). Typical industrial catalysts include soluble platinum species such as the platinum–divinyltetramethyldisiloxane complex (Karstedt's catalyst) (221). These catalysts exhibit high turnover rates and are useful in concentrations as low as 1–2 ppm.

Side reactions or postcuring reactions are possible in the formation of silicone networks. In most cases, the silicon-bound hydride is in stoichiometric excess to enhance reaction rates. Disproportionation reactions involving terminal hydride groups have been reported (222). A major side reaction consumes Si—H to give redistributed siloxane in the resulting polymers and gaseous silane as a by-product.

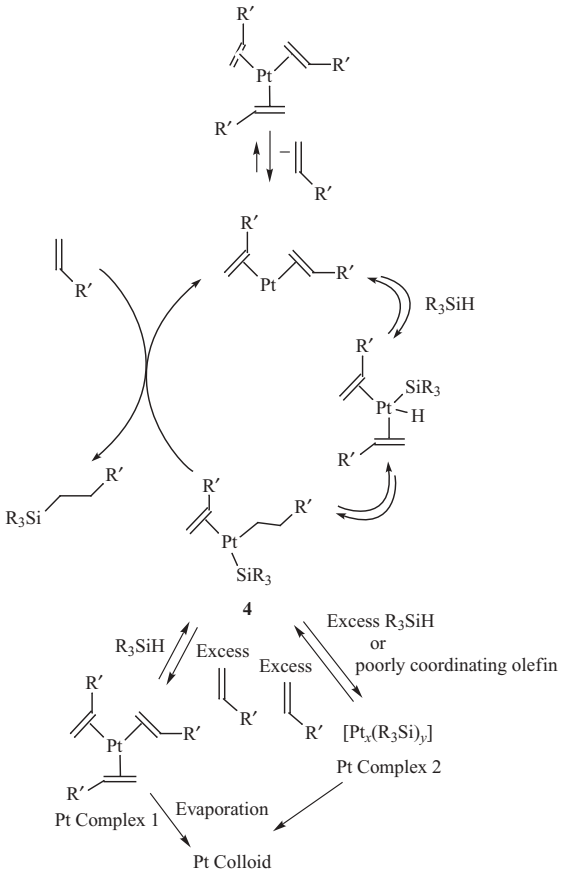
Excess silicon hydride may undergo hydrolysis. The silanol thus formed can then condense with another hydride, resulting in networks with a higher crosslink density (223–225). Isomerization of a terminal olefin to a less reactive internal olefin has been noted (222). Vinylsilane/hydride interchange reactions have been observed particularly when less active catalysts are employed (217).

$$R_3SiH + R'_3SiCH{=}CH_2 \rightleftharpoons R'_3SiH + R_3SiCH{=}CH_2 \quad (21)$$

Several mechanisms have been proposed for the platinum-catalyzed homogeneous hydrosilylation reaction. The most commonly invoked mechanism, proposed by Chalk and Harrod in 1965, consists of elementary steps similar to homogeneous hydrogenation, oxidative addition, migratory insertion, and reductive elimination (226). However, this mechanism fails to describe the induction period or the presence of colloidal species at the end of the reaction. Lewis proposed an alternative mechanism based on the intermediacy of colloids that were detected by transmission electron microscopy after evaporation of catalytically active solutions (227,228).

More recently, extended X-ray absorption fine structure (EXAFS) has been used to identify the actual catalytic species in both model systems and networks (229). At the completion of the hydrosilylation reaction, the state of the platinum

species is dependent upon the reaction conditions. With a stoichiometric excess of olefin, a mononuclear platinum species containing six platinum–carbon bonds, such as platinum coordinated to three olefin groups, is obtained. However, in the presence of high silicon hydride concentrations or in reactions employing poorly coordinating olefins such as hexenes, the platinum product is multinuclear and contains platinum–silicon bonds. Upon addition of the deficient reagent (olefin or silicon hydride), the platinum products can interconvert to the catalytically active form. Colloids have been found in a postmortem analysis of hydrosilylation reactions upon evaporation or destabilization of the reactant solutions. EXAFS analysis of solutions frozen during model reactions of cross-linking systems (functional siloxane monomers) showed that regardless of reactant stoichiometry, the platinum intermediates during the catalytic portion of the reaction were mononuclear and contained both platinum–silicon and platinum–carbon bonds. A mechanism was therefore proposed that incorporates the Chalk–Harrod postulate with the addition of exchange and hydrosilylation of the ligands on the platinum during the induction period, and a pathway to colloid formation at the end of the reaction. Ab initio calculations reported on the platinum-catalyzed hydrosilylation of ethylene support the Chalk–Harrod mechanistic steps of oxidative addition, migratory insertion, and reductive elimination during the catalytic cycle (230).



Catalyst inhibitors are often included in formulations to increase the pot life of these systems. An ideal silicone addition cure composition would combine instant cure at elevated temperature with infinite pot life at ambient conditions. Unfortunately, real systems always deviate from this ideal situation. One mechanism of inhibition consists of equilibrium between the inhibitor (I) and catalyst ligands (L) (231).

$$PtL_n + x\ I = PtL_{n-x}I_x + x\ L_n \tag{22}$$

Hydrosilylation with inhibited complexes is generally less rapid than with platinum(0) olefin compounds. Complexing ligands such as phosphines and amines are excellent inhibitors but often form complexes so stable that they act as poisons and prevent cure even at elevated temperatures. Unsaturated organic compounds such as acetylenic alcohols, acetylene dicarboxylates, maleates, fumarates, and eneynes are preferred inhibitors (231–242). Steffanut and coworkers (243) have reported the use of platinum(0) complexes with electron-deficient olefinic ligands as hydrosilylation catalysts. Some of these complexes are self-inhibiting. Platinum–fumarate or maleate complexes formed from the reaction of platinum(0) compounds with dimethyl fumarate or dimethyl maleate must undergo reduction of the fumarate or maleate ligand with silicon hydride, prior to becoming active hydrosilylation catalysts (244). An alternative inhibition strategy is to encapsulate the platinum catalysts with cyclodextrin, thermoplastics, or silicones (245–247).

Condensation Cure. The condensation of silanol groups to form siloxanes is an extremely important industrial reaction and may be represented in its simplest form as follows:

$$R_3SiOH + R'_3SiOH \rightarrow R_3SiOSiR'_3 + H_2O \tag{23}$$

Unfortunately, because self-condensation of silanols on the same silicone can occur readily, the controlled reaction of disilanol or trisilanol compounds with telechelic silanol polymers to form a three-dimensional network is not feasible. Instead, networks are derived from reactions of telechelic polymers with crosslinkers containing reactive groups such as alkoxysilanes, acyloxysilanes, silicon hydrides, or ketoximinosilanes, as in the reactions 24–27 (207). The choice of the cross-linking agent depends on the specific product characteristics desired.

$$R_3SiOH + R'_3Si(OCH_3) \rightarrow R_3SiOSiR'_3 + CH_3OH \tag{24}$$

$$R_3SiOH + R'_3Si(OOCCH_3) \rightarrow R_3SiOSiR'_3 + CH_3COOH \tag{25}$$

$$R_3SiOH + R'_3SiH \rightarrow R_3SiOSiR'_3 + H_2 \tag{26}$$

$$R_3SiOH + R'_3Si(ON{=}\underset{\displaystyle CH_3}{\overset{\displaystyle |}{C}}{-}CH_2CH_3) \longrightarrow R_3SiOSiR'_3 + HO{=}N{-}\underset{\displaystyle CH_3}{\overset{\displaystyle |}{C}}{-}CH_2CH_3 \tag{27}$$

Condensation catalysts include acids and bases, as well as organic complexes of metals. Both tin(II) and tin(IV) complexes with oxygen-donor ligands are

extremely useful. It has been suggested that the tin(IV) catalyst is converted to its active form by partial hydrolysis followed by reaction with the hydrolyzable silane to yield a tin–silanolate species (eqs. 28 and 29) (248,249).

$$R_2Sn(OCOR')_2 + H_2O \rightarrow R_2Sn(OCOR')OH + R'COOH \quad (28)$$

$$R_2Sn(OCOR')OH + Si(OR')_4 \rightarrow R_2Sn(OCOR')(OSiR')_3 + R'OH \quad (29)$$

The organotin silanolate reacts with the PDMS diol by either attack on the SiOC bond or by silanolysis of the SnOC bond (248,249). Other metal catalysts include chelated salts of titanium and tetraalkoxytitanates, which have also been shown to form silanolate species similar to those postulated for tin catalysts (250, 251). Formation of a cross-linked matrix involves a combination of the three steps in equations 30–32.

$$R'_3Si(OR) + H_2O \rightarrow R'_3SiOH + ROH \quad (30)$$

$$R_3SiOH + R'_3SiOH \rightarrow R_3SiOSiR'_3 + H_2O \quad (31)$$

$$R'_3Si(OR) + R'_3SiOH \rightarrow R'_3SiOSiR'_3 + ROH \quad (32)$$

The role of water in condensation cross-linking is dependent upon whether the material is a one- or two-component curing system (252). One-component systems do not cure until they are exposed to water. Two-component systems usually contain water in one of the components and begin to cure as soon as the components are mixed. Other work suggests that tin(II) catalysts can function in the absence of water (253). Studies of the relative rates of hydrolysis and condensation of multifunctional silanes, $R_xSi(OR)_{4-x}$, in the presence of acidic or basic catalysis have shown that the first Si—OR group hydrolyzes much more rapidly than subsequent groups (254). Silanol–silanol condensation is much slower than silanol–alkoxysilane condensation, even if the alkoxysilane is monofunctional, thus suggesting that in the presence of a cross-linker, chain extension will not occur to a significant extent (255–258).

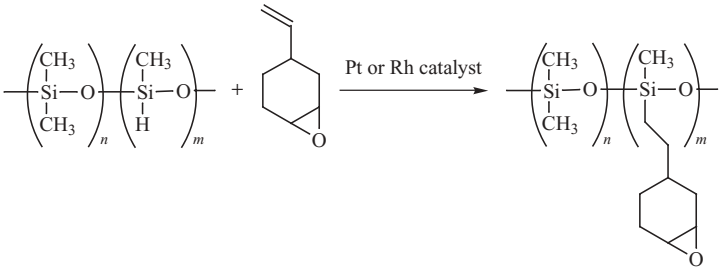
Condensation cure can also be carried out in emulsions (259–271). In this case, the cross-linker and PDMS are emulsified using anionic, cationic, or nonionic surfactants in water, and a condensation catalyst such as dibutyltin dilaurate is added. The formulation can also be cured without a tin-catalyst if self-catalytic hydrolyzable silanes are included (265). The polymer can then undergo cross-linking, forming a continuous film when the water is evaporated.

High Energy Radiation Cure. Silicones can be vulcanized by high energy radiation examples of which include γ-irradiation, X-ray, and electron beam. High energy radiation interacts with shell electrons of atoms of the silicone materials and induces ionization. The generated radical cations and free radicals initiate chemical reactions that lead to cross-linking (272). The properties of silicones cross-linked by high energy irradiation are indistinguishable from those vulcanized with peroxides (273). But silicone rubber cross-linked by γ-irradiation

does, however, have two advantages: better resistance to aging in humid environments and greater hydrolytic stability at elevated temperatures because the compositions are catalyst-free (274). Radiation cure of methylvinyl silicone rubber is a random cross-linking process with no differentiation between methyl and vinyl groups (275). Substitution of phenyl for methyl groups on the siloxane chain increases the radiation resistance. Silicone hydride groups are highly sensitive to radiation (276).

Photoinitated Radiation Cure. Attachment of reactive functional groups such as mercaptans, acrylates, and oxiranes to a polysiloxane backbone can be used to render a silicone susceptible to curing by lower energy electromagnetic radiation such as ultraviolet (UV) or low energy electron beam (EB) (277). Thiols can be added across an olefin using an aromatic ketone as the photoinitiator (EB) (278,279). Unfortunately, the odor associated with thiols has limited the commercial acceptance of this technology. Two systems, which are widely used in the industry for silicone release and protective coatings, are silicones containing pendent acrylate groups (free-radical cure mechanism) and oxirane or vinyl ether functional siloxanes (acid-catalyzed). The acrylate functional polysiloxanes are prepared by allowing epoxy-functional siloxanes to react with acrylic acid or from the esterification of siloxane containing alcohol groups with acrylic acid (280–283). Cross-linking occurs upon the generation of free radicals by EB irradiation of the silicone matrix or by UV-initiated decomposition of benzophenone-based photoinitiators. The most important limitation of this process is sensitivity to oxygen. The typical industrial coating line requires oxygen levels below 50 ppm.

Silicones functionalized with oxiranes or vinyl ether groups can be cured by UV irradiation in the presence of diaryliodonium or sulfonium salts containing triflate, PF_6, or SbF_6 counterions (284–290). Decomposition of the onium salt under UV irradiation leads to the formation of strong acid that initiates very rapid polymerization of oxiranes or vinyl ether groups (291–293). Recently, a new class of onium salts prepared with the tetrakis(pentafluorophenyl)borate (TPFB) anion has been introduced as a UV photoinitiator (294–296). The presence of the large, weakly nucleophilic TPFB anion improves the solubility of the iodonium salts in the siloxane matrix and increases the reactivity of the formed acid (297,298). The cationic polymerization of oxiranes and vinyl ethers is not sensitive to the presence of oxygen and can be carried out under ambient conditions. Cycloaliphatic epoxies are highly reactive in the ring-opening polymerization reaction initiated by strong acids and so the typical commercial system is based on polysiloxanes with pendent cyclohexeneoxide moieties. Such polymers are readily prepared by the hydrosilylation of 4-vinylcyclohexeneoxide with hydrogen functional polysiloxane in the presence of catalytic amount of platinum or rhodium (299) (eq. 38).



(33)

Formation of a siloxane network via hydrosilylation can also be initiated by a free-radical mechanism (300–302). A photochemical route makes use of photosensitizers such as peresters to generate radicals in the system. Unfortunately, the reaction is quite sluggish. Several complexes of platinum such as (η-cyclopentadienyl)trialkylplatinum(IV) compounds have been found to be photoactive. The mixture of silicone polymer containing alkenyl functional groups with silicon hydride cross-linker materials and a catalytic amount of a cyclopentadienylplatinum(IV) compound is stable in the dark. Under UV radiation, however, the platinum complex undergoes rapid decomposition with release of platinum species that catalyze rapid hydrosilylation and network formation (303–308). Other UV-active hydrosilylation catalyst precursors include (acetylacetonate)Pt(CH_3)$_3$ (309), (acetylacetonate)$_2$Pt (310–312), platinum triazene compounds (313,314), and other sytems (315,316).

Characterization of Silicone Networks. The cross-linking of silicones as a function of time can be monitored using a variety of techniques such as infrared spectroscopy, dynamic mechanical analysis, dielectric spectroscopy, ultrasound, differential scanning calorimetry, and thermomechanical analysis (317–324). Infrared spectroscopy is especially useful with addition cure systems because the disappearance of the SiH peak in the starting silicone hydride can be readily monitored. Dynamic mechanical analysis has been used to study the critical time for gelation of a PDMS network (317). Fourier-transform infrared dichroism has been used to investigate the molecular orientation of PDMS networks. In a study of the isothermal dielectric properties of condensation-cured networks at room temperature as a function of catalyst concentration during cure, the effect of catalyst concentration was reflected in the value of the loss factor (318). The gel point of an addition-cured network can be determined using ultrasound techniques (320). A step-like increase in the longitudinal wave velocity is exhibited at the sol–gel transition point. Differential scanning calorimetry has been used with hydrosilylation-cured systems to determine rates of conversion and to develop a kinetic model for the rubber injection-molding process (322).

In addition to the above techniques, inverse gas chromatography, swelling experiments, tensile tests, mechanical analyses, dynamic light scattering, and small-angle neutron scattering have been used to determine the cross-link density of cured networks (325–332). Solid-state ^{29}Si NMR and chemical degradation methods have been used to characterize cured networks structurally (333). ^{1}H and ^{2}H NMR and spin echo experiments have been used to study the dynamics of cured silicone networks (334–338). Stress relaxation experiments have been employed to examine the chemistry of vulcanized silicone networks (339).

Model Networks. Construction of model networks allows development of quantitative structure property relationships and provides the ability to test the accuracy of the theories of rubber elasticity (340–343). By definition, model networks have controlled molecular weight between cross-links, controlled cross-link functionality, and controlled molecular weight distribution of cross-linked chains. Silicones cross-linked by either condensation or addition reactions are ideally suited for these studies because all of the above parameters can be controlled. A typical condensation-cured model network consists of an α,ω-polydimethylsiloxanediol, tetraethoxysilane (or alkyltrimethoxysilane), and a

tin-cure catalyst (344). A typical addition-cure model is composed of α,ω-vinylpolydimethylsiloxane, $M^H{}_4Q$, and a platinum-cure catalyst (345–347).

Using both condensation-cured and addition-cured model systems, it has been shown that the modulus depends on the molecular weight of the polymer and that the modulus at rupture increases with increased junction functionality (348). However, if a bimodal distribution of chain lengths is employed, an anomalously high modulus at high extensions is observed. Finite extensibility of the short chains has been proposed as the origin of this upturn in the stress–strain curve. Calculations have been performed on the effect of including a trimodal distribution of chain lengths on ultimate properties. The study concluded that incorporation of very long chains into a bimodal network of long and short chains could lead to elastomers with improved properties (349). Monte Carlo simulations of the elastic behavior of PDMS networks have been performed (350,351).

The effect of pendent chains on the mechanical properties of model PDMS has been studied. It was found that the loss modulus of these networks was a function of the concentration and molecular weight of the dangling chains. The elastic properties of networks with pendent chains were found to be lower than those that were completely cross-linked (352).

Monodisperse model networks have been prepared using prepolymers with polydispersivities close to 1.0. Equilibrium tensile measurements on such networks prepared from fractionated PDMS show single-curve elastic moduli of all the networks (353,354). Simulations of the effect of molecular weight distribution on the equilibrium modulus indicated that with increasing polydispersity, the affine structure factor is found to decrease. Low extents of reaction were observed for the more monodisperse systems. The observed low extent of reaction is due to the reduced number of cross-links with increased molecular weight of chains in the system (355). Dynamic mechanical measurements have been reported for networks prepared by telechelic condensation of monodisperse PDMS with tetraethoxysilane (356). The tensile and swelling behaviors of PDMS networks of high junction functionality have been determined using hydride-terminated and hydride on chain siloxane reactions with vinyl-stopped PDMS (357). In an examination of the mechanical behavior and swelling properties of networks prepared by cross-linking fractionated vinylmethylpolydimethylsiloxane with pentamethylcyclopentasiloxane (358), the dynamic mechanical properties measured were in good agreement with the swelling rates. It has been found that a lowering of the elastic modulus increases broadness of the molecular weight distribution of networks (359). There is a good correlation between theoretical predictions and the experimental value of the tensile modulus for monodisperse networks prepared from vinyl-terminated silicones and $M^H{}_4Q$ (333).

Filled Silicone Networks. Few applications use silicone elastomers in the unfilled state. The addition of fillers results in a severalfold improvement in properties. Fillers can be broadly categorized as reinforcing and nonreinforcing (or semireinforcing). Reinforcing fillers increase tensile strength, tear strength, and abrasion resistance, whereas nonreinforcing fillers are used as additives for reducing cost, improving heat stability, imparting color, and for increasing electrical conductivity (360).

Nonreinforcing fillers include calcium carbonate, clays, silicates, and aluminates. They are primarily used as extending fillers; that is, they serve the purpose

of reducing cost per unit volume. Pigment-grade oxides, especially ferric oxides, are used as fillers and stabilizers for high temperature compounds used in oxidizing environments. Other fillers such as fumed titania, alumina, and zirconia find applications for extended heat stability, for imparting color, and for improving the electrical conductivity of the formulation. Although carbon black is the most common reinforcing filler for other vulcanized rubber/elastomeric applications, it is not commonly used as a reinforcing filler in silicones. Instead, it finds applications in improving electrical conductivity and pigmentation (361).

Fillers that are used for providing reinforcement include finely divided silicas prepared by vapor-phase hydrolysis or oxidation of chlorosilanes, dehydrated silica gels, precipitated silicas, diatomaceous silicas, and finely ground high assay natural silicas (362–366). The size, structure, and surface chemistry of the filler all play important roles in determining the final degree of reinforcement (367–369). The most important criteria for reinforcement are the availability of sufficient surface area and a strong van der Waals or hydrogen-bonding interaction between the polymer and the filler (a covalent linkage is not essential) (370,371). Fillers made by the fumed process have typical surface areas around 200 m^2/g and provide the maximum reinforcement. Several comparative studies of the effectiveness of fumed versus precipitated silica show that for fumed silicas, interaction with siloxane occurs by randomly distributed silanols, whereas for precipitated silica, a more complex structure is involved probably involving short chains of polysilicic acid. (365,372,373).

Several properties of the filler are important to the compounder (374). Properties that are frequently reported by fumed silica manufacturers include surface area, the acidity of the filler, nitrogen adsorption, oil absorption, and particle size distribution (375,376). Adsorption techniques provide a measure of the surface area of the filler, whereas oil absorption is an indication of the structure of the filler (377). Measurement of the silanol concentration is critical, and some techniques that are commonly used in the industry to estimate this parameter include methyl red absorption and methanol wettability tests (367,368,373). Other techniques to characterize fillers include weight loss, various spectroscopies, such as diffuse reflectance infrared spectroscopy (DRIFT), inverse gas chromatography (IGC), and photoacoustic IR, NMR, Raman, and surface forces apparatus (372,378–385).

Structuring refers to the formation of an elastic mass before cure that impedes normal processing operations such as molding and extrusion. Intensive working may be required to restore plasticity. Plasticity and process aids are therefore incorporated as monomeric or oligomeric organosilicon compounds. Alternatively, the silanol concentration on the silica surface can be controlled by filler treatment to prevent structuring (386,387). Reaction of the silica particles with hot vapors of chlorosilanes, low molecular weight cyclic siloxanes, and hexamethyldisilazane (HMDZ) are some of the commonly used filler treatments in the industry (361,388). It has been proposed that pretreatment of the filler reduces the strength of silica–silica and silica–polymer interactions (389).

Polymer–filler interactions have been studied by deuterium NMR spectroscopy. In unstrained networks, two regions of local chain mobility were identified, that within the absorption layer and that outside. In a uniaxially strained sample, the chains were immobilized near the filler surface. Chain order is increased in filled systems relative to unfilled systems (390). Molecular orientation

in stretched networks was also studied using Fourier transform infrared dichroism. Filler introduction led to an increase in orientation, which was attributed to a higher microscopic strain in the elastomeric network (391).

The final mechanical properties of the elastomer compound are a function of the concentration of the reinforcing filler in the formulation. In the small strain limit, Einstein relationships have been proposed for changes in viscosity and modulus as a function of volume fraction of the filler (392,393). Although these relationships work well for spherical and low structure fillers, they do not correctly predict the final properties of systems filled with high structure nonspherical particles. The high structure of the filler leads to a system that is not free draining, resulting in an augmentation of the filler concentration caused by the rubber trapped in the internal void space (occluded rubber) (394–397). An empirical modification to the Einstein relationship for modulus has been proposed (398). However, these relationships do not account for the secondary agglomeration that results in highly non-Newtonian and thixotropic behavior (399–405). The reasons for improvement in the failure properties of these systems are not well understood (405,407,408). Some mechanisms that have been proposed include the ability of a filled system to increase energy dissipation at the tip of the crack through viscoelastic processes, and the ability of the dispersed particles in cooperatively arresting or deflecting the growth of cracks, thereby delaying the onset of catastrophic failure. Results of tensile, IR dichroism, and birefringence experiments show strong upturns in the stress with increasing elongation while segmental–orientation–strain properties remain linear. The upturn in the stress results from limited extensibility of the chains. A model based on Monte Carlo calculations shows strong differences between stress and orientation effects (409). A phenomenon often discussed in connection with filler reinforcement is stress softening, which probably arises because of the progressive detachment, or breaking, of network chains attached to filler particles (410).

Fillers have also been shown to influence abrasive wear of silicone rubbers. The wear rates increase slowly with filler concentration until a critical volume fraction is reached, after which wear rates increase significantly with increasing filler loading. A model, which included the stress concentration induced by the filler, showed a positive correlation between the wear rate and the damage zone volume (411).

A good dispersion of the filler particles is essential for ensuring satisfactory ultimate properties (412–418). The first processing step involves the initial incorporation of the filler in the polymer matrix, and is limited primarily by the wettability of the filler. The next step involves a fracture of the aggregates and their uniform dispersion under shear. Heat treatment is often used to promote wetting and improve polymer–filler interactions (419). Dispersion is measured in terms of the remaining agglomerates, which cause premature failure in tensile testing and other ultimate properties. A trend in obtaining uniform dispersions is *in situ* precipitation of silica by catalytic hydrolysis of tetraethyl orthosilicate (TEOS) in a preformed silicone matrix using sol-gel techniques (420). Dynamic mechanical losses in addition-cured PDMS networks containing *in situ* precipitation of silica indicated that the glass-transition temperature showed only a slight dependence on the presence of the filler particles but the filler reduced both the degree and rate of crystallization for the *in situ* filled networks (421).

Properties and Uses

Silicone properties and uses have been discussed extensively (1,422–425).

Silicone Fluids. Silicone fluids are used as damping fluids, dielectric fluids, polishes, cosmetic and personal care additives, textile finishes, hydraulic fluids, paint additives, photocopy fuser oils, and heat-transfer oils. Polydimethylsiloxane oils are manufactured by the equilibrium polymerization of cyclic or linear dimethylsilicone precursors. Monofunctional organo-silane end groups, typically trimethylsilyl (M), are used, and the ratio of end group to chain units (D), ie, the ratio M/D, controls the ultimate average molecular weight and viscosity (162). Low viscosity fluids, $<10^5$ cSt, are generally prepared by acid-catalyzed equilibration. The reaction can be run continuously or in a glass-lined batch reactor at temperatures up to 180°C. Solid-acidified montmorillonite (Filtrol) or sulfuric acid on carbon catalysts are removed by filtration, and the end products are stripped under high vacuum and temperature to remove residual low molecular weight cyclic or linear siloxanes (426).

High molecular weight ($>10^6$ cSt) silicone oils and gums are prepared by base-catalyzed, ring-opening polymerization of cyclicdiorganosiloxanes, such as D_4, or by condensation polymerization of silanol-terminated PDMS. Both methods are practiced commercially. Potassium silanoate, prepared from HO–(D_n)–OH and KOH, or transient catalysts such as tetramethylammonium or tetrabutylphosphonium hydroxide, are used in the ring-opening polymerization method (147,427,428). The potassium silanoate is quenched at the end of the reaction, eg, with phosphoric acid. The transient catalysts can be decomposed at temperatures >150°C. Condensation polymerization also requires a catalyst, eg, linear phosphonitrilic chlorides (LPNC) (112–115). Ultimate molecular weight is controlled by the removal of water. LPNC catalysts can be deactivated thermally or by the addition of bases such as hexamethyldisilazane.

The physical properties of PDMS fluids have been extensively studied (1,429–431). The properties of a typical 50 cSt silicone oil (the silicone industry commonly uses centistokes, cSt, as a measure of the viscosity of a silicone polymer where 1 cSt = 1 mm^2/s) are presented in Table 2. Linear silicone fluids have low melting points and second-order (glass) transition temperatures. High molecular weight PDMS has a T_m of −51°C and a T_g of −86°C (432). The low intermolecular forces in silicones also lead to low boiling points, low activation energies for viscous flow, high compressibility, and generally Newtonian flow behavior. High molecular weight polymers (M_w > 35,000) exhibit non-Newtonian flow, especially at high shear rates. This same phenomenon also results in a material having relatively poor physical properties at high molecular weight.

Unlike the linear analogues, cyclic dimethylsiloxanes are low melting solids and the T_m generally decreases with increasing ring size. Physical properties for a series of M-stopped oligomers, MD_xM, and cyclic compounds, D_x, are listed in Table 3.

Many of the applications for silicone oils are derived from the wide temperature range over which they can be used. Addition of a small amount of phenylsiloxane in the form of diphenyl or phenymethylsiloxy groups, and/or incorporation of a slight amount of branching, suppresses the T_m of the dimethylsilicones and can reduce the pour points to as low as −100°C (433,434). Methylsilicone oils are

[a]Refs. 1 and 430.

stable in air at 150°C for extremely long periods of time (435) and undergo only slow degradation up to 200°C. In vacuum or inert atmospheres, dimethylsilicone oil can be heated to 300°C for a limited amount of time (436). The thermal properties of silicones are important for medical applications (437). Heat-resistant silicone fluids have increasing amounts of phenyl-containing substituents. High molecular weight methylphenylsilicones can be used in air at temperatures up to 250°C for several hundred hours and can withstand brief exposures up to 450°C in the presence of inert gases (438). Table 4 compares silicone polymers with equivalent petroleum-based materials and demonstrates the wide range of temperature over which they can be used.

Dimethylsilicone fluids decompose via two principal mechanisms: retrocyclization to low volatile cyclic siloxanes such as D_3 and D_4, and thermal oxidation of the alkyl side chains to give formaldehyde, CO_2, water, and T groups (430). The retrocyclization process is catalyzed by acids or bases and can occur at temperatures above 140°C. Catalytic acidic or basic sites on glassware and metallic containers are often the source of degradation of PDMS fluids. Heating in air to 200–250°C causes thermal oxidation of PDMS, and the cross-linking from T and Q group formation ultimately results in gellation. Stabilizers such as *p*-aminophenol, naphthols, metal acetonylacetonates, and iron octoate are commonly used to improve thermal stability (439–443).

For higher molecular weight PDMS ($M_n > 2500$), the number-average molecular weight is related to the bulk viscosity by the following formula (the viscosity units are in cSt):

$$\log(\text{viscosity}) = 1.00 + 0.0123(M_n)^{1/2} \quad (34)$$

Table 4. Viscosity of Silicone Oil vs. Petroleum Oil

Temperature, °C	Silicone η, mm^2/s (=cSt)	Petroleum η, mm^2/s (=cSt)
100	40	11
38	100	100
−18	350	11,000
−37	660	230,000
−57	1560	Solid

The number-average molecular weight of dimethylsiloxane can also be determined from the intrinsic viscosity (dL/g) (extrapolated to zero viscosity) in toluene or methyl ethyl ketone according to equations 35 and 36 (444,445):

$$\underset{\text{Toluene}}{[\eta] = 2\times10^{-4}(M_n)^{0.66}} \quad \underset{\text{Methylethylketone}}{[\eta] = 8\times10^{-4}(M_n)^{0.5}} \tag{35}$$

$$\log(\eta + b) = a \log T + c$$
$$\text{VTC} = \eta_{38c} - \eta_{99c} \tag{36}$$

Compared to petroleum-based fluids, silicone oils show relatively small changes in viscosity as a function of temperature (1,430). A common measure of the viscosity change with temperature is the viscosity–temperature coefficient (VTC). Typical dimethylsilicone VTC is 0.6 or less. Phenylsilicones are slightly higher. Organic oils are typically 0.8 or greater. The viscosity–temperature curves are depicted in Figure 3, where a, b, and c are constants.

Figure 4 shows viscosity–temperature curves for a series of silicone oils from 20 to 10,000 cSt, an SAE 10 petroleum oil, and a diester-based oil (368). Silicones with phenyl, trifluoropropyl, or larger alkyl groups show larger viscosity changes with increasing temperature than dimethylsilicone oils. Low molecular weight silicone oils ($< 1000\ mm^2$) exhibit Newtonian flow behavior and undergo only small changes in viscosity under shearing conditions (446). Higher viscosity PDMS fluids shear thin at higher shear rates. The fluids are stable to shear stress, however, and recover to their original viscosity after being passed through small capillaries under pressure. Figure 4 shows the effect of shear rate on viscosity for a series of PDMS fluids of different molecular weights.

Many of the unique properties of silicone oils are associated with the surface effects of dimethylsiloxanes. Silicones impart water repellency to fabrics, act as antifoaming agents (447), as release liners for adhesive labels, and as polishes and waxes (448). Dimethylsilicone oils can spread onto many solid and liquid surfaces to form films of molecular dimensions (449,450). This phenomenon is greatly affected by even small changes in the chemical structure of siloxane in the siloxane polymer. Increasing the size of the alkyl substituent from methyl to ethyl dramatically reduces the film-forming ability of the polymer (449). Phenyl-substituted silicones are spread onto water or solid surfaces more slowly than PDMS (451).

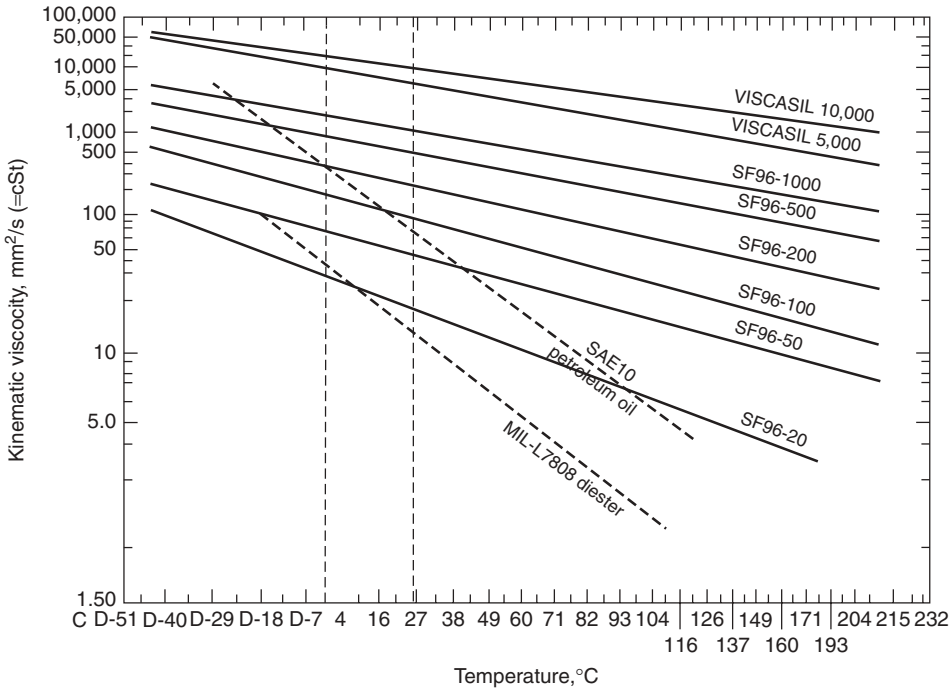

Fig. 3. Kinematic viscosity–temperature relationship of dimethylsilicone fluids.

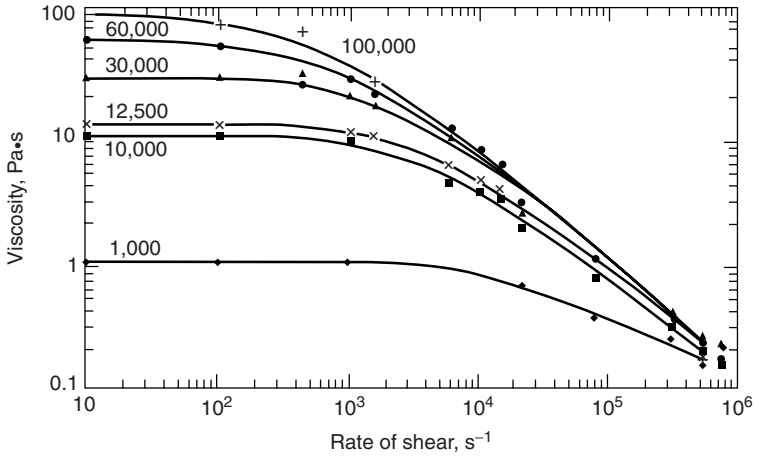

Fig. 4. Shear rate vs viscosity for PDMS. Numbers on curves indicate molecular weights. To convert Pa·s to P, multiply by 10.

Dimethylsilicone polymers are often described as having a combination of silicate and paraffin structures. The orientation of the polymer chains onto surfaces, physically, by chemical affinity, or bonding, can contribute to the observed surface properties. The surface tension of hexamethyldisiloxane, MM, is 15.7 mN/m

(dyn/cm). Increasing incorporation of D-units (MD_xM) increases the value to about 20 dyn/cm for higher viscosity fluids. Silicone fluids are characterized by their hydrophobicity (resistance to water), and the contact angle between PDMS and water is between 100° and 110°. Carefully deposited dimethysilicone on soda lime glass has a contact angle of about 60° at room temperature; the angle increases with increasing temperature to about 100° at 390°C and then decreases at the decomposition temperature (1).

Gases are very soluble in dimethylsilicone polymers, and PDMS is permeable to water vapor. The solubility of air, nitrogen, and carbon dioxide at 101.3 kPa (1 atm) is 0.17, 0.19, and 1.00 cm^3/cm^3, respectively (452). About 250–300 ppb of water can dissolve in dimethylsiloxane at 25°C and 95% relative humidity (453). The water solubility of silanol-terminated oligomers increases with decreasing molecular weight; the lowest silicone monomer, dimethylsilanediol, is water-miscible. Silicone oils are soluble in nonpolar organic solvents such as benzene, toluene, dimethyl ether, chloroform, methyl ethyl ketone, methylene chloride, or kerosene. Incorporation of phenyl and especially trifluoropropyl or β-cyanoethyl groups onto the polymer decreases the solubility of siloxane in nonpolar organic solvents (446). These derivatives are slightly soluble in acetone, ethanol, and butanol, and relatively immiscible in methanol, ethylene glycol, and water. Exposure to strong acids or bases leads to reequilibration of the polymer.

Silicone fluids have good dielectric properties, loss factor, specific resistance, and dielectric strength at normal operating conditions, and the properties vary only slightly with temperature (1,430,454). These properties in combination with relatively low flammability have led to the use of silicones in transformers and other large electrical appliances (455). The dielectric constant of a 1000-cSt oil is 2.8 at 30°C and 2.6 at 100°C. The loss factor is low, 1.2×10^{-4} at 20°C, and varies irregularly with frequency. Specific resistance is $4 \times 10^{15}\ \Omega \cdot$ cm at 20°C and decreases with increasing temperature or with exposure to moisture. The dielectric strength is 120 kV/cm (20°C, 50 cP, 6 kV/s).

Silicone oils are good hydrodynamic lubricants but have generally poor frictional lubricating properties (456–458). The latter can be improved by incorporating chlorophenyl groups into the polymer side chains (459). For steel on steel, the coefficient of friction is about 0.3–0.5. The load-bearing capacity of PDMS (Almen–Wieland machine) is only 50–150 kg, compared with ∼1000 kg for polychlorophenylmethylsiloxane and up to 2000 kg for mineral oil.

The thermal conductivity of dimethylsilicone with viscosities >100 cSt is 15.5 J/(s · cm · °C) (3.7×10^{-4} $cal^{-1} \cdot cm^{-1} \cdot °C^{-1}$), and is roughly constant with increasing viscosity (460). The specific heat is 1.55–1.70 J/(g · °C) (0.37–0.41 cal/(g · °C) over the 20–200°C range and is practically independent of viscosity. Thermal expansion of PDMS is ∼0.1/°C (460).

Liquid silicone oils are highly compressible and remain liquid over pressure ranges where normal paraffin oils have already solidified (461). This property, combined with a wide temperature use range, is the reason for silicone use in a large number of hydraulic applications. The adiabatic compressibility of 1000-cSt dimethylsilicone oils is ∼1000 Pa^{-1} (100 cm^2/dyn). This value decreases slightly with increasing viscosity, similar to paraffin oils. PDMS oils can withstand pressures greater than 3.4 GPa (35,000 kg/cm^2) even though they are compressed by >30%.

Dimethylsilicone fluids are transparent to visible light and microwave but absorb UV radiation at wavelengths below 280 nm (462). Siloxanes absorb strongly in the infrared between 1000 and 1100 cm^{-1} (Si—O stretching), 1300 and 1350 cm^{-1} (Si—C stretching), and 2950 and 3000 cm^{-1} (C—H stretching) (463). The speed of sound in PDMS is 987.3 m/s for a 1000-cSt fluid at 30°C and decreases with increasing temperature (464). Methylsilicone fluids are cross-linked when exposed to gamma ray or electron beam irradiation (465). Polymers containing aromatic substituents are more resistant than dimethylsilicone polymers.

Silicone Heat-Cured Rubber. Silicone elastomers are made by vulcanizing high molecular weight ($>5 \times 10^5$ gm/mol) linear PDMS polymer, often called gum. Fillers are used in these formulations to increase strength through reinforcement. Extending fillers and various additives, eg, antioxidants, adhesion promoters, and pigments, can be used to obtain certain properties (1,466).

Peroxides are typical vulcanizing agents and the mechanism of cure involves free-radical abstraction of a proton from a silicon methyl group, followed by dimerization of the methyl radicals to form ethylene cross-links (eq. 19) (219,467,468). Higher cure speed can be obtained with a mixture of peroxides (469). Vinyl-containing polymers are often used to control the cross-linking reaction and to accelerate the cure rate. Commonly used peroxides include di-*tert*-butyl peroxide [110-05-4], benzoyl peroxide [94-36-0], di(*p*-cumyl) peroxide, and di(*p*-chlorophenyl) peroxide. The choice of peroxide is based on the desired cure temperature and rate. Table 5 lists some common peroxide curing agents, typical cure temperatures, and some recommended processing conditions.

Recent work on peroxide curing agents (470) suggests that bis-peroxides such as that shown below are especially efficient agents for curing silicone rubber.

Table 5. Cure Agents for Silicone Rubber[a]

Curing agent	Commercial name	Activation temperature, °C	Application
Active paste[b] composition			
Di(2,4-dichlorobenzoyl) peroxide	Cadox TS-50 or Luperco CST	104–132	Hot-air vulcanizing

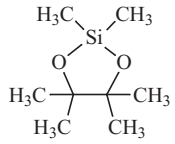
Unlike natural rubber, silicone rubber does not stress-crystallize when elongated, which leads to relatively poor physical properties. Unfilled silicone rubber has only a 0.35-MPa (50-psi) tensile stress at break; thus, silicone rubber must be compounded with 10–25 wt% reinforcing fillers, typically fumed silica, to improve the final rubber product properties (471–474). Other common fillers include precipitated silica, titanium dioxide, calcium carbonate, magnesium oxide, and ferric oxide. Pigments and colorants are also used. The addition of fillers to the gum stock can result in structuring during storage, which decreases the workability of the material. To prevent structuring, the filler is often treated with agents such as hexamethyldisilazane to reduce surface hydroxyl functionality, or with processing aids such as silanol functional silicone oils, diphenylsilanediol, or dimethylpinacoyloxysilane, (361,475).



The processing methods for silicone rubber are similar to those used for natural rubber (1,476–478). Polymer gum stock and fillers are compounded in a dough or Banbury-type mixer. Catalysts are added and additional compounding is completed on water-cooled roll mills. For small batches, the entire process can be carried out on a two-roll mill.

Heat-cured silicone rubber is commercially available in several forms: as gum stock, reinforced gum, or partially filled gum. These compounds can be uncatalyzed, catalyzed, or can contain catalyst dispersions. Catalyzed compounds are ready for use without additional processing. Silicone rubber is often freshened, ie, the compound is freshly worked on a rubber mill until it is a smooth continuous sheet. The freshening process eliminates the structuring problems associated with polymer–filler interactions. Rubber can be extruded on wire and cured in place (479).

It is common practice in the silicone rubber industry to prepare specific or custom mixtures of polymer, fillers, and cure catalysts for particular applications. The number of potential combinations is enormous. Improved properties of the rubber can be achieved if a premix of some of the inputs is performed. A premixing process for fumed silica, for example, involves the breaking down of gum particles into a fine dispersion in a bed of fumed silica. As the process continues, fumed silica coats the gum surface preventing reagglomeration of these particles (480).

In general, the mixture is selected to achieve some special operating or processing requirement, and the formulations are classified accordingly. Table 6 lists some of the commercially important types of silicone rubbers.

Table 6. Properties of Different Classes of Silicone Rubbers[a]

Class	Hardness, durometer	Tensile strength, MPa[b]	Elongation, %	Compression set,[c] %	Useful temperature range, °C		Tear strength, J/cm^2[d]
					Min.	Max.	
General purpose	40–80	4.8–7.0	100–400	15–50	−60	260	0.9
Low compression set	50–80	4.8–7.0	80–400	10–15	−60	260	0.9
Extreme low temperature	25–80	5.5–10.3	150–600	20–50	−100	260	3.1
Extreme high temperature	40–80	4.8–7.6	200–500	10–40	−60	315	
Wire and cable	50–80	4.1–10.3	100–500	20–50	−100	260	
Solvent-resistant	50–60	5.8–7.0	170–225	20–30	−68	232	1.3
High strength flame retardant	40–50	9.6–11.0	500–700				2.8–3.8

Silicone rubber is most commonly fabricated by compression-molding of catalyzed formulated gum compounds at 100–180°C under 5.5–10.3 MPa (800–1500 psi) pressure. Mold release compounds are usually employed. Under these conditions the rubber is cured in a few minutes. Extrusion processing is used in the manufacture of tubes, rods, wire and cable insulation, and continuous profiles. Initial properties, so-called green strength, are obtained by curing in hot air or steam tunnels from 276 to 690 kPa (40–100 psi) at 300–450°C for several minutes. Final physical properties are achieved by postcuring in air or steam, typically for 30–90 min. When silicone rubber must be bonded to other surfaces, eg, metals, plastics, or ceramics, primers are used. Silicate or titanate esters from the hydrolysis of tetraethoxysilane or tetraethoxyltitanium are often used as primers. Silicone-rubber coated textiles and glass cloth are made by initially dissolving gum stock in solvent and applying the rubber by dip coating. The fabric is then dried and the rubber cured in heated towers. Tubes and hose can be formed on mandrels from this fabric into complex shapes. Foamed or sponge silicone rubber can be made by incorporating chemical blowing agents into the rubber stock, which typically eliminate nitrogen or carbon dioxide under the thermal curing conditions. Sponge silicone rubber made in this way has a closed cell structure and densities of 0.4–1.0 g/cm^3.

Vulcanized silicone rubber is characterized by its wide temperature use range (−50 to >200°C), excellent electrical properties, and resistance to air oxidation and weathering conditions (484). Improvements in properties such as heat aging can be achieved by *in situ* treatment of the filler during rubber manufacture (480). Silicone rubber is also extremely permeable to gases and water vapor. The mechanical properties of silicone rubber are generally inferior to most organic (butyl)

Table 7. Properties of Silicone Gums[a]

rubbers at room temperature. Tables 7–9 list some typical physical properties for vulcanized silicone rubber. Silicone rubber can be made with varying degrees of hardness. Shore A values from 20 to 90 are typical; the best physical properties are generally obtained with values from 50 to 70. The properties of silicone vary with temperature (483). The Young's modulus drops from 10^5 to 2×10^2 MPa (14.5×10^4 to 2.9×10^4 psi) over a temperature range from −50°C to room temperature and is then fairly constant till 260°C. Tensile strength at break decreases from 6.9 MPa (1000 psi) at 0°C to 2.1 MPa (300 psi) at 300°C. Typical elongation at break values range from 300 to 700%, depending on the composition.

The compression set of silicone rubber is similar to organic types of rubber at low (0–50°C) temperatures, ranging from 5 to 15% (489). Above 50°C, silicone

rubber is superior, but compression set increases with time and temperature. Improvements in the compression set of silicone rubber are achieved with *in situ* treatment of the filler (490). Silicone rubber is more tear-sensitive than butyl rubber, and the degree of sensitivity is a function of filler size and dispersion, cross-link density, and curing conditions. The electrical properties of silicone rubber (491,492) are generally superior to organic rubbers and are retained over a temperature range from −50 to 250°C (76). Typical electrical values for a heat-cured silicone rubber are shown in Table (9).

Silicone rubber film is 10–20 times more permeable to gases and water vapor than organic rubber (489). The water permeability of silicone rubber is $\sim 14 \times 10^6$ mol/m^2: s · Pa, which means that silicone rubber can absorb about 35 mg of water per square centimeter of surface area after a 7-day exposure (486). Table (7) shows the permeability of silicone to common gases. Organic solvents can diffuse into and swell silicone rubber, significantly decreasing the physical properties of the material. The degree of swelling depends on the solubility parameters of the solvent and the rubber, as illustrated in Figure 5.

Solvent-resistant rubber based on either trifluoropropylmethylsiloxane or β-cyanoethylmethylsiloxane has been developed for special applications, eg as fuel tank sealants, where the material will be exposed to aggressive solvents. Those based on trifluoropropylmethylsiloxane are more important commercially. Pure water has little effect on silicone; however, long exposures in the presence of acid or base catalysts causes degradation and reversion of the rubber to a sticky gum (483,494). Prolonged exposure to temperatures above 300°C in air causes the rubber to stiffen and ultimately to become brittle (483). As with silicone oil, the principal chemical pathways of degradation are retrocyclization and oxidation of the polymer alkyl groups. Heating in air at 125°C causes a decrease in elongation and an increase in hardness, but no important changes in tensile properties are observed.

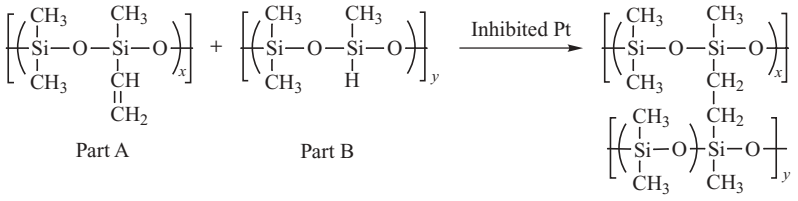
Silicone rubber burns with a high char yield, and the residual material is nonconducting silicon dioxide. The limiting oxygen index for a typical rubber formulation is about 20. Flame-retardant versions are available with oxygen index

values as high as 40–50 (481). In general, silicone rubber is not resistant to gamma or electron beam radiation and undergoes cross-linking, which leads to embrittlement (495). Increasing levels of phenyl-containing silicone in the rubber improves the radiation resistance (496).

Silicone Liquid-Injection-Molding Rubber. An increasingly important processing technique for silicone rubber is liquid injection molding. These materials are also referred to as liquid silicone rubber (LSR). Unlike heat-cured rubber, which is typically compression-molded from high viscosity gum compounds, liquid-injection-molded (LIM) rubber is made from low viscosity starting materials, 1000–20,000 mPa · s (=cP), and is cured in molds similar to those used for plastic injection molding. The principal advantages of LIM include rapid cycle times and the ability to fill complex mold shapes because of the low viscosity of the inputs. Rubber parts can be cured in 10–40 s using low molding pressures, approx. 2–20 MPa (300–3000 psi), and low curing temperatures, typically 150–260°C (497). LIM processing is increasingly being used for applications such as electrical connectors, O-ring seals, computer keypads, baby bottle nipples, valves, electrical components, health care products, and sporting equipment such as goggles and scuba masks.

Silicone LIM rubber is made from a two-component polymer system. One part (Part B) contains a linear polydimethylsiloxane polymer with pendent Si—H functionality, reinforcing fillers such as fumed silica, extending fillers, pigments, and stabilizers. The second part (Part A) contains linear PDMS with terminal and pendent vinyl groups; reinforcing and extending fillers; a platinum hydrosilylation catalyst; and a catalyst inhibitor, commonly olefins, alkynes, amines, or phosphines. Incorporation of trifluoropropylsilyl groups is possible if solvent resistance is desired (498).

After the components are mixed and heated, the catalyst initiates the cross-linking reaction by addition of the Si—H group to the double bond (eq. 37). Latent cure catalysts have been developed that allow the formulation of one-component products (499). These systems work by incorporation of platinum ligands that deactivate the platinum hydrosilylation catalysts at room temperature. When heated to temperatures above 100°C, these catalysts become active (see also Silicone Network Formation).



(37)

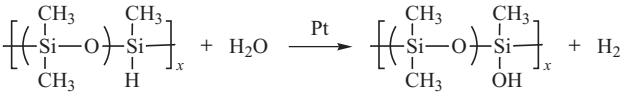
Cured silicone LIM rubber can be fabricated with physical properties equivalent to heat-cured rubber (500). Shore A hardness can range from 30 to 70, depending on formulations. Typical physical properties include tensile strengths as high as 9.7 MPa (1400 psi), elongations at break of 500–775%, and tear strengths

>30 N/mm (180 lb/in.). Compression sets of less than 10% can be achieved if the material is baked after processing.

New applications for LIM are being developed because of advances in uncured rheological properties, property improvements achieved from fillers, and advances in molding and processing (501). The rheological properties of the uncured LIM can vary from manufacturer to manufacturer (497). Fillers can enhance or degrade the thermal stability of the cured LIM (502). The final properties of LIM materials can be tailored. These properties include adhesion, hardness, green strength, elongation, and tensile strength. In addition, the precured viscosity, rheological properties, and cure speed can be modified (503). Finally, improvements in mold design (504) processing conditions (505), and advances in mold filling simulations have greatly improved the utilization of LIM materials.

Foam Rubber. Flexible foamed silicone rubber can be fabricated with flame retardancy greatly superior to that of the urethane-type foam. A self-blowing, low to medium density (80–240 kg/cm^3, 5–15 lb/ft^3) silicone foamed rubber can be prepared using polymers similar to those used in LIM products (506–509). Two components are mixed at room temperature: one part contains PDMS with pendent SiH functionality and fillers, and the other consists of terminal and pendant vinyl-containing PDMS, reinforcing and extending fillers, a platinum hydrosilylation catalyst and inhibitor, water, alcohol, and an emulsifying agent. Typical time for foam formation is less than 20 min.

Two chemical reactions occur simultaneously when the components are mixed. One is the platinum-catalyzed reaction of hydroxyl groups from water or alcohol with polymer SiH to give hydrogen gas (eq. 38). This reaction is the source of the blowing agent that forms the foam. The second reaction is the cross-linking of SiH and Si–vinyl, which increases the polymer viscosity ultimately leading to gelation and curing to give an elastomer. Proper control of the kinetics of these two reactions is critical to achieving foam having good physical properties. Emulsion-derived foam is possible as well (510).



(38)

Silicone foam thus formed has an open cell structure and is a relatively poor insulating material. Cell size can be controlled by the selection of fillers, which serve as bubble nucleating sites (511). The addition of quartz and other fillers (512) greatly improves the flame retardancy of the foam; char yields of >65% can be achieved. Cone calorimetry, UL 94, and other measurements have shown the excellent flammability properties of silicone foam (513). Because of its excellent flammability characteristics, silicone foam is used in building and construction fire-stop systems and as pipe insulation in power plants, in transportation systems as carpet underlay, and in seating. Typical physical properties of silicone foam are listed in Table (10).

Silicone Resins. Silicone resins are an unusual class of organosiloxane polymers. Unlike linear polysiloxanes, the typical silicone resin has a highly

branched molecular structure. The most unique, and perhaps most useful, characteristics of these materials are their solubility in organic solvents and apparent miscibility in other polymers, including silicones. The incongruity between solubility and three-dimensional structure is caused by low molecular weight (M_n < 10,000 g/mol) and broad polydispersivity of most silicone resins.

A wide variety of organosilicone resins containing a combination of M, D, T, and/or Q groups have been prepared and many are commercially manufactured. In addition, resins containing hydrosilation-reactive SiH and SiVi groups or other functionalities, including OH and phenyl groups, are known. Three classes of silicone resins are most widely used in the silicone industry: MQ, TD, and T resins.

MQ Resins. These resins are composed of clusters of quadrafunctional silicate Q groups end-capped with monofunctional trimethylsiloxy M groups. The structure of an MQ resin molecule is defined by three characterization parameters: M/Q ratio, molecular weight, and %OH. Standard analytical techniques have been used to quantify these parameters, including ^{29}Si NMR to determine M/Q ratio, GPC for molecular weight, and FIIR for %OH (515). Most commercially useful MQ resins have an M/Q ratio between 0.6 and 1. Ratios lower than 0.6 result in insoluble solids, whereas those greater than 1 produce liquids (516). Molecular weight is related to M/Q ratio; higher molecular weights are associated with lower M/Q ratios. Typical molecular weights are M_n = 10,000 g /mol for a resin with an M/Q of 0.6, and M_n = 2000 g/mol for an M/Q of 1.0 (416,515). The silanol content (% OH by weight) of these resins, typically ranging between 0 and 3%, is process-dependent. An IR study indicates that OH groups are intramolecularly associated through hydrogen bonding (516). A computer-generated molecular structure of a common commercially prepared MQ resin has been reported (517). This structure, shown in Figure 6, consists of a chain of silicate clusters end-capped with trimethylsiloxy groups.

MQ resins are commercially manufactured by one of two processes: the ethyl silicate or the sodium silicate process. In the ethyl silicate process, the resins are prepared by cohydrolysis of tetraethoxysilane and trimethylchlorosilane in the

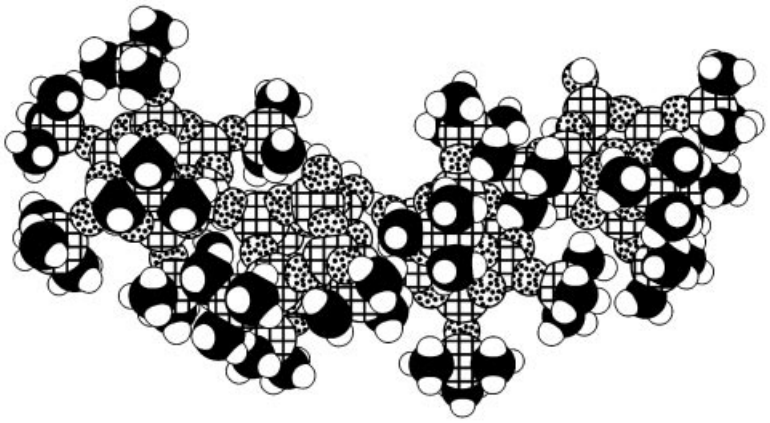

Fig. 6. Molecular structure of a typical MQ resin, $[M_{0.62}Q^{OH}{}_{0.17}Q_{0.83}]_{32}$: ○, H; ●, C; ⊕, Si; and ⊙, O.

presence of an aromatic solvent (eq. 39). This process is versatile and reproducible; it can be used to prepare soluble MQ resins with M/Q ratios ranging from 0.6 to 4 (518,519). The products of these reactions typically contain high levels of residual alkoxysilane groups.

$$Si(OCH_2CH_3)_4 + (CH_3)_3SiCl \xrightarrow{H_2O,\ solvent} [M_xQ]_y\ resin \qquad (39)$$

A more economical route to MQ resin uses inexpensive sodium silicate and trimethylchlorosilane (eq. 40) (520). The sodium silicate process is initiated by acidifying an aqueous sodium silicate solution to pH 2. The resulting hydrosol quickly builds molecular weight. The rate of this increase is moderated by the addition of an alcohol such as 2-propanol. The hydrosol is subsequently silylated by the addition of trimethylchlorosilane. This process, which is kinetically sensitive and limited to synthesizing M/Q ratios of 1 or less, is preferred when high OH (> 1%) MQ resins are required (521).

$$\left[(SiO_2)(Na_2O)_{0.3}\right]_{5.5}(aq) + HCl \xrightarrow{2\text{-Propanol}} \underset{hydrosol}{Stabilized\ silicate} \xrightarrow[2.\ Strip/filter]{1.\ (CH_3)_3SiCl} M_{0.7}Q\ resin \qquad (40)$$

Both the ethyl and sodium silicate processes can be modified by substituting SiH- or SiVi-functional chlorosilanes or combinations of chlorosilanes to produce hydrosilation-reactive MQ resins (521,522).

The most prominent use of MQ resins is as the tackifying agent for silicone pressure-sensitive adhesives (PSA) (523–525). The other main component of silicone PSA is a silicone gum. This mixture of MQ resin and silicone gum is applied to a tape backing such as polytetrafluoroethylene (PTFE) or poly(ethylene

terephthalate) (PET) and cured in the presence of a peroxide catalyst to provide an adhesive tape. MQ resins are also commonly used as control-release additives for silicone paper release products, as reinforcing agents for liquid-injection-moldable silicones, in masonry sealants, and in leather/textile water-repellent coatings (523,526–530). An additional use of MQ resins is as a surfactant. MQ resins are commercially attractive for use in defoaming applications as well as for stabilizing frothed urethane for high density carpet backing. Virtually every use for MQ resins is as a blend with a PDMS. These blends have been characterized as interpenetrating networks (517,531,532). MQ resin/PDMS blends are microphase-separated. One phase is PDMS-rich and has a glass-transition temperature of -107°C. This T_g does not change with changes in the blend ratio. The other phase is an MQ resin/PDMS-miscible phase, the T_g of which varies linearly from -100 to 200°C as the composition of the blend is changed from 30 to 90% MQ resin (517). These unique viscoelastic properties contribute to the versatility of silicone products containing MQ resin.

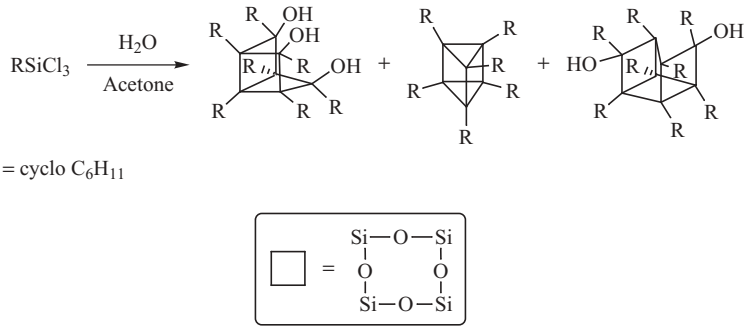
TD Resins. The other important class of silicone resins is TD resins. These materials are simply prepared by cohydrolyzing mixtures of chlorosilanes in organic solvents (eq. 41, where R is typically CH_3 or C_6H_5 (533). TD resins with T > 60 mol% T are substantially less soluble in PDMS than are MQ resins.

$$x\,\mathrm{RSiCl_3} + y\,\mathrm{R'_2SiCl_2} \xrightarrow[\text{Solvent}]{\mathrm{H_2O}} \mathrm{T}_x\mathrm{D}_y\,\text{resin} \tag{41}$$

A variety of liquid and solid resins can be prepared by varying the T/D ratio. Commercial TD resins are available containing from 5 to 95% T groups. Mixtures of methyl and phenylchlorosilanes are also frequently used. Some TD resins are modified by the addition of catalysts to reduce the silanol content, thereby increasing the molecular weight. Contrary to MQ resins, which are very stable, TD resins are unstable toward silanol condensation reactions.

TD resins are used as protective coatings, electrical coatings, saturants, laminates, and water repellents (1). TD resins are also useful in high performance paints. Compositions high in silanol content are utilized in reactive formulations. Low silanol TD resins are used as a nonreactive additive to alkyd paint formulations. Attractive features of TD resin-based protective coatings include superior, UV-resistant weatherability and excellent high and low temperature properties. Silicone electrical coatings are preferred when good dielectric insulation is required over a broad temperature range. TD resins are also used to saturate glass or Kevlar fabrics. After curing, these flexible composites are used in a variety of applications. TD resin-based water repellents are used chiefly with siliceous substrates. Some typical TD silicone resin properties are as follows: dielectric strength = 68,000 V/mm; dielectric constant = 2.9 at 60 Hz and 25°C; dissipation factor = 0.006 at 60 Hz and 25°C; surface resistivity = 1×10^{14} Ω/in.^{2}; and volume resistivity = 1×10^{14} Ω · cm.

T Resins. T resins have been historically called silsesquioxanes. Crystalline polyhedral silsesquioxanes can be synthesized by hydrolytic condensation of $RSiCl_3$ (eq. 42), where R = *c*-C_6H_{11} (534–538).



(42)

These cage structures can be derivatized with heteroatoms (539) to form catalysts or organic ligands that can act as precursors to hybrid organic/inorganic materials (540) or ligands (536).

A unique, amorphous T resin particle has been reported (541). This material, known by the trade name Tospearl (Tospearl is a trademark of the General Electric Co.), is a spherical resin particle made by the controlled, base-catalyzed hydrolysis and condensation of $CH_3Si(OCH_3)_3$ (eq. 43).

$$CH_3Si(OCH_3)_3 + H_2O \xrightarrow{NH_3} [CH_3Si(O_{3/2})]_r \quad (43)$$

Highly cross-linked spheres with an average particle size from 0.5 to 12.0 μm have been produced. Extremely narrow particle size distributions are possible. The particle size and degree of monodispersivity are controlled by kinetic factors during the hydrolysis. Applications for Tospearl powders include wear resistance, antiblocking properties, light-diffusion control, and lubrication (542).

T resins are also an important component of silicone powder coatings. T resins useful in powder coatings are obtained by the hydrolysis of $MeSiCl_3$ or the cohydrolysis of CH_3SiCl_3 and $C_6H_5SiCl_3$. These silicone formulations provide high temperature (service temperatures >800°F) and impact resistance (543,544) in solvent-free coatings.

Another key application for silsesquioxanes is in electronic insulating films having ultralow dielectric constants (< 2.7) (545–548). A solution of T resins in organic solvents is synthesized by cohydrolysis of $MeSiCl_3$ and $HSiCl_3$ in the presence of a nonpolar solvent, a polar solvent (alcohol), and a phase transfer catalyst (547). The resulting polymer has a caged structure with essentially no hydroxyl or alkoxy substituents. A film with a low dielectric constant is prepared by spin coating the organic solution of resin onto an integrated circuit device, followed by thermal curing at about 450°C. Films, having thicknesses of about 1.0 μm and low levels of internal stress, insulate the individual circuit elements of the integrated circuit.

Organosilicone Coating Products. Silicone products are used in a large variety of coating applications; most prominent among these are silicone pressure-sensitive adhesives (PSA), plastic hardcoats, and paper release coatings (523–525).

Pressure-Sensitive Adhesives. Silicone PSAs are used primarily in specialty tape applications that require the superior properties of silicones, including resistance to harsh chemical environments and temperature extremes (523–525). Silicone PSAs are also used in applications requiring long service life, electrical insulation, and protection from moisture. Another distinct advantage of silicone PSAs is their ability to wet low surface energy tape substrates such as PTFE.

Silicone PSAs are blends or interpenetrating networks (IPNs) composed of a tackifying MQ resin cured in a cross-linked polysiloxane network. The synthesis and structure of MQ resins have been described above. The polysiloxane network is traditionally derived by free-radical cross-linking of a high molecular weight PDMS polymer or gum using a peroxide catalyst, such as benzoyl peroxide or 2,4-dichlorobenzoyl peroxide. The curing reaction is performed immediately after the PSA has been coated onto a tape substrate, such as PET, PTFE, or Kapton. Uncured PSAs are supplied as a solution in an organic solvent. Some silicone PSAs also incorporate phenyl groups in the gum portion of the adhesive to increase the application temperature.

Another important aspect of the chemistry of silicone PSAs is the molecular interaction between the tackifying MQ resin and the PDMS network. For optimal adhesive properties it is important that some covalent bonding exists between the resin and the PDMS. This bonding is usually achieved by promoting a silanol condensation reaction between residual OH groups on the resin and on the end caps of the PDMS. The condensation reaction can occur either during blending of the PSA components or during processing of the tape. Studies of the viscoelastic properties of cured silicone PSAs indicate that these materials are microphase-separated (517,531,532). The adhesive properties of PSAs are a function of the unique rheological properties of the MQ resin/PDMS blends.

The key adhesive properties of a silicone PSA are tack, peel adhesion, and cohesive strength (lap shear). The required balance of these properties is controlled by several factors. A PSA composition rich in MQ resin usually favors low tack and high peel adhesion and cohesive strength values. A high cross-link density or a larger number of covalent bonds between the MQ resin and the PDMS network favors high cohesive strength at the expense of tack and peel adhesion. Low peel adhesion is observed when uncured cyclic or linear silicones are present. Other PSA properties important to the tape manufacturer, ie, viscosity, solvent content, cure time, and temperature, are typically controlled by varying the type and amount of organic solvent and peroxide cure catalyst. Primers are also frequently used to promote adhesion of the PSA to the tape backing.

One advance in silicone PSA chemistry is the use of Pt-catalyzed hydrosilylation reactions as the method of cure (549,550). Advantages of hydrosilylation-cured silicone PSAs include lowering the level of solvent, lowering cure temperatures, increasing line speeds, and the ability to be used with a broader range of tape backings. In this technology, lower molecular weight polymers containing hydrosilylation-reactive SiH and SiVi groups are substituted for the traditional OH-end-capped PDMS gum. A Pt catalyst and inhibitor are used instead of a peroxide (549,550).

There are several important, specialized applications for silicone PSA tapes. Platers tape mask selected areas of parts during etching or plating operations. Masking tapes are also used as protective coatings against high temperatures,

radiation, harsh chemical environments, or moisture. These tapes are used frequently in the manufacture of printed circuit boards (551). Splicing tapes are used to join plastic films. Silicone PSAs are often used to splice low surface energy materials or to provide high cohesive strengths at extreme temperatures. Plasma or flame spray tapes are used to protect selected metal surfaces during sandblasting or flame spraying operations. Silicone PSAs are particularly useful as the adhesive for electrical insulating tapes. A common application is as a wire wrap in motor coils. Silicone PSAs are also used in medical applications, notably as an adhesive for bandages and transdermal drug delivery systems (552).

Paper Release Coatings. Paper release coatings are a fast-growing segment of silicone technology. These materials are used in label systems in which the silicone coating is part of the disposable paper liner. The role of the silicone is to provide a low surface energy interface between the liner and PSAs. Silicone release coated substrates provide both protection for the adhesive during coating, handling, and storage, and subsequent easy release of the substrate from the adhesive surface immediately prior to use (553). The process of converting paper to a release liner involves in-line coating in which cross-linkable silicone polymers are applied to the substrate and then cured either thermally or via radiation. The dominant product form is a thermally cured solventless paper release coating comprised of a vinyl-terminated PDMS, an SiH-containing cross-linker, a Pt hydrosilylation catalyst, and a cure inhibitor. Vinyl-terminated polymer chains are more reactive than D-vinyl groups, resulting in faster cure (554). Hydrosilylation inhibitors are used to ensure that the siloxane formulation does not cure prior to deposition, thereby providing a bath-life sufficient for industrial processes. Typical hydrosilylation inhibitors are alkynols or alkyl maleates. Control release additives are frequently used in paper release coatings to increase the force required to remove the liner from the adhesive label (555). These additives are usually MQ resins that function by changing the viscoelastic properties of the coating. It is also preferred that these resins contain reactive Si–vinyl groups that cross-link into the silicone network. Ideal curing conditions involve temperatures of 150°C or lower and line speeds up to 460 m/min. Key properties for release coatings are cure speed, integrity of cure, and stable release values.

The need for faster line speeds, which result in increased productivity, and lower temperatures for thermally sensitive substrates is driving the technology of silicone paper release coatings. Advances include faster thermal curing and radiation-curable paper coatings. Substitution of 5-hexenyl groups for vinyl groups has been reported to increase the cure rate of thermal paper release coatings (556,557). However, the industry is rapidly evolving toward the use of UV-curable products. These coatings use silicone polymers and control release resin additives that are substituted with functional groups that can be cross-linked using photoinitiated catalysts (epoxides) or groups that can be directly photocured (acrylates, vinyl ethers) (277,558,559). An alternative to UV light for curing silicone release coatings is EB processing, although the initial capital investment for this technology is higher (297).

Typical substrates for silicone release coatings are supercalendered kraft paper, glassines, and thermally sensitive films such as polyethylene and polypropylene. Paper is currently the most widely used substrate, although thermally sensitive films are a growing market segment. One challenge with films is adhesion of

the cured silicone to the substrate. Typically, an adhesion promotor is required in addition to the cross-linkable silicone polymers to ensure anchorage of the cured silicone to the substrate.

Fiber Finishing Applications. Because of their unique properties, silicones have been used in both textile and hair care applications for decades. For textiles, early interest focused on water repellency (560–563), but now they are used in a wide variety of applications on fabrics derived from both natural and synthetic fibers, woven and nonwoven (264,562). For example, because of their low surface energy and extreme flexibility, silicones are among the best fabric softeners used in textile finishing. Silicone-treated fabric exhibits lower interfiber friction (565) that can lead to wrinkling benefits (durable press and wrinkle recovery). Fabric strength (566,567) and abrasion resistance (566,568,569) are other properties improved with some silicone treatments. Fabrics made from wool and other fiber types have been made shrink-resistant with certain silicone treatments (570–572). Silicones functionalized with polyether groups can impart hydrophilicity as well as softness or enhanced crease resistance to polyester and other fabrics (573–576).

Treated textile is typically rated by various ASTM or AATCC methods or by trained panelists. Standard methods exist for assessing tear strength, tensile strength, fiber friction, wettability, wrinkle recover angle, durable press rating, abrasion resistance, etc. (566,577–581). Panelists are often used to evaluate benefits such as softening, antiwrinkling, or stain removal.

For textile applications, silicones can be classified as nonreactive, conventional, reactive, or organoreactive (578,581). Polydimethylsiloxane fluids are typical nonreactive silicones. They can provide useful tactile and physical properties, but not durability. Conventional reactive silicones include SiH or SiOH polymers. These types, often having structures that give rise to three-dimensional networks upon curing, have been widely studied for durable water repellency and softening. Organoreactive silicones are substituted with groups that are capable of reacting directly with fibers. Textile finishes derived from these types of silicones, typical examples of which include silanol endcapped aminosilicones and epoxysilicones, can also provide durable benefits.

Softening is one of the most common target benefits achieved with silicone treatments (562,577,582–588). Softening benefits can be significant with silicone levels of 0.1% by weight on fabric. Aminosilicones are typically among the best softeners, providing the best feel (566,589). Studies have shown that silicone softeners can provide good durability and enhanced wrinkle recovery with a higher retention of mechanical properties when compared with traditional organic cationic softeners (578). Finishes can be hydrophobic or hydrophilic. Epoxy-substituted silicone materials modified with polyether groups, known for many years, can provide durable hydrophilic softening (590). Microemulsion technology has been applied, particularly with amino-functional silicones to improve fabric penetration and overall softening properties (591). Performance achieved with aminosilicones has been compared with that resulting from treatment with silanol polymers in the presence of alkoxy silane cross-linkers on cotton (578).

One recent study evaluated the softening benefits of aminosilicones on cotton as a function of pH and type of amino group (592). It was found that, in terms of softening, there is an optimum degree of polymer substitution as well as extent

to which the amino groups should be ionized. Electrostatic interactions between protonated amines and cotton are the primary driving force of attraction, but significant repulsive forces result from a high charge density. Computer simulations suggested that the primary amine contributes much more to the interaction energy than does the secondary amine within aminoethylaminopropyl-substituted polymers.

Wrinkle resistance and recovery are two key benefits for which silicones are widely studied (567). For example, it was found that silk and silk/wool blends exhibited improved wrinkle recovery when treated with a cationic microemulsion of an aminosilicone (580). Silicones are often added to durable press/shrinkage resistance treatments, and have been used in combination with a range of currently available cellulose cross-linking systems to both enhance the overall durable press benefits and counteract the strength loss associated with cross-linking (593,594). Silanol-terminated polymers were found to increase the durable press rating with glyoxal treatments (595,596). Treatment with aminosilicone polymers results in better durable press, retention of strength, and abrasion resistance when used with dimethyloldihydroxyethyleneurea (DMDHEU) cross-linking systems in some cases (597), although yellowing of white fabric can be a problem (568). Others have described the use of a durable hydrophilic silicone (polyether substituted) finish to impart hydrophilic softness and durable press properties (598,599). Durable press treatments for cellulosic-based textiles have also been patented where the silicone cross-links the cellulose fibers in the presence of an acid or base catalyst (600). It has also been claimed that certain silicone treatments improve wrinkle resistance and reduce the loss of tear strength when used with formaldehyde (601,602). Many other wrinkle-reducing compositions including silicone have been patented (584–586,603–608). While covalent bonding between organofunctional silicone and fiber surfaces is often invoked in the literature as a way of explaining durable benefits, it is rarely backed up with unambiguous evidence. An IR method for characterizing ester linkages to cotton has recently been described (609).

Silicone lubricants have also been studied as cotton processing aids (610). One study found an effective lubrication system containing a 1% loading by weight of a cationic silicone emulsion (611).

There are obvious links between silicone treatments for textiles and those for hair. Indeed, silicones have been used extensively in hair care products for 50 years, primarily in shampoos and conditioners (612–616). Aminofunctional silicones make hair feel soft and are thus outstanding for hair conditioning. Aminosilicones are effective because of their high pK_a and the fact that untreated hair has an isoelectric point of approx. pH 3 (617). Polyether-substituted silicones impart hydrophilicity and can be useful in compatibilizing different components of a formulation. They are also light conditioners and have antistatic characteristics. Phenyl silicones provide shine and luster. Alkyl-substituted silicone give hair volume and manageability. Silicone resins are substantive and also add volume as well as set retention. High molecular weight PDMS provides good dry feel properties and combing. These materials can be used alone or in combination.

Room Temperature Vulcanizable (RTV) Silicones. One-component, moisture-curable, room-temperature vulcanizable (RTV) silicones represent one of the largest-volume and commercially most successful silicone technologies. When exposed to atmospheric moisture, RTV silicones undergo hydrolysis and

condensation reactions and cure into high strength elastomers. Sealants and adhesives are the chief uses of RTV silicones. The rate of cure of these products is dependent on temperature and humidity. In the uncured state, in the absence of moisture, one-part products have a shelf life of 6 months to several years. The cured elastomers have excellent primerless adhesion to substrates as varied as glass, metals, wood, masonry, and plastics. Additional benefits include excellent weatherability, durability, electrical insulation, chemical resistance, stability at high temperatures, and flexibility at low temperatures. RTV products having a wide range of viscosities, from low viscosity self-leveling potting compositions to high viscosity thixotropic pastes, are commercially available. One of the few disadvantages of RTV systems is a slow rate of cure, often requiring more than 7 days in low humidities to achieve optimum properties. The cure speed can be increased by raising the temperature or by using a two-part formulation that includes water in one of the parts. Water can also be provided by the *in situ* reaction of carbonyl compounds with primary amines in a two-part formulation (618,619). Although two-part sealant formulations are exceedingly simple (silanol polymer, fillers, and alkoxysilane cross-linker; separate cure catalyst) and have long shelf lives, consumer demand has driven the development of more complex, but also more convenient, one-part formulations.

RTV Silicone Chemistry. There are two basic cure chemistries operative in RTV silicones: those based on rapidly hydrolyzing groups (acetoxy, ketoxime) and those requiring catalysts to promote hydrolysis (alkoxy-based systems) cure systems. Acetoxy-based RTV silicones were first commercialized in the early 1960s (620,621). The general chemical reactions of these first-generation products are shown in Figure 7.

In the first reaction, a multifunctional acetoxysilane cross-linker, such as methyltriacetoxysilane, reacts with a silanol-terminated PDMS, which releases acetic acid and forms a polymer containing multiple, hydrolytically unstable acetoxysilane end groups. This polymer plus fillers and other additives are compounded under anhydrous conditions and packaged as a one-part system. When exposed to atmospheric moisture, this functionalized polymer hydrolyzes, releasing more acetic acid and producing diolfunctionalized polymer end groups. This

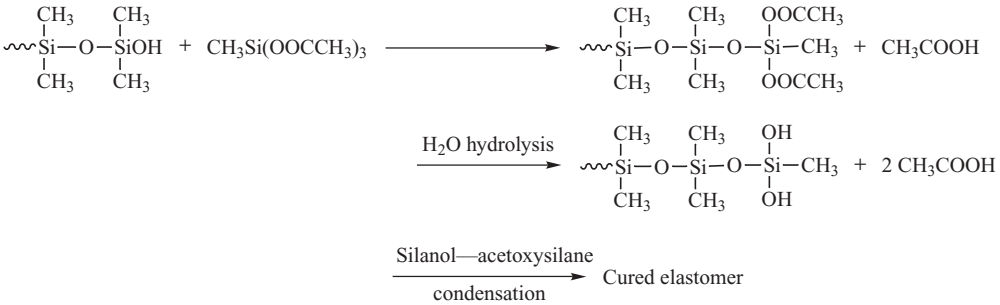


Fig. 7. Basic chemistry of acetoxy-based RTV silicones. The reactions for curing methoxy-based RTV silicones are the same; in that case, the methoxy group (OCH_3) replaces acetoxy ($OOCCH_3$), and methanol (CH_3OH), rather than acetic acid (CH_3COOH), is formed.

intermediate then undergoes self-condensation reactions, resulting in a silicone rubber. Tin(IV)-derived catalysts are frequently used to accelerate the cure of these products. Acetoxy-based RTV silicones have the advantage of having a long shelf life in the uncured state and rapid cure on exposure to moisture; however, their commercial applications are limited by the odor and corrosive nature of acetic acid.

Methoxy-based RTV silicones were introduced commercially in the late 1960s to overcome the deficiencies of their acetoxy predecessors (622). The reactions involved in curing of methoxy-based RTV silicones are similar to their acetoxy analogues.

The principal differences are that methoxy-based cross-linkers such as methyltrimethoxysilane do not spontaneously react with silanol-end-capped PDMS, and methoxysilane-terminated PDMS does not react with atmospheric moisture under neutral pH conditions. Catalysts are thus required for both of these reactions. Amines, Ti and Al complexes, and ammonium carboxylate salts are well-practiced end-capping catalysts (623–626). More recently, novel reagents such as tetralkylammonium fluorides and phosphate esters have been reported (627,628). Tin- and titanium-based catalysts are chiefly used as moisture cure catalysts (623,624,629–635). Unfortunately, these catalysts often promote undesirable siloxane redistribution reactions, which lead to instability of these RTV silicones in the uncured state. Methanol, released during the capping process, also functions in tandem with these cure catalysts in destabilizing compositions via siloxane redistribution reactions (636). Two strategies are used to overcome these side reactions and prepare commercially useful methoxy-based RTV silicones. In the first, an end-capping catalyst based on ammonium formate salts and Ti- and Sn-based cure catalysts containing specific ligands are employed. The ligands of interest are typically either hindered branched alkoxides (631–634), β-diketonates (623,630,635,637), or similar functional groups (638,639), which kinetically or thermodynamically stabilize the metal ions against alkoxy exchange reactions. As a result, these compounds have been found to be poor siloxane redistribution catalysts, and therefore are useful catalysts in RTV silicones having shelf lives of $\geq$ 6 months. In the second strategy, one-part RTV silicones with a higher degree of stability are achieved by removing methanol either physically or with methanol scavengers such as hexamethyldisilazane (629) or cyclic alkoxyaminosilanes (640,641). The latter react with methanol *in situ* to form products that also function as adhesion promoters.

RTV Silicone Compositions, Properties, and Applications. A typical commercial RTV silicone is a blend of a PDMS, end-capped with OH groups or alkoxysilanes. The compositions typically contain excess cross-linking silane, reinforcing fillers, plasticizing oils, adhesion-promoting silanes, a cure catalyst, and other optional additives. The key properties are the tensile strength and adhesion of the cured elastomer, the shelf life and thixotropic behavior of the uncured product, and the cure rate. The tensile strength of an RTV silicone is a function of the cross-link density of the silicone elastomer and the amount and type of reinforcing filler. Useful fillers include high surface area, silane-treated fumed silica (hexamethyldisilazane or D_4 are often used as treating agents), and calcium carbonate. The latter filler is either derived from natural sources or prepared synthetically (precipitated $CaCO_3$) and commonly treated with organic surface modifiers, such

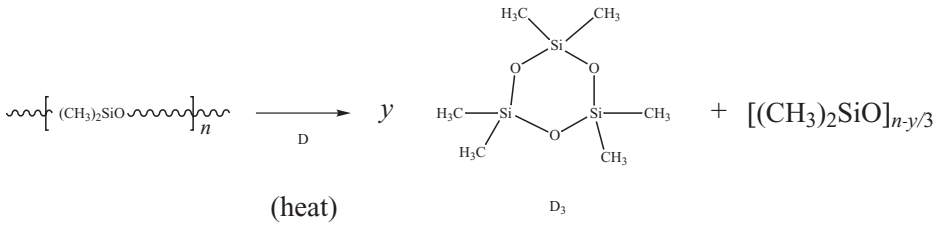
as stearic acid. Plasticizing fluids are usually trimethylsiloxy-end-capped PDMS fluids, which are used to improve thixotropy and adhesion. The outstanding adhesive properties of RTV silicones are affected by almost every ingredient of the composition. Adhesion promoters, typically trialkoxy- or dialkoxy-substituted functional silanes, are frequently used to enhance adhesion to difficult substrates such as glass, metals, and plastics. Examples include γ-aminopropyltrimethoxysilane, β-cyanoethyltriethoxysilane, and γ-glycidoxypropyltrimethoxysilane. Other additives used in RTV silicones are iron and rare-earth oxides for improved high temperature stability, platinum for flame retardancy, fungicides for high humidity applications, and a variety of pigments. One-part silicone RTV silicones are sold in three primary markets: household consumer products, construction products, and industrial adhesives. Noncorrosive RTV silicones using methoxy-based cure chemistry are useful as electronic potting compositions. Typical RTV silicone properties are given in Table (11).

Analysis and Testing of Silicones

The unique chemical, physical, and spectroscopic properties of organosilicon compounds are reflected in the analytical methodology used for the detection, quantification, and characterization of these compounds. Several thorough, up-to-date reviews dealing with analytical methods applied to silicones have been published (642–645).

Chemical Analysis. The presence of silicones in a sample can be ascertained qualitatively by burning a small amount of the sample on the tip of a spatula. Silicones burn with a characteristic sparkly flame and emit a white sooty smoke on combustion. A white ashen residue is often deposited as well. If this residue dissolves and becomes volatile when heated with hydrofluoric acid, it is most likely a siliceous residue (646). Quantitative measurement of total silicon in a sample is often accomplished indirectly, by converting the species to silica or silicate, followed by determination of the heteropoly blue silicomolybdate, which absorbs at 800 nm, using atomic spectroscopy or UV spectroscopy (647–650). Pyrolysis GC with mass spectroscopic detection of the pyrolysate is a particularly sensitive tool for identifying silicones (651,652). This technique relies on the pyrolytic conversion of silicones to cyclics, predominantly to D_3 [541-05-9], which is readily detected and quantified (eq. 44).



(44)

Functional groups in silicone monomers and polymers are characterized by chemical reactivity. For example, chlorosilanes are hydrolyzed, and the halogen is quantified by titration with alkali or silver nitrate (653). Other types of halogen substitution may require more drastic methods of decomposition. Silicon hydride is assayed by determining the hydrogen evolved after base-catalyzed hydrolysis or alcoholysis (654). Silanol concentration can be calculated by measuring the methane evolved with methyl Grignard reagent.

The structural architecture of silicone polymers, such as the number of D, T, and Q sites and the number and type of cross-link sites, can be determined by a degradative analysis technique in which the polymer is allowed to react with a large excess of a capping agent, such as hexamethyldisiloxane, in the presence of a suitable equilibration catalyst (655). Triflic acid is often used as a catalyst because it promotes the depolymerization process at ambient temperature (eq. 45).

$$\underset{\text{M}}{[(CH_3)_3SiO]_m}\,\underset{\text{D}}{[(CH_3)_2SiO_2]_n}\,\underset{\text{T}}{[CH_3SiO_3]_o}\,\underset{\text{Q}}{[SiO_4]_p} + (CH_3)_3SiOSi(CH_3)_3 \longrightarrow$$

$$\underset{\text{M}}{[(CH_3)_3SiO]_m}\,\underset{\text{D}}{[(CH_3)_2SiO_2]_n}\,\underset{\text{T}}{[CH_3SiO_3]_o}\,\underset{\text{Q}}{[SiO_4]_p} + Si(OC_2H_5)_4 \xrightarrow[\text{or } KOC_2H_5]{KOH}$$
$$m\,(CH_3)_3SiOC_2H_5 + n\,(CH_3)_2Si(OC_2H_5)_2 + o\,CH_3Si(OC_2H_5)_3$$

(45)

Instrumental Methods. A variety of spectroscopic techniques are available for the characterization of silicones. The analysis of bulk samples of silicone oils and related compounds can be accomplished via standard techniques; descriptions of these techniques and literature references relevant to silicone analysis are summarized in Table (12).

However, full characterization of functionalized siloxanes, particularly those containing high degrees of polymerization, can be difficult. Therefore, separation techniques coupled with various detection devices are typically employed. Supercritical fluid chromatography is effective for the separation of silicone oligomers that have molecular weights less than 3000 Da (688,689). Time-of-flight secondary ion mass spectrometry (TOF-SIMS) is applicable up to 10,000 Da (660).

A number of techniques have been developed for the trace analysis of silicones in environmental and biological samples. In these analyses, care must be taken to avoid contamination of the samples because of the ubiquitous presence of silicones, particularly in a laboratory environment. Stopcock grease, pump oil, soap, tubing,

Table 12. Spectroscopic Methods for Analysis of Silicones

Technique	Information provided	Reference
Mass spectrometry	Identification, structural information, molecular weight information, and quantification; information is dependent on the mode of ionization; particularly useful when combined with a chromatographic separation technique, such as in GC–MS, HPLC–MS, and pyrolysis GC–MS	651,652, 656,657, 657–662
IR/UV spectroscopy	Identification, structural information, quantification, and functional group identification; can be employed as detectors in chromatographic separations	663–672
NMR[a]	Detailed structural information; molecular weights can be determined by end group analysis; solid-state cp-mas techniques can be used to characterize solid samples and cross-linked elastomers	673–681
Atomic spectrometric methods (AA/emission)	Quantitatively detects total silicon in the sample; sensitivities in the ppb range are possible; particularly useful when used in combination with chromatographic separation devices; can be used to detect trace elemental contaminants in silicones	682–687

[a] Of particular interest are ^{1}H, ^{13}C, and ^{29}Si nuclei.

septa, o-rings, and labels are just some examples of sources of silicone in the laboratory. Depending on the method of detection, interference from inorganic silicate can also be problematic; hence, non-silica-based vessels are often used in these determinations. Particularly difficult are silicon-specific analyses such as those involving atomic spectrometric techniques where ppb levels of silicon are present.

Silicones have been extracted from environmental samples with solvents such as hexane, diethyl ether, methyl isobutylketone, ethyl acetate, and THF, using either sequential or Soxhlet techniques (690–695). Silicones of a wide range of molecular weights and polarities are soluble in THF. This feature, coupled with its volatility and miscibility with water, makes THF an excellent solvent for the extraction of silicones from wet samples, ie, soils and sediments. Trace levels of silicones extracted from environmental samples have been measured by a number of techniques, including atomic absorption spectroscopy (AA), inductively coupled plasma-atomic emission spectroscopy (ICP-AES), pyrolysis GC–MS, as well as ^{1}H and ^{29}Si NMR spectroscopy (674,684,692,696–700). The use of separation techniques, such as gel permeation and high pressure liquid chromatography interfaced with sensitive, silicon-specific AA or ICP detectors, has been particularly advantageous for the analysis of silicones in environmental extracts (685,701–704).

Determination of Physical Properties. Common properties of silicone polymers, such as refractive index, density, and viscosity, are measured using

conventional techniques (705). Molecular weights can be determined by standard methods, provided suitable reference standards are available. Empirical viscosity/molecular weight correlations are also useful as a simple means of obtaining approximate molecular weights (706). End group analysis by suitable spectroscopic or chemical methods can give reliable number-average molecular weight data. Long-chain branching in silicone polymers can be ascertained chemically, by determining the ratio of branch sites to end groups using degradation methods (655,656), or instrumentally, by measuring molecular size–viscosity relationships, for example, using a GPC instrument coupled to a differential viscometry or light-scattering detector (707,708). The level of cross-linking in silicone polymers, quantified in terms of the average molecular weight of strands between cross-links, is often measured by solvent swelling or modulus measurements, which are related to the combined effects of physical and chemical cross-links (709,710). Chemical cross-links can be quantified by NMR techniques or by degradative analysis to determine actual concentrations of T and Q cross-link sites (655).

Thermal stability, highly significant in silicone evaluation, is monitored by thermogravimetric analysis (TGA), differential scanning calorimetry (DSC), or dynamic mechanical analysis (DMA). Because environmental factors and chemical neutrality affect performance at high temperatures, oven-aging tests on finished products are frequently required. Measurement of weight loss on heat aging is frequently more sensitive than direct chemical methods for detecting the presence of trace amounts of strong acid or base, which reduce polymer stability.

A great variety of analytical techniques have been applied to silicone processing and quality control. In the early days of commercial production, the composition of chlorosilane intermediate mixtures was determined by analytical distillation and weight determination of fractions, supplemented by wet analysis of hydrolyzable chlorine and specific gravity measurements. These methods have largely been supplanted by GC and GC–MS methods. Gas chromatography is also used to monitor alkoxysilanes, acyloxysilanes, and the lower boiling point linear and cyclic siloxanes. On-line (in-process) monitoring of continuous and semicontinuous processes employs these and other relevant techniques.

Quality control testing of silicones utilizes a combination of physical and chemical measurements to ensure satisfactory product performance and processibility. For example, in addition to the usual physical properties of cured elastomers, the plasticity of heat-cured rubber and the extrusion rate of RTV elastomers under standard conditions are important to the customer. Where the silicone application involves surface activity, a use test is frequently the only reliable indicator of performance. For example, the performance of an antifoaming agent can be tested by measuring the foam reduction when the silicone emulsion is added to an agitated standard detergent solution. The product data sheets and technical bulletins from commercial silicone producers can be consulted for more information.

Properties of silicone fluids can be determined by a number of ASTM tests that were developed for the petroleum industry. ASTM D2225 describes methods of testing silicone fluids. ASTM tests typically used for determining standard physical properties are as follows: flash point, D92 and D93; pour point, D97; specific gravity, D1298; viscosity, D445; refractive index, D1807; and volume resistivity, D1169.

Health and Environmental Aspects

Few materials of commercial importance possess a range of applications as diverse as silicones. The widespread acceptance of silicones has given rise to remarkable growth of these materials since their first commercial production in the mid-1940s. In 1950, approximately 10^3 t of silicones was produced. By 1965, production amounted to 1.4×10^4 t and in 1999, production reached an estimated 3.5×10^5 tons in the United States alone (711). More recently, silicones have found increasing use in personal care products, such as deodorants, shampoos, and cosmetics. As a result of their widespread use and remarkable inertness toward light, heat, and chemical agents, an understanding of the environmental fate and distribution of silicones is important. Several reviews dealing with this subject are available (712–715), including a recently published comprehensive overview of environmental fate and effects of silicones (716).

Some examples of biological applications of silicones are biofouling release coatings, oil spill containment, and vitreous humor substitutes. Silicone elastomer coatings have been developed as nontoxic alternatives to toxic antifouling paints for ship hulls and power plant intakes (717–720). Solutions containing silicone have been developed to encapsulate and solidify oil slicks for easy removal (721,722). Silicone vitreous substitutes are used after retinal attachment surgery (723–725).

Organosilicones have been detected in terrestrial, aquatic, and atmospheric environments (Table 13).

Table 13. Silicones in Environmental Samples

Location	Silicone, ppm[a]	Organic silicone, pp[b]	Reference
Nagara River[c] sediment	0.3–5.8	2–54.2	697
Dye factory	41–6290	0–1150	
Sewage plant sludge	144	10.2	
Night soil plant	34.3		
Domestic wastewater treatment plant		2.4–4.9	
Blue Plains[d] wastewater treatment plant		4	726
Sludge	89–104		726,727
Filter cake	26–46		726
Potomac River[d]	0.46–3.07		727
Delaware Bay	0.1–1.56	34	727
Chesapeake Bay	0–36.1	30	727,728
Bight[e] wastewater treatment plant	0.48		729
Hudson River[e] sediment	10–350		730

[a] Wt Si/dry wt.
[b] Aquatic samples.
[c] Japan.
[d] Washington, D.C.
[e] New York.

The highest concentrations of environmental silicones are found in the sludges of wastewater treatment plants and upstream of process plants. Much lower levels are found in water or sediment samples except at certain point sources, such as in effluents of dyeing factories and other industries that employ silicones in their processes. In general, levels of organosilicones in sludges and sediments have been found to correlate with the total organic content of these media as determined by pyrolysis weight losses. This implies a migratory aptitude similar to that of other organic pollutants. For example, analysis of undisturbed, ^{210}Pb-dated sediment taken from Puget Sound in Washington indicates the presence of organosilicone in a 15-year-old sludge but not in a 60-year-old sample (731,732). This result suggests that silicones do not migrate appreciably of their own accord but follow sediment movement. Another study of the geochronology of sedimentary siloxanes was conducted in the Ala Wai Canal in Hawaii. The cores, dated using ^{210}Pb and ^{137}Cs measurements, showed the highest concentration of silicone in the most contemporary sediments. The study also found spikes in silicone concentration that could be traced to storm events (733).

Silicones have been detected in water from various rivers and in effluent from wastewater treatment facilities. They are barely detectable in water from municipal treatment facilities. Water solubility (S) of silicones has been found to correlate with the octanol–water partition coefficients (K_{OW}) for a series of trimethylsilyl-capped siloxane oligomers of various molecular weights according to equation 46 (734).

$$\text{Log } K_{OW} = 3.047 - 1.148 \log S \tag{46}$$

This expression can be used to predict solubilities from the octanol–water partition coefficients. Solubility and K_{OW} data for four oligomeric siloxanes are listed in Table 14.

The rapid drop in solubility and increase in K_{OW} with increasing molecular weight are evident from these data.

Because of their hydrophobic nature, silicones entering the aquatic environment should be significantly absorbed by sediment or migrate to the air–water interface. Silicones have been measured in the aqueous surface microlayer at two estuarian locations and have been found to be comparable to levels measured in bulk (732). Volatile surface siloxanes become airborne by evaporation, and higher molecular weight species are dispersed as aerosols.

Silicone contamination has been implicated as a cause of failure in telephone switching systems and other devices that contain relay switch contacts

Table 14. Effect of Siloxane Molecular Weight on Water Solubility and Octanol–Water Partition Coefficient

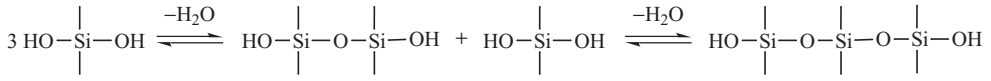
Molecular weight	Solubility in H_2O, ppm	$\log K_{ow}$
1,200	1.6	2.86
6,000	0.56	3.26
25,000	0.17	3.83
56,000	0.076	4.25

(735). Analysis of airborne particulates near telephone switching stations showed the presence of silicones at these locations. Where the indoor use of silicones is intentionally minimized, outdoor levels were found to be higher than inside concentrations (736). Samples of particulates taken at two New Jersey office buildings revealed silicone levels that were considerably higher indoors than outdoors. In these cases, indoor silicone aerosols are believed to be generated primarily by photocopiers, which use silicone fuser oils.

Airborne organic silicon has been detected in samples collected at Barrow, Alaska (737). Organosilicone levels corresponding to an airborne concentration of 8 ng/m^3 were detected. As a comparison, these samples were determined to hold approximately 20 ng/m^3 of phthalate-based plasticizers. Two pathways have been proposed for the removal of atmospheric organosilicones: degradation resulting from a reaction with OH radicals and wet deposition from the gas phase by incorporation into areosols (738).

Knowledge of the transformation of silicones under various environmental conditions is key to understanding the fate of these materials. Model studies predict that a large fraction of silicones entering the environment through wastewater treatment systems, ie, municipal treatment plants or septic systems, will ultimately be deposited on soils as a result of absorption or of sludge amendment (739,740). The chemistry of silicones on soils is thus an important factor in assessing the overall environmental impact of these materials. The accumulation of silicone in sediments has been observed in freshwater and marine sites heavily impacted by wastewater discharge. The concentrations ranged from 0.6 ± 0.1 ppm to 78 ± 20 ppm, which were still below the "no observable effect concentration" for the sediment organisms (741).

Silicone fluids degrade when exposed to soils (694,742–744). The rate of degradation depends on soil type and moisture content. Degradation is slow but observable on moist soils and becomes quite rapid when the available moisture content of the soil drops below 5% (745). The products of soil-induced abiotic degradation are typically silanol-terminated monomers and oligomers. Dimethylsilanediol, the simplest monomeric unit derived from silicone hydrolysis, is an important degradation product of abiotic silicone degradation. This compound is produced when silicones are exposed to soils and sediments even when the overall extent of polymer degradation is small, indicating a possible kinetic preference for its formation. As a polar, water-soluble species, dimethylsilanediol exhibits environmental distribution properties drastically different from the silicones from which it is derived (746). In organic solvents, dimethylsilanediol undergoes rapid self-condensation producing oligomeric products, whereas in dilute (<400 ppm) aqueous solution (eq. 47), it is the major constituent among the water-soluble oligomeric silanols (747). Therefore, (**1**) is expected to be the principal waterborne silicone species found in most environmental samples.



(47)

Irradiation of water-soluble silicon species such as dimethylsilanediol with artificial sunlight (xenon arc lamp) in the presence of environmentally significant levels of nitrate led to their rapid disappearance ($t_{1/2}$ = 4–9 days) (748). Silicate was determined to be the ultimate photodegradation product. Transformation of the soluble silicones to silicate under these conditions was complete in about 35 days. Irradiation of an emulsified high molecular weight silicone fluid [degree of polymerization (DP) = 50] resulted in negligible (1.7%) conversion to silicate in the same time period. Degradation did not occur in the dark or in the absence of nitrate. Nitrate is thought to act in this system by providing a source of photochemically generated hydroxyl radicals (eq. 48). Oxidative attack of these reactive species on the silicon–carbon bonds leads eventually to silicate and CO_2.

$$NO_3^- + H_2O \rightarrow NO_2 + HO^\bullet + HO^- \quad (48)$$

Water-soluble silanols such as dimethylsilanediol were found to undergo successive oxidative demethylations with tropospheric UV irradiation in the presence of suitable chromophores, such as nitrogen oxides (749). The water-soluble methylated silicones did not promote diatom (*Navicula pelliculosa*) growth but the demethylated photoproducts did. The sequence of soil-induced degradation of silicones to water-soluble species, followed by light-induced conversion to silicate, suggests a pathway, conceptually at least, for the mineralization of silicones.

Polydimethylsiloxane does not biodegrade at an observable rate under normal conditions of environmental exposure. For example, a ^{14}C-labeled 300-cSt PDMS fluid showed no evidence of biodegradation when exposed to activated sludge over a period of 70 days (750). In a similar microbiological screening study, silicones were found to be inert to all applied cultural conditions (751). However, when ^{14}C-labeled PDMS was applied to soil and allowed to degrade to low molecular weight species, the degradation products were further degraded to silicate and $^{14}CO_2$, presumably via a biotic pathway (752). This degradation has been observed both in the laboratory and in the field (694,753,754). ^{14}C-dimethylsilanediol is biodegraded on soils at a rate of $\approx$1% per month (755). The rate of $^{14}CO_2$ production can be increased an order of magnitude by the addition of certain carbon sources, such as 2-propanol and methylsulfone, to the medium. Thus, by a combination of abiotic, soil-mediated degradation and biotic or light-induced conversion of the degradation products, silicones can undergo complete mineralization in the environment (756). The rates at which this mineralization occurs depend on the conditions of environmental exposure.

Economic Aspects

Silicone polymers continue to be an important article of commerce globally. The industry grew at an average annual rate of 6–8% during the 1990s. The total global markets for silicone/silane materials totaled nearly $6.7 billion in 1998. The world capacity for silicones as of 1999 has been estimated at about 1.7 billion pounds (757). The silicones industry is a global enterprise with Dow Corning, General Electric, and SKW/Goldschmidt being the major producers of silanes. Table 15 lists the approximate sales of the principal producers for 1991 and 1998 (757).

Table 15. Total Silicone/Silane Sales of Principal Producers for 1991 and 1998

	Sales, $ millions	
Company	1991	1998[a]
Dow Corning	1850	2400
General Electric	750	1215
Shin-Etsu	750	600
Wacker Chemie	675	870
Rhodia	460	400
Degussa/SKW	—	670
Crompton	—	400
Others	465	134

[a]Ref. 757.

The recent merger of Degussa with SKW/Goldschmidt created a new global player similar in size to Shin-Etsu. This was part of a flurry of consolidation activities in the industry during the latter part of the 1990s. Also, joining forces during the period were GE and Bayer, Witco and Crompton-Knowles, and Hüls and Degussa.

SILK

Introduction

Silks can be defined as externally spun fibrous protein secretions. Of all the natural fibers, silks represent the only ones that are spun. Silk fibers have been used in textiles for thousands of years, owing to their unique visual luster, tactile properties, and durability. These fibers are remarkable materials displaying unusual mechanical properties. Strong, extensible, and mechanically compressible, silks display interesting electromagnetic responses, particularly in the UV range for insect entrapment; form liquid crystalline phases related to processing; and exhibit piezoelectric properties (1). Silks were used in optical instruments as late as the mid-1900s because of their fine diameter and high strength and stability over a range of temperatures. Spider silks are reportedly used in the South Pacific for gill nets, dip nets, and fishing lures, as well as in weaving and ceremonial dress (1).

Types of Silk

Silks are synthesized by a variety of organisms, including silkworms, spiders, scorpions, mites, and flies. Few of these silks have been characterized. Silks differ in properties, composition, and morphology, depending on the source. Silkworm cocoon silk from *Bombyx mori* is the most well characterized, owing to the extensive use of these fibers in the textile industry for over 5000 years in a practice originating in China. The dragline silk from the orb-weaving spider, *Nephila clavipes*, is

Table 1. Function and Location of Spider Silk Glands[a]

Silk	Gland	Function
Dragline	Major ampullate	Orb web frame and radii construction, safety line
Viscid	Flagelliform	Prey capture
Glue-like	Aggregate	Prey capture, attachment
Minor ampullate	Minor ampullate	Orb web frame construction
Cocoon	Cylindrical	Reproduction
Wrapping	Aciniform	Wrapping captured prey attachment to environmental
Attachment	Piriform	Substrates

[a]Ref. 3.

the most well characterized of the different spider silks. Spider silk has not been domesticated for textile applications because spiders are more difficult to raise in large numbers owing to their solitary and predatory nature. Unlike the cocoon silk from the silkworm, orb webs are not reelable as a single fiber.

Silkworm Cocoon Silk. The cocoon silk from *B. mori* contains two structural fibroin filaments coated with a family of glue-like sericin proteins, resulting in a single thread having a diameter of 10 to 25 μm. Wild silkworms generally have larger-diameter threads, ranging up to 65 μm and displaying a variety of different cross-sectional morphologies. The life cycle of *B. mori* runs for 55 to 60 days, and the organism passes through a series of developmental stages or molts. Silk production occurs during cocoon formation around day 26 in the cycle during the fifth larval instar just before molt to the pupa. The silkworm passes through four different metamorphosizing phases: egg or embryo, larva, pupa, and moth (adult). Smaller quantities of silk are produced at all larval stages except during molts.

Spider Silk. Spider silks function in prey capture, reproduction, and as vibration receptors, safety lines, and dispersion tools. Spider silks are synthesized in glands located in the abdomen and spun through a series of orifices (spinnerettes). The types and nature of the various silks are diverse and depend on the type of spider (2). Some general categories of silks and the glands responsible for their production are listed in Table 1.

Structure

Composition. Table 2 summarizes the amino acid composition of various silk proteins. The silkworm cocoon silk contains two structural proteins, the fibroin heavy chain (mol. wt. ca 350,000) and fibroin light chain (mol. wt. ca 25,000), plus the family of sericin proteins (mol wt 20,000–310,000) to hold the fibroin chains together in the final cocoon fiber and accessory proteins. Other silks, such as the caddis fly and aquatic midge, which spin silks underwater to form sheltered tubes, have also been characterized and consist of a family of proteins having high cysteine content and running from low to very high ($>10^6$) molecular weights (4). Some silkworm silks from wild strains have been reported to contain up to 95% alanine (1).

The consensus crystalline amino acid repeat in the *B. mori* silkworm cocoon silk fibroin heavy chain is the 59mer: GAGAGSGAAG[SGAGAG]$_8$Y. More detailed

Table 2. Amino Acid Composition of Silks

		B. mori		*P. c. ricini*[a]	*N. clavipes*
Amino acid	Abbreviation	Fibroin	Sericin	Fibroin	Dragline
Glycine	G	42.9	13.5	33.2	37.1
Alanine	A	30.0	5.8	48.4	21.1
Serine	S	12.2	34.0	5.5	4.5

[a]Philosamia cynthia ricini = wild–type silkworm silk.

analysis of these repeats indicates that the fibroin contains alternate arrays of repeating GAGAGS and GAGAGY. Valine or tyrosine replacements for alanine exist in the second repeat (5). These core repeats are surrounded by homogenous nonrepetitive amorphous domains. The repetitive structures in the protein are thought to be the result of genetic level continuous unequal crossovers or genetic recombination events during evolution.

The spider dragline silk from the principal ampullate gland contains at least one protein, called MaSp1, for major ampullate silk protein, previously termed spidroin 1; molecular weight is around 275,000 (6). It remains unclear whether additional proteins play a significant role in the dragline silk fiber. There is no sericin or glue-like protein associated with the dragline fiber. MaSp1 contains amino acid repeats considerably shorter than those found in the silkworm fibroin and not as highly conserved. The repeats contain polyalanine domains consisting of six to nine residues, and a 15-amino acid region showing a GGX repeat motif, where X = alanine, tyrosine, leucine, or glutamine (6,7).

Secondary Structure. The silkworm cocoon and spider dragline silks are characterized as an antiparallel β-pleated sheet wherein the polymer chain axis is parallel to the fiber axis. Other silks are known to form α-helical (bees, wasps, ants) or cross- β-sheet (many insects) structures. The cross- β-sheets are characterized by a polymer chain axis perpendicular to the fiber axis and a higher serine content. Most silks assume a range of different secondary structures during processing from soluble protein in the glands to insoluble spun fibers (see PROTEIN FOLDING).

The crystalline structure of silk was first described in the 1950s as an antiparallel, hydrogen-bonded β-sheet based on the characterization of *B. mori*

fibroin (8), and further modifications to this early model have been made over the years (9,10). Two crystalline forms for silk have been characterized on the basis of X-ray diffraction and ^{13}C-cross-polarization/magic-angle spinning (CP/MAS) NMR spectroscopy. The random coil or silk I, ie, the prespun pseudocrystalline form of silk present in the gland in a water-soluble state, is predominant in the gland; silk II, ie, the spun form of silk which is insoluble in water, becomes predominant once the protein is spun into fiber (9,11). The unit cell parameters in the silk II structure are 940 pm (a, interchain), 697 pm (b, fiber axis), and 920 pm (c, intersheet). The chains run antiparallel with interchain hydrogen bonds roughly perpendicular to the chain axis between carbonyl and amine groups. Van der Waal forces stabilize intersheet interactions owing to the predominance of short side-chain amino acids (glycine, alanine, serine) in these crystalline regions. Solid-state ^{13}C NMR studies of *N. clavipes* dragline silk have concluded that the polyalanine runs in the MaSp1 are in a β-sheet conformation (12).

The structure of silk I remains incompletely understood. This structure is unstable and upon shearing, drawing, heating, spinning, or exposure in an electric field or exposure to polar solvents, such as methanol or acetone, converts to silk II. The change in unit cell dimensions during the transition from silk I to silk II during fiber spinning is most significant in the intersheet plane, where an 18.3% decrease in distance occurs between overlying sheets (13). This change results in the exclusion of water, thus reducing solubility of the protein. Silk II is more energetically stable than silk I and the energy barrier for the transition is low, whereas the return barrier is high and considered essentially irreversible (1,14). Because the instability or metastable nature of the silk I conformation leads to difficulty in obtaining an orientated sample for fiber diffraction analysis and detailed structural characterization, different models have been proposed to describe the silk I structure (14,15).

Crystallinity. Generally, spider dragline and silkworm cocoon silks are considered semicrystalline materials having less crystalline flexible chains reinforced by strong stiff crystals (3). The orb web fibers are Composite Materials (qv) in the sense that they are composed of crystalline regions immersed in less crystalline regions, which have estimates of 30–50% crystallinity (3,16). Earlier studies by X-ray diffraction analysis indicated 62–65% crystallinity in cocoon silk fibroin from the silkworm, 50–63% in wild-type silkworm cocoons, and lesser amounts in spider silk (17).

Structure of the Spider Orb Web. The construction of the orb web is a feat of engineering involving material tailoring, optimization of material interfaces, and conservation of resources to promote survival of the spider (2,3). In addition, the web absorbs water from the atmosphere, and ingestion by the spider may provide a significant contribution to water intake needs (18). Around 70% of the energy is dissipated through viscoelastic processes upon impact by a flying insect into the web (3). Thus the web balances stiffness and strength against extensibility, both to keep the web from breaking and the insect from being ejected from the web by elastic recoil (3). The ability to dissipate the kinetic energy of a flying insect impacting the web is based on the hysteresis of radial threads and also aerodynamic damping by the web (18,19). Some orb webs appear to be at least in part recycled by ingestion as a conservation tool, and some of the amino acids are reused in new webs.

Processing

***In Vivo* Processing.** Silks are synthesized in specialized glands within the organism. Initially, some degree of self-organization or assembly occurs as a result of protein–protein interactions among the crystalline repeats in the protein chains (13). In the spider gland, changes in physiological conditions such as pH and salt concentrations accompany the processing and, presumably, help maintain solubility, despite increasing protein concentration during passage through the various regions of the gland (1). In silkworm there are three distinct regions to the glands and two sets of these organs feeding into one final thread (20,21). The fibroin is synthesized in the posterior region of the gland and the protein moves by peristalsis to the middle region of the gland where it is stored as a viscous aqueous solution until needed for spinning. The protein concentration is 12–15% in the posterior region of the gland where fibroin chain synthesis occurs, increases to around 20–30% in the middle region of the gland where the fibroin is stored and sericin is synthesized, and is significantly higher in the anterior region of the gland where spinning is initiated (20). The two lobes of the gland join just before the spinnerettes in the anterior region and the fiber is spun into air. Aside from binding together the fibroin chains in the final spun fiber, sericin in this process may function in plasticization to ease the flow through the spinneret, as a reservoir for divalent cations, or as a water-holding medium to promote plasticization of the fiber after spinning.

Rheological experiments indicate that crystallinity in the fiber correlates positively with shear and draw rates, and an extrusion rate of around 50 cm/min was found to be a minimum threshold for the appearance of birefringence and the conversion of the soluble silk solution in the gland to the β-sheet found in the spun fiber (20,22). In the posterior region of the gland, 0.4–0.8 mm in diameter, the silk solution is optically featureless; a range of secondary structures are present, including random coil and silk I; and the shear rate is low. In the middle region of the gland, the diameter is 1.2–2.5 mm, streaming birefringence is observed, and the shear rate is also low. In the anterior region of the gland, the diameter is narrow (0.05–0.3 mm), the shear rate is high, water appears to be actively transported out of the gland, the pH decreases, and active ion exchange occurs. Viscosity also increases but presumably decreases prior to spinning as a result of the liquid crystalline phase. At this point the characteristic silk II structure forms. In the pair of major ampullate glands in the spider, which are the location of dragline protein synthesis, a similar process occurs as summarized for the silkworm. This gland is smaller, however, and there is no sericin contribution in the middle region of the gland. A lyotropic nematic liquid crystalline phase of the protein forms prior to spinning in both the spider and the silkworm, as well as in many of the different glands of the spider responsible for the different silks (23). Recent studies also suggest that silk fibroin forms into micelles and then gel states in the gland as a mode to optimize protein concentration within the aqueous processing environment (24,25).

Commercial and Artificial Processing. Commercially, silkworm cocoons are extracted in hot soapy water to remove the sticky sericin protein. The remaining fibroin or structural silk is reeled onto spools, yielding approximately 300–1200 m of usable thread per cocoon. These threads can be dyed or modified

for textile applications. Production levels of silk textiles in 1992 were 67,000 t worldwide. The highest levels were in China, at 30,000 t, followed by Japan, at 17,000 t, and other Asian and Oceanian countries, at 14,000 t (26). Less than 3000 t are produced annually in each of eastern Europe, western Europe, and Latin America; almost no production exists in North America, the Middle East, or Africa. The 1993 projections were for a continued worldwide increase in silk textile production to 75,000 t by 1997 and 90,000 t by 2002 (26).

Most solvents used to solubilize globular proteins do not suffice for silks owing to extensive hydrogen bonding and van der Waals interactions, and the exclusion of water from the intersheet regions. Silks are insoluble in water, dilute acids and alkali, and most organic solvents; they are resistant to most proteolytic enzymes (6,27). Silkworm fibroin can be solubilized by first degumming or removing the sericin using boiling soap solution or boiling dilute sodium bicarbonate solution, followed by immersion of the fibroin in high concentration salt solutions such as lithium bromide, lithium thiocyanate, or calcium chloride. These salt solutions can also be used to solubilize spider silk, as can high concentrations of propionic acid–hydrochloric acid mixtures and formic acid (6). After solubilization in these aggressive solvents, dialysis into water or buffers can be used to remove the salts or acids, although premature reprecipitation is a common problem. Ternary-phase diagrams of silk, water, and chaotropic salt for processing windows have been published (28,29) for native silkworm silks and for genetically engineered versions of silkworm silk.

Films or membranes of silkworm silk have been produced by air-drying aqueous solutions prepared from the concentrated salts, followed by dialysis (11,30). The films, which are water-soluble, generally contain silk in the silk I conformation with a significant content of random coil. Many different treatments have been used to modify these films to decrease their water solubility by converting silk I to silk II in a process found useful for enzyme entrapment (30). Silk membranes have also been cast from fibroin solutions and characterized for permeation properties. Oxygen and water vapor transmission rates were dependent on the exposure conditions to methanol to facilitate the conversion to silk II (31). Thin monolayer films have been formed from solubilized silkworm silk using Langmuir techniques to facilitate structural characterization of the protein (32). Resolubilized silkworm cocoon silk has been spun into fibers (33), as have recombinant silkworm silks (34).

Recent studies have included the formation of electrospun nanometer-diameter fibers, hydrogels, and 3D porous scaffolds prepared from these proteins (35–37).

Properties

Mechanical Properties. The mechanical properties of silks are an intriguing combination of high strength, extensibility, and compressibility (Table 3).

Resistance to axial compressive deformation is another interesting property of the silk fibers. Based on microscopic evaluations of knotted single fibers, no evidence of kink-band failure on the compressive side of a knot curve has been observed (38,40). Synthetic high performance fibers fail by this mode even at relatively low strain levels. This is a principal limitation of synthetic fibers in some structural applications.

Table 3. Mechanical Properties of Silks and Other Fibers[a]

Fiber	Elongation, %	Modulus, GPa[b]	Strength, GPa[b]	Energy to break, J/kg[c]
Fibroins				
B. mori	15–35	5	0.6	7×10^4
Other silkworms	12–50	2–4	0.1–0.6	$(3–6) \times 10^4$
Draglines

[e]Rates of >500,000%s.

Fibers. *B. mori* cocoon silk ranges from 10 to 25 μm in diameter; dragline silk from *N. clavipes* from 2.5 to 4.5 μm in diameter. Web fibers from some spiders have diameters as low as 0.01 μm. A silking rate of ~1 cm/s is considered equivalent to natural spinning rates for the spider (20). Some spider silks have been observed to supercontact up to around 50% when unconstrained and exposed to high moisture; other silks such as the silkworm cocoon silk do not contract under similar experimental conditions (41). A skin core has been reported using light microscopy and electron microscopy. However, more recent data using dragline silk from *N. clavipes* refute this finding (42).

Thermal Properties. Spider dragline silk was thermally stable to about 230°C based on thermal gravimetric analysis (TGA) (38). Two thermal transitions were observed by dynamic mechanical analysis (DMA), one at −75°C, presumed to represent localized mobility in the noncrystalline regions of the silk fiber, and the other at 210°C, indicative of a partial melt or a glass transition. Data from thermal studies on *B. mori* silkworm cocoon silk indicate a glass-transition temperature, T_g, of 175°C and stability to ~250°C (37). The T_g for wild silkworm cocoon silks was slightly higher, from 160 to 210°C.

Genetic Engineering

An understanding of the genetics of silk production in silkworms and spiders should help in developing processes for higher levels of silk expression generated by recombinant deoxyribonucleic acid (DNA) methods. The ability of the silkworm to produce large amounts of protein, around 300 μg of fibroin per epithelial cell lining the silk producing gland, has generated a great amount of interest from molecular biologists and developmental biologists in elucidating the genetic

regulation of this system. Genetically engineered or recombinant DNA silkworm and spider silks have been produced using either native genes or synthetic genes (34,43,44) (see GENETIC METHODS OF POLYMER SYNTHESIS). It is interesting to note that studies of variations in native silkworm populations indicate differences in sizes of the crystalline-encoding domains resulting from a high degree of polymorphism in length and organization of the fibroin gene and thus the encoded proteins (45,46). A significant degree of variation in protein size, apparently, can be tolerated in native populations of silkworms and, possibly, spiders. Owing to the highly repetitive nature of the genes and the encoded proteins, the deletion or addition of repeats has little impact on secondary structure and functional performance within a certain window of sizes.

Applications

Because of the advent of improved analytical techniques, together with the tools of biotechnology, a new generation of products is envisioned with silk. The ability to tailor polymer structure to a precise degree leads to interesting possibilities in the control of macroscopic functional properties of fibers, membranes, and coatings, as well as improved control of processing windows. Biotechnology offers the tools with which to solve limitations in spider silk production that have not been overcome with traditional domestication and breeding approaches, such as those used successfully with the silkworm. This is of interest because of the variety of silk structures available and the higher modulus and strength as compared to silkworm silk.

Hybrid silk fibers containing synthetic fiber cores having silk coextruded or grafted have been synthesized. Cosmetics and consumer products, such as hair replacements and shampoos containing silk, have also been marketed. Sutures (qv), biomaterials for tissue repairs, wound coatings, artificial tendons, bone repair, and related needs may be possible applications, since immunological responses to the silks are controllable (see TISSUE ENGINEERING). It is also reasonable to speculate on the use of silk webbing for tissue cell growth, nerve cell growth, and brain repair applications such as temporary scaffolding during regrowth and reinfusion after surgery. Cell culture Petri plates having genetically engineered silkworm silks containing cell binding or adhesive domains have already been produced and are sold commercially. These recombinant silks are stable during injection molding with polystyrene. The demonstration of fiber spinning from resolubilized silkworm silk provides further opportunities in material fabrication using native and genetically engineered silk proteins.

SOLID-STATE EXTRUSION

Introduction

Solid-state extrusion (SSE) is one of the well-known methods used for attaining a high oriented state of polymers (1–4). It enables the production of fibers, films, pipes, shapes, including those of large cross section and of various configurations—all possessing high strain–stress characteristics. SSE is based on deformation at temperatures just below the polymer melting temperature, or for amorphous polymers just above the glass-transition temperature. The deformation is mainly by extrusion (qv) through conical or slit dies, it is used for shape forming and structure modification of polymer materials of different nature, such as homopolymers, polymer blends, filled polymer composites, etc (4–10).

For the production of high modulus high density polyethylene (HDPE), polytetrafluoroethylene (PTFE) and other polymers the solid-state extrusion is frequently used at the first stage of a two-step drawing process (11–16). The polymer is first drawn up to the limiting draw ratio at a fast rate and subsequently slowly superdrawn at a temperature that depends on the morphology. Extrusion draw ratio (EDR for short; it is defined as the ratio of die entrance to exit cross-sectional areas), pressure, extrusion rate, temperature, and die geometry are the parameters that effectively influence the process of the high oriented polymer production, the polymer structure and properties.

This article gives a brief information on different SSE methods and their influence on structure and properties of polymer materials. Attention is primarily paid to the most known methods, such as plunger extrusion and hydrostatic extrusion. Two new methods of SSE implementation are analyzed in brief, which, in contrast to the conventional ones, are based on polymer simple shear, not drawing. Lately, they have been of high interest in view of the production of nanostructural metallic materials (17) and are now known as methods of severe plastic deformation (SPD).

Encyclopedia of Polymer Science and Technology. Copyright John Wiley & Sons, Inc. All rights reserved.

The treatment by the scheme of simple shear under pressure results in the intensive refinement of metal crystallites with the formation of ultrafine grain substructures possessing unique properties (17). SPD of polymer materials has become the subject of investigation recently. The investigation results show that simple shear considerably affects the structure and properties of polymers (18,19). In contrast to the conventional SSE, the solid-state extrusion based on simple shear does not result in final changes of billet shape and dimensions. That is why, the problems relating to the conventional SSE are included in the section "Extrusion with Changes in Billet Shape", while the SPD methods for polymers and a brief analysis of the experimental results are given in the section "Extrusion Based on Simple Shear".

Extrusion with Changes in Billet Shape

The SSE process based on changes in polymer-billet shape is, first of all, characterized by the EDR value. The limited EDR value is determined by polymer type, molecular weight and morphology. For example, for HDPE it may reach more than 40 (1). For polyoxymethylene (POM), polypropylene (PP), PTFE the maximum values of draw ratio equal 10, 6, and 4 (20–22), respectively. For polymethylmethacrylate (PMMA), polystyrene (PS), polycarbonate (PC), and other amorphous polymers they are even lower (21,23). The extruded specimens are highly oriented and possess improved mechanical properties. In the case of semicrystalline polymers, the extrusion results in a considerable increase of tensile modulus and strength (1,2). With amorphous polymers, a considerable increase of plasticity is observed alongside with increase of tensile moduli (21,23).

Extrusion Methods. There exist two approaches to SSE implementation. These are the methods of plunger and hydrostatic extrusion. The first investigations by using the plunger extrusion were made on polyethylene. Extrudates were produced by melt crystallization under pressure and by orientation in a capillary rheometer of the Instron type (1,24–26). Moreover, the crystallization of polymer took place at die entrance and in the rheometer cylinder. Such a technique made it possible to produce short transparent and strong fibers of less than 1 mm diameter or films of similar characteristics.

In more recent experiments, the polymer billet was formed prior to SSE. The extrusion process was implemented with both the capillary rheometer and by using a high pressure chamber and a pressing equipment (6–8,25,27), thus the potential applications of the method have become wider. Figure 1**a** is a schematic showing the process of plunger extrusion, which is the most frequently applied in practice. The polymer is extruded by a rod through the die of conical shape. With the dies of different deforming-channel sections (such as slot, round, square, screw ones) it is possible to produce high oriented fibers or films, to change the shape and to draw the polymer billet for having shapes of improved physical and mechanical properties.

For the structural modification of polymers the method of solid-state coextrusion (SSCE) is used (28,29). This is a technique for polymers which is difficult to draw, or if the highest draw is desired. The polymer to be drawn is extruded within a second more ductile polymer (within a sandwich arrangement). The process has

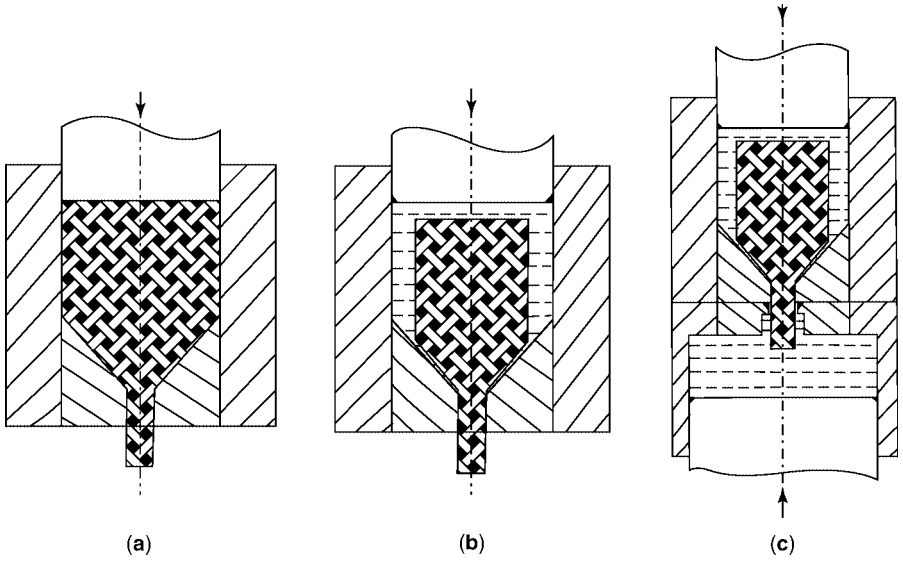

Fig. 1. Schematic representation of plunger extrusion (**a**), hydrostatic extrusion (**b**), and hydrostatic extrusion with backpressure (**c**).

been used for the extrusion of films (split-billet coextrusion) and fibers (concentric-billet coextrusion). In particular, the SSCE technique was used for the production of highly oriented films of semicrystalline polyamides (28), poly(vinylidene fluoride) (30,31), HDPE (25,28,29), poly(L-lactic acid) (32), and amorphous PS (29) and poly(ethylene terephtalate) (PET) (33). This technique makes it possible to coextrude polymers of different molecular weights at temperatures much lower than the melting temperature and to produce superthin films of high strength characteristics.

In the process of hydrostatic extrusion, the polymer billet is forced by a compressed liquid through a narrowing die. The high pressure develops due to rod travel, as shown in Figure 1**a** and 1**b**, or is generated by a high pressure compressor (the so-called "compressor version of the hydrostatic extrusion"). This processing method prevails over the plunger extrusion since there is no friction of the billet material on the channel walls in the high pressure chamber, and the friction between the polymer and the die is low because of liquid penetration into the gap. Besides, in the hydrostatic extrusion the effect of material plasticization is largely realized at the expense of high pressure action (26), so brittle polymers can be deformed as well (21,23). If necessary to increase polymer ductility, the deformation with backpressure is carried out (Fig. 1**c**) (26). The first investigation of the hydrostatic-extrusion process as well as of the structure and properties of extrudates were done approximately at the same time, as for the plunger extrusion (34–36), and they were being actively developed later on (20–23,25,37,38).

For SSE, monolithic or powder billets are used. In the latter case, the polymer powder is compacted, heated to the temperature close to the melting temperature and then extruded. The extrudates of ultra high molecular weight polyethylene (UHMWPE) (8), polymerization-filled polyethylene composites (7,9)

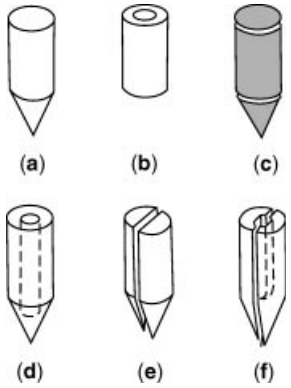

Fig. 2. Billets for SSE (**a, b, c**) and shells for SSCE (**d, e, f,**): (**a**) solid plug, (**b**) pipe billet, (**c**) powder billet, (**d**) concentric shell, (**e**) full width shell, and (**f**) half width shell.

of polyetherketone (39), polyarylate (40) have been produced in this way. With the plunger extrusion of a powder billet, high EDR values are attained at temperatures much lower than in the case when a monolithic sample is deformed. The powder billet is also used for the production of high oriented polymers by the SSCE method and twostep drawing process (12,13).

Polymer-billet geometry is defined by SSE scheme. In Figure 2, there are some variants of billets for the plunger (**a**–**f**) and hydrostatic (**a**, **b**) extrusion to be used in the described SSE techniques. The hydrostatic extrusion is of a lesser potential application as it is necessary to protect the compacted powder from liquid penetration and to seal the billet in the die to prevent liquid from leakage under pressure rise (coextrusion).

Extrusion Conditions. For a brief and clear presentation of the subject matter we make use of the approach of system analysis to represent SSE as a system having inputs and outputs, and set forth the relationships. The input variables $\{X\}$ are parameters controllable for the purpose of affecting the output variables $\{Y\}$. In the case of SSE, with a predetermined material of the billet, the former parameters are: the extrusion draw ratio, die geometry, velocity of plunger motion for the plunger extrusion, and plunger hydroextrusion; pressure in chamber in the case of compressor version of the hydroextrusion; backpressure or drag force applied to the extruded product; temperature of chamber and die heating; structure of billet material; dimensions and geometry of the billet; and lubricant and fluid (for hydroextrusion).

In SSE, the output variables are: extrusion pressure, velocity of product exiting, value of extrudate swell, degree of deformation and strain rate, and structure and properties of the processed material.

The Normal Solid-State Extrusion Process and Its Violations. The normal course of SSE is characterized by a nonstationary stage at the beginning of the process and a constant velocity of product exiting during the rest of the process. In this case, the extrudate has a regular cylindrical shape with smooth surface having no visible defects.

In the case of plunger extrusion, at the stationary stage of the normal process the velocity of the exiting extrudate υ_e is described by the relation $\upsilon_e = R\upsilon_p$,

where υ_p is the velocity of plunger motion, R is the extrusion draw ratio. For the plunger version of the hydrostatic extrusion $\upsilon_e = R\upsilon_p\, S_p/S_b$, where S_b is the cross-sectional area of the billet, S_p is the cross-sectional area of the plunger. For the compressor version of the hydrostatic extrusion, at the stationary stage of the process the velocity of extrudate existing is determined by the value of pressure (a move detailed explanation is given below).

The normal course of SSE is only realized at a definite range of input parameters. Outside the range there occurs some disturbances in the normal process: a discontinuous movement of the extrudate without an essential change of its shape (the stick-slip effect); the unstable flow of the polymer in the paraxial zone of the extrudate resulting in polymer turbidity; the pulsating flow with a considerable deformation of extrudate shape; and the occurrence of spiral-like cracks on its surface.

The above defects are due to different reasons. In the article (41), the stick-slip effect is related to self-excited oscillations initiated by the dependence of static friction–stress between the billet and the die at the time when they are in contact. The latter is connected with the viscoelastic properties of the rough billet surface and by lubricant squeezing out from the region of contact. Ward and co-workers (1) explain the stick-slip effect by the heating of billet during the deformation. The pulsatory flow is assumed to be due to a competition between the viscosity and high elasticity of polymers (42).

In accordance with different physical causes of interruption in the normal course of SSE (eg 41,42), criteria have been obtained and the boundaries of the input-variable range have been determined for the normal regime of the process. For example, for the stick-slip effect the lower bound of the velocity of plunger motion has been determined in (41). The upper bound of the velocity region of normal process has been derived in (42) based on the Weissenberg (Debora) criterion.

In (41,44), different engineering approaches to stick-slip effect elimination have been proposed. The most effective are the application of a tractive force to the front end of the product being extruded.

Extrusion Pressure. The characteristic feature of the plot of extrusion pressure P vs the logarithm of extrusion draw ratio $\ln R$ is that it is convex to the axis of $\ln R$ (Fig. 3). In the case of the hydrostatic extrusion of metals, the dependence is practically linear (44). This difference is because with polymers there is a more intensive strain hardening, strain rate, and pressure hardening as compared to metals. At a qualitative level this is shown as follows.

As the work of plastic deformation is equal to that of external forces, it follows, in the first approximation, that the hydrostatic-extrusion pressure P can be determined by the formula (45):

$$P = \int_0^{\varepsilon^* + \ln R} \sigma_s(\varepsilon, \dot{\bar{\varepsilon}}, \bar{p}, \bar{T})\, \mathrm{d}\varepsilon \qquad (1)$$

where $\sigma_s(\varepsilon, \dot{\bar{\varepsilon}}, \bar{p}, \bar{T})$ is the strain resistance of polymer, ε is the strain, $\dot{\bar{\varepsilon}}$, $\bar{p}$, $\overline{T}$ are values of the strain rate, pressure, and temperature averaged with respect to the volume of deformation center, respectively; ε^* is the strain induced by the entrance

and exit zones of the die (it depends on the value of die cone angle and does not depend on the extrusion ratio).

By double differentiation of relation 1 we have

$$\frac{\mathrm{d}^2P}{\mathrm{d}(\ln R)^2} = \left(\frac{\partial\sigma_s}{\partial\varepsilon} + \frac{\partial\sigma_s}{\partial\dot{\bar{\varepsilon}}}\frac{\mathrm{d}\dot{\bar{\varepsilon}}}{\mathrm{d}(\ln R)} + \frac{\partial\sigma_s}{\partial\bar{p}}\frac{\mathrm{d}\bar{p}}{\mathrm{d}(\ln R)}\right)\Bigg|_{\varepsilon^*+\ln R} + \\ + \int_0^{\varepsilon^*+\ln R} \frac{\mathrm{d}}{\mathrm{d}(\ln R)}\left(\frac{\partial\sigma_s}{\partial\dot{\bar{\varepsilon}}}\frac{\mathrm{d}\dot{\bar{\varepsilon}}}{\mathrm{d}(\ln R)} + \frac{\partial\sigma_s}{\partial\bar{p}}\frac{\mathrm{d}\bar{p}}{\mathrm{d}(\ln R)}\right)\mathrm{d}\varepsilon \tag{2}$$

In view of polymer strain, velocity, and pressure hardening, all the derivatives of σ_s in the righthand part of relation (2) are positive. Besides, the average values of the strain rate and pressure at the center of deformation are increasing with extrusion draw ratio, ie the derivatives of $\dot{\bar{\varepsilon}}$ and $\bar{p}$ with respect to ln R are also positive. It follows that the right-hand part of relation (2) and, thus, the second derivative of P with respect to ln R are also positive, hence we have the convex plot of function $P = P(\ln R)$ with respect to the axis of R. According to (2), more intensive the effects, the higher the strain, strain rate and, stress hardening of the material.

On the dependence of extrusion pressure on die cone angle 2β there is a minimum (Fig. 3**b**). This is because of the competition of two factors that affect the extrusion pressure: contact friction and additional deformation ε^* at the input and output from the conical part of the die. The first and the second factor become significant with a decrease or an increase in cone angle, respectively.

In view of the fact that the polymer strain resistance depends much on strain rate and temperature, in plunger extrusion and plunger version of hydrostatic extrusion the extrusion pressure increases with the velocity of plunger motion

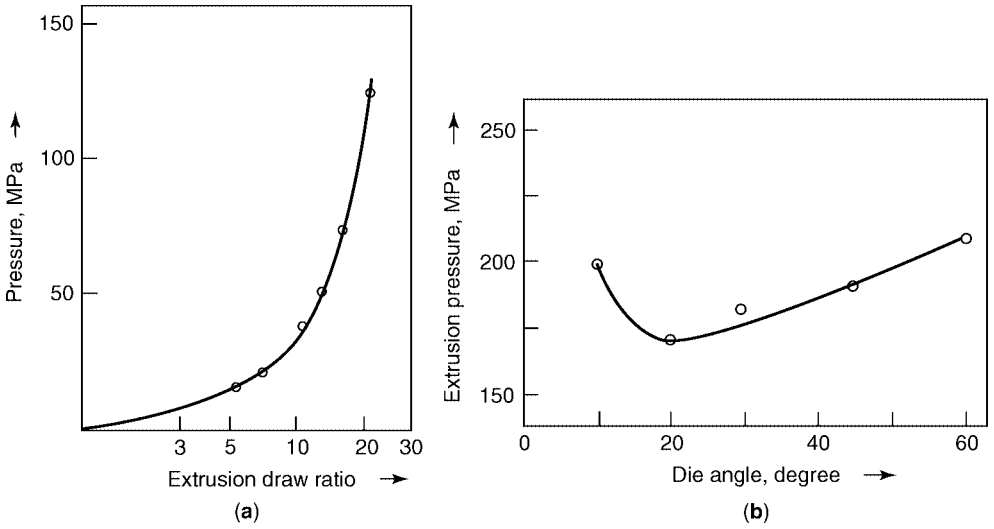

Fig. 3. Typical graphs of extrusion pressure versus extrusion draw ratio (log scale) (**a**) and die angle (**b**). (**a**) Rigidex SOLPE, $2\alpha = 30^\circ$ (43). (**b**) High density polyethylene, EDR = 6.75 (38).

and decreases with temperature rise. For the compressor version of the hydrostatic extrusion, pressure in the chamber determines the velocity of extrudate exiting.

The above-mentioned dependences of SSE pressure on input parameters can be taken into account within the framework of mechanical models of the process. In the most detailed ones (20), the relationships for calculation of pressure have been derived with a rather good agreement between theory and experiment. The value of extrusion pressure can be estimated, in a first approximation, by formula (1), where $\varepsilon^* = (\pi/2)\tan(\beta/2)$ (46). The $\sigma_s(\varepsilon)$ dependence should be experimentally determined with the average, in deformation center, temperature and rate of deformation. It is easy to show that the latter is approximately equal to $\dot{\varepsilon} = \frac{2v_e}{d_e} R^{\frac{3}{2}} \tan\beta$ where d_e is the diameter of the extrudate.

The Velocity of Extrudate Exiting. It has been already pointed that the rate of extrusion is an output variable only in the case of the compressor version of hydrostatic extrusion. For the plunger processes, under the normal flow, the rate of extrusion is an independent quantity. If the working fluid is pumped to the chamber by a compressor, and in the chamber there is a control valve for releasing unnecessary liquid, then it is possible to maintain the extrusion pressure at a preset level. In this case, the velocity of product exiting depends on pressure and temperature. According to theoretical estimates, and to experiment (38), the extrusion rate exponentially increases with pressure.

The Swelling of Extrudates. In the case of SSE, a phenomenon of extrudate swelling at the die exit is observed. Taking it into account, the quantities of the actual extrusion draw ratio $R_d = S_b/S_e$ and the nominal extrusion draw ratio $R_n = S_b/S_d$ are introduced, where S_e is the area of the extrudate cross section, S_d is the area of the die exit. Parameter R_a correlates with the EDR value.

This phenomenon is related to a partial relaxation of viscoelastic strain in polymer during the extrusion. Its value is determined by both the polymer characteristic properties and the SSE conditions (1,5,23). With an increase in EDR value the swelling diminishes sometimes close to zero, the same as was observed for the linear polyethylene with $M_W = 1 \times 10^5$ (1). A considerable swelling is characteristic of semicrystalline polymers possessing high molecular weight, as well as of amorphous polymers. To reduce the swelling, the use is made of dies with a longer calibrating zone.

Peculiarities of the Mechanics of Powder Extrusion. Mathematical modeling of the SSE process by the method of continuum mechanics is based on defining equations relating the components of stress and strain tensors. Among them is the yield condition. For the isotropic monolithic materials it is in the Tresca, Mizes or Hill form (47).

The mathematical description of the powder billet SSE cannot rely on the above conditions of plasticity, as they do not take the change in density of the extruded sample into account. Nor the conditions of plasticity used to model the compaction of metal powders are suitable for this case (48). They imply that with the increase in hydrostatic pressure the relative density of powder material tends to unity. However, in the case of hydrostatic compaction of polymer powders, the relative density of compacts tends to a value less than unity, which is typical of the polymer. The reason is in difference of compaction mechanisms for the metal and polymer powders.

For polymers, the compaction proceeds in two stages. The first stage consists in shear and turning of some particles relatively each other. They experience high elastic strain resulting in the increase of the area of real contact and forces of the interparticle friction. The second stage of compaction is mainly conditioned by high elastic–plastic straining of the particles that fill the free volume. After releasing the external pressure the polymer material decreases its density as the elastic deformation is reversible.

A condition of plasticity has been proposed (49) that makes allowance for a changing of the density of powder polymer during the deformation under pressure. It was the basis for the elaborated SSE theory to predict the density of extrudates (50). It follows, in particular, that during the SSE a nonmonotonic dependence of the density of extrudates on the extrusion ratio is possible. The presence of the effect has been verified experimentally.

Deformation Mechanism. The deformation mechanism has been studied in more detail for the case of semicrystalline polymers, polyethylene, in particular (1,2). There exist a number of models explaining the evolution of polymer structure at high draws. The models can be subdivided into two categories (2), namely, the microfiber plus the tie molecule model, as proposed by Peterlin and co-workers and the extended chain model, which is similar to Ward's crystalline bridge model.

According to the Peterlin's model (51,52), the starting material consists of the packed lamellae with chain folds, while the completely extruded one consists of oriented microfibrils. In the lamellar structure, within the lamella there is a macromolecule that forms folds in direction normal to chain axis. In the fibrillar structure, the macromolecule is within the microfiber, but already in direction parallel to chain axis. Microfibers consist of crystal blocks and noncrystalline regions connected by taut tie molecules. Under drawing, the lamellar structure changes to the fibrillar one at the expense of shearing, rotation, chain tilt, and slip processes taking place in lamella. The axial modulus is proportional to the number of load-bearing tie molecules that cross the noncrystalline regions to connect adjacent crystalline blocks along the microfiber.

Ward's model (53,54) provides the presence of "crystalline bridges" formed from groups of crystallized taut intrafibrillar tie molecules between the crystallites. This morophology consists of fibrillar stacks of crystallites, linked by intercrystalline bridges, or of a continuous crystal containing disordered regions. In either case, the crystalline phase is essentially continuous in the crystallographic *c*-direction. The degree of continuity increases with EDR. This model is intermediate between a lamellar and an extended-chain structure (2).

The results of the electron-microscopy investigations of the oriented polyethylene suggest several consecutive stages of the deformation mechanism (2). At the first stage, lamellae move rigidly apart with the strain accommodated almost entirely by the interlamellae amorphous layer. At the second stage, the tie chains become highly extended and slip initiates in the crystalline lamellae. After this, strain-induced crystallization of the oriented amorphous fibers occurs. At the third stage, the blocks of crystal are pulled out of the lamellae; as block shear continues, the portion of lamellae that is below a critical size decrystallizes and contributes to strain softening. Finally, both the blocks form the crystal shear process and the strain-induced crystallization become aligned along the tensile axis.

The SSE process of semicrystalline polymers is highly influenced by their molecular weight. Extrusions of bulk crystallized polyethylene of high molecular weight proceed at slower rates and lower maximum EDR than lower molecular weight grades (2). The deformation resistance imposed by the higher degree of entanglement between molecular chains tends to inhibit high elongation.

Properties. The SSE of polymers results in the formation of a structural state possessing high anisotropy of properties, in particular, the strain–stress characteristics, thermal expansion, thermal conductivity, and gas permeability. This anisotropy is closely connected with orientation of chains and reconstruction of structure in crystalline and amorphous regions. For example, for semicrystalline thermoplastics, already at a comparatively low extrusion ratio, the chains in the crystalline phase turn out to be almost completely oriented in the direction of deformation. In the amorphous region, the chain organization is less perfect, but the degree of orientation continuously increases during the drawing. It depends on many factors: structure organization and molecular weight of the polymer, billet type, degree of drawing, and conditions of the extrusion process.

Semicrystalline Polymers. Extrusion of semicrystalline polymers, in particular polyolefins, essentially influences their mechanical properties. The SSE can increase ten-fold their tensile modulus, as compared to the starting material. Solid plugs of HDPE deformed to EDR = 40 have tensile modulus of about 70 GPa (1). For low density polyethylene (LDPE) the limit draw ratio is less than 9 (55), which can be the result of difficulties in generation of a metastable ductile monoclinic form. As a result, the tensile modulus reaches a value of less than 1 GPa (55). The maximum value of the tensile modulus of the extruded PP is 17 GPa (34). Increase in yield strength and tensile strength occurs simultaneously with the increase of tensile modulus (22,26,56). With EDR increasing, the elongation decreases.

For equal EDR values, the values of tensile modulus and tensile strength are, as a rule, the higher, the lower the extrusion temperature (1,55,57). For these magnitudes, the dependences on die angle have been determined. For HDPE, they are extreme with a maximum in the range $2\beta = 15$–30° (58).

At compression, the effect of extrusion draw on the strain–stress characteristics of samples is not so pronounced (22). As shown (22), for PP, the increase in the modulus of elasticity and yield strength occurs under compression in a direction normal to that of extrusion. In the case of a load applied along the extrudate axis, there is a decrease in the above characteristics, as compared to the initial material.

The mechanical properties of other semicrystalline polymers similarly depend on the conditions of deformation process (4,59,60). The thermal properties of semicrystalline polymers subjected to SSE have a highly pronounced anisotropy. Thus, the measurements of thermal conductivity of linear polyethylene done in a wide temperature range in directions parallel ($K^{\parallel}$) and normal ($K^{\perp}$) to the direction of extrusion, have shown that $K^{\parallel} > K^{\perp}$ (1,61). With EDR increase, the $K^{\parallel}/K^{\perp}$ ratio increases significantly.

Upon heating the extrudates there occurs a recovery of shape (dimensions) due to thermal shrinkage (1,56,62). The larger the EDR, the more stable the dimensions of the oriented samples in a wide temperature range. In superdrawn samples of linear polyethylene, a noticeable shrinkage occurs practically near the

melting temperature of the material (1). The beginning of the shrinkage process depends on the extrusion temperature: the lower the SSE temperature, the earlier begins the shrinkage. The value of the maximum shrinkage stresses increases with increasing EDR and decreasing extrusion temperature (62).

The extrusion of powder billets ensures a considerable improvement of some physical and mechanical characteristics (5). It is used in the case of materials for which the solid plug method is not efficient enough, eg UHMPE and PTFE (9,63). For PTFE, the maximum value of the so attained flexural modulus at 24°C is 20 GPa at an EDR 40 (64).

As compared to the SSE method, the SSCE makes it possible to realize considerably higher extrusion ratios with semicrystalline polymers. Coextrusion is widely used in a two-stage draw technique for drawing of powders (12,13,65) and single-crystal aggregates of polymers grown from dilute solutions (66). For example, a two-stage draw technique was successfully applied to the superdrawing of PTFE virgin powder (13). The films, compression-molded from powder below the melting temperature T_m, were initially coextruded with draws till EDR of 20. These extrudates were further drawn by a second-stage pin draw in the temperature range 300–370°C that covers the T_m. For this, a small portion of the extrudate, gripped at both ends, was rapidly heated by contacting it with the surface of a hot metal cylinder. Then, the extrudate was quickly elongated to the desired length. During elongation, the contacted area of the extrudate was continuously moved from one end to another end at a rate of ~1 m/min to heat and elongate a new sample portion successively. The maximum total draw ratio was 160. The maximum tensile modulus and strength achieved in this work were 102 and 1.4 GPa, respectively.

The aggregates of the solution-grown crystal mats of UHMPE and ultrahigh molecular polypropylene (UHMPP) are ductile to a draw ratio of 350 and 80, respectively. Tensile drawing and a combination of SSCE followed by tensile drawing give the highest and most efficient draw for mats of UHMPE and UHMPP. The tensile modulus of UHMPE of molecular weight $M_W = 8 \times 10^6$ for the limiting draw ratio reaches 230 GPa, and tensile strength—5.4 GPa. For UHMPP of $M_W = 8 \times 10^6$ these values are 36 and 2.5 GPa.

In article (15), films of atactic poly(acrylonitrile) were initially drawn uniaxially, by SSCE to EDR = 16, followed by tensile draw at different temperatures. For this polymer the highest tensile-modulus value was 28.5 GPa and strength—1.6GPa.

Amorphous Polymers. As compared to semicrystalline polymers, the SSE exerts a lower effect on tensile modulus and tensile strength of linear amorphous polymers. It has been shown (23) that the room-temperature hydrostatic extrusion of PMMA gives an increase in the above parameters only by dozens of percent. A similar result has been attained during the three-point bending tests of the extruded PC (23).

The hydrostatic extrusion under elevated temperatures, when higher EDR values are attained, results in a significant effect. In the case of SSE at a temperature of 120°C with the EDR = 6, the tensile modulus and strength of high impact polystyrene become twice as large and equal to 3.8 GPa and 57 MPa, respectively. In the extrudates, the plasticity characteristics (elongation at break, impact strength) are higher than in the initial samples and there is a more than a

twofold increase with the EDR and extrusion temperature (23). During the extrusion of a powder billet, eg polyarylate (40), there occurs a simultaneous increase in the strength and plasticity properties as well.

In article (67), where the peculiarities of SSCE of the atactic PS were studied, it is shown that the chain orientation and extension increase with EDR and molecular weight. For a sample of molecular weight 6×10^5 it was possible to achieve a maximum EDR of 27 by multiple draw steps. For the lowest molecular weight PS, the resulting films were brittle. The highest molecular weight sample, 1.8×10^6, on the other hand, was drawable only to a EDR of 7. The results suggest (2) that in the amorphous polymer, chain entanglements provide the necessary intermolecular network, which facilitates molecular extension and the concomitant orientation. For very high molecular weight, the high viscosity prevents relaxation of the elongated chain. For low molecular weight samples the entanglement network is vastly reduced, and the resulting extensive chain slippage leads to less efficient orientation and extension.

In the case of cross-linked polymers (eg epoxy polymers), the SSE induces the increase in microhardness, tensile modulus, yield stress, and strength (68). Moreover, depending on EDR value these parameters are changing because of the competition between the processes of orientational hardening and mechanical destruction. SSE influences the structure and properties of polymers based on interpenetrating polymer networks similarly (68).

Extrusion Based on Simple Shear

Equal Channel Angular Extrusion. In this technique (69), a billet is extruded through a die containing two channels, equal in cross section, intersecting at an angle Φ (Fig. 4**a**). During extrusion the billet undergoes severe shear deformation but retains the same cross-sectional geometry so that it is possible to repeat extrusion for a number of passes. Between two consequent passes it is possible to rotate the billet around its longitudinal axis, creating different equal channel angular extrusion (ECAE) routes (69). Another factor that significantly affects the microstructural development is the channel-intersection angle, which determines the shear strain Γ from an individual pass (69).

$$\Gamma = 2\cot\left(\frac{\Phi}{2}\right) \tag{3}$$

Smaller Φ will result in higher shear strain from each pass. Usually Φ is equal to 90°–120°

Already in one of the first articles dealing with ECAE application to modify linear LDPE (LLDPE) structure (18) it has been shown that this technique is efficient in orienting the lamellar structure of semicrystalline polymers. Upon four ECAE passes the string-like lamellar bundles in LLDPE are composed of many well-aligned crystal lamellae. The sheaf-like crystal lamellar bundles tend to orient approximately along the extrusion direction. Signs of fragmented crystal lamellae are also observed.

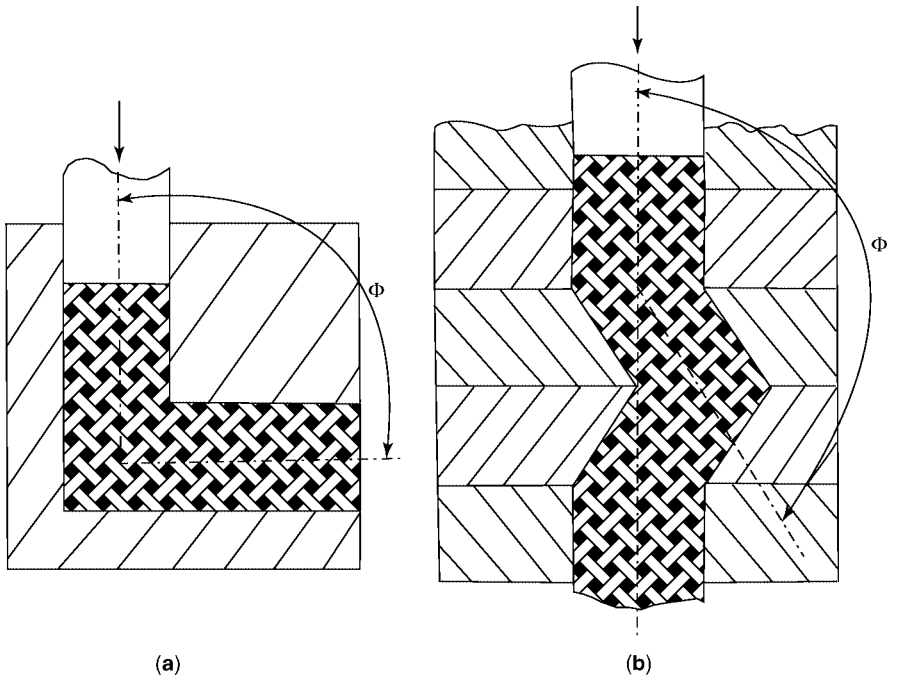

Fig. 4. Schematic representation of equal channel angular extrusion (**a**) and equal channel multiple by angular extrusion (**b**).

The large strain plastic deformation induced by ECAE, not only generates a high degree of molecular orientation but also gives better molecular packing. As a result, the polymer extrudates can exhibit improved rigidity, strength, barrier properties, and impact resistance (19). In particular, the samples of one-pass extruded PC cut along the extrusion direction have flexural modulus and critical stress-intensity factor K_{LC} values that are higher than those of the annealed PC by 15 and 40%, respectively.

The above technique has been developed into a method of equal channel multiple-angular extrusion (ECMAE) (70). It is based on forcing a polymer billet through several pairs of channels having equal cross section. The channels can intersect with each other at different angles and in different planes as well (Fig. 4**b**). A special feature of the ECMAE is that in an extrusion cycle with relatively low angles of the channel intersection (meaning that in each zone the deformation is low), the total deformation value per cycle is comparable with or exceeds the same for ECAE. At the same time, the implementation of any ECMAE scheme is accompanied by the change in shear direction including to the opposite one in a sequential zone.

ECMAE controls the deformation process more effectively and the expected result is attained quicker as compared to ECAE. The ECMAE equipment ensures the increase in manycycle extrusion output, a decrease in single deformation intensities for polymers of low plasticity, a possibility of providing a strict alternation of intensity values and shear directions for a guided structure forming. This has

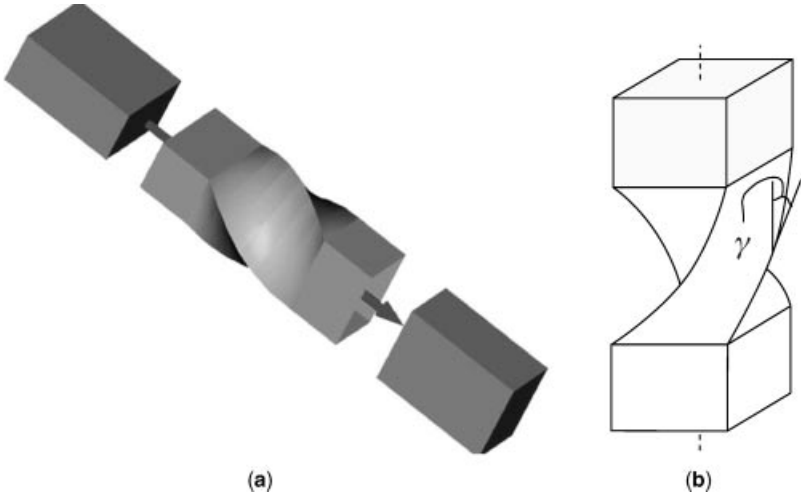

Fig. 5. Schematic presentation of the twist extrusion process (**a**) and of twist channel (**b**).

been confirmed by our experiments done on LDPE, HDPE, PTFE, nylon-6, and PC (71).

Twist Extrusion. In this technique, a billet is extruded through a die with a twist channel (Fig. 5) (72). The angle γ between the twist line and the direction of extrusion changes along the vertical axis of the die, furthermore, it is equal to zero on its starting and ending points.

The above properties of the channel geometry guarantee that the extrusion does not change the form of the workpiece, which allows to accumulate severe plastic deformations by iteratively extruding the workpiece through the die. Figure 5 shows a twist channel with a rectangular cross section. Generally, the cross section can be quite arbitrary, which allows one to use twist extrusion for obtaining not only semimanufactured article, but also prism-shaped end products. Note that by extruding on a mandrel, it is possible to get products with an inner channel.

The main factor that significantly affects the microstructural development is angle γ, which determines the shear strain Γ from an individual pass (72):

$$\Gamma = 2\tan\gamma \tag{4}$$

Another factor that significantly affects the microstructural development is the route of billet deformation consisting of a successive use of dies having the right-handed and left-handed screw channel.

The results of our WAXS investigations of LDPE and HDPE subjected to twist extrusion show that there are changes in the intensities of corresponding diffraction peaks reflection from planes (110) and (200), as compared to starting materials. The same changes have been found in the corresponding diffraction peaks of nylon-6. Several passes of twist extrusion result in the accumulation of plastic deformation in the samples affecting the level of their mechanical properties, microhardness, in particular. In the case of the LDPE, the increase in the number of cycles results in 1.5 times increase of microhardness.

Applications

Solid-state extrusion has various commercial applications. This method is used for the production of polyethylene ultrahigh-modulus fibers known under the trade name Tenflor (2). High-modulus ribbons and tapes produced from polyolefins by SSE are used as strappings and electrical insulation. In pipe production, the SSE makes it possible to manufacture biaxially oriented products possessing necessary properties in both the axial and tangential as well as radial directions (4). Owing to the suppression of cold flow (73), it is recommended to use fluoropolymer extrudates as efficient seals in structures operating in corrosive media. The thermal-shrinkage thermoplastics rods produced by SSE find their use as clamps in locking devices (74), as well as in various engineering structures (75).

SURFACE ANALYSIS

Introduction

The surface properties of polymers are important in many applications and they are dependent on the structure and composition of the outermost molecular layers. The surface layer thickness involved is typically of the order of a few nanometers. Understanding surface structure–property relationships therefore requires analytical techniques which have this degree of surface sensitivity (or specificity). Two techniques stand out: X-ray photoelectron spectroscopy (XPS) (1), also known as ESCA (electron spectroscopy for chemical analysis), and secondary ion mass spectrometry (SIMS) (2). The information provided by these methods is highly complementary and they are frequently used in combination. This article describes the physical bases and analytical capabilities of XPS and SIMS and illustrates their application in polymer surface characterization (3).

X-ray Photoelectron Spectroscopy

Physical Basis. In XPS, the sample inside a high vacuum system (pressure $<10^{-5}$ Pa or 10^{-7} torr) is irradiated with soft X rays, usually Mg Kα (1253.6 eV) or Al Kα (1486.6 eV). The primary event is photoemission of a core electron, but relaxation processes also lead to emission of Auger electrons or photons, as shown in Figure 1. The emitted electrons are collected by an electrostatic energy analyzer and detected as a function of kinetic energy E_K, producing a spectrum such as illustrated in Figure 2.

The intense, narrow peaks are due to photoelectrons emitted from core orbitals (eg C 1s). The binding energies of these electrons are given by the equation

$$E_B = h\nu - E_K - \phi \quad (1)$$

Encyclopedia of Polymer Science and Technology. Copyright John Wiley & Sons, Inc. All rights reserved.

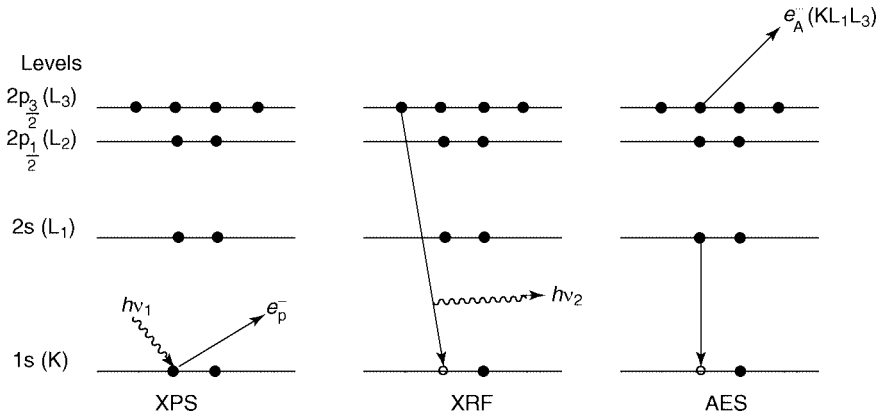

Fig. 1. Photoemission and subsequent relaxation processes (X-ray fluoresence and Auger electron emission) in XPS.

where $h\nu$ is the X-ray photon energy and ϕ is a catch-all term which includes the spectrometer work function. Core level binding energies are highly characteristic and allow the identification of all elements except H and He. The peak intensities are proportional to the number of atoms within the sampled volume and the

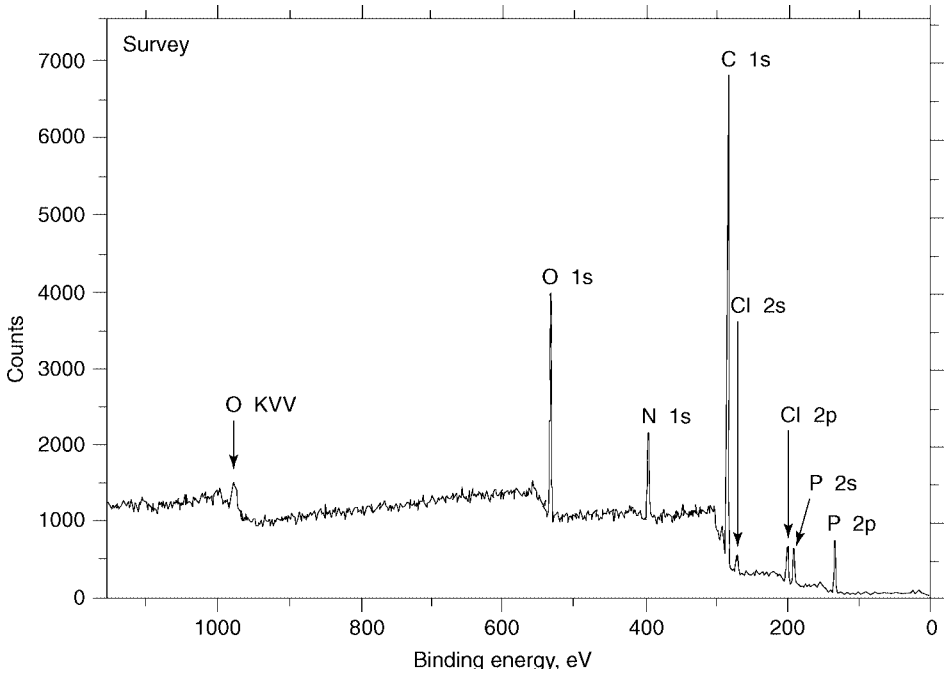

Fig. 2. XPS survey scan of poly(phenoxyphosphazene), containing C, O, N, and P, excited by monochromatic Al Kα radiation. Note the presence of Cl impurity from a synthesis intermediate. Reproduced from Ref. 6, by permission of Cambridge University Press.

surface composition can be calculated from

$$C_A = I_A S_A \Big/ \sum_n (I_n S_n) \tag{2}$$

where C_A is usually expressed as atomic% (of all elements determined, hydrogen excluded). The n elements give measured intensities (peak areas) of I_A–I_n and the peaks are associated with relative sensitivity factors S_A–S_n. When the photoemission cross sections (σ) for the most intense core levels of each atom are compared, it is found that the variation across the periodic table is about a factor of 100, if Li and Be are excluded. The cross section is the most important parameter influencing the relative sensitivity factor. Hence, XPS does not suffer unduly from inherent sensitivity effects and detection limits are 0.1 at% or better with modern instruments.

Close to zero binding energy (BE) an envelope of much lower intensity peaks, the valence band, is due to photoemission from the molecular orbitals.

The other broader peaks (appearing in series) are due to Auger electrons. The energy of an Auger electron is given approximately by

$$E_{ABC} = E_A - E_B - E_C^* - \phi \tag{3}$$

where E_A is the BE of the photoionized level A, E_B the BE of the level B from which an electron moves to fill the hole created, and $E_C{}^*$ the BE of the level C from which the Auger electron is emitted (the * indicates that level C is in the presence of a hole in level B, so $E_C{}^*$ is not the same as E_C, the ground state BE) (Fig. 1). These kinetic energy values are also element characteristic, although not all elements produce strong Auger signals under typical XPS conditions, and they are obviously independent of the exciting photon energy.

The exciting photons can penetrate many micrometers into a polymer, but the photoemitted electrons can only travel a short distance (a few nanometers) from their point of origin before they lose energy and, therefore, no longer satisfy equation 1. These inelastically scattered electrons give rise to the spectral background which increases in intensity with decreasing kinetic energy. To a first approximation, the inelastic mean free path (ie, the mean distance traveled by an electron between inelastic collisions), λ, is the parameter which determines the information (or sampling) depth of XPS. On the basis of the assumption that electron attenuation follows an exponential (Beer–Lambert) law, the vertical sampling depth below the surface from which 95% of the observed signal originates is given by

$$d = 3\lambda \sin\theta \tag{4}$$

where d and θ are defined in Figure 3. λ is a function of kinetic energy, according to a power law of the form $\lambda \propto E^x$ where, typically, $0.5 < x < 1$. Based on data appropriate for poly(methyl methacrylate), Table 1 provides a guide to sampling depths in polymer surface analysis. For flat surfaces the variation of sampling depth with θ (the "take-off" angle) provides a means of non-destructive depth profiling, as illustrated in Figure 4.

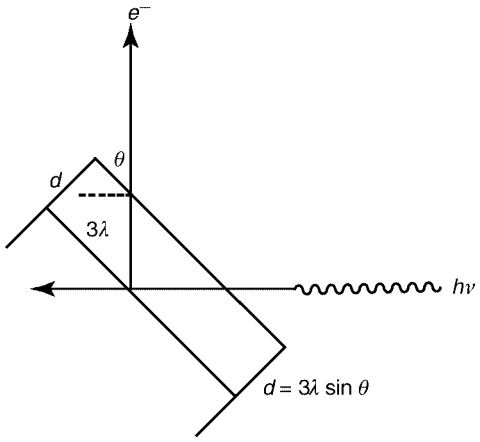

Fig. 3. Angular dependence of the (vertical) sampling depth in XPS.

Instrumental Aspects. The soft X-ray sources used in XPS are Mg K$\alpha_{1,2}$ and Al K$\alpha_{1,2}$ as noted above. These unresolved doublet lines have half-widths of 0.70 and 0.85 eV respectively, and so the Mg source is preferred on resolution grounds. However, Al Kα radiation can be monochromated by Bragg reflection from quartz crystals, reducing the half-width to <0.30 eV. Using bent crystals the beam can also be focused, which increases the flux density and compensates for intensity lost by monochromation. A further advantage of monochromation is that the high energy Bremsstralung radiation and lower intensity satellite lines are removed, resulting in a cleaner XPS spectrum.

Insulating samples, such as most polymers, tend to charge positively when irradiated with X rays because of electron emission. When a nonmonochromated source is used, a sufficient flux of low energy electrons is generated from various metal surfaces within the instrument to return to the sample surface and compensate such charging, leading to a stable surface potential which is usually just a few volts positive. This is not the case with monochromated sources and an external source of low energy electrons has to be supplied from a "flood gun."

Table 1. XPS Sampling Depths as a Function of Core Level Kinetic Energy and Take-Off Angle (Measured from the Surface Plane)

			Sampling depth (95% signal), nm					
	Kinetic energy, eV		Mg Kα			Al Kα		
Core level	Mg Kα	Al Kα	10°	45°	90°	10°	45°	90°
F 1s	568	801	0.8	3.4	4.8	1.1	4.5	6.3
O 1s	723	956	1	4.1	5.8	1.3	5.2	7.3
N 1s	852	1185	1.1	4.7	6.6	1.4	5.7	8
C 1s	967	1200	1.3	5.2	7.3	1.5	6.2	8.7
Si 2p	1152	1385	1.5	5.9	8.4	1.7	6.9	9.7

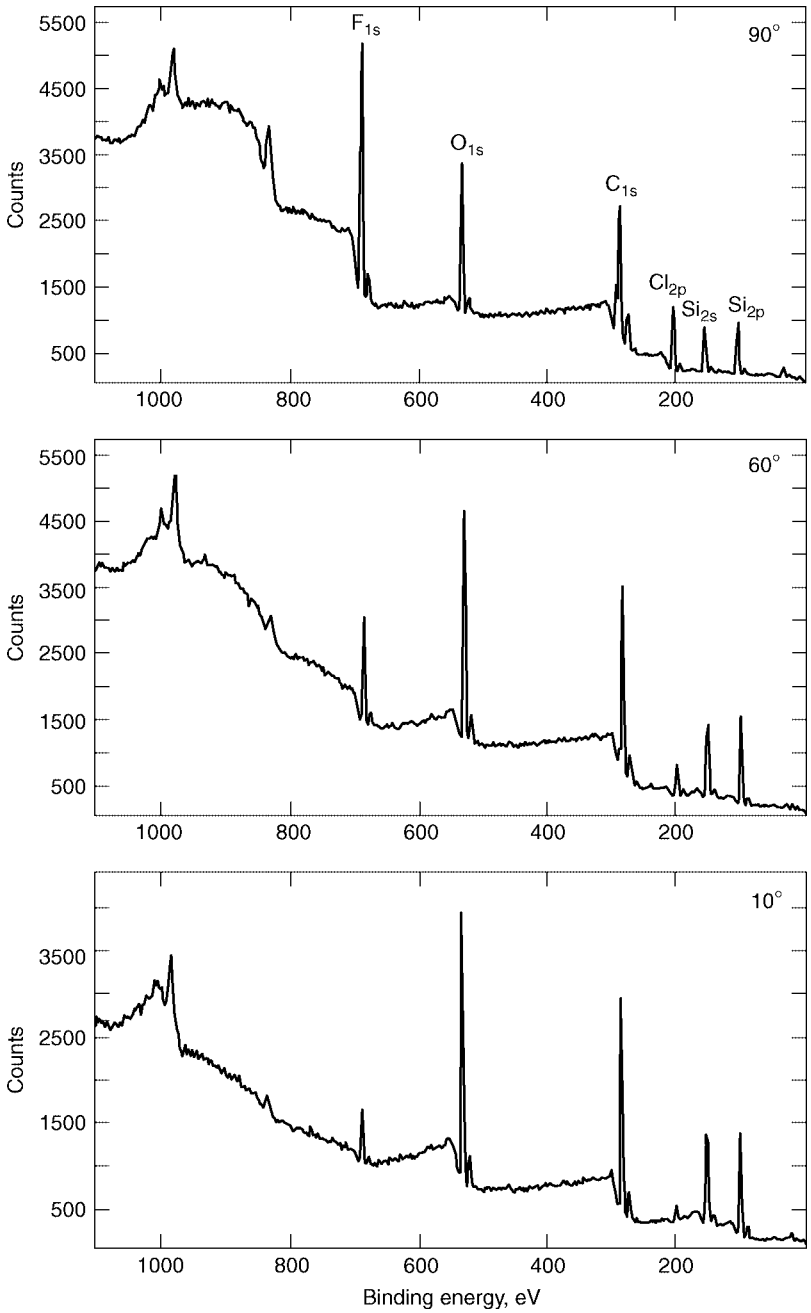

Fig. 4. Spectra from the surface of a molded plaque of poly(ethylenechlorotrifluoroethylene) contaminated with polydimethlysiloxane (silicone) taken at take-off angles of 90°, 60°, and 10° with respect to the surface. Note the rapid attenuation of the substrate signals (F 1s, Cl 2p) with increasing surface sensitivity (decreasing take-off angle). Reproduced from Ref. 3, by permission of Cambridge University Press.

There are no particular problems in handling polymeric materials in the vacuum required by the technique since any outgassing is usually slow, although high additive level rubber formulations are an exception. In such cases, cooling the sample during examination overcomes the problem. Radiation damage is also minor in most situations, and is further reduced when the X rays are monochromated, but it cannot be ignored. Two situations stand out: long acquisition times during multi-element imaging or high resolution studies of low intensity peaks; studies of thin films on high photoelectron cross-section substrates, including most metals (damage by electrons traveling through the film).

During the last 10 years there have been several approaches to providing high spatial resolution in XPS for imaging and local area analysis. One involves the production of a scanning X-ray microprobe, others achieve parallel imaging with broad area illumination and sophisticated electron optics (microscopy). In all cases the spatial resolution is inherently <10 μm, the actual resolution usually being limited by the counting statistics. For microscopy, the energy analyzer is used to preselect the energy (window) corresponding to a core level peak of interest and an image of intensity distribution from a chosen field of view acquired. A similar image is recorded at an appropriate background energy. The peak-background image is computed to realize the intensity distribution corresponding most closely to the chosen peak. Microanalysis simply involves recording spectra as normal from an area defined either by beam position and raster size (microprobe) or by apertures in the electron optics (microscope).

XPS Spectral Features and Information

Core Levels. Core level BEs are sufficiently unique to allow unambiguous element identification (see for instance the difference in BEs of the core levels in Table 1). However, all core level BEs are subject to relatively small variations, depending on the chemical environment, referred to as chemical shifts. The chemical shift range is usually <10 eV and, since peak half-widths are of the order of 1 eV, the dynamic range is low (compared to the somewhat related NMR case). An example is given in Figure 5.

The charge-potential model is a simple model that relates the core level BE to atomic charge:

$$E_i = E_i^0 - kq_i = eV_i \quad \text{where} \quad V_i = \sum q_i / r_{ij} \; (i \# j) \tag{5}$$

where E_i is the BE of the particular core level on atom i, $E_\mathrm{i}{}^0$ is a reference energy, k is a constant, q_i is the charge on atom i, and V_i sums the potential at atom i due to point charges on atoms j.

For two atoms (i) in different chemical environments, equation 5 gives

$$\Delta E_i = k\Delta q_i + e\Delta V_i \tag{6}$$

In molecular solids, atoms j are essentially the atoms bound to atom i and ΔV_i is relatively small; thus electronegativity effects will dominate Δq_i. An increase in positive charge is therefore accompanied by an increase in BE. The major

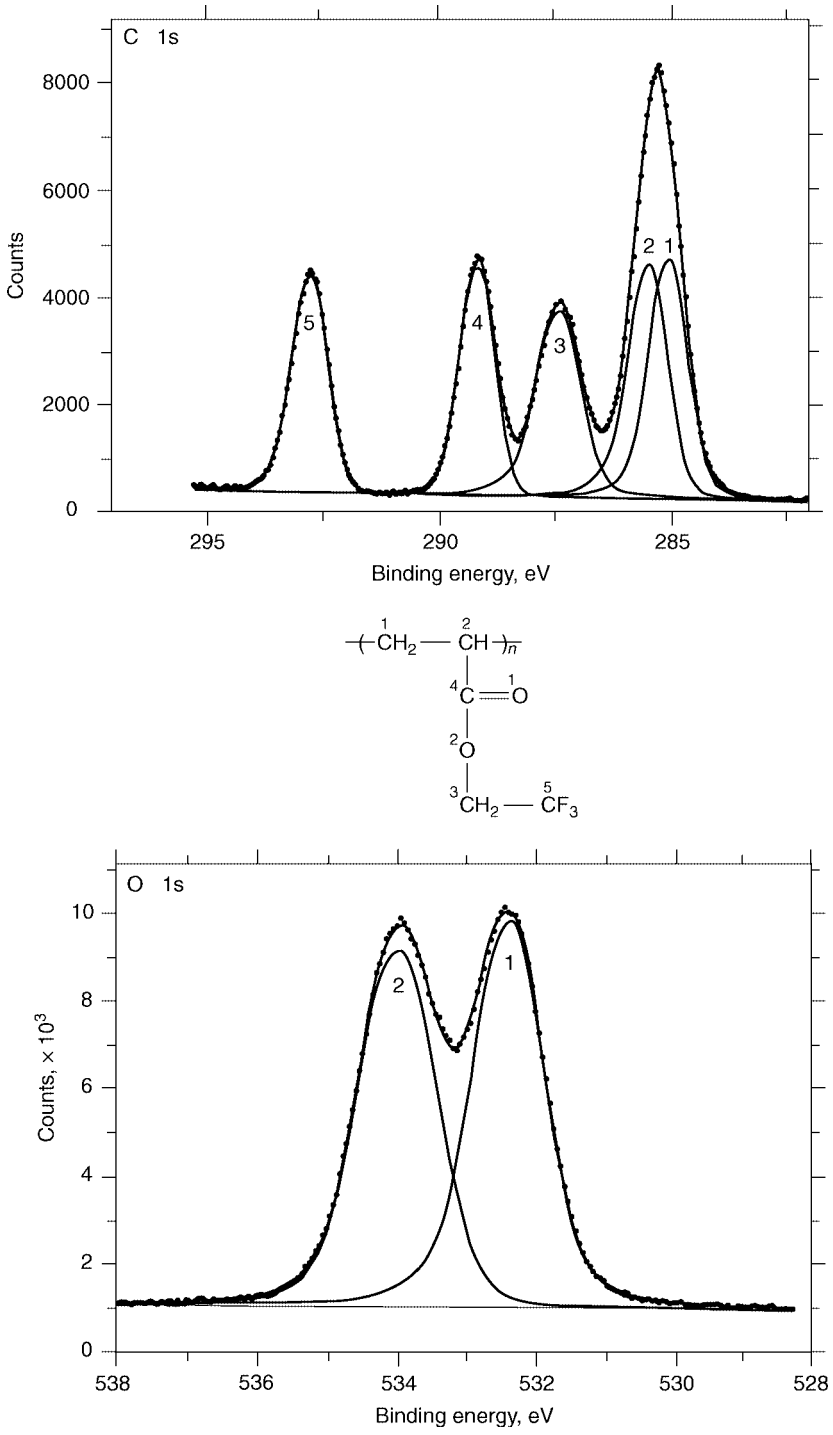

Fig. 5. High resolution C 1s and O 1s spectra from poly(trifluoroethylacrylate). Reproduced from Ref. 4, by permission of SurfaceSpectra.

simplification of equation 6 is that it ignores final state effects. The measured BE is actually the difference between the final and initial state energies, and so any chemical shift must involve consideration of both of these. The core hole of the final state has a polarizing effect on surrounding electrons, both interatomic (on atom i) and extraatomic (on atoms j). The electronic response is referred to as relaxation. Again, in molecular solids, relaxation energies are fairly constant, so initial state (particularly electronegativity) effects tend to dominate, as seen in Figure 5.

As this example illustrates, the low chemical shift dynamic range means that the components representing different functional groups overlap, sometimes severely. To accurately measure their BEs and relative intensities the components need to be resolved by curve-fitting, and this, in turn, demands some understanding of peak shape, which is variable. The underlying peak shape is a mixed Gaussian–Lorentzian (Voigt) function where the G–L ratio is determined by the experimental parameters. Additionally, when the energy resolution is very high, high BE asymmetry may be observed. This is particularly true of the C 1s peak which is affected by vibrational fine structure (due to the C—H stretch mode). A database of high energy resolution spectra of over 100 pure homopolymers (from which Figure 5 is taken) provides a great deal of information on this subject and collates data on chemical shifts for all the important core levels in polymer spectra (4,5).

As noted above, BEs from insulators are affected by surface charging. For equation 6 to be meaningful any two spectra need to be compared in the absence of this variable. This is done by referencing all measurements to a peak of known BE, usually the position of the C 1s component from aliphatic hydrocarbon (common to many polymers) assigned to 285 eV.

Shake-Up Satellites. Shake-up satellites may be observed on the low kinetic energy (high BE) side of intense core level peaks. They occur when valence electron reorganization (relaxation), following photoemission from a core level, results in the excitation of a valence electron to a higher unoccupied level. Conjugated and, especially, aromatic systems show shake-up satellites with intensities of 5–10% of the main peak, usually separated by $<$10 eV. Two transitions are important: from the two filled orbitals $b_{1\pi}$ and $a_{2\pi}$ to the unoccupied $b^*_{2\pi}$ orbital (ie $\pi \rightarrow \pi^*$). When the separation of these orbitals is small, the shake-up satellites can overlap the chemically shifted core level components, as illustrated in Figure 6. Atoms directly attached to unsaturated centers will also show shake-up satellites in their spectra (eg Cl in polychlorostyrene).

Valence Bands. Photoemission from the molecular orbitals gives rise to the valence band in the $\sim$0–20 eV BE region. Cross sections for these orbitals are typically a factor of 20–50 times lower than for the main core levels (eg C 1s). The valence band envelope is a sensitive function of polymer structure and so it can provide "fingerprint" information in situations where the core level spectra are inadequate. An example is given in Figure 7 for hydrocarbon polymers whose C 1s spectra are virtually identical, even at the highest energy resolution. Valence band spectra can be sensitive to the various types of isomerism, to geometrical conformation and tacticity, and even to degree of crystallization.

Functional Group Labeling (Derivatization). Core level chemical shifts are often ambiguous because of the small dynamic range (see Refs. 4 and 5). Particularly in the case of multifunctional surfaces, often the result of treatments carried

off to modify surface properties (eg adhesion), significant problems of functional group identification are encountered. A strategy for overcoming this problem is that of derivatization, whereby the surface is exposed to a agent which reacts specifically with one functional group and labels it with a distinctive element. An example is the reaction of surface alcohol (—OH) groups with trifluoroacetic anhydride to generate trifluoroacetate groups which can be quantified either from the

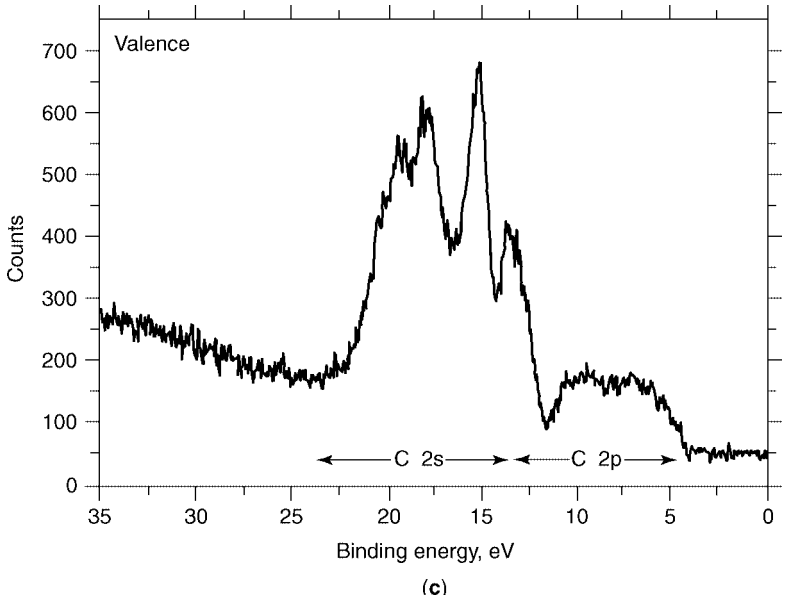

Fig. 7. (Continued)

F peak or the C 1s(CF_3) component. However, these reactions rarely proceed to completion within the XPS sampling depth and they can lead to surface reorganization, even when solvents are avoided. In recent times this approach has lost favor as the problems have become clear.

Secondary Ion Mass Spectrometry

Physical Basis. In SIMS, the sample in ultrahigh vacuum ($<10^{-7}$ Pa) is bombarded with energetic ions (typically 8–25 keV depending on the source, see below). These penetrate below the surface to a distance of several nanometers while transferring their energy to the material. In the immediate vicinity of the primary ion track, where the energy density is highest, many bonds are broken and atoms are set in motion. Secondary and higher generation collisions set up a collision cascade radiating from the impact point. Isomerization of the original translational energy also leads to electronic and vibrational excitation. As a result of the collision cascade, fragments of the material close to the surface can be desorbed (sputtered) into the vacuum. These fragments range in size from single atoms to large assemblies. Most of the sputtered material is neutral but about 1% is charged (positively or negatively). These secondary ions, the vast majority being singly charged, can be extracted into a mass spectrometer for mass analysis.

As with gas-phase organic mass spectrometry, SIMS spectra are information-rich and provide fingerprints. However, the processes leading to the spectra (both positive and negative ion spectra are utilized) are not well understood. The charged fragments can be formed directly in the collision cascade; or by ion/electron attachment, electron impact, and ion–molecule reactions in the selvedge (the affected region near the surface which may have some characteristics of a plasma); or

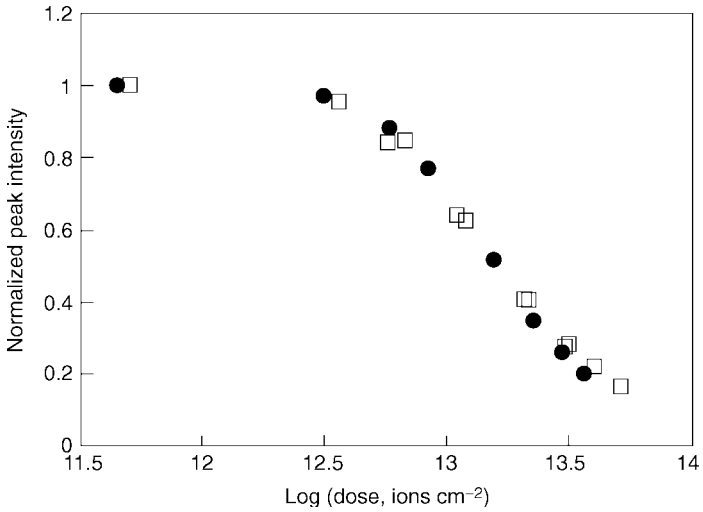

Fig. 8. Relative intensities of diagnostic fragments from PMMA ($+m/z$ 126 and $-m/z$ 185) as a function of primary ion dose (using 8 keV Cs^+). Individual spectra were acquired with a dose of $<5 \times 10^{11}$ ions cm^{-2}. ● m/z −185, □ m/z + 126. Reproduced from Ref. 6.

by unimolecular decomposition of fragments with high internal energies in the vacuum.

For the study of organic materials, in particular, it is essential to limit the primary ion dose, so that the spectrum is representative of undamaged material (the static SIMS regime). The aim is to ensure that no part of the surface receives more than one primary ion impact (affecting an area of order 10 nm in diameter) during the analysis. By measuring spectra as a function of primary ion dose it is possible to determine the "static SIMS limit," ie, the dose above which the spectra are dose-dependent (6). Figure 8 illustrates such data for poly(methyl methacrylate), a representative polymer (the origins of the chosen fragments are described under SIMS Polymer Spectra). Under the conditions used the static SIMS limit is a primary ion dose of about 3×10^{12} ions cm^{-2}.

There are very few studies which relate to the SIMS information depth for polymers, but the consensus view is that this is of the order of 1 nm. Atomic fragments may emerge from somewhat deeper below the surface but large molecular species arise only from the uppermost molecular layer or two.

Instrumental Aspects. The early developments of static SIMS (largely driven by polymer surface analysis requirements in terms of practical application) were carried out with noble gas ion sources and quadrupole mass analyzers (QMS). The latter had the benefits of compactness, ready availability, and relatively straightforward adaptability to SIMS use in UHV systems. Although all the essential features of polymer surface analysis were introduced using this technology, the QMS has major limitations for static SIMS. Firstly, it is a serial device, so that only one mass at a time can be detected. Secondly, it has a limited mass range (<1000 Da) and the transmission (ie, sensitivity) decreases with mass (by at least m^{-1}). Thirdly, it is only possible to achieve a uniform mass resolution

($m/\Delta m$) over this range of about unity. These limitations led to the introduction of energy-compensating time-of-flight (ToF) mass analyzers.

In ToF-SIMS the primary ion beam is pulsed, producing primary ion "packets" of about 1 ns duration. The secondary ions are accelerated over a short distance to typically 3 keV energy and injected into the ToF analyzer. In a linear ToF this is simply a field free tube in which the ions of different mass travel with different velocities and separate, to arrive at a detector sequentially. The flight time is related to the square root of the mass, so the "time spectrum" can be converted to a mass spectrum by suitable calibration. The mass analysis, which takes <200 μs, is carried out between primary ion pulses. The spectrum is therefore acquired in parallel and the ion dose is minimized. The secondary ions leave the surface with an energy distribution which, while only a few percent of the energy after acceleration, is enough to degrade the mass resolution. Different ToF designs compensate for this initial energy distribution in different ways, but modern instruments achieve $m/\Delta m$ of 10,000 or more. The mass range is theoretically infinite, but in practice the difficulty of registering the arrival of very large slow ions gives an upper limit of about 10 kDa. For most polymer surface studies an upper mass of 2 kDa is more than sufficient and over this range the transmission is independent of mass. Overall, the ToF approach has a 10^4 increase in sensitivity compared to a QMS.

The pulsed nature of ToF-SIMS provides a further benefit for the analysis of insulating materials. These charge up under positive ion bombardment and stabilizing the surface potential is essential, otherwise secondary ion detection is rapidly curtailed. In ToF-SIMS this is efficiently achieved by irradiating the sample with a broad flood of low energy (typically 20 eV) electrons between each primary ion pulse. This is especially important during high spatial resolution imaging (which is virtually impossible with a QMS because the ion beam current density is much higher and continuous). Because of all these advantages, ToF-SIMS is the preferred method for polymer surface analysis and during the last decade the QMS approach has been eclipsed.

A variety of ion sources are used in ToF-SIMS. Electron impact sources are used to produce Ar^+, Xe^+, and $SF_5{}^+$. Surface ionization sources produce Cs^+. Both of these types of source are used mainly for spectroscopy where spatial resolution is not important (although beam diameters of a few tens of micrometers are used). Liquid metal ion sources produce Ga^+, In^+, and, most recently, $Au^+/Au_2{}^+/Au_3{}^+$. These sources allow the production of highly focused beams with diameters down to 30 nm. There is an advantage to using high mass primary ions since the efficiency of production of large organic fragments (ie, the secondary ion yield divided by the primary ion dose) increases significantly with primary ion mass at any given ion energy.

An important aspect of imaging by ToF-SIMS is the ability to store (in memory) the whole spectrum for each pixel in the scanned array. This large data set, called a raw data file, can then be interrogated retrospectively. Two smaller data files are first created: one in which all the spectral intensity is summed for each pixel to generate a total intensity image and another in which the spectra from each pixel are summed to generate a total or average spectrum. The intensity variation in the total image is due to both topography effects (as in SEM) and major compositional differences. Regions of interest can be studied by selecting a

number of pixels and the spectrum from them recreated—retrospective microanalysis. From the total spectrum, peaks of interest can be selected (singly or collectively) and the intensity in all pixels displayed—retrospective chemical imaging or mapping. Thus two scans over the field of view to collect both positive and negative ion raw data files capture all the available information.

SIMS Spectral Features and Information

Modern, high mass resolution, ToF-SIMS instruments make detection of elements relatively easy. With the standard isotopic mass defined for $^{12}C = 12.0000$, all the elemental isotopes from ^{16}O (15.9949) upwards have masses slightly below the nominal unit mass. Organic fragments, being largely composed of carbon and hydrogen ($^{1}H = 1.0078$), have exact masses which are slightly above the nominal unit mass. Thus, for example, the single isotope of Mn^+ ($^{55}Mn = 54.9380$) would have a serious interference with a common hydrocarbon fragment, of the same nominal mass, $C_4H_7^+$ (exact mass = 55.0548). However, with a mass resolution of only 1500 (defined as $m/\Delta m$, where Δm is the full width at half maximum peak intensity) these two peaks are completely resolved. Modern instruments can usually deliver a mass resolution well above this figure, even for insulating samples which pose some problems because of surface texture or shape, and $m/\Delta m$ of >3000 would be expected. Hence the identification of elemental species is usually straightforward. Peaks due to metallic species are usually most intense in the positive ion spectrum with the alkali and alkaline earth-metals having particularly high positive ion yields. However, the expected pattern of intensities for multi-isotope metallic species can be distorted by the formation of hydrogen-attachment ions such that $^{n+1}Me^+$ overlaps $[^nMe + H]^+$ (these peaks are unlikely to be resolved). These points are illustrated in Figure 9. The major Zn isotopes are conveniently separated by two mass units so that the relative importance of the H-attachment ions can easily be observed.

Hydrogen is detected with high yield with both polarities but most other elements of interest for polymer surface analysis are detected in the negative ion spectrum. Carbon is detected as C^-, but the accompanying CH^- is always more intense. Similarly, oxygen is detected as O^- and OH^-. The relative intensity ratio OH^-/O^- is much more variable (structure-dependent) than CH^-/C^-. The halogens give very high negative ion yields. When present in high concentration and with the appropriate structural proximity they may be observed as addition fragments X_2^- and X_3^-. Nitrogen is not usually detected as an elemental peak at m/z 14 but rather as a combination ion, CN^- and additionally CNO^- if the structure is appropriate. Oxidized nitrogen functions produce NO_2^- and NO_3^-. Sulfur is detected as S^- (interfering O_2^- can usually be neglected) and SH^-. Oxidized sulfur appears as SO_x^- (x = 1–4) and SO_4H^-. Phosphorus is usually present in the oxidized state and detected as PO_2^- and PO_3^-.

SIMS Polymer Spectra

The interpretation of polymer spectra has been the subject of a significant body of literature and most of this has been summarized by Briggs (3). *The Static SIMS*

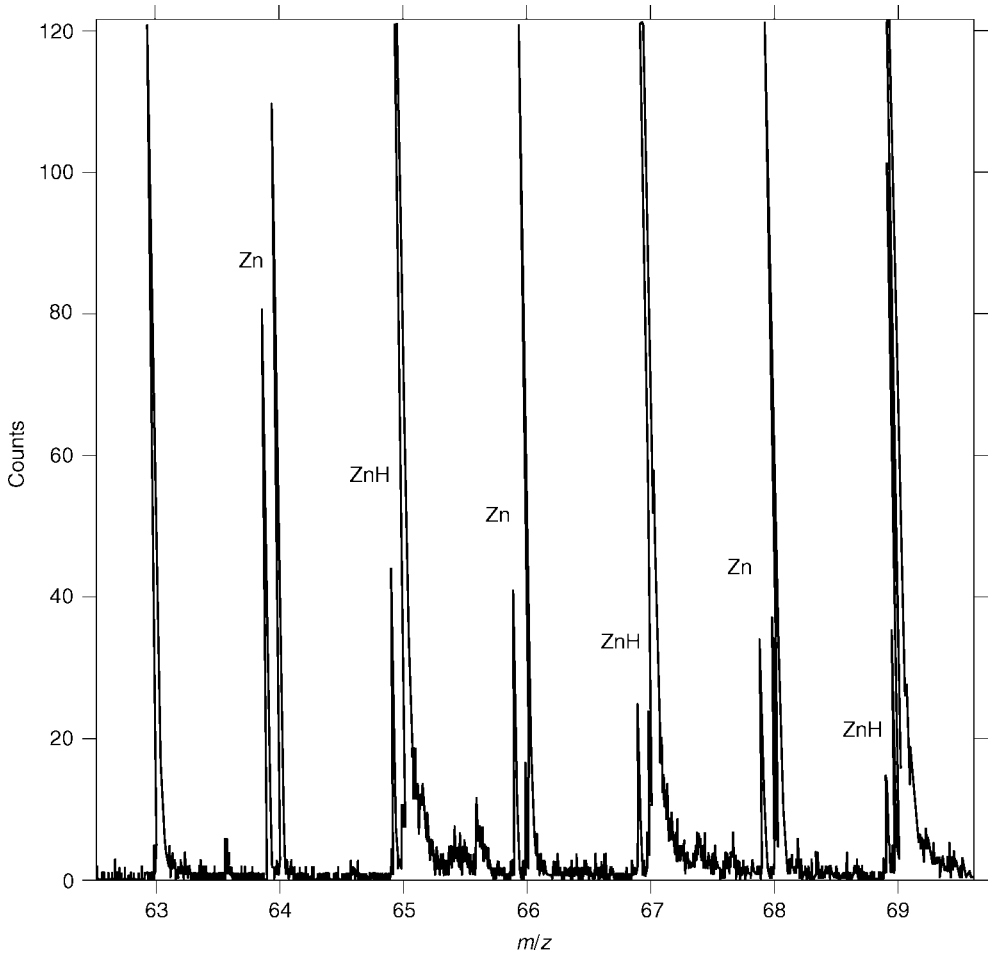

Fig. 9. Part of the positive ion ToF-SIMS spectrum from a polystyrene film sample. The most intense peaks (mostly expanded off scale) are $C_xH_y^+$ fragments from the polymer. The presence of zinc is revealed by the the mass resolved peaks at below unit mass representing the Zn^+ isotopes at nominal *m/z* 64 (47%), 66 (28%), and 68 (19%) together with an equivalent pattern for ZnH^+. Reproduced from Ref. 3, by permission of Cambridge University Press.

Library (7) contains ToF-SIMS spectra of some 200 reference polymers together with the structures of characteristic fragments. The following is, therefore, intended only to illustrate some general principles, which can be exemplified in detail using these two sources. Earlier original references, almost always involving unit-mass resolution quadrupole data, are given in Reference 3.

Hydrocarbon Polymers. Figure 10 shows the positive ion spectrum from high density polyethylene (HDPE), $(CH_2CH_2)_n$. Each cluster of peaks is due to $C_nH_m^+$ where $m = n,\ldots, 2n + 1$. For more complex aliphatic hydrocarbon polymers with pendant groups the smooth decrease in intensity of the clusters from C_2 is interrupted, and the relative intensities of the ions within each cluster

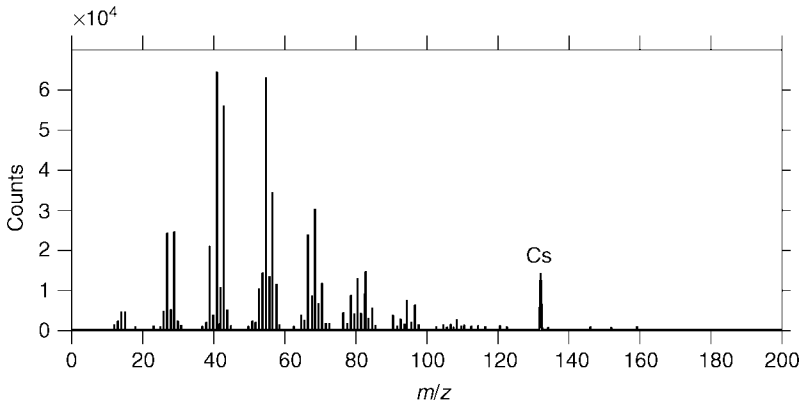

Fig. 10. Positive ion ToF-SIMS spectrum from HDPE. Reproduced from Ref. 2, by permission of SurfaceSpectra.

changes, as certain alkyl ions with methyl substituents are resonance-stabilized. Unsaturated aliphatic hydrocarbon polymer spectra are additionally characterized by a general weighting of intensity within each C_nH_m cluster toward lower values of m compared with saturated analogues.

The positive ion spectra of aromatic hydrocarbon polymers are exemplified by that of polystyrene in Figure 11. Compared to the aliphatic hydrocarbon spectra the $C_nH_m{}^+$clusters extend to much higher masses and have much lower m/n ratios as expected from the higher degree of unsaturation. Most of the prominent peaks are due to cyclic and polycyclic hydrocarbon ions, with the cyclic tropyllium ion $C_7H_7{}^+$ (m/z 91) being the most diagnostic. The negative ion spectra of all hydrocarbon polymers are very simple. C_1 and C_2 clusters dominate and above C_4 (aliphatic) or C_6 (aromatic) clusters the spectra are very weak. The $C^-/CH_2{}^-$ (m/z 12/14) intensity ratio is significantly higher for aromatic hydrocarbons compared with aliphatic hydrocarbons (saturated or unsaturated).

Aromatic Polymers. In addition to hydrocarbon polymers containing styrene, aromatic polymers comprise a large class of polymers. Attachment of heteroatoms to the phenyl ring, either in-chain or in a pendant group, leads to characteristic ions. Thus ring-substituted styrene polymers give substituted tropyllium ions, $C_7H_6X^+$ (eg X = OH, F, Cl, Br), and aromatic polyethers give $C_6H_5O^-$.

In-Chain Functionality. In the spectra of hydrocarbon polymers there is no obvious manifestation of the repeat unit chemistry. Introduction of in-chain functionality changes the situation. Figure 12 shows the positive ion spectrum of nylon-6 (polycaprolactam), $[(CH_2)_5CONH]_n$, where the amide function interrupts a hydrocarbon backbone. In addition to mainly hydrocarbon fragments at low mass, a prominent series of peaks appears due to multiple repeat unit fragments $[n\mathrm{M} + \mathrm{H}]^+$ where M is the repeat unit mass (113 amu). This behavior is much more typical of polymer spectra with multiple repeat unit fragments visible in either positive or negative ion spectra, or both, depending on the specific chemistry and opportunity for large stable fragment ion formation. [The relative intensity of these high mass ions is somewhat unusual in this case but they can be dramatically enhanced by the use of a polyatomic primary ion, such as $SF_5{}^+$.]

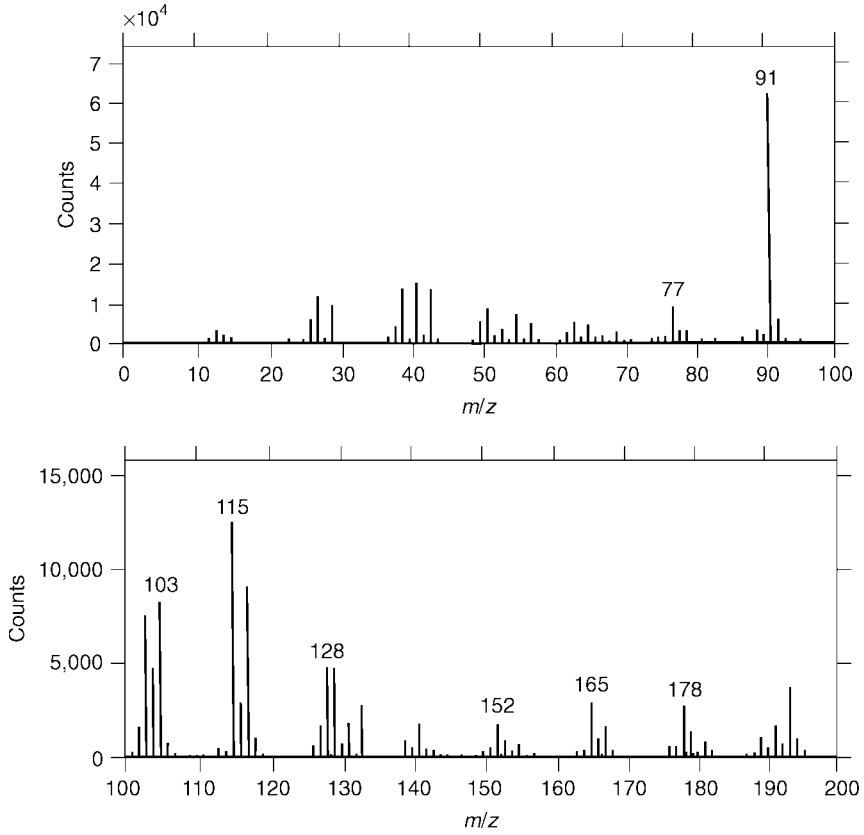

Fig. 11. Positive ion TOF-SIMS spectrum from polystyrene in the mass range m/z = 0–200. Reproduced from Ref. 3, by permission of Cambridge University Press.

Main-chain oxygen functionalized polymers also behave in this way. Thus, linear polyethers give series such as $[n\mathrm{M} + \mathrm{H}]^+$and $[n\mathrm{M} + \mathrm{OH}]^-$. In-chain polyesters either of the poly(lactone), $(\mathrm{R{-}COO})_n$, or the poly(diacid-diol), $(\mathrm{R_1COOR_2COO})_n$, types give series such as $[n\mathrm{M} + \mathrm{H}]^+$ and $[n\mathrm{M}{-}\mathrm{OH}]^-$, with probable $\mathrm{R{-}C{\equiv}O^+}$ structures, and $[n\mathrm{M} + \mathrm{H}]^-$ and $[n\mathrm{M} + \mathrm{OH}]^-$, with probable $\mathrm{R{-}COO^-}$ structures. Of course, there are many other ions formed by fragmentation at other points in the chain.

Side-Chain Functionality. Several classes of polymers consist of a hydrocarbon backbone with an oxygen-containing side chain. Collectively, they can be grouped into vinyl and acrylic polymers. Vinyl polymers have the general structure $(\mathrm{CH_2CHX})_n$. In poly(vinyl ethers) X = —OR, in poly(vinyl ketones) X = —C(=O)R, and in poly(vinyl carboxylates) X = —OC(=O)R. These polymers give positive ion spectra with hydrocarbon contributions from the backbone and from the side chain R group if this has a significant number of carbon atoms (especially if linear). Repeat unit ions are observed for the ethers but the dominant ions for the other polymers tend to be side-chain fragments, especially $\mathrm{R{-}C{\equiv}O^+}$. In the negative

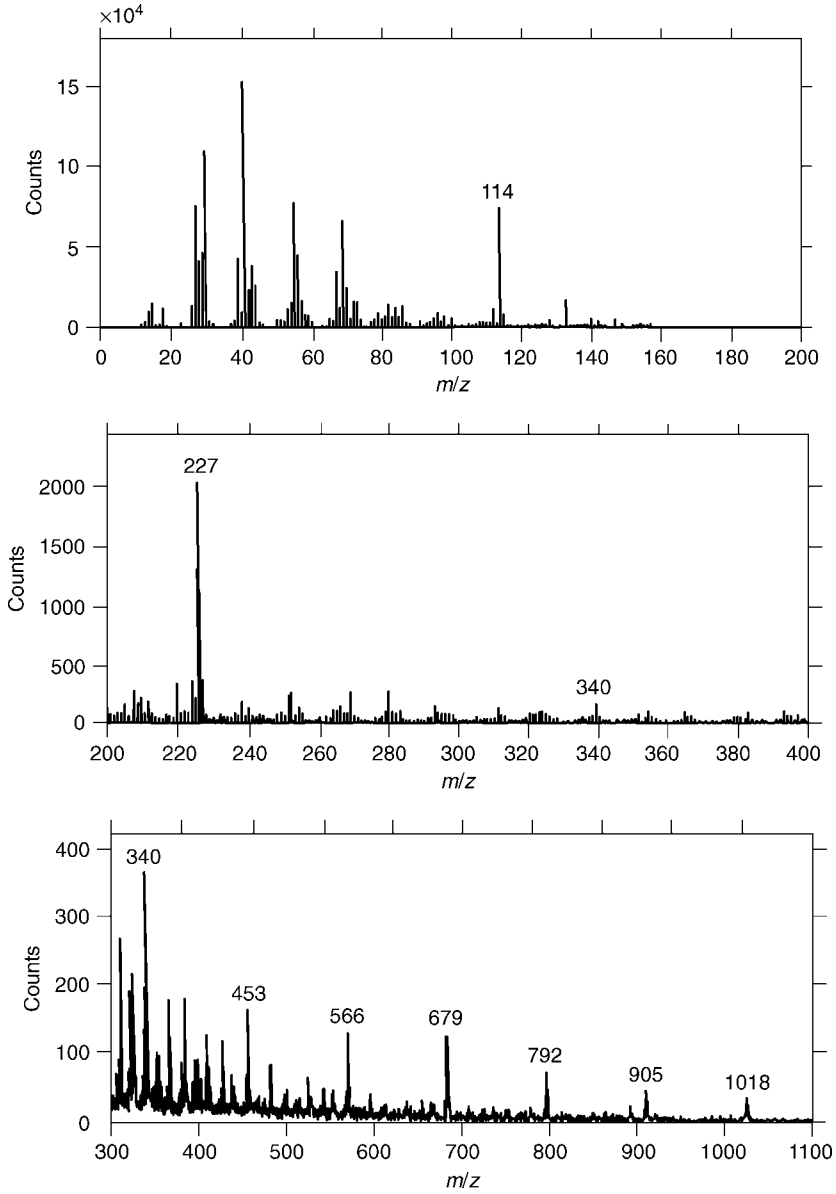

Fig. 12. Positive ion TOF-SIMS spectrum from nylon-6 (polycaprolactam). Highlighted peaks represent multiple repeat unit fragments $[n\mathrm{M}+\mathrm{H}]^+$ from $n = 1$ (m/z 114) to $n = 9$ (m/z 1018). Reproduced from Ref. 3, by permission of Cambridge University Press.

ion spectra, repeat unit ions are seen for the ketones, RO^- dominates in the case of the ethers, and RCOO^- dominates in the case of carboxylates.

Acrylic polymers are based on esters of acrylic acid and methacrylic acid and copolymers are very common. Figure 13 shows the positive ion spectrum of poly(methyl methacrylate) (PMMA). Compared with the other oxygen-containing side-chain polymers discussed above, the spectrum appears to be influenced to a

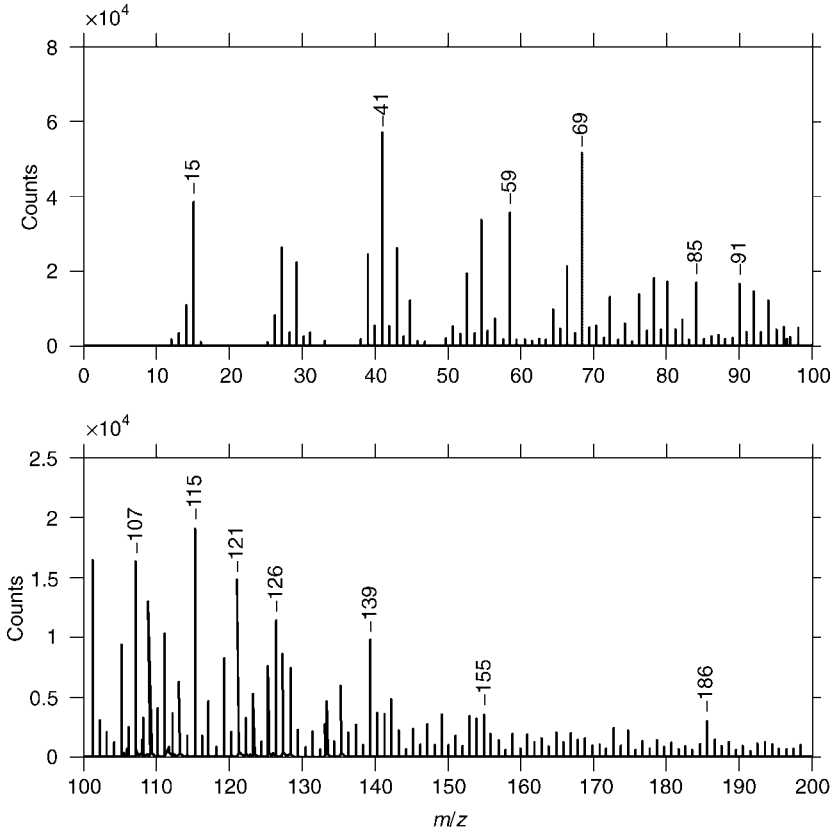

Fig. 13. Positive ion TOF-SIMS spectrum from poly(methyl methacrylate) (PMMA) in the mass range $m/z = 0$–200. Reproduced from Ref. 6.

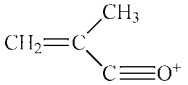
greater extent by hydrocarbon fragments from the backbone. However, at high mass resolution, most peaks are seen to be multicomponent, often with a hydrocarbon component, but frequently due only to oxygen-containing fragments—some examples are illustrated in Figure 14. Interesting repeat unit fragments are even-mass radical cations (eg m/z 126, 154, 196, 200); these appear as essentially single-component peaks as illustrated by m/z 126 in Figure 14. With higher methacrylates (R larger than CH_3) the positive ion spectrum becomes more hydrocarbon-like. The common diagnostic ion is the methacryloyl ion at m/z 69:



The negative ion spectrum of PMMA is shown in Figure 15. With the absence of "hydrocarbon noise" this is a much simpler spectrum and the pattern of peaks clearly reflects the repeat unit mass of 100 amu. Negative ion peaks characteristic of all methacrylates, because the side-chain alkyl group (R) has been lost, are at m/z 85, 109, 125, and 139. Specific ions having one or more intact side chains have the generic formulae: $[M+55]^-$, $[2M\text{-}15]^-$, $[2M+41]^-$, $[2M+55]^-$, and $[3M\text{-}15]^-$,

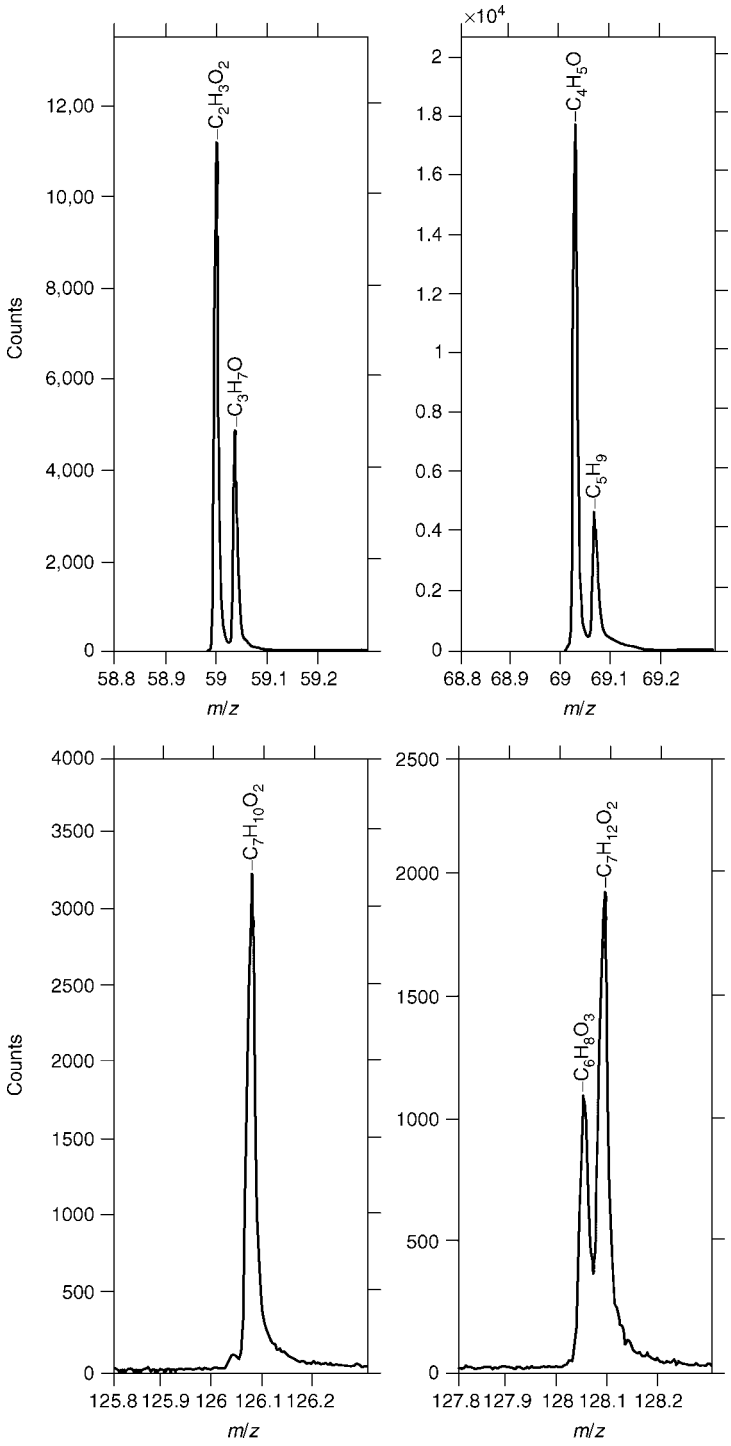


Fig. 14. High mass resolution details of some of the peaks in Figure 13. Reproduced from Ref. 6.

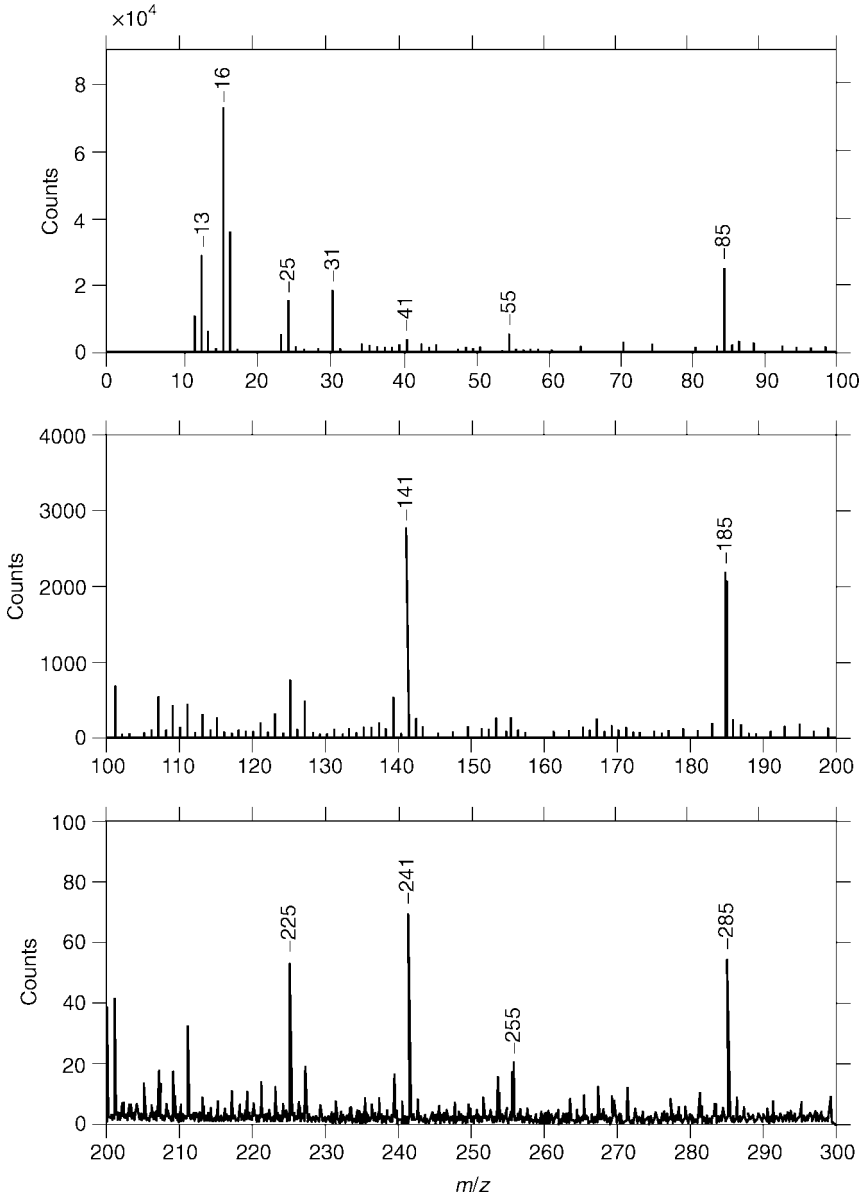

Fig. 15. Negative ion TOF-SIMS spectrum from poly(methyl methacrylate) (PMMA) in the mass range $m/z = 0$–300. Reproduced from Ref. 6.

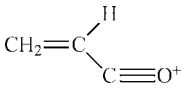
where M is the monomer mass. In the PMMA spectrum these are at m/z 155, 185, 241, 255, and 285.

Acrylate homopolymers behave similarly, except that the repeat unit ions are much less stable. The characteristic common positive fragment is the acryloyl ion at m/z 55:

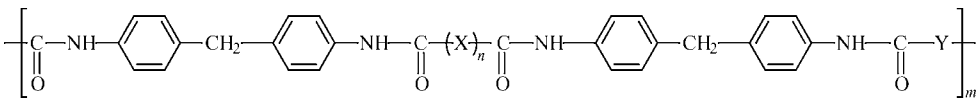


Common negative ions appear at *m/z* 65, 67, 71, and 81, while specific ions are $[M\text{-}H]^-$, $[M+13]^-$, $[M+27]^-$, $[M+39]^-$, and $[M+53]^-$.

The spectra of random acrylic copolymers display the monomer-specific features of the components together with fragment ions which reflect the linking of the different monomers in the chain. These are the equivalent of the multiple repeat unit ions from a homopolymer, but now the monomers need not be the same. In all cases the negative ion spectra are the most informative. Thus, for example, the $[2M\text{-}15]^-$ ion from a methacrylate homopolymer could appear as $[2M_1\text{-}15]^-$, $[2M_2\text{-}15]^-$, or $[M_1M_2\text{-}15]^-$, where M_1 and M_2 are the two monomers in a random copolymer.

Nitrogen-Containing Polymers. The polyamide nylon-6 has been discussed above. Other polylactams behave similarly and display a characteristic pair of peaks at $[2M+H]^+$ and $[2M\text{-}OH]^+$. Diacid–diamine polyamides, $(R_1CONHR_2)_n$, show some similarity to in-chain polyesters having dominant fragments of the type $R{-}C{\equiv}O^+$. However, since there is no equivalent of the $RCOO^-$ ion from nylons, the negative ion spectra are usually lacking in high mass molecular fragments. The characteristic peaks are simply CN^- and CNO^-. Nitrogen content is generally obvious from the positive ion spectra through the higher than normal incidence of even mass peaks (due to fragments with one, or an odd number of, N atoms).

Another important class is the polyurethanes. A common structure is:



where a polyether $(X)_n$ is reacted with a diisocyanate (in this case MDI) and chain-extended with either a diamine or a diol (Y). The positive ion spectrum is principally a superposition of the polyether spectrum (discussed above) and fragments of the diisocyanate. In the case of 4,4′-methylenebis(phenylene isocyanate) (MDI), characteristic peaks are at *m/z* 106, 132, 180, and 233. The polyether can be replaced by a polyester in which case its spectrum will be a significant component of the polyurethane spectrum.

Halogen-Containing Polymers. These polymers are characterized by intense negative ions from the halogen. Aliphatic chlorine-containing polymers such as poly(vinyl chloride), $(CH_2CHCl)_n$, give positive ion spectra which at first sight resemble hydrocarbon spectra. However, at high mass resolution many peaks are seen to have additional components containing one or two Cl atoms.

Highly fluorinated polymers give an intense CF_3^+ peak at *m/z* 69, even if this group is not present in the molecule. Poly(tetrafluoroethylene), $(CF_2CF_2)_n$, gives generic fragments $C_xF_y^{+/-}$ and poly(vinylidene fluoride), $(CH_2CF_2)_n$, gives generic fragments $C_xF_yH_z^{+/-}$. An important class of lubricants are the perfluoropolyethers. These are homo- or copolymers involving the units (CF_2O), (CF_2CF_2O), and $(CF_2CF(CF_3)O)$. Complex repeat unit sequences are seen in both polarity spectra with characteristic low mass ions being CFO^+ (*m/z* 47) and CF_3O^- (*m/z* 85). Low molecular weight materials with the same repeat units are often differentiated by their end groups which give diagnostic peaks.

Silicones. Silicone rubbers and oils are usually based on polydimethylsiloxane, $(Si(CH_3)_2O)_n$. They all give spectra readily identified through the positive ions at *m/z* 28, 47, 147, 107, 221, and 281. The relative intensities of these peaks vary as a function of molecular weight, end groups, and cross-link density in the rubbers.

Organic Molecules on Surfaces

Probably the most important aspect of ToF-SIMS analysis involves the use of the technique to understand the variation in surface properties, such as wettability, adhesion, and friction, which are sensitive to submonolayer coverage of molecular species. ToF-SIMS is unique in its sensitivity and molecular speciation capability. However, unlike the situation with gas-phase organic molecule identification by electron impact mass spectrometry, there are, as yet, no well-established "rules" which allow molecular identification directly from the spectra. The situation is also complicated, in most cases, by the superposition of the spectrum of the substrate and the potential presence of more than one organic molecule.

Organic molecules usually give quasi-molecular ions of the type $[M+H]^+$ and $[M\text{-}H]^-$, where M is the molecular weight, in addition to characteristic fragments. In the case of polymer substrates, the intensity from the substrate spectrum is, typically, only high in the region *m/z* 0–200. Quasi-molecular ions are usually of higher mass, and even though their absolute intensity may be rather low, they are easily observed relative to the contribution from the substrate. An example is given in Figure 16, which shows the positive ion spectrum from the surface of pretreated (electrochemically oxidized) polypropylene. Below *m/z* 120 the spectrum is essentially due to hydrocarbon polymer fragments (compare with Fig. 10). Higher mass peaks are due to contamination and segregated additive molecules. The phosphite antioxidant Irgafos 168 gives rise to the distinctive set of peaks around *m/z* 650. Although $[M+H]^+$ for the phosphite is expected at *m/z* 647 (7), it is believed that the spectrum is mainly due to the oxidized, phosphate, product (the molecule is present to decompose hydroperoxides) which would give $[M+O+H]^+$ at *m/z* 663.

Pattern recognition is the key to organic molecule identification. Common "surface contamination" molecules fall into a relatively small number of chemical families, depending on their function, eg surfactants, lubricants, and the various types of polymer additives (plasticizers, antioxidants, etc). Thus, many surfactants are based on quaternary ammonium salts, many plasticizers are dialky phthalates, most antioxidants are di-*t*-butyl phenol derivatives, etc. The result is that each family member is likely to give a spectrum with some common fragment ions while having unique molecular ions. Alternatively, the whole spectrum may conform to a particular pattern but with components "shifted" by fixed mass intervals, eg, fatty acids which have a common hydrocarbon series in the positive ion spectrum plus molecular ions/fragments which increase in mass by 14 amu (CH_2) as the homologous series is ascended. The easiest way to recognize these patterns is to study the collections of relevant spectra, collated by function, in *The Static SIMS Library* (7).

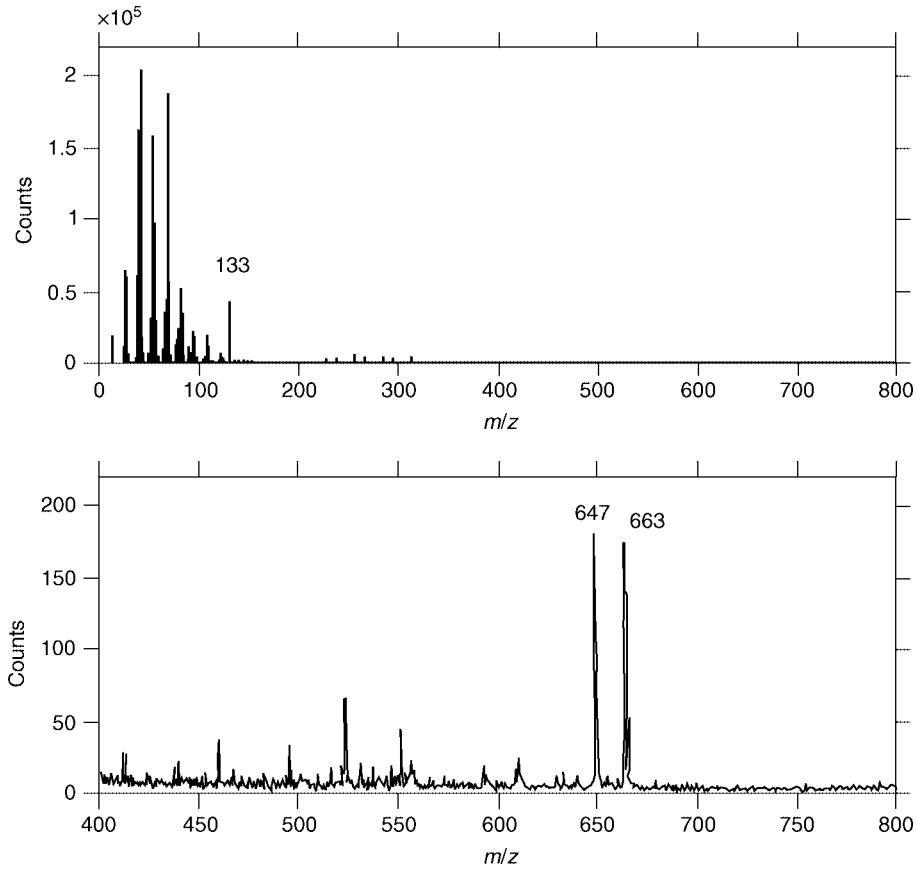


Fig. 16. Positive ion ToF-SIMS spectrum from the surface of pretreated (electrochemically oxidized) polypropylene, illustrating the typical signal noise of polymer fragments at low mass and additive molecular ions at high mass (see text). The peak at *m/z* 133 is due to primary Cs^+ ions. Reproduced from Ref. 2, by permission of SurfaceSpectra.

A number of cautionary points need to be made about pattern recognition. Firstly, some molecules are prone to cationization, that is the quasi-molecular ion may be $[M+Me]^+$ rather than, or in addition to, $[M+H]^+$, where Me is an alkali-metal ion. Sodium cationization is the most commonly encountered. Molecules containing ethylene oxide units (common amongst surfactants) are readily Na-cationized as are phthalate esters (plasticizers).

Secondly, molecules containing fatty acid residues are unlikely to be present as single components. This is because the starting materials, of natural origin, are mixtures which are not fully separated. For instance, stearates are frequently a mixture of stearate and palmitate derivatives (illustrated in Fig. 17), and saturated derivatives with C_nH_m chains may be accompanied by the unsaturated (C_nH_{m-2}) analogue.

Thirdly, the spectrum of a molecule present in a monolayer (or less) may differ from that of the molecule in multilayers. Cationization potential is one aspect of this "matrix effect". In a multilayer situation involving an *intimate* mixture of

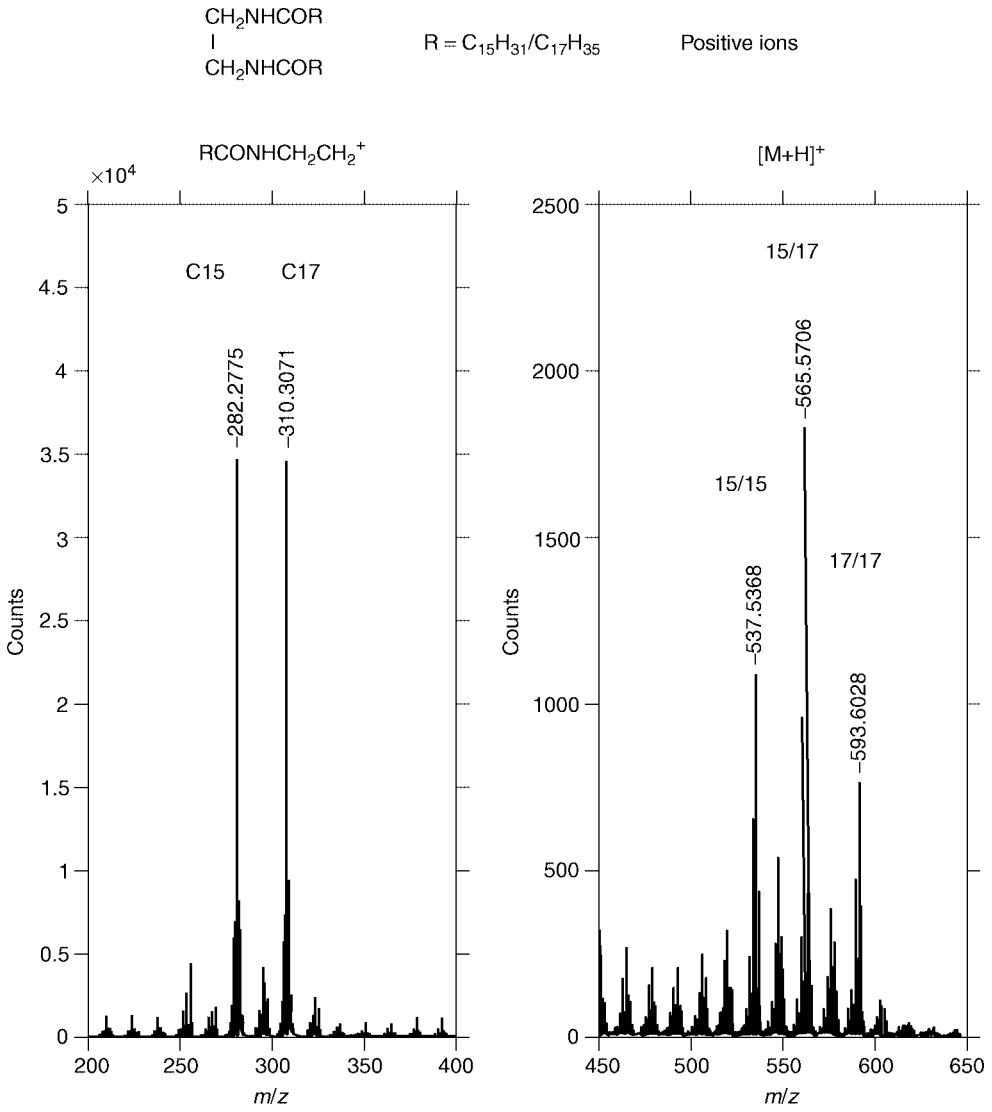

Fig. 17. Parts of the positive ion ToF-SIMS spectrum of ethylene bis-stearamide. In fact the material is a mixture of three molecules in which $C_{17}H_{35}$ and $C_{15}H_{31}$ groups are approximately equally distributed, as shown by the $RCONHCH_2CH_2^+$ fragments at *m/z* 282 and 310 (composition confirmed from accurate mass measurement). The molecular ion region accordingly has an approximately 1:2:1 triplet of peaks. [Similarly in the negative ion spectrum the $RCONH^-$ fragments give a 1:1 doublet and the $[M\text{-}H]^-$ parent ions form a 1:2:1 triplet.] Reproduced from Ref. 2, by permission of SurfaceSpectra.

two molecules, the spectra of either component may be different from that of the isolated component. This is particularly the case when one molecule is a rich source of H^+, such that the second molecule can give rise to $[M+H]^+$ ions even though it may not do so (or only weakly) when isolated.

Quantitative Aspects of SIMS

Unlike XPS, SIMS is an inherently nonquantitative technique—ie, there is no direct relationship between a peak intensity and the concentration of the species it represents. This is because secondary ion yields are strongly dependent on the chemical environment (or matrix), examples of which were noted in the previous section. Matrix effects in SIMS are most notable for yields of elemental species from inorganic matrices, but the situation is less severe for polymer matrices. Thus, relative intensities such as O^-/CH^- or F^-/CH^- correlate with XPS atomic ratios (O/C, F/C) when trends in composition are restricted to similar materials.

There have been many quantitative studies of copolymers, in which the intensities of fragments representing monomers or larger units have been correlated with composition. An early example, shown in Figure 18, concerns random hydroxyethylmethacrylate/ethylmethacrylate (HEMA/EMA) copolymers and the use of characteristic negative ions (8). Fragments at *m/z* 127 and 155 are essentially representative of HEMA and EMA monomers respectively and relative intensity plots of the form A/A+B give smooth trends (upper curves). The intensities of fragments at *m/z* 141 and 185, believed to represent HEMA–EMA linked monomers (middle curves), maximize in midrange as expected. The intensity of the fragment at *m/z* 213, representing EMA-EMA links, increases rapidly with EMA content (lower curve), also as expected. The ratio I(213)/I(155) represents the ratio of diads to singles. For a random copolymer where diad (AA) signals come from sequences B-$(A)_n$-B where $n > 2$, a statistical analysis predicts that the ratio of diads to singles (isolated A units) will be proportional to the mole fraction of A, as seen in the lower plot. The choice of fragments for such plots is not always so obvious and in many cases better results are obtained by using multivariate statistical analysis techniques which utilize the whole spectrum. This subject is discussed thoroughly in Reference 9.

The end groups of a polymer can have a marked effect on the SIMS spectra (3,10). If these are chemically distinct from the rest of the chain, because of the use of specific initiation or termination reactions, they will give rise to readily identifiable peaks. However, in all cases end groups can have a disproportionate effect on spectra because only one bond needs to be broken to produce a fragment whereas two bonds need to be broken to generate an in-chain fragment. Ratios of fragments due to end groups and in-chain fragments in homopolymer spectra depend on molecular weight, typically up to 20,000–30,000. This provides a unique method for monitoring surface average molecular weight, which can be particularly important in this range. Low molecular weight fractions of the distribution may migrate to the surface and significantly alter mechanical properties relative to the bulk polymer as well as leading to adverse surface behavior.

Application Examples

Surface Oligomer Detection and Imaging. The case of cyclic trimer (three monomers in a ring formation) on the surface of poly(ethylene terephthalate) (PET) film is interesting. The crystallization of cyclic trimer on PET surfaces

Fig. 19. (Contiuned)

heated to temperatures above 120°C or exposed to certain solvent vapors is well established and can be the source of problems in the wide use of this polymer in film and fiber products. The crystals were first characterized *in situ* (ie, without resort to solvent extraction from the surface) using quadrupole static SIMS (11). While the pure polymer spectrum exhibits only a weak positive ion at *m/z* 577, representing $[3M+H]^+$where M is the repeat unit mass (192 amu), this peak is around 20 times more intense (relative to the base peak at *m/z* 104) from the pure trimer crystals because it represents the molecular ion. An uncertainty remaining from the quadrupole static SIMS study was whether all the trimer on the surface was contained in the crystals, or whether amorphous trimer might also be present on the film surface between the crystals. A later ToF-SIMS imaging study was able to clarify this point (12).

Figure 19**a** shows a total positive ion image of a PET film surface after heating at 170°C for 48 h. The essentially hexagonal crystals cover a wide size range

of order 1–50 μm. From a raw data stream file containing the full spectrum at each pixel in the 256 $\times$ 256 array, it is possible to retrospectively analyze regions of the surface which are covered by the crystals and regions which appear to be bare film. This leads to the spectra shown in Figure 19**b**. The *m/z* 577/104 ratio in the intercrystalline regions is identical, within experimental error, to that of the original film surface which strongly suggests that all the trimer on the surface is crystalline. The crystals themselves are easily mapped using the *m/z* 577 trimer molecular ion (reconstructed from the raw data file) as shown in Figure 19**c**. Compared with the total ion image, which is dominated by topographic contrast, this image has higher contrast because of its chemical specificity. The study similarly confirmed that the crystals on solvent-exposed films, which have a needle-like habit quite different from those produced by heat treatment, are also due to cyclic trimer.

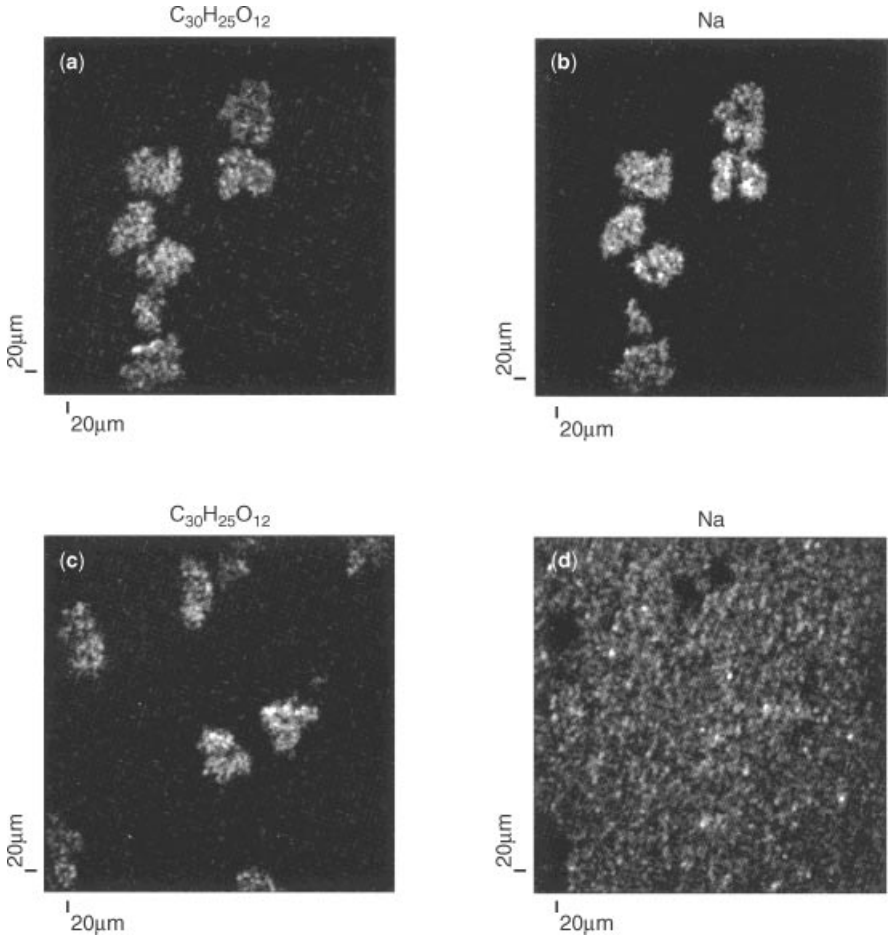

Fig. 20. Images of trimer crystals ($C_{30}H_{25}O_{12}^+$ at *m/z* 577) and sodium (Na^+ at *m/z* 23) for PET made with terephthalic acid (**a**, **b**) and dimethyl terephthalate (**c**, **d**). Both films were heated for 2 h at 180°C. Adapted from Ref. 12.

The advantage of retrospective analysis of image data files is illustrated by the behavior of sodium. This is usually present at very low levels (tens of ppm) in PET. Its appearance in the spectra after heat treatment was therefore intriguing. Figure 20 shows images from two types of PET film, one manufactured from polymer made using terephthalic acid (TA) and the other from polymer made using dimethyl terephthalate (DMT). Both films were identically treated for 2 h at 180°C. In the case of the TA polymer the sodium is clearly associated with the crystals, while in the DMT polymer case the sodium is more evenly distributed, but shows a lower than average concentration in certain crystals (12).

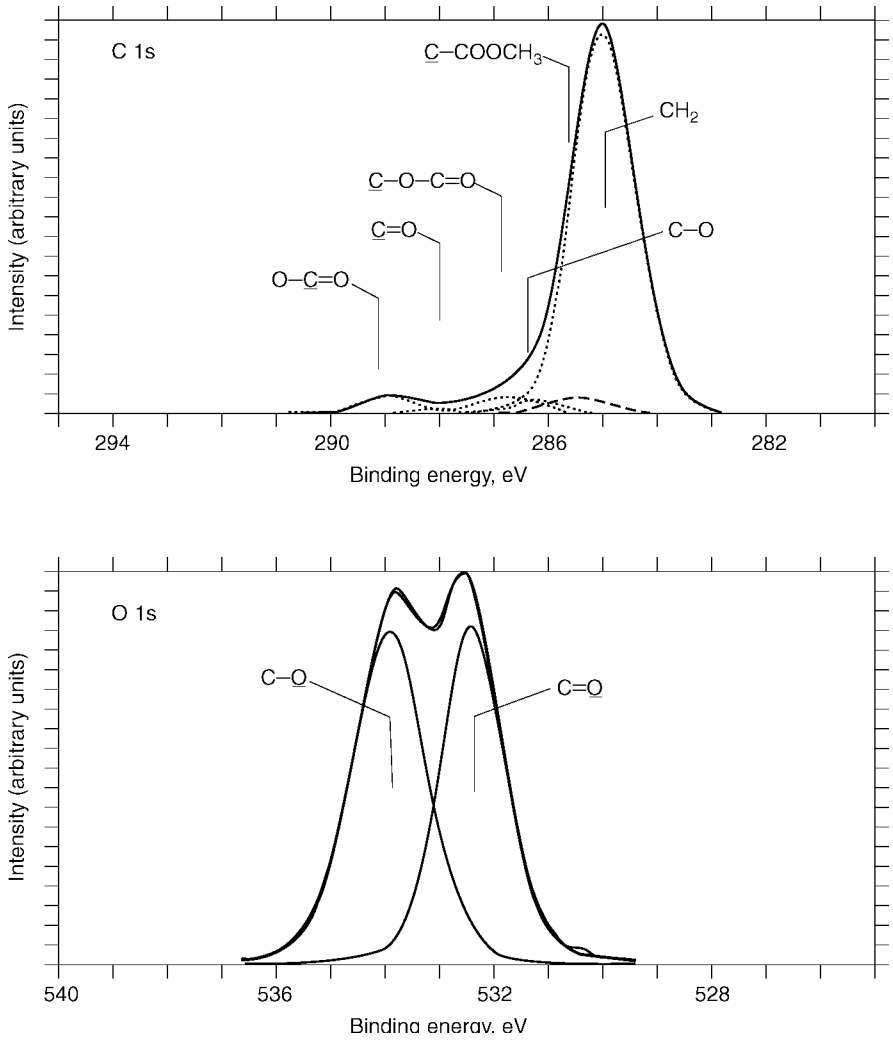

Fig. 21. C 1s and O 1s spectra from the surface of a thermally pressed poly(ethylene-*co*-methyl acrylate) film containing 23.4% methyl acrylate (45° take-off angle). Reproduced from Ref. 13.

Surface Morphology of EMA Copolymers. EMA copolymers are semicrystalline, with ethylene enrichment of the crystalline phase and methyl acrylate (MA) enrichment in the amorphous phase. They are commonly used in films and adhesives. The distribution, composition, and orientation of these phases at the surface are expected to have a major influence on the surface propereties which are critical to these applications (eg, cling, sealing, and adhesion). Galuska carried out a detailed study of a range of polymers with an MA content ranging from 6.8 to 33 wt% (13). Thermally pressed films were used.

Typical C 1s and O 1s spectra are shown in Figure 21. The ether and ketone components are due to adventitious oxidation during film pressing, so the most reliable measure of MA content is the carboxyl component. Thus, from the C 1s spectra the surface oxygen concentration due to MA could be extracted. Measurements were made as a function of take-off angle to vary the sampling depth. These results are shown in Figure 22. The interpretation of the surface morphology based on this data involves a periodic structure due to segregation of the amorphous phase into ethylene- and MA-rich layers as a result of MA clustering. Of particular interest is the behavior at the very surface (20A analysis depth correlation) where there is an abrupt change in behavior above 20% MA content.

In the ToF-SIMS positive ion spectrum the peaks characteristic of LDPE and PEMA appear but as the MA concentration increases some of the hydrocarbon peaks (eg CH_3^+, $C_5H_9^+$, $C_6H_{11}^+$, $C_7H_{13}^+$), initially with the relative intensities expected from LDPE, increase in intensity and EMA-specific ions, eg, $C_2H_3O_2^+$, are detected (high mass resolution required). Two of these ions, normalized to the nonspecific $C_2H_3^+$ ion, are plotted as a function of bulk MA content in Figure 23.

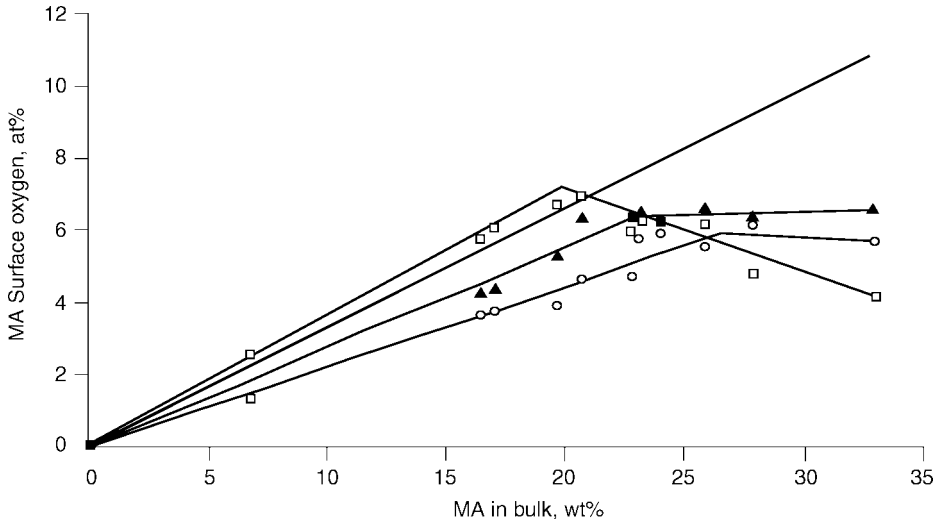

Fig. 22. Surface MA oxygen concentration vs bulk MA content for thermally pressed poly(ethylene-co-methyl acrylate) films as determined from XPS at three different take-off angles. The bold line would be obtained for a surface composition identical with the bulk. ——— Bulk Ma oxygen calibration, □ 20° Take-off angle (20 Å), ▲ 45° take-off angle (40 Å), ○ 90° take-off angle (60 Å). Reproduced from Ref. 13.

As with the XPS data for the lowest analysis depth a dramatic change occurs at about 20% bulk MA content. It is believed that ions like $C_7H_{13}^+$ represent polymer backbone with attached MA side chains, whereas the $C_2H_3O_2^+$ ion represents the side chain itself. The behavior of the two curves strongly suggests that a rearrangement of the polymer chains at the surface occurs at this critical MA concentration so that the ester side chains are preferentially orientated inwards.

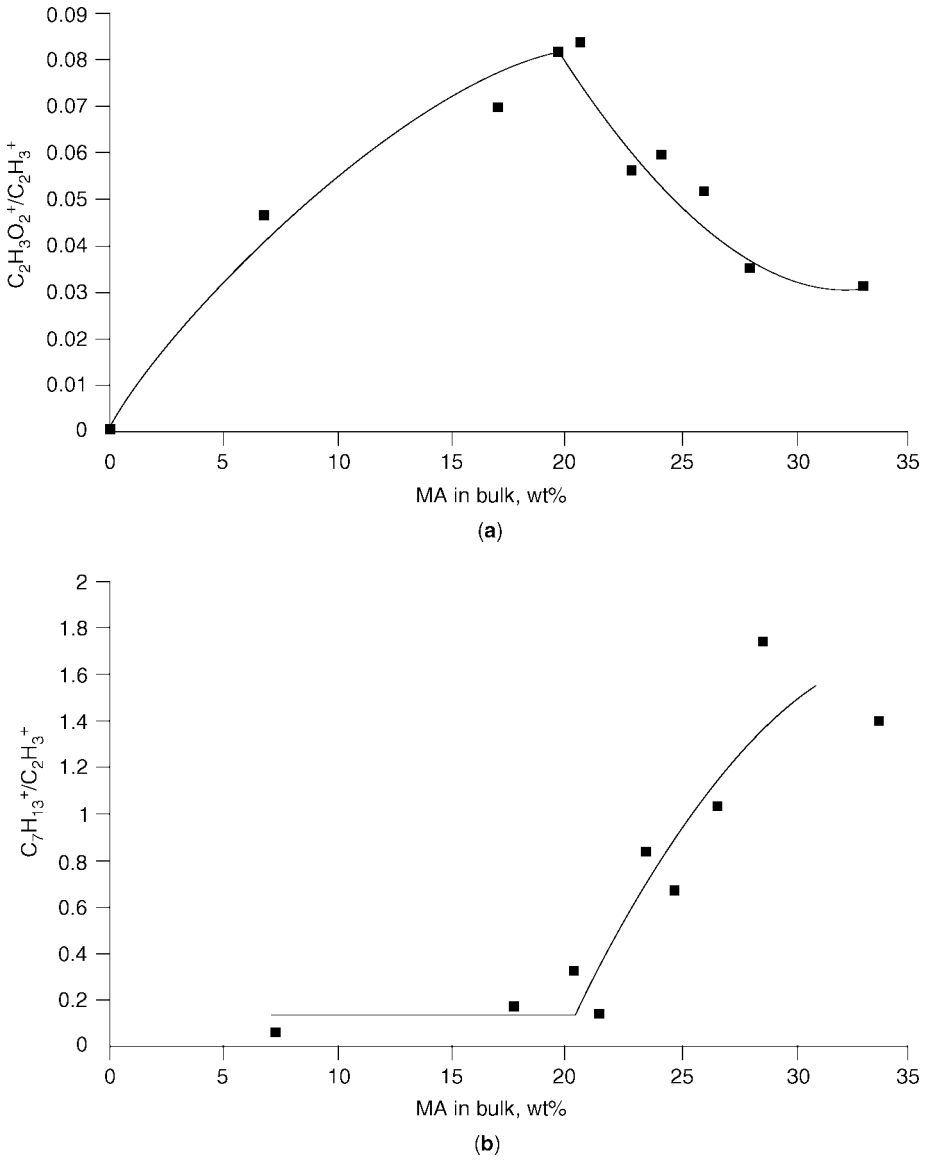

Fig. 23. ToF-SIMS intensity plot for $C_2H_3O_2^+$ (**a**) and $C_7H_{13}^+$ (**b**) (both relative to $C_2H_3^+$) as a function of bulk MA content for the thermally pressed poly(ethylene-*co*-methyl acrylate) films of Figure 22. Reproduced from Ref. 13.

TELECHELIC POLYMERS

Introduction

Telechelic polymers are defined as macromolecules that contain two reactive end groups. A pioneering work on the synthesis functional polymers and their conversion to the final products with specific properties by reacting with functional groups may be dated back to 1947 (1). However, the concept was not fully recognized until 1960 (2). Significant contributions to the development of this class of polymeric materials are still found in the current literature. In the last decade there has been a rapid growth in the development and understanding of new controlled radical polymerizations (3). Precise control of functionality, molecular weight, and uniformity (molecular weight distribution) can now be made not only by ionic polymerization routes but also by newly developed living radical polymerization (qv) techniques. Another striking development has been achieved in the metathesis polymerization. Many new catalysts have been developed and applied to preparation of advanced materials (4–8). The range of monomers and functional groups used in the preparation of telechelic polymers has been expanded in recent years as a result of such developments.

This article describes the general techniques for the preparation of telechelics. A special emphasis has been placed on controlled radical and metathesis polymerization methods.

A polymer can be considered to be telechelic if it contains end groups that react selectively to give a bond with another molecule. Depending on the functionality, which must be distinguished from the functionality of the end group itself, telechelics can be classified as mono-, di-, tri-, and multifunctional telechelics (polytelechelics) (9). The functionality is defined as

$$f = \frac{\text{Number of functional groups}}{\text{Number of polymer chains}} \tag{1}$$

Encyclopedia of Polymer Science and Technology. Copyright John Wiley & Sons, Inc. All rights reserved.

Telechelic polymers can be used as cross-linkers, chain extenders, and precursors for block and graft copolymers. Moreover, star and hyper-branched or dendric polymers are obtained by coupling reactions of monofunctional and multifunctional telechelics with appropriate reagents. Various macromolecular architectures obtained by the reactions of telechelics are represented in Figure 1.

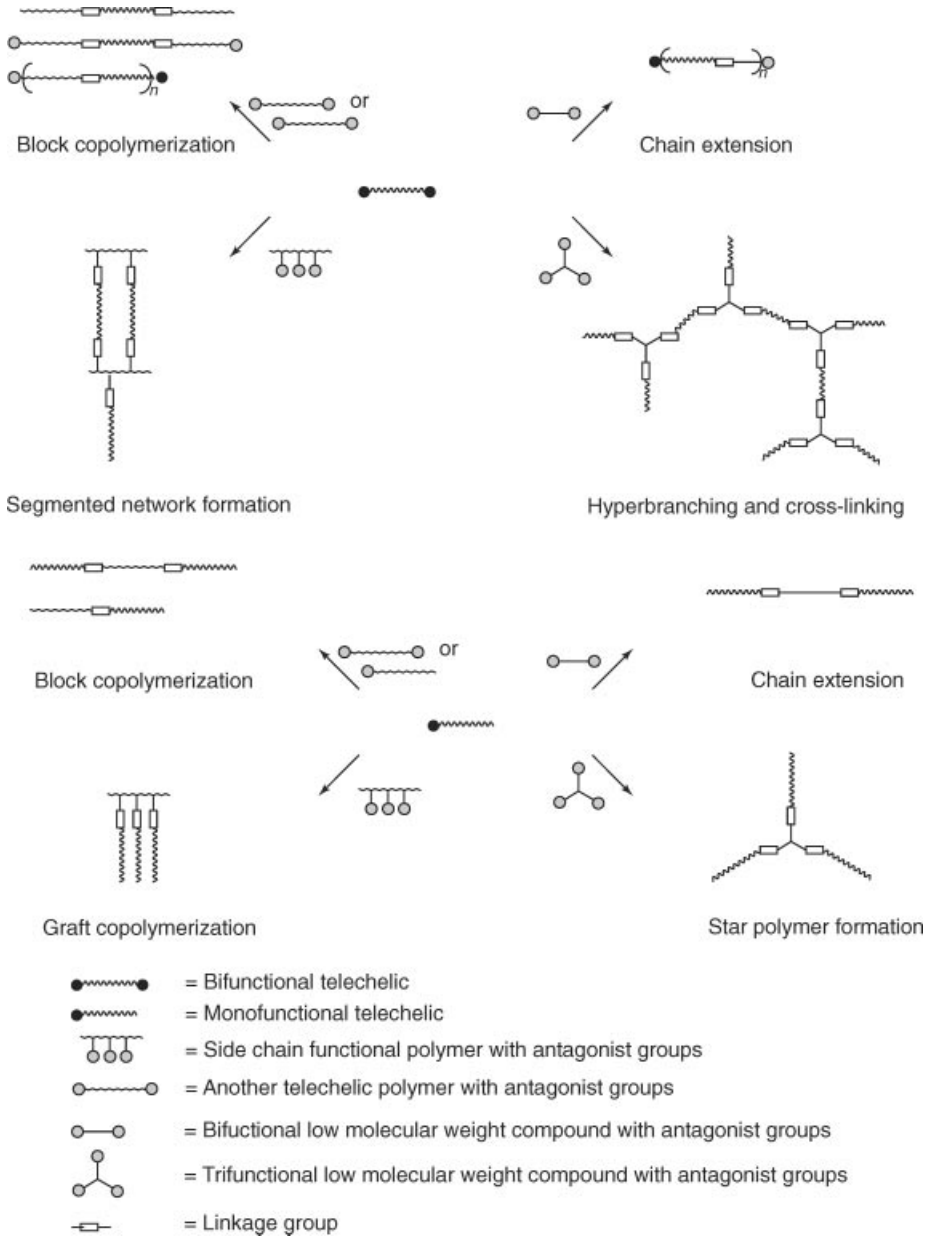

Fig. 1. Various architectures obtained by the reactions of telechelics.

The functionality of the end group itself is important. When such groups are bifunctional (eg, vinyl groups) they can participate in polymerization reactions, yielding graft copolymers or networks; such telechelic polymers are called macromolecular monomers, macromonomers, or macromers.

Industrial interest in telechelics was stimulated by the development of thermoplastic elastomers, which consist of ABA block and multiblock copolymers. Liquid telechelic polymers are the basis for reaction injection molding. Liquid telechelics that can be used for network formation offer processing advantages and may result in materials with improved properties (10).

Radical Polymerization

Free radical polymerization, is the most widely used methodology in synthetic polymer chemistry owing to its simplicity, applicability to many monomers, and relatively high tolerance to impurities and functional groups.

Conventional Radical Polymerization. Telechelics can be synthesized by radical polymerization (qv) in two ways: End groups can be controlled using a large concentration of (functional) initiator (dead-end polymerization), or polymerization can be conducted in the presence of suitable transfer agents (telomerization) (10–14).

The first method has serious limitations because well-defined end groups can be observed only if not more than one type of primary radical is formed that does not cause side reactions such as transfer. Moreover, a propagating radical will readily react with another radical, primary or macroradical, either through disproportionation or through coupling reactions (termination) (Fig. 2). The former will produce monofunctional telechelics with both a saturated and an unsaturated chain end, while only the latter will yield bifunctional telechelics.

Table 1 shows the percentage of termination by coupling (combination) for some common monomers (15).

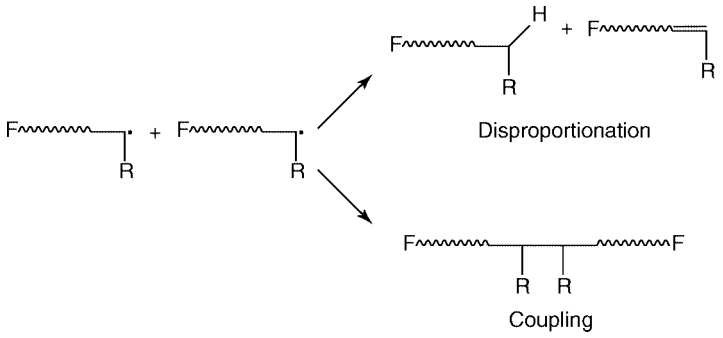

Fig. 2. Termination reactions.

Functional Initiators

Azo Initiators. In this section we report the preparation of telechelics involving thermally labile azo compounds. Upon heating, aliphatic azo compounds evolve nitrogen, thus forming two carbon-centered free radicals (see Initiators, Free-Radical).

$$R^1\text{—}N{=}N\text{—}R^2 \xrightarrow{\triangle} R^{1\cdot} + R^{2\cdot} + N_2 \qquad (2)$$

The activation energies for this reaction are, supposing R^1 and R^2 are aliphatic, between 60 and 160 $kJ \cdot mol^{-1}$. Azo groups are, therefore, a highly suitable radical source with respect to the energy required. Despite being thermally labile, azo groups are photoactive, too. Aliphatic azo groups evolve nitrogen with quantum yields as high as $\Phi = 0.44$ (AIBN 16). However, the absorbance is relatively low, being $\varepsilon = 13\ cm^2 \cdot mol^{-1}$ at $\lambda_{max} = 350$ nm (AIBN 17). In order to obtain telechelics, the initiating azo compound has to be at least bifunctional: it must carry one or more functional sites other than the azo function itself. Because of the potential variability in the chemical nature of the azo initiators it is possible to prepare telechelics with a wide variety of functional groups (Table 2).

Telechelics with certain functional groups can be prepared directly from the precursor initiators or, alternatively, via modification of the available telechelics. For instance, hydrolysis of nitrile groups yields carboxyl-terminated oligostryrene while isocyanate end groups are obtained directly from the azide telechelics or by treatment of amino-terminated polymers with phosgene (19). The functional group approach to synthesize amino telechelics causes some complications since amino compounds participate in chain-transfer reactions. Yagci and co-workers (37,38) proposed a convenient and simple synthetic route for the preparation of amino telechelics via free radical polymerization using (acyloxy) imino azoinitiator and subsequent photolysis and hydrolysis.

(4)

(5)

Peroxide Initiators. Hydroxyl radicals formed by a redox reaction with H_2O_2 are highly reactive, and have not been reported for the small-scale preparation of telechelics. However, the industrial preparation of hydroxy-terminated butadiene oligomers probably involves such process (39).

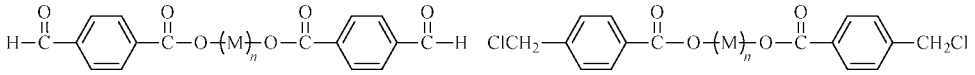

Fig. 3. Structure of telechelics obtained by functional benzoyl peroxide initiators.

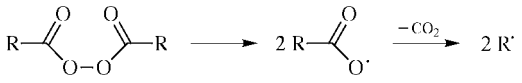
Diacyl peroxide decomposition can yield two types of radicals ($RCOO^{\bullet}$, $R^{\bullet}$):



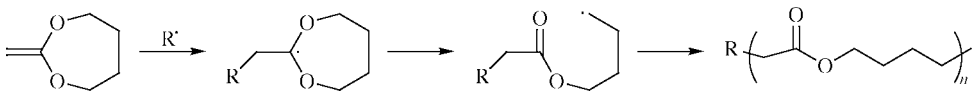
(6)

However, these peroxides have not been utilized for the preparation of telechelics. The less reactive aroyl peroxides give styryl telechelics (40). When employing benzoyl peroxides p-substituted with chloromethyl or aldehyde groups, the telechelics require no further modification before being used as prepolymers (Fig. 3).

Ethylene polymerized with diethyl peroxydicarbonate contains terminal ester groups (41). Using ^{14}C-labeled cyclohexane peroxydicarbonate, the fate of the primary radicals during the polymerization of methyl methacrylate (MMA) and styrene has been studied (42). Although this reference includes no detailed analysis of the products, it indicates that ROOCO-terminated polystyrene telechelics may be obtained by this technique. A similar method has been used for the preparation of telechelic polybutadiene (43). The carbonate end groups are easily modified into terminal hydroxyl groups by hydrolysis. Hydrogenation of the carbonate functionalized telechelic polybutadiene, followed by hydrolysis, yields hydroxy-terminated polyethylene telechelics.

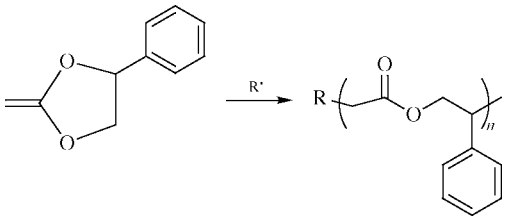
Free Radical Copolymerization of Alkenes with Unsaturated Heterocyclic Compounds

Free radical ring-opening polymerizations of unsaturated heterocyclic compounds are driven by formation of a carbon–oxygen double bond at the expense of a less stable carbon–carbon double bond. By the reaction mechanism outlined in reaction 7, the seven-membered keten acetals, such as 2-methylene-1,3-dioxepane, undergo essentially complete ring opening, leading to the corresponding polyester (44–51).

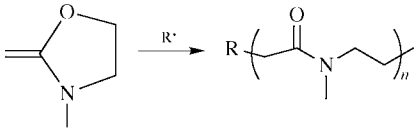


(7)

Similarly, the five-membered phenyl-substituted and nitrogen analogue monomers yield the corresponding polyester and polyamide.

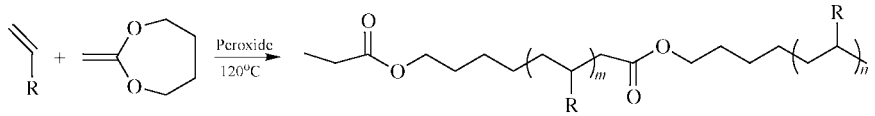


(8)



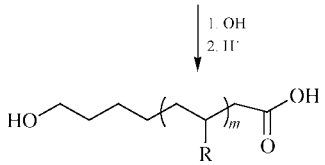
(9)

Telechelic polystyrene and polyethylene containing a hydroxyl and a carboxylic end group are obtained by copolymerizing a small quantity of 2-methylene-1,3-dioxepane with a large quantity of styrene or ethylene, and then hydrolyzing the resulting polymers (reactions 10 and 11).



(10)

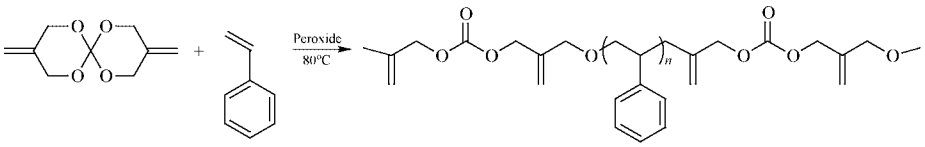
R = H or Ph



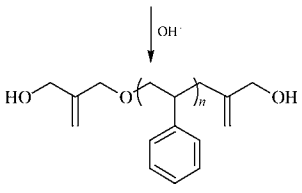
(11)

Copolymerization (qv) of common monomers with cyclic ketene thioacetals result in telechelics containing a thiol and a carboxylic acid group as chain ends.

Finally, the unsaturated spiro-*ortho*-carbonate shown in reactions 12 and 13 undergoes double ring opening during free radical copolymerization so as to introduce carbonate groups into the backbone of an addition polymer. Therefore, telechelic polystyrene containing two primary hydroxy chain ends is obtained by hydrolysis of the copolymer from styrene and the spiro monomer.



(12)



(13)

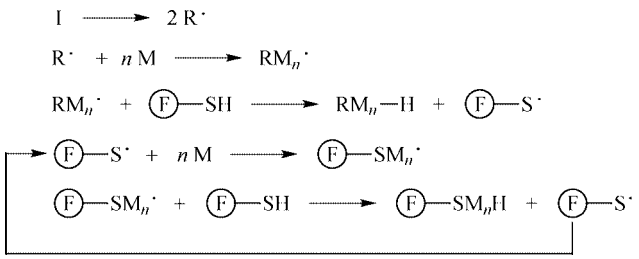


Fig. 4. Functionalization of polymers by chain transfer agents.

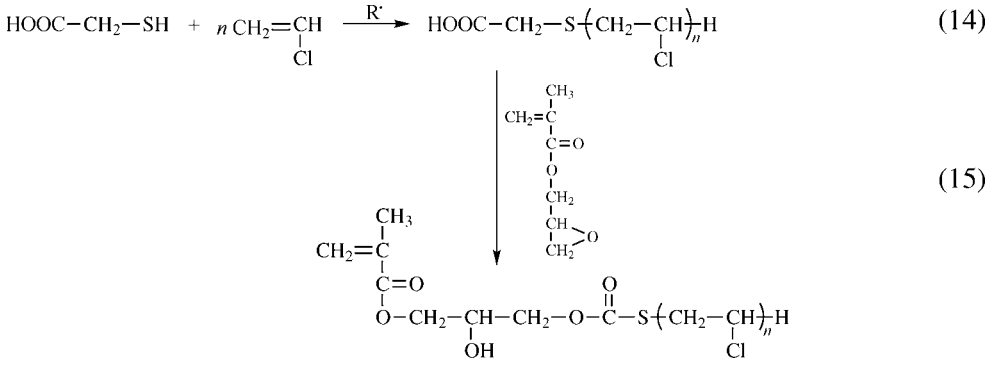
Transfer Techniques

Transfer Agents. In free radical polymerization, thiols are often employed as chain transfer agents. Chain transfer reactions involving thiols proceed via hydrogen atom abstraction as illustrated in Figure 4.

Consequently, these molecules do not offer any scope for introducing functionalities at both ends. However, monofunctional telechelics have been successfully prepared by using thiols. For example, Boutevin and co-workers (52,53) introduced polymerizable vinyl groups to poly(vinyl chloride) (PVC) according to that strategy. 3-Mercaptopropionic acid has been used as functional chain transfer agent producing a PVC with one carboxylic acid end group (reaction 14). This monofunctional telechelic was converted into a macromonomer according to reaction 15.



(14)

(15)

Polystyrene macromonomers (54) with molecular weight of 10^3–10^4 were also prepared. Polymerization of methacrylate or vinyl chloride in the presence of 2-mercaptoethanol (55,56) and subsequent treatment of the resulting polymer with methacrolyl chloride led to methacryl end capped polymethacrylates and PVC.

Free radical polymerization in the presence of a chain transfer agent (telogen) is often called *telomerization reaction*. Many different telogens have been reported (57); the most studied and well-documented telogen is CCl_4 (Fig. 5).

CBr_4 and CHI_3 are not suitable owing to their very high transfer constant, which yields only oligomeric materials.

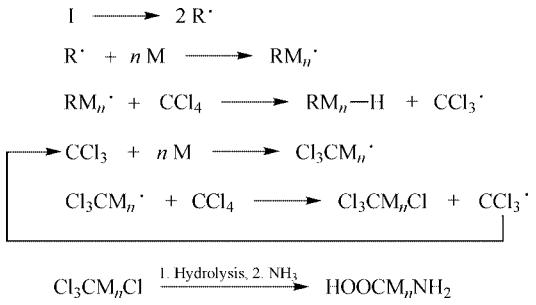


Fig. 5. Telomerization: Synthesis of α,ω-aminoacids.

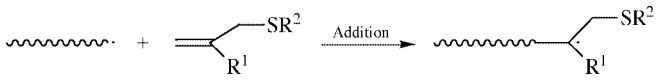
Addition–Fragmentation Agents. In recent years, addition–fragmentation reactions turned out to be a versatile and exceptionally interesting tool for polymer synthesis. These reactions aim at gaining control over molecular weight and make it possible to synthesize end-functionalized polymers, often macromonomers, which may further be employed in block or graft copolymerization (58–60). The principle of addition–fragmentation type reactions can be described briefly as follows: Free radicals, macro radicals, add to olefinic double bonds of a specially designed addition–fragmentation agent. The intermediate thus produced is relatively unstable and prone to fragmentation, what mostly means β-fragmentation. In this step a new radical is generated, which initiates polymerization. As a result, a growing radical chain has been terminated and a new chain initiated (chain transfer) (61). addition–fragmentation reactions combine the advantage of high efficiency in chain transfer with the possibility of end-functionalizing the polymer. Thus, macromonomers and mono- and bifunctional polymers are prepared when functionality is introduced into one or both of the substituents R^1 and R^2, as illustrated in the example of allylic sulfides.



(16)

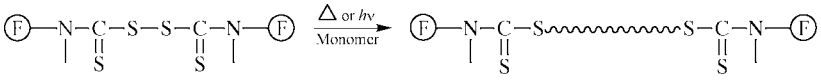
(17)

(18)

Other allylic compounds which participate in addition fragmentation reactions and yield telechelics analogous to allylic sulfides include allylic bromides, allylic phosphonate, allyl peroxides, and allylic stannane and vinyl ethers (62).

Iniferters. The peculiar behavior of thiuram disulfides in free radical polymerization was first identified by Tobolsky (63,64). These molecules can act simultaneously as an *ini*tiator, chain trans*fer* agent, and *ter*minator in a polymerization reaction and generally referred as *iniferters* by anomy to their role (65,66). Photochemically and thermally activated iniferter characteristics of thiuram disulfides

led to the derivation of telechelics. Telechelic preparation is based on the concept of locating the required function on the alkyl group of the thiuram disulfide and using it in the photo or thermal polymerization. Since end groups are introduced via initiation and transfer and common bimolecular termination between two growing chains are negligible, perfect bifunctional telechelics are available along this route.



(19)

Several functional disulfides and substituted tetraphenylethylenes were also used as iniferters in free radical polymerization. Table 3 shows various functional iniferters used for deriving telechelics.

The functionalities of the telechelics prepared by iniferter method were reported to be close to 2, within experimental error. The formation of the nonfunctional polymers was claimed to be negligible because of the triple function of the iniferter.

Controlled Radical Polymerization

Accurate control of polymerization process is an important aspect for the preparation of well-defined telechelics and end-functionalized macromolecules. Such control of chain ends was traditionally accomplished using living ionic polymerization techniques. But it is well known that the ionic processes suffer from rigorous synthetic requirements and in some cases they are sensitive to the functional groups to be incorporated. As described above in detail, free radical polymerization is flexible and less sensitive to the polymerization conditions and functional groups. However, conventional free radical processes yield polydisperse polymers without control of molecular weight and chain end. Competing coupling and disproportionation steps and the inefficiency of the initiation steps lead to functionalities less than or greater than those theoretically expected. Recent developments in controlled/living radical polymerization provided the possibility to synthesize well-defined telechelic polymers with controlled functionality also with radical routes (75). As it will be shown below, all the three standard methods for controlled/living radical polymerization, namely atom transfer radical polymerization (ATRP) (76,77), stable free radical mediated polymerization (SFRP), also called as nitroxide mediated polymerization (NMP) (78), and reversible addition–fragmentation chain transfer polymerization (RAFT) (79), were used for the preparation of telechelic polymers.

Atom Transfer Radical Polymerization. Atom transfer radical polymerization (ATRP) (80,81) involves reversible homolytic cleavage of a carbon–halogen bond by a redox reaction between an organic halide (R-X) and a transition metal, such as copper(I) complexed with 2,2′-bipyridine (bpy), as illustrated in reaction 20:

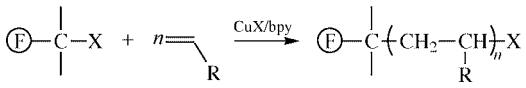
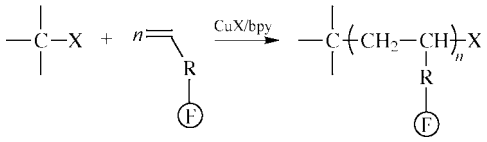
Polymer functionalization by ATRP can be achieved by using functional initiators and monomers and the chemical transformation of the halogen end groups. These routes are summarized in reactions 21-23.

Through Initiator Functionality



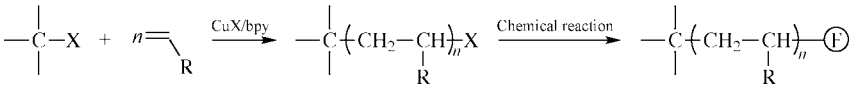
(21)

Through Monomer Functionality



(22)

Through Chemical Reaction of Halide End Groups



(23)

Quite a number of functional initiators were successfully used in ATRP to prepare functional styrene and acrylate type polymers (82). For this purpose initiators should be equipped with the desired functional groups as well as with a radical stabilizing group on the α-carbon atom such as aryl, carbonyl, nitrile, and multiple halogens to ensue successful ATRP. Notably, direct bonding of halogen to aryl or carbonyl group does not facilitate radical generation. In this connection, it should also be pointed out that any functionalities in the initiator should not interfere with ATRP, ie, should be inert to catalyst. The telechelic polymers prepared by using functional initiator approach in ATRP are presented in Table 4, along with the functional groups. Carboxylic acid functionalization by ATRP is rather difficult since the acid functionality poisons the catalyst. However, ATRP of MMA by using 2-bromoisobutyric acid was reported to proceed. Various protected initiators were also reported for carboxylic acid functionalization (113,114). Hydrolysis of the protecting groups yields polymers with the desired carboxylic acid functionalities.

Some other functionalities including bifunctionalities (115–117) were introduced to polymers by ATRP. Substituted aromatic and aliphatic sulfonyl chlorides were shown to be efficient initiators for ATRP and were used as initiators for the incorporation of functionalities to polystyrenes and polyacrylates (118). In these applications heterogeneous $CuCl(bpy)_3$ systems were utilized.

Obviously, ATRP leads to the formation of monofunctional telechelics since the other chain always contains halogen as a result of the fast deactivation process. These polymers could be called *heterotelechelic* since halogen is also a functional group. Therefore, α,ω-telechelics can only be prepared by transformation of the

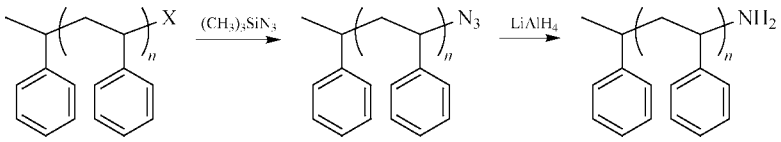
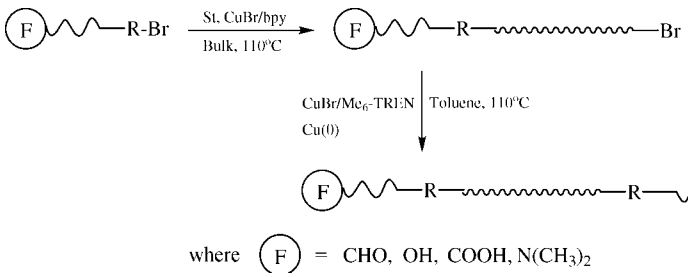
halide end group by means of nucleophilic substitution, free radical chemistry, or electrophilic addition catalyzed by Lewis acids (119). Typical example of such displacement is represented in reaction 24, which illustrates the reactions used to replace the halogens with azides and consequently leading to amino-functional telechelics (120,122).



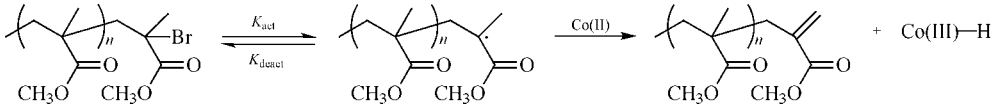
(24)

Other examples of halogen atom displacement to produce alcohol, C_{60}, epoxy, maleic anhydride, triphenylphosphine, and ketone functionalized polymers are described in the literature (123–125). The halide displacement is particularly important to prepare bifunctional hydroxy telechelics, which find application in the preparation of segmented polyester and polyurethanes (126). In such applications the first hydroxyl group can be incorporated by using hydroxy-functional initiator derivatives (127). The second hydroxyl group functionalization can then be achieved by direct displacement of halogen group with an amino alcohol or utilizing allyl alcohol. Diols can also be prepared by coupling of monohydroxy functional polymeric halides. In this connection it is noteworthy to mention the recent work (106) regarding atom transfer coupling process for the synthesis of bifunctional telechelics. Polymers monofunctionalized with aldehyde, aromatic hydroxyl, dimethyl amino groups were obtained by ATRP of styrene using functional initiators in the presence of the CuBr/bpy catalytic complex. Bifunctional

telechelics with double molecular weights as compared to the starting materials were prepared by coupling of monofunctional polymers in atom transfer radical generation conditions, in the absence of monomer, using CuBr as catalyst, tris[2-(dimethylamino)ethyl]amine (Me_6TREN) as ligand, Cu(0) as reducing agent, and toluene as solvent. The overall process is depicted in reactions 25 and 26.

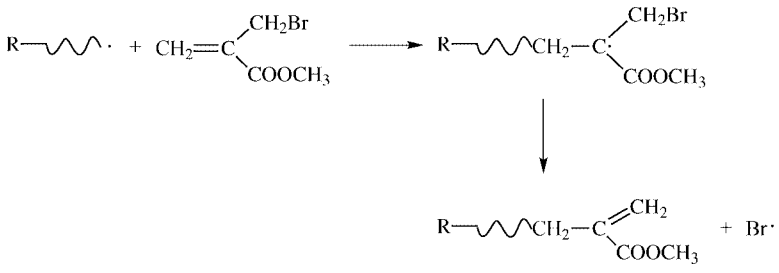


Incorporation of unsaturated end groups to polymers by ATRP is limited to certain groups. Only allyl and vinyl acetate groups were successfully incorporated (Table 4). Other polymerizable groups such as epoxides and oxazolines are not reactive toward radicals. In order to produce polymers with a more reactive unsaturated end groups such as methacrylates, a combined ATRP and catalytic chain transfer process was proposed (128). In this methodology, the catalytic chain transfer agent was added to the ATRP of MMA near to the end of polymerization, leading to the formation of ω-unsaturated PMMA macromonomer with low polydispersity and controlled molecular weight (reaction 27).



(27)

Here, the CTC agent acts as a chain transfer terminator but does not initiate new chain in the classical manner. Similarly, Haddleton and co-workers (129) used methyl(2-bromomethyl)acrylate in transition-metal-mediated controlled radical polymerization to replace the ω-halogen end group via addition–fragmentation to yield a methacrylate-based macromonomer.

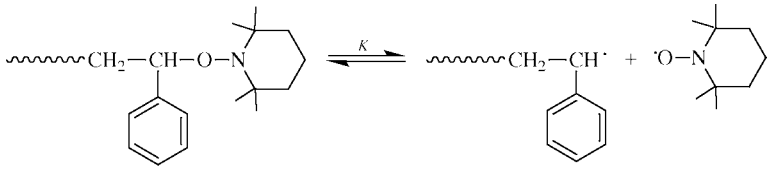


(28)

(29)

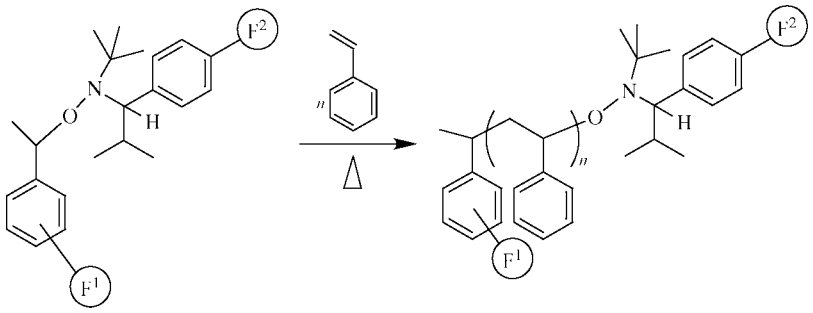
More recently, a convenient, one-pot synthesis of telechelic polymers with unsaturated end groups was developed (130). Addition of excess ethyl(2-bromomethyl)acrylate to ATRP of acrylate monomers after 80–90% conversion resulted in the formation of mono- and bifunctional polymers. The average degree of end functionality was almost quantitative ($f = 1$ for a monofunctional and $f = 2$ for a bifunctional initiator).

Nitroxide Mediated Living Radical Polymerization. Another controlled radical polymerization developed in recent years is stable free radical mediated polymerization (SFRP), also called as nitroxide mediated radical polymerization (NMP) (78,131). This type polymerization can be realized through reversible deactivation of growing radicals by stable radical such as 2,2,6,6-tetramethylpiperidinyloxy (TEMPO).



(30)

It is possible to prepare telechelic polymers by NMP procedure since it tolerates a wide variety of functional groups (78). For the synthesis of telechelics by NMP there are two general methods, ie, functional groups can be placed at the initiating chain end, F^1, or the nitroxide mediated chain end, F^2.

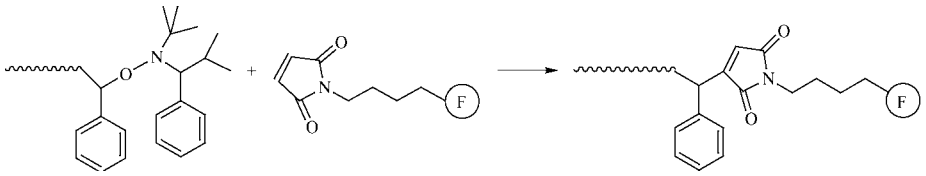


(31)

Telechelics with a variety of functional groups can essentially be prepared by using functional nitroxides (Table 5).

It was reported that high degree of functionalization, ie, greater than 95%, is possible even at molecular weights up to 50,000–75,000 by NMP method (152).

A wide variety of functional groups including polynuclear aromatic pyrene group can also be introduced by taking advantage of monoadditioin of maleic anhydrides and maleimide derivatives to alkoxy amine end group followed by elimination of mediating nitroxide radical (153). The thermal stability of the telechelics was increased as the alkoxyamine group was removed.



(32)

Table 5. Functional Groups Attached to Polymers by Nitroxide Mediated Living Free Radical Procedures

Functional group	Reference
OH	132–140
	141,142
	140
	143,144
	137,144–147
CN	141,148

$P(O)_2OH$	140
NH_2	78
COOH	78

Reversible Addition–Fragmentation Chain Transfer Polymerization. Controlled radical polymerization can also be achieved by reversible addition–fragmentation chain transfer polymerization (RAFT) (79). In this technique, after the initiation, the RAFT agents reversibly deactivate the polymer chains as the rate constant of chain transfer is faster than the rate constant of propagation (Fig. 6).

Telechelics can be prepared by RAFT process by selecting suitable RAFT agents (79).

Among the controlled radical polymerization methods discussed here, ATRP is the most applied route for the preparation of telechelics since besides the initiator functionalization, the terminal halogen produced in ATRP can easily be converted to many useful functionalities, eg by nucleophilic substitution (82).

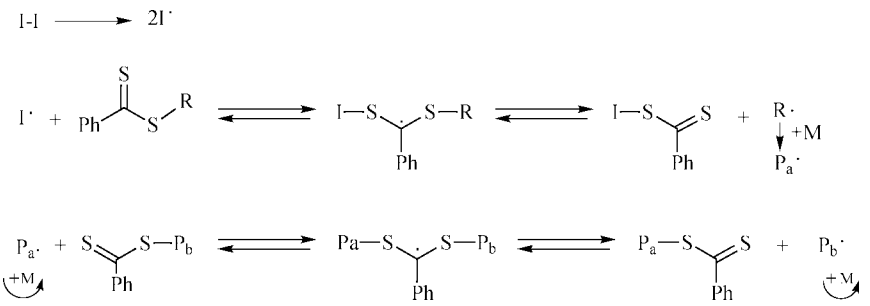

Fig. 6. Reversible addition–fragmentation chain transfer polymerization (RAFT).

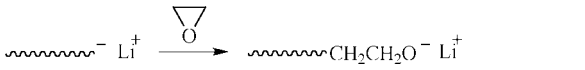
Displacement of nitroxides and dihioesters is more difficult in respective NMP and RAFT processes.

Anionic Polymerization

Anionic Polymerization (qv) (154–159) and, in particular, living polymerization can be used for the synthesis of telechelics. Living polymerization is characterized by the absence of termination and transfer and, when initiation is rapid and quantitative, by narrow dispersity that can be described by a Poisson distribution, and by linear increase of molecular weight with conversion. The propagating species are carbanions or other negatively charged species. Bivalent growing chains allow the generation of two terminal end groups and the facile synthesis of telechelic polymeric materials, depending on the monomer, initiator, solvent, and termination agent (160).

Hydroxyl End Groups. Living polystyrene is terminated by the addition of oxirane, which generates hydroxylate end groups (161,162).

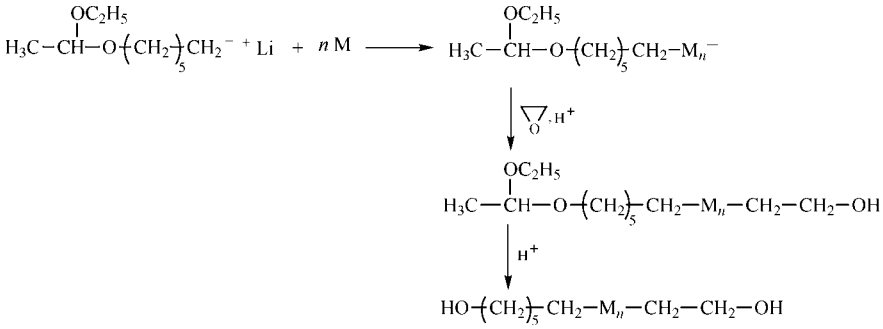


(33)

The alcoholate ion can initiate the polymerization of ethylene oxide, but the rate is low enough so that polyether formation can be avoided by quenching immediately after termination (163).

Other monomers, such as butadiene (164) and isoprene (165), have been polymerized and hydroxylated by the reaction of the corresponding living polymers with ethylene oxide. Bifunctional living polybutadiene has been generated in hexane using living oligomeric isoprene or 2,3-dimethylbutadiene as initiator (166). The hydroxyl functionality varies between 1.7 and 2.0.

Organolithium initiators with blocked hydroxyls increase the functionality of the products since one OH function is introduced with the initiator and the other one via termination, eg with oxirane (167).



(34)

(35)

(36)

Formaldehyde can also be used as termination agent yielding OH end groups (159).

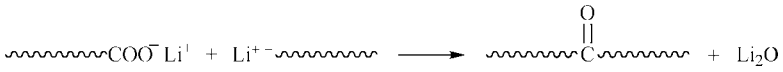
(37)

Other aldehydes and ketones lead to complications, particularly if keto–enol tautomerism is possible.

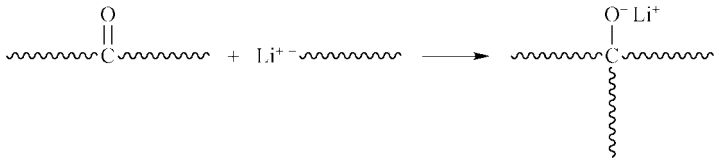
Mercapto End Groups. Living polystyrene reacts quantitatively with thiirane to form terminal mercapto groups (168). Termination with thiirane was also used for the formation of telechelic polyisoprene containing SH end groups.

Carboxyl End Groups. Termination of bifunctional living polystyrene by solid CO_2 yields polymers with carboxyl end groups (169). Because of its commercial potential, this reaction has been studied in depth. In addition to carboxyl groups (60%), dimeric ketones (30%) and trimeric carbinols (10%) are formed with gaseous CO_2 (170).

(38)

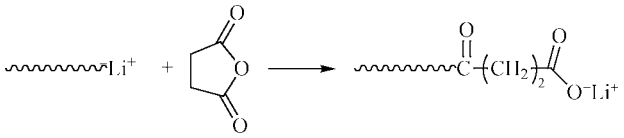


(39)



(40)

Almost quantitative carboxyl formation is observed if the polymer is converted to an intermediate Grignard (171) compound. The CO_2 is added rapidly, accompanied by a significant increase in viscosity of the monofunctional polymers and gelling of the bifunctional polymers. Yields depend on the reaction rates and on stirring efficiency. Alternatively, a anhydride can be used as termination agent (reaction 41).



(41)

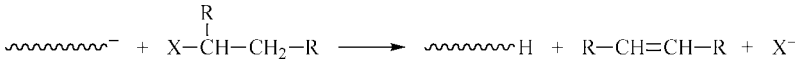
Reactions with excess phosgene give acylchloride end groups (172) but Wurtz-type side reactions can occur (173).

Halide End Groups. The most direct route for the preparation of halide terminal groups is the reaction of living polymers with a halogen, eg, chlorine (174,175) or iodine (176). Quantitative reaction is prevented by the occurrence of Wurtz coupling reactions. The percentage of halide end groups is increased by an intermediate Grignard step. For example, in this way, bromine gives an excellent yield of bromine-terminated telechelics.

A more general route employs an excess of primary α,ω-dihalides (175).

(42)

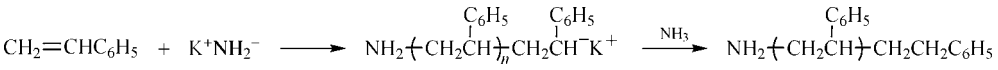
Secondary and tertiary halides lead to side reactions by β-elimination (177).



(43)

α,α-Dihaloxylene or 1,4-dihalo-2-butanone gives primary benzylic and allylic halides. Yields are increased by first converting the polymer into a Grignard salt. This process has been applied to prepare halogen-terminated telechelics from polybutadiene (178).

Amino End Groups. The polymerization of styrene initiated by potassium amide in liquid ammonia yield polymers with one primary amine group per chain (179).

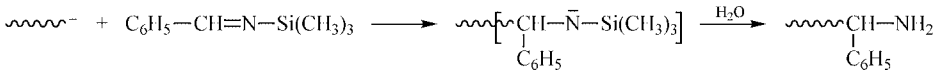


(44)

Initiators with the blocked amino groups, such as *p*-thio-*N*,*N*-bis(trimethylsilyl)aniline, have been used for anionic polymerization (Fig. 7).

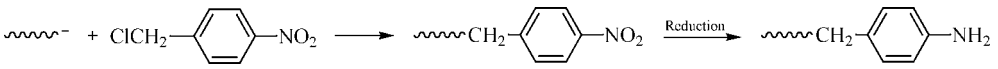
Bifunctionality is achieved by coupling with dimethyldichlorosilane. The primary amine end groups are regenerated by acid hydrolysis (180).

An alternative route for the introduction of amine end groups by reaction with blocked functional terminating agents (181) is as follows:



(45)

An indirect route for the introduction of amine end groups on aromatic ring has been described (182).



(46)

Secondary amine groups are generated by reaction with *N*-alkyl aziridines (176).

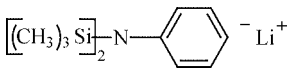


Fig. 7. Initiator with the blocked amino group.

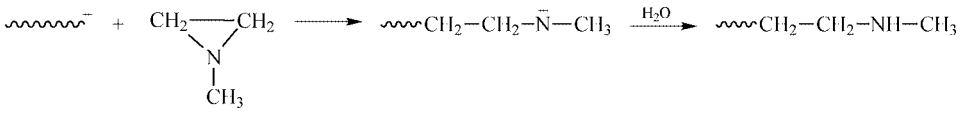
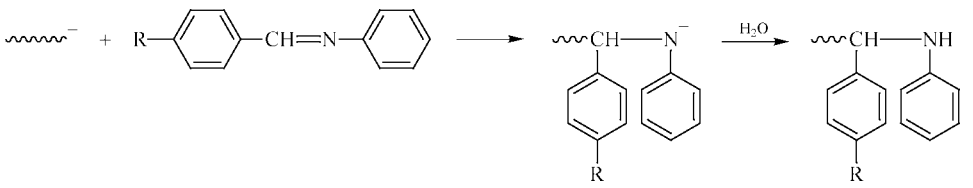


(47)

An interesting alternative is shown below (183):

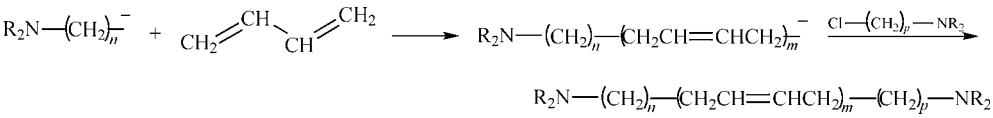


(48)

Tertiary amine terminated polymers are made by reaction with α-chloro-ω-amino-alkanes (184).

(49)

Living polybutadiene prepared with a tertiary amine functionalized alkyl lithium initiator is terminated by an α-chloro-ω-amino-alkane (185).



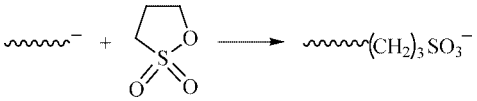
(50)

Ionic End Groups. Telechelics with quaternary ammonium end groups are prepared by quaternization of telechelic tertiary amines with organic halides (184). Unstable salts are formed by the reaction of living polymers with boron and aluminum alkyls. Only the triphenylboron derivatives are stable enough to be examined spectroscopically.

Reaction of living polymers with sulfur trioxide gives sulfonate salts. The reactivity of such salts as well as side reactions is reduced by complexation with a tertiary amine (185).

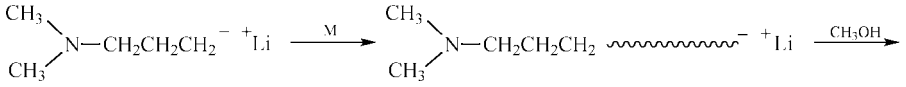
(51)

Termination of living polymers with sultones yields sulfonates. This reaction has been claimed to be quantitative in tetrahydrafuran at −78°C (186).

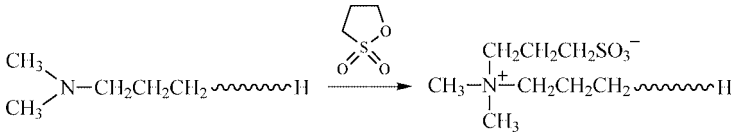


(52)

The synthesis and dilute and bulk solution properties of end-functionalized polymers with zwitterionic end groups have recently been reviewed (187). Reportedly, such polymers with different architectures (linear, block, and star copolymers) can be prepared by means of anionic polymerization. First, dimethylamine groups were introduced by using 3-dimethylaminopropyllithium as functional initiator. This group was then switched to sulfozwitterionic one by reaction with propanesultone.



(53)



(54)

Organometallic Groups. The reaction of living polymers with $Pb(C_4H_9)_3Cl$ yields polymers containing $Pb(C_4H_9)_3$ end groups. These end groups undergo homolytic scission at the carbon–lead bond, giving terminal free radicals (188).

Dipolystyryl aluminum chloride, prepared by stoichiometric reaction of 1 mol of $AlCl_3$ and 2 mol of living polystyrene, is used together with titanium halide catalyst to synthesize styrene–ethylene block copolymers (189).

Recently, new methods for preparation of telechelic polymers with better functionalization using alkyl aluminum initiated anionic polymerization were described (190–193).

Recent Trends in Functionalization of Telechelics. As described before, the direct carboxylation of polymeric organolithium with carbon dioxide in hydrocarbon solution often results in inefficient functionalization (170). Alternatively, an *ortho*-ester functionalized alkyl chloride, namely 4-chloro-1,1,1-trimethoxy butane, was used to prepare *ortho*-ester functionalized polymers (194).

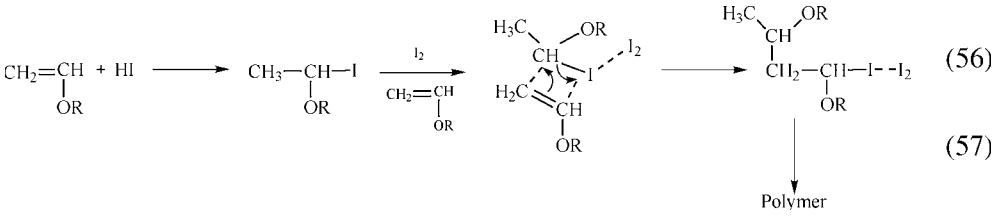
(55)

The *ortho*-ester functionalized polymers can be hydrolyzed to the corresponding carboxyl functionalized polymers. Similarly, functionalization with the oxiranes, glycidylpropyltrimethoxysilane, 3,4-epoxy-1-butene, and 1,1,1-trifluoro-2,3-epoxypropane has been investigated (195) to prepare trimethoxysilyl functionalized polymers, 1,3-diene functionalized macromonomers, and trifluoromethyl functionalized polymers, respectively. Secondary amine functionalized polymers were prepared by termination with *N*-(benzylidene)methylamine and also using an *N*-benzyl tertiary amine functionalized alkyl lithium initiator followed by hydrogenolysis of the benzyl group.

Carbocationic Techniques

The preparation of telechelics by carbocationic polymerization (qv) of vinyl monomers (196,197) has received little attention because of the high reactivity and low selectivity of growing species. The synthesis of useful telechelics requires the control of molecular weight and end groups; this was not possible until the discovery of living cationic polymerization.

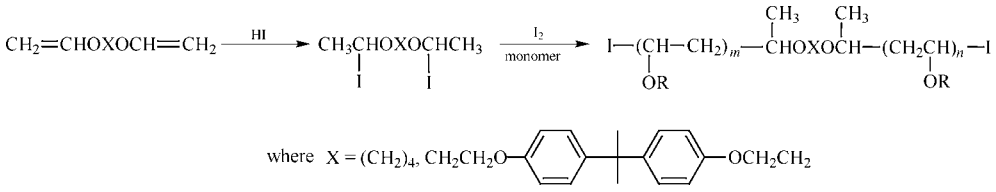
Poly(alkyl vinyl ethers). The initiation of vinyl ether polymerization with $HI–I_2$ yields polymers with narrow molecular weight distribution (198–200).



(56)

(57)

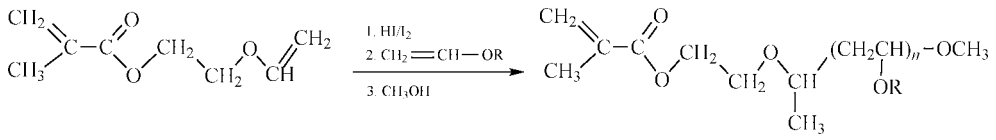
The reaction of bifunctional monomers with $HI–I_2$ gives α,ω-iodine telechelics.



(58)

This method has been used to produce telechelics from ethyl vinyl ether (EVE), methyl vinyl ether (MVE), and hexadecyl (cetyl) vinyl ether (CVE) (201, 202).

Treatment of living poly(EVE) with mono- or diamines yields telechelics with amino end groups (201). Vinyl ether based macromonomers have been prepared by a one-pot method (203–205).



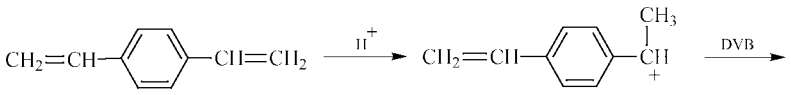
(59)

Several other functionalities were also introduced to poly(alkyl vinyl ethers) by living carbocationic polymerization (Table 6).

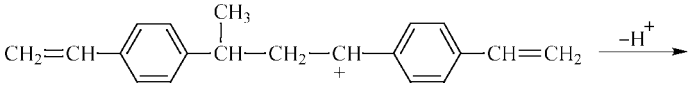
Polydivinylbenzene. Linear unsaturated polymers are obtained by a selective reaction between divinylbenzene (DVB) and cationic initiators such as CF_3SO_3H or CH_3COClO_4 (210–213). A sequence of protonation, propagation, and transfer steps yields telechelics with α,ω-vinyl end groups.

Table 6. Telechelic Poly(alkyl vinyl ethers)

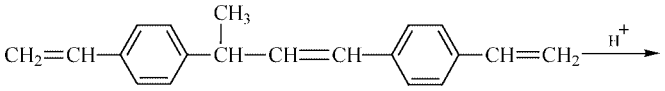
Functionality	Polymer	Reference
Hydroxyl	Poly(2-chloroethyl vinyl ether)	206
Aldhyde	Poly(2-chloroethyl vinyl ether)	206
Malonic ester	Poly(isobutyl vinyl ether)	207
Malonic ester	Poly(methyl vinyl ether)	207
Azo	Poly(isobutyl vinyl ether)	208
Imide	Poly(isobutyl vinyl ether)	209
Amino	Poly(isobutyl vinyl ether)	209



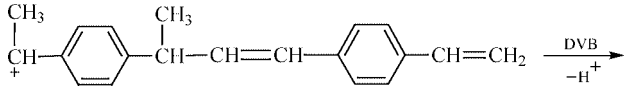
(60)



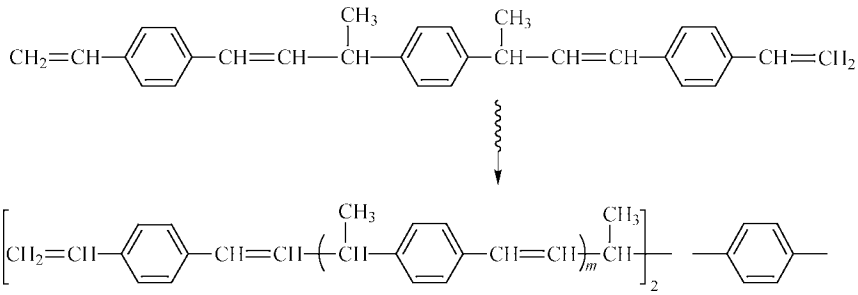
(61)



(62)

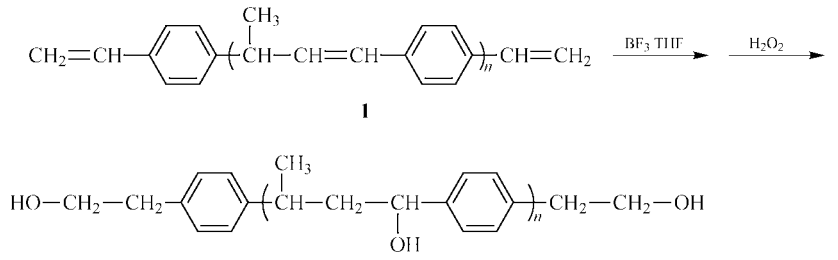


(63)

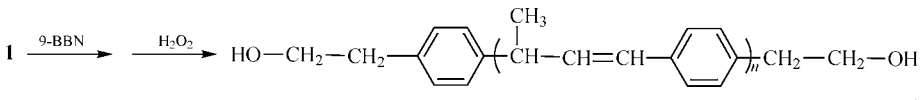


(64)

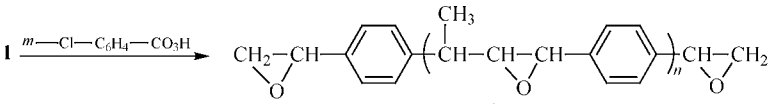
Reactions with 9-borabicyclo[3.3.1]nonane (9-BBN) and H_2O_2 yield hydroxyl-terminated telechelics (211).



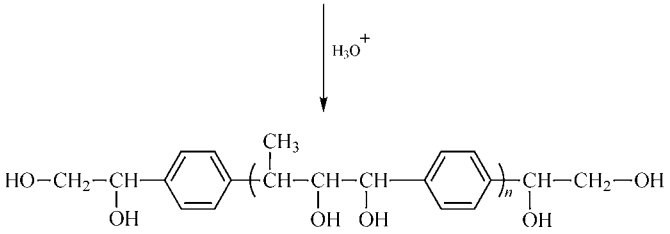
(65)



(66)

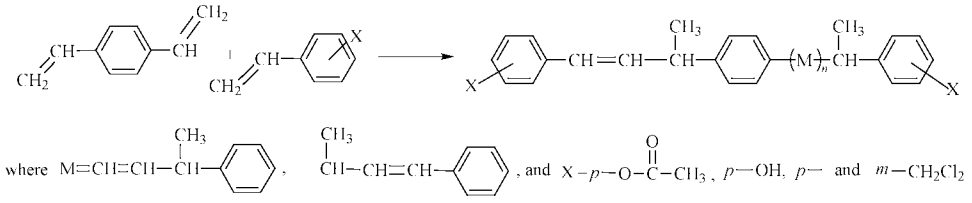


(67)



(68)

Although one keeps control over the end groups the final product may not be called a pure telechelic but a chain functionalized polymer. $\alpha\omega$-Acetoxy-poly(DVB) was synthesized from *p*-DVB, *p*-acetyl styrene, and CH_3COClO_4 in benzene at 70°C (212,213).



(69)

Polyisobutylene. On the basis of the reaction sequence shown in Figure 8, the conditions under which telechelics form can be predicted.

Head groups are controlled by initiation; propagation, termination, and transfer control the molecular weight and terminal groups. This method was first used for the synthesis of telechelics from isobutylene (214,215). The technique has been refined and is then called the inifer technique (216–221).

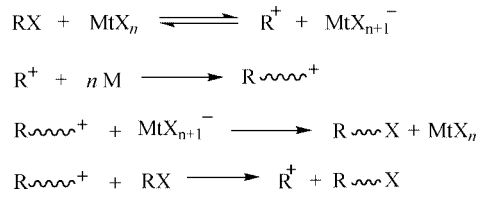


Fig. 8. Telechelics by inifer process. Here Mt is metal, M is monomer, and X is halide.

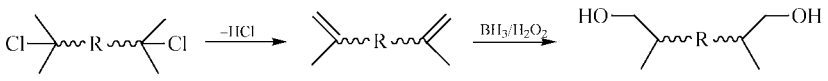
The compounds shown in Figure 9 act as both initiator and transfer agents, which led to the term inifer.

Notably, the number of functionality of the telechelics thus formed is related to the number of chloro groups present in the inifer. Preparation of telechelics by this method requires low temperatures and highly pure starting materials.

Quenching of living carbocationic polymerization also leads to *tert*-chlorine-telechelic polyisobutylenes (222). Synthesis of mono- (223–226), di- (227–235), tri- (236), and tetrafunctional (237) polyisobutylenes carrying Cl termini was reported.

The chloro end group is easily converted to olefinic or primary alcohol end groups (238–242).



(70)

One-pot dehydrochlorination–metalation of *tert*-chloro-telechelic polyisobutylenes (PIB) by combinations of *n*- with *sec*-butyl lithium (243) and of *n*-butyl lithium with *tert*-butoxide (244) leads to terminally lithiated polyisobutylenes. Oxyethylation and reaction with CO_2 of the latter yielded primary alcohols and carboxylate termini, respectively (244).

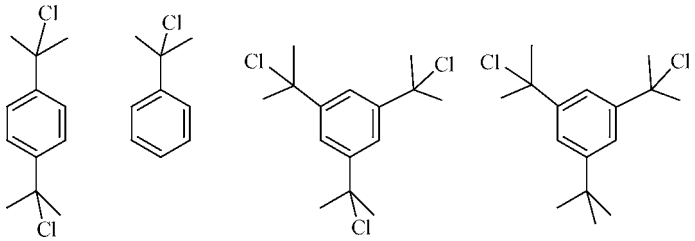


Fig. 9. Examples of inifers.

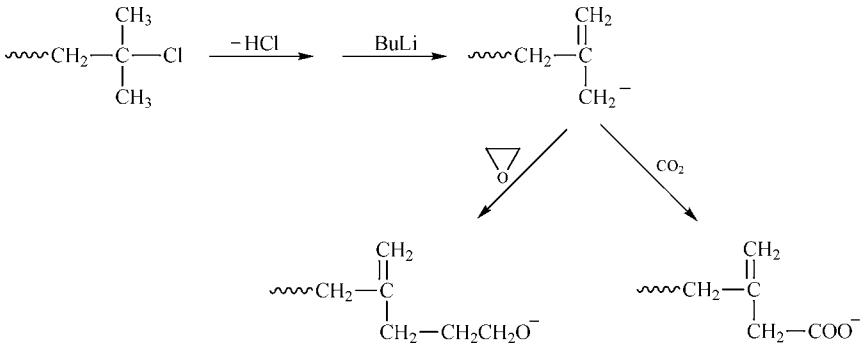
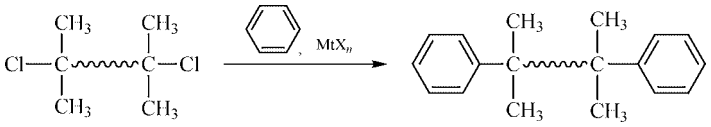


(71)

(72)

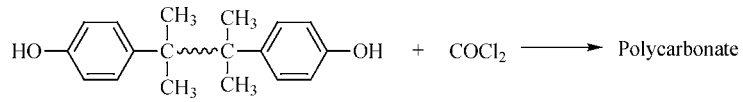
Friedel–Crafts alkylation of benzene, toluene, or phenol gives a variety of diaryl products (245):



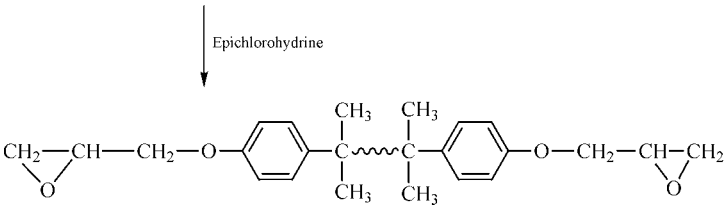
(73)

Nitration of the aromatic units followed by reduction yields an amine telechelic (245,246).

A phenol end group formed by Friedel–Crafts alkylation can be used for further derivatives (247,248).

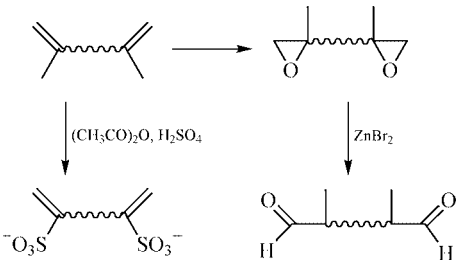


(74)



(75)

α,ω-Olefin telechelics can be converted into diepoxides and further to dialdehydes. Sulfonation of polyisobutylene with acetyl sulfate yields the corresponding sulfonate (249,250).

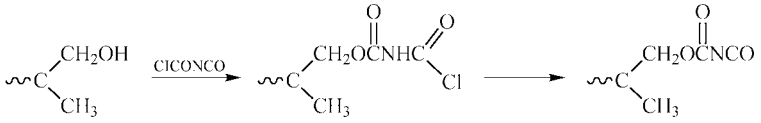


(76)

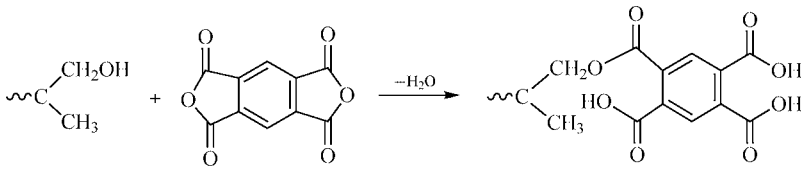
(77)

Similarly, di- and triallyl telechelic polyisobutylenes have been converted to di- and triepoxy telechelics (241,242). Hydrosilation of olefinic telechelics in the presence of suitable catalysts gives telechelics with reactive SiCl groups (251).

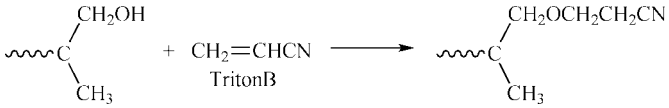
The hydroxy-terminated telechelics were used as starting material for numerous derivatives (252,253):



(78)



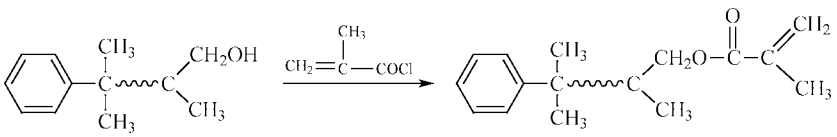
(79)



(80)

An improved Gabriel synthesis was used for amino-terminated telechelics (254).

Macromonomers can be synthesized from a hydroxy-terminated polymer by reaction with methacryloyl chloride (255).



(81)

Instead of RCl, tertiary esters were used in combination with BCl_3 for the synthesis of telechelics from isobutylene. The polymerization mechanism shown in Figure 10 was suggested (256,257):

Various other initiator systems for the controlled/living polymerization of isobutylene have been reported (222). The capping reaction of living polyisobutylene with 1,1-diphenylene ethylene (DPE) results in the formation of a stable and fully ionized diarylcarbenium ion, which can be used for chain-end functionalization by quenching with appropriate nucleophiles as shown in reactions 82 and 83 (258–261).

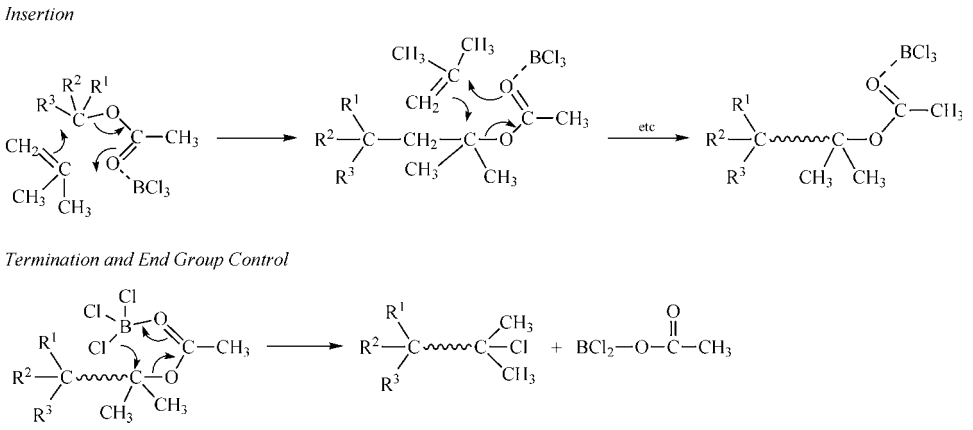


Fig. 10. Function of $(R_1R_2R_3)COOCH_3/BCl_3$ in the polymerization of isobutylene.

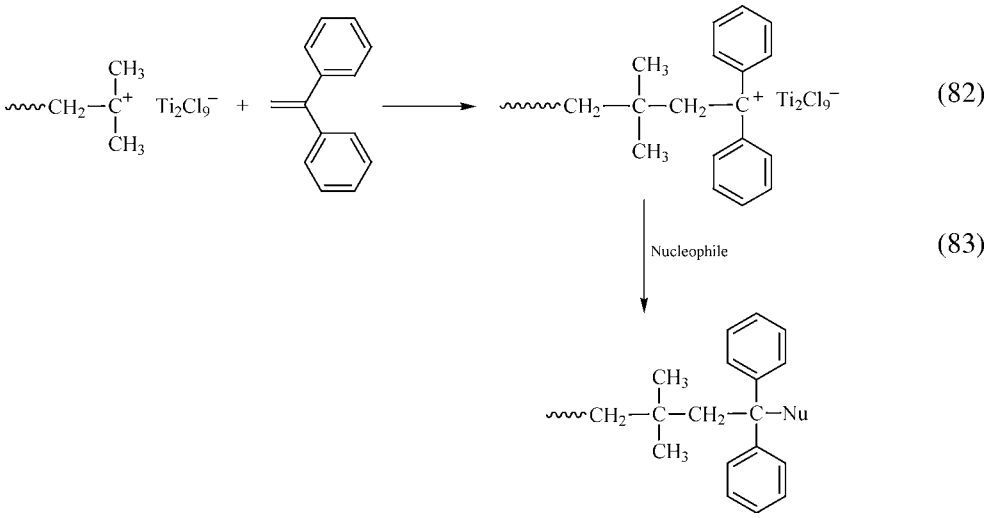
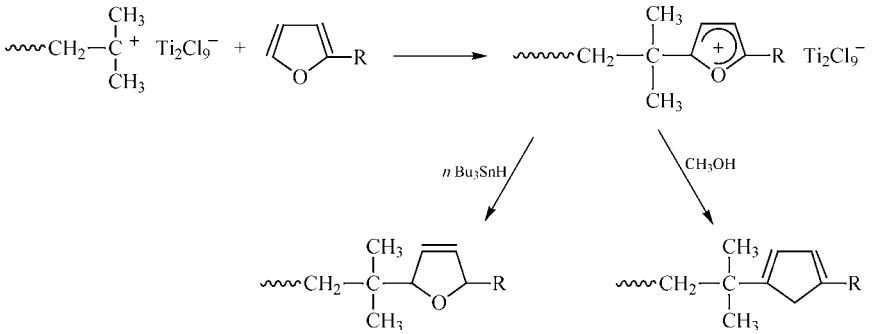


(82)

(83)

Using this strategy, a variety of chain-end functional polyisobutylenes including methoxy, amine, carbonyl, and ester end groups, have been prepared (262). By the rational combination of initiation and capping techniques, a series of α,ω-asymetrically functionalized PIBs have also been obtained (262–264). It was shown that living polyisobutylene could also be end-capped with 2-alkylfurans. Quenching the resulting cation with tributyltin hydride and methanol yielded polyisobutylene with dihydrofuran and furan functionality, respectively (265,266).

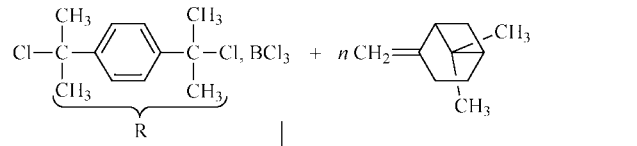


(84)

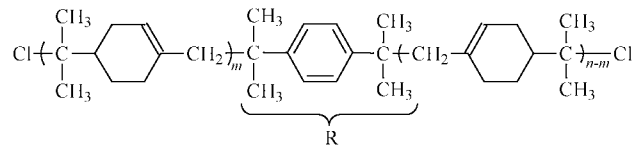
(85)

It appears that 2-alkylfurans are more suitable capping agents when subsequent functionalizations at elevated temperatures are required.

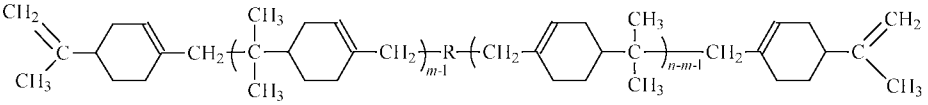
Polypinene. β-Pinene is converted into telechelics with 1,4-diisopropylchlorobenzene and BCl_3 as initiator (267).



(86)



(87)



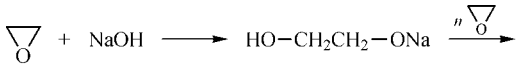
Polystyrene and Derivatives. Telechelic polystyrene, poly(2,4,6-trimethylstyrene), poly(*p*-methylstyrene), and poly(*p*-chlorostyrene) can be prepared by living carbocationic polymerization (269–271) or by inifer method (272). While end-quenching the living carbocationic polymerization gave quantitatively polymers with *sec*-benzylic termini, the dicumyl chloride/BCl_3 inifer system yielded α,ω-dichloro telechelics. Telechelics with olefine end groups were also prepared by dehydrochlorination (272,273).

Ring-Opening Polymerization

The synthesis of telechelics by ring opening has attracted great interest because of the commercial potential of the resulting compounds, such as polyether polyols. The end groups are introduced by initiation, end capping, or transfer reactions.

Cyclic Ethers.

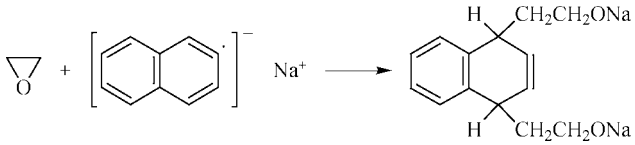
Oxiranes. Both anionic and cationic polymerization can be used to synthesize telechelics from oxiranes. Anionic polymerization of oxirane (ethylene oxide) yields α,ω-dihydroxy poly(ethylene oxide) (274,275).



(88)

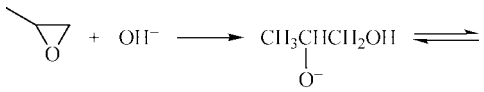
(89)

Polymerization with sodium naphthalene yields a chain with two simultaneously growing ends (276,277).

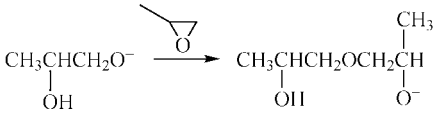


(90)

The anionic polymerization of methyl oxirane occurs predominantly by breaking of the oxygen–methylene bond, yielding terminal secondary alcohol functionality.

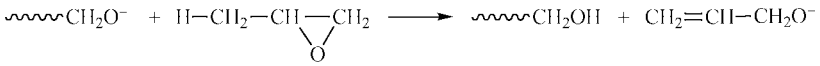


(91)

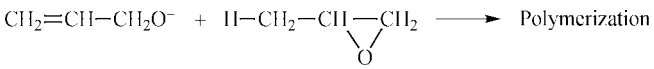


(92)

It should be mentioned that an important transfer reaction is occurring, leading to an allylic chain end:



(93)

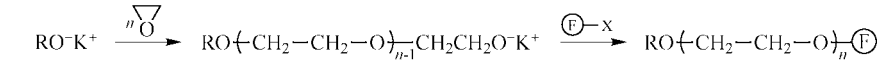


(94)

Hydroxyl end groups can be converted to various other functional groups (278). Generally, oxirane telechelics are synthesized either by one of the following methods: (*1*) end-capping of the living polymerization (termination method), (*2*) initiation of living polymerization (initiation method), and (*3*) transformation of hydroxyl end groups (279,280). Methods (*1*) and (*2*) are simple and usually afford most well-defined telechelics of a controlled degree of polymerization with a

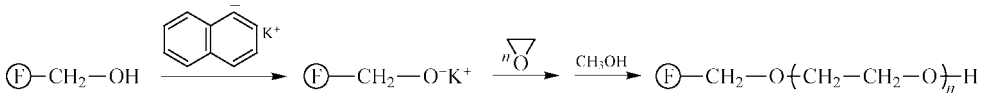
narrow polydispersity, but critically depend on the proper combination of anionic living polymerization with an effective terminator or initiator carrying desired functionality. Suitable terminators include alkyl and acid chlorides possessing functional groups.

Termination



X = Cl, C(O)Cl
F = Functional group (95)

Initiation

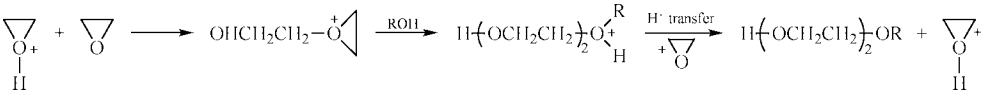


(96)

This way many poly(ethylene oxide)s with various functional groups including photo- and electroactive, and polymerizable groups were prepared (280–283). Moreover, suitable combinations of termination and initiation methods yield heterofunctional telechelics.

Although living anionic polymerization seemed to be the versatile method for the preparation of telechelic from oxiranes, with substituted oxiranes some side reactions leading to unsaturated species occur (reaction 93). An alternative initiating system based on aluminum complexes of Schiff bases was proposed for the preparation of α,ω-telechelics form differently substituted oxiranes (284–286).

The usual cationic polymerization of oxiranes cannot be used to synthesize telechelic polymers owing to a high tendency of backbiting resulting in cyclic oligomers (287). However, a process involving the addition of a hydroxyl end group to an activated (protonated) monomer has been described (287–289).



(97)

The polymer chain contains the less reactive (nucleophilic) hydroxyl end group. The driving force for this reaction comes from the protonated monomer, and no cyclic oligomers are formed. Similar results have been obtained from the polymerization of methyloxirane (290) and chloromethyloxirane in the presence of ethylene glycol (291). Photo- and azo-functional telechelics were also prepared by the so-called activated monomer polymerization (292,293).

Tetrahydrofuran. The cationic polymerization of tetrahydrofuran (THF) is living in the sense that, under certain conditions, the concentration of oxonium

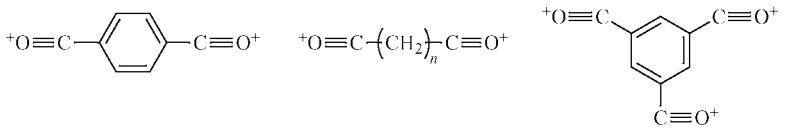


Fig. 11. Examples of bi- and trifunctional initiators with BF_4^-, PF_6^-, or SbF_6^- as counterions.

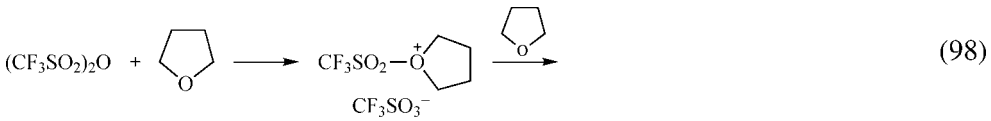
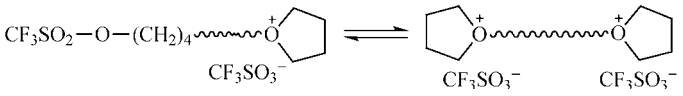
ions remains constant (294). The species is highly reactive and can be transformed into end groups by reaction with suitable nucleophiles. Polytetrahydrofuran (PTHF) with one functional end group is thus obtained after end capping of the living polymers produced with a monofunctional initiator. For the synthesis of bi- or trifunctional telechelics, initiators with corresponding functionality must be used (Fig. 11) (295,296).

Independent activity of all initiator functions of these bi- and trifunctionalized initiators has been reported. Copolymers can be formed if 10–20% of the THF is replaced by methyloxirane (297).

Anhydrides of super acids such as trifluoromethane sulfonic acid or fluorosulfonic acid yield two active ends (298,299).



(98)

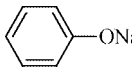


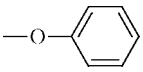
(99)

Molecular weight and functionality are controlled only at low initiator concentration because of the low solubility of the initial bisoxonium salt (299).

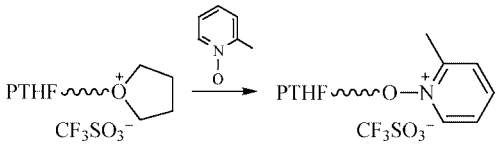
Because of the reversibility of the polymerization and the high reactivity of the oxonium functions, bi- and trifunctional PTHFs are not easy to use. However, addition of a nucleophile to a solution of living polymer yields telechelics that are easier to handle (300). End-capping reagents and the resulting end groups are shown in Table 7.

Table 7. End-Capping Reagents and End Groups

End-capping reagent	End group
NH_3 (liquid)	$-NH_2$
KOCN	$-NCO$
H_2S	$-SH$
$HOOC(CH_2)_2COOH$	$-COOH$
$C_2H_5NH_2$	$-NHC_2H_5$
$CH_2{=}CHCH_2NH_2$	$-NHCH_2CH{=}CH_2$
LiBr	$-Br$
	


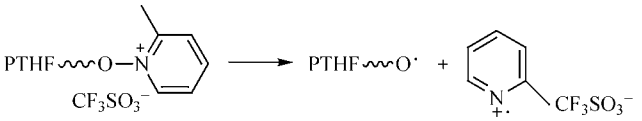


Some other functionalities such as photosensitive benzoin (301) and alkoxy pyridinium (reaction 100) (302), pyrrole (303), methacrylate groups (304) can also be introduced to PTHF by selecting suitable nucleophiles.



(100)

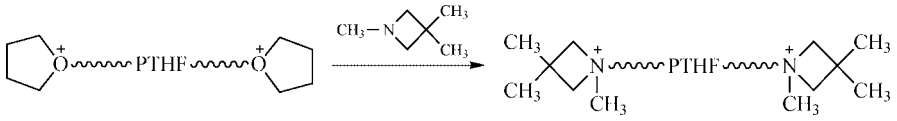
The pyridinium salt end-functionalized PTHFs can be used as polymeric initiators for photoinduced reactions. Upon photolysis the pyrdinium moiety decomposes and polymeric radicals are formed. Depending on the additives present in the system, hydroxy telechelics (305) or block copolymers (302) are thus formed.



(101)

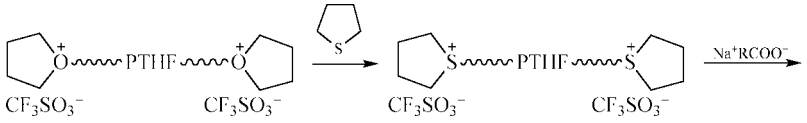
(102)

An interesting reaction is the so-called active species exchange (306).

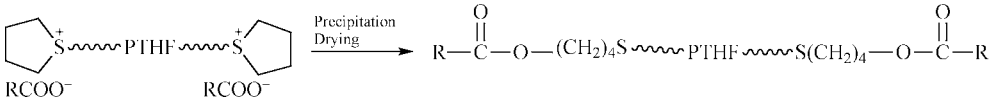


(103)

The less reactive, weak electrophilic azetidinium ions undergo ring-opening reactions with charged nucleophiles such as carboxyl ions. The reaction of PTHF with thiolane gives similar results (307).

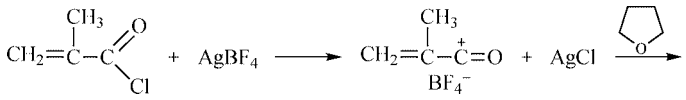


(104)

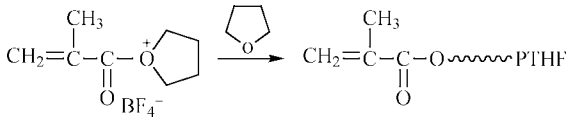


(105)

End groups have also been introduced by using a functionalized initiator (308,309).

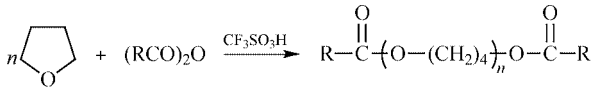


(106)



(107)

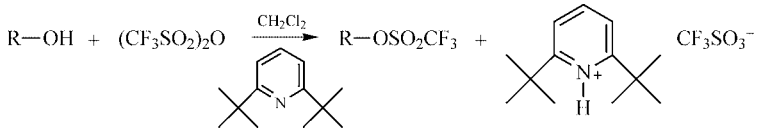
Proton-initiated polymerization of THF in the presence of carboxylic acid anhydrides gives ester-terminated end groups.



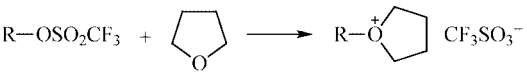
where R = CH_3, $CH{=}CH_2$, $C(CH_3){=}CH_2$ (108)

Hydrolysis results in the corresponding hydroxy-terminated PTHF.

Recently, it was shown that hydroxyl groups can be transformed *in situ* to a triflate ester in the presence of a proton trap for the initiation of the cationic ring-opening polymerization of THF. Providing that suitably functionalized hydroxyl groups are selected and the hydroxyl group is not attached to a bulky alkyl group (310), PTHF telechelics with narrow molecular weight distribution and quantitative functionalization can be obtained. Macromonomers with acrylate, methacrylate, and allyl functional groups have been successfully synthesized (311).

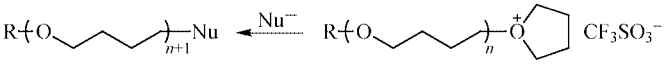


(109)

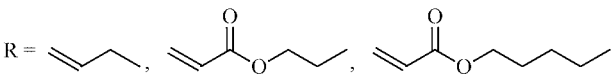


(110)

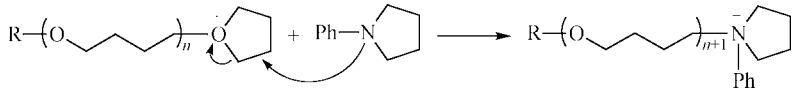
(111)



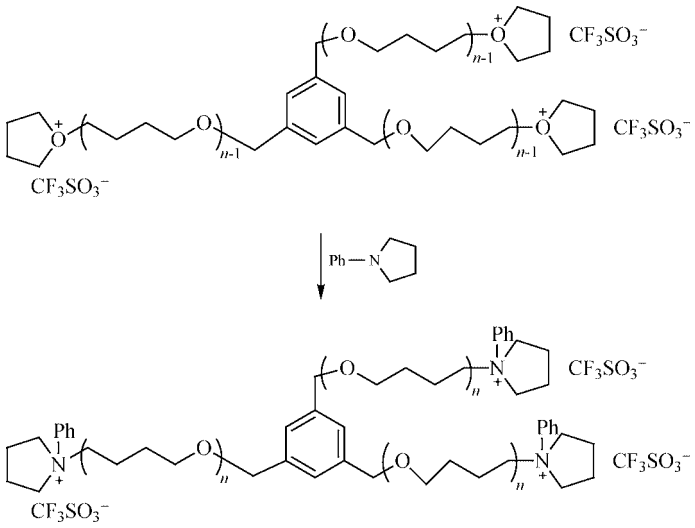
(112)



Interesting variation of end-capping reaction with *N*-phenylpyrrolidine (reaction 113) can be used to prepare mono-, bi-, and trifunctional star-shaped, telechelic PTHF having *N*-phenylpyrrolidinium salt groups as illustrated in the example of trifunctional living PTHF.

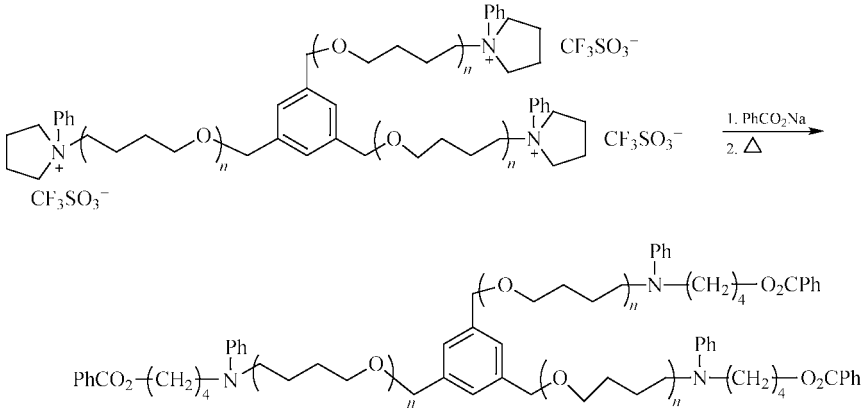


(113)



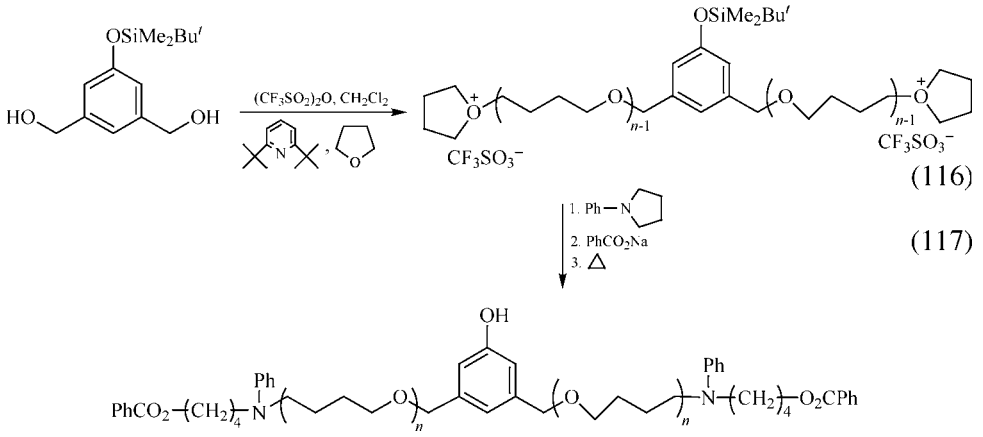
(114)

Heat treatment of the polymers carrying carboxylate anions results in a quantitative ring-opening reaction.



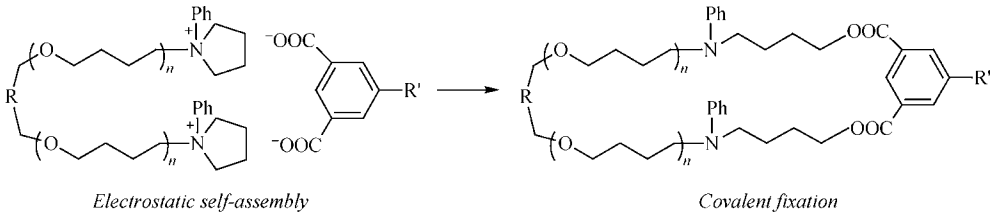
(115)

Another class of telechelic PTHFs has also been prepared, in which functional groups were located not only at the chain ends but also at the interior desired position. In this case, the *tert*-butyldimethylsilyl-protecting group was removed during the precipitation to yield α,ω-*kentro*-telechelic polymers (312).



Moreover, *eso*-telechelic PTHF having pyrrolidinium salt groups at the prescribed inner positions were also prepared (313).

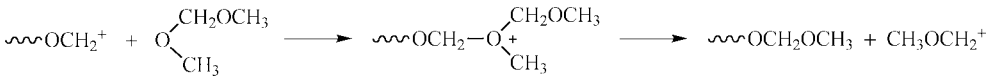
Cyclic polymers, having one or two functional groups, are termed as *kyklo*-telechelics with analogy to the Greek word *kyklos* (which means cyclic). Such telechelics can be prepared again by the electrostatic self-assembly and covalent fixation process as depicted in reaction (118).



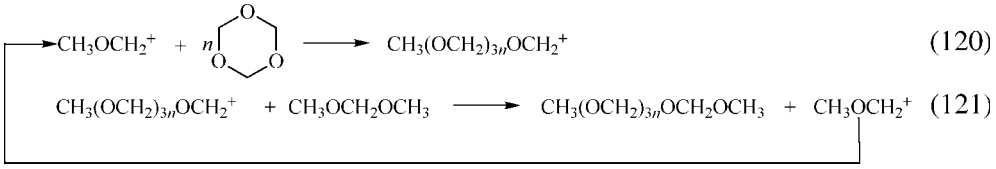
(118)

By suitably selecting R and R′ groups, various mono- and bifunctional telechelics having hydroxyl and allyl groups were prepared (314).

Cyclic Acetals. A number of cyclic acetals of varying ring size have been polymerized with cationic initiators (315); trioxane and dioxolane are the most important. Polymerization of trioxane in the presence of a transfer agent such as dimethyl formal or an anhydride yields polyoxymethylene with ether and ester end groups, respectively (316).



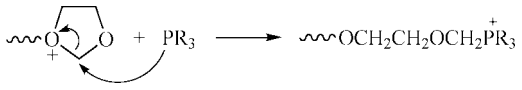
(119)



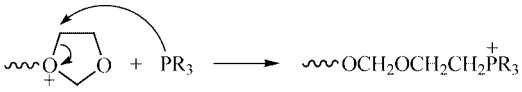
(120)

(121)

Triflic acid or anhydrides initiates polymerization of 1,3-dioxolane (DXL) and 1,3-dioxepane (DXP) (317). After transformation of the active ends into phosphonium salts, the functionality of these polymers was determined with ^{31}P NMR ($f = 2$).



(122)



(123)

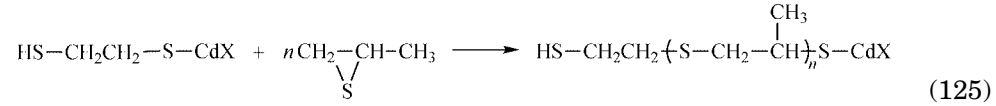
Another pathway yields a thermodynamically more stable product, but is kinetically less favorable. Because of extensive chain transfer the polymerization of DXL is not living. However, if a functionalized acetal is added to the monomer, telechelic polymers, eg α,ω-bisacrylate of poly(DXL) (318), are obtained. Similarly, addition of trimethylamine to growing poly(DXL) initiated with triethyloxonium hexafluoroantimonate yields telechelics with one trimethylammonium and one ethoxy end group (319).

An activated monomer mechanism similar to that described for oxiranes has been proposed to account for the formation of hydroxy-terminated poly(DXL) (320).

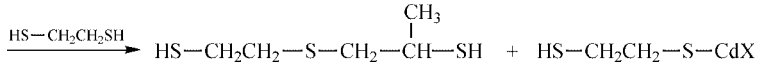
Cyclic Sulfides. The three-membered cyclic thiiranes can be polymerized cationically, anionically, or by a coordination mechanism. The four-membered cyclic thietanes can be polymerized by cationic and anionic mechanisms, but five-membered rings cannot be polymerized. Polymerization of propylenesulfide initiated with sodium naphthalene yields telechelics with naphthalene groups on both ends, if the living chain is terminated 1-chloromethylnaphthalene (321).

The propagating species in the anionic polymerization of propylene sulfide are thiolate anions, and therefore, reactions 124-126 can be used for the synthesis of α,ω-mercaptopoly(propylene sulfide)s (321,322).

(124)



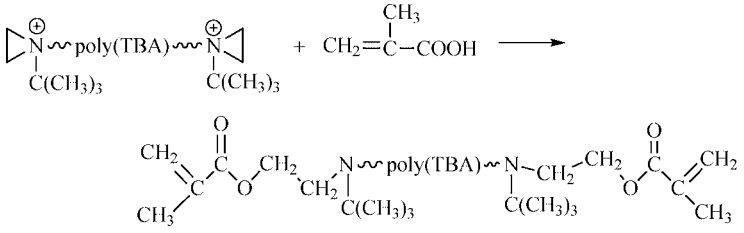
(125)



(126)

The cationic polymerization of thiiranes has not been reported as a method for the synthesis of telechelics, because of the rapid chain transfer to polymer and degradation of the active polymer to low molecular weight cyclic products (323).

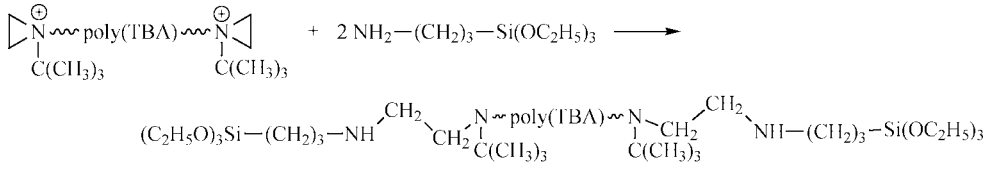
Cyclic Amines. The three-membered cyclic amines and the four-membered cyclic amines can be polymerized only by cationic mechanism (324). Monofunctional initiators, such as methyl triflate (325), produce monofunctional telechelics from *t*-butylaziridine (TBA). Addition of the monomer to a bifunctional living PTHF solution (326) gives bifunctional poly(TBA). This is a method of making ABA block copolymers. The aziridinium end groups react with acrylic acids to form the corresponding esters (327).



(127)

Reactions with pyrommellitic acid or with polyamines such as diethylenetriamine give cross-linked products (328).

End capping with γ-aminopropyltriethoxysilane groups yields telechelics that form networks after hydrolysis (328).



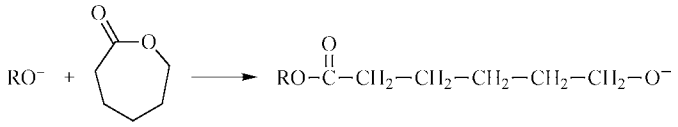
(128)

Lactones. Lactones are polymerized by anionic and cationic initiators (329). Nearly all four-, seven-, and eight-membered rings polymerize, but the five-membered rings do not, nor do many of six-membered rings (see RING-OPENING POLYMERIZATION).

The anionic initiators for the polymerization of β-lactones are usually organic bases such as tertiary amines (330). The chain transfer reactions involving a proton abstraction form the α-position and α,β-unsaturation can be avoided with α,α-disubstituted-propiolactones such as pivalactone (331–333).

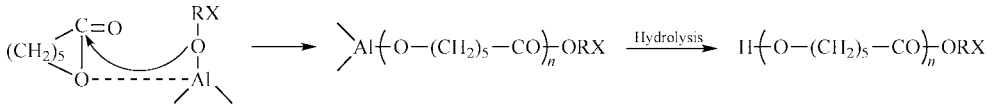
Pivalactone (α,α-dimethyl-β-propiolactone) (PVL) can be converted to telechelics and used for the preparation of block copolymers (331,332). An asymmetrical telechelic is prepared from PVL (334) with cyclic amine initiators. These telechelics have α-cycloammonium and ω-carboxyl end groups.

ε-Caprolactone can be polymerized by alcoholates.



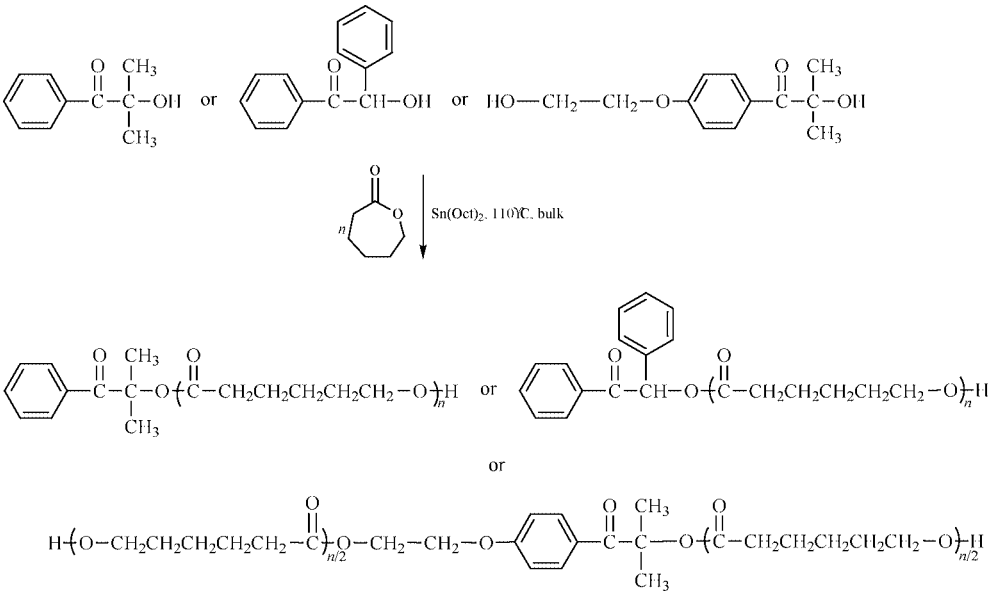
(129)

An alcoholate end group can, however, attack the ester groups of the chain, broadening the molecular weight distribution (335,336) and forming cyclic monomers. Living polymers of ε-caprolactone have been obtained with bimetallic oxoalkoxides and porphionato aluminum alcoholates (337). The selective end group functionalization of poly(ε-caprolactone) (PCL) was investigated by using aluminum alkoxides carrying functional alkoxy groups as initiators (338–341). Aluminum alkoxides carrying functional alkoxy groups (X = Br, $-CH_2N(Et)_2$, $-CH_2-CH=CH_2$, $-CH_2OC(O)C(CH_3)=CH_2$, etc) provide asymmetrical telechelic polyesters (342–344).



(130)

It was also shown that functional zinc alkoxides are also effective initiators for the ring-opening polymerization of ε-caprolactone under very mild conditions via a polymerization mechanism described for aluminum alkoxides (345). Tin octoate, $Sn(O(O)CCH(C_2H_5)C_4H_9)_2$, is another type of initiator to synthesize telechelics based on PCL. In particular, when it is used in conjunction with hydroxyl functional compounds or prepolymers, telechelics, linear and star-shaped block copolymers, or networks can be obtained via corresponding alkyl octoate formation (346–354). More recently, novel end-chain and mid-chain telechelics functionalized with photoactive groups of PCL were synthesized (355).



(131)

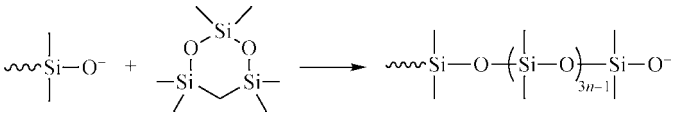
It was also reported that macromonomers based on end-functionalized PCL were prepared by different strategies using lipase enzymes as the catalysts (356–359). In the first strategy, an alcohol containing the target end-functionality initiated the ring-opening polymerization of ε-caprolactone. Alternatively, acids and esters containing the target end-functionality were added to prepolymerized ε-caprolactone. Either or both strategies yielded mono- and ditelechelics (359).

Hydroxy telechelics of PCL can be transformed to thiol functionalized polymers under mild conditions by using 2,4-dinitrophenylthioacetic acid as the protecting group (360).

ε-Caprolactone polymerization initiated with trialkyloxonium salt in combination with an alcohol (361) is easily controlled. A similar reaction has been described for cyclic ethers (288).

Siloxanes. Polysiloxanes are used as segments in block copolymers because of their low temperature flexibility, high gas permeabilities, excellent electrical properties, biocompatibility, and surface properties.

Linear polysiloxanes are prepared by anionic and cationic polymerization of cyclosiloxanes (362), such as hexamethylcyclotrisiloxane (D_3) and octamethylcylotetrasiloxane (D_4). Anionic polymerization is initiated by hydroxides, alcoholates, phenolates, silanolates, and siloxanolates. The active species is the silanolate anion.

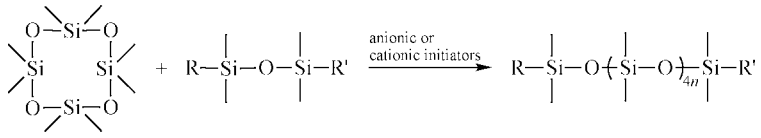


(132)

Cationic polymerization is initiated by strong protonic acids, such as sulfuric acid, trifluoromethane sulfuric acid, or trifluoroacetic acid.

Both anionic and cationic species undergo backbiting during polymerization, creating equilibrium between chains and rings (363,364).

Bifunctional polysiloxanes with a variety of end groups are obtained by using end blockers with different end groups R (365–367).



(133)

End groups include amino, dimethylamino, piperazine, carboxyl, ethylene oxide, and hydroxymethylene (Table 8).

A large number of polysiloxanes with functional end groups are commercially available (368).

The hydrosilation of unsaturated functional compounds with polysiloxanes containing Si—H end groups can also be used for the preparation of polysiloxane telechelics (369).

Table 8. Commercial Telechelic Polydimethylsiloxanes[a]

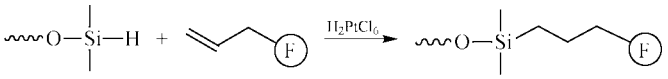
[a] Ref. 368.

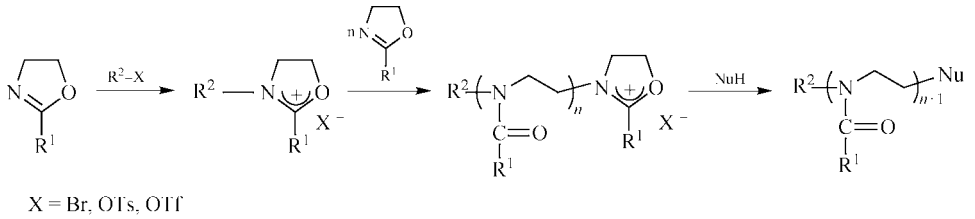


(134)

Synthesis of chain or end-functional polysiloxanes with methacrylate (370), hydroxy propyl (371), epoxy (372), benzoin (373), carboxyl ester or carboxyl amido (374), and chloromethylphenethyl (375) groups were described.

Alternatively, the chemical transformation of functional groups attached to the siloxane prepolymers by reacting with appropriate reagents provides desired functionalization. For example, electroactive pyrrole functional polysiloxanes were prepared from the corresponding amino telechelics (375).

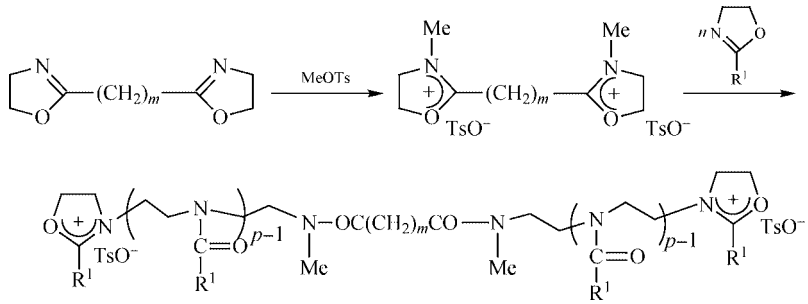
Oxazolines. Cationic polymerization of 2-alkyl-2-oxazolines provides an excellent methodology for the easy introduction of functional end groups (376). Polymerization proceeds via oxazolinium species and functional groups can be incorporated at both initiation and termination steps by using functional initiator and nucleophile, respectively.



X = Br, OTs, OTf

(135)

Poly(oxazoline) telechelics with hydroxyl, amino, triphenylphosphonium, piperidine, pyrrole, styryl, acrylamide, acrylate, methacrylate, and butadiene end groups were successfully synthesized (377–387). Reaction of methyltosylate (MeOTs) with bisoxazolines gives rise to the formation of bis(oxazolinium tosylate) (387). Living polymerization of monofunctional oxazolines having propagating species at both ends can be initiated by the addition of the monomer.



(136)

Termination of the living ends with suitable nucleophiles yields difunctional thiol, vinylbenyzl, carboxylic acid, *t*-butylmalonate, benzyl and unsaturated ester telechelics (387–389).

Metathesis Polymerization

Olefin metathesis has been of interest both industrially and academically because of its great synthetic utility (4). Mechanistically related metathesis reactions include ring opening metathesis (ROM), ring-closing metathesis (RCM), cross-metathesis (CM), acyclic diene metathesis (ADMET) polymerization, and ring-opening metathesis polymerization (ROMP) (Fig. 12) (5–8,390,391).

Acyclic Diene Metathesis Polymerization. Acyclic diene metathesis (ADMET) and the other metathesis polymerization methods are closely related to the catalyst system employed. Besides classical catalysts, Schrock-type alkylidenes and Grubbs-type carbenes can be used in ADMET polymerization.

ADMET polymerization and depolymerization methods have been used in the synthesis of telechelic oligomers. The metathesis depolymerization of 1,4-polybutadiene is accomplished in the presence or absence of a monofunctional diene by using either of the catalysts presented in Figure 13. Telechelic oligomers with terminal alkene, ester, and silyl ether and imide functional groups may be

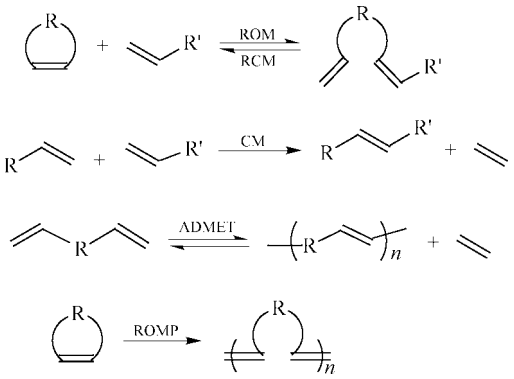


Fig. 12. Metathesis pathways.

prepared (392,393). Amine and alcohol functions are not well tolerated with the current catalysts and can be incorporated to polymers by using protecting group strategy. Telechelics with both of these types of end groups were synthesized using direct ADMET polymerization of dienes in the presence of a functional group protected α-olefin (394,395).

Ring-Opening Metathesis Polymerization. In ring-opening metathesis polymerization (ROMP), the use of functionalized acyclic alkenes as chain transfer agents not only permits the regulation of the polymer molecular weight but also opens a simple and efficient route to telechelics (4). Because of their higher reactivity, *cis*-alkenes are preferably employed for this purpose.

A broad variety of difunctional allylic olefins have been used for the synthesis of amino-, carboxyl-, and halide-terminated polybutadienes by means of the Grubbs catalyst **I** (396–398). With the same catalyst, commercially interesting hydroxy telechelic polybutadienes could be obtained by the cleavage of the acetyl end-capped polymer or the copolymer, as depicted in Figure 14 (399,400).

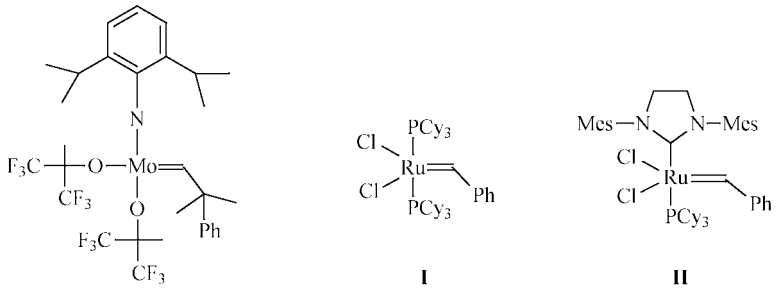

Fig. 13. Well-defined metathesis catalysts.

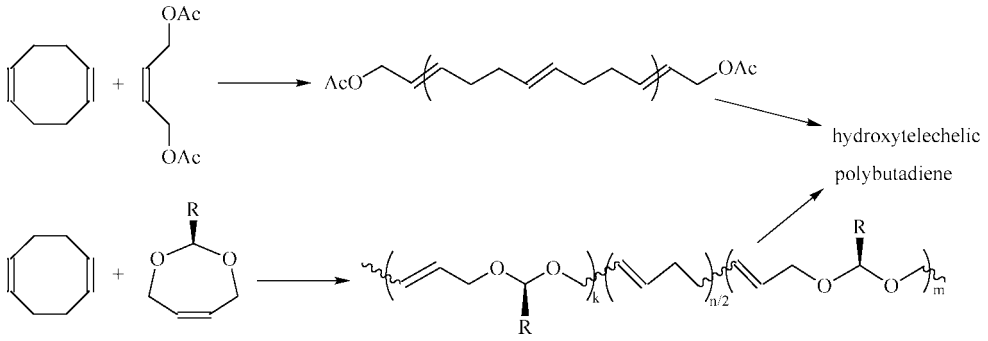

Fig. 14. Hydroxytelechelic polybutadiene by ROMP and hydrolysis.

ROMP in the presence of unprotected alcohols led to decreased yields and significant amounts of aldehyde end groups due to isomerization (399–401). However, ROMP with the addition of 1,4-bis(acetoxy)-2-butene (43) or even the related unprotected diols was performed successfully with the highly active Grubbs catalyst **II**. In the latter case, THF was added to minimize isomerization to aldehydes (401). Br- and Cl-telechelic poly(butadiene)s were employed for the synthesis of ABA triblock copolymers by subsequent grafting from the ROM polymers with methyl methacrylate (MMA) or styrene via ATRP (398). The preparation of poly(butadiene)s with cross-linkable end groups, such as epoxides or methacrylates, was reported by Grubbs and co-workers (402). Related syntheses of acetoxy end-terminated polymers with Grubbs-type catalysts were performed not only for cyclooctadiene but also for norbornene and 7-oxanorbornene derivatives (403,404).

End-functionalized poly(norbornene)s capped with one or two acetoxy or alcohol groups were prepared with the Grubbs catalyst **I** and mixed NHC/phosphine catalysts (405). Acetoxy and hydroxyl end-capped polymers were prepared by Gibson and Okada from bis(*tert*-butylester)-substituted norbornene by means of the Grubbs catalyst **I**. Subsequent hydrogenation of the hydroxy functionalized polymer gave the corresponding poly(norbornene) (406).

A further interesting approach for chain-end functionalization was reported. The treatment of a living ROM polymer Grubbs catalyst **I** with molecular oxygen led to monoaldehyde-end-capped polymers in high yields (407). With W- or Mo-based catalysts, the analogous synthetic protocol would partially lead to a coupling reaction, thereby yielding polymers with doubled molecular weight (6,407,408).

The synthesis of a homologous series of unsatured oligomeric esters by cross-metathesis of cyclopentene and MMA is reported (409,410). Ozawa and co-workers (411) reported on the polymerization of norbornene in the presence of various functionalized terminal olefins as chain-transfer agents. Mechanistic considerations let them assume that the obtained polymers each bore one vinyl end group and one functional end group.

Nomura and co-workers reported that norbornene-based macromonomers of the following structure (Fig. 15) containing ring-opened poly(norbornene) derivatives in the side chain can be prepared efficiently by the ROMP using well-defined molybdenum catalysts and subsequent end-group reactions (412,413).

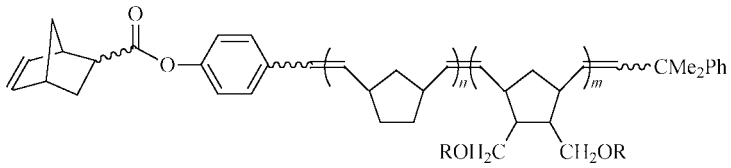

Fig. 15. Structure norbornene-based macromonomers.

Interestingly, these macromonomers were copolymerized with norbornene derivatives via ROMP to yield various macromolecular architectures (414).

ROMP approach was also applied by several groups to prepare polymers having functional groups reactive toward ATRP (398,414,415).

Chain Scission

Telechelics can also be prepared by the cleavage of high molecular weight moieties by oxidation, reduction, rearrangements, and irradiation (Table 9).

Oxidation. Treatment of PVC with ozone (416–418) gives telechelics; the attack probably starts at the vinyl double bonds.

Ozonolysis can be used as an analytical method for polymers containing carbon–carbon double bonds (438–441).

Acid, acid chlorides, and hydroxy-functionalized telechelics have been described (418). The reaction of polybutadiene with controlled amounts of ozone can be used to prepare hydroxy-terminated telechelic polybutadienes (419). The oxidative cleavage of copolymers of isobutylene with dienes has been studied

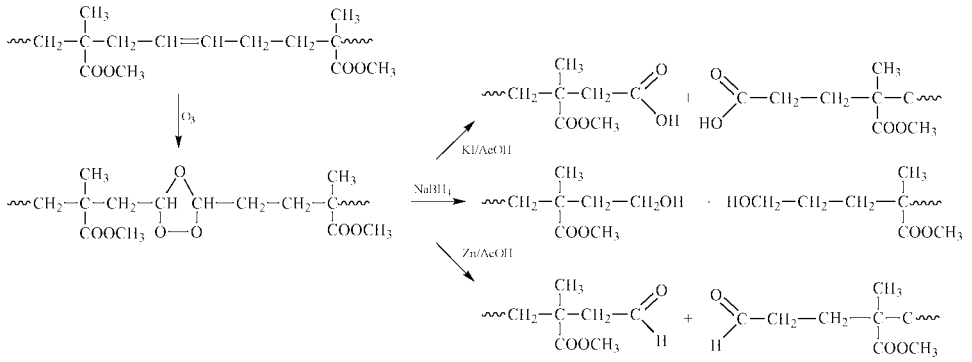

Fig. 16. Telechelic oligomers by ozonolysis.

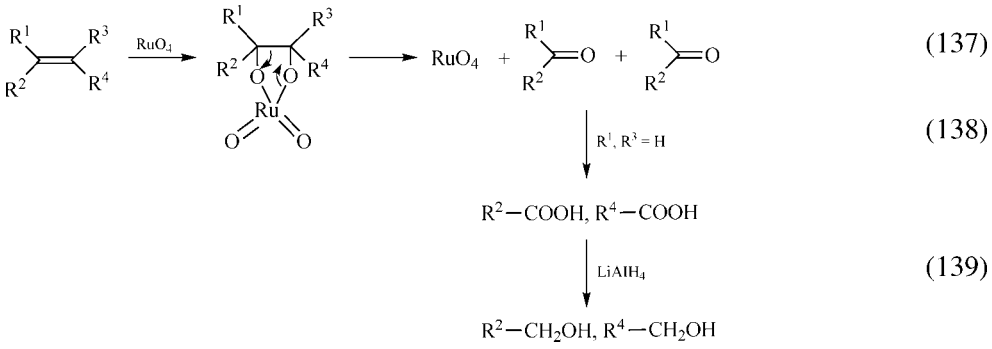
extensively (442–444), in particular the formation of carboxyl-terminated telechelics
(424–427). Ebdon and co-workers (445–451) prepared a variety of telechelic oligomers with terminal aldehyde, hydroxyl, ketone, or carboxylic end groups by ozonolysis of suitable copolymers of MMA or St containing small amounts of C=C bonds (Fig. 16). These bonds were introduced using either a diene or acetylene as comonomer.

Polystyrene and a poly(styrene-*stat*-butadiene) have been reacted with ozone in various solvents to establish conditions necessary for the production of telechelics having high and controllable end group functionalities. Workup with sodium borohydride or Zn/acetic acid gives dihydroxy- or dialdehyde-ended oligostyrenes, respectively. Oxidative workup with SeO_2/H_2O_2 yields carboxyl end groups. Side reactions associated with the synthesis of telechelic oligostyrenes by the ozonolysis route, ie, attack of the α-position of the backbone but also of the aromatic unit, can be minimized by the use of *N*-dialkyl amides as ozone scavenger (452).

Side reactions can be avoided with a selective oxidizing agent such as ruthenium tetroxide (453) which is soluble in many solvents. It can be used in catalytic quantities in combination with another oxidizing agent, eg, peracetic acid (454). Ruthenium dioxide in combination with periodate can be used in water or in organic solvents in the presence of a phase transfer catalyst (424,425).



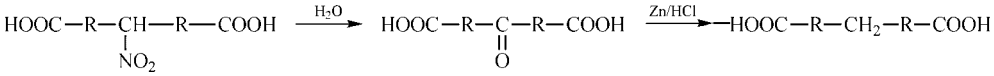
(137)

(138)

(139)

Butyl rubber yields asymmetrical α-carboxyl-ω-ketone telechelics with RuO_4, whereas poly(isobutylene-*co*-2,3-dimethylbutadiene) yields symmetrical α,ω-ketone and α,ω-carboxyl telechelics (426–429). If the incorporation of the diene is sterically specific, ideal functionalization ($f = 2$) can be obtained with these methods, provided that high molecular weight starting materials are employed (430). Cleavage of partially hydrogenated polybutadiene with RuO_4 gives α,ω-carboxypolyethylene (431).

Many other oxidizing agents can be used to cleave polymer chains. For example, fuming nitric acid cleaves polyethylene to yield carboxyl telechelic polyethylene (455–459). However, nitration of the polymer chain is a side reaction. The nitro groups can be converted to ketones without further reduction of molecular weight (460).



(140)

Reduction. Liquid thiokols are telechelics produced commercially by a reductive cleavage reaction (434–438).

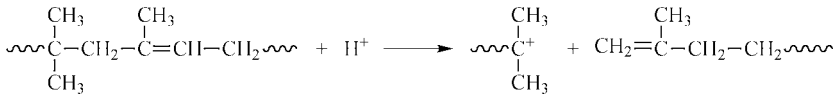
(141)

(142)

(143)

Other Degradation Methods. Ethylene–propylene telechelics with hydroxyl end groups (437) are prepared by thermal degradation followed by ozonolysis and reduction of the end group by an alkylaluminum compound. Products with molecular weights of approx 1000 with a functionality $f = 1.7$ were obtained (437).

Degradation of polyisobutylene or poly(isobutylene-*co*-isopropylene) at low temperature in the presence of a Lewis acid yields α,ω-diolefin telechelics (461).



(144)

The radiolysis of polyisobutylene also gives α,ω-olefin telechelics (462).

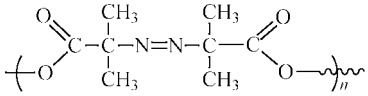


Fig. 17. Polyazoester.

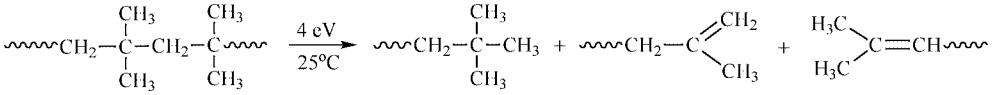
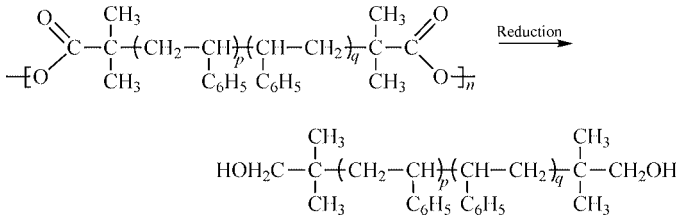


(145)

An interesting pathway to telechelics is the synthesis of polymers containing heat- or light-sensitive groups in the main chain, for example, azo groups (432, 433,463). Thus, polycondensation of AIBN with diols yields polyesters (Fig. 17).

Decomposition of the azo function in the presence of styrene yields AB block copolymers, which can be converted into α,ω-dihydroxyl polystyrene by a reductive cleavage of the ester bonds.



(146)

Another potential photochemical route to prepare telechelics is the photolysis of copolymers of MMA with various vinylketones. Upon irradiation these copolymers undergo chain scission almost entirely by a Norrish Type I process, giving oligomers with allylic end groups (464,465).

Step-Growth Polymerization

Step-growth polymerization is a simple method of preparing reactive oligomers (466), many of which cannot be prepared by the methods described previously. Increasing commercialization of thermoplastic elastomers, based on tri- or multiblock copolymers, has led to a growing interest in telechelics of polymers with high glass-transition temperatures, which may be used as rigid blocks. Polymers with high glass-transition temperatures are frequently prepared by a step-growth polymerization. Almost all functional groups can, in principle, be utilized for step-growth polymerization. However, side reactions such as cyclization and decarboxylation limit the molecular weight, functionality, and yield. AR^1A and BR^2B are followed to react ($x < y$),

(147)

and the molecular weight of the products is given by

$$D\bar{P}_n = \frac{(1+r)}{(1+r-2rp)}$$

where DP_n is the number-average degree of polymerization, $r = (AR^1A):(BR^2B)$ with $(AR^1A) < (BR^2B)$, and p = conversion of AR^1A.

At 100% conversion of the minor reactant, the molecular weight of the product is determined by the following equation:

$$D\bar{P}_n = \frac{(1+r)}{(1-r)}$$

and the end groups are those of the major component.

This method can be applied for the preparation of α,ω-dicarboxyoligoesters, α,ω-dicarboxyoligoamides. It has also been applied to the preparation of α,ω-diphenol oligocarbonates and epoxy resins (467–472).

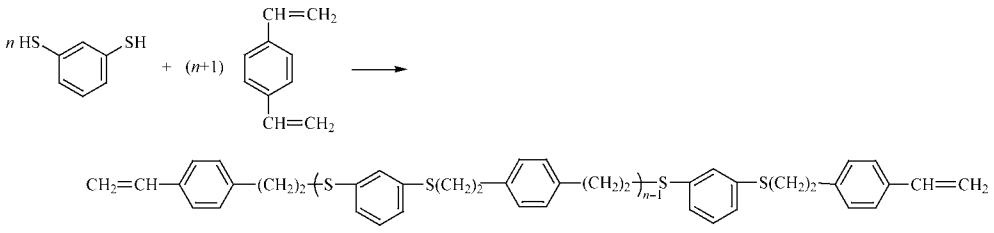
In an alternative method of achieving nonstoichiometry, AR^3X or BR^4X (where X represents a functional group which does not react with A or B) is added to the reaction system. At complete conversion, X forms the end groups of the polymer:

$$n\,AR^1A + n\,BR^2B + m\,BR^4X \longrightarrow XR^4B\text{—}(AR^1ABR^2B)_n\text{—}R^4X \qquad (148)$$

The latter method is also useful for preparing monofunctional telechelics. In this case a monofunctional reactant is used. For example, R^4B gives

$$n\,AR^1A + n\,BR^2B + R^4B \longrightarrow R^4\text{—}(BAR^1ABR^2)_n\text{—}B \qquad (149)$$

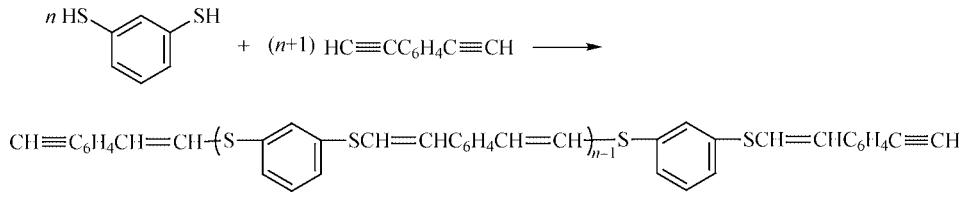
Nonstoichiometric Reactions. This addition of an SH group to a carbon–carbon double bond involves radical intermediates, but nevertheless exhibits the typical features of a polycondensation reaction. The end group and molecular weight are controlled by stoichiometry of the reactants (473).



(150)

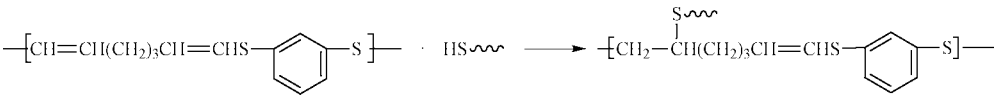
Thus an excess of the divinyl reactant yields products with olefinic end groups, whereas an excess of the dithiol component yields products with mercapto end groups. For products of molecular weight below 5000, end group analysis can be used to determine the molecular weight. Similar addition reactions have also

been carried out with triple bonds (474,475), ie using 1,4-diethynylbenzene in place of DVB.



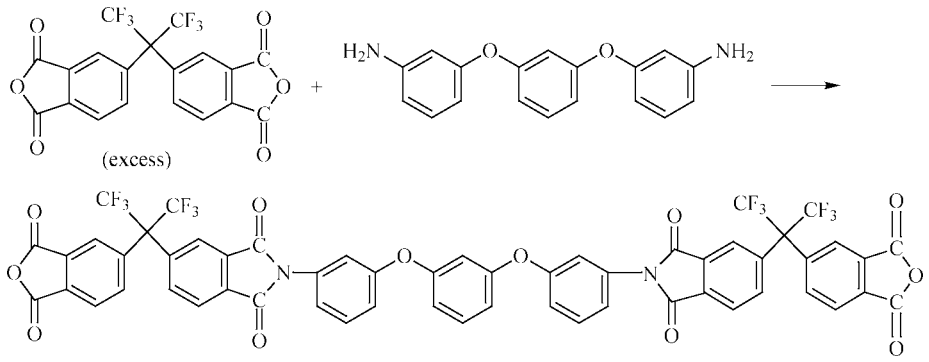
(151)

Aliphatic α,ω-dialkynes give telechelics only when the alkyne is used in excess. If the dithiol is in excess, the SH end groups react with the double bonds of the polymer backbone to produce branched or finally cross-linked products.



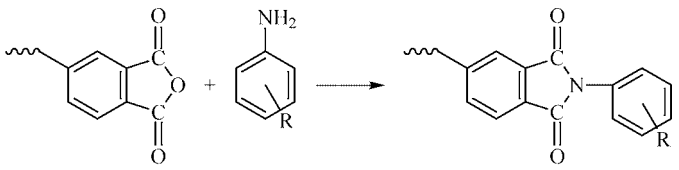
(152)

Telechelics can also be prepared by conventional polycondensation (476).



(153)

The acid anhydride end groups can subsequently be modified by reaction with substituted aromatic amines.



where R = — $CH{=}CH_2$, —$CH{=}CH{-}CH{=}CH_2$, or —$CH{=}CHC_6H_5$ (154)

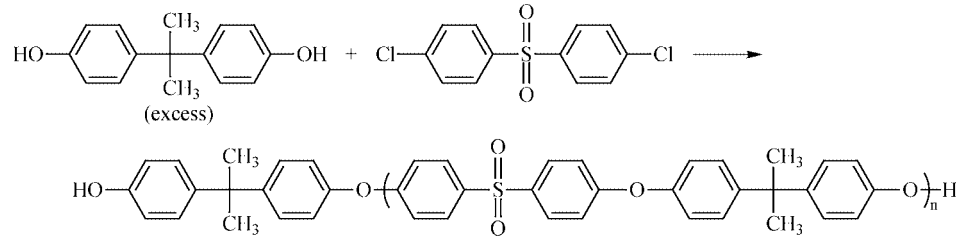
7	3320	3600		3380

[a] Ref. 482.
[b] Number-average.

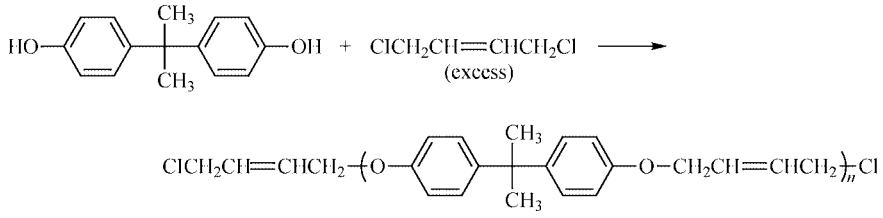
Other examples of telechelic synthesis by polycondensation reactions involving an excess of one of the reactants, followed by modification of the resulting end groups, have also been described (477–481).

Studies (482,483) of the polycondensation of bisphenol A and *p*-dichlorodiphenyl sulfone show that molecular weight and end groups can be controlled by using nonstoichiometric ratios of the reactants; agreement with theory is excellent (Table 10).



(155)

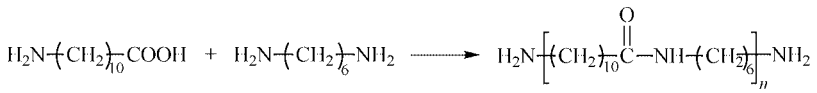
With the aid of phase-transfer catalysts, several polycondensates can be obtained under mild conditions. An example is given in reaction 156:



(156)

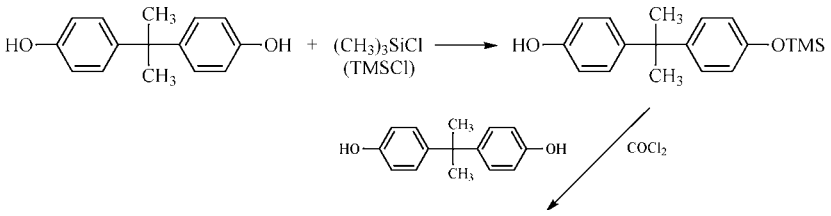
This reaction was carried out in a water–chlorobenzene mixture in the presence of NaOH and tetrabutyl ammonium hydrogen sulfate (484).

For polycondensation where a single reactant contains both functional groups, an additional reactant can achieve the necessary nonstoichiometry:



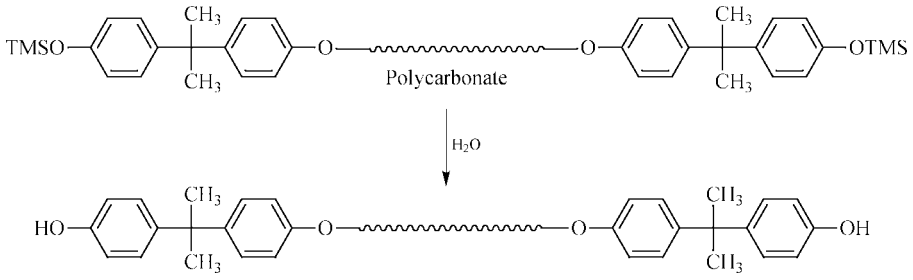
(157)

End groups and molecular weight are controlled by the diamine concentration (485). The introduction of protecting groups results in the following reactions (486):



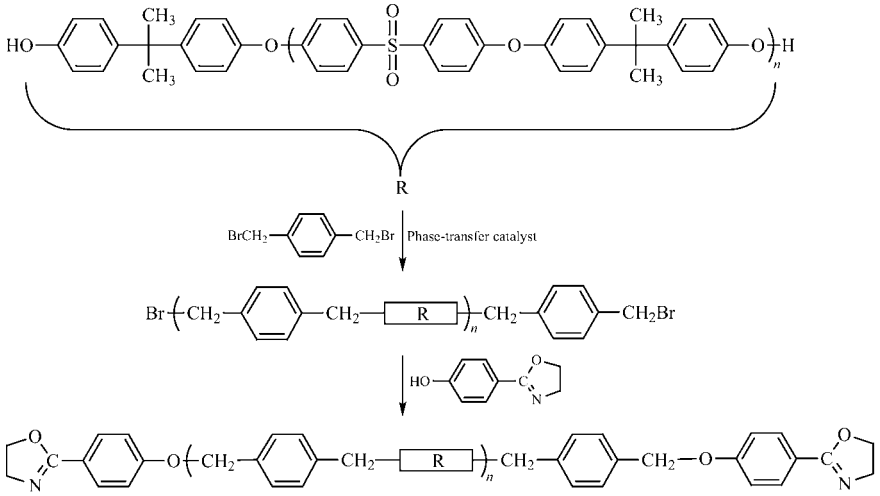
(158)

(159)



(160)

Phase-transfer catalysts have also been used for the modification of telechelics (487).



(161)

(162)

Macromonomers

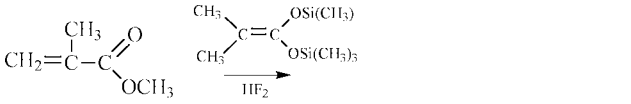
Macromolecular monomers, called *macromonomers* or *macromers*, can be defined as oligomers or polymers with a polymerizable end group. Such groups may be

vinyl, acrylic, heterocyclic (ring opening polymerization), dicarboxylic, or dihydroxylic (step-growth polymerization). The increasing interest in these materials stems from the growing need for well-defined graft copolymers for which macromonomers often are ideal starting materials (488–496). The length and number of branches of the graft copolymers can be controlled by the molar mass and feed ratio of macromonomers to comonomers. In the previous sections, the synthesis of macromonomers has been described particularly when the chemistry involved is similar to that for the telechelics with other functional groups. The principal focus of the following part will be to describe well-established general approaches for the synthesis of macromonomers. For a wider view, the reader's attention should be directed to the review articles (279,280,497,498) and a book (499) solely devoted to macromonomers.

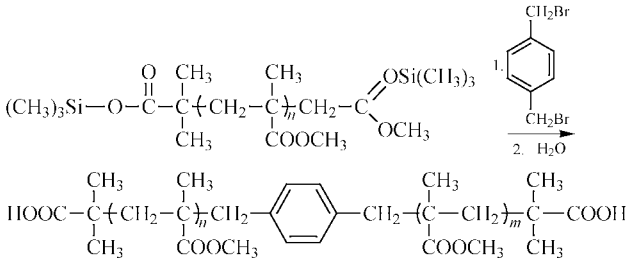
Anionic Polymerization. Anionic methods for the synthesis of macromonomers can be divided into initiation and end-capping (Table 11).

Although the initiation method is widely used, side reactions of the unsaturated head groups often lead to low functionality.

Polar monomers, such as MMA, rarely give high yields of macromonomers by straightforward anionic polymerization. However, group-transfer polymerization (517–522), which is a special case of Anionic Polymerization (qv), gives macromonomers with perfect functionality.



(163)

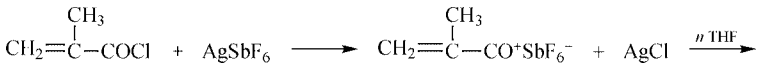


(164)

The reaction of the alcoholate of polyoxyethylene with acetylene yields a macromonomer (523).

(165)

Cationic Polymerization. Both initiator and end-capping methods can be used to obtain macromonomers by cationic polymerization (see CARBOCATIONIC POLYMERIZATION). Telechelics can be made this way from PTHF (Table 12). A typical reaction is given below:



(166)

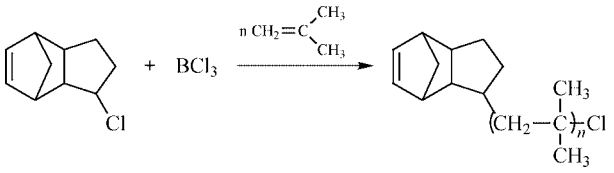
			529

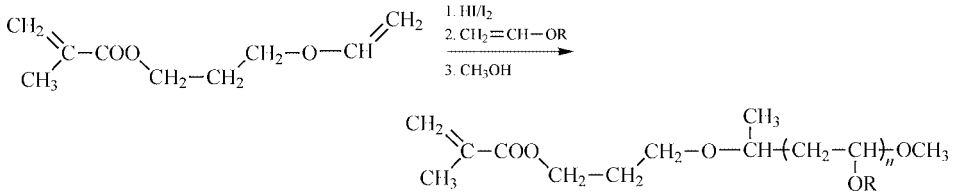
Macromonomers from 2-isobutylene have been prepared by the inifer method (532,533).



(170)

This macromonomer has been copolymerized with ethylene and propylene in the presence of Ziegler–Natta catalysts.

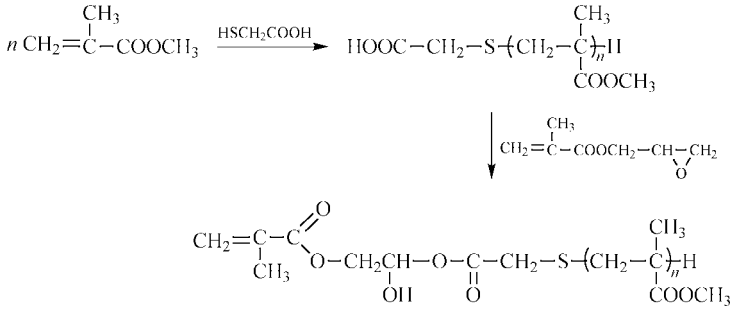
The living polymerization of vinyl ethers using the HI/I_2 (534,535) or the acetal/TMST method (536) can be used for macromonomer synthesis.



(171)

These macromonomers are characterized by narrow molecular weight distribution and excellent functionality.

Radical Polymerization. Macromonomers can also be synthesized by radical polymerization (537,538).



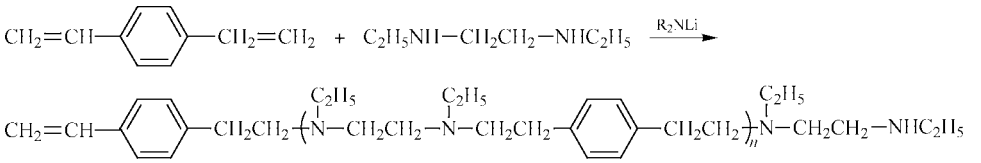
(172)

With thioglycolic acid as a chain-transfer agent, macromonomers are prepared from dimethylaminoethyl methacrylate and other acrylate and methacrylate derivatives (539). Iodoacetic acid is used as the transfer agent for polystyrene macromonomers (540).

3-Mercaptopropionic acid can be used as a transfer agent for preparing telechelics from acrylamide and *N*-vinylpyrrolidone (541).

All these reactions first lead to simple COOH-terminated (monotelechelic) polymers and are converted into macromonomers by a glycidylmethacrylate (eg reaction 172).

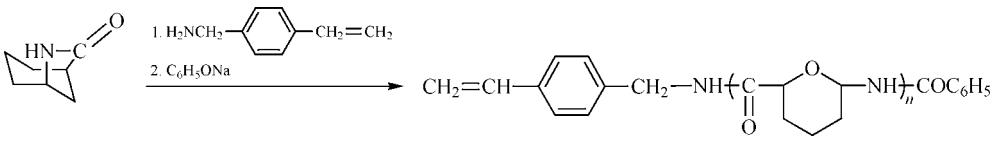
Other Methods. Reaction between DVB and 1,2-ethylamino ethylene in the presence of lithium amide yields macromonomers (542,543).



(173)

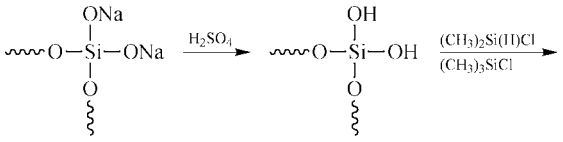
Macromonomers of poly(crown ether)s (543) and polypeptides (544) have also been prepared by this method.

The ring-opening polymerization of bicyclic oxalactams gives macromonomers (545,546).



(174)

Nonpolymerizable end groups can be converted into polymerizable end groups in the presence of phase-transfer catalysts (484,547). An example of this technique is the synthesis of macromonomers from water glass (548).



(175)

TEMPLATE POLYMERIZATION

Introduction

The term "replica" polymerization for polymerization of simple vinyl monomers was first used by M. Szwarc (1) in 1954, and then displaced by "matrix" or "template" polymerization (2). Since this time, many articles and reviews have been published (3–11). The concept of template polymerization originates from natural processes such as DNA replication and the biosynthesis of proteins. As we know, the growth of living organisms is associated with very complicated processes of polymerization. Low molecular weight substrates—such as sugars, amino acids, fats, water in animals, and carbon dioxide in plants—are precursors of polymers (polypeptides, polynucleic acids, polysaccharides, etc.) (see POLYPEPTIDE SYNTHESIS; POLYNUCLEOTIDES; POLYSACCHARIDES). They are organized in tissues and are thus reproducible. In many biological reactions, such as DNA replication

Encyclopedia of Polymer Science and Technology. Copyright John Wiley & Sons, Inc. All rights reserved.

or polypeptide creation, not only are low molecular weight substrates and polymeric products present in the reaction medium, but also macromolecular compounds called matrices or templates which control the process. In spite of the fact that only nonbiological systems are discussed here, the biological processes constitute an inimitable model for template polymerization of synthetic monomers. In both cases, the process (synthetic or natural) is connected with the ability of two polymers (template- and polymer-produced—often named the daughter polymer) to form more or less stable interpolymer complexes.

Template polymerization is a particular case of a more general group of processes, such as polymerization in an organized system.

Many factors may affect the organization of monomer units during polymerization. For example, solid-state polymerization takes place when molecules of the monomer are surrounded by molecules already organized in a crystal lattice. A specific type of polymerization occurs on the surface of solids. Numerous monomers with long hydrocarbon chains can form monolayers at the gas–water interface, and are also oriented at the surface of the water. The polymerization of such organized systems leads to the preparation of polymers with peculiar morphology and properties. It is the method for polymer synthesis in ultrathin films in different form. Polymerization in the presence of minerals and clays is considered to have occurred on earth before life started. For instance, montmorillonite binds proteins so strongly that they cannot be washed out without being destroyed. Another type of polymerization of organized systems is polymerization in a liquid crystalline state.

However, in this article the term *template polymerization* will only be used for one-phase systems. The *template* is usually a linear preformed polymer added to the polymerization system.

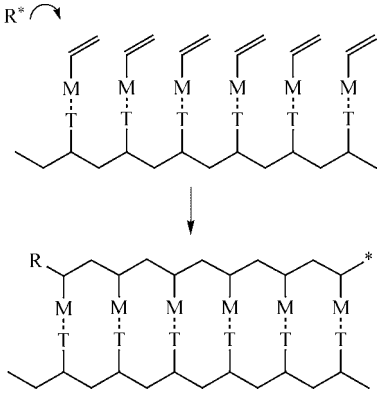
When studying template systems, it is important to compare the template process and products of the reaction with conventional polymerization carried out under the same conditions but in a system in which the template is replaced by a low molecular nonpolymerizable analogue (blank reaction). The influence of the template on the process and on the product is usually called the *template effect* or the *chain effect* (3–6). The template effects can be expressed as follows:

(1) *Kinetic effect*: usually an enhancement of the reaction rate and changes in the kinetic equation;
(2) *Molecular effect*: the influence on the molecular weight and molecular weight distribution of the daughter polymer. In the ideal case, the degree of polymerization of the daughter polymer is the same as the degree of polymerization of the template used, which is sometimes called replication;
(3) *Effect on tacticity*: the daughter polymer may have a complementary structure to the structure of the template used;
(4) in the case of template copolymerization, the template effect deals with the change in reactivity ratios and the sequence distribution of units. This effect is very important in biological synthesis, for instance in DNA replication.

The template processes can proceed as template polycondensation, polyaddition, ring-opening polymerisation (qv), and ionic or radical polymerization (qv) (6,7) and the general rules characteristic for these processes can be applied.

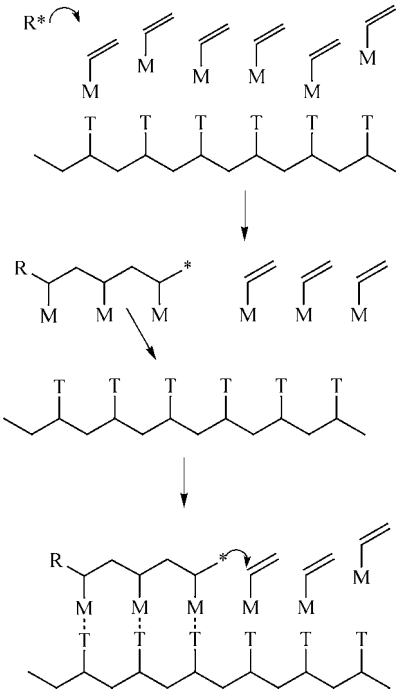
Radical Template Polymerization

Much information and experimental data have been published about radical template polymerization. It is generally accepted (3–11) that template polymerization can proceed according to two different mechanisms: type I (the "zip" mechanism) or type II (the "pick-up" mechanism). In the case of type I, monomer units are connected to a template by strong forces (electrostatic, hydrogen bridges, or even covalent bonds). This is illustrated in the following scheme:



(1)

In the type II case, the monomer at the beginning of the reaction is "free" and polymerization starts outside the template. When oligoradicals reach a critical length, complexation with the template occurs, and propagation proceeds along the template by adding monomer molecules from the surrounding solution. This is illustrated in the following scheme:



(2)

Tan and Challa (3,4) proposed using the relationship between the relative polymerization rate R_{rel} and concentration of monomer or template as a criterion for distinguishing between type I and type II template polymerization.

The most popular method is to examine the initial rate or relative rate R_{rel} as a function of base mole concentration of the template, [T], at constant monomer concentration [M].

For type I mechanism, when strong interactions exist between the monomer and the template, R_{rel} vs [T] shows a maximum for $[T] = [M]_0$.

For type II mechanism, R_{rel} increases with [T] to the critical concentration of the template, c^* (the concentration at which template macromolecules start to overlap) and then remains stable. It is worth noting that c^* (concentration in moles per volume) depends on the molecular weight of the template. The most complete kinetic model for radical-initiated template polymerization has been developed and described by Tan and Alberda van Ekenstein (12).

Typical examples of template polymerization systems are listed in Table 1.

The propagation and termination rate constants have been determined for many systems (5,12,43–46). In most cases, the propagation rate constant is lower than that for a reaction carried out in the same conditions but without a template. The termination rate constant in the template polymerization is much lower in comparison with the blank reaction. Retarded termination may be caused by retarded segmental diffusion of the template-bound radicals. This leads to the template increasing the overall rate of polymerization. Much experimental data from the literature confirm this, and it is sometimes called the *kinetic template effect*.

It has been found that for many monomer–template–solvent systems, the rate of reaction is proportional to the initiator concentration in power n and monomer concentration in power m, as in simple radical polymerization (qv). However, exponents n and m in the presence of template are different in comparison with the same system without the template.

An interesting case of template polymerization was described by Papisov and co-workers (47–49). The authors used two templates with different strengths of interaction with respect to the daughter polymer. The first template was poly(vinylpyrrolidinone) and the second, poly(ethylene glycol monolaurate). Methacrylic acid was used as a monomer.

On the basis of kinetic measurements with various concentrations and ratios of both templates, the authors found that there are conditions in which poly(methacrylic acid) molecules, in the course of growing, move from the strong, but short poly(vinylpyrrolidinone) template to the weaker template—polyethylene glycol monolaurate micelles. The circumstances of such a substitution reaction (exchange reaction) are described by the equation

$$c_1 K_1^{\varepsilon 1} = c_2 K_2^{\varepsilon^*} \tag{3}$$

where c_1 and c_2 are concentrations of template 1 [poly(vinylpyrrolidinone)] and template 2 [poly(ethylene glycol monolaurate)], K_1 and K_2 are effective strength constants for templates 1 and 2, and ε_1 and ε^* are the corresponding degrees of polymerization.

The template effect of tacticity has been shown by several authors (15,50–53). These authors found that polymerization of methyl methacrylate in the presence of isotactic poly(methyl methacrylate) proceeds as a template reaction. Extensive

Table 1. Typical Examples of Template Polymerization Systems

Monomer	Template	Solvent	Initiator	Reference
Acrylic acid	Poly(ethylene imine)	H_2O	$K_2S_2O_8$	13
N-Vinylpyrrolidinone	Poly(acrylic acid)	DMF	$K_2S_2O_8$	14
Methyl methacrylate	iso-Poly(methyl methacrylate)	DMF	TBCP[a]	15
Acrylic acid	Poly(ethylene glycol)	H_2O	$K_2S_2O_8$	16
Methacrylic acid	Poly(ethylene glycol)	H_2O	$K_2S_2O_8$	16,17
Methacrylic acid	Poly(4-vinylpyridine)		AIBN	18
Methacrylic acid	Poly(2-vinylpyridine)	DMF, DMSO, dioxane	AIBN	19–21
Methacrylic acid	Poly(vinylpyrrolidinone)	H_2O	$Na_2S_2O_8$ or UO_2SO_4 + photo.	22–24
Acrylic acid	Poly(vinyl pyrrolidinone-*co*-acrylamide)	H_2O	$K_2S_2O_8$	25
p-Styrene sulfonic acid	Polybase ionenes	H_2O/isopropyl alcohol	AIBN	26,27
Vinyl sulfonic acid	Polybase ionenes		ACA[b]	26,27
Methacrylic acid, acrylic acid	Polybase ionenes	H_2O	$K_2S_2O_8$	28
Sodium acrylate	Poly(allylamine) hydrichloride	H_2O	$K_2S_2O_8$ AIBN	29
Sodium vinyl sulfonate	Poly(allylamine) hydrichloride	H_2O	$K_2S_2O_8$	30
Acrylic acid, sodium styrenesulfonate	Chitosan	H_2O	$K_2S_2O_8$	31
N-Vinylpyridine	Poly(acrylic acid)		None	32–34
N-Vinylimidazole	Poly(methacrylic acid)	H_2O	ABIAP[c]	35–39
N-Dimethylaminoethyl methacrylate	Poly(acrylic acid)	H_2O/acetone	AIBN + UV	40
Acrylic acid	Poly(acrylic acid)	Set of solvents	AIBN	41
Monomer with uracil groups	Polymer with adenine groups	pyridine	AIBN	42

[a] Bis(*p-tert*-butyl cyclohexyl) dipercarbonate.
[b] 4,4-Azobis-4-cyanovaleric acid.
[c] 2,2′-Azobis(2-amidopropane) · 2HCl.

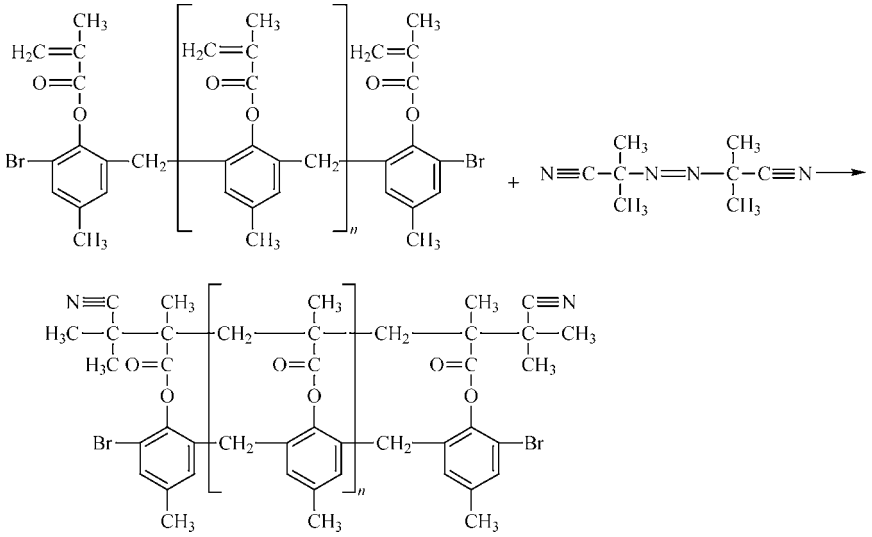
examination of the template polymerization process led the authors to general and important conclusions about the influence of molecular weight, the tacticity of the template, and the temperature and nature of the solvent. It was found that stereoregular poly(methyl methacrylate) can influence the microstructure of the daughter poly(methyl methacrylate).

The template molecular effect was observed by Ferguson (15), who found that the degree of polymerization of poly(acrylic acid) obtained in template polymerization onto poly(vinylpyrrolidinone) is remarkably similar to the degree of polymerization of the template. These results were surprising even to the authors, since they suggest that monomer radical propagation starts at one end of the template and continues to the other end of the templates when termination occurs. This was explained by the authors (15) in terms of the possibility of longer propagation of growing molecule in the presence of the higher molecular weight of the template and the interaction of the growing molecule with two or more template molecules.

The case described was rather exceptional, and was induced by the advantageous selection of initiator concentration. The dependence of the degree of polymerization of the template on the degree of polymerization of the daughter polymer was examined (11) for polymerization of methacrylic acid onto poly(vinylpyrrolidinone) in ethyl alcohol. In these experiments, fractions of poly(vinylpyrrolidinone) were used. The degree of polymerization of the daughter polymer can differ substantially from the degree of polymerization of the template used.

In type I template polymerization, in its most extreme case when monomer units are connected with the template by covalent bonds, the Brownian motion of the monomer units is replaced by conformational changes of the template molecules. Moreover, the distance between two monomer units is virtually independent of the overall concentration, and cannot be changed by dilution of the template solution.

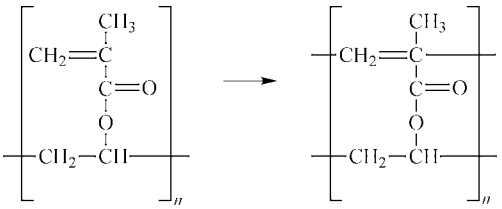
For this type of polymerization, Kämmerer found (54–56) that for the oligomeric template, with an excess of azobisisobutyronitrile (AIBN), the reaction takes place according to a scheme which can be called a replication:



(4)

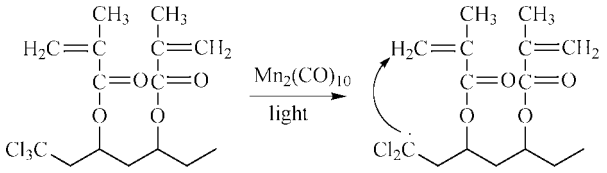
The template in this case was rather stiff, and excess of an initiator leads to termination by primary radicals. In this case the degree of polymerization of the daughter polymer was exactly the same as the degree of polymerization of the template (not taking end groups into account).

Another example is the synthesis of a ladder polymer as examined in Reference 57. Poly(vinyl alcohol) esterified by methacrylic chloride was used as a template. Polymerization can be represented by the following reaction:



(5)

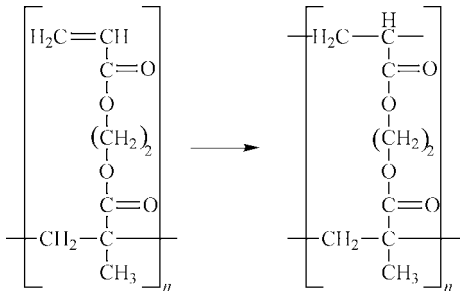
The polymerization can begin in any of the groups present and may proceed in any direction. In other words, since the reactive groups, are independent of one another and initiation occurs randomly, polymerization leads to isolated reactive groups, which are both potential cross-linking sites and breaks in the ladder structure. Cross-linking as an intermolecular reaction can be minimized by conducting the reaction at an appropriate dilution. If, however, initiation is not random but starts at one end of the template, we might expect to obtain a very regular ladder structure. Such a case was considered by Bamford (2), but has never been checked experimentally. Active radicals in multimonomer—poly(vinyl methacrylate)—can be created from $-CCl_3$ end groups, in the presence of manganese carbonyl, $Mn_2(CO)_{10}$, by irradiation with light. The radicals would be expected to initiate selectively at one end of the template according to the following reaction:



(6)

Template polymerization of multi-acrylate and multi-methacrylate with longer spacers has been studied (58–61). The reaction proceeds according to the

following scheme:

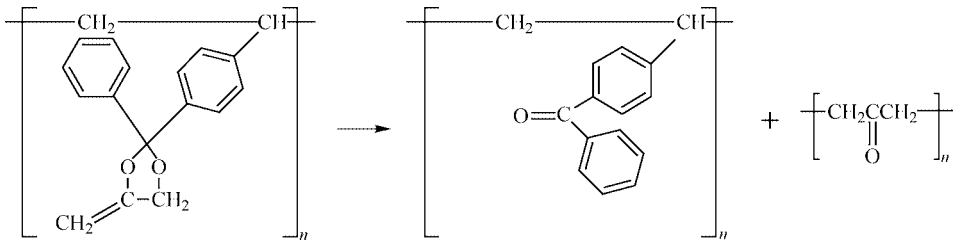


(7)

It was found that neither the average molecular weight nor the distribution of molecular weights change during polymerization, provided the molecular weight is high enough and the concentration is low (60,61). For multi-acrylates, it was found that distribution of molecular weights is the same up to more than 50% of conversion of double bonds. This means that under correct conditions, intermolecular reaction can be neglected and the polymerization proceeds as a template process. However, for high conversion and high monomer concentration, an increase of molecular weight takes place, and eventually the product becomes insoluble and cross-linked. Very similar behavior was observed for the photopolymerization of multi-methacrylate (62). The kinetics of template polymerization of multi-methacrylates, poly(2-methacryloyloxyethyl methacrylate) and poly(2-acryloyloxyethyl methacrylate), have been studied.

Template polymerization for polypeptide synthesis was reported by Ballard and Bamford (63) and described in detail in Reference 2. The substrate for the synthesis was *N*-carboxy-α-amino acid anhydride (NCA). The first step consists in the reaction of NCA with secondary amine on the end of the polypeptide template. The ring-opening process and the elimination of CO_2 then proceeds as a chain reaction. Valuable experimental material concerning the polymerization of many different *N*-carboxyanhydrides initiated by many different polypeptides (64–66) as well as by poly(vinyl pyridine) (67,68) was collected by Imanishi and co-workers.

Sugiyama and co-workers (69,70) report a very interesting template process by the ring-opening polymerization induced by radicals. The polyethylene template was connected with 2,2-diphenyl-4-methylene-1,3-dioxolane groups by the covalent bonds. The process can be illustrated by the following reaction:



(8)

In this case the daughter polymer is not connected to the template either by hydrogen bonds or covalent bonds.

Template Radical Copolymerization

In the literature there is less information about template copolymerization than about template homopolymerization. However, the process seems to be very interesting on account of the fact that the template can influence not only the molecular weight and tacticity of the daughter polymer but also the composition and distribution of units in the copolymer macromolecule. Two different schema of template copolymerization can be considered. First, the template can be a homopolymer and one or both monomers can interact with the template. Second, the template can be a copolymer, or in the system two different templates exist. Literature in the field is not numerous.

It was found that the composition and the distribution of units in copolymerization is controlled mainly by the propagation process. From this point of view, equations have been formulated (71) concerning how the reactivity ratios depend on the template concentration and individual reactivity rate constants of monomers taking part in the template copolymerization process. However, if long critical length is necessary for the adsorption of the growing macroradical onto the template, any template effect can be destroyed (72).

It seems that the template effect can be pronounced only if interactions between at least one of the monomers is sufficiently strong. Examples of the systems in which one or both monomers were connected with the template by covalent bonds have been described (73–78). Copolymerization of multimonomers similar to the oligomers described by Kämmerer with styrene leads to semiladder copolymers, and after hydrolysis to short-block copolymers (73).

Step-Growth Template Polymerization

Template polycondensation or template polyaddition is much less elaborated than the chain template reaction. However, many cases of homo- and heteropolycondensation have been considered (11).

Strong interaction between monomers and the template is a prerequisite for the template process, while in simple polycondensation high temperature and low pressure is applied. However, in mild conditions using the direct polycondensation method it was demonstrated that terephthalic acid connected with poly(4-vinylpyridine) (79), poly(ethylene oxide) (80), poly(vinylpyrrolidinone) (81) and activated by triphenyl phosphite reacts with hexamethylenediamine, giving polyamides with high molecular weight.

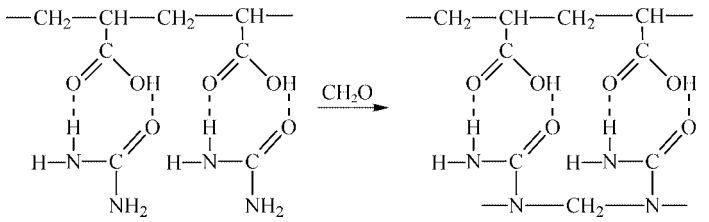
Another example of template polycondensation was described by Ogata and co-workers (82–85). Polycondensation of dimethyl tartrate or dimethyl muconate with hexamethylenediamine was increased by the presence of poly(vinylpyrrolidinone) and poly(vinyl alcohol). It was also found that polysaccharides increase the polycondensation rate. It seems that hydroxyl groups play a substantial role in the absorption of monomers onto the template.

Polycondensation of various amino acids by means of triphenyl phosphite in the presence of poly(vinylpyrrolidinone) was also reported (86).

A very interesting method of polycondensation of active esters containing nucleic acid bases with diamines was described by Hattori and co-workers (87). Di-*p*-nitrophenyl methylsuccinate with thymine or theophylline was condensed with piperazine. The reaction was carried out in a pyridine/methylene chloride mixture or dimethyl formamide (DMF) in the presence of a copolymer of styrene and styrene derivatives with adenine groups as a template. The strong interaction between the complementary groups (adenine in the template and thymine in the monomer) leads to the template effect. The maximum acceleration effect was observed for copolymers with adenine content about 54% in the case of polycondensation with piperazine.

It was found that the rate of reaction differed depending on the percentage of adenine groups in the copolymer.

A template polycondensation of urea with formaldehyde in the presence of acrylic acid was published by Papisov and co-workers (88–92). The authors suggest that a complex with polyacid is formed during the reaction. The complex has a different structure than does urea–formaldehyde resin mixed with poly(acrylic acid). The reaction can be written as follows:



(9)

The theoretical consideration and models for a kinetic description of the template reaction in biological systems was published by Simha and co-workers (93). The model was constructed on the basis of addition reaction in order to apply to the synthesis of biological molecules, for instance DNA replication.

Potential Applications

The most promising applications of template polymerization seems to be the production of materials in which the daughter polymer and the template together form a final product, because the synthesis of polymers requiring further separation of the product from the template is not acceptable for industry. The template process can be applied in order to produce a set of new materials on the basis of ladder-type polymers, semi-adder copolymers, the properties of which are not yet well known.

Template polymerization is a convenient way to produce polycomplexes and polycomplex composites, polymer blends, and interpenetrating networks or networks with nonrandom distribution of cross-linking points.

The polycomplexes obtained by template polymerization have been used for spinning fibers (27).

The quite remarkable properties of composites obtained by template polycondensation of urea and formaldehyde are described by Papisov and co-workers (92). The structure and properties of such composites can be widely varied by changing initial composition and reacting conditions.

Rätzsch (94) reported an application of template polymerization similar in technique to photolithography. However, up to this point template polymerization has not found any industrial application.

THERMOCHROMIC POLYMERS

Introduction

In recent years functional polymers changing their visible optical properties in response to an external stimulus have met with growing interest. According to the external stimulus which affects the optical properties, these so-called chromogenic polymers are classified as thermochromic (stimulus: temperature), photochromic (stimulus: light), electrochromic (stimulus: electric field), piezochromic (stimulus: pressure), ionochromic (stimulus: ion concentration), and biochromic (stimulus: biochemical reaction). Because of their advanced properties the demand on chromogenic polymers for future applications will become enormous. Smart windows, tunable light filters, large area displays as well as sensors, which can visualize, eg, temperature or pressure profiles, are the most important potential innovations based on chromogenic polymers. For all these applications laboratory prototypes demonstrating the effect have been presented. A few of them have already reached the readiness for marketing and certainly others will follow in the near future.

This article focuses on thermochromic polymer systems. An overview of the different types of such polymer systems is given and the origin of the thermochromic effect, their specific material properties, and potential applications are discussed. Table 1 displays the various generic types of thermochromic polymers. Following this classification, thermochromic polymer systems in which the color appears owing to a Bragg reflection on a periodic structure are discussed first. In such systems the thermochromic effect is caused by a temperature dependence of the layer periodicity. Thus the wavelength of the reflected light can only change continuously. Another inherent feature of such thermochromic systems is that the visible color depends on the viewing angle. Because of these disadvantages the potential applications of thermochromic polymer systems based on Bragg reflection are limited. The second classification is about thermochromic polymer systems varying their color or color intensity owing to temperature-dependent molecular changes of the chromophoric group. This class of thermochromic polymers can in principle switch between any user-defined colors. The third class of

Table 1. Generic Types of Thermochromic Polymers Classified by the Effect on Light Causing the Thermochromic Behavior

Effects on light	Origin	Macroscopic behavior	Polymer class
Reflection	Periodic structures	ΔI, $\Delta\lambda_{max}$	Cholesteric liquid crystalline polymers
			Crystalline colloidal arrays embedded in a gel network
			Gels
Absorption	Chromophoric groups	ΔI, $\Delta\lambda_{max}$	Conjugated polymers
			Hydrogels containing indicator dyes

polymer systems reviewed are those changing their transparency with temperature by reversible switching between a transparent and a light scattering state. In the literature this subclass of thermochromic materials is generally denoted as thermotropic. The main interest in thermotropic polymer systems appears to be from their potential application in sun protecting glazing. Recently, a novel class of polymer systems changing both transparency and color with temperature has been described and will be reviewed.

Thermochromic Polymer Systems Based on Bragg Reflection

Liquid Crystalline Polymers with Thermochromic Properties. In several liquid crystalline phases a helical superstructure occurs if either a chiral compound is added or the liquid crystalline compound itself consists of a chiral molecular structure (1,2). In this way, the nematic phase, for example, transforms into the so-called cholesteric phase. Depending on structure and concentration of the chiral compound as well as on the phase type, the pitch (P) of the helical superstructure can be in the range between 100 nm and infinite. Incident light is selectively reflected, if the wavelength (λ) satisfies the Bragg condition $\lambda = nP \cos\theta$ (n stands for the mean reflective index of the liquid crystal and θ for the angle between the incident light and the orientation of the helix). In many systems the wavelength of the reflected light is in the visible region; thus these liquid crystals become intensively colored. The pitch generally changes with temperature and can be modified by applying an electric field.

Thermochromic polymer foils based on cholesteric liquid crystals are already commercially available from various manufacturers including Hallcrest Ltd., Merck KGaA, and Davis Liquid Crystals Inc. Such thermochromic sheets consist of a black backing layer, a layer of the cholesteric liquid crystal, and a protective clear polyester layer. They can indicate temperature changes ranging from a fraction of a degree to over 20°C by varying their color continuously through the entire visible region.

Chiral liquid crystalline polymers possessing thermochromic properties themselves are described in numerous publications. Besides synthetic polymers, many cellulose derivatives have been found to possess cholesteric mesophases with selective reflection in the visible wavelength region. The pentyl ether of hydroxypropyl cellulose is an example for such a cholesteric polymer (3). At room temperature it shows selective reflection at about 500 nm. With increasing temperature the wavelength of the selective reflection maximum smoothly increases, reaching 650 nm at about 80°C. For applications in information technology, those materials are of special interest which allow fixation the cholesteric order at any user-defined color (4). A fixing of the helical pitch takes place in a glassy state (5–7) as well as in cross-linked polymeric structures (3,8–12). Therefore, cholesteric polymers with a glass-transition temperature within the cholesteric phase range as well as cholesteric mixtures which are polymerizable and form cross-linked polymeric networks are suitable for this purpose. The preparation of patterned multicolor cholesteric liquid crystal polymer networks have been reported (12). The cholesteric liquid crystal polymer networks were obtained by photopolymerization of a mixture containing 20% of a chiral monoacrylate CBC

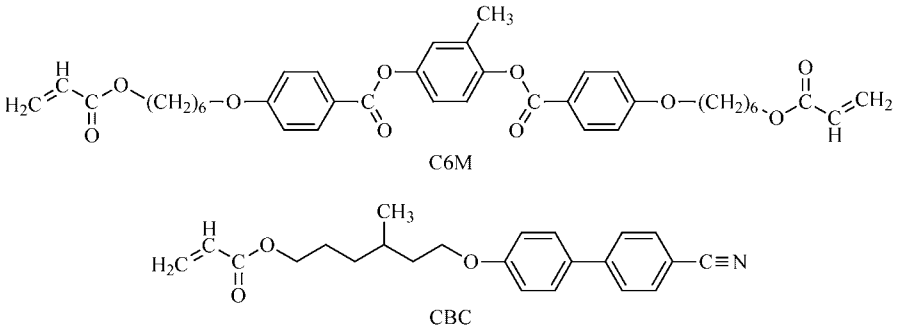

Fig. 1. Molecular structure of the acrylates C6M and CBC.

(see Fig. 1), 25% of a nonreactive commercial chiral dopant CB15 (Merck), 54% of a nonreactive commercial liquid crystal BL59 (Merck), 0.5% of a diacrylate C6M (see Fig. 1), and 0.5% Irgacure 651 photoinitiator at different temperatures. This mixture exhibits a cholesteric phase with a strong temperature dependence of the pitch. At 55°C it reflects red light, at 35°C green light, and at 30°C blue light. Thus, by performing the photopolymerization at different temperatures (55, 35, and 30°C), red, green, and blue polymer networks with a temperature-independent color were obtained. In a next step the preparation of a patterned multicolor polymer network was carried out by using masks and performing the photopolymerization step by step in different regions at different temperatures. It was concluded that by using a light source to induce patterned heating of the mixture, followed by fixing via UV-induced photopolymerization, it should be possible to produce much more complicated structures.

The formation of liquid crystalline phases with thermochromic properties in a poly(β-peptide) was reported in Reference 13. The color changes were observed by using polarizing optical microscopy. However, this method was not found to be suitable for determining thermochromism.

Thermochromic Gel Networks Based on Bragg Reflection. Polymer gel networks with thermochromic properties, based on Bragg reflection, are frequently described in the literature, whereby most of the systems are composed of a polymer and an organic solvent. It has been reported that poly-1-butene flakes swells in benzene, toluene, *o*-xylene, *m*-xylene, *p*-xylene, or tetrachloroethylene and exhibits reversible color changes with temperature between the melting point of the solvent and the sol–gel transition temperature (14). With increasing temperature the color of the poly-1-butene gels changes in the order of blue, violet, red, orange, and yellow. This thermochromic effect is explained by Bragg reflection on the microstructure of the gelled poly-1-butene. A similar behavior was observed by the same author for gelled isotactic polypropylene in benzene, toluene, and xylene (15). For example the color of a 3% isotactic polypropylene gel in benzene was found to change from blue at room temperature to yellow at about 70–80°C.

A thermochromic hydrogel based on Bragg reflection has been reported (16). The described system consists of crystalline colloidal arrays of monodisperse polystyrene spheres embedded in a poly(*N*-isopropyl acrylamide) (PNIPAM) hydrogel, which was prepared by first dispersing highly charged and monodisperse

polystyrene spheres in an aqueous solution containing the PNIPAM monomer, followed by a photochemically initiated polymerization. A temperature-dependent strong swelling or shrinking of the polymer matrix takes place. The embedded polystyrene spheres follow this volume change, causing thereby a modification of their lattice spacing and thus of their Bragg reflection wavelength. To characterize the optical properties of the novel thermochromic material, films of different layer thickness were prepared and the temperature dependence of their diffracted wavelength determined. While the bulk material is translucent because of light scattering on the colloidal particles, thin films become transparent. At room temperature 125-μm-thick hydrogel film was used to detect the thermochromic effect by absorption measurements. In this way, a continuous change of the diffracted wavelength from 704 nm at 11.7°C to 460 nm at 34.9°C was measured, which corresponds to nearly the entire visible range. However, note that the thermochromic effect is coupled with strong volume changes. An increase of the diffracted wavelength from 400 to 800 nm corresponds to a swelling in each direction by a factor of 2 and thus to an eightfold increase of the volume.

Crystalline colloidal arrays which vary the intensity of the Bragg reflection in dependence on temperature without changing the wavelength of the diffracted light have also been developed (16). Such materials were obtained by dispersing highly charged and monodisperse colloidal particles of PNIPAM with a size of 100 nm in deionized water. In water these PNIPAM colloids self-assemble and form a body-centered cubic array which diffracts light following the Bragg diffraction law. Below their lower critical solution temperature of about 32°C the PNIPAM colloids begin to swell, leading to an increase of the sphere diameter from about 100 nm above this temperature to about 300 nm at 10°C. The lattice spacing of the cubic array and thus the reflected wavelength (at a constant glancing angle between the incident light and the diffracting crystal plane) depend only on the particle density of the PNIPAM colloids. The intensity of the Bragg reflection of crystalline colloidal arrays, on the other hand, depends on the array ordering as well as on the scattering cross section of the colloidal particles, which is influenced by the particle size of the colloids. As a result the reversible swelling or shrinking of the PNIPAM colloids with temperature causes pronounced changes in the intensity of the Bragg reflection. As an example the optical properties of a crystalline colloidal array of PNIPAM colloids (diameter: 100 nm) with a lattice constant of 342 nm were reported. At 40°C the nearest neighbor sphere distance amounts to 242 nm and at the Bragg reflection wavelength nearly all incident light is reflected. On the other hand at 10°C the PNIPAM colloids are almost touching and only a weak Bragg reflection occurs.

Thermochromic Polymer Systems Based on the Absorption of Light

Conjugated Polymers. The occurrence of thermochromic properties is frequently observed in conjugated polymers (17,18) like polyacetylenes (19), polydiacetylenes (19), polythiophenes (20), and polyanilines (21). Many conjugated polymers exhibit absorption of light in the visible range as well as high reflectivity. Hence, they often are colored and show a metallic appearance. Thermochromism in conjugated polymers has its origin in changes of the conformation as they

abruptly occur at phase transitions whereby even the slightest modification of the conformational structure can cause significant color changes. Especially the planarity of the polymer backbone plays an important role. Any twisting of the chain leads to a decrease of the effective conjugation length and thus to a blue (hypsochromic) shift of the absorption in the UV–vis region. In general the color changes of conjugated polymers are reversible. However, kinetic effects can cause an irreversibility which can be useful for thermal recording (22). In Reference 23, synthesis and optical properties of a liquid crystalline polydiacetylene are described. At each of its mesogenic phase transitions a thermochromic effect was detected. That means thermochromic and mesogenic properties of the investigated polydiacetylene are coupled with one another. The structural and optical properties of poly[2′,5′-bis(hexadecyloxy)-1,4-phenylene-1,3,4-oxadiazol-2,5-diyl] have been reported in Reference 24. The polymer was found to possess liquid crystalline properties in a wide temperature range, whereby at 120°C an order–order transition from a smectic H into a smectic A phase takes place. Moreover, a thermochromic behavior was observed within the temperature range of 25–140°C. With increasing temperature the polymer changes its color continuously from yellow-green at 25°C to blue at 130°C. To characterize this thermochromic behavior in more detail, UV–vis absorption and fluorescence emission spectra were measured at different temperatures. For both, a continuous evolution with temperature was found. In contrast to the results reported in Reference 23, in Reference 24 even at the smectic H to smectic A phase transition no discontinuous change of the UV–vis and fluorescence intensities could be detected.

Another way to obtain thermochromic polymers is to incorporate a thermochromic material into a polymer matrix. Thermochromic polymers have been obtained by dispersing poly(3-alkyl thiophene)s in host polymers (25,26). Poly(3-alkyl thiophene)s belong to the group of conjugated polymers, exhibiting thermochromism according to temperature-induced changes of the conjugation of the π-electron system. The thermochromic switching temperature of the polythiophene pigments can be tailored by chemical modifications. In this way a set of pigments that visually and reversibly change colors at a prescribed temperature in the region of -35 to $+125$°C was developed. These pigments are thermally stable until more than 200°C. Commercially available paints, plastics, and rubbers were used as host polymers, whereby 0.1–1.0 wt% of the pigments were necessary to obtain a visible thermochromic effect. However, a detailed description of the chemical structure of the pigments or a list of the available switching temperatures and color changes has not been reported so far.

A thermoplastic polymer with thermochromic properties was recently presented by Seeboth et al. (27). This polymer switches on heating at a certain temperature from blue to colorless. Figure 2 displays a photograph demonstrating this thermochromic switching effect. A foil of the novel thermochromic polymer is partially heated in hot water above the switching temperature. Clearly the cool blue and the hot colorless state can be seen. So far, neither the origin of the thermochromic effect nor the composition of this thermochromic polymer has been reported.

Masterbatches of polyethylene and polypropylene containing microencapsulated thermochromic materials are already commercially available from various manufacturers. The thermochromic materials used in these microcapsules are

Fig. 2. Thermochromic switching from blue to colorless of a thermoplastic polymer foil.

composed of an electron-donating chromogenic compound, an electron acceptor, and a solvent (28). Suitable electron-donating chromogenic compounds are, for example, substituted phenylmethanes and fluorans. These so-called leuco dyes or color formers (29) are either colorless or weakly colored. However, on reaction with an electron acceptor, as for example a phenol, an opening of the lactone ring occurs. In the open ring state the conjugated π-electron system is extended, enabling color formation. By the addition of appropriate solvents the color-forming reaction becomes reversible. In the molten state these solvents function as an inhibitor of the color-forming reaction. On the other hand during the crystallization of the solvent the donating chromogenic compound reacts with the electron acceptor; thus the crystalline state becomes colored. For example a mixture of 1 wt% 2-chloro-6-diethylamino-3-methylfluoran, 5 wt% 2,2′-bis(4-hydroxyphenyl)-propane, and 94 wt% 1-hexadecanol is colorless above 48°C in the molten state and develops a vermilion color on cooling below 48°C when the crystallization of the 1-hexadecanol takes place. The reversible lactone ring opening reaction of 2-chloro-6-diethylamino-3-methylfluoran, which is the origin for this thermochromic effect, is shown in Figure 3. Although these masterbatches show excellent thermochromic switching behaviors, the use of microencapsulated thermochromic mixtures results in a variety of limitations including poor thermal and shear stability which cause difficulties in processing.

Gel Networks. In the literature a few examples of thermochromic gel networks consisting of conjugated polymers swelled in organic solvents are reported. The thermochromic effect described for these gels appears owing to changes of

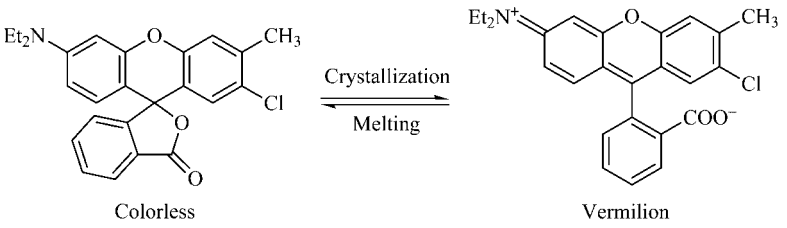

Fig. 3. Reversible lactone ring opening reaction of 2-chloro-6-diethylamino-3-methylfluoran.

the molecular structure of the polymer backbone at their respective gel–sol transition temperature. One of the reported systems consists of polydiacetylene gelled in *o*-dichlorobenzene or other gel-forming solvents (30). Upon heating above the gel–sol transition temperature reversible pronounced color changes are observed. Colors and transition temperatures could be varied by using different solvents as well as by changing the composition. A weak thermochromic effect caused by temperature-dependent molecular changes of the chromophoric group in a gel network has also been reported (31). On heating in benzene a poly[2-(3,7-dimethyloctoxy)-5-methoxy-1,4-phenylenevinylene] gel shows a gradually red to yellow color change at approximately 35°C, which corresponds to the gel–sol transition temperature. After cooling to room temperature the yellow state remains metastable. It eventually reverts after several hours to the red gel phase. The authors explained the thermochromic behavior of this system by a reduction of interchain π–π interaction at the gel to solution transition, at which the relation between aggregated and isolated chain sections abruptly changes.

The first example of a thermochromic effect of dyes embedded in a transparent hydrogel was reported by Seeboth et al. (32). The described thermochromic effect appears by the addition of suitable indicator dyes, with pK_a values between 7.0 and 9.4, to a definite poly(vinyl alcohol) (PVA)/borax/surfactant hydrogel network. With increasing temperature the used gel matrix shifts the equilibrium of the indicator dyes toward their deprotonated forms, leading thereby to gradual color changes with temperature. In dependence on the used indicator dye(s) a switching between a colorless and a colored state or between two or even more different colored states occurred. For example a gradual color change from colorless at 10°C to a deep violet at 80°C was observed for a PVA/borax/surfactant hydrogel containing the so-called Reichard betaine 2,6-diphenyl-4-(2,4,6-triphenyl-1-pyridino)-phenolate (DTPP), whose pH-sensitive equilibrium is shown in Figure 4.

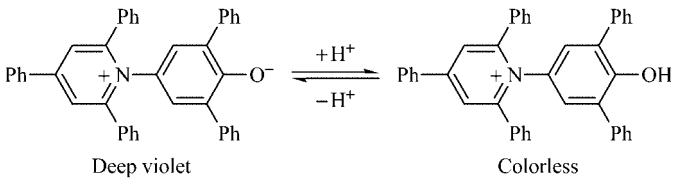

Fig. 4. Proton-transfer equilibrium between the phenol and phenolate form of the indicator dye 2,6-diphenyl-4-(2,4,6-triphenyl-1-pyridino)-phenolate.

Fig. 5. Thermochromic switching of a 3-mm-thick Cresol Red containing PVA/borax/surfactant hydrogel layer placed between two glass plates.

A Cresol Red containing PVA/borax/surfactant hydrogel on the other hand switches from yellow at 10°C to wine-red at 80°C and a Bromothymol Blue and Cresol Red containing PVA/borax/surfactant hydrogel from yellow (below 5°C) via green (between 15 and 25°C) to violet (above 60°C). A photograph displaying the thermochromic switching of the Cresol Red containing PVA/borax/surfactant hydrogel is shown in Figure 5. The 3-mm-thick layer spacing of a double-glazing assembly is filled with this thermochromic hydrogel and partially heated in a hot water bath. While the cold zone remains yellow the color in the hot zone has switched to wine-red. In order to characterize the thermochromic effect in more detail, UV–vis absorption measurements were carried out. As examples of the obtained results the UV–vis absorption spectra of the DTPP and of the Cresol Red containing PVA/borax/surfactant hydrogels measured at different temperatures are displayed in Figures 6 and 7, respectively. One absorption maximum growing continuously with increasing temperature appears in the spectra of the DTPP containing PVA/borax/surfactant hydrogel (Fig. 6). This absorption at about 550 nm is caused by the phenolate form of DTPP and its growing intensity indicates a rising phenolate concentration with increasing temperature. In Figure 7 for all temperatures two absorption maxima, one at 419 nm, which corresponds to the absorption of the phenol form of Cresol Red, and the other one at 581 nm, which corresponds to the absorption of the phenolate form of Cresol Red, are observed. With

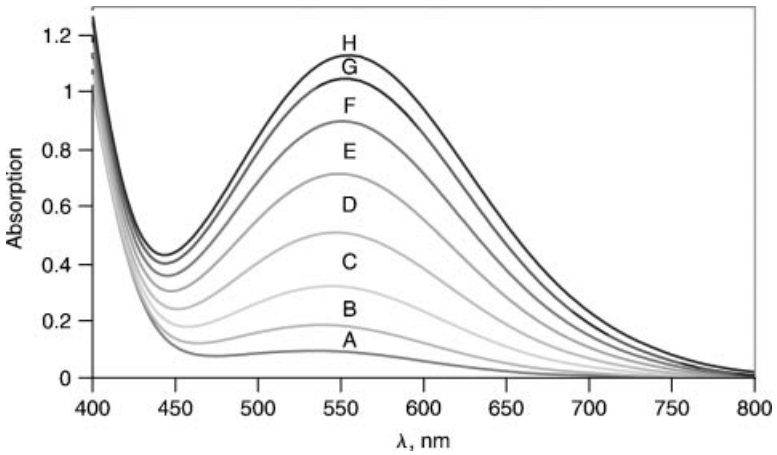

Fig. 6. Visible absorption spectra of a 2,6-diphenyl-4-(2,4,6-triphenyl-1-pyridino)-phenolate containing PVA/borax/surfactant hydrogel in dependence on temperature (d = 1 cm). — 10°C (A); — 20°C (B); — 30°C (C); — 40°C (D); — 50°C (E); — 60°C (F); — 70°C (G); — 80°C (H).

increasing temperature the intensity of the absorption band at 581 nm increases while simultaneously the intensity of the absorption band at 419 nm decreases. All spectral curves meet at an isosbestic point at 486 nm, supporting thereby the suggested model of a temperature-dependent equilibrium between two different forms of the indicator dye as the origin of the observed thermochromic effect.

In addition to the transparency another important feature of these hydrogels is that the thermochromic effect is not accompanied by volume changes. Therefore such hydrogels are applicable for smart windows, large area displays, and tunable color filters.

Transparency/Scattering Switching

Some thermotropic polymer systems switch at a certain temperature reversibly between a highly transparent and a light scattering state. Such an optical effect can be caused either by a phase transition between an isotropic and an anisotropic (liquid crystalline) state or by a phase separation process. Two different classes of thermotropic polymer materials have been extensively studied in recent years: polymer blends and polymer gels.

Thermotropic Polymer Blends. Only a few pairs of polymers are miscible with one another over the complete concentration range. There are also polymer pairs known which either mix or do not mix depending on temperature; both an increase as well as a decrease of the miscibility (qv) with increasing temperature are possible. In the phase diagrams of such polymer pairs a two-phase region appears either below a so-called upper critical solution temperature (UCST) or above a so-called lower critical solution temperature (LCST). Within a wide concentration range polymer blends of both these systems are thermotropic. Blends with an UCST in the phase diagram switch from translucent to transparent by increasing the temperature, whereas polymer blends of systems with an LCST switch in the opposite manner. For application in sun protecting glazing, a reduction of the transmission with increasing temperature is required and therefore the development of thermotropic polymer blends in recent years has focused on systems with an LCST. In 1993 Siol et al. (33) from the Roehm GmbH developed thermochromic polymer blends consisting of chlorinated rubber and polymethacrylates. Depending on the composition the transition from the transparent into the translucent state (cloud point) could be varied between 60 and 140°C. In the same year Eck et al. (34) presented polymer blends with a much better reversibility of the thermotropic switching. Moreover, cloud points between 30 and 40°C could be realized, which is the required temperature range for sun protecting glazing. These polymer blends were derived from poly(propylene oxide) and a styrene–hydroxyethyl methacrylate copolymer cross-linked with a trifunctional cyclic isocyanate. By cross-linking the copolymer in the presence of poly(propylene oxide) a semi-interpenetrating network is formed leading to an increase of the stability of the microphase separation above the cloud point and thus to a much better reversibility of the thermotropic switching. A similar cross-linked thermotropic polymer blend was developed in 1995 by BASF (35). In the first step blends of poly(propylene oxide) and a copolymer of styrene, hydroxyethyl methacrylate, and a small portion of 4-acroyloxy butyl carbonato benzophenone were prepared. However, instead of adding a cross-linking agent, radical polymerization under UV-light was used to form the semi-interpenetrating network. This method allows preparation of thermotropic coatings first and polymerization to the semi-interpenetrating network later on. In this way, the evenness of the coating surfaces and thus their optical quality could be improved. The optical properties of the two polymer blends prepared by W. Eck and by BASF respectively are presented in References 36 and 37. For a 400-μm-thick layer of the polymer blend prepared by W. Eck on glass a change of the integrated normal-hemispherical transmission from 92% at 20°C to 30% at 90°C and for a 600-μm-thick layer of the polymer blend prepared

by BASF on glass a change of the integrated normal-hemispherical transmission from 89% at 30°C to 38% at 85°C were obtained.

Thermotropic Polymer Gels. Thermotropic polymer gels can be based either on the appearance of lyotropic liquid crystalline phases or on phase separation processes. Similar to polymer blends, phase diagrams of polymer gels may also show LCST and UCST. Because of their greater practical relevance development in recent years has focused on polymer gels in which the phase separation process takes place on heating.

Since their first observation, lyotropic liquid crystalline polymers like poly(benzyl glutamate) (38,39), hydroxypropyl cellulose (40,41), and fully aromatic polyamides (42) have been extensively studied. Common properties of these polymers are their good solubility in water and the structural feature of a more or less rigid polymer backbone (stiff polymer chain). In certain concentration ranges these polymers undergo in water as well as in some organic solvents a transition from an isotropic phase to a polymer solvent system with pronounced long-range order and thus a transition from a transparent into a light scattering state.

The preparation of lyotropic liquid crystalline polymer gel networks and the determination of their thermotropic properties were reported in Reference 43. The investigated systems are poly(ethylene glycol) (PEG)/PVA/borax hydrogels, whereby the concentration of both polymers, their molecular masses, and the degree of cross-linking were varied. Within a wide range of composition the PEG was found to form lyotropic liquid crystalline domains in the PVA/borax hydrogel network as detected by microscopic observations of schlieren and radial-droplet structures between crossed polarizers. In dependence on the composition the transition from the lyotropic liquid crystalline phase into an isotropic liquid phase (clearing temperature) could be shifted between about 15 and 90°C. In all samples this transition takes place without affecting the PVA/borax hydrogel network. As a consequence of this the mechanical properties are not influenced by the optical switching process. On heating above their respective clearing temperature the transparency of the hydrogels were found to increase from below 5% to more than 70%, whereby contrast ratios of up to 85:1 were observed. This value is similar to the contrast ratios of the nematic to isotropic phase transition of thermotropic or polymer dispersed liquid crystals. The transparency versus temperature curves of some selected examples of these PEG/PVA/borax hydrogels as well as of an ethoxylated PVA/borax hydrogel are shown in Figure 8. With rising PVA concentration and increasing molecular mass of the PEG an increase of the clearing temperature and thus of the translucent to transparent switching temperature can be observed. As can be seen, the molecular mass of the PEG also influences the steepness of the transparency changes. While the samples containing PEG with a molecular mass of 20,000 change their transparency within a temperature range of a few degrees, a broadening of the switching temperature range to about 30–40°C takes place by increasing the molecular mass of the PEG to 70,000.

Phase separation processes in gel networks have been well known for a long time. In the past two decades the interest in thermotropic gel networks has rapidly increased because of their potential application in sun protecting glazing. This discussion focuses on recent developments in the preparation of thermotropic polymer gel networks based on synthetic as well as on biopolymers, the influence of

the addition of salts on the material properties, and the construction of hybrid solar and electrically controlled light filters. Moreover, polymer gel networks which combine thermotropic and color changing properties are reviewed.

Polymer Gel Networks Based on Synthetic Polymers. Gel networks are composed of a swollen cross-linked polymeric network and a solvent. According to the nature of the cross-linker two categories—chemical and physical gels—can be distinguished. In chemical gels the cross-linker connects two polymer chains by covalent bonds. Such gels generally show a strong swelling or shrinking with temperature. Physical gels on the other hand are formed by noncovalent interactions such as ionic interaction, hydrophobic interaction, and/or hydrogen bonding between the polymer chains and a cross-linking agent. Suitable cross-linkers for this purpose are, for example, salts, polyvalent alcohols, borax, phosphonic acid derivatives, and other complex-building organic compounds. Compared with chemical gels the advantage of physical gels is that in most cases their volume does not change much with temperature, which is an essential condition, eg, for their use in sun protecting glazing.

For the preparation of thermotropic polymer gel networks mainly water-soluble polymers like poly(acrylic acid) derivatives, poly(vinyl alcohol), polyglycol, poly(vinyl acetal) resins, polyether, and cellulose derivatives have been successfully used. The first observation of a thermoresponsive volume phase transition in a nonionic hydrogel was reported by Tanaka in 1984 (44). It was found that a PNIPAM hydrogel exhibits a reversible collapse transition at about 34°C, which is accompanied by a transformation from a highly transparent into a translucent state. Hydrogels of PNIPAM or PNIPAM copolymers (45–47) are still the most frequently studied class of temperature responsive hydrogels. The optical properties of the PNIPAM hydrogel and its suitability for the construction of sun protecting glazing were investigated in Reference 48. Although the optical properties of the PNIPAM hydrogel are quite promising, the volume changes and surface

pattern formation at the transition temperature are a strong hindrance for commercial application. In 1995, a thermotropic hydrogel based on poly(methyl vinyl ether) cross-linked with methylene-bisacrylamide was presented by Chahroudi (49,50). A variation of the composition allows adjustment of the switching temperature in the range between about 10 and 65°C. This thermotropic hydrogel system is commercially available as Cloud Gel (Suntek Corp.). Investigations of the temperature dependence of the optical properties of Cloud Gel were carried out by Wilson (36) and by Wittwer et al. (51). In comparison with thermochromic polymer blends much higher contrast ratios of the transparent to translucent switching were obtained. A 1-mm-thick layer of Cloud Gel was found to change the integrated normal-hemispherical transmission in the visible range from 92% at 25°C to 6% at 50°C; just 1°C above the transition temperature a drop down of the transmission by about 65% was observed. Thermotropic hydrogels with excellent switching properties have also been developed by Seeboth et al. (52). In systems which tend to form anisotropic phases, improved switching properties of the transparent to translucent transition were found. The prepared hydrogels consist of polyalkoxides with various polyethylene/polypropylene unit ratios, which were cross-linked by the addition of salts or complex-building organic as well as inorganic compounds. These physical gels generally show no swelling or shrinking with temperature. Depending on the composition, switching temperatures ranging from room temperature to 80°C were obtained and the transparency of the translucent state could be adjusted within wide ranges. Maximum contrast ratios comparable with those of Cloud Gel were obtained. Moreover, in concentration ranges in which anisotropic phases are formed multiple transparence minima and/or maxima occur in the transmission versus temperature curves.

Polymer Gel Networks Based on Biopolymers. Biopolymers, like polysaccharides, are nontoxic and inexpensive raw materials, are available in large quantities, and compared with synthetic polymers, have the benefit of environmental compatibility. Because of these advantages, the suitability of biopolymers for the preparation of novel thermotropic hydrogels has been studied in recent years. Thermotropic hydrogels based on cellulose derivatives in combination with an amphiphilic component and various amounts of NaCl were developed by Watanabe (53). By varying the composition, thermotropic switching temperatures ranging from room temperature up to 60°C could be realized. Moreover, it was possible to modify the rate of transparency change with temperature. With one of these thermotropic hydrogels, an intelligent window a square meter in size was constructed and successfully tested under practical conditions over a period of two years. In Reference 54 thermochromic hydrogels, which are also based on cellulose derivatives, were reported. It was shown that no amphiphilic component is necessary to prevent an irreversible flocculation of suspended hydroxypropyl cellulose, if hydroxyethyl cellulose is added. Although biological decomposition is often mentioned as an advantage of biopolymers, it is also the most important hindrance for their commercial use because contact of the biopolymers with microorganism must be prevented during production and the total life time of the product.

Incorporation of Salts into Thermotropic Aqueous Polymer Systems. The addition of salts can strongly influence the material properties of aqueous polymer

systems. Even small amounts can lead to pronounced changes of the structural and macroscopic properties. Often cross-linking of the polymer chains takes place by the incorporation of the salt ions, whereby three-dimensional networks are formed. Systematic investigations of the effect of different salts on morphology, phase transition temperatures, water binding capability, as well as optical and rheological properties of thermotropic aqueous polymeric systems have been carried out by numerous authors in recent years. The influence of different salts and their concentration on the phase separation temperature of thermotropic aqueous polymer systems was studied by Alexandridis et al. (55) as well as by other authors (56–58). For all investigated systems a linear shift of the phase separation temperature dependent on the salt concentration was observed. Moreover, at a given concentration different salts were found to shift the phase separation temperatures of the aqueous polymer systems according to their salting-in or salting-out strength, which is described by the so-called Hofmeister series. Salts with a salting-in phenomena lead to an increase of the phase separation temperature, whereas salts with a salting-out phenomena have the opposite effect. The influence of LiCl on the water binding properties of an aqueous polyalkoxide system is reported in Reference 59. For four different LiCl contents the water binding properties of the investigated polyalkoxide were determined by DSC measurements. The obtained results are shown in Figure 9. Each curve consists of three linear regions. At low water contents all water is so strongly bound to the polymer that it cannot be frozen (nonfreezing bound water). Above the maximum content of nonfreezing bound water additional water is more weakly bound to the polymer. This type of water freezes at low temperature (freezing bound water). Its melting point and melting enthalpy is lower than that of pure water. Finally, at high water contents the polymer is saturated with water and additional water builds a separate phase of free water. As can be seen in Figure 9, the addition of LiCl influences the water binding properties of the polyalkoxide. Proportional to the LiCl content an increase of the non-freezing-bound water capacity of the polyalkoxide and an increase of the binding enthalpy of freezing-bound water were observed. Both results indicate that the interaction between water and polymeric system becomes stronger with increasing LiCl content. Reference 59 also reports an influence of the addition of LiCl on morphology, as well as optical and rheological properties of the investigated polyalkoxide system. As an example Figure 10 shows the temperature dependence of the optical transmission and of the dynamic viscosity of three samples with a fixed polyether/water mixing ratio of 4:1 and various LiCl contents of 0, 3, and 6 wt%. The observed changes of the optical transmission–temperature curves are caused by morphological changes through the addition of LiCl. The pronounced viscosity changes, on the other hand, show the formation of cross-linked structures, whereby in different phases gelation occurs in different LiCl concentration ranges.

Hybrid Solar and Electrically Controlled Light Filters. Compared to electrochromic glazings, smart windows based on thermotropic hydrogels have the advantages of lower costs and a much higher transparency in the clear state. However, for specific applications switching on demand is required. The construction of a hybrid solar and electrically controlled transmission changing light filter based on thermotropic hydrogels has been described (60). The described arrangement consists of a 2- or 3-mm-thick thermotropic hydrogel layer placed between

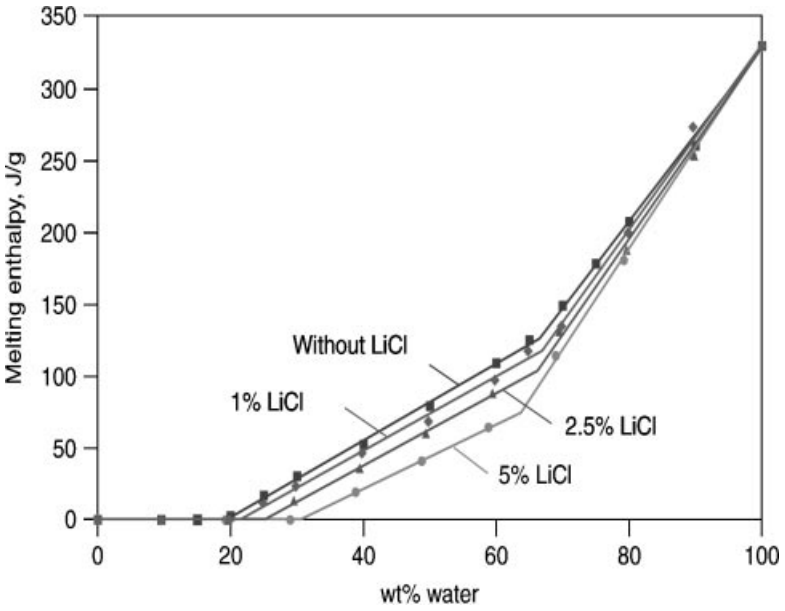

Fig. 9. Water melting enthalpy as a function of water content of polyether/LiCl/water systems.

two tin-doped indium oxide (ITO) coated glass substrates, whereby the ITO layers were placed either inside or outside the double glazing item. When heated passively by solar energy or actively by applying an electric voltage on the ITO layers the thermotropic hydrogel switches from the transparent into the light scattering state. Even for the arrangement where the ITO layers are in direct contact with the hydrogel, no electrolysis was observed under the experimental conditions. Besides the position of the ITO layers, their thickness, the applied voltage as well as the thermochromic hydrogel material used was varied and the switching times of the glazing items were determined. Figure 11 shows the transmission–time curves of one of the investigated light filters at varying applied electric voltages. As can be seen, even 133-nm-thick ITO layers which reduce the maximum transparency of the light filter by about 10% allow fast switching times in combination with high contrast ratios. An increase of the ITO layer thickness decreases the wattage, which is necessary to achieve a constant switching time. On the other hand the transparency of the glazing item is thereby also reduced. For one of the investigated glazing items a transmission change from about 62% to $\leq$ 1% and a switching time of 5 min was achieved by applying a wattage of 0.246 W/cm^2.

It was concluded that a further optimization of all components of the glazing item and especially of the layer thickness as well as the material properties of the incorporated thermotropic hydrogel will lead to a further significant reduction of the required wattage.

Gel Networks for Reversible Transparency and Color Control with Temperature. A novel class of polymer gel networks which change both their color and transparency with changing temperature has been developed (61). Starting from a

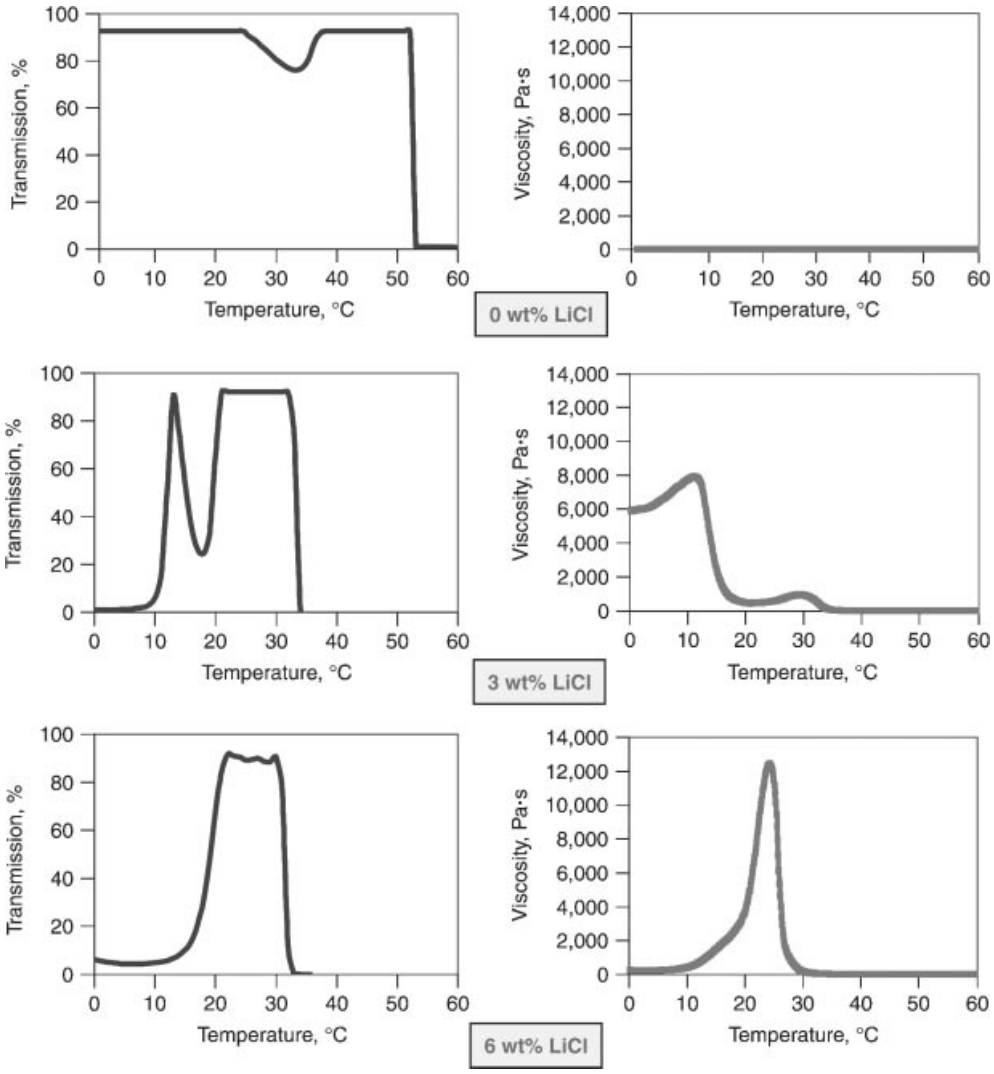

Fig. 10. Temperature dependence of the optical transmission at 600 nm ($d = 1$ cm) and of the dynamic viscosity (measuring conditions: parallel plates of 25-mm diameter, frequency: 1 rad/s) of LiCl containing aqueous polyether samples with a fixed polyether/water mixing ratio of 4:1 and various LiCl contents ranging from 0 to 6 wt%.

thermotropic hydrogel composed of a polyalkoxide and an aqueous LiCl containing buffer solution the color changing properties were obtained by adding one of the pH-sensitive indicator dyes Chlorophenol Red, Nitrazine Yellow, or Bromothymol Blue. The addition of these dyes was found to have only a slight influence on the thermotropic switching behavior of the hydrogel matrix. The switching behavior appears due to a phase separation process as is typical for such polyalkoxide/LiCl hydrogel systems. The color changing effect on the other hand has its origin in temperature-induced pH changes of the gel network similar to the effect observed

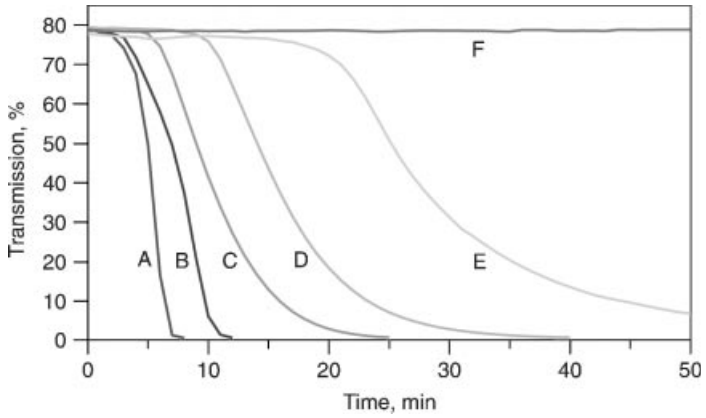

Fig. 11. Transmission versus time curves of a thermotropic gel containing light filter (12 × 15 cm) in dependence on the applied voltages; thickness of the gel layer $d = 3$ mm and thickness of the ITO layers = 133 nm. ___ 8 V/4.8 W (A); ___ 6 V/2.7 W (B); ___ 4 V/1.2 W (C); ___ 3 V/0.7 W (D); ___ 2 V/0.3 W (E); ___ 1 V/0.1 W (F).

earlier for phenol-substituted indicator dyes in a PVA/borax/surfactant gel network (32). As an example the UV–vis absorption spectra at two different temperatures and the transparency versus temperature curve of a hydrogel prepared by mixing 3.95 g polyalkoxide, 0.25 g LiCl, 0.8 g of an aqueous buffer solution (pH 10), and 0.12 g of a 2.2% aqueous solution of Bromothymol Blue are displayed in Figures 12 and 13, respectively. Both effects, the thermotropic switching at about 36°C and the temperature dependent cross over between an absorption band at $\lambda = 408$ nm and one at $\lambda = 617$ nm can be clearly seen. As a result of these effects the hydrogel changes its appearance from green transparent below 33°C, via yellow transparent until about 36°C to yellow translucent above this temperature. With increasing temperature the phenol–phenolate equilibrium of Bromothymol Blue in the polyalkoxide/LiCl/water system is shifted from the green colored phenolate form to the yellow colored phenol form. This result is in contrast to the behavior of phenol-substituted indicator dyes in a PVA/borax/surfactant gel network for which the opposite shift of the phenol–phenolate equilibrium with temperature was observed. Thus it can be concluded that the reversible color change of indicator dyes in gel systems depends on the specific composition of the gel networks. However, the origin of this effect on a molecular level is still under discussion.

Another example of a color and transparency changing gel network is reported in Reference 62. Starting from a Phenol Red containing PVA/borax/surfactant hydrogel which changes its color but not its transparency in dependence on temperature, thermotropic properties were obtained by adding small amounts of a more hydrophobic polymer. For this purpose a polyalkoxide was used. At a content of 0.8 wt% polyalkoxide thermotropic behavior based on a phase separation process was found to appear without affecting the color changing behavior very much. With further increasing polyalkoxide content the degree of the reduction of transparency with temperature is increased and the starting temperature of this process is shifted to lower temperatures. Moreover, the

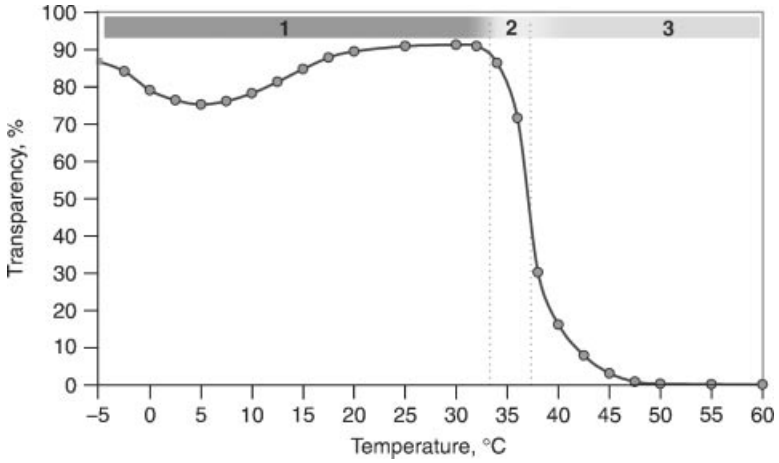

Fig. 12. Transparency versus temperature curve of a Bromothymol Blue (BB) containing hydrogel composed of a polyalkoxide and an aqueous LiCl containing buffer solution ($\lambda = 750$ nm, $d = 0.1$ cm, [BB] $= 1.9 \times 10^{-4}$ mol/L). 1 = green transparent; 2 = yellow transparent; 3 = yellow opaque.

influence of the concentration of the zwitterionic sulfobetaine surfactant on the color changing and thermotropic behavior was studied. PVA/borax/Phenol Red hydrogels containing 1.1 wt% polyalkoxide and various sulfobetaine concentrations below and above their critical micelle concentration (cmc $= 3.8 \times 10^{-3}$ mol/kg) were prepared and the UV–vis absorption spectra as well as the temperature dependence of the transparency of these hydrogels were measured. In the UV–vis absorption spectra two bands occur. The first one at $\lambda = 440$ nm corresponds

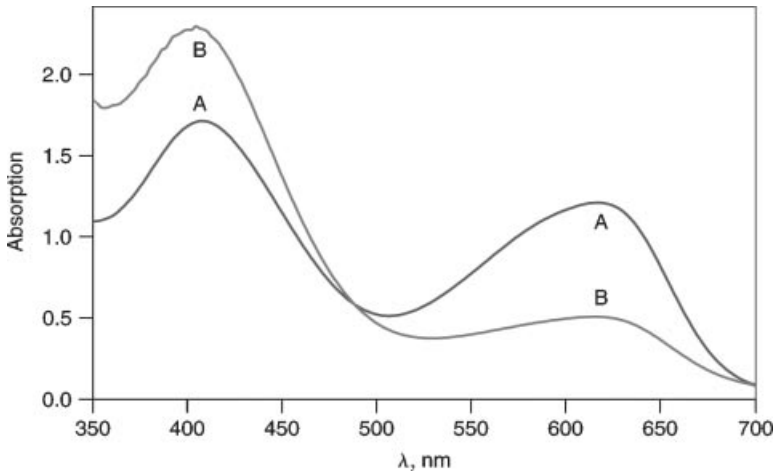

Fig. 13. UV–vis absorption spectra of a Bromothymol Blue containing hydrogel composed of a polyalkoxide and an aqueous LiCl containing buffer solution in dependence on temperature (d = 0.1 cm). —— −5°C (a); —— 38°C (b).

to the phenol form and the second one at $\lambda = 563$ nm to the phenolate form of Phenol Red. With increasing sulfobetaine concentration a decrease of the intensity of both UV–vis absorption bands occur. It is well known that above the cmc surfactants can influence the UV–vis absorption behavior of water-soluble dyes. However, here this effect takes place at the lowest sulfobetaine concentration of 2.5×10^{-3} mol/kg, which is significantly below the cmc. Also, a small but significant and reproducible influence of the surfactant concentration on thermotropic behavior is reported even below the cmc. To explain this behavior the authors suggested the formation of complexes between dye molecules and aggregates of sulfobetaine, but also discussed an interaction of the dye with single sulfobetaine molecules as an alternative model.

Application of Thermochromic Polymers

The potential applications of thermochromic material include temperature tunable light and heat radiation filters, large area displays, and temperature indicators visualizing the temperature of the surrounding medium or the temperature profile of a surface which is coated with the thermochromic material.

Materials changing their color with temperature are already used in a variety of commercial products such as textiles, toys, baby spoons, coffee pots, aquarium thermometers, novelty items, pans with a thermospot, and labels for wine bottles, indicating the proper drinking temperature (63–65). However, the commercialization of thermochromic materials is just at the beginning and certainly this market will rapidly grow in the near future. Potential industrial and processing applications are, eg, monitoring of overheating of machine parts, observation of thermal leaks, and controlling processing temperature. In the field of storage and transportation thermochromic materials with an irreversible switching could assure the observance of required temperature ranges. For example heat-sensitive materials require a storage and transportation temperature below a maximum value and for frozen food the temperature has to kept below 0°C. In medical technology skin temperature indicators might find application for diagnostic purposes. Another big market addresses security aspects. Road signs with integrated thermochromic effects could warn of icy conditions. Thermochromic coatings of heating plates, fire doors, radiators, and other parts of domestic appliances which become hot during their use could indicate that the surface is too hot to be touched. The development of thermochromic polymers suitable for all these applications is actually in progress and in some cases prototypes have already been presented.

The interest in thermotropic materials on the other hand appears more because of their optical properties than because of their ability to detect temperature changes. Such materials are optical shutters for light as well as for heat radiation. The major market for such materials arises from their potential application as functional layers in the construction of sun protecting glazing (66,67). In modern architecture glazing has become a high-tech-component with a wide range of properties and functions. Besides the classic function as viewing window glazing elements enable the use of daylight for the illumination of the building and the passive use of the solar energy for space heating. To realize these functions more and more parts of the building facade are substituted by large area view

and illumination windows, skylights, and sunroofs. In many modern buildings more than 80% of the facade area consists of glazing elements. In buildings with large glazing areas the incident solar radiation plays an important role in energy performance. While on cold days, such as during the winter, the incident solar radiation reduces the energy consumption for space heating, on hot days, such as during the summer, solar radiation causes overheating inside the buildings and thus an enormous increase of the energy consumption for space cooling. To reduce this negative effect regulation of the incident solar radiation is necessary. Today, this is achieved by mechanical optical shutters like venetian blinds, awnings, and sun blinds. An innovative solution which is under development is the use of sun protecting glazings whose optical properties can either be actively adjusted or automatically adjust themselves according to changes of the climatic conditions. Thermotropic glazing in which a functional layer of a thermotropic material is incorporated into the glazing assembly is the most promising type of sun protection glazing and closest to reaching market readiness.

As early as 1950 sun protecting glazing based on a thermotropic gel network was set up and tested in the residence of the Munich zoo for a period of about 10 years. This glazing assembly consists of a mixture of 5 wt% of poly(vinyl methyl ether) in agar-agar filled between a double glazing. However, the transmission change of the glazing assembly was insufficient for commercial use. In more recent

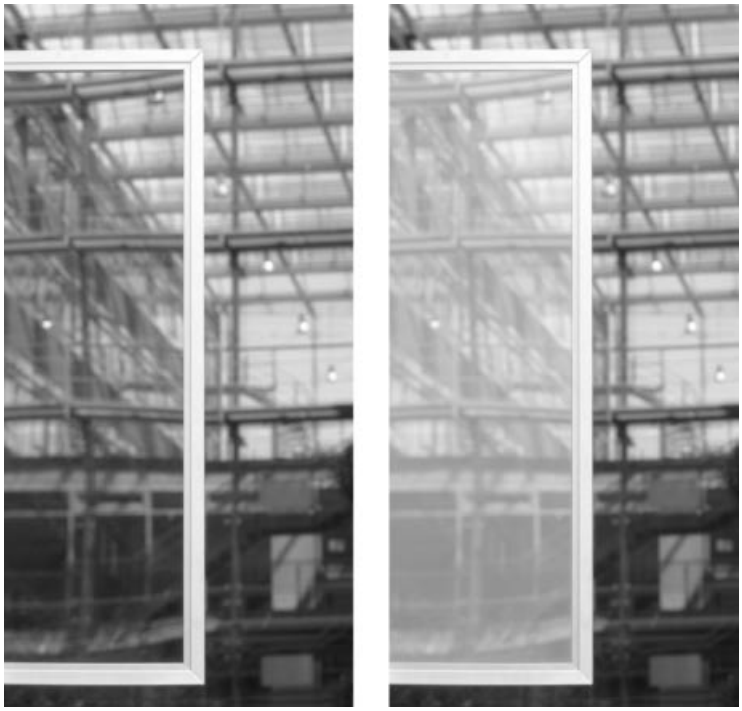

Fig. 14. Switching behavior of a sun protecting glazing (100 × 50 cm) containing a 2-mm-thick thermotropic hydrogel layer at 20°C (left side) and slightly above the switching temperature of 30°C (right side).

years advanced prototypes of sun protecting glazing based on thermotropic hydrogels with strongly improved optical properties have been presented by Chahroudi (49,50), Watanabe (53) and Seeboth (52). These glazings possess a transparency of about 90% in the transparent state and can reach a transparency of less than 10% in the translucent state. Moreover, the transparency change takes place homogeneously without the appearance of streaks. As an example, the switching of a 100 × 50 cm large prototype of a thermotropic glazing presented by Seeboth is shown in Figure 14. To commercialize thermochromic glazings based on hydrogels technology transfer from the laboratory scale to an industrial scale has to take place. Thus, for example, an automated production line for putting the polymer between the double glazing could be established.

THERMODYNAMIC PROPERTIES OF POLYMERS

Introduction

The thermodynamic properties of macromolecules cover a broad field of materials science. As with any material, macromolecules are well described if two sets of information are available: structure and energetics. Each of the two information sets can be separated into a microscopic and a macroscopic part. The microscopic description deals with matter on an atomic scale and with sizes in the nanometer range, and the macroscopic description, on a phase or larger scale, with sizes larger than micrometers. The thermodynamic properties cover the macroscopic description of energetics. For full understanding, however, the connection to the microscopic description is needed, which is achieved through statistical thermodynamics (qv). Another link to the microscopic description is offered by the kinetics that can be observed macroscopically, but for its interpretation and understanding a microscopic-level model must be available.

For many years, the thermodynamic description of macromolecules lagged behind other materials because of the unique tendency of polymeric systems to assume nonequilibrium states. Most standard sources of thermodynamic data are, thus, almost devoid of polymer information (1–7). Much of the aversion to include polymer data in standard reference sources can be traced to their nonequilibrium nature. In the meantime, polymer scientists have learned to recognize equilibrium states and utilize nonequilibrium states to explore the history of samples. For a nonequilibrium sample it is possible, for example, to thermally establish how it was transferred into the solid state (determination of the thermal and mechanical history). More recently, it was discovered with the use of temperature-modulated differential scanning calorimetry (TMDSC) that within the global, nonequilibrium structure of semicrystalline polymers, locally reversible melting and crystallization processes are possible on a nanophase level (8).

Equilibrium thermodynamic data are presented here to provide a base on which to judge the material on hand. It must always, however, be kept in mind that the actual samples analyzed are often not in equilibrium. Particularly, semicrystalline samples are not fully crystalline, do not contain perfect crystals that melt at the equilibrium melting temperature, and do not phase separate or mix when the thermodynamics are favorable (9–11). Similarly, many data must still be questioned as to their closeness to equilibrium or to the perfection of their extrapolation to equilibrium.

Basic to the thermodynamic description is the heat capacity which is defined as the partial differential $C_p = (\partial H/\partial T)_{n,p}$, where H is the enthalpy and T the temperature. The partial differential is taken at constant pressure and composition, as indicated by the subscripts p and n, respectively; A close link between microscopic and macroscopic description is possible for this fundamental property. The integral thermodynamic functions include enthalpy H entropy S, and free enthalpy G (Gibbs function). In addition, information on pressure p, volume V, and temperature T is of importance (PVT properties). The transition parameters of pure, one-component systems are seen as first-order and glass transitions. Mesophase transitions, in general, were reviewed (12) and the effect of specific interest to polymers, the conformational disorder, was described in more detail (13). The broad field of multicomponent systems is particularly troubled by nonequilibrium behavior. Polymerization thermodynamics relies on the properties of the monomers and does not have as many problems with nonequilibrium.

The instrumentation for (14) is covered mainly by calorimetry (15), thermogravimetry (16), and (17,18). Calorimetry is categorized into adiabatic calorimetry, covering the temperature range from 10 to 400 K (19–21), and differential scanning calorimetry (DSC), covering the temperature range from 200 to 1000 K (22,23). Isothermal or close-to-isothermal calorimetry includes combustion, reaction, and dissolution calorimetry (24). Much information on thermal analysis is collected in the Proceedings of the International Confederation for Thermal Analysis and Calorimetry (ICTAC) (25), and the North American Thermal Analysis Society (NATAS) (26). The broad range of literature is abstracted selectively (27). The thermal characterization of polymeric materials was described for the first time in an extensive treatise covering many types of polymers and many techniques of Thermal Analysis (qv) (28).

Heat Capacities of Solids and Liquids

Heat capacity C_p is of importance not only for the evaluation of the integral thermodynamic properties, such as enthalpy, entropy, and free enthalpy (Gibbs function), but also for the precise separation of latent heats of transition from motional energies and for the determination of glass transitions (29). Experimentally, in the low temperature region (0–100 K), heat capacity measurements are dominated by adiabatic calorimetry. Above that region, DSC has gained increasing prominence. Typical precision of measurements is now $\pm 3\%$ in the temperature range above 10 K for both solid and liquid heat capacities, although modern methods of a temperature-modulated DSC may increase the precision to levels as high as

±0.1% by eliminating heat losses through measuring the change of the calorimeter response as a function of frequency response of the calorimeter (30).

Below 10 K, the heat capacity C_p, although of interest for the theory of motion, does not contribute much to the integral H at higher temperature. It is dependent on the physical state (crystalline, semicrystalline, or amorphous), whereas the C_p of solids, from about 50 K to the glass-transition temperature T_g, is largely independent of the physical structure.

The theory of the heat capacity of solids is well established (31). The heat capacity is largely of vibrational origin and to a great extent described by the harmonic oscillator approximation. Classifying the vibrations into skeletal and group vibrations is useful. The former are of relatively low frequency, strongly coupled, and represent the intra- and intermolecular vibrations of the chain molecules. The skeletal vibrations dominate the heat capacity in the low temperature region (<100 K). All efforts to calculate the intermolecular, skeletal vibrations from crystal-structure and force-constant data were unsuccessful in the past. Heat capacity measurements still provide the best means for evaluation of the low frequency, integral vibrational spectrum. The intramolecular skeletal vibrations are somewhat higher in frequency and are accessible in their upper frequency range through isolated-chain normal-mode calculations (32). Such calculations also permit the evaluation of the numerous group vibrations. After an approximate vibrational spectrum has been established, the heat capacity at constant volume can be calculated up to, and even above, equilibrium melting temperatures of the polymeric materials. Figure 1 shows the cumulative frequency spectrum of polyoxymethylene (POM), and Figure 2 illustrates the the corresponding heat capacity contributions of the skeletal and group vibrations (**D** and **C**, respectively) as well as the total C_v (**B**) and C_p (**A**) (for theta temperatures, see Table 1).

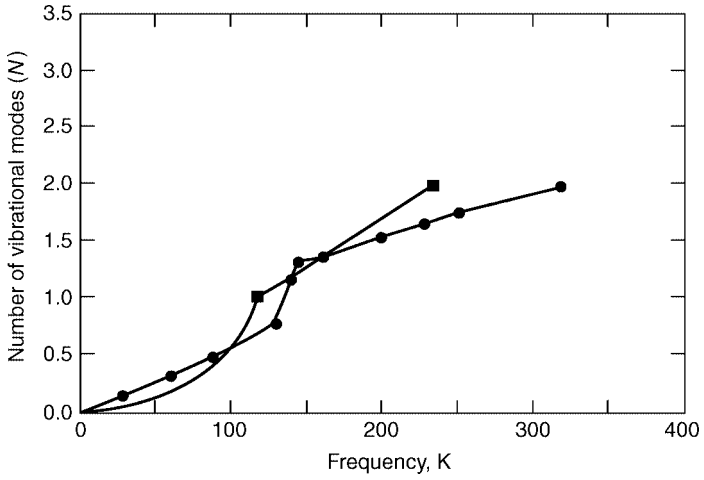

Fig. 1. Cumulative vibrational spectrum of the skeletal vibrations of polyoxymethylene (POM). ●, Experimental crystalline POM; ■, calculated with the Tarasov equation ($N = 2$).

[a]The glass-transition temperature is listed as T_g; ΔC_p is the change of the heat capacity at T_g for the fully amorphous sample; T_m is the equilibrium melting temperature; ΔH_f, the heat of fusion for the 100% crystalline sample; S, H, and G are the entropy, enthalpy, and Gibbs function, respectively; S_0 represents the residual entropy at absolute zero; θ_3 and θ_1 are the characteristic temperatures for the contributions of the skeletal vibrations to the heat capacity; N represents the number of skeletal vibrations per repeating unit (the total number of vibrations is given by the number of degrees of freedom = three times the number of atoms in the repeating unit); C_p denotes the heat capacity at constant pressure.

Data as of November 1994 (33); (a) represents the amorphous sample, and (c) the 100% crystalline; the mark ** represents heat capacities for a semicrystalline polymer. The continually updated full version of the data bank with tables and graphs can be accessed at the Internet over our Web page (34). The critically reviewed experimental data which provided the base for the data bank are available through References 35–44.

[b]The change in the heat capacity, listed in J/K · mol, at T_g as derived from the ATHAS recommended, experimental data. The mark * in this column indicates that the data were derived, instead, from the difference between experimental, liquid C_p and the calculated, solid C_p. The first numeral in parentheses refers to the number of small mobile beads that make up the repeating unit (such as CH_2—, O—, or $CHCH_3$—). The average increase in C_p at T_g of all listed molecules per small bead is 11.5 ± 1.7 J/K · mol. The second numeral refers to large beads (such as C_6H_4—). The increase in C_p of a large bead at T_g is double or triple that of a small bead.

[c]The melting temperature is the best estimate of the equilibrium melting temperature, and the heat of fusion in kJ/mol of repeating unit is computed for 100% crystallinity.

[d]An X in this column indicates that enthalpy, entropy, and Gibbs energy are available, on the basis of the ATHAS recommended data (34); ? indicates that the data is unknown.

[e]Residual entropy in the glassy state at zero temperature, in J/K · mol.

[f]The number of skeletal vibrational modes used in the Tarasov equation with the theta temperatures of the previous two columns. Values of theta temperatures in parentheses are estimates on the basis of data from polymers of similar backbone structure.

Table 1. (Continued)

[g] Temperature range of the ATHAS recommended experimental heat capacity data. The computations of heat capacities of solids are based on these data and are usually carried out from 0.1 to 1000 K, to provide sufficiently broad ranges of temperature for the addition schemes and for analysis of superheated polymers, as in laser ablation studies.
[h] The *trans*-PBUT has an additional condis state at lower temperature. The crystal–condis crystal transition is at 356 K, and the heat of transition is 7.8 kJ/mol (45,46).
[i] Between T_g and T_m, the C_p of the liquid cannot be extrapolated from melt since the liquid heat capacities of the fluorinated polymers are nonlinear.
[j] The PTFE has additional crystal–crystal–condis crystal transitions at 292 and 303 K; their combined heats of transition are 850 J/mol (47).
[k] For deuterated, amorphous, solid polystyrene and ring-only deuterated polystyrene, heat capacities lead to Tarasov θ_3 and θ_1 temperatures of 55, 244 K and 49, 278 K, respectively. The thermodynamic functions S, H, and G are found in Reference 48. For other data, see Reference 49.
[l] The listed glass-transition temperature has been assigned to relaxation processes of the n-alkyl side groups. The T_{gu} has been assigned to the backbone (44).
[m] The glass-transition and the ΔC_p in two amino acids PLSER and PLMET have been estimated for the main chain (50).
[n] The PPX has two lower first-order transitions, leading to condis crystals at 504 and 560 K with heats of transition of 5.0 and 1.5 kJ/mol (51).
[o] Semicrystalline PPO shows the existence of a rigid-amorphous phase which governs the thermal properties from T_g to T_m. Fusion, superheating, and annealing are directly affected by the rigid-amorphous phase (52).
[p] The glass-transition temperature of quenched PBT is 248 K, and the change in C_p at T_g is 107 J/K · mol. Semicrystalline PBT has a T_g at 310 to 325 K, and the change in C_p at 320 K is 77 J/K · mol. In addition, it shows existence of a rigid-amorphous fraction (53).
[q] The POB shows a disordering transition at 616.5 K with a heat of transition of 3.8 kJ/mol (54).
[r] The PON shows a disordering transition at 614.5 K with a heat of transition of 0.4 kJ/mol (54).
[s] Above T_g, poorly crystallized samples show a rigid–amorphous fraction that does not contribute to the increase in heat capacity at T_g (55).
[t] The PDMSi shows two small transitions. One is at 240 K with a heat of transition of 0.1 kJ/mol and the other at 432.5 K with a heat of transition of 0.56 kJ/mol is probably a transition from one crystal form to another (56).
[u] The PDPSi shows a disordering transition from condis crystal I to condis crystal II at 338.3 K with a heat of transition of 1.4 kJ/mol (56).
[v] The PDES has an additional condis state at a lower temperature. The crystal–condis crystal transition is at 206.7 K; its heat of transition is 2.72 kJ/mol (57).

The Einstein function (58) inverts frequency to heat capacity. Integrating the data of Figure 1 over all frequencies leads to the heat capacity

$$\frac{C_v}{NR} = \int_0^{\theta_{max}} \frac{(\theta/T)^2 \exp(\theta/T)}{[\exp(\theta/T) - 1]^2} \, d\theta \tag{1}$$

where T is the temperature and θ is the frequency, both expressed in kelvin ($\theta = h\nu/k$, with ν representing the frequency in Hz; h and k are Planck's and Boltzmann's constants, respectively; 1.0 Hz $= 4.799 \times 10^{-11}$ K, 1.0 cm$^{-1} = 1.4388$ K).

The integration of equation 1 is evaluated in steps for the various regions of the frequency distributions found for macromolecules. The lowest vibrational frequencies (skeletal) usually follow a quadratic function up to a frequency limit called θ_D or θ_3. This is the well-known Debye approximation (59) of the low temperature heat capacity at constant volume, C_v (**B**), which in this temperature range

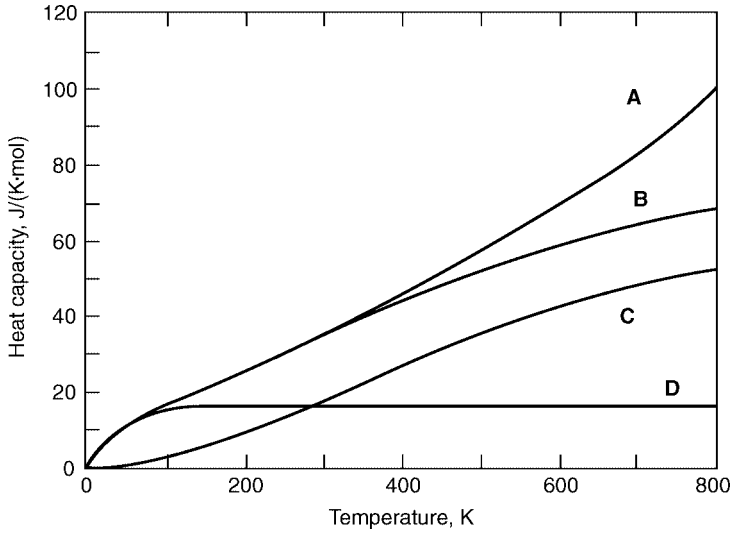

Fig. 2. Heat capacity contributions of the skeletal and group vibrations of solid polyoxymethylene, calculated by the Advanced Thermal Analysis System (ATHAS). **A**, C_p; **B**, C_v; **C**, group vibrations; **D**, skeletal vibrations. To convert J to cal, divide by 4.184.

is little different from C_p (**A**)

$$D_3\left(\frac{\theta_D}{T}\right) = \frac{C_v}{NR} = \left(\frac{12\,T^3}{\theta_3^3}\right)\int_0^{\theta_3/T} \frac{x^3 dx}{\exp(x-1)} - \frac{3\theta_D/T}{\exp(\theta_D/T)-1} \tag{2}$$

For two- or one-dimensional structures, such as are found in crystals of layer and chain molecules, the frequency distribution changes to linear and constant functions, respectively. The corresponding integrals are called the two- and one-dimensional Debye functions (60,61)

$$D_2\left(\frac{\theta_2}{T}\right) = \frac{C_v}{NR} = \left(\frac{6T^2}{\theta_2^2}\right)\int_0^{\theta_2/T} \frac{x^2 dx}{\exp(x)-1} - \frac{2\theta_2/T}{\exp(\theta_2/T)-1} \tag{3}$$

$$D_1\left(\frac{\theta_1}{T}\right) = \frac{C_v}{NR} = \left(\frac{2T}{\theta_1}\right)\int_0^{\theta_1/T} \frac{x\,dx}{\exp(x)-1} - \frac{\theta_1/T}{\exp(\theta_1/T)-1} \tag{4}$$

The N in equations 1-4 refers to the appropriate number of vibrators and x stands for $h\nu/kT = \theta/T$. The sum of all N is three times the number of atoms in a repeating unit, the number of degrees of freedom. Tarasov proposed a special combination of equations 2 and 4 for the skeletal vibrations of a linear chain (62)

$$T(\theta_3/T,\ \theta_1/T) = \frac{C_v}{NR} = D_1(\theta_1/T) - (\theta_3/\theta_1)\left[D_1\left(\frac{\theta_3}{T}\right) - D_3\left(\frac{\theta_3}{T}\right)\right] \tag{5}$$

Table 2. Group Vibration Frequencies of Polytetrafluoroethylene

	Einstein terms		Box distribution		
Normal mode	N_E	ν_E (cm^{-1})	N_b	ν_L (cm^{-1})	ν_U (cm^{-1})
ν_1 (asymmetric CF_2 stretching)	0.20	1449	0.67	1250	1440
	0.13	1256			
ν_2 (C—C stretching)			0.53	1161	1379
			0.47	1161	1229
ν_3 (symmetric CF_2 stretching)	0.17	1149	0.83	723	1154
ν_4 (CF_2 wagging)	0.20	576	0.20	630	672
			0.60	587	672
ν_5 (CF_2 rocking)	0.27	755	0.73	307	519
ν_6 (CF_2 bending)	0.13	385	0.87	283	385
ν_7 (CF_2 twisting)	0.23	294	0.77	190	289

The Tarasov equation holds for most linear macromolecules. Its limits are reached when phenylene groups are included in the backbone chain as in poly(oxy-1,4-phenylene) or poly(ethylene terephthalate) (63), or alternating heavy and light mass backbone units occur, as in poly(vinylidene fluoride) or poly(vinylidene chloride)s (64). A detailed analysis of skeletal vibration is available (32). Table 1 lists data of N, θ_1 and θ_3 for a selected number of polymers. For group vibrations, which are usually of much narrower distribution, it is sufficient to use single-frequency Einstein terms or to average over a frequency range that leads to a box-distribution function

$$B\left(\frac{\theta_U}{T}, \frac{\theta_L}{T}\right) = \frac{C_v}{NR} = \frac{\theta_U}{(\theta_U - \theta_L)}\left[D_1\left(\frac{\theta_U}{T}\right) - \frac{\theta_L}{\theta_U} D_1\left(\frac{\theta_L}{T}\right)\right] \tag{6}$$

where θ_U and θ_L are the upper and lower frequencies of the group vibrational range. Table 2 shows, as an example, the various approximated frequency regions used for the group-vibration spectrum of polytetrafluoroethylene as derived from a dispersion curve.

In the final step of computation, C_v is connected with the measured C_p. Both the thermal expansivity α and the isothermal compressibility κ must be known for this thermodynamics-based calculation

$$C_p - C_v = \alpha^2 VT/\kappa \tag{7}$$

where V represents the molar volume. Since α and κ are usually, at best, available at one temperature, the semiempirical Nernst–Lindemann expression must be utilized with modifications that account for the slow excitation of the vibrations involving the light atoms and strongly bound atoms in polymers (65,66)

$$C_p - C_v = 3RA_0 C_p T / T_m^0 \tag{8}$$

where $T_m{}^0$ is the equilibrium melting temperature and A_0 is a constant that for many polymers has a value close to 3.9×10^{-3} K · mol/J (66).

In the temperature region from above 100 K to the glass or melting transition, the intramolecular skeletal vibrations of most polymers can be evaluated after computation of the group vibrations. The intermolecular vibrations are commonly already excited at 100 K, while the remaining skeletal vibrations approach full excitation at room temperature, and then contribute a constant amount NR to the heat capacity. The values of the skeletal vibrations, N, are listed in Table 1, together with the temperature range of available experimental data. The group vibrations, as listed in Table 2 for polytetrafluoroethylene, cause another gradual increase in C_p above room temperature (note that the repeating unit is CF_2- and not C_2F_4-). It can be seen in Figure 2 that the Dulong–Petit high temperature limit for the heat capacity at constant volume, C_v, for polyoxymethylene of $12\,R = 100$ J/(K · mol) is not reached at the decomposition temperature. The highest frequencies are the CH_2 stretching vibration (as high as 4000 K).

Between the glass and melting transitions of semicrystalline macromolecules, special thermal effects can be observed. Semicrystalline macromolecules have a microphase- or nanophase-separated structure with many molecules bridging two or more phases in a nonequilibrium state. As soon as the noncrystalline portions of the molecules experience a glass transition, C_p increases. The phase boundaries result in a broadening of the glass-transition region of partially crystalline polymers beyond the high temperature end seen in noncrystalline samples due to stress transmitted into the noncrystalline phase. A detailed thermal analysis of poly(ethylene terephthalate) showed drastic changes of the relaxation energies on partial crystallization (see also Figure 11, below) (67,68). Often the increase in C_p is, in addition, less than expected from the crystallinity determined from the heat of fusion when assuming a macroscopic two-phase system (crystallinity model). The missing increase in C_p was proposed to be caused by a third phase, a rigid–amorphous nanophase, as part of the semicrystalline structure (69). In the meantime, TMDSC allowed to demonstrate that the rigid–amorphous phase RAF is produced at the same time as the crystals, and also disappears along with the crystals and may show a separate T_g below or above the melting temperature (8). In the second case, melting is retarded because of a limited mobility in the rigid noncrystalline phase (70).

Increases as well as decreases in enthalpy can also be observed between T_g and T_m in case the phase-structure changes, ie, the composition changes because of a latent heat. The change of the enthalpy is then not only caused by a heat capacity, $(\partial H/\partial T)_{n,p}$, but must be written as

$$dH = (\partial H/\partial T)_{n,p}\, dT + (\partial H/\partial T)_{T,p}\, dn \tag{9}$$

or, if the crystallinity w^c changes in a measurable way with temperature, as

$$dH/dT = C_p^{\#} = w^c C_{p,c} + (1 - w^c) C_{p,a} - \Delta H_f (dw^c/dT) \tag{10}$$

Treating dH/dT as an "apparent" heat capacity $C_p{}^{\#}$, equation 10 allows the separation of the latent heat contribution from the thermodynamic heat capacity if $C_{p,c}$ and $C_{p,a}$, the crystalline and amorphous heat capacities, are known (as well as the temperature-dependence of the heat of fusion, ΔH_f).

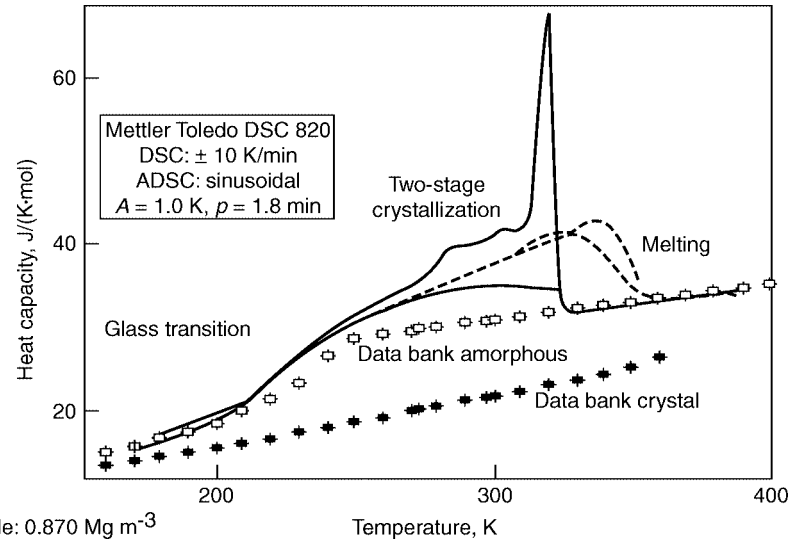

Fig. 3. Differential thermal analysis of linear low density polyethylene on cooling (continuous lines), followed by heating (broken lines), showing a high content of reversing crystallization and melting. Standard DSC: thin lines; TMDSC: thick lines. The overall supercooling contrasts the partially reversible crystallization and melting after an overall metastable, semicrystalline structure has been set up on the initial cooling. The modulation amplitude on TMDSC is given by the letter A, and the modulation period by p.

Well-known processes which can decrease or increase the enthalpy of a nonequilibrium, semicrystalline polymer on its path to higher stability are premelting (11), crystal perfection, reorganization, recrystallization (9,10), and cold crystallization (71). Recently it was found that within the metastable, global nanophase structure of semicrystalline polymers, it is also possible to observe local, reversible phase equilibria (8). Special techniques of the temperature-modulated DSC must be used to get quantitative information about the reversible equilibria. Folded-chain crystals and fringed-micellar structures show considerable reversibility in the crystallization and melting range. Figure 3 compares, as an example, TMDSC cooling and heating curves with analogous, standard DSC traces for linear low density polyethylene. The high temperature crystallization and melting mainly represents chain-folded crystals with partial reversibility. Closer toward T_g, fringed micellar crystals prevail with almost complete reversibility. More rigid macromolecules, as well as extended-chain molecules, do not exhibit such reversibility, as is shown in Figure 4, for extended-chain polyethylene (8).

The heat capacity of liquid macromolecules can be measured above the glass-transition or the melting-transition temperature. The group vibrations change little on fusion. The changes of the skeletal vibrations due to volume expansion also have little influence on heat capacity, since, once excited, the heat capacity contribution remains unchanged on lowering of the frequency. The change in volume expansion is noticed in a sizable increase in C_p at the glass transition, caused largely by a potential energy increase (hole formation). However,

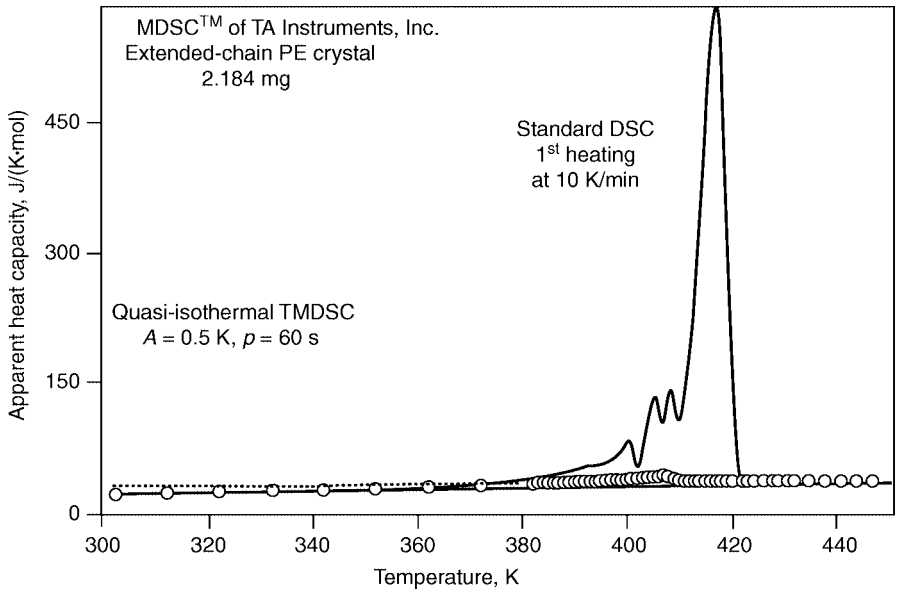

Fig. 4. Analysis of the melting of extended-chain crystals of polyethylene grown to 98% crystallinity, using high pressure crystallization (9,10,13). The standard DSC shows the sum of the latent heat and heat-capacity contributions of equations 9 and 10. The minor low temperature peaks reveal low molecular mass fractions and a small amount of remaining chain folding. The quasi-isothermal TMDSC was carried out sequentially for 20 min or longer at the temperatures indicated by the small circles. ○ 1st heating. The modulation had an amplitude A and period p. Practically no reversing melting can be seen. The small remaining reversible fraction could be accounted for quantitatively by the low molar mass portion and the remaining chain folding (8).

quantitatively, little is known about the theory of liquid heat capacity. Attempts to compute heat capacities of liquid macromolecules were based on a separation of the partition function into a vibrational part (approximated by the vibrational spectrum of the solid, as described above), a conformational part [approximated by the rotational isomers model (72) or a description using a one-dimensional Ising model (73)], and an external, configurational part (approximated by data derived from the difference in heat capacity at constant pressure and volume as given by eq. 7).

Empirically, liquid heat capacities are often observed to change linearly with temperature. They have a smaller increase with temperature than solids, and are additive with regard to their constituent groups. In case of atomic backbone repeating units, such as Se (74), O (75), or S (76), the group contribution of the heat capacity decreases with temperature. This occurs most likely because of increasing changes of vibrational modes of motion to internal rotations whose heat capacity contributions decrease with temperature from R to $R/2$. Table 3 shows the relationship between C_p and temperature T for common groups, based on an empirical addition scheme (77). An error of less than $\pm 5\%$ in the temperature range of 250–750 K is typical. References to all known liquid heat capacities and their temperature ranges are given in Table 1.

Table 3. Relationships between Liquid C_p and Temperature T for Different Structure Groups in Linear Macromolecules

Group	$C_{p,\mathrm{a}}$, J/(K · mol)
Methylene, CH_2	$0.0433\,T + 17.92$
Phenylene, C_6H_4	$0.1460\,T + 73.13$
Carboxyl, COO	$0.002441\,T + 64.32$
Carbonate, OCOO	$0.06446\,T + 84.54$
Dimethylmethylene, $C(CH_3)$	$0.2013\,T + 18.79$
Carbonyl, CO	$0.07119\,T + 32.73$
Naphthylene, C_6H_{10}	$0.2527\,T + 114.49$
Dimethylphenylene, $C_6H_2(CH_3)_2$	$0.2378\,T + 111.41$
Oxygen, O	$-0.00711\,T + 28.13$
Sulfur, S	$-0.02028\,T + 46.59$
Selenium, Se	$0.000032608\,T^2 - 0.049766\,T + 52.408$

Other Thermodynamic Functions

Enthalpy, Entropy, and Free Enthalpy. By knowing solid and liquid heat capacities of linear macromolecules, other thermodynamic functions can be obtained through the following relationships

$$H_{\mathrm{T}} - H_0 = \int_0^T C_p \, \mathrm{d}T \tag{11}$$

$$S_{\mathrm{T}} - S_0 = \int_0^T \frac{C_p}{T} \, \mathrm{d}T \tag{12}$$

$$G_{\mathrm{T}} = H_{\mathrm{T}} - TS_{\mathrm{T}} \tag{13}$$

For perfect, crystalline solids, the entropy at 0 K is zero, ${S_{\mathrm{c}}}^0 = 0$. Thus, absolute entropies can be calculated directly. Information to the available data is given in Table 1. For crystalline, linear macromolecules, the derived thermodynamic functions are reported as follows

$$\begin{array}{rc} \textit{Enthalpy}: & H^c_{\mathrm{T}} - H^c_0 \\ \textit{Entropy}: & S^c_{\mathrm{T}} \\ \textit{Free enthalpy}: & G^{\mathrm{c}}_{\mathrm{T}} - H^c_0 \end{array}$$

For amorphous solids, the residual entropy at 0 K can be calculated by equating the entropy at the equilibrium melting temperature ${T_{\mathrm{m}}}^0$

$$S^c_{T^0_{\mathrm{m}}} + \Delta S_{\mathrm{f}} = S^a_{T^0_{\mathrm{m}}} \tag{14}$$

where ΔS_f is the equilibrium entropy of fusion of fully crystalline solids. It follows that

$$S^{\mathrm{a}}_0 = S^{\mathrm{c}}_{T^0_{\mathrm{m}}} + \Delta S_f - \left(S^{\mathrm{a}}_{T^0_{\mathrm{m}}} - S^{\mathrm{a}}_0\right) = \int_0^{T^0_{\mathrm{m}}} \left(C^{\mathrm{c}}_p - C^{\mathrm{a}}_p\right) d(\ln T) + \Delta S_f \tag{15}$$

An analysis of many macromolecules indicates that the residual entropy of amorphous macromolecules at absolute zero is 2–4 J/K · mol per mobile bead, as listed in Table 1 (76,77). With the knowledge of $S_0{}^a$, the absolute entropy of amorphous solids can be calculated. The crystalline state at 0 K is chosen as a standard state for all enthalpy and free enthalpy data. The functions $(H_T{}^a - H_0{}^c)$ and $H_T{}^c - H_0{}^c)$ are directly related to the heats of fusion at temperature T

$$H_T^a - H_0^c = \left(H_T^a - H_0^a\right) + \left(H_0^a - H_0^c\right) \tag{16}$$

$$H_0^a - H_0^c = \left(H_{T_m^0}^c - H_0^c\right) + \Delta H_f - \left(H_{T_m^0}^a - H_0^a\right) \tag{17}$$

From the absolute entropy and $H_T{}^a - H_0{}^c$, the free enthalpy (Gibbs function) $G_T{}^a - H_0{}^c$ can be calculated for amorphous solids. For amorphous linear macromolecules, the reported thermodynamic functions listed in the sources for Table 1 are

Enthalpy:	$H_T^a - H_0^a$, $H_T^a - H_0^c$
Entropy:	$S_T^a - S_0^a$, S_T^a
Free enthalpy:	$G_T^a - H_0^c$

Figure 5 shows the changes of these thermodynamic functions of polyethylene with temperature.

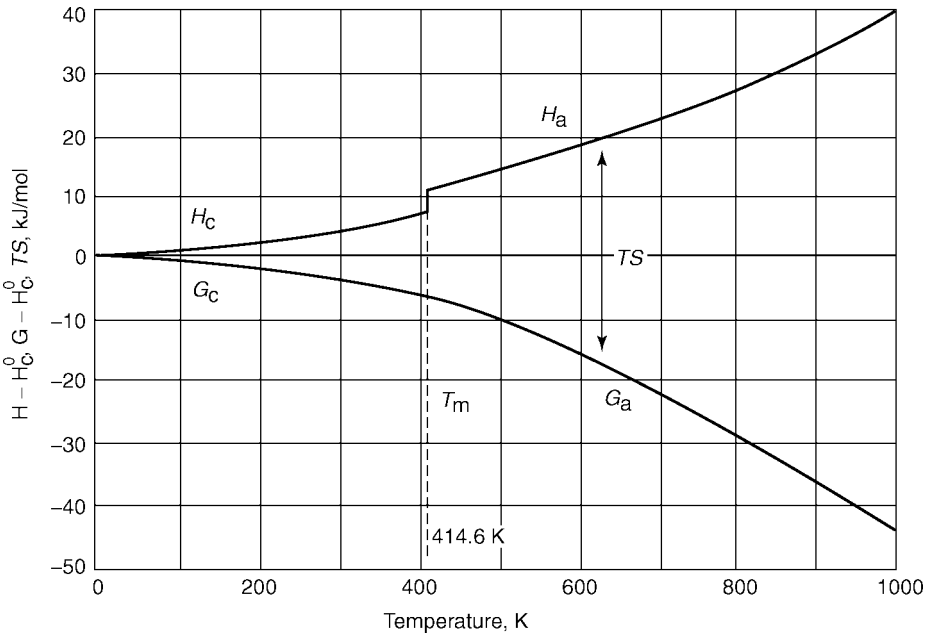

Fig. 5. Enthalpy, entropy, and free enthalpy of polyethylene as derived from heat capacities. The origin of H and G has been set arbitrarily to zero at absolute zero in temperature, and the energy equivalent TS is plotted instead of S.

Table 4. Pressure–Volume–Temperature Data of Macromolecules[a]

Polymer	Temperature range, K	Pressure, Pa $\times 10^4$	Ref.
Polyethylene, linear	414–472	0–2000	80
Polyethylene, branched	385–498	0–2000	81
Isotactic polypropylene	443–570	0–2000	82
Isotactic poly(1-butene)	406–519	0–2000	82
Poly(4-methyl-1-pentene)	508–615	0–2000	83
Polytetrafluoroethylene	603–645	0–400	84
Poly(ethylene terephthalate)	543–615	0–2000	85
Polysulfone	468–643	0–2000	86
Polystyrene	223–523	100–1800	87

Polyarylate	303–613	100–1800	86
Phenoxy resin	303–573	100–1800	86

[a] To convert Pa to mm Hg, multiply with 0.0075.

Pressure, Volume, and Temperature. The pressure–volume–temperature (PVT) diagrams of linear macromolecules in different states provide another set of important thermodynamic functions, as is shown in Figure 6, for polypropylene. Using high pressure dilatometry, macromolecules have been analyzed in their liquid states, as shown in Table 4. All data can be fitted to the empirical Tait equation listed in Figure 6. Both constants of the Tait equation are exponential functions of temperature.

Empirical Tait equation:
$$v(p,T) = v_0(T)\{1 - 0.0894 \ln[1 + p/B(T)]\}$$

$v_0(T)$ = Volume at zero (atm) pressure

$B(t)$ = Tait parameter

Theoretical treatments of the equation of state are based on the lattice theory. The Simha–Somcynsky theory suggests a hole theory of polymeric liquids by determination of the reduced parameters p^*, v^*, and T^* (78,79). This statistical

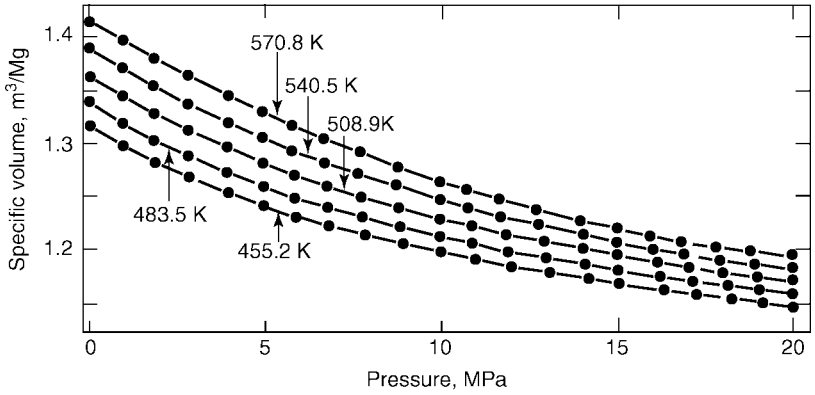

Fig. 6. Experimental (circles) and theoretical (curves) isotherms for polypropylene. The curves are based on the Simha–Somcynsky theory and show good agreement with the data ($v^* = 1.1954$ cm^3/g, $p^* = 530$ kPa, $T^* = 11{,}155$ K) (78,79).

mechanical theory describes a polymer melt as consisting of N molecules having s segments, each of which need not be identical to the chemical repeating unit. They are placed in a quasi-lattice of coordination number z, with the fraction y of the lattice sites occupied; the hole fraction is, thus, $1 - y$. Each molecule is to have $3c$ external (volume-dependent) degrees of freedom. A "square-well" approximation of the 6–12 potential is used as intersegmental potential, specified by the potential energy minimum ε^* and the hardcore volume v^* of the segment. The partitionfunction of the system contains a Boltzmann lattice–energy factor, a combinatorial factor representing the entropy of segment mixing and empty lattice sites, and a statistical-mechanical free-volume term. From the partition function, the equation of state may be calculated in the form of

$$\tilde{p}\tilde{v}/\tilde{T} = f[\tilde{v},\ \tilde{T},\ y(\tilde{v},\ \tilde{T})] \tag{18}$$

The function $y(\tilde{v},\ \tilde{T})$ is determined by the minimization of the Helmholtz free energy with respect to y.

$$(\partial \tilde{F}/\partial y)_{\tilde{v},T} = 0 \tag{19}$$

This leads to a transcendental equation for y which requires numerical solution. The equation of state and the determining equation for y are written in terms of reduced variables $\tilde{p} = p/p^*$, $\tilde{v} = v/v^*$, and $\tilde{T} = T/T^*$. The reducing parameters, p^*, v^*, and $T,^*$ contain the molecular characteristics of the system as follows (for a system of one gram of material) (88,89)

$$v^* = Nsu^* = (N_A/M)v^* \tag{20}$$

$$T^* = (z-2)s\epsilon^*/ck \tag{21}$$

$$p^* = (z-2)\epsilon^*/v^* \tag{22}$$

where N_A represents Avogadro's number, M is the molecular mass per segment, and k is the Boltzmann constant. Even though the equation of state is written in terms of reduced variables, it does not conform to a principle of corresponding states since the determining equation of y also explicitly contains the flexibility ratio $3c/s$. However, the equations of state calculated for different values of $3c/s$ are superimposable. This means that the equation of state effectively conforms to a principle of corresponding states, but it also means that the ratio $3c/s$ cannot be calculated from PVT data. Conventionally, the theoretical equation of state is evaluated by setting $3c/s = 1$ ie, the theory is formulated in terms of an effective segment having exactly one external degree of freedom. The molecular mass M_0 of this segment follows to be

$$p^*v^*/T^* = (1/3)kN_A/M_0 = R/3M_0 \tag{23}$$

where R is the gas constant. The choice $3c/s = 1$ makes T^* directly proportional to the energy parameter of the effective segment, and $M_0v^* = N_Av^*$ becomes the molar hardcore volume of the effective segment.

In order to avoid the uncertainty of the parameter c which characterizes the decrease in the external degrees of freedom, a much simpler mathematical form of the equation of state was proposed on the basis of the Ising (lattice) fluid model (88,89)

$$\tilde{\rho}^2 + \tilde{p} + \tilde{T}[\ln(1-\tilde{\rho}) + (1-1/r)\tilde{\rho}] = 0 \tag{24}$$

where $\tilde{\rho}$ is the reduced density ($\tilde{\rho} = \rho/\rho^*$), $\tilde{p}$ and $\tilde{T}$ are the same as defined above, and r is the number of lattice sites occupied by the r-mer. These equation-of-state parameters are related to the molecular mass M by

$$RT^* \ \rho^*/p^* = M/r \tag{25}$$

where R is again the gas constant.

Since r remains explicit in the reduced equation of state, a simple corresponding-state principle is not, in general, satisfied. For a polymeric liquid, however, $r \to \infty$, and the equation of state is reduced to

$$\tilde{\rho}^2 + \tilde{p} + \tilde{T}[\ln(1-\tilde{\rho}) + \tilde{\rho}] = 0 \tag{26}$$

Thus, all polymer liquids of sufficiently high molecular mass should satisfy a corresponding-state principle.

Earlier than either of the two theories mentioned above, Flory and co-workers (90,91) proposed an equation of state in a reduced form as

$$\tilde{p}\tilde{v}/\tilde{T} = \tilde{v}^{1/3}/(\tilde{v}^{1/3} - 1) - (1/\tilde{v}\tilde{T}) \tag{27}$$

Again, the reduced variables are defined as they were before: $\tilde{p} = p/p^*$, $\tilde{v} = v/v^*$, and $\tilde{T} = T/T^*$. In this theory, the reduced quantities (with an asterisk) reflect the molecular characteristics of the system.

Experimental PVT data reported so far have been described best by using the Simha-Somcynsky equation (eq. 18) (78,79), and somewhat less well by equation 27 (90,91). Equation 24 (88,89) is substantially poorer, especially at elevated pressure.

All PVT diagrams studied so far refer to polymer liquids. Substantial experimental difficulty arises in the extension to the semicrystalline state because of the nonequilibrium nature. No determined attempt at extrapolation to equilibrium data has been made to date, despite the possibility to approximate equilibrium crystal properties from unit cell parameters of X-ray data.

Transition Properties

First-Order Transitions. The principal transitions in macromolecules are those concerned with enthalpy (latent heat) and entropy changes. They are called first-order transitions according to a classification requiring the first derivative of the change in free enthalpy with respect to temperature not to be zero (92). For a single-component system (pure compound), thermodynamic equilibrium states

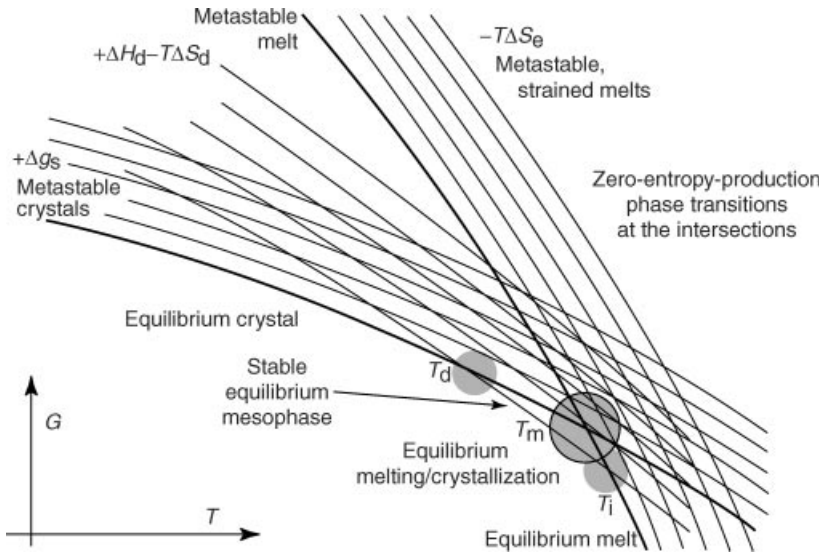

Fig. 7. Free enthalpy of equilibrium and metastable states. The solid lines represent G of the equilibrium crystal and liquid and their extrapolations beyond T_m. The G of metastable crystals and melts are largely parallel to the equilibrium states. Adding a mesophase with an intermediate entropy between liquid and solid may produce, as shown, an equilibrium mesophase between T_d, of disordering and T_i, the temperature of isotropization. Such mesophase shifts T_m into the nonequilibrium region.

are always at the lowest Gibbs energy G, as shown in Figure 7. A crystal must melt at a sharp melting temperature ${T_m}^0$. The transition shows a change in the slope of free enthalpy in going from one phase to the other. The relationship of the melting temperature to changes in enthalpy and entropy is

$$T_m^0 = \frac{\Delta H_f^0}{\Delta S_f^0} \tag{28}$$

where ${\Delta H_f}^0$ and ${\Delta S_f}^0$ are the heat and entropy of fusion, respectively.

Equilibrium crystals are defined as crystals with negligible surface effects (of infinite size) and, if any, only equilibrium defects. Complications exist, however, in the study of the transition of linear macromolecules caused by a common formation of lamellar or fibrillar crystals which are metastable and contain nonequilibrium defects (9). Therefore, even pure, one-component, crystalline macromolecules have usually a broad melting-transition range and do not approach equilibrium, although it was found recently that local equilibria may exist on the overall metastable phase structure (8). The experimental methods to approach equilibrium developed for nonpolymeric materials involving slow heating or annealing before analysis were singularly unsuccessful for macromolecules (11).

Early observations of melting transitions revealed the change of three thermodynamic functions, the degree of order (entropy), volume, and enthalpy. For the first function, a general statement about the different contributions from

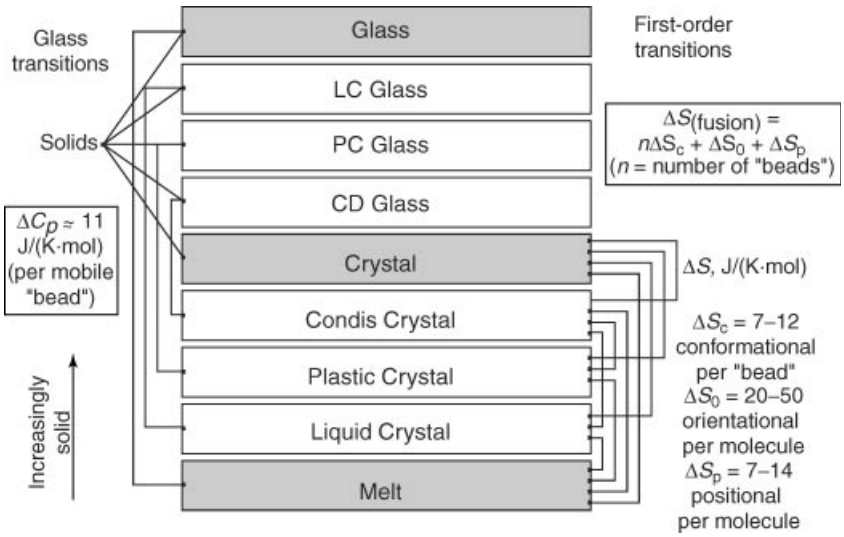

Fig. 8. Illustration of the classical condensed phases (melt, crystal and glass) and the six possible mesophases (liquid, plastic, and condis crystals and their corresponding glasses). The possible first-order transitions and their entropies of transition are marked on the right and the glass transitions and their change in heat capacity at T_g, on the left.

positional, orientational, and conformational entropy changes can be made (11). In fact, a general scheme of these entropy contributions was developed (12), as is shown in Figure 8. The most important mesophases for macromolecules are the liquid and condis crystals (13).

No such statement can be made for the volume or enthalpy changes on transition, although similar crystal structures and molecules may lead to similar changes (93). Further general observations on fusion are the lowering of ${T_m}^0$ by solvents (as a second, noncrystallizable component) and the lowering of ${T_m}^0$ for small crystals (11). The last effect has also been used to describe the fusion of small, nonequilibrium crystals as commonly found in metastable, semicrystalline polymers (11,94).

To find the equilibrium melting temperature and heat of fusion, extrapolations must be made from measurements on metastable, small crystals or on equilibrium crystals of small molecules. Only since the 1960s are crystals of extended chain macroconformation and macroscopic size available for some macromolecules. These crystals have been analyzed with respect to their melting behavior (11,95,96), which permits the discussion of equilibrium melting from both an experimental and a theoretical point of view. Although these equilibrium crystals cannot grow at ${T_m}^0$, their melting can be observed at ${T_m}^0$. Table 1 also gives a summary of all critically reviewed heats of fusion and equilibrium melting temperatures. These data deviate substantially from those expected from nonequilibrium experiments (11).

In addition to complete, one-step fusion, it is possible that some order is retained during a phase transition of the first order. In this case, mesophases are formed as shown in Figure 8. These are phases of intermediate order and mobility

(12). The entropy of fusion may be approximated by

$$\Delta S_f = \Delta S_{pos} + \Delta S_{or} T + n \Delta S_{conf} \quad (29)$$

where the three ΔS contributions are due to positional, orientational, and conformational entropy changes during the transitions. Only the last term depends on molecular size n, as also shown in Figure 8. The liquid crystals retain a small amount of orientational order because of the presence of a rod-or disk-like mesogen in the molecule; plastic crystals retain full positional order because of an almost spherical molecular shape, which permits rotation in the crystal; and condis crystals show dynamic conformational disorder in the crystal.

The phase changes of semicrystalline macromolecules that are usually not in equilibrium must make use of irreversible thermodynamics (11,97). On the other hand, even a system that is initially in equilibrium may go through a nonequilibrium transition because of kinetic restrictions, such as the superheating of crystals (98) or the more widely recognized supercooling of polymer melts on crystallization (10). The latter cases are often treated by kinetic arguments by introducing nucleation barriers (10,88,89,99).

Trying to obtain data from nonequilibrium experiments, one finds that the metastability of the system can change during the study. In order to avoid or distinguish those effects, three methods have been developed and are commonly applied for the study of nonequilibrium phase transition. The first involves the study of the transition as a function of time; the second avoids changes in the amorphous–crystalline interface by cross-linking the molecules; and the third hinders reorganization through chemical etching of the amorphous areas, producing small, equilibrium (but oligomeric) crystals, the transitions of which can be related to the small polymer crystals (11). Equilibrium transitions to be compared to the nonequilibrium measurements are listed in Table 1.

Glass Transitions. The glass-transition temperature is the main characteristic of the solid and mobile states of macromolecules with mesophase or amorphous structure. The mobile states become solid on cooling through the glass-transition temperature if crystallization does not intervene, as indicated in Figure 8. The microscopic process involved is the freezing of large-scale, molecular motion without change in structure. Since the heat capacity of the glass is always lower than that of the liquid at the same temperature, and since there is no latent heat involved, the glass transition takes superficially the appearance of a thermodynamic second-order transition (92). The freezing of molecular motion is, however, time-dependent, and, therefore, the glass transition must be called an irreversible process, and its characterization must include the time scale of the measurement. The glass transition occurs at a recognizable transition temperature because of a rather large temperature dependence of the relaxation time for large-scale molecular motion (micro-Brownian motion). Since the glass transition occurs over a larger temperature region, a characterization must involve five temperatures, as shown in Figure 9. The glass-transition temperature T_g is commonly the temperature of half-freezing, as it can be determined by heat capacity, expansion coefficient, or compressibility, as examples.

Detailed, and sometimes conflicting, theories of the glass transition, mainly applied to linear macromolecules, are discussed elsewhere (100–107). The theories

are all simplified and do not describe the glass transition fully. Their principal shortcoming is the omission of the cooperative nature of the glass transition. Unfreezing one configuration significantly helps the neighboring molecular segments to move. The frequency dependence of the glass transition cannot only be determined by mechanical analysis and dielectric measurements, but also with temperature-modulated calorimetry. A comparison of the different results is available (108,109) (see, GLASS TRANSITION).

A critical survey of over 20 macromolecules revealed that the heat capacity increase at the glass-transition temperature is about 11.3 J/K per mole of mobile units (110). The division of a repeating unit into mobile units is not fully unambiguous. However, independent motion can be expected between the different rotational isomers for mobile groups as, for example, for phenylene, carboxyl, or methylene groups. These groups are then to be counted as separate mobile units. Furthermore, the effect of a mobile unit is somewhat size-dependent. Large units seem to contribute two times or even three times the increase in heat capacity at the glass transition (76,77,111). In Table 1, the number of mobile units, assumed for the respective repeating units, is given in parentheses in column 2. Also listed are critically reviewed glass-transition temperatures and heat capacity increases at the glass-transition temperature.

The change in volume V, enthalpy H, and entropy S, as well as the derivative heat capacity C_p, and thermal expansivity α on cooling and heating are shown schematically in Figure 10. Coupling equal heating and cooling rates leads to the glass-transition behavior which is illustrated in Figure 9. It permits measurement on heating as well as on cooling. The thermodynamic quantities change almost reversibly between the values characteristic for the glass and the liquid at a temperature determined by the time scale of measurement. Different cooling and heating rates cause hysteresis effects. Shown is an endotherm after the glass transition due to slower cooling than heating.

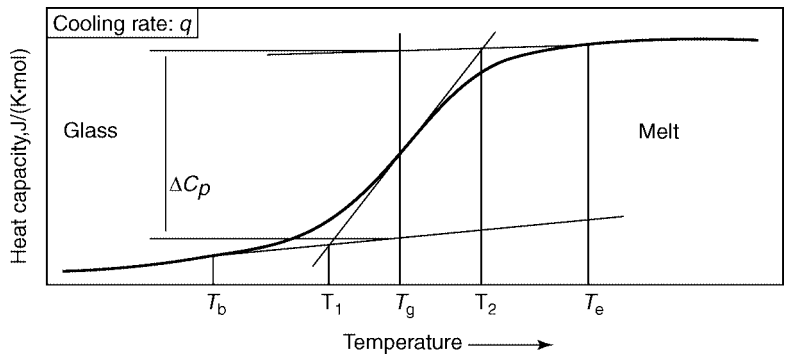

Fig. 9. Heat capacity in the glass-transition region. The first perceptible beginning of the glass transition T_b is judged by the first increase in C_p from that of the solid state; T_1 and T_2 are the extrapolated beginning and end of the glass transition. The difference between T_1 and T_2 is indicative of the broadness of the main portion of the glass transition. The glass-transition temperature T_g is chosen at half-devitrification when judged by the C_p increase. The temperature T_e is the end of glass transition; it is reached when C_p attains the value of the mobile phase. The time-scale is fixed by the cooling rate q.

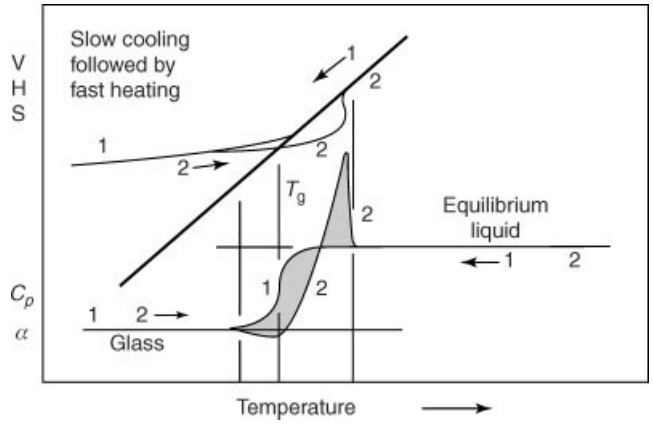

Fig. 10. Schematic drawing of the changes in volume, enthalpy, entropy, and the derivative properties (heat capacity C_p and expansivity α) on slow cooling followed by fast heating through the glass-transition region. The numeral 1 marks the response on cooling, the numeral 2, on heating. The two shaded areas are of equal magnitude and can be used to characterize the thermal history.

The glass transitions are not only affected by their previous thermal history, as demonstrated in Figure 10, but also by their mechanical (and dielectric) history. Stress, induced during sample processing such as drawing, may be frozen in on cooling through T_g. The stress introduces weak points with respect to chemical degradation. On heating into the vicinity of the glass transition, the stress causes shrinkage or deformation of the sample. Thermal analysis can detect the stress as it is released at T_g in the form of an exotherm. While exotherms induced by hysteresis decrease with increasing heating rate when a quickly cooled sample is reheated more slowly and may even turn into endotherms, the stress-related exotherms are of constant area (enthalpy) and may only broaden over a wider temperature range with increasing heating rate.

Semicrystalline samples show changes in the glass transition of the amorphous fraction which lead to a broadening of the transition range and shifts of the midpoint of the transition to higher temperature. In addition, the crystals may form a rigid–amorphous fraction, as described in the section about the heat capacities of solids and liquids at the beginning of this article on thermodynamic properties (75–77). Figure 11 illustrates the change of the glass transition of amorphous poly(ethylene terephthalate) with increasing crystallinity. The absolute levels of the heat capacity after the glass transition do not correspond to the level of crystallinity. The missing increase in heat capacity is linked to the presence of a rigid–amorphous fraction which undergoes its glass transition at a higher temperature (67), as was described above, in connection with the discussion of the heat capacity of semicrystalline structures.

Liquid Multicomponent Systems. For the description of multicomponent systems, the number of moles, N_i, or concentrations of each of the components is added to temperature and pressure as variables of state. For each extensive function of state, such as *V, U* (internal energy), *S, G, H*, C_p, and C_v (for example,

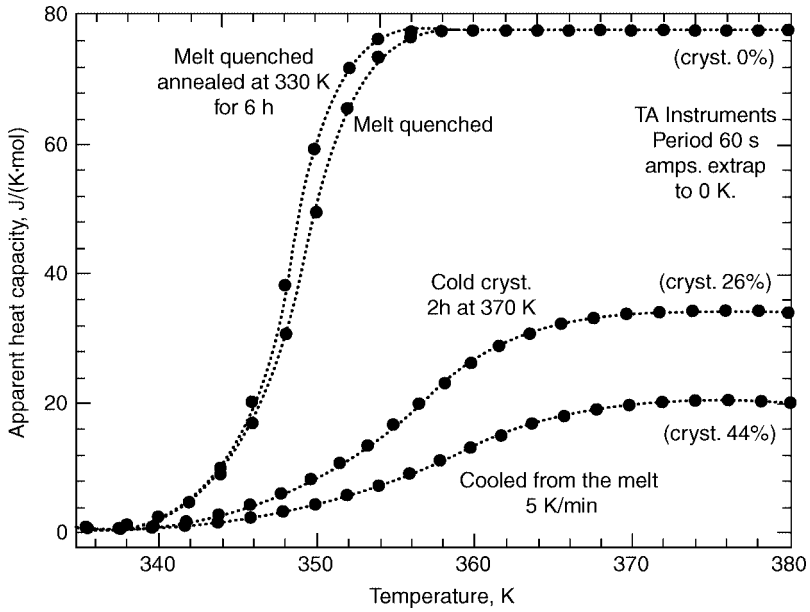

Fig. 11. Glass transitions of poly(ethylene terephthalate) with different degrees of crystallinity produced by the indicated thermal histories. The curves were measured with quasi-isothermal TMDSC at the temperatures marked by the filled circles, with modulation amplitudes extrapolated to zero and periods of 60 s (67).

for each component A, B, etc), the following derivatives can be written

$$\left(\frac{\partial X}{\partial N_{\mathrm{A}}}\right)_{T,p,N_{\mathrm{B}}} = X_{\mathrm{A}}, \left(\frac{\partial X}{\partial N_{\mathrm{B}}}\right)_{T,p,N_{\mathrm{A}}} = X_{\mathrm{B}} \tag{30}$$

The quantities X_{A}, X_{B}, etc, are called the partial molar quantities. The partial molar free enthalpy is also called the chemical potential and given the letter μ. In general, the partial molar quantities are not additive, but the following relationship can be derived between two different components (easily generalized for multicomponent systems)

$$dX = X_{\mathrm{A}}\, dN_{\mathrm{A}} + X_{\mathrm{B}}\, dN_{\mathrm{B}} \tag{31}$$

Integration of equation 29 without changing the composition gives

$$X = N_{\mathrm{A}}X_{\mathrm{A}} + N_{\mathrm{B}}X_{\mathrm{B}} \tag{32}$$

The total differential of equation 31 must be

$$dX = X_{\mathrm{A}}\, dN_{\mathrm{A}} + N_{\mathrm{A}}\, dX_{\mathrm{A}} + X_{\mathrm{B}}\, dN_{\mathrm{B}} + N_{\mathrm{B}}\, dX_{\mathrm{B}} \tag{33}$$

Comparison of the coefficients of equations 32 and 30 reveals the important equations

$$N_A\, dX_A + N_B\, dX_B = 0 \text{ or } dX_A = -\left(\frac{N_B}{N_A}\right) dX_B \tag{34}$$

which permit the calculation of the change in partial molar quantities of one component from the other.

Whether a single-phase solution or several phases are formed in a multicomponent system depends on compatibilities among the components. Generally speaking, three kinds of compatible systems are possible when dealing with macromolecules. Best known are the cases 1 and 2 which concern compatibility of small molecules with macromolecules and one macromolecule with another. The special effect introduced by the macromolecule is caused by its large molecular size, as expressed by the Flory–Huggins equations, given, below. The third kind involves the compatibility within copolymer molecules where the mixing within the molecule is fixed by the synthesis. In most cases the molecules are not altered during phase changes, unless the molecules have a dynamic structure as, for example, caused by transesterification and transamidation. As long as the sequences of repeating units of the different components within the copolymers are short, possible exothermic heats of solution are commonly insufficient to overcome the entropic driving force for mixing of the sequences between different molecules and compatibility (solubility) results, as shown in Figure 12. As the sequences get sufficiently longer, phase separation occurs and molecular segments undergo

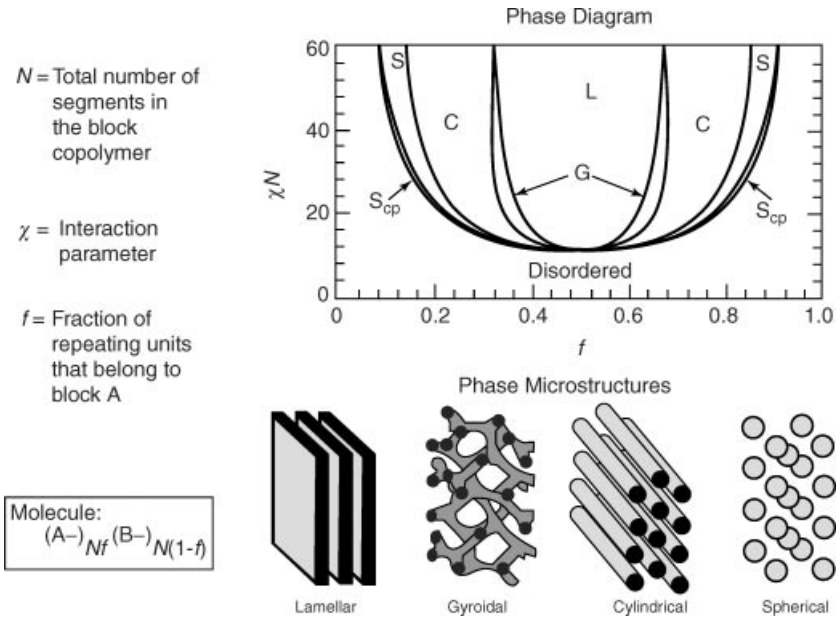

Fig. 12. Phase diagram and phase microstructures for block copolymers. The areas L, G, C, and S correspond to the structures sketched at the bottom; S_{cp} represents more complicated structures (112).

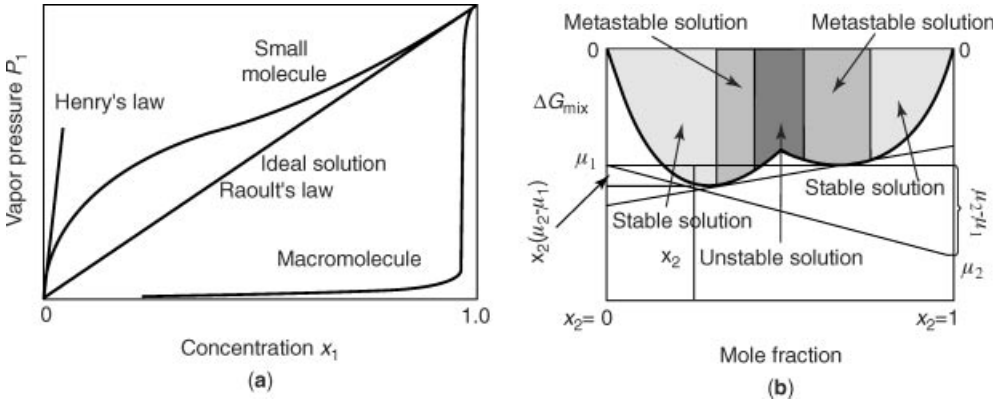

Fig. 13. Vapor pressure P_1 of and free enthalpy of mixing $[\Delta G_{mix} = \mu_1 + x_2\,(\mu_2 - \mu_1)]$ for solutions of components 1 and 2.

decoupling within the molecule, now usually called a block copolymer. Since the decoupled molecular segments must cross the phase boundary at the points of decoupling, special microphase structures arise which produce a minimum in interfacial energy, as shown in Figure 12 (112,113).

The temperature of the transition between two different phase structures is thermodynamically defined by the equality of their partial molar free enthalpies μ_1 and μ_2. Figure 13**a** illustrates the so-called ideal solution in a plot of the vapor pressure P_1 as a function of concentration in terms of the mole fraction x_1 (Raoult's law, $x_1\,P_0 = P_1$, where P_0 is the vapor pressure of the pure solvent 1). In this ideal case, only the entropy of mixing, $\Delta S_1 = -RT \ln x_1$, changes the chemical potential of the solvent, ${\mu_1}^s$, from its pure state, ${\mu_1}^0$, as expressed by

$$\mu_1^s = \mu_1^0 + RT \ln x_1 \tag{35}$$

Note that x_1 is smaller than 1, causing the positive entropy and negative contribution to the chemical potential stabilizing the solution. The vapor pressure lowering and other colligative properties are used to determine molecular masses of the solute 2.

A more quantitative treatment must also consider the change in enthalpy on mixing. The solubility parameter δ as defined as

$$\delta = (\Delta E_{vap}/V)^{1/2} \tag{36}$$

where ΔE_{vap} is the energy of evaporation to a gas at zero pressure and V is the molar volume. If there are no specific forces such as strongly polar groups, hydrogen bonds, or largely different geometries in solution and pure components, the enthalpy of mixing per unit volume is given by

$$\Delta h = v_1 v_2 (\delta_1 - \delta_2)^2 \tag{37}$$

where v_1 and v_2 are the volume fractions of the two components. Since the overall thermodynamic stability relative to the pure states must be negative for a stable

solution, the positive value of equation 37 must be overcome by the increase in entropy of mixing as shown by equation 35. Figure 13**a** displays the effect of a positive heat of mixing on the with the upper bold line. The vapor pressure of the solvent is increased and approaches the pure solute concentration ($x_1 = 0$) with the Henry's law slope which is usually accounted for by introducing an activity a_1 in place of the mole fraction x_1 ($a_1 {P_1}^0 = P_1$). For quantitative vapor pressure measurement, the approach to Raoult's law for dilute solutions is applicable, even in the presence of an enthalpy of interaction. For macromolecules, another deviation from Raoult's law must be accounted for the large size of the macromolecule. For macromolecules, a_1, the activity of the low molar mass solvent, is close to zero for most of the concentration range before it approaches Raoult's law; ie, a large mole fraction dissolves in a polymer melt without resulting in noticeable vapor pressure. Perhaps, this should not be surprising if one remembers that x_1 must be large compared to x_2 to achieve comparable masses for the two components. The Flory–Huggins equation (114–118), to be described next, will resolve this problem and describes the vapor pressure in Figure 13**a** for cases such as natural rubber dissolved in benzene.

The first step is to describe an ideal entropy of mixing for the polymer solute neglecting any interaction energy

$$\mu_2^s - \mu_2^o = RT[\ln v_2 + (1-x)(1-v_2)] \tag{38}$$

where v_2 and $v_1 = (1 - v_2)$ are the volume fractions replacing the mole fractions x_2 and x_1. This expression was derived by placing the solution on a lattice with molecules 1 occupying one unit cell each, and the macromolecules using x unit cells ($x = V_2/V_1$). Note that with $x = 1$, ie, for equal sizes of both components, the equation describing the mixing reverts back to Raoults law ($v_2 = x_2$, $v_1 = x_1$). Another, easier, derivation of equation 37 is given by Hildebrand (119). He assumes that ideal liquids have a universal free volume fraction v_f. On mixing, the molecules expand as in an ideal gas. They change from the free volumes in the pure states, $V_{f1} = V_1 v_f$ and $V_{f2} = V_2 v_f$, to the total free volume $V_{f1,2} = V_{total} v_f$, also described by equation 38. For real solutions the enthalpic contribution, as described by equation 37, must be added to equation 38. Since, however, any change in interaction will also disturb the ideal entropy of mixing, a new interaction parameter χ is defined per lattice unit cell in terms of a free enthalpy instead of an enthalpy parameter

$$\mu_2^s - \mu_2^o = RT\left[\ln v_2 + (1-x)(1-v_2) + \chi x (1-v_2)^2\right] \tag{39}$$

Figure 13**b** illustrates, then, the change of the free enthalpy of mixing by adding the appropriate chemical potentials of the components as suggested by equation 32. The interaction term χ produces the deviation in the free enthalpy of mixing which permits two concentrations to yield the same chemical potential, as indicated. These two concentrations are equally stable and may phase separate. A further increase in concentration on the left, or decrease on the right, however, still yields a decrease in chemical potential, though less than a phase separation would. This change in free enthalpy of mixing continues until the points of inflection of the curve of the free enthalpy of mixing are reached. At these points further changes in

concentrations cause an increase in free enthalpy of mixing, making the solution unstable and causing a spontaneous, spinodal decomposition into two phases.

For a multicomponent system where all components are macromolecules, a single phase is rarely found, since ΔS becomes much smaller for large molecular sizes. The positive enthalpy of mixing of equations 37 and 39, which is more closely proportional to the number of repeating units than the number of total molecules, usually overcompensates the entropy term of equations 35 and 38 and prohibits solution. Generally speaking, macromolecules are miscible in a multicomponent system only when they are of low molecular mass or are block copolymers as shown in Figure 12, because they are very similar chemically and physically, or because of specific interactions causing a negative ΔH. A large percentage of single-phase multicomponent systems that are of practical use belong to the last group. A table of many small molecule solvents of macromolecules is given in Reference 120. Compatible polymer systems are listed in References 121 and 122. An example of a phase diagram of polystyrene dissolved in acetone for two different molar masses is shown in Figure 14 (123). Because of the change of the interaction parameter of equation 39 with temperature, an upper critical solution temperature (UCST), as well as a lower critical solution temperature (LCST), is observed, with intermediate behavior at higher molar mass.

Glassy Multicomponent Systems. In the glassy states of single-phase, multicomponent systems, only a single glass transition is possible at the temperature where the large-scale motion freezes. A special observation is that a solution

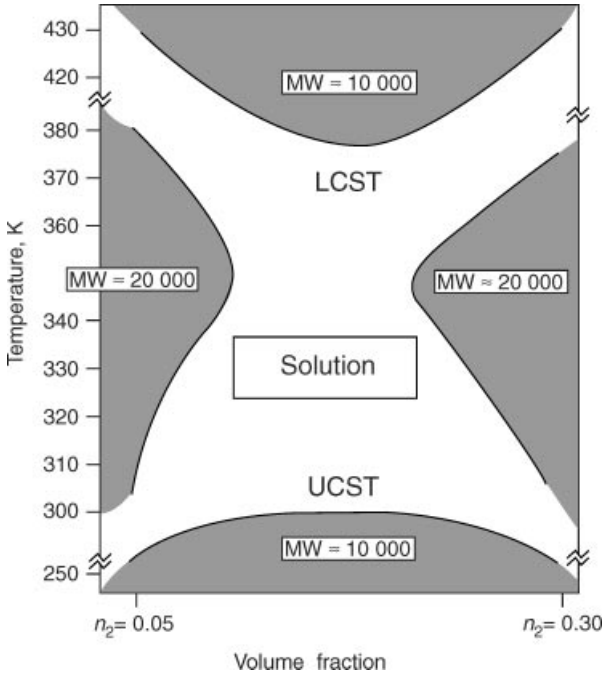

Fig. 14. Phase diagram of polystyrene in acetone, illustrating the development of an LCST and UCST by changing the molar mass.

of two small molecules or within a homogeneous copolymer system shows little change in the breadth of the glass transition, as defined in Figure 9, when compared to the pure components. If, however, one or more of the components of the solution are macromolecules, the temperature region of the glass transition is considerably broadened. This effect must be caused by the inability of the macromolecules to fully mix. Along the molecule, the arrangement of the repeating units remains unchanged on dissolution and causes nanophase regions of unmixed repeating units. Little knowledge about this effect exists beyond the experimental observation of the broadening of the glass transition (124).

The effect of composition on the glass-transition temperature $T_g(w)$ of a two-component, one-phase system has been described empirically (125) as

$$T_g(w) = wT_{g_1} + (1-w)T_{g_2} + w(1-w)K \tag{40}$$

where w is the mass fraction of component one and K is an empirical parameter chosen for good fit over the whole concentration range. Another empirical equation, the Gordon–Taylor equation, makes use of the adjustable parameter L

$$T_g(w) = [wT_{g_1} + L(1-w)T_{g_2}]/[w + L(1-w)K] \tag{41}$$

Both expressions have been linked to the conformational entropy at the glass transition (126,127). A number of additional equations have been compared to the experimental data as illustrated in Figure 15. The Gibbs–Di Marzio equation,

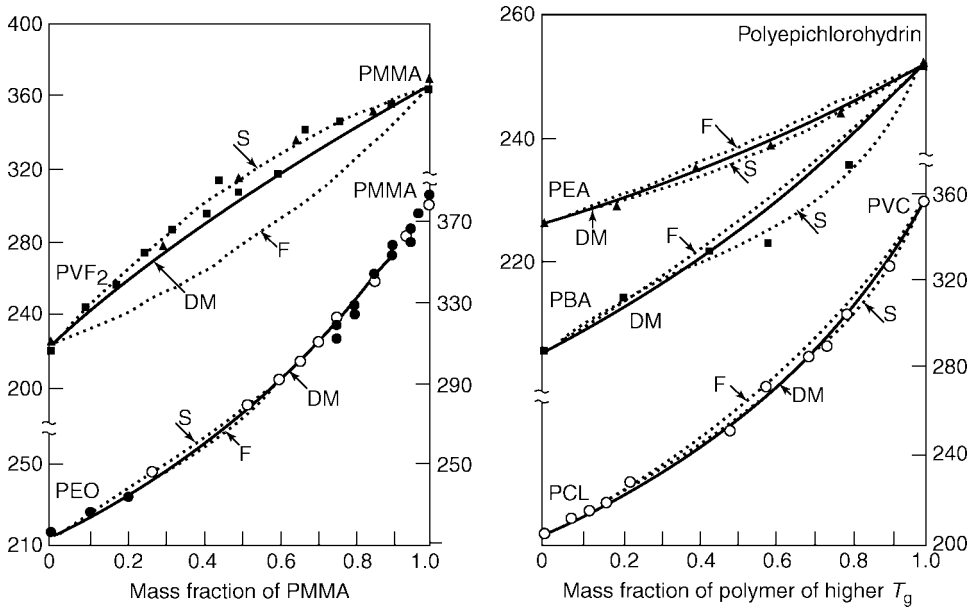

Fig. 15. Changes of the glass transition temperature for a series of polymer solutions and an effort to fit the data to equations 42 to 44. [PMMA = poly(methyl methacrylate), PVF_2 = poly(vinylidene fluoride), PEO = poly(ethylene oxide), PEA = poly(ethylene adipate), PBA = poly(butylene adipate), PVC = poly(vinyl chloride), PCL = poly(ε-caprolactone)].

abbreviated DM, is given by

$$T_g = B_1 T_{g_1} + B_2 T_{g2} \tag{42}$$

where B_1 and B_2 are the flexible bond fractions, and the Fox equation, abbreviated F, is

$$1/T_g(w) = (w/T_{g_1}) + (1-w)/T_{g_2} \tag{43}$$

Both equations are easily generalized to *PVT* equations of state assuming that the solution can be based on additivity of the homopolymer properties. The Gordon–Taylor equation, in contrast, is recovered from DM if L assumes the value $\gamma_2 w/[\gamma_1(1-w)]$ where γ represents the number of the respective flexible bonds. Finally, to add effects of specific interactions, the Gordon–Taylor equation has been expanded into a virial equation in terms of the variable w_{2c} which is the expansivity-corrected mass fraction of equation 41 [$w_{2c} = Lw_2/(w_1 + Lw_2)$]. This is the Schneider equation, S, written as

$$[T_g(w) - T_{g_1}]/[T_{g_2} - T_{g_1}] = (1+K_1)w_{2c} - (K_1+K_2)w_{2c}^2 + K_2 w_{2c}^3 \tag{44}$$

where K_1 and K_2 are the appropriate interaction constants.

Figure 15 documents that volume additivity (eq. 41) and additivity of flexible bonds (eq. 42) do not describe the data. Specific interactions as in equation 44 are needed (128). While equations 40 to 44 are often used indiscriminately for homopolymer solutions *and* copolymers, it was shown that sequence distributions in copolymers, as given by polymerization kinetics, can also be of influence on the glass transition (129,130).

Crystalline Multicomponent Systems. A multicomponent system that crystallizes with a common crystal structure is said to form mixed crystals. Formation of mixed crystals is often possible for components that crystallize in their pure state with the same crystal shapes (isomorphism). For linear macromolecules, a further condition must be fulfilled, the chain conformations of the components must match. For energy reasons, crystals usually can only be obtained with macromolecules close to their equilibrium conformations. In these conformations, close packing must be achieved with the second component, a rather rare event, although examples are known of limited solubility and cocrystallization with small molecule solvents (9).

For the more frequent case where one or more pure crystals can reach stability on cooling with the liquid solution, a eutectic phase diagram results. The free enthalpy of the pure crystal must then reach the chemical potential of its component in the solution. For equilibrium, the Flory–Huggins expression of equation 38 was used, with the free enthalpy of fusion represented by $\Delta G_f = \Delta H_f \Delta T_m / T_m{}^0$. Assuming that the molecules 2 make up the larger, macromolecular solute, one can write

$$\mu_2^s - \mu_2^0 = -\Delta G_{f_2} = -\Delta H_{f_2} \Delta T_m / T_{m_2}^0 = RT\left[\ln v_2 + (1-x)(1-v_2) + \chi x (1-v_2)^2\right] \tag{45}$$

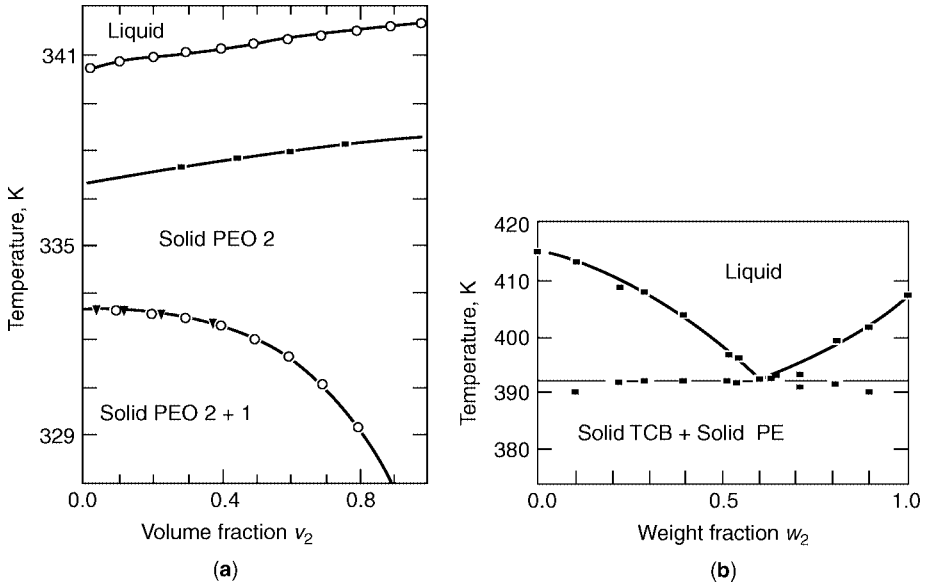

Fig. 16. (**a**) Phase diagram of poly(ethylene oxide) 3,500/100,000 mol-wt mixtures at different concentrations. The open circles represent the calculation of T_{m_2} and T_{m_1}, calculated by using the Flory–Huggins equations 46 and 47, respectively. The filled symbols represent the experimental data. (**b**) Phase diagram of polyethylene dissolved in 1,2,4,5-tetrachlorobenzene (TCB). The experimental data were obtained by melting after crystallization. The macromolecular crystals, 2, were not at equilibrium, but melted considerably lower than $T^0_{m_2}$ (see Table 1).

which can be rearranged to

$$\Delta T_{m_2} = \left[-RT^0_{m_2}/\Delta H_{f_2} \right] \left[\ln v_2 + (1-x)(1-v_2) + \chi x (1-v_2)^2 \right] \tag{46}$$

and for the smaller solvent molecule 1, an analogous expression can be derived

$$\Delta T_{m_1} = \left[-RT^0_{m_1}/\Delta H_{f_1} \right] \left[\ln v_1 + (1-\{1/x\})(1-v_1) + \chi (1-v_1)^2 \right] \tag{47}$$

Figure 16**a** is a comparison of the calculated two branches of the eutectic phase diagram for a high and a low molar mass poly(ethylene oxide). The high molarmass curve shows only a small decrease in the melting temperature with decreasing volume fraction v_2 until the logarithmic term in equation 46 forces an approach to the eutectic temperature close to the melting temperature $T^0_{m_1}$. The experimental data show a strong deviation from equation 46 for the macromolecule because of nonequilibrium effect, mainly caused by chain folding (131).

An experimental phase diagram of polyethylene dissolved in 1,2,4,5-tetrachlorobenzene (TCB) is shown in Figure 16**b** (132). Both polymer and low molar mass solvent have similar equilibrium melting temperatures. On the left-hand side of the phase diagram, the liquidus line follows equation 47, the right-hand side does not follow equation 46. Again, this indicates the usual nonequilibrium state of polymer crystals. Besides too low melting temperatures, low

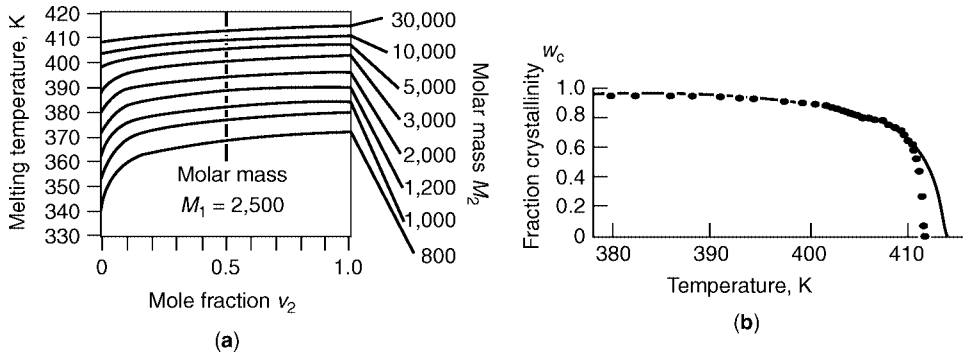

Fig. 17. (**a**) Equilibrium phase diagrams of the given molar masses of polyethylene in a low molar mass solvent of $M_1 = 2500$. (**b**) The experiments (filled circles) and the calculated crystallinities for a polyethylene of number-average molar mass of 8500 Da and a mass average molar mass of 153,300 Da.

crystallinities also are usually seen. Other complications are the presence of a rigid amorphous fraction as mentioned above in connection with the description of the pure crystals, and also the restrictions of equilibrium mixing and demixing required during melting and crystallization. If the latter processes occur too slowly, the melting or crystallization may decouple from the mixing or demixing and nonequilibrium structures may arise. An example of the change of the phase diagram because of partial decoupling of the processes during crystallization is illustrated in Figure 17. The samples were crystallized at elevated pressure to attain almost 100% crystallinity, but equilibrium, eutectically separated extended-chain crystals of the broad molar mass distribution, describable with the multicomponent form of equation 46, are seen only to the first third of melting (95). At higher temperatures, nonequilibrium mixed crystals of lower T_{m_2} are observed.

Crystallization with phase separation of random copolymers is much more complicated because usually only one component crystallizes. This component restricts the mobility of the second component to such a degree that it cannot crystallize at all. In theory, the types of phase diagrams detailed above (eutectic systems and solid solutions) should also exist for the copolymers. However, the different repeating units are connected by covalent bonds; the size effect outweighs the possible effect of demixing (11). Only local, metastable equilibrium may be achieved. The basic two-phase equilibrium theory of crystallization and melting of copolymers was developed by Flory (133). It contains the stringent condition that all crystallizable repeating units (A units) are freely available to add to crystals A. No other units can be included in the crystal of A (no isomorphism). The noncrystallizable repeating units (B units) can thus at best be located at the A crystal surface (outside the crystal proper). A general review of the earlier work is given in Reference 134. The kinetics of crystallization for copolymers is described in (135,136). Progress since then has been slow, and further work on the melting of copolymers is urgently needed. No tabular data of value can be given at present. Recent progress reports are available (137,138).

Thermodynamics of Polymer Reactions

Thermodynamics is, similarly, well suited for the description of processes which lead to changes of the molecular structure, as just seen for phase changes. A reaction with unfavorable thermodynamics expressed by a positive ΔG does not occur. However, with a negative ΔG, a reaction may still fail kinetically, while another mechanism may succeed. A typical example is the preparation of polypropylene. Although the polymerization of propylene is possible thermodynamically, it was not achieved until the work of Ziegler (139) and Natta (140), who discovered the catalyzed mechanism with favorable kinetics. Thus, much effort has been devoted to understand the kinetics of polymerization (118). Early work concentrated on predicting molecular masses and their distribution. In this section the thermodynamics of polymerization is briefly discussed. Most attention is paid to addition (chain) polymerization, but the theory is also applicable to condensation (stepwise) polymerization. The subject is extensively reviewed (141–145).

A chemical or physical reaction can only occur if there is a decrease in the free enthalpy, as discussed above. In most polymerization reactions, the entropy decreases because the polymer lacks translational and rotational motion. It has been argued that the loss of the rotational entropy is balanced by the gain of internal rotational and vibrational entropy in the polymer, and that the total loss is, therefore, equal to the translational entropy of the monomer (146). Thus, since the entropic contribution to ΔG is positive, the enthalpy of polymerization must be negative and more than compensate for the entropic term for the reaction to occur. Indeed, polymerizations are typically exothermic reactions. Polycondensations are usually acid–base type reactions that are exothermic. Addition polymerizations occur typically with the creation of two single bonds from one double bond. The bond strength of two single bonds is, however, always higher than that of one double bond; hence, those reactions are also exothermic. From the increasingly negative entropic contribution to ΔG with temperature, it follows that above a certain temperature ΔG becomes greater than zero and polymerization is no longer possible. Instead, the equilibrium of the polymerization reaction is shifted toward the monomer and a depolymerization reaction occurs. The temperature at which ΔG is zero is called the *ceiling temperature*, and is a characteristic of a polymerization reaction. It depends on the pressure of the reactant and obeys a Clausius–Clapeyron-type relation (143). Polymerizations are typically accompanied by a decrease in the system volume; thus, an increase in pressure raises the ceiling temperature. It also follows that higher pressures increase the yield of the reaction.

In some special cases, however, the polymerization is an endothermic reaction (positive ΔH) compensated by an increase in entropy. Such a case is the polymerization of elemental, eight-membered, cyclic sulfur, S_8 (147). It follows that, in such a polymerization, a minimum temperature exists below which polymerization is not possible and an inverse ceiling temperature, a floor temperature, exists. This situation can also occur in ring-opening polymerizations, where a priori predictions of the signs in ΔS and ΔH are not possible (148).

The qualitative discussion can be quantified for the prediction of the extent of a polymerization reaction.

In addition or chain polymerization, the reaction can be represented as

$$M_n^* + M_1 \rightleftarrows M_{n+1}^* \tag{48}$$

where $M_n{}^*$ is the growing chain and M_1 the monomer. The species $M_n{}^*$ and $M^*{}_{n+1}$ are indistinguishable and, therefore, the equilibrium constant is

$$K_e = \frac{\left[M_{n+1}^*\right]_e}{\left[M_n^*\right]_e [M_1]_e} \approx [M_1]_e^{-1} \tag{49}$$

The equilibrium constant K_e is equal to the free-enthalpy change $\Delta G = -RT \ln K_e$, so that

$$\ln[M_1]_e = \Delta H/(RT) - \Delta S/R \tag{50}$$

or in differential form

$$\mathrm{d}\ln[M_1]_e/\mathrm{d}T = \Delta H/(RT)^2 \tag{51}$$

where $[M_1]$ is the chemical activity of the monomer, which, in a first approximation, equals its concentration. The concentration $[M_1]_e$ is the equilibrium monomer concentration at the ceiling temperature. For the polymerization to proceed, the monomer concentration $[M_1]$ must be higher than $[M_1]_e$. For lower concentrations, depolymerization occurs.

In step polymerization, the reaction can be represented as

$$\mathrm{A} + \mathrm{B} \rightleftarrows \mathrm{C} + \mathrm{D} \tag{52}$$

where A and B are the reacting species. The species in an esterification are —OH and —COOH, and C is the resulting polymer, a polyester, and D is the by-product, H_2O. The reaction constant is $K = [\mathrm{C}][\mathrm{D}]/([\mathrm{A}][\mathrm{B}])$. For the reaction to occur, K must be smaller than the equilibrium constant K_e. This is usually forced by removing the by-product D from the system.

From the above discussion, the importance of the knowledge of ΔH and ΔS, and therefore ΔG for polymerization reactions, is obvious. The enthalpy and entropy of some polymerization reactions are given in Table 5. The experimental methods for their determination have been reviewed (141,149,150). For the determination of the entropy, the direct method is based on equation 50. From a plot of the equilibrium concentration of the monomer vs $1/T$, both ΔH and ΔS can be computed. Another method involves the estimation of ΔS from kinetic frequency factors (146).

In most cases, however, the change in enthalpy and entropy are calculated from the difference between the enthalpies (heats) of formation and entropies of formation of the products (polymer) and the reactants (monomer). Naturally, to do so, both the enthalpy and entropy of the polymer and the monomer must be known. The heat of formation of a substance which can be produced by direct reaction of its elements is the heat of the reaction, but only very few and simple substances can be formed directly from their elements. Therefore, experimentally, the heat

[b] State of the monomer (first letter) and of polymer (second letter); g = gas (hypothetical for polymer), l = liquid, c = glassy condensed phase, c′ = crystalline or partially crystalline condensed phase, and s = solultion in the specified solvent.

[c] Temperature where ΔH and ΔS were measured or corrected to.

[d] The gaseous state is hypothetical; $\Delta H_{g,g}$ and $\Delta S_{g,g}$ were calculated from semiempirical schemes and correspond to the experiment only after correction with the sublimation enthalpy and entropy of the polymer.

[e] When several values are available, a second or third value is given in parentheses; for more measurements the range is indicated.

of formation of an organic substance is usually found indirectly through heats of combustion. In such an experiment, the substance is burned in an autoclave and the heat of combustion is measured. From the heat of combustion and the known heats of formation of the products, the heat of formation can be calculated. Details are given in physical chemistry textbooks (151).

The entropy of formation of a substance can be found from calorimetric measurements of the heat capacity from 0 K to the temperature of measurement, as outlined in equation 12. The entropy of formation is then simply the difference of the entropy of the substance and that of the constituent elements. The heat of formation and the entropy of various substances are given in standard thermodynamic tables at 298.15 K. It is often assumed that, at about room temperature, the heat and entropy of formation do not depend strongly on temperature; however, this is a misconception. The dependence of these quantities on temperature is evident from equations 11 and 12. The heats of formation, entropies, and other useful thermodynamic quantities are found in a number of standard data sources (1–7,152–157).

The enthalpy and entropy of formation of a compound can also be calculated with the help of various semiempirical addition schemes. In such schemes, each chemical bond is associated with a characteristic energy, transferable from one substance to another. The sum of the energy of the bonds of a compound is corrected for nonbonding interactions, such as stabilization due to resonance or destabilization due to steric hindrance, etc, to yield the heat of formation (158). In other schemes, no corrective terms are implied, but the number of the tabulated bonds is much higher. In this case, the results are more accurate (159). For the calculation of the entropy of formation, a similar method was applied, but here the entropy contributions of whole chemical groups were tabulated (160). More information on such schemes as applied to polymers and monomers is given in References 161–163. These semiempirical methods give the heat (and entropy) of formation of the compound in its gaseous state. The resulting data must be corrected by subtracting the enthalpy (and entropy) of vaporization for liquids, or of sublimation (vaporization and fusion) for solids. In Table 5 the states of the monomer and polymer are given. A gaseous polymer is, of course, hypothetical. In several cases the enthalpy and entropy of polymerization were calculated for both the polymer and monomer in the gaseous state. Correction according to the previous rules is then necessary.

THERMOFORMING. See Volume 8.

THERMOSETS

Introduction

Thermosets may be defined as network-forming polymers. Unlike thermoplastic polymers, chemical reactions are involved when producing or fabricating parts. As a result of these reactions the materials cross-link and become "set," ie, they can no longer flow or dissolve. Cure most often is thermally activated, hence the term *thermoset*, but network-forming materials whose cure is light or radiation activated are also considered to be thermosets. Some thermosetting adhesives cross-link by a dual cure mechanism, ie, by either heat or light activation. In contrast to cross-linked elastomers or rubbers, the glass-transition temperature (T_g) of thermosets is generally above room temperature.

Encyclopedia of Polymer Science and Technology. Copyright John Wiley & Sons, Inc. All rights reserved.

In this article we describe the distinguishing characteristics of thermosetting materials; the more common thermosetting resins including their cure chemistry; thermoset nanocomposites; cure and properties, including cure kinetics; the development of residual stress as a result of curing; cure monitoring; and conclude with a description of selected thermoset processes.

Uncured thermosets are mixtures of small reactive molecules, often monomers. They may contain additives such as catalysts to promote or accelerate cure. Most thermosets are used in filled or reinforced form to reduce cost, modify physical properties, act as a binder for particles or fibers, reduce shrinkage during cure, or to provide or enhance flame retardance. In general, thermosets possess good dimensional stability, thermal stability, chemical resistance, and electrical properties. Because of these attributes, they find widespread use in several applications such as adhesives; primary and secondary structural members in aerospace; countertops and floors for manufacturing facilities and homes; printed circuit boards, conductive polymer elements, and encapsulation materials for electronic applications; dental materials, especially adhesives; and recreational products such as tennis racquets, bicycle frames, golf clubs, and fishing rods. Epoxy resins (qv) are probably the best-known members of the thermoset family whose members also include phenolic resins (qv), unsaturated polyester, polyurethanes (qv), dicyanate, bismaleimide, acrylate, and many others (see POLYESTERS, UNSATURATED; ISOCYANATE-DERIVED POLYMERS). Good thermoset references include Rosato (1), Prime (2), Pascault and co-workers (3), and Van Mele and co-workers (4). The first of these is process-oriented and the others are cure- and chemistry-oriented.

Characteristic Behavior of Thermosets

Thermosets are distinct from thermoplastic polymers in one major respect: their processing includes the chemical reactions of cure. As illustrated in Figure 1, cure begins by the growth and branching of chains. As the reaction proceeds, the increase in molecular weight accelerates, and eventually several chains become linked together into a network of infinite molecular weight. The abrupt and irreversible transformation from a viscous liquid to an elastic gel or rubber is called the gel point. The gel point (qv) of a chemically cross-linking system can be defined as the instant at which the weight-average molecular weight diverges to infinity (5).

Cure is illustrated schematically in Figure 1 for a material with co-reactive monomers such as an epoxy–diamine system. Reaction in the early stages of cure (**a** to **b** in Fig. 1) produces larger and branched molecules and reduces the total number of molecules. Macroscopically, the thermoset can be characterized by an increase in its viscosity η (see Fig. 2 below). As the reaction proceeds (1**b** to 1**c** in Fig. 1), the increase in molecular weight accelerates and all the chains become linked together at the gel point into a network of infinite molecular weight. The gel point coincides with the first appearance of an equilibrium (or time-independent) modulus as shown in Figure 2. Reaction continues beyond the gel point (1**c** to 1**d** in Fig. 1) to complete the network formation. Macroscopically, physical properties such as modulus build to levels characteristic of a fully developed network.

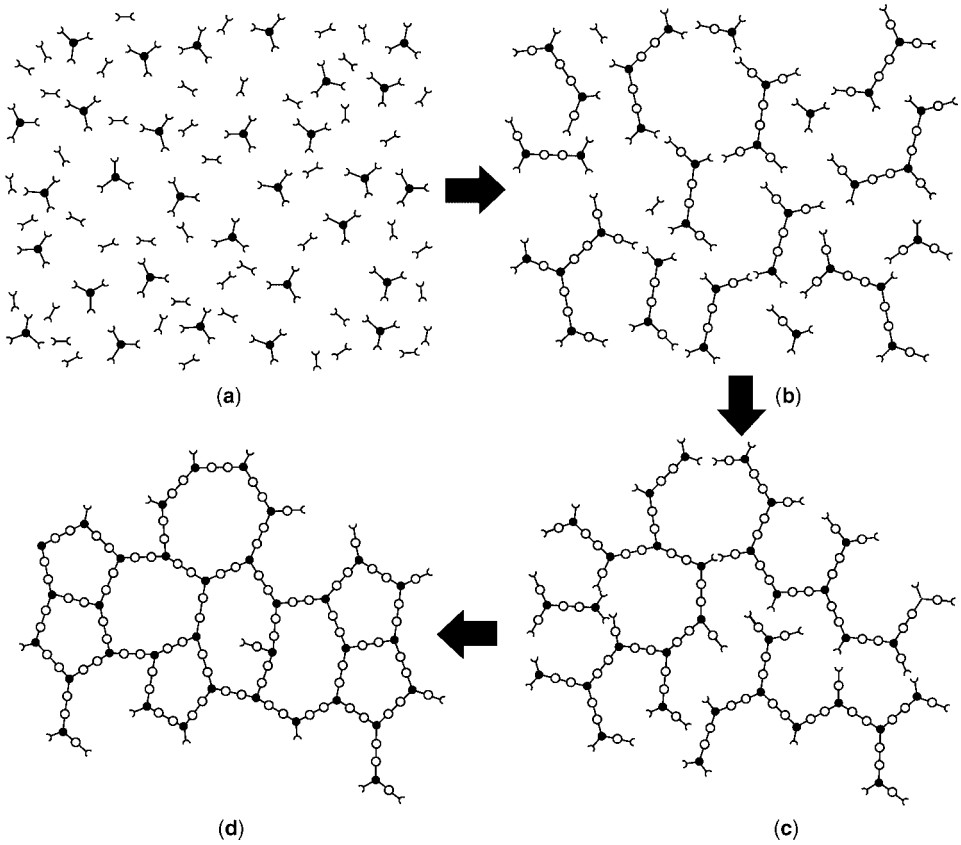

Fig. 1. Schematic, two-dimensional representation of thermoset cure. For simplicity difunctional and trifunctional co-reactants are depicted. Cure starts with A-stage monomers (**a**); proceeds via simultaneous linear growth and branching to a B-stage material below the gel point (**b**); continues with formation of a gelled but incompletely cross-linked network (**c**); and ends with the fully cured, C-stage thermoset (**d**). From Ref. 2.

Gelation is the incipient formation of a cross-linked network, and it is the most distinguishing characteristic of a thermoset. A thermoset loses its ability to flow and is no longer able to be processed above the gel point, and therefore gelation defines the upper limit of the work life. As an example, for a *Five Minute Epoxy*, which can be found in any hardware store, the "five minutes" refers to the gel point. After the two parts are mixed the user must form an adhesive joint within 5 min before the material becomes rubbery, and then keep the repaired part fixtured until cure is sufficiently complete, typically for several hours. A distinction may be drawn between the phenomenon of molecular gelation and its consequence, macroscopic gelation. Molecular gelation occurs at a well-defined stage of the chemical reaction, provided the reaction mechanism is independent of temperature and free of noncross-linking side reactions (7–9). It is dependent on the functionality, reactivity, and stoichiometry of the reactants. Macroscopic consequences of gelation include a rapid approach toward infinite viscosity and development of elastic properties not present in the pregel resin. The gel point

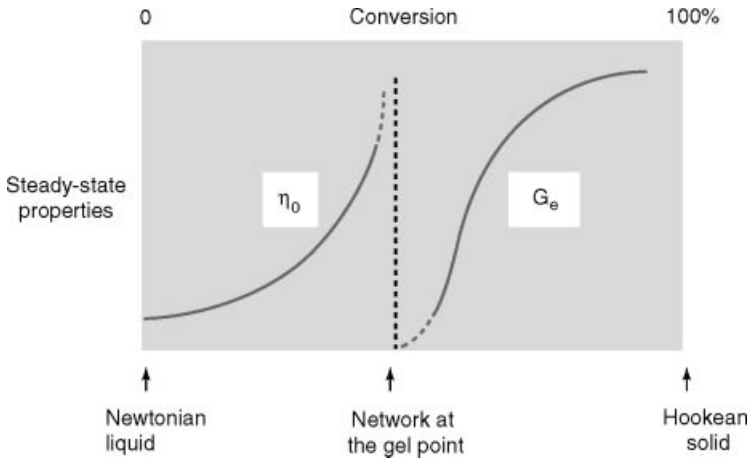

Fig. 2. Macroscopic development of rheological properties (eg, η_0 = zero-shear viscosity) and mechanical properties (eg, G_e = equilibrium shear modulus) during network formation, illustrating the approach to infinite viscosity and the first appearance of an equilibrium modulus at the gel point. From Ref. 6.

may be calculated if the chemistry is known (7,8). Molecular gelation may be detected at the point at which the reacting resin just becomes insoluble, or as the point where the mechanical loss tangent becomes frequency-independent (5–10). Macroscopic means to approximate gelation include the time to reach a specific viscosity, the $G' = G''$ crossover in a dynamic rheology measurement, and a series of frequency-independent damping peaks accompanied by a small increase in storage modulus in a dynamic mechanical measurement. Gelation in condensation or step-growth systems typically occurs between 50 and 80% conversion (degree of cure $\alpha - 0.5$–0.8). For high functionality and free-radical initiated or chain-growth systems, gelation may occur at much lower conversions. The degree of conversion at the gel point α_{gel} is constant for a given thermoset, independent of cure temperature, ie gelation is isoconversional. For this reason the time to gel versus temperature can be used to measure the activation energy for cure. Gelation does not usually inhibit cure (eg, the reaction rate remains unchanged on passing through gelation), and it cannot be detected by techniques sensitive only to the chemical reaction, such as differential scanning calorimetry (DSC). Beyond the gel point, the reaction proceeds toward the formation of one infinite network with substantial increase in cross-link density, glass-transition temperature, and ultimate physical properties.

Vitrification, a completely distinct phenomenon from gelation, may or may not occur during cure depending on the cure temperature relative to the T_g for full cure. Vitrification is glass formation due to T_g increasing from below T_{cure} to above T_{cure} as a result of the cure reaction, and is defined as the point where $T_g = T_{cure}$ (11). Vitrification can occur anywhere during the reaction to form either an ungelled glass or a gelled glass. It can be avoided by curing at or above $T_{g\infty}$, the glass-transition temperature for the fully cured network. In the glassy state, the rate of reaction will usually undergo a significant decrease and fall below the chemical reaction rate as the reaction becomes controlled by the diffusion

of reactants. It is common for complete vitrification to result in a decrease in the rate of reaction by 2–3 orders of magnitude. Unlike gelation, vitrification is reversible by heating, and chemical control of cure may be reestablished by heating to devitrify the partially cured thermoset. Vitrification may be detected by a step increase in heat capacity by modulated-temperature DSC (MTDSC) and by dynamic mechanical analysis (DMA) as a frequency-dependent transition resulting in a glassy modulus, typically >1 GPa (~150,000 psi).

Generally, the shift from chemical control to diffusion control of the reaction may be observed by a decay of the reaction rate, which is often observed when T_g reaches 10–15°C above T_{cure} (see Figs. 7 and 8). Though not common, it is possible for diffusion to control the cure kinetics prior to vitrification; it is also possible for sluggish reactions to remain under chemical control well into the glassy state (see Refs. 2–4).

Isothermal time–temperature-transformation (TTT) cure diagrams, as illustrated in Figure 3, are a useful tool for illustrating the phenomenological changes that take place during cure, such as gelation, vitrification, complete cure, and degradation (11,12). Three critical temperatures are marked on the temperature axis of the TTT cure diagram: T_{g0}, the glass transition temperature of the completely unreacted thermoset; ${}_{gel}T_g$, the temperature at which gelation and vitrification coincide; and $T_{g\infty}$, the glass-transition temperature of the fully cured network (see Table 1). In this generalized diagram, the times of gelation and the times of vitrification are plotted as functions of the cure temperature. At temperatures below T_{g0}, reaction takes place in the glassy state and is therefore slow to occur. To minimize reaction during storage, unreacted systems should be stored well below T_{g0}; 20–50°C below T_{g0}, ie deep into the glassy state, is recommended.

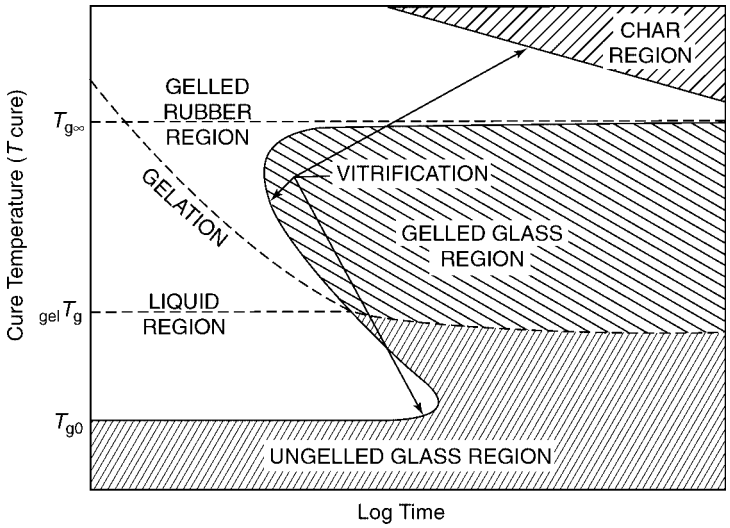

Fig. 3. Generalized time–temperature-transformation (TTT) cure diagram. A plot of the times to gelation and vitrification during isothermal cure versus temperature delineates the regions of four distinct states of matter: liquid, gelled rubber, gelled glass, and ungelled glass. From Ref. 12.

Table 1. Glossary of Characteristic Cure Parameters

α	Chemical conversion (eg, of epoxide or isocyanate groups), degree of cure
α_{gel}	α at the gel point
t_{gel}	Time to gelation, gel time
t_{vit}	Time to vitrification
T_{cure}	Cure temperature, a process parameter
T_g	Glass-transition temperature, a material property
T_{g0}	T_g for uncured thermoset with degree of conversion $\alpha = 0$
${}_{gel}T_g$	T_g for thermoset with degree of conversion α_{gel}
$T_{g\infty}$	T_g for fully cured thermoset with degree of conversion $\alpha = 1$

See the later section in this article on Adhesive Processes for comments about storing premixed and frozen adhesives. Between T_{g0} and ${}_{gel}T_g$, the liquid resin will react without gelation until its continuously rising glass-transition temperature becomes coincidental with the cure temperature, at which stage vitrification begins and the reaction may become diffusion controlled. Note that ${}_{gel}T_g$ is the temperature at which gelation and vitrification occur simultaneously.

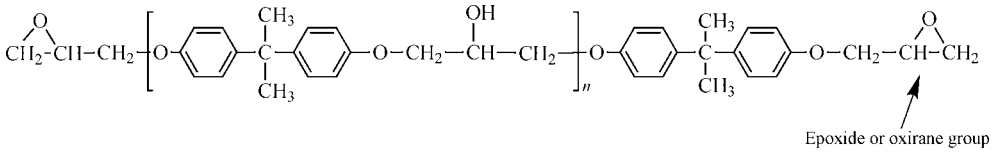
At temperatures between ${}_{gel}T_g$ and $T_{g\infty}$, the viscous liquid changes to a viscoelastic fluid, then to a rubber, and finally to a glass. Gelation precedes vitrification, and a cross-linked rubbery network forms and grows until its glass-transition temperature coincides with the cure temperature, where the reaction may become diffusion controlled. At temperatures above $T_{g\infty}$, the network remains in the rubbery state after gelation unless other reactions occur, such as thermal degradation or oxidative cross-linking. Note that in the manufacture of carbon–carbon composites, network degradation is part of the process (see PHENOLIC RESINS). The handling and processing of thermosets are very much dependent on gelation and vitrification. For example, thermosets are often identified at three stages of cure: A, B, and C. A-stage refers to an unreacted resin; B-stage to a partially reacted and usually vitrified system, *below the gel point*, which, upon heating to devitrify, can flow and be processed and cured; and C-stage to the completely cured network. Thus, to B-stage a thermoset requires vitrification prior to gelation, and this can be accomplished by maintaining the reaction temperature below ${}_{gel}T_g$. B-staging often provides systems that are optimized for processing. In general, thermosets that need to be solid during the precure stage of processing, eg powder coatings, will be B-staged to $T_g > T_{process}$, while thermosets that need to have some flow or tack during precure processing, eg prepregs, will be B-staged to $T_g \leq T_{process}$. Prepregs are sheets of oriented fibers or fabric that are impregnated with resin and B-staged; typically several layers are laminated together under heat and pressure to fabricate a part. To avoid vitrification and achieve complete cure in a reasonable time generally necessitates cure at temperatures close to or greater than $T_{g\infty}$.

Thermosetting Resin Systems

As previously mentioned, in the uncured state, thermosetting materials are generally mixtures of small reactive molecules that form networks; catalysts, initiators and/or accelerators; and particulate, fiber-based, or nanosize fillers. There

are several families of thermosetting materials. Here we briefly review some of the more important classes both in terms of volume as well as key engineering applications.

Epoxies. Probably the best-known thermoset is epoxy (13) (see EPOXY RESINS). The largest use of epoxies is in protective coatings, with other applications including printed circuit board (PCB) laminates, electronic materials, structural composites, flooring and adhesives. The higher cost of epoxy resins vis-à-vis commodity thermosets and thermoplastics is justified by their superior properties and longer service life. Cured epoxies provide excellent mechanical strength and toughness; outstanding chemical, moisture, and corrosion resistance; good thermal, adhesive, and electrical properties; absence of volatiles and low shrinkage on cure; and good dimensional stability. Epoxy resins are characterized by a structure containing the epoxide or oxirane group (see structure **1** below). The most widely used epoxy resins are the diglycidyl ethers of bisphenol A:



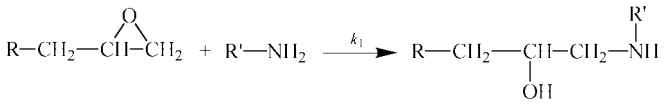
1

Others include brominated bisphenol A resins which impart fire resistance, epoxy phenol novolac (EPN) resins, bisphenol F epoxy (DGEBF) resins, epoxy cresol novolac (ECN) resins, cycloaliphatic epoxy resins, and tetraglycidyl-4,4′-diaminodiphenylmethane (TGDDM).

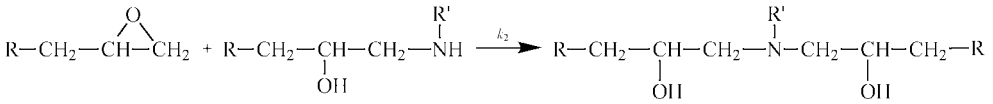
The number of repeat units, n, in structure **1** can be as high as 35 but is usually 0–6, 0 being the monomer. Epoxy resins can be cured by a variety of cross-linking agents known as hardeners (reactive comonomers) or by catalysts that promote homopolymerization. Common examples of homopolymerization include the anionic polymerization promoted by Lewis bases such as tertiary amines and imidizoles, and cationic polymerization promoted by Lewis acid BF_3 complexes such as boron trifluoride monoethylamine ($BF_3{\cdot}NH_2C_2H_5$). Photoinitiated cationic cure of epoxies, especially cycloaliphatic epoxies, with photoinitators such as aryldiazonium and diaryliodonium salts provide coatings and adhesives with long shelf life and near-instantaneous cure. But it is more common to cross-link epoxies with a co-reactant such as a diamine, polyamide, or acid anhydride. The low exotherm of epoxy–anhydride systems make them suitable for uses in large mass epoxy cures. Amines account for close to 50% of all epoxy curing agents. For cross-linking to occur, at least one of the reactants must be trifunctional or higher. Epoxy resins are typically difunctional, reacting through the oxirane group, although in some cases, such as homopolymerization or when epoxy is in stoichiometric excess, reaction can occur through the —OH groups.

Diamines, a well-studied co-reactant with epoxy, are tetrafunctional where each amine hydrogen can react. The reactions of primary amine and secondary amine with epoxide are illustrated in equations 1 and 2, respectively. The heat of reaction ΔH_{rxn} for epoxy–amine is ~106 kJ/mol (~25.5 kcal/mol) for reaction with

both primary amine and secondary amine (2–4). The activation energy for cure can vary from 40–125 kJ/mol (10 to 30 kcal/mol) (2–4).



(1)



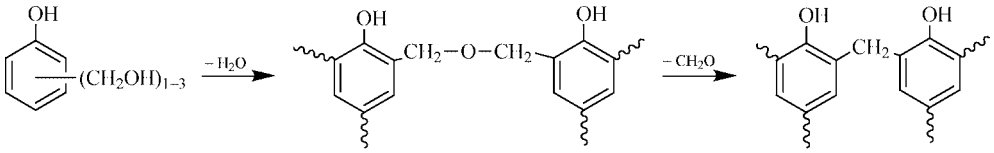
(2)

For equal reactivity of primary amine and secondary amine with epoxy $k_2/k_1 = 0.5$. But there is usually a substitution effect where the secondary amine is less reactive and $k_2/k_1 < 0.5$, often in the range of 0.40–0.45. When steric hindrance is significant, k_2/k_1 can be < 0.1.

In general, aliphatic amines are used with bisphenol A resins where room-temperature cures are desired and heat-deflection temperatures (HDT) or glass-transition temperatures (T_g) below 100°C can be tolerated. Aromatic amines can provide HDTs and T_g's up to 170°C but require curing at elevated temperatures. Anhydride cured bisphenol A systems offer long pot life, low exotherm, excellent adhesion and electrical properties, and HDT/T_g values between 125 and 170°C. A small amount of tertiary amine is frequently used to accelerate the cure reaction, which proceeds by addition esterification and addition etherification. Cycloaliphatic epoxides respond well to acidic hardeners and can have HDT/T_g values approaching 200°C. Tetraglycidyl-4,4′-diaminodiphenylmethane (TGDDM) is a tetrafunctional epoxide which is often cured with diaminodiphenylsulfone (DDS) to form high temperature, high performance epoxy systems for aerospace applications. Commercial TGDDM/DDS systems, which are typically epoxy-rich, represent materials in which secondary amine hydrogens are significantly less reactive than primary amine hydrogens and the etherification reaction of epoxide with hydroxyl is significant.

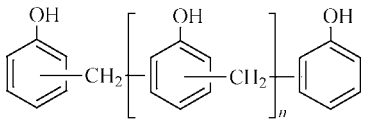
Phenolic Resins. Phenol–formaldehyde resins are employed in a wide range of applications, including commodity construction materials such as plywood to high technology applications such as honeycomb and carbon–carbon composites (see PHENOLIC RESINS). They are composed of a wide variety of structures based on the reaction products of phenols with formaldehyde. Either resole or novolac resins are formed, depending on the mole ratio of formaldehyde to phenol (F/P) and catalyst.

Resole resins are produced from an excess of formaldehyde (F/P > 1) and contain reactive methylol groups that can condense to a network structure. The cross-linking reactions in these one-part systems are exothermic and produce water and formaldehyde as volatile products, as illustrated in equation 3.



(3)

Novolac resins are produced from an excess of phenol (F/P<1) to form linear polymers, as illustrated in structure **2**, with molecular weights of 200–5000 and glass-transition temperatures of 45–70°C. In two-stage novolac systems cross-linking is accomplished by reaction with hexamethylenetetramine (hexa), which is prepared from formaldehyde and ammonia and may be considered a latent source of formaldehyde.



2

Amino Resins. Amino resins are the reaction product of an aldehyde with a compound containing an amino ($-NH_2$) group (see AMINO RESINS). Both urea and melamine react with formaldehyde, first by addition to form methylol compounds, and then by condensation to form cross-linked polymers through methylene bridge and methylene ether formation. The cross-linking reactions are exothermic and produce water and formaldehyde as volatile products in reactions similar to resole phenolics, illustrated in equation 3. Urea–formaldehyde and melamine–formaldehyde account for the bulk of the amino resins. Their characteristics include water solubility and unlimited colorability with dyes and pigments. Applications include decorative high pressure phenolic laminates, adhesives in the laminated wood and furniture industries, and as an additive to textile fabrics to impart wash and wear properties.

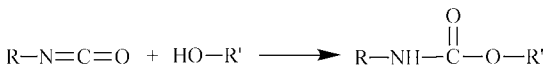
Polyester Resins. Unsaturated polyester resins consist of a linear unsaturated polyester polymer, a cross-linking monomer, activators or accelerators, and inhibitors to retard cross-linking until the resin is to be used (see POLYESTERS, UNSATURATED). Cross-linked polyesters are mainly used in glass fiber reinforced form for large structural parts. The linear unsaturated polyester is typically the condensation product of an unsaturated dibasic acid such as maleic anhydride, a glycol such as ethylene glycol, and a saturated dibasic acid such as phthalic anhydride to modify the degree of unsaturation. The most common cross-linking monomer is styrene; methyl methacrylate is added for resistance to sunlight and weathering.

Polyester resins can be cross-linked by a free-radical initiator, usually an organic peroxide. Free radicals may be formed by thermal decomposition of an initiator such as *tert*-butyl perbenzoate or benzoyl peroxide, by ultraviolet (UV) or visible light decomposition, or by chemical decomposition in ambient temperature applications utilizing activators such as dimethylaniline. Inhibitors such as hydroquinone consume free radicals initially and reaction does not proceed until the inhibitor system is completely consumed. After an induction period the free

radicals initiate exothermic cross-linking reactions involving the unsaturation in the polyester chains and the styrene monomer with gelation occurring at low levels of conversion. Reaction proceeds to form a highly cross-linked, three-dimensional network.

Allyl Resins. Allyl resins are diallyl monomers and B-staged prepolymers that can be cross-linked by free-radical polymerization through their double bonds. The allyls in widest use are diallyl phthalate (DAP) resins and diallyl isophthalate (DAIP) resins. The prepolymers can be used as the sole resin, whereas the monomers are commonly used as cross-linking agents for unsaturated polyesters; use of triallyl isocyanurate as a cross-linking monomer results in excellent high temperature properties. These resins are exceptional in their ability to maintain electrical properties under high temperature and high humidity conditions. They are also characterized by excellent dimensional stability, chemical resistance, and a chemical purity that minimizes ionic contamination. Specialty allyls have been traditionally used in eyewear applications.

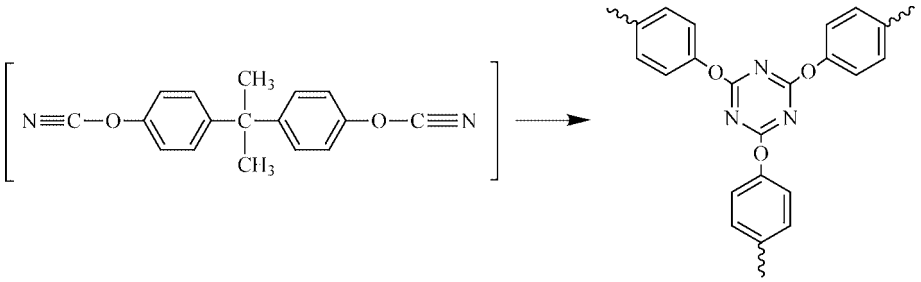
Polyurethanes. Polyurethanes are produced by the reaction of a polyfunctional isocyanate with a polyol or other reactant containing two or more groups reactive with isocyanate, usually hydroxyls (see POLYURETHANES). Thermoset polyurethanes require that one reactant be trifunctional or higher and that the T_g of the cross-linked network be above room temperature. Products include rigid foams, coatings, adhesives, and binders. The reaction of an isocyanate with an alcohol, illustrated in equation 4, is exothermic and forms a urethane or carbamate linkage without the production of volatile products. Blocked isocyanates provide room temperature stable, one-component systems, such as wire and coil coatings that can be cured at high temperatures. Typically, temperatures above 120°C are required to release the blocking group and regenerate the isocyanate group. Polyurethane powder coatings, which are B-staged solid systems applied to a substrate as a dry powder, often employ blocked isocyanates. Coalescence and cure at high temperatures result in tough, durable coatings.



(4)

Dicyanate Resins. Bisphenol A dicyanates were commercialized in the late 1970s. The initial use was for high circuit density and high speed circuit boards (see ISOCYANATE-DERIVED POLYMERS). During initial testing, exposure to high relative humidity caused moisture stability problems. Moisture resistance was improved by blending bisphenol A dicyanates with epoxy resins to reduce the amount of ester linkages in the resulting copolymer. During the 1980s and 1990s many more new dicyanate ester monomers were developed (14), including a bicyclopentadiene containing dicyanate (Dow 71787.02) (15). The bicyclopentadiene modified cyanate exhibits excellent electrical and mechanical properties and enhanced processability. Bisphenol A dicyanates had high T_g's but were brittle and had low fracture toughness. Several approaches were developed to toughen cyanate esters including the use of core/shell rubbers (16) and thermoplastic toughening agents such as polyethersulfone, polysulfone, and polyetherimides (17).

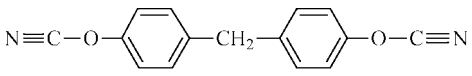
The predominant curing pathway for cyanate ester is via cyclotrimerization using metal coordination catalysts. Three types of metal coordination catalysts are used; metal naphthenates, metal acetylacetonates (AcAc), and metal octoates. Of these, Cu AcAc and Mn octoate are the most popular. Nonylphenol is also required as a cocatalyst. Reaction 5 shows the cyclotrimerization reaction of bisphenol A dicyanate to form the triazine network structure:



(5)

For very high T_g applications, dicyanates are cured without addition of epoxy modifiers leading to a very tight network via cyclotrimerization. The advantage of the cyanate ester family of monomers is the ability to formulate with epoxy resins. Typical resins in electronic applications are combinations of tailored epoxy monomers and oligomers along with cyanate esters.

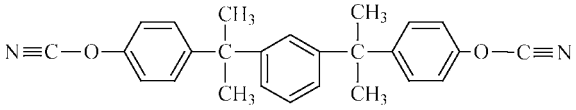
Mitsubishi Gas Chemical pioneered the development of circuit substrates by blending bisphenol A dicyanates with epoxies and a small amount of bismaleimide. The resulting bismaleimide/triazine/epoxy (BT epoxy) laminates are the industry standard for low dielectric, high T_g chip packaging substrates. Cyanate ester networks have very high T_g's, high modulus, and low dielectric constant and have an attractive dielectric loss factor. These properties made the cyanate ester family of resins attractive for circuit packaging applications. Liquid cyanate ester monomers (bisphenol F dicyanates) have low viscosity at 25°C and exhibit good compatibility with other cyanate ester resins, epoxy resins, and bismaleimide resins (17). Blending liquid cyanate ester resins with other cyanate ester and epoxy resins provided a pathway to control the rheological properties without sacrificing the final cured performance. Liquid cyanate esters enabled the development of underfill resins for chip packaging applications, where low viscosity is required during processing. After curing, cyanate ester resins provide high T_g, low coefficient of thermal expansion, high toughness, and low moisture absorption required for underfill applications. The chemical structure of liquid bisphenol F dicyanate is shown as structure **3**:



3

Dicyanate resins are versatile thermosets and have been used in a wide variety of applications. For example, RTX-366 (Hunstman Chemical) is a high molecular weight cyanate ester oligomer with excellent dielectric properties (low

dielectric constant and loss factor) along with low moisture absorption (18). RTX 366, shown in structure **4**, has been used in low outgassing and dimensionally stable, high tolerance composites for communication satellites, space antennas, microwave transparent radomes, and aircraft film adhesives.

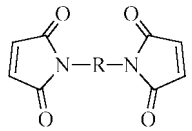


4

Additionally, cyanate ester resin blends formulated with RTX 366 have low moisture absorption, increased fracture toughness, and excellent dielectric properties, leading to use as advanced circuit board substrate materials.

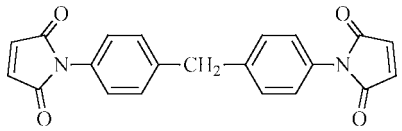
Bismaleimide Resins. Polyimide resins are a class of high performance resins that have gained wide acceptance in a variety of applications (see POLYIMIDES). Bismaleimides are thermosetting polyimides that cure by addition reactions that avoid formation of volatiles. Unlike condensation polyimides which evolve volatiles during curing and are typically used as thin films, bismaleimide resins contain unsaturated double bonds which can be cured via several chemical pathways (free-radical, Michael addition, or cycloaddition, such as Diels–Alder). Thermal polymerization without the evolution of volatile byproducts enables bismaleimide resins to be used in a large number of applications from electronic materials (such as die attach adhesives), coatings, films, structural adhesives, encapsulants, and high performance fiber-reinforced composites.

Bismaleimide resins have the following generic structure (**5**):



5

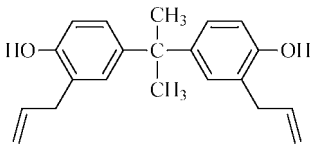
Depending on the desired properties, the R group can be either aliphatic or aromatic. For high T_g networks, aromatic bismaleimides are used. The most common component in bismaleimide resins is 4,4′bismaleimidodiphenylmethane (BMI) (**6**):



6

The BMI resin is a high melting point crystalline solid and when thermally cured, the resulting networks are very brittle. Bismaleimides are rarely used alone in the solid form. In most applications, reactive comonomers (eg vinyl and allyl

compounds, allyl phenols, aromatic amines) are used to achieve the desired final properties and processing characteristics. Commercially available resin systems are typically two-component systems. For example, the Matrimid 5292 system from Huntsman Chemical (Matrimid 5292 originally developed by Ciba Geigy) is a blend of BMI and o,o′-diallyl bisphenol A (DBA) (**7**).



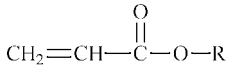
7

DBA has low viscosity and is used in place of solvents to enhance the processability and increase the toughness of the BMI composite. The DBA copolymerizes with BMI causing a decrease in the cross-link density, leading to a tougher network. BMI resins for composites are cured at temperatures in the range of 200–250°C.

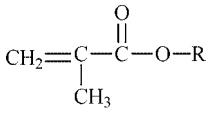
Liquid BMIs with long-chain aliphatic structures between the maleimide groups are used for low modulus, low T_g, high flexibility applications. For electronic applications, BMIs have made a significant impact in die attach adhesives. Liquid BMIs can be used to formulate high performance die attach adhesives because of the ability to achieve very fast curing rates via free-radical polymerization with no void formation. Typical formulations are cured with peroxides and can have cure speeds of less than 1 min (snap cure) at curing temperatures in the range of 175–220°C. For these systems, a significant amount of the network formation is completed within seconds allowing semidconductor chips to be rapidly attached to leadframes or substrates and maintain a very high production rate at the die bonder. Additionally, the die attach formulations can be tailored to have low T_g, low modulus (to control stress and warpage during processing), low moisture absorption, and high adhesion at elevated temperatures. A potential drawback of the peroxide curing is short work life and the need to store the formulated adhesive at low temperatures to prevent slow reaction during storage. Typical work life (working time after thawing) is between 12 and 36 hours and premixed and frozen adhesives are typically stored at −40°C.

Acrylates. Acrylate-containing monomers can be used to rapidly form high cross-link density networks using free-radical initiators, radiation initiators (UV and electron beam), and Michael addition initiators. Very fast cure speed can be obtained over a wide range of formulations making this particularly useful for high speed curing of coatings and adhesives.

Typical acrylic monomers contain either the acrylate functionality (structure **8**) or the methacrylate functionality (structure **9**), where R can be aromatic or aliphatic, and also contain linear, branched, or cyclic alkanes, ethers, or esters (see ACRYLIC ESTER POLYMERS).



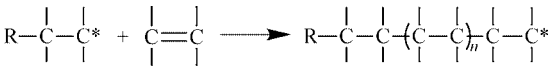
8



9

Free-radical curing coatings and adhesives can be formulated using temperature sensitive free-radical initiators such as peroxide and azonitrile compounds. Typical peroxide initiators are benzoyl peroxide and cumyl hydroperoxides. The most common azonitrile compound is 2,2′-azobisisobutyronitrile (AIBN). With these initiators, free radicals are generated by thermal decomposition leading to an active free radical. Once a free radical is formed it propagates to form a polymer by the following reaction pathway, where reaction 6 illustrates initiation and reaction 7 propagation:

(6)



(7)

Selection of the functionality and stoichiometry of the monomers or oligomers can yield cross-linked networks with various physical and mechanical properties. For example, monomers are commercially available with mono-, di-, tri-, and multifuntionality. Choosing various ratios of di-, tri-, and multifunctional acrylate-containing monomers, the curing speed, T_g, hardness, solvent resistance, and flexibility can be tailored for a specific application. Choice of the peroxide is critical since there are a wide range of initiation temperatures. When using free-radical initiators with low cure onset temperatures, one needs to be careful with the shelf life of coatings or work life times for paste adhesives. Additionally, the free-radical curing mechanism is sensitive to oxygen inhibition. Oxygen is an effective free-radical scavenger and in order to achieve uniform curing in the thickness of the coating, oxygen must be eliminated at the surface by using an inert atmosphere (typically nitrogen) or by the addition of chemical additives that are good oxygen scavengers.

Another common curing mechanism for acrylate-containing polymers is to cure using UV light. Typical UV-cured coatings contain a free-radical-generating photoinitiator. Radicals are generated upon exposure to UV light and quickly initiate free-radical polymerization. Common photoinitators include benzophenone and the diaryl ketone derivatives including zanthone, thiozanthone, and 2-chlorothioxanthone, along with Michler's ketone, benzyl, and anthraquinone (19). Under UV irradiation, solventless coatings and adhesives can be cured extremely fast at high line speeds.

To expand the formulation toolbox, acrylates can be used as co-reactants and reactive diluents in epoxy systems cured using amines. Acrylate esters react with amine curing agents through a Michael addition reaction, resulting in a secondary

amine–acrylate adduct that can further react with epoxy resins. In this manner, highly cross-linked networks with controlled properties can be formulated.

Fast-curing coatings and adhesives using acrylate-containing monomers are used in high performance automotive primers and topcoats, concrete bridge deck coatings, industrial floorings, and specialty coatings for wood and paper. In the microelectronics industry, many photoresists use acrylate-containing monomers and oligomers. High performance die attach adhesives use a wide variety of acrylate-containing monomers, allowing solvent-free formulations, very fast curing, and control of key physical properties such as T_g and modulus.

UV curing is used in high performance coating applications, such as topcoats for flooring applications (polymer and wood flooring), coatings for metal and wood furniture, along with plastic and metal container coatings. UV curing is used extensively in the processing of photoresists in the microelectronics industry. Photodefinable soldermasks used to protect the outside surfaces of circuit boards and chip substrates make considerable use of acrylate-containing polymers.

Nanocomposites

Nanocomposites are a subset of nanotechnology. "Nano" refers to a size scale measured in nanometers (nm), or 10^{-9} m. A working definition for the nanoscale is molecules and structures with at least one dimension between 1 and 100 nm (20,21). In addition to size, shape is also a component of nanostructures, eg self-assembling nanomaterials that form nanofibers, ribbons, and molecular template structures (22,23). The benefits of using nanoscale constituents, such as clay platelets, carbon nanotubes and nanofibers, and silica-based organic hybrids, have been widely studied since the early 1990s (see NANOCOMPOSITES, POLYMER-CLAY; NANOCOMPOSITES, LAYER-BY-LAYER ASSEMBLY). Pioneering advances at Toyota research (24,25) led to a nylon-6/clay nanocomposite with remarkable property enhancements at low filler loading which stimulated further research and development. The unique combination of large interfacial area and small interparticle distances, obtained at low filler loadings, is responsible for material responses unexpected from that observed in conventional microcomposites. Nanocomposite filler loading is typically $<10\%$ and often $<5\%$ by weight as compared to 20–40% for conventional materials. The addition of nanoscale constituents provides not only reinforcement at low volume fractions but also synergism with the matrix molecules with which it shares the same size scale. Significant property enhancements are generally observed at loadings of 1–5 vol%. They include enhancements in modulus, strength, and toughness; dimensional stability at elevated temperature; decreased swellability and barrier resistance to small molecules; thermal stability and fire retardancy; and electrical and thermal conductivity. Both increases and decreases in T_g have been observed in thermoset nanocomposites.

Thermoset/Clay Nanocomposites. A number of studies have reported the processing and properties of thermoset/clay nanocomposites (26). Nanoclay materials, such as montmorillonite, are layered silicates, ie they have a lamellar structure. Elementary clay platelets consist of a 1-nm thick layer. Stacking of layers leads to a regular gap called a gallery or interlayer whose d-spacing can be measured by X-ray diffraction. The interlayer space can be penetrated by

organic cations or polar organic liquids. Exchange reactions with organic cations (eg, aminoacids or alkylammonium ions) renders the silicate surface organophilic. Such materials are referred to as *organically modified layered silicates* (OLS). To gain the property enhancements described above requires dispersion of the filler at the nanometer level, ie down to the elementary clay platelet. Two morphologies are possible: an intercalated nanocomposite in which the unreacted resin penetrates the interlayer and is subsequently cured; and an exfoliated or delaminated nanocomposite where clay layers are individually dispersed in the thermoset matrix. Intercalation leads to increased *d*-spacing and can eventually result in exfoliation. Many nanocomposite systems are a blend of intercalated and exfoliated structures. The ability to process thermoset nanocomposites depends on several compositional factors such as resin viscosity and reactivity, catalysts, and the effect of the nanoparticle itself. The filler can play a significant role in the rheology of the uncured system as well as catalyze the chemical cross-linking reactions. Organically modified layered silicates frequently catalyze the reaction so that the rate of intragallery cure exceeds extragallery cure and that in the bulk matrix. The extent and rate of cure determine gelation and ultimately the final morphology, ie intercalated or exfoliated.

Pinnavai and co-workers (27) achieved exfoliated morphologies using epoxy resins. The ability to achieve an exfoliated morphology is presumed to be due to the polarity of these systems, which promotes diffusion into the clay galleries. Subsequent to diffusion into the interlayer, it was suggested that the maximum layer expansion is obtained when the intragallery cure rate exceeds that outside the gallery, allowing exfoliation to occur before gelation freezes the morphology. It was also shown that the alkylammonium ions catalyze homopolymerization of the epoxy. The same authors (28) observed two DSC exotherms for these systems. The lower temperature and lower activation energy exotherm was attributed to cure of epoxide on the internal gallery surfaces where the acidity of the clay exchange cation was assumed to play a major role in catalyzing epoxy homopolymerization. The higher temperature peak was attributed to cure of extragallery epoxide. Miyagawa and co-workers (29) studied the thermal–mechanical properties and nanostructure of an anhydride-cured epoxy reinforced with an organoclay (OLS), natural montmorillonite modified with a ternary ammonium salt. Nanocomposites were made with clay loadings of 2.5–6.2% by weight (1.6–4.0% by volume). Following fabrication of the 2.5 wt% clay nanocomposite, the *d*-spacing was observed to expand from 1.80 to 5.84 nm, suggesting that the epoxy system was intercalated between the layers causing additional exfoliation of the clay platelets. Dynamic mechanical analysis showed a 43% increase in storage modulus at 30°C for the 6.2 wt% nanocomposite, significantly greater than that predicted from microreinforcement and nearly a 100% increase in storage modulus above T_g for the 2.5 wt% material. T_g was found to decrease linearly with increasing clay loading, with a ∼15°C decrease for 6.2 wt% clay. It was speculated that the T_g depression may be due to a stoichiometric imbalance caused by preferential adsorption of one of the resin components on the clay surface or in the clay galleries. Messersmith and Giannelis (30) prepared and cured several epoxy–organoclay nanocomposite systems. The curing reaction appeared to involve the hydroxyethyl groups of the alkylammonium ions in the galleries, which participate in the cure reaction and result in direct attachment of the polymer network to the molecularly dispersed

silicate layers. Nanocomposites exhibited a broadened but slightly higher T_g than the neat epoxy. The dynamic storage modulus of nanocomposite containing 4 vol% clay was ~58% higher in the glassy region and 450% higher in the rubbery plateau region than neat epoxy.

Phenolic resin nanocomposites have been fabricated with montmorillonite and alkyl ammonium modified montmorillonite (31,32). It was found by X-ray diffraction that the clays were intercalated by the uncured phenolic resin. The interaction between the organic modifier and the phenolic resin played an important role in determining the stable nanostructure and the final morphology. Ganguli and co-workers (33) investigated the influence of organoclay nanoparticle addition on the rheology and cure of a phenolic dicyanate system, developing cure kinetics and TTT diagrams. The organoclay (OLS) was natural montmorillonite modified with a ternary ammonium salt. While the neat system exhibited Newtonian flow, the uncured nanodispersed system exhibited pseudoplastic flow, attributed largely to resin–clay interactions. Evolution of the morphology during cure was dependent on the rate of intergallery diffusion of the prepolymer resin system and subsequent gelation and vitrification, as well as intra- and extragallery cure kinetics. An intercalated morphology was indicated. Gelation and vitrification times and activation energies for the nanocomposite systems were lower than that of the neat resins, indicating a catalytic effect of the clay on the curing reaction. It was speculated that enhanced intergallery cure kinetics may be leading to a more rapid vitrification which limits resin diffusion into the layers and subsequent exfoliation.

Silica Nanocomposites. Miyagawa and co-workers (34) studied the thermal–mechanical properties and nanostructure of epoxy–anhydride and epoxy–amine systems reinforced with silica nanoparticles at loadings of 2.5–10% by weight. Storage moduli for both systems were significantly greater than the theoretical calculation for spherical particles, which was attributed to a chain network of aggregated silica particles observed by transmission electron microscopy. Individual silica particle diameters of 15–50 nm were measured. A decrease in T_g with silica loading was observed for the epoxy–anhydride system. At higher loadings, inhomogeneous mixing was attributed to the very high viscosities due to matrix–particle interactions. The critical energy release rate and Izod impact strength increased with silica loading for homogeneous samples.

Polyhedral Oligomeric Silsesquioxane Nanocomposites. These reagents offer an opportunity for preparing molecularly dispersed nanocomposites (35). They combine a hybrid inorganic–organic composition with nanosized cage structures having dimensions of 1–3 nm, comparable to those of most polymeric segments or coils. Polyhedral oligomeric silsesquioxane (POSS) compounds contain an inner inorganic framework made up of silicon and oxygen, which is externally covered by organic substituents that can embody a range of polar structures and functional groups. For example, monofunctional and multifunctional epoxy–POSS compounds react with epoxy systems and methacryl–POSS compounds react with acrylic and vinyl ester resin systems. Lee and Lichtenhan (36) described the viscoelastic response of monofunctional epoxy–POSS/epoxy systems containing 5% and 10% by weight POSS. The cured systems were transparent. The glass-transition temperature was observed to increase (~8°C for the 10% material) and broaden with increased loading of the monofunctional POSS into

the network. Surprisingly, the instantaneous modulus was not observed to be affected by incorporation of the POSS nanoreinforcement. Experiments below T_g showed that physical aging in the glassy state was retarded, ie the time required to reach structural equilibrium was longer for POSS–epoxy than for neat epoxy. Pittman and co-workers (37) investigated the viscoelastic and mechanical properties of multifunctional epoxy–POSS/epoxy systems containing 5% and 25% by weight POSS. At sufficiently high cure temperatures, incorporation of the POSS macromer into the epoxy network broadened the glass transition but had little effect on T_g, taken as the peak in tanδ by dynamic mechanical analysis (DMA). The storage moduli at temperatures above T_g were higher than those of neat epoxy and increased with increasing POSS content, improving thermal dimensional stability. However, flexural strengths of epoxy/POSS nanocomposites were lower than that of neat epoxy. Pittman and co-workers (38) have also conducted investigations on several additional POSS/thermosetting systems, including phenolic, dicyanate, and vinyl ester. The phenolic and dicyanate systems are being examined to generate carbon–carbon materials with silica nanophases. The authors speculate that the silica-like nuclei should be effective char promoters and oxygen permeation barriers.

Carbon Nanotube and Carbon Nanofiber Nanocomposites. The discovery of single-wall carbon nanotubes (SWNT) has renewed focus on composites with SWNT, multiwalled carbon nanotube (MWNT) and carbon nanofiber (CNF) reinforcements, together referred to as 1D Nanocarbon composites (39). These constituents offer promise for new lightweight materials with incredible mechanical, electrical, and thermal properties. 1D Nanocarbon materials are envisioned as multifunctional materials, eg single materials used for structures as well as electrical and/or thermal conductors. One example is electronics in a space satellite that need to be lightweight and mechanically supported, have the excess heat dissipated, and be protected from electromagnetic interference (EMI). Other examples are structures that are also batteries and structures that store hydrogen for fuel cells.

1D Nanocarbon composites offer the capability of comparable one-dimensional and two-dimensional reinforcement as conventional carbon-fiber composites, but at much lower loadings. They also offer the unique capability of three-dimensional reinforcement, and at volume fractions less than conventional two-dimensional quasi-isotropic laminates of comparable stiffness. 1D Nanocarbon can also be added at low volume fractions to the matrix for conventional continuous fiber-reinforced composites. Enhanced properties that are envisioned include reduced residual stress by lowering the coefficient of thermal expansion and reducing cure shrinkage, and reduced hygrothermal instability and microcracking. Potential benefits include improved aging and dimensional stability. "Through thickness properties," ie properties in the thickness direction, which are heavily influenced by the matrix properties, also stand to benefit. Small additions of 1D Nanocarbon can significantly improve mechanical properties and transport properties, such as electrical and thermal conductivity, perpendicular to the continuous fiber reinforcement.

Some 1D Nanocarbon materials are already being commercialized, but significant challenges remain. While the nanoscale offers property enhancements not observed with larger reinforcing materials, it also makes dispersion and fiber

alignment more difficult. In addition continuum models may not apply on the size scale of molecules, necessitating the development of new models to guide further development.

Cure and Properties of Thermosets

The basic phenomena of cure were described in the section on characteristic behavior of thermosets. In this section we describe the cure process through the measurement of cure for actual thermoset systems. The most common analytical tools for measuring cure are differential scanning calorimetry (DSC); Fourier transform infrared (FT-IR) and Raman spectroscopy; and rheology, dynamic mechanical analysis (DMA), and dielectric analysis (DEA). Thermogravimetric analysis (TGA) provides a simple and accurate means for measuring filler content where the filler is thermally inert; for measuring cure for thermosetting systems in which a volatile component such as water is a product of the cure reaction, as is the case with many phenolics; and for measuring thermal and thermal–oxidative stability (see THERMAL ANALYSIS and VIBRATIONAL SPECTROSCOPY).

Calorimetry. Differential scanning calorimetry (DSC) measures heat flow into a material (endothermic) or out of a material (exothermic). Thermoset cure reactions are exothermic, ie heat is produced as a result of the chemical reactions. As illustrated in Figure 4, the *heat of reaction*, ΔH_{rxn}, is the total heat liberated from an uncured thermosetting system and can be measured in a DSC heating experiment. ΔH is expressed as heat per mole of reacting groups (kJ/mol or kcal/mole) or per mass of material (J/g or cal/g). The basic assumption underlying the application of DSC is that the measured heat flow dH/dt [the ordinate of a DSC measurement, measured in J/s (watts) or cal/s] is proportional to the rate of the chemical cure reaction, $d\alpha/dt$, as shown in equation 8.

$$d\alpha/dt = \frac{(dH/dt)}{\Delta H_{rxn}} \tag{8}$$

In cases such as the epoxy–amine reaction, it is further assumed that the heat of reaction for epoxy with primary amine is the same as that for the reaction of epoxy with secondary amine, and that the activation energies are the same. For systems with a symmetrical DSC exotherm these parameters are usually within a few percent of each other (2–4). As pointed out in the section on epoxy resins, there is usually a substitution effect where the secondary amine is somewhat less reactive than the primary amine, but the effect on the overall kinetics measured by DSC is not significant. In the small number of systems where steric hindrance is significant, the substitution effect is much larger, eg $k_2/k_1 < 0.2$, the DSC exotherm exhibits a high temperature shoulder or even two distinct exotherms, and an overall reaction cannot be assumed. The above assumptions have proven to be good providing that other thermal events are not occurring at the same time to interfere with measurement of the cure reaction (2–4). One example of an interfering event is the endothermic evaporation of water of condensation from some phenolic

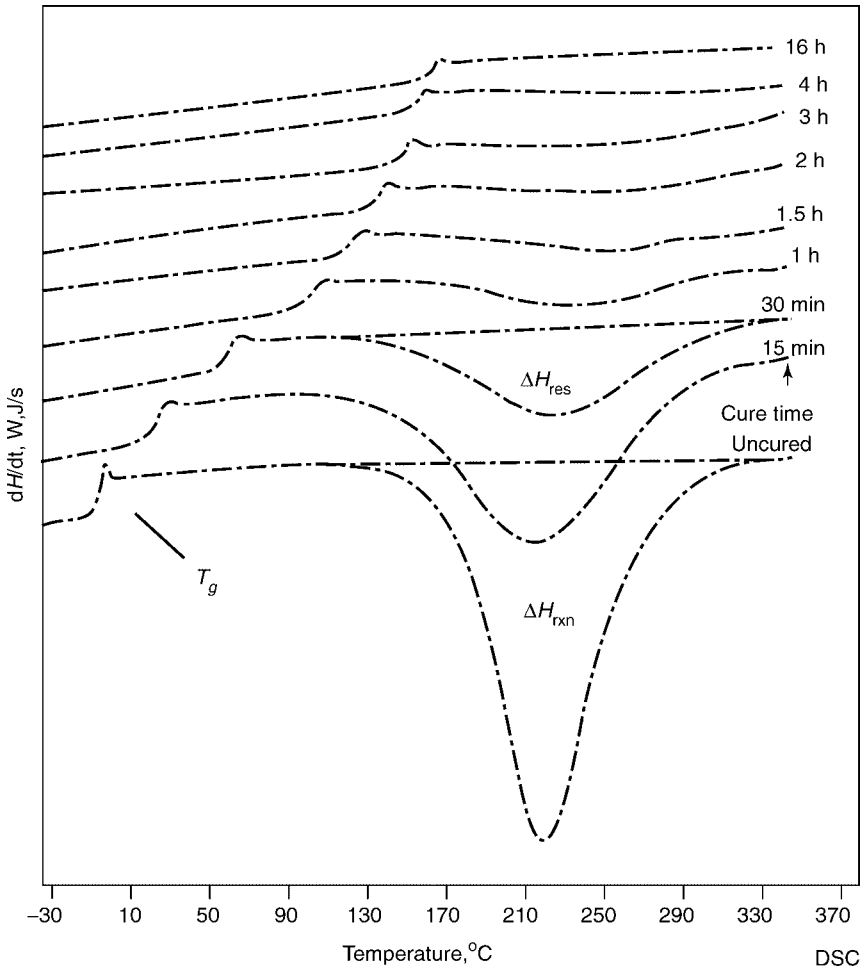


Fig. 4. A series of DSC temperature scans at 10°C/min of an epoxy–amine cured isothermally at 160°C for different times, showing T_g increasing and the residual exotherm decreasing with increasing cure times. From Ref. 40.

and amino resins, which occurs simultaneously with and as a result of the cure reaction.

In terms of a DSC measurement the conversion or degree of cure at time t, α_t, is defined as

$$\alpha_t = \frac{(\Delta H_{rxn} - \Delta H_{res})}{\Delta H_{rxn}} \tag{9}$$

where ΔH_{res} is the residual heat of reaction at time t, also illustrated in Figure 4. Sometimes the symbol x is used instead of α to denote conversion or degree of cure.

Figure 5 shows conversion vs ln(time) curves for the same epoxy for cure temperatures from 100–180°C. Conversion was calculated from equation 9. Note

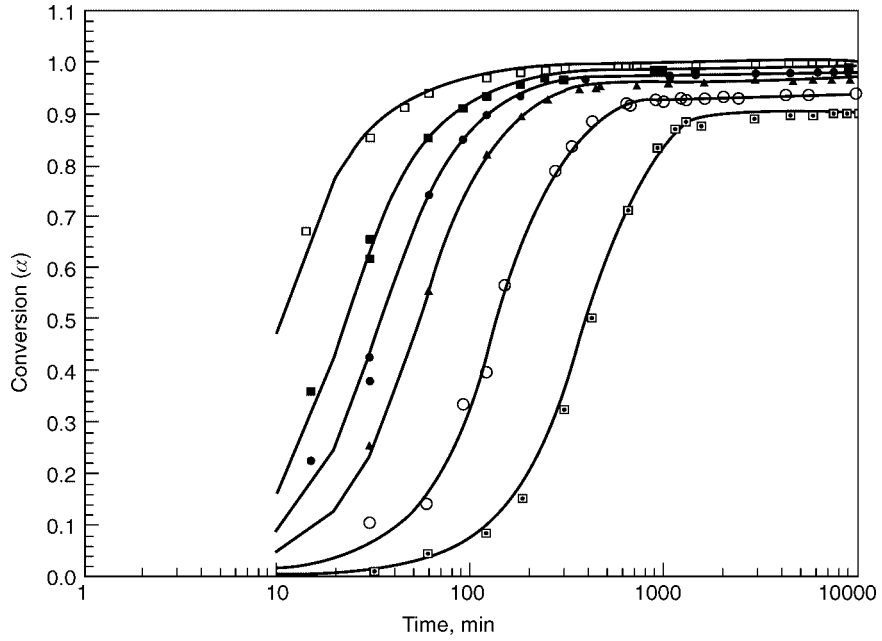

Fig. 5. Conversion versus time data for the same epoxy–amine system shown in Figure 4: ■ 100°C, ○ 120°C, ▲ 140°c, ◆ 150°C, ■ 160°C, □ 160°C. From Ref. 40.

that the curves are parallel during the first part of cure and, at the lower cure temperatures, less than 100% conversion is achieved.

As can be observed in Figure 4, there appears to be a relationship between the glass-transition temperature and conversion measured from the residual exotherm. Several workers have shown that for most thermoset systems there is indeed a unique relationship between the chemical conversion of a thermoset and its glass-transition temperature, independent of the cure temperature and thermal history (see, for example, Refs. 41–43). While a few exceptions have been noted, this appears to be the general case (see Ref. 2). Thus, measurement of T_g may be assumed equivalent to direct measurement of conversion.

Figure 6 illustrates the T_g–conversion relationship for an epoxy–amine system cured at several temperatures. All the data can be seen to collapse to a single curve and are fit to the empirical DiBenedetto equation (44,45). Excellent theoretical treatises of the T_g–conversion relationship can be found in References 41–43. As can be seen from the increasing curvature of the data in Figure 6, T_g is a more sensitive measure of cure than is conversion, as measured by ΔH_{res}, in the latter stages of cure, which are often the most critical. From the slope of the curve for the final 10% of cure [5.4°C/(% conversion)] and an ability to measure T_g to ±2°C, control of degree of cure to 0.5% from measurement of T_g is readily feasible. For thermosetting systems in which weight loss is associated with cure or for which there is no simple or unambiguous measure of cure, T_g is often the only practical means to monitor extent of cure.

The similarity of the T_g–time data in Figure 7 with the conversion–time data of Figure 5 is a consequence of the T_g–conversion relationship and illustrates

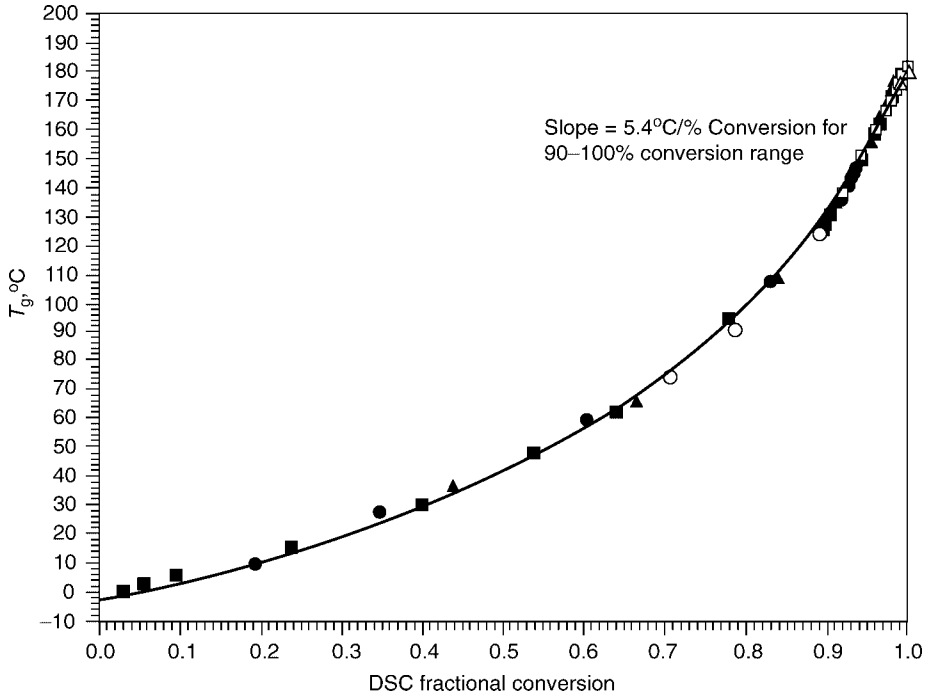

Fig. 6. Relationship for T_g and fractional conversion for the same epoxy–amine system shown in Figure 4. Different symbols represent material cured at different temperatures: ■ 100.5°C, ● 117.2°C, ▲ 139.1°C, ○ 157.1°C, □ 180.7°C, △ 200.4°C,—— DiBenedetto equation. The solid curve represents the best-fit calculation from the modified DiBenedetto equation (44, 45). From Ref. 40.

the ability to monitor cure through measurement of T_g. Figure 7 also directly illustrates vitrification, defined as T_g increasing to T_{cure} as a result of cure, and designated at each cure temperature by an arrow. Note that the progress of cure is significantly impeded shortly after vitrification, which marks the shift from chemical control to diffusion control of the reaction.

Cure Kinetics. This topic is important in two regards: the characterization of the cure behavior of a material and the design and optimization of cure processes. Cure kinetics generally fall into two categories. Aging or storage kinetics after reactants have been mixed, but prior to their use: reaction of prepregs, premixed and frozen adhesives, and powder coatings during storage fall in this category. The objective in this case is to minimize reaction. Of primary significance is cure of the thermoset after the prepreg has been formed into a structure, the resin has infused into a preform in a vacuum-assisted resin-transfer molding (VARTM) process, or the adhesive joint has been formed. Included here are the characterization, design, and optimization of cure processes, where issues such as the optimum time to apply pressure in an autoclave process, the time/temperature to reach full cure, and the increase in temperature required to reduce the cycle time by 50% are considered. Development of a kinetic equation is often needed for software that models the thermal cure process. When combined with rheological

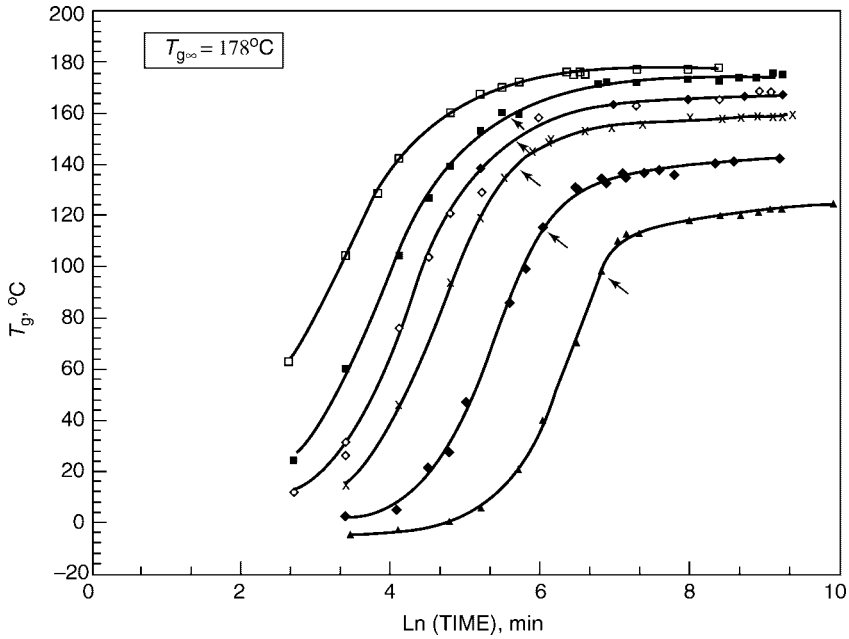

Fig. 7. T_g versus ln(time) for data at different cure temperatures: ▲ 100°C, ◆ 120°C, × 140°C, ◇ 150°C, ■ 160°C, □ 180°C. Isothermal vitrification ($T_g = T_{cure}$) at each cure temperature is designated by an arrow. Same epoxy–amine system as in Figures 4-6. From Ref. 40.

models, the flow behavior or chemorheology of the reacting system can be projected (46).

Cure kinetics is the mathematical relationship between time, temperature, and conversion. Three aspects of cure kinetics are considered: traditional kinetic analyses, model-free kinetics, and time–temperature superposition or TTS kinetics. Traditional kinetics involves models such as nth order and autocatalytic, fits conversion–time data taken at several temperatures to these models to determine reaction orders and measure rate constants, and measures the activation energy E from the Arrhenius equation. Model-free kinetics performs an isoconversional analysis on data from DSC data taken at three or more heating rates, where activation energy is allowed to vary with temperature. This methodology will not be discussed further here; those interested are referred to specific applications to thermoset cure (47,48). An assumption of TTS kinetics is that cure can be described by a single activation energy, independent of conversion and temperature, which is a good assumption for most thermosetting systems. TTS kinetics creates master cure curves by superimposing conversion–time and T_g–time curves through the T_g–conversion relationship utilizing the Arrhenius equation. It may be applied to the characterization of cure as well as to the monitoring and control of systems which cure according to complex time–temperature profiles.

Isothermal conversion–time data can be measured continuously from the beginning to the end of the reaction, or individually by scanning a series of partially cured samples. Two reliable techniques to obtain conversion–time data are isothermal DSC and spectroscopic techniques. Continuous isothermal DSC

measurements have the advantage of simultaneously measuring conversion (α) and rate of conversion ($d\alpha/dt$), which allows use of derivative forms of the rate equation such as equations 10 and 11. A disadvantage of this method is the danger of not recording the initial reaction that may take place during heating to temperature (2). Individual measurements can yield very accurate data and, in the case of DSC, give both T_g and conversion (see Fig. 4 as an example). However, they are time-consuming and since the reaction rate is not measured, integrated forms of the rate equation must be used.

Equation 10 shows the general nth-order rate equation

$$\frac{d\alpha}{dt} = k(1-\alpha)^n \tag{10}$$

where k is the rate constant and n is the reaction order. One example is the second-order reaction of an isocyanate with an alcohol to produce a polyurethane, as illustrated in equation 4. Integrated forms of this equation exist for first-order, second-order, and general nth-order reactions (2), so that either continuous or individual methods may be applied. Since there are only two unknowns, simple linear regression analysis may be used to determine values for k and n. Equation 11 shows a common autocatalytic rate equation proposed by Sourour and Kamal (49)

$$\frac{d\alpha}{dt} = (k_1 + k_2\alpha^m)(1-\alpha)^n \tag{11}$$

where k_1 is the catalyzed rate constant, attributed to impurities and/or fiber or particle surfaces; k_2 is the autocatalyzed rate constant, due to catalytic species produced by the reaction; and m and n are reaction orders. An example is the reaction of an epoxy resin with a diamine to produce an epoxy thermoset, as illustrated in equations 1 and 2. The chemistry for a stoichiometrically balanced reaction suggests that $m = 1$ and $n = 2$. For real systems, values are often close but not identical to these. In the epoxy–amine reaction the alcohol, which is also a product of the reaction, catalyzes further reaction, resulting in autocatalysis. Since there are four unknowns, nonlinear regression analysis must be employed, although k_1 can be evaluated independently as the extrapolated reaction rate at $\alpha = 0$. Autocatalytic kinetics are usually evaluated by the derivative form of the autocatalytic rate equation (eq. 11) with data collected by continuous isothermal DSC measurements. Activation energy E and preexponential factor A are measured from the Arrhenius equation:

$$k = A\exp\left(\frac{-E}{RT}\right) \tag{12}$$

where k is the rate constant, R is the gas constant (1.987 cal/K·mol $\equiv$ 8.314 J/K·mol) and T is absolute temperature. Also note that two activation energies are measured for autocatalytic cure, E_1 and E_2, corresponding to the two rate constants k_1 and k_2. Xie and co-workers (50) used this approach to investigate the effect of multiwalled carbon nanotubes (MWNT) on the cure of an epoxy–amine

system. MWNT were found to accelerate the cure with a pronounced increase in k_1 at all temperatures and a significant decrease in E_1. These authors also introduced a diffusion factor to describe the effects of vitrification on cure in the later stages. References 51–53 discuss incorporating the shift from chemical control to diffusion control upon vitrification into kinetic analyses.

For applications of TTS kinetics we consider cure reactions that can be described by a single activation energy, independent of conversion and temperature. The majority of cure reactions fall in this category, and they typically exhibit a single, symmetrical DSC exotherm. This includes epoxy–amine cure, where the primary amine–epoxy reaction and the secondary amine–epoxy reaction may have different activation energies. They are usually within a few percent of each other, and an average or overall activation energy gives a good description of the cure (see Fig. 8 below as an example). In cases where the activation energies are significantly different, the DSC exotherm will be skewed or there will be two distinct exotherms, in which case a more complex analysis of cure must be undertaken (2). Activation energies for cure are typically between 40 and 125 kJ/mol (10 and 30 kcal/mol). For an activation energy of 40 kJ/mol, an increase in temperature from 100 to 110°C will increase the rate of cure by a factor of ~2. For an activation energy of 125 kJ/mol, the increase will be a factor of 7. More detailed discussions

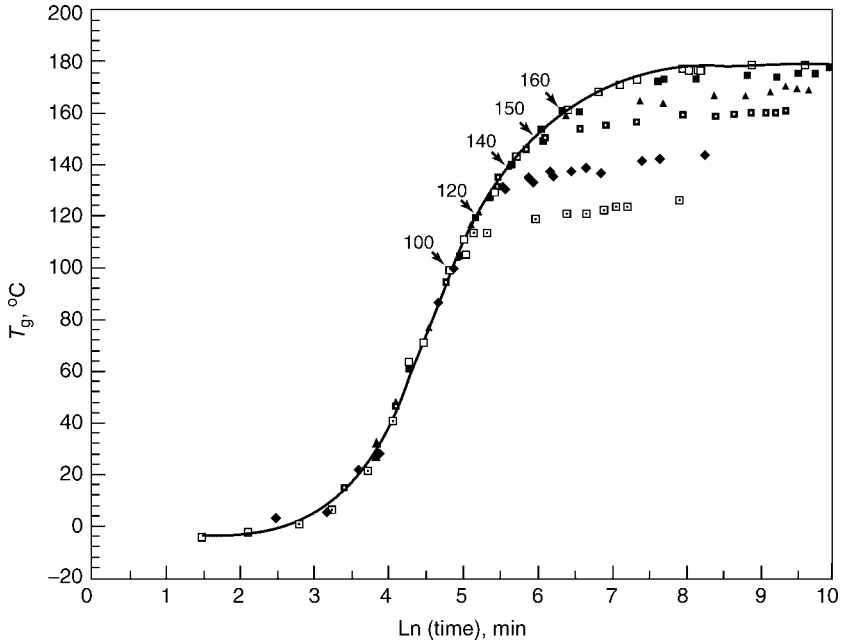

Fig. 8. Superposition of the T_g versus ln(time) data to form a master curve at 140°C by shifting each curve in Figure 7 by a constant factor [ln $(a_T) = \ln(t_{140°C}) - \ln(t_T)$] (see eq. 13) along the ln(time) axis so that its beginning section ($T_g < 90°C$) coincides with the curve for $T_{cure} = 140°C$. Isothermal vitrification points at different cure temperatures are marked by arrows. Note that vitrification points at all cure temperatures lie on the master curve, ie vitrification occurs during chemical control of the reaction: ▫ 100°C, ◆ 120°C, □ 140°C, ▲ 150°C, ■ 160°C, □ 180°C. From Ref. 40.

of kinetics, not only related to cure but also to storage life before cure and aging after cure, can be found in References 2–4.

$$a_T = \frac{t_2}{t_1} = \exp\left[\frac{E(T_1 - T_2)}{R(T_1 - T_2)}\right] \tag{13}$$

The assumption of a single or overall activation energy means that the only effect of temperature is to speed up or slow down the reaction. As illustrated in Figure 5, when E is constant conversion–time curves (or T_g–time curves through the T_g–conversion relationship; see Fig. 7) will be parallel on a ln(time) plot, allowing construction of master cure or aging curves via time–temperature superposition (2,54). Equation 13 defines the shift factor a_T, which is described by the Arrhenius equation where t is the time to constant conversion or constant T_g, E is the activation energy, and T is the absolute temperature. Master curves are useful for succinctly summarizing all of the kinetic data taken at different temperatures and for predicting behavior at times and temperatures that may be of interest but differ from those that were measured. Note the parallel nature of the curves prior to vitrification in Figures 5 and 7. Figure 8 shows the master curve from shifting the data of Figure 7 along the ln(time) axis using the measured overall activation energy of 63.5 kJ/mol (15.2 kcal/mol) (40). These data were shifted to a reference temperature of 140°C by means of equation 13. Figure 8 clearly shows the reaction under chemical control (master curve, solid line). Only the chemically controlled reaction, which follows Arrhenius kinetics, is subject to time–temperature superposition. Following vitrification, the individual curves deviate from the master curve as the reaction slows and becomes controlled by diffusion of reactants in the glassy state.

Note that in most thermoset cure processes, temperatures are high enough relative to $T_{g\infty}$ to avoid vitrification. A good example is a fast curing, two-component polyurethane used in a pultrusion process (55). Parts are made by mixing the components in-line and rapidly processing and curing. In this study conversion–time data were collected from isothermal DSC measurements. The master cure curve shown in Figure 9 was obtained by shifting these data to times at a reference temperature of 80°C by means of equation (13), using the activation energy for cure measured from multiple heating rate DSC measurements (2). To obtain additional data at high conversion but without the complication of vitrification, heat-hold-cool DSC measurements were made that simulated process cure profiles. Equivalent cure times at the same reference temperature of 80°C were calculated from the profiles by shifting individual points along the profile to times at 80°C by means of equation 13 and summing those points (2,54). The master curve was found to fit the second-order kinetic equation (eq. 10 with $n = 2$) and a complete mathematical description of cure was provided. From this kinetic equation the development of conversion along the profile shown in Figure 10 was determined. A conversion of 96.5% for the polyurethane resin cured according to this profile was estimated. The kinetic equation for cure also allowed the computation of the master curve shown in Figure 9 as "Kinetic Equation."

Modulated Temperature DSC. This is a relatively new technique with tremendous application to thermosets (4). By superimposing a sine wave on the

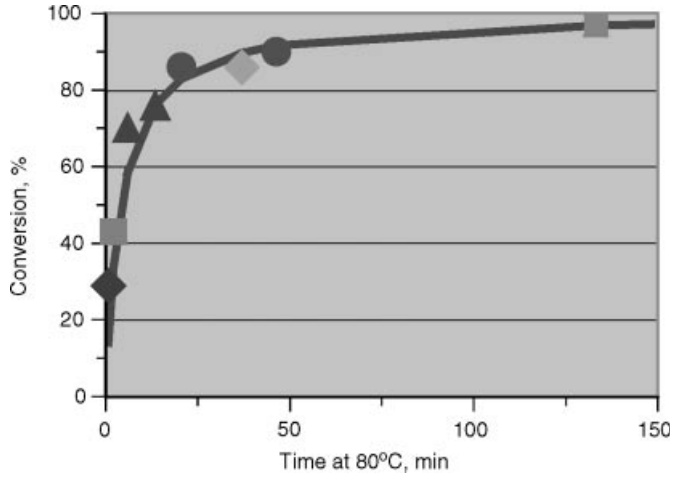

Fig. 9. Master cure curve for polyurethane pultrusion resin system. Data points from isothermal DSC and DSC simulated cure profiles were shifted to times at 80°C by means of equation 14 using the activation energy measured from multiple heating rate DSC. The solid line is calculated from the second-order kinetic equation found to fit the master curve. ◆ 30°C, ■ 45°C, ▲ 60°C, ● 80°C, ◆ 130° profile, ■ 160°C profile, ——— kinetic equation From Ref. 55.

conventional linear heating rate or isothermal temperature, reversible thermal events such as heat capacity and T_g can be separated from those that are nonreversing such as cure. Modulated temperature DSC (MTDSC) allows for the simultaneous measurement of heat capacity, heat flow, and the phase angle between heat flow and heating rate (termed *heat flow phase*). This technique has revolutionized the measurement of T_g, which is measured as a step increase in the heat capacity on heating, by eliminating nonreversing phenomena such as enthalpy relaxation and residual cure from the heat flow measurement.

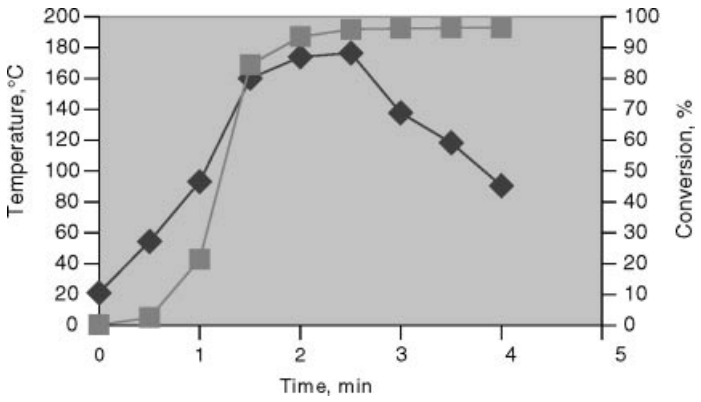

Fig. 10. Time–temperature profile for pultrusion process and development of conversion along the process. —◆— Temperature, °C, —■— conversion. From Ref. 55.

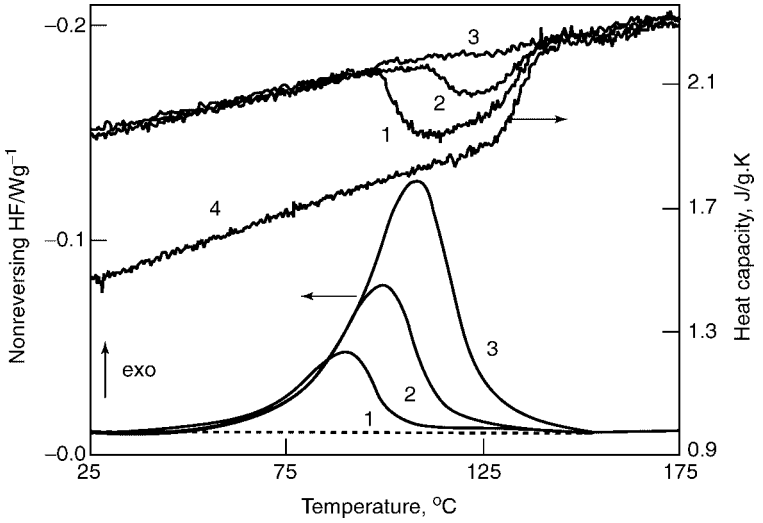

Fig. 11. Nonisothermal cure of an epoxy–anhydride at 0.2 (1), 0.4 (2), and 0.7°C/min (3), and for the fully cured material (4): nonreversing heat flow and heat capacity. From Ref. 4.

Vitrification will occur during thermoset cure when the increasing T_g becomes equal to the cure temperature. This will happen during isothermal cure if the cure temperature is below $T_{g\infty}$, the glass transition for the fully cured thermoset. It will also occur during heating providing the heating rate is sufficiently slow relative to the reaction rate. This is illustrated by the heat capacity curves in Figure 11. At a heating rate of 0.2°C/min (Curve 1), vitrification and the onset of diffusion control can be observed as a decrease in heat capacity beginning at about 100°C. The reaction remains under diffusion control as indicated by the heat capacity remaining between the upper liquid/rubber curve and the lower glassy curve until the reaction is complete, at which time the heat capacity returns to the upper liquid/rubber curve. At 0.4°C/min heating rate (Curve 2) the reaction shifts from chemical control to diffusion control at a higher temperature and over a smaller extent of reaction, and at 0.7°C/min (Curve 3) the entire reaction occurs under chemical control without vitrification.

Many thermoset systems that are brittle have been found to benefit from incorporation of rubber or thermoplastic modifiers that significantly toughen the system (56,57). In the uncured state these modifiers are compatible with the resin system, forming a homogeneous solution. The system transforms into a phase-separated structure because of the increasing molecular weight and network formation of the reacting matrix. The competition between the rates of cure and of phase separation determines the mechanism of the reaction-induced phase separation. The ability of MTDSC for real-time monitoring of reaction-induced phase separation was demonstrated with the cure of an epoxy–aniline–polyethersulfone (PES) system (4). In this case phase separation was observed as vitrification of the segregating dispersed PES-rich phase during isothermal cure at 100°C.

Combined with modeling and FT–Raman spectroscopy, MTDSC can provide specific details of cure reactions such as epoxy–amine in terms of the individual

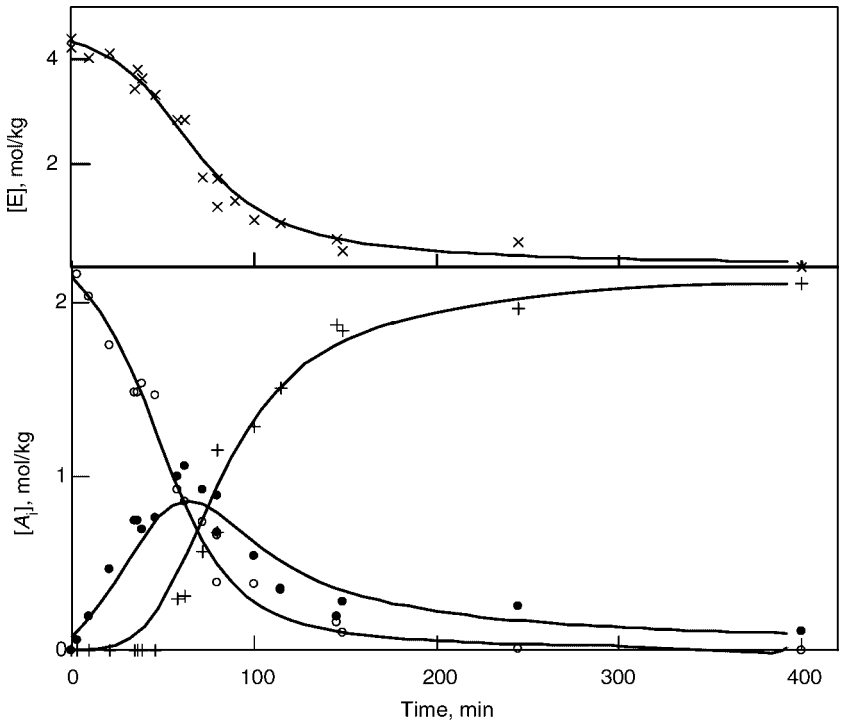

Fig. 12. Evolution of the concentration of epoxide [E] (×), primary amine [A1] (○), secondary amine [A2] (●), and tertiary amine [A3] (+) as measured by FT-Raman spectroscopy for a stoichiometric mixture of DGEBA–aniline cured at 100°C; simulation from MTDSC kinetic model (solid lines). From Ref. 58.

reactants (58). When an overall conversion can be obtained from the heat flow signal, as was shown for the epoxy–aniline system, additional information is available in the heat capacity signal where the primary and secondary amine–epoxy reactions contribute differently to the reaction heat capacity. As a result the evolution of specific reactive groups during cure can be modeled, as shown in Figure 12 where the projections from MTDSC are compared with FT–Raman measurements.

Fourier Transform Infrared and Raman Spectroscopy. These techniques are able to analyze organic and inorganic materials, including thermosets. Results are obtained by spectral interpretation, eg, band allocation to functional groups and comparison with reference spectra, or imaging such as two-dimensional mapping of functional groups (see VIBRATIONAL SPECTROSCOPY). They are capable of monitoring the cure reaction from the liquid state through gelation to the completion of conversion, and even into the glassy state with good precision, sensitivity, and temporal resolution. Determination of chemical conversion versus time and temperature can be made from measurements of functional group intensity with progress of the reaction. For the epoxy–amine reactions shown in equations 1 and 2, for example, one can measure consumption of epoxide and primary amine, production and subsequent consumption of secondary amine, and production of tertiary amine and hydroxyl, thus allowing simultaneous examination of

several kinetic processes associated with cure. Fourier transform infrared (FT-IR) and Raman spectroscopy may have advantages over other techniques such as DSC for their ability to distinguish multiple simultaneous reactions which may have different heats of reaction and activation energies.

Normal vibrations related to a change in dipole moment are infrared active. Functional reactive groups in thermosetting systems, such as epoxide, amine, and hydroxyl, typically have large dipole moments and strong infrared absorptions. Near infrared (FT-NIR) spectroscopy (12,000–4,000 cm^{-1}) has several advantages over the traditional mid-IR (MIR) spectroscopy (4000–400 cm^{-1}), including less complex absorption spectra and the transparency of glass in this region, which allows it to be used as a sample support and for the possibility of *in situ*, real-time cure monitoring, eg by fiber optic NIR spectroscopy (59). In the near-IR range, absorption bands are due to the combination and overtone of fundamental vibrations observed in the MIR region. Their absorptivities are lower, which requires NIR samples to be thicker, eg up to 1 mm or more, and which makes sample preparation simpler than that often required for MIR samples. The strongest absorption bands belong to the highest anharmonic vibrations, which involve the hydrogen atom. In epoxy resin systems, for example, only C—H, N—H, and O—H vibrations are active. As a consequence, NIR absorption spectra are less complex than their counterpart recorded in the MIR region and bands associated with reactive functional groups are better separated. In general the measurements are quantitative because of observed agreement with the Beer–Lambert Law, where absorbance has a linear dependence on concentration. Epoxide, primary amine, and secondary amine concentrations can be measured directly. Kinetic calculation allows one to determine other functional group concentrations not easily measured. The cure of epoxy model systems has been characterized by FT-NIR spectroscopy (60–66). Quantitative measurements are in good agreement with those obtained from other techniques, as illustrated in Figure 13. In this study (64) the cure of a

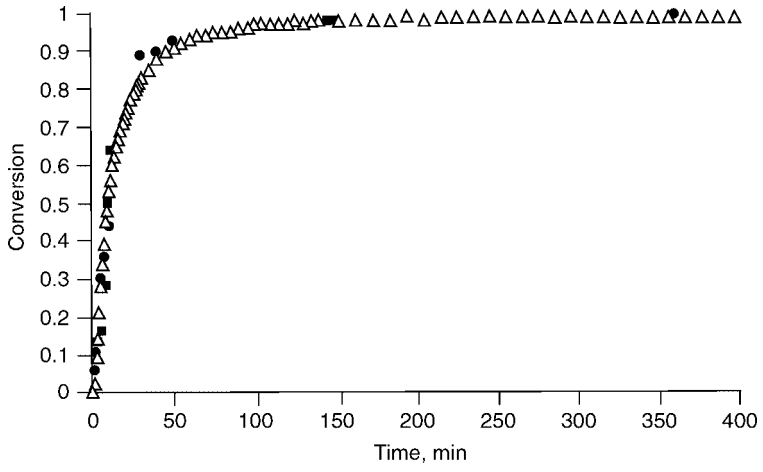

Fig. 13. Comparison of the epoxide conversion in stoichiometric DGEBA–poly(oxypropylene)triamine system at 100°C by DSC (●), SEC(□), and NIR (△). From Ref. 64.

1:1 stoichiometric epoxy–amine system at 100°C was studied by NIR, DSC, and size-exclusion chromatography (SEC, also known as gel-permeation chromatography, GPC). NIR conversion was measured from the concentration of epoxide obtained from the epoxide band at 4528 cm^{-1}, a combination of the stretching fundamental at 3050 cm^{-1} with the CH_2 deformation fundamental at 1460 cm^{-1}, as defined in equation 14.

$$\alpha_{t,NIR} = \frac{A_0 - A_t}{A_0 - A_\infty} \tag{14}$$

where A_0 represents the normalized absorbance initially, A_t the absorbance at time t, and A_∞ the absorbance at complete cure. DSC conversion was measured from the residual exotherm of samples cured for different times at 100°C (see eq. 9). SEC conversion was measured from 1% tetrahydrofuran (THF) solutions of pregel samples cured with the DSC samples. NIR band assignments for the epoxy–amine reaction can be found in References 61–63 and 67. Each functional group has at least two absorption bands. The first, located between 5100 and 4000 cm^{-1}, is assigned to a combination of fundamental vibrations. The second, located at higher wavenumbers, originates from the overtone of the fundamental vibration. Typically, epoxide, primary amine, and hydroxyl concentrations are measured from well-separated absorption bands in the combination region (5100–4000 cm^{-1}). Epoxide and primary amine as well as secondary amine can be measured from the higher wavenumber overtone region where some overlapping of absorptions occurs, often necessitating spectra to be decomposed. When the concentrations of epoxide, primary amine, and secondary amine are known, the hydroxyl and tertiary amine concentrations and the extent of etherification can be deduced from epoxy–amine chemistry and kinetic considerations (67–69). The ratio of rate constants for the epoxy–secondary amine reaction (eq. 2) to the epoxy–primary amine reaction (eq. 1) can be measured. $R = k_2/k_1 = 0.5$ for equal reactivity, which is often assumed, eg, for kinetic analyses from DSC measurements. Paz-Abuin and co-workers (65) report a simple method and R values around 0.4 for three systems but <0.2 for an epoxy–cycloaliphatic amine system. St. John and George (62) reported $R = 0.22$ for a TGDDM/DDS system and also found that the epoxy–secondary amine reaction was affected by gelation, whereas the epoxy–primary amine reaction was not.

While IR is an absorption technique that depends on a changing dipole moment, Raman is a scattering technique that depends on changing polarizability in strong covalent bonds such as C=C and C—O. Like near infrared, sample preparation is simple; water may be used as a solvent and glass as a substrate or container. The frequency range is 4000–50 cm^{-1}. In Raman spectroscopy the sample is excited with laser light. The interaction between the oscillating molecule and the incident radiation will result in both elastic Rayleigh scattering and inelastic Raman scattering. The much stronger Rayleigh scattering is filtered out and a grating disperses the Raman scattered light onto a detector to generate a spectrum. The epoxy–amine reaction has been studied by Raman spectroscopy (58,60,70).

Rheology, Dynamic Mechanical Analysis, and Dielectric Analysis. Thermosetting resins allow a wide range of processing options. When low

molecular weight monomers or oligomers are used as the starting materials, the viscosity can be very low, enabling a wide variety of application methods. Typically, with the application of heat, the low molecular weight species begin to react and increase their molecular weight. As the network builds, the viscosity increases.

Steady shearing rheological methods are good for precisely measuring the viscosity early in the curing and up to the gel point. For low viscosity monomers and oligomers, cone and plate and parallel plate geometries are typically used. Additionally, most rheometers allow precise temperature control, enabling isothermal curing studies to be conducted. If viscosity development is required over the entire conversion range, then steady shearing rheometry is not the recommended choice, since large torques will build up after the gel point and could potentially damage the torque transducers (see RHEOLOGICAL MEASUREMENTS).

Dynamic mechanical methods (typically oscillatory parallel plate rheometry) are commonly used to measure the dynamic mechanical properties from the liquid state to the solid state. By using small-amplitude oscillatory deformations (linear viscoelastic regime), the dynamic storage and loss moduli can be obtained. From these quantities, the viscosity and modulus can be calculated (71) (see DYNAMIC MECHANICAL ANALYSIS).

The dynamic moduli are obtained by applying a time varying strain:

$$\gamma = \gamma_0 \sin(\omega t) \tag{15}$$

where γ_0 is the shear strain amplitude and ω is the frequency. For small strain amplitudes the resultant stress is

$$\sigma = \sigma_0 \sin(\omega t + \delta) \tag{16}$$

where σ_0 is the shear stress amplitude and δ is the phase angle.

For small strain amplitudes, for polymers in the linear viscoelastic regime, the resultant stress is

$$\sigma = \gamma_0 [G' \sin(\omega t) + G'' \cos(\omega t)] \tag{17}$$

where $G'(\omega)$ is the dynamic storage modulus, and $G''(\omega)$ is the dynamic loss modulus. From the dynamic moduli, $G'(\omega)$ and G$''(\omega)$, the complex viscosity $\eta^*(\omega)$ can be calculated (71):

$$\eta^*(\omega) = \frac{\sqrt{[G'(\omega)]^2 + [G''(\omega)]^2}}{\omega} \tag{18}$$

In Figure 14, the complex viscosity is plotted as a function of time for an isothermal cure of an epoxy-based thermoset. The initial viscosity is low and increases rapidly at various temperatures.

In many composite applications, B-staged resins and fiber-reinforced prepregs are used. For B-staged thermoset resins, measuring the viscosity profile during nonisothermal curing provides valuable insight into the flow window, or the time when the resin is able to flow during processing. In Figure 15, the

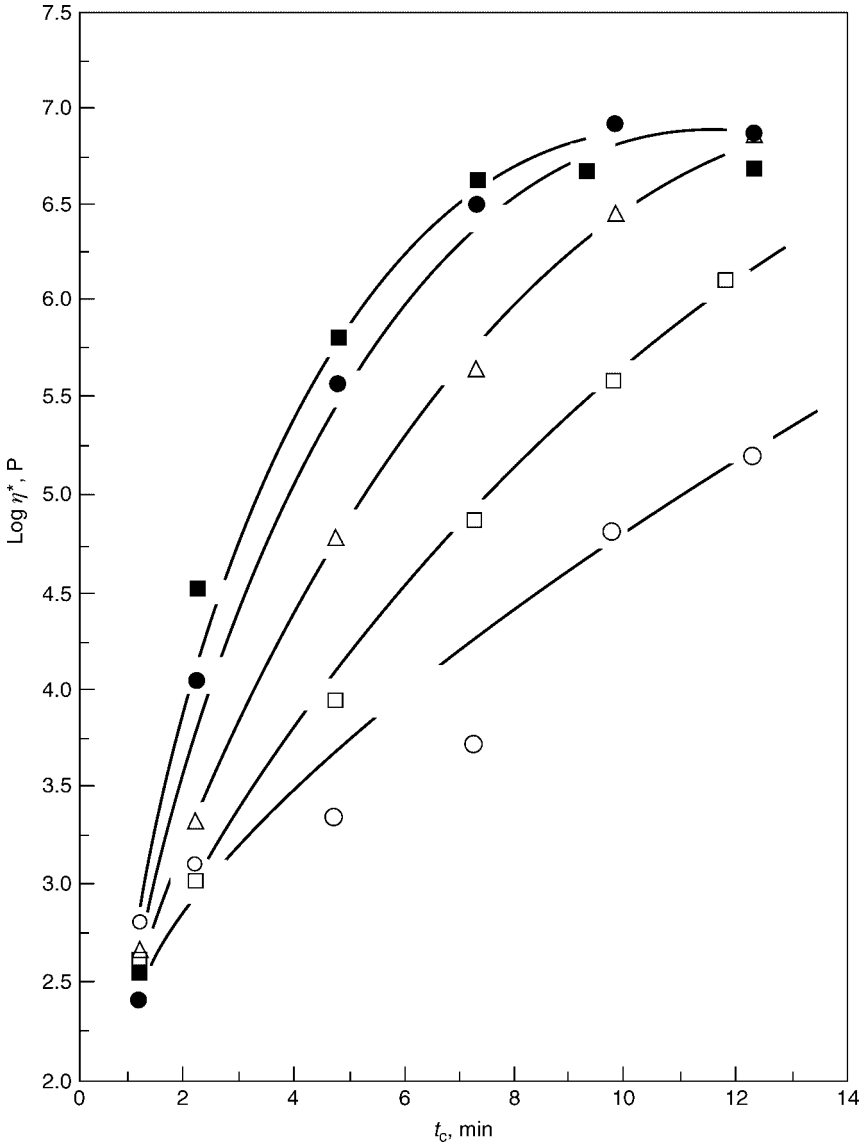

Fig. 14. Complex viscosity versus curing time for isothermal curing of epoxy resin. (1Pa·s = 10 P). ○ 123°C, □ 135°C, △ 145°C, ● 157°C, ■ 162°C. From Ref. 72.

complex viscosity and the percent conversion are plotted as a function of time for a heating rate of 9.8°C/min to 175°C. In this experiment, the rheometer run was aborted at specific time intervals, and the sample rapidly quenched and analyzed for T_g and conversion using DSC (72). The initial B-stage conversion was 23%. The viscosity rapidly decreases as the resin softens at T_g. With further heating, the viscosity reaches a minimum and then the rapid cross-linking reaction causes the viscosity to increase. During the initial softening of the resin, the conversion did not change, indicating that the temperature dependence of the

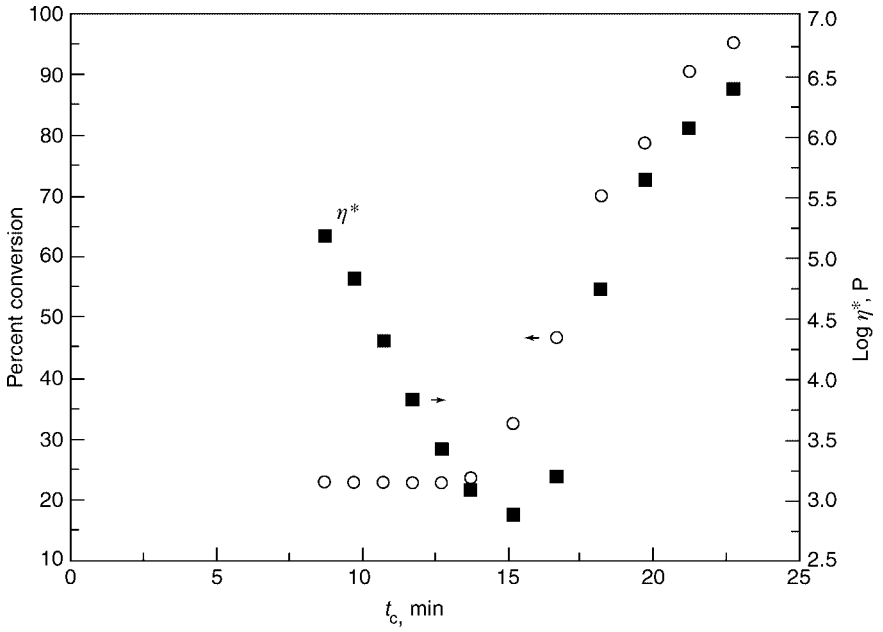

Fig. 15. Complex viscosity (■) and epoxy conversion (○) as a function of curing time for a sample heating rate of 9.8°C/min. (1Pa·s = 10 P). From Ref. 72.

viscosity is the controlling factor. When the viscosity approaches the minimum, the conversion begins to increase dramatically, indicating the onset of rapid consumption of reactive groups. The continuation of the reaction causes the viscosity to increase and ultimately leads through gelation toward full cure.

Whereas steady shear rheometry can measure the initial stages of cure up to the gel point (as illustrated in the left-hand portion of Fig. 2), dynamic mechanical analysis (DMA) can measure the cure process of unsupported thermosets from just beyond gelation to vitrification or the completion of cure, as well as the properties of cured thermosets (see the right-hand portion of Fig. 2). Oscillatory rheometry can measure viscoelastic properties during cure from the liquid state to the solid state, as illustrated in Figures 14 and 15. Figure 16 shows the 40°C isothermal cure of an epoxy resin in the shear sandwich mode, analogous to dynamic rheometry in the parallel plate mode, at frequencies from 0.1 to 100 Hz (73). The frequency-dependent increase in storage modulus to ∼1 GPa and the frequency-dependent loss peaks signify vitrification during cure. When uncured thermosets in liquid or paste form are applied to a substrate such as a metal shim (2,74), wire mesh (2,54,75–77), or glass fiber or filter media (2,12,40,78), cure can be measured from the uncured state to the completion of the reaction. Isothermal gelation and vitrification can be measured directly at several temperatures to generate TTT diagrams such as Figure 3 (12), or cure can be followed by measuring T_g versus time at several temperatures such as in Figure 7 (40,76–78). Figure 17 illustrates the wire-mesh technique which has been used in the characterization of cure of magnetic disk coating (76), powder coatings (54), and dielectric and conducting polymer thick films (77). Figure 18 shows the multifrequency DMA during

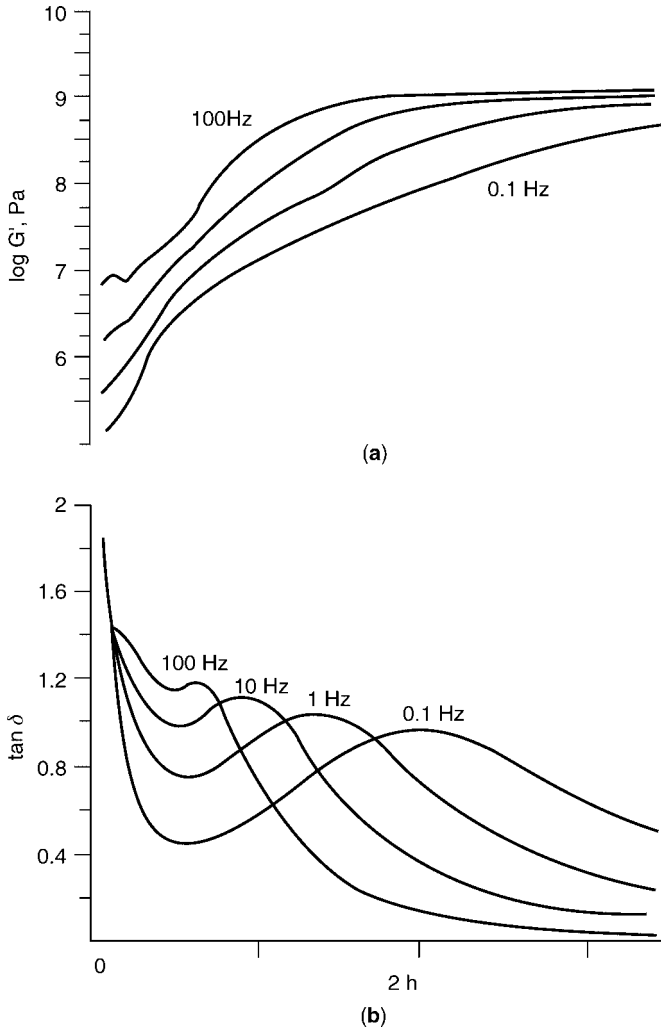

Fig. 16. Cure of epoxy resin in the shear sandwich mode at 40°C: (**a**) shear storage modulus; (**b**) tan δ. From Ref. 73.

heating of a B-staged epoxy from below T_g through the completion of cure (79). The frequency-dependent transition starting near room temperature is the glass transition of the B-staged epoxy, which gels near 140°C during heating at 2°C/min., as evidenced by the small increase in storage modulus and frequency-independent tan δ peaks.

Analogous to the dynamic mechanical measurements, dynamic dielectric measurements can also be used effectively to measure the changes in thermosetting polymers during curing. Typical dielectric measurements use two polarized electrodes. Early methods used parallel plate electrodes. More recently, interdigitated comb electrodes have proven to be more versatile for cure monitoring. All dielectric measurements are made by applying a sinusoidal voltage across the

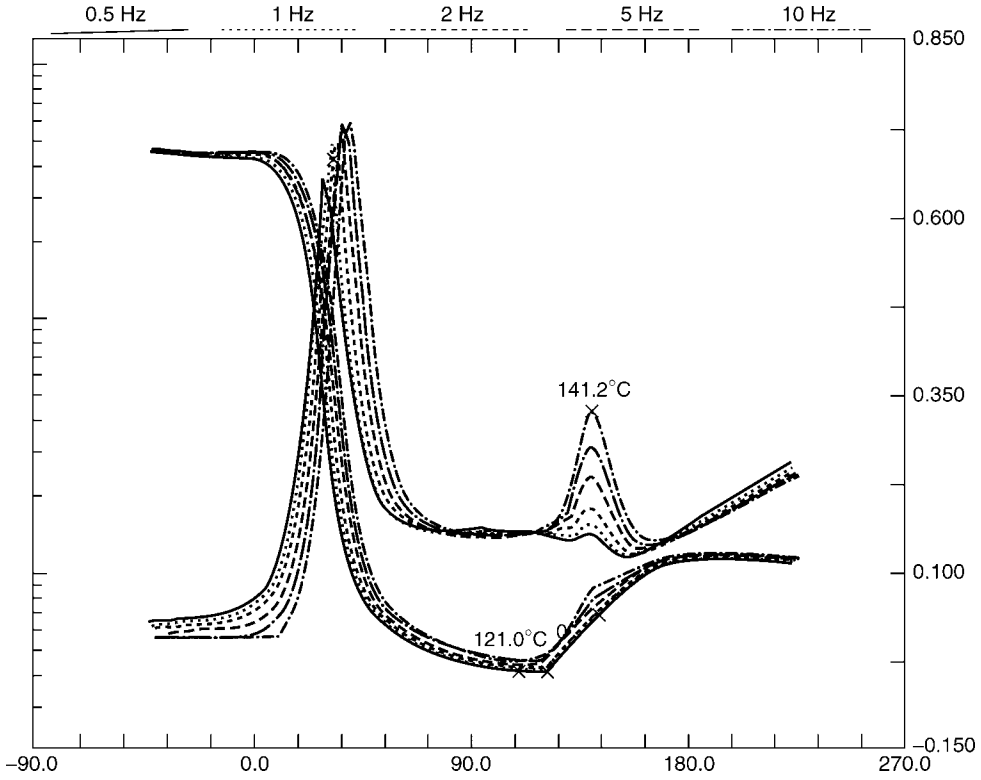

Fig. 18. Multifrequency dynamic mechanical analysis of a B-staged, fiber glass-reinforced adhesive during 2°C/min scan (68): 0.5, 1, 2, 5, 10 and 20 Hz. From Ref. 79.

material between the electrodes and measuring the in-phase and out-of-phase current. From these measurements the conductance and capacitance are obtained. The conductance is a measurement of the dissipation of energy (like the dynamic loss modulus in rheology and DMA), and the capacitance is an indication of the energy stored (analogous to the dynamic storage modulus). In the case of the dielectric measurement, the conductivity consists of two components, one arising from dipole orientation and the second arising from ionic conductivity (80).

The dielectric loss factor $\varepsilon''(\omega)$ can be expressed as

$$\varepsilon'' = \frac{\sigma}{2\pi f \varepsilon_0} + \varepsilon''_d \tag{19}$$

where σ is the ionic conductivity, f is the frequency, ε_0 is the permittivity of free space, and ε''_d is the lumped contribution from all dipoles. The ionic conductivity for a given material is controlled by the number and charge of the ionic species and, most importantly, the mobility of the ion (see DIELECTRIC RELAXATION).

For thermoset curing, there is typically a large change in segmental mobility during curing because of the stiffening of the developing cross-linked network. Measuring the dielectric loss factor as a function of time and temperature is an effective monitor of cure (80).

In Figure 19, the dielectric loss factor is plotted as a function of time for isothermal curing of an epoxy resin. Early in the curing, the viscosity is low, and thus the ionic mobility is high, leading to a large value in the loss factor. As curing proceeds, the increase in molecular weight and cross-linking cause the ionic mobility to decrease because of the tightening of the network and lower segmental mobility. The series of frequency-dependent loss peaks have been correlated with vitrification (81), analogous to those observed by DMA in Figure 16**b**. An excellent review of dielectric measurements and cure monitoring for thermosetting resins may be found in a review by Senturia and Sheppard (80).

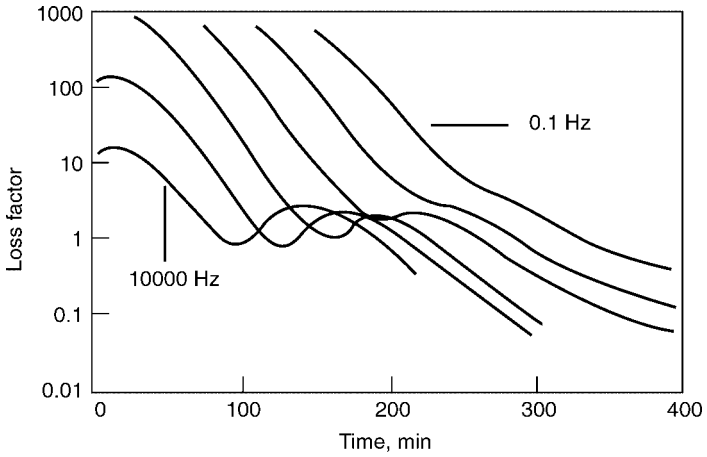

Fig. 19. Dielectric loss factor as a function of time for isothermal curing of an epoxy resin. From Ref. 82.

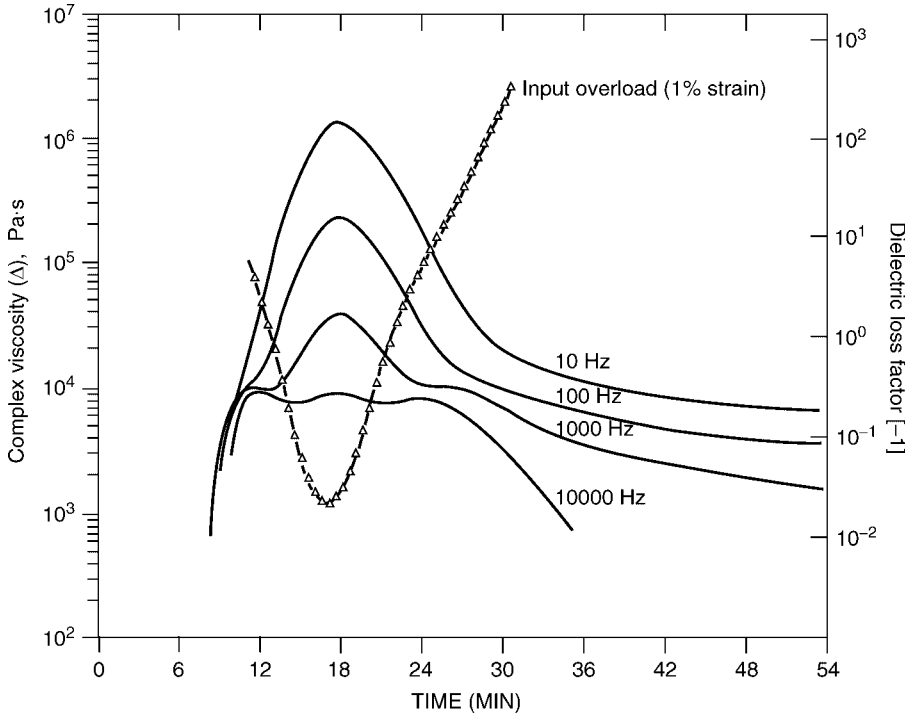

Fig. 20. Dielectric loss factor and complex viscosity plotted as a function of time for a nonisothermal ramp to the cure temperature. From Ref. 82. To convert Pa·s to p, multiply by 10.

Several important industrial applications involve the processing of B-staged prepregs in composite fabrication. Embedded dielectric cure monitors can be used to investigate the changes in the network structure during curing.

In Figure 20, the dielectric loss factor at several frequencies is plotted as a function of time for a nonisothermal ramp and hold at the cure temperature. Also in Figure 20 the complex viscosity (at 1 Hz) is plotted as a function of cure temperature. In this case, the viscosity and dielectric properties were measured simultaneously in a parallel plate rheometer (82). The figure clearly indicates increasing conductivity as the temperature exceeds the T_g of the B-staged resin and the viscosity decreases. With further curing, the viscosity goes through a minimum and then increases because of the rapid tightening of the cross-linked network. The dielectric loss factor goes through a maximum and then decreases rapidly as the cross-linking reaction proceeds. From the simultaneous measurement, the correlation of the loss factor and the complex viscosity can be established (82). Interestingly, because of the limitation of the torque sensor, the viscosity data could not be collected through the completion of the cure. The dielectric sensor is capable of measuring the continued segmental mobility change far into the reaction, giving a more complete analysis of the curing profile. In Figure 20, the final cure temperature was chosen to be lower than the T_g of the fully cured network. During cure, the T_g of the network will reach the cure temperature causing vitrification. At this

point, the reaction rate will be dramatically slowed and the resin will transition from rubbery to glassy. In Figure 20, at vitrification, the torque limit was exceeded because of the large increase in modulus at vitrification, but the temperature was held constant and dielectric data acquisition continued. One may note the continued but very slow curing reaction that continues at elevated temperatures even in the gelled glass region.

Weight Loss. Thermogravimetric analysis (TGA) measures mass flow out of a sample, ie weight loss. Weight loss in thermoset systems includes the loss of solvents and volatile products associated with cure, and degradation products associated with thermal and thermal-oxidative stability. Composition, for example, percent solids and filler content, can be measured from evaporation of solvents or complete decomposition of the resin system, respectively. For several thermosets, such as phenolic and amino resins, an integral part of cure is the formation of condensation products, such as water or formaldehyde (see eq. 3). For blocked isocyante systems, unblocking involves volatile loss and the unblocking temperature can be measured by DSC (83) and TGA (84).

Figure 21 is a TGA of a phenolic resole resin in air (85), showing 30–40% weight loss attributed to cure between 30 and 300°C and complete decomposition between 400 and 650°C. Pyrolysis in nitrogen leaves a significant residue or char. Pyrolysis of a carbon fiber phenolic composite in an inert atmosphere leads to a carbon–carbon composite where the char is the matrix (86). Analysis of the volatile products of Figure 21 by TGA coupled with mass spectroscopy (MS) showed that, in addition to water, products associated with cure included volatile starting materials such as phenol from 30 to 150°C; evolved gasses associated with the major portion of cure from 100 to 250°C, including loss of the allyl group

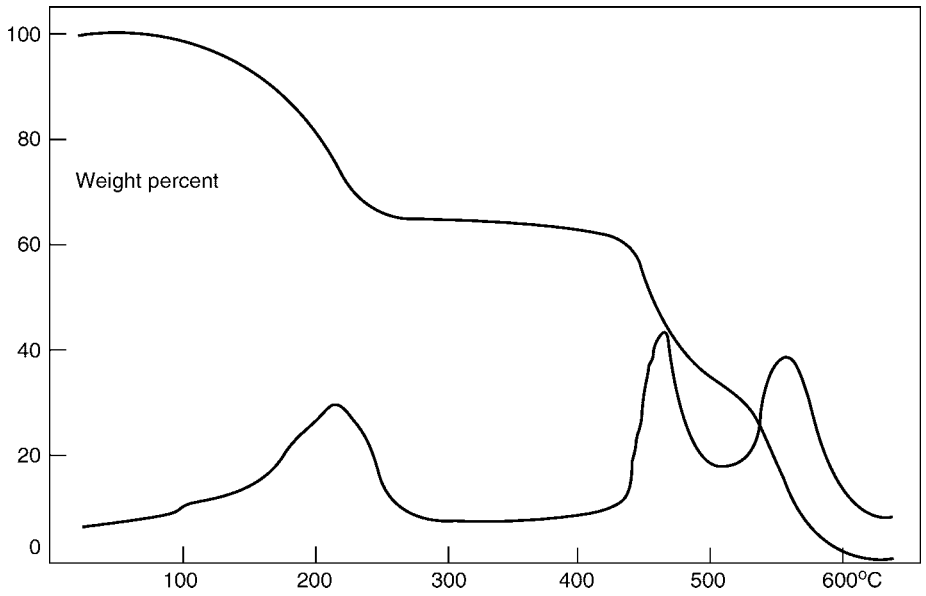

Fig. 21. Thermogravimetric analysis of phenolic resole resin, showing weight losses due to cure (30–300°C) and decomposition (400–650°C). 10°C/min in air. From Ref. 85.

from the allyl phenyl ether resin; and products associated with the latter portion of cure and/or the first stages of decomposition (200–300°C), such as methanol. It was speculated that the allyl functions as a thermally labile protecting group and its loss play a key role in cure. Decomposition was observed to occur in three steps between 400 and 650°C. The first step, accounting for ~10% of the cured polymer weight, occurred over the entire range of decomposition and consisted primarily of C_2H_4O, most likely a fragment from the decomposition of the methylene–ether bridge (see methylene–ether bridge in eq. 3). The weight loss from step 2, ~40% of the cured polymer and occurring between 400 and 500°C, consisted primarily of phenols and substituted phenols. Step 3, between 480 and 600°C and consisting primarily of CO_2, made up the remaining ~50%. The degradation products detected were consistent with a predominantly cross-linked structure which is the condensation product of 2,4,6-trimethylol phenol containing both methylene and methylene–ether cross-links. No major differences were observed between air and nitrogen pyrolyses, except that in the latter, no CO_2 is produced.

Figure 22 demonstrates the utility of TGA in measuring the uniformity of filler content within a part (87). Figure 23 shows the measurement of filler content and relative thermal stability of a series of filled molding compounds (88).

Thermal degradation of thermoset networks have been studied by TGA, often in conjunction with complementary techniques. Musto and co-workers (89) investigated the thermal oxidative stability of an epoxide–diamine (TGDDM/DDS) network and an epoxide–diamine/bismaleimide (TGDDM/DDS/BMI) interpenetrating network (IPN) system by TGA, DMA, and time-resolved FT-IR spectroscopy. Kinetics and degradation mechanisms were explored. It was found that the IPN

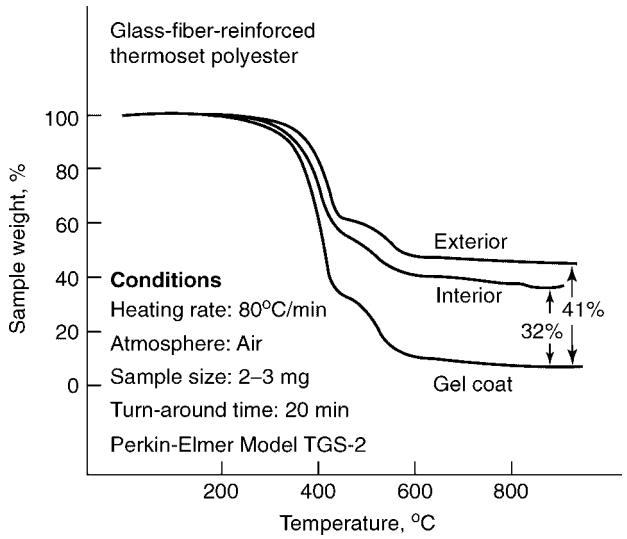

Fig. 22. TGA shows a large nonuniformity of filler content for a molded motor housing. A 9% difference was measured between the bulk ("interior") and a narrow inside ridge ("exterior"). The outer surface, which contained little or no filler, was presumed to be the gel coat. From Ref. 87.

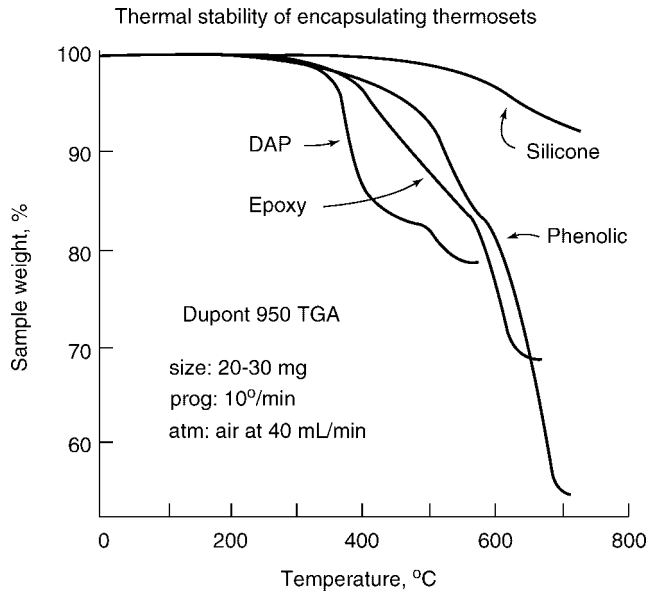

Fig. 23. TGA measurement of relative stability, used as identification tool for encapsulating compounds. Filler content is also measured. From Ref. 88.

systems were more stable than the binary epoxy–amine systems, which was attributed to the higher thermal oxidative stability of the bismaleimide.

Residual Stress

Residual stresses can lead to dimensional instability or even fracture in thermoset systems, causing reduction in part or bond efficiency or durability. Even a small amount of strain can be significant in some cases, such as the bonding of fiber-optic components where alignment is critical. Residual stresses develop within thermosetting systems cured in a geometrically constrained environment because of shrinkage that accompanies cure. Subsequent thermal cycling produces additional stresses because of thermal mismatch between the resin and the constraining environment. These stresses are often responsible for premature failures and defects observed in composite materials. In one- or two-dimensional constraining geometries, such as an adhesive bond, stresses due to shrinkage are negligible compared to thermal stresses that build on cooling through the glass transition (90,91).

Additional stresses can be induced by the process, eg, in the molding of integrated circuit (IC) devices (92). Bair and co-workers (93) defined a figure of merit for the development of stresses on an IC device as it is cooled during processing:

$$\text{residual stress} \propto (\alpha_m - \alpha_s)(E_m)(T_{anch} - T) \tag{20}$$

Residual stress is the product of three terms: the difference in expansion coefficients of the thermoset matrix and the substrate it is attached to $(\alpha_m - \alpha_s)$,

the elastic modulus of the matrix (E_m), and the difference between the anchoring temperature T_{anch} and the test or use temperature (T). T_{anch} was defined as the smallest of T_g, T_{cure}, or $T_{post-cure}$. On the basis of this relationship, means to reduce residual stress include matching of expansion coefficients by adding low expansion fillers to the thermoset matrix, reducing the thermoset modulus, eg, by incorporation of rubber modifiers, and by curing through gelation at temperatures as close to operating conditions as is feasible. Equation 20 does not consider stresses due to shrinkage.

Shuto and co-workers (94) investigated the thermal strains that develop during cure and cooling of resins for laser-diode molding. High T_g epoxy and low T_g silicone were bonded to silicon substrates at elevated temperatures and slowly cooled to room temperature. The epoxy system showed a small strain during cure (because of shrinkage) but much larger strain during cooling through T_g. The silicone system with low modulus throughout the measurement cycle exhibited negligible strain during cure or cooling. Qian and co-workers (95) modeled the thermal bending of the magnetic recording head gimbal assembly for hard disk drives with elastic theory. The bending or deflection arises from the thermal expansion coefficient difference between the ceramic slider and the stainless-steel suspension which are bonded together with a thermoset adhesive. They showed that adhesive modulus had a significant effect on slider deflection, with major deflection when the adhesive is glassy but decreasing dramatically with decreasing modulus. The same authors generalized the model to consider the adhesive as a viscoelastic solid (96). Inclusion of the measured creep compliance master curves of a low and a high modulus adhesive allowed calculation of the time dependence of the slider thermal deflection.

The effect of the cure process on the development of residual stress was investigated by Djokic and co-workers (97). The system studied was a bonded thermoset composite patch for repair or strengthening of aircraft structures. The objective was to develop optimized cure cycles to achieve a combination of minimum residual stresses and cycle time, and maximum level of cure. While reduction in cure temperature led to less residual stress, it was at the cost of increased cycle time and incomplete cure when $T_{cure} < T_{g\infty}$. Post-cure at higher temperatures tended to eliminate most of the benefit of the low temperature cure. What showed promise in meeting the objectives was a three-temperature multistep cure cycle that anchored the adhesive at moderate temperature; reduced the temperature so that T_{cure} just exceeded T_g, ie induced the onset of vitrification; and ramped at a rate that allowed T_g to increase at approximately the same rate as T_{cure}. By minimizing ($T_{cure} - T_g$) it was felt that relaxation times would be long enough to minimize relaxation of stresses that developed during the heating and high temperature portion of the cycle. This approach has some similarity to reactive thermoset processing (RTP), which is discussed in the section Thermosets and Processes, in Ref. 98.

Cure Monitoring

In situ monitoring of cure is an important and evolving part of thermoset processing, providing guidance for optimal times to adjust process parameters such as pressure and temperature and to know with confidence when cure is completed.

In some cases even more detail, such as gelation and vitrification, can be detected. Dielectric and ultrasonic methods have been used for many years to monitor thermoset processes and continue to evolve. Newer methods include fiber-optic smart sensors and fiber Bragg grating sensors. At present, only two types of microsensors are widely used in both academic research and industry to monitor cure in real time: dielectric sensors and fiber-optic sensors. Both can be embedded in multiple locations of a composite prior to cure and become part of the finished product. In addition to monitoring cure, these sensors can track the composite through its lifetime. Ultrasonic and near-infrared attenuated total reflection (NIR-ATR) contact sensors allow processes to be monitored without embedding the sensor. Fluorescence probe-label methodology is an alternative method being investigated.

Frequency-dependent dielectric measurements are a convenient sensing technique for monitoring the cure of thermosets (99). Whereas epoxy–amine systems (100–104) have been the most frequently studied, other systems such as glass/polyester prepreg (105) have also been reported. The changes in dielectric properties during cure are due to three main contributions: the decrease in ionic conductivity because of an increase in viscosity, which hinders the translational diffusion of ions; rotational diffusion of permanent dipoles in the electric field; and changes in the dipole moment because of increases in molecular weight and cross-link density and the replacement of monomer dipoles with often weaker dipoles attached to the network, eg the replacement of amine and epoxy dipoles by hydroxyl dipoles in epoxy–amine systems.

Dielectric cure monitoring generally relies on measurement of the ionic conductivity (σ in eq. 19). The conductivity during cure of epoxy–amine systems have been characterized to establish relationships between conductivity and viscosity (103,104), conductivity and T_g (104), and relationships to the conversion of epoxide (103). Recently, models were established to relate changes in the dipole component of the complex permittivity to the advancement of cure through the T_g–conversion relationship, expanding the capabilities of dielectric sensing to monitor cure (102).

Industrial applications of embedded dielectric sensors include quality assurance/quality control, process monitoring and process control applications involving thermosetting resins, composites, paints, and coatings. For industrial processes, the dielectric sensor may be either embedded (implantable) or reusable (mounted in the tool or mold cavity). In both cases, the electrode geometry is primarily two-planar interdigitated comb electrodes mounted on an inert substrate. Various sensor geometries (sensor line widths, substrates, etc) are available depending on the material being measured, tool geometry, and process type. The material being tested must come in intimate contact with the sensor, since the dielectric sensor measures the dielectric properties in the fringe fields between the fingers of the comb electrode (80). The in-process sensors monitor the dielectric loss factor (ε'', see eq. 19), which for thermoset curing is mainly driven by the mobility of the ions in the polymer. The ion viscosity is calculated from the loss factor and can be used to determine the process flow window and monitor the cure endpoint (see www.micromet.com/holometrix/micromet.htm for details on *in situ* dielectric cure monitoring).

So-called "smart composites" are being developed with embedded fiber-optic sensors, which have potential for monitoring of the composite part from the curing stage into its working life and to its ultimate end of life. This technology has

potential for several applications including aircraft structures where smart composites can lead to a reduction in maintenance, repair, and downtime of future aircraft. While fiber-reinforced composites are attractive because of their good engineering properties, these properties are strongly dependent on processing which is the most critical and costly stage in the manufacturing of composite structures. *In situ* cure monitoring opens the possibility to implement on-line control of the process, leading to transformation of the classical manufacturing stage into real smart processing, and thus to dramatic increases in quality and reliability as well as reduction in cost. Crosby and co-workers (106) describe transmission near-IR optical sensors to directly measure the degree of cure, as discussed in the section FTIR and Raman Spectroscopy. Cusano and co-workers describe an optoelectronic sensor, a low cost, on-line approach sensitive to refractive index variation, for cure monitoring (107) and optoelectronic characterization of the cure process in thermoset-based composites (108). A quantitative relationship between refractive index and DSC extent of cure was observed, demonstrating the capability of this sensor to monitor *in situ* cure kinetics. These authors indicated that future work will integrate the curing sensor with a fiber Bragg grating sensor in order to provide simultaneous monitoring of conversion, temperature, and residual stress. Murukeshan and co-workers (109) describe a fiber Bragg grating sensor system with potential to monitor cure of smart composites. Bragg grating fibers were embedded between adjacent layers of carbon fiber and graphite fiber composite plies.

Remote cure monitoring by noninvasive methods has potential advantages vis-à-vis embedded sensor techniques. Xu and Schlup (110) demonstrated the feasibility of using NIR-ATR spectroscopy as a contact sensor method with several epoxy–amine systems. A novel macrodielectric sensor was described for monitoring flow front position and cure in the resin–transfer molding (RTM) process (111). Rath and co-workers (112) describe the process monitoring of a series of compression molding compounds by ultrasonic measurements. The transducers, embedded in the compression mold, were designed to operate at elevated temperature and pressure. Both longitudinal sound velocity (related to storage modulus) and relative attenuation (related to energy loss) track the progress of cure, from devitrification of the molding compounds to completion of cure, and vitrification should that occur. Differences were observed among the molding compounds as well as effects of filler content, moisture content, and amount of hardener.

Fluorescence spectroscopy utilizing specific fluorophores as an unbound probe and/or as a label bound to the forming network shows promise for *in situ* monitoring in epoxy–amine systems (113,114). By correlation with NIR measurements, details such as onset of tertiary amine formation, point of maximum concentration of amino groups, measurement of gelation, and onset of vitrification seem plausible.

Thermoset Processes

Thermosets are reactive systems that undergo transformation from liquid to gel to rigid glassy solid, and these transformations are of necessity incorporated into the process. For thermal processes, variables are time, temperature, and pressure.

For light or radiation activated processes, variables are time, temperature, and intensity. Rheology is important because a thermoset system first needs to flow. For example, an adhesive or coating needs to flow to wet a surface and form an interface, the matrix polymer needs to flow to consolidate the prepreg layers and form a laminate, and the resin needs to flow to wet fibers and fill a mold in a pultrusion process. Speed and efficiency of these flow-related steps, which affect both cost and performance, are dependent on the rheology of the system where viscosity is decreasing with temperature but increasing with conversion. This typically results in a minimum in viscosity with process time. There is an optimal point in the process to apply pressure, which usually coincides with the minimum in viscosity (see Fig. 20). If pressure is applied too soon, resin will be squeezed out of the part; if it is applied too late, consolidation and mold filling will be incomplete. Flow-related steps must be completed prior to gelation and the part often needs to be physically supported until well past the gel point to prevent changes in dimension or weakening of an interface. This is often accomplished by fixturing an adhesively joined system or maintaining a part in a mold to allow cure to advance. While vitrification is generally to be avoided during cure, thus occurring during cooling, there are occasions when it can be incorporated into a process with advantage. For example, a novel processing scheme, referred to as reactive thermoset processing (RTP), proposes to eliminate expensive fixturing by maintaining the curing thermoset in the "just glassy" state, where the curing thermoset is dimensionally stable but still sufficiently reactive (98). RTP may also be effective in reducing residual stresses induced by the process (97).

Selection of the manufacturing process is influenced by several variables, including quantity, size, thickness, design, and cost. Thermosets are fabricated by processes using either no pressure or pressure ranging from moderate to high at temperatures of 20°C (room temperature cure) to those approaching or even exceeding 200°C. Ambient cure, especially of larger parts, often takes advantage of the exothermic heat of the cure reaction. When parts are very large, overheating can be a problem and the heat of reaction may need to be managed. Many thermoset systems incorporate fibers to enhance properties; most others incorporate fillers to modify properties or reduce cost. Contact processes refer to the assembly of fibers and resins in a mold processed and cured without pressure. Articles may be small or as large as boat hulls 25 m long or longer. Equipment may be simple or highly specialized. The most common thermal processes include open contact molding methods (hand lay-up, spraying, vacuum assisted resin-transfer molding); matched mold methods (compression molding, resin-transfer molding, reactive injection molding); and other methods (filament winding, cold press molding, pultrusion, continuous laminating, encapsulation, and e-beam).

Described below are several thermoset processes, starting with adhesive processes. The descriptions are not meant to be comprehensive, but rather they illustrate the variety of processing options that exist for thermosets (see also COMPOSITES, FABRICATION, and Ref. 1 for descriptions of additional thermoset processes).

Adhesive Processes. Most commercially available adhesive systems consist of either thermoplastic hot melt or reactive thermosetting resins. Typical thermoset adhesive formulations contain base resin monomers and oligomers, curing agents (hardeners), catalysts, adhesion promoters, and various fillers. Adhesive properties depend on the complete mixing and adequate dispersion of the

various ingredients. It is critical that solids be well dispersed. Typical solid components of adhesives are fillers, catalysts, or hardeners. Three roll mills or multishaft mixers with high speed dispersing blades are used to disperse solids into low viscosity components. The high shearing action helps break up solid agglomerates and ensure that the fillers are completely wet out and uniformly distributed in the resin. Once the fillers have been completely dispersed, additional low viscosity components can be incorporated into the formulation using double planetary or multishaft mixers in order to produce a homogeneous mixture. The high shearing action during filler wet-out and the mixing process introduces air into the formulation. The final mixing operation is typically done under vacuum to completely outgas the resin mixture. Most commercially available double planetary and multishaft mixers have the capability to apply vacuum and control temperature during the mixing operation.

For reactive chemistries, the resultant mixtures are placed in containers or syringes and frozen to well below T_{g0} to minimize cure reactions from occurring during storage. These types of adhesives are termed *premixed and frozen*. Depending on the catalyst and chemistry, the work life (the time the adhesive will retain the required processing parameters) can range from hours to days. Some adhesives are packaged in two parts. Typical home-use epoxies come packaged in a dual syringe with parts A and B. The hardener/catalyst is in one part and the resin components are in the other part. This allows a long storage life at room temperature. Once dispensed, the two-part adhesive must be thoroughly mixed and used within the required time. For most industrial adhesives, a *Five Minute Epoxy* type of formulation is not acceptable, since the work life is too short. At a minimum, the work life should be at least 8 h, allowing use over a single shift operation. Most premixed and frozen adhesives have about a 24-h work life.

When a premixed and frozen adhesive is used in production, care must be exercised during thawing to minimize voiding and separation of the adhesive from the wall of the syringe. Additionally, the environment should be controlled to minimize condensation from being incorporated into the adhesive. Rapid thawing increases the likelihood of voiding. Once the adhesive containing syringe is properly thawed, it is placed on a dispensing device. Typical dispensers include needle dispensers that deliver a prescribed amount of adhesive onto the desired surface. The adhesive is then dispensed into line, star, glob, or other patterns depending on the application.

After the adhesive is dispensed, the material is cured. Most adhesives have thermal curing reactions. The most common application is to cure the adhesive in an environmentally controlled oven (typically under nitrogen purge to minimize oxidation). Adhesives with very rapid curing are termed *snap cure* (about 1–2 min at high temperatures) or *spot cure* (approximately 10 s at high temperatures). Specifically in electronic applications, the required high manufacturing throughput requires adhesives with very fast curing speeds. Some adhesives are also B-staged to remove tackiness and give long shelf life, but under additional heating can soften, flow, and cure into a high performance network.

Very fast curing reactions can proceed after exposure to uv radiation or low wavelength visible light (blue light). Typical applications of UV cure include wood coatings (particleboard and simulated wood finishes), flexible coating for vinyl flooring, and coatings for metal surfaces (19). UV exposure is also extensively used

in photoresist technology. However, adhesive applications are often limited by the inability of light to reach the interior of the adhesive joint. Dual-cure adhesives overcome this problem, allowing the exposed adhesive at the joint edges to be cured by UV or blue light, rapidly tacking the parts to be bonded. Subsequently, the bond interior can be thermally cured without the need for expensive fixturing.

Manual Processes. A good example of manual processing is fiber glass-reinforced plastic (FRP) applications utilizing unsaturated polyester resins (see POLYESTERS, UNSATURATED). A random-chopped strand fiber glass mat is precut to fit the open-mold contour and impregnated by hand or spraying in successive plies with catalyzed polyester resin. The application of glass mat and resin at ambient temperatures is now universally employed and called the hand-lay-up or contact-molding process. The quality of the product depends on the skill of the operator in removing air and voids. Fabricated products include chemical equipment, sanitary fixtures, architectural structures, and fiber glass boats. In the spray-up technique, used for bathtub and shower applications, for example, the catalyzed resin and chopped glass fiber are laid down simultaneously on the mold surface with specialized spray equipment. The appearance of FRP products is greatly enhanced by incorporating a polyester gel coat, which may contain pigments and is usually sprayed directly onto the treated mold surface and allowed to cure. The thixotropic characteristics of gel coats need to be controlled and attention must be paid to gel-time drift caused by absorption and deactivation of the accelerator by the pigments and by thixotropic agents such as fumed silica. Resin and glass-fiber reinforcement is applied directly over the gel coat by hand-lay-up or spray-up techniques to produce a product, such as boats and bathtubs, in which the surface of the composite has a glossy appearance free of glass fibers.

Vacuum Bag and Autoclave. Articles made by hand lay-up or spray-up processes are allowed to cure without external pressure. While this is sufficient for many applications, maximum consolidation is not achieved and some porosity remains. The application of even moderate pressure can frequently overcome these drawbacks, and result in better mechanical properties, higher quality parts, and lower weight than achieved by contact molding. One way to apply moderate pressure is to enclose the wet article in the mold inside a flexible membrane or bag and apply a vacuum. Atmospheric pressure presses the bag uniformly against the wet article, generating pressures between 70–100 kPa (10–14 psi). Vacuum inside the bag also tends to degas the article, reducing its porosity. Still higher pressures can be obtained by placing the vacuum assembly in an autoclave at pressures in the range of 700–1400 kPa (~100–200 psi). The bag must be well sealed to prevent infiltration of high pressure air, steam, or water into the molded part. An initial vacuum may be used in the autoclave process to aid in gas and void removal, but the bag is usually vented to atmospheric pressure during the high temperature, high pressure portion of the cure cycle so as not to induce additional void growth from reduced pressure.

Cold Press Molding. This process is an economical method for manufacturing intermediate volumes of products, using low pressure, room temperature cure and inexpensive molds (1). Glass-fiber preform or mat is placed between the matching molds, and liquid resin is added. Gel coats may be employed and woven roving may be added for strength. The mold is closed and the resin permeates the fabric and cures, accelerated by its exothermic heat. Pressures are moderate

(140–350 kPa = 20–50 psi), and molds can be made of inexpensive metal, plaster, or reinforced thermoset. Edges need to be trimmed; ribs, bosses, and other fairly complex shapes are not easily produced.

Resin Transfer Molding. This low cost process is used to mass-produce small and mid-size parts of various shapes with two finished sides. The process requires two matched dies that are clamped together. The catalyzed resin is injected at ambient temperature into the cavity at low pressure, which allows much faster gel and cure times than open molding processes. Gel times for polyester cure are in the 3–5 min range and molding cycles can be as short as 20 min (see POLYESTERS, UNSATURATED). The size of articles that can be produced by RTM is limited by the costs of constructing molds and clamping equipment. Products can be pigmented, gel-coated, and finished. The resin systems may be modified by various types and amounts of fillers. RTM articles can include encapsulated core materials, rib formers, and structural inserts.

Vacuum-Assisted Resin-Transfer Molding. This single-sided molding process offers numerous cost advantages over traditional RTM because of lower tooling costs, room temperature processing, and scalability to large structures. Because it is a single-sided process, dimensional tolerance is less precise than with RTM. Vacuum-assisted resin-transfer molding (VARTM) is a resin infusion process in which dry reinforcement plies are placed onto a metal tool, usually aluminum, coated with a release agent. The preform is covered with a release film and multiple layers of a distribution medium. A vacuum bag is placed on top of this layered construction and a resin inlet and an outlet are positioned at opposite ends of the preform inside the vacuum bag. Vacuum is then drawn providing a driving force that promotes resin infusion first through the distribution medium and then through the fiber preform. When the laminate is completely saturated with resin, the inlet and the outlet are shut and the panel is allowed to cure either at room temperature or at higher temperatures in an oven. The VARTM process is poised for exponential growth as this manufacturing technology is inserted into major defense and commercial programs.

Compression Molding. Compression molding is a high volume, high pressure process suitable for molding complex, high strength, and fairly large articles that need excellent surface finish (1). Thermoset polyester resins, for example, sheet molding compounds (SMC) and bulk molding compounds (BMC), are commonly used. Matched molds are mounted in a hydraulic or mechanical molding press. A weighed charge of SMC or BMC, or a preform or mat treated with resin, is placed in the open mold. The two halves of the mold are closed and heat and pressure are applied. For polyesters temperatures are typically 100–160°C and pressures 1–13 MPa (150–2000 psi). Depending on thickness, size, and shape of the article, curing cycles range from <1 to about 5 min. The mold is opened and the finished product removed.

Reactive Injection Molding. *Reactive injection molding* (RIM), also known as liquid injection molding (LIM), is a process in which a mixture of two or more reactive materials is injected into a mold where the materials react to form a thermoset structure. Advantages include low cost, low pressure requirements, and flexibility in mold configuration. Conventional systems, such as isocyanate with polyol to produce a polyurethane, release little or no volatiles. The generation of substantial volatiles in the mold is obviously undesirable and has

presented a significant obstacle to phenolic-based systems, although some have been reported (see PHENOLIC RESINS). Rigid, cross-linked structural polyurethane foam systems produced by the RIM process contain a sandwich structure of solid skin and a lower density microcellular core in a single operation (see POLYURETHANES). Polyurethane structural foams utilize the smooth, hard skins as a source of impact strength, stability to heat distortion, and combustion resistance. The development of internal mold release (IMR)-based foam systems has further increased the productivity of the RIM process by reducing cleaning time and application of mold release between cycles. The metered component streams are mixed and injected into a closed mold. The chemical cure reaction begins immediately. The exothermic heat evolved vaporizes a low boiling solvent contained in the polyol component, causing the liquid mass to foam. The mixture becomes progressively more viscous, gels, and at the completion of the reaction is transformed into a rigid thermoset network. Cycle times of 1 min or less can be achieved.

Pultrusion. In pultrusion a combination of liquid resin and continuous fiber is pulled continuously through a heated die of the required shape for continuous profiles, such as structural channel, angles, rods, and sheets (1). The plastic sides and top of stepladders are common examples of pultrusion. Commonly employed resins are polyesters, epoxies, and polyurethanes. A typical process might be 3–5 min in duration where resin temperatures ramp rapidly from ambient to temperatures in excess of 150°C, hold for a short time, and ramp back down (see Fig. 10).

Continuous Lamination. Flat and corrugated, translucent to opaque panels are commonly fabricated by continuous lamination (1). A layer of liquid polyester resin is deposited on a moving belt and passed by a chopper that cuts glass fiber rovings into lengths of 35–50 mm, and deposits them in a random mat on the resin. Fibers and resin are compacted and covered with a film, such as cellophane or poly(ethylene terephthalate) and passed through squeeze rolls. The envelope may be passed through corrugators or remain flat. It next passes through an oven to cure the resin. Subsequently, the cover film is stripped, and the continuous sheet is cut into desired lengths.

E-beam Processing. Since the 1980s, the use of electron-beam (e-beam) irradiation has evolved as a promising new technology for curing thermoset composite materials. This process contrasts with traditional curing methods, such as autoclave, pultrusion, or compression molding, in which high temperature is used to initiate thermoset polymerization. In the e-beam process, a high energy electron beam is used to drive the polymerization reaction directly. To accomplish this, uncured prepreg lay-ups or resin-infused preforms are passed through a "curtain" of high energy electrons, typically on a conveyor belt system over several passes. The electron beam is generated by one of many types of accelerators, most of which operate with a beam energy of 3–10 MeV and beam power of 1–150 kW. Several hundred commercial facilities exist worldwide to provide this service, and it was envisioned that the composite community could take advantage of this infrastructure to reduce the cost of fabricating some composite components, although additional facilities dedicated to composite fabrication may also be required. Use of this reduced-temperature processing technology is seen as a potential breakthrough in lowering the costs of composite manufacturing, and it can provide additional environmental, design, and large size scale benefits (115). An excellent

summary of the history, applications, and materials involved in e-beam curing is given in Reference 116.

The primary advantage of e-beam curing is lower process temperatures, which cascades to several major benefits such as reduced tooling cost, reduced residual stress upon cool-down, and ability to co-cure or co-bond dissimilar materials (ie, materials with different coefficients of thermal expansion). Control of temperature during e-beam curing is made difficult because of the release of exothermic heat of reaction, whereas the temperature rise due to radiation input alone is significantly less than the total heat of reaction. Cure of thick parts with high dose rates can often lead to excessive temperature rise and runaway exothermic reactions. However, if radiation dose is applied slowly enough, the process temperature can be kept to a reasonably low level (50–75°C typically), and the advantages cited above can be realized. Another major benefit is extended shelf life of resin systems, which leads to less scrap. Because the resins are not thermally reactive, at least not at ambient temperature, the resins do not require freezer storage and can be stored almost indefinitely (although dark storage may be required, since UV may promote polymerization in certain resin chemistries). An additional advantage of e-beam curing is that size limitations may potentially be removed with movable, robotic methods of applying the electron beam.

Electrons accelerated to 3–10 MeV are traveling at about 99% the speed of light. Approximately 50% of the beam energy is lost in "hard collisions" that remove electrons from host atoms and thereby produce ionized species. As a result of hard collisions, polymerization can occur by free-radical or ionic mechanisms. Materials that proceed via free-radical polymerization include acrylic/methacrylic systems, maleic and fumaric polyester resins, maleimides, and thiole–ene systems. Of these systems, resins based on acrylic and methacrylic functionalities have been studied the most (116). The other major material system to be studied is that of epoxy polymerized via a cationic mechanism, which requires a diaryliodonium or triaryliodonium salt catalyst.

One of the primary technical hurdles limiting widespread application of e-beam curing to aerospace composite materials is that special resins and/or curing conditions must be developed. None of the currently qualified epoxy or bismaleimide resins used on aircraft (ie thermally cured resins) can be simply substituted into an e-beam curing process without making compositional or process modifications. E-beam curable resins that have been developed during the past decade have improved dramatically (116,117), but they still do not offer the same range of properties achieved in qualified thermally cured aerospace resins, such as toughened epoxies. Additional technical hurdles are a poor understanding of the curing process during irradiation, poor repeatability from one run to the next, lack of understanding of long-term durability and predictive capacity, and a lack of understanding of the fundamental mechanisms of cure for e-beam systems (115).

Significant additional progress will require understanding of the basic chemical mechanisms, kinetics of curing, and the development of cross-linking. Fortunately these issues have begun to receive attention in the last few years, during which several basic studies on the kinetics of e-beam curing have been published (118,119). One of the major objectives is the set-up and use of various real-time sensors in a basic research facility recently established by the University of

Dayton Research Institute in cooperation with the Air Force Research Laboratory (120,121). These sensors, which include thermal, spectroscopic, and other techniques, are enabling the generation of new knowledge, understanding, and optimization of the e-beam curing process for composite materials.

TISSUE ENGINEERING

Introduction

Accidents and diseases lead to devastating tissue losses and organ failures, which result in more than 8 million surgical operations each year in the United States alone (1). These problems convert to a national annual healthcare cost of approximately half trillion U.S. dollars. The state-of-the-art clinical therapies to tissue losses and organ failures can be categorized into three approaches, ie, transplantation, surgical reconstruction, and the use of prostheses. Each of these approaches has contributed to solving or alleviating the severity of these clinical problems, while all of them have serious limitations.

Organ transplantation became successful in the early 1960s because of the success of immunologic suppression in the clinical setting (2). Transplantation has saved, and is continuing to save, countless lives. This approach, however, is severely limited by the dearth of donor organs. For example, fewer than 3000 available donors are way shorter than the needs of approximately 30,000 Americans for liver transplants each year (3). Surgical reconstruction utilizes tissues harvested from the patient to rebuild a critically needed body part. The use of the patient's own tissue is advantageous in that it has a higher success rate resulting from the avoidance of immune rejection than using tissues from other sources. However, the need for second site of surgery, limited supply, inadequate size and shape, and the morbidity associated with donor site are all major concerns (4,5). In response to the shortages of needed tissues and organs, prostheses are developed to replace certain body parts for their structural and mechanical functions. There are approximately 100,000 people in the United States with transplants, while there are more than 10,000,000 with biomedical implants (6). However, the prostheses are made from artificial materials, are not biologically functional, and are therefore subject to long-term complications and rejections.

Tissue engineering is a new approach to resolve the missing tissue and organ problems. *Tissue engineering* has been defined as an interdisciplinary field that applies the principles of engineering and the life sciences toward the development of biological substitutes that restore, maintain, or improve tissue function (3). There are three strategies in tissue engineering (3,7):

(1) The use of isolated cells or cell substitutes to replace those cells that supply the needed function, including genetic or other manipulations before the cell infusion (8);
(2) The delivery of tissue-inducing substances, such as growth and differentiation factors, to targeted locations (9,10);
(3) Growing cells in three-dimensional (3-D) matrices (scaffolds) or devices, where cells can be either recruited from the host tissues *in vivo* or seeded (encapsulated) *in vitro* (3).

The advantage of the use of isolated cells is the simplicity. Cells are often directly injected into the targeted locations to avoid complex procedures and associated complications. The disadvantages include cell death and loss of function

Encyclopedia of Polymer Science and Technology. Copyright John Wiley & Sons, Inc. All rights reserved.

because cells need the right nutritional and substrate environment to grow and function. The success of using tissue-inducing substances is dependent on the economical large-scale production and purification of the bioactive molecules, and on the development of delivery systems that can deliver these molecules with the desired profiles. Certain gene therapy techniques can also be used for this approach. The above two approaches, ie, the use of isolated cells or tissue-inducing substances, are considered when the defects are very small and well contained. For engineering tissues of practical size scale and with predetermined 3-D structures, these two approaches are seriously limited. Therefore, the third approach, ie, growing cells in 3-D matrices (scaffolds) or devices, has become increasingly active.

Some of these matrices or devices are used to develop immobilized cell systems, either as implants or extracorporeal devices (11,12). The core of this technology is semipermeable membranes or matrices that have well-defined molecular weight or size cutoff (13,14). They serve as immunoprotective barriers to support cell growth and function, which allow nutrients, metabolic products, and wastes to diffuse through, but not immune cells or antibodies. These devices offer certain biological functions but are not living tissue/organ replacements (see MEMBRANE TECHNOLOGY). Some other 3-D matrices work as templates (called scaffolds) to guide cells to grow, synthesize biological molecules and extracellular matrix components, and facilitate the organization and formation of functional tissues and organs (15–17). After fulfilling the templating function, the scaffolds degrade and disappear, leaving nothing foreign to the biological system (Fig. 1). There are many additional advantages in this approach. Patient-derived cells (stem cells or differentiated cells) or future universal cell sources (nonimmunogenic) can be used so that there will be minimum complication associated with immune rejections. These cells can be expanded *in vitro* to solve the donor shortage limitations. Any tissue/organ structure can be potentially mimicked by the scaffolding design. The engineered tissues will have the capacity of growing, modeling, and remodeling in concert with dynamic changes in physiological environment of the body. In this approach, biodegradable polymers (natural or synthetic) are the materials of choice. Polymers (or macromolecules) are currently used as scaffolds for nearly every tissue type including bone and other mineralized tissues. Besides polymers, only limited inorganic materials are used for certain mineralized tissue engineering research.

Although growing cells on two-dimensional (2-D) substrates (such as petri dishes and culture plates) dates back centuries, designing 3-D scaffolds for tissue engineering is a new field, where polymer science and engineering play pivotal roles.

There are a few basic requirements that have been widely accepted for designing polymer scaffolds. First, the scaffold has to have high porosity and proper pore size. These pores allow cell seeding and migration to achieve the needed relative uniform distribution. The pores also provide the space for cell proliferation and neo tissue deposition. The pores also satisfy the needed mass transport requirements for nutrients, signaling molecules, metabolic products, and wastes. The porous structure should also allow for vascularization and innervation for sustained function of the regenerated tissues when implanted *in vivo*. High porosity is also beneficial because of the reduced polymer amount and its degradation

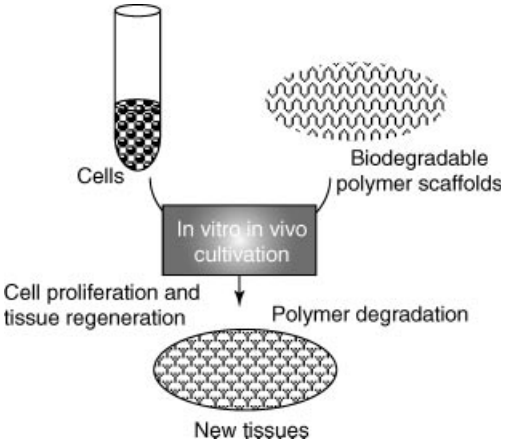

Fig. 1. Schematic diagram showing the tissue engineering concept. Scaffolding materials (temporary synthetic extracellular matrices) are designed, on which mammalian cells can grow to regenerate the needed tissue or organ in three dimensions (3-D). Because the scaffolds are biodegradable, they will resorb after fulfilling the template function and leave nothing foreign in the body.

products in the neo tissues, which can provoke unwanted inflammatory response from the host. Second, a high surface area (a.k.a. surface-to-volume ratio) is needed, which is the 3-D surface area of the porous scaffolds (not just the outside surface area). Many cell types are anchorage-dependent, ie, they can survive, grow, and function only when they are attached to an appropriate substrate. The high surface area provides cells with the sufficient area to attach, grow, and deposit neo tissue components. Third, biodegradability is generally required, and a proper degradation rate is needed to match the neo tissue formation. If the scaffold degrades too fast, it can collapse before the new tissue is formed so that it fails to serve as a 3-D guidance for the neo tissue organization. If the scaffold degrades too slowly, it remains for a prolonged time period after the neo tissue is formed and stabilized. It may hinder the new tissue replacement of the scaffold space, and may cause complications associated with long-term foreign body reactions. Fourth, the scaffold must have the needed mechanical integrity to maintain the predesigned tissue structure to serve the 3-D guidance. However, scaffolds are often not as mechanically strong as the tissues to be replaced because of the required high porosity for scaffolds. They usually serve the scaffolding purpose well as long as they can maintain the structural integrity under the cultivation or implantation conditions, while the goals are that the engineered tissues from the scaffolds are mechanically and biologically functional as their natural counterparts. Fifth, the scaffold should not be toxic to the cells (biocompatible). In addition to the polymer, the degradation products of the polymer should not be toxic to the cells, which is usually a more restricting requirement than for the polymer. Sixth, ideally the scaffold should positively interact with cells, including enhanced cell adhesion, growth, migration, and differentiated function. To achieve these positive cell–scaffold interactions, surface or bulk modifications of the

polymer structure are often employed (18–21). Even drug, protein, or gene delivery techniques are often considered in the scaffold design (22–25).

Polymers in Tissue Engineering

As discussed above, polymers play a pivotal role in tissue engineering. To fulfill the diverse needs in tissue engineering, various polymers have been exploited in tissue engineering research, including natural polymers (macromolecules), natural polymer-derived materials, synthetic polymers, and synthetic polymers made of natural monomers or modified with natural moieties. Various copolymers, polymer blends, or polymeric composite materials are also used. This section is not intended to be a complete and exhaustive review of all the polymers used in tissue engineering. Instead, some of the most frequently used polymers (macromolecules) in tissue engineering are briefly reviewed.

Polymers for Porous Scaffolds. The polymers to be discussed in this category can form stable porous structures in the solid form to serve as pre-designed 3-D scaffolds. They generally do not dissolve or melt under *in vitro* tissue culture conditions (in an aqueous tissue culture medium) or when implanted *in vivo*.

Linear Aliphatic Polyesters. Linear aliphatic polyesters are the most frequently used synthetic biodegradable polymers in tissue engineering and many other biomedical applications (26–28). These polymers degrade through hydrolysis of the ester bonds in the polymer backbone. The degradation rates and profiles differ between these polymers owing to their compositional, structural, and molecular weight differences.

Polyglycolide, also called poly(glycolic acid) (PGA), polylactide, also called poly(lactic acid) (PLA), and their copolymers, poly(lactide-*co*-glycolide), also called poly(lactic acid-*co*-glycolic acid) (PLGA), are a family of linear aliphatic polyesters called poly(α-hydroxy acids) or poly(α-hydroxy esters) (Fig. 2). These polymers can be synthesized by direct condensation of the hydroxy acid monomers (resulting in low molecular weight polymers, such as lower than 10,000) or more commonly by a ring-opening polymerization of the cyclic dimers (to achieve a higher molecular weight), from where the names of polyglycolide and polylactide stem.

Among the family of glycolic acid and lactic acid homopolymers and copolymers, PGA is the simplest in chemical structure, has many advantageous properties, and is therefore one of the most widely used scaffolding polymers (17). Because of the chain structural regularity, PGA is highly crystalline and has a high melting point of around 220°C (17). It does not dissolve in most common organic solvents. Because of its hydrophilic nature, PGA degrades rapidly in aqueous solutions or *in vivo*, and loses mechanical integrity between 2 and 4 weeks depending on the molecular weight and physical structure of the scaffolds or implants, and *in vitro* or *in vivo* conditions (17,29). It was the material used to develop the first synthetic absorbable suture, and has been processed into nonwoven fibrous fabrics as one of the most widely used scaffolds in tissue engineering today.

PLA is also widely used for scaffold fabrication because of its biodegradability. Because of the extra methyl group in PLA repeating unit in comparison to PGA, PLA is more hydrophobic. The hydrophobic methyl group reduces the molecular affinity to water and leads to a slower hydrolysis rate of PLA.

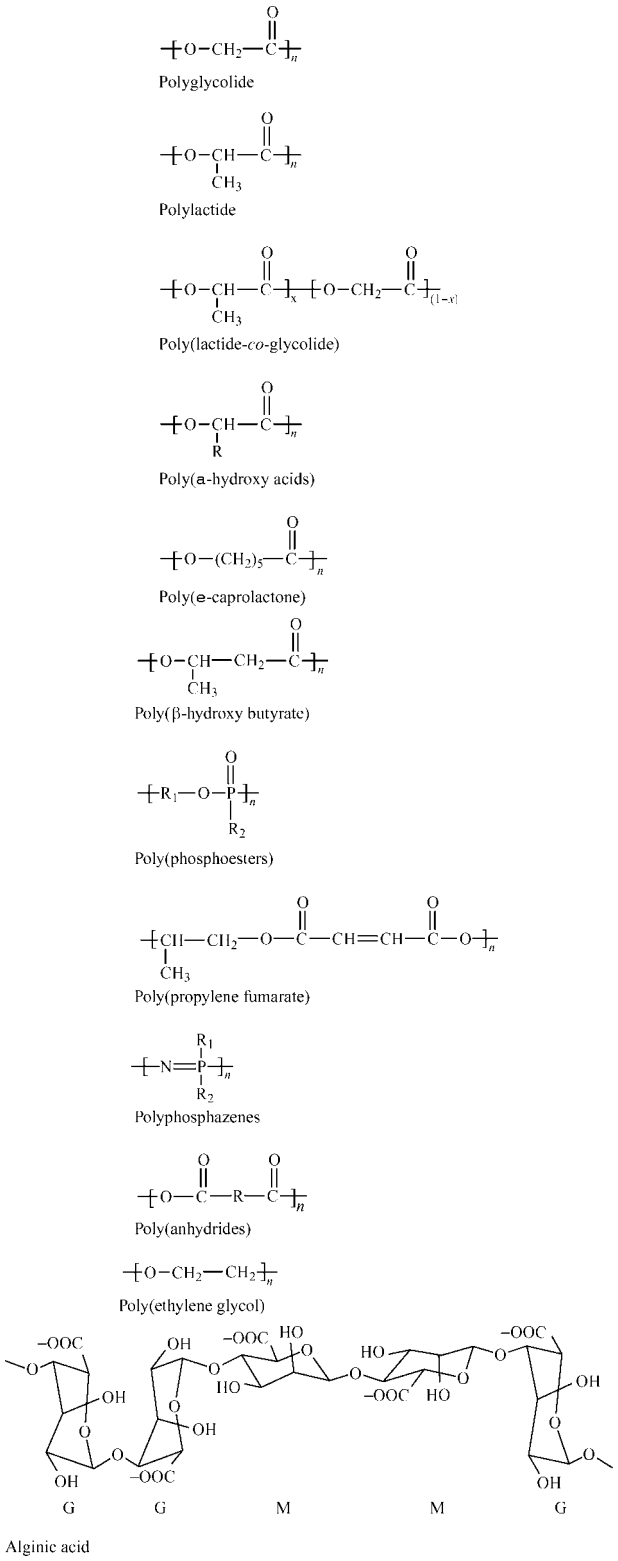

Fig. 2. Polymers frequently used as scaffolds for tissue engineering.

It takes months to years for a PLA scaffold or implant to lose mechanical integrity *in vitro* or *in vivo* (30,31). Lactic acid is a chiral molecule and exists in two stereoisomeric forms, ie, the D-lactic acid and L-lactic acid. The two stereoisomers lead to four different types of PLA: poly(D-lactic acid) (PDLA), poly(L-lactic acid) (PLLA), racemic poly(D,L-lactic acid) (PDLLA) and meso poly(D,L-lactic acid) (meso-PLA). Because of the stereoregularity, PDLA and PLLA are semicrystalline, and are less susceptible to water attack (hydrolysis), resulting in slower degradation rates. The racemic copolymer PDLLA is amorphous, and therefore more susceptible to hydrolysis, resulting in a faster degradation rate. Since L-lactic acid is the natural stereoisomer of the lactic acid in the body, PLLA is the frequently used PLA. To achieve intermediate degradation rates between PGA and PLLA, various lactic acid and glycolic acid ratios are used to synthesize PLGAs. However, there is not a linear relationship between degradation rate and lactic acid content. When lactide is copolymerized with glycolide, two distinctly different effects with regard to degradation are introduced. The first is that the lactic acid unit is more hydrophobic, contributing to a slower degradation rate. The second effect is that stereoregularity is disrupted by the different repeating units, resulting in a lower crystallinity or amorphous structure, contributing to a faster degradation rate. The resulting degradation rate is a compromise of these two factors. Theoretically, when the LA/GA ratio is higher than 50:50, these two factors are in the same direction when the amount of lactide is increased. When the LA/GA ratio is lower than 50:50, these two factors are against each other when the amount of lactide is increased. However, in a large middle range of the composition, the copolymer is amorphous and the crystallinity does not play a role. In both high and low ends of the LA/GA ratio, the crystallinity of the specific scaffold or device plays an important role on the degradation rate. In addition, high crystallinity increases modulus, yield strength, and ultimate strength of the polymers.

In addition to the biodegradability and biocompatibility, these polymers (PLA, PGA, and PLGAs) are among the few synthetic polymers approved by the Food and Drug Administration (FDA) for certain human clinical applications such as surgical sutures and some implantable devices. There is, however, some controversy around the use of these polymers for orthopedic applications. Based on a study of more than 2500 patients operated on using pins, rods, bolts, and screws made of PGA or PLA, 4.3% were affected by a clinically significant local inflammatory tissue reaction (32). Similarly, other biodegradable polyesters suited for manufacturing absorbable fixation implants appear to also elicit adverse tissue responses. These adverse tissue reactions are generally considered to result from the released acid during degradation. For polymer scaffolds with extremely high porosity used in tissue engineering applications (usually $\geq$90%) as opposed to solid implant devices used in orthopedics, the acid release (pH variation) is a less severe problem (17,30).

Polymer degradation is often categorized into bulk degradation (bulk erosion) and surface degradation (surface erosion) in the fields of biomedical engineering and biotechnology (33,34). There are actually differences between erosion and degradation. Degradation is the bond cleavage of the polymer, resulting in reduction in molecular weight of the polymer. Erosion is the mass loss process. For ideal bulk degradation, hydrolysis (or other forms of degradation) occurs in the entire polymer volume simultaneously. The length of time that polymer persists

can be altered by changing chemical composition but not by the material's size and shape. For ideal surface degradation, hydrolysis (or other forms of degradation) only occurs on the external surface of the material, ie, at the interface between the material and its immediate surrounding environments, such as medium or body fluids. Erosion rate is directly proportional to the external surface area. The length of time that polymer persists can be altered by varying the sample volume (thickness). Surface erosion is often advantageous for controlled drug delivery applications. For example, a thin slab erodes by reducing its thickness and maintaining a nearly constant surface area to achieve constant release rate.

PLA, PGA, and PLGA polymers degrade via bulk hydrolysis. However, the length of time that a polymer persists is affected by the shape and size of the material because the degradation does not occur homogeneously. Common sense would lead people to think that the surface layer degrades faster since this area is exposed to the most abundant medium or body fluids, which hydrolyze ester bonds in the polymer chains. The reality is just the opposite (35). The cleavage of ester bonds yields carboxyl and hydroxyl end groups. The produced carboxyl end groups are capable of catalyzing the hydrolysis of remaining ester bonds in the polymer chains. In the surface layer, the chains containing carboxyl end groups or the generated small acid molecules diffuse out of the device and the acidity is reduced. This autocatalysis phenomenon is enhanced by the diffusion limitations in the thick devices. In the interior, the acidity increases as ester bonds are hydrolyzed while the acidic by-products are trapped. The increased acidity further catalyzes hydrolysis, leading to heterogeneous degradation, ie, a faster degradation in the interior than on the surface.

For semicrystalline polymers such as PGA and PLLA, the degradation behavior is also related to the crystallinity and domain structures of the polymers (17). The amorphous domains are easily attacked by water molecules and degrade first. Initial mass loss occurs in the amorphous domains and causes an apparent crystallinity increase (17). As the polymer further degrades, the crystalline domains also degrade, which leads to drastic decrease in melting point and mechanical properties, and finally leads to the disintegration of the entire material (see BIODEGRADABLE POLYMERS, MEDICAL APPLICATIONS).

There are other linear aliphatic polyesters, such as poly(ε-caprolactone) (PCL) and poly(hydroxy butyrate) (PHB) (Fig. 2), which are also used in tissue engineering research and other biomedical applications. PCL has been investigated for a variety of biomedical applications. It can degrade by microorganisms, hydrolytic, enzymatic, or intracellular mechanisms under physiological conditions (36,37). PCL is a semicrystalline polymer. It has a very low glass-transition temperature of around -62°C, and thus is always in the rubbery state and has high material permeability under physiological conditions. For highly porous scaffolds, material permeability however does not contribute significantly to the scaffold permeability. Compared with PLA, PGA, and PLGA, PCL degrades at a significantly slower rate (38), which makes PCL less attractive for general tissue engineering applications but more attractive for long-term implants and controlled release applications.

Poly(hydroxy butyrate) (PHB), also called poly(β-hydroxy butyrate) or poly(hydroxy butyric acid), is the simplest member of the polyhydroxyalkanoate (PHA) polyesters (see POLY(3-HYDROXYALKANOATES)). PHB is made by

microorganisms via fermentation. It is biocompatible and biodegradable, but is highly crystalline and therefore very brittle. PHB degrades very slowly (years *in vivo*) because of the high crystallinity and hydrophobicity (39,40). PHB-based copolymers are less crystalline and mechanically more flexible, but degrade also very slowly because of the hydrophobic nature, and therefore are less popular compared to PGA, PLA, and PLGA for tissue engineering applications.

Other Important Synthetic Biodegradable Polymers. Poly(phosphoesters) (PPE) are a class of biodegradable polymers synthesized in the Leong group (Fig. 2) (41). PPE contains P(O)—O—C linkage in the polymer backbone and the pentavalent phosphorus atom allows for attachment of a pendant component. PPE degrades through hydrolysis of phosphoester bond in the PPE backbone. The variation in backbone structure and pendant side group allows for variation in structure and properties of these polymers. They have been used for controlled drug delivery and gene delivery applications (42), and are also explored for certain tissue engineering applications (43) (see CONTROLLED RELEASE TECHNOLOGY; GENE-DELIVERY POLYMERS).

Poly(propylene fumarate) (PPF) (Fig. 2) has been synthesized as a biodegradable polymer that degrades through hydrolysis of the ester bonds similar to glycolide and lactide polymers. PPF is an amorphous unsaturated polymer and has been extensively studied in the Mikos group as either a prefabricated (44) or an injectable biomaterial (45) for bone tissue engineering. Its copolymers with poly(ethylene glycol) (PEG), poly(propylene fumarate-*co*-ethylene glycol) polymers, can form hydrogels (46).

Polyphosphazenes (qv) contain a long-chain backbone of alternating phosphorus and nitrogen, with two side groups attached to each phosphorus (Fig. 2) (47). Various synthesis routes are used to prepare these polymers, allowing different side groups (R) to be attached to the backbone. These polymers can have very different properties, from degradable to nondegradable, by changes in the side groups. Polyphosphazenes are finding more and more applications in controlled drug delivery applications (48,49), and are also finding ways into the tissue engineering research (50,51).

Although polyanhydrides (qv) are attempted for use as tissue engineering scaffold (52), they are designed primarily for controlled drug delivery purposes in the Langer group (53). These polymers are very hydrophobic, and degrade through surface erosion. The surface erosion characteristic allows easy accomplishment of constant release rate for sustained drug delivery purpose. Drugs are also well protected when embedded in such polymers owing to the nearly no water penetration before the polymer erodes. Similarly, poly(ortho esters) are primarily designed for controlled drug delivery applications because of their surface erosion properties (54). Nevertheless, they have been explored for tissue engineering scaffolding applications as well (55).

Amino acids are natural nutrients. Polymers derived from amino acids may have advantageous biocompatibility, as demonstrated by PLA. However, amino acid based polymers often do not have good material properties. They are often difficult to process into 3-D structure, and possess poor mechanical properties. Tyrosine-derived polymers have been developed in the Kohn group as biodegradable polymers, which have shown certain promising properties (56), and have been used for bone tissue engineering research (57).

Nondegradable polyurethanes (qv) have been widely used for biomedical applications because of their elastic properties (58). The segmented polyurethanes allow the structural variations to achieve a range of mechanical properties. A major limitation of polyurethanes for biomedical applications is the involvement of toxic precursors (such as toluene diisocyanates) in the synthesis. Recent efforts have been on development of biodegradable polyurethanes or urethane-based polymers using less toxic diisocyanates (59). These polymers have good mechanical properties and have been explored for vascular and other tissue engineering applications (60,61). Considering the general audience in the field of polymer science and engineering, synthetic polymers and 3-D scaffold fabrications are the main foci of this article. However, it should be noted that natural polymers, such as proteins and polysaccharides, have also been used for tissue engineering applications. Collagen (qv) is a major natural extracellular matrix component (62). Collagen proteins possess triple-helix structure over a large portion of the molecules. Among the various collagen proteins the most abundant is type I collagen. Collagen has been used for various tissue regeneration applications especially for soft tissue repair (63,64). The use of collagen as a scaffolding material, however, remains challenging because of the potential pathogen transmission and immune reactions, poor handling and mechanical properties, and less controlled biodegradability (enzymatic) of the natural material from biological sources. On the other hand, collagen as a natural extracellular component has useful biological properties desired for tissue engineering applications. Yannas and colleagues have developed collagen-glycosaminoglycan (GAG) copolymers and fabricated them into scaffolds for tissue engineering (65,66). Denatured collagen (gelatin) is also processed into porous materials for tissue repair (67). Polysaccharides (qv) are another class of natural polymers, eg, alginate (68) and chitosan (69), which have been explored as tissue engineering scaffolds.

Polymers for Hydrogel Scaffolds. Hydrogels (qv) are cross-linked hydrophilic polymers that contain large amounts of water without dissolution. Hydrogels are attractive candidates for certain tissue engineering applications because of the ability to fill irregularly shaped tissue defects, allowance of minimally invasive procedures such as arthroscopic surgeries, and the ease of incorporation of cells or bioactive agents (70–75).

Among the synthetic hydrogels, PEG (Fig. 2) has been more frequently studied for tissue engineering research than other synthetic hydrogels. PEG has been extensively used in biomedical applications often to prevent protein and cell adhesion (76). This property also made PEG useful for prevention of tissue adhesions after surgery (77,78). In the tissue engineering field, PEG has been used as a model system for studies related to adhesion peptides. In such a case, the inertness of this polymer to cells and proteins is ideally utilized. PEG–diacrylamide was synthesized by the Hubbell group (79). A photopolymerization step can be performed in contact with cells, providing a means to produce scaffolds for tissue engineering. A PEG-based interpenetration network has been used for cartilage tissue engineering by Elisseeff and colleagues (80). Peptide-modified PEG materials have been used by Griffith and West groups to study relationships between cell behavior (such as adhesion, spreading, and migration) and peptide density and spacing (81–83). A major limitation of PEG hydrogel for tissue engineering scaffolds is its lack of degradability. Efforts are made to impart degradability to PEG by either

formulating copolymers with PLA or PGA, or by introducing enzyme-degradable linkages into the PEG backbone (84–86).

Alginate is the salt form of alginic acid. Alginic acid, a polysaccharide from seaweed, is a family of natural copolymers of β-D-mannuronic acid (M) and α-L-guluronic acid (G) (Fig. 2) (87,88). They have been processed into gel beads encapsulating living cells as a means of immunoprotection (89). Alginate hydrogels cross-linked using calcium sulfate ($CaSO_4$) have recently been used as cell delivery vehicles for *in vivo* tissue engineering research (74,90,91). Peptide-modified alginate has been studied to improve cell attachment (74). However, one of the major disadvantages of the use of $CaSO_4$ is that gelation kinetics is difficult to control, and the resulting structure is not uniform. Structural uniformity in tissue engineering scaffolds is necessary not only for uniform cell distribution, but also for well-controlled material properties. Mechanical properties are more consistent throughout the gel and between batches if structural uniformity can be achieved. We have developed methods to control the gelation rate so that cross-linking is allowed to take place uniformly throughout the gel to form a structurally uniform and mechanically strong alginate gel with predesigned 3-D shapes (Fig. 3**a**) (70). Cells can be uniformly incorporated into such gels (Fig. 3**b**).

Collagen, in addition to porous foam, has also been used as hydrogels for a variety of tissue repair and regeneration studies (92,93). Collagen gels have been studied as a therapeutic option for the treatment of burn patients or chronic wounds (94). Cartilage defect repair has been studied using chondrocyte–collagen gel constructs (95). Studies have also been conducted with collagen gels to deliver mesenchymal stem cells and biological agents to improve healing of ligaments and tendons (96).

Polymer Processing and 3-D Scaffolds for Tissue Engineering

In the body, tissues are organized into 3-D structures as functional organs and organ systems. Each tissue or organ has its own characteristic architecture depending on its physiological function. This architecture is also believed to provide the necessary channels for mass transport and spatial cell organization (15). Mass transport includes signaling molecules, nutritional supplies, and metabolic waste removal. Spatial cellular organization allows for cell–cell and cell–extracellular matrix interactions to occur, which are critical to physiological functions of a tissue or organ. To successfully engineer functional tissues and organs, the scaffolds have to be designed to facilitate the desired cell distribution and to guide tissue regeneration in 3-D. This section is, therefore, devoted to the 3-D pore structure and pore wall architecture of scaffolds for tissue engineering.

Textile Technologies and Traditional Fibrous Scaffolds. The textile technologies have developed over thousands of years to produce various fibrous fabrics for clothing, filtration, packaging, and many other industrial and household applications. Fibrous fabrics have excellent mechanical properties. It was natural that fibrous materials found many biomedical applications in recent years including sutures from biodegradable polymers. It was also not surprising that earlier tissue engineering scaffolds were fibrous fabrics of biodegradable polymers

fabricated using textile technologies. PGA, PLA, and many other semicrystalline polymers can be processed into fibers using an extruder and these fibers can be further processed into woven, knit, or nonwoven fabrics using the textile technologies (see NONWOVENS, STAPLE FIBER).

One of such scaffolds widely used in tissue engineering research is PGA nonwoven scaffolds (Fig. 4). PGA is typically melt-spun into fibers with a diameter of around 15 μm. These fibers are then processed into nonwoven fabrics using textile technologies such as carding, needling, heat pressing, and so forth. Porosity higher than 90% can be easily achieved. These PGA nonwoven scaffolds degrade via hydrolysis both *in vitro* and *in vivo*. The mass of PGA scaffolds decrease exponentially *in vitro*, fitting well to a first-order degradation kinetics (17). The amorphous regions in the fibers degrade first presumably because of the easy access by water

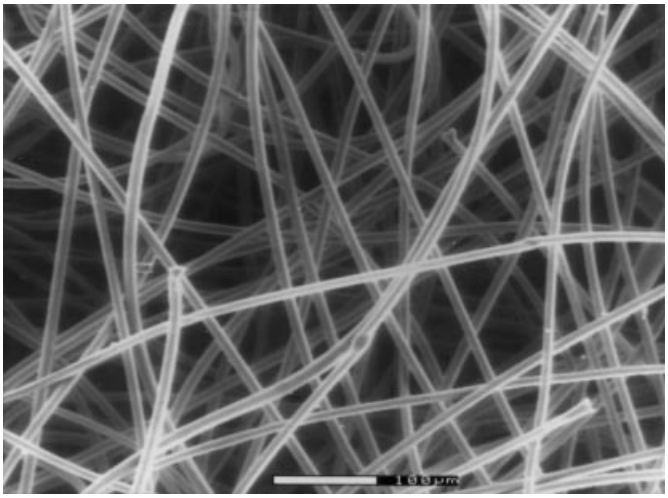

Fig. 4. SEM micrograph of a PGA nonwoven scaffold with a porosity of approximately 95% and a fiber diameter of approximately 15 μm.

molecules. The crystalline regions start to degrade soon after, leading to loss of molecular orientation in the fibers and decrease in mechanical properties. These PGA scaffolds have been used either alone or combined with other biodegradable polymers for the engineering of cartilage (97–99), tendon (100), ureter (101), intestine (102), blood vessels (103,104), heart valves (105), and other tissues.

Although PGA nonwoven scaffolds have stimulated a large wave of tissue engineering research and generated considerable excitement in the field, there are several limitations of PGA nonwoven scaffolds, such as low mechanical strength, fast degradation rate (losing mechanical properties within 2 weeks), difficulty in pore shape control, and limited fiber diameter variations. Therefore, many other processing techniques have been developed to fabricate scaffolds for desired properties in various tissue engineering applications.

Particulate-Leaching Techniques. Particulate-leaching is another technique that has been widely used to fabricate porous materials as scaffolds for tissue engineering applications. This technique was first developed by Mikos and colleagues (16), and was improved and standardized for large batch fabrications (7). This process is schematically illustrated in Figure 5, which is often called salt-leaching technique because NaCl crystals are most often used as the particles for pore generation (porogen). Briefly, salt is first ground into small particles, and the particles are then separated into different size ranges using standard sieves. The particles of desired size are added into a mold of a needed shape. A polymer solution is prepared and cast into the salt-filled mold. After the evaporation of solvent, the salt crystals are leached away using water to form the pores of the polymer foam (Fig. 6).

There is no complicated equipment needed for this technique. The process is easy to carry out and the materials used (water and salt) are economical. The technique is also versatile and can be used to fabricate foams from a variety of polymers as long as the polymer can be dissolved in a solvent that does not dissolve

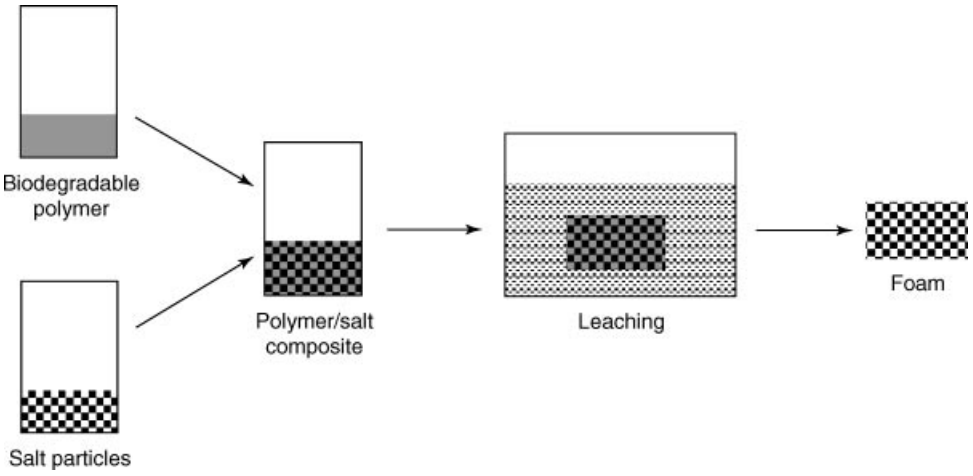

Fig. 5. Schematic illustration of the salt-leaching technique for porous foam fabrication.

the salt. The pore size can be controlled by the size of the salt crystals, and the porosity can be controlled by the salt/polymer ratio. For example, larger particle size results in larger pore size, and higher salt/polymer ratio results in higher porosity. Therefore, this technique is widely used in the tissue engineering field. However, certain critical variables such as pore shape and interpore openings are not controlled. For example, salt crystals have the characteristic cubic shape (Fig. 6). A spherical pore shape is not achievable using salt crystals. The resulting pores are often not well-connected because the polymer solution tends to penetrate between salt particles. To overcome the shortcomings of the salt-leaching

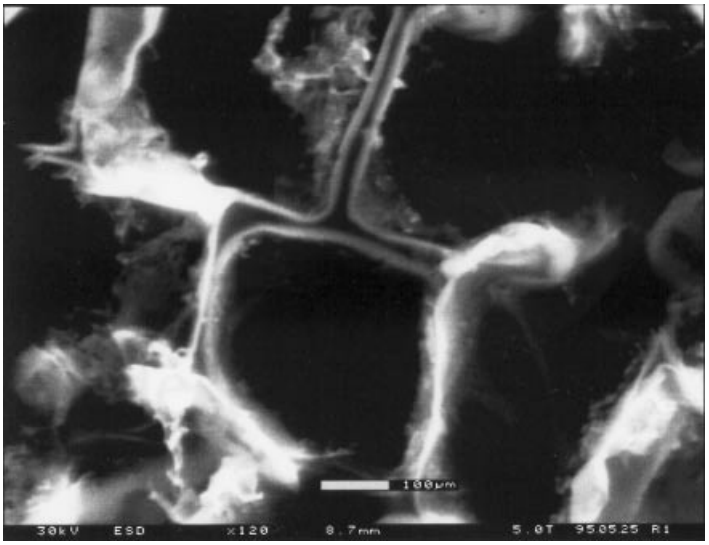

Fig. 6. SEM micrograph of a PLLA foam fabricated using the salt-leaching technique.

technique as well as the textile technologies, various other techniques have been developed to have better control over the pore structure of the scaffolds.

Phase Separation and Novel Architectures of Scaffolds. For a homogeneous multicomponent system, under certain conditions the system becomes thermodynamically unstable and tends to separate into a multiphase system in order to lower the system free energy. Controlled phase separation processes are desired for the generation of porous structures for tissue engineering scaffolding fabrication. For a polymer solution, phase separation can be induced in several different ways such as non-solvent-induced phase separation, chemically induced phase separation, and thermally induced phase separation. When phase separation occurs, a polymer solution separates into two phases, a polymer-rich phase (with a high polymer concentration) and a polymer-lean phase (with a low polymer concentration). After the solvent is removed by extraction, evaporation, or sublimation, the polymer-rich phase solidifies. Depending upon the system and phase separation conditions the resulting materials are different in physical form: powder, closed-pore foam, or open-pore foam (Fig. 7). Porous materials formed through phase separation have been utilized as membranes for filtration and separation (106). However, the pores formed through phase separation usually have diameters on the order of a few to tens of micrometers and are often not uniformly distributed, which are not suitable for tissue engineering applications.

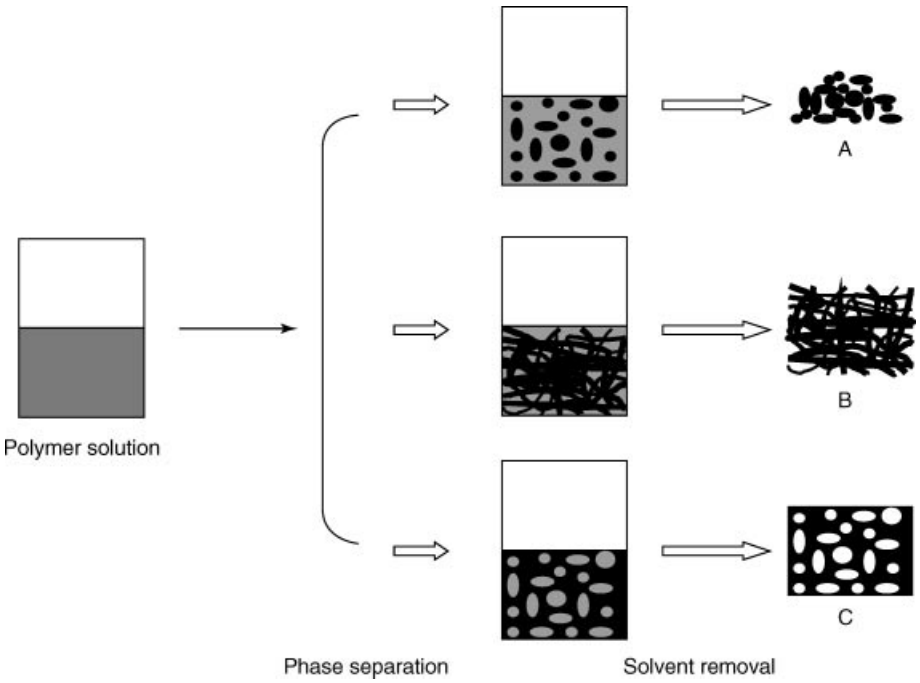

Fig. 7. Schematic illustration of phase separation processes that lead to different material forms: A, powder; B, open porous structure suitable as a scaffold for tissue engineering; and C, foam with closed pores.

As discussed earlier, a scaffold must have a pore size big enough for accommodating cells, allowing proliferation, and having room for new tissue synthesis. They also need to have high surface area to enhance cell adhesion. The pore structures should also allow for vascularization and innervation, and should facilitate diffusion of nutrients and waste materials. Thermally induced phase separation techniques have been explored in our laboratory for fabricating scaffolds to satisfy the requirements of tissue engineering. This type of phase separation is based on the thermodynamic and kinetic behavior of polymer solutions, which is a complicated process (26,107,108). The important variables are the polymer, solvent, concentration of the polymer solution, and the phase separation temperature. These variables have been manipulated to generate a variety of porous architectures for scaffold fabrication as briefly discussed below.

Solid–Liquid Phase Separation. Phase separation can be achieved by inducing solvent crystallization by decreasing the temperature of a polymer solution. This process is defined as a solid–liquid phase separation (solid-phase formation in a liquid phase). To achieve this, the crystallization temperature (freezing point) of the solvent in the polymer solution needs to be higher than the liquid–liquid phase separation temperature, or the liquid–liquid phase separation is kinetically too slow to take place before the temperature reaches the solid–liquid phase separation. When the temperature of the solution decreases and reaches the crystallization temperature, the solvent crystallizes and the polymer is expelled from the solvent crystallization front (separated from the solvent crystal lattice). After the removal of the solvent crystals (sublimation or solvent exchange), the space originally taken by the solvent crystals becomes pores. By manipulating the phase separation variables, foams with a variety of pore morphologies can be obtained. For example, PLLA and PLGA solutions have been used to fabricate interconnected pore structures as scaffolds using solid–liquid phase separation techniques (Fig. 8) (5,109). This technique can be used to fabricate scaffolds of more than one type of materials, including composite scaffold fabrication (Fig. 8**c**) (109). These interconnected pore structures also allow further modification of the pore wall surfaces after the scaffold fabrication. Bone-like apatite coating on such polymer scaffolds via a biomimetic process is such an example (20). Proteins and other bioactive molecules can also be used for such internal pore surface modifications (110).

By manipulating the phase separation conditions, various pore structures can be achieved. For example, many tissues (such as nerve, muscle, tendon, ligament, dentin, and so on) have oriented tubular or fibrous bundle architectures. To facilitate the organization and regeneration of such tissue types, a scaffold with a high porosity and an oriented array of open microtubules may be desirable. To achieve this goal, a novel phase separation technique has been developed for the creation of a parallel array of microtubules (Fig. 9) (111). In such a process, nucleation of the solvent is induced at one side of the polymer solution. The nuclei will grow in all directions until they contact with each other on this side. Then they cannot grow further in this plane, and are forced to grow along the direction perpendicular to this plane, leading to the formation of an array of parallel rod-like solvent crystals. The polymers are expelled from the solution and squeezed into thin walls surrounding these parallel solvent rods. After the removal of these rods, a parallel array of microtubules is formed as demonstrated. This oriented

tubular scaffold has anisotropic mechanical properties similar to fibrillar and tubular tissues, and has been shown to facilitate cell organization into oriented fibrillar or tubular tissues (Fig. 10) (111).

Liquid–Liquid Phase Separation. In contrast to solid–liquid phase separation, lowering temperature can induce liquid–liquid phase separation of a polymer solution with an upper critical solution temperature and when the crystallization temperature of the solvent is sufficiently lower than the phase separation temperature. In an equilibrium phase diagram of a polymer solution, the spinodal curve divides the liquid–liquid phase separation region into two regions: a thermodynamically metastable region (between the binodal and spinodal) and a thermodynamically unstable region (enclosed by the spinodal) (Fig. 11). Above the

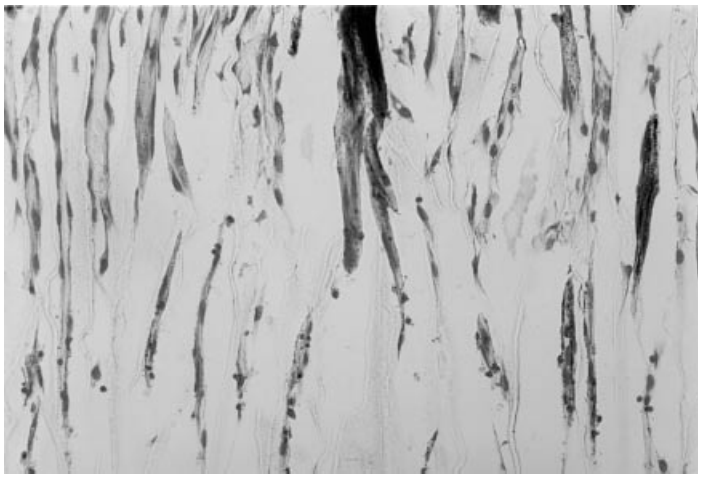

Fig. 10. MC3T3-E1 cells cultured on a PLLA scaffold with parallel open microtubular architecture for 4 weeks *in vitro*, von Kossa's silver nitrate staining. Reprinted from Ref. 111. © 2001, by permission of John Wiley & Sons.

binodal curve, the solution is homogeneous. When the temperature of the polymer solution is lowered to a point below the binodal curve, the solution is not thermodynamically stable and tends to separate into two phases, a polymer-rich phase and a polymer-lean phase, to lower the system free energy. In a solution of very low polymer concentration, when the temperature is lowered to a point in the metastable region (between binodal and spinodal), the phase separation occurs via a nucleation and growth mechanism. This process can lead to the formation of small polymer-rich domains (droplets) in a polymer-lean matrix. After the removal of the solvent, polymer powder is formed (Fig. 7**a**). When the temperature is lowered into an unstable region (spinodal region), the phase separation occurs via a spinodal decomposition mechanism. This process leads to the formation of a

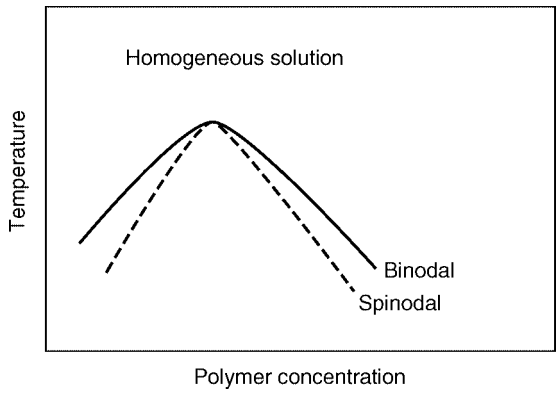

Fig. 11. Schematic equilibrium phase diagram for a polymer solution with an upper critical solution temperature.

bicontinuous structure, in which the polymer-rich and polymer-lean phases are both continuous phases. After the removal of the solvent, foam with open-pore structure is formed (Fig. 7**b**). In a solution of very high polymer concentration, when the temperature is lowered to a point in the metastable region, the phase separation leads to the formation of small solvent (polymer-lean) domains in a polymer-rich matrix. After the removal of the solvent, polymer foam of closed-pore structure is formed (Fig. 7**c**). If the polymer is crystalline, the phase separation process is more complicated (26). There is a competition between the liquid–liquid phase separation and polymer crystallization under certain conditions, making the final pore structure more complex (26,112).

Thermally induced liquid–liquid phase separation can be utilized to fabricate scaffolds for tissue engineering. For example, a solvent can be selected, where the crystallization temperature is sufficiently lower than the liquid–liquid phase separation temperature of an amorphous polymer solution. A liquid–liquid phase separation can be induced by lowering the temperature into the unstable region on the phase diagram but above the solvent crystallization temperature. For the PLA and PLGA family, a mixture of dioxane and water has been used for liquid–liquid phase separation to fabricate polymer scaffolds with interconnected pore structure (Fig. 12) (112,113).

Nanofibrous Matrix. Collagen (qv) is a major natural extracellular matrix component and possesses a fibrous structure with fiber bundles varying in diameter from 50 to 500 nm (62,114). To mimic the nanofibrous architecture of collagen and to overcome the concerns over materials from a natural source such as pathogen transmission and immune rejection, a novel phase separation technique has been developed in our laboratory to fabricate nanofibrous matrices from synthetic biodegradable polymers (112). For example, PLLA solutions are cooled to induce phase separation and gelation. The solvent is directly sublimated or first exchanged with a different solvent and then sublimated. Several solvents and solvent mixtures have been utilized to fabricate the desired nanofibrous matrices in our laboratory (Fig. 13) (112).

Three-Dimensional Pore Architecture Design. As discussed above various novel scaffolds have been developed for tissue engineering to address the critical shortage of donor tissues/organs. These scaffolds have facilitated the tissue engineering research in demonstrating the feasibility and tremendous potential of tissue engineering. However, these scaffolds are not perfect. One of the common shortcomings of these fabrication technologies is the lack of precise control of 3-D pore architecture of the scaffolds. To tackle this problem, computer-assisted-design and computer-assisted-manufacture (CAD and CAM) techniques that have been widely used in modern manufacture industry are finding ways into the field of tissue engineering (115).

These techniques were early explored by a group of materials scientists and chemical engineers at MIT (116,117). They used one of the solid free-form fabrication (a.k.a. rapid prototyping) techniques, called 3-D printing (3DP). With such a technique, complex-shaped objects can be designed using CAD softwares and directly fabricated from the generated CAD models. For example, they fabricated various structures from biodegradable polymers by ink-jet printing a binder onto sequentially laid polymer powder layers. The advantages of such a technique include the precise control of geometry and the feasibility for repeated fabrication

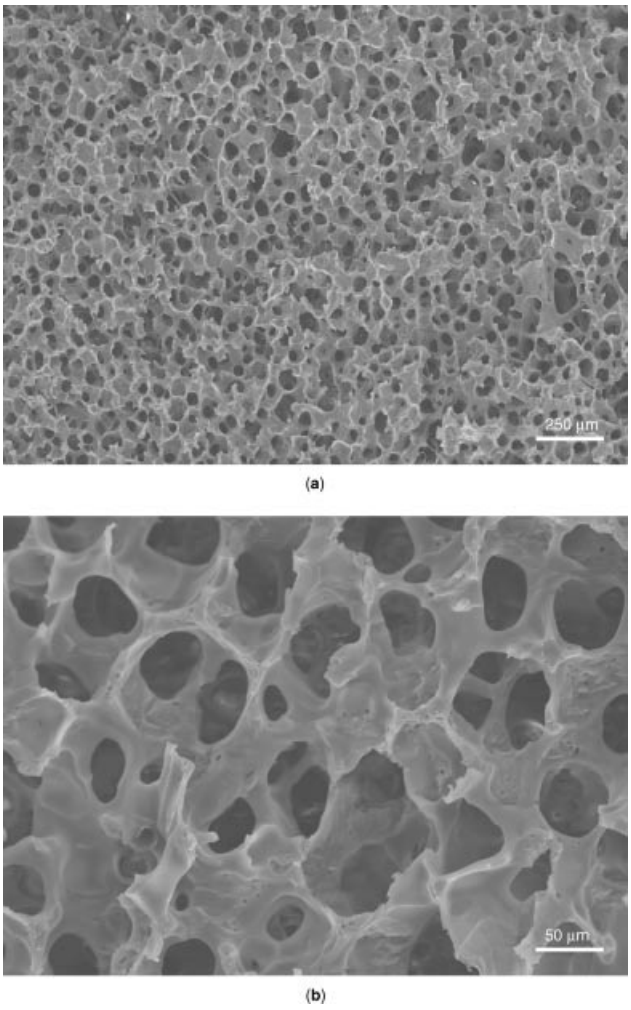

Fig. 12. SEM micrographs of a porous scaffold prepared from a 10% solution of PLGA (85/15) in a mixture of dioxane/H_2O (80/20) at two different magnifications: (**a**) low magnification and (**b**) high magnification. Reprinted from Ref. 112. © 1999, by permission of John Wiley & Sons.

of the same structure (118). However, the smallness of the powder particles and the binder drops (pixels) are limited (a few hundred micrometers). The accuracy of positioning the printing nozzle is also limited. The size of a feature (shape of a pore or architectural component) is dependent on the resolution of the pixel size and positioning control. Therefore the preciseness of the technology is seriously limited.

The anticipation of the future improvement of the resolution of such technologies has, nevertheless, maintained the research momentum in this direction. Similarly, another rapid prototyping technique, fused deposition modeling, has been used to fabricate 3-D scaffolds (119). This technique is suitable for processing thermoplastic polymers. A heated nozzle is utilized to extrude polymer

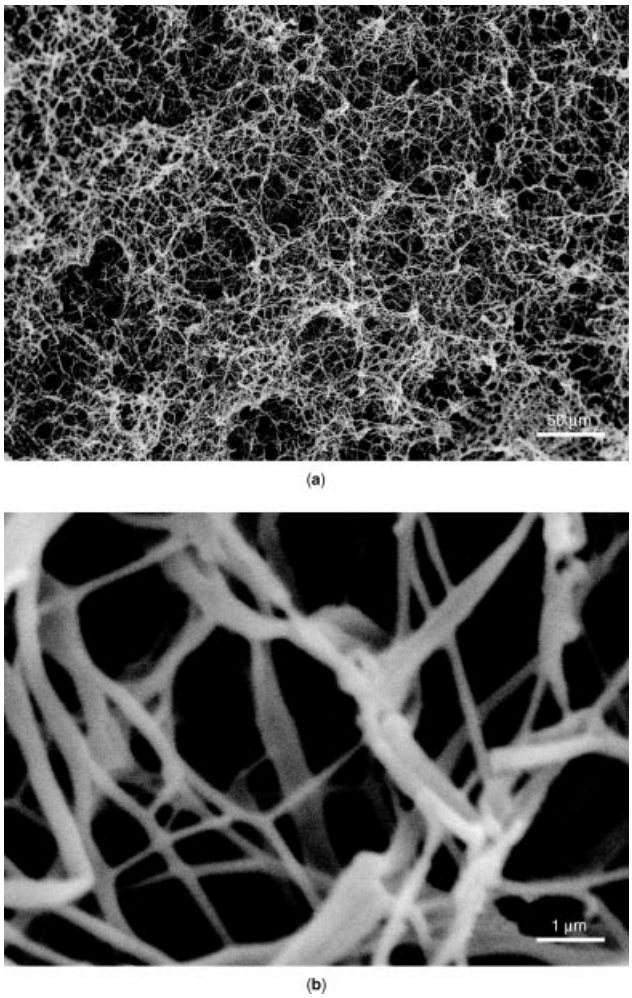

Fig. 13. SEM micrographs of a PLLA nanofibrous matrix prepared from 2.5% (w/v) PLLA/THF solution at a phase separation temperature of 8°C: (**a**) 500×; (**b**) 20,000×. Reprinted from Ref. 112. © 1999, by permission of John Wiley & Sons.

filament on to a platform. A layer is patterned by depositing the continuous polymer filament and raster in the *x–y* directions. The motion along *z* direction allows layer-by-layer integration of the 2-D patterns into 3-D structures. In our laboratory, a similar process is used to fabricate the negative replica of the scaffold. A polymer solution is cast into such a mold and solidified after the removal of the solvent. The mold is then dissolved away to form the polymer scaffold with the designed 3-D pore network (Fig. 14).

Lithography is another processing technique that is actively explored for 3-D scaffold fabrication. Stereolithographic models derived from X-ray computed tomography and CAD software were used to recreate complex anatomic structure of a human pulmonary and aortic graft. These stereolithographic models were used to generate biodegradable heart valve scaffolds by a thermal processing technique (120). Hydroxyapatite scaffolds with various pore shapes have also been fabricated

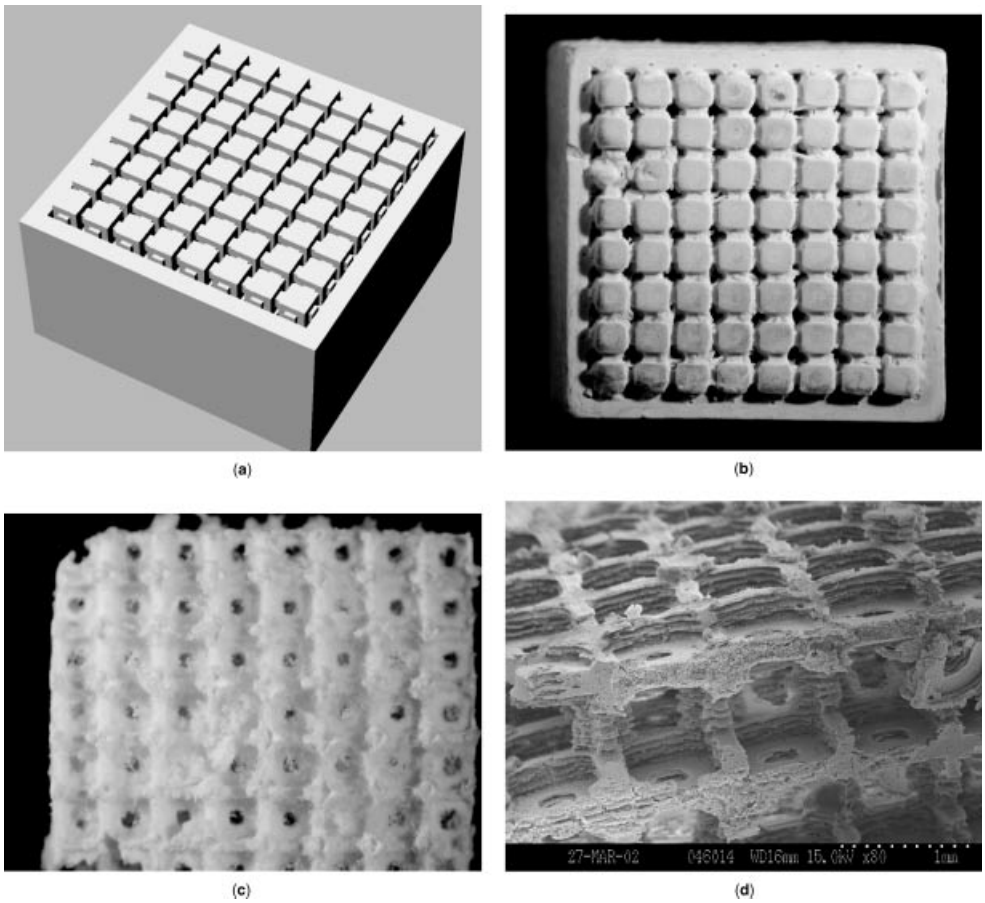

Fig. 14. Scaffold fabrication using rapid prototyped negative replica: (**a**) A computer-generated 3-D negative replica of a scaffold with a cubical pore shape; (**b**) the negative replica of the scaffold fabricated using a rapid prototyping machine; (**c**) the polymer scaffold fabricated using the negative replica; (**d**) SEM micrograph of the internal pore structure of the generated scaffold (V. J. Chen and P. X. Ma, unpublished data, 2003).

by casting ceramic slurry into molds generated using stereolithography and a subsequent sintering process (Fig. 15) (121). Lithography techniques have also been used to fabricate devices to localize cell populations in patterned configurations on rigid substrates as a potential artificial liver (122). A complex silicon structure of branched vascular channels as a model for liver fabrication has also been developed using stereolithography (123).

However, in addition to the special equipment requirements all these fabrication techniques have their inherent shortcomings such as limited material selections and inadequate resolution like the 3DP techniques discussed earlier. Furthermore, the resulting constructs have structural heterogeneity due to the "pixel assembly" nature of these fabrication processes.

In our laboratory, reversed fabrication processes have been developed to overcome these shortcomings for tissue engineering scaffold fabrications (Fig. 16)

(124). To fabricate 3-D biodegradable polymer scaffolds with well-controlled interconnected spherical pores, paraffin spheres are fabricated with a dispersion method. These paraffin spheres are then transferred into a 3-D mold of a designed shape or anatomical shape of a body part. The spheres are bonded together in the mold through a heat treatment process. A polymer solution is cast into the paraffin assembly in the mold (Note: the solvent used should not be a solvent of the paraffin spheres). After removal of the solvent through evaporation or other means, the polymer–paraffin sphere assembly is immersed in a solvent of the paraffin but not a solvent for the polymer (such as hexane for PLA or PLGA scaffolds) to dissolve the paraffin sphere assembly. In this way, an interconnected spherical pore structure is created in a predetermined shape by the mold (Fig. 17). Importantly, the generated scaffolds have homogeneous foam skeleton (platelet-like, continuous,

or other complex features, depending on the polymer and phase separation conditions) with homogeneous material properties, which are not easily achievable with free-forming, 3DP or lithography because of the limitation of pixel-by-pixel construction. Equally importantly, the spherical pore size is determined by the

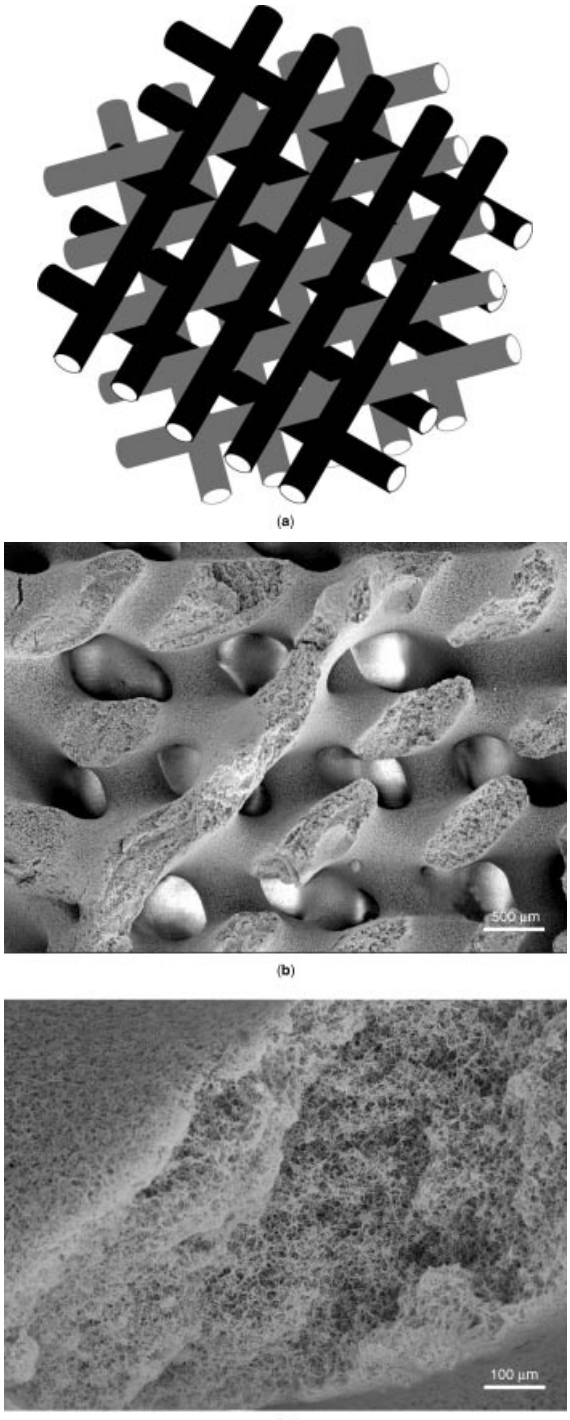

Fig. 18. PLLA nanofibrous scaffold with helicoidal tubular macropore network prepared from PLLA/THF solution and a helicoidal sugar fiber of the scaffold assembly: (**a**) schematic illustration of helicoidal sugar fiber assembly; (**b**) SEM micrograph of the scaffold at an original magnification of 35×, and (**c**) original magnification of 250×. paraffin sphere size used, which can be controlled through paraffin sphere preparation. The features generated are significatly better than those achievable with the resolutions of the current 3-D fabrication machines. Furthermore, the interpore openings are circular and the size of these openings is adjustable through manipulating the heat treatment conditions. For example, longer heat treatment time leads to larger openings between the pores (124). Finally there is no expensive equipment investment compared to the textile technologies or rapid prototyping techniques, which allows this technology to be easily adapted in a research as well as an industrial setting.

To improve the 3-D structure of nanofibrous scaffolds for cell seeding and distribution, mass transport, vascular invasion, and tissue organization, techniques have also been developed in our laboratory to build predesigned macropore networks in nanofibrous matrices (15). For example, larger water-soluble fibers (diameters from 100 μm to 1 mm) are prepared from sugar as a geometrical porogen element, and are assembled into various 3-D structures (such as helicoidal) (Fig. 18**a**). PLLA solution is then cast into this 3-D assembly and is thermally induced to phase-separate for nanofibrous matrix formation. After the solvent removal, the sugar fiber assembly is dissolved away using water to achieve nanofibrous scaffolds with predesigned helicoidal tubular pore network (Figs. 18**b** and 18**c**). Similarly, we have combined the interconnected spherical pore network described earlier with nanofiber techniques to generate nanofibrous scaffolds with interconnected spherical macropores (Fig. 19) (125).

As discussed above, tissue engineering scaffold fabrication is a fast evolving area. Many other polymer processing techniques such as gas-foaming, emulsion freeze-drying, and so forth have also been explored (126–128). Current efforts for these techniques include overcoming the disadvantages of closed-pore structures and undesired pore size ranges.

Again this article is intended to introduce the general concepts of tissue engineering in relation to polymer science and engineering, but is not intended to be a complete and exhaustive review of the field of tissue engineering. There are

TRANSPORT PROPERTIES

Introduction

Transport properties determine a polymer's ability to move through some medium or to have some penetrant medium move between its constituent segments. This definition encompasses processes with diverse driving forces such as concentration and pressure gradients, and even electrical or temperature gradients capable of motivating one component relative to another. This article emphasizes polymer transport properties under conditions of low to intermediate penetrant concentration, where extraordinary differences can exist between the diffusivities of penetrants having relatively small differences in molecular size or shape.

This article focuses on transport that proceeds by the solution-diffusion mechanism. Transport by this mechanism requires that the penetrant sorb into the polymer at a high activity interface, diffuse through the polymer, and then desorb at a low activity interface. In contrast, the pore-flow mechanism transports penetrants by convective flow through porous polymers and will not be described in this article. Detailed models exist for the solution and diffusion processes of the solution-diffusion mechanism. The differences in the sorption and transport properties of rubbery and glassy polymers are reviewed and discussed in terms of the fundamental differences between the intrinsic characteristics of these two types of polymers.

The transport properties of glassy and rubbery polymers are related to their microstructural morphology. For a penetrant to diffuse, a minimum characteristic packet of unoccupied volume is required. The penetrant diffuses by jumping through transient gaps between packets of unoccupied volume. The lifetime, size, and shape of these volume packets and the transient gaps that connect them are dependent upon the micromotions of the polymeric media. New techniques such as

positron annihilation lifetime spectroscopy (PALS) and molecular modeling allow for elucidation of dynamic activities at the molecular scale. While a description at this length-scale offers fundamental information about the diffusion process, it is not yet possible to predict the macroscopic transport properties with sufficient accuracy for practical applications. In this regard, quantitative phenomenological models and more molecularly based treatments are complementary, and both will be considered.

Terminology

Reference Frames and Fluxes. In speaking of a diffusional flux, it is necessary to specify a reference frame from which the diffusion process is to be observed. Generally, a reference velocity such as the mass, molar, or volume average bulk velocity (v,v^*, or $v^\blacklozenge$, respectively) in the system is selected, and movement of the component of interest relative to this reference velocity is defined to be true diffusion. For practical reasons, a fixed reference frame is generally also considered to relate the mathematical treatment of this molecular scale transport process to an actual physical system with well-defined dimensions. In this case, the total flux relative to the fixed reference frame is partitioned into two parts: bulk flow and true molecular diffusion. This partitioning is necessary, because even in the absence of an externally imposed bulk flow, interdiffusion of molecules with respect to each other produces an effective bulk flow relative to fixed coordinates if the molecules have different masses (1,2).

The definitions of the mass, molar, and volume average bulk velocities are given in Table 1 along with selected mass and molar flux expressions related to each of the specified reference velocities for a binary system of components A and B. The mutual diffusion coefficient D_{AB} is the diffusivity of component A and B in the mixture as defined below. The mutual diffusion coefficients appearing in Table 1 are identical in all of the expressions and $D_{AB} = D_{BA}$.

Additional discussion of these definitions and relationships between the different reference frames and fluxes are discussed in detail elsewhere (3,4). In principle, any reference frame for analysis may be selected; however, a proper choice can reduce the mathematical difficulties. For example, in a one-dimensional diffusion process within fixed boundaries, where ideal mixing of components is a reasonable approximation, selecting the volume average frame of reference is wise because

Table 1. Average Velocities and Forms of Fick's First Law for Binary Diffusion[a]

Average velocity	Definition of average velocity	Form of Fick's first law[b]
Mass average	$v = \omega_A v_A + \omega_B v_B$	$j_i = -\rho D_{AB} \nabla\omega_i = \rho_i(v_i - v)$
Molar average	$v^* = x_A v_A + x_B v_B$	$j_i^* = -M_A C D_{AB} \nabla x_A = C_i(v_i - v^*)$
Volume average	$v^\blacklozenge = \rho_A v_A V_A/M_A + \rho_B v_B V_B/M_B$	$j_i^\blacklozenge = -D_{AB} \nabla \rho_i = \rho_i(v_i - v^\blacklozenge)$

[a] ω_i and ρ_i refer to the mass fraction and mass density of component i, respectively; ρ refers to the total solution mass density, and V_i and M_i are the molar volume and molecular weight of component i, respectively. The velocity of component i, v_i, represents the average velocity of component i relative to fixed coordinates due to both bulk and true diffusive movement.

[b] j_i and $j_i^\blacklozenge$ are the mass fluxes of the component i relative to the mass average and volume average velocities, respectively, and J_i^* is the molar flux relative to the molar average velocity.

the volume average bulk velocity as defined above is zero, and hence the fluxes viewed from both a fixed reference frame and a reference frame moving at the local volume average velocity are identical. In this case the fundamental differential equation of one-dimensional diffusion in an isotropic medium reduces to

$$\frac{\partial \rho_A}{\partial t} = \frac{\partial}{\partial z}\left(D_{AB}\frac{\partial \rho_A}{\partial z}\right) \tag{1}$$

Documented solutions for equation 1 exist for a limited number of complex concentration-dependent diffusion coefficients and boundary conditions (5).

Alternatively, for steady-state analysis involving a case with component B replaced by P, for polymer, a static reference frame and the mass average velocity as a reference velocity may be selected. The mass flux of component A (penetrant) relative to the fixed reference frame is given in general by

$$n_A = -\rho D_{AP}\frac{\partial \omega_A}{\partial z} + \omega_A(n_A + n_P) \tag{2a}$$

where n_A is the total mass flux of A relative to a fixed reference coordinate system, the first term on the right is the flux of A relative to the mass average velocity, and the last term is the flux of A due to bulk flow of fluid relative to the fixed coordinate system. However, since $n_P = 0$ in this case (since $v_P = 0$ for the membrane polymer relative to the fixed reference frame at steady state), the general expression for n_A simplifies to

$$n_A = \frac{-\rho D_{AP}}{(1-\omega_A)}\frac{\partial \omega_A}{\partial z} \tag{2b}$$

The $1/(1 - \omega_A)$ term is commonly referred to as the *frame of reference term*. For many cases of importance in polymeric systems such as in gas permeation, ω_A is relatively small, and the $1/(1 - \omega_A)$ factor can safely be neglected so that the flux relative to fixed coordinates is equal to the flux relative to moving coordinates. Even for intermediate concentrations ($0.1 < \omega_A < 0.5$), this factor may often be of second-order importance compared to difficulties in accurately determining the mutual diffusion coefficient due to strong concentration dependencies. However, not accounting for the factor $1/(1 - \omega_A)$ can lead to very significant errors in flux calculations in highly swollen systems (eg, 90–95% solvent), even if the mutual diffusion coefficient is accurately determined (6).

Mutual Diffusion Coefficients. A better appreciation of the separation of bulk and true diffusive fluxes and the significance of the mutual diffusion coefficient D_{AP} is useful prior to considering factors that determine this coefficient. Consider, for example, the transient problem of a block of polymer placed in contact with an external solvent (penetrant) phase. When a small penetrant moves into a polymer under transient conditions, most of the polymer movement, measured relative to a fixed coordinate, is thought to be due to bulk flow arising from the outward swelling of polymer segments into the region that was occupied previously by the external solvent phase (5). Because of its intrinsically high mobility, the penetrant (solvent) tends to interpose itself between the polymer segments

and invade the domain initially occupied solely by the polymer, thereby acting as the prime mover for the mixing process.

The initial invasion of the solvent effectively induces a local swelling stress. The polymer sample responds to this swelling stress and moves in a direction opposite to the invading solvent flux. This backward bulk motion thereby carries entrained solvent molecules against the direction of the simple concentration-driven diffusive flux. Unlike the steady-state membrane case, it is clearly not acceptable to assume the mass flux of polymer is zero in this situation, and some relationship between n_A and n_P must be defined. This issue becomes important for cases involving the interaction of strong swelling solvents with glassy polymers in transient sorption processes. Also in this case, a very strong concentration dependence of D_{AP} may exist, in some cases approaching a step function. In these situations, the "polymer fixed" frame of reference is often used for mathematical convenience. In this reference frame, D_{AP} is defined relative to the penetrant concentration in the unswollen polymer. On the other hand, if the polymer was not assumed to be fixed, D_{AP} would be defined relative to the concentration in the swollen polymer. D_{AP} for these two reference frames are not necessarily equal; however, diffusivities in different reference frames can be readily interconverted. A more thorough treatment of this subject is given in References 5 and 7.

However, for most cases involving gases and even low sorbing vapors or liquids, swelling of the polymer and non-Fickian complications are minimal. In these situations, solutions to equation 1, unconfused by bulk flow, provide an adequate description of the process and allow estimation of the mutual diffusion coefficient. In such cases with a constant diffusion coefficient, standard solutions of equation 1 for M_t, the amount of material sorbed (or desorbed) at time t relative to M_∞, the amount of material sorbed (or desorbed) at infinite time, can be used for this estimation of the mutual diffusion coefficient. If the initial and final concentrations in the sample of thickness ℓ are uniform and the external penetrant activity is held constant, two mathematically equivalent solutions to equation 1 are given (5):

$$\frac{M_t}{M_\infty} = 4\left[\frac{D_{AP}t}{\ell^2}\right]^{0.5}\left\{\frac{1}{\pi^{0.5}} + 2\sum_{n=1}^{\infty}(-1)^n \text{ ierfc}\left[\frac{n\ell}{2(D_{AP}t)^{0.5}}\right]\right\} \tag{3a}$$

$$\frac{M_t}{M_\infty} = 1 - \sum_{n=0}^{\infty}\frac{8}{(2n+1)^2\pi^2}\exp\left[-(2n+1)^2\pi^2\frac{D_{AP}t}{\ell^2}\right] \tag{3b}$$

On the one hand, equation 3a is generally referred to as the *short time solution* because good accuracy is achieved for values of $M_t/M_\infty \leq 0.6$ even if the infinite summation term is neglected. On the other, equation 3b is referred to as the *long time solution* because good accuracy is achieved for values of $M_t/M_\infty \geq 0.6$ if only the first term in the summation is used.

In cases where there are significant, but not extreme, concentration dependencies of the diffusion coefficient (changes in D_{AP} of up to 50–100% over the course of an experiment), an average coefficient can be used in equations 1, 2, and 3 with little loss in accuracy. For such cases, the average diffusion coefficient $\bar{D}$ is

defined as follows:

$$\bar{D} = \frac{\int_{(\omega_A)_0}^{(\omega_A)_\infty} D_{AP} d\omega_A}{(\omega_A)_\infty - (\omega_A)_0} \tag{4}$$

where $(\omega_A)_0$ and $(\omega_A)_\infty$ refer to the uniform penetrant mass fractions in the polymer at the beginning and at the end of the sorption run, respectively.

The experiment could also be run over a narrow concentration interval to determine the concentration dependence of $\bar{D}$. In this latter case, the average diffusion coefficients determined from half-time analysis are good approximations for D_{AP} over that particular concentration interval. $\bar{D}$ is calculated simply by rearrangement of equation 3a by neglecting the infinite summation terms with $M_t/M_\infty = 0.5$:

$$\bar{D} = 0.0492 \frac{\ell^2}{t_{1/2}} \tag{5}$$

where $t_{1/2}$ is the time required to achieve one-half of the mass uptake that ultimately occurs at equilibrium for the interval sorption experiment. Equation 5 applies for experiments in which the sample has two exposed faces. For a single-sided exposure the coefficient in equation 5 is replaced by 0.1968. Alternate half-time expressions for different geometries such as cylinders and spheres have been presented (5). To analyze the later stages of sorption using an average diffusion coefficient $\bar{D}$, equation 3b indicates that a plot of $\ln(1 - M_t/M_\infty)$ vs t gives a straight line with a slope equal to $\pi^2\bar{D}^2/\ell^2$.

Self vs Mutual Diffusion Coefficients. The self-diffusion coefficient $D_A{}^*$ is measured by observing the rate of diffusion of a small amount of radioactively-tagged component A in a system composed of a uniform chemical composition of untagged components A and B. Because of the essentially identical physical natures of the tagged and untagged penetrant, observing the process of interdiffusional exchange of the tagged and untagged molecules allows measurement of the true mobility of the tagged molecules with respect to the stationary solution of known concentration. By varying the concentration of A and B in the presence of a small amount of tagged component A, the concentration dependence of the diffusion coefficient of the tagged molecule can be obtained, uncomplicated by bulk-flow considerations, namely

$$D_A^* = RT\mathcal{M}_A = \frac{RT}{\zeta_A} \tag{6}$$

where $\mathcal{M}_A$ is the mobility of A, ζ_A is the molar friction coefficient, the product of the effective viscosity of the medium and the effective diameter of the penetrant (8).

In addition to pure mobility considerations, thermodynamic factors enter in determining the concentration dependence of the mutual diffusion coefficient. A single mutual diffusion coefficient exists for a given binary pair under fixed local

conditions (8). For molecules with similar sizes, shapes, and interaction potentials, the ratio of the self-diffusion coefficients of two components are related to the inverse ratio of the molar volumes, ie, $D_A{}^*/D_B{}^* = V_B/V_A$ (8). Under these conditions the individual self-diffusion coefficients may be related to the corresponding mutual diffusion coefficient D_{AB} in terms of the mole fractions of the two components and the partial derivative of the activity vs mole fraction relationship for the penetrant in the polymer at the local mole fraction of interest:

$$D_{AB} = \left(\frac{\partial \ln a_A}{\partial \ln x_A}\right)_{T,p} \left[D_B^* x_A + D_A^* x_B\right] \tag{7}$$

The activity derivative can be readily evaluated from sorption vs activity measurements. The subscripts T and p, indicating which variables are held constant, will be dropped for simplicity in the subsequent equations. Equation 7 was given earlier (4) using classical diffusion analysis for systems in which there is negligible volume change of mixing.

Although the inverse molar volume ratio relationship suggested above is probably adequate for small molecules with similar sizes, shapes, and interaction potentials, it is not clear that it applies in all cases where marked differences exist in the relative sizes of components A and B. A weight fraction based weighting of the respective $D_i{}^*$ values is probably more general. Except in the range of extremely high solvent fractions, the mobility, and hence the self-diffusion coefficient of a polymer in the presence of a low molecular weight solvent, is many orders of magnitude lower than that of the solvent. Therefore, with the reasonable approximation that $D_P{}^* = D_B{}^* \approx 0$, equation 7 can be expressed in terms of the mass fraction of component A as follows:

$$D_{AP} = D_A^* \omega_P \left(\frac{\partial \ln a_A}{\partial \ln \omega_A}\right) = D_A^* (1 - \omega_A)\left(\frac{\partial \ln a_A}{\partial \ln \omega_A}\right) \tag{8}$$

Diffusion Coefficients in Multicomponent Systems. The value of the diffusion coefficient of a species in a binary system is often not the same as the value in a multicomponent system. The diffusion coefficients can be modified in multicomponent systems as a result of added frictional forces at the atomistic scale. The multiple diffusing species interact in various complex ways that can be described using equation 9, which is derived from the so-called Stefan–Maxwell relations (4):

$$D_{im} = -\frac{n_i - x_i \sum_{j=1}^{n} n_j}{\sum_{j=1}^{n} \frac{x_i n_j - x_j n_i}{D_{ij}}} \tag{9}$$

where D_{im} is the diffusion coefficient of species "i" in the mixture, D_{ij} are the binary diffusion coefficients, x_i is the mole fraction of species "i", and n_i is the molar flux of "i". The diffusion coefficients calculated from equation 9 are used in a generalized

form of equation 2a for multicomponent diffusion:

$$n_i = -cD_{im}\nabla x_i + x_i \sum_{j=1}^{n} n_j \tag{10}$$

More detailed treatments of multicomponent diffusion are available (4,9).

Solution-Diffusion Mechanism

Small molecule transport through nonporous polymers proceeds by the solution-diffusion mechanism. This a three-step mechanism where penetrant molecules (*1*). sorb into the polymer phase from a high activity external gas or liquid phase, (*2*). diffuse across the polymer driven by a chemical potential gradient, and (*3*). desorb from the polymer phase to a low activity gas or liquid external phase. While these three general steps of the solution-diffusion mechanism are agreed upon, the specifics of sorption into and out of the polymer phase and diffusion across it are still active areas of research. As will be seen in later sections of this article, there are many ways to conceptualize the sorption and diffusion processes.

Regardless of how one conceptualizes the diffusion process, the solution-diffusion mechanism states that the flux through the polymer is proportional to a chemical potential gradient. If a chemical potential gradient does not exist, in the absence of an imposed bulk flow, no net transport of penetrant occurs through the polymer. This proportionality is stated mathematically as

$$J_A = -L\frac{\partial \mu_A}{\partial z} \tag{11}$$

where J_A is the flux of A through the polymer, μ_A is the chemical potential of penetrant A in the polymer phase, and L is the direct phenomenological transport coefficient in irreversible thermodynamics terminology. C is the concentration of A sorbed in the polymer, and $\mathcal{M}_A$, once again, is the mobility of A.

In the absence of electromotive forces, the chemical potential of a dissolved penetrant in the polymer phase is given by

$$\mu_A = \mu_A^0 + RT\ln(\gamma_A C_A) + V_A\left(p - p_A^0\right) \tag{12}$$

where ${\mu_A}^0$ is the chemical potential of the pure penetrant at the reference pressure ${p_A}^0$. Moreover, γ_A is the activity coefficient at concentration C_A, and the partial molar volume of the penetrant is V_A. The reference pressure is usually set as the pure component vapor pressure. With the knowledge that a chemical potential gradient must exist through the polymer, from inspection of equation 12 one can imagine three possible ways to affect such a gradient: (*1*) a concentration gradient across the polymer, (*2*) a pressure gradient across the polymer, or (*3*) the coexistence of both pressure and concentration gradients across the polymer. In an elegant series of articles, Paul and co-workers showed that a concentration gradient solely affects the gradient in chemical potential. The fact that no

pressure gradient exists through the membrane interior can be proved using a simple mechanical argument. In the common laboratory setup for gas separations, the membrane is supported on the low pressure side by a porous metal support. If a pressure is exerted on the upstream side of the membrane by the gas, the metal support must exert an equal and opposite pressure on the downstream side of the membrane. For this reason, the pressure inside the membrane is equal to the upstream pressure (6). By using a constant pressure through the membrane, Paul was able to rationalize the observed dependence of flux on the external pressure difference for both hydraulic permeation and pervaporation systems (10). Furthermore, Paul conducted a series of experiments using a composite membrane consisting of a stack of three to four rubber membranes to measure the concentration gradient through the membrane. It was shown that the concentration gradient determined from these measurements alone accounted for the entire chemical potential gradient (11). This result excluded the possibility of a pressure gradient inside the membrane for solution-diffusion transport processes.

With this knowledge of the physical situation, it is an easy exercise to derive Fick's Law from the more general statement of equation 11.

$$J = -L\frac{\partial \mu_A}{\partial z} = -L\frac{\partial \mu_A}{\partial C_A}\frac{\partial C_A}{\partial z} = -D_{AB}\frac{\partial C_A}{\partial z} \tag{13}$$

Since $D_{AB} = (D_A{}^* C_A/RT)(\partial \mu_A/\partial C_A)$ (5), the phenomenological coefficient L can be related back to the underlying penetrant mobility.

$$L = \frac{D_A^* C_A}{RT} = \frac{1}{\zeta_A}C_A = \mathcal{M}_A C_A \tag{14}$$

Amorphous Rubbery Polymers

Gases and Low Activity Vapors. At low concentration ($\omega_A \to 0$) and in systems where Henry's law applies ($\partial \ln a_A/\partial \ln \omega_A \to 1$), D_{AB} approaches the infinite-dilution self-diffusion coefficient $(D_A{}^*)^0$. Therefore, the mutual diffusion coefficient is a good estimator of the infinite-dilution self-diffusion coefficient for most gases in polymers at atmospheric pressure and below. Even at relatively high pressures with condensable gases and low activity vapors such as CO_2, SO_2 and propane, deviations from Henry's law can generally be described in terms of the Flory–Huggins isotherm or a similar simple expression. Therefore, self-diffusion coefficients, and thus the mobility of the penetrant, can be calculated using equations 5 and 6 or by using permeation data in conjunction with equilibrium sorption data to determine ($\partial \ln a_A/\partial \ln \omega_A$) at the appropriate ω_A value.

Rubbers are essentially high molecular weight liquids with the ability to adjust their segmental configurations rapidly over significant distances (>0.5–1 nm) and local volumes (12). Nevertheless, the rotational and translational motions of sorbed penetrants are rapid compared to the motions of the segments of the polymer (13,14). The limiting step in diffusion of such small molecules through the

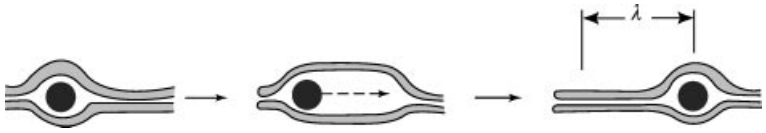

Fig. 1. Generation of a gap for the penetrant with subsequent collapse of the volume that previously housed the penetrant, emphasizing the mutual nature of the binary diffusion process.

rubber involves the generation of a sufficiently large gap for the penetrant to move into, with subsequent collapse of the sorbed cage that previously housed the penetrant (Fig. 1). This description emphasizes the mutual nature of the binary diffusion process, since both the penetrant and surrounding polymer segments tend to undergo a minute translation in their positions as a result of the event. Given the overall mass of the polymer and the small fraction of the total chain involved in a primitive diffusion jump by a small penetrant, this change is miniscule, but nonzero, even for the polymer.

In typical polyolefins, the most common moving segment is a crankshaft composed of four to five backbone carbon atoms (Fig. 2). For diene and other hydrocarbon polymers, similar cooperative motions involving several repeat units are also probably the most common types of motions observed over time scales of importance to diffusion. As expected, for penetrants such as gases that are clearly smaller than the size of the most common moving segment of the polymer, the infinite-dilution diffusion coefficient tends to show a steady drop with increasing penetrant size (Fig. 3). The tendency for diffusion coefficients of larger penetrants to approach an asymptotic plateau has been discussed (15). Branched penetrants tend to approach a lower, but still similar, asymptotic limit in a given medium. This effect suggests that larger penetrants are capable of moving in a somewhat segmental fashion as does the polymer itself. In this case, the asymptotic limit of the linear penetrants in Figure 3 presumably reflects the mobility of the more or

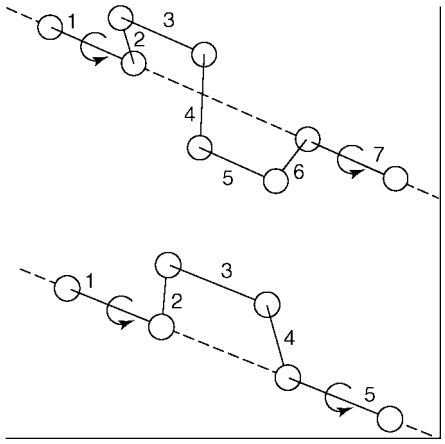

Fig. 2. The crankshaft motion requiring the simultaneous rotation of several sequential $-CH_2-$ moieties about bonds 1 and 7 or 1 and 5.

less freely orienting segments of the polymer that are themselves undergoing a self-diffusion process. Therefore, while the self-diffusion coefficient of the polymer center of mass may be orders of magnitude lower than that of intermediate-sized penetrants, segmental mobility in the polymer is still quite high. Not surprisingly, the asymptotic mobilities of penetrants in glassy polymers are orders of magnitude lower than those in the typical rubbery polymers.

Concerted movements of several adjacent segments of chain comprising the sorbed cage of a simple gaseous penetrant are believed to provide the source of the penetrant-scale hole needed for diffusion. Lennard–Jones collision diameters (σ), van der Waals volumes (b), and actual measured values of the partial molar volumes of various gases in polydimethylsiloxane (PDMS) (16) are shown in Table 2. These partial molar volumes in PDMS are close to the van der Waals volumes, very close to infinite-dilution partial molar volumes in several low molecular weight liquids (17), and are measures of the volume of the cage in which the sorbed penetrant resides at equilibrium. The occupied volume is calculated by viewing the molecule acting as a freely rotating sphere of diameter equivalent to the Lennard–Jones diameter σ. Based on these data, it is clear that only a fraction of the actual equilibrium cage volume is occupied and the remainder is in a sense "free volume" available to be shared with the neighboring polymer segments to facilitate the mutual diffusion process.

Estimates of the amounts of total free volume required for a diffusional jump of several gaseous penetrants in a copolymer of poly(vinyl chloride) and poly(vinyl acetate) have been made (18) (Table 2) (Fig. 4). Although the data in Table 2 are

[c] Ref. 17

for two different polymers, for an order of magnitude analysis they can be taken as representative of movement in typical rubbery polymers. The required free volumes for diffusional jumps are significantly greater than the penetrant volumes. Therefore, most of the free volume involved in a given jump must be supplied by a momentary fluctuation in the rubbery polymer segmental position due to a local thermal fluctuation, rather than being locally present in the equilibrium sorbed cage. This fact can be treated in several ways, eg, via Activated State Theory or Free-Volume Theory.

Activated State Theory. The diffusion process by which small molecules intermingle with a polymer can be considered a random walk of the penetrant among the segments of the polymer. Consistent with this qualitative description, the activated state theory assumes that holes covering a spectrum of different volumes and involving segments of several polymer molecules are continuously formed and destroyed because of thermal fluctuations. The rate of diffusion depends on the concentration of transient holes that are sufficiently large to accept diffusing molecules. Assuming a Boltzmann distribution, the concentration of a given size of holes decreases exponentially with the energy associated with its formation. The temperature dependence of the diffusion coefficient for the activated state theory can be expressed as

$$D = D_0 \exp\left(\frac{-\Delta E_d}{RT}\right) \tag{15a}$$

where D_0 is the preexponential factor and ΔE_d is the energy of activation for diffusion.

The indication by equation 15a that $\ln(D)$ is linearly dependent on $1/T$ has been verified for many systems well above the glass-transition temperature T_g

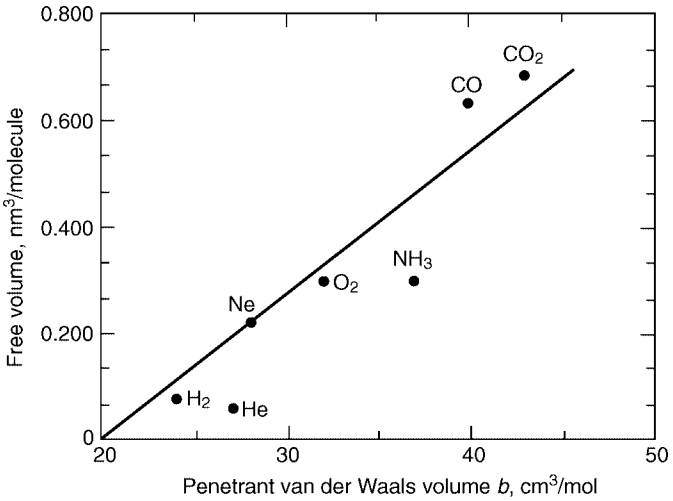

Fig. 4. Estimated required free volume for a diffusional jump for various penetrants in PVC–PVA copolymer (17).

(ie, $T > T_g > T_g + 100$ K). For penetrants smaller than the size of the primary moving segment of the polymer, the size of the molecule generally determines both the size of the required hole and the activation energy required for diffusion, as shown in Figure 5 (15). This tendency for the activation energy of diffusion for the larger penetrants to approach an asymptotic value similar to that of the activation energy of viscous flow for the uncross-linked polymer had been noted (15). This asymptotic behavior is thought to represent a similarity between the mobilities of large penetrants and the primitive segmental mobility of the polymer that participates in viscous flow (19).

The Eyring theory of rate processes (20) has been used as the basis of most theories for D_0:

$$D_0 = e\lambda^2 kT/h \exp\left(\frac{\Delta S^*}{R}\right) \tag{15b}$$

where ΔS^* is the entropy of activation and λ is the average jump length. For penetrants smaller than the average size of the jumping unit of the polymer, both the preexponential factor and activation energy increase with the size of the penetrant molecule. The actual diffusion coefficient of the penetrant decreases with penetrant size since the exponential weighting of E_d dominates the product in equation 15a.

Molecular models of the diffusion process help clarify the meaning of ΔE_d. A molecular rationalization of the value of ΔE_d in terms of the product of cohesive energy density (CED) and the volume of 1 mol of cylindrical cavities having a length λ and a diameter equal to that of a diffusing molecule, d_A, has been suggested (21). With this assumption,

$$\Delta E_d = \text{CED}\, d_A^2 \pi\lambda/4 \tag{16}$$

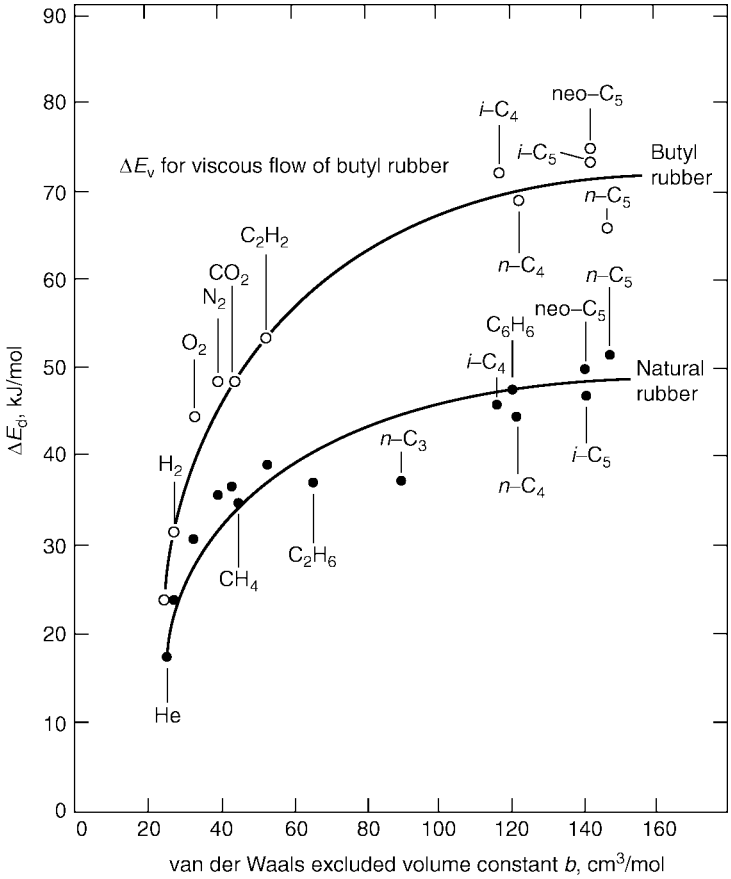

Fig. 5. Activation energy required for diffusion for various penetrants. To convert kJ/mol to kcal/mol, divide by 4.184.

An apparent diffusional jump length using such a cylindrical activation volume can be calculated. Assuming the total free volume for a diffusional jump to be equal to the activation volume, the value 0.69 nm^3 per molecule for CO_2 in Table 2 can be used to calculate $\lambda = 8.4$ nm. This seems physically unrealistic. Moreover, a large jump length (1.1 nm) would still be calculated if this same amount of free volume associated with the diffusion jump for CO_2 were converted to a spherical volume fluctuation. Even this length seems too high, since all of the activated volume may not be directly usable for a linear translation of position. Furthermore, this conceptualization of the activation energy is not in agreement with experimentally observed behaviors. Experimentally determined values of the activation energy extrapolate to zero at some value of the penetrant molecular diameter d_A greater than zero, and correlations of E_d and d_A obtained experimentally are not of the simple proportionality expected from equation 16.

To account for the experimentally observed behavior of the activation energy, a more refined picture of the diffusion jump process must be introduced. Instead of Figure 1, it may be preferable to visualize the activated volume as a bulge in a tube

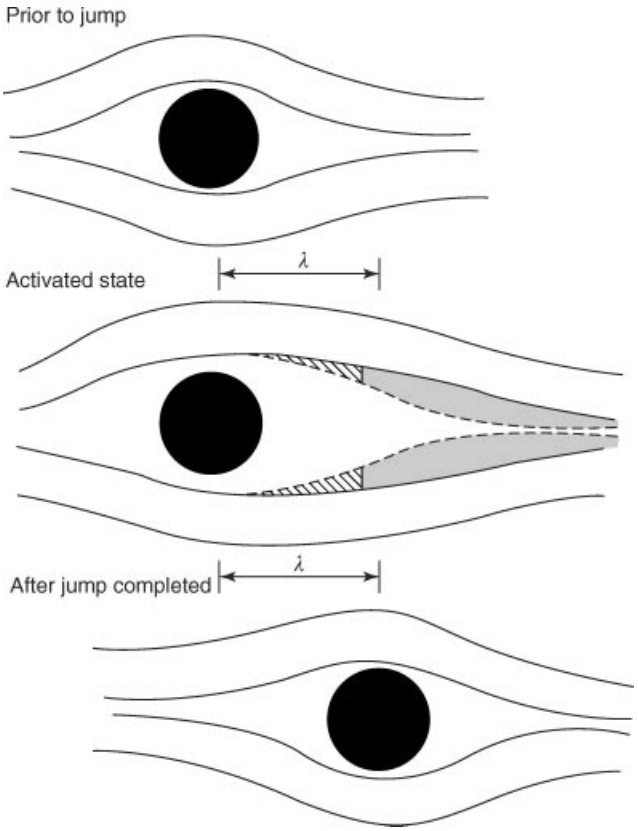

Fig. 6. Activated volume as a bulge in a tube with the openings of the bulge smaller than the penetrant diameter. ▧, Directly usable fraction of activation volume; ▩, not directly usable fraction of activation volume.

with the openings of the bulge smaller than the penetrant diameter (Fig. 6) (22). In this case, on the average, the penetrant can only execute its $\pm\lambda$ diffusional jump from the center of the bulge to one or the other side, even though the entire free volume must exist to accommodate the fact that polymer chains are not infinitely flexible, especially on the short time scale of a diffusional jump. In other words, the chains must have a considerable transition length over which the segments reapproach their original packing density; however, the volume associated with these regions is not directly usable by the penetrant in terms of $\pm\lambda$ translations of its center of mass.

These ideas were formalized mathematically by Brandt (23), who assumed that the activation energy was composed of two contributions: (*1*) an energy E_α associated with bending two initially straight chain segments away from each other to accept the penetrant molecule, and (*2*). an energy E_β needed to overcome repulsion of the bent chain segments by neighboring chains. The intermolecular energy E_α is calculated on the basis of the potential energy barrier to chain rotation, ψ_0, a measure of chain stiffness. The repulsive component E_β is calculated analogously to equation 16; however, the internal polymer pressure p_I is used instead of the

cohesive energy density. Using this framework, Brandt calculated the activation energy as follows:

$$\Delta E_d = E_\alpha + E_\beta = 18\psi_0 b_d (d_A - d_S)^2 / a_d^3 + N_A p_I d_p a_d (d_A - d_S)/2 \quad (17)$$

where N_A is Avogadro's number, b_d is the length of a backbone bond projected onto the chain axis, a_d is the length of the bent chain segments, and d_s is the initial chain spacing prior to penetrant inclusion. This conceptualization of the activation energy accounts for many of the shortcomings of equation 16. The activation energy is equal to zero when $d_A \leq d_s$, which is in accord with the nonzero extrapolations of ΔE_d versus d_A from experimental data. It is also apparent from inspection of equation 17 predicts that no simple relation should exist between the activation energy and the penetrant molecular diameter. Furthermore, equation 17 predicts that the dependence of the activation energy on the penetrant molecular diameter is weaker for flexible chain polymers, where ψ_0 is small. This model of the activation energy is the basis for more complex treatments by Pace and Daytner (24), and Dibenedetto and Paul (25).

Free-Volume Theories. The basic idea of the free-volume theories is that the mobilities of the polymer segments and the penetrant molecules in a polymer–penetrant mixture are primarily determined by the amount of free volume in the system. As originally proposed (26),

$$\mathcal{M}_A = A_d \exp\left[\frac{-B_d}{v_f}\right] \quad (18a)$$

where $\mathcal{M}_A$ is the mobility of the penetrant, v_f is the average locally available fractional free volume of the system, and A_d and B_d are empirical free-volume parameters that are assumed to be independent of penetrant concentration and temperature. The parameter A_d depends on the size and kinetic velocity of the penetrant. The parameter B_d is equivalent to the critical hole free volume necessary for a penetrant to make a diffusive jump (13). This expression was modified by arguing that crystalline material reduces the free volume in direct proportion to the amount of crystalline material present (27):

$$\mathcal{M}_A = A_d \exp\left(\frac{-B_d}{\Phi_a v_f}\right) \quad (18b)$$

where Φ_a is the amorphous volume fraction of the penetrant free polymer at zero pressure and the temperature of the system. Alternate treatments of the effects of crystallinity will be considered later in terms of a chain immobilization factor (see eq. 45).

According to free-volume theories, the diffusion coefficients of organic vapors in polymers are strongly concentration-dependent, because mobilities are extremely sensitive to changes in the average free volume of the system. A small penetrant that is unconstrained on two sides by covalently bonded neighbors introduces much more free volume into the polymer–penetrant mixture than a polymer segment of equivalent size. Increased penetrant concentration thereby alters the effective viscosity of the medium, and a significant increase in the penetrant

mobility results. The free-volume approach is simple and has evolved (28,29) into several readily useful forms. Its primary drawback lies in the difficulty of providing a precise physical definition for the parameter defined as the free volume.

The native polymer, totally devoid of penetrant, still possesses a certain distribution of free-volume packets, which wander spontaneously and randomly through the polymer. Intuitively, proponents of free-volume theory argue that a penetrant can execute a diffusive jump when a free-volume element greater than or equal to a critical size presents itself to the penetrant. In fact, the polymer chains may also execute a self-diffusive jump when a packet of sufficient size presents itself to a segment. This is the mechanism that causes the slow interdiffusion of polymer chains.

Increasing system temperature causes volume dilation, resulting in increased free volume. Thus the diffusion coefficient increases with temperature. The free-volume fraction v_f may be represented as a linear addition of several variables (28,29):

$$v_f(T,p,\varphi_1) = v_{fs}(T_s,p_s,0) + \alpha(T - T_s) - \beta(p - p_s) + \gamma\varphi_A \tag{19}$$

where v_{fs} is the fractional free volume of the pure, penetrant-free, amorphous, rubbery polymer at some reference temperature T_s, usually the glass-transition temperature, and reference pressure p_s, usually 101.3 kPa (1 atm). The penetrant volume fraction is Φ_A and the coefficients coefficients α, β, and γ are positive constants, the values of which are evaluated empirically. These coefficients characterize the effectiveness of temperature, pressure, and penetrant concentration, respectively, for changing the free volume in the amorphous phase:

$$\alpha = \left(\frac{\partial v_f}{\partial T}\right)_s \beta = \left(\frac{\partial v_f}{\partial p}\right)_s \gamma = \left(\frac{\partial v_f}{\partial \varphi_1}\right)_s \tag{20}$$

where s denotes some reference state. The free-volume thermal-expansion coefficient α can be estimated as the difference between the thermal expansion coefficient for an amorphous material above and below its glass-transition temperature. The parameter β can be related to the conventional compressibility coefficient β' by (30)

$$\frac{\beta}{1 - v_f^*} = \beta' = -\frac{1}{V}\left(\frac{\partial V}{\partial p}\right)_T \tag{21}$$

where v^*_f is the fractional free volume of the pure polymer at zero pressure. If the glass-transition temperature is used as the reference temperature, v^*_f is given by

$$v_f^* = v_{fs} + \alpha(T - T_g) + \beta p_s \tag{22}$$

Combination of equations 18 and 19 and use of the definition of mobility leads to the following expression for the polymer self-diffusion coefficient, when

the reference temperature is taken to be the glass-transition temperature:

$$D_A^* = A_d \exp\left(\frac{-B_d}{\Phi_a\{v_{fs} + \alpha[T - T_g] - \beta[p - p_s] + \gamma\varphi_A\}}\right) \tag{23}$$

Thus the self-diffusion coefficient D^*_A and its variation with concentration and temperature can be estimated if A_d, B_d, and γ are known. A correlation for γ as a function of the fractional increase in volume caused by a penetrant molecule has been developed (29). In the absence of data for a given polymer, v_{fs} and α can be approximated as the universal values of 0.025 and 4.8×10^{-4}/°C, respectively, in accordance with the theory of Williams, Landel, and Ferry (31) that interprets the glass-transition point to be an isofree volume state. This approximation is valid in the temperature range from T_g to 100°C above T_g.

In principle, each of the coefficients in equation 22 can be evaluated independently by observing the effects on $D_A{}^*$ over a sufficiently wide range of temperatures, external hydrostatic pressures, and sorbed penetrant concentrations. Hydrostatic effects on β can be decoupled from penetrant sorptive effects on γ by using a very low sorbing penetrant, such as helium in the presence of a fixed partial pressure of the penetrant of interest. On the one hand, hydrostatic pressure is expected to have a rather small effect on $D_A{}^*$ since solid polymers are only slightly compressible. On the other, increases in temperature and sorbed penetrant concentration cause large increases in the free-volume fraction v_f and in the self-diffusion coefficient $D_A{}^*$.

The permeability P is an important transport coefficient that represents the normalized molar flux N_A across a polymer film of thickness ℓ with a partial pressure driving force Δp at steady state:

$$P = \frac{N_A}{\Delta p/\ell} \tag{24}$$

Under steady-state conditions, n_P in equation 2a is zero, and for the low sorbed mass fractions typical of gases in polymers, an expression for $N_A = n_A/M_A$ can be substituted to yield

$$P = \frac{-\rho D_{AP}\ell}{M_A \Delta p}\frac{\partial \omega_A}{\partial z} \tag{25a}$$

where M_A is the molecular weight of component A. Integration between the upstream and downstream conditions gives

$$P = \frac{-1}{p_2 - p_1}\int_{\omega_{A1}}^{\omega_{A2}} \frac{-\rho D_{AP}(\omega)\, d\omega_A}{M_A} \tag{25b}$$

where ω_{A2} and ω_{A1} are the equilibrium penetrant weight fractions in the polymer at upstream (p_2) and downstream (p_2) faces. At low concentrations, D_{AP} reduces

to D_A^*. Transformation of equation 25a from mass fractions to volume fractions gives

$$P = \frac{-1}{p_2 - p_1} \int_{\varphi_{A1}}^{\varphi_{A2}} \frac{-\rho D_A^*}{M_A} \frac{d\omega_A}{d\varphi_A} d\varphi_A \tag{25c}$$

where $d\omega_A/d\varphi_A$ can be evaluated using the specific volumes of the polymer and penetrant. Substitution for D_A^* from equation 22 for the case of negligible downstream pressure yields the following expressions (32) when Henry's law applies ($\varphi_{A2} = k_A p_2$) at the upstream membrane face:

$$\ln P = \ln[RTA_d k_A] - \frac{B_d}{\Phi_a v_f^*} + \frac{p_2 B_d}{\Phi_a (v_f^*)^2}\left[-\beta + \frac{\lambda k_A}{2}\left(1 + \frac{2\beta p_2}{v_f^*}\right)\right] \tag{26}$$

Therefore, the free-volume theory permits theoretical plots of permeability as a function of temperature, penetrant pressure, and amorphous volume fraction in the rubbery polymer.

It is worth noting that in a series of articles, Vrentas and Duda (33–36) have introduced and applied a more rigorous free volume theory than the one presented above. In their approach, Vrentas and Duda include an energy factor, E_J, to the preexponential term A_d. This factor accounts for the energy required for a penetrant molecule to jump into an adjacent open hole. The exponential parameter B_d is modified to account for the molar volume of the moving polymer segment. Furthermore, Vrentas and Duda propose that only part of the total free volume is available for diffusion and is denoted by $\hat{V}_{fh}$. This concept of only a fraction of the free volume participating in diffusion is similar to the activation energy model of Brandt (see Fig. 6). The Vrentas and Duda model ultimately leads to a prediction of the thermodynamic diffusion coefficient:

$$D_T = A_{d0} \exp\left(\frac{-E_J}{RT}\right) \exp\left[\gamma_{ov}\left(w_A + \frac{w_P M_A}{M_{PJ}}\right)\frac{\hat{V}_h^*}{\hat{V}_{fh}}\right] \tag{27}$$

where w_A and w_P are mass fractions of the penetrant and polymer, respectively, and M_A and M_{PJ} are the molecular weight of the penetrant and the jumping polymer segment respectively. $\hat{V}_h^*$ is the specific volume of holes of the minimum size required for a diffusive jump. γ_{ov} is a parameter, with a value between 0.5 and 1, originally introduced by Cohen and Turnbull that accounts for the ability of a free volume hole to be available to multiple jumping segments. Although the added sophistication of this model probably captures a more accurate picture of the diffusion process, the accompanying added mathematical complexity has hindered widespread adoption of the model.

Membrane and Barrier Implications. In the case of typical rubbers, crankshaft and other related rotational motions of the repeat units are so large that little difference in diffusion coefficients exists for simple gaseous penetrants, the sizes of which differ by less than a few hundredths of a nanometer. Of course, since permeation is a solution-diffusion process, membranes or selective barriers

do not operate strictly on the basis of size selection. Under a fixed partial pressure driving force for component i, the flux through a material of given thickness ℓ is determined by the permeability, as can be seen by rearrangement of equation 24.

$$N_{\mathrm{i}} = \Delta p_{\mathrm{i}} P_{\mathrm{i}} / \ell \tag{28}$$

The permeability can be expressed as the product of a diffusivity and solubility coefficient:

$$P_{\mathrm{i}} = \bar{D}_{\mathrm{i}} \bar{S}_{\mathrm{i}} \tag{29}$$

The diffusivity and solubility coefficients in the above expression are effective averages applying across a polymer film between its upstream and downstream faces. The presence of other copermeating components can often be neglected for gases and low activity vapors permeating through rubbers (37). The average mutual diffusion coefficient $\bar{D}_i$ is given below for penetrant A in the polymer component P:

$$\bar{D}_{\mathrm{i}} = \frac{\int_{\omega_{\mathrm{A1}}}^{\omega_{\mathrm{A2}}} D_{\mathrm{AP}}\, d\omega_{\mathrm{A}}}{\omega_{\mathrm{A2}} - \omega_{\mathrm{A1}}} \tag{30}$$

When the presence of other components cannot be neglected, the system can still be treated approximately by considering the membrane in the presence of the additional component to be a new effective medium; however, this is at best a rough approximation since it neglects the bulk-flow contribution and thermodynamic influence of additional components on the flux of component A. Multicomponent thermodynamic issues are beyond the scope of this discussion, but have been treated (38).

The solubility coefficient, $\bar{S}_i$, is found from combination of equations 25b, 29 and 30 as:

$$\bar{S}_i = \frac{C_{i2} - C_{i1}}{p_{i2} - p_{i1}} \tag{31}$$

where C_{i2} and C_{i1} are the concentrations of "i" in the membrane at the upstream and downstream faces, respectively. p_{i1} and p_{i2} are the partial of "A" at the upstream and downstream faces, respectively. Under ideal conditions of fixed upstream pressure and negligible downstream pressure, the $\bar{S}_i$ parameter is equal to the secant slope of the sorption concentration vs pressure isotherm evaluated at the upstream partial pressure p_{i2} of the component

$$\bar{S}_i = \frac{C_i}{p_{i2}} \tag{32}$$

where C_i typically has units of cm^3(STP)/cm^3 polymer, and S_i can be related to the Henry's Law constant k_i in equation 26 for the gas in the polymer using partial molar volumes such as those in Table 2 in a subsequent expression (see eq. 32).

The temperature dependence of solubility coefficients are typically described in terms of van't Hoff expressions shown below (39):

$$\ln\left(\frac{S_i(T_2)}{S_i(T_1)}\right) = -\frac{\Delta H_s}{R}\left[\frac{1}{T_2} - \frac{1}{T_1}\right] \tag{33}$$

Equation 33 only applies when the solubility coefficient is independent of concentration or for solubility coefficients specified at the same concentration. The enthalpies of sorption ΔH_s are typically small and slightly negative (Fig. 7**a**). The solubilities and enthalpies of sorption of different penetrants are determined largely by their critical temperatures or other related measures of tendency to exist in a condensed phase such as normal boiling points or Lennard-Jones potential well depth $\epsilon/\bar{k}$ (Fig. 7**b**) (40).

From the dependence of permeability on both solubility and diffusivity, it is clear that two opposing factors affect the permeability as temperature is increased, namely

$$\ln\left(\frac{P(T_2)}{P(T_1)}\right) = \ln\left(\frac{D(T_2)S(T_2)}{D(T_1)S(T_1)}\right) = -\left[\frac{E_d + \Delta H_s}{R}\right]\left[\frac{1}{T_2} - \frac{1}{T_1}\right] \tag{34}$$

The positive diffusional activation energy is larger in absolute value than the negative ΔH_s, and so the overall permeability increases as temperature increases, but to a lower degree than the diffusion coefficient itself. It should be noted that the use of equation 34 is only strictly valid when the diffusion and solubility coefficients are independent of concentration.

The separation factor or permselectivity between two penetrants A and B, α_{AB}, is important in membrane separation systems. This factor is equal to the ratio of the downstream (permeate) mole fractions of component A relative to component B divided by the ratio of the upstream mole fractions of A relative to B. Under conditions of negligible downstream pressure, the permselectivity is simply equal to the ratio of the permeabilities of components A and B. In addition, since the presence of one component has a negligible effect on the permeability of the other at low pressures in rubbery materials, pure component permeabilities can often be used as good estimates of mixed-gas permeabilities:

$$\alpha_{AB} = \frac{P_A}{P_B} = \left(\frac{x_A}{x_B}\right)_1 \Big/ \left(\frac{x_A}{x_B}\right)_2 = \left(\frac{D_A}{D_B}\right)\left(\frac{S_A}{S_B}\right) \tag{35}$$

The subscripts 1 and 2 refer to downstream and upstream conditions, respectively. The ratio of the two diffusion coefficients is commonly called the diffusivity selectivity of a membrane and the ratio of the two solubilities, the solubility selectivity. A typical range of permeabilities and selectivities achievable with rubbery materials is indicated in Table 3 for several gas pairs of commercial interest. More extensive tabulations are available (41). The presence of polar groups in the polymer molecule generally leads to low diffusivity for penetrants (15); eg, the diffusivity decreases strongly on increasing the nitrile content in a series of

butadiene–acrylonitrile copolymers. The higher the nitrile content, the greater the attraction between neighboring chains. These interchain attractions are quantified by the cohesive energy density (CED). High CED tends to elevate the diffusion activation energy and hence depress the diffusivities according to equation 15b.

The diffusivity selectivities of the various rubbers in Table 3 are generally low, consistent with the large scale of segmental motions in rubbery materials relative to the penetrant sizes that must be distinguished. Besides difficulties in achieving high selectivities, rubbery materials are generally unable to be self-supporting under pressure in a high surface area hollow fiber form. This problem can be circumvented by placing a thin film of the rubber on a microporous support to make a composite membrane (42). Generally, however, the much higher selectivities of glassy polymers for separating gases make glasses the favored polymeric materials in separation applications.

For cases involving a random copolymer or a miscible blend of two amorphous rubbery polymers, the behavior is generally a volume fraction weighted average of the permeabilities of the two homopolymers. On the other hand, the transport properties of immiscible blend systems depend significantly on the relative permeabilities and the morphology of the immiscible blend.

Nonideal Transport Effects in Rubbery Polymers

Plasticization and Hydrostatic Effects. New complexity arises in the basic transport properties of a polymer at higher penetrant activities, since the local concentration of penetrant within the polymer can become quite high. At higher pressures (approaching the saturated vapor pressure), these high concentrations can occur in cases where favorable polymer–penetrant interactions promote solubility. This is common for organic vapors and even for small polar or quadrupolar molecules such as CO_2, H_2S and SO_2. *Transport plasticization* is defined as a significant increase in the diffusivity of a penetrant because of facilitation of local polymer segmental motion caused by another penetrant molecule in its neighborhood. This definition applies both to the increase in diffusivity of a penetrant caused by the presence of its own kind and increases caused by a different component. Even for pure component penetrants, a detailed fundamental analysis of this phenomenon on a molecular basis has not been achieved; however, various free-volume analyses are available (43).

Plasticization is typically an unfavorable phenomenon in separation applications because permselectivity is reduced as the diffusivity of a slower penetrant is increased. In the case of gases, plasticizing phenomena are suppressed because of hydrostatic compression in some polymers despite rather high sorption levels. Analysis in terms of the free-volume approach requires consideration of the compressibility of the rubbery matrix. In fact, exposure to the hydrostatic pressure of low solubility gases, such as helium or nitrogen, may actually compress out free volume and thereby reduce the ability of polymer segments to open gaps for movement of other segments or sorbed penetrants.

Some data (44) indicate a marked reduction in diffusivity of *n*-butane as the external pressure of helium is increased, and it was concluded that helium gas applied to silicone rubber acts only as a pressuring medium within experimental

limitations. The helium decreases the free volume of the silicone rubber and thus decreases its molecular motion. Plasticization and hydrostatic effects on the permeability of carbon dioxide, helium, nitrogen, methane, and ethylene in silicone rubber also have been studied (45). Over an extended pressure and concentration range, both compression of free volume and eventual plasticization have been observed for these different penetrants. As the amount of sorbed penetrant increases, the plasticization effect eventually overcomes the hydrostatic compression effect on the rubbery matrix for the more condensable penetrants such as carbon dioxide and ethylene.

The local solubility and diffusivity must be considered to see when true transport plasticization occurs. For this it is more useful to consider the local mutual diffusion coefficient $D_{AP}(C)$ rather than the average value assessed from equation 30. The local mutual diffusion coefficient is a measure of the ability of a penetrant to move through the membrane at a point where the local conditions are well defined in terms of the local penetrant concentration C_A, volume fraction φ_A, weight fraction ω_A, or penetrant fugacity, whichever is most convenient.

Figure 8 (45) shows the permeation data for methane, carbon dioxide, ethylene, helium, and nitrogen in silicone rubber at 35°C over a broad range of pressures. The data agree reasonably well with the data reported previously over a smaller pressure range (46). For helium and nitrogen, which have low critical temperatures, the permeability decreases with increasing pressure, while it increases with increasing pressure for carbon dioxide and ethylene, which have relatively high critical temperatures. For methane, with an intermediate critical temperature, the permeability shows negligible pressure dependence.

The sorption isotherms shown in Figure 9 (16) for each of the penetrants obey Henry's law at low pressures, and the more strongly sorbing carbon dioxide and ethylene show Flory–Huggins swelling behavior at high pressures. The lines in these plots are, in fact, modified Flory–Huggins fits to the data according to equation 36, which includes the presence of the small amount of cross-linking in the sample (47):

$$\ln\left(\frac{p}{p_0}\right) = \ln(\varphi_A) + (1-\varphi_A) + \chi(1-\varphi_A)^2 + V_A\left(\frac{v_e}{V_0}\right)\left((1-\varphi_A)^{1/3} - \frac{(1-\varphi_A)}{2}\right) \tag{36}$$

where p is the penetrant pressure, p_0 is the vapor pressure of the penetrant, V_A is the partial molar volume of the penetrant, v_e is the effective number of cross-links expressed in moles, V_0 is the volume of the penetrant-free polymer, and χ is the Flory–Huggins interaction parameter. The permeability and sorption isotherms can be used along with the following expression to calculate the local concentration-dependent mutual diffusion coefficient (48):

$$D_{AP}(C_{A_2}) = \left[\left\{P(p) + p\frac{dP}{dp}\right\}\left(\frac{dp}{dC_A}\right)\right)\Bigg|_{p2} \tag{37}$$

The Flory–Huggins expression can be used to evaluate the dp/dC_A term at the upstream pressure for conditions where Henry's law does not apply; however, only the region of Henry's law is discussed here. Figure 10 shows the local diffusion coefficient for the various penetrants as a function of local fugacity in silicone

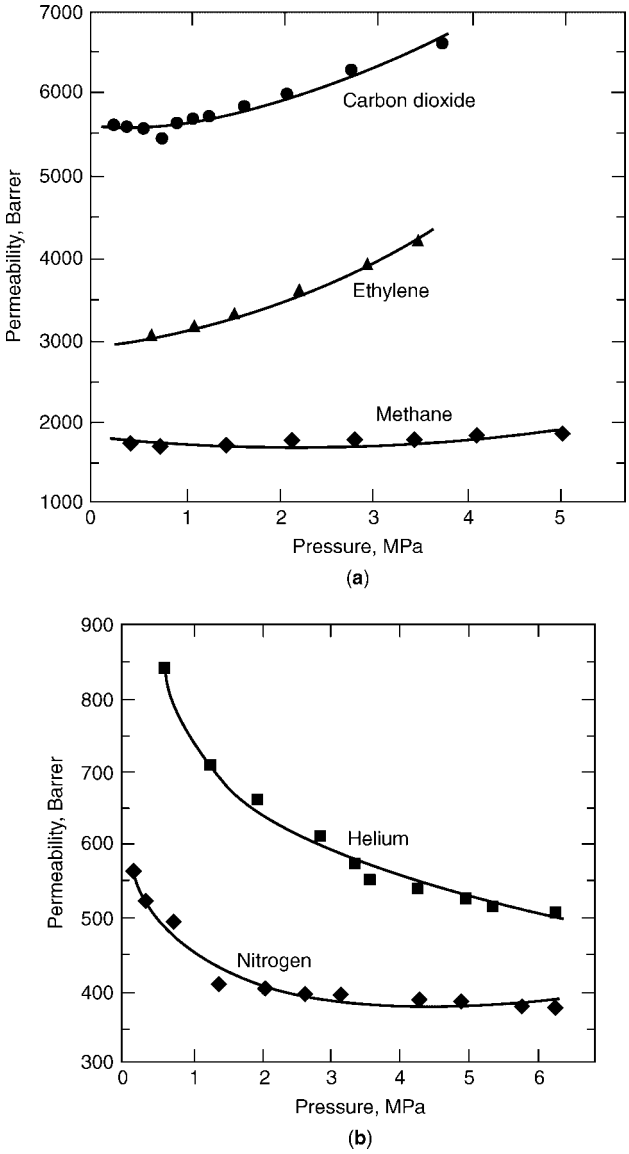

Fig. 8. Comparison of the pure-gas permeabilities of various gases in silicone rubber at 35°C. (**a**) CO_2, C_2H_4, and CH_4; (**b**) He and N_2 · 1 Barrer = 10^{-10} [cm^3(STP)cm]/($cm^2 \cdot s \cdot cm$ Hg) = 0.335 mmol/(m · s · TPa). To convert MPa to psi, multiply by 145.

rubber (45). This can be easily converted to a plot of $D_{AP}(C)$ vs C using the sorption isotherm data if desired. For carbon dioxide, the fugacity differs by as much as 22% from the pressure at the maximum pressure studied. The chemical potential difference is of course the true thermodynamic driving force for diffusion and should be used in mixed-gas calculations.

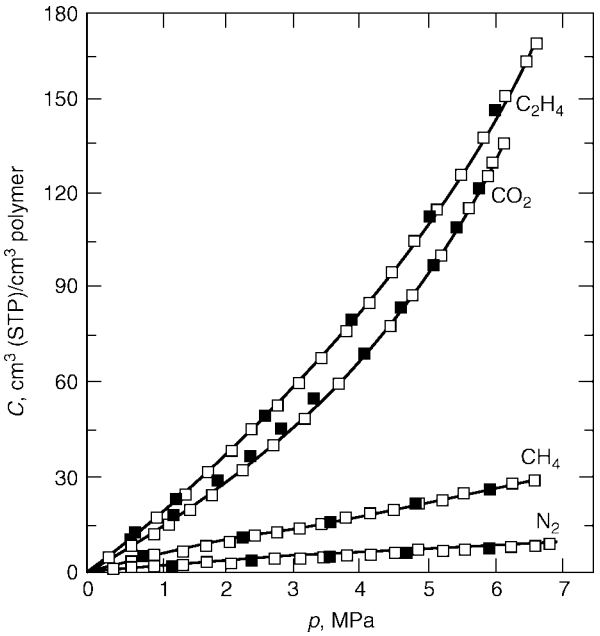

Fig. 9. Sorption isotherms for Sorption and desorption of various gases in silicone rubber at 35°C. □, Sorption; ■, desorption. To convert MPa to psia, multiply by 145.

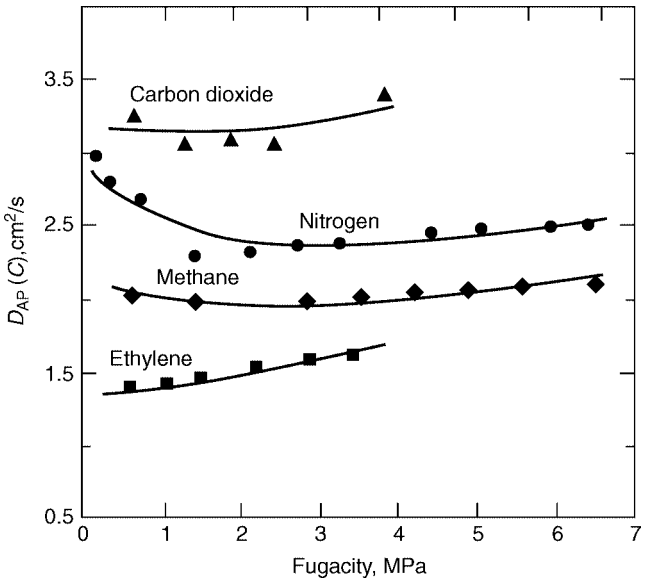

Fig. 10. The local effective diffusion coefficient of various penetrants in silicone rubber. To convert MPa to psia, multiply by 145.

The local diffusion coefficient of nitrogen decreases with increasing pressure until around 2.1 MPa (300 psia), where it levels off and slowly begins to rise with increasing pressure. These results indicate that the fractional free volume of the polymer is reduced because of nitrogen's hydrostatic pressure. At higher nitrogen pressures the solubility level is sufficient to oppose the compressive effect and cause the diffusivity to begin to increase with pressure as free volume is added by the penetrant. The results for methane and carbon dioxide show a slight decrease in diffusivity with increasing pressure, but both gases reapproach their original diffusivity at higher pressures because of their higher solubilities. Ethylene exhibits an immediate increase in diffusivity with pressure that is not surprising, given its significant solubility and the large dilation in volume with increasing ethylene pressure, shown in Figure 11 (16). Even below 0.7 MPa (100 psia), more ethylene is sorbed than nitrogen in the silicone rubber at 7 MPa (1000 psia).

The negative slope of the permeability vs pressure plot for helium and nitrogen in Figure 8**b** and the positive permeability slope for the other gases in Figure 8**a** can be explained by these two competing effects caused by the penetrant pressure. The data in Figure 11**b** show an actual compression in volume, even though a small but measurable amount of sorption was observed under these conditions. The results are believed to occur because of the low solubility of helium and high compressibility of silicone rubber. Therefore, the two competing factors that determine the volume dilation of the polymer are (*1*) the sorption of gas into the polymer that results in an increase in free volume, and (*2*) the hydrostatic pressure on the film that reduces the free volume. The second effect is usually small and is overcome for gases that have significant sorption levels. The net result of these two opposing effects determines whether the permeability (and diffusivity) will increase or decrease with increasing pressure. These two competing factors can be described quantitatively by equations 23 and 26.

The expression for the local mass diffusion flux accounting for the frame of reference term discussed in equation 2b is given below:

$$n_A = \frac{-\rho D_{AP}}{1-\omega_A}\frac{\partial \omega_A}{\partial z} \tag{38}$$

Using equations 7 and 37, the effective mutual diffusion coefficient obtained from analysis of the permeability versus pressure data can be related to the self-diffusion coefficient of the penetrant, namely

$$D_{AP} = D_A^*(1-\omega_A)\left(\frac{\partial \ln a_A}{\partial \ln \omega_A}\right) \tag{39}$$

The factor $(\partial \ln a_A/\partial \ln \omega_A)$ is available from the sorption measurements such as those in Figure 9. For the cases considered here, where Henry's law applies, this factor is simply equal to unity, whereas it is given by equation 40 for the case where curved isotherms characterized by the Flory–Huggins equation apply.

$$\left(\frac{\partial \ln a_A}{\partial \ln \omega_A}\right) = \frac{\omega_P \rho_A^2}{(\omega_A \rho_P + \omega_P \rho_A)^2}\left(1 - \frac{2\chi \omega_A \rho_P}{\omega_A \rho_P + \omega_P \rho_P}\right) \tag{40}$$

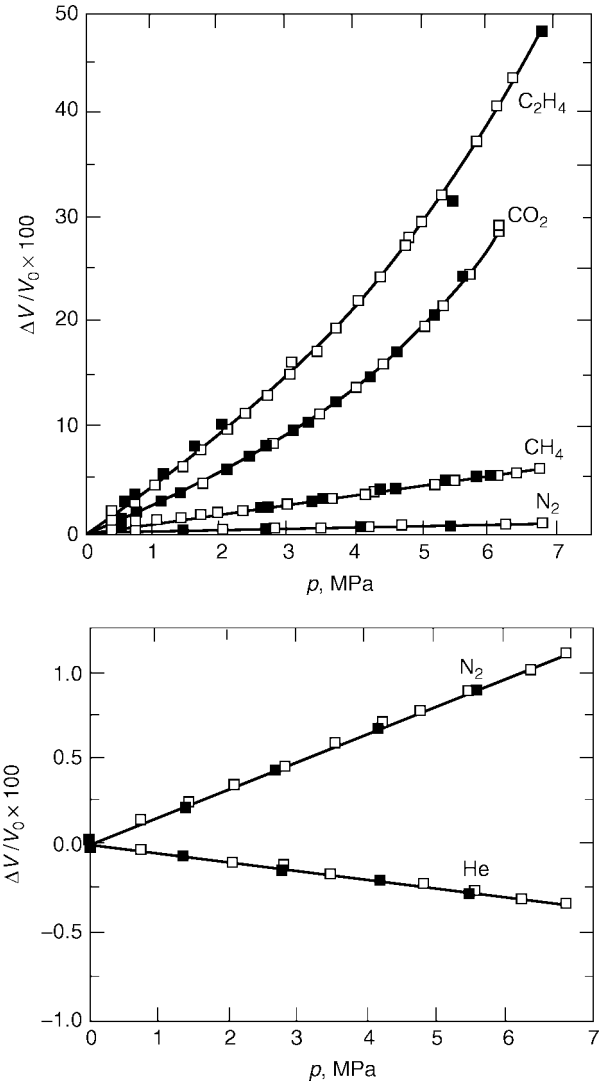

Fig. 11. Volume dilation isotherms for Sorption of various gases in silicone rubber at 35°C. □, Sorption; ■, desorption (46). To convert MPa to psia, multiply by 145.

where ρ_A and ρ_P are the mass densities of the pure penetrant and polymer, respectively.

Penetrant mobilities ($\mathcal{M}_A$) were determined as a function of local fugacity for silicone rubber (45). The mobility of nitrogen decreased with increasing pressure, but the mobility of carbon dioxide increased, suggesting that nitrogen acts predominantly as a pressurizing agent and CO_2 acts primarily as a plasticizing agent. The permeability of helium and nitrogen decreased with increasing pressure because of the reduction in free volume caused by the hydrostatic pressure of the gas. Therefore, at high pressure, these gases tend to lower the permeability of each component unless another component has sufficient solubility to overcome the

hydrostatic effect. To test this hypothesis the silicone rubber films were exposed to both a 10/90 mol% mixture and a 50/50 mol% mixture of carbon dioxide and nitrogen.

The presence of additional penetrants in the feed stream can be accounted for by the addition of a term in the free-volume equation to account for the presence of each penetrant and the applied hydrostatic pressure above $p_s = 101.3$ kPa (1 atm) as follows:

$$D_A^* = RT\mathcal{M}_A = A_d \exp\left(\frac{-B_d}{v_{fs} + \alpha[T - T_g] - \beta[p - p_s] + \gamma_1\varphi_1 + \gamma_2\varphi_2 + \cdots}\right) \tag{41}$$

The carbon dioxide permeability for both mixtures was depressed below the pure carbon dioxide values, but the carbon dioxide permeability for the 50/50 mixture did not display a decreasing tendency with pressure as was observed for the 10/90 CO_2/N_2 mixture. Therefore, at the lower nitrogen partial pressures observed in the 50/50 mixture, the impact of the hydrostatic pressure effect is reduced by the swelling effect of CO_2. Although the swelling effect of CO_2 cannot completely overcome the hydrostatic pressure effect of CO_2 nitrogen, it greatly offsets its influence.

Important extensions of the foregoing example, where hydrostatic pressure effects may be of considerable importance, involve supercritical extraction using high pressure CO_2 or ethylene for processing of foods, pharmaceuticals, and purification of polymers by removal of trace monomers (49). This topic involves greater complexity than the binary diffusion case. Moreover, the factor involving the activity coefficient derivative may become very significant near the critical point. Transport behavior in these systems, however, can be anticipated on the basis of the results shown for the pure components. Little enhancement in the self-diffusion coefficient of the penetrant in these rubbery polymers is apparent at pressures below the critical pressure; however, both carbon dioxide and ethylene begin to overcome the effects of hydrostatic pressure and to show upturns in their mobilities as the critical conditions are approached. Most of the work in the area of mass transport under supercritical conditions in polymers has been rather qualitative, but more quantitative analysis should be possible using the free-volume model.

Penetrant Clustering. Clustering may reduce the effective mobility of a penetrant such as water or methanol that can self-associate. The activated state representation of diffusion is typically used to discuss the suppressed diffusion coefficient for a clustered penetrant. If the diffusion process involves primarily jumps by monomeric, unassociated penetrants, energy must be available both to make a gap to allow the penetrant to jump into and to cause the dissociation of one of the penetrants in a local region adjacent to the gap. Therefore, higher activation energies for diffusion and, hence, lower diffusion coefficients at activities above which clustering occurs are expected if this visualization is correct. Work to document this point of view has been done for silicone rubbers (50), poly(alkyl methacrylates) (51), and hydrocarbon rubbers (52). Typical diffusion coefficients and activation energies for diffusion of water and methanol, both of which tend to cluster in hydrophobic environments, are shown for various rubbery materials

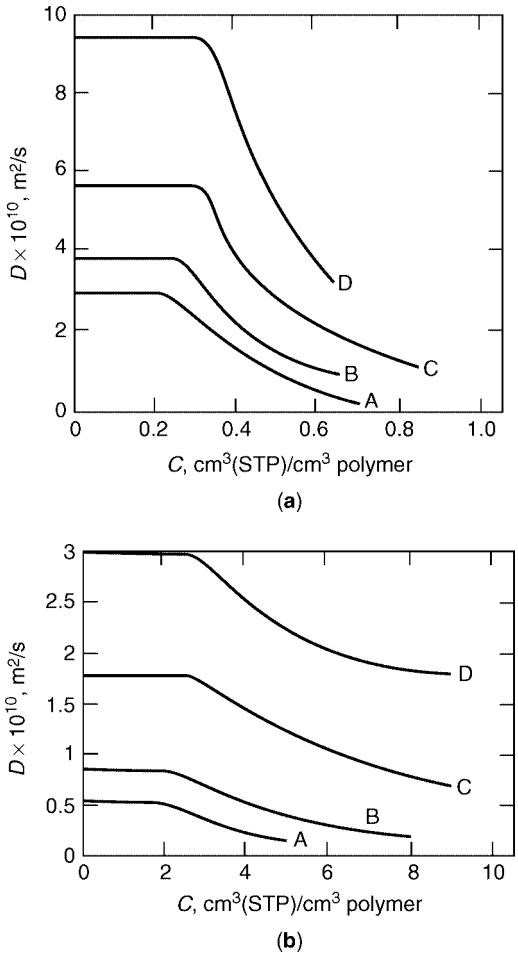

Fig. 12. (**a**) Effects of water clustering on diffusion in rubbers. Concentration dependence of the diffusion coefficient for water in Cariflex IR305: A, 37°C; B, 42°C; C, 50°C; D, 61°C. (**b**) Effects of methanol clustering on diffusion in rubbers. Concentration dependence of the diffusion coefficient for methanol in Cariflex IR305: A, 26°C; B, 31.1°C; C, 50°C; D, 60°C.

in Figures 12**a** and 12**b** (52) and in Table 4 as a function of concentration over conditions prior to and after the onset of clustering.

The sorption behavior in clustering systems is often discussed in terms of the cluster integral G_{AA} given below in terms of the partial molar volume V_A, the activity a_A, and the volume fraction of penetrant φ_A:

$$\frac{G_{AA}}{V_A} = -(1-\varphi_A)\left(\frac{\partial(a_A/\varphi_A)}{\partial a_A}\right)_{p,T} - 1 \tag{42}$$

G_{AA} may be determined from equilibrium sorption data as a function of penetrant partial pressure. Based on the theory of Zimm and Lundberg (53), the cluster function given by (φ_A G_{AA}/V_A) equals the excess number of A molecules

above the number that would exist in the neighborhood of an arbitrarily chosen type A molecule if the mixing were totally random, ie, no clustering. As shown in Figure 12, the effective mutual diffusion coefficient is constant below the activity at which clustering occurs. The activity at which the cluster function deviates significantly from zero corresponds to the point at which the diffusion coefficient begins to drop significantly, and the activation energy begins to increase.

Intermediate-Size Penetrants. These penetrants are defined as molecules with sizes approaching a polymer segment, but much smaller than an entire polymer chain. The infinite-dilution mutual diffusion coefficients for increasingly large, but not macromolecular, penetrants approach the diffusion coefficient for the segment of a polymer diffusing within itself. Movement of the entire polymer molecule itself is clearly a slower and more complex concerted process than the local movement of its segments; however, the segmental mobility and the self-diffusion coefficient of the entire molecule can be related as discussed later.

For intermediate-size penetrants such as typical organic solvents, the self-diffusion coefficient of the polymer is much smaller than that for the penetrant. Consistent with this expectation, equation 8 has been found to be appropriate (36) for mass fractions of toluene as high as 85%. Therefore, for low and intermediate penetrant concentration, equation 8 should still apply as it did in the case of gases and other small penetrants.

The data in Figure 3 reflect the tendency to approach an infinite-dilution asymptotic mobility as the diameter of these intermediate-sized penetrants

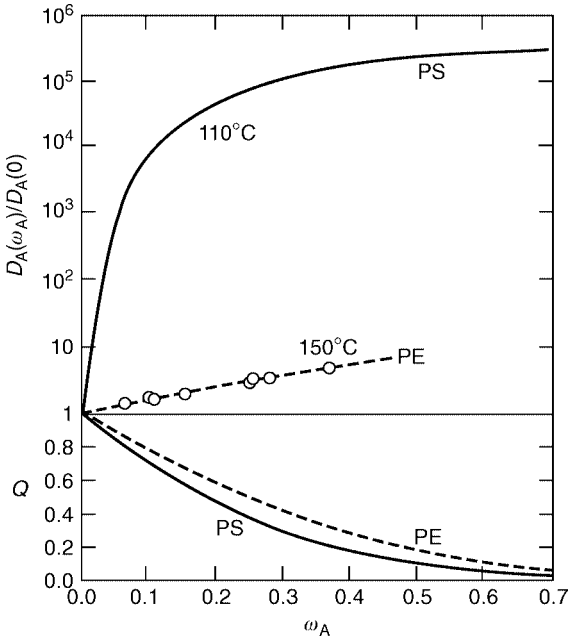

Fig. 13. Concentration dependence of the self-diffusion coefficient and the thermodynamic factor Q for the toluene–polystyrene system at 110°C and for the *o*-xylene–polyethylene system at 150°C. $Q = (1 - \omega_A)(\partial \ln a_A/\partial \ln \omega_A$. From Ref. 45.

increases (see eq. 6):

$$\lim_{\omega_A \to 0} \{D_{AP}\} = \lim_{\omega_A \to 0} RT\mathcal{M}_A(1-\omega_A)\left(\frac{\partial \ln a_A}{\partial \ln \omega_A}\right) = RT\mathcal{M}_A = \frac{RT}{\zeta_A} \tag{43}$$

Care must be used in applying such arguments when estimating practical diffusion coefficients, however, since increases in ω_1 above the infinite-dilution limit can cause significant changes in the effective mobility of the penetrant. Moreover, the $(\partial \ln a_A/\partial \ln \omega_A)$ term can deviate from unity at weight fractions as small as 10–20%, as was indicated in the case of carbon dioxide and ethylene earlier. In the case of *o*-xylene diffusion in polyethylene at 150°C, both the effects of plasticization and of the $(\partial \ln a_A/\partial \ln \omega_A)$ term on the self-diffusion coefficient have been analyzed and are shown in Figure 13 (34).

Except for supercritical extraction conditions, hydrostatic pressure effects are typically of negligible importance for simple solvent vapors diffusing in polymers, since the saturation vapor pressure is low, <101.3 kPa (1 atm), in most applications. The predictive power of the approach is indicated by the results for the mutual diffusion coefficient of toluene in a toluene–polystyrene system (Fig. 14) (35).

The rather complex behavior represented in Figure 14 was analyzed in terms of the respective contributions to the self-diffusion coefficient and the significant reduction in the thermodynamic $(1 - \omega_A)(\partial \ln a_A/\partial \ln \omega_A)$ terms in equation 39. These two constituent contributions indicate that the dramatic increases in the

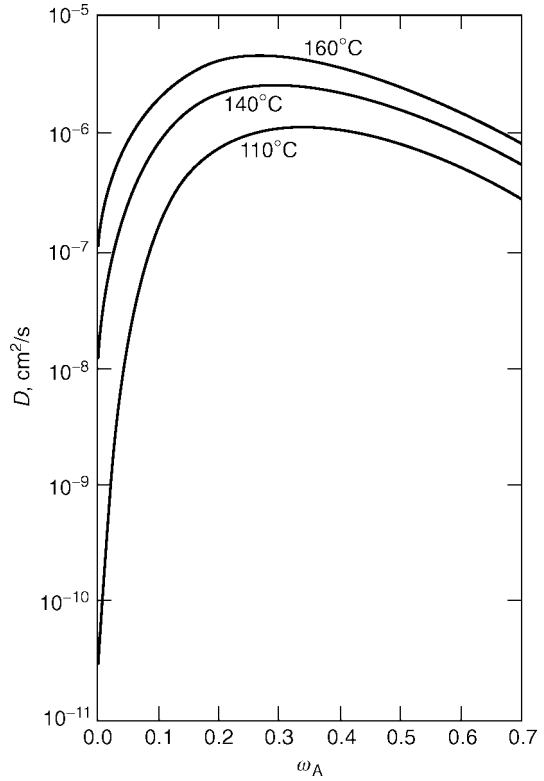

Fig. 14. Dependence of diffusivity on mass fraction for the toluene–polystyrene system.

mutual diffusion coefficient at low solvent mass fractions in the polystyrene system at 100°C is primarily due to dramatic transport plasticization-induced changes in the penetrant self-diffusion coefficient, rather than due to the thermodynamic term.

The strong temperature dependence of the infinite-dilution diffusion coefficient in the vicinity of the glass-transition temperature of the polymer ($T_g = 105$°C for polystyrene) cannot be predicted by a simple exponential expression such as the activated state model (equation 15a) unless the energy of activation is allowed to vary. Variation in the activation energy in this region, where backbone segmental motions are beginning a transition from a primarily oscillatory nature around relatively fixed positions to include large rotary crankshaft motions, is not unreasonable, but it cannot be predicted directly from the activated state theory. On the other hand, such near- T_g behavior is a natural expectation of the free-volume theory based on the Williams–Landel–Ferry (WLF) description of the effects of free volume on polymer properties.

Recent attempts to apply the free-volume approach below the glass transition have also been made (33). This sub- T_g problem often includes additional factors not related simply to Fickian transport processes, since the movements of intermediate-sized penetrants in contact with glassy polymers often induce complex time-dependent relaxations.

Semicrystalline and Cross-Linked Rubbery Polymers

Gases and Low Activity Vapors. Regions of crystallinity or points of chemical cross-linking have somewhat similar effects on the transport properties of a rubber causing restriction of swelling and suppression of long-range chain segmental motion. Semicrystalline polymers, however, are more complex than cross-linked materials because of tortuosity caused by the presence of the typically impermeable crystalline regions. Similarly, adding fillers such as glass, talc, or mica particles to an amorphous matrix prior to cross-linking can make the transport properties of the resultant material take on a semicrystalline-like character if the interfacial adhesion between the filler and matrix phase is good. Promotion of adhesion can be achieved by using interfacial wetting agents such as silanes and titanates that bond to the inorganic surface and can either chemically bond or physically interact with the elastomer matrix. In the absence of such adhesion promoters, the barrier properties may be degraded because of interfacial defects not found in semicrystalline materials under most conditions.

The effects of fillers or crystallites can be influenced considerably not only by the volume fraction of this phase, which affects the solubility of a component directly, but also by the area-to-thickness aspect ratio and orientation of the filler with respect to the direction of permeation. The orientation factor affects the apparent diffusivity by determining how the crystallites or fillers behave as tortuous impediments to penetrants. This effect is not considered in the simple free-volume analysis (eq. 18a). Since the effect of orientation can be significant, approaches which account for tortuosity and chain mobility are more desirable. Examples of materials where orientation effects are significant include phase-separated urethane–elastomer block copolymers and random copolymers of ethylene and vinyl alcohol since the two components are able to cocrystallize in the same crystal lattice. This latter copolymer is used as a barrier in which the permeability of the material can be tailored by varying the amount of the highly polar, diffusion-inhibiting (vinyl alcohol) component without strongly affecting the crystallinity.

Studies of gas sorption and transport strongly support the notion of the impenetrability of crystalline domains by even tiny gas molecules. As shown in Figure 15, the solubility coefficient ($\bar{S}_i = C_i/p_i$) of both gases and low activity vapors are essentially proportional to the volume fraction of amorphous material Φ_a and the intrinsic solubility coefficient for the totally amorphous material $\bar{S}_a$ (54), ie

$$\frac{\bar{S}}{\bar{S}_a} = \Phi_a \tag{44}$$

The effects of crystallinity on the diffusion coefficient can be more complex than this simple volumetric exclusion, since the crystallites may act not only as tortuous barriers, but also as effective restrictors of chain motion analogous to chemical cross-linking. This twofold effect has been treated (54) in terms of a tortuosity factor τ, and a chain immobilization factor β^*, both of which increase with increasing crystalline fraction. The parameters D and D_a are the diffusion

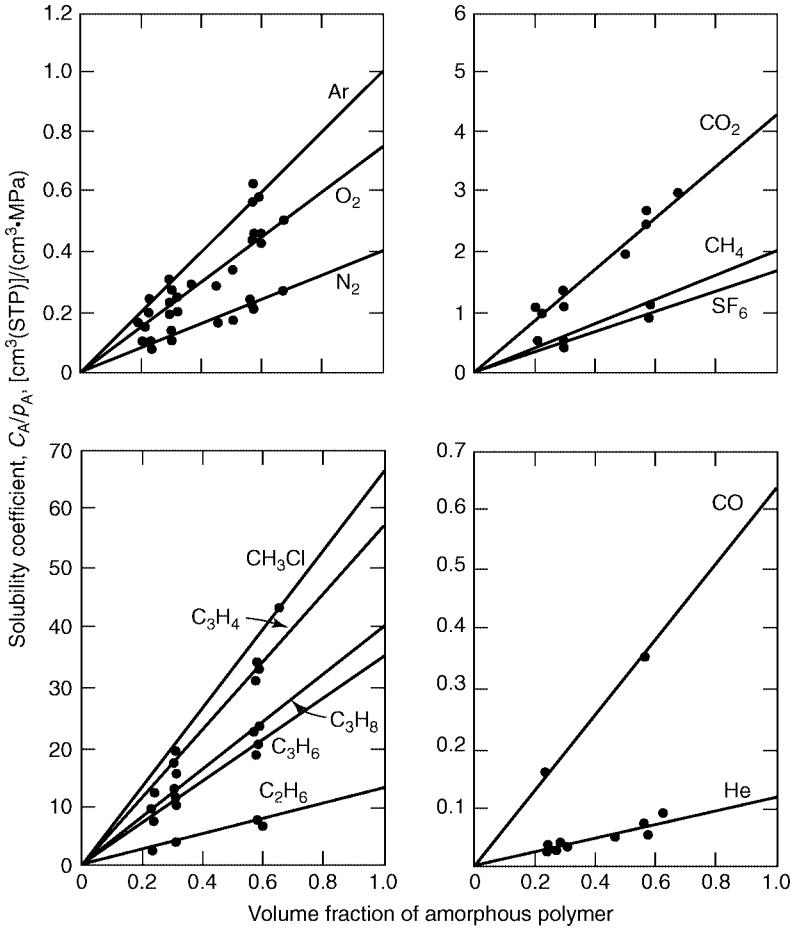

Fig. 15. Linear relationship between the infinite dilution solubility coefficient and the amorphous fraction in polyethylene at 25°C (30). To convert to [cm^3(STP)cm]/(cm^3 · MPa) to [cm^3(STP)]/(cm^3 · atm), multiply by 0.1013.

coefficients in the actual sample and in a totally amorphous sample, respectively:

$$D = \frac{D_a}{\tau\beta^*} \tag{45}$$

Chain restriction effects due to the effective cross-linking of crystallites may be negligible for helium compared to other penetrants due to the much smaller free volume required for an activated jump by helium. For example, 0.075 nm^3 is the required free volume for a jump of helium in poly(vinyl acetate) as opposed to 0.3 nm^3 for O_2 and 0.69 nm^3 for CO_2. This premise allowed estimation of the two factors in equation 45 for polyethylene (40). A 65% reduction in helium diffusivity for a 50% amorphous fraction material relative to a hypothetical branched polyethylene with no crystallinity was attributed to tortuosity. The diffusivities of the amorphous polyethylene were approximated as equivalent to

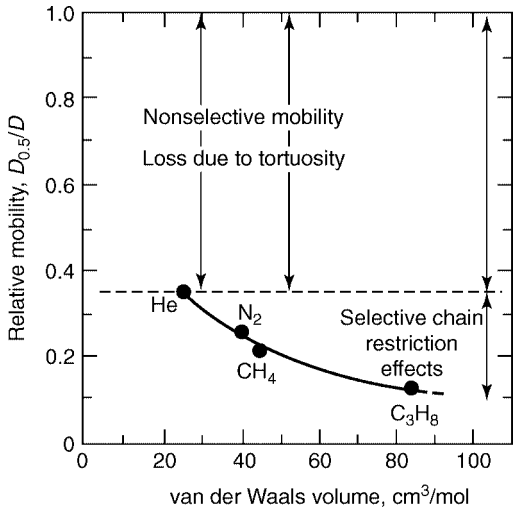

Fig. 16. Relative mobilities in semicrystalline and amorphous polyethylene for several penetrants as a function of penetrant van der Waals volume.

those of unvulcanized natural rubber. The reduction in diffusivity from simple tortuosity in polyethylene was estimated to be uniformly equal to 65% for all penetrants, and additional depressions in diffusivity relative to the amorphous reference were attributed to chain restriction effects due to the crystallites. The relative mobilities in the semicrystalline and amorphous samples are summarized in Figure 16.

In a treatment of the effects of crystallinity on transport in rubbery polymers using a modification of free-volume expressions (26), it was suggested that the introduction of crystallinity reduces the freedom of motion of amorphous chain segments between crystals. Although these ideas are physically consistent with those described above in terms of the chain immobilization factor β^*, a rather different analytical form of the diffusion coefficient is obtained.

The complementary effects of orientation and crystallinity can be treated in terms of the τ factor, since the aspect ratio and degree of orientation may alter the degree to which tortuosity influences the suppression in D. However, τ must currently be used for characterization rather than being an *a priori* predictable factor. A thorough treatment of the effect of uniaxial elongation at room temperature has been given for CO_2 diffusion in low density polyethylene (55). The effects of the orientation are complex. Prior to the onset of plastic deformation at 6% elongation, the solubility increases about 3%, and the diffusivity increases about 10%, and so a net increase of about 13% is observed in the permeability, presumably because of the introduction of free volume in the sample that dilates during the elongation. Such dilation is characteristic of materials with a Poisson ratio less than 0.5.

On the basis of increase in the sorption coefficient, it is suggested that the deformation causes dilation of the amorphous regions. At larger deformations, D falls below its original value for the unoriented crystalline material, since small increases in free volume are unable to offset the very large increase in tortuosity.

This increase in tortuosity can be anticipated as crystalline regions become more deformed by slippage and crystal lamellae rotate to adopt orientations more parallel to the film surface. Such organization makes efficient use of the lamellae as overlapping tortuous barriers capable of producing larger reductions in the effective diffusion coefficient than would be possible with spherical crystallites or even randomly oriented lamellae of equivalent volume fraction. Moreover, the alignment of chains in the amorphous regions between the plastically deformed spherulites may also act to increase the chain immobilization factor β^*.

Larger permanent deformations (up to 300% elongation), induced by either uniaxial drawing or roll processing at room temperature, reportedly produce reductions in diffusivity, solubility, and permeability (56). Larger reductions were seen for roll processing as compared to the simple drawing process, presumably due to the elimination of interfacial defects between the crystalline and amorphous phases in the rolling process.

The effects of crystalline regions on glassy materials have been found to be less extreme than for rubbery materials. For example, the chain immobilization factor affects the diffusion of different sizes of penetrants only in rubbery materials (57). This effect has been explained in terms of the low mobility of chain segments in glassy environments compared to the rubbery state. The concept of chain immobilization by crystallites loses significance in glasses, since the rigidity of the polymer backbone apparently outweighs any additional restriction on mobility imposed by crystallinity.

Although it appears in general that the assumption of impenetrability of crystalline domains is valid, poly(4-methyl-1-pentene) (PMP) may have crystals that do not fit this pattern (58). Gaps of almost 0.4 nm appear to exist between the chain segments in this material, which is consistent with the low crystal density of <0.85 g/cm^3 (Fig. 17). Contrary to the polyethylene case, these results provide provocative support for the possibility that measurable sorption does occur in the crystalline regions of this polymer. The two independent measures of crystallinity offered by X-ray and thermal analysis were found to be in good agreement.

Although the crystalline regions of PMP were found to be penetrable, the CO_2 and CH_4 permeabilities are still dependent on Φ_a, since the solubilities and diffusivities in the more structured phase were lower than in the amorphous phase. It was concluded that gases such as CO_2 and CH_4 dissolve in the crystalline regions of PMP at about 1/3 to 1/4 the extent in the amorphous phase (58). Moreover, the diffusion coefficients of CO_2 and CH_4 are about 37% and 64% lower, respectively, in the crystalline phase than the amorphous phase.

The nonzero intercept in the solubility coefficient vs amorphous fraction plot in Figure 18 (59) supports the notion that sorption occurs in the crystalline regions. Although the data provide rather strong support for the ability of small gases to penetrate the crystals of PMP, it is possible that defects at the interface between the crystalline and amorphous regions are the source of the nonzero intercept. This mechanism could also explain the tendency for the solubility associated with the crystalline phase to increase proportionally to the crystalline fraction since more interfacial defects would accompany the increasing crystalline fraction. However, it is unclear why permeation and diffusion through such regions would have lower diffusion coefficients as opposed to the amorphous phase, unless severe restriction of chain segmental mobility occurs in this region. For PMP, close to its T_g, the

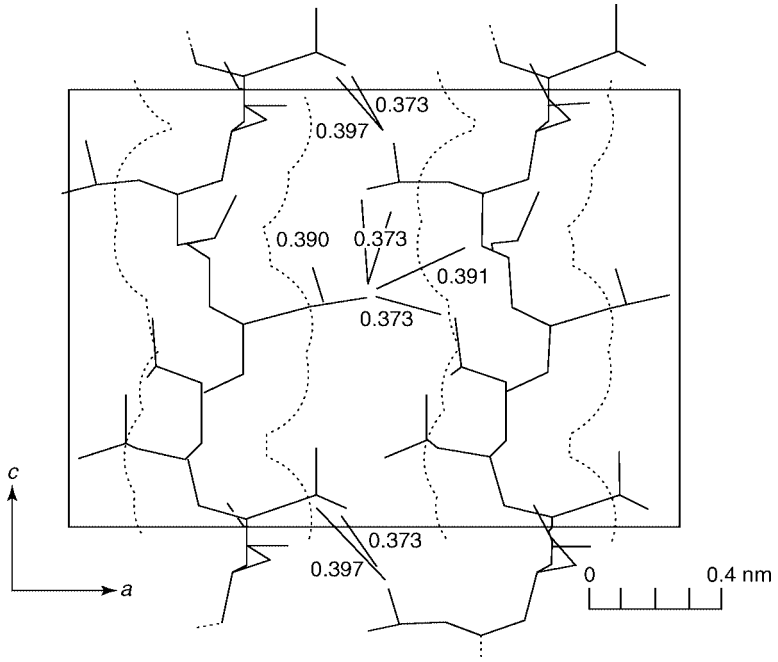

Fig. 17. Crystalline domains of poly(4-methyl-1-pentene).

concept of chain immobilization by crystallites is expected to be less significant than in the case of rubbery polyethylene because the rigidity of the glassy PMP backbone is expected to outweigh immobility imposed by neighboring crystallinity. Nevertheless, complementary proof of the important conclusions is desirable, and may be possible by consideration of the data in Table 5.

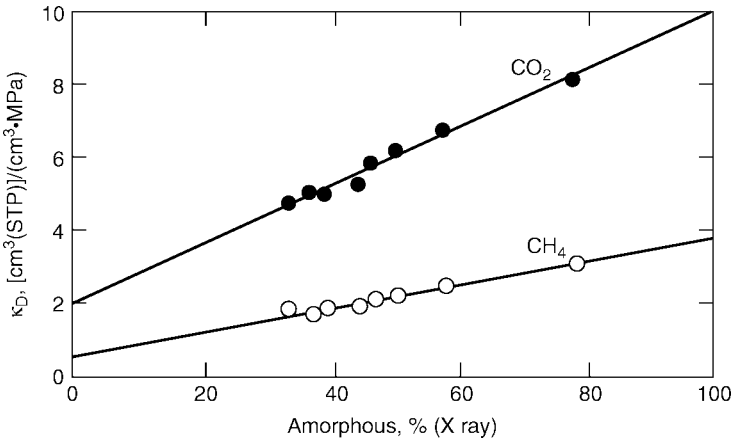

Fig. 18. Solubility coefficient vs amorphous fraction for poly(4-methyl-1-pentene). To convert [cm^3(STP)]/(cm^3 · MPa) to [cm^3(STP)]/(cm^3 · atm), multiply by 0.1013.

[a] Zeolite sieving diameters.
[b] Ref. 53

The zeolite sieving diameters in this table represent effective minimum dimensions as compared with the Lennard–Jones diameters for various penetrants. For more or less spherical penetrants such as CH_4, the two diameters agree rather well. In the case of a nonspherical molecule such as CO_2, however, restricted environments such as a zeolite can detect a minimum projected dimension that differs from the Lennard–Jones diameter characteristic of tumbling in a relatively unrestricted liquid or gaseous environment. The crystalline cage of the PMP may be acting similarly to a zeolite, and if this is the case it is anticipated that larger penetrants such as propane may, indeed, be effectively excluded from entering the crystalline region. In this case, the same type of behavior is expected for the solubility coefficient for propane in PMP as is illustrated for propane in polyethylene, ie, $\bar{S}/\bar{S}_a$ directly proportional to Φ_a and passing through the origin.

High Activity Vapor and Liquid Transport in Semicrystalline Rubbery Polymers

In considering the transport behavior of high activity vapors and liquids in semicrystalline polymers at low solubility (eg, water in polyethylene), small degrees of transport plasticization or clustering may need to be considered to generalize the $\bar{D}$ and $\bar{S}$ to include dependence on activity. Combination of these more general relations for $\bar{D}$ and $\bar{S}$ into the permeability relationship of equation 29 should approximately describe the steady-state permeability of the amorphous fraction of the material. Generally, the permeability of the crystalline fraction is assumed to be zero. Tortuosity and chain-restriction effects should be of decreasing importance as the extent of swelling increases. At high degrees of swelling (above 70% solvent fraction), frame of reference corrections must be incorporated in formulating steady-state permeability expressions.

For high solubility penetrants, great complexity is often observed in sorption–desorption kinetics or transient permeation due to time-dependent rearrangements of crystalline regions in response to swelling-induced stresses (59,60). These

are non-Fickian diffusional behaviors. Protracted approaches to equilibrium in the surface concentration may make the approach to sorption equilibrium or steady-state permeation behavior much slower than expected on the basis of the effective diffusion coefficient determined from equation 37 (5).

Using sorption–desorption kinetics, the extent of non-Fickian behavior decreases as the thickness of the film increases. Presumably, as the ratio of the time scale for diffusion to the time scale for stress-induced relaxation (ℓ^2/D) becomes large, the time-dependent relaxation occurs so rapidly (relatively) that it has a small effect on the diffusion process. In other words, in the limit where molecular-scale responses to swelling stresses are rapid compared to the rate of diffusion, the process appears to be Fickian. This is the case for totally amorphous rubbery polymers that behave as high molecular weight liquids.

Film formation protocols may cause significant nonuniformity in structure between a thin surface layer and the bulk of the film, especially when casting on a chilled roll. This effect can cause apparent thickness-dependent behavior of permeability and diffusivity parameters. Effectively, the film behaves as a laminate with different transport properties that can be treated according to a simple laminate model involving series resistances. Of course, assessment of the thickness of the surface layer must be possible for this approach to have utility. The skin layer reportedly increases in thickness as the rate of crystallization increases (61) because of contact with surfaces that promote surface nucleation. The diffusion coefficient of ethane in the 25-μm-thick surface layer of a quenched polyethylene film has been reported to be about twice as high as that in the bulk, because of favorable orientation of crystallites in this skin region of the semicrystalline film (62). In some cases, true laminate structures composed of chemically different materials are needed to obtain optimum performance in barrier applications. An example is the commercial food packaging made from ethylene–vinyl alcohol (EVOH) copolymers coextruded with polypropylene to form a laminate (63). In the dry state, the EVOH copolymers are among the best, easily processible oxygen barriers known. However, at elevated relative humidities (>80–90%), water disturbs the strong hydrogen bonds between the vinyl alcohol repeat units in the amorphous regions and reduces its barrier properties significantly. At still higher relative humidities and temperatures typical of retort conditions needed to kill microorganisms, actual disruption of crystalline domains is likely. To mitigate such problems, polypropylene layers are used to sandwich the barrier layer using multilayer coextrusion technology. This minimizes the quantity of the more expensive oxygen barrier (EVOH) but provides a package with sufficient mechanical strength.

Modeling of the transient-state transport process of water and oxygen through such a laminated barrier material also containing intermediate tie layers to promote adhesion is complex. Reported partial solutions use different physical approximations (64). Typically, the approach is to model the total amount of water, which is the major plasticizing agent transported into the barrier film through the outer polyolefin guard layer during retort, and relate this weight fraction to a new effective oxygen permeability of the partially humidified barrier layer. During subsequent cooling and drying of the container, the water is removed by back permeation out of the package into the dry storage environment over an extended period of time determined by the relative thicknesses of the outer guard layer and

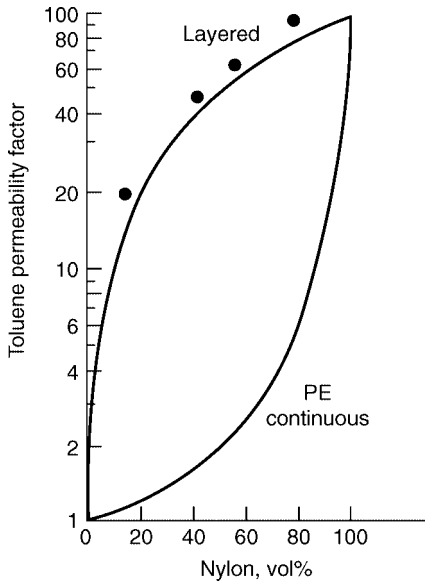

Fig. 19. Permeability of toluene in nylon–polyethylene barriers. The data (●) for a laminar blend is compared to theoretical permeabilities in a true laminate (upper curve) and in a homogeneous blend (lower curve). The permeability factor is the permeability in pure polyethylene divided by the permeability in the mixture.

the inside oxygen barrier layer. During this drying period a significant oxygen invasion can occur. Consequently, more complex structures are sometimes used to provide a desiccant material in the tie layer between the outer guard layer and the barrier layer to prevent the penetration of water into the barrier layer during the retort operations (65).

A laminar-blend technique can be used to achieve properties intermediate between those of the relatively expensive laminates formed by coextrusion and those of an inexpensive, but less effective, dispersion of a barrier component in a matrix of another material. For the laminate, the total barrier resistance is composed of the additive resistances contributed by each of the layers in the structure. For a simple dispersion of component A in a matrix of B, a volume fraction weighting of the permeabilities of the two components applies unless large aspect ratios are achieved (66). Laminar-blend technology achieves large aspect ratios by smearing out the dispersed barrier layer into thin lamellae with large area to thickness aspect ratio. Figure 19 shows the data and results of model calculations based on the two limiting cases of a true laminate or a homogeneous dispersion in comparison to the barrier properties of a laminar blend of nylon-6,6 and polyethylene for use in hydrocarbon barrier applications. The larger the aspect ratio of the primary barrier component, the closer the approach to the true multilayer laminate properties due to overlapping of the barrier lamellae (67). Such barrier-container issues involve not only a consideration of transport properties of materials, but also an economic weighing of the costs of processing and materials to achieve an optimum structure.

Glassy Polymers

Glassy polymers, polymers existing at a temperature below their T_g, are differentiated from rubbery polymers in discussions of physical properties because their responses in most experiments are quite different. Essentially all of the differences arise from the characteristic scales of the micromotions that occur at the segmental level in rubbery and glassy polymers. As noted earlier, the high molecular weight liquid-like nature of rubbers provides them with the ability to adjust their segmental configurations rapidly over significant distances by large-scale motions, such as the crankshaft example (Fig. 2); however, in the glassy state, only severely hindered torsional motions are possible.

The frequency and amplitude of torsional segmental motions increase as the temperature is raised and the glass transition is approached. Close to T_g, the frequency of torsional motions increases dramatically and gives rise to true rotational motions typical of rubbery materials. However, in glasses well below T_g, the intramolecular backbone motions occurring over time scales of seconds or microseconds are much less extensive than in rubbers and are believed to be primarily torsional oscillations (68).

A distribution of these torsional oscillations results from subtle differences in chain packing throughout the glass. The average of this distribution is sensed by most probes of the material, including spectroscopic and diffusion experiments. A corresponding cumulative distribution of average gap sizes forms spontaneously and randomly throughout the glass in response to the concerted torsional motion of repeat units. For penetrants smaller than the limiting moving segment size, the tendency of the penetrant mobility to decrease with increasing penetrant size should be clear. This visualization is in effect the basis for applying free-volume theories, discussed previously in the context of rubbery materials, to glassy polymers.

If the available gap is larger than the critical dimension of a penetrant, a diffusion jump can be taken. If the available gap is too small, a jump is precluded. The fraction of diffusion jumps available to penetrant A vs B that are actually selective is small in rubbers, unless the size difference between penetrants is very large. For glassy materials, on the other hand, the range of motions, and hence the size of transiently opening gaps, is more narrowly distributed, thereby providing a much more selective environment for penetrant diffusion. Indeed, the infinite-dilution diffusion coefficients of glassy PVC and natural rubber in Figure 20 (69) illustrate the tendency of the glass to maintain size and shape selectivity over a larger range of penetrant sizes than the rubber. The diffusivities are more strongly dependent on penetrant size in the glass. At the same time, the more highly restricted range of molecular motion possible in the glass leads to lower diffusion coefficients.

The higher diffusivity selectivities often make glasses more favorable than rubbers for small molecule permselective membranes. The lower diffusivities also favor glasses over rubbers for barrier applications. On the other hand, rubbers are used in some membranes when a very large solubility selectivity is available, such as in separating organic vapors from air. Complex non-Fickian and plasticization phenomena can occur in applications where a significant amount of penetrant is

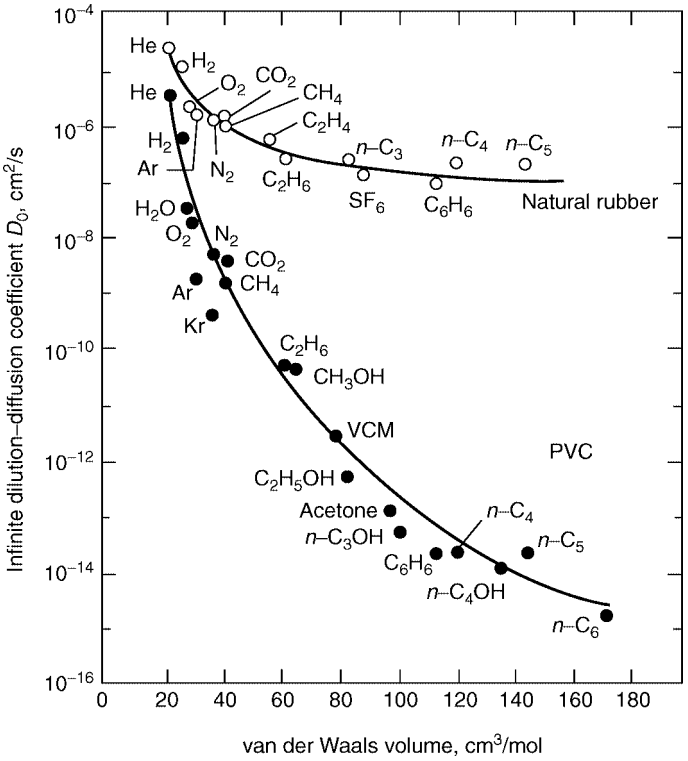

Fig. 20. Diffusion coefficients for a variety of penetrants in natural rubber at 25°C and rigid poly(vinyl chloride) at 30°C.

present in a glass. The diffusion coefficients of penetrants in glasses may increase by several orders of magnitude if the weight fraction of the penetrant reduces the T_g to the use temperature.

This plasticization phenomena can be observed in some glassy polymers exposed to high pressures of condensable gases, such as CO_2. Moreover, a pressure dependence of permeability occurs for glassy polymers prior to plasticization, whereas rubbery materials tend to have essentially pressure-independent permeabilities. The decrease in permeability of component A with increasing partial pressure of either component A or B prior to the onset of plasticization (70) shown in Figure 21 (71) is characteristic of glassy polymers.

The pressure at which plasticizing effects begin to overcome permeability depression depends primarily on the ratio of the partial pressure of the penetrant in the feed stream to the corresponding vapor pressure of the penetrant at the system temperature. As the pressure approaches the vapor pressure, solubility tends to increase rapidly, thereby inducing plasticization or clustering responses such as those already discussed for rubbery polymers. Even below the plasticization point, additional complexities not encountered with rubbery polymers are often observed in glassy materials. For example, low vapor pressure components such as water can cause depression of the permeability of other gases when water is

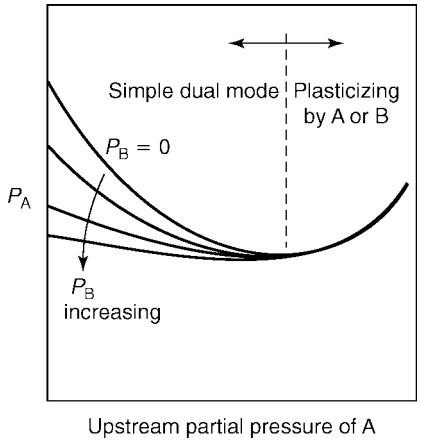

Fig. 21. Permeability of a glassy polymer to penetrant A (P_A) in the presence of varying partial pressures of penetrant B.

present at even a few hundred pascals (70). Components such as CO_2 that are only slightly supercritical can also produce a reduction in the permeability of another component if plasticization is not occurring. Although the vapor pressure of a supercritical component is not defined, a useful effective value can be obtained by extrapolation of a semi-log plot of vapor pressure versus the inverse absolute temperature to the system temperature. For instance, an effective vapor pressure of 7.3 MPa (72 atm) is obtained for CO_2 at 35°C by this method. Therefore 2 MPa (20 atm) of CO_2 should have flux depressing effects similar to only 1.6 kPa (12 torr) of water vapor having a vapor pressure of only 5.6 kPa (42 torr) at 35°C. This approach cannot be applied unambiguously to highly supercritical gases.

Sorption Models for Glassy Polymers. The sorption isotherms of glassy polymers are typically concave to the pressure axis at low pressures and tend to approach a straight line as the pressure is increased (see Fig. 22). This sorption behavior contrasts with that of a rubbery polymer, where the isotherm is typically linear at low pressures and then becomes convex to the pressure axis at high pressures, indicating the onset of plasticization or clustering. While there is general agreement in the literature on the mechanism of sorption into a rubbery polymer, there are many competing models of sorption in glassy polymers. The dual-mode model was the first successful attempt to describe sorption of small molecules in glassy polymers. The dual-mode model is still very popular today because of its simplicity and wide applicability. However, the physical basis of the dual-mode model, which rests on the concept of two dissolved penetrant populations, has never been conclusively proven. Furthermore, the parameters of the dual-mode must be measured for each system independently, and the parameters for sorption differ from those for desorption. In light of these shortcomings, multiple models have been proposed as alternatives to the dual-mode model, although none as yet enjoys the same widespread acceptance. A fairly recent review of these models is available (72). In this section, the dual-mode model, along with two alternatives, the site-distribution model and the nonequilibrium lattice fluid

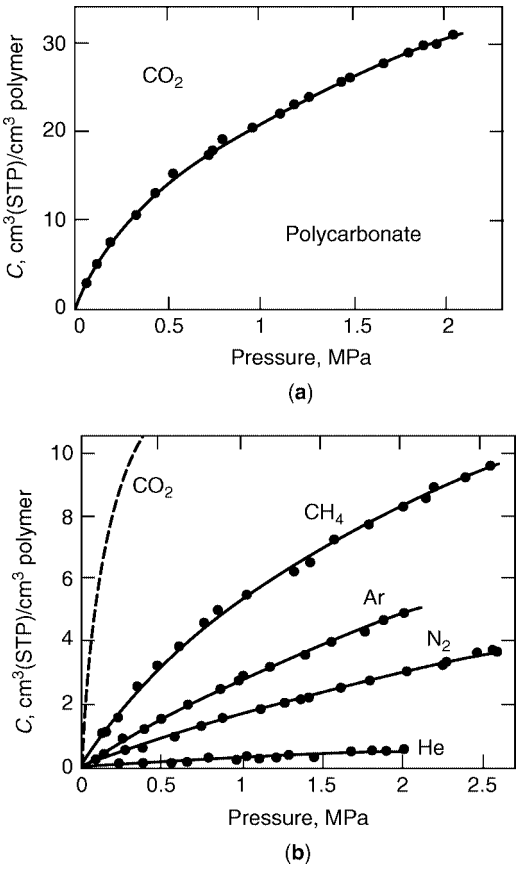

Fig. 22. Sorption isotherms for various gases in bisphenol A polycarbonate at 35°C. To convert MPa to atm, multiply by 10.

model, is presented. The two alternate models were chosen for review because they illustrate two rather different approaches. The site-distribution model is a phenomenological model based on the free-volume distribution of the glassy state, while the nonequilibrium lattice fluid model is based on nonequilibrium thermodynamics.

Dual-Mode Model. The physical basis of the dual-mode model rests on the concept of unrelaxed free volume in the glassy state. The concept of unrelaxed free volume $V_g - V_\ell$, where V_g is the specific volume of the glass and V_ℓ is the extrapolated specific volume of a hypothetical rubber, is illustrated in Figure 23 (71). The extremely long relaxation times for segmental motion in the glassy state lead to trapping of nonequilibrium chain conformations in glasses, thereby presumably permitting miniscule gaps to exist between chain segments. This results in the additional unrelaxed free volume, which causes the specific volume of a glass to be higher than the extrapolation for a hypothetical rubber.

The dual-mode sorption model considers the glassy solid to consist primarily of an equilibrium-densified matrix with a small volume fraction of uniformly

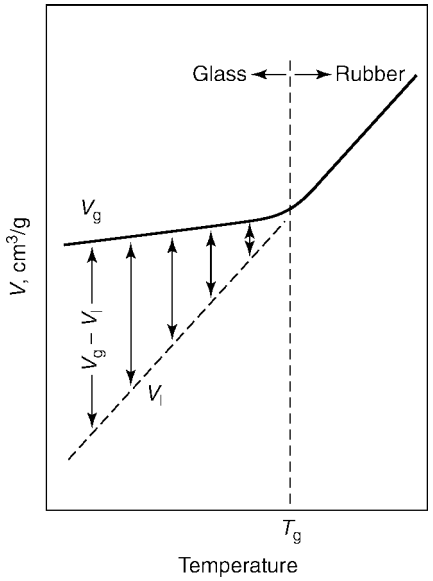

Fig. 23. Schematic representation of the unrelaxed volume, $V_g - V_\ell$, in a glassy polymer. V_g = glass specific volume; V_ℓ = equilibrium volume of densified glass. The unrelaxed volume disappears at the glass-transition temperature.

distributed molecular-scale gaps, or holes, throughout the matrix. Gaps that are smaller in size than a penetrant molecule may be locally redistributed during the sorption process in the initial exposure of the polymer to a penetrant (71). This model has proved to be very useful for interpreting a wide spectrum of phenomena including pure component and multicomponent permeation and sorption and penetrant-induced dilation in gas–glassy polymer systems. The development of the dual-mode model has been reviewed (73,74).

The dual-mode model has also been applied with some success to the sorption and transport behavior of small- and intermediate-size organic molecules in glasses (75). Above some size, however, the penetrant may be too large to be accommodated solely within individual holes, and two truly distinct environments may not actually exist for these penetrants. Even in this case, however, the concept of unrelaxed free volume remains valid, and observations of sorption and dilation behavior that apply to gases also apply qualitatively to larger penetrants up to the point of extreme plasticization where an actual glass transition occurs.

If a hypothetical equilibrium-densified glass, V_ℓ in Figure 23, is exposed to a given pressure of a penetrant, a sorption concentration C_D, characteristic of true molecular dissolution, occurs, as it does in rubbery polymers or liquids. In a nonequilibrium glass V_g, the additional volume present in the form of intersegmental gaps, or holes, provides for additional low energy berths for penetrants that do not require the energy expense of dilating the matrix as in the case of the dissolved mode (C_D) population. In this case, an additional sorption population with concentration C_H can occupy these sites in local equilibrium with the dissolved mode population. This hole-filling population is often described by a Langmuir isotherm. The dual-mode model can be written analytically up to reasonably

high pressures for a penetrant indicated by subscript A, in terms of the sum of a Henry's law expression for C_D and a Langmuir expression for C_H, namely

$$C_A = C_{D_A} + C_{H_A} \tag{46}$$

$$C_A = k_{D_A} p_A + \frac{C'_{H_A} b_A p_A}{1 + b_A p_A} \tag{47}$$

where k_{D_A} is the coefficient that characterizes sorption of the penetrant in the densified regions of the matrix and p_A is the penetrant partial pressure. The value of k_{D_A} has been correlated with the Lennard–Jones potential of the gas (76) and the free volume of the polymer (77). The b_A and C'_{H_A} parameters are the Langmuir affinity and capacity constants, respectively. Several researchers have shown that C'_{H_A} approaches zero at the glass transition in generally the same way that $V_g - V_\ell$ approaches zero (78,79). In fact, the value of C'_{H_A} has been predicted well as the product of the unrelaxed volume fraction $[(V_g - V_\ell)/V_\ell]$ and the inverse equivalent sorbed volume of penetrant molecules. The volume per molecule can be estimated with reasonable accuracy using data from gas adsorption on zeolites or activated carbons. The value of $[(V_g - V_\ell)/V_\ell]$ can be estimated using dilatometry in most cases (80).

The dual-mode model is easily extended to include gas mixtures (81). In terms of partial pressures, the expressions for mixed-gas sorption are usually written as

$$C_A = k_{D_A} p_A + \frac{C'_{H_A} b_A p_A}{1 + b_A p_A + b_B p_B} \tag{48}$$

$$C_B = k_{D_B} p_B + \frac{C'_{H_E} b_B p_B}{1 + b_A p_A + b_B p_B} \tag{49}$$

The dual-mode model thus predicts a reduction in sorption of any gas, at a fixed partial pressure, as the partial pressure of a second gas is increased. Sorption of binary mixtures of CO_2/N_2O and CO_2/CH_4 in poly(methyl methacrylate) (PMMA) is predicted to within 2% by this model. Moreover, Figure 24 shows pure and mixed-gas data (82) for the sorption of CO_2 and CH_4 in poly(phenylene oxide) (PPO). The solid lines represent dual-mode model predictions for a partial pressure of 0.5 MPa (5 atm) for each component using parameters from the pure-gas isotherm. The dual-mode sorption model provides an accurate description of the solubility of both pure and mixed-gases for these polymers over the range of partial pressures studied. The small differences between mixed-gas permeability model predictions and experimental data may be due to differences in conditioning of the polymer in single- and mixed-gas environments. These differences might also be attributable to changes in the diffusivity of mixture components due to the presence of another component; diffusivity is not as easily predicted as solubility because of potential plasticization effects for strongly sorbing penetrants. These effects appear to be less significant for equilibrium sorption coefficients than for diffusion coefficients.

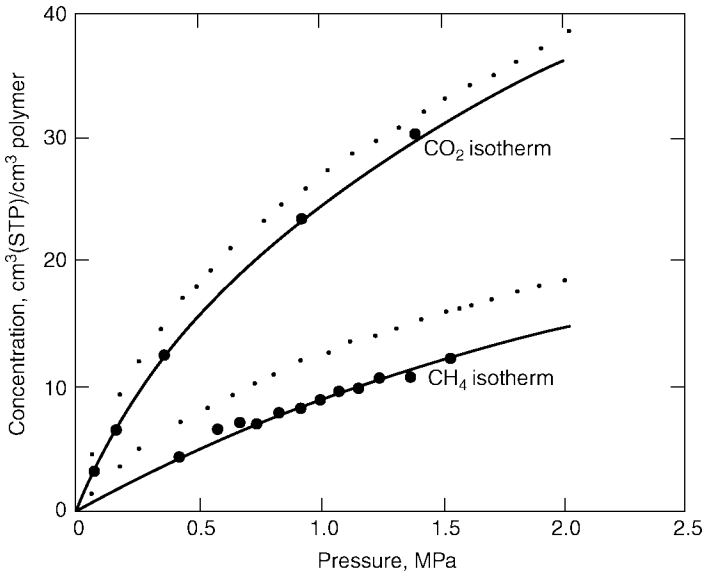

Fig. 24. Mixed-gas sorption for the PPO/CO_2/CH_4 system at 35°C. Dotted lines show pure-gas sorption and solid lines show model predictions for $p_{CO_2} = p_{CH_4} = 0.5$ MPa (5 atm) (76). To convert MPa to atm, multiply by 10.

Site-Distribution Model. In the dual-mode model, penetrants are pictured as being sorbed into either a low energy microvoid site or a high energy densified site within the glassy polymer matrix. These two idealized sorbed populations are probably an oversimplification of the actual penetrant–polymer environment. Experimental evidence to validate the assumption of two dissolved penetrant populations has been conflicting and somewhat inconclusive (44,83–85). In the site-distribution model, the glassy matrix is pictured as containing free volume distributed throughout as spherical holes. The distribution of hole volumes in the glass is assumed to be Gaussian. This Gaussian distribution of free volume throughout the polymer results in a corresponding Gaussian distribution of sorption site energies. As penetrant is dissolved into the polymer, the low energy sorption sites are preferentially occupied. As the penetrant activity is increased, higher energy sorption sites are filled. The site-distribution model uses Fermi–Dirac statistics to determine the occupancy at each energy level, where the integral of the site density times the occupancy level is the total penetrant concentration (86).

The distribution of free volume pictured in the site-distribution model is the result of volume fluctuations in the liquid polymer being frozen into the glass as the polymer is quenched below T_g. The shape of the free-volume distribution is assumed to be Gaussian and is expressed by

$$n(V_h) = \frac{1}{\sigma_v \sqrt{\pi}} \exp\left(- \frac{(V_h - V_{h0})^2}{{\sigma_v}^2} \right) \tag{50}$$

where, $\sigma_v = \sqrt{2k_B T_g V_{h0}/B}$ is the width of the distribution. V_{h0} is the average hole volume and B is the bulk modulus at the T_g. When a gas molecule of volume, V_g, is sorbed into a hole an elastic contribution, G_{el}, is made to the total Gibbs energy:

$$G_{el} = \frac{2}{3}\mu_s \frac{(V_g - V_h)}{V_h} \tag{51}$$

where, μ_s is the shear modulus. The total Gibbs energy, G, consists of this elastic contribution plus an enthalpic contribution from penetrant–polymer interactions and an entropic contribution from penetrant confinement in the sorption site. Only the elastic contribution to the Gibbs energy is assumed to vary with hole volume. Through the use of Fermi–Dirac statistics the occupancy of the sorption sites is calculated, with the total penetrant concentration equaling

$$C_A = \frac{V_{mol} N_0}{N_A} \int_{-\infty}^{\infty} \frac{1}{\sigma_G \sqrt{\pi}} \exp\left(- \frac{(G - G_0)^2}{\sigma_G^2} \right) \frac{1}{1 + \exp[(G - \mu)/RT]}\, dG \tag{52}$$

The V_{mol}/N_A prefactor is necessary to put the concentration into the common units of cc STP/cc polymer. V_{mol} equals 22,400 cc STP/mole, and N_A is Avogadro's number. G_0 is the Gibbs energy of a hole of average size V_{h0}. The chemical potential of the penetrant gas phase is given by μ. The width of the Gibbs energy distribution is given by σ_G and is related to the width of the free volume hole size distribution, σ_v. N_0 is the number of sorption sites.

The site-distribution model results in four fitting parameters: H_0, S_0, N_0, and σ_G. The parameters H_0 and S_0 are used to calculate $G_0 = H_0 - TS_0$. S_0 is the change in entropy from the gas phase to solution in a polymer. The value of S_0 in most cases is roughly equal to the change in entropy from the gas phase to the solid. The number of sorption sites, N_0, can be treated as a purely adjustable parameter but is often estimated as $6.7 \times 10^{21}/\text{cm}^3$ (86). The distribution width σ_G can be calculated from measurable quantities or treated as an adjustable parameter. Correlations do exist between the distribution width and T_g and the volume of the gas molecule, V_g (87). For high T_g polymers, more volume fluctuations exist in the liquid polymer state. When these high T_g polymers are quenched to the glassy state, the volume fluctuations are frozen and a wide distribution of sorption sites results. When large gas molecules are dissolved, there is a greater elastic strain which results in a large energy distribution.

The site-distribution model has recently been extended to mixed-gas sorption, and is able to account for competitive sorption effects (88). As with the dual-mode model, the site-distribution model allows for the prediction of mixed-gas sorption by using parameters obtained from experimentally less complicated pure-gas sorption measurements. Like the dual-mode model, the site-distribution model is phenomenological, while the dual-mode model uses the bulk specific volume V_g and extrapolated equilibrium volume V_ℓ as key parameters; the site-distribution model relies upon the bulk shear modulus μ_s as a key parameter. The use of bulk parameters to characterize sorption which occurs at the atomistic scale is questionable from a fundamental point of view; nevertheless, such models provide useful tools to describe and even predict the effect of conditioning and physical aging

on the free-volume distribution in glassy polymers. Conditioning of the polymer with a highly soluble gas such as CO_2 produces packing disruptions throughout the glass which remain after conditioning as low energy sorption sites. Physical aging, on the other hand, reduces the number of low energy sites and results in a narrower energy distribution (89). The physical insight provided by the site-distribution model and the possibility of future development into a truly predictive model are advantages which must be weighed against the added mathematical complexity.

Nonequilibrium Lattice Fluid Model. The nonequilibrium lattice fluid (NELF) model is a nonequilibrium thermodynamics approach to modeling sorption in a glassy polymer. The model pictures penetrants as a single dissolved population in a nonequilibrium glassy matrix (90). The penetrant concentration in the glassy phase is calculated by requiring that the chemical potential of the penetrant in the gaseous phase equal the chemical potential of the penetrant in the glassy phase. NELF is a modified form of the Sanchez–Lacombe (SL) lattice fluid model for a rubbery polymer. The SL lattice fluid model places polymer segments and vacancies onto a lattice (91,92). The placements of vacancies on the lattice simulate free volume in the polymer. The number of vacancies is dependent on the pressure and temperature of the system. Within this conceptual framework, the SL lattice fluid model expression for the Gibbs free energy of a pure component is (92)

$$G = rnRT^* \left\{ -\tilde{\rho} + \frac{\tilde{P}}{\tilde{\rho}} + \frac{\tilde{T}}{\tilde{\rho}} \left[(1-\tilde{\rho})\ln(1-\tilde{\rho}) + \frac{\tilde{\rho}}{r}\ln(\tilde{\rho}) \right] \right\} \tag{53}$$

In the above equation $\tilde{\rho}$, $\tilde{T}$, and $\tilde{P}$ are the reduced density, temperature, and pressure, respectively. These variables are defined as: $\tilde{\rho} = \rho/\rho^*$, $\tilde{T} = T/T^*$, and $\tilde{P} = p/P^*$. The parameters ρ^*, T^*, and P^* are obtained from the P-V-T properties of the pure component. The parameter r in equation 53 is the number of lattice sites occupied by a single molecule.

In order to extend the SL lattice fluid model to a penetrant-polymer mixture, a set of mixing rules is used to calculate ρ^*, T^*, and P^* for the mixture from the penetrant and polymer parameters. The proper set of mixing rules is given by Doghieri and Sarti (90). Using ρ^*, T^*, and P^* for a mixture of n_1 moles penetrant and n_2 moles polymer, the Gibbs free energy of the mixture is obtained from (90)

$$G = RT^*(r_1 n_1 + r_2 n_2) \left\{ -\tilde{\rho} + \frac{\tilde{P}}{\tilde{\rho}} + \frac{\tilde{T}}{\tilde{\rho}} \left[(1-\tilde{\rho})\ln(1-\tilde{\rho}) + \frac{\varphi_1}{r_1}\ln(\varphi_1\tilde{\rho}) \right] \right\} \tag{54}$$

where r_1 and r_2 are the number of lattice sites occupied by a molecule of "1" and "2," respectively, in the mixture. φ_1 is the volume fraction of penetrant in the mixture.

In the SL lattice fluid model approach, the equilibrium density is found by minimizing the Gibbs free energy. The following equilibrium conditions are enforced for the pure component and the mixture (90):

$$\left(\frac{\partial G}{\partial \rho} \right)_{T,p,n} = 0 \text{ at equilibrium for the pure component} \tag{55a}$$

$$\left(\frac{\partial G}{\partial \rho}\right)_{T,p,n_1,n_2} = 0 \text{ at equilibrium for the mixture} \tag{55b}$$

The chemical potential of the system is then calculated at values of the density which satisfy the above conditions at each temperature and pressure.

In a nonequilibrium system, the conditions for equilibrium (eqs. 55a and 55b), no longer hold. NELF bypasses the need for an equilibrium condition through the use of an internal order parameter. The order parameter characterizes the degree the system is out of equilibrium. One can imagine multiple possible choices of order parameters in the glassy state, such as the fractional free volume at the T_g (93) or simply the mixture density (94). NELF specifically makes use of the polymer partial density, ρ_2, as its order parameter. A discussion of the rationale and implications of picking an order parameter is given by Doghieri and Sarti (90). Nevertheless, with NELF the order parameter ρ_2 is related to the reduced density of the mixture by

$$\tilde{\rho} = \frac{\rho_2}{\omega_2}\frac{1}{\rho^*} \tag{56}$$

The chemical potential of the dissolved penetrant is then given as (95)

$$\frac{\mu_1}{RT} = \ln\left(\frac{\omega_1\rho_2}{\omega_2\rho_1^*}\right) - \frac{M_1P_1^*}{\rho_1^*RT_1^*}\left\{\begin{array}{c}\left[1+\left(\dfrac{T_1^*P^*}{T^*P_1^*}-1\right)\dfrac{\omega_2\rho^*}{\rho_2}\right]\ln\left(1-\dfrac{\rho_2}{\omega_2\rho^*}\right)\\ +\dfrac{T_1^*P^*}{T^*P_1^*}+\dfrac{\rho_2}{\omega_2\rho^*}\left[\dfrac{T_1^*}{T}\left(1+\dfrac{P^*}{P_1^*}-\left(\omega_2\dfrac{\rho^*}{\rho_2^*}\right)^2\dfrac{\Delta P_{12}^*}{P_1^*}\right)\right]\end{array}\right\}+1 \tag{57}$$

where ω_1 and ω_2 are the weight fractions of penetrant and polymer. ΔP^*_{12} is a binary interaction term and is assumed equal to $(\sqrt{P_1^*}-\sqrt{P_2^*})^2$ (91). The weight fraction of penetrant in the glassy phase is solved for by requiring that the chemical potential of dissolved penetrant, given by equation 57, equal the chemical potential of the penetrant in the gas phase. The chemical potential in the gas phase may be calculated using the SL lattice fluid model or an equation of state such as Peng–Robinson.

The truly impressive feature of NELF is that it is a completely predictive model of small molecule sorption in glassy polymers, if information about the polymer partial density, ρ_2, is known. Unfortunately, ρ_2 is obtained from dilatometry data, and these data exist for only a very small number of penetrant–polymer systems, which limits the general practical applicability of the model. In light of this shortcoming, two approaches have been used to make NELF more widely applicable. The first approach assumes that the polymer partial density is equal to the density of the pure polymer, $\rho_2{}^0$ (96). This approach limits NELF to low pressures, where no polymer swelling occurs; however, in this pressure range, NELF is still completely predictive. The second approach to increase the applicability of NELF introduces one or two adjustable parameters (95). In this approach, the polymer partial density is assumed to vary linearly with pressure such that

$$\rho_2 = \rho_2^0(1-kp) \tag{58}$$

where k is the swelling coefficient. If the pure polymer density is known, equation 58 is substituted into equation 57 and k is treated as an adjustable parameter. If the pure polymer density is unknown, then both ${\rho_2}^0$ and k are treated as adjustable parameters. This approach allows for the prediction of the entire isotherm from just one or two sorption measurements. Another drawback of NELF is that values of ρ^*, T^*, and P^* are required for both components. These values are available for most common penetrants (92,97). However, fewer of these values exist for polymers because they are obtained from the P-V-T behavior of the polymer above T_g. Many high performance glassy polymers of interest have extremely high glass transitions, which makes obtaining P-V-T data in the rubbery state experimentally challenging.

Transport Models for Glassy Polymers

The following three multicomponent transport models have been used to explain the depression of the permeability of a component in a mixture relative to its pure component value (Fig. 21): the Petropoulos model and the competitive sorption model, both of which assume that direct competition for diffusive pathways within the glass is negligible, and a more general permeability model in which direct competition can occur between penetrant molecules for both sorption sites and diffusion pathways. All three of the models presented here are based upon the framework of the dual-mode model. It is worth mentioning that the site-distribution model has recently been extended to account for diffusion (98) and that free volume models exist for transport in glassy polymers (99).

Simple Dual-Mode Transport Models. As a direct extension of the dual-mode sorption model, it is convenient to treat pure-gas permeability as the sum of two terms, which are characteristic of the two sorbed penetrant populations. Petropoulos first developed such an expression in terms of the chemical potential gradient of the sorbed gas (100). For the case where there is a vacuum downstream and a pressure p_{A_2} of component A upstream, the following expression results:

$$P_A = k_{D_A} D_{TD_A} + \frac{C'_{H_A} D_{TH_A}}{p_{A_2}} \ln(1 + b_A p_{A_2}) \tag{59}$$

where D_{TD_A} and D_{TH_A} are diffusion coefficients characteristic of the Henry's law (dissolved), and the Langmuir (hole-filling) populations of sorbed gas molecules. Extension of the Petropoulos model to include gas mixtures involves numerical integration of the flux equations for components A and B (101).

Taking an approach similar to that of Petropoulos, a model was developed (102) representing the flux for gas A in terms of concentration gradients rather than chemical potential gradients:

$$J_A = -D_{D_A} \frac{dC_{D_A}}{dx} - D_{H_A} \frac{dC_{H_A}}{dx} \tag{60}$$

where D_{D_A} and D_{H_A} are diffusion coefficients characteristic of Henry's law and the Langmuir populations of sorbed gas molecules. After substitution of equation 47

into equation 60, the flux expression can be integrated analytically to give the equation for pure-gas permeability, again for the condition of zero downstream pressure and an upstream pressure of p_{A_2}:

$$P_A = k_{D_A} D_{D_A} \left\{ 1 + \frac{F_A K_A}{1 + b_A p_{A_2}} \right\} \tag{61}$$

where $F_A = D_{H_A}/D_{D_A}$, $K_A = C'_{H_A} b_A / k_{D_A}$, and p_{A_2} is the upstream pressure of pure component A, with the downstream pressure assumed to be negligible. This equation represents the partial immobilization dual-mode transport model of Koros and Paul. By plotting pure-gas permeability data for component A, values of F_A, D_{D_A}, and D_{H_A} can be determined. The sorption parameters k_{D_A}, C'_{H_A}, and b_A can be determined independently in equilibrium sorption measurements, and so the parameters in either equation 59 or equation 61 can be easily determined. Therefore, by making only pure-gas sorption and permeation measurements, all of the model parameters can be determined in either of these simple dual-mode formulations of the transport expressions.

Assuming that the diffusion coefficients D_{D_i} and D_{H_i} for components in a gas mixture are unchanged from their pure-gas values, the simple expression represented above can be extended to gas mixtures. After substitution of equation 48 into equation 60, the flux equation can be analytically integrated to give the following expression for the permeability of component A in a binary mixture of gases A and B (103):

$$P_A = k_{D_A} D_{D_A} \left\{ 1 + \frac{F_A K_A}{1 + b_A p_{A_2} + b_B p_{B_2}} \right\} \tag{62}$$

Similarly, for component B,

$$P_B = k_{D_B} D_{D_B} \left\{ 1 + \frac{F_B K_B}{1 + b_A p_{A_2} + b_B p_{B_2}} \right\} \tag{63}$$

Assuming that D_{TD_i} and D_{TH_i} are constant in mixed feed situations, the Petropoulos expressions can be generalized for mixed-gas feeds; however, numerical solutions are required in this case. Equations 62 and 63 and the analogous predictions in terms of the chemical potential driving force model of Petropoulos indicate that the presence of a second gas B lowers the permeability of gas A only by reducing the sorption of gas A.

Advanced Dual-Mode Transport Models. To account for the effect of nearby gas molecules on the ability of a given gas molecule to find sites into which it might jump, Barrer proposed and developed a model that adopts a somewhat more complex description of the diffusion process in glassy materials (104). A gas molecule is capable of executing four distinct types of diffusional jumps, depending on which of the two distinct sorption environments it is diffusing from and diffusing into (104,105). Denoting the Henry's law and Langmuir

environments as D and H, respectively, the four possible jumps can be depicted as follows:

$D \rightarrow D$ (dissolved to dissolved)	$D \rightarrow H$ (dissolved to hole)
$H \rightarrow D$ (hole to dissolved)	$H \rightarrow D$ (hole to hole)

Each jump is described by a distinct primitive diffusion coefficient D_{DD}, D_{DH}, D_{HD}, or D_{HH} that is related to the average mobility of a penetrant in each of the two environments D_{D_A} and D_{H_A} as shown below:

$$D_{D_A} = D_{DD_A} + D_{DH_A}(1 - \theta_A) \tag{64}$$

$$D_{H_A} = D_{HD_A} + D_{HH_A} \tag{65}$$

where $\theta_A = C_{H_A}/C'_{H_A}$ represents the fraction of Langmuir sorption sites occupied by sorbed gas A molecules. Consequently, the model predicts that D_{D_A} decreases as the concentration of gas in the polymer increases. In effect, this model predicts a reduction in the number of diffusional pathways available to a penetrant molecule. When combined with the dual-mode sorption model for describing the fraction of filled holes, the flux equations can be integrated to give the permeability of a pure-gas A:

$$P_A = k_{D_A} D_{DD_A} + \frac{C'_{H_A} b_A (D_{HH_A} + D_{HD_A}) - k_{D_A} D_{DH_A}}{1 + b_A p_{A_2}} + 2k_{D_A} D_{DH_A} \frac{\ln(1 + b_A p_{A_2})}{b_A p_{A_2}} \tag{66}$$

Using nonlinear regression techniques to fit the pure-gas permeability vs pressure data for gas A, values for $D_{DD_A} + D_{DH_A}$, and $(D_{HH_A} + D_{HD_A})$ can be determined.

The extension of this model to mixed-gases is considerably more difficult than the extension of the simple dual-mode transport models. To include gas mixtures, the Barrer model must be modified to accurately describe the fraction of filled Langmuir sorption sites when more than one gas species is present in the polymer. To account for the presence of a second gas, the flux expressions can be rewritten using the following definition for the fraction of filled holes:

$$\theta_{total} = \frac{C_{H_A}}{C'_{H_A}} + \frac{C_{H_B}}{C'_{H_B}} \tag{67}$$

where θ_{total} represents the fraction of the total unrelaxed volume occupied by either penetrant A or B, and therefore is not available for allowing a penetrant to jump into it.

This model results in a system of nonlinear differential equations that must be solved numerically. Figure 25 (82) shows pure-gas permeability data for CO_2

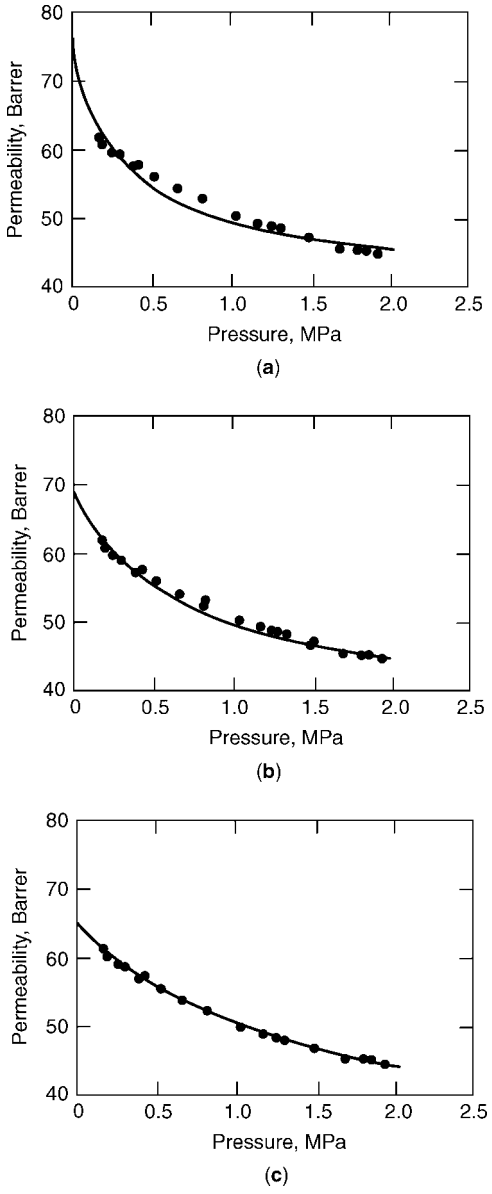

Fig. 25. Permeability of pure CO_2 in poly(phenylene oxide). The solid lines represent (**a**) the Koros and Paul, (**b**) the Petropoulos model, and (**c**) the Barrer model. To convert MPa to atm, multiply by 10.1 Barrer $= 10^{-10}$ [cm^3(STP)cm]/($cm^2 \cdot s \cdot cm$ Hg) $= 0.335$ mmol/(m · s · TPa).

in poly(phenylene oxide) along with the theoretical fits for the Petropoulos, Koros and Paul, and Barrer models, respectively. The Barrer model provides a slightly more accurate fit of the permeability data than either of the simpler models, especially in the low pressure region. This is expected because of the additional model parameter.

Figures 26 and 27 (82) show mixed-gas permeability data for an equimolar mixture of CO_2 and CH_4 in PPO along with predictions made using the Petropoulos, Koros and Paul, and Barrer models. Mixed-gas permeability is depressed relative to the pure-gas values for both components. As expected, the mixed-gas Barrer model predicts lower permeability for both components than either of the simpler models.

Below about 1 MPa (10 atm) total pressure, all three mixed-gas models give fairly accurate predictions for CO_2 permeability in the mixture. Above this pressure, however, CO_2 data lie below all model predictions. By contrast, permeability data for CH_4 in the equimolar mixture lie above all three predictions over the entire range of upstream partial pressures.

The Barrer model provides a better prediction for mixed-gas carbon dioxide permeability data, while methane permeability is predicted more accurately by the simpler model of Koros and Paul. Thus none of the models emerge as having a clear advantage over the other two in predicting PPO/CO_2/CH_4 permeability. However, several factors can be suggested as possible sources of error inherent in all of the models.

One possible discrepancy involves fugacity effects at high pressures, but fugacity effects do not fully account for the differences between permeability data and model predictions. The relative deviations of fugacity-based predictions from experimental data are somewhat smaller than those with pressure-based calculations for all three models (82).

It is unlikely that deviations from the mixed-gas sorption model are to blame for the discrepancies between mixed-gas permeability data and model predictions because the mixed-gas sorption model provides an accurate description of PPO/CO_2/CH_4 sorption. However, different conditioning effects between the equilibrium sorption and permeation conditions may introduce a significant source of error. In equilibrium sorption the polymer experiences uniform conditioning, while during permeation a conditioning profile exists through the polymer. These different conditioning histories ultimately may lead to nonnegligible differences in sorption.

From a purely practical point of view, the Koros and Paul model for mixed-gas permeability is significantly more straightforward than either the Petropoulos or Barrer model in terms of parameter calculation and comparisons between different gas–polymer systems. Although the Barrer model provides a tighter fit of pure-gas permeability data, it does not provide the more accurate prediction of mixed-gas permeability for which it was initially proposed. The inability of the more complex model to correct for the small differences between mixed-gas permeability data and the two simpler model predictions suggests that these subtle deviations may be the result of the fundamental assumptions of all three models. In terms of transition-state theory, all three of these models assume that the activated state is the same regardless of whether the penetrant was originally sorbed in a Henry's law or a Langmuir site, which leads to independent, additive fluxes through the Henry's law and Langmuir modes. This assumption is not valid if the local density around a Langmuir site is less than the density of the dissolved polymer matrix. In this case, the activated state of a penetrant sorbed in a Langmuir site will be lower in energy than that of a penetrant sorbed in a Henry's law site. Petropoulos has recently developed a more general

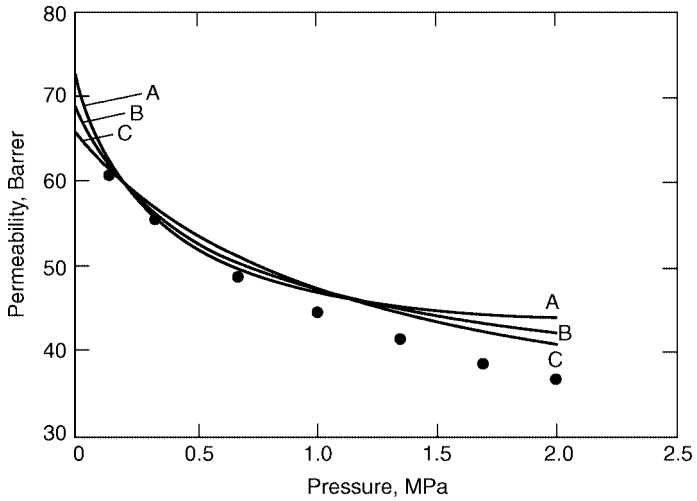

Fig. 26. CO_2 permeability for the PPO/CO_2/CH_4 system at 35°C using an equimolar gas mixture, compared with the three permeability model predictions: **A**, the Koros and Paul model; **B**, the Petropoulos model; and **C** the Barrer model. To convert MPa to atm, multiply by 10.1 Barrer $= 10^{-10}$ [cm^3(STP)cm]/($cm^2 \cdot s \cdot$ cm Hg) $= 0.335$ mmol/(m · s · TPa).

dual-mode transport model that incorporates this more complex picture of the diffusion process (106).

Another likely source of error in all three models is related to the very high solubility of CO_2 in PPO. In both the Koros and Paul and Barrer models, the characteristic diffusivity parameters are assumed constant on the

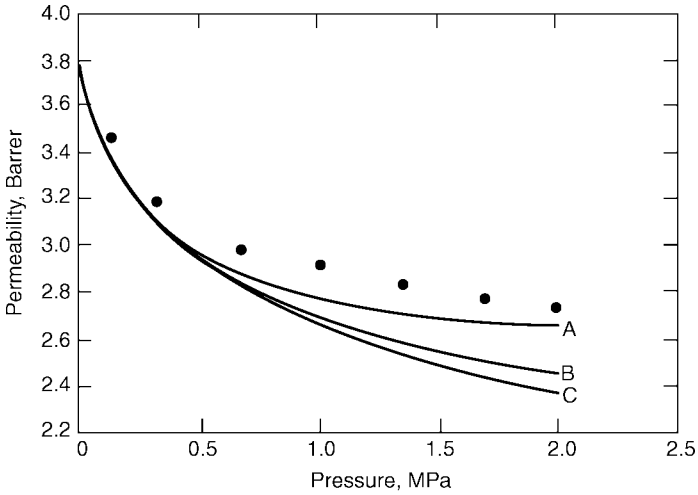

Fig. 27. CH_4 permeability for the PPO/CO_2/CH_4 system at 35°C using an equimolar gas mixture, compared with the three permeability model predictions: **A**, the Koros and Paul model; **B**, the Petropoulos model; and **C**, the Barrer model. To convert MPa to atm, multiply by 10.1 Barrer $= 10^{-10}$ [cm^3(STP)cm]/($cm^2 \cdot s \cdot$ cm Hg) $= 0.335$ mmol/(m · s · TPa).

basis of the assumption that polymer segmental mobility does not significantly change as a result of penetrant-induced dilation. This approximation ultimately breaks down and plasticization begins to dominate the behavior of the system (Fig. 21).

Polymers highly dilated with CO_2 have significantly decreased glass-transition temperatures, implying that polymer segmental motion is facilitated by high CO_2 concentration (107,108). Such increased polymer motions make it easier for gas molecules to execute diffusional jumps from one point to another in the polymer matrix. Thus, dilation may not only manifest itself in higher sorbed gas concentrations, but in increased gas diffusivity as well. As noted earlier, such changes in transport characteristics of a polymer due to high concentrations of sorbed penetrants are termed *transport plasticization*. Failure to account for this molecular-scale phenomenon is probably a significant source of the small but measurable inadequacies of the mixed-gas permeability models. The diffusivity parameters of CO_2 as determined by pure-gas sorption and permeability may, in fact, represent apparent values, which reflect the effects of CO_2 dilation. On the other hand, pure-gas diffusivity parameters for CH_4 cannot supply any information as to how much the methane diffusivity would be influenced by CO_2-induced plasticization. Thus, the mixed-gas permeability data for methane may be higher than model predictions because of increased methane diffusivity in the plasticized polymer.

Conversely, the presence of CH_4 may suppress CO_2-induced plasticization of the polymer, relative to its pure CO_2-dilated state, by compression of the free volume introduced by CO_2 sorption. It may thereby suppress CO_2 diffusivity below model predictions. Studies have also sought to refine the original idea of a constant C'_H parameter by considering plasticization-induced reductions in C'_H due to depression in the effective T_g (109).

It is most likely that the prediction of the permeability of gas mixtures containing CO_2 could be improved by accounting for the effects of CO_2-induced plasticization on transport parameters. This could be tested best at higher CO_2 pressures where such effects should be significant and, in fact, would correspond to conditions of practical importance in enhanced oil recovery operations where CO_2 and CH_4 must be separated at pressures as high as 6.9 MPa (1000 psia) and with CO_2 contents above 50%. The dual-mode transport model of Petropoulos has recently been extended to account for the effects of plasticization in both pure- and mixed-gas environments (110).

Although extensive data for mixed-gas permeation in the plasticization regime are not available, good pure-gas values are available and illustrate some important points. The permeability of CO_2 in various substituted polycarbonates shown in Figure 28 (111) increases with pressure above a certain characteristic value for each of the polymers. The shapes of the permeability curves are like the curve shown schematically in Figure 21. Plasticization occurs despite the fact that the downstream pressure is maintained at a vacuum of less than 1330 Pa (10 mm Hg). To determine when true transport plasticization occurs, the local diffusion coefficient $D_{AP}(C_A)$, which measures the ability of a penetrant to move through the membrane at a point where the local concentration of penetrant is equal to C_A, must be considered. The sorption isotherms for CO_2 in the various materials are shown in Figure 29 (111), and application of the standard

formula (eq. 37) for determination of $D_{AP}(C_A)$ leads to the results shown in Figure 30 (111).

The characteristic tendency of the $D_{AP}(C_A)$ curves to rise to a plateau at intermediate concentrations does not reflect true plasticization, but instead reflects the saturation of preexisting intersegmental packing defects as considered in the dual-mode theory. The deviation upward from the plateau at higher concentrations indicates a breakdown in the constancy of the local diffusion coefficient for the normally-packed matrix and thereby signals the onset of extreme transport plasticization. Despite the markedly different thermal-transition points of the various glassy materials, it is interesting that all of them show plasticizing inflections at around 35 ± 2 cm^3 polymer. On the other hand, the local partial pressure (or fugacity) at which plasticization is reached varies greatly for the different materials, suggesting that the useful operating range for the various materials will also vary considerably. For bisphenol A polycarbonate (PC), the upturn point in local diffusion coefficient is not reached until roughly 2.76 MPa (400 psia); for tetramethylhexafluoro-bisphenol A polycarbonate (TMHFPC), the point occurs at ~0.93 MPa (135 psia) because of the much higher solubility in this open, packing-inhibited material.

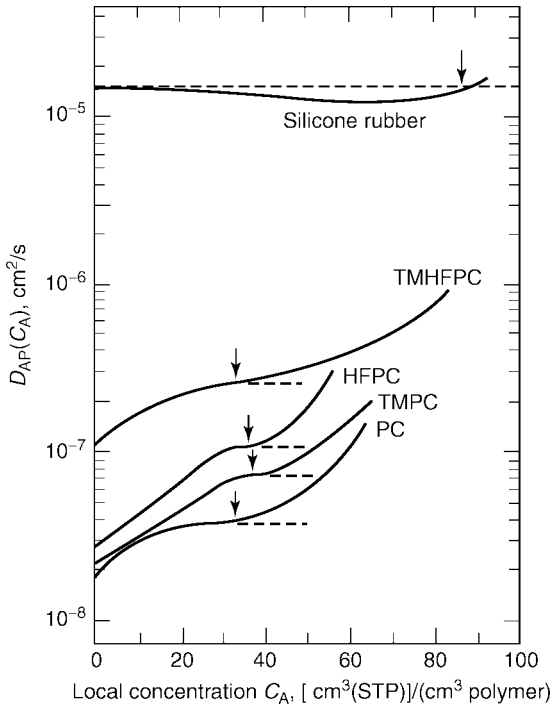

Fig. 30. Effective diffusion coefficient for carbon dioxide at 35°C. The arrows show the approximate concentration at which plasticization occurs as indicated by the upward inflection in the curve.

Measurements on PC and tetramethylbisphenol A polycarbonate (TMPC) indicate that the overall volume dilations due to sorption of 35 cm^3 (STP) CO_2/cm^3 polymer are 3.8% and 2.9%, respectively (111), suggesting that less volume dilation is required to induce plasticization in the more rigid TMPC (T_g = 198°C) than the PC (T_g = 150°C). X-ray diffraction measurements indicate higher intersegmental spacings in TMPC, than in PC (112). It may be that more dilation is needed to free a neighboring segment of the more packable PC. In addition, because of the larger sorption coefficient in TMPC, the plasticization condition is reached at a lower CO_2 pressure.

History Effects in Glassy Polymers

Penetrant-Induced Effects. History-dependent properties of glassy polymers are well documented in terms of thermal (113,114) and mechanical (115) properties. Studies have related excess enthalpy changes measured by differential scanning calorimetry to changes in small-molecule sorption (116,117). Many studies have reported penetrant-induced history-dependent (or conditioning) effects for gas and vapor sorption and transport properties in glassy polymers. The ability to display long-lived changes in sorption, diffusion, and permeation properties

Table 6. Partial Molar Volumes of CO_2 in Organic Liquids

Medium	Partial molar volume, cm^3/mol
Carbon tetrachloride	48.2
Chlorobenzene	44.6
Benzene	47.9
Acetone	44.7
Methyl acetate	44.5
Methanol	43.0
Average	*45.5*

distinguishes glassy materials from rubbery ones and is believed to arise from the long relaxation times in glasses that reflect their inhibited segmental motions (68).

If a sufficient amount of some penetrant is absorbed into a glassy polymer and then totally removed, the amount of excess volume and enthalpy of the sample will have been changed. In a real sense, the material is no longer the same, since it is now in a different nonequilibrium state. If the upstream face of a glassy film is exposed to a conditioning agent while maintaining the downstream face at vacuum, it is possible to induce a conditioning profile of excess volume and enthalpy. A complete treatment of this phenomenon is exceedingly complex, and since the excess enthalpy and excess volume of a nonequilibrium glass tend to change correspondingly, it is common to use excess volume as the primary variable for discussion. This is convenient since it allows direct monitoring of changes in sorption-induced nonequilibrium properties by dilatometry. Experiments illustrate that dilation and sorption for the glass have marked hystereses (Fig. 31) (16), whereas rubbers behave simply as equilibrium materials with no measurable hysteresis.

The essentially linear nature of the dilation response of the glass during sorption may seem surprising at first, given the marked nonlinearity of the sorption isotherm. This response, however, is consistent with the dual-mode sorption model and, in fact, is rather an important independent verification that the model has a realistic physical basis. The dual-mode viewpoint suggests that only the fraction of the total sorption associated with the actual separation of chain segments to accommodate penetrant will cause volume dilation. Since the gap-filling population in a glass contributes substantially less to dilation than the Henry's law population, the infinite-dilution partial specific volume of a penetrant is lower in the glassy polymer than in low molecular weight solvents or rubbery polymers in which no gap filling occurs.

Infinite-dilution partial molar volumes for CO_2 in various low molecular weight liquids (Table 6) are insensitive to the type of medium and decrease only slightly as interactions between the medium and CO_2 increase. This approximation may be somewhat inappropriate for highly supercritical gases such as nitrogen or methane, but for CO_2 near ambient temperature it appears valid. The average of the CO_2 partial molar volumes in the organic liquids is approximately 46 cm^3/mol. The value for CO_2 in silicone rubber determined from analysis of

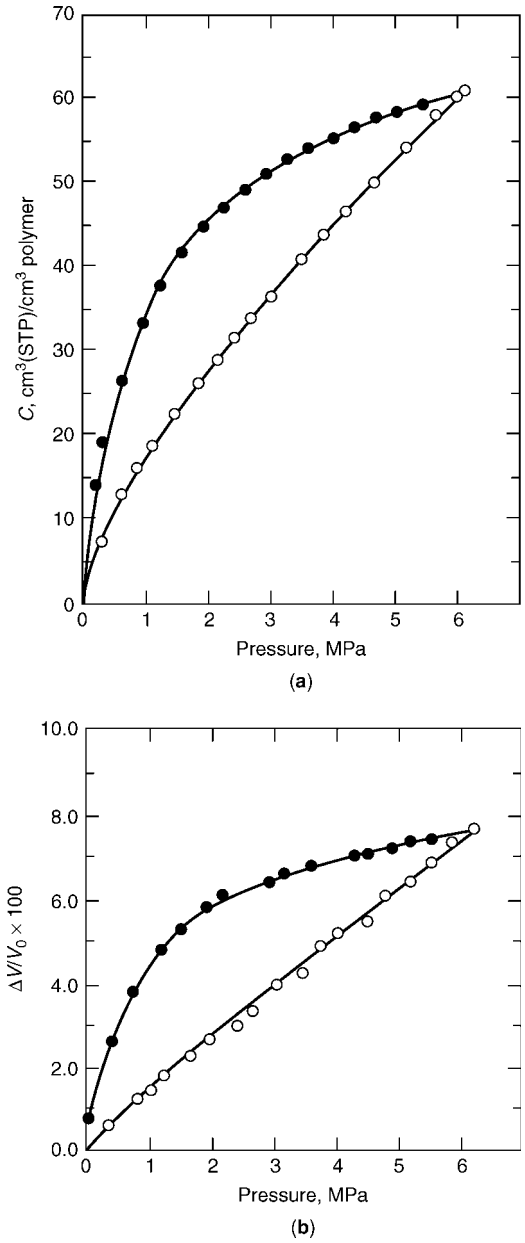

Fig. 31. (**a**) Sorption and (**b**) dilation isotherms for CO_2 in bisphenol A polycarbonate at 35°C. ○, Sorption; ●, desorption. To convert MPa to psia, multiply by 145.

sorption and dilation data is also approximately 46 cm^3/mol. In measurements (118) of the partial molar volume for CO_2 in low density polyethylene over a temperature range of 25–55°C, no strong temperature dependence is observed. The average value reported over this temperature range, 44.5 cm^3/mol, is also

in good agreement with the value in low molecular weight liquids and silicone rubber.

An impressive quantitative test of the dual-mode model is possible using partial molar volume results. Dilation of the glassy matrix is predictable using the average value of the partial molar volume from Table 6 (119) for CO_2. If the Langmuir sorption term in the dual-mode sorption model corresponds to a true hole-filling process, the volume dilation relative to V_0, the unswollen polymer volume, can be predicted using the fraction of CO_2 sorbed according to linear Henry's law sorption terms, $k_D p$. Volume dilation predictions assuming that the entire population causes dilation correspond to the dashed line in Figure 32, whereas the solid line is the prediction based on the assumption that only the Henry's law population causes the dilation. The solid line is remarkably effective for predicting dilation (120). Similar success has been demonstrated using the Henry's law prediction for other glassy polymers (118).

The effects of conditioning on subsequent sorption behavior of glasses, as well as the hystereses seen in both the dilation and mass uptake curves in Figure 31, have been studied. On total removal of the CO_2, the nonzero intercept on the volume dilation axis represents the additional excess volume introduced during sorption–desorption cycles. For this same system of CO_2 and bisphenol A polycarbonate, the experiments measuring the permeability while steadily increasing the upstream pressure, then monotonically decreasing the upstream pressure back to zero, add insight. During the experiment, the downstream face of the film is always maintained under vacuum. The CO_2 permeability in PC shown in Figure 33 (121) displays the shape typical of a dual-mode response at low pressures, followed by

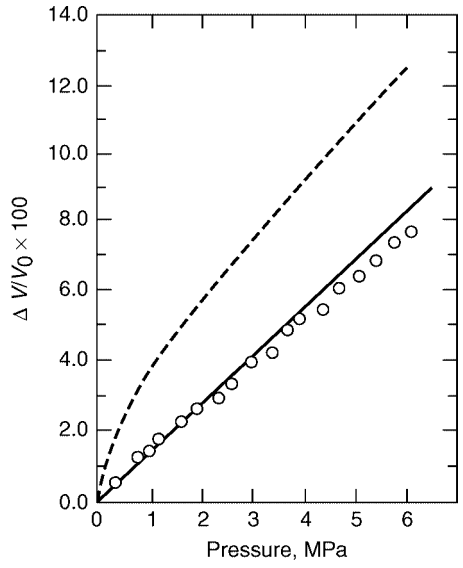

Fig. 32. Volume dilation by sorption of CO_2 in bisphenol A polycarbonate at 35°C. The dashed line is the prediction assuming that the entire population causes dilation, whereas the solid line is the prediction based on the assumption that only the Henry's law population causes the dilation. To convert MPa to psia, multiply by 145.

plasticization at high pressures during the pressurization leg of the cycle. During depressurization, the permeability increases steadily as the pressure is reduced. The nominal time to reach steady state for the 0.127-mm sample of polycarbonate is much less than one day if simple Fickian kinetics applies; longer times were used to guarantee true equilibration because polymer relaxation effects might protract the process. The permeability at 3.4 MPa (500 psia) following the normal equilibration time (5 days) was shown to be negligibly different from the value after a 63-day equilibration time (121).

At low pressures, the permeabilities for the depressurization legs are about 100% larger than the permeability for the pressurization leg of the cycle. The increase in the permeability for the depressurization can be explained in terms of the enhanced solubility and diffusivity in the disturbed matrix. The disturbances to the matrix appear to be more subtle than those responsible for the true packing defects characterized by the C'_H parameter. In the dilated state, the disturbances can be thought of as causing a generalized reduction in the cohesive energy density of the polymer, thereby making it energetically easier to make a cavity to insert a gas molecule into a dissolved state. On total removal of the disturbing penetrant, some of these subtle disturbances may coalesce as a result of slow segmental movement to produce new packing defects of sufficient size to accommodate a penetrant.

Typically, even at high pressure the lower sorbing gases, such as nitrogen, helium, and even methane, are not able to induce the hysteretic responses (conditioning) observed with CO_2. The lower condensability, and hence lower solubility of these supercritical gases, is presumably responsible for their lack of conditioning capability. Although these low sorbing gases are not able to induce a hysteretic

response, they can maintain the disturbed matrix in an open state if the solubility is sufficiently high under the conditions used after the exposure to the primary conditioning gas (122).

Similar effects have been noted for gases using intermediate-size penetrants as the disturbing and probing agents (123–126). The use of PMMA, PVC, or polystyrene monodisperse microspheres allows study of these larger penetrants with exceedingly small diffusion coefficients. Effects consistent with the general ideas noted above are seen in these cases, but additional complexity often enters because of protracted glassy state relaxation.

Sample Dimension Dependent Effects. Recently, it has been noted that the permeability of glassy polymers decreases over time and the selectivity increases over time. Interestingly, the decreases in permeability and increases in selectivity are accelerated for thin films, on the order of a micrometer in thickness. The study of the gas transport properties in thin films is not only academic because film thicknesses of this order are often used in semiconductors, in adhesives, and in packaging. Furthermore, the skin thicknesses of asymmetric hollow fibers, the most common industrial membrane geometry, are usually 1 μm or less.

The work of Pinnau and co-workers with asymmetric films was the first to show dramatic time-dependent gas transport properties (127,128). Later, Pfromm and co-workers showed similar behavior in free-standing polyimide and polysulfone films (129). Figure 34 shows that for a 0.5-μm thick polyimide film, the N_2 permeability decreases by approximately 50% over a 6000-h period, while the He/N_2 selectivity increases by approximately 25% in the same time period. The decrease in permeability is not nearly as dramatic for the thick films. Rezac and co-workers (130) and McCaig and co-workers (131) saw similar effects in polyimide/ceramic and polycarbonate/ceramic composite membranes, respectively. Chung and Teoh observed the same effects in asymmetric hollow fiber gas separation membranes (132).

The time-dependent gas transport properties illustrated above are usually described in terms of physical aging. Physical aging is a well-known phenomenon in glassy polymers that results from their nonequilibrium nature. As already mentioned, the segmental motions of the polymer chains are severely hindered in the glassy state, but these motions are not completely excluded. The hindered segmental motions allow for the recovery of unrelaxed free volume, $V_g - V_\ell$ (see Fig. 22). The gradual approach to the equilibrium volume, V_ℓ, is called physical aging (68).

Two mechanisms are often used to describe physical aging: lattice contraction and diffusion of free volume. In the lattice-contraction mechanism, the polymer chains are pictured as uniformly moving closer together, as if the lattice spacing throughout the polymer has decreased. The kinetics of the lattice contraction are not dependent on the sample dimensions. The diffusion of free volume or holes was first proposed by Alfrey (134). In this mechanism, packets of free-volume are pictured as diffusing from the interior to the surface of the sample where they are eliminated. Since the diffusion of free-volume process is assumed to be Fickian, the loss of free volume becomes dependent on the sample dimensions.

Curro and co-workers (135) proposed that contributions from both the lattice contraction and diffusion of free volume mechanisms represented the overall volume recovery in the glass. McCaig and co-workers extended this idea to capture

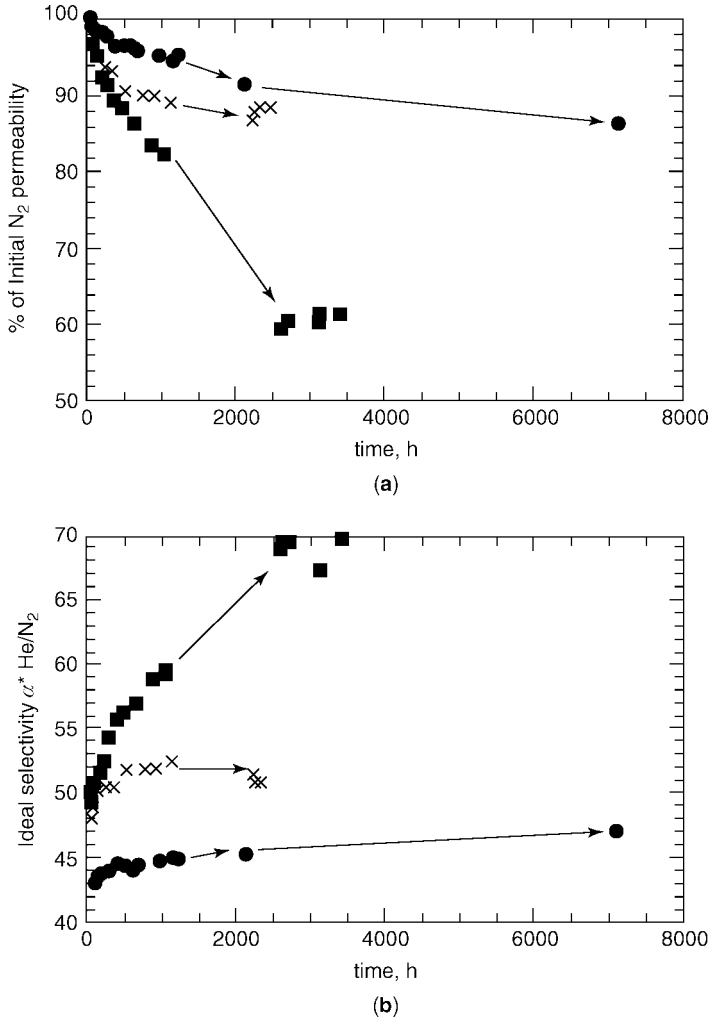

Fig. 34. (**a**) Decrease in N_2 permeability and (**b**) increase in He/N_2 selectivity for polyimide films of varying film thickness: ●, 28.45 μm; ×, 2.54 μm; and ■, 0.5 μm. Arrows indicate storage in dry air at 35°C. From Ref. 133.

the effect the free volume recovery had on the permeability of the glass (136). In this approach, the free volume is related to the permeability by the commonly used correlation:

$$P(t) = A\exp[-B/v_f(t)] \tag{68}$$

where A and B are parameters dependent on the penetrant–polymer pair and $v_f(t)$ is the time-dependent fractional free volume. The time dependence of the free volume loss from the lattice contract mechanism was modeled as a first-order exponential with time constant τ. The time dependence of the free-volume loss from the free-volume diffusion mechanism was calculated by solving the diffusion equation with a concentration-dependent diffusion coefficient. The concentration

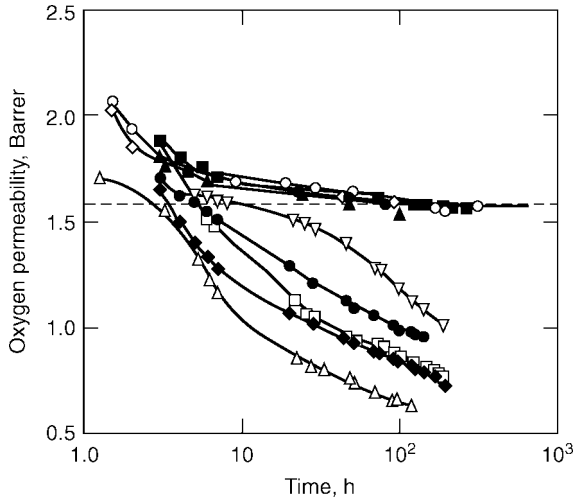

Fig. 35. Oxygen permeability decay through BPA–BnzDCA films illustrating physical aging effects for the following film thicknesses: ○, 33 μm; ■, 28 μm; ◇, 9.7 μm; ▲, 4.4 μm; ▽, 1.85 μm;, ●, 0.99 μm; □, 0.74 μm; ◆, 0.58 μm; △, 0.25 μm. Reprinted from Ref. 131 with permission from Elsevier..

dependence of the free volume diffusion coefficient was assumed to be of the form:

$$D = D_g \exp\left[-Z\left(\frac{1}{v_f(t)} - \frac{1}{v_f^g}\right)\right] \tag{69}$$

where $v^g{}_f$ is the fractional free volume of the slowly cooled glassy polymer, D_g is the diffusion coefficient when $v_f = v^g{}_f$, and Z is a material parameter. The concentration dependence of the diffusion coefficient captures the experimentally observed self-retarding nature of physical aging. The diffusion coefficient of free volume decreases as free volume is eliminated from the sample. This is the same concentration dependence seen for the diffusion coefficient with many small penetrants.

The dual-mechanism approach of McCaig and co-workers described above was able to describe the oxygen permeability decay in bisphenol. A benzophenonedicarboxylic acid (BPA–BnzDCA) films of varying thickness remarkably well. This data is illustrated in Figure 35. All films, regardless of thickness, experience an initial sharp decline in permeability. This drop is due to the lattice-contraction mechanism, which is independent of sample dimension. Only in the thin films where the half-thickness ℓ was less than 2.5 μm was a contribution from the free-volume diffusion mechanism observed.

Orientation-Induced Effects. Orientation and combined heat and orientation processing affect the transport properties of glassy polymers. Especially when crystallites are present, the effects can become surprisingly large. As noted for rubbery semicrystalline materials, the obvious improvements in barrier properties associated with organization of lamellar crystalline domains with their platelets perpendicular to the direction of penetrant flow can produce significant

reductions in permeability. Simple crystallinity appears to act principally as tortuous blocking elements to increase the path length of penetrants in their random walks across the film (eqs. 18b and 45).

Depending on the aspect ratio, orientation of the crystallites can have minimal or profound effects. The results in Table 7 show roughly an order of magnitude reduction in the permeability of CO_2 in a sample of biaxially oriented Kapton polyimide as compared to a chemically identical, but essentially unoriented, sample of the same polyimide of pyromellitic dianhydride and oxydianiline (PMDA–ODA). The reductions in permeability caused by the biaxial orientation are greater for the larger CH_4 molecule as indicated by the higher permselectivity in the Kapton. X-ray scattering measurements indicate the presence of small platelet-like aggregates in the Kapton (137). The orientation of the platelets perpendicular to the direction of permeation adds significantly to the tortuosity of the Kapton samples. This is reflected in the solubility and diffusivity data in Table 7. The primary effect on permeability is due to the diffusivity component. It has been suggested that the platelet dimensions are on the order of 20 nm $\times$ 20 nm $\times$ 5 nm.

In studies of oxygen and water vapor permeability in PVC having low crystallinity (ca 3–5%) (138), the effects of biaxial orientation, draw rates, temperature of draw, and subsequent annealing temperatures have been reported. As expected, the effects of orientation are much less significant in PVC than in more highly crystalline materials in which the effectiveness of flow impediments can be influenced greatly by orientation. The oxygen and water permeability typically decrease by less than 50% with the various processing parameters, and in fact show increases in some cases.

In another study of the effects of uniaxial orientation on PVC and other essentially amorphous glasses (139), a wide range of penetrants has been considered and permeability, solubility, and diffusivity effects caused by various orientation variables have been explicitly determined (Fig. 36) (139). The orientation, measured by birefringence, leads to improved barrier properties, and appears to have an effect on both the apparent solubility coefficient $k_a = C/p$ and the apparent diffusivity determined by time-lag measurements.

One of the few studies of transport in liquid crystalline glassy polymers has yielded some interesting results (140). The liquid and more ordered nematic morphologies characteristic of these highly rigid rod-like materials is compared in Figure 37 to more flexible chained materials such as glassy poly(ethylene terephthalate) (PET), PVC, or rubbery polyethylene discussed previously.

polyacrylonitrile (PAN) and are much superior to those of the structurally similar, but nonliquid crystalline PET (Table 8). PAN provides a permeation barrier largely on the basis of its tremendous resistance to penetrant diffusion. The low diffusion coefficients are associated with the intersegmental polar attractions of the acrylonitrile pendent groups. The strong polar attractions produce a high cohesive energy density that in turn increases activation energy for diffusion and thereby suppresses the diffusion coefficient. Resistances to intrasegmental motion caused by the size of the acrylonitrile group are believed to be of secondary importance in suppressing diffusion compared to the strong intersegmental forces.

The rigid liquid crystal material does not have particularly strong intersegmental attractions, and although it has significant intrasegmental resistance to rotation, it is not even as rigid as the polyimide materials noted earlier. Because of the highly ordered structure of the liquid crystalline material, the extremely

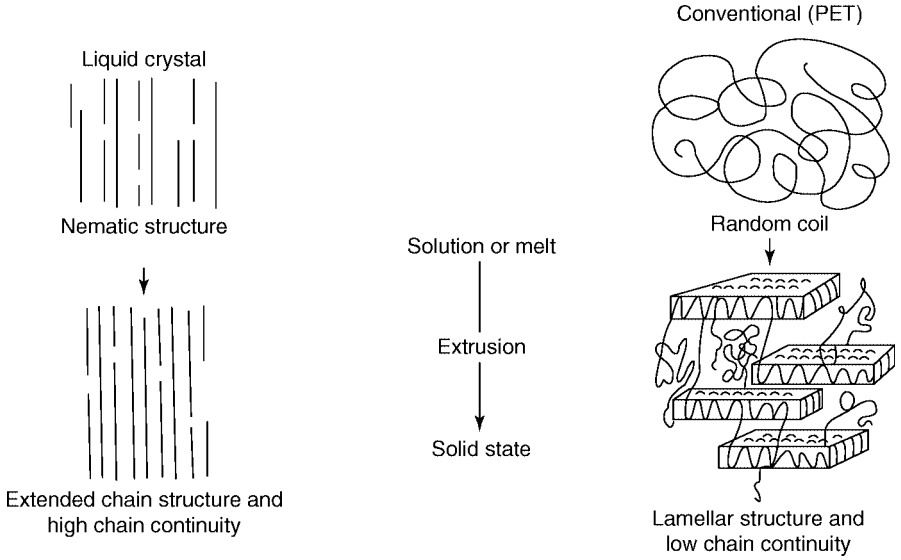

Fig. 37. Comparison of liquid crystal and conventional random coil polymer properties.

low gas solubilities reported are not surprising; however, it is surprising that the diffusivities in this highly crystalline medium are not significantly different from those of PET, which has a much lower crystalline fraction.

Non-Fickian Transport Behavior

The topic of non-Fickian transport encompasses all cases in which the simple form of the flux equation given by equation 1, with a concentration-dependent diffusion coefficient and constant-system boundary conditions, is insufficient to describe the observed time-dependent behavior of the system. This definition includes cases with position-dependent diffusion and solubility coefficients. For example, a film conditioned with a swelling agent (eg, CO_2) used to induce different properties at the upstream and downstream faces falls in this category. Another variation of this problem includes cases in which quenching or orientation produces transverse swelling stresses during the sorption kinetics process. Such position dependencies, superimposed on concentration-dependent transport coefficients, considerably complicate the response characteristics of a system. Nevertheless, mathematical analysis of the problem is possible by generalizing procedures used for the case of concentration-dependent, time-invariant coefficients if the position-dependent profile of the transport properties can be defined.

Complex concentration dependence of the sorption and diffusion coefficients can be accommodated within the framework of Fickian transport if nonisotropic variations in properties are not too serious. The use of an average diffusion coefficient and an average solubility coefficient defined over a particular range of external penetrant boundary conditions are acceptable for many practical applications.

Unlike the situation with Fickian systems, when dealing with non-Fickian systems data derived from the kinetic responses of a system cannot be readily extended to other configurations with significantly different boundary conditions or sample dimensions. By far the most difficult problems encountered in the domain of non-Fickian processes involve time-dependent changes in transport and sorption properties, ie, additional time dependence, beyond that caused by simple time variation in the local concentration. The additional time-dependent problem is the most difficult to treat because it generally involves introducing additional physical expressions. Transverse swelling stresses typify such cases (141). In this example, the additional physics are accommodated by a linear viscoelastic approximation to account for the time-dependent relaxation of stresses induced in the medium by swelling.

Another example of this class is solvent-induced crystallization (142). The effects of crystallization kinetics and rate of movement of the boundary between penetrated and unpenetrated regions have been treated. Moreover, effects of increasing impediments to diffusion caused by the increasing crystalline fraction during the same time scale as that of the solvent transport are included in the model of the system. Such models become exceedingly complex and fall outside the domain of the present discussion; however, they clearly require the input of information related to transport properties and their dependence on local conditions.

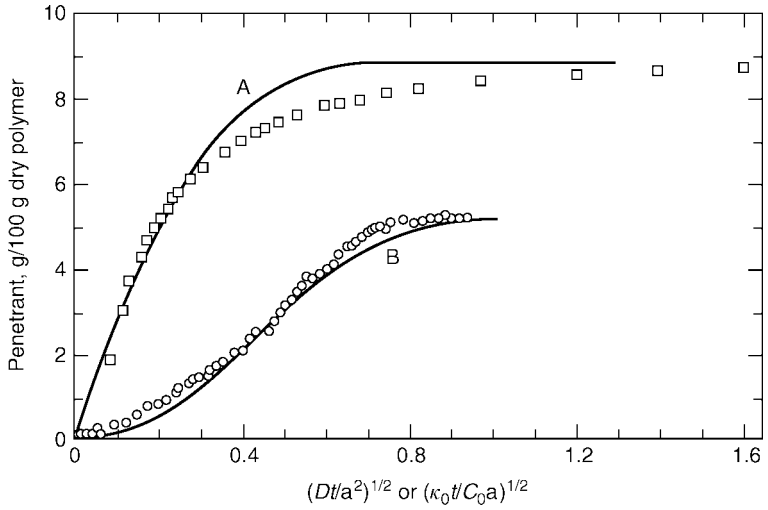

Fig. 38. Comparison of theoretical curves and experimental data for n-hexane sorption in the large- and small-diameter spheres at $P/P_0 = 0.75$ and 30°C. **A**, Fickian model, diameter = 184 μm; **B**, Case II model, diameter = 0.534 μm.

Testing samples of different macroscopic dimensions of a given material under certain conditions can bring unusual factors into play.

Indeed, entirely different responses can be observed as the time required for relaxation of stresses varies relative to the time required to change the local concentration at a point in the material. The dependence of mass absorbed M_t on time at early time in a sorption run is often used to categorize the type of transport process occurring. A simple dependence on the square root of time ($t^{0.5}$) is an indication of Fickian transport (recall eq. 3a), whereas dependence t^a, $a >$ 0.5 on is indicative of non-Fickian transport and is termed anomalous.

A limiting case of non-Fickian response in which $a = 1.0$ is typically referred to as *Case II diffusion* to differentiate it from normal Fickian (Case I) diffusion. Case I (Fickian) diffusion shows a linear increase in sorption as a function of the square root of time. By contrast, Case II kinetics are characterized by linear mass uptake with time as shown in Figure 38, where uptake of n-pentane in polystyrene at high activity (penetrant partial pressure) shows a Fickian response in small spheres and a non-Fickian response in larger diameter spheres (143). The data strongly suggest that diffusion into the small spheres is so rapid that there is insufficient time to generate a Case II concentration profile. Apparently the diffusional equilibration in the small spheres is essentially complete before the complex step concentration profile associated with Case II sorption can be established. This behavior is similar to other observations (144).

The general problem of two independent time scales for diffusive equilibration and molecular relaxation existing in a system has been considered (145). Fickian transport is obtained when the time scale of the relaxation is either effectively zero or infinite compared to the time required to establish a concentration profile in the sample. These two limits have been called the elastic and viscous Fickian diffusion limits, respectively.

The elastic limit is characteristic of samples exposed to gases or low activities of vapors that experience little segmental disruption relative to the native polymer and are able to accommodate the sorption by elastic deformation of intrasegmental bonds or slight disruption of intersegmental bonds while maintaining the essential integrity of the entanglements of interpenetrating chains in the matrix. On removal of the perturbing penetrant, the matrix is able to recover to its original condition.

The viscous limit applies when significant swelling occurs and reorganization of the entanglement network may occur sufficiently rapidly during the solvent invasion to relax any local stresses that may tend to build. In this situation, only a complex concentration-dependent diffusion coefficient is required to describe the locally changing environment through which a penetrant must move. An example of this behavior is the initial desorption of solvent from a highly swollen polymer.

Between these two limiting Fickian cases lies an important domain in which significant swelling (greater than 10% by volume) occurs. Under such conditions, the polymer deformation in response to a local swelling stress caused by a local penetrant concentration is rapid (but not infinite) as compared to the time required to produce a change in local concentration. Typical uptake behavior in such Case II situations is linear with time as shown for the large spheres in Figure 38. The chief attributes (146) of these systems are a sharp advancing boundary existing between an inner glassy core and an outer swollen rubbery shell; a swollen gel behind the advancing penetrant front close to equilibrium with the external solvent supply; and a boundary between the swollen gel and glassy core, which advances at a constant velocity.

An induction time prior to the onset of the linear uptake in mass with time is also a characteristic common in Case II systems (147). However, this behavior is somewhat difficult to discern using the gravimetric and optical methods usually employed. An induction time is consistent with the criterion for the relatively rapid polymer deformation in response to a local swelling stress compared to the time required to produce a change in concentration profile. The approach of the surface concentration to true equilibrium in such non-Fickian systems is protracted (148). A connection has been made between the effective deformation stress acting to dilate the matrix and a thermodynamically calculable osmotic swelling stress (149). Case II front movement is visualized to occur when local stresses build to a sufficient extent to allow crazing. Combining the two concepts of an induction time at the surface and an osmotically driven local dilational stress, the yielding problem has been formulated in terms of a concentration-dependent viscosity of the matrix (150).

Thus, in essence, the Case II process is initiated when a surface element of sufficient thinness experiences a significant reduction in viscosity and is able to relax some of the stresses due to the elastically deformed chains of the polymer. This relaxation of stresses allows more solvent to invade the thin element, further depressing the viscosity, and thereby autocatalytically accelerating the stress relaxation. This results in a surface concentration that exponentially approaches its equilibrium value. While this outermost element is undergoing its rapid, but not instantaneous, relaxation, the solvent that is now available to the next infinitesimally thin element invades it as has occurred in the first exposure of the surface element. The transport to this interior element is essentially instantaneous,

because of the much lower resistance to diffusive supply through the swollen gel as compared to diffusive invasion of the virgin polymer in the second element. In this case, therefore, the second element experiences significant relaxation by the time the first is approaching its equilibrium conditions with respect to the external penetrant. A third, fourth, and progressive repetition of this process leads to a negligible concentration gradient in the swollen gel behind the front, and a small and very sharp concentration gradient in some characteristically small number of volume elements ahead of the front.

Assuming the viscosity is dependent on the local penetrant volume fraction φ_A in the volume element under consideration (147),

$$\eta = \eta_0 \exp(-m\varphi_A) \tag{70}$$

where m is an empirical constant and η_0 is the viscosity of the virgin polymer containing no penetrant. This expression is, again, related to the free-volume concepts discussed in relation to equations 18a and 19 with regard to diffusion coefficients. Further treatment (147) has focused on the magnitude of the induction time for front initiation, neglecting all diffusional resistance in the gel layer behind the front and assuming an effective average diffusion coefficient $\bar{D}$ of the penetrant in the partially plasticized thin element ahead of the front. The front velocity should be proportional to the square root of the ratio of the local effective diffusivity in each of the infinitesimal volume elements preceding the relaxation front and the unplasticized viscosity of the glassy material prior to penetration, namely

$$V(T) \propto \left(\frac{D(T)}{\eta_0(T)}\right)^{0.5} \tag{71}$$

Evidence is given to support this suggestion (147). In the study, it was concluded that the relative activation energies for the effective solvent diffusion coefficient and the intrinsic viscosity of the glass were 58.6 kJ/mol (14 kcal/mol) and 167 kJ/mol (40 kcal/mol), respectively. Based on the earlier discussion of Figure 5, the infinite-dilution values of the activation energy for the diffusion coefficient and viscosity of the glass are expected to be similar. The lower activation energy for the diffusion coefficient $\bar{D}$ in the partially plasticized glass ahead of the front as compared to the viscosity of the unplasticized glass, η_0, is not surprising.

Recent theoretical and experimental work has significantly advanced the understanding of Case II transport; however, because of the general complexity of this work, a review of it is beyond the scope of this article. The interested reader is directed to the work of Petropoulos and co-workers (151), Wu and Peppas (152), Huang and Durning (153), and the references therein.

Facilitated Transport

Facilitated transport involves the coupling of a reversible chemical reaction to the mass transfer through the polymer. This type of transport is very common in biological systems, and is capable of substantially increasing the flux and selectivity of synthetic polymers. Facilitated transport still proceeds by the solution-diffusion

mechanism; however, the penetrant now has two diffusive pathways through the polymer. The penetrant can sorb into the membrane and diffuse down its chemical potential gradient, or the penetrant can complex with the carrier upon sorption and diffusion down a penetrant-carrier complex chemical potential gradient. The second pathway is only available to penetrants that complex with the carrier. The presence of a carrier usually increases the sorption of the complexing penetrant as well.

The inclusion of the complexation reaction in facilitated transport greatly increases the mathematically complexity of the flux equations at steady state. The concentration through the polymer of the penetrant, c_A, the carrier, c_c, and the penetrant–carrier complex, $c_{A–c}$, must satisfy the following continuity equations:

$$D_A \frac{d^2 c_A}{dx^2} - r_{A–c} = 0 \tag{72a}$$

$$D_c \frac{d^2 c_c}{dx^2} - r_{A–c} = 0 \tag{72b}$$

$$D_{A–c} \frac{d^2 c_{A–c}}{dx^2} + r_{A–c} = 0 \tag{72c}$$

where D_A, D_c, and $D_{A–c}$ are the diffusion coefficients of the penetrant, carrier, and penetrant-carrier complex, respectively. The net reaction rate of complexation is $r_{A–c}$. The boundary conditions for the above equations are determined from an appropriate sorption model. Cussler solved the above set of equations analytically for the two limiting cases of fast reaction and fast diffusion (154). Except for these limiting cases, numerical methods are required to determine the flux of each species.

Facilitated transport has been reported in a number of systems. One of the most common systems uses silver as a carrier for olefins (155–157). Olefins are able to complex with silver, while paraffins are not. Transport of carbon dioxide has been facilitated through the use of amine complexes (158–160). Porphyrins have been used to facilitate the transport of oxygen and increase oxygen/nitrogen selectivity (161–163). Several methods have been used for carrier inclusion in the polymer: (*1*). carriers are blended as ionic salts with the polymer, (*2*). carriers are bonded to the polymer backbone through the use of crown ethers, and (*3*). carriers are used as the exchange sites on ionic exchange membranes. Regardless of the carrier and the inclusion technique, all facilitated transport membranes still currently suffer from unstable performance. The carrier is often poisoned by contaminants in the feed stream, and in some cases the carrier simply leaches out of the membrane. These issues must be resolved before there is widespread industrial adoption of facilitated transport membranes.

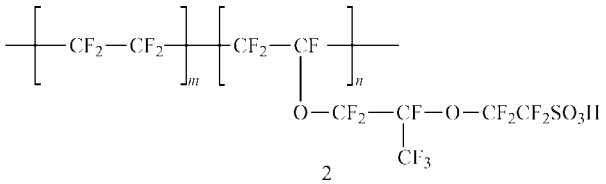
Contradictory to facilitated transport, the use of scavengers attempts to inhibit transport of particular penetrants. Scavengers are adsorbents that are blended with the polymer. This technology is often used in food packaging.

Unfortunately, most of the literature on scavenging techniques is only available in patents (164–166). Scavengers typically attempt to limit transport of oxygen, water, and organoleptics. Anthraquinone and iron have been used as oxygen scavengers. Clays, molecular sieves, and other common desiccants have been used as water scavengers. Antioxidants, such as butylated hydroxytoluene (167), are often used as organoleptic scavengers.

Proton Exchange Membranes

In recent years, a great deal of research has been focused on proton exchange membranes (PEMs) for use in fuel cells. Fuel cell based vehicles are touted as a more efficient, environmentally-friendly replacement for internal combustion engines. The fuel cell harnesses energy from the chemical reaction of hydrogen and oxygen to form water. In this reaction, the cathode and anode are separated by the PEM which allows passage of protons and theoretically blocks passage of other species. The electrons produced from the reaction are routed through an external circuit to provide power.

Nafion produced by Dupont is the most commonly used PEM material. Nafion is a hydrated perfluorosulfonic acid (PFSA) polymer. The Nafion backbone is hydrophobic, while side-chain sulfonic acid groups are hydrophilic. The repeat unit of Nafion is given as structure (**2**).



2

Hydrated Nafion is thought to have a morphology composed of a hydrophobic matrix with dispersed hydrophilic sulfonic acid clusters connected by pores (168). At low hydration levels, the pores between sulfonic acid clusters are thought to be collapsed. At high hydration, the pores become open and the sulfonic acid clusters are truly interconnected. As a result of this rather complex morphology, a great detail of debate exists in the literature about the mechanism of transport in Nafion. Models of transport based on the solution-diffusion mechanism have been proposed (169,170). These models picture Nafion as a one-phase homogenous material where transport is driven by chemical potential gradients. Alternative models, based on the pore-flow mechanism, have also been proposed for transport in Nafion (171,172). In these models, Nafion is pictured as a porous material, where transport is achieved by convective flow through pores. Neither type of model is able to describe all of the observed transport phenomena in Nafion. Recently, it has been argued that a combination of the solution-diffusion and pore-flow models may be appropriate for Nafion (173,174). At low hydration levels, solution-diffusion based transport is the dominant mode because no interconnected pores exist. At high hydration levels, pore flow based transport is dominant because now

an interconnected pore network does exist. At intermediate levels of hydration, the two mechanisms of transport are both present.

Since the scope of this article is limited to transport in dense, nonporous polymers, the rest of this discussion is limited to transport where a solution-diffusion mechanism is assumed to occur. In this regime, the flux of "A" is given by (175)

$$j_A = -D_A\left(\frac{dc_A}{dx} + z_A c_A \frac{F}{RT}\frac{d\psi}{dx}\right) \tag{73}$$

where z_A is the charge of "A", F is Faraday's constant, and ψ is the electrostatic potential. For protons, which have a charge of $z_A = 1$, the gradient in electrostatic potential is the dominant driving force, and the flux equation reduces to

$$j_{H^+} = -\frac{D_{H^+} c_{H^+} F}{RT}\frac{\Delta\psi}{L} \tag{74}$$

where L is the membrane thickness. In the literature, the flux is often reported as a current density i, which equals

$$i = Fj_A = \frac{\sigma\,\Delta\psi}{L} \tag{75}$$

where the conductivity $\sigma = D_A c_A F^2/RT$. In the case of noncharged penetrants, the charge equals zero, and equation 73 reduces to Fick's law. The above equations are exact only when the diffusion coefficient is constant, the membrane is uniformly charged, and electroosmosis effects are neglected.

Positron Annihilation Lifetime Spectroscopy

From the models of transport through both rubbery and glassy polymers given previously, it becomes apparent that knowing the free-volume distribution of the material is crucial for a microscale description of gas transport. Recently, positron annihilation lifetime spectroscopy (PALS) has been developed to probe the free volume of glassy polymers. PALS injects positrons, antielectrons, into the material where they have an extended lifetime because of interactions with the sample. The lifetime of the positronium species is on the order of a few nanoseconds and is sensitive to the electron density of the environment. This makes PALS a model-dependent technique which is capable of measuring free-volume holes that exist for 10^{-9} s or longer. PALS is able to resolve free-volume hole sizes in the range of 1–10Å;. Reviews of PALS are available (176–178).

The positron source is usually ^{22}Na, which releases a positron every 1.5 ms as it decays into ^{22}Ne. Approximately 3 ps after the positron is emitted from the source, gamma radiation of energy 1.28 MeV is released. This energy release is detected and marks the positron "birth." Once inside the sample, the positron annihilates by one of the three possible modes. The first and shortest lived mode results from the *para*-positronium, *p*-Ps, species which is formed when the positron

extracts an electron from the sample with opposite spin. The *p*-Ps species annihilates with its own electron after a lifetime of 125 ps. The lifetime of *p*-Ps is independent of the environment. The second mode of annihilation results from free positrons which have a lifetime of 100–500 ps. The third and longest lived mode results from the *ortho*-positronium, *o*-Ps, species which is formed from a positron and an extracted electron with opposing spins. The *o*-Ps decays after approximately 10^3 ps when it extracts or picks off another electron from the sample. After each annihilation event, regardless of the mode, gamma radiation of energy 0.511 MeV is released. This energy is detected and marks the "death" of the positron. The spectrum produced from these annihilation events is most commonly fit using three exponential decays. The resulting parameters are I_1, I_2, and I_3 for the intensity of each mode and the time constants τ_1, τ_2, and τ_3.

Since the behavior of the *o*-Ps species is dependent on the polymer free volume, the parameters associated with it, I_3 and τ_3, can be used to characterize the glassy structure. The probability of *o*-Ps formation and the concentration of free-volume holes are related to the intensity I_3. The time constant τ_3 is sensitive to the size of the free-volume holes. Simplistically, the time constant is short in small free-volume holes because the close proximity of the *o*-Ps to neighboring mass within the sample makes it easier for the *o*-Ps to pick off an electron. The semiempirical relationship between the time constant τ_3 and the free-volume hole radius R is given below (179).

$$\tau_3 = \frac{1}{2}\left[1 - \frac{R}{R_0} + \frac{1}{2\pi}\sin\left(\frac{2\pi R}{R_0}\right)\right]^{-1} \tag{76}$$

R_0 is equal to $R + \Delta R$ where ΔR is the electron layer thickness. The value of ΔR was found empirically and is usually assumed to equal 1.66Å;. Equation 76 assumes that the *o*-Ps resides in the center of a spherical free-volume hole, and so it follows that the hole volume V_h is equal to $4/3\pi R^3$. The fractional free volume of the material is given by (180)

$$v_\mathrm{f} = CV_\mathrm{h}I_3 \tag{77}$$

where C is a material parameter determined from the P-V-T properties of the polymer. The free volume probability-density function, $V_\mathrm{h}\,p dv_\mathrm{f}$, is given as (181)

$$V_\mathrm{h} p\, dv_\mathrm{f} = -3.32\left\{\cos\left[\frac{2\pi R}{R + 1.66}\right] - 1\right\}\frac{\alpha(\lambda)}{(R + 1.66)^2 K(R) 4\pi R^2} \tag{78}$$

where the fraction of holes between V_h and dV_h is $V_\mathrm{h}\,p dv_\mathrm{f}\,dV_\mathrm{h}$. In equation 78, $\alpha(\lambda)$ is the annihilation probability-density function. This function is obtained from a continuous fit of the positron lifetime spectra. $K(R)$ is a correction for the capture probability of *o*-Ps in different size holes. A detailed description of equation 78 is given elsewhere (182).

Because PALS is still a very new technique for characterizing glassy polymers, only a limited number of materials have been investigated which are also of interest from a gas transport standpoint (181,183–187). The most thorough

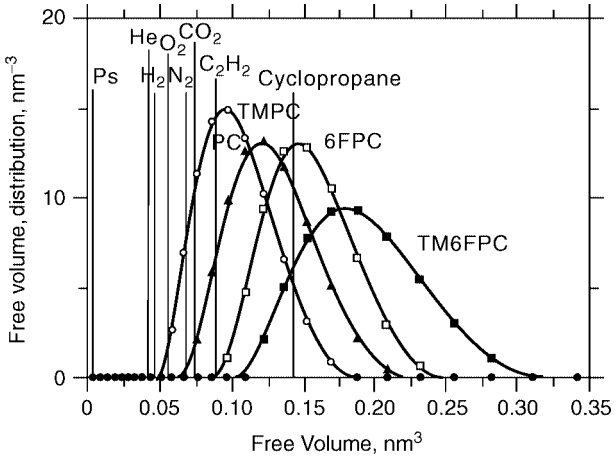


Fig. 39. Free-volume hole distributions of various polycarbonates. Dashed lines are the molecular volumes of common penetrants. Reprinted from Ref. 181. This material is used by permission of John Wiley & Sons, Inc.

study of this kind yet conducted was carried out by Shantarovich and co-workers, where positron lifetime spectra were collected for 10 glassy polymers (187). Jean and co-workers used PALS to study the same polycarbonates shown in Figure 28: PC, TMPC, HFPC, and TMHFPC (181). The distribution of free-volume hole sizes in these polymers is given in Figure 39 along with the molecular volume of common penetrants. The materials with larger average free-volume hole size also had a wider distribution of hole sizes. The diffusion coefficient of O_2 and CO_2 through these materials correlated well with the experimentally determined fractional free volume from equation 77. The ability of PALS to determine both the hole size distribution and the fractional free volume opens up a number of very interesting questions. For example, how will the transport differ in materials of the same fractional free volume but with different free-volume distributions?

Another interesting set of articles (188,189) uses PALS to investigate the behavior of the free-volume as the polymer is subjected to high pressure gases. As PC is pressurized to approximately 4.14 MPa (600 psi) by N_2, the free-volume hole radius obtained from the positron lifetime spectra increases. Continuing to increase the N_2 pressure from 4.14 MPa (600 psi) to 8.28 MPa (1200 psi) results in a decrease in the free-volume hole radius. No hysteretic effects were observed upon depressurization. This behavior was explained as plasticization and hydrostatic effects similar to those already discussed in the context of rubbery polymers. The N_2 is claimed to initially plasticize or soften the polymer resulting in larger free-volume holes. These results appear rather contrary to concepts noted with regard to the effect of pressurization on free volume in Fig. 8. As the pressure is increased more, the polymer compresses resulting in smaller free-volume holes, which is consistent with Fig. 8. A very different effect was observed when PC was exposed to high pressure CO_2. The free-volume hole size was observed to monotonically increase with CO_2. Upon depressurization, a large hysteresis was seen. After CO_2 exposure, the fractional free volume and average hole size were larger. This

behavior results from the strong conditioning effect of CO_2 that was described in a previous section.

Although PALS has been applied successfully to determine the glassy polymer microstructure, the technique has several limitations. In many low polar liquids, the positronium species forms a "bubble." This bubble results from repulsions between the electron in the positronium and electrons in the surrounding. Obviously, formation of such a bubble would affect the free-volume characterization. This bubble formation process may be possible in rubbery polymers, but is generally not thought to occur in glassy polymers (176). Inhibition or quenching effects can also affect the lifetime of the positronium species. Halogen-containing polymers can lead to inhibition effects when the positronium interacts with the halogen atom. Nitroaromatics, such as polyimides, may react with the positron causing quenching (190). Perhaps, the largest disadvantage of PALS is that it is a model-dependent technique. In this respect, characterization of free-volume distributions in polymers using PALS is analogous to obtaining the pore-size distribution of a porous material from vapor sorption–desorption experiments.

Molecular Modeling of Transport in Amorphous Polymers

The rapid increase in computing power over recent years has led to a significant body of research, which seeks to describe penetrant sorption and diffusion in amorphous polymers through the use of computer simulations. Two main goals exist for computer simulations: first, to gain a better fundamental understanding of the transport mechanism through amorphous polymers; and second, to accurately predict the transport properties (ie, the diffusion and solubility coefficients) of novel polymers. The first goal is motivated by the fact that small-molecule transport is determined by the structure of the penetrant–polymer environment on an atomistic scale. Excluding the recent use of PALS structural information on this length-scale is not accessible from traditional macroscopic transport experiments but is accessible from molecular dynamic (MD) simulations. The second goal, accurate prediction of transport properties, seeks to eliminate expensive and labor-intensive experiments. Several reviews are available on computer simulations of gas diffusion through amorphous polymers (191,192).

The starting point for all computer simulation methods is the choice of a potential energy function or force field, $\Phi(R)$. This function gives the potential energy of a system of N atoms at positions r_i. The positions of all atoms in the system are represented by the three dimensional vector $R = (r_1, r_2, \ldots, r_N)$. The force-field accounts for all bonded and nonbonded interactions between atoms in the system. Bonded interactions include bondlength and bond-angle deformations and conformational deformations. These interactions are usually described as mechanical springs with the spring constant related to experimentally known bonding energies. The nonbonded interactions include van der Waals forces and other molecular forces and are accounted for empirically by a Lennard–Jones potential. Since the nonbonded interactions include contributions from each atom pair in the system, current computational power limits the number of atoms in the system to less than 10,000 (191). Many force-field models exist and proper selection is crucial for accurate results.

Once the force-field is chosen the motion of atoms in the system is simulated using classical equations of motions:

$$\frac{du_{\mathrm{i}}(t)}{dt} = \frac{1}{m_{\mathrm{i}}} F_{\mathrm{i}}[R(t)] \tag{79a}$$

$$\frac{dr_{\mathrm{i}}(t)}{dt} = u_{\mathrm{i}}(t) \tag{79b}$$

where $u_i(t)$ is the velocity of atom i with mass m_i, at time t. The force on i, F_i, is given by

$$F_i = -\frac{\partial \Phi(R)}{\partial r_i} \tag{79c}$$

Equations 79a, 79b, and 79c are a coupled set of second-order differential equations. Methods exist to solve these equations numerically only for small timesteps. The timestep can not be greater than about 1 fs, which is about a tenth of the C—H bond oscillation time. Because such extremely small timesteps are required, an upper limit of several nanoseconds is imposed on current MD simulations (191).

The limit of MD models to at most 10,000 atoms on current workstations results in model systems that are cubic volume elements with a side length of just a few nanometers. Many approaches have been attempted to initially populate the system with atoms. The approach described by Theodorou and Suter seems to have gained the most use in recent literature (193,194). In this method the cubic volume element is filled by growing the chain one backbone bond at a time. Rotational isomeric states (RIS) theory is used to calculate the conditional probability of each conformation. As the chain is grown, the conformation angle is selected statistically to agree with the RIS information. After the chain has grown a few repeat units, it is likely to cross the boundary of the volume element. When this happens, the chain growth is continued by reentering the volume element on the opposite side. Chains grown in this manner typically achieve the overall density target, but the chain growth often results in regions of severe atomic overlap. To combat this effect, a series of static energy minimizations and dynamic simulations are carried out to equilibrate the structure. After equilibration, it is possible to get the density of the volume element to within a few percent of the experimentally determined density; however, such a high level of agreement is not currently possible for all materials because of deficiencies in the force field.

The particle trajectories from the MD simulations can be used to determine the self-diffusion coefficient using the Einstein equation:

$$D_{\mathrm{A}}^{*} = \langle |r(t) - r(0)|^2 \rangle / 6t = \frac{\lambda^2 f}{6} \tag{80}$$

where $r(t)$ is the position of a penetrant atom at time t, $r(0)$ is the initial position of the penetrant, and the angular brackets indicate an average over all penetrants in the system. The term $\langle |r(t) - r(0)|^2 \rangle$ is the mean-squared displacement of the

penetrant. f simple indicates the average frequency of a diffusional jump of length λ. The diffusion coefficient in equation 80 ideally allows one to estimate the self-diffusion coefficient in equation 6. The Einstein equation gives accurate results for rubbery polymers; however, in glassy polymers, anomalous diffusion effects act to degrade the accuracy (195). In anomalous diffusion the penetrant is not proceeding by a truly random walk from one free-volume hole to the next which is assumed by the Einstein equation. This effect results from penetrant oscillations inside the free-volume holes that occur between diffusive jumps from one hole to the next. Since the simulation time is only a few nanoseconds, these oscillations have a nonnegligible effect on the mean-squared displacement. It is important to note that this definition of anomalous diffusion is different than non-Fickian diffusion, discussed previously, which is also commonly referred to as *anomalous diffusion* in classic texts (5).

Gusev and Suter have developed a transition-state theory that is based on a Monte Carlo scheme which requires less computational power than the MD simulations and therefore is able to calculate diffusion coefficients where anomalous diffusion effects are negligible (192,196–198). In this method a three-dimensional grid is overlaid on a fully equilibrated MD volume element. A typical grid spacing is 0.03 nm (191). The insertion energy of a penetrant molecule is calculated at each grid location. In this calculation the insertion energy comes from the nonbonded contribution of the force field. The volume element is then mapped as regions of high and low packing on the basis of whether the insertion energy was high or low. This mapping allows for the identification of pathways between adjacent low energy regions. Each of these pathways is assigned a jump probability which is based on the Boltzmann distribution. This jump probability is affected by the thermal motion of the polymer atoms which is characterized by the mean-squared displacement of polymer atoms, $\langle\Delta\rangle^2$. This parameter is often gained from a short MD simulation. It should be noted that the Gusev and Suter method does not account for polymer relaxation as a result of penetrant insertion, and so this theory is only reasonable for small penetrants up to methane. With the appropriate jump probabilities, the penetrant diffusion is simulated using a Monte Carlo scheme. The insertion energy E_{ins} calculated during this process can also be used to calculate the solubility coefficient S:

$$S = \exp(-\mu_{\text{ex}}/RT) \tag{81}$$

where the excess chemical potential $\mu_{\text{ex}} = RT \ln \langle \exp(-E_{\text{ins}}/k_{\text{B}}T)\rangle$ (199). Diffusion and solubility coefficients calculated using the above techniques are usually within a factor of 3 to 5 of experimentally determined values. This degree of agreement is not accurate enough for many applications.

Molecular modeling of the type described above has been conducted on a number of polymer systems. Of these systems the great majority have been based on rubbery polymers. It is only recently that molecular simulations based on glassy polymer systems are appearing in the literature (200–206). From these studies, differences in the diffusion mechanism of rubbery and glassy polymers are starting to emerge. In both cases, the penetrant can spend relatively long periods of time (several hundred picoseconds) bouncing around inside the free-volume hole. At some point in time, a transient gap opens up because of thermally induced polymer

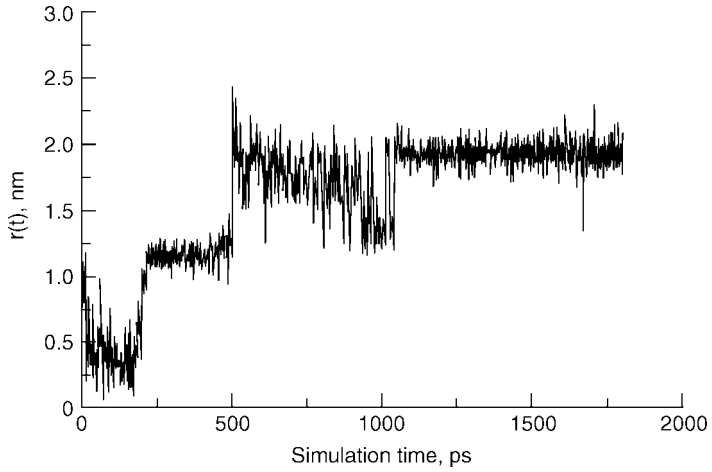

Fig. 40. H_2 diffusion through PEEK shows diffusion jumps of 5–10Å; separated by several hundred picoseconds of oscillations in free volume. Reprinted from Ref. 200, with permission from Elsevier.

motion between free-volume holes. While the gap is open, the penetrant may make a diffusive jump between holes. These jumps are usually estimated to be 5–10Å; in length (see Figs. 40 and 41). In rubbers the gaps between free-volume holes is only open for a few picoseconds, and the penetrant does not have the opportunity to make a backwards jump into the original free-volume hole. This is not the case in glassy polymers, where the channel between voids can be open for an extended period of time (several nanoseconds). This allows the penetrant molecule to jump back and forth numerous times between the two connected free-volume holes. The back-and-forth motion experienced by the penetrant in this behavior does not add to the overall diffusion coefficient (see eq. 80). This effect has been suggested

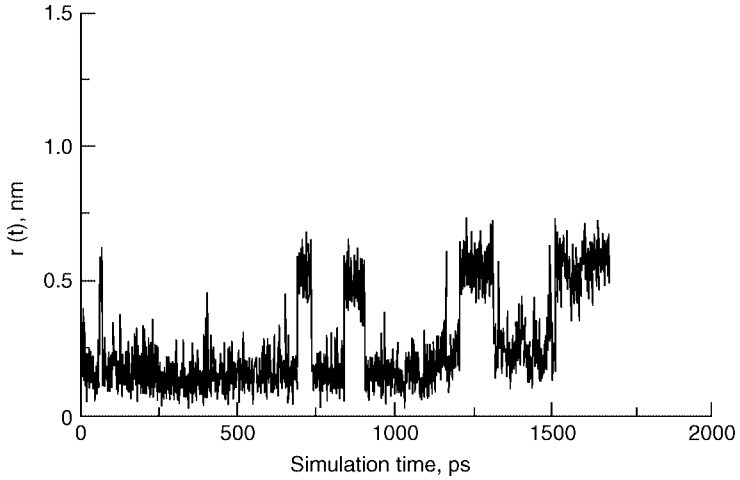

Fig. 41. N_2 diffusion through PEEK shows back-and-forth diffusion jumps that have been observed in many glassy polymers. Reprinted from Ref. 200, with permission from Elsevier.

as a contributing factor to explain why rubbery polymers exhibit much higher diffusion coefficients than glassy polymers (191), since it reduces the frequency f of a successful jump in equation 80. However, there has been recent evidence that even amorphous rubbery polymers may be significantly affected by anomalous diffusion because of alignment of the polymer chains at the nanoscale (207).

The frontier in the field of transport properties of polymers involves bridging the gap between the molecular scale penetrant–polymer environment and the macroscale solubility and diffusion coefficients. Impressive efforts to achieve this goal have already been made through the use of PALS and molecular modeling. The continued increase in computing power will allow for molecular dynamic simulations of larger volume elements for longer time periods. These improvements should cure many of the current inaccuracies inherent in molecular modeling, and allow for the first time a truly predictive method of determining polymer transport properties.

The topics discussed in this article only dealt with small-molecule diffusion through polymers. Another interesting and complex topic involves the diffusion of large polymeric penetrants through a polymeric medium. de Gennes provided a theoretical treatment of a polymer chain diffusing through a cross-linked rubber (208). In this treatment the polymer chain motion is referred to as *reptation*, since the motion of the chain is similar to that of a snake. The diffusing polymer chain is confined to a tube defined by the surrounding cross-linked matrix which restricts transverse motions. More complex treatments of reptation allow for the self-diffusion of the surrounding polymer matrix (209). The diffusion of macromolecular penetrants is of importance in a number of industrial applications including crack healing and adhesion between polymer surfaces, and in the use of polymer composites and blends.

ULTRASOUND-INDUCED RADICAL POLYMERIZATION

Introduction

Ultrasound comprises sound waves typically in the range of 20 kHz to approximately 500 MHz, which cause compression and expansion in a fluid. The frequency and intensity (amplitude) are the most important properties to characterize the pressure wave. The use of ultrasound can be divided into two areas: low intensity, high frequency ultrasound (2–500 MHz, 0.1–0.5 W/cm^2) and power ultrasound with a high intensity and a low frequency (20–100 kHz, $>$10 W/cm^2). The former does not alter the state of the medium through which it travels and is commonly used for nondestructive evaluation and medical diagnosis (1). This type of ultrasound cannot be used for reactions. Contrarily, power ultrasound uses the energy to create cavitations, which involve the formation, growth, and implosive collapse of microscopic bubbles in a liquid. These bubbles are generated when the "negative" pressure during the rarefaction phase of the sound wave is sufficiently large to disrupt the liquid (see Fig. 1). The implosive collapse of the bubbles can locally produce extreme temperatures and pressures (5000°C, 20 MPa) for very short times, because of compression of the gas phase inside the cavity (2,3). These hotspots can lead to irreversible changes such as the formation of excited states, bond breakage, and the generation of radicals. Power ultrasound is applied for cleaning purposes, treatment of kidney stones, plastic welding, and for chemical reactions. Table 1 summarizes the different types of ultrasound and their applications.

With respect to polymerization processes, ultrasound has significant potential as a clean and safe technology. After the production of most types of polymers, catalyst and initiator residues contaminate the product. Since ultrasound generates the radicals *in situ* (4,5), no initiator or catalyst is required to start a polymerization reaction. An additional advantage of ultrasound is the intrinsic safe

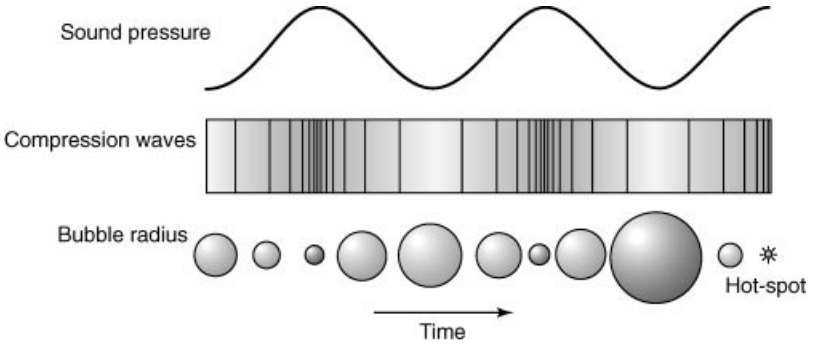

Fig. 1. Schematic representation of bubble growth and collapse in a liquid irradiated with ultrasound and the resulting hot-spot due to adiabatic compression.

operation, because turning off the electrical power supply will immediately stop the radical formation and, consequently, the polymerization reaction. Besides polymerization, polymer scission also can occur through irradiation with ultrasound (6). The rapid flow around a cavitation bubble stretches and ultimately breaks the polymer chain. At a sufficiently small chain length, typically 10^4 g/mol, further fracture of the polymer is prevented (7). In this way ultrasound-induced polymer scission provides an additional means to tune the molecular weight of the product.

In the following sections, the physical background of ultrasound-induced cavitation and radical formation is described. Subsequently, an overview of the various types of ultrasound-induced polymerizations is given, including bulk, precipitation, and emulsion polymerization. Finally, the breakage of polymer chains by cavitation is discussed.

Ultrasound Fundamentals

To understand ultrasound-induced radical polymerization, insight in the physical background of sonochemistry is a prerequisite. The rate at which ultrasound-induced reactions occur is generally determined by the collapse of the cavitation

Table 1. Overview of Different Types of Ultrasound, Including the Various Applications

Power ultrasound (20–100 kHz)	Sonophoresis (20 kHz, low power)	Therapeutic ultrasound (1 MHz, high power)	Nondestructive ultrasound (> 2 MHz, low power)
Sonochemistry	Transdermal drug delivery	Therapeutic massage	Flaw detection
Welding		Controlled release	Medical diagnoses

Cell disruption			
Sterilization			
Kidney stones			

bubbles. The movement of these cavities depends on the frequency and intensity of the sound wave as well as on the physical properties of the liquid.

Ultrasound in Liquids. Sound passes through an elastic medium as a longitudinal wave, ie, a series of alternating compressions and rarefactions. This means that liquid is displaced parallel to the direction of motion of the wave. The maximum displacement velocity together with the density (ρ) and the speed of sound in the medium (v) determine the ultrasound intensity and the maximum acoustic pressure ($P_{A,max}$) (8). The variation of the acoustic pressure (P_A) as a function of time (t) at a fixed frequency (f) is described by equation 1:

$$P_A = P_{A,max} \cdot \sin(2 \cdot \pi \cdot f \cdot t) \tag{1}$$

The acoustic pressure amplitude determines the growth of a cavitation bubble and consequently the chemical effects upon collapse. The amplitude of the pressure wave can be measured with a hydrophone or can be calculated using a calorimetric method (9,10), in which it is possible to determine the ultrasound power (Q_{US}) that is transferred to the liquid. With the ultrasound power and the surface area of the ultrasound source (A_{US}), the acoustic amplitude can be calculated according to equation (2), for which the ultrasound intensity is the power input divided by the surface area of the source (11).

$$P_{A,max} = \sqrt{2 \cdot \rho \cdot v \cdot \frac{Q_{US}}{A_{US}}} \tag{2}$$

Cavitation Bubble Dynamics. Ultrasound waves in a liquid cause the molecules to oscillate around their mean position. During the positive-pressure cycle the distance between the molecules decreases, while during the negative pressure period the distance increases. At a sufficiently high intensity a critical distance between the molecules is exceeded during the negative pressure period, and a cavity is formed. Because of the presence of nuclei such as dissolved gases and solid impurities, cavities are formed at far lower sound pressures than theoretically predicted.

After the formation of a cavity, a critical acoustic pressure has to be overcome to initiate the explosive growth of this bubble. The Blake threshold pressure (P_B) describes this critical pressure [eq. 3 (12)]:

$$P_B = P_0 - P_v + \frac{4}{3} \cdot \sigma \cdot \sqrt{\frac{2}{3} \cdot \frac{\sigma}{\left(P_0 + 2 \cdot \frac{\sigma}{R_0} - P_v\right) \cdot R_0^3}} \tag{3}$$

Equation 3 assumes that the external pressure (P_0), the vapor pressure (P_v), the surface tension (σ), and the equilibrium radius of the bubble (R_0) determine the required negative pressure in the liquid to start an explosive growth of a cavity (13). The Blake threshold pressure is based on a static approach and is only valid when the surface tension dominates all dynamic effects, eg, mass transfer and viscosity.

This explosive growth is followed by an implosive collapse. During this collapse, the content of the bubble is almost adiabatically heated, which leads to local,

short-lived hot-spots in the liquid. Depending on the specific conditions, bubble wall velocities, pressures, and temperatures in the bubble can increase up to 1500 m/s, 20 MPa, and 5000 K, respectively. The influence of the medium characteristics and the physical conditions on the implosion can be calculated with a dynamic bubble model (14,15). The dynamic movement of a bubble in a sound pressure field can be described with the Rayleigh-Plesset equation (eq. 4), which includes the density of the fluid (ρ), the gas pressure, the surface tension, the equilibrium radius of the bubble, the vapor pressure, the polytropic index of the gas phase (κ), the liquid viscosity (η) and the acoustic pressure.

$$R \cdot \frac{\mathrm{d}^2}{\mathrm{d}t^2}R + \frac{3}{2} \cdot \left(\frac{\mathrm{d}}{\mathrm{d}t}R\right)^2 = \frac{1}{\rho} \cdot \left[\left(P_0 + \frac{2 \cdot \sigma}{R_0} - P_\mathrm{v}\right) \cdot \left(\frac{R_0}{R}\right)^{3^*\kappa} + P_\mathrm{v} - \frac{2 \cdot \sigma}{R} - \frac{4 \cdot \eta \cdot \frac{\mathrm{d}}{\mathrm{d}t}R}{R} - P_0 - P_A(t)\right] \quad (4)$$

By combining the Rayleigh–Plesset equation with a mass and energy balance over the bubble, the temperature and pressure in the bubble can be calculated (16,17). The model also describes the dynamic movement of the bubble wall, which results in a calculated radius of the cavitation bubble as a function of time (see Fig. 2). The explosive growth phase and the collapse phase of the bubble can clearly be distinguished. Moreover, in case dynamic effects are more important than the surface tension, the cavitation threshold can be calculated with the dynamic model, while the Blake threshold pressure cannot be used at these conditions.

Parameters Influencing Cavitation. The intrinsic rate of a polymerization reaction is determined by the initiation, propagation, and termination rate. However, only the initiation rate is influenced by ultrasound. The amount of

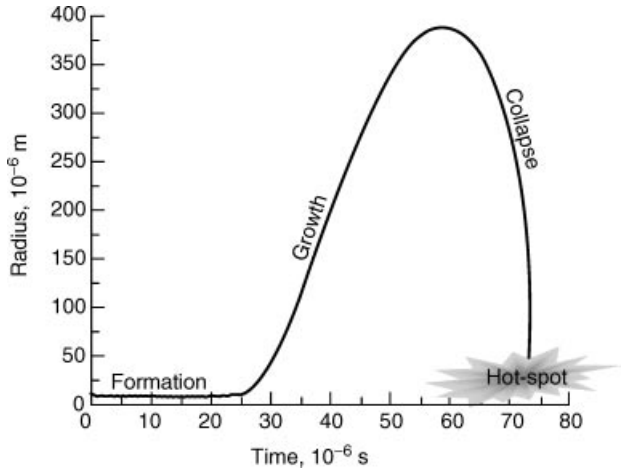

Fig. 2. Illustrative radius of a cavitation bubble as a function of time, calculated in water at ambient pressure.

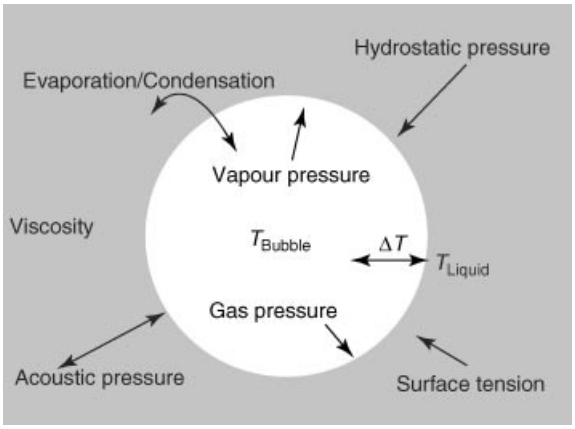

Fig. 3. Schematic representation of a bubble, including the processes and physical properties that determine the cavitation process.

radicals formed due to sonification is a function of the number of cavities created and the number of radicals that are formed per cavitation bubble. The bubble wall velocity during collapse and the hot-spot temperature determine the rate at which radicals are formed, both inside and outside a single bubble. These two parameters depend on the physical properties of the liquid as well as on the physical and chemical processes occurring around the cavity. The most important properties and processes occurring in a cavitation bubble are schematically depicted in Figure 3. The number of cavities is, for instance, determined by the impurities in the liquid, the static pressure, the ultrasound intensity, and the vapor pressure. This emphasizes that the overall radical formation rate is influenced in a complex way (18,19). In the following, the effect of the most important parameters will be discussed.

Temperature. When the reaction temperature is altered, the liquid properties will change. Although all these properties (viscosity, surface tension, sound velocity, vapor pressure, etc) have an influence on the chemical effect of cavitation, the change in vapor pressure dominates the other liquid properties. As the temperature is raised, the vapor pressure in the bubble is increased, which cushions the implosion of the cavity. This results in a lower local temperature inside the cavity at higher overall temperatures. Consequently, fewer radicals are formed per cavitation bubble. On the other hand, a higher vapor pressure can lead to easier bubble formation because of the decrease of the cavitation threshold. In most cases, however, an increase in reaction temperature will result in an overall decrease in the radical formation rate. Therefore, ultrasound-induced reactions exhibit opposite behavior as compared to common radical reactions (20).

Static Pressure. A high static pressure can prevent the formation of cavitation bubbles, as the Blake threshold pressure increases. This implies that less or no cavitations are formed at higher static pressures. To counteract this effect, a higher acoustic pressure is required, which will result in a more violent collapse of a cavitation bubble.

Viscosity. At increasing viscosities the growth and collapse of a cavitation bubble is retarded, because of the higher drag of the liquid. At a certain viscosity

the drag force becomes too high and the bubble has insufficient time to grow to a critical radius. If this radius is not reached, no collapse will occur. Additionally, the higher viscosity slows down the collapse, which makes it possible for heat to be transferred to the liquid. Because of this heat transfer, lower hot-spot temperatures are reached and subsequently less radicals are being generated.

Ultrasound Intensity. At first the radical formation rate will increase to a maximum with increasing ultrasound intensity (18). This is caused by the higher cavitation intensity per bubble and the larger number of cavitation bubbles. At too high ultrasound intensities, however, a cloud of cavitation bubbles is formed near the ultrasound source, because of which the pressure wave is no longer transmitted efficiently to the liquid. As a result, the cavitation intensity and, consequently, the radical formation rate decrease with a continued increase in intensity (18). An optimum radical formation rate with ultrasound intensity can thus be found.

Ultrasound Frequency. The frequency of ultrasound has a significant effect on the cavitation process. At very high frequencies (>1 MHz), the cavitation effect is reduced as the inertia of a cavitation bubble becomes too high to react to fast changing pressures. Most ultrasound-induced reactions are therefore carried out at frequencies between 20 and 900 kHz. The optimum ultrasound effect as a function of frequency depends on the reaction system; eg, water dissociation has an optimum frequency at approximately 500 kHz (21). For bulk polymerizations the maximum radical formation rate is obtained at 20 kHz. At this frequency the highest strain rates are produced, which results in a high radical formation rate by polymer scission (22).

Cavitation-Induced Polymerization

Generally, free-radical polymerization consists of four elementary steps: initiation, propagation, chain transfer, and termination (see RADICAL POLYMERIZATION). When ultrasound is used to initiate polymerization, radicals can be formed both from monomer and from polymer molecules. This implies that because of radical formation by polymer scission, an additional elementary step is involved in ultrasound-induced polymerization, as indicated in Figure 4.

The radicals from polymer and monomer are generated by two different mechanisms. The monomer molecules are dissociated by the high temperatures inside the hot-spot, whereas the polymer chains are fractured by the high strain rates outside the bubble (23,24). It has to be noted that the radicals are only formed in the immediate vicinity of the ultrasound source where cavitation occurs. Subsequently, these radicals are dispersed throughout the reactor. A typical ultrasound reactor used for batch polymerization is given in Figure 5. This system uses a horn to transmit the 20-kHz ultrasound vibrations to the liquid (4,5,9). To allow for comparison of different experiments, the total configuration of the reactor has to be exactly the same. This includes the flow rate of the gas, which is bubbled through the reaction mixture to create nuclei. A different ultrasound system is the plate transducer, which does not have a fixed frequency (8,13). This type of transducer is typically used for polymerizations where the optimum frequency is higher than 20 kHz, such as emulsion polymerizations. In the literature several types of ultrasound-induced polymerizations have been reported, ie, bulk,

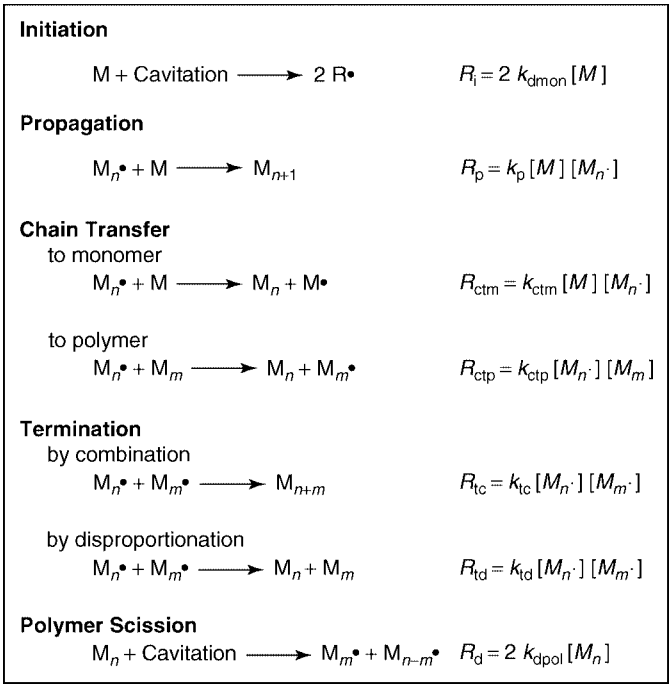

Fig. 4. Reaction mechanism of ultrasound-induced radical polymerization, assuming intrinsic polymerization and avoiding thermal initiation.

precipitation, and emulsion polymerization. Additionally, an interesting application of ultrasound polymerization is the synthesis of block copolymers.

Bulk Polymerization. Most ultrasound-induced bulk polymerizations are performed at room temperature (22). This low temperature is chosen because

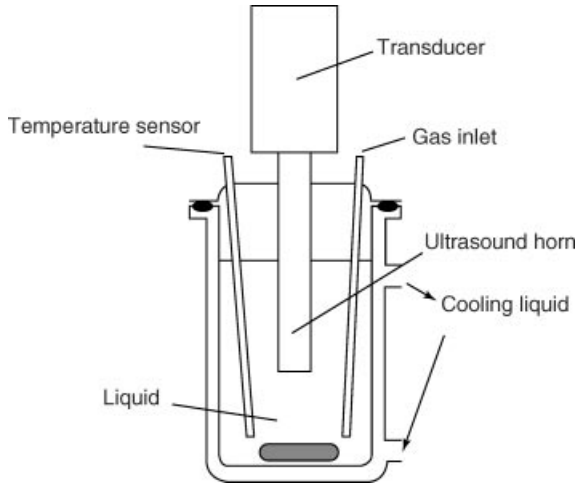

Fig. 5. Typical batch reactor of 200 mL used for ultrasound-induced polymerization reactions.

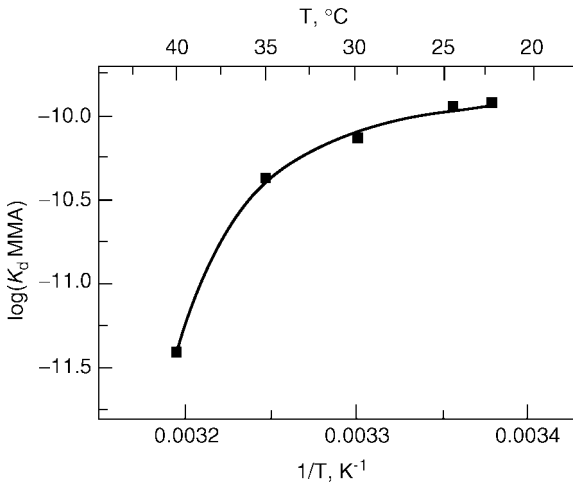

Fig. 6. Arrhenius plot for monomeric radicals generated by ultrasound in bulk MMA at an ultrasound intensity of 62 W/cm^2 (9).

radical formation induced by ultrasound appears to be more efficient at lower temperatures (9) (see also section under (Parameters Influencing Cavitation)). Figure 6 shows that at temperatures above 40°C almost no radicals are formed in methyl methacrylate (MMA) by ultrasound. In contrast to conventional thermal initiators such as potassium persulfate, ultrasound can initiate a polymerization reaction at ambient temperatures. It should be noted, however, that the propagation rate increases with an increasing temperature. Therefore, a suitable temperature in terms of propagation rate constant and radical formation rate has to be chosen to optimize ultrasound-induced polymerization. Additionally, the type of monomer is important. For example, styrene radicals will be less reactive and will probably be more stable than MMA radicals because of the conjugated system. Moreover, the aromatic ring will increase the chance for decomposition of the monomer. In literature several bulk polymerizations initiated by ultrasound have been reported; eg, the polymerization of methyl methacrylate (4,25,26), ethyl methacrylate (27), *n*-butyl methacrylate (5,23), and styrene (28).

Since the basic reaction kinetics are well known (25,29), the ultrasound-induced polymerization of MMA is the farmost studied system. Typically, the resulting molecular weight of the obtained poly(methyl methacrylate) (PMMA) is in the range of 1×10^5 to 6×10^5 g/mol. An experimental study on the ratio between radicals originating from monomer and polymer in a MMA/PMMA ($M_w = 3.5 \times 10^5$ g/mol) bulk system has revealed that the polymer chains dissolved in the reaction mixture produce far more radicals than the monomer molecules (30). According to Figure 4 the formation rate constant for monomeric and polymeric radicals is assumed to be first order in polymer and monomer concentration, respectively, from which it can be calculated that the radical formation rate constant from polymer chains is substantially higher; ie, 10^{-4}/s versus 10^{-9}/s from monomeric units. The influence of the weight percentage polymer present in the liquid on the dissociation constants for monomer and polymer is given in Figure 7.

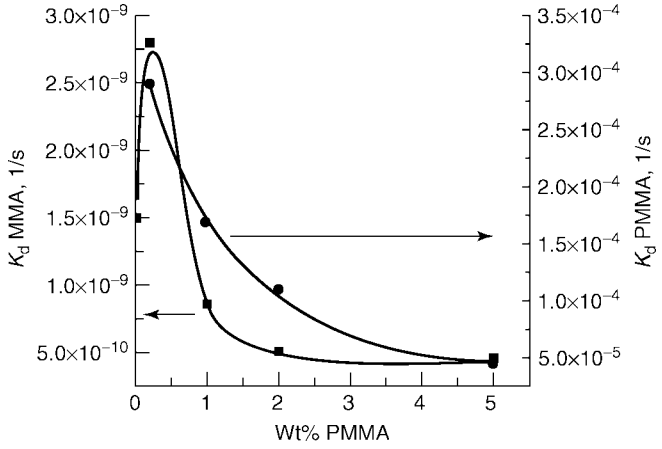

Fig. 7. Radical formation rate constants from monomer and polymer as a function of the wt% polymer dissolved at a temperature of 20°C and an ultrasound intensity of 62 W/cm^2 (30). ■ MMA; PMMA.

An important parameter during ultrasound-induced bulk polymerizations is the viscosity. As the reaction proceeds, the formed polymer chains cause a drastic increase in the viscosity, resulting in slower growth and collapse of the cavity. Since the cavitations become less effective, the radical formation rate from both monomer and polymer will decrease, as shown in Figure 7. At a conversion of approximately 20% the collapse is no longer sufficiently strong to induce hot-spot temperatures that are able to generate monomeric radicals. Moreover, the strain rates outside the collapsing bubble are not large enough to produce polymeric radicals by polymer scission (5). As a consequence, the polymerization ultimately stops at this conversion, which represents a serious drawback for the development of ultrasound-induced bulk polymerization towards industrial application.

Precipitation Polymerization. As described in the previous section, ultrasound-induced bulk polymerizations are limited to relatively low conversions, because a strong viscosity increase upon reaction hinders cavitation. To obtain higher conversions, precipitation polymerization forms a potential solution. Because the produced polymer precipitates from the reaction medium, the viscosity and consequently the radical formation rate are expected to remain virtually constant. In this perspective, liquid carbon dioxide is a suitable reaction medium, because most monomers have a high solubility in CO_2, whereas it exhibits an antisolvent effect for most polymers. Moreover, CO_2 is regarded as an environmentally friendly compound, which is nontoxic, nonflammable, and naturally abundant. Since higher pressures are required for CO_2 to act as an antisolvent (31–33), the possibility of ultrasound-induced cavitation in pressurized carbon dioxide systems has been studied (34).

During pressurization of a liquid, the Blake threshold pressure increases, which implies that higher acoustic pressures are needed to produce cavitations. Obviously, no cavitation occurs when the Blake threshold pressure exceeds the maximum acoustic pressure that can be applied with the currently available equipment. The vapor pressure of the liquid, however, can counteract the static

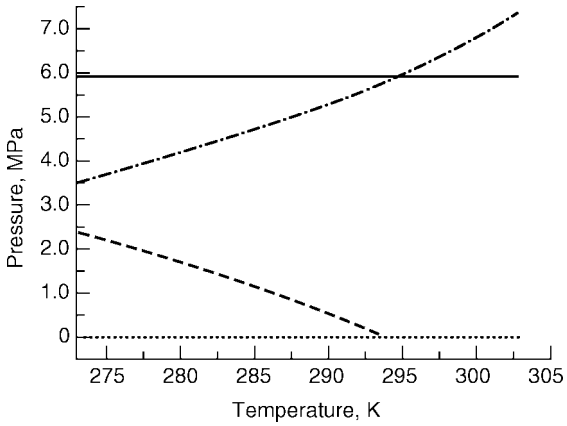

Fig. 8. Calculated Blake threshold and vapor pressure for water and carbon dioxide at 5.82 MPa (34). _____ Blake threshold H_2O; - - - - - Blake threshold CO_2; ▪ ▪ ▪ ▪ ▪ vapor pressure H_2O; – – – – – vapor pressure CO_2.

pressure. As a result of this, the Blake threshold is reduced in liquids with a high vapor pressure; eg, CO_2, ethylene and ammonia. This enables cavitation at increased static pressures (34). To illustrate this effect, Figure 8 shows the calculated Blake threshold pressure of carbon dioxide and water at 5.82 MPa as a function of temperature. The threshold curves are calculated using equation (3), in which the vapor pressure is the most important parameter, next to the hydrostatic pressure and the surface tension. For water the Blake threshold is determined only by the static pressure and the surface tension of the liquid, because of the low vapor pressure of water. As the vapor pressure does not change significantly with increasing temperature, the threshold pressure of water is virtually constant at 5.8 MPa, making cavitation impossible to occur. In the case of carbon dioxide, which condenses at a substantially higher pressure, only an acoustic pressure of 0.5 MPa is required to generate cavitation at 5.8 MPa static pressure and a temperature of 290 K.

The dynamic movement of the bubble in CO_2 has been calculated using equation 4. Initially, a small cavity with a radius of 10^{-5} m is present, which consists of argon and the corresponding vapor of the liquid phase. In the simulations, an ultrasound wave with an acoustic pressure of 1 MPa and a frequency of 20 kHz is imposed on this bubble. The variation of the radius of the bubble is shown in Figure 9. As the acoustic pressure for water at 5.82 MPa is lower than the Blake threshold pressure, almost no bubble movement is observed and no cavitation can occur. In contrast to the situation in water, carbon dioxide at 5.82 MPa allows for cavitation and the bubble exhibits a similar movement compared to water at 0.1 MPa. Moreover, the maximum temperature (585 K) and maximum bubble wall velocity (777 m/s) reached during collapse in liquid CO_2 are in the same order of magnitude as compared to water at ambient pressure (722 K and 840 m/s, respectively). To validate these simulations, cavitation experiments have been performed in pressurized CO_2–MMA systems using the radical scavenger 1,1-diphenyl-2-picrylhydrazyl (35). The radical formation rate appears to be in

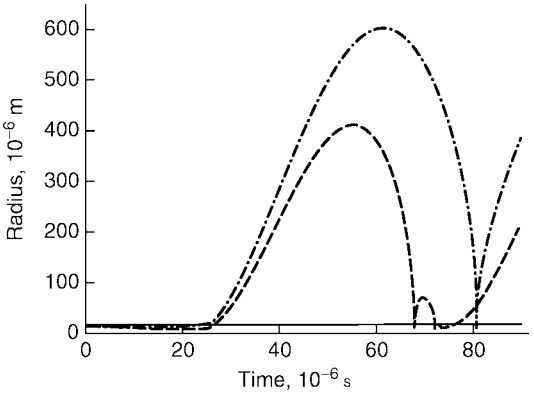

Fig. 9. Calculated radius of a cavitation bubble as a function of time in water and CO_2 (34). H_2O at 0.1 MPa; H_2O at 5.82 MPa; CO_2 at 5.82 MPa.

the order of 1.5×10^{14}/s, for which no noticeable difference occurs at varying MMA–CO_2 ratios.

Ultrasound-induced polymerizations of MMA in CO_2-expanded MMA have resulted in high molecular weight polymers (see Table 2). With respect to the initial polymerization rate, both polymerizations in CO_2 have a reaction rate in the same order of magnitude as compared to the bulk experiment at ambient pressure. Although the reaction rates are similar, the polymer produced at 0.1 and 0.7 MPa CO_2 pressure have much higher molecular weights than the reference polymer in bulk. A possible explanation for the difference in molecular weight is the fact that a precipitated polymer is not susceptible to ultrasound-induced polymer scission (see the next paragraph), whereas the dissolved polymer chains in the bulk experiment can break because of cavitation. In addition, it is possible that the precipitated polymer chains are swollen with monomer and continue to grow, while termination is not likely to occur in that particular situation.

During high pressure view-cell experiments of a solution of 4 wt% polymer in MMA at 0.7 MPa CO_2 and 20°C, a second phase (polymer phase) has clearly been observed. This illustrates the strong antisolvent effect of CO_2. Before the polymer actually precipitates, the antisolvent already causes a lower viscosity in the CO_2-expanded system as compared to the bulk system. Because CO_2 is a poor solvent for most polymers, the gyration radius of the polymer will be lower. This means fewer entanglements between polymer molecules, and subsequently a lower viscosity. Although the viscosity does not increase, so far only relatively low

Table 2. Results of Ultrasound-Induced Polymerizations of MMA at 20°C and Different CO_2 Pressures[a]

CO_2 pressure, MPa	Reaction time, min	Conversion, %	Initial polymerization rate, mol/m^{3}s	M_n, kg/mol
0	180	3.1	0.034	110
0.1	270	3.8	0.018	471
0.7	145	2.5	0.024	428

[a] Ref. 35.

conversions have been obtained, as a result of the large reactor scale compared to the ultrasound power input to the system. As soon as the reactor and ultrasound power are better scaled, it is expected that high conversions will be reached (35).

Emulsion Polymerization. The generation of radicals by ultrasound can also be applied in emulsion polymerization, which comprises a free-radical polymerization in a heterogeneous reaction system, yielding submicrometer polymer particles in a continuous aqueous phase. In literature a number of publications have appeared over the years on the application of ultrasound in emulsion polymerization (36–46). Ultrasound can be applied both for emulsification purposes as well as at higher conversions in the emulsion polymerization process (see HETEROPHASE POLYMERIZATION).

In the beginning of the polymerization, emulsification and nucleation govern the course of the process. The monomer droplets have to be small enough to provide a negligible resistance to monomer transport from the droplets through the aqueous phase to the growing polymer particles. Only in the case of sufficient emulsification, intrinsic polymerization kinetics can be assumed. This implies that in conventional emulsion polymerization, vigorous stirring is required to disperse the monomer droplets. When ultrasound is applied as an energy source for emulsification, a very uniform emulsion of small monomer droplets is obtained without additional stirring. The high implosion velocity of the cavitation bubbles ensures that the monomer droplets are well dispersed. A special case involves mini- or microemulsion polymerization. Depending on the surfactant system used and the emulsification induced by ultrasound, the monomer droplets become so small that they can serve as nucleation loci. In ordinary emulsion polymerization, the main locus of nucleation is within the monomer-swollen micelles. Typically, polymer particles produced by ultrasound-induced emulsion polymerization have a diameter of approximately 50 nm and a molecular weight of 3×10^6 g/mol (36,37).

During emulsion polymerization induced by ultrasound, the redundancy of initiator is advantageous in terms of process control and safety. Moreover, initiator residues do not contaminate the product. In contrast to ultrasound-induced bulk polymerizations, high conversions can be obtained in ultrasound-induced emulsion polymerization (38,39). Since a heterogeneous reaction system is involved, in which the polymer is insoluble in the continuous aqueous phase, the viscosity of the water phase does not increase upon reaction. The cavitation events occur in the continuous phase, producing radicals mainly from water and surfactant molecules (40). Subsequently, the oligomeric radicals enter the monomer swollen polymer particles and continue to polymerize. Examples of ultrasound-induced emulsion polymerization are described for styrene (37,39,41), MMA (36,40,42–45), *n*-butyl acrylate (46), and the copolymerization of vinyl acetate and butyl acrylate (38).

Synthesis of Block Copolymers. Anionic and living radical polymerization are the most important techniques for synthesis of block copolymers (qv) which are used in many applications where different polymers are connected to yield a material with hybrid properties (47); for instance, as compatibilizing agent between immiscible polymers (48). Alternatively, ultrasound can be used to produce these block copolymers, for which two different methods are applicable.

The first route to synthesize block copolymers by ultrasound starts with the dissolution of a homopolymer in a different monomer (49). Subsequently,

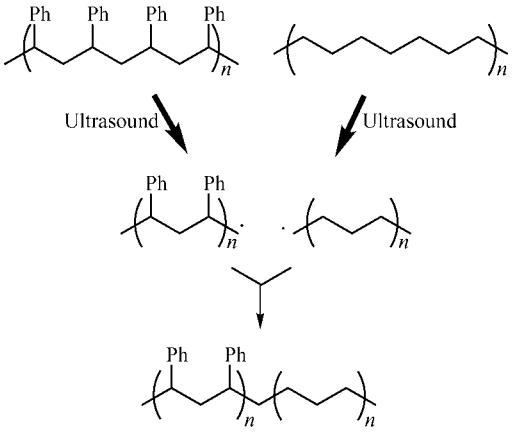

Fig. 10. The production of a block copolymer from two homo polymers with ultrasound (5).

ultrasonic scission of the polymer chains generates polymeric radicals, which initiate the polymerization reaction with the monomer present. In this way ultrasound provides the controlled formation of block copolymers, for which examples are polyethylene with acrylamide (49) and PMMA with styrene (50). Secondly, dissolving two different homopolymers in a nonreactive solvent can lead to block copolymers as well. In this case, the generated polymeric radicals have to undergo termination by cross combination (see Fig. 10) (51,52). If no cross combination occurs, the original homopolymers are reproduced again. The advantage of the second method is that block copolymers can be produced from homopolymers of which the polymer–monomer systems are immiscible. Using this approach the synthesis of the block copolymer of polystyrene and poly(methyl phenyl silane) (51) as well as the block copolymer of poly(vinyl chloride) and poly(acrylonitrile-*co*-butadiene) (52) is described.

Cavitation-Induced Polymer Scission

In terms of product properties, the molecular weight distribution is an important characteristic of polymers. In the polymer industry often a post-processing step is applied to alter the molecular weight of the polymers; eg, the peroxide-induced degradation of polypropylene (53). In this process, fracture of the polymer chain occurs at a random site. An alternative method is ultrasound-induced polymer scission, which involves a much better controlled, nonrandom process (7). This enables a relatively straightforward production of the desired molecular weight as well as the formation of block copolymers, as described in the previous section.

Mechanism. Although there is still some debate about the precise origin of scission, it has been shown that ultrasound-induced polymer breakage is a direct consequence of cavitation, because under conditions that suppress cavitation, no degradation is observed. In this nonrandom scission process the polymer is fractured at the centre of the chain (54–56). This is clearly shown in Figure 11,

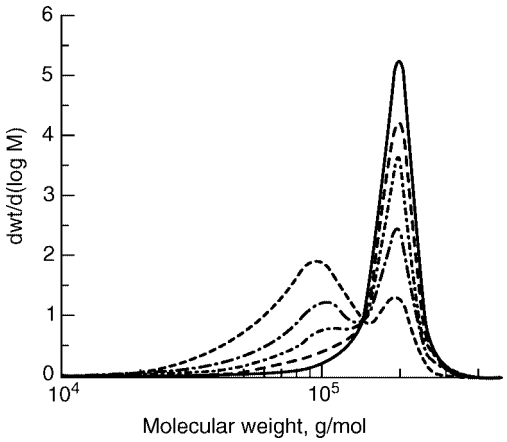

Fig. 11. Molecular weight distributions of an ultrasound-induced polymer scission experiment of PMMA with an initial M_n of 18.0×10^4 g/mol and a polydispersity of 1.05 (35). ——— 0 min; - - - - - 5 min; ——— 10 min; — — — — 20 min; • • • • • • 40 min.

in which a polymer with a peak value of 90 kg/mol is produced from the initial molecular weight distribution with a peak value of 180 kg/mol and a polydispersity of 1.05. It is often thought that the extreme temperatures inside the bubble upon implosion contribute to the degradation. However, temperature degradation implies a random process, and thus does not explain the scission at the middle of the chain. Ultrasound-induced chain fracture arises from the high strain rates on the polymer chain upon implosion. The generally accepted scission mechanism can best be described as the chain being caught in the rapid flow of solvent, as is schematically shown in Figure 12 (57). The chains are thus subjected to extremely large shear forces. Under sufficiently strong flow conditions, the solvent drag force causes extension of the coiled polymer molecule. If the drag force on the stretched polymer molecule exceeds the bond strength, scission will occur in the middle of the chain; otherwise no breakage occurs and a constant molecular weight (M_{lim}) is reached (58). This limiting molecular weight is no longer fractured as the forces acting on the chain are smaller than the force required to break a bond.

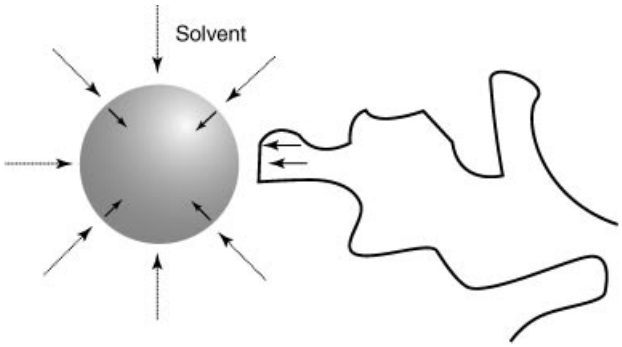

Fig. 12. Schematic presentation of the generally accepted mechanism of degradation of polymer by cavitational collapse (23).

In our view, the generally accepted mechanism of ultrasound-induced polymer scission, in which the polymer chain is uncoiled though not completely straightened near the cavitation bubble, does not explain the preferred breakage at the centre of the chain. Breakage in the middle of the chain can only occur when the polymer chain is completely stretched (59). Because of the gradient in radial solvent velocity near a cavity, a frictional force is exerted on the polymer molecule. The maximum stress will be in the centre of the polymer chain, which is in analogy with flow-induced polymer scission (60). When the bond scission probability along the chain is known from experimentally obtained molecular weight distributions, it is possible to deduce the molecular conformation of the polymer chains prior to bond rupture; ie, whether the chains are completely straightened.

Scission Kinetics. The kinetics of ultrasonic scission can be directly ascribed to the implosion velocity of the cavitation bubbles and the polymer that is fractured. The scission rate and the limiting molecular weight are thus influenced by the ultrasonic wave, the solvent properties, and the polymer structure.

The influence of ultrasound intensity, liquid viscosity, and liquid temperature on the degradation rate and limiting molecular weight have been studied by Price and West (51). A higher intensity results in a faster scission and a lower limiting molecular weight (see Fig. 13). Lower temperatures and lower viscosities have similar influences on the scission rate and M_{lim}. These three effects can be ascribed to the higher implosion velocity, which induces higher strain rates around the bubble and, therefore, lead to a lower limiting molecular weight and a higher scission rate.

The initial molecular weight of the polymer does not influence the implosion velocity of a cavity or the limiting molecular weight that is reached. However, the molecular weight has a large influence on the fracture rate of the polymer chains. The slopes of the degradation curves in Figure 14 indicate a higher scission rate for polymers with a higher initial molecular weight. This is a consequence of the higher solvent drag force on the longer chains. As a result, narrow molecular

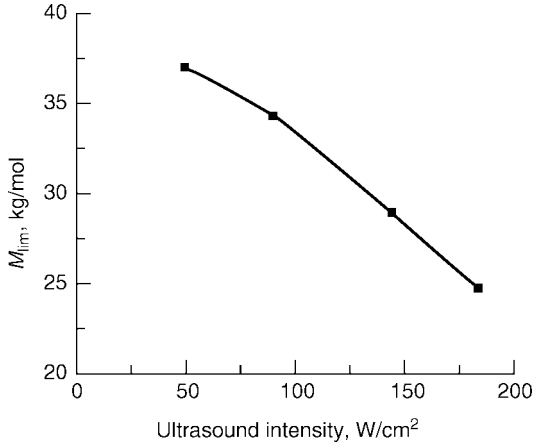

Fig. 13. Effect of ultrasound intensity on the limiting number-average molecular weight during the degradation of 0.5 wt% polystyrene in toluene at 25°C (51).

weight distributions can be produced by ultrasound-induced polymer scission, because a high molecular weight polymer is fractured faster. Note that a similar limiting molecular weight is obtained for all three scission experiments shown in Figure 14 as the final conditions are equal after several breakage events of the higher molecular weight polymers.

Conclusions

The examples described in this article indicate that ultrasound is a promising technology in terms of the development of more sustainable polymer processes, because it allows for a clean and safe polymerization reaction, yielding well-defined products. Although no large-scale industrial polymerization process based on ultrasound exists as yet, commercial applications in other fields such as ultrasound cleaning and sterilization prove that ultrasound is a readily available technique and relatively simple to implement in existing equipment. Nevertheless, the application of ultrasound for polymerization purposes requires a thorough understanding of both ultrasound parameters and liquid properties, which provides a continuing challenge in physics, chemistry, and engineering.

VEGETABLE FIBERS

Introduction

Fibers for commercial and domestic use are broadly classified as natural or synthetic. The natural fibers are vegetable, animal, or mineral in origin. Vegetable fibers, as the name implies, are derived from plants. The principal chemical component in plants is cellulose (qv), and therefore they are also referred to as cellulosic fibers. The fibers are usually bound by a natural phenolic polymer, lignin (qv), which also is frequently present in the cell wall of the fiber; thus, vegetable fibers are also often referred to as lignocellulosic fibers, except for cotton, which does not contain lignin.

Vegetable fibers are classified according to their source in plants as follows: (*1*) the bast or stem fibers, which form the fibrous bundles in the inner bark (phloem or bast) of the plant stems, are often referred to as soft fibers for textile use; (*2*) the leaf fibers, which run lengthwise through the leaves of monocotyledonous plants, are also referred to as hard fibers; and (*3*) the seed-hair fibers, the source of cotton (qv), which is the most important vegetable fiber and is discussed in another article. There are over 250,000 species of higher plants; however, only a very limited number of species have been exploited for commercial uses (less than 0.1%). The commercially important fibers are given in Table 1 (1–3).

The fibers in bast and leaf fiber plants are integral with the plant structure, providing strength and support. In bast fiber plants, the fibers are next to the outer bark in the bast or phloem and serve to strengthen the stems of these reed-like plants. The fibers are in strands running the length of the stem or between joints (Fig. 1). To separate the strands, the natural gum binding them must be removed. This operation is called *retting* (controlled rotting). For most uses, particularly for textiles, this long composite-type strand fiber is used directly; however, when such fiber strands are pulped by chemical means the strand is broken down into much shorter and finer fibers, the ultimate fibers shown in Figure 1.

Table 1. Vegetable Fibers of Commercial Interest[a]

Commercial name	Source	Botanical name of plant	Growing area
		Bast or soft fibers	
China jute	Abutilon	*Abutilon theophrasti*	China
Flax		*Linum usitatissimum*	North and south temperate zones
Hemp		*Cannabis sativa*	All temperate zones
Jute		*Corchorus capsularis; C. olitorius*	India
Kenaf		*Hibiscus cannabinus*	India, Iran, CIS, South America
Ramie		*Boehmeria nivea*	China, Japan, United States
Roselle		*Hibiscus sabdariffa*	Brazil, Indonesia (Java)
Sunn		*Crotalaria juncea*	India
Urena	Cadillo	*Urena lobata*	Zaire, Brazil
		Leaf or hard fibers	
Abaca		*Musa textilis*	Borneo, Philippines, Sumatra
Cantala	Manila maguey	*Agave cantala*	Philippines, Indonesia
Caroa		*Neoglaziovia variegata*	Brazil
Henequen		*Agave fourcroydes*	Australia, Cuba, Mexico
Istle		*Agave* (various species)	Mexico
Mauritius		*Furcraea gigantea*	Brazil, Mauritius, Venezuela, tropics
Phormium		*Phormium tenax*	Argentina, Chile, New Zealand
Pineapple	Piña	*Ananas comasus*	Hawaii, Philippines, Indonesia, India, West Indies
Sansevieria	Bowstring hemp	*Sansevieria* (entire genus)	Africa, Asia, South America
Sisal		*Agave sisalana*	Haiti, Java, Mexico, South Africa, Brazil
		Seed-hair fibers	
Coir	Coconut husk fiber	*Cocos nucifera*	Tropics, India, Mexico
Cotton		*Gossypium* sp.	United States, Asia, Africa
Kapok		*Ceiba pentandra*	Tropics
Milkweed floss		*Chorisia* sp.	North America
		Other fibers	
Broom root	Roots	*Muhlenbergia macroura*	Mexico
Broom corn	Flower head	*Sorghum vulgare technicum*	United States
Crin vegetal	Palm leaf segments	*Chamaerops humilis*	North Africa
Palmyra palm	Palm leaf stem	*Brossus flabellifera*	India
Pissava	Palm leaf base fibers	*Attalea funifera*	Brazil
Raffia	Palm leaf segments	*Raphia raffia*	East Africa

[a]Refs. 1–3.

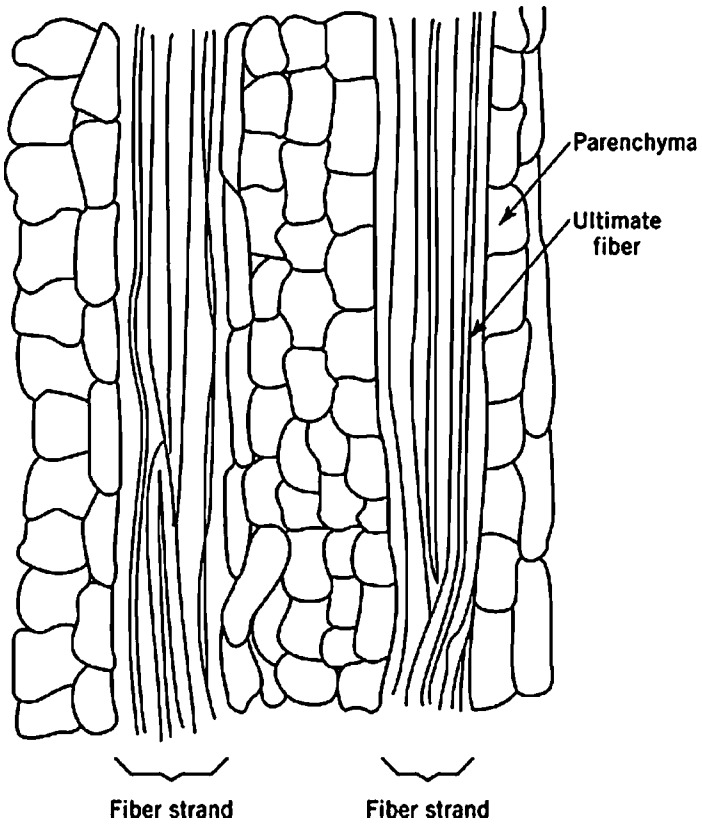

Fig. 1. Typical longitudinal section of bast fiber showing very long fiber strands composed of many ultimate fibers (see Table 3 for dimensions).

The long leaf-fibers contribute strength to the leaves of certain nonwoody, monocotyledonous plants. They extend longitudinally the full length of the leaf and are buried in tissues of a parenchymatous nature. The fibers found nearest the leaf surface are the strongest. The fibers are separated from the pulp tissue by scraping because there is little bonding between fiber and pulp; this operation is called *decortication*. Leaf fiber strands are also multicelled in structure.

Ancient humans used cordage in fishing, trapping, and transport, and in fabrics for clothing. Rope and cord making started in Paleolithic times, as seen in cave drawings. Rope, cords, and fabrics were made from reeds and grasses in ancient Egypt (400 BC). Ropes, boats, sails, and mats were made from palm leaf fibers and papyrus stalks and writing surfaces, known as papyrus, from the pith section. Jute, flax, ramie, sedges, rushes, and reeds have long been used for fabrics and baskets. Jute was cultivated in India in ancient times and used for spinning and weaving. The first true paper is believed to have been made in southeastern China in the second century AD from old rags (bast fibers) of hemp and ramie and later from the bast fiber of the mulberry tree.

Scientists at the U.S. Department of Agriculture (USDA) Northern Regional Research Center in Peoria, Illinois, carried out an extensive screening of over 500

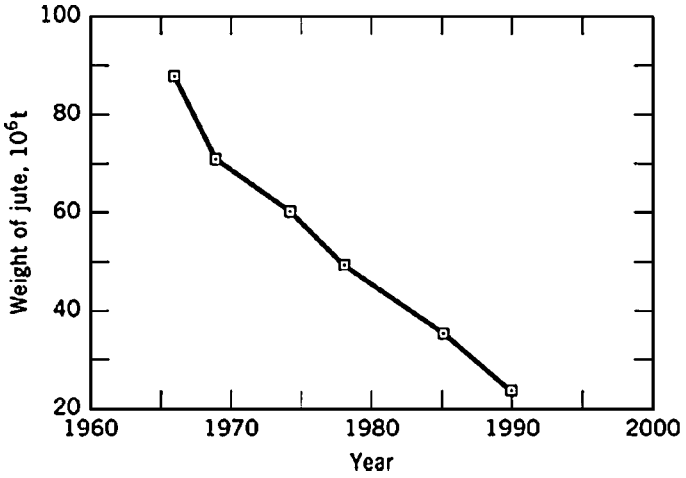

Fig. 2. Export of jute goods from India (1965–1990).

species of plants as potential sources of papermaking fibers (4–7). The species were rated for agronomic potential, chemical composition, fiber properties, and physical characteristics. The species with the greatest potential were in the genera *Hibiscus, Crotalaria, Sorghum, Cannabis, Gynerium, Lygerum,* and *Sinarundinaria*.

World markets for vegetable fibers have been steadily declining in recent years, mainly as a result of substitution with synthetic materials. Jute has traditionally been one of the principal bast fibers (tonnage basis) sold on the world market; however, the precipitous decline in jute exports by India (Fig. 2) indicates the decreasing market demand for this fiber that has been vitally important to the economies of India (West Bengal), Bangladesh, and Pakistan.

General Properties

Chemical Composition. The chemical composition of the principal commercial vegetable fibers is given in Table 2 (8,9). These compositions are for the commercial fibrous materials after processing and differ from the chemical composition of the whole plant material that is frequently cited in the literature (1,10). Chemically, cotton is the purest, containing over 90% cellulose with little or no lignin. The other fibers contain 40–75% cellulose, depending on processing. Boiled and bleached flax and degummed ramie may contain over 95% cellulose. Kenaf and jute contain higher contents of lignin, which contributes to their stiffness. Although the cellulose contents shown in Table 2 are fairly uniform, the other components, eg, hemicelluloses, pectins, extractives, and lignin vary widely without obvious pattern. These differences may characterize specific fibers.

Fiber Dimensions. Except for the seed-hair fibers, the vegetable fibers of bast or leaf origins are multicelled (Fig. 1) and are used as strands (see Table 3) (1,2,9,11). In contrast to the bast fibers, leaf fibers are not readily broken down into their ultimate cells. The ultimate cells are composites of microfibrils, which, in turn, are comprised of groups of parallel cellulose chains.

[c]Young's modulus.
[d]To convert N/tex to g · f/den, multiply by 11.33.

Physical Properties. Mechanical properties are given in Table 4 (1,11, 12). Bast and leaf fibers are stronger (higher tensile strength and modulus of elasticity) but lower in elongation (extensibility) than cotton. Vegetable fibers are stiffer but less tough than synthetic fibers. Kapok and coir are relatively low in strength; kapok is known for its buoyancy.

Among the bast textile fibers, the density is close to 1.5 g/cm^3, or that of cellulose itself, and they are denser than polyester, as shown in Table 5. Moisture regain (absorbency) is highest in jute at 14%, whereas that of polyester is below 1%. The bast fibers are typically low in elongation and recovery from stretch. Ramie fiber has a particularly high fiber length/width ratio.

Table 5. Textile-Associated Properties of Bast Fibers Compared to Polyester[a]

Property	Cotton	Flax	Hemp	Jute	Ramie	Polyester
Density, g/cm^3	1.54–1.5	1.50	1.48	1.50	1.51	1.22–1.35
Moisture regain, %	8–11	12	12	13.7	6	0.4–0.8

The microfibrils in vegetable fibers are spiral and parallel to one another in the cell wall. The spiral angles in flax, hemp, ramie, and other bast fibers are lower than cotton, which accounts for the low extensibility of bast fibers.

Bast Fibers

Bast fibers occur in the phloem or bark of certain plants. The bast fibers are in the form of bundles or strands that act as reinforcing elements and help the plant to remain erect (Fig. 1). The plants are harvested and the strands of bast fibers are released from the rest of the tissue by retting, common for isolation of most bast fibers. The retted material is then further processed by breaking, scutching, and hackling. A general description of the processing of bast fibers is given below with modifications for specific fibers described in the following sections.

Processing.

Harvesting and Pretreatment. At optimum maturity, the plants are pulled or mowed by hand or machine and, if necessary, threshed to remove seeds. The plants are spread out in a field to dry.

Retting. The removal of the bast fibers from bark and woody stem parts is promoted by a biological treatment called retting (rotting). This is an enzymatic or bacterial action on the pectinous matter of the stem. After retting, the bundles are dried in fields. Retting may be carried out in several ways.

Dew retting involves the action of dew, sun, and fungi on the plants spread thinly on the ground. Dew retting takes 4–6 weeks, but the action is not uniform and it tends to yield a dark-colored fiber. However, it is far less labor-intensive and less expensive than water retting. It is commonly used in regions of low water supply and accounts for 85% of the western European crop, especially in France, and also in the former Soviet Union.

Water retting involves immersion of bundles of plants in stagnant pools, rivers, ditches (dam retting), or in specially designed tanks (tank retting). The biological effect is achieved through bacterial action and takes 2–4 weeks for dam retting. In tanks with warm water (tank retting), the time is reduced to a few days. Water retting gives a more uniform product. In stream retting the plants are immersed in slow-moving streams for a longer time and the quality of the product is high.

Chemical retting involves immersion of the dried plants in a tank with a solution of chemicals, such as sodium hydroxide, sodium carbonate, soaps, or mineral acids. The fibers are loosened in a few hours, but close control is required to prevent deterioration. Chemical retting is more expensive and does not produce a superior fiber to that obtained from biological retting.

Breaking and Scutching. The dried retted stalks in bundles are passed through fluted rolls to break or reduce the woody portion into small particles, which are then separated by scutching. The scutching is done by beating with blunt wooden or metal blades by hand or mechanically.

Hackling. The bundles are hackled or combed to separate the short and long fibers. This is done by drawing the fibers through sets of pins, each set finer than the previous one. As a result the fibers are further cleaned and aligned parallel to one another.

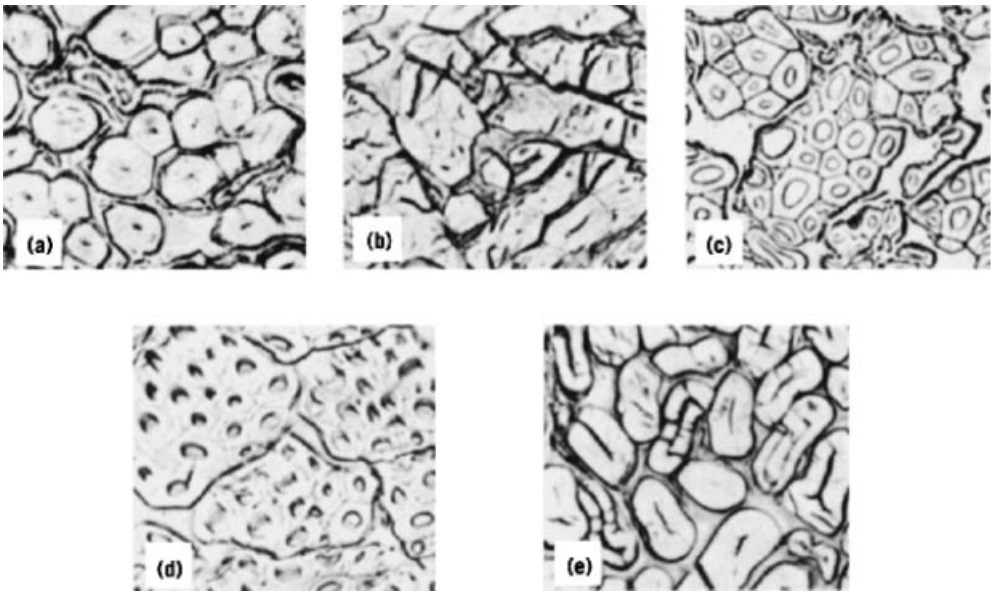

Fig. 3. Cross-sections (500×) of bast fibers: (**a**) flax; (**b**) hemp; (**c**) jute; (**d**) kenaf; and (**e**), ramie. Courtesy of the American Association of Textile Chemists and Colorists (14).

Flax. The flax fiber from the annual plant *Linum usitatissimum* (flax family, Linaceae) has been used since ancient times as the fiber for linen. The plant grows in temperate, moderately moist climates, for example, in Belgium, France, Ireland, Italy, and Russia. The plant is also cultivated for its seed, from which linseed oil is produced. A by-product of the seed plant is the tow fiber used in papermaking.

The bast fibers are dew or water retted with dew retting generally yielding a gray fiber. High quality flax fiber is produced by water (stream) retting in the river Lys in Belgium. A cross-sectional view of the flax fiber is shown in Figure 3**a**, the fibers are round to polygonal with a small lumen. The boiled, bleached fiber contains almost 100% cellulose. The flax fiber is the strongest of the vegetable fibers, even stronger than cotton. The fiber is highly absorbent, an important property for clothing, but is particularly inextensible. The most important application is in linen for clothing, fabrics, lace, and sheeting. Flax fiber is also used in canvas, threads and twines, and certain industrial applications such as fire hoses. Chemical pulping of flax provides the raw material for production of high quality currency and writing paper. Flax fiber is also commonly used in cigarette papers. Flax fibers are graded for fineness, softness, stretch, density, color, uniformity, luster, length, handle, and cleanliness.

Hemp. The source of hemp fiber is the plant *Cannabis sativa* (mulberry family, Moraceae) originating in central China. It is grown in central Asia and eastern Europe. The stem is used for fiber, the seeds for oil, and leaves and flowers for drugs, among them marijuana. The stalks grow 5–7 m tall and 6–16 mm thick. The hollow stems, smooth until the rough foliage at the top, are hand-cut and spread on the ground for dew retting for the highest quality product. Water retting

is used on sun-dried bundles from which the seeds and leaves have been removed. Strands of hemp fiber can be 2 m in length. The fibers are graded for color, luster, spinning quality, density, cleanliness, and strength.

A cross-sectional view of hemp fiber is shown in Figure 3**b**. It has a "Z" twist in contrast to the "S" twist of flax. Hemp is regarded as a substitute for flax in yarn and twine. Its earlier use in ropes has been replaced by leaf and synthetic fibers. Hemp fiber is used in Japan, China, Hungry, and Italy to make specialty papers, including cigarette paper, but bleaching is difficult. The fiber is coarser and has less flexibility than flax. There is currently interest in reintroducing hemp into the United States and Canada as an alternate fiber crop for farmers. However, this is wrought with political and legal problems because of the inability to distinguish industrial hemp from hemp plants with high narcotic content.

Jute. Jute fiber is obtained from two herbaceous annual plants, *Corchorus capsularis* (linden family, Tiliaceae) originating from Asia, and *Corchorus olitorius* originating from Africa. The former has a round seed pod, and the latter a long pod. Jute is grown mainly in India, Bangladesh, Thailand, and Nepal.

The plants are harvested by hand, dried in the field for defoliation, and water (pool) retted for periods up to a month. The depth of the retting pools is dependent on the volume of rainfall during the monsoon season in Southeast Asia. Thus, a year with less rainfall results in low water levels in the retting pools and a lower grade jute product due to contamination with sand and silt. The fibers for export are graded for color, length, fineness, strength, cleanliness, luster, softness, and uniformity. The color ranges from cream white to reddish brown, but usually the fiber has a golden luster. A cross-sectional view of the fiber is shown in Figure 3**c**. The fibers are polygonal in cross section with a wide lumen. Jute has traditionally been an important textile fiber, second only to cotton; however, jute has been steadily replaced by synthetics in the traditional high volume uses such as carpet backings and burlap (hessian) fabrics and sacks (Fig. 2). The strands are also used for twine, while kraft pulping of jute gives ultimate fibers for cigarette papers. The Indian government in cooperation with the United Nations Development Program has been involved in a significant jute diversification program to find new uses for jute in finer yarns and textiles, composites and boards, and paper products. A particularly promising outlet for jute is in molded composites with thermoplastic materials for interior automobile head, door, and trunk liners (1).

Kenaf and Roselle. These closely related bast fibers are derived from *Hibiscus cannabinus* and *Hibiscus sabdariffa* (mallow family, Malvaceae), respectively. The fibers have other local names. Kenaf is grown for production in China, Egypt, and regions of the former Soviet Union; roselle is produced in India and Thailand. Plantation-grown kenaf is capable of growing from seedlings to 5 m at maturity in 5 months. It is reported to yield about 6–10 tons of dry matter per acre, nine times the yield of wood (15,16).

The plants are hand-cut, mowed, or pulled in developing countries, while mechanized harvesting methods are under investigation in the United States. Ribboning machines are sometimes used to separate the fiber-containing bark before retting for recovery of the kenaf strands. For pulping, the kenaf is shredded or hammermilled to 57-cm pieces, washed, and screened.

A cross-sectional view of kenaf is shown in Figure 3**d**. The ultimate cells are nearly cylindrical with thick cell walls. Kenaf fibers are shorter and coarser than

those of jute. Both chemical (kraft) and mechanical pulps have been produced from kenaf, and successful demonstration runs of newsprint have been made for the Dallas Morning News, the St. Petersburg Times, and the Bakersfield Californian with a furnish of 82% kenaf chemithermomechanical pulp and 18% softwood kraft pulp. Kenaf fiber is also considered a substitute for jute and used in sacking, rope, twine, bags, and as papermaking pulp in India, Thailand, and the Balkan countries. Roselle bleached pulp is marketed in Thailand.

Ramie. The ramie fiber is located in the bark of *Boehmeria nivea*, a member of the nettle family (Urticaceae). The plant is a native of China (hence, its name China grass), where it has been used for fabrics and fishing nets for hundreds of years. It is also grown in the Philippines, Japan, Brazil, and Europe. The ramie plant grows 1–2.5 m high with stems 8–16 mm thick. The roots send up shoots on harvesting, and two to four cuttings are possible annually, depending on soil and climate.

The plant is harvested by hand sickle and, after defoliation, is stripped and scraped by hand or machine-decorticated. Because of the high gum (xylan and araban) content of up to 35%, retting is not possible. The fibers are separated chemically by boiling in an alkaline solution in open vats or under pressure, then washed, bleached with hypochlorite, neutralized, oiled to facilitate spinning, and dried.

The degummed, bleached fiber contains 96–98% cellulose. A cross-sectional view is shown in Figure 3**e**. The ramie fibers are oval-like in cross-section, with thick cell walls and a fine lumen. The cell wall constituents in the ramie fiber, like other bast fibers except flax, have a counterclockwise twist. Ramie is the longest of the vegetable fibers and has excellent luster and exceptional strength; however, it tends to be stiff and brittle. Wet strength is high and the fiber dries rapidly, an advantage in fish nets.

Traditional uses for ramie have been for heavy industrial-type fabrics such as canvas, packaging material, and upholstery. Increased production of the fiber in Asia, particularly China, has promoted the use in blended fabrics with silk, linen, and cotton which can now be found on the market.

Sunn Hemp. The stems of the herbaceous plant *Crotalaria juncea* (legume family, Fabaceae), called sunn or sunn hemp, provide a bast fiber. The plant is native to India, the chief fiber producer, and it is also grown in Bangladesh, Brazil, and Pakistan. It has a long tap root and grows to a height of up to 5 m. Harvesting is done manually by pulling or cutting. The plant is defoliated in the field, water retted, and processed similarly to jute. The white fiber is graded by color, firmness, length, strength, uniformity, and extraneous matter content. Sunn is used for canvas, paper, fishing nets, twine, and other cordage.

Urena and Abutilon. These are less important vegetable fibers of a jute-like nature. *Urena lobata* (Cadillo) of the mallow family (Malvaceae) is a perennial that grows in Zaire and Brazil to a height of 4–5 m with stems 10–18 mm in diameter. Because of a lignified base, the stems are cut 20 cm above the ground. The plants are defoliated in the field and retted similarly to jute and kenaf. The retted material is stripped and washed and, in some cases, rubbed by hand. The soft, near-white fiber is graded for luster, color, uniformity, strength, and cleanliness. It is used for sacking, cordage, and coarse textiles.

Abutilon theophrasti is a herbaceous annual plant producing a jute-like fiber. The plant is native to China and is commercially grown in China and the former

Soviet Union. Because of its association with jute in mixtures and export, it is also called China jute. The plant grows to a height of 3–6 in. with a stem diameter of 6–16 mm. After harvesting by hand and defoliation, bundles of the stems are water retted and the fiber is extracted by methods similar to those for jute. The fiber is used for twine and ropes.

Leaf (Hard) Fibers

Hard or cordage fibers are found in the fibrovascular systems of the leaves of perennial, monocotyledonous plants growing in Central America, East Africa, Indonesia, Mexico, and the Philippines. They are generally of the Agave and Musa genera. The leaf elements are harvested by cutting at the base with a sickle-like tool, and bundled for processing by hand or by machine decortication. In the latter case, the leaves are crushed, scraped, and washed. The fibers are generally coarser than the bast fibers and are graded for export according to national rules for fineness, luster, cleanliness, color, and strength.

Abaca. The abaca fiber is obtained from the leaves of the banana-like plant (same genus) *Musa textilis* (banana family, Musaceae). The fiber is also called Manila hemp from the port of its first shipment, although it has no relationship with hemp, a bast fiber. The mature plant has 12–20 stalks growing from its rhizome root system; the stalks are 2.6–6.7 m tall and 10–20 cm thick at the base. The stalk has leaf sheaths that expand into leaves 1–2.5 m long, 10–20 cm wide, and 10 mm thick at the center; the fibers are in the outermost layer. The plant produces a crop after 5 years, and 2–4 stalks can be harvested about every 6 months.

In the Philippines, the principal supplier of abaca fiber, the fibrous layer in the sheath is separated with a knife between the layers, and the strips of fiber-containing layers, called tuxies, are pulled off and cleaned by hand to remove the pulp. In Indonesia and Central America these operations are performed mechanically. Hand- and spindle-stripped fiber is graded for braids, fine textiles, and cordage; decorticated fiber is another class. A cross-sectional view is shown in Figure 4**a**. The abaca fiber has a large lumen and the presence of silicified plates is not unusual.

Abaca fiber is unique in its resistance to water, especially salt water, and it is used for marine ropes and cables, although it has been largely replaced by synthetic fibers. Abaca fiber is the strongest of the leaf fibers (Table 4), followed by sisal, phormium, and henequen; it is also the strongest among the papermaking fibers. It is used for sausage casings and it is the preferred fiber for tea bags because of its high wet strength, cleanliness, and structure that permits rapid diffusion of the tea extract.

Cantala, Manila Maguey. *Agave cantala* is a member of the agave family (Agavaceae) that includes sisal. It originated in Mexico and was transported to Indonesia and the Philippines, where it is now produced commercially. The plant grows in a moist, humid soil. The fiber is extracted in Indonesia mechanically by a decorticator (raspador) and in the Philippines by retting in seawater and cleaning by hand or with a decorticator. The cantala fiber is lighter in color than other agaves, and its strength depends on its preparation.

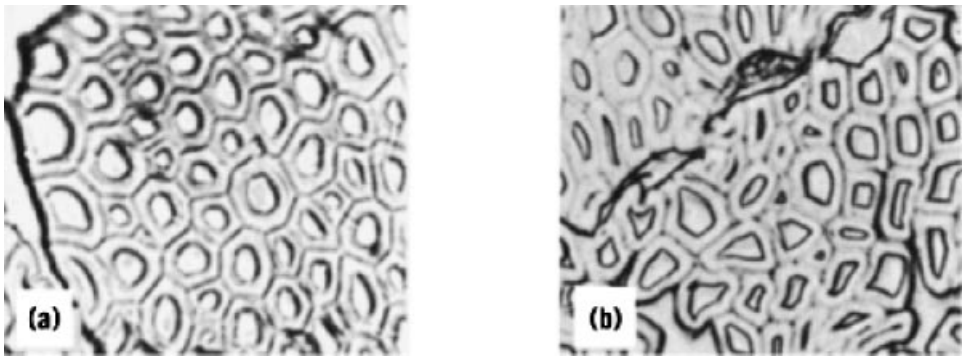

Fig. 4. Cross-sections (500×) of leaf fibers: (**a**) abaca and (**b**) sisal. Courtesy of the American Association of Textile Chemists and Colorists (14).

Caroa. Caroa is a hard leaf fiber, resembling sisal, obtained from *Neoglaziovia variegata*, a plant of the pineapple family (Bromeliaceae) growing wild in eastern and northern Brazil. The sword-shaped leaves are 1–3 m long and 2.5–5 cm wide. The fiber is extracted by hand scraping after beating or retting. The fiber is used for cordage and acoustic material.

Henequen. *Agave fourcroydes* grows in Mexico where it was first cultivated by the Mayans in the Yucatan (Yucatan Sisal). The plant produces for 20–30 years. The lower bottom leaves, which are up to 2 m long and 10–15 cm wide, are cut, machine-decorticated, and cleaned. Henequen fibers are white to yellowish red and are inferior to sisal in strength, cleanliness, texture, and length, the other grading criteria. Henequen is grown for local use in Cuba (Cuban Sisal) and El Salvador. Twines, small ropes, coarse rugs, and sacks are made commercially from henequen.

Istle. Istle is the general name for several agave species and related plants producing short, coarse, hard fibers. The commercial name is tampico. The plants from which the fibers are harvested include tula istle (*Agave lophantha*), jaumave istle (*Agave funkiana*), and palma istle (*Samuela carnerosana*). They are grown in central and northern Mexico. The fibers are recovered by hand scraping and drying; the palma istle is gummy and requires presteaming. The jaumave istle fibers closely resemble animal bristles in brushes.

Mauritius Hemp. Mauritius hemp, also called piteira, is obtained from *Furcraea gigantea,* also a member of the Agavaceae. The plant is mostly grown on the island of Mauritius, but is also harvested in Brazil and other tropical countries. The leaves are longer and heavier than those of the agaves. The fiber is extracted by mechanical decortication. It is whiter, longer, and weaker than sisal fiber. Because of its color it is used in blends.

Phormium. The *Phormium tenax* plant yields a long, light-colored, hard fiber also known as New Zealand hemp or flax, although it has none of the bast fiber characteristics. The plant is a perennial of the Agavaceae with leaves up to 4 m long and 10 cm wide. The fibers are recovered by mechanical decortication.

Sansevieria. This genus of the Agavaceae is a perennial also known as bowstring hemp from its use in bow strings. The plant is native to tropical Africa

and Asia but is widely grown, mainly as an ornamental plant. It is of minor importance as a fiber plant, even though the fiber is of high quality. The highest grade of *Samuela cylindrica* fiber is greenish yellow, very soft and fine, and compares with sisal in strength.

Sisal. The true sisal fiber from *Agave sisalana* is the most important of the leaf fibers in terms of quality and commercial use. Originating in the tropical western hemisphere, sisal has been transplanted to East Africa, Indonesia, and the Philippines. It is named after the port in the Yucatan from which it was first exported. The sisal plant leaves grow from a central bud and are 0.6–2 m long, ending in a thorn-like tip. The fibers are embedded longitudinally in the leaves, which are crushed, scraped, washed, and dried. The highest grades are further cleaned with a revolving drum. The growth of the sisal plant depends on water availability; it stores water during the wet season and consumes it during periods of drought.

A cross section of the sisal ultimate fiber is shown in Figure 4**b**. The sisal fiber is coarse and strong, but compared with the abaca fiber it is inflexible, although with a relatively high elongation under stress. It is also resistant to salt water. The principal applications are in binder and baling twine and as a raw material for pulp for products requiring high strength. A large pulp mill is operating in Brazil based on sisal.

Seed- and Fruit-Hair Fibers

The seeds and fruits of plants are often attached to hairs or fibers or encased in a husk that may be fibrous. These fibers are cellulosic-based and of commercial importance, especially cotton, the most important natural textile fiber.

Coir. This fiber, obtained from husks of the fruit of the coconut palm, *Cocos nucifera* (palm family, Arecaceae), is mainly produced in India and Sri Lanka. The fruits are broken by hand or machine, and the fiber extracted from the broken husks from which the coconut has been removed for the copra. The husks are retted in rivers, and the fiber separated by hand beating with sticks or by a decortication machine. The fibers are washed, dried, and hackled, and used in upholstery, cordage, fabrics, mats, and brushes.

Kapok. Kapok fiber is obtained from the seed pods of the kapok tree, *Ceiba pentandra*, of the Kapok tree family (Bombacaceae) which is indigenous to Africa and southeast Asia; the fiber is produced mainly in Java. The tree grows to a height of 35 m. The seeds are contained in capsules or pods that are picked and broken open with mallets. The floss is dried and the fiber is separated by hand or mechanically. A nondrying oil is produced from the seeds with properties similar to cottonseed oil. The fiber is exceedingly light, with a circular cross section, thin walls, and a wide lumen. Kapok fibers are moisture-resistant, buoyant, resilient, soft, and brittle, but not suitable for spinning. The traditional uses were in life jackets, sleeping bags, insulation, and upholstery; however, synthetics have replaced most of the applications as filling material and now kapok is mainly used for life preservers. Kapok-filled life preservers can support up to three times the weight of the preserver and do not become waterlogged.

Palm and Other Fibers

Piassava and Crin Vegetal. These palm (palm family, Arecaceae) fibers are obtained from the palm leaf base of *Attalea funifera* growing in Brazil and the palm leaf segments of *Chamaerops humilis* growing in North Africa. The former are used for cordage and brushes, the latter for stuffing.

Broom Root and Broom Corn. Broom root fiber is obtained from the root of the bunch grass, *Muhlenbergia macroura* (Poaceae), found in Mexico, where it grows 1–3 m high. The long fibers are bleached in fumes of burning sulfur before grading according to length. They are used in stiff scrubbing and scraping brushes and whisk brooms.

Broom corn is the fiber obtained from the flower head of another grass, *Sorgum vulgare technicum*, grown in the United States. The fibers are less stiff than those of the broom root and are used in brooms.

Economic Aspects

The principal bast and leaf fibers are produced in yields of 2–5%, with some exceptions such as flax (15%) and kapok (17%), on a green plant basis. The world production of several cordage (leaf) and textile (bast) fibers is given in Table 6.

Table 6. World Production (10^3 t) of Major Vegetable Fibers in 2002[a]

Fiber	Major countries		World production
Flax (fiber and tow)	China	221	647
	France	77	
	Egypt	63	
	Russia Fed.	62	
	Benelux	30

Pulp for papermaking	X			X	X	X	X	X				
Biobased composites	X			X	X		X	X				

[a] Also phormium leaf fibers.

Vegetable fiber production on the world market has dropped substantially because of periods of economic recession and synthetic fiber replacements. U.S. imports of vegetable fibers have also dropped in recent years for similar reasons (with the exception of flax wastes). The precipitous decline in jute exports from India are shown in Figure 2. Although most vegetable fibers are converted to lower cost commodity products, some of the fibers are converted into the most expensive products in their respective industries, eg, U.S. currency (paper).

Uses

Vegetable fibers have application in a broad range of fibrous products, including textiles and woven goods, cordage and twines, stuffing and upholstery materials, brushes, paper, and new biobased composites (Table 7). The uses for each of the specific fibers have been discussed in the designated sections. The traditional uses for the vegetable fibers have been eroded by substitution with synthetics on the world market. The declining uses include cordage, mats, filling material, brushes, etc. However, the unique properties of the bast fibers have allowed continued use in such specialty papers as bank notes, some writing papers, and cigarette papers.

Work at the USDA and Kenaf International (Texas) during the past decade demonstrated the potential of both growing and processing kenaf fibers for newsprint and other paper products in the United States (15). Another promising use for vegetable fibers is in the new biobased composites that are now marketed in various parts of the industrialized world (1). The vegetable fibers are mixed with thermoplastic or thermosetting resin matrices and either extrusion or compression molded into a variety of useful shapes. Such products are already utilized in the automotive industry for automobile interior door and head liners and as trunk liners. Although vegetable fibers will continue to provide indigenous populations with traditional uses, new innovative applications need to be developed to maintain international markets for the fibers.

VINYL ACETATE POLYMERS

Introduction

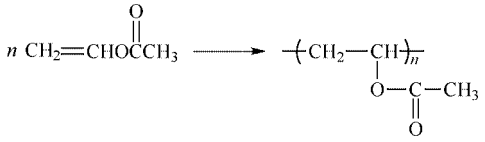
Vinyl acetate [108-05-4] (VAc), CH_2=CHOOCCH$_3$, the ethenyl ester of acetic acid, is primarily used for the manufacture of poly(vinyl acetate) [9003-20-7] (PVAc) and vinyl acetate copolymers. Poly(vinyl acetate) homo- and copolymers are found as components in coatings, paints and sealants, binders (adhesives, nonwovens, construction products, and carpet-backing), and miscellaneous uses such as chewing

Encyclopedia of Polymer Science and Technology. Copyright John Wiley & Sons, Inc. All rights reserved.

gum and tablet coatings. Applications have grown over the years in a number of areas (1–4).

Vinyl acetate is a colorless, flammable liquid having an initially pleasant odor which quickly becomes sharp and irritating. Table 1 lists the physical properties of the monomer. Information on properties, safety, and handling of vinyl acetate has been published (5–9). The vapor pressure, heat of vaporization, vapor heat capacity, liquid heat capacity, liquid density, vapor viscosity, liquid viscosity, surface tension, vapor thermal conductivity, and liquid thermal conductivity profile over temperature ranges have also been published (10). Table 2 (11) lists the solubility information for vinyl acetate. Unlike monomers such as styrene, vinyl acetate has a significant level of solubility in water which contributes to unique polymerization behavior. Vinyl acetate forms azeotropic mixtures (Table 3) (12).

The most important chemical reaction of vinyl acetate is free-radical polymerization (13,14). The reaction is summarized as follows:



Polymerization can be initiated by organic and inorganic peroxides, azo compounds, redox systems, light, and high energy radiation. Polymerization is inhibited or strongly retarded by aromatic hydroxyl, nitro or amine compounds, and by oxygen, quinone, crotonaldehyde, copper salts, sulfur, conjugated polyolefins, and enynes. Tabulations of quantitative information, eg, polymerization-rate constants, chain-transfer constants, and activation energies for the polymerization reactions of vinyl acetate, are available (13,14). Vinyl acetate has been polymerized by bulk, suspension, solution, and emulsion methods. It copolymerizes readily with some monomers but not with others. Some reactivity ratios are presented in Table 4 for common comonomers. The Q (monomer reactivity factor) and e (electronic factor) values are 0.026 and −0.22, respectively (14).

Hydrolysis of vinyl acetate is catalyzed by acidic and basic catalysts to form acetic acid and vinyl alcohol which rapidly tautomerizes to acetaldehyde. This rate of hydrolysis of vinyl acetate is 1000 times that of its saturated analogue, ethyl acetate, in alkaline media (15). The rate of hydrolysis is minimal at pH 4.44 (16). Other chemical reactions which vinyl acetate may undergo are addition across the double bond, transesterification to other vinyl esters, and oxidation (15–21).

World production of vinyl acetate monomer was 4×10^6 t in 1999. This represented 84% of the total capacity. In 2002, North American companies produced 1654×10^3 t of vinyl acetate. See Table 5 for producers and their capacities (22). The dominant method of production in North America is by the reaction of ethylene with acetic acid and oxygen in the presence of palladium catalyst. New construction in recent years has been focused in southeast asia, although European and North American producers have expanded their plants.

Vinyl acetate's main use is as a monomer. Consumption patterns vary by world area, however. In the United States, consumption in 2002 was as follows: 82%, poly(vinyl acetates) including poly(vinyl alcohol); 8%, ethylene vinyl acetate;

Table 1. Properties and Characteristics of Vinyl Acetate

Property	Value
Formula weight	86.09
Physical state	liquid
Flammable limits in air (101.3 kPa[a]), vol %	LEL 2.6, UEL 13.4
Flash point, °C

6%, ethylene–vinyl alcohol; 1%, vinyl chloride/vinyl acetate copolymer; 3%, miscellaneous. In Japan and China the major final consumption is for poly(vinyl alcohol). Half of Western Europe's consumption of vinyl acetate goes to producing poly(vinyl acetate).

Most of the applications for vinyl acetate are mature. The strongest growth areas are in ethylene–vinyl alcohol, poly(vinyl butyral), and vinyl acetate–ethylene resins. Growth of use for ethylene–vinyl alcohol is expected at 10–15%/year through 2004. Poly(vinyl butyral) is used in safety glass in automobile windshields. The U.S. market is mature for this use, but has a potential as a replacement for tempered glass in Europe. A potential market exists for side and rear automobile windows worldwide (23).

Overall growth in consumption through 2004 is forecasted as follows: United States, 3%/year; Western Europe, 2.8%/year; and Japan, 1–2% (23).

Vinyl acetate monomer is supplied in three grades, which differ in the amount of inhibitor they contain but otherwise have identical specifications. A low *p*-hydroquinone grade, containing 3–7 ppm *p*-hydroquinone, is preferred if it is expected to be used within two months of delivery. For monomer stored up to four months before polymerization, the grade containing 12–17 ppm *p*-hydroquinone is used. When indefinite storage is anticipated, a grade containing 200–300 ppm diphenylamine is supplied. Typical manufacturers' specifications are given in Table 6 (5–9).

Table 6. Typical Manufacturers' Specifications for Vinyl Acetate

Specification	Value
Vinyl acetate, wt%, min	99.8
Boiling point, °C	72.0–73.0
Acidity as acetic acid, wt%, max	0.007
Carbonyls as acetaldehyde, wt%, max	0.013
Water, wt%, max	0.04
Color, APHA system	0.5
Suspended matter	none

In storage, vinyl acetate should be kept away from ignition sources. It should be stored in a cool environment away from heat, direct sunlight, oxidizing materials, and free-radical generating chemicals to avoid rapid uncontrolled polymerization. Bulk storage should be blanketed with dry nitrogen. The monomer is actually more stable at a lower oxygen concentration (24). In the presence of oxygen, there is a tendency to form polyperoxides which could lead to polymerization. Using dry gas helps avoid the potential for hydrolysis to acetic acid and acetaldehyde. Additional information concerning the safe handling and transportation of vinyl acetate is provided in the Material Safety Data Sheet (MSDS) for vinyl acetate (5,25).

Gas chromatography is an excellent method to determine vinyl acetate and its volatile contaminants. If wet chemical techniques are used, vinyl acetate is assayed by adding excess bromide to an aliquot of material, followed by addition of excess potassium iodide and titration with standard sodium thiosulfate. Acidity is determined by direct titration in methanol solution with a standard caustic solution, aldehydes are determined by the addition of excess sodium bisulfite followed by titration with standard iodine solution, and water is determined by the Karl Fischer method. *p*-Hydroquinone and diphenylamine can be determined by standard titration techniques, or spectrophotometrically in the UV region after evaporation of vinyl acetate. Several companies describe in their product brochures empirical procedures for determining the polymerization activity of the monomer. In these tests, a given amount of monomer is polymerized under standard conditions and the rate of temperature increase or volume shrinkage and induction period are measured. Appropriate ASTM specifications and test procedures are D2190, D2191, D2193, and D2083.

The National Institute for Occupational Safety and Health (NIOSH) recommends a ceiling limit of 4 ppm for 15 min of exposure to vinyl acetate vapor. The American Conference of Governmental Industrial Hygienists (ACGIH) recommends an 8-h TLV Time Weighted Average of 10 ppm and a 15-min. short-term exposure limit of 15 ppm to its vapor. Vinyl acetate is a severe eye and skin irritant, forming blisters on the skin, and redness, swelling, or corneal burns on the eyes. The vapor is irritating to the nose and throat, and high levels of exposure may result in pulmonary edema. Nausea, headache, or weakness may result with inhalation of mists. Good industrial hygiene practices should be followed and adequate ventilation provided. Repeated or prolonged exposure should be avoided. The ACGIH has designated vinyl acetate as an A3 Animal Carcinogen. This designation refers to an agent which is carcinogenic in experimental animals at a relatively high dose. The International Agency for Research on Cancer (IARC) has evaluated vinyl acetate as a Group 2B material (26). This evaluates VAc as probably carcinogenic to humans on the basis of the sufficient evidence of the carcinogenicity of acetaldehyde in experimental animals. Both VAc and acetaldehyde were found to induce nasal tumors in rats on inhalation. VAc was also found to be genotoxic to human cells *in vitro* and to animal cells *in vivo*.

Vinyl acetate has moderate acute toxicity if ingested. The LD_{50} for oral ingestion in rats is 2.9 g/kg body weight; for absorption through the skin, the LD_{50} in rats is more than 5 mL/kg in 24 h. First-aid procedures to be followed in the event of overexposure to vinyl acetate are as follows:

Type of exposure	Treatment
Ingestion	Do not induce vomiting; drink large quantities of milk
Inhalation	Provide fresh air; keep victim warm and quiet; apply artifical respiration if necessary
Skin contact	Wash with water
Eye contact	Flush with water for 15 min; contact physician immediately

Vinyl Acetate Polymers

Properties. Poly(vinyl acetate) (PVAc) polymer resins are manufactured in a variety of molecular weights. Some physical properties of the polymer are listed in Table 7 (27–29). With increasing molecular weight, properties vary from viscous liquids to low melting solids to tough, horny materials. They are neutral, water-white to stray-colored, tasteless, odorless, and nontoxic. The resins have no sharply defined melting points but become softer with increasing temperature. Because of their solubility parameter, they are soluble in organic solvents, eg, esters, ketones, aromatics, halogenated hydrocarbons, carboxylic acids, etc, but are insoluble in the lower alcohols (excluding methanol), glycols, water, and nonpolar liquids such as ether, carbon disulfide, aliphatic hydrocarbons, oils, and fats. Alcohols, eg, ethyl, propyl, and butyl, containing 5–10 wt% water dissolve PVAc; butyl alcohol or xylene, both of which only swell the polymer at normal temperatures, dissolve it when heated. The electrical properties are strongly affected by the ability of poly(vinyl acetate) to absorb water. Whereas dried resin has a dielectric constant ϵ of 3.3 and a loss factor ϵ' of 0.08 $\pm$ 0.02 at 35°C and 60 Hz, after exposure to 100% relative humidity the numbers become 10 and 0.7, respectively (30,31).

As with many thermoplastic resins, strength properties increase with molecular weight; tensile strengths up to 50.3 MPa (7300 psi) may be obtained. The softening point, as determined by the ring-and-ball method or by the Kraemer and Sarnow method, also increases with molecular weight, as shown in Table 8 (32,33). Poly(vinyl acetate) resin is commercially available in pure, dry form as beads, granules, or lumps and is graded according to viscosity at 20°C of a 1 *M* solution in benzene (86.09 g or 1 *M* of repeating units of the resin dissolved in benzene to make 1 L). In Europe, the Fikentscher *K* value, also derived from viscosity measurements, is used to characterize commercial resins.

On cooling below room temperature, poly(vinyl acetate)s become brittle. The brittle point may be lowered by plasticization or copolymerization. When heated above room temperature and above the polymer glass-transition temperature (30°C), all viscosity grades become very flexible, and at 50°C become limp. The glass-transition temperature of PVAc is depressed by the incorporation of moisture causing the polymer to be more flexible under humid conditions. Poly(vinyl acetate) can be heated at 125°C for hours without changing, but at 150°C it gradually darkens, and at over 225°C it liberates acetic acid forming a brown insoluble resin which carbonizes at a much higher temperature. The products of thermal

decomposition of PVAc are at 150–200°C acetic acid, and at 300–350°C aromatic compounds, ie, benzene, toluene, naphthalene, etc (34). PVAc resists oxidation and degradation by UV and visible radiation; therefore its aging qualities are excellent.

The NMR spectrum of PVAc in carbon tetrachloride solution at 110°C shows absorptions at 4.86δ (pentad) of the methine proton; 1.78δ (triad) of the methylene group; and 1.98δ, 1.96δ, and 1.94δ, which are the resonances of the acetate methyls in isotactic, heterotactic, and syndiotactic triads, respectively. Poly(vinyl acetate) produced by normal free-radical polymerization is completely atactic and noncrystalline. The NMR spectra of ethylene vinyl acetate copolymers have also been obtained (35). The IR spectra of the copolymers of vinyl acetate differ from that of the homopolymer depending on the identity of the comonomers and their proportion.

The chemical properties of PVAc are those of an aliphatic ester. Thus, acidic or basic hydrolysis produces poly(vinyl alcohol) and acetic acid or the acetate of the basic cation. Industrially, poly(vinyl alcohol) is produced by a base-catalyzed ester interchange with methanol, where methyl acetate forms in addition to the polymeric product. The chemical properties of PVAc can be modified by copolymerization. When a comonomer having a carboxylic acid group or a sulfuric acid group is used, the copolymer becomes soluble in dilute aqueous alkali or

ammonia. These copolymers also adhere better to metals than homopolymers or neutral copolymers because of the interaction between the acid groups and the metal surface. Copolymerization with monomers such as butyl acrylate can improve flexibility and provide specific adhesion to surfaces. Monomers such as *n*-methylol acrylamide copolymerized with vinyl acetate provide sites for cross-linking either during polymerization reaction or in use. Other comonomers such as vinyl Versatate (vinyl neodecanoate) reduce the potential for hydrolytic breakdown of the polymer chain by shielding the VAc group from attack.

In poly(vinyl acetate) copolymer emulsions, the properties are significantly affected by the composition of the aqueous phase and by the stabilizers and buffers used in the preparation of these materials, along with the process conditions (eg, monomer concentrations, pH, agitation, and temperature). The emulsions are milk-white liquids containing ca 55 wt% PVAc, the balance being water and small quantities of wetting agents or protective colloids. The use of poly(vinyl acetate) or copolymer emulsions eliminates the need for expensive, flammable, odorous, or toxic solvents and the need for the recovery of such solvents. They are easy to apply and the equipment is easy to clean with water, if done promptly. Emulsions also offer the advantage of high solids content with fluidity, since the viscosity of emulsions are independent of the molecular weight of the resin in the particles.

The specific gravity at 20°C for all poly(vinyl acetate) emulsions is about 1.1. There generally is a slight odor of residual monomer in standard materials, but if this is removed by some means, such as steam stripping or further reaction, the emulsions are virtually odorless. Traces of acetic acid can be neutralized with a base, eg, ammonia, sodium bicarbonate, or triethanolamine, and when the free monomer has been removed, the pH of the resulting emulsion can be adjusted to remain constant at ca 7. The product developer can choose from ingredient and process options to develop properties for the intended end use. These properties include particle size and molecular weight distributions, pH, emulsion viscosity, particle charge, environmental resistance (solvent, moisture, temperature, and

UV), film characteristics (modulus, elongation, toughness), and stability to storage, freezing, dilution, mechanical action, and compounding.

Poly(vinyl acetate) polymer and copolymer properties may be modified through the addition of plasticizers and fillers. Cross-linking agents react with copolymers of vinyl acetate containing a cross-linkable group. The material properties can be altered to allow improved flow, rigidity, and toughness. Various resins, plasticizers, thickening agents, solvents, pigments, extenders, and some dyes may be added. Plasticizers are often added to provide increased flexibility to the dried film, but these usually are not incorporated before the final formulation is made because their presence may adversely affect stability, particularly in cold weather.

When the emulsion is applied to a surface, water is lost by evaporation and absorption if the surface is porous. The particles stick together and eventually coalesce to form a tough and somewhat clear continuous coating. Clarity is often improved by the presence of plasticizer, which also enhances the film's resistance to water. This may be due to the improvement in coalescence of the films. Films from most emulsions containing poly(vinyl alcohol) as the protective colloid are likely to re-emulsify on contact with water, unless they contain relatively large quantities of plasticizer or solvent, or are costabilized with a surfactant which helps plasticize the polymer. The films are unaffected by light, oxygen, chlorine in moderation, and dilute solutions of acids, alkalies, and salts. The films are also inert to oils, fats, waxes, and greases, unless these are mostly aromatic. Some solvents, namely acetone, alcohol, ethyl acetate, benzene, and toluene, dissolve or at least swell the film. The extent of dissolution depends on the branching in the chain.

Poly(vinyl acetate) emulsion films adhere well to most surfaces that have relatively high surface energy, (eg, wood, paper, glass, and metal), and have good binding capacity for pigments (qv) and fillers (qv). The ability to bond to other surfaces may be enhanced with the use of comonomers. Ethylene copolymers have shown good adhesion to PVC. Elasticized films are strong and flexible at ordinary temperatures.

An important property of a PVAc film is its permeability to water vapor. The permeability to saturated water vapor at 40°C is 2.1 g/(h · m^2) for a film 0.025 mm thick. This allows the film to be laid down on a damp surface with trapped moisture gradually passing through the film without lifting or blistering it.

Poly(vinyl acetate) polymers are environmentally friendly because they easily biodegrade. Poly(vinyl acetate) may be hydrolyzed to poly(vinyl alcohol) which is then assimilated by naturally occurring organisms. In the use of emulsion polymers, the associated components (stabilizers, initiators, etc) should be scrutinized for their effect on the environment. Poly(vinyl acetate) is nontoxic and is approved by the U.S. Food and Drug Administration (FDA) for food applications (qv) (CFR 176.170, 175.105). Components in the emulsion polymer system which may migrate from the film into the food may impact the approval of the total package. In food applications the impact on odor and taste of residual low molecular weight components may be important in the selection of a product for use.

Polymerization Processes. Vinyl acetate has been polymerized industrially by bulk, solution, suspension, and emulsion processes (36). Perhaps 90% of the material identified as poly(vinyl acetate) or copolymers that are predominantly vinyl acetate are made by emulsion techniques. Detailed information is in

patent and scientific literature and in procedures available in the brochures from monomer producing companies (15,36).

Emulsion Polymerization. Poly(vinyl acetate)-based emulsion polymers are produced by the polymerization of an emulsified monomer through free radicals generated by an initiator system. Descriptions of the technology may be found in several references (37–41) (see HETEROPHASE POLYMERIZATION).

Recipe. An emulsion recipe, in general, contains monomer, water, protective colloid or surfactant, initiator, buffer, and perhaps a molecular weight regulator. The recipe may contain 30–70% monomer, but most commercially available emulsions contain ca 55 wt% solids, although copolymer emulsions have been commercially introduced which have greater than 70% solids content. Several monomers are copolymerized commercially with vinyl acetate in emulsion polymerization and numerous others have been copolymerized on a laboratory scale. Among the comonomers most commonly used industrially in emulsion copolymerization with vinyl acetate are ethylene, dibutyl maleate, bis(2-ethylhexyl) maleate, ethyl-, butyl-, and 2-ethylhexyl acrylates, vinyl laurate, and vinyl neodecanoate (13,15). Vinyl hydrogen maleate and vinyl hydrogen fumarate have also been used as comonomers, as have acrylic acid, maleic anhydride, and sodium ethylenesulfonate, in order to incorporate an acidic or ionic group in the polymer. The neutral comonomers are added primarily to decrease the brittle temperature of the polymer below commonly encountered ambient temperatures, since many uses of PVAc require some degree of flexibility in service. They may also improve the compatibility of the polymer with surfaces of different compositions and energies. The monomers that contain acidic groups are added primarily to make the copolymer soluble in basic media, eg, aqueous ammonia. They also help improve adhesion to metallic surfaces. Copolymerization with monomers which lower the glass-transition temperature, gives a polymer which is innately and permanently flexible. In comparison, the lowering of the brittle point accomplished by addition of plasticizers such as dibutyl phthalate, tricresyl phosphate, etc, to the preformed polymer may be lost with the migration of the plasticizer out of the film. The most efficient plasticizing comonomer on a weight or price basis is ethylene. Copolymerization of vinyl acetate with ethylene is the most significant in the adhesive market (42).

Many different combinations of surfactant and protective colloid are used in emulsion polymerizations of vinyl acetate as stabilizers. The properties of the emulsion and the polymeric film depend to a large extent on the identity and quantity of the stabilizers. The choice of stabilizer affects the mean and distribution of particle size, which affects the rheology and film formation. The stabilizer system also impacts the stability of the emulsion to mechanical shear, temperature change, and compounding. Characteristics of the coalesced resin affected by the stabilizer include tack, smoothness, opacity, water resistance, and film strength (43,44).

Poly(vinyl acetate) emulsions can be made with a surfactant alone or with a protective colloid alone, but the usual practice is to use a combination of the two. Normally, up to 3 wt% stabilizers may be included in the recipe, but when water sensitivity or tack of the wet film is desired, as in some adhesives, more may be included. The most commonly used surfactants are the anionic sulfates and sulfonates, but cationic emulsifiers and nonionics are also suitable. Indeed,

some emulsion compounding formulas require the use of cationic or nonionic surfactants for stable formulations. The most commonly used protective colloids are poly(vinyl alcohol) and hydroxyethyl cellulose, but there are many others, natural and synthetic, which are usable if not preferable for a given application.

Issues to be considered in selecting the best stabilizing system are polymeric chain branching which increases with high temperature and the presence of some stabilizers, polydispersity of the particles produced, and grafting copolymerization, which may occur because of the reaction of vinyl acetate with emulsifiers such as poly(vinyl alcohol) (45,46).

In general, the greater the quantity of stabilizers in a recipe, the smaller the particle size of the emulsion. At the higher emulsifier levels ($\geq$1 wt%) used for emulsion polymerization, the polymer forms tiny particles that do not settle but remain indefinitely suspended. Particle sizes resulting from high surface active agent to low protective colloid ratios may be 0.005–1 μm; such emulsions contain lower solids and have lower viscosities. Commercial poly(vinyl acetate) emulsions used in adhesives usually are made with higher ratios of protective colloids in the recipes and usually contain ca 55 wt% solids. Average particle sizes are 0.2–10 μm and the viscosity of the emulsion is 400–5000 mPas (= cP). These latter compositions, ie, with higher ratios of protective colloids, are occasionally described as stable dispersions rather than true emulsions (47–51). The term *latex* is also used to denote these products, particularly those with small, ie, $<$0.2 μm, particle size.

The initiators used in vinyl acetate polymerizations are the familiar free-radical types, eg, hydrogen peroxide, peroxysulfates, benzoyl peroxide, *tert*-butyl hydroperoxide, lauryl peroxide, and redox combinations. In redox combinations, reducing agents such as sodium metabisulfite, sodium formaldehyde sulfoxylate, and ascorbic acid are among those commonly used along with transition-metal salts such as ferrous sulfate. Emulsion polymerizations are usually conducted with water-soluble initiators; benzoyl peroxide has been used in emulsion polymerizations with water-soluble initiators, especially where monomer has been added continuously during the reaction. Radiation-induced initiation has been explored because the activation energy is lower (29 kJ/mol), allowing polymerization to take place at lower temperatures (52).

Buffers are frequently added to emulsion recipes and serve two main purposes. The rate of hydrolysis of vinyl acetate and some comonomers is pH-sensitive. Hydrolysis of monomer produces acetic acid, which can affect the initiator, and acetaldehyde which as a chain-transfer agent may lower the molecular weight of the polymer undesirably. The rates of decomposition of some initiators are affected by pH and the buffer is added to stabilize those rates, since decomposition of the initiator frequently changes the pH in an unbuffered system. Vinyl acetate emulsion polymerization recipes are usually buffered to pH 4–5, eg, with phosphate or acetate, but buffering at neutral pH with bicarbonate also gives excellent results. The pH of most commercially available emulsions is 4–6.

Often a chain-transfer agent is added to vinyl acetate polymerizations, whether emulsion, suspension, solution, or bulk, to control the polymer molecular weight. Aldehydes, thiols, carbon tetrachloride, etc, have been added. Some emulsion procedures call for the recipe to include a quantity of preformed PVAc emulsion, and sometimes antifoamers must be added (see FOAMS).

Process. A polymerization process may consist of simply charging all ingredients to the reactor, heating to reflux, and stirring until the reaction is over while controlling the heat removal at the reaction temperature using cooling systems. However, this simple procedure is seldom followed. Typically, only a portion of the monomer and catalyst is initially charged and the remainder is added during the course of the reaction. Better control of the rate of polymerization can be maintained in this fashion, which is particularly important in industrial-scale operations where large quantities of material are involved and heat-transfer capacity may be limited. Continuous monomer addition in emulsion polymerization usually leads to smaller particle size and a more stable dispersion. On the molecular level, monomer fed over the course of the reaction results in more branches in the polymer chain, if the monomer content of the reaction mix is held low. Consequently, the rate of monomer addition has an effect on final film properties. Copolymerizations usually must be conducted with a continuous monomer feed to obtain homogeneous polymer compositions, especially if there is a significant disparity in the reactivities of the two monomers. Emulsifiers may also be added in increments to help stabilize growing particle populations. In a Kuraray comparison of batch to semicontinuous systems (53), films from emulsions made batchwise were found to have better tensile strength than films made from semicontinuous emulsions.

Various finishing techniques are used to reduce the residual monomer in the emulsion polymer. These include raising the temperature, adding a more concentrated initiator, or using mechanical means, such as stripping. Industrially, polymerizations are carried out to over 99% conversion, and thus there is no need to reduce the unreacted monomer unless very low levels are required to meet regulatory, product, or workplace requirements. Most poly(vinyl acetate) emulsions contain less than 0.5 wt% unreacted vinyl acetate, which minimizes development of acetic acid and acetaldehyde by monomer hydrolysis on long storage. Rohm and Haas has patented an ultrafiltration (qv) process for recovering and recycling polymer emulsions from dilute wastewater (54).

All of these processes are operated in conventional glass-lined or stainless steel kettles or reactors. The pressure rating of the reactors depends on the volatility of the monomers used. In the homopolymerization of the vinyl acetate and its copolymerization with monomers of low vapor pressure, the use of vessels with a pressure rating close to atmospheric pressure is sufficient. The ethylene–vinyl acetate copolymer (EVA) processes must of necessity be operated under high pressure (42). Agitation design in these systems is important, taking into consideration the need to blend all the ingredients without zones of high concentration and remove the heat from the reaction mass while avoiding subjecting the reaction mixture to conditions of high shear which could destabilize the material. Heat removal in atmospheric pressure reactions, especially those carried out close to or higher than the boiling point of the vinyl acetate, uses reflux condensers. In vinyl acetate polymerizations where low temperatures are maintained to avoid chain transfer, which results in lowering the average molecular weight, internal coils, jackets on the reactors, and external heat exchangers are used.

Control of the process is important to ensure reproducibility of the product. Methods have been developed to control the composition of copolymers and their molecular weight (55,56). Calorimetric methods have been described to estimate

conversion and provide the basis for control of the reaction. Other properties such as density and particle size can also be monitored to gauge the reaction progress and development of the product properties (57–59). Agitator design is important in controlling particle size and can influence the kinetics, molecular weight, and coagulum formation (60).

Continuous emulsion copolymerization processes for vinyl acetate and vinyl acetate–ethylene copolymer have been reported (61–66). Cyclic variations in the number of particles, conversion, and particle-size distribution have been studied. Control of these variations based on on-line measurements and the use of preformed latex seed particles have been discussed (63,64).

Continuous polymerization systems offer the possibility of several advantages including better heat transfer and cooling capacity, reduction in downtime, more uniform products, and less raw material handling (61,62). In some continuous emulsion homopolymerization processes, materials are added continuously to a first kettle and partially polymerized, then passed into a second reactor where, with additional initiator, the reaction is concluded. Continuous emulsion copolymerizations of vinyl acetate with ethylene have been described (63–66). Recirculating loop reactors which have high heat-transfer rates have found use for the manufacture of latexes for paint applications (61).

Mini-emulsion processes have been developed where the monomer is emulsified under high energy with either a long-chain alcohol or a polymer producing very small droplets. The long-chain alcohol retards the diffusion of the monomer out of the droplets (67). Polymerization takes place primarily in the droplets, allowing the development of fine, narrow particle-size distributions (68). The proceedings of a symposium on the emulsion polymerization of vinyl acetate is available (69).

Bulk Polymerizations. In the bulk polymerization of vinyl acetate, the viscosity increases significantly as the polymer forms, making it difficult to remove heat from the process. Low molecular weight polymers have been made in this fashion. Continuous processes are known to be used for bulk polymerizations (70).

Suspension Polymerization. At very low levels of stabilizer, eg, 0.1 wt%, the polymer does not form a creamy dispersion that stays indefinitely suspended in the aqueous phase but forms small beads that settle and may be easily separated by filtration (71). This suspension or pearl polymerization process has been used to prepare polymers for adhesive and coating applications and for conversion to poly(vinyl alcohol). Products in bead form are available from several commercial suppliers of PVAc resins. Suspension polymerizations are carried out with monomer-soluble initiators predominantly, with low levels of stabilizers. Suspension copolymerization processes for the production of vinyl acetate–ethylene bead products have been described, and the properties of the copolymers determined (72). Continuous tubular polymerization of vinyl acetate in suspension (73,74) yields stable dispersions of beads with narrow particle-size distributions at high yields.

Solution Polymerization. Solution polymerization of vinyl acetate is carried out mainly as an intermediate step to the manufacture of poly(vinyl alcohol) (see VINYL ALCOHOL POLYMERS). A small amount of solution-polymerized vinyl acetate is prepared for the merchant market. When solution polymerization is carried out, the solvent acts as a chain-transfer agent and, depending on its transfer constant, has an effect on the molecular weight of the product. The rate of

polymerization is also affected by the solvent but not in the same way as the degree of polymerization. The reactivity of the solvent-derived radical plays an important part. Chain-transfer constants for solvents in vinyl acetate polymerizations have been tabulated (13). Continuous solution polymers of poly(vinyl acetate) in tubular reactors have been prepared at high yield and throughput (75,76).

Mechanisms. Because of its considerable industrial importance as well as its intrinsic interest, emulsion polymerization of vinyl acetate in the presence of surfactants has been extensively studied (77–79). The Smith-Ewart theory, which describes emulsion polymerization of monomers such as styrene, does not apply to vinyl acetate. Reasons for this are the substantial water solubility of vinyl acetate monomer, and the different reactivities of the vinyl acetate and styrene radicals; the chain transfer to monomer is much higher for vinyl acetate. The kinetics of the polymerization of vinyl acetate has been studied and mechanisms have been proposed (80–84).

Initiation. Radicals formed from the initiator species, or generated by chain transfer, initiate the dissolved monomer in the water phase as well as in the micelles (aggregates of stabilizer molecules). Homogeneous nucleation applies to moderately soluble monomers like vinyl acetate (75,79,85). In homogeneous nucleation, oligomers grow from monomers in the water phase. After reaching the solubility limit, they precipitate and partially stabilized primary particles are formed. The particles grow by absorbing and converting monomer to polymer and also by coagulation. Where PVOH is used as a protective colloid, grafting may occur onto the PVOH backbone and the growing polymer may maintain its solubility in water to a higher degree of polymerization (86). The efficiency of the initiator system may be dependent on the stabilizer used. The presence of oxygen may be inhibitory in nature, probably due to the high chain-transfer constant of the oxygen–vinyl acetate adduct (Table 9). pH is also important as the initiator efficiency may be affected, especially in redox systems.

Propagation. The rate of emulsion polymerization has been found to depend on initiator, monomer, and emulsifier concentrations. In a system of vinyl acetate, sodium lauryl sulfate, and potassium persulfate, the following relationship for the rate of polymerization has been suggested (87):

$$R_p = k_p[M]_0^{0.34}[E]_0^{0.5}[I]_0^{0.5}$$

where R_p is in g/(cm^3 of H_2O) in seconds, $[M]_0$ is the monomer concentration, $[E]_0$ the emulsifier concentration, and $[I]_0$ the initiator concentration. The polymerization rate is constant during the period when monomer conversion is between 15 and 80%. The number of particles per unit volume of aqueous phase is given by the following equation:

$$N_p = [E]_0^{0.094}[I]_0^{0.04}$$

The Smith–Ewart theory predicts $R_p = K[I]^{0.4}$. The rate of polymerization of vinyl acetate is virtually independent of emulsifier concentration, depending on the study, whereas the Smith–Ewart theory predicts the rate to be proportional to the 0.6th power of the emulsifier concentration for monomers such as styrene. This may be due to the high chain transfer to the vinyl acetate monomer. The

Table 9. Chain-Transfer Constants

Compound	$C_s \times 10^4$	°C
n-Heptane	17.0	50
Toluene	20.75	60
Methanol	6	60

	2.6×10^{-3}	75
Poly(vinyl acetate)	1.5×10^{-4}	60

resulting small radical size has higher mobility, allowing diffusion out of the particle into the aqueous phase and causing reinitiation there. This has a significant effect in lowering the molecular weight of the polymer and increasing the overall rate. At high conversions where monomer concentrations are low (due to either a low feed rate of monomer or in later stages of the reaction), the transfer to polymer becomes important, leading to branched chains. Transfer can also occur to the stabilizing species resulting in permanent incorporation into the polymer matrix. An assessment of the best values of the rate constants for propagation and termination is given below (21):

$$\textit{Propagation } k_p \text{ [L/(mol·s)]} = 3.2 \times 10^7 \exp(-3150/T)$$

$$\textit{Termination } k_t \text{ [L/(mol·s)]} = 3.7 \times 10^9 \exp(-1600/T)$$

For example, at 60°C, k_p = 2300 and k_t = 2.9 × 10^7. An estimate of kinetic chain lifetime, ie, the time from initiation to termination by reaction with another radical, is 1–2 s at 50°C and 4% per hour rate of polymerization. If there are five chain-transfer steps in the course of the kinetic chain, then a PVAc molecule forms in 0.2–0.4 s. Faster rates of conversion give shorter kinetic chain lifetimes in inverse proportion, but an increased percentage of conversion leads to longer chain lifetimes. At 75% conversion and at 60°C, the radical lifetime is ca 10 s.

Vinyl acetate polymerizes chiefly in the usual head-to-tail fashion, but some of the monomers orient head-to-head and tail-to-tail as the chain grows. The fraction of heat-to-head addition increases with temperature. For example, a 1.15 mol% head-to-head structure and a 1.86 mol% structure were determined at 15°C and 110°C, respectively (88).

In vinyl acetate polymerizations, the molecular weights of the products increase with the extent of conversion: the ratio of weight to number-average degree of polymerization also changes, becoming larger at higher conversions (89,90). The dilute solution viscosity of poly(vinyl acetate) can be related to the molecular weight by the following equations (30):

$$[\eta] = 0.0102\,M^{0.72}\text{dL/g in acetone solvent at } 30^{\circ}\text{C}$$

$$[\eta] = 0.314\,M^{0.60}\text{dL/g in methanol solvent at } 30^{\circ}\text{C}$$

These equations apply to linear polymers of $M_w/M_n = 2.0$.

Chain Transfer. At the molecular scale, vinyl acetate polymerizations are generally understood as free-radical polymerizations, but are characterized in particular by a relatively large amount of chain transfer (13). This high reactivity of the PVAc growing chain radical is attributed to its low degree of resonance stabilization. The high reactivity of the vinyl acetate radical also contributes to the high rate constant for propagation in vinyl acetate polymerization compared to styrene, the acrylates, and the methacrylates. Chain transfer to monomer is an extremely important factor controlling the molecular weight (13). Several determinations of the transfer constant to monomer C_m, ie, the ratio of rate constants of the transfer reaction and the propagation step k_{tr}/k_p, show that C_m increases from 1×10^4 to 3×10^4 from 0 to 75°C (13,91,92).

Chain transfer to monomer and to other small molecules leads to lower molecular weight products, but when polymerization occurs in the relative absence of monomer and other transfer agents, such as solvents, chain transfer to polymer becomes more important. As a result, toward the end of batch-suspension or batch-emulsion polymerization reactions, branched polymer chains tend to form. In suspension and emulsion processes where monomer is fed continuously, the products tend to be more branched than when polymerizations are carried out in the presence of a plentiful supply of monomer.

Chain transfer also occurs to the emulsifying agents, leading to their permanent incorporation into the product. Chain transfer to aldehydes, which may be formed as a result of the hydrolysis of the vinyl acetate monomer, tends to lower the molecular weight and slow the polymerization rate because of the lower activity of the radical that is formed. Thus, the presence of acetaldehyde condensates as a poly(vinyl alcohol) impurity strongly retards polymerization (93). Some of the initiators such as lauryl peroxide are also chain-transfer agents and lower the molecular weight of the product.

Investigation has shown that chain transfer to polymer occurs predominantly on the acetate methyl group in preference to the chain backbone; one estimate of the magnitude of the predominance is 40-fold (94,95). The number of branches per molecule of poly(vinyl acetate) polymerized at 60°C is ca 3, at

80% conversion. It rises rapidly thereafter and is ca 15 at 95% conversion and 1–2 $\times$ 10^4 number-average degrees of polymerization.

Grafting and Stabilizers. The degree of grafting of poly(vinyl acetate) (PVAc) on poly(vinyl alcohol) (PVA) and other stabilizers during emulsion polymerization strongly affects latex properties such as viscosity, rheology, and polymer solubility (96). The composition and structure of poly(vinyl alcohol) significantly affects the emulsion polymerization of vinyl acetate. The chain distribution of residual acetate groups in poly(vinyl alcohol) is important to successful vinyl acetate emulsion polymerization. A block-like distribution is preferred over a random distribution (97–100). The structure of poly(vinyl acetate-*co*-vinyl alcohol) emulsion particles has been determined by electron microscopy. The latex particle is formed of a great many smaller particles packed together by flocculation processes (101,102).

An extensive series of papers (103–111) have been published on the grafting of vinyl acetate and styrene on poly(vinyl alcohol) studying the effects of type and concentration of the poly(vinyl alcohol), initiator, and reaction temperature. The partially acetylated poly(vinyl alcohol) was the superior grafting base because of the attachment of the poly(vinyl acetate) segments to the polymerizing particle. The resulting latices with the anchored poly(vinyl alcohol) chains had superior stability. The methine hydrogen atom of the poly(vinyl alcohol) was proposed to be a grafting site in all cases as opposed to the acetyl groups. In mixed systems of poly(vinyl alcohol) and ethoxylated cetyl alcohol both benzene-soluble and water-soluble fractions of graft copolymer were identified, with their ratio dependent on the ratio of initially charged-to-delay fed stabilizer and the stirring speed (112).

Emulsion polymerizations of vinyl acetate in the presence of ethylene oxide- or propylene oxide-based surfactants and protective colloids also are characterized by the formation of graft copolymers of vinyl acetate on these materials. This was also observed in mixed systems of hydroxyethyl cellulose and nonylphenol ethoxylates. The oxyethylene chain groups supply the specific site of transfer (113). The concentration of insoluble (grafted) polymer decreases with increase in surfactant ratio, and R_p (max) is observed at an ethoxylation degree of 8 (114).

Porous membranes with selective permeability to organic solvents have been prepared by the extraction of latex films prepared with moderate ratios of PVA–PVAc graft copolymer fractions. The extracted films are made up of a composite of spherical cells of PVA, PVAc microgel, and PVA–PVAc graft copolymers (115).

Poly(vinyl acetate) chains are also stabilized as aqueous-soluble anionic species by complexation with a surfactant. The charge on the water-soluble species prevents their absorption into the particle (116).

The kinetics of vinyl acetate emulsion polymerization in the presence of alkyl phenyl ethoxylate surfactants of various chain lengths indicates that part of the emulsion polymerization occurs in the aqueous phase and part in the particles (117). A study of the emulsion polymerization of vinyl acetate in the presence of sodium lauryl sulfate reveals that a water-soluble poly(vinyl acetate)–sodium dodecyl sulfate polyelectrolyte complex forms, and that latex stability, polymer hydrolysis, and molecular weight are controlled by this phenomenon (118).

Problems with grafting and morphological changes in the particles are reviewed (119). Vinyl acetate has been grafted onto atactic polypropylene (120) and casein (121).

Copolymers. The effects of emulsion polymerization process type or latex and polymer properties have been studied. Vinyl acetate copolymerizes easily with a few monomers, eg, ethylene, vinyl chloride, and vinyl neodecanoate, which have reactivity ratios close to its own (see Table 4). The kinetics and the effect of process parameters on the copolymerization of vinyl acetate with ethylene have been studied (122,123). With some monomers, eg, maleic anhydride, it tends to form alternating copolymers. Other monomers with high r_2 and low r_1, eg, alkyl acrylates, tend to form copolymers much leaner in vinyl acetate than the initial charge composition with near homopolymer formed by the faster reacting comonomer. A process is required in which the faster reacting monomer is kept at a low concentration relative to the vinyl acetate, preferably by adding it over the course of the reaction. Studies have been carried out to design processes that result in copolymers which have narrow composition distributions (55,56). The morphology of the polymer particle depends on the monomer characteristic and the process. Thus, emulsion copolymerization of vinyl acetate–butyl acrylate comonomer systems by a delayed monomer addition process yields a core-shell structure particle, in which poly(butyl acrylate)-rich copolymer forms the core and vinyl acetate-rich copolymers form the shell (124).

Block copolymers of vinyl acetate with methyl methacrylate, acrylic acid, acrylonitrile, and vinyl pyrrolidinone have been prepared by copolymerization in viscous conditions, with solvents that are poor solvents for the vinyl acetate macroradical (125). Similarly, the copolymerization of vinyl acetate with methyl methacrylate is enhanced by the solvents acetonitrile and acetone and is decreased by propanol (126). Copolymers of vinyl acetate containing cyclic functional groups in the polymer chain have been prepared by copolymerization of vinyl acetate with *N*,*N*-diallylcyanamide and *N*,*N*-diallylamine (127,128).

Alternating equimolar copolymers of vinyl acetate and ethylene and alternating copolymers of vinyl acetate and acrylonitrile have been reported (129,130). Vinyl acetate and certain copolymers can be produced directly as films on certain metallic substrates by electroinitiation processes in which the substrate functions as one electrode (131).

New terpolymers of vinyl acetate with ethylene and carbon monoxide have been prepared and their uses as additives to improve the curing and flexibility of coating resins, eg, nitrocellulose, asphalt, phenolics, and polystyrene, have been described (132–134). Vinyl acetate and vinylidene cyanide form highly alternating copolymers.

The low vinyl acetate ethylene–vinyl acetate copolymers, ie, those containing 10–40 wt% vinyl acetate, are made by processes similar to those used to make low density polyethylene for which pressures are usually >103 MPa (15,000 psi). A medium, ie, 45 wt% vinyl acetate copolymer with rubber-like properties, is made by solution polymerization in *tert*-butyl alcohol at 34.5 MPa (5000 psi). The 70–95 wt% vinyl acetate emulsion copolymers are made in emulsion processes under ethylene pressures of 2.07–10.4 MPa (300–1500 psi).

Blends. Latex film properties are commonly modified through the blending of latexes, eg, a "soft" polymer is made slightly harder by blending with a "hard" latex.

Poly(ethyl methacrylate) (PEMA) yields truly compatible blends with poly(vinyl acetate) up to 20% PEMA concentration (135). Synergistic improvement in material properties was observed. Poly(ethylene oxide) forms compatible

homogeneous blends with poly(vinyl acetate) (136). The T_g of the blends and the crystallizability of the PEO depend on the composition. The miscibility window of poly(vinyl acetate) and its copolymers with alkyl acrylates can be broadened through the incorporation of acrylic acid as a third component (137). A description of compatible and incompatible blends of poly(vinyl acetate) and other copolymers has been compiled (138). Blends of poly(vinyl acetate) copolymers with urethanes can provide improved heat resistance to the product providing reduced creep rates in adhesives used for vinyl laminating (139).

Economic Aspects. In 2000, approximately 1.4×10^6 t of poly(vinyl acetate) emulsions and resins (dry content, including copolymers) were produced in North America, Western Europe, and Japan. The United States accounted for 50% of production, Western Europe accounted for 39%, Japan accounted for ca 9%, and the remainder was attributed to Canada and Mexico (140).

In general, poly(vinyl acetate) production is located close to end use industries (textile mills, adhesive plants, etc). In the United States, small-volume captive producers also contribute to the market.

In the United States, poly(vinyl acetate) consumption will follow general economic growth. Adhesives for use in packaging and construction will exhibit the largest growth. Demand for paper coatings will grow at less than GDP. Demand for PVAc copolymers for use in latex paint formulations will also grow. These formulations replace solvent-based paints that government regulations are limiting because of solvent emissions from the coatings.

Western European consumption of poly(vinyl acetate) and its copolymers is forecasted to grow at the rate of 1.5%/year. PVAc homopolymers will grow at the rate of 1%/year. Copolymers with ethylene are expected to grow at the rate of 3.4% through 2005. Redispersible powers will show the most dynamic growth increasing at the rate of 5%/year. Paint and coatings demand will decline because of substitution by acrylic-based emulsions. Japanese demand for poly(vinyl acetate) emulsions and resins should grow at the rate of 2%/year. Adhesives will be the biggest market (140).

Specifications and Standards. Typical specifications of the commercially available emulsions are tabulated in Table 10. However, there are exceptions to the ranges given. For example, most emulsions contain 55–56 wt% solids, but some are available at 46–47 wt% with viscosities of 10–15 mPa·s (= cP), and others at 59 wt% solids with viscosities of 200–4500 mPa·s. Specialty copolymer emulsions are available containing 72 wt% solids and viscosities under 2000 mPa·s (141).

Borax stability is an important property in adhesives, paper additives and resins (qv), and textile a plications where borax is a frequently encountered substance. This is a function of poly(vinyl alcohol) used for stabilization of the product. Other emulsion properties tabulated by manufacturers include tolerance to specific solvents, surface tension, minimum film-forming temperature, dilution stability, freeze–thaw stability, percent soluble polymer, and molecular weight. Properties of films cast from the emulsions are also sometimes listed, including clarity, gloss, light stability, water resistance, flexibility, heat-sealing temperature, specific gravity, and bond strength. Homopolymer resin specifications usually include viscosity grade (1.0 molar solution in toluene at 20°C), 1.5–800 mPa · s (= cP) ∼ 10%; volatiles, 1–2 wt%; acidity as acetic acid, 0.1–0.3 wt%; and

Table 10. Poly(vinyl acetate) Emulsion Specifications

Property	Range	Method
Solids, wt%	4–72	Moisture balance or oven
Viscosity, mPa · s (= cP)	200–4500	Viscometer
pH	4	pH meter
Residual monomer, % max	0.5	Titration or gas Chromatography
Particle size	0.1–3.0	
Particle charge	Neutral or negative	
Density at 25°C, g/cm^3	0.92	Pyknometer
Borax stability	Stable or unstable	Stable to borax addition
Mechanical stability	Good or excellent	Maintain stability for set period in high speed high shear blender
Freeze–thaw stability	Passes 0–5 cycles	Remains fluid after multiple cycles of freezing and thawing
Accelerated sedimentation, %	<4	Sediment after centrifuging diluted sample
Coagulum	<50 GMs on 100-mesh screen	Filter through a screen or stacked screens
T_g (glass-transition temperature), °C		DS calorimetry

softening point. Data are also given on heat-sealing temperature, tensile strength, elongation, and abrasion resistance. For alkali-soluble resins, the solubility in ammonia and its viscosity are listed (see Table 10).

Poly(vinyl acetate) and its copolymers with ethylene are available as spray-dried emulsion solids with average particle sizes of 2–20 μm; the product can be reconstituted to an emulsion by addition of water, or it can be added directly to formulations, eg, concrete. The powders may be used to raise solids of a lower solids latex. Solutions of resin in methyl and ethyl alcohol at 2–50 wt% solids are also available.

Emulsions are shipped in 19-L pails, 209-L drums, 11.0–18.9-m^3 (3000–5000 gal) tank trucks, and 38–76-m^3 (10,000–20,000 gal) railroad tank cars. During storage and handling, care should be taken not to destabilize or otherwise alter the character of the product. Storage tanks must be maintained clean and free from microbial contamination. Latices must not be put into a tank which contains a material with which it is incompatible. Routine cleaning is scheduled to remove skins or other accumulations of dried latex. Some of the large particle size latices may settle if stored for a long time and may need to be agitated to retain consistency. Latices corrode ordinary steel (qv) and must be stored in tanks with stainless steel, glass, plastic, or coated surfaces. Suitable coatings are baked phenolic, epoxy phenolic, or PVC. Storage should be at around room temperature, because excessive exposure to high or low temperatures may cause phase separation. Large shipments are insulated against cold. Precautions should be taken to avoid the formation of foam during unloading. If containers are not full during

shipment, foam may be generated because of sloshing. Containers should be closed to prevent evaporation of water, which leads to skin formation. Diaphragm pumps and screw pumps are preferred to centrifugal pumps (qv). High shear pumps such as centrifugal pumps may destabilize the latex causing the formation of grit or coagulum. In the case of colloid-protected latices, an irreversible reduction of viscosity may occur. Latices are susceptible to biocontamination, largely due to the stabilizer systems. In handling the latices, care should be taken to avoid exposure to microbial sources. Producers add microbicidal agents to protect the material against a moderate level of incident contamination. Biocontamination can result in the generation of foul odor, discoloration, and destabilization of the latex. Dry resins should be stored at or below room temperature to prevent caking.

Uses.

Adhesives. The uses of poly(vinyl acetate) adhesive are packaging and wood gluing (142,143). Table 11 (144) lists characteristics of poly(vinyl acetate) (PVAc) emulsions important to adhesive applications. PVAc copolymer adhesives are finding application in more diverse areas such as construction and adhesion to more difficult-to-bond surfaces because of the range of adhesion and the flexibility that may be built into the polymer. The emulsion form of PVAc is especially suitable for adhesives because of several properties that are peculiar to emulsion systems. The stability of PVAc emulsions allows them to accept many types of modifying additives without being damaged. For example, solvents, plasticizers, tackifying resins, and fillers can be added directly to homopolymer and copolymer emulsions without requiring pre-emulsification, unlike the elastomeric adhesive latexes. Homopolymer emulsions containing partially hydrolyzed poly(vinyl acetate) as a protective colloid can accept greater amounts of these modifying additives than any other type of emulsion without coagulating.

The stability of the emulsions further permits them to be compounded in simple liquid-blending vessels by means of agitators, eg, marine-type propellers, paddles, or turbines. The adhesives can be adapted to any type of machine application, ie, from spray guns to rollers to extruder-type devices. Different applicators are fairly specific in their viscosity requirements, as are the various substrates receiving the adhesive.

Poly(vinyl acetate) emulsions can be used in high speed gluing equipment. In contrast to aqueous solutions of natural or synthetic products which lose water slowly, the emulsions quickly lose water and invert and set rapidly into a bond.

Poly(vinyl acetate) homopolymers adhere well to porous or cellulosic surfaces, eg, wood, paper, cloth, leather, and ceramics. Homopolymer films tend to creep less than copolymer or terpolymer films. They are especially suitable in adhesives for high speed packaging operations.

Copolymers wet and adhere well to nonporous surfaces, such as plastics and metals. They form soft, flexible films, in contrast to the tough, horny films formed by homopolymers, and are more water-resistant. As the ratio of comonomer to vinyl acetate increases, the variety of plastics to which the copolymer adheres also increases. Comonomers containing functional groups often adhere to specific surfaces; for example, carboxyl-containing polymers adhere well to metals.

Plasticization, whether internal (by copolymerization) or external (with additives), is also extremely important for proper performance at the time of application. The ease of coalescence and the wetting characteristics of the polymer

emulsion particles are related to their softness and the chemical nature of the plasticizer.

New vinyl acetate–acrylate (VAA) emulsion copolymers stabilized with poly(vinyl alcohol) have been developed. The acrylic component of the VAAs contributes to improved compatibility with tackifiers (145).

Cross-linked polymer emulsions accept water-miscible solvents better than straight-chain emulsions. In the film state, the former resist water and organic solvents better and tend to have higher heat-sealing temperatures, which signify a greater resistance to blocking and cold flow. Straight-chain polymers can have high molecular weights, which contribute to high heat-sealing temperatures. Varying the conditions of polymerization results in either straight-chain or cross-linked polymer emulsions. The incorporation of functional monomers such as *n*-methylol acrylamide or acrylic acid into the polymer provides the ability to cross-link the product in the application either through heat, catalysis, or by a curing agent. In these cases, the polymer flows onto the substrate surface, then develops its strength on curing. Wood glues which can withstand boiling water immersion have been prepared in this fashion (146).

Tack enables an adhesive to form an immediate bond between contacting surfaces when they are brought together. It permits the alignment of an assembly and prevents the adherends from separating before the adhesive sets. Tack is differentiated into two types: (*1*) wet tack, also called grab or initial tack, is the tack of an adhesive before the liquid carrier, ie, organic solvent or water, has fully evaporated; (*2*) dry tack, also called residual tack or pressure sensitivity,

is the tack remaining after the liquid carrier has evaporated. Wet tack is often necessary in paper-converting operations. Applicators with little or no pressure on the combining section require emulsion adhesives with enough wet tack to bond strongly at the slightest touch. Emulsions containing poly(vinyl alcohol) as a protective colloid have stronger wet tack than those protected with a cellulose derivative. If more wet tack is required of the poly(vinyl alcohol)-protected adhesive, both a solvent and a plasticizer can be added and the solids content can be increased. Dry tack is needed where two nonporous surfaces are to be bonded. The nature of the adherends does not permit the water in the adhesive to escape by penetration or evaporation, and so the adhesive must dry before the adherends are joined, yet still retain enough tack to form a permanent bond. Film-to-film and film-to-foil laminations are good examples of applications requiring dry tack.

The *setting speed of an adhesive* is the time during which the bond formed by the adhesive becomes permanent. Before the setting of an emulsion adhesive can occur, inversion of the emulsion must take place; that is, it must change from a dispersion of discrete polymer particles in an aqueous continuous phase to a continuous polymer film containing discrete particles of water. The point at which the adhesive has actually set is that point at which an assembly, whether joint or lamination, can no longer be disassembled without damaging one or more of the adherends. Rapid setting speeds are necessary in many types of packaging adhesives intended for use with high speed gluing equipment. The rapid inversion possible with PVAc emulsions and their low viscosities allow them to be compounded into adhesives that not only set rapidly but also machine easily at high speeds. This machinability permits their application by practically any means, including glue guns, rollers, and spray guns.

Increases in setting speed can be achieved by increasing the dispersed phase content; that is, by increasing the amount of water-insoluble substances contained in the emulsions. This crowds the aqueous phase of the emulsion, hastening inversion and setting. Adding tackifying resins is one way to crowd the emulsion; adding plasticizers and solvents is another, but these additives mainly increase the setting speed by softening the polymer particles and hastening their coalescence. Surface-active agents also increase setting speed by helping the water in an adhesive to penetrate porous surfaces more rapidly; they can also retard it by stabilizing the emulsion. The usual way to prepare a high speed adhesive is to add both a solvent and a plasticizer to the base emulsion.

Poly(vinyl acetate) emulsions are excellent bases for water-resistant paper adhesives destined for use in manufacturing bags, tubes, and cartons. Glue-lap adhesives, which require moderate-to-high resistance to water, exemplify this type. When routine water resistance is required, a homopolymer vinyl acetate emulsion containing a cellulosic protective colloid is effective for most purposes. Next effective are emulsions containing fully hydrolyzed poly(vinyl alcohol) as a protective colloid, followed by those containing partially hydrolyzed poly(vinyl acetate).

When more than routine water resistance is required, a copolymer vinyl acetate emulsion can be used. The plasticizing comonomer in the polymer particles increases their intrinsic coalescing ability; thus, they can coalesce more readily than homopolymer particles to a film that has a higher resistance to water. This resistance to water does not extend to the organic solvents, however, which are

better resisted by homopolymer films. The soft copolymers have lower solubility parameters than homopolymers and are more readily attacked by solvents of low polarity, eg, hydrocarbons.

Despite their high resistance to water, copolymer emulsions are seldom chosen to bond paper to paper, as the less expensive homopolymer emulsions are effective enough. When copolymers are used in paper adhesives, it is done so chiefly to join coated or uncoated papers to films so as to take advantage of the lower critical surface tension required for wetting the copolymers. Because most packaging adhesives must be able to form strong paper-to-paper bonds, homopolymer vinyl acetate emulsions containing cellulosic protective colloids are always the first choice. The water resistance of any emulsion can be increased by improving its coalescence into a film either by adding solvents and plasticizers to it or by adding specific coalescing agents, eg, diethylene glycol monoethyl ether or diethylene glycol monoethyl ether acetate. Emulsions containing completely hydrolyzed poly(vinyl alcohol) can also be incorporated with cross-linking agents, which further insolubilize them. Cross-linking agents, however, can make a formulation unstable, so that it must often be used within a few hours after it has been compounded.

For any adhesive to be effective, it must first thoroughly wet the surface to be bonded; hence, it must be fluid at the time it is applied. Fluidity is not a problem with emulsion adhesives; wetting, however, can be problematic, especially when slick or coated surfaces are to be joined. An example is the manufacture of high gloss, clay-coated cartons, or the adhering of waxed papers. Copolymer emulsions tend to wet slick surfaces better than homopolymer emulsions because of the extra mobility and softness given to the polymer particles by the plasticizing comonomer. Their dried films also tend to conform better with this type of substrate. Homopolymer emulsions containing poly(vinyl alcohol) as a protective colloid wet paper surfaces well and are the first choice for paper-to-paper packaging adhesives. The setting ability of these emulsions can be increased by incorporating either nonionic wetting agents or partially hydrolyzed poly(vinyl acetate), or both. Small amounts of partially hydrolyzed poly(vinyl acetate) present in an adhesive also help it to wet lightly waxed papers.

The viscosity of an adhesive directly influences its penetration into a substrate; as the viscosity increases, the penetrating power decreases. It also determines the amount of mileage or spread that can be obtained. An optimum viscosity exists for each substrate and each set of machine conditions and must be achieved in order to manufacture an efficient adhesive. Poly(vinyl acetate) emulsions are frequently too low in viscosity to be metered efficiently or to perform well as adhesives by themselves. They must be bodied to working viscosities, eg, by adding thickeners.

Blocking and cold flow are undesirable properties. Blocking refers to dried adhesive surfaces that become sticky, causing unwanted bonding. Cold flow occurs with a polymer having a low softening point; if the temperature of the adhesive assembly warms to the softening range of the polymer, the bond slips. The temperature at which a dried adhesive film forms an instantaneous bond between two surfaces when heat is applied is its *heat-sealing temperature*. This property is closely related to the blocking temperature and to the temperature at which cold flow or creep can occur.

The heat-sealing temperature of an emulsion is related to the thermoplasticity of the poly(vinyl acetate) particles dispersed in it. Thermoplastic polymers are softened by heat; those of relatively high molecular weight or those that are cross-linked soften at higher temperatures than those of low molecular weight. In addition, poly(vinyl acetate) homopolymers soften at higher temperatures than do copolymers (with monomers that lower the glass-transition temperature) which have similar molecular weight. Another factor which affects the heat-sealing temperature of an emulsion is the amount of poly(vinyl alcohol) in it, if any, since poly(vinyl alcohol) has a high melting point. High heat-sealing temperatures, which are desirable in an emulsion adhesive because they indicate resistance to blocking and cold flow, are usually attainable with emulsions containing large amounts of poly(vinyl alcohol) as a protective colloid.

Fillers are added to emulsion adhesives to build the total solids content, to reduce penetration into a porous substrate, and to lower costs. Plasticizers are added to emulsion adhesives to modify several properties of both the emulsion and the finished adhesive film. By softening the polymer particles dispersed in the emulsion and increasing their mobility, plasticizers cause them to flow together more easily. This usually increases the viscosity of the emulsion and tends to destabilize it for faster breaking and setting speeds at the time it is applied. In addition, the increased softness and mobility help the emulsion to wet smooth, nonporous surfaces, eg, films, foils, and coated papers, thereby increasing its adhesion to them. Also, the softened polymer particles coalesce more rapidly and at a lower temperature than is possible with the unplasticized emulsion. This improved coalescence increases the water resistance of the adhesive film. Plasticizers are usually high boiling esters, eg, phthalates. Phosphate esters are useful as fire-retardant plasticizers.

Solvents are frequently used to perform several functions in emulsion adhesives. Solvents promote adhesion to solvent-sensitive surfaces, they increase the viscosity of the emulsion and intensify the tack of the wet adhesive, and they improve the coalescing properties of the film. Low boiling solvents impart only wet tack to the adhesive film, whereas high boiling solvents confer both dry and wet tack and lower the heat-sealing temperature. The solvent can impart the necessary speed to the wet adhesive but, because it evaporates, it does not cause the dried bond to creep, which often happens with a plasticized film that ages under stress. Solvents promote adhesion to solvent-sensitive adherends by softening and partially dissolving them, thus allowing the adhesive to wet or penetrate the surface or both. Because of the increasing regulatory pressure on solvent emissions, there is a need to develop these properties without volatile materials.

Tackifiers are used to increase the tackiness and the setting speed of adhesives. They increase tackiness by softening the poly(vinyl acetate) polymer in the wet and the dry adhesive film. Tackifiers are usually rosin or its derivatives or phenolic resins. Other additives frequently needed for specific application and service conditions are antifoams, biocides, wetting agents, and humectants.

Specialized copolymer latices, which are inherently and permanently tacky, are available as pressure-sensitive emulsions. They are mechanically stable and have excellent machinability. They are compatible with many other PVAc latices and, therefore, can be easily blended with other resins for modification of surface tack, peel strength, and creep.

Poly(vinyl acetate) dry resins and ethylene–vinyl acetate (EVA) copolymers are used in solvent adhesives, which can be applied by total industrial techniques, eg, brushing, knife-coating, roller-coating, spraying, or dipping. Proper allowances must be made for evaporation of solvent during or before bonding. Poly(vinyl acetate) resins and EVA copolymers containing 21–30 wt% vinyl acetate are widely used in hot-melt adhesive applications. Homopolymers are compounded with 25–35 wt% plasticizer and 25–30 wt% extender resins. These additives increase fluidity and adhesion as well as reduce cost. Ethylene–vinyl acetate resins are mixed with waxes, rubbers, and resin to make the hot-melt adhesive compound. Hot-melt adhesive application processes may be extremely rapid both in application and setting speed, cause no problems resulting from solvent or water evaporation, and provide bonds of high water resistance. The adhesive materials have indefinite shelf lives. Hot-melts are largely used in packaging, laminating, and bookbinding. For the last application, alkali-soluble copolymers are frequently used to facilitate the reclamation of scrap paper.

Film and foil adhesives based on internally plasticized copolymer adhesives have been suggested. For instance, vinyl acetate–ethylene or vinyl acetate–acrylate copolymers may be used for adhesion of films to porous surfaces. For metallic foil adhesion, copolymers containing carboxylate functionality are suggested.

Spray-dried powders find application in adhesives to build solids, increase viscosity, improve tack, and decrease drying time (147). A primary use is in joint compounds with other applications in mastics and grouts, and patching compounds (148).

Paints. Paints prepared from poly(vinyl acetate) and its copolymers form flexible, durable films with good adhesion to clean surfaces, including wood, plaster, concrete, stone, brick, cinder blocks, asbestos board, asphalt, tar paper, wallboards, aluminum, and galvanized iron (149). Adherence is also good on painted surfaces if the surfaces are free from dirt, grease, and rust. Developments in emulsion polymerization for paint latices have been reviewed (150).

Poly(vinyl acetate) latex paints are the first choice for interior use (151). Their ability to protect and decorate is reinforced by several advantages belonging exclusively to latex paints: they do not contain solvents so that physiological harm and fire hazards are eliminated; they are odorless; they are easy to apply with spray gun, roller-coater, or brush; and they dry rapidly. The paint can be thinned with water, and brushes or coaters can be cleaned with soap and tepid water. The paint is usually dry in 20 min to 2 h, and two coats may be applied the same day.

Poly(vinyl acetate) latex paints are also widely used as exterior paints. Their durability, particularly their resistance to chalking, far surpasses that of any conventional oleoresinous paints, which chalk soon after application. The good nonchalking properties of PVAc paints result from their resistance to degradation by UV light. Latex paints that are correctly formulated from quality PVAc latices develop little or no chalk, thus giving maximum tint retention, and they last a long time before repainting becomes necessary. The blister resistance of PVAc paints is another important advantage for their exterior use. Latex paint films are permeable enough to permit water vapor to penetrate them, which prevents blistering and peeling. Their film formation is not impaired if they are painted on damp surfaces or are applied under very humid conditions.

Several types of plasticizing comonomers can be copolymerized with vinyl acetate to produce latices suitable for manufacturing paints. The older, less common comonomers are the alkyl maleates and fumarates, eg, dibutyl maleate and dibutyl fumarate. Acrylic esters, eg, butyl acrylate and 2-ethylhexyl acrylate, as well as ethylene, are the most widely used comonomers in the 1990s. The chief reason for using a comonomer in vinyl acetate polymers is to increase the deformability of the paint film permanently, thus permitting it to expand and contract as the dimensions of the substrate change with changes in temperature. The plasticizing comonomer also softens the polymer particles. For a film to form from a latex paint, the polymer particles must deform and fuse to form a continuous film. This coalescing ability is directly related to the amount of comonomer present. In both interior and exterior paints, the improvement in coalescence that is obtainable by using high comonomer levels results in a general improvement in all the properties necessary for interior and exterior paints. High levels of comonomers, such as ethylene or butyl acrylate, must be added with care. If high comonomer levels are used with low molecular weight polymers, the resulting paint film suffers from excessive dirt pickup at high temperatures because it becomes soft and tacky. It is required, therefore, that high molecular weight polymers be prepared, because only with these is a sufficient amount of comonomer incorporated to give the tint retention without dirt pickup required in exterior paints.

The strength of a polymer increases with its molecular weight; consequently, the toughest paint films are formed from latex polymers having the highest molecular weights. For exterior paints, there is a federal specification of a minimum intrinsic viscosity of 0.45 dL/g. The minimum intrinsic viscosity of commercial paint polymers usually is 0.60–1.0 dL/g and above.

Special vinyl acetate copolymer paints have been developed with greatly improved resistance to blistering or peeling when immersed in water. This property allows better cleaning and use in very humid environments. These lattices exhibit the water resistance of higher priced acrylic resins (152). VAc, vinyl chloride–ethylene terpolymers have been developed which provide the exterior resistance properties of vinyl chloride with the flexibility of the ethylene for exterior paint vehicles (153).

The critical pigment volume concentration (CPVC) of vinyl acetate paints is 48–60%. Generally, the smaller and softer the polymer particles, the higher the CPVC and the greater the pigment-binding capacity of the latex. The most widely used white pigment is titanium dioxide in the form of rutile or of anastase. The color pigments used in latex paints are of two types: the organic pigments (see PIGMENTS, ORGANIC), which are usually hydrophobic, and the inorganic pigments (see PIGMENTS, INORGANIC), which are usually hydrophilic. The hydrophilic pigments are relatively easy to incorporate into water-base paints. The hydrophobic pigments are more difficult to incorporate, but this can be overcome by choosing the correct blend of surfactants for a particular pigment. The organic colorants commonly used are toluidine red, Hansa yellow, phthalocyanine blue and green, pigment green B, and carbon black, among others. Examples of acceptable inorganic colorants are iron oxide red, brown, yellow, black, and chrome oxide green. Colorants that should not be used are those that are reactive, partially water-soluble, or sensitive to pH changes.

In addition to latex and pigment, paint formulations contain dispersants and wetting agents (both surfactants), defoamers, thickeners and protective colloids, freeze–thaw stabilizers, coalescing agents, and biocides. The coalescing agents used in the paint formulations tend to be volatile. In order to reduce the odor levels and reduce solvent emissions, some paint producers are researching latex bases which require less or no solvent to aid in coalescence and yet provide a durable, glossy surface (154). Copolymers are potentially useful in meeting this requirement (155,156).

Paper. Poly(vinyl acetate) emulsions and resins have been used as the binder in coatings for paper and paperboard since 1955 (157–159). The coatings may be clear, colored, or pigmented, and are glossy, odorless, tasteless, greaseproof, nonyellowing, and heat-sealable. Conventional paper-coating equipment is used; formulations normally contain 60–65 wt% solids with a pigment-to-binder ratio of 1:5. Printing quality and ink-pick resistance are excellent. In papermaking, emulsions applied as wet-end additions to the furnish improve the strength and durability of the final product. Plasticized emulsions may be used to give the product toughness and flexibility.

Emulsions used in paper coatings must meet special requirements: the particle size must be small (ca 0.1 μm) and its distribution rather narrow. These properties provide good pigment binding efficiency and high gloss. They must have exceptionally good mechanical stability and freedom from off-sized latex particles or grit, and must exhibit no trace of dilatant flow in a pigment slurry. These properties are required for modern high speed paper-coating applications. They should also be compatible with starch and alginate natural resins frequently used as cobinders (160).

Nonwoven Binders and Textiles. The use of vinyl acetate copolymers as binding agents for nonwoven fabrics has grown rapidly. Vinyl acetate–ethylene copolymer latices have been particularly successful in part because of their low cost but also because of their excellent adhesion to a wide range of substrates, their water and alkali resistance, and their low flammability (161–164). Products made from these binders include paper towels, wipes, and personal hygiene articles. Self-cross-linking polymers are available as are polymers requiring external curing agents. Many of the self-cross-linking polymers release formaldehyde (qv) as part of the reaction. Because formaldehyde has been listed as a potential carcinogen, alternative chemistries have been developed to reduce or eliminate formaldehyde content in the products.

Poly(vinyl acetate) emulsions are widely used as textile finishes because of their low cost and good adhesion to natural and synthetic fibers. In textile piece goods finishing, dispersions diluted with water to 1–3 wt% resin are most often used to obtain a stiff or crisp hand on woven cotton fabrics. Concentrations of 2–20 wt% emulsion are recommended for bodying, stiffening, and bonding. Principal applications include the stiffening of felts. Finishes to improve snag resistance and body or hand of nylon hosiery are based on PVAc emulsions.

Poly(vinyl acetate) emulsions are used to prime-coat fabrics to improve the adhesion of subsequent coatings or to make them adhere better to plastic film. Plasticized emulsions are applied, generally by roller-coating, to the backs of finished rugs and carpets to bind the tufts in place and to impart stiffness and hand. For upholstery fabrics woven from colored yarns, PVAc emulsions

may be used to bind the tufts of pile fabrics or to prevent slippage of synthetic yarns.

The emulsion formulations are generally applied to cloth by padding from a bath and squeezing off the excess. Modifying a formulation in the pad box, eg, to increase or decrease firmness, can be easily done by adding an emulsion or softener. The alkali-soluble vinyl acetate copolymers previously mentioned can be used as warp sizes during weaving.

Concrete Additives. Poly(vinyl acetate) was first used in concrete in the 1940s as a thermoplastic polymer to strengthen the concrete matrix. In contrast to other polymers, the resistance to water permeation is low due to the hydrolysis of the poly(vinyl acetate) (165,166). Ethylene copolymers have been developed which have improved water resistance and waterproofness. The polymer can be used in the latex form or in a spray-dried form which can be preblended in with the cement (qv) in the proper proportion. The compressive and tensile strength of concrete is improved by addition of PVAc emulsions to the water before mixing. A polymer solids to total solids ratio of ca 10:90 is best. The emulsions also aid adhesion between new and old concrete when patching or resurfacing.

Other. Vinyl acetate resins are useful as antishrinking agents for glass fiber reinforced polyester molding resins (167). Poly(vinyl acetate)s are also used as binders for numerous materials, eg, fibers, leather (qv), asbestos, sawdust, sand, clay, etc, to form compositions that can be shaped with heat and pressure. Joint cements, taping compounds, caulks, and fillers are other uses.

Emulsions containing added poly(vinyl alcohol) and dichromate are used to make light-sensitive stencil screens for textile printing and ceramic decoration. The resins are used in printing inks, nitrocellulose lacquers, and special high gloss coatings. Inks made with PVAc and metallic pigments look like foil because the formulations have a high leafing power, do not induce tarnish, and contribute no unwanted color or aging.

Vinyl acetate polymers have long been used as chewing gum bases. They have been studied as controlled release agents for programmed administration of drugs and as a base for antifouling marine paints (168,169).

WATER-SOLUBLE POLYMERS

Introduction

Water-soluble macromolecules represent a diverse class of polymers ranging from biopolymers that mediate life processes to synthetic polymers of immense commercial utility. In this article water-soluble polymers have been grouped into the categories biopolymers, nonionic, ionic, and associative, based on key structural features. Recently developed controlled polymerization techniques imparting important technological features to water-soluble polymers are also discussed.

General Considerations

Structure. Solution properties and ultimate performance of water-soluble polymers are determined by specific structural characteristics of the hydrated polymer chain. Primary structure depends directly on the nature of the repeating units (bond lengths, valence bond angles) effective compositions, and locations along the backbone. The polymer structure may derive from a single monomer [ie, poly(ethylene oxide) or polyacrylamide] or from multiple monomers. These units may be placed to yield random, alternating, block, graft, or more intricate architectures such as stars or dendrimers (Fig. 1). Biopolymers such as proteins and polynucleotides have multiple repeating units specifically ordered by template polymerization.

Secondary structure in water-soluble polymers is related to configuration, conformation, and intramolecular effects such as hydrogen bonding and ionic interactions. Tertiary structure involves intermolecular and water-polymer interactions; quaternary structure requires multiple chain aggregation or complexation.

Encyclopedia of Polymer Science and Technology. Copyright John Wiley & Sons, Inc. All rights reserved.

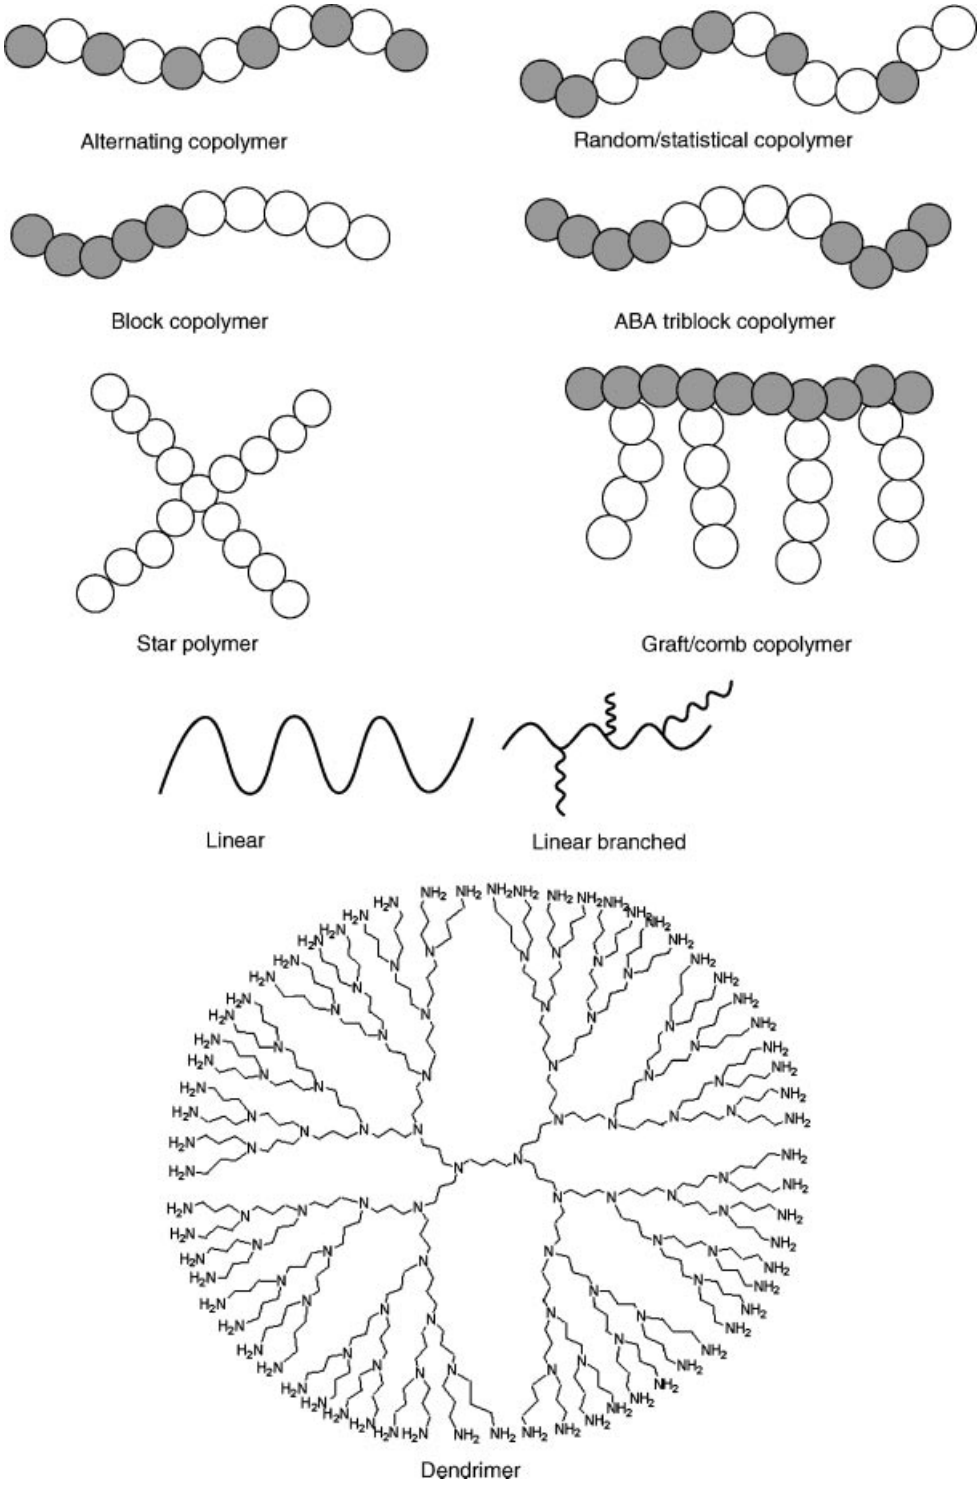

Fig. 1. Structural representation of polymer architectures (1).

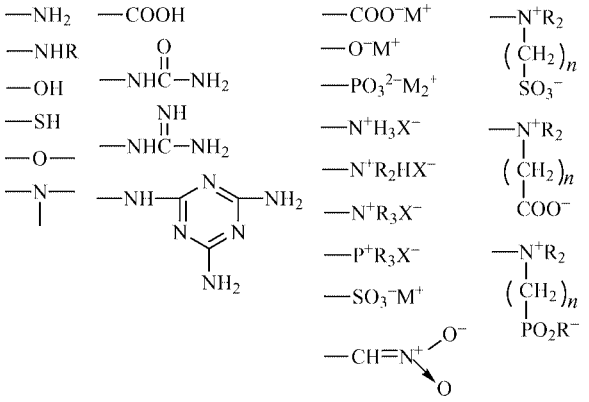

Fig. 2. Examples of functional groups imparting water solubility.

A large number of functional groups (Fig. 2) can impart water solubility in copolymers. The degree of solubility is dependent on the number, position, and frequency of these moieties. Hydration relies on interaction at polar (ionic and hydrogen bonding) sites.

Hydrodynamic Volume. Polymers are often described in terms of hydrodynamic volume (HDV) or that volume occupied by the solvated chain. HDV and molecular shape, determined from light scattering measurements, may be used along with chemical microstructure to predict rheological behavior.

Theoretical attempts to relate dimensions of polymers to chemical structure were pioneered by Flory (2). Statistical macromolecular size in solution can be modeled from first principles by considering the number and length of bonds along with valence bond angles and conformational restrictions. Excluded volume, segmental interactions, specific intramolecular interactions, and chain solvation contribute to dimensions.

Ionic interactions (repulsive or attractive) can also dramatically affect HDV. For charged polymers, ionic effects often dominate behavior, especially in aqueous solutions. Theoretical treatments for predicting polyelectrolyte dimensions and phase behavior are discussed by Barrat and Joanny (3); scaling theory for charged polymers is reviewed by Dobrynin, Colby, and Rubinstein (4).

A number of synthetic strategies may be employed to increase macromolecular coil size (HDV) for water-soluble polymers. Monomers with water-soluble moieties may be polymerized to high molecular weight. Effective bond lengths along the backbone may be increased by introducing chain stiffening-elements. These include covalent rings (polysaccharides), charge–charge repulsions (polyelectrolytes), and helical segments (nucleic acids and proteins). The shape of the solvated coil is determined by placement of charged groups, hydrophobic moieties, hydrogen bonds, chiral centers, or restrictive rings along the molecular backbone. The native shapes of globular proteins, for example, are a result of water-induced organization of strategically placed hydrophilic and hydrophobic moieties.

Polymers dissolved in water can have structures (Fig. 3) ranging from random coils to microheterogeneous polymeric vesicles. Solution behaviors of the various types are quite diverse. Water-soluble random and extended coil polymers are

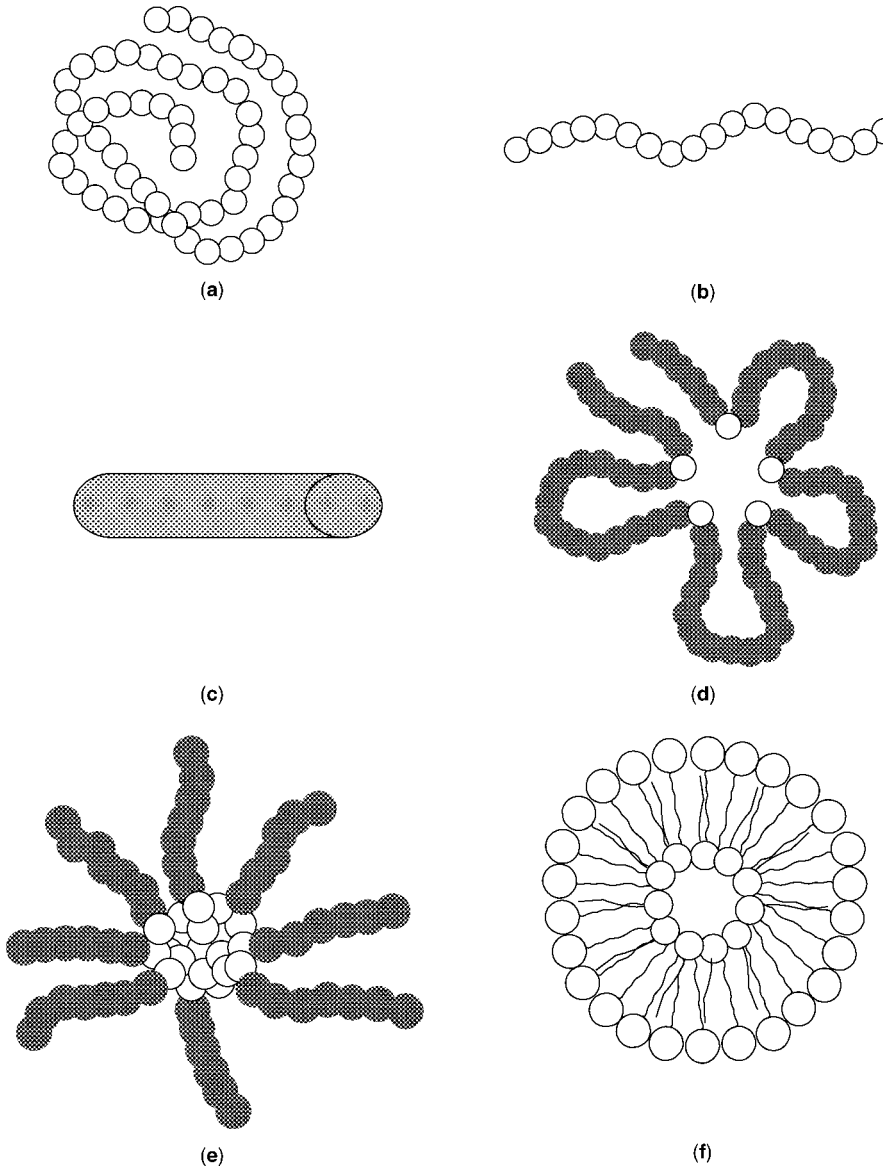

Fig. 3. Structural dependence of molecular shapes of copolymers in aqueous media. (**a**) Hydrated random coil; (**b**) hydrated extended coil; (**c**) rod-like polymer; (**d**) unimeric micelle; (**e**) multimeric micelle; (**f**) vesicle.

often used for rheology control in various applications. Extended rods in aqueous solution may exhibit lyotropic liquid crystalline behavior. Amphiphilic molecules such as hypercoils, polymeric micelles, and vesicles are used in formulation, drug delivery, and phase-transfer catalysis.

Role of Water in Solvation/Phase Behavior. Water plays an extremely important role in determining the properties and ultimate utility of polymers in solution. Solvation of polymer chains may involve simple interaction of ionic, polar,

or hydrogen-bonded hydrophilic segments of linear chains with water (Figs. 3**a** and 3**b**) or more complex solvation of amphiphilic structures (Figs. 3**d**, 3**e**, and 3**f**). For amphiphilic polymers, water structure around the hydrophobic portion of the chain is thought to be more ordered than in the bulk whereas hydrophilic portions disorder water structure. Amphiphilic macromolecules, including stimuli-responsive copolymers, have been studied in great detail and are the subject of several books and reviews (5–7). Although the precise nature of water structuring is the subject of continuing debate and extensive research, polymer solubility and phase behavior is rationalized in terms of entropy- or enthalpy-dominated events.

Some polymers such as poly(acrylic acid) or polyacrylamide precipitate from aqueous solutions when cooled (normal solubility behavior) whereas others such as poly(ethylene oxide), poly(propylene oxide), or poly(methacrylic acid) phase separate when heated (inverse solubility behavior). Solution turbidimetry is often used to obtain plots of phase-separation temperatures termed *cloud point* vs concentration for fixed solvent conditions. Changes in ionic strength, molecular weight, and addition of co-solvents or structure breakers affect the shapes of phase behavior curves. The important conclusion of such studies is that the total free energy of the polymer and water must be considered to predict phase behavior. The structure and dynamics of water surrounding polynucleotides, proteins, polysaccharides, and lipids are also major determinants of biological activity (8–10).

Viscosity and Rheology. Viscosity yields important information as to the disposition of the polymer chains in solution and is routinely used to evaluate polymers for particular applications. Dilute solution measurements can yield intrinsic viscosity $[\eta]$, which is a direct indication of the hydrodynamic volume of an isolated polymer chain. This fundamental parameter is related to molecular weight M through the Mark–Houwink–Sakurada (MHS) relationship (eq. 1):

$$[\eta] = KM^a \tag{1}$$

The parameters K and a are characteristics of a polymer chain under specific conditions of solvency and temperature. Values of a can be related to chain extension in dilute solution.

Flexible polyelectrolytes generally are more extended than nonionic polymers owing to charge–charge repulsions along the chain, particularly at low ionic strength. Estimates of $[\eta]$ under such conditions are made by the Fuoss (11) relationship (eq. 2) rather than the traditional Huggins relationship (eq. 3). η_{sp} is the specific viscosity, c is polymer concentration, B and k are characteristic constants. Alternatively, small-molecule electrolytes may be added in sufficient quantity to suppress the charge–charge interactions and equation 3 may then be used.

$$\frac{\eta_{sp}}{c} = [\eta]/(1 + B\sqrt{c}) \tag{2}$$

$$\frac{\eta_{sp}}{c} = [\eta] + kc \tag{3}$$

The MHS relationship (eq. 1) is often used in conjunction with experimentally determined values of molecular weight and intrinsic viscosity to determine chain

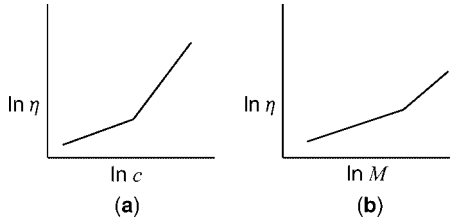

Fig. 4. Relationship between apparent viscosity and (**a**) concentration at constant molecular weight; (**b**) molecular weight at constant concentration.

stiffness indicated by values of a. Values can range from 0.5 for random coils in theta conditions to nearly 2.0 for extended rods.

In semidilute and concentrated solutions, polymer molecules are no longer isolated from one another. Chain–chain interactions at and above a critical concentration c^*, often termed the *overlap concentration*, lead to increased values of apparent viscosity η. Apparent viscosity can be related to concentration and molecular weight by equation 4, in which b and d are scaling constants.

$$\eta \propto c^b M^d \tag{4}$$

Usually plots of ln η vs ln c at constant molecular weight (Fig. 4**a**) or ln η vs ln M at constant concentration (Fig. 4**b**) are used to measure entanglement onset. Measurements are made at constant shear rate, temperature, and solvent conditions.

Rheological characteristics of aqueous solutions are dictated by molecular structure, solvation, and by inter- and intrachain associations. In many cases, segmental interactions must be accounted for in more rigorous terms than simple statistical encounters. Enthalpic interactions or entropically driven hydrophobic associations must be considered.

Rheological behavior is dependent on polymer type and can be clearly illustrated, providing appropriate interactive parameters of polymer concentration, ionic strength, pH, shear rate or shear stress, temperature, and time are taken into account. Representative plots are shown in Figure 5 for major behavioral patterns. Figure 5**a** illustrates the shear thickening (dilatant), Newtonian, and shear thinning (pseudoplastic) behavior. Figure 5**b** represents time dependence on viscosity for rheopetic and thixotropic polymers. Figure 5**c** illustrates the viscosity-concentration dependence in water for a polyelectrolyte and nonionic polymer in dilute solution.

Synthetic Methods. Water-soluble copolymers are prepared by step-growth or chain-growth mechanisms. Linear or branched systems may be formed from single monomers or from multiple monomers. Distribution of monomers, along the backbone or side chain, can be controlled in a number of ways. In nearly all cases, sequence selection is obtained by carefully controlling monomer reactivity, concentration, addition order, and reaction conditions. Most chain-growth, water-soluble polymers are prepared by classical free radical polymerization techniques.

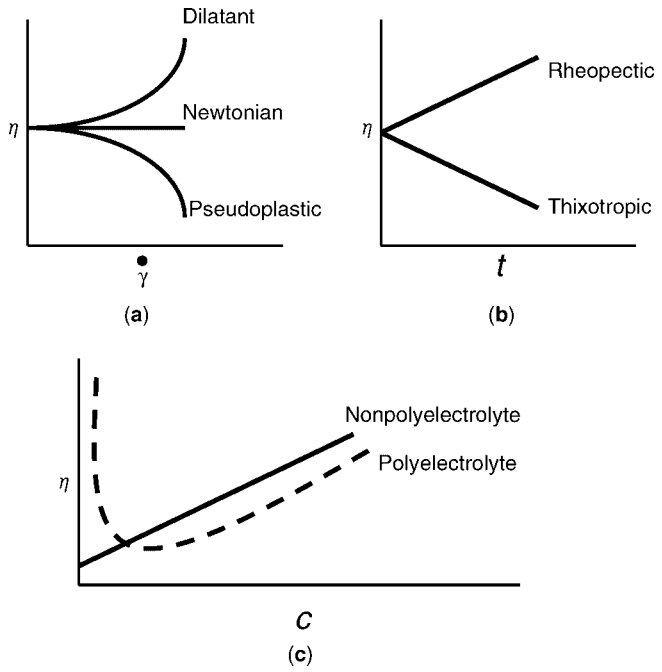

Fig. 5. Rheological characteristics of water-soluble polymers. All variables other than those on the axes are held constant. (**a**) Viscosity vs shear rate; (**b**) viscosity vs time; (**c**) viscosity vs concentrations below c^*.

Step-growth condensation reactions may be carried out in organic solvents, interfacially, in bulk, microheterogeneously, or on a solid support. Active esters are often employed in solution methods at relatively low temperatures to yield water-soluble polyesters or polyamides. Synthetic polypeptides, polynucleotides, and polysaccharides are commonly made by sequential addition of protected monomer units onto polymer supports.

Major commercial synthetic water-soluble polymers are made by chain-growth polymerization of functionalized alkenes, carbonyl monomers, or strained ring compounds, as illustrated in Figure 6. These may be initiated utilizing free

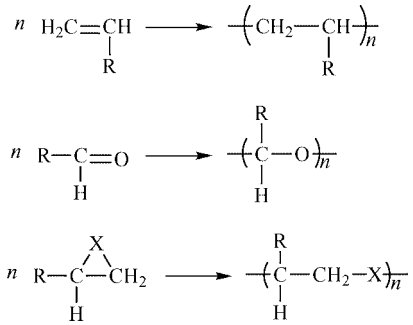

Fig. 6. Synthetic pathways to common water-soluble chain growth polymers.

radical, cationic, anionic or coordinated cationic initiators, depending on monomer structure. Of particular *commercial* interest are syntheses of water-soluble polymers in solutions, dispersions, suspensions, or emulsions. In cases where hydrophobic monomers are to be incorporated with hydrophilic species, microemulsions, or micellar polymerization methodologies are required.

During the last 10–20 years significant advances have occurred in polymer synthesis. Noteworthy is the development of less demanding living polymerization techniques, such as group transfer polymerization (GTP) (12,13) and oxyanionic polymerization (14,15). Most recently, rapid technological advances have been made in the so-called controlled/living free radical polymerizations

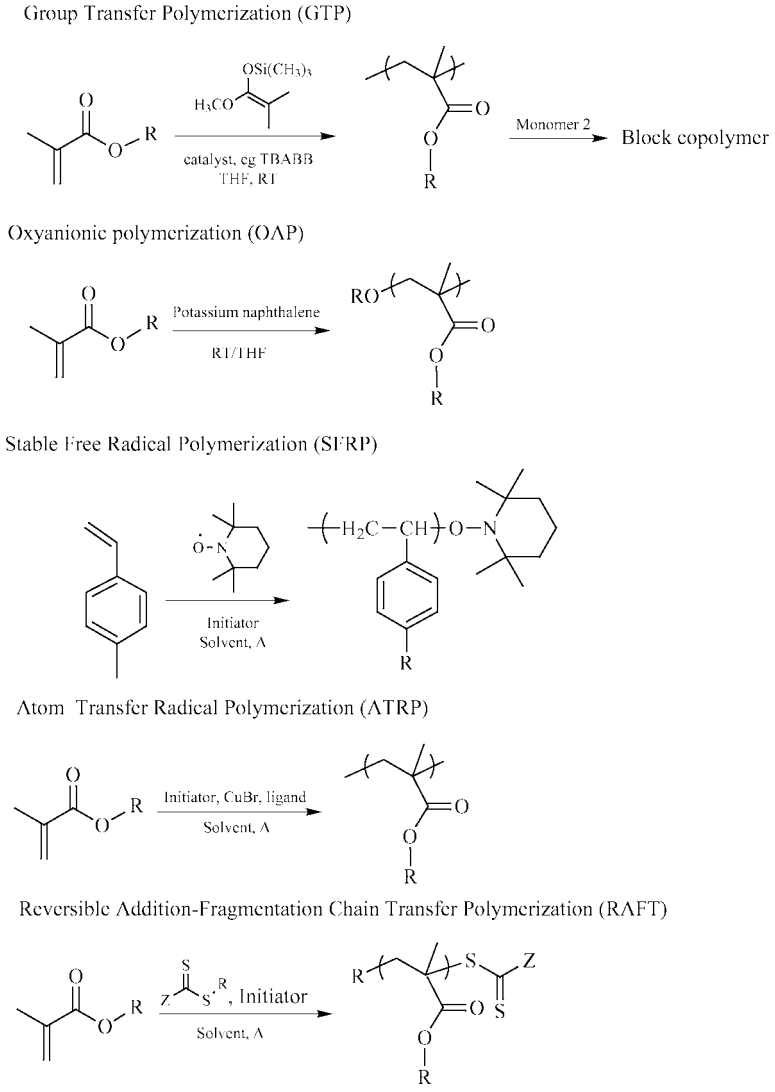

Fig. 7. Controlled or controlled/living polymerization techniques potentially applicable to synthesis of water-soluble or amphiphilic copolymers.

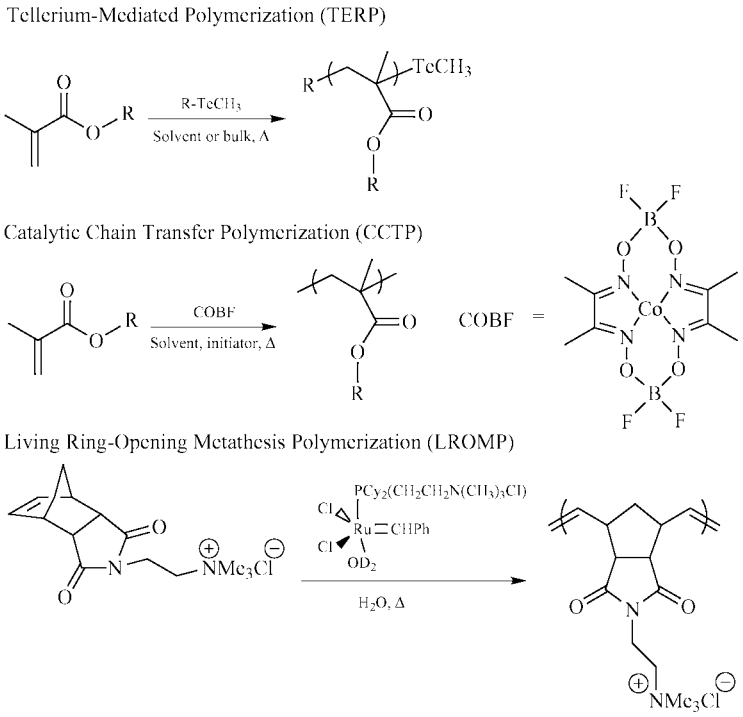

Fig. 7. (Continued)

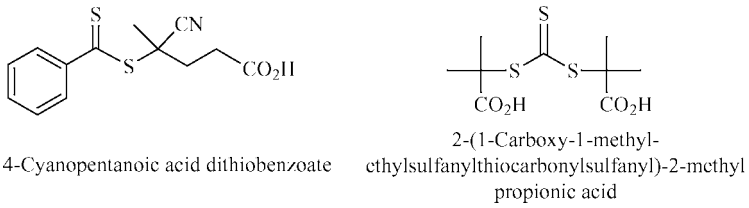
(CLRP), such as stable free radical polymerization (SFRP) (16,17), atom transfer radical polymerization (ATRP) (18–23), reversible addition-fragmentation chain transfer (RAFT) polymerization (24–27), and tellerium-mediated radical polymerization (TERP) (28–31). Additionally, catalytic chain transfer polymerization (CCTP) (32,33) and living ring-opening metathesis polymerization (LROMP) (34–37) have also been developed. All of these techniques, to some greater or lesser degree, have been employed for the synthesis of novel water-soluble (co)polymers (Fig. 7) with much of the research having been conducted in academic research laboratories (see ANIONIC POLYMERIZATION; LIVING RADICAL POLYMERIZATION).

Whereas each of these techniques has its merits, many have severe limitations either with respect to monomer choice or reaction conditions. The most versatile of the above techniques are arguably the CLRP techniques and have received the greatest attention, to date, with respect to the preparation of novel water-soluble (co)polymers (38,39). These techniques generally exhibit the versatility associated with conventional free radical polymerizations but simultaneously bear many of the characteristics associated with living polymerizations. They are highly tolerant of functional substituents with virtually all vinylic monomers being polymerized by one, or more, of the techniques; additionally, polymerization may be conducted under a wide range of conditions (bulk, solution, dispersion, emulsion etc). Also, molecular weights can be tuned via the monomer/initiator ratio; (co)polymers with narrow molecular weight distributions are typically



4-Cyanopentanoic acid dithiobenzoate

2-(1-Carboxy-1-methyl-ethylsulfanylthiocarbonylsulfanyl)-2-methyl propionic acid

Fig. 8. Structures of chain transfer agents CTP and CTSP.

produced and materials with complex architectures, such as blocks or stars, can be obtained (40,41). With specific reference to the preparation of water-soluble polymers, ATRP and RAFT have been the most widely examined, with RAFT being the most versatile, at least with respect to monomer choice. For example, certain species such charged (meth)acrylamido monomers can, at present, *only* be polymerized in a controlled fashion by RAFT (42–45). Key to control in RAFT polymerizations is an appropriate thiocarbonylthio compound, called a chain transfer agent (CTA). While many have proven to be effective, such as the dithioesters, trithiocarbonates, xanthates, and dithiocarbamates (38,46,47), to conduct the polymerizations directly in water requires the use of a suitable water-soluble CTA. Of those reported to date, 4-cyanopentanoic acid dithiobenzoate (CTP) has proven to be the most generally effective (46–48), with others such as 2-(1-carboxy-1-methylethylsulfanylthiocarbonylsulfanyl)-2-methylpropionic acid (CTSP) (Fig. 8) also proving particularly effective for acrylamido and methacrylamido monomers (49,50).

Naturally Occurring Polymers

A large number of water-soluble polymers are derived from biological sources. Termed *biopolymers*, this class includes polynucleotides (qv), polypeptides and polysaccharides (qv). Because these polymers perform special biological functions, they have specific microstructures and are often perfectly monodisperse. In the following section the general structural features of major biopolymer types will be reviewed as related to water solubility.

Polynucleotides.

Structure. Nucleic acids (Fig. 9) are biopolymers that carry genetic information involved in the processes of replication and protein synthesis. The primary structural units of the nucleic acids, the mononucleotides, are composed of a 5-carbon cyclic sugar with a phosphate ester at the C-5 carbon. A heterocyclic amine base (purine or pyrimidine) is attached at C-1. RNA and DNA are terpolymers with sugar phosphate backbones (3′ and 5′ position) and pendent bases on the 1′ position. Deoxyribonucleic acids (DNAs) contain the deoxyribose sugar (no hydroxyl group at the 2′ position on the sugar ring). The usual bases substituted at the 1′ position are adenine (A), guanine (G), thymine (T), and cytosine (C). Ribonucleic acids contain a ribose sugar and the principal bases A, G, C, and uracil (U).

Studies of the structure of DNA by a large number of investigators led to the proposal by Watson and Crick (51) of the classic DNA double helix. Major

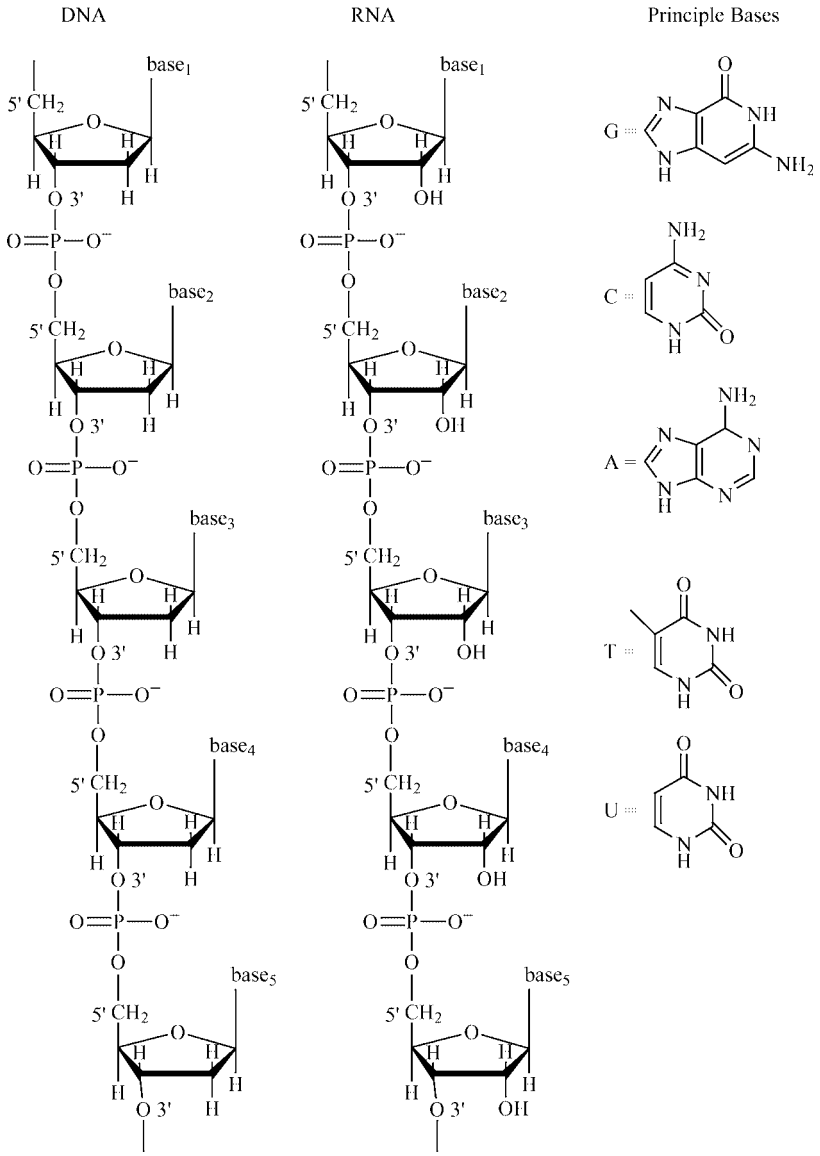


Fig. 9. Structural representations of DNA and RNA; principal bases present in nucleic acid. U,T, and C are the pyrimidines; A and G are the purines.

contributions as to base content and of X-ray structure were made by the groups of Chargaff (52) and Wilkins and co-workers (53). This proposal not only allowed explanation of DNA stability but also provided a framework for postulation of template polymerization during the replication and transcription processes.

The template synthetic process allows organization of the DNA helix into an assembly having two antiparallel strands of DNA (Fig. 10). The pendent bases on the strands are paired in such a manner that A is always paired with T and G with C. The strong hydrogen bonding of the complimentary pairs in hydrophobic

Fig. 10. DNA double-stranded helix (54).

regions orients the hydrophilic-charged phosphate groups outwardly. One negative charge per phosphate unit gives the DNA polyanionic character. The balance of hydrophilic and hydrophobic forces and the presence of divalent ions such as Mg^{2+} are also responsible for chain stability under physiological conditions. Three conformational variations of the double helix have been confirmed by X-ray diffraction—the A, B, and Z forms. Conformational variation, location of certain base-paired sequences, and specific modification (methylation for example) can lead to supercoiling, branching, and direct binding to other polynucleotides or to specific proteins. Such structural organization has major implications in gene regulation (transcription, silencing, etc).

The molecular weights of DNA, depending on the source, can be extremely large. For example, the recently sequenced human genome has been reported to have over 27,000 genes and 3 billion base pairs (55). By contrast, a simple bacterium such as *Escherichia coli* has 5 million (54) chromosomal base pairs. In addition, the latter contains cyclic DNA, called plasmids, which contain from 1000 to 10,000 base pairs. Recombinant DNA technology is routinely utilized to insert synthetic genes or genes from other species into such plasmids. The resultant recombinant DNA segments then serve as templates for synthesis of specific proteins with pharmacological, agricultural, or materials applications.

Ribonucleic acids are synthesized from the DNA template through transcription. The mononucleotides contain ribose. Unlike DNAs, RNAs are single stranded, although twisting may occur in a complementary fashion matching base pairs. RNAs are much lower in molecular weight than DNAs. The three major types—messenger RNA (mRNA), transfer RNA (tRNA), and ribosomal RNA (rRNA)—are involved in a multistep process of protein synthesis (56,57).

Beyond their well-established roles in protein synthesis, RNAs termed *ribozymes* have been shown to catalyze a number of biochemical reactions. Significantly, short hairpin sequences of RNA can hybridize with DNA to suppress (silence) gene expression (58). Alternatively, some of these short RNA sequences bind in a complementary fashion to mRNA resulting in destruction of the latter and preventing protein translation from that gene segment (58).

Synthesis. Recently, nucleic acids have been synthesized from mononucleotides, some with altered or substituted bases. Synthetic methods, along with nucleic acid sequencing methods, have allowed rapid advancement in identifying gene sequences responsible for specific protein synthesis. Kornberg and coworkers first prepared synthetic DNAs polymerized from mononucleotides using isolated enzymes, DNA polymerases (59). Likewise, RNA polymerases have been found for synthesis of oligomeric RNAs (60). DNA also can be made from RNA using reverse transcriptase enzymes. The resulting complementary DNA can be greatly amplified using the polymerase chain reaction process (PCR) (61). These are readily characterized and in many instances introduced into plasmids or other vectors for recombinant protein synthesis. Automated synthesis of single-stranded polynucleotides can be accomplished utilizing sequential protection/deprotection chemistry (62). Although entirely synthetic methods are quite slow compared to biosynthesis, designed oligonucleotides for targeting or diagnostic purposes (including micro arrays with variable sequences for rapid screening) can be readily produced. Post-reaction chemistry including ligation and PCR can then be utilized to produce significant quantities of desired oligonucleotides.

Polypeptides and Proteins. Most polypeptides and proteins are water-soluble or water-swellable. Enzymes are proteins that catalyze all chemical reactions of biological origin. Enzyme functions include oxygen transport, muscle movement, nerve response, nutrient digestion and storage, hormonal regulation, gene expression, and protein synthesis (63).

Structure. Despite the large number of functions, all proteins are similar with repeating structures along the backbone chosen from 20 amino acid monomers (Fig. 11). These polymers, the structures of which are assembled from a template coded by mRNA, are monodisperse. Each protein has a unique sequence and molecular weight. The 20 amino acids, capable of appearing in various microstructural combinations, sequence lengths, and total molecular lengths, allow assembly of a nearly unlimited number of distinct proteins with specific physical properties and behavioral characteristics.

Primary structure (covalent bond lengths and bond angles) is determined by the microstructure of the amino acid repeating units along the chain. Numerous procedures, including sequential degradation, gel electrophoresis, dye binding, and immunoassays, have been used to determine sequences (63).

Secondary structure of proteins is determined by configuration and conformation along the backbone of the polymer. The resistance to bond rotation of the C—N bond of the peptide unit, the configuration about the chiral carbon, and conformational restrictions to rotation by short-range charge–charge interactions or intramolecular hydrogen bonding play major roles in secondary structure.

The three-dimensional structure, or tertiary structure, depends strongly on primary and secondary structure with the added elements of long-range intramolecular hydrogen bonding, polar and ionic effects, and chain solvation. An

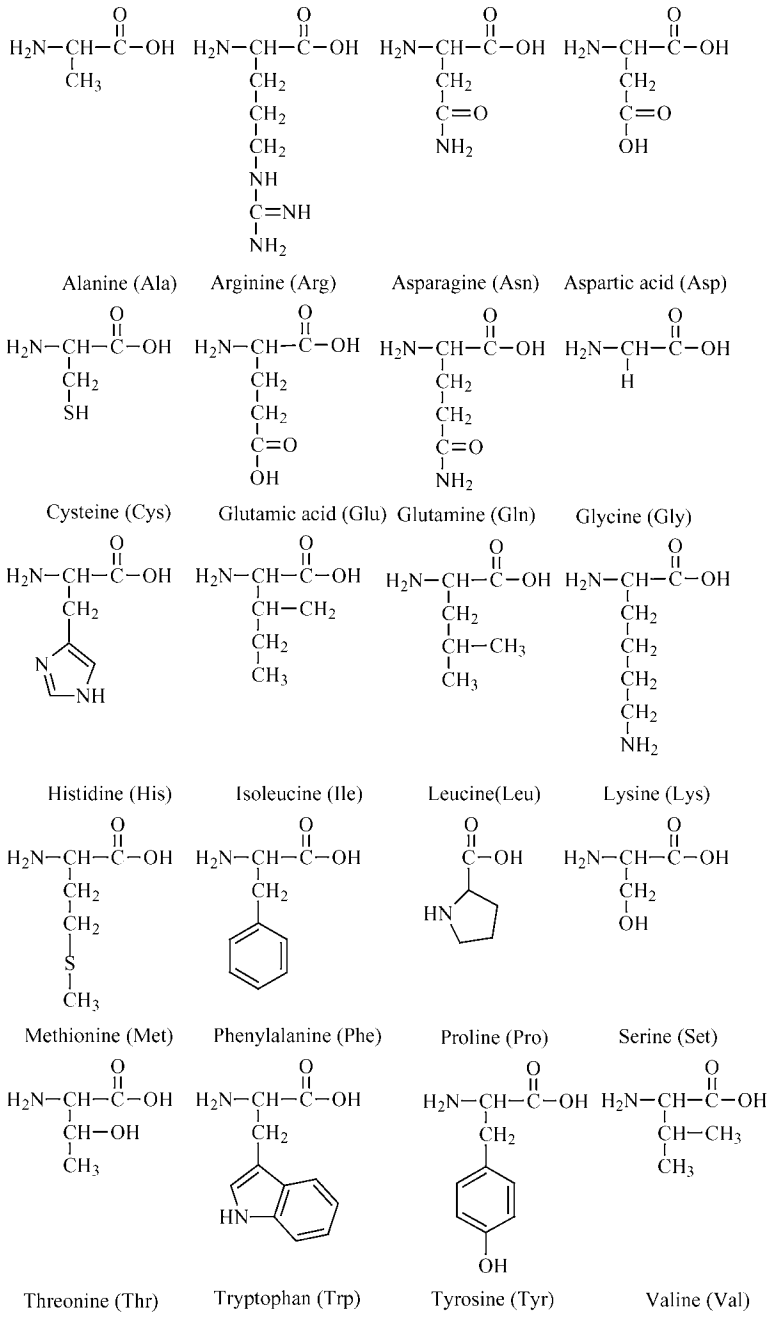

Fig. 11. Chemical structures of the 20 amino acids.

example of the three-dimensional structure of myoglobin is shown in Figure 12. The compact structure illustrates the hydrophobic interior, helical features from intramolecular hydrogen bonding and the L-amino acids, and polar external groups for hydration (see PROTEIN FOLDING).

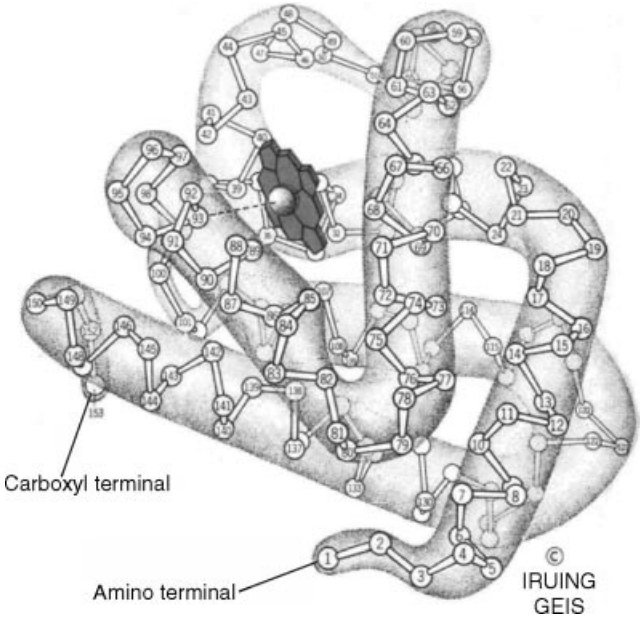

Fig. 12. Tertiary structure of myoglobin (64).

Many proteins exist in subunits of a composite structure. The organization of these subunits is termed the *quaternary structure* and is particularly important in enzyme-mediated reactions. The tertiary and quaternary structure of native protein in water can be disrupted by addition of electrolytes, alkali solutions, urea, or detergents, and by increasing temperature. The properties change markedly; eg, enzyme activity is often lost. In most cases this denaturation is not reversible. The solubilities of proteins vary considerably based on composition and conditions of ionic strength, pH, and concentration. Those with the highest density of polar groups or electrolyte character are most soluble. Therefore, solubility in water is lowest at the isoelectric point and increases with increasing basicity or acidity. A review of enzyme activity as related to protein structure is given by Fersht (65).

Protein Synthesis. Protein biosynthesis is complex, involving more than 300 macromolecules (63). Five stages can be identified involving (*1*) activation of amino acid monomers and transfer to ribosomes, (*2*) initiation of polymerization, (*3*) propagation, (*4*) termination and release, and (*5*) folding and processing. Ordering of the monomers is dictated by operation of the triplet code in which a sequence of three consecutive nucleotide units on mRNA positions a specific amino acid for polymerization.

Synthetic polypeptides can be made by sequential addition of protected amino acids onto a solid support. This procedure, pioneered by Merrifield (66,67) has been used to prepare hundreds of peptides of varying sizes and functions. A review of the technique and recent modifications are found in Reference 68.

The study of genes responsible for identifiable biological products and processes (genomics) (69) and the more ambitious study of translated proteins, their isoforms, modifications and interactions (proteomics) (70) has advanced at an incredibly fast pace during the last five years. In a very short time a number of genes

have been targeted for recombinant expression in a variety of hosts to produce a wide range of new drugs and to develop new diagnostic markers.

Commercial Use. In addition to the rapid growth of genetically engineered enzymes and hormones for medical and agricultural applications, other water-soluble proteins are isolated from biological sources in a more traditional manner for commercial application. Enzymes are used as detergent additives, for hydrolyzing polysaccharides and proteins, to isomerize various glucose and sucrose precursors, for wine and beer making, for leather tanning, and for mineral recovery. Support-bound enzymes are becoming commercially significant for large-scale substrate conversion.

Polysaccharides

Water-soluble polysaccharides are a diverse class of biological macromolecules with a wide range of structural and behavioral characteristics. More than 100 sugars and sugar derivatives comprise the monomers available for polysaccharide synthesis (63). Covalent linkages between repeating units may occur at different ring positions; linear and branched structures with single or multiple monomers may be formed (see POLYSACCHARIDES).

Industrial polysaccharides have traditionally been extracted from renewable resources in the plant and animal kingdom. Examples include starch and gums from plant seeds, pectin from fruits, and algin and carrageenan from algae. Recently, microbial sources have produced commercially useful polysaccharides such as dextran, curdlan, pullulan, xanthan, and pharmacologically active oligosaccharides.

Polysaccharides are cyclolinear or branched polymers formed by enzyme-directed step-growth condensation reactions of various activated sugar molecules (71). Some common monomer units are shown in Figure 13; other units include

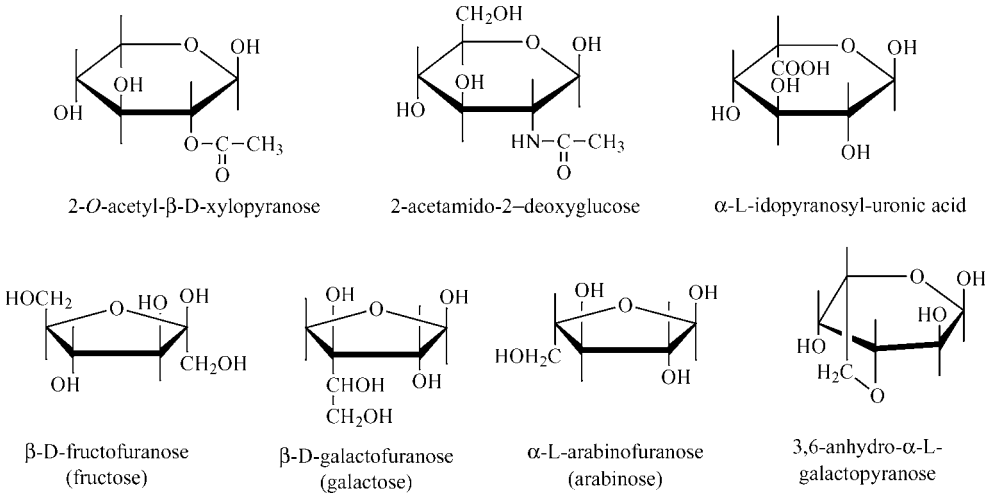

Fig. 13. Common structural units in naturally occurring polysaccharides (71).

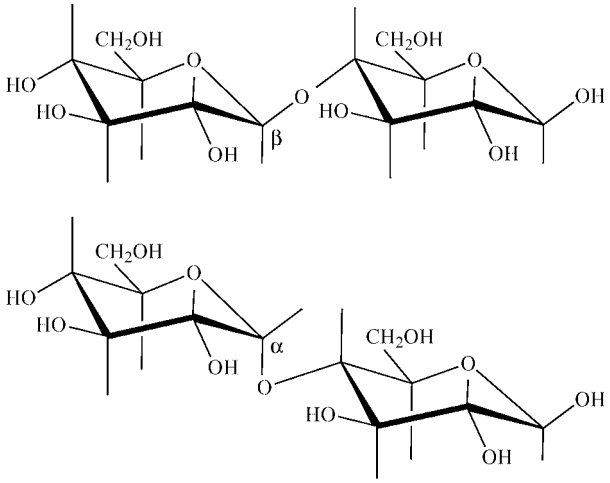

Fig. 14. Dimerization of glucopyranose units to yield α and β structures.

glycerol and other polyhydroxyalcohols, phosphate, sulfate, malonate, and pyruvate.

Aqueous solution properties, including solubility, phase behavior, and viscosity, are highly dependent on the macroscopic nature (linear, branched) of the chain as well as the chemical microstructure (polar characteristics, sequencing) of the repeating units. As with proteins, the presence of acidic or basic functionality causes pH, electrolyte, and temperature-dependent behavior. Degrees of polymerization may vary from 30 to 1×10^5. Of primary importance in the solution behavior of water-soluble polysaccharides are the configurations of asymmetric carbon atoms in the cyclic monomers and the ring conformations of the resulting covalent backbone units.

Dimerization of glycopyranose (Fig. 14) by condensation of the hydroxyl group at C-1 on one ring with C-4 on the other can lead to two isomers, depending on whether the reaction is equatorial–equatorial or axial-equatorial. The former linkage is designated β, the latter, α. Polymers formed by successive α-1 $\rightarrow$4 linkages, eg, amylose, have markedly different properties than polymers formed by successive β-1$\rightarrow$4 linkages, eg, cellulose.

Polysaccharides based on glucopyranose occur with backbones through carbons 1$\rightarrow$2, 1$\rightarrow$3, 1$\rightarrow$4, and 1$\rightarrow$6. The less-ordered structures are more water-soluble in general, with the α-1$\rightarrow$3 and the β-1$\rightarrow$6 forms exhibiting highest aqueous solubility; β structures often form strong inter- or intramolecular hydrogen bonds, making solubilization difficult.

Branched structures, especially for α linked polysaccharides, enhance solubility. Heterogeneity in types of repeating units, backbone linkages, and polar or charged functionality also imparts greater solubility. Excellent reviews of the effects of the structural conformation of monosaccharides are found in References 71 and 72.

Water-soluble polysaccharides can be classified according to structure and commercial applications. Classes include storage polysaccharides, pectins, plant gums, seed and bark mucilage, algal polysaccharides, bacterial and fungal

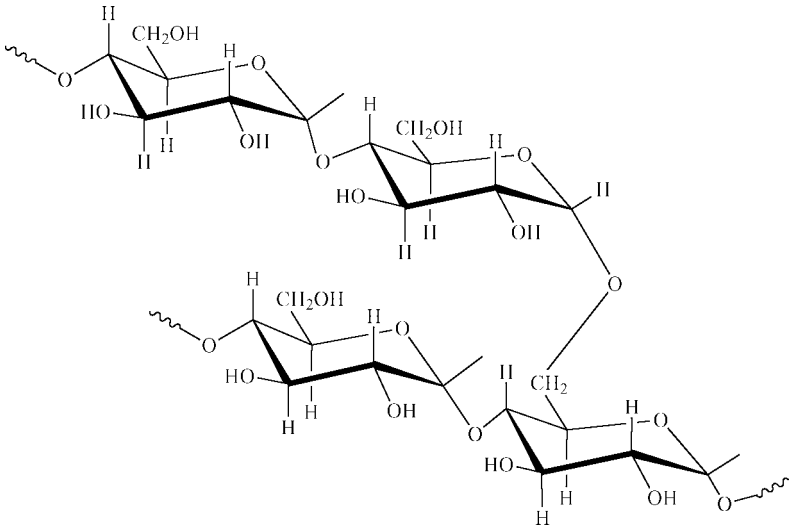

Fig. 15. Structure of amylopectin (73).

polysaccharides, mucopolysaccharides, and synthetically modified polysaccharides. For more detailed descriptions see References 72–75.

Storage Polysaccharides. *Starch and Starch Derivatives*. Amylose and amlyopectin are the major components of starch granules found in food reserves of all green plants. Commercial starch is obtained from sources such as corn, sorghum, rice, wheat, and potatoes. The compositions of the amylose and amylopectin vary with source.

Amylose is the linear polysaccharide of α-1$\rightarrow$4-D-glucopyranose having a molecular weight of $1.6 \times 10^5 - 2.6 \times 10^6$. Amylose is not water-soluble in an unmodified state but can be dispersed in water. In the solid state it is reported to exist as a left-hand six-fold helix; in solution it behaves like an extended helix (74). Shearing and heating of starch cause hydration and swelling termed *germination*. Gradually the amylose in this dispersion precipitates through association in a process called *retrogradation*.

Amylopectin (Fig. 15), the water-soluble portion of starch, is an α-1$\rightarrow$4-D-linked glucopyranose with α-1$\rightarrow$6-D-branches. Amylopectin is polydisperse with a molecular weight of $5 \times 10^7 - 4 \times 10^8$.

A number of starch derivatives (73,74) have been prepared in order to control solubility, viscosity, and phase behavior over a temperature range or under conditions of shear and added electrolytes. Major modifications include lowering molecular weight enzymatically or chemically, oxidation, forming derivatives, and cross-linking. Derivatives include starch esters, phosphates, sulfates, and ethers. Cationic, anionic, and amphoteric starches have been prepared as well as starch–graft copolymers, some with super absorbent properties.

Starch (qv) and starch derivatives have a number of applications in the food industry as viscosifiers, gelatinizers, fillers, and paste formers; in the textile and paper industries for coatings, sizing agents, rheology modifiers, and pigment binders; and in the medical area as surgical powders, absorbents, adhesives, and in pharmaceuticals.

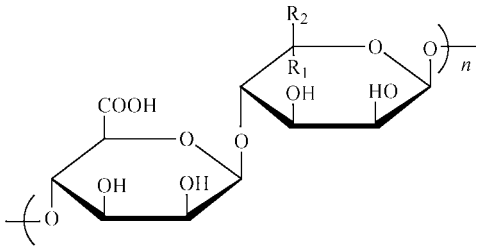

Fig. 16. Structure of β-D-mannuronic acid.

Glycogen. Glycogen is the storage polysaccharide in animals and is found in highest concentration in the liver and muscle tissues. The backbone of glycogen is α-1→4-D-linked glucopyranose units with large numbers of α-1→6-D-branch points.

Glucans. Algae form two types of storage polysaccharides. Starch type algal polysaccharides are α-D-glucans similar to those found in land plants, except they contain a small number of α-1→3-D-linkages and are of lower molecular weight (76). Laminaran is the main carbohydrate food reserve of several green seaweeds and is a β-1→3-D-linked D-glucan with β-1→6-D-branches. Other sources include fungi, yeast, flagellates, and diatoms.

Laminaran has two forms distinguished by solubility in cold water. Differences are related to the degree of 1→6 branching. Both are soluble in hot water and have molecular weights from 3500 to 5300. Laminaran has been used for surgical dusting powder and has been reported to have antitumor activity.

Algal Polysaccharide. *Alginic Acid*. Alginic acid represents the generic group of polymers (74) composed of D-mannuronic acid and L-guluronic acid extracted from brown algae (77). Alginic acid is not soluble in pure water, but easily dissolves in aqueous solutions of alkali metal hydroxides or carbonates. The structure (77) of alginic acid shown in Figure 16 is complicated with three types of segments: poly(β-1→4-D-mannuronic acid); poly(α-1→4-L-gluronic acid); and those in alternating patterns. The ionic forms of algins are polyelectrolytes with extended structures. The precise properties are determined by the structural disposition of these segments. Alginates are used as thickeners and stabilizers in the food industry, in pharmaceutical, cosmetic, and coating formulations, and as flocculants.

Sulfated Derivatives. Sulfated algal polysaccharides (78) are a class of heteropolymers with alternating α-1→3-D- and β-1→3-D- (carrageenan and furcellaran) or alternating α-1→3-L- and β-1→3-D- galactans (agar). Conformational differences have been shown between the nongelling λ carregeenan and gel-forming κ and ι forms (Fig. 17) (71). Molecular weights range from 1×10^5 to 1×10^6.

Carrageenan has diverse industrial applications including use in toothpaste, ice cream, chocolate milk, jellies, puddings, pet foods, pharmaceutical and industrial suspensions, antiulcer treatments, shampoos, creams, lotions, and oil/water and water/oil emulsions. Carrageenan reacts with denatured proteins and has been shown to exhibit properties similar to those of the animal mucopolysaccharides, such as anticoagulant activity and induction of growth of new connective tissue.

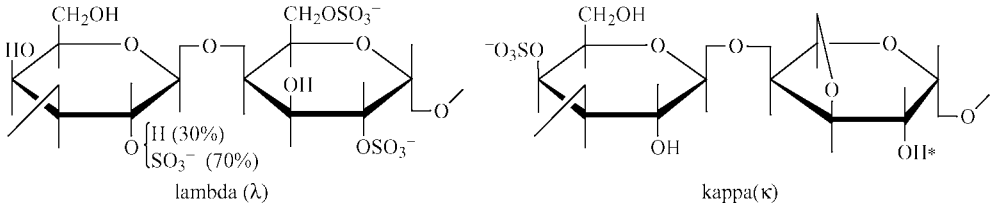

Fig. 17. λ and κ carrageenan. In ι carrageenan, OSO_3^- replaces OH^* in the κ-form (72).

Pectins. Pectins (pectic and pectinic acids or their derivatives) are gel-forming water-soluble polysaccharides found in the primary cell walls and intercellular layers in land plants. They are found in abundance in apples, sugar beets, and the rinds of citrus fruits. Pectic acids are poly(α-D-galactopyranoslyuronic acids) with varying degrees of neutralization. Pectinic acids are also galactouronglycans but with significant quantities of methyl ester groups. Pectins are soluble in water and exhibit pseudoplastic behavior. When heated at appropriate pH, in the presence of divalent electrolytes and sugars, they form spreadable gels (74). For this reason pectins are used for making jams and jellies.

Plant Gums. Plant gums or exudate gums are formed spontaneously at sites of injury to the plant. The exudate is a viscous fluid consisting of complex, highly branched polysaccharides with residues of hexuronic acid and two or more neutral sugars. Many plant gums are used commercially as thickening agents or emulsion stabilizers. Commercially important are karaya gum, gum tragacanth, gum Arabic, and gum ghatti (76).

Seed Mucilages. Guaran is a purified polysaccharide from the guar plant seed. It is a linear chain of β-1→4-linked D-mannopyranosyl units onto which is linked an α-1→6-D-galactopyranosyl unit (Fig. 18). Molecular weights are estimated to be 2.2×10^5 (79). Guaran forms high viscosity, pseudoplastic solutions at low concentrations, is nonionic, and is little affected by electrolyte addition or pH changes. Guar easily forms gels with transition metal elements or borate ions and is therefore useful in drilling, cementing, and fracturing in oil-filed applications. It has also been used as a thickener and stabilizer in the manufacture of ice cream, cheese, pet foods, and deodorant gels.

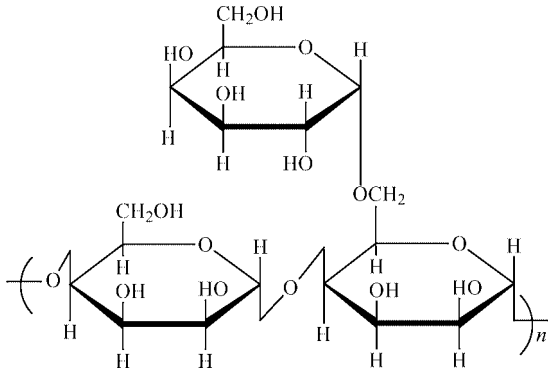

Fig. 18. Structure of guaran.

Extracellular Polysaccharides. One of the most important extracellular bacterial polysaccharides is dextran. Dextrans are high molecular weight α-1$\rightarrow$6-D-glucopyranose polymers with varying proportions of α-1$\rightarrow$4 and α-1$\rightarrow$3 branch linkages. Dextran is produced from sucrose by a number of bacteria from the family *Lactobacillaceae*. Dextran has a variety of commercial applications, including use as a plasma substitute, an anticoagulant, or in studies of cells, viruses, and proteins. Fractionated commercial dextrans are used as standards in various studies of the properties of water-soluble polymers. Dextran–graft copolymers have utility in viscosifications, superabsorbancy, and oil-field applications (80).

Bacterial and Fungal Polysaccharides. Microbes generate a large number of polysaccharides, many of which are not produced by the higher plants or animals. A large number of microbial polysaccharides are used in the food, cosmetic, and pharmaceutical industries. Particular polysaccharides, when isolated from the dried bacteria, have been shown to induce an immune response and generate antibodies in organisms exposed to them. Several of these capsular polysaccharides have been used to develop vaccines for various bacterial infections such as meningitis and typhoid fever (81).

Xanthan (qv) is an extracellular bacterial polysaccharide produced by *Xanthomonas campestris*. Xanthan is a branched polysaccharide with β-1$\rightarrow$4-D-glucopyranose units along the backbone. On every other unit the oxygen at C-3 is substituted with a trisaccharide unit. Approximately half the β-D mannose units have a pyruvic acid group linked as an acetal derivative. Molecular weight has been estimated to be 2×10^6.

The solutions are viscous as low polymer concentrations, pseudoplastics, and insensitive to salt, temperature, and pH over a wide range. Much controversy remains as to changes in the tertiary structure with changing solution conditions. Single, double, and even triple helical structures have been proposed as well as quaternary structures from side-by-side double helix dimers (72,75,82).

Other water-soluble microbial polysaccharides include the anionic polysaccharides gellan from *Pseudomonas elodea* and bacterial alginate from *Pseudomonas aeruginosa*, and the neutral polysaccharides scleroglucan, curdlan, and pullulan (72,75,76,83).

Scleroglucan and schizophyllan (Fig. 19) are examples of fungal polysaccharides (72,75,81,84). Their structures are identical except for the distribution of

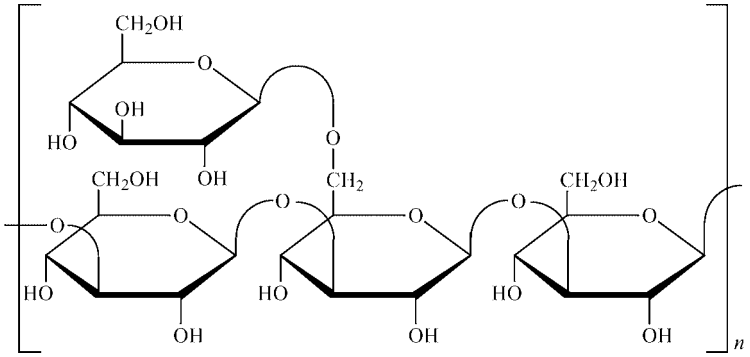

Fig. 19. Structures of scleroglucan and schizophyllan (75).

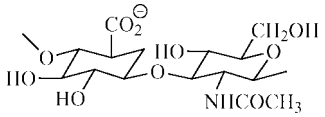

Fig. 20. Structure of hyaluronic acid.

side chains along the polymer backbone. Both are rod-like macromolecules forming triple helices in aqueous solutions. They are used industrially as viscosifiers and in polymer flooding for enhanced oil recovery. They have also been shown to exhibit specific biological activity against cancers and infections.

Mucopolysaccharides of Higher Animals. Mucopolysaccharides of higher animals are generally found in the connective tissues. They form highly viscous aqueous solutions that gel readily. These polysaccharides consist of amino sugars (D-glucuronic acid or L-iduronic acid) and may have *N*-acetyl, *O*-sulfate, or *N*-sulfate groups. Their functions include induction of calcification; control of metabolites, ions, and water; and healing of wounds. Several of these polymers are under study for medical, cosmetic, and personal care applications.

Hyaluronic acid (Fig. 20) is a regularly alternating copolymer of D-glucuronic acid and 2-acetamido-2-deoxy-D-glucose (77). It is found in most connective tissues, especially in umbilical cord, vitreous tissue, joint fluid, and skin. It is synthesized by fibroblasts in the mesenchymal tissue and also by bacteria. Hyaluronic acid binds a large amount of water in the interstitial spaces and is thought to be involved with the control of permeability and thus resistance of the tissues to infection. Hyaluronic acid is involved in the wound-healing process and is produced in large amounts at the site of the wound in the days following the injury. Hyaluronic acid also serves as a lubricant in the joints. Commercially, hyaluronic acid has application in postoperative healing in eye surgery.

Chondroitin and chondroitin sulfates (Fig. 21) are found in cartilage, skin, cornea, sclera, and bone. They show high viscosity and water retention and play a role in the connective tissue similar to that of hyaluronic acid. Sulfate groups contribute additional ion-binding capacity.

Dermatan sulfate (β-heparin) is found in the skin, lungs, tendons, spleen, brain, and heart. Dermatan sulfate exhibits high water retention and acts in a way similar to the chondroitin sulfates. It is also an anticoagulant.

Heparin (85) is found in the heart, liver, lung, spleen, muscle, kidney, and blood. It is synthesized in the mast cells and has a molecular weight of

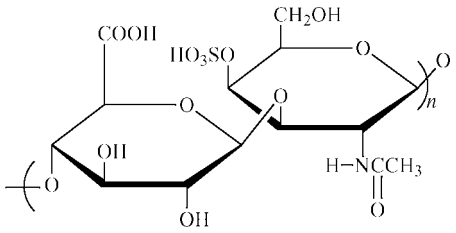

Fig. 21. Structure of chondroitin sulfate. In dermatan sulfate the —COOH group extends axially from the bottom face (77).

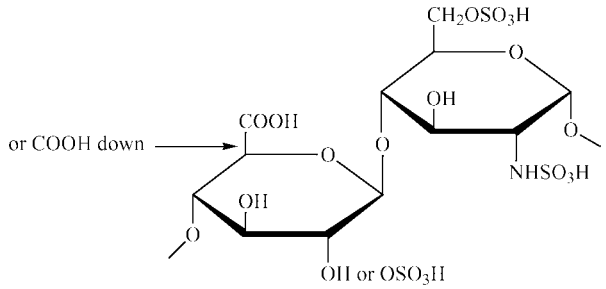

Fig. 22. Structure of heparin.

5000–25,000. Heparin is a mixture of polysaccharide chains of varying lengths and heterogeneity. It consists of 2-acetamido-2-deoxy-α-D-glucopyranosyl, α-D-glucopyranosyluronic acid, and L-iduronic acid residues containing various proportions of *O*-sulfate, *N*-sulfate, and *N*-acetyl groups (Fig. 22). It is an anticoagulant and antilipemic agent and is widely used in cardiovascular surgery and therapy.

Synthetically Modified Polysaccharides. Water solubility can be conferred on a number of naturally occurring polysaccharides by synthetic derivations producing charged or polar functionality. Two of nature's most abundant polysaccharides, cellulose and chitin, have been synthetically modified in a multitude of ways to produce polymers with significant commercial utilization (86,87).

Cellulose Derivatives. Cellulose (qv) is a β-1$\rightarrow$4-D-anhydroglucopyranose copolymer (Fig. 23) that serves as the major structural component of plants. When the cellulose molecule is extended, it is a flat ribbon with hydroxyl groups protruding laterally and is capable of forming both intra- and intermolecular hydrogen bonds. This form allows the strong interaction with neighboring chains that makes dissolution difficult. In fact, strongly interactive solvents are necessary for solubilization. Molecular weights range from 5×10^5 to 1.5×10^6, depending on the source. Water-soluble cellulose ethers can be prepared by nucleophilic substitution, ring opening, or Michael addition mechanisms (72).

Carboxymethylcellulose (CMC) is usually prepared by the reaction of cellulose with the sodium salt of chloroacetic acid in aqueous alkaline organic slurries. The extent of substitution on C-2, C-3, and C-6 is related to the degree of disruption of hydrogen bonding, steric factors, and reaction conditions (72,87). The acid form of CMC is a polyelectrolyte with limited solubility and a pK_a of 4. The monovalent metal or ammonium salts are soluble; divalent cations result in borderline solubility; multivalent cations allow gel formation. Solutions of sodium CMC are pseudoplastic for high viscosity grades with degrees of substitution (DS) of 0.9–1.2. Solutions of less uniformly substituted, high molecular weight CMC

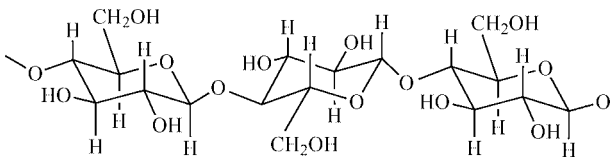

Fig. 23. Structure of cellulose.

with low DS are thixotropic; CMC is stable over the pH range 4–10 (see CELLULOSE ETHERS).

CMC is used in sizing for textile and paper applications and as a thickener, stabilizer, suspending agent, or binder in foods, pharmaceuticals, and cosmetics. CMC is a fluid loss and rheology modifier in drilling muds.

Hydroxyethylcellulose (HEC) and hydroxypropylcellulose (HPC) are prepared by nucleophilic ring opening of ethylene oxide and propylene oxide, respectively, by the hydroxyl anions on the anhydroglucose ring of cellulose. Reactions are conducted commercially in caustic aqueous slurry processes (72). Laboratory methods recently have been reported for preparation of cellulose ethers, esters, and carbamates under homogeneous reaction conditions in organic solvents (88–91). Such solvents may lead to development of new commercial processes for cellulose derivatives with more uniform substitution.

HEC is a nonionic polymer with little surface activity in solution and is compatible with a wide range of surfactants and salts. Solutions are pseudoplastic at higher molecular weights and concentrations. Molecules behave as rigid rods in dilute aqueous solution. Commercial HEC has molar substitution (MS) between 1.8 and 3.5 degree of substitution of 0.8–1.8.

HPC is more hydrophobic than HEC owing to the presence of the methyl group on the side chain. The polymer is soluble in organic solvents but phase separates from water above 45°C. In concentrated solutions, HPC exhibits lyotropic liquid cryalline behavior (61). Commercial HPC has MS values between 3.5 and 4.5 and DS values of 2.2–2.8 (72,87).

HEC is used in coatings, cements, thickeners, pharmaceuticals, oil-well fracturing, cementing, and drilling applications, and in cosmetics, inks, paper finishes, lubricants, gels, and agricultural formulations. HPC is used for warp sizing, flocculations, wetting, thickening, binding, formulation of hair sprays, cosmetics, pharmaceuticals, and personal care items.

Methylcellulose is prepared commercially by reaction of the respective methyl chloride or dimethyl sulfate with alkali cellulose with organic slurry systems, batch methods, or continuous processes (72,87). The methyl ether derivatives have a DS range from 1.5 to 2.0, the uniformity of which depends on the heterogeneity of the reaction medium and other reaction conditions. Substitution occurs preferentially at the C-6 and C-2 positions. Methylcellulose exhibits both an upper and lower critical solution temperature as signified by gel formation on heating or cooling homogeneous solutions. Uses for methyl cellulose include gelling fluids, viscosifiers, pharmaceutical coatings, and food additives.

Hydroxypropylmethylcellulose (HPMC) is one of the many mixed ethers of cellulose. It is prepared by reactions of alkali cellulose with methyl chloride and propylene oxide in a slurry process. Reaction conditions may be varied to control compositions despite the greater reactivity of methyl chloride. HPMC is an extremely effective viscosifier compared to conventional cellulose ethers. Its microheterogeneous nature, phase behavior, and interaction with surfactants allow use in food, pharmaceutical, and coatings applications (72,87).

Cellulose sulfates and phosphates are water-soluble derivatives prepared by reactions of alcohol/water/organic diluent mixtures of sulfuric or phosphoric acids. Phosphate derivatives are flame retardant but have not been commercialized (72).

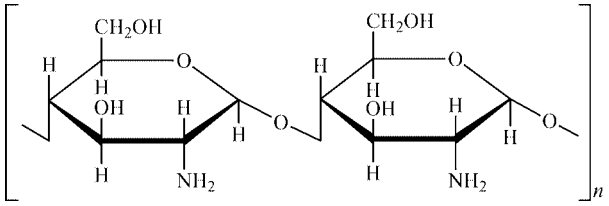

Fig. 24. Chitosan.

Chitin Derivatives and Chitosan. Chitin (92) is a water-insoluble, high molecular weight polymer of 2-acetamido-2-deoxy-D-glucopyranosyl units linked through β-1→4-D bonds. This most abundant skeletal material of invertebrates is recovered from shrimp, crab, or lobster waste materials. Fungi are also an important commercial source of chitin. Chitin may be converted to chitosan by partial or complete deacetylation. In the protonated form (Fig. 24), this cationic polyelectrolyte is water-soluble with a number of potential commercial uses including flocculation, viscosification, wound healing, medical dressing, pharmaceutical formulation, drug delivery, membrane technology, and animal nutrition.

Chitin can be derivatized (92–95) by reaction of the hydroxyl substituents on carbons 3 and 6 of the anhydroglucose ring. *N*-substituted derivatives at C-2 can be obtained from reactions on chitosan or partially deacetylated chitin. Hydroxyethylchitin and other water-soluble derivatives are useful wet-end additives in papermaking and flocculants for anionic waste streams (see CHITIN AND CHITOSAN).

Inorganic Water-Soluble Polymers

Poly(metaphosphoric acid) (96,97) (Fig. 25) is formed by controlled dehydration of NaH_2PO_4. The lower molecular weight sodium hexametaphosphate is available commercially. High molecular weight analogues can be prepared with various cations. The other widely abundant inorganic polymers, poly(silicic acid) (Fig. 26) and its sodium or potassium salts are highly branched, associated, high viscosity polymers. Aqueous solutions of silicates have been used as raw materials for centuries in window-glass formation and insulating-glass fibers (96).

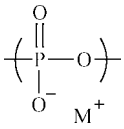

Fig. 25. Poly(phosphoric acid) salt.

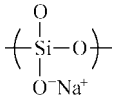

Fig. 26. Poly(silicic acid) salt.

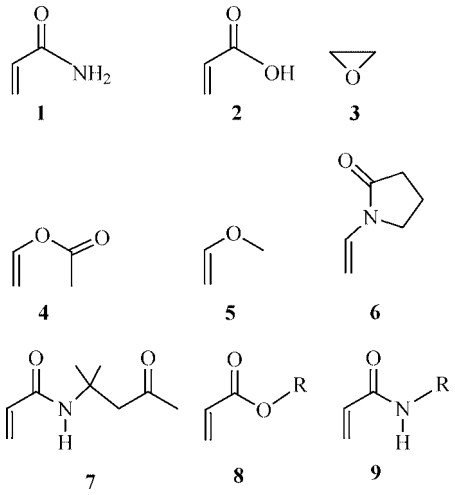

Fig. 27. Examples of uncharged monomers utilized in the synthesis of water-soluble, nonionic copolymers.

Nonionic Polymers

A number of commercially available and experimental nonionic monomers including those shown in Figure 27 have been utilized to prepare a large number of water-soluble (co)polymers. Water solubility is a result of a high concentration of polar or hydrogen-bonding functional groups on the repeating units. Major commercial polymers are based on acrylic, vinyl, oxide, or imine functionality.

Polyacrylamide. Acrylamide (AM) monomer **1** is polymerized by free-radical initiators, eg, azo compounds, redox, catalysts, light, and radiation (Fig. 28). This monomer is unique among vinyl and acrylic monomers because it can be polymerized to ultrahigh molecular weight (10^6–10^7). This extraordinary feature of acrylamide polymerization is attributed, in part, to the ease of purification of AM monomer and to the unusually high ratio of its propagation to termination rate constants (k_p/k_t). In fact, AM has the highest k_p/k_t of any free radically polymerizable monomer. Polyacrylamide (PAM) can be prepared via solution, inverse emulsion, inverse microemulsion, or precipitation techniques (98–100) (see ACRYLAMIDE POLYMERS).

Low temperature initiation, high monomer concentration, and a small amount of added 2-mercaptobenzimidazole, a radical scavenger, are reported to be the optimal reaction conditions for preparing high molecular weight, soluble polymers. High total solids concentrations usually result in intractably high solution viscosities. Inverse emulsion polymerization offers the opportunity for lowered

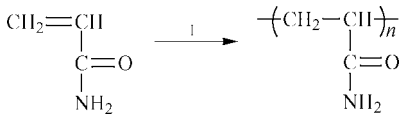

Fig. 28. Polymerization of acrylamide.

viscosities without compromising polymer molecular weights (101–103). Inverse microemulsion polymerization results in rates 10–200 times faster than conventional inverse emulsion systems (104). Precipitation polymerization can also be accomplished using a solvent (eg, *tert*-butyl alcohol) that dissolves the AM monomer but not the PAM (100).

Solution polymers are usually isolated by precipitation or dialysis/freeze drying. However, such solid products are hard to re-dissolve. Recently this problem was overcome by the discovery that water-in-oil (w/o) emulsions of polyacrylamide can be inverted by adding a water-soluble surfactant to produce an oil-in-water (o/w) emulsion. Thus a low HLB surfactant is used for polymerization and a high HLB surfactant is used for phase inversion (103). The resulting polymers re-dissolve easily. Inversion must be complete or polymer (activity) is lost.

AM is difficult to polymerize by any of the "controlled/living" polymerization techniques. However, McCormick and co-workers have recently made significant progress in this area by reporting the CLRP, via RAFT, of AM in both aqueous and organic media (47,49,50). To achieve "living" conditions, judicious choices must be made with respect to RAFT chain transfer agent (CTA) and polymerization conditions.

PAM has reported T_g values of 165 and 188°C. No matter which value is correct, it is clear that PAM remains glassy to relatively high temperatures. Although PAM is slow to dissolve, it is soluble in water in all proportions. However, PAM solution viscosities show a time dependence, attributed to intramolecular conformational changes (98). Because PAM can be polymerized to very high molecular weight, it is a highly efficient aqueous viscosifier. Solution viscosities of nonionic PAM are insensitive to changes in pH (between 1 and 10). Above pH = 10, it is subject to hydrolysis. Solutions of nonionic polyacrylamide are also tolerant of electrolytes (eg, NaCl). Viscosities increase with increasing molecular weights, according to equation 5.

$$[\eta] = 1.0 \times 10^{-2} M_w^{0.755} \text{ (water, 25°C)} \tag{5}$$

Polyacrylamides function as flocculating agents, in rheology control, and as adhesives.

Poly(acrylic acid). Poly(acrylic acid) (PAA) can be prepared by direct free-radical polymerization of **2** in aqueous solution (6) or by precipitation polymerization in benzene. Alcohols and mercaptans are commonly used chain-transfer agents for regulating polymer molecular weight. Alternatively, PAA can be prepared by hydrolysis of poly(alkyl acrylates) (6) (Fig. 29).

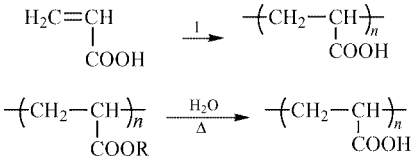

Fig. 29. Preparation of poly(acrylic acid) by direct polymerization or by hydrolysis of a polyacrylate.

Both RAFT and NMP controlled/living techniques are suitable for the direct polymerization of acrylic acid. The RAFT polymerization of AA has been reported in DMF (24,105), various alcohols (106,107), water (108), and dioxane (109) employing a variety of RAFT CTAs including dithioesters, xanthates, dithiocarbamates and trithiocarbonates. AA is also susceptible to controlled polymerization by NMP (110,111).

The T_g of PAA has been variously reported as 75, 106, and 126°C, depending on the mode of measurement. However, the highest value is probably the most accurate. Solid polymers are hard, clear, brittle materials. In aqueous solutions, viscosity increases with increasing molecular weight. PAA undergoes a number of reactions in solution, ie, hydrolysis, esterification, dehydration, and complex formation with polyethers. PAA is an excellent thickener for lattices. PAA has been used in oil recovery, as a dispersant for inorganic pigments, as a flocculant, and as an adhesive.

Poly(ethylene oxide). Poly(ethylene oxide) (PEO) is prepared by ring-opening polymerization of the ethylene oxide monomer **3** (112,113). Polymers of molecular weight greater than 1×10^5 are prepared by heterogeneous catalysis (eg, alkaline earth carbonates) in low boiling aliphatic hydrocarbons. Few of the details of the commercial manufacture have been made public (see ETHYLENE OXIDE POLYMERS).

PEO is a white free-flowing powder with commercial grades from 100,000 to 5 million molecular weight (114). It has a T_m of about 65°C and a T_g of −45 to −53°C. Above the melting point it can be processed as a thermoplastic, ie molded or extruded. However, owing to its high melt viscosity, incorporation of plasticizer is often desired. PEO resins are completely soluble in water at room temperature, but show a lower critical solution temperature (LCST) near the boiling point of water. The LCST is lowered by the addition of inorganic salts according to the following order: $PO_4^{3-} > SO_4^{2-} > F^- > Cl^- > I^- > K^+ > Na^+ > Li^+$. Aqueous solutions of high molecular weight PEO show high extensional and shear viscosities and pseudoplastic rheology.

Poly(vinyl alcohol). Poly(vinyl alcohol) (PVA) is manufactured by alcoholysis/hydrolysis of poly(vinyl acetate), which is, in turn, produced by free-radical polymerization of vinyl acetate monomer **4** (114) (Fig. 30) (see VINYL ALCOHOL POLYMERS).

Polymerization of vinyl acetate monomer can be effected by bulk, solution, or emulsion techniques. The poly(vinyl acetate) formed is then dissolved in solvent (eg, CH_3OH) and alcoholized/hydrolyzed with acidic or basic catalysts. Vinyl acetate can also be polymerized in a controlled fashion via RAFT/MADIX (115). PVA is insoluble in CH_3OH and precipitates. It is isolated by filtration, washing, and drying.

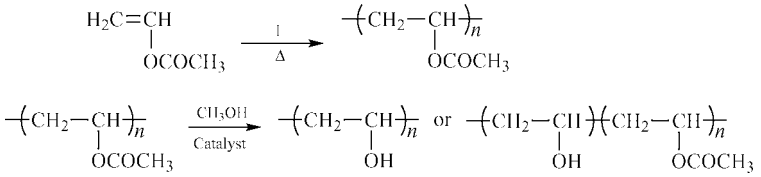

Fig. 30. Polymerization of vinyl acetate.

Properties of PVA depend on the degree of alcoholysis/hydrolysis and polymer viscosity/molecular weight. Bulk/film properties (eg, tensile strength, tear resistance, elongation, and flexibility) of PVA increase with increasing extent of alcoholysis/hydrolysis and with increasing viscosity/molecular weight. The tensile strength is exceptional compared with other water-soluble polymers. Water solubility/sensitivity is at a maximum at 88% alcoholysis/hydrolysis. Beyond that level, polymer–polymer interactions via intramolecular H-bonding become so extreme that solvation of the polymer becomes difficult.

Other noteworthy properties of PVA are its film-forming ability, its barrier, adhesive, and emulsifier properties, and its grease, oil, and solvent resistance. PVA films and coatings do not require a curing cycle because tough films can be formed by evaporation. PVA film also has remarkable gas impermeability, forming barriers to oxygen, nitrogen, carbon dioxide, hydrogen, helium, and hydrogen sulfide. However, PVA does exhibit permeability to ammonia and water vapor. Its adhesive binding strength is attributable, in part, to its film-forming ability and its high strength. PVA has surface activity as an o/w emulsifier and/or protective colloid. Oil and solvent resistance increases with extent of hydrolysis.

Poly(vinyl alcohol) is used alone or combined with extenders, pigments, etc, in the preparation of high wet-strength adhesives for paper. It is an excellent binder for textiles and sizing agent for paper and can be used to emulsify a wide range of materials including vegetable oils, mineral oils, solvents, plastics, waxes, and resins. Its emulsifying, binding, film-forming, and thickening behaviors are useful in cosmetic formulation. PVA films can also be used for making oxygen tents.

Poly(methyl vinyl ether). Methyl vinyl ether (MVE) **5** is isomeric with PPO, but is significantly more water-soluble. Indeed, it is the methyl ether derivative of poly(vinyl alcohol). MVE is readily polymerized using carbocationic methods (116–118). This also facilitates the preparation of novel MVE-based block copolymers. Purification of homo polymers and copolymers prepared by the termination of living poly(methyl vinyl ether) (PMVE) with *n*-alcohols involves a combination of solvent removal, dialysis, and freeze drying (118).

MVE can also be polymerized under alternating free radical conditions with, for example, maleic anhydride to yield poly(9-methylvinylether-alt-maleic anhydride).

The T_g of PMVE is -34°C (119) and as such exists in a rubbery state at standard temperatures and pressures. PMVE exhibits broad solubility. Common solvents include benzene, halogenated hydrocarbons, ethanol, *n*-butanol, acetone, ethylacetate, cold water, heptane and cyclohexenes. Common nonsolvents include hexane, ethylene glycol, and dioxyl ether (119). PMVE is readily soluble in water, but like many nonionic water-soluble polymers, PMVE exhibits inverse temperature water-solubility. The cloud point varies over a broad range depending on MW. For example, low molecular weight PMVE with a D_p of 19 is reported to have a cloud point of 18°C while some commercial grades have significantly higher cloud points at ca 35°C (117).

Poly(*N*-vinylpyrrolidinone). *N*-Vinylpyrrolidinone (NVP) monomer **6** polymerizes under free-radical conditions via bulk, solution, and suspension methods (Fig. 32).

Azo initiators are preferred over persulfate initiators because the latter react with the monomer. One of the curious features of this polymerization is that it has a

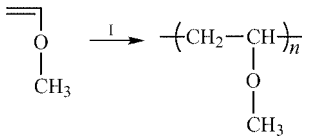

Fig. 31. Polymerization of methyl vinyl ether.

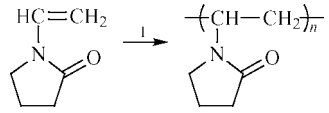

Fig. 32. Polymerization of *N*-vinylpyrrolidinone.

maximum rate of polymerization in the presence of about 1 mol of water (120,121). Presumably, a specific complex forms between the monomer and a water molecule. NVP does not polymerize to particularly high molecular weight, in part because it is difficult to purify the monomer.

The T_g of PNVP is 175°C, but this value is reduced considerably by small amounts of water. Dry-cast films of PNVP are hard and transparent. However, the presence of strong intermolecular dipole–dipole interactions causes it to have a high processing temperature. Consequently, PNVP has never found acceptance for molded parts. PNVP has interesting solution properties. It is readily soluble in water and forms complexes with a wide variety of substances, eg, iodine, polyacids, phenolics. Solutions of PNVP are stable to electrolytes. Solution viscosities increase with increasing polymer molecular weight. PNVP (bulk or solution) is also characterized by high thermal or thermohydrolytic stability and chemical resistance. PNVP is also compatible with a wide range of hydrophilic and hydrophobic resins and modifiers.

PNVP has found applications in a wide variety of industries, including medicine, pharmaceuticals, cosmetics, textiles, beverages, adhesives, and paper (121,122). For example, PNVP was an early plasma and blood volume extender. It is used extensively in pharmaceutical tablets. Its complex with iodine is a germicide. It is used as a component in cosmetics, hair shampoos, and sprays and is a stabilizing agent for beer. PNVP also exhibits excellent adhesion to glass (see *N*-Vinylamide Polymers).

Polyelectrolytes

Polyelectrolytes (qv) are polymers with charged functional groups attached along the chain. These polymers are usually classified as either polyanions (negative charges) or polycations (positive charges). Associated with the polyions are counterions or gegenions of the opposite charge in sufficient numbers to maintain electroneutrality (123).

Water-soluble polyelectrolytes exhibit a number of common traits with water-soluble nonionics. However, differences arise from the presence of charges on the macromolecular backbone and more mobile counterions electrostatically bound to

an extent determined by pK_a, solvent, and local dielectric effects. Generally, phase behavior and enhanced solubility result from increased segmental hydration and increased free energy of mixing.

The interactions between fixed charges on the polymer chain in dilute solution normally expand (repulsive) or contract (attractive) coil dimensions. Counterion binding also influences hydrodynamic volume and involves specific ion binding as well as atmospheric ion binding. Theoretical discussions of these effects can be found in References 123 and 124.

Polyelectrolytes with flexible chains and high charge density are more expanded in water than nonionic polymers, especially at low ionic strength. Determination of intrinsic viscosity is difficult in this regime (Fig. 5**c**). Electrostatic repulsions not only cause increases in hydrodynamic volume but also increases in shear sensitivity or non-Newtonian behavior.

The extent of ionization of polybases or polyacids depends on the relative base or acid strength, degree of solvation, and dielectric constant of the solvent. Poly(acrylic acid), for example, ionizes progressively in aqueous basic solution to yield a copolymer with ionized acrylate units and un-ionized acrylic acid units along the backbone; neighboring group hydrogen-bonding effects accelerate initial ionization. Eventually, however, ionization becomes more difficult owing to excessive buildup of charge along the backbone.

Polyelectrolytes have been studied extensively because molecular structures can be tailored to allow large conformational changes with pH, temperature, or added electrolytes. Molecular parameters that influence behavior include number, type, and distribution of charged repeat units on the chain, hydrophobic/hydrophilic balance, distance of charged moiety from the backbone, and counterion type. Solution properties including phase behavior, hydrodynamic volume, and binding can be altered, offering utilization in flocculation, adhesion, stabilization, compatibilization, viscosification, suspension, etc.

Anionic Polyelectrolytes. Anionic poly(acrylic acid) (PAA) can be synthesized in two ways, ie direct polymerization of **1A** (Fig. 33) or via hydrolysis of a suitable precursor polymer (6). In the direct method, salts of acrylic acid are homopolymerized or copolymerized by free-radical initiation in aqueous media. Usually the rate of polymerization of the ionic monomer is lower than the corresponding nonionic monomer, presumably owing to charge repulsion between the growing chain and the incoming ionic monomer. Direct polymerization of acrylic acid salt solutions has some commercial advantages because the nonvolatility of acrylic acid salts allows simultaneous polymerization and spray drying (or drum drying) to produce high molecular weight polymers directly. Hydrolysis (saponification) is the alternative method for producing anionic poly(acrylic acid) (Fig. 34). Hydrolysis of syndiotactic esters gives syndiotactic salt, and hydrolysis of isotactic esters gives isotactic salts.

The T_g of anionic poly(acrylic acid) [eg poly(sodium acrylate)] is substantially higher (251°C) than that of nonionic poly(acrylic acid) (102°C) because of the strong intermolecular forces due to ionomeric clustering. Physical/mechanical properties (eg, moduli) are also generally higher for salts vs free acids in the bulk phase. Atactic and syndiotactic salts of acrylic acid are water-soluble, but isotactic forms are not. Salts of poly(acrylic acid) show characteristic polyelectrolyte solution behavior (6).

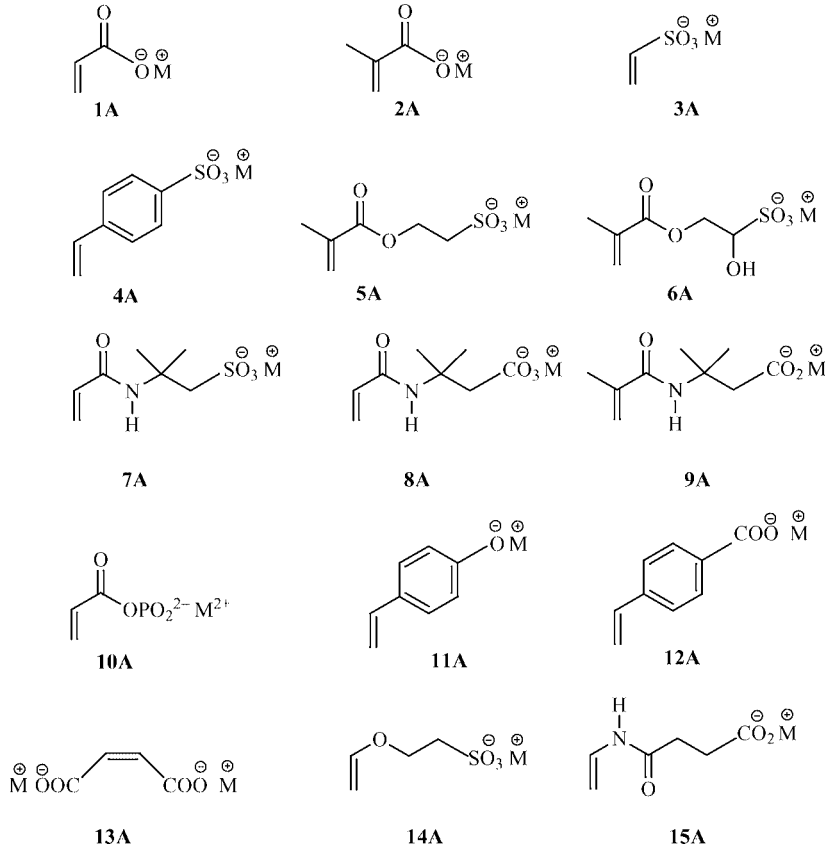

Fig. 33. Examples of monomers utilized in preparing anionic polyelectrolytes.

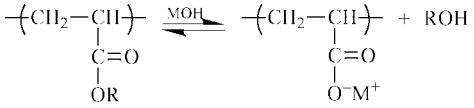

Fig. 34. Preparation of poly(acrylic acid) salts via hydrolysis of a precursors poly(alkyl acrylate).

The applications of anionic poly(acrylic acid) include use as latex thickeners, oil-field chemicals, dispersants, and flocculants. In addition, poly(acrylic acids) containing small amounts of cross-linking agents are water-swellable polymers that have found use as superabsorbents.

Poly(methacrylic acid) and Its Salts. A wide variety of methods have been used to prepare poly(methacrylic acid) (PMAA) (6) (Fig. 35). Free-radical

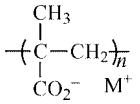

Fig. 35. Structure of poly(methacrylic acid) salt.

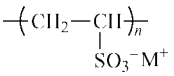

Fig. 36. Structure of poly(vinylsulfonic acid) salt.

polymerization by hydrogen peroxide, persulfate, or redox systems in aqueous solution yields atactic polymer with syndiotactic tendency. At higher pH, a higher syndiotactic content is produced. Stereoregularity can be obtained by hydrolysis of appropriate precursor polymers.

Controlled structure PMAA can be prepared by the deprotection of an appropriate precursor polymethacrylate which has itself been polymerized under living conditions. Both anionic polymerization and GTP have been used to prepare PMAA employing a variety of PMAA precursor monomers such as benzyl methacrylate (125), *tert*-butyl methacrylate (126), trimethylsilyl methacrylate (127) and 2-tetrahydropyranyl methacrylate (128,129). Removal of the protecting group yields the desired PMMA.

The sodium salt of methacrylic acid **2A** has also been polymerized directly in aqueous media via ATRP employing a PEO macro-initiator (130). Short chain, controlled structure oligomers of PMAA may also be prepared by CCTP (131).

Poly(methacrylic acid) in the nonionized form in solution has a compact conformation and low intrinsic viscosity. Upon ionization to the polyelectrolyte form, chain expansion occurs and viscosity increases. Unlike PAA, PMAA shows inverse solubility-temperature behavior. The presence of chain-stiffening methyl groups and their added hydrophobicity are responsible for the phase and viscosity behavior. Tacticity also plays an important role.

PMAA and its copolymers with acrylamide are used in viscosification and flocculation. Copolymers of MAA and its salts have been used as components of superabsorbents, coatings, adhesives, and in drilling operations.

Poly(vinylsulfonic acid) and Its Salts. Poly(vinylsulfonic acid) (PVSA) (Fig. 36) is prepared by polymerization of ethylenesulfonic acid or its sodium salt **3A** under free-radical conditions. It is purified precipitating aqueous solutions of the sodium salt form with methanol or dioxane.

The sodium and ammonium salts of PVSA are soluble in water but insoluble in organic solvents (6). The calcium salt is insoluble. Potentiometric titration studies indicate that PVSA is a strong acid that ionizes completely in water. Ion binding selectivity with alkali metals has been observed in viscosity and phase separation studies. Mark–Houwink–Sakurada (MHS) parameters of $K = 2.22$ and $\alpha = 0.65$ have been obtained for sodium PVSA in 0.5 M NaCl at 25°C.

Poly(styrenesulfonic acid) and Its Salts. Poly(styrenesulfonic acid) (PSSA) (6) (Fig. 37) may be prepared by free-radical polymerization of the monomer in solution using the free acid, sodium, or potassium salt **4A** form.

PSSA may also be prepared by sulfonation of polystyrene or by hydrolysis of poly(*n*-propyl *p*-vinylbenzenesulfonate). The latter cases allow preparation of tactic structures. Copolymers can also be prepared by free-radical copolymerization of appropriate monomers or post-reaction. Polymers are purified by precipitation of aqueous solutions with methanol, alkaline methanol, or other alcohols. Controlled structure PSSA homopolymers and block copolymers may also be prepared directly in aqueous media via RAFT using 4-cyanopentanoic acid dithiobenzoate as the CTA and V-501 as the radical source (48). NMP has been successfully

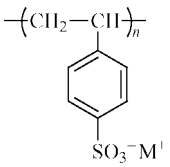

Fig. 37. Structure of poly(styrene sulfonate) salt.

employed in the preparation of near-monodisperse PSSA homo/copolymers. For example, PSSA homopolymer can be prepared in an ethylene glycol/water mixture (3:1 vol/vol) using TEMPO and sodium bisulfite/potassium persulfate as the redox initiating pair (132,133).

Atactic PSSA is soluble in water, methanol, and ethanol but insoluble in hydrocarbons. PSSA salts are insoluble in common organic solvents but soluble in water. Ultraviolet and fluorescence spectrometry measurements can yield information on features including local environment, neighboring groups, and tacticity. MHS values and solution properties are reviewed in Reference 56. Cross-linked PSSA has been used commercially as an ion-exchange resin and in heavy metal binding studies. Fractionated PSSA has been offered as a standard for aqueous gel-permeation chromatography.

Other Sulfonic Acids. Extensive development work has been conducted on acrylic sulfonate-containing monomers. 2-Sulfoethyl methacrylate (SEM) monomer **5A** has proved to be of limited commercial value owing to the hydrolytic instability of the ester linkage. However, recently well-defined homopolymers of 3-sulfopropyl methacrylate (SPMA) were prepared under aqueous RAFT conditions with 4-cyanopentanoic acid dithiobenzoate and V-501 as the CTA/initiator pair at 70°C (39). This same hydrolytic instability has been a serious problem with 3-sulfo-2-hydroxypropyl methacrylate. In contrast, 2-acrylamido-2-methylpropanesulfonic acid (AMPSA) **6A**, prepared by the reactions of SO_3 with isobutylene followed by the Ritter reaction with acrylonitrile (134), is quite hydrolytically stable.

AMPS or 2-acrylamido-2-methyl propanesulfonate **7A** is highly reactive in both homo- and copolymerizations and can be incorporated by homogeneous, solution, or emulsion polymerization techniques. With advances in CLRP, acrylamido monomers such as AMPS (specifically in its Na+ form) are now easily polymerized in a controlled manner, as homopolymers, statistical copolymers, or block copolymers. Indeed PAMPS and its copolymers may be prepared under facile conditions via RAFT, directly in water employing CTP and V-501 as the CTA/initiator pair (42,44,45). Applications include improving emulsion stability (135), flocculation (136), improving dry strength in paper (137), sludge dispersal in boiler-water treatment (138), and silt control in cooling water systems (139). Copolymers of the sodium salt of AMPS with acrylamide copolymers (140–142) and ampholytic terpolymers (143,144) have potential in oil-field applications and in superabsorbency, respectively.

Other Anionic Carboxylate Monomers. The anionic carboxylate monomers **8A** and **9A**, prepared by the Ritter reaction involving acrylonitrile or methacrylonitrile and 3,3-dimethylacrylic acid have been copolymerized in the sodium salt form to yield calcium-tolerant copolymers with utility in enhanced oil recovery (145–148). Monomer **8A**, for example, has been copolymerized with **7A**

under RAFT conditions to yield novel stimuli-responsive water-soluble polymers capable of reversible pH-induced micellization (42,44). Sodium 4-vinylbenzoate **12A** has also been polymerized under both NMP and ATRP conditions (133,149).

Other examples of specialty anionic monomers shown in Figure 33 include salts of vinylphosphonates **10A**, vinylphenolates **11A**, vinyl benzoate **12A**, maleic acid **13A**, 3-vinyloxypropane sulfonates **14A**, and *N*-vinylsuccinimidic acid **15A**.

Cationic Polyelectrolytes. Cationic polymers are a class of polyelectrolytes that derive their unique properties from the density and distribution of positive charges along a macromolecular backbone as well as molecular weight. Chain conformation and solubility depend on the extent of ionization and interaction with water. Cationic functional groups can strongly interact with suspended, negatively charged particles or oil droplets and are useful for many applications (76,150–153) including waste treatment and paper making. A number of the most common monomers utilized for preparation of cationic polyelectrolytes are shown in Figure 38.

Polymethacrylic Cationics.

Poly(2-(dimethylamino)ethyl methacrylate). 2-(Dimethylamino)ethyl methacrylate [DMAEMA, **1C** (Fig. 38)] is readily polymerized under a variety of conditions such as conventional free radical polymerization (154), living free radical polymerization, specifically ATRP and RAFT, anionic polymerization (155), group transfer polymerization (156) and oxyanionic polymerization (157,158). For example, conventional free radically prepared copolymers of **1C** with *N*-vinyl-2-pyrrolidone (159,160), *N*-phenylmaleimide (161), and ethylene (162) have been reported. While 1C is readily polymerized via both ATRP and RAFT, to date ATRP has received the most attention as a means of preparing controlled-structure homo- and copolymers of **1C** in both aqueous (163) and organic media (164,165) with Cu(I) species as the catalysts employing a variety of different ligands (166–169). It should be noted that under certain conditions **1C** may undergo a transesterification reaction when polymerized via ATRP in MeOH and MeOH/H_2O mixtures (170). It is also possible to directly polymerize quaternized versions of **1C** via aqueous or mixed H_2O/MeOH ATRP (171). **1C** has been successfully polymerized via RAFT in EtOAc with CTP and V-501 as the CTA/initiator pair (172), and also under bulk conditions with cumyl dithiobenzoate and AIBN (173).

Synthesis of Other Amine-Containing Polymethacrylates. Figure 38 shows the structures of other amine-containing methacrylic monomers. Like poly(2-dimethylamino)ethyl methacrylate) (PDMAEMA), the homopolymers of these monomers are water-soluble, albeit under somewhat more limiting conditions. The copolymerization of **2C** with methacrylic acid has been reported under conventional free radical conditions in methanol using AIBN as the initiator (174). The controlled polymerization of **2C**, **3C**, **4C**, and **5C** have been reported under GTP conditions (175–179) and oxyanionic conditions (15,180). Homopolymers of **2C** have also been prepared under ATRP conditions (181). Interestingly, **6C** can be polymerized in a controlled fashion by both oxyanionic and classical anionic techniques even though it contains a secondary amine species (180,182).

Aqueous Solution Characteristics. The behaviors of the polyamine methacrylates in aqueous media are both interesting and varied. The polymer

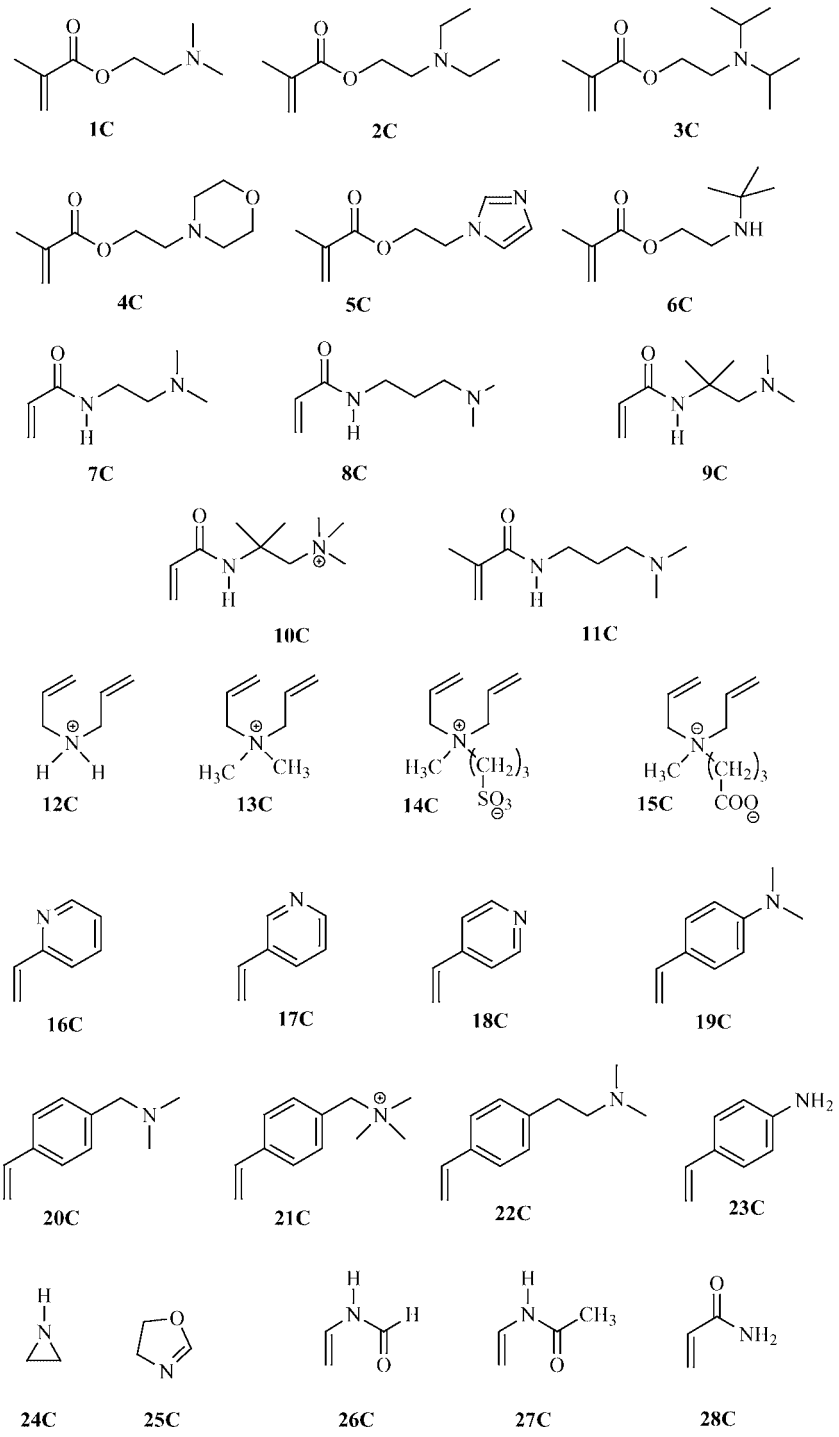

Fig. 38. Chemical structures of common amine-containing monomers (**1C–23C**) and reactive precursors (**24C–28C**) to amine-containing polymers.

from **1C** is a weak polybase which is soluble over most of the useful pH range. However, in its non ionized form, and like most nonionic water-soluble polymers, it shows inverse-temperature water-solubility. The neutral polymer has a lower critical solution temperature (LCST), or cloud-point (C_p), between ~32 and 47°C depending on its molecular weight. In its protonated form, however, it remains readily soluble up to 100°C.

The other "common" tertiary amine polymethacrylates, PDEAEMA, PDiPAEMA, and PMEMA from **2C** and **3C**, are also responsive to applied stimuli in aqueous solution. These are only soluble in aqueous media at low pH, ie under those conditions in which the tertiary amine residues are protonated and thus cationic. Under basic conditions, where the 3° amine groups are neutral both species are hydrophobic and thus phase separate. So, simply adjusting the pH of an aqueous solution for homopolymers derived from **2C** or **3C** results in phase separation. Polymers from **4C** and **1C** are soluble over the entire useful pH range, but do have an LCST in the range 34–54°C, the exact C_p being molecular weight dependent. However, the former is also susceptible to changes in electrolyte concentration. Certain salts such as sodium sulfate readily "salt out" this polymer inducing a phase change (183). These various responses to different applied stimuli have been exploited for the synthesis of novel self-assembled polymeric micelles.

Poly(meth)acrylamido Cationics. (Meth)acrylamido species are one of the most important commercial class of water-soluble monomers with wide-ranging applications. Cationic polyacrylamides are most often prepared by the normal free radical polymerization of the amine-containing monomer, and then most often in a copolymerization. For example, the protonated form of **9C** and the monomer **10C** are both readily copolymerized with **28C** to yield high molecular weight statistical copolymers in which the molar composition is virtually identical to the feed composition (184,185).

The controlled polymerization of amine-containing (meth)acrylamido monomers has, until recently, remained elusive. None of the classical living techniques can be employed and of the controlled free radical polymerization techniques only RAFT has the versatility required for this particular class of monomer. Even so, there is only one report of the controlled polymerization of an amine-containing monomer, namely *N*-[3-(dimethylamino)propyl] methacrylamide, **11C** (186). **11C** is readily homopolymerized in aqueous media (neutral pH) at 70°C using 4-cyanopentanoic acid dithiobenzoate as the RAFT CTA and V-501 as the azo initiator, at an initial molar ratio of 5/1. Under these conditions reasonable control was attained as evidenced by the molecular weight control and resulting polydispersities. Control over the RAFT polymerization of **11C** was attained by conducting the polymerizations in a buffered solution (pH = 5.0). Under these conditions possible side reactions such as monomer hydrolysis followed by aminolysis of the CTA is essentially eliminated (such side reactions have been previously shown to be significant in the homopolymerization of **28C**) (47,186).

Amine functionality can also be introduced into acrylamido polymers via post-polymerization modification of polyacrylamide from monomer **28C**. Strategies include the Mannich reaction (introduction of tertiary-amine functionality), Hofmann degradation (yields polyvinylamine residues) and transamidation reactions. The Mannich reaction is reversible; however, subsequent quaternization of the Mannich product prevents the reverse reaction (187).

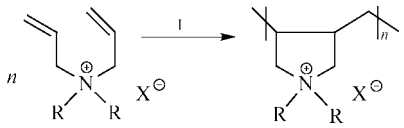

Fig. 39. Cyclopolymerization of diallyl ammonium monomers.

Polydiallylammonium Cationics. Diallyl ammonium monomers, such as **13C**–**15C** in Figure 38, can be polymerized via so-called cyclopolymerization (Fig. 39) (188).

DADMAC **13C**, for example, can be readily polymerized under these cyclopolymerization conditions to yield PolyDADMAC in which a structure composed of 5-membered *N*-heterocycles predominates. **13C** will readily polymerize at ∼35°C employing ammonium persulfate as the initiator. **13C** is readily copolymerized with other diallyl monomers, with acrylamido monomers such as **28C** or diacetone acrylamide, or quaternized **1C**. Extensive reviews of cyclopolymerization and cyclocopolymerization can be found in Reference 188. Recent examples of cyclocopolymerization with sulfobetaine (**14C**) and carboxybetaine (**15C**) diallyl ammonium monomers are given in References (188–191).

Polyvinylpyridines

2-, 3- and 4-vinylpyridines (**16C**, **17C**, and **18C**) are all readily polymerized under normal free radical conditions. Of these species, **18C** has been the most widely studied. An extensively studied derivative of **17C** is 2-methyl-5-vinylpyridine (or 6-methyl-3-vinylpyridine) and its quats (192–195). For example, 1,2-dimethyl-5-vinylpyridinium methyl sulfate is readily polymerized in aqueous solution at room temperature with common free radical initiators such as AIBN or potassium persulfate. In fact it will spontaneously polymerize at concentrations in excess of ∼75% (196).

It is also possible to prepare vinylpyridine-based (co)polymers in a controlled fashion with predetermined molecular weights and narrow molecular weight distributions. For example, the controlled polymerization of **16C** and **18C** is possible via anionic polymerization (197–201).

Also, **16C**, **17C**, and **18C** have been polymerized via nitroxide-mediated controlled radical polymerization employing a variety of different nitroxides (202–209). For example, **17C** may be polymerized under bulk or solution conditions (in ethylene glycol) employing 2,2,6,6-tetramethylpiperidin-1-oxyl (TEMPO) as the persistent free radical and benzoyl peroxide as the free radical initiator to yield controlled structure homopolymers with narrow molecular weight distributions (210). More recently, the controlled polymerization of **18C** using a β-phosphonylated nitroxide, namely *N*-*tert*-butyl-*N*-(1-diethylphosphono-2,2-dimethylpropyl) nitroxide, was reported and was shown to be extremely effective for the homopolymerization of **17C** as well as facilitating the synthesis of novel AB diblock copolymers (202).

The controlled polymerizations of **16C** and **18C** have also been reported using RAFT chemistry (211,212). Triblock copolymers of **17C** and styrene were prepared

using dibenzyl trithiocarbonate as the RAFT CTA and AIBN as the azo initiator. The RAFT polymerization of **16C** and **18C** has additionally been achieved using cumyl dithiobenzoate and AIBN as the CTA/initiator pair (212). Homopolymers of **16C** and **18C** were prepared under bulk conditions at 60°C. Excellent control over both the molecular weight and molecular weight distribution was observed with the polydispersity indices for the homopolymers all in the range 1.10–1.25. It was also shown that the corresponding AB diblock copolymers of **16C** with **18C** could be readily prepared using either homopolymer as the macro-CTA for the polymerization of the second block (212).

As well as NMP and RAFT, **16C** and **18C** have been polymerized via ATRP (213–215). For example, **18C** may be polymerized in a controlled fashion using 1-phenylethyl chloride as the initiator and CuCl/5,5,7,12,12,14-hexamethyl-1,4,8,11-tetraazamacrocyclotetradecane (Me_6[14]aneN_4) as the catalyst/ligand pair in propanol at 40°C (215).

Polymers from **16C** and **18C**, and presumably **17C**, may be hydrogenated to form the corresponding polyvinylpiperidines (6), or oxidized to the corresponding water-soluble *N*-oxide. The polyvinylpyridines may also be readily derivatized via quaternization with an appropriate alkylating agent, such as methyl iodide. The monomeric quats are readily water-soluble but can be prone to spontaneous polymerization above critical concentrations (216). The nature of the counterion can also affect the propensity of the quaternized monomers to autopolymerize.

Aqueous Solution Characteristics. The polymer from **16C** becomes water-soluble at a critical degree of ionization (protonation) of ca 30 mol% (217). In comparison, the polymer from **18C** only becomes water-soluble at an apparent degree of ionization of 70 mol%. The polymeric quats behave as strong polyelectrolytes and are readily water-soluble.

Amine-Containing Styrenic Monomers

Several amino-styrenic monomers are known; for example see **19C**–**23C** in Figure 38. The simplest of these, the primary amine species 4-vinylaniline (or 4-aminostyrene), **23C**, is susceptible to polymerization under conventional free radical conditions, as are **19C**–**22C**. For example, the UV-induced graft polymerization of **23C** from a Si surface was recently disclosed (218). These monomers tend to polymerize most effectively in aqueous media in their hydrochloride salt form. Given the reactive nature of the amine functionality in **23C** it is also a suitable precursor for the synthesis of novel amide-based styrenics (219). The controlled polymerization of **19C**, **20C**, and **22C**, under classical anionic conditions is also possible (220,221). For example, AB diblock copolymers of **22C** with styrene can be prepared at −78°C, in THF using cumyl potassium as the initiator with **22C** being polymerized first. Near-monodisperse *n*-butyl quats of **19C**, **20C**, and **22C** have also been reported. These were prepared by the post-polymerization modification of polymers from **19C**, **20C**, and **22C** with *n*-butyl bromide (220).

Homo and copolymers comprised of amine-containing styrenic monomers have also been reported by controlled free radical polymerization techniques. Both NMP and RAFT have been employed with varying degrees of success. For example, **20C** was block copolymerized with sodium 4-styrenesulfonate which was

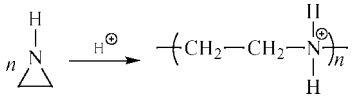

Fig. 40. Polymerization of ethyleneimine.

employed as a macro-initiator and had been prepared using TEMPO in a 3:1 ethylene glycol water mixture at 120°C with potassium persulfate as the initiator (133). More recently, McCormick and co-workers reported the synthesis of novel diamine AB diblock copolymers comprised of **21C** with the protonated form of **20C** (48). These were prepared directly in aqueous media using CTP as the RAFT CTA and V-501 as the azo initiator. Well defined block copolymers were obtained with excellent control over the molar mass and molar mass distribution. Also, new RAFT-synthesized AB diblock copolymers of *N*,*N*-dimethylacrylamide and **20C** have been reported (222). This work demonstrated the importance of blocking order in RAFT polymerizations when the two comonomers are from different monomer families. While highly efficient blocking was achieved when *N*,*N*-dimethylacrylamide was polymerized first, very poor crossover efficiencies were seen in the case of the styrenic-based macro-CTA.

Aqueous Solution Characteristics. The amine monomers tend to be water-soluble only in their protonated or quaternized forms. For example, homopolymers from **19C** are water-soluble at pH's below ~5.3; above this value they are hydrophobic and phase separate. This behavior is completely reversible and has been exploited by several researchers for the preparation of reversible pH-induced supramolecular nanoassemblies (48).

Poly(ethylene imine). Poly(ethylene amine) (PEI) is the simplest polybase. It can be prepared directly via the acid-catalyzed polymerization of ethyleneimine (aziridine, **24C**) (Fig. 40). **24C** may be prepared via a number of routes with ethanolamine being a convenient precursor (223). The cationic polymerization of **24C** is very rapid due to the release of the ring strain associated with the monomer. However, the synthesis of PEI under these conditions leads to highly branched structures due to chain transfer reactions involving the —NH— species in the polymer backbone. Cyclic products can also be produced under these conditions. Copolymerization with an appropriate comonomer can reduce the degree of chain branching (224).

The polymerization of suitable precursor monomers, with subsequent conversion to PEI, is the only route to truly linear products. The most common precursors studied are the substituted oxazolines (Fig. 41), with the 2-substituted-2-oxazolines **25C** being the most thoroughly investigated (225).

Polyvinylamine. Along with PEI, polyvinylamine (PVAm) prepared from **26C** is the simplest polybase, and is related to PEI in a similar manner to the

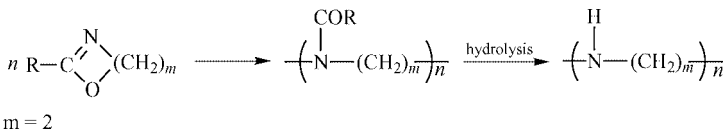

Fig. 41. Polymerization of substituted oxaolines.

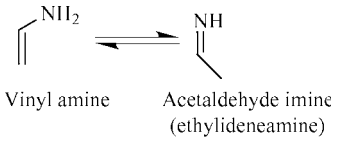

Fig. 42. Vinylamine tautomerization.

relationship between PVOH and PEO, ie as constitutional isomers. Also like PVOH, PVAm cannot be prepared by the direct polymerization of the vinyl amine monomer because it very readily tautomerizes to acetaldehyde imine (Fig. 42).

As such, PVAm must be prepared by indirect methods employing protected monomers which, once polymerized, can be converted to PVAm. The most common employed precursors are the *N*-vinylamides (eg **26C** and **27C**) which after polymerization may be converted to PVAm via hydrolysis. For example, suitable precursors include poly(*N*-vinylacetamide) (PNVA) (226) and poly(*N*-vinylformamide) (PNVF) (227). PNVF is more readily hydrolyzed than other *N*-vinylamides. It is also possible to prepare PVAm via the Hofmann degradation of polyacrylamide prepared from **28C** (228). These precursor polymers are typically prepared using normal free radical polymerization chemistries and as such have broad molecular weight distributions. Recent advances in controlled radical polymerization methodologies, and especially the RAFT technology, should facilitate the synthesis of controlled-structure near-monodisperse PVAm. For example, it is now possible to polymerize **28C** in a controlled fashion under RAFT conditions (49,50). There is also at least one report detailing the RAFT polymerization of **26C** (229).

Miscellaneous Cationic Monomers

While the most common, amine-based species are not the only type of cationic monomers/polymers. There are several other functional species capable of yielding cationic species, namely the sulfonium (230), phosphonium (231,232), and pyrylium (233) species. Several examples of such species are shown in Figure 43.

For example, the statistical free radical polymerizations of **32C** and **33C** with *N*-isopropyl acrylamide were successfully conducted in DMSO employing AIBN at 50°C (234,235). This yielded readily water-soluble copolymers with a thermosensitive component. Such copolymers are also interesting since they can exhibit antibacterial properties against *Escherichia coli* and *Staphylococcus aureus* (234,236,237). Novel water-soluble sulfonium monomers such as **31C** can be polymerized and used as precursor polymers for the synthesis of light-emitting polymers such as poly(2,5-bis(trimethylsilyl)-1,4-phenylenevinylene (238).

Polyzwitterions. Amphoteric water-soluble polymers are polymeric systems containing both anionic and cationic charges. Such polyzwitterions may be subdivided into two major families, the *polyampholytes* and the *polybetaines* (239). Each of these groups may be further subdivided into specific types of each (see below). Figure 44 shows a number of monomers which have been used in pairs (cationic with anionic) to form polyampholytes.

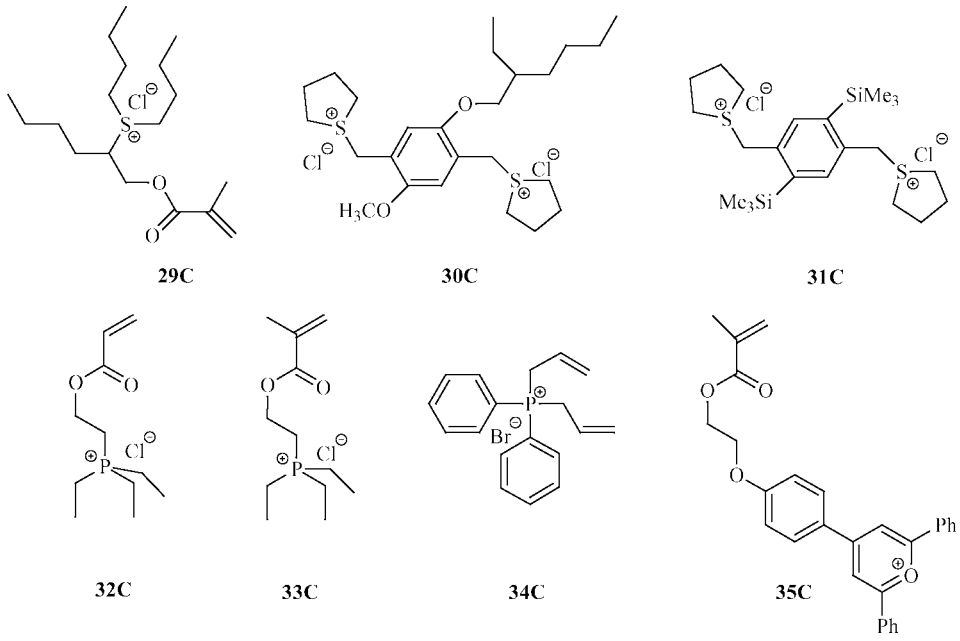

Fig. 43. Specialty cationic monomers.

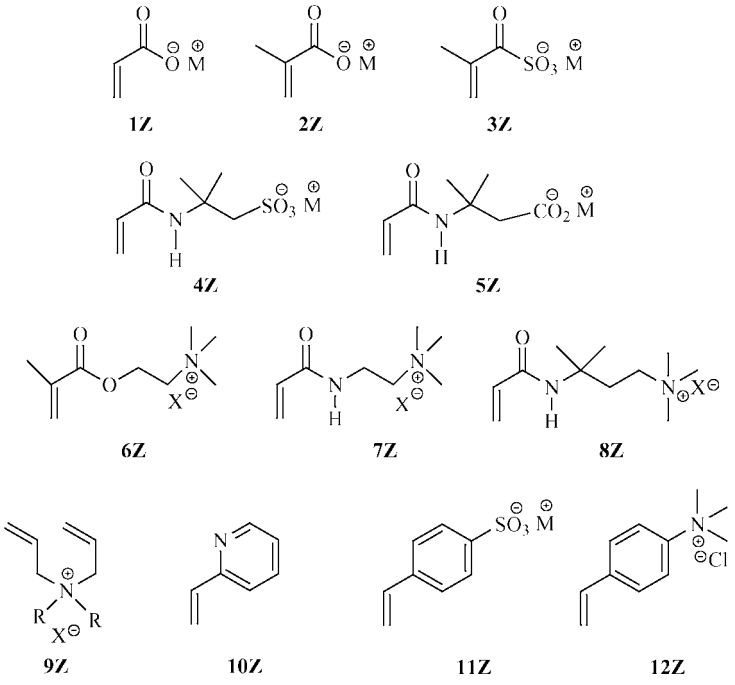

Fig. 44. Monomer pairs utilized in preparing polyzwitterions.

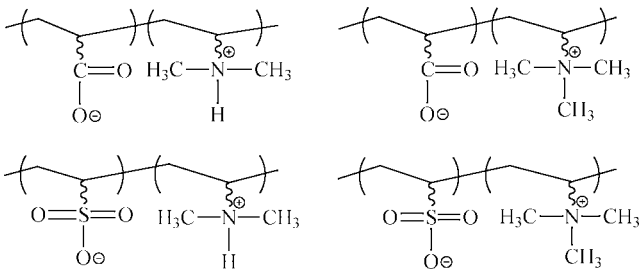

Fig. 45. Polyampholyte structures.

Polyampholytes. Polyampholytes are those materials in which the anionic and cationic charges reside on *different* mer units. Due to this, polyampholytes may be either charge balanced or unbalanced depending on the molar ratio of the anionic/cationic monomers. Polyampholytes may also be subdivided into four inherently different types. There are those in which the anionic and cationic residues may be neutralized, those where the cationic residue may be neutralized but the anionic residue is insensitive to changes in pH, those in which the anionic charges may be neutralized but the cationic residues are insensitive to pH changes, and finally those in which both the anionic and cationic residues are insensitive to changes in the pH (see Fig. 45).

Synthesis. Polyampholytes are most readily prepared by the direct statistical copolymerization of anionic and cationic monomers typically in aqueous media, via conventional free radical polymerization. Examples of such materials were first reported in the 1950s (240–244). Using this approach a wide range of copolymers and terpolymers, often with a neutral hydrophilic monomer such as acrylamide, have been reported. For example, early reports of statistical polyampholytes include the methacrylic acid-*stat*-2-(dimethylamino)ethyl methacrylate copolymers (245), from **1Z** and **2Z** with **6Z** and the *N*,*N*-diethylallylamine-*stat*-acrylic acid copolymers from **1Z** and **6Z** (246). More recently, synthesis and properties of novel polyampholytic terpolymers have been described (247–250). For example, the aqueous solution properties of novel ampholytic terpolymers of acrylamide, sodium 3-acrylamido-3-methylbutanoate **5Z** and 3-(acrylamidopropyl)trimethylammonium chloride **8Z** have been studied in detail (187).

It was not until the 1970s that the first block polyampholytes were reported (251,252). Anionic polymerization was used to prepare precursor AB diblock copolymers of 2-vinylpyridine **10Z** with trimethylsilyl methacrylate (TMSMA). The TMSMA residues were subsequently hydrolyzed to poly(methacrylic acid) residues to yield the corresponding AB diblock polyampholytes. Anionic polymerization has also been employed to prepare other block polyampholytes (253–258). GTP has also been successfully employed for the preparation of block polyampholytes. As with anionic polymerization, protected acid monomers must be employed since methacrylic acid (MAA) cannot be polymerized directly by this technique. A variety of protected monomers have been reported to be suitable as a means of introducing MAA residues, with 2-tetrahydropyranyl methacrylate being the most effective (Fig. 46).

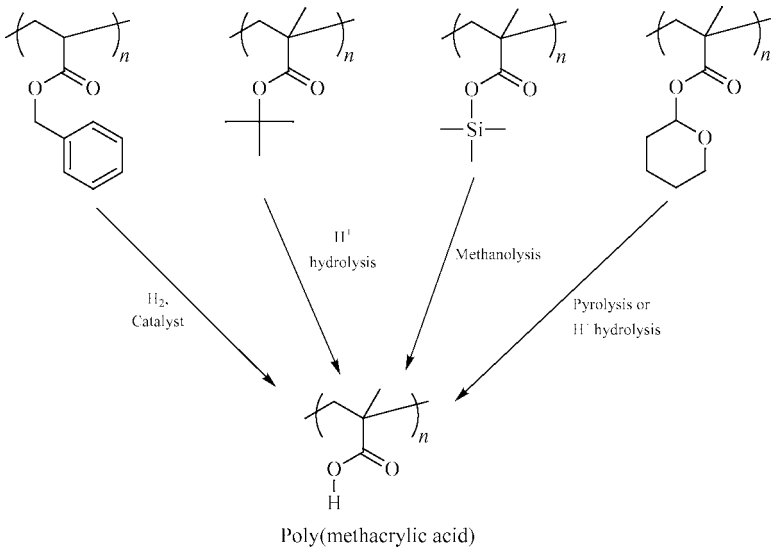

Fig. 46. Deprotection chemistry utilized to produce polymethacrylic acid or its salts.

For example, AB diblock and ABC triblock polyampholytes comprised of basic DMAEMA **6Z** and acidic MAA residues, and hydrophobic methyl methacrylate residues in the case of the triblocks, have been reported (128,259–262).

While these living polymerization techniques do offer the ability to prepare block polyampholytes they are both synthetically demanding and somewhat limiting with respect to monomer choice for example. There are a handful of reports detailing the synthesis of block polyampholytes using controlled/living polymerization techniques discussed earlier (Fig. 47). For example, Gabaston and co-workers have described the TEMPO-mediated SFRP of block copolymers of sodium 4-styrenesulfonate **11Z** with 4-(dimethylamino)methyl styrene **12Z** (133),

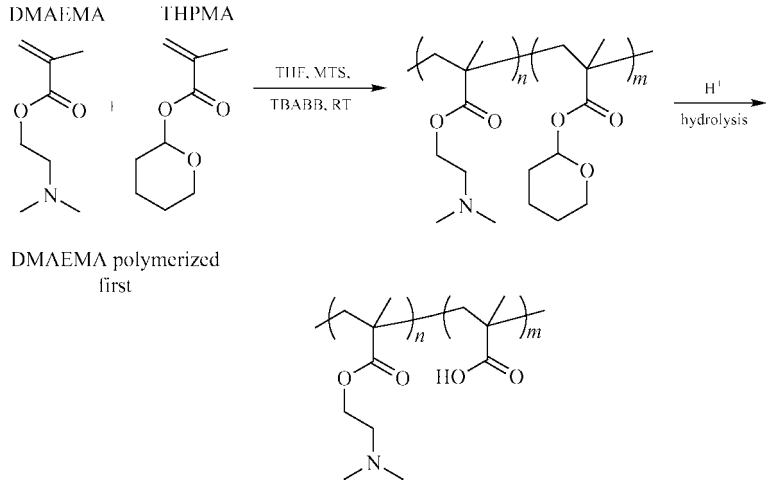

Fig. 47. GTP synthesis of AB diblock polyampholytes.

and several authors have reported the synthesis of block polyampholytes using ATRP although they still employed protecting group chemistry for the methacrylic acid residues (263–265).

Solution Properties. The aqueous solution behavior of polyampholytes is dictated by coulombic interactions between the basic and acidic residues. Polyampholytes have the ability to exhibit both polyelectrolyte and antipolylelectrolyte behavior in aqueous media. Which type of behavior is exhibited depends on factors such as solution pH, copolymer composition, the relative strengths of the acidic and basic residues, and the presence/absence of low molecular weight electrolyte (239). A feature of polyampholytes—in particular those comprised of weak acidic and basic residues—is the so-called *isoelectric point*, or IEP. This is simply defined as the solution pH at which the polyampholyte is electrically neutral. Statistical polyampholytes often remain soluble at and around the IEP whereas block polyampholytes tend to be soluble above and below but insoluble at this critical pH. The IEP may be determined either by titration or by measuring the reduced viscosity as a function of pH—the IEP also represents the point at which the polyampholyte chain is in its most compact conformation and thus corresponds to the minimum in reduced viscosity (239,266). With a knowledge of the respective pK_a's and copolymer composition it is also possible to predict the IEP (267).

Polybetaines. *Polybetaines* are materials in which the anionic and cationic functional species are part of the *same* mer unit (Fig. 48). Because of this the number of anionic, or potentially anionic, residues is always exactly equal to the number of cationic residues. The cationic residue in polymeric betaines is typically a quaternary ammonium species. The anionic functionality can vary and leads to the classification of polymeric betaines as sulfobetaines (sulfonate functional group), carbo or carboxybetaines (carboxylate functional groups), phosphobetaines (phosphate functional group), and etheneolatebetaines (dicyanoetheneolate functional group) (239).

Synthesis. Betaine monomers may be prepared in a number of different ways. For sulfobetaines, the most common, and easiest, method is to react a monomer containing a tertiary amine residue with either 1,3-propanesultone or 1,4-butanesultone (268). This is an extremely facile reaction and proceeds readily at RT in common solvents such as THF or CH_3CN to yield the corresponding sulfobetaine monomer. Alternatively, the tertiary amine functionality may be reacted

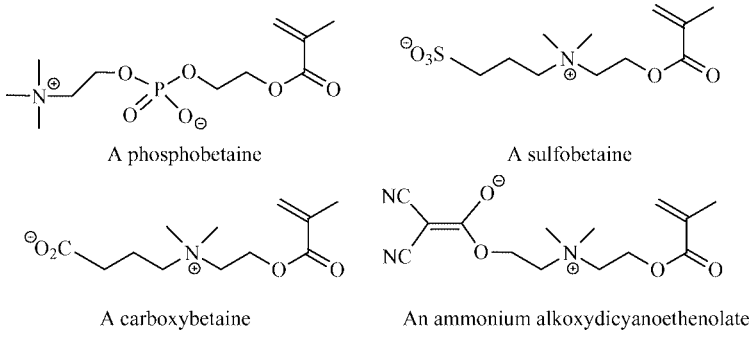

Fig. 48. General structures of selected methacrylic-based betaines.

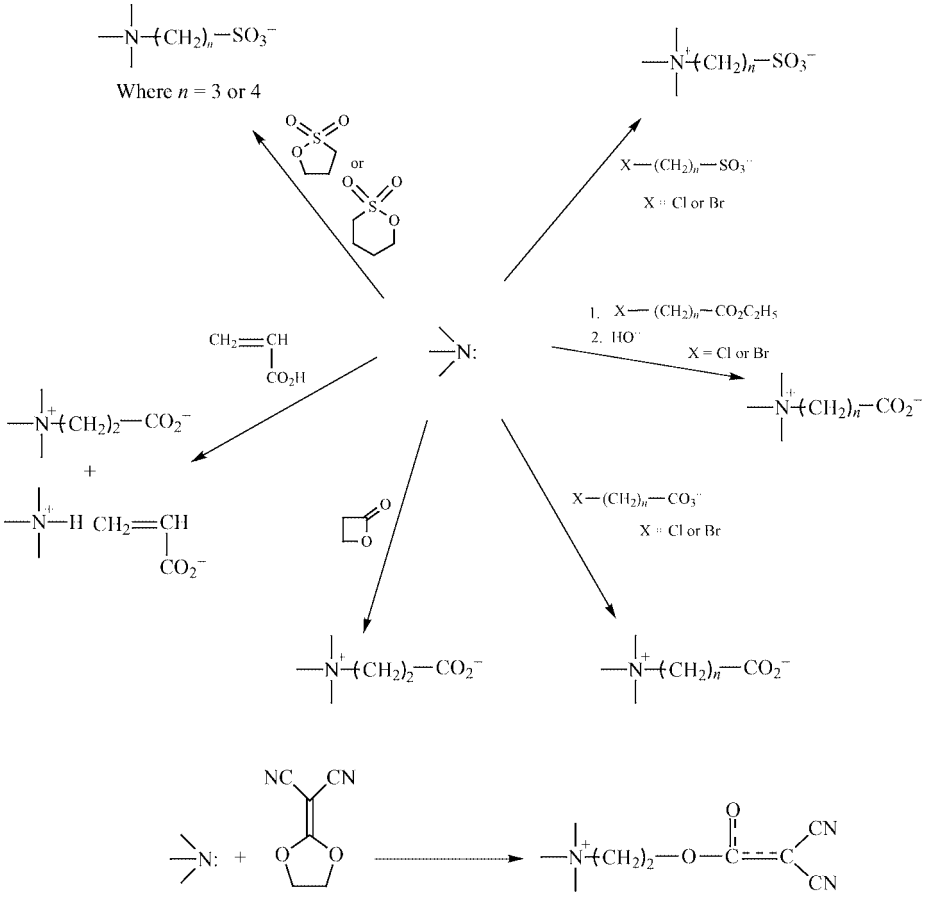

Fig. 49. General synthetic routes for sulfo/carboxybetaines.

with a haloalkylsulfonate species (269). Carboxybetaine monomers may be prepared via a number of different routes (Fig. 49). They may be obtained from the reaction of a suitable lactone (270) with a tertiary amine species, although this is somewhat limited to highly strained lactones to avoid competing nucleophilic attack at the carbonyl group. Alternatively they can be obtained from the Michael addition of a tertiary amine to acrylic acid (271), although again this route is prone to side reactions and simple salt formation. Perhaps the most versatile route for the preparation of carboxybetaines involves the reaction of a tertiary amine with a haloalkylcarboxylate to yield the carboxy betaine directly, or by reaction with the corresponding haloalkylester to yield the quaternized species followed by ester hydrolysis to yield the carboxybetaine (272,273).

Phosphobetaine monomers may also be prepared via a number of routes (239,274). Probably the most common phosphobetaine monomer is 2-(methacryloyloxy)ethyl phosphorylcholine (MPC), although other derivatives are also known (275–278). MPC is prepared from the reaction of 2-hydroxyethyl methacrylate with 2-chloro-2-oxo-1,3,2-dioxaphospholane, followed by ring

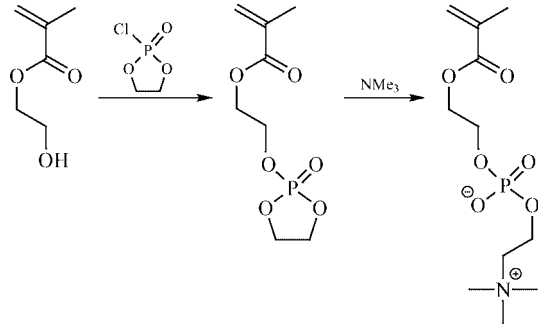

Fig. 50. Synthesis of MPC.

opening of the intermediate phospholane with trimethylamine (Fig. 50). This is a general synthetic procedure which can be applied to any alcohol functional monomer. There are very few examples of the dicyanoetheneolate betaines. These particular species are prepared from the reaction of a tertiary amine monomer with 2,2-dicyanoketene-1,2-ethylene acetal (279–281).

Polymeric betaines are most readily prepared by the direct polymerization of the betaine monomers, typically in aqueous salt solution. Since their initial report in 1957, by Ladenheim and Morawetz (282), there have been a large number of polymeric betaines reported based on many different families of monomers (239). Polymeric betaines may also be prepared under condensation polymerization conditions thus yielding polymers in which the betaine functionality is attached directly to the (co)polymer backbone (283–285).

Controlled structure polymeric betaines were reported for the first time only recently (286). The first examples were those prepared from the post-polymerization modification of poly(2-(dimethylamino)ethyl methacrylate) (PDMAEMA), and its block copolymers, which had been prepared under GTP conditions (286,287). Initial reports detailed the modification of hydrophilic-hydrophobic block copolymers, but this was subsequently extended to the selective modification of diamino hydrophilic-hydrophilic block copolymers (276).

The *direct* polymerization of betaine monomers in a controlled fashion has been reported by ATRP (288–291), and, most recently, via RAFT (38,43,292,293). Methacrylic derivatives of carboxy-, sulfo-, and phosphobetaines have been prepared via ATRP, while RAFT is more versatile with respect to monomer choice, and examples of styrenic, methacrylic and acrylamido sulfobetaines have been disclosed.

Solution Properties. Zwitterionic polymers show interesting aqueous solution behavior. As a general rule, they are *insoluble* in pure water due to the formation on intra- and interchain ion contacts resulting in an ionically cross-linked network-type structure. Polyampholytes and polybetaines which are not soluble become soluble upon the addition of low molecular weight electrolytes, such as NaCl (Fig. 51). This dissolution process can best be understood in terms of the low molecular weight electrolyte penetrating the ionically cross-linked network whereupon the ions screen the net attractive interactions between the polymer chains and hence promote solubility. The addition of the salt also results in antipolylelectrolyte behavior, ie chain expansion upon the addition of the salt.

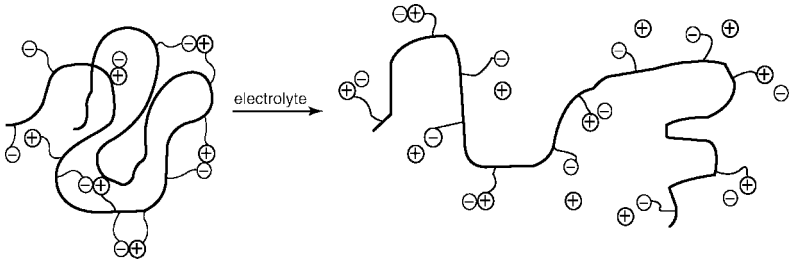

Fig. 51. Schematic illustration of polyampholyte response to added electrolyte.

Applications of Polyzwitterions. Polyzwitterions have wide-ranging applications. For example, statistical polyampholytes comprised of 2-vinylpyridine **10Z** and acrylic acid **1Z** have been evaluated as desalination membranes, while others have been used in sewage treatment, flocculation, coagulation, drilling fluids, enhanced oil recovery, and drag reduction.

Polymeric betaines have applications in areas similar to those of the polyampholytes described above. Additionally, phosphobetaines in particular have found application in the biomedical field. (Co)polymers comprised of MPC and various alkyl methacrylates (294,295) for example have been shown to exhibit both good bio and hemocompatability and have found application as coatings for medical devices such as catheters or arterial stents as well as materials for contact lens application. The success of MPC-based materials, and other phosphobetaines, is attributed to their biomimetic characteristics, ie their structural and chemical similarity to naturally occurring phospholipids. Recently, sulfobetaine-based materials were also shown to exhibit similar properties indicating that these bio/hemocompatability characteristics may not be unique to polymer phosphobetaines but perhaps to polybetaines in general (296).

Stimuli-Responsive Amphiphilic Polymers

Amphiphilic copolymers with appropriate balance of hydrophilic and hydrophobic sequences along or pendent to the micromolecular backbone can self-organize in water (297). In principle, intramolecular (closed) or intermolecular (open) associations can result. Intramolecular self assembly can, for example, lead to unimeric or multimeric micelles (Fig. 52**a,b**) with solution behavior resembling that of small molecule surfactants above their critical micelle concentration. Intermolecular assembly (Fig. 52**c**) often results in network or associative thickening behavior. Judicious choice of polymerization methods and conditions, monomer selection, post reactions, etc allows molecular construction of a wide variety of systems capable of self-assembly. Strategic placement of functional groups along the macromolecular backbone can also lead to reversible association in response to external stimuli including pH (298,299), ionic strength (300), light (301–303), temperature (304), and shear stress (297,305).

The earliest synthetic polymeric micelles, often referred to as *polysoaps*, were prepared as biological protein mimics (306–308). Copolymers synthesized

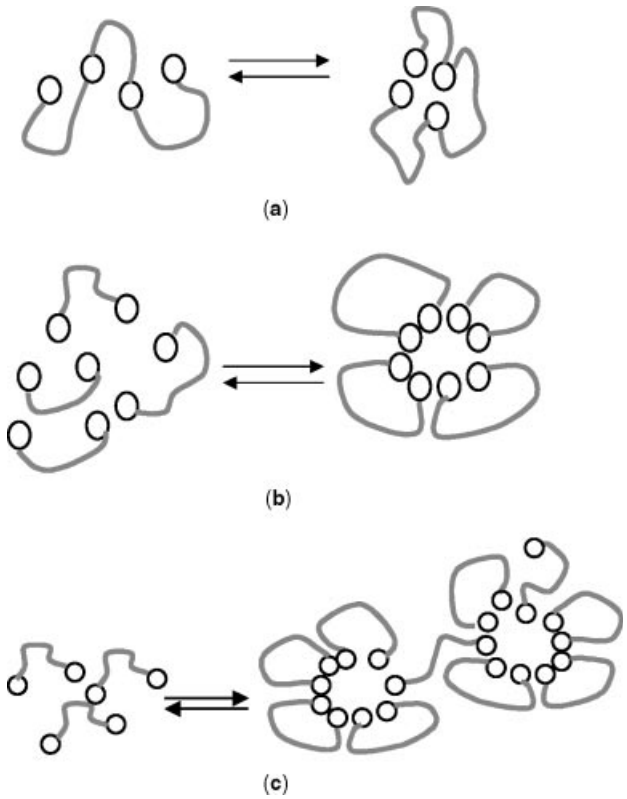

Fig. 52. Behavior of amphiphilic copolymers in response to stimuli.

by partial *n*-dodecylation of poly(2-vinyl pyridine) or by hydrolysis of poly(maleic anhydride-*alt*-alkylvinyl ethers) possessed surfactant-like properties in water (309–312). The initial associative thickeners, on the other hand, were prepared by (*1*) substitution of water-soluble cellulose derivatives with long chain alkyl groups (153,313–317) (*2*) partial esterification of poly(styrene-*alt*-maleic anhydride) with nonionic surfactants (318–321), (*3*) step growth polymerization of hydrophobically modified diisocyanates with poly(oxyethylene glycols) (322), or (*4*) by statistical chain growth free radical polymerization of a variety of hydrophobic and hydrophilic monomers under heterogeneous reaction conditions including emulsion polymerization (323,324) and micellar polymerization (325–330).

Despite a number of successes in preparing polymers with aqueous solution behavior depicted in Figs. 21**a** and 21**c**, little understanding of the nature of associative polymer domains existed prior to 1990. As well, studies of block copolymer associations had been limited to phase behavior in selective organic solvents. Since then, rapid developments in characterization of reversible microdomains via static and dynamic fluorescence spectroscopy (331–351), NMR spectroscopy (345,352–359) light scattering (171,175,360–364), and rheological techniques (365–370) have led to a better understanding of the structural parameters governing assembly/disassembly in water. Likewise, the development of

facile controlled/living free radical polymerization techniques for preparing block copolymers with well-defined structures has led to better models for study.

It can be established that the extent of closed or open associations depends on the architectures of the macromolecular chains. Molecular parameters affecting such associative behavior include hydrophilic and hydrophobic block lengths, placement and molecular weight of the segments, polymer concentration, flexibility and spacer lengths side-chain functionality. Responsiveness to pH, electrolyte, and to temperature changes depends markedly on the nature of the functional groups (cations, anions, zwitterions), their proximity to hydrophilic or hydrophobic units, and the ionic strength of the surrounding aqueous media. Some theoretical models have been put forth that describe unimolecular micelle formation progressing to bridged micelles and eventually networks (371–373).

Statistical Amphiphilic Polymers

Statistical amphiphilic polymers with ionic charges along the macromolecular backbone represent most of the stimuli-responsive systems reported in the literature. In principle, hydrophilic monomers from Figures 27, 33, 38, 43, or 44 can be copolymerized with hydrophobic comonomers or macromonomers under conditions allowing sufficient incorporation of the latter. The most successful methods have been "micellar" polymerization (324,325,347,348) in which high concentrations of surfactants are added to solubilize the hydrophobic monomer in the aqueous phase or emulsion polymerization utilizing macromonomers having amphiphilic character (323,324). Table 1 gives examples of associative polymers and the type of responsiveness reported in the literature. A comprehensive review (305) presents details of the synthetic routes to and behavioral characteristics of associative polyelectrolytes as determined by a wide variety of analytical techniques.

Well-Defined Amphiphilic Copolymers. Well-defined, controlled structure amphiphilic copolymers may be prepared using a range of polymerization techniques that includes anionic, cationic, and controlled free radical approaches. The materials may be "simple" AB diblock copolymers or more structurally complex species such as ABA or ABC triblock copolymers for example.

Hydrophilic-Hydrophobic Block Copolymers. These materials represent the "simplest" type of amphiphilic block copolymer. Materials are comprised of one block which is inherently hydrophobic, such as polystyrene or poly(methyl methacrylate), and a second block which is hydrophilic such as poly(methacrylic acid). For example, anionic polymerization may be employed for the synthesis of AB diblock copolymers comprised of styrene with 2- (438) or 4-vinylyridine (439). In the case of the styrene-2-vinylpyridine copolymers, self-assembly, under appropriate aqueous conditions, leads to the formation of block copolymer micelles with styrene forming the hydrophobic core and the 2-vinylpyridine forming the stabilizing corona. These block copolymer micelles are highly stable in 0.1 *M* HCl. Similarly, styrene–acrylic acid block copolymers may likewise be prepared via anionic polymerization using *tert*-butyl acrylate as a protected precursor for the acrylic acid residues. Such block copolymers exhibit similar self-assembly behavior in aqueous media (440,441). Other examples of such hydrophilic-hydrophobic

[a]Letters refer to repeating units in Figure 53.

block copolymers capable of supramolecular self-assembly include the poly(2-(dimethylamino)ethyl methacrylate-*block*-methyl methacrylate) (442). and the poly(3-(*N*-2-methacroyloyethyl)-*N*,*N*-dimethylammonio)propanesulfonate-*block*-methyl methacrylate) copolymers (287,443). In both instances the block copolymers were prepared via group transfer polymerization. Cationic polymerization also offers a route to amphiphilic vinyl ether-based AB diblock copolymers. For example, the synthesis and micellization properties of isobutyl vinyl ether-*block*-methyl tri(ethyleneglycol) vinyl ether copolymers have been reported (444). Also the self-association of AB diblocks comprised of methyl tri(ethyleneglycol) vinyl ether (hydrophilic block) and benzyl vinyl ether (hydrophobic block) have

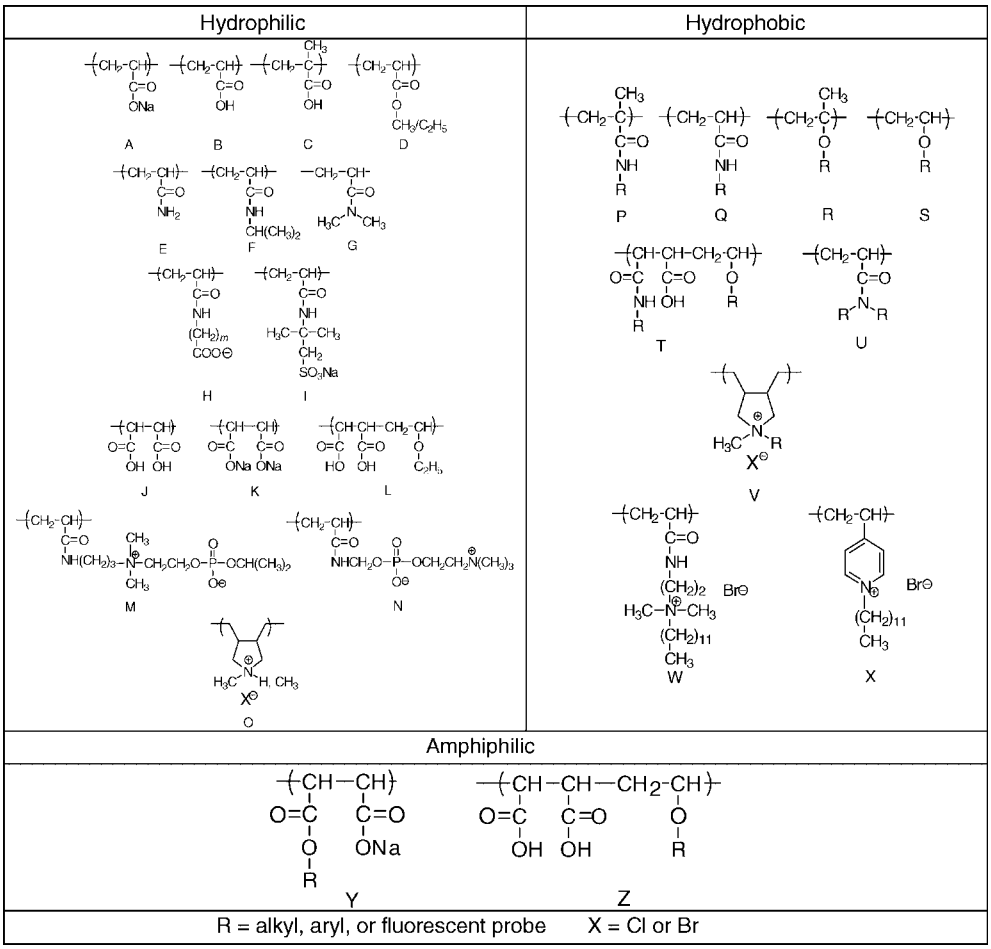

Fig. 53. Polymer segments utilized in statistical polymers with stimuli-responsive associative behavior in water. For polymers incorporating a fluorescent probe the letters Fl are used in Table 1.

been investigated (445). In water, micelles with hydrodynamic diameters in the range 10–26 nm were observed depending on the molar composition of the block copolymer.

Hydrophilic/Tunably Hydrophilic/Hydrophobic Block Copolymers. The next level of complexity for amphiphilic block copolymers are those comprised of one block which is permanently hydrophilic with the second block being tunably hydrophilic/hydrophobic, ie under a set of conditions A, the second block is readily water soluble and thus the block copolymer exists as unimers, but upon the application of a certain stimulus (change in pH or temperature for example) to condition B the second block becomes hydrophobic. Provided appropriate block copolymer compositions are employed this will lead to self-assembly. Additionally, such behavior is typically completely reversible. While there are now numerous examples of such “smart” self-assembly these types of systems have not been

as thoroughly investigated as the inherently hydrophilic/hydrophobic species, with perhaps one notable exception being the PEO/PPO and PEO/PPO/PEO, PPO/PEO/PPO block copolymers.

Group transfer polymerization has proven to be an extremely useful technique for the synthesis of such AB diblock copolymers. For example, the synthesis of AB diblock copolymers in which the A block was 2-(dimethylamino)ethyl methacrylate (**1C** in Fig. 38) and the B block was either **2C** or **3C** in Figure 33 have been reported. **1C** is temperature responsive whereas **2C** and **3C** are both pH responsive. At low pH when both the tertiary amine blocks (**1C** + **2C** or **1C** + **3C**) are protonated the block copolymers are molecularly dissolved. Raising the solution pH above the p*K*a of tertiary amine residues for **2C** and **3C** renders these blocks hydrophobic and as such the block copolymers self-assemble to form micelles with the hydrophobic **2C** (or **3C**) residues in the core, stabilized by coronal chains of 1. Supramolecular self-assembly is completely reversible—lowering of the pH back below the respective p*K*a's results in molecular redissolution (183).

More recently controlled free radical polymerization methodologies have been employed for the preparation of novel "smart" AB diblock copolymers. Nitroxide-mediated polymerization was utilized for the synthesis of sodium 4-styrenesulfonate-block-sodium 4-vinylbenzoate block copolymer (133). These strong acid/weak acid species exhibit reversible pH-induced self-assembly, with the sodium 4-styrenesulfonate residues remaining ionized and thus permanently hydrophilic over the useful pH range whereas the sodium 4-vinylbenzoate block can be reversible protonated (the carboxylate residue has a pK_a ~4.0). The same block polymers can also be prepared via RAFT, albeit with somewhat more control. Other workers reported the preparation of such AB diblock copolymers as well as some analogous amine-based styrenic diblock copolymers, (48) shown in Figure 54.

Similarly, such AB diblocks may be prepared based on the acrylamido family of monomers. For example, the synthesis of novel AB diblock copolymers comprised of the two anionic monomers sodium 2-acrylamido-2-methylpropanesulfonate (AMPS) and sodium 3-acrylamido-3-methylbutanoate (AMBA) have been reported (42,44). By analogy with the styrenic block copolymers, these AMPS-AMBA species also exhibit reversible pH-induced self-assembly by virtue of the fact that the AMBA residues may be reversible protonated, switching the residues from a hydrophilic (high pH) to a hydrophobic (low pH) state. Similar AB diblocks of AMPS with sodium 6-acrylamidohexanoate which also exhibit pH-induced micellization have been reported by Yusa and co-workers (45) RAFT has

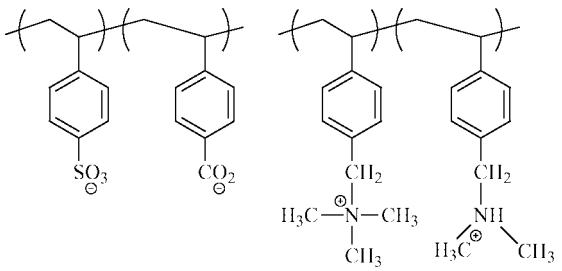

Fig. 54. Responsive AB block copolymers from ionic styrenic monomers.

additionally proven very useful for the preparation of AB diblock copolymers comprised of blocks from different monomer families. For example, AB diblocks of *N*,*N*-dimethylacrylamide (DMA) with *N*,*N*-dimethylbenzyl vinyl amine (DMBVA) were recently disclosed. These particular blocks are also capable of undergoing reversible pH-induced micellization (222). The DMA residues are nonionic, permanently hydrophilic whereas the styrenic-based DMBVA block is water soluble in its protonated form, but hydrophobic in its nonionized state. As such, simply raising the pH of an acidic solution of the block copolymer results in self-assembly and the formation of aggregates with the hydrophobic DMBVA blocks residing in the core which is stabilized by the DMA block. RAFT has also been utilized for the preparation of AB diblocks in which one of the blocks is a salt-responsive specie (293). For example, AB diblocks of *N*,*N*-dimethylacrylamide with 3-[2-(*N*-methylacrylamido)-ethyldimethylammonio]propanesulfonate (MAEDAPS).

Doubly "Smart" Block Copolymers. Doubly "smart" or responsive copolymers are those in which *both* the blocks of the copolymer are tunably hydrophilic/hydrophobic. As such this potentially facilitates the preparation of both normal and inverse micelles in the *same* solvent (NB: normal and inverse micelles are well known but switching between the two often requires a change of solvent). Some authors have termed such materials *"schizophrenic" block copolymers*. At present these represent the least studied of the amphiphilic block copolymers. Examples of such materials include the poly(2-(*N*-morpholino)ethyl methacrylate-*block*-2-(diethylamino)ethyl methacrylate) (177,446) and the poly(propylene oxide-*block*-2-(diethylamino)ethyl methacrylate) copolymers (447). A number of these types of block copolymers have been studied (263,264,448,449). As a representative example, a precursor poly(2-(dimethylamino)ethyl methacrylate-*block*-2-(*N*-morpholino)ethyl methacrylate) (DMAEMA-MEMA) copolymer was reacted with 1,3-propanesultone to yield the corresponding sulfopropylbetaine-MEMA block copolymer (Fig. 55) (448). At temperatures between 30 and 40°C a block copolymer comprised of an equimolar ratio of the two comonomers exists as molecularly dissolved unimeric chains. Upon raising the temperature above the cloud point of the MEMA block, the copolymer self-assembles forming polymeric micelles with the now-hydrophobic MEMA residues residing in the core with the sulfobetaine blocks in the corona.

Sulfobetaine-core micelles were obtained by lowering the solution temperature below 20°C at which point increased attractive electrostatic interactions result in phase separation of the sulfobetaine block and thus micelle formation. A similar doubly temperature responsive block copolymer, prepared via RAFT, was reported which was based on acrylamido monomers (292).

Shell and Core Cross-Linked Nanoassemblies. Shell or core cross-linked nanoassemblies represent a group of materials which can, in principle, be derived from any of the amphiphilic species described in the earlier sections. Clearly the self-assembled structures described above are dynamic species. However, one can envisage the need for "locked" structures for certain applications. One method to achieve this is via cross-linking of either the coronal or core chains. To facilitate either approach there must be a suitable reactive species in the core or corona susceptible to chemical modification after self-assembly.

Shell cross-linked micelles, also referred to as *knedel* or *SCK micelles*, were first reported in 1997 (450,451). For example, an amphiphilic AB diblock

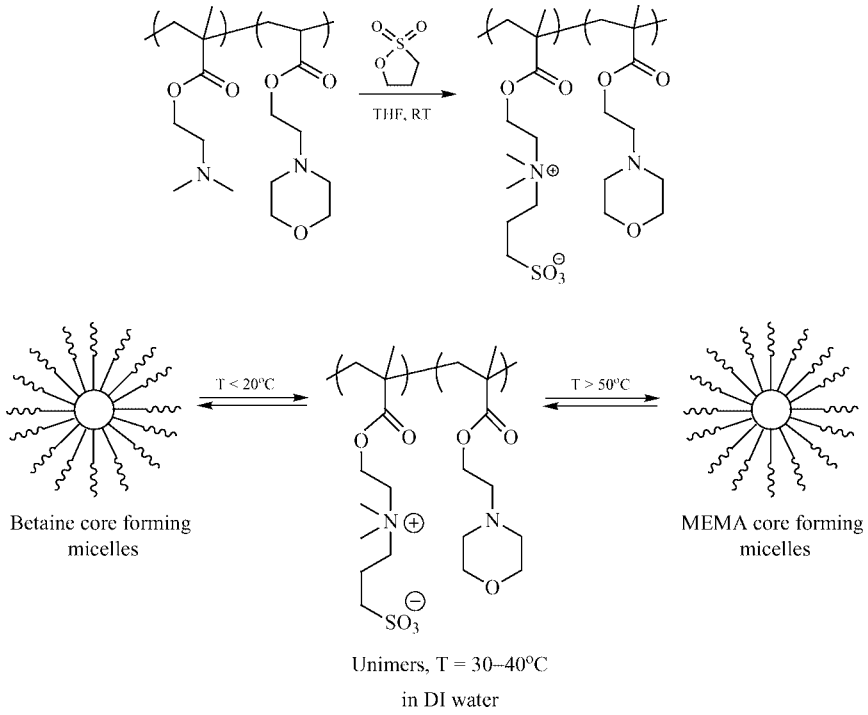

Fig. 55. An example of a "schizophrenic," methacrylic-based AB diblock copolymer and conditions leading to self-assembly.

copolymer comprised of hydrophobic polystyrene with hydrophilic partially quaternized poly(4-vinylpridine) was prepared by the sequential living anionic polymerization of styrene and 4-vinyl pyridine followed by quaternization of some of the 4-vinylpyridine residues with 4-vinylbenzyl chloride. Micelles are prepared by dissolving the quaternized block copolymer in a mixture of water and THF. Finally, shell cross-linking is accomplished by polymerizing the styrenic residues in the shell (present as a result of the quaternization reaction) in the presence of a free radical initiator (452). Examples in which the micelle coronal shell consists of hydrophilic acrylic acid residues, with a variety of hydrophobic cores, may be conveniently shell cross-linked using 2,2′-(ethylenedioxy)bis(ethylamine). Thus, cross-linking is achieved via an amidation reaction using a bifunctional primary amine (453–457). Other examples of these novel nanomaterials include those with polysilane cores and partially cross-linked poly(methacrylic acid) coronas (458,459), and micelles in which the reactive, cross-linkable functionality is either methacrylic acid or DMAEMA residues, with the actual cross-linking being achieved with bis-(2-iodoethoxy)ethane (460–462). The effectiveness of bis-(2-iodoethoxy)ethane as a cross-linking agent is illustrated in Figure 56.

Here so-called Type I and Type II zwitterionic SCK micelles can be prepared from the hydrophilic-hydrophobic precursors poly(2-(dimethylamino)ethyl methacrylate-*block*-2-tetrahydropyranyl methacrylate) (DMAEMA-THPMA) copolymers prepared via group transfer polymerization (128,129,461). Micellization of the DMAEMA-THPMA block copolymers in a water/THF mixture

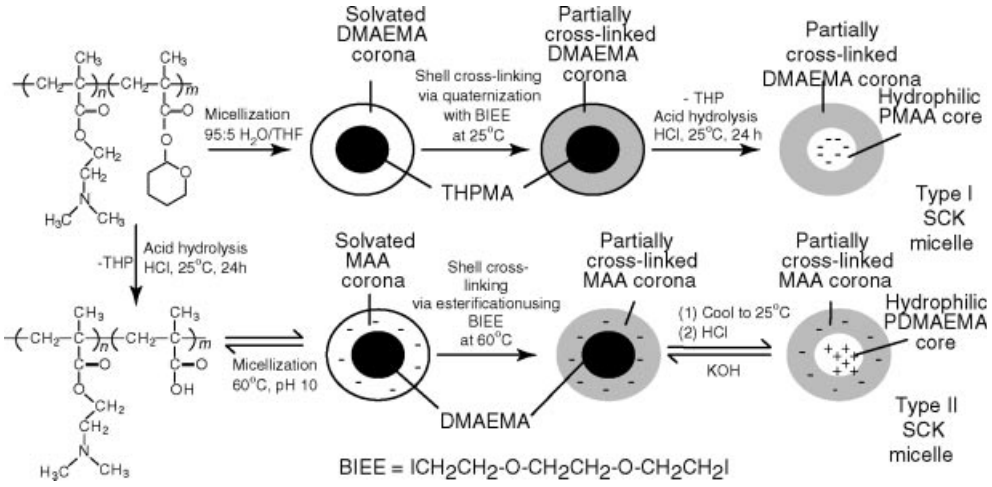

Fig. 56. An example of bis-(2-iodoethoxy)ethane as a cross-linking agent.

(95:5) results in the formation of core-shell structures in which the hydrophobic THPMA species forms the core and the hydrophilic DMAEMA species the corona. The reactive tertiary amine residues in the coronal may be cross-linked using bis-(2-iodoethoxy)ethane in a *quaternization* reaction (Menshutkin Reaction). Subsequent hydrolysis of the micelles cores leads to the formation of the Type I SCK species. Alternatively, the DMAEMA-THPMA precursor block copolymers may be initially deprotected to form the block polyampholytes. Heating an aqueous solution of this block polyampholyte above the cloud point of the DMAEMA residues results in the formation of inverse micelles in which the now-hydrophobic DMAEMA residues form the micelle core and ionized poly(methacrylic acid) chains form the corona. These carboxylate coronal chains may also be cross-linked using bis-(2-iodoethoxy)ethane, in this instance via an esterification reaction.

A potential drawback of shell cross-linking is the need to perform such chemistries under relatively dilute conditions to avoid the occurrence of inter-particle cross-linking. However it was recently demonstrated that SCK micelles could be successfully prepared at high solids with ABC triblock copolymers in which the *C block* forms the *micelle core*, the *A block the outer coronal chains* and the *cross-linkable B block the inner coronal chains*. Here, the outer A block is effectively acting as a steric barrier to inter-particle cross-linking (463,464).

Most recently the core cross-linking approach was adopted for the preparation of novel nanoassemblies derived from pH-responsive AB diblock copolymers prepared via RAFT (222). Here the A block was the permanently hydrophilic DMA species with the tunably hydrophilic/hydrophobic DMBVA forming the B block. In aqueous media, at high pH, these block copolymers form core-shell structures with the DMA residues forming the corona and the DMVBA chains in the core. Addition of a hydrophobic, difunctional, alkyl halide namely 1,4-bisbromomethylbenzene results in this species being sequestered into the hydrophobic core of the micelles where it reactions with the tertiary amine residues via the Menshutkin reaction to yield the core-cross-linked species. Successful core cross-linking was

verified via NMR spectroscopy, dynamic light scattering and transmission electron microscopy.

Concluding Remarks

Water-soluble polymers are an extremely important class of materials that permeate every facet of our lives. This class of materials encompasses a wide range of interesting species ranging from naturally occurring proteins, peptides, RNA, DNA, and sugars (carbohydrates) to complex synthetic nanoassemblies such as the well-defined core-cross-linked AB diblock polymeric micelles.

Clearly there have been significant advances in the field of water-soluble polymers since the previous edition of this encyclopedia. Arguably the most important development in recent years has been the discovery and application of more facile controlled/living polymerization techniques for the synthesis of highly functional, well-defined, model, materials. Of these, the controlled/living free radical polymerization techniques, and especially reversible addition–fragmentation chain transfer (RAFT) are proving to be especially versatile.

It is likely that such developments will continue to revolutionize water-soluble polymer synthesis in the years to come with chemists taking up the challenge to prepare ever more complex structures capable of supramolecular self-assembly for a wide variety of specialized applications.

WOOD COMPOSITES

Introduction

Wood composites can be defined as materials made by gluing together small pieces of wood, residue materials from wood processing operations, or other elements into larger materials to produce products with specific definable mechanical and physical properties. Wood composite products continue to be among the most widely utilized building materials throughout the world. They are commonly manufactured as lumber, flooring, roofing, paneling, palettes, decking, fencing, cabinets, furniture, millwork, structural beams, etc.

The increased number and importance of wood composite products are directly related to the decreased supply of high quality large timber, and as the quality and variety of wood composite products increases, and new applications for them are found, the trend toward increased use and importance of wood composites should continue. Wood composites offer numerous advantages over lumber. They can be produced from waste wood, agricultural residues, little used and low commercial value wood species, as well as smaller and fast growing trees, which can relieve stress on old growth forests that are increasingly unavailable for use. Also, the increased homogeneity of the raw material obtained by combining small wood elements allows a wide variety of composite products to be produced that have consistent, high quality properties. The properties can often surpass those of lumber (eg, have stronger and more uniform properties throughout the product, and be completely free of growth characteristics, weak spots, or defects such as knots), and often, the product can be produced with customized engineered properties, dimensions, and complex shapes (eg, complex roof shapes, cathedral ceilings, cantilevered supports).

The exact properties and the appropriate end use for a composite depend on the wood species and wood adhesive, and are very dependent on the size, shape,

and arrangement of the wood in the composite. In fact, the names of the composite products are mostly based on the wood geometry (wood shape and size) and their arrangement in the product, without involving the name of the wood species or adhesive. These elements (species and adhesive) can be changed with far less effect on properties than changing wood geometry or arrangement.

The procedure for making a wood composite begins with the raw wood being processed by removal of leaves and bark, then being cut into pieces of the desired size and shape, followed by drying to the desired moisture content, and then going through a sorting process to ensure the wood pieces meet the selection criteria. This process is followed regardless of wood species or wood geometry. Some composite processes allow more than 90% of the tree stem to be utilized with either small or large diameter trees, while lumber can only be produced from large diameter trees and even then typically less than 50% of the tree can be converted to the intended product.

A large number of product types having quite different properties can be prepared using the same wood element. Processing conditions to convert the wood element into a composite product will depend on the type of adhesive selected and/or if the product being produced is pressed, impregnated, extruded, etc. Therefore, wood composites can be classified into two major types: (*1*) wood bonded with thermoset adhesives and (*2*) wood combined with other materials such as cement and thermoplastics.

This article outlines some of the features and components of wood composites, describes some major wood composite products and properties, and describes some future directions in the wood composites industry. For additional information the reader is referred to some recent reviews (1–7).

Wood Bonded with Thermoset Adhesives

Wood composite products are conventionally manufactured from wood materials having various geometries (eg, fibers, particles, strands, flakes, veneers, and lumber) combined with a thermoset resin and bonded in a press (4). The press applies heat (if needed) and pressure to activate (cross-link) the adhesive resin and bond the wood material into a solid panel, lumber, or beam having good mechanical (strength and stiffness) and physical (form, dimensional stability, etc) properties.

Types of Wood Elements. A wide range of wood elements are employed to produce an increasing number of wood composite products. These elements can be broadly divided into two categories: “long grain” and “short grain” elements based on their size and shape (Table 1). The largest of the commonly used long grain wood elements, excluding lumber itself, is veneer. Shorter grain elements include strands, flakes, wafers, particles, and fibers. It should also be noted that increasing numbers of wood composite products are employing recycled wood such as sawdust and wood flour, which can be considered to be a separate wood type. Agrofibers are increasingly being employed as a raw material to produce commercial products similar to wood composites but with varying degrees of success. Some of the reasons for the rising interest in agrofibers include their low density and low abrasion, the potential to improve some properties such as stiffness, and potential cost savings when used as a filler for thermoplastics, and because many

Table 1. Types of Wood Elements Used In Wood Composites[a]

	Length		Width		Thickness	
Elements	cm	in.	cm	in.	cm	in.
Lumber	120–600	48–240	10–30	4–12	12.5–50	0.5–2
Veneer	120–240	48–96	10–120	4–48	0.5–12.5	0.02–0.5
Strands	1.27–7.5	0.5–3	0.63–2.5	0.25–1	0.25–0.625	0.010–0.025
Flakes	1.25–7.5	0.5–3	0.125–7.5	0.5–3	dito	0.010–0.025
Wafers	3.3	1.3	2.5–7.5	1–3	0.625–1.25	0.025–0.05
Particles	0.125–1.25	0.05–0.5	0.0125–0.125	0.005–0.05	0.125–1.25	0.005–0.050
Fibers	0.1–0.63	0.04–0.25	0.0025–0.0075	0.001–0.003	0.025–0.075	0.001–0.003

[a]Adapted from Ref. 7.

of these materials are the by-products of annual crops (8). In the United States and Canada wheat straw is currently the most important agrofiber furnish but many other agrofibers are of interest. Agrofiber preferences vary with availability and geographical region of the world (9). Soybean and cotton stalks, kenaf, flax, coffee and rice husk, hemp, fescue straw, ramie, and sugarcane bagasse are just some of the agrofiber raw materials being used or studied. Composites made from various agrofibers include low density insulating board, medium density fiberboard, hardboard, and particleboard (9,10). The mechanical properties for some agrofiber composites are reported in the literature, but additional research is needed, particularly on the long-term durability and weathering properties of these composites (10).

Thermoset Wood Adhesives

A wide range of adhesive types and chemistries are used to bond wood elements to one another (Table 2), but relatively few adhesive types are utilized to form the composites themselves. The vast majority of pressed-wood products use synthetic thermosetting adhesives. In North America the most important wood adhesives are the amino resins (qv), eg, urea–formaldehyde (UF) and melamine–formaldehyde (MF), which account for 60% by volume of adhesives used in wood composite products, followed by the phenolic resins (qv) eg, phenol–formaldehyde (PF) and resorcinol–formaldehyde (RF), which account for 32% of wood composite adhesives (12,13). The remaining 9% consists of cross-linked vinyl (X-PVAc) compounds, thermoplastic poly(vinyl acetates) (PVA), soy-modified casein, and polymeric diphenylmethylene diisocyanate (pMDI). Some products may use various combinations of these adhesives to balance cost with performance.

The thermosetting amino and phenolic adhesives are by far the predominant adhesives used in making wood composites. These adhesives are described below, but more detailed information is available elsewhere (4,7,16–21) (see ADHESIVE COMPOUNDS).

Urea–Formaldehyde (UF) Adhesives. UF resins are produced in a two-stage condensation polymerization process through the reaction of urea with excess formaldehyde. In the first stage of the polymerization process, urea and

Table 2. Characteristics of Major Wood Composites Bonded with Thermoset Adhesives

Types of composites	Raw materials[a]	Adhesives used	Structural (S) vs nonstructural (NS)	Applications	Typical thickness, mm (in.)	Typical density, kg/m^3 (lb/ft^3)
Particleboard	Particles	UF, MF, MDI	Mostly NS	Furniture, cabinetry, floor underlay, stair treads,	6–57 ($\frac{1}{4}$–2$\frac{1}{4}$)	640–800 (40–50)
Medium density fiberboard (MDF)	Fibers	UF, pMDI	NS	Furniture, kitchen and bath cabinet, fixtures, molding, millwork, laminate flooring	5–38, max. 76 (3/16–1$\frac{1}{2}$, max. 3)	640–800 (40–50)
Construction and industrial plywood	Softwood veneer, some hardwood	PF	S	Roof, floor, wall sheathing, single-layer floor, siding, floor underlayment, preserved wood foundations, laminated veneer lumber	6–31.5 ($\frac{1}{4}$–1$\frac{1}{4}$)	450–500 (28–31)
Decorative plywood	Hardwood veneer, some softwoods	UF, MF, RF, PVAc	Mostly NS	Decorative wall paneling, furniture, cabinetry, decorative flooring	6–19 ($\frac{1}{4}$–$\frac{3}{4}$)	400–880 (25–55)
Oriented strandboard (OSB)	Strand, flake, wafer	PF, pMDI	S	Roof, floor, wall sheathing, floor underlayment, siding, I-beams web stock, hybrid products	6–32 ($\frac{1}{4}$–11/8)	580–700 (36–44)
Laminated veneer lumber (LVL)	Softwood veneer	PF, pMDI	S	Floor and roof joists, roof ridge beams, roof truss chords, window and doorheaders, wood I-joist flanges, concrete form, scaffold planking, window and door joinery	19–75 ($\frac{3}{4}$–3 in.), 27–50 in. wide, up to 24.4 m (80 ft) long	
Wood I-joist	Lumber, LVL, OSB, plywood	Cold setting glue (eg, RF, PRF), pMDI	S	Floor and roof construction	Flange sizes (1.5–3 in. in depth, 2.5–3.5 in. in width), Joist depths range from 9$\frac{1}{2}$ to 50 in. and lengths up to 50 ft	
Glulam beams	Lumber, some LVL	RF, PRF, MF		Headers, girders, purlins, beams, arches, bridges, marinas, power transmission structures	Up to 50 m long	
Parallel strand lumber (PSL)	Strands from softwood veneer	PF	S	Headers, beams, columns and posts; industrial uses such as bridge structures and power poles; and with CCA pressure treatment, post, beams and columns for decks, balconies, car-ports	280 by 430 cross section (11 by 17), length up to 66 ft	
Laminated strand lumber (LSL)	Strand	pMDI	S	Industrial and light structural applications	140 mm (5.5 in.) thick, 2.4 m wide, 10–15 m long	

[a] Refer to Table 1. The data in this table are adapted from various references 3–6,11–16.

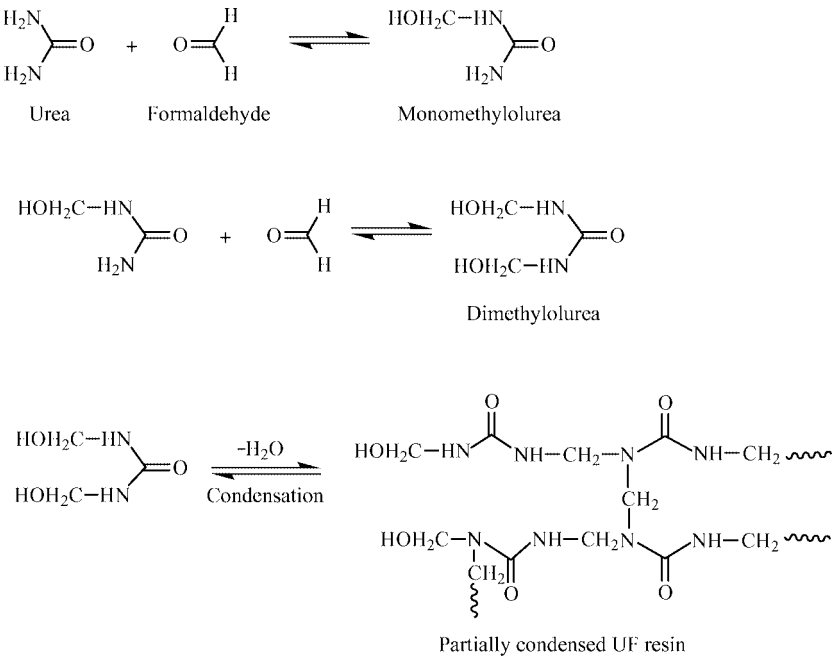

Fig. 1. Polymerization reaction of UF resin.

formaldehyde are heated under slightly alkaline conditions (pH 7–8) to produce methylolurea resins (Fig. 1). Depending on the synthesis conditions (eg, the *relative* urea-to-formaldehyde molar ratios, the reaction temperature, and pH), up to four molecules of formaldehyde can bond to urea owing to the four replaceable hydrogen atoms of urea. The methylolureas produced at this stage are low molecular weight prepolymer solutions that have no adhesive properties. During the second stage, these prepolymer solutions are slightly acidified, which causes the methylolureas produced in the first stage to condense with one another. As this occurs the prepolymer molecular weight increases, and as the polymerization of the UF resin advances further the growing chains begin to cross-link through the formation of methylene–ether links. At the desired point in this polymerization process the aqueous suspension of UF adhesive is neutralized, which stops the reaction before the resin precipitates, and cooled. Water is removed under reduced pressure (vacuum) to produce a final resin content of about 65% nonvolatile resin solids. The final stage of the condensation polymerization, which produces a solid cross-linked thermoset, is completed during production of the wood composite. It is accomplished by the addition of a small amount of acid catalyst to the UF suspension immediately prior to its application to the wood element and occurs during the pressing cycle to produce the wood composite.

UF resin is applied to wood furnish as an aqueous suspension. With the addition of a catalyst such as an acid, the curing can occur at room temperature in a few days, but most industrial processes employ high temperatures and ammonium salts to shorten the bonding cycle (7). In the presence of heat and catalyst, UF condenses into a cross-linked three-dimensional network of macromolecules

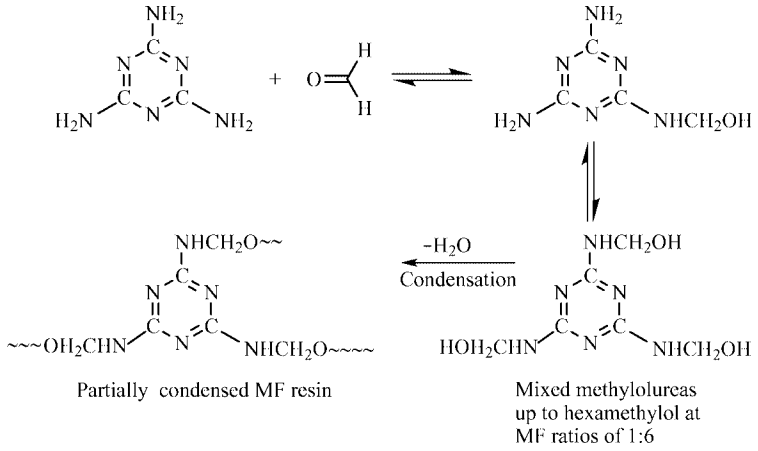

Fig. 2. Formation of MF resin.

that provide bonding. UF resin cures rapidly, provides strong adhesion in a permanently dry environment, and is the least expensive of the major wood adhesives. For these reasons, UF resin is by far the dominant commercial adhesive and is widely used throughout the world for bonding wood and wood-based composites. Despite these attributes, UF resins have three major drawbacks: (*1*) their brittleness once cured, (*2*) their limited resistance to moisture in the cross-linked state (limiting their use to interior products), and (*3*) the potential for formaldehyde emission from UF-bonded wood composites.

Although the urea (U) to formaldehyde (F) molar ratios can be in the range of 1:1.2 to 1:2, governmental regulations on the permissible level of free formaldehyde have forced resin producers and wood-composite manufacturers to lower the molar ratio, and so today resins with a U:F ratio as low as 1:1.1 are not uncommon. The potential for formaldehyde release from UF resin-bonded wood composites is caused by two factors: (*1*) release of a portion of the excess formaldehyde that did not react and (*2*) hydrolysis of susceptible bonds in the UF resin producing the urea and formaldehyde reactants (hydrolytic degradation), which can occur in the presence of moisture and heat during the pressing operation or subsequent installation (18,19). The low moisture resistance of UF resins limits their application to interior products, but if greater moisture resistance is required various urea derivatives or melamine are included in the UF formulation.

Melamine–Formaldehyde (MF) Adhesives. MF resins are produced by a condensation process by reacting melamine with excess formaldehyde (Fig. 2). The reaction proceeds in a manner similar to that between formaldehyde and urea but progresses to a greater extent (see MELAMINE–FORMALDEHYDE RESINS).

Cured MF resins are considerably more water-resistant than UF resins. This is attributed to the lower solubility of melamine in cold water compared to urea (18,19), and the overall greater hydrophobicity of the MF. These resins also have superior heat resistance and shorter curing times than UF resins because of the higher functionality of melamine compared to urea (up to six molecules of formaldehyde can react with melamine). Therefore, MF-bonded composites can be employed in both interior and in some exterior applications.

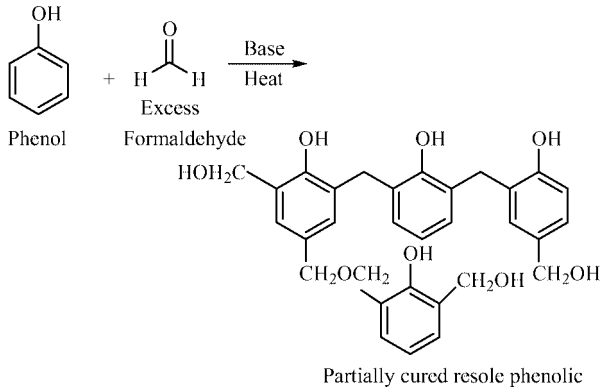

Fig. 3. Formation of resole PF resins.

However, MF resins are costly (about 3.5 times the price of UF based on 100% resin solids), and can only be cured properly at high temperature, which adds to the cost. This is a serious commercial drawback.

As previously mentioned, MF and UF resins are often combined. In the case of UF resins it is done to improve their moisture resistance, to accelerate their cure rate, and to reduce formaldehyde emission from UF-bonded wood composites, while in the case of MF resins it is done to reduce the cost. However, because of the differences in reactivity between urea and melamine mixing these components can complicate the curing. The conditions needed to cure the MF can overcure the UF, and conditions designed to properly cure the UF can leave the MF component undercured. However, when a suitable cure cycle is found for the blended resin, a good combination of properties can be achieved.

Phenol–Formaldehyde (PF) Adhesives. PF resins are produced by the reaction of a phenol and formaldehyde. Depending upon the phenol-to-formaldehyde (P:F) molar ratios and the type of catalyst, two types of PF resins can be produced: resole and novolac PF resins (Figs. 3 and 4).

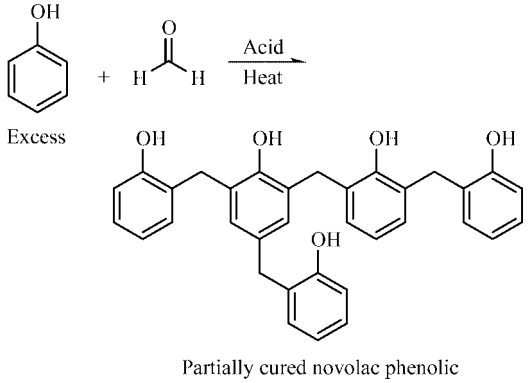

Fig. 4. Formation of novolac PF resins.

Resole PF resins are produced by the reaction of phenol with excess formaldehyde (P:F molar ratio 1:1.8 to 1:2.2) in the presence of an alkali catalyst (Fig. 3). Because resole resins contain reactive methylol groups, they are self-curing resins that can condense with active sites on the phenol rings to form a cross-linked network in the presence of heat even without additional hardener. Resole resins have a very branched structure (Fig. 3) and are by far the more important of the two types of PF resins for wood composites.

Conversely, novolac PF resins are produced by the reaction of excess phenol with formaldehyde (P:F molar ratio 1:0.8 to 1:1) in the presence of an acid catalyst. Unlike resole resins, novolac PF resins have a more linear structure (Fig. 4) and do not self-cure because they lack the residual reactive methylol groups of resoles. Therefore, an external curing agent such as hexamethylenetetraamine must be added to novolac resins to yield a cross-linked structure. Novalac PF resins cured under acidic conditions are not recommended for wood composites for long-term structural applications.

In the presence of heat and on the addition of sodium hydroxide (NaOH) or other catalyst, resole PF resins condense into a three-dimensional cross-linked network having reactive sites suitable for wood bonding. While too much heat accelerates the degradation of UF resins, use of heat is desirable in PF-bonded composites to achieve a high degree of cross-linking. It should also be mentioned that the curing rate of PF resins is strongly influenced by the amount of NaOH added to the resins, with the higher NaOH content affording a faster cure up to a point. However, use of an excessive amount of NaOH in PF resins has adverse effects, including increasing the affinity of the composite for absorbing moisture from the air, which in turn results in PF-bonded composites having a higher thickness swell. As is the case with UF bonding, the adhesion to the wood surfaces in PF-bonded wood composites is achieved through secondary and/or physical bonding. PF resins have greater moisture resistance and greater strength retention when exposed to a high moisture environment than UF resins, and so are employed extensively in the manufacture of wood composites slated for exterior applications. Long-term aging studies in which plywood specimens prepared using various adhesives bonds were exposed to natural weathering confirmed the superior moisture resistance of PF. The PF-bonded specimens retained up to 90% of their original strength even after 8 years, while the UF-bonded specimens lost 100% of their original strength after only 4 years in service (7).

Resorcinol–Formaldehyde (RF) Adhesives. RF resins are a type of phenolic adhesive that are distinguished by a very high reactivity relative to PF resins. This greater reactivity is due to the two phenolic hydroxyl groups on resole. The groups *activate* one another by making each other more electron-rich. Therefore, the first hydroxyl group is much more reactive than the phenol hydroxyl group, and following its reaction the remaining hydroxyl group is still highly reactive. Consequently, although RF adhesives are generally prepared using excess resorcinol to produce a novolac-type resin, in contrast to PF novalacs, these resins set rapidly *with the addition of hardener* even at low temperatures (eg, anywhere from 5 to 70°C). This is termed *cold curing*. The high reactivity between resorcinol and formaldehyde with additional hardener, eg paraformaldehyde, allows the cure to proceed rapidly to completion. The reaction can be further accelerated by applying heat. Attempts to produce a resole RF resin typically result in an unusable

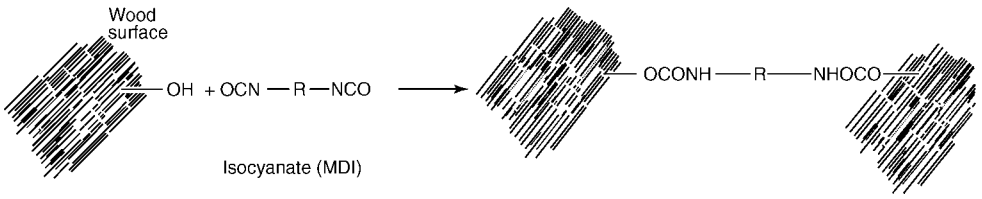

Fig. 5. Reaction of wood with MDI resin.

gel (18–20). Despite the ability to cure at room or elevated temperatures and give composite products having good moisture resistance, RF adhesives are not used extensively because they are among the most expensive of the thermoset adhesives, being second only to the isocyanates in cost. Nevertheless, RF adhesives are used as binders for selected wood products.

Isocyanates. Polymeric diphenylmethane diisocyanate (pMDI) is the most commonly used isocyanate wood adhesive mainly because of its lower volatility and toxicity when compared to other isocyanates such as toluene diisocyanate and dicylcohexylmethane diisocyanate. Some of the advantages enjoyed by pMDI include the fact that it is a liquid polymer, and so it does not require a solvent carrier for application, it is free of formaldehyde, and also it does not require acidic (the case with UF) or alkaline catalysts (the case with PF). It is an effective wood adhesive because the high reactivity of the isocyanate (—N=C=O) groups allows the resin to cure rapidly, and it has the potential to covalently bond directly to the wood by reacting with the hydroxyl groups on the wood surface (Fig. 5) (7,18–20).

The ability of pMDI to cure rapidly is due to the high reactivity of isocyanate (—N=C=O) groups that react rapidly with active hydrogen atoms. Wood possesses active hydrogens from hydroxyl groups on wood surfaces and from moisture in the wood. When the isocyanates react several reactions occur simultaneously but at different rates. The —N=C=O groups first add water to form unstable carbamic acid groups that then dissociate into an amine and carbon dioxide. The resulting amine is more reactive than water and reacts rapidly with another isocyanate to form a polyurea (22). The —N=C=O groups can also add cellulosic hydroxyl groups on the wood surface to form covalent bonds via urethane linkages (Fig. 5). pMDI can cure at ambient temperature in the presence of moisture and so it can also be used in cold pressing of wood-based composites, but hot pressing is usually preferred to shorten the press cycle.

pMDI forms covalent bonds and polar interactions with wood and tolerates both high moisture content in the wood and lower press temperatures during composite manufacture. When wood composites are prepared with equal amounts of adhesive and the bond strength and the dimensional stability of wood composites are compared it is found that pMDI's bond strength and dimensional stability of composites prepared with it are generally superior to those of amino and phenolic resins in both dry and moist environments. Despite these advantages, pMDI adhesives also have some disadvantages. There are some perceived health hazards associated with the manufacturing process, and it can bond to the metal surfaces of a hot press, which is undesirable, although this can be prevented by applying

release agents to the surfaces of the press. However, the primary drawback is cost. pMDI is the most expensive of the wood adhesives.

Other Wood Adhesives. There is considerable interest in developing adhesives from renewable resources that can be used as a primary adhesive or as an adhesive component (an "extender") to replace a portion of petroleum-based adhesives. These natural and renewable resources include lignin, tannins, and natural oils such as soy bean and proteins.

Lignin. Lignin is a waste product produced in large quantities by the pulp and paper industry that is often burned as fuel. Lignin-modified PF resins have been formulated to bond fiberboards, strandboards, and structural plywood (14,15,23–29). Lignin (qv) is employed in this manner primarily to reduce the consumption of oil-based products and to a lesser extent for cost savings since lignin can be less expensive than phenols. The lignin is usually methylolated *in situ* during the PF resin formulation, replacing anywhere from 15 to 35% of the phenol (12,13). Some lignins (eg, lignosulfonates) have also been added directly into the adhesive formulation as a PF resin extender (24–26). Although lignin-based adhesives are used in bonding wood composites, these adhesives require longer press times, produce darker coloration of the panel, and potentially have lower strength relative to PF without lignin (19,25). However, composites having good dimensional stability and good performance under conditions of high moisture have been reported for boards produced with lignin-extended resins, so interest in developing these adhesives continues (4).

Tannin. Tannin is an inexpensive naturally occurring polyphenol found mostly in the bark of trees but also as a component of the wood of some species. Tannin, like lignin, has also been used as a substitute for phenol in the manufacture of PF resins (4,30,31). Although using tannin-based adhesives in the manufacture of wood composites is thought to have potential, some reports indicate that these resins have lower cohesive strength and lower moisture resistance compared to common exterior wood adhesives (30). The poor performance of tannin-based adhesives is attributed to their limited ability to cross-link into a three-dimensional network, their high initial viscosity, and a short pot life owing to the high reactivity of tannin with formaldehyde. However, extensive research has been conducted in recent years to improve the performance of tannin-based adhesives. For example, the addition of small amounts of amino or phenolic resins (4) or metallic ion catalysts (18) has been shown to effectively increase the degree of cross-linking, thereby improving the strength and moisture resistance of tannin adhesives. Reducing the pH or adding hardeners such as hexamethylenetetramine during resin formulation has been shown to decrease the initial viscosity of some tannin-based adhesives (19) thus extending their pot life. These breakthroughs have allowed tannin-based glues to be used in the manufacture of wood composites in South Africa, New Zealand, India, South America, and to some extent in North America.

Other adhesives such as hot melt adhesives (HMA), poly(vinyl acetate) (PVA, catalyzed or uncatalyzed), pressure-sensitive adhesives (PSA), or elastomeric adhesives (based on natural or synthetic rubbers) are also used in wood bonding (7). However, their use is mostly limited to nonstructural applications (eg, secondary manufacturing processes such as kitchen furniture, interior joinery, decorative paper, and packaging) where strength and water resistance are of limited concern.

Advances in Wood Composite Adhesives

Improvements in wood composite properties can be achieved in three areas: (*1*) improvements in wood properties, (*2*) improvement in adhesive properties, and (*3*) improvement in the overall wood composite design. Most advances in wood composites witnessed over the last 10–15 years have been brought about by improved manufacturing equipment and improved composite design (eg, oriented strandboard, I-joist, parallel strand lumber, and laminated strand lumber), while significant advances in future wood composites seem likely to involve changes in wood properties (eg, genetic modification to produce species with some desired property such as improved resistance to decay). However, given the importance of developing alternatives to petroleum-based materials, development of new adhesives may yield the next generation of significant advances in wood composite products.

Some of the more recent research efforts that may lead to new adhesive types are categorized as follows: (*1*) adhesives from natural products, (*2*) adhesives generated *in situ* in the wood, (*3*) adhesive modifications to facilitate processing, and (*4*) adhesive modification for improved properties. Examples of these approaches are given below.

Prior to the 1930s all adhesives were based on natural products (eg, proteins such as animal blood, casein, soy protein). Use of adhesives from natural products steadily decreased thereafter with the development of synthetic polymers that had superior properties. Recently, renewed interest has been shown in using natural products to replace, entirely or in part, petroleum-based adhesive components with natural products, without sacrificing the performance levels achieved with modern petroleum-based adhesives. The purposes are often to reduce cost and dependence on petrochemicals, to reduce formaldehyde emissions, and improve selected properties (eg, biodegradability).

For example, there is renewed interest in using soy-based adhesives for fiber-based composites. New research is underway to develop soy-based adhesives that have improved properties and durability, and that have low volatile emissions (32).

Lignin-modified PF has been utilized for more than 20 years in a variety of different wood products (fiberboards, strandboards, structural plywood, etc.) where the lignin extender has lowered the cost. More recently lignosulfonates have been utilized as extenders to replace up to 35% of phenol in PF formulations (15). It has also been evaluated as an extender for other resins such as epoxy and polyurethane. Considerable research has recently been directed toward incorporating lignin into copolymers or grafting reactive monomers onto lignin allowing it to be copolymerized (33). One recent example of this approach describes using enzymes to copolymerize lignin with alkenes to produce well-defined lignin acrylate copolymers within fibers and pressing those fibers into medium density fiberboard (MDF) (34).

Work in South Africa and in South America has resulted in development of adhesives based largely or entirely on tannins. Tannins, which like lignins are renewable natural products, have the advantage of affording adhesives with low or no formaldehyde emissions, but tannin-based adhesives tend to be brittle. A useful tannin-based particleboard adhesive was reported using tannin extract

from radiata pine bark that was formulated with 5% isocyanate and 5% urea (13). Another report described a tannin-based adhesive in which a significant number of the phenolic groups of the tannin had been esterified to produce a less brittle adhesive (35). The partially esterified tannin was blended with paraformaldehyde and the resulting resin afforded a less brittle adhesive that had better properties than those of the unmodified tannin adhesive.

Because lignin and tannin are phenolic species they have both been evaluated as extenders for PF and UF adhesives. It was subsequently shown that they could be used as primary adhesives. Because these natural phenolics can function as primary adhesives, and because these and other phenolics are components of wood and bark, researchers are investigating reactions of wood's natural phenolic components *in situ* to form a composite without added adhesives. Bark contains not only high amounts of tannins, but also carbohydrates and various other reactive phenolic components. Composites have been prepared by subjecting bark particles to high temperature and pressure to react the phenolic components within the bark so that these components cross-link *in situ* to serve as the sole binder for composites (13). A 1999 publication reported a similar approach for binding wood (36). In that work, birch wood was heated for 1–15 min at 170–230°C under 2 MPa pressure from hot steam. These conditions were used to hydrolyze the polysaccharides within the wood. Under the acidic conditions (formic and acetic acid from hemicellulose and sugars) the resulting sugars reacted with phenolic fragments originating from hydrolyzed lignin. These reactions yield a polymeric binder *in situ*, and have several advantages over adding adhesives to wood. These advantages include eliminating the need for equipment to apply adhesive to wood, no formaldehyde emissions from added synthetic adhesive, and this approach accommodates a high moisture content in wood, which is a major processing advantage. Nevertheless, the long processing time required at high temperature is expensive and additional research is required to evaluate the composite properties, so it is not yet known if this approach will be cost-effective.

Research efforts have been directed towards developing new adhesives that address some disadvantages associated with the processing of pressed wood composites. Pressed wood composites using thermosetting adhesives typically employ a high temperature press cycle. This process requires that the wood furnish be dried to a moisture content typically below 5%. Pressing wood with higher moisture content at higher temperatures can produce a poor product because of "blows," delaminated wood produced when water vapor generated within the mat during the hot-press cycle is rapidly released. Development of effective adhesives that tolerate high moisture content wood has been a goal for many years because drying the wood furnish to a low moisture level is time-consuming and costly, and the potential exists for overdrying some of the wood furnish. Moisture-tolerant isocyanate and PF adhesives are currently available that can tolerate high moisture content furnish (above 15%). Isocyanate adhesives have been used for many years with composites that use higher moisture-content conditions such as "wet wood." Under these conditions isocyanate adhesives have less tendency to delaminate than other adhesives (37). This is probably because of several characteristics of isocyanate-bonded wood composites, including that they can be pressed at a lower temperature than is usual for UF and PF adhesives, isocyanates can chemically bond to the wood rather than rely only on mechanical adhesion, and the cured

adhesive retains greater flexibility than UF and PF adhesives. PF adhesives that can be used with wet wood are also available, but their exact composition and method of function is not clear, although these adhesives may make use of higher formaldehyde content, a coupling agent to promote wood bonding, and/or be a PF/isocyanate blend.

Approaches have been developed that allow some other adhesives to be used with wet wood. The simplest of these approaches uses foamed adhesives. Foaming allows the adhesive to be applied at a higher solid content, often having only 15–20% water, and so higher moisture content in wood can be tolerated, and the composite cures faster since less moisture needs to be removed during cure. A recent investigation reported use of a soy protein-modified PF as a foamed adhesive for plywood production (38). The soy replaced animal blood in the formulation, which not only improves durability but can alleviate health concerns.

Another major difficulty with hot-pressed wood composites is adequate thermal transfer across the thickness of the composite. Heat is transferred through the press platens, sometimes with the aid of steam. However, wood is a low thermal transfer medium and so there is risk of overcuring resin nearer the surfaces of the composite, while undercuring resin in the interior. This is particularly true with thicker composites. Also the pressing step is probably the most expensive of the processing steps so any adhesive modification that reduces the press time and facilitates a more uniform cure is a significant advantage for cost and properties. Matuana (39) reported using thermally conductive filler material such as synthetic graphite (carbon filler) in the mat or adhesive to facilitate thermal transfer. Use of the carbon filler not only reduced the required cure time but also significantly increased the internal bond strength of the wood composites.

Wood composites are now being considered for use under increasingly demanding conditions and so adhesive modifications to improve specific composite properties, such as improved strength, durability, and dimensional stability, are needed. These types of modifications which usually increase adhesive cost were previously considered not cost-effective, but now might find markets. Early efforts to improve properties included adding thermoplastic polymers to the reactive adhesive prepolymer and applying the thermoplastic-modified prepolymer to the wood furnish and pressing. Examples of this approach include adding poly(furfural alcohol), a water-soluble polymer, to a UF prepolymer (40) and using chlorinated natural rubber to modify PF (41). The poly(furfural alcohol) did not improve properties, while the chlorinated natural rubber did improve properties but required processing conditions that were not industrially viable. These efforts highlight issues that must be addressed for an industrially useful modification. Any modifications must allow the processing conditions to be similar to those used now. Therefore, solvent should not be required, and prepolymer viscosity, stability, and cure conditions should be similar to those used now, and the resulting properties must be improved sufficiently so that an increased resin cost is worthwhile. A series of publications by Ebewele and coworkers (42–45) described modifying UF resins with di- and trifunctional amines and ureas without excessive increases in viscosity or processing difficulty. Particleboard made with the modified UF resins had an internal bond (IB) strength that was significantly greater than the IB strength of the control particleboards before and after exposure to moisture. Recently a method was reported that yielded

thermoplastic-modified UF adhesives that could be processed in the same way as unmodified control UF and gave wood flour composites with improved mechanical properties and moisture resistance. A premade thermoplastic polymer suspension (46–48), or aqueous slurry of acrylic and vinylic monomers, and a radical polymerization initiator (49) were combined with the UF prepolymer. The modified UF was used to prepare hot-pressed wood flour composites with significant improvements in notched Izod impact strengths. Further development simplified the method and modified UF resins were employed for hot pressing of particleboards (50) that, depending on the choice of thermoplastic monomers employed, also gave a higher IB strength and the neat resin showed lower moisture uptake than unmodified UF neat resin. Zanetti and co-workers (51) recently reported substantial increases in the IB strength of melamine–urea–formaldehyde (MUF) resins by the addition of small amounts (10%) of acetals to MUF resins. The authors reported that the acetals worked by improving the solubility of melamine and higher molecular weight reactive oligomers in the MUF resin and also appeared to disrupt the clustering of colloidal particles of MUF. This modification afforded 25–50% increases in IB strength and yet required no additional modification of the MUF formulation or the processing conditions.

Wood Composites Bonded with Thermoset Adhesives

The principal wood composite products currently in use in the United States and Canada, based on volume, are plywood (17.5 million cubic meters), oriented strandboard (16.8 million cubic meters), particleboard (10.3 million cubic meters), medium density fiberboard (3.4 million cubic meters), hardboard (2.0 million cubic meters), hardwood plywood (1.0 million cubic meters), and laminated veneer lumber (1.2 million cubic meters) (13). These products are described below. While all of these composites occupy an important place in the market now, some of these products are gaining in importance while others appear to be losing market share to other composite products.

Wood composites for structural and nonstructural applications that are bonded with thermosetting glues can be produced in many different geometries, including panels (3 ft or more in width by 3/8 to 1 in. thick), lumber (2 in. or more in width by 2–4 in. thick), or beams ($3\frac{1}{8}$ in. wide by 9 in. or more in depth) (Table 2). The exact procedure for making wood composites depends on the type of wood furnish (wood geometry), the desired arrangement of the particles in the final product, and the adhesive to be used, as well as the cure cycle if the adhesive needs to be reacted during the process step. These processing variables determine the characteristics of the final products, including mechanical properties, water resistance, dimensional stability, surface quality, and workability. Regardless of the increasing number of wood composite products being introduced into the market, the different sizes and shapes of these products, and the different volumes of these products that are produced, the fabrication process is a highly automated one, and once the adhesive mixture is applied to the wood furnish the general manufacturing method for preparing these composites is similar (Fig. 6).

The composite fabrication process begins once the trees have been processed into a dried furnish and the furnish is transported to a device such as rotating drum (as is the case for flakes, particles, and fibers). Here, the adhesive and other

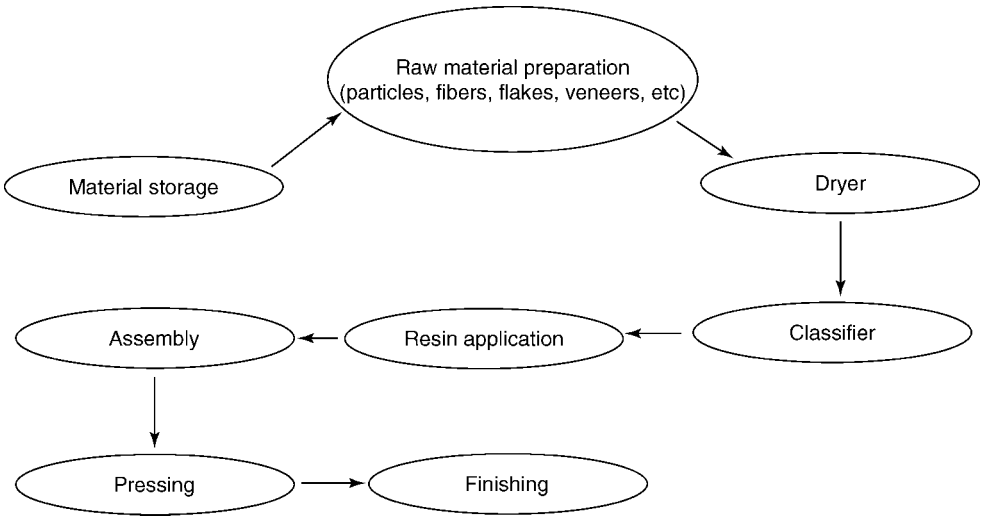

Fig. 6. A typical wood composites manufacturing process.

additives are applied to the furnish by air spray, airless spray, or a high shear atomizer. The rotating drum possesses nozzles that are fed by hose lines connected to resin storage drums. Adhesive resin mixtures are applied to veneer-based wood products (plywood, laminated veneer lumber) by a roll coater, curtain coater, spray coater, or liquid or foam extrusion. The amount of adhesive applied to the furnish varies with the product and adhesive type. Common additives are also applied during this step and include wax (to improve dimensional stability by reducing moisture absorption), wood preservatives (for protection against insect and fungal attack), and fire retardants.

After resin application, the coated wood furnish moves to a forming apparatus. The forming apparatus arranges the furnish appropriately into a mat having the specified dimensions and orientation of wood raw material to give the desired product type with the desired dimensions and density after pressing. This mat is then prepressed to remove much of the air, ie, consolidate a loosely formed mat into a rigid mat which has a certain degree of cohesion to reduce its thickness. The formed mat then goes to a hot press where it is subjected to a selected press cycle. Here it is heated and pressed at the desired temperature and pressure for specified periods of time to bond the wood into a composite part of the desired thickness. The pressed wood composite finally goes on to the finishing steps where the panel is sized, sanded, trimmed to the desired thickness and dimensions, edge sealed, and packaged for shipment. In some cases the hot composite product is stacked to help retain heat and continue the cure out of the hot press, as is the case with phenolic resins.

The biggest differences in processing for each type of wood composite reside in the geometry and arrangement of wood furnish, the adhesive type and amount applied, and the cure cycle. The following sections describe the main characteristics of the major wood composite products made with thermoset adhesives.

Plywood. Plywood panels have been produced and marketed in the United States for more than five decades. They are considered a material of choice in the building industry because of outstanding structural performance as defined by

a high strength-to-weight ratio, excellent dimensional stability, and durability compared to other building material (6). Plywood typically consists of an uneven number of thin layers of wood veneers, called plies, that are glued together into a panel. The individual plies are typically arranged in the panel so that their grains are perpendicular to one another (right angles of 90°). The plies are arranged at 90° to one another to improve the dimensional stability and make the properties of the plywood more uniform along both the vertical and horizontal axes. The anisotropic nature of wood results in a tendency to swell less parallel to the grain than perpendicular to the grain and simultaneously gives wood greater strength parallel to the grain than perpendicular to the grain. Therefore, arranging individual plies at 90° to one another affords greater dimensional stability, decreases the tendency to split, and generally evens out the strength properties in all directions. If the grain angles were not varied then the plywood would have less dimensional stability and be much stronger along the grain axis but weaker perpendicular to the axis. The appearance of the final product can be improved if desired by applying a decorative surface veneer to give the final plywood a desired appearance. The final overall properties of the plywood depend on many factors, including the wood species, the quality of wood veneers, the order of placement of the veneer plies in the panel, the type and amount of adhesive applied, and the curing or pressing conditions.

Both hardwood and softwood species are utilized in the manufacture of plywood. Softwoods (Douglas-fir, western hemlock, larch, white fir, ponderosa pine, redwood, and southern pine are examples) are generally preferred in construction applications where strength and stiffness are required. Hardwood plywood is generally preferred for decorative applications where appearance is most important and strength is a limited criterion, although hardwood plywood can also be designed for structural applications. In decorative applications, hardwood plywood often competes with thin MDF which can be given a high quality overlay giving it an appearance similar to that of hardwood plywood.

Oriented Strandboard (OSB). Oriented strandboard (OSB) panels have been developed as an alternative to plywood in building construction. The emergence of OSB was driven in part by a decreased supply of large diameter logs suitable for veneer production, and by innovation and productivity changes in the North American wood products industry over the past few decades as well as the structural performance of OSB products, which are suitable for use in most plywood applications but at a much lower cost. In addition, OSB manufacture allows small, low grade timber resources to be processed into a marketable product. This effectively saves raw materials that are in short supply and promotes efficient utilization of wood (3,5,6).

OSB panels are made up of rectangular strands (wafers or flakes) of wood approximately 0.030 in. thick, bonded together with exterior-grade adhesive under extreme heat and pressure to develop adequate strength properties in the panel. During this process, long grain strands are compressed and mechanically oriented more or less parallel to each other and arranged into three to five distinct layers. These layers are oriented at ca 90° to one another, ie, strands are aligned lengthwise in layers perpendicular to each other similar to veneer plywood. The strands near the surface are typically $\geq$ 3 in. long but shorter strands are

sometimes used in core layers. The core layers are also sometimes randomly arranged rather than oriented. The strands for the faces are typically oriented parallel with the long direction of the panel, whereas the core layers are oriented perpendicular to the length of the panel. Hardwood species, alone or in combinations with softwood species, can be used in the manufacture of OSB panels, but preferably lower density wood species (eg, aspen poplar in the northern part of North America and southern yellow pine in the south) are employed because strands of these woods can be compressed into medium density boards with sufficient contact between strands during pressing for good bonding (4).

The alignment of strands and the use of long strands give OSB panels improved mechanical (strength and stiffness) and physical (dimensional stability) properties in the direction of alignment, which make them acceptable in a wide range of industrial, residential, and commercial applications (Table 2). Even though OSB panels are being used as a substitute for plywood, their potential for use in some structural applications has been limited because of poor dimensional stability and durability compared to that of plywood. OSB panels will swell in thickness, and like all wood products decay when they come into extended contact with water. Since most of the thickness swelling is not reversed when the panels are re-dried, the products are regarded as unacceptable for some applications where high moisture contact is expected (52–54).

Particleboard. Particleboard is prepared using small dried-particles combined with a thermally curable adhesive or other suitable binder and bonded together under high heat and pressure into panels of the desired thickness. The raw materials used to produce particleboard consist of wood wastes from sawmills, primarily from milled or ground wood chips, sawdust, and planer shaving. In some cases recycled cellulosic materials and plant residues such as wheat straw and bagasse are utilized as furnish to make particleboard. Most particleboard is formed into flat panels. However, molded and extruded particleboard products such as furniture parts, molded door skins, and molded pallets are also produced.

Particleboard usually consists of a three-layered panel with two surface layers (outer layers) and one core layer (inner layer). The face furnish is usually thinner than that in the core. This permits the strength and stiffness of the panel to be tailored and the faces to be produced with smooth surfaces. The American National Standard for Particleboard, ANSI A208.1, classifies particleboard by density, properties, and class, and is the voluntary particleboard standard for the North American industry (Table 3).

Medium Density Fiberboard (MDF). MDF is manufactured from refined wood chips or other fine cellulosic materials combined with a synthetic resin. The adhesive coated furnish is joined together under heat and pressure to form a versatile material having varying characteristics depending on the composition and processing conditions (Tables 2 and 3).

The surface of MDF can be controlled so that it is smooth, flat, and uniform in appearance and free of wood growth features such as knots and grain patterns. MDF panels are highly valued by woodworkers because they machine well and are suitable for finishing operations such as direct printing (eg, wood grains), thin laminating (eg, paper, decorative foil laminates), and painting (eg, custom colors). These attributes allow MDF panels to serve as excellent substitutes for solid wood

Table 3. Selected Properties of Wood-Based Composite Panels

Physical properties	Plywood[a]	OSB[b]	Particleboard[c]	MDF[a]
Density, lb/ft^3[d]	28–31	36–44	40–48	<40 to >50

in many interior applications such as kitchen cabinets, furniture, door parts, and moldings (Table 2).

Composite Lumbers and Beams. Composite lumbers and beams comprise a large and diverse family of products known as engineered wood products (EWPs). EWPs include laminated veneer lumber (LVL), laminated strand lumber (LSL), parallel strand lumber (PSL), glulam, and I-joists, among others.

LVL [also known as structural composite lumber (SCL)] technology was developed in Finland. Trus Joist became the first U.S. producer of LVL in 1970 (3,6). LVL is a structural building material manufactured by layering dried and graded wood veneers with waterproof adhesive into billets of various thicknesses and widths. Generally, high quality laminates are used at the faces and low quality laminates in the center of the lumber. This specific arrangement gives LVL greater strength (by a factor of 2 or more) than conventional solid lumber having equivalent dimensions. In LVL billets, all veneers are laminated with the grain angle parallel to the longitudinal axis of the wood (one-grain direction) rather than arranging the veneer grains perpendicular to one another as in plywood. PF and pMDI are the resins that are typically employed to produce LVL and so the billets are hot-pressed or radio-frequency-pressed to consolidate the laminates. Common wood species used for LVL include Douglas fir, larch, southern yellow pine, and poplar, but other wood species can be used as the raw material. As an engineered wood product, LVL is an ideal structural building material for applications in housing, commercial, and industrial construction. Typical applications include floor and roof joists, roof beams, roof truss chords, flanges for prefabricated wood I-joists, concrete form, and scaffolding plank, among others (Table 2).

Wood I-joists are hybrid beam elements that are made by gluing together lumber and panel composites to produce a dimensionally stable lightweight member having specified engineering properties. The product utilizes the geometry of the I-shaped cross section composed of two flanges (top and bottom) of various widths linked by a web (or two webs) of various depths (Table 2). The flanges are typically LVL, or finger-jointed sawn lumber of various machine stress-rated grades, while the webs are either structural grade OSB or structural plywood. The flanges are designed to resist bending strength and provide stiffness, while the web is designed to resist shear forces in the beam. Thus, the I-shaped geometry of these products gives a high strength-to-weight ratio. I-joists are marketed as building products that do not warp, twist, or shrink, and their dimensions are more uniform than those of conventional sawn lumber joists. The wood I-joists performs much better than solid lumber because greater joist spacing can be used and their frames are lighter and more dimensionally stable than lumber, making their installation less costly for the builders. Wood I-joists are used in residential and light commercial construction in applications such as floor and roof joists, rafters, and purloins, among others (Table 2). Wood I-joists are certified by the APA-Engineered Wood Association as the APA-Engineered Wood System (APA-EWS), and are manufactured in compliance with Performance Rated I-Joists (PRI-400), Performance Standard for APA-EWS I-Joists.

Glued laminated timber, or glulam, is a structural beam element manufactured by gluing laminates of solid wood lumber, finger-jointed lumber, or LVL. The individual lumber elements are oriented parallel to the longitudinal axis of the beam and laminated flat-wise to bond along the entire length and width of the lumber elements. Based on the stiffness rating of the individual laminations high quality laminates are generally applied at the beam faces, while low quality laminates are placed in the middle of the beam. This combination is preferred since the load is carried by the beam in the top and bottom faces, while the middle only has to resist shear. A cold curing resin adhesive such as resorcinol or phenol–resorcinol is usually used to produce the beam by applying the adhesive and clamping or cold-pressing the laminates. Since little or no heat is required for the cure, curved glulam members and other customized shapes can easily be produced. Glulams are manufactured in accordance with the American National Standards Institute (ANSI) ANSI standard A190.1 for structural glued laminated timber. The strength values (bending and shear) for glulam are higher than for lumber. Glulam members are typically used as headers, beams, arches, etc (Table 2). The production of glulam is not expected to grow significantly in North America because of the scarcity and high cost of laminating grade lumber, combined with stiff competition from LVL and other engineered wood products such as LSL and PSL, which are expected to grow because they have excellent structural properties and they employ more readily available raw materials (5,6).

PSL is an engineered wood product developed by MacMillan Bloedel, Ltd., of Canada and was first commercialized in 1988 (3,6). PSL is made in a similar manner to glulam beams with the difference being that strands of broken-up veneer (about $\frac{1}{2}$ in. wide and up to about 37 in. long) are employed instead of solid lumber laminates. The strands are oriented and laid-up into a mat in a lengthwise direction, ie, aligned parallel to one another. The strands are glued with a water-resistant adhesive (PF) and are consolidated in a continuous microwave press. PSL is stronger, stiffer, and more stable than sawn lumber having the same

cross section and is free of splits, knots, and warp. PSL is employed in various applications such as head beams, trusses, and other structural frames (Table 2).

LSL is another type of engineered wood product in which all the strands are aligned in one direction, ie, LSL is an oriented strand lumber. The strands in LSL are shorter than in PSL and produced from strand wood rather than veneer. The strands are typically longer than strands utilized in oriented strandboard. Pressing includes steam injection rather than radio-frequency heating, and isocyanate resin is typically used rather than PF adhesive. LSL is used in industrial and light structural applications (Table 2).

Wood Thermoplastic Composites

Wood-based composites continue to be among the most widely used building materials throughout the world. While thermoset wood composites date back to the early 1900s (a wood flour/PF composite called Bakelite®), wood combined with thermoplastic composites have become of major commercial importance only since the 1980s in the United States, although they have been in use longer in Europe (2). Wood-plastic composites (WPCs) represent a rapidly growing industry in the United States in both the plastic processors and forest products industries (56–58).

To plastic processors wood and other lignocellulosic fibers (eg, agrofibers) represent a vast supply of readily available raw materials for all types of WPCs. Statistics show that 2.5 million tons of fillers were used in North America in 2001 with the most important fillers being inorganic materials (2.3 million tons) such as calcium carbonate (1 million tons), glass fiber (0.77 million tons), and other mineral fillers such as clay, talc, mica (0.55 million tons). Only 182,000 t was natural fibers (57). The inorganic materials enhance some composite properties (eg, strength and modulus) and are extensively employed as fillers, but have several drawbacks. They are produced from nonrenewable sources and they have high density, so products prepared with inorganic fillers tend to be heavy. Furthermore, these inorganic fillers cause equipment wear during processing (59). Therefore, on a volumetric basis, their use may not be very cost-effective. During the past two decades, wood fibers and other lignocellulosic materials have begun to penetrate the filled thermoplastic markets because they possess many advantages relative to the common inorganic fillers. These advantages include high specific stiffness and strength, easy availability, lower density, lower cost on a unit-volume basis, low hardness which minimizes wear of the processing equipment, renewability, recyclability, safety, and biodegradability (60,61). The replacement of inorganic fillers with lignocellulosic fibers also provides an opportunity to increase processing productivity rates (56).

The forest products companies, on the other hand, see plastics as a way to expand sustainable forest resource utilization through the use of wood waste, fibers from underutilized species, and reclamation and recycling of wood, other agricultural species and waste, and paper materials from municipal solid waste streams (62), as well as a way to make new construction materials with attributes that wood does not have (56).

WPCs are typically manufactured by first mixing dried cellulosic materials (in powder or fibrous form) with various plastics and other processing ingredients (eg, lubricants, fusion promoters, coupling agents, flame and smoke retardants, ultraviolet stabilizers). Cellulosic materials that are used in the production of WPCs include wood flour or particle, flax, jute, or other agricultural waste. The most commonly employed plastics are polyethylene (PE), polypropylene (PP), polystyrene (PS), and poly(vinyl chloride) (PVC). These thermoplastics are selected mainly because they can be processed at lower temperatures (150–220°C) to prevent the degradation of cellulosic materials (2). Generally, wood flour and other coarse particles (10–100 mesh size) are easier to handle during processing than long fibers which tend to agglomerate and cause dispersion problems during mixing. However, because of their higher aspect ratio, long fibers provide greater reinforcing effects in WPCs than particles. The fiber can be difficult to disperse but the dispersion problems can be offset by using compatibilizers during processing (60,63,64). Once mixed, the blended material is processed into the desired shape by conventional plastic processing equipment such as an extruder, injection molder, and a hot press (compression molding). Most of the WPCs used in construction applications are extruded to a profile of uniform cross section (solid or hollow) and any practical length, whereas products having more complex shapes such as those used in the automotive industry or other consumer products are injection- or compression-molded.

WPCs comprise an emerging class of materials that combine the favorable performance and cost attributes of both wood and plastics (Table 4). Because WPCs are true hybrid materials, they have strength and stiffness properties that are somewhere between both materials. They have outstanding bolt, drill, screw, and nail retention and they machine similarly to wood. Generally, WPCs are stiffer than neat plastics and have attributes that solid wood does not have. If properly manufactured, WPCs are more resistant to moisture (water absorption and thickness swell) than wood and resist attack by insects and fungi better than other wood

Table 4. Some Physicomechanical Properties of WPCs and Comparative Performance of WPCs with (Oak) and Softwood (Pine) Solid Wood

Tests	Test methods	HDPE/WF[a]	PVC/WF[a]	Northern oak[b]	Ponderosa pine[b]
Specific gravity	ASTM D143	0.96–1.1	1.36	0.56–0.63[b]	0.38–0.40[b]
MOR, psi[c]	ASTM D790	790–1423	2100–4500	14300[b]	9400[b]
MOE, 10^3 psi[c]	ASTM D790	160–510	700–980	1820[b]	1290[b]
Water absorption, %	ASTM D1037	0.7–4.3	1.2	—	17.2
Thickness swell, %	ASTM D1037	0.2	—	—	2.6
Nail withdrawal, lb	ASTM 1761	90–170	—	—	50
Screw withdrawal, lb	ASTM 1761	430–600	—	—	165
Hardness, lb	ASTM 143	1290	—	1290[b]	460[b]
Linear coefficient of expansion (per °F)	ASTM 696	16×10^{-6}	17×10^{-6}	—	25×10^{-6}

[a]HDPE/WF and PVC/WF contained 50–70% wood fiber.
[b]MOE and MOR values measured at 12% moisture content (7).
[c]To convert psi to MPa, divide by 145.

products. This outstanding performance is due to the fact that the plastic matrix encapsulates the individual wood fibers, thus interfering with moisture uptake by the wood element. Moisture can only be absorbed into the exposed sections of the wood. WPCs can be sanded, stained, painted, and finished just like natural solid wood. However, sealants and paints are not required for protection because WPCs resist moisture better than wood, and WPC products can be prepared with colorants and other additives during the processing phase, which eliminates the need for additional finishing.

Because of their performance, easy installation, and cost-effectiveness, WPC products are being selected by homebuilders over other materials such as solid wood, concrete, clay, and aluminum, especially as building materials for applications like decking, siding, and window and door frames. WPCs are also used as molded panel components for automotive interiors. The market for these composites continues to expand in the United States and other parts of the world. In 1999, 460 million pounds of WPCs were produced in North America (56). In 2000, production of these composites increased to 760 million pounds and experts believe that the production of WPCs will continue to grow particularly because of their acceptance as a substitute for chromated copper arsenate pressure-treated lumber (57,58).

Although a variety of WPC products have been commercialized, some drawbacks in their properties may limit the market potential of these products. For example, WPCs are more brittle and have lower impact resistance than neat plastic products (61,65). In addition, their high density (62–85 lb/ft^3), which is almost twice that of solid lumber (22–40 lb/ft^3 for various pine species), may hinder their acceptance in the conventional structural lumber market (66). In general, unfilled plastics are more ductile than WPCs because the incorporated brittle wood fibers alter the ductile mode of failure of the matrix making the composites more brittle (61,65,67). The higher density of WPCs compared to the unfilled plastic and solid wood is mainly due to the compression of wood cell walls during processing. The final specific gravity of WPCs manufactured by injection molding, extrusion, and compression molding, even when made with a 0.9 specific gravity thermoplastic resin, is over 1 because the wood cell walls are crushed or compressed nearly to the specific gravity of solid wood without air spaces (approximately 1.5), and voids between and within the wood fiber structure are completely filled with resin (68,69).

Several attempts have been made to overcome the drawbacks of dense WPCs (65,70–72). Significant improvements in the impact strength of WPCs are achieved by incorporating impact modifiers into the formulation (65). However, impact modification of WPCs does not enhance their ductility or reduce the density of the products (65). The creation of a microcellular void structure (wood-like structure) in WPCs through foaming has recently been found appropriate to reduce the weight of the composites (70–73). The lightweight WPCs, as a result of the presence of microcells, exhibit enhanced ductility and impact resistance. However, the reduced density can be achieved at the expense of other mechanical properties such as strength and stiffness (72,74) (Table 5).

There currently are no manufacturing standards for WPCs and the standard test methods for evaluating the mechanical and physical properties of WPC products are under development by the American Society for Testing and Materials (ASTM), committee D7 on Wood. The lack of manufacturing standards combined

Table 5. Mechanical Properties of Microcellular Pure Plastic and WPC Foams

	Mechanical properties[b]							
	Strength at break, MPa[c]		Tensile modulus (stiffness), GPa[d]		Elongation at break, %		Notched Izod impact strength, J/m[e]	
Samples[a]	Unfoamed	Foamed	Unfoamed	Foamed	Unfoamed	Foamed	Unfoamed	Foamed
Pure plastic (PVC)	17	14	0.06	0.07	84	126	72	206
WPC	14	13	0.37	0.20	28	63	31	87

[a]The density of pure PVC was 1.35 g/cm^3 whereas the densities of the composites with 30% wood fibers were in the range of 1.35–1.45 g/cm^3. The densities of foamed PVC and WPC samples were 0.60 g/cm^3.
[b]Properties are expressed as specific properties, ie, property divided by the specific density of the sample (72).
[c]To convert MPa to psi, multiply by 145.
[d]To convert GPa to psi, multiply by 145,000.
[e]To convert J/m to ft·lbf/in., divide by 53.38.

with the increased use of WPCs by the construction industry have also resulted in concern about the durability of these products exposed to outdoor environments. In applications such as decks and docks, landscaping timber, fencing, signposts, playground equipment, window frames, etc, the products can be in ground contact and/or are in an above-ground environment where there often are risks of material deterioration. When WPCs are in ground contact, biological agents such as fungi and subterranean termites may be the main cause of degradation (75,76). On the other hand, exposure to sunlight and moisture can cause degradation in an above-ground environment (77,78). Freeze-thaw durability may also be of significant importance in colder regions where freeze-thaw action is prevalent. These climatic environments may cause millions of dollars of material damage and high material cost may be involved to replace damaged products. Therefore, the durability of these composites is of special concern for their use in outdoor applications and is currently being extensively studied.

WOOL

Raw Wool Specification

Wool is the fibrous covering from sheep (1) and is by far the most important animal fiber used in textiles. It appears to have been the earliest fiber to be spun and woven into cloth. In 2000–2001, world greasy wool production was 2.3×10^9 kg from 1×10^9 sheep, which is equivalent to 1.4×10^9 kg of clean wool (2) (Tables 1 and 2). This is down from a peak of 2.0×10^9 kg in 1989–1990.

Wool belongs to a family of proteins, the keratins, that also includes hair and other types of animal protective tissues such as horn, nails, feathers, beaks, and outer skin layers. The relative importance of wool as a textile fiber has declined over the past decades with the increasing use of synthetic fibers for textile products. Wool, however, is still an important fiber in the middle and upper price ranges of the textile market. It is also an extremely important export commodity for several nations, notably Australia, New Zealand, South Africa, and Argentina, and commands a price premium over most other fibers because of its outstanding natural properties. These include soft handle (the feel of the fabric), water absorption (and hence comfort), and superior drape (the way the fabric hangs). Table 2 shows wool production and sheep numbers in the world's principal wool-producing countries.

The principal characteristics of clean wool types are average diameter, measured in micrometers (referred to as microns), and average length, measured in millimeters. Essentially all fine diameter wool is produced by merino sheep or merino crossbreeds. Over 75% of the sheep in Australia (the world's largest wool producer) are merino sheep, which are also bred in large numbers in South Africa, Argentina, and the former USSR. The softness, fineness, and lightness of fabrics is determined primarily by fiber diameter, and so the price is very sensitive to the mean diameter (3) (Fig. 1).

Encyclopedia of Polymer Science and Technology. Copyright John Wiley & Sons, Inc. All rights reserved.

Table 1. World Production (10^6 kg) of Wool (2000/2001)[a]

Source	Fiber diameter, μm	Greasy	Clean
Merino	<24.5	932	572
Crossbred	24.6–32.5	540	308
Other (carpet)	>32.5	852	494
Total		*2324*	*1374*

[a]From Ref. 2.

Medium diameter wool includes sheep breeds of English origin, eg, southdown, hampshire, dorset, and cheviot, as well as crossbreds, eg, columbia, targhee, corriedale, and polwarth, from interbreeding with merinos. Coarse diameter wool comes from sheep chiefly bred for meat, eg, lincoln, cotswold, and leicester.

Raw wool from sheep contains other constituents considered contaminants by wool processors. These can vary in content according to breed, nutrition, environment, and position of the wool on the sheep. The main contaminants are a solvent-soluble fraction (wool grease), protein material, a water-soluble fraction (largely perspiration salts, collectively termed *suint*), dirt, and vegetable matter (VM) (eg, burrs and seeds from pastures).

In buying raw wool, wool processors are concerned about its quality, the quantity of pure fiber present, and its freedom from contamination (4). For the fine and medium wools used for apparel, the major characteristics are average fiber diameter, yield (ie, the percentage content of pure fiber), content and type of VM, average fiber length, strength of fiber staples, and the position of any weak spot along the fibers. For very fine wools, the frequency and clarity of waves (crimp) in the staples has a significant effect on price. The range of fiber diameters, color of the clean wool, and the number (if any) of naturally colored fibers present can also be important. For carpet-type wools (long wools), the important properties

Table 2. Wool Production and Numbers of Sheep in Principal Wool-Producing Countries (2000/2001)[a]

[a]From Ref. 2.

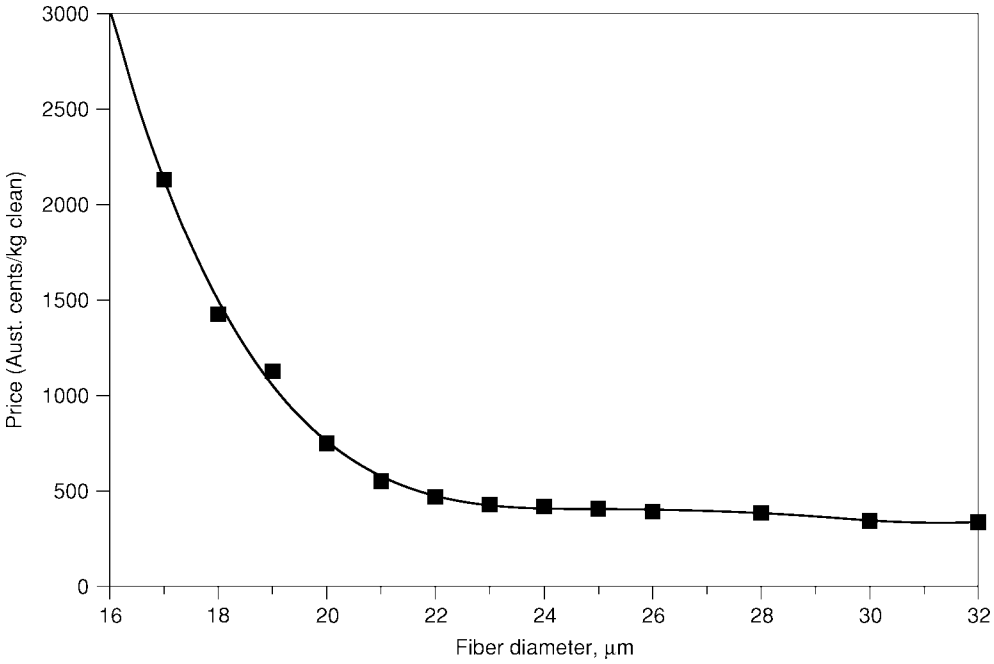

Fig. 1. Dependence of Australian wool prices on fiber diameter (1999/2000) (3).

(5) are yield, fiber diameter, fiber length, color, bulk (the volume occupied by the fibers in a yarn), and VM content. Also important for coarse wools is the degree of medullation. This is associated with cells containing air, arranged along the fiber axis. The presence of medulla cells increase light scattering by the fibers, restricting the use of these wools for some purposes.

Until the early 1970s, the characteristics of different wools were largely evaluated visually by wool classers and valuers. With the development of sampling techniques and equipment capable of rapid and economical measurement of yield, diameter, and VM (6,7), objective measurement and the sale of wool by sample became dominant in major wool-exporting countries. In sale by sample, cores are drawn from each lot and tested for yield, diameter, and VM content in accordance with international standards (8,9). Measurements of staple length, strength, and position of weakness are also now in routine commercial use. In addition, a full-length display sample, representative of each lot and obtained by standard procedure (10), is available for buyers to appraise other characteristics. Sale by sample decreased costs by reducing the handling of bulk wool in wool-brokers' stores and selling operations. It also enabled the processing performance of wool to be predicted in topmaking (11) and spinning (12).

Fiber Characteristics

New instrumentation for measuring fiber diameter (13,14) has meant that data on the range of diameters present (CV_D) and fiber curvature (related to crimp frequency) are now available. The impact of these is fairly well established (15).

These instruments have also been introduced on-farm so that the fleece quality of each animal can be assessed from a mid-side (16) or whole-fleece (17) sample. In some cases it is possible to gain increased returns from separating out the finest fleeces but bigger gains are possible from accelerating the rate of genetic progress. A remaining objective of research is to facilitate the introduction of a system of sale of raw wool by description in which a sale sample will not be required for inspection.

Fiber Growth. Wool fibers are produced from multicellular tube-like structures known as follicles. These follicles are located in the skin layers (dermis and epidermis) of sheep, and two types of follicles, primary and secondary, are usually identified. Primary and secondary follicles are described from the order of their initiation and development in foetal skin. The primary follicles develop first, in the unborn lamb. Secondary follicles develop later and in finer wooled sheep derived secondary follicles subsequently form by branching from the original secondaries, with which they share a common orifice (18). Each primary follicle has a sebaceous gland and a sweat gland together with an arrector muscle, whereas secondary follicles usually have only an associated sebaceous gland (19).

Fiber Morphology. Wool fibers consist of cells, where flattened overlapping cuticle cells form a protective sheath around cortical cells. A scanning electron micrograph of a clean merino wool fiber is shown in Figure 2. In some coarser fibers, a central vacuolated medullary cell type may be present.

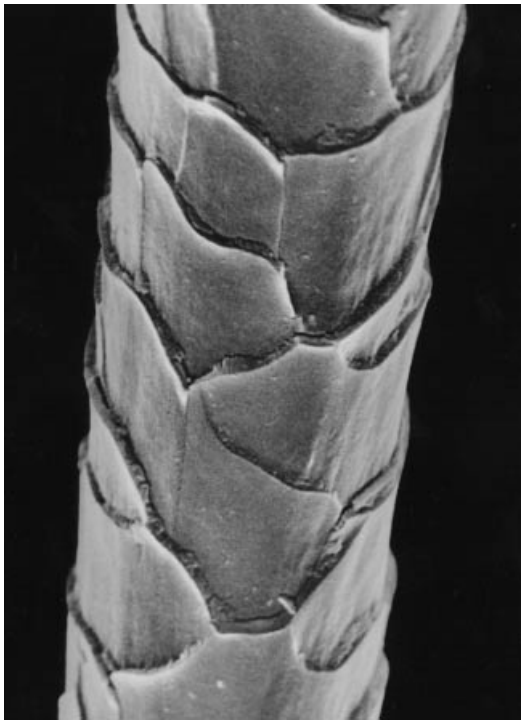

Fig. 2. Scanning electron micrograph of merino fiber, showing overlapping cuticle cells.

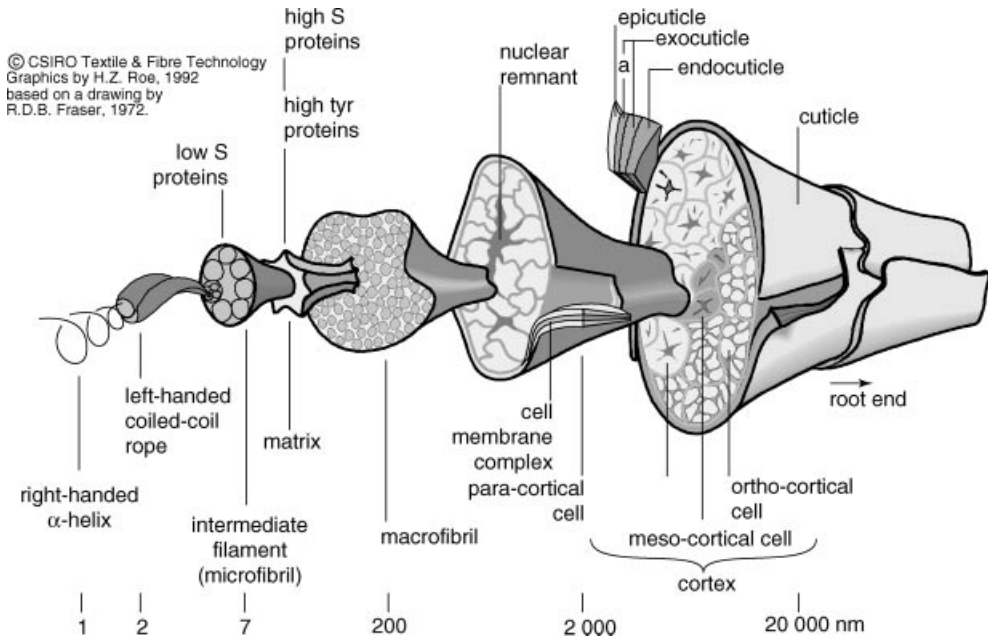

Fig. 3. Schematic of the structure of a fine merino wool fiber.

In fine wool, such as that obtained from merino sheep, the cuticle is normally one cell thick (approximately $20 \times 30 \times 0.5$ μm) and usually constitutes about 10% by weight of the total fiber. Sections of cuticle cells show an internal series of laminations (Fig. 3), comprising outer sulfur-rich bands known as the exocuticle and inner regions of lower sulfur content called the endocuticle (20). On the exposed surface of cuticle cells, a membrane-like proteinaceous band (epicuticle) and a unique lipid component form a hydrophobic-resistant barrier (21). These lipid and protein components are the functional moieties of the fiber surface and are important in fiber protection and textile processing (22).

The cortex comprises the main bulk and determines many mechanical properties of wool fibers (Fig. 3). Cortical cells are polyhedral, spindle-shaped, and approximately 100 μm long. They consist of a class of biological filaments known as intermediate filaments (23) embedded in a sulfur-rich matrix. The intermediate filaments (originally termed microfibrils), together with the matrix, are organized into large macrofibrillar units and these are often observed in sections of cortical cells. In fine merino wool, two main types of cortical cell, known as ortho- and para-, are arranged bilaterally. Orthocortical cells show different intermediate filament/matrix packing arrangements from those of paracortical cells (24). The arrangement of ortho- and paracortical cells differs among wool types. For example, in lincoln wool an annular (orthocortical core surrounded by paracortex) cellular arrangement is present. Merino fibers possess a characteristic crimp and in these fibers the orthocortex is located on the outer side of the crimp curvature.

A continuous intercellular material is present between cuticle and cortical cells which, despite being a relatively minor fraction of the total fiber weight, is of

increasing interest because of its presumed role in the penetration of water and chemical reagents into wool fibers. This region, called the cell membrane complex, is approximately 25 nm wide (25). It comprises a continuous phase of intercellular material, together with the apposing cellular membranes of the cuticle and cortical cells.

Over the past decade, major advances have been made in our knowledge of the cellular and molecular processes in wool follicles that lead to the formation of the wool fiber cuticle, fiber surface, and fiber cortex. In the wool follicle, presumptive cuticle cells undergo flattening during their passage up the follicle and are interlocked with the cuticle cells of the inner root sheath (IRS). When examined by transmission electron microscopy (TEM), the developing fiber cuticle cells demonstrate densely stained intracellular laminae forming in the outer regions of the cells. As the laminae develop, they separate to form an outermost layer, the a-layer, and an underlying layer. Together, these layers comprise the exocuticle.

The remaining cellular volume contains an innermost lightly stained endocuticle (20). In the final stages of cuticle differentiation, proteolipid complexes are formed on the presumptive fiber surface. Unusual mixtures of fatty acids are present in these complexes, which lead to the formation of a hydrophobic surface on the emergent wool fiber (26).

During their upward growth in the follicle, fiber cuticle cells remain adhered to the IRS cuticle by intercellular laminae that develop between two cell types (20). This produces a membrane complex that is different in appearance to that formed between differentiated cortical cells. The main differences exist in the presumptive surface of fiber cuticle cells, where the original plasma membrane appears to be disrupted. This process has been observed by using energy-filtered TEM (21), where it appears that the intercellular laminae are precursors to the formation of a new fiber cuticle surface membrane. It seems reasonable to conclude that a specialized hydrophobic membrane must be synthesized, because a plasma membrane is designed to exist only in a physiological environment and could not perform the protective and other specialist functions of the fiber surface membrane. The mechanism involving separation of inner root sheath cuticle and fiber cuticle cells is essentially unknown, but the cleavage plane appears to occur along a densely stained ultrafine band located in the center of the intercellular laminae (21).

Cortical cells form from a central or annular stream of germinal epithelia. During their early differentiation they undergo elongation and alignment processes. The initial sites for the formation of keratin structural components (arising concurrently with cell elongation) are at the outer boundaries (plasma membranes) of cortical cells, often in association with desmosomes (27,28). At high magnification, these initial keratin structures appear to consist of intermediate filaments (IFs) of 7–8 nm in diameter. These show appreciable staining when viewed after application of the heavy-metal preparations commonly used for contrast enhancement in TEM studies (28). After the formation and packing of IFs into lattice structures, a densely stained proteinaceous material appears to occupy the interfilamentous spaces. This proteinaceous material forms a matrix that is generally considered to be composed of high sulfur and high tyrosine proteins. The formation of these various structural components from their constituent proteins follows this two-stage sequential differentiation (29). As differentiation

proceeds, the IF matrix aggregates to form structures, often known as macrofibrils, which increase in size and eventually occupy the bulk of presumptive cortical cells (30).

Chemical Structure

Wool belongs to the family of proteins called α-keratins, which also include materials such as hooves, horns, claws, and beaks (31). A characteristic feature of these "hard" keratins is a higher concentration of sulfur than "soft" keratins, such as those in skin. Although clean wool consists mainly of proteins, wool also contains approximately 1% by mass of nonproteinaceous material. This consists mainly of lipids plus very small amounts of polysaccharide material, trace elements, and, in colored fibers, pigments called melanin. The lipids are both structural and free.

Protein Composition. Proteins, or polypeptides, are formed by multiple condensation of α-amino acids via their amino and carboxyl groups to form secondary amide (ie peptide) bonds (—CONH—). The general structure of all proteins or polypeptides may be represented as (—NHCHRCO—), where R represents the side chain of the amino acid. The peptide grouping is also known as an amino acid residue, because it is the part of the amino acid that remains after the condensation reaction. Complete acid hydrolysis of wool yields 18 amino acids, the relative amounts of which vary considerably between fibers from different sheep breeds, from different individuals of the same species, and sometimes along the length of single fibers from the same animal (31). These differences are the result of several factors, including genetic origin and nutrition. Studies on the chemical structure of wool have been largely confined to fine merino fibers, although aspects treated herein are relevant to all wool types. Typical figures for two different samples of wool are given in Table 3.

The side groups of the amino acids derived from wool vary markedly in size and chemical nature and play an important role in the physical and chemical properties of the fiber. Those containing nonpolar, hydrocarbon groups are hydrophobic and of low chemical reactivity. The polar, aliphatic hydroxyl groups of serine and threonine are chemically more reactive than the hydrocarbon residues. The side chains that have the most overall influence on the properties of wool are, however, the acidic groups of aspartic and glutamic acids and the basic groups of hystidine, arginine, and lysine. These acidic and basic groups give wool an amphoteric character and play an important role in wool dyeing. They are also responsible for wool's ability to combine with large amounts of acids or bases. The individual polypeptide chains of wool are held together and stabilized by both covalent and noncovalent bonds and interactions.

The most important of these is the disulfide bond (Fig. 4). This occurs by reaction of pairs of cysteine residues to form cystine (disulfide) linkages (—S—S—) between different polypeptide molecules, or between segments of the same molecules, as shown. The disulfide interchain cross-links have been compared with the rungs of a ladder. They are important because they prevent movement of chains and chain segments and, thus, are responsible for the higher stability and lower solubility of wool fibers compared with most proteins. The disulfide cross-links are readily rearranged through a thiol/disulfide interchange reaction

Table 3. Amino Acid Composition of Merino Wool

Amino acid[a]	Amino acid content, residues/100 residues: Sample 1[b]	Sample 2[c]	Nature of R group
Glycine	8.6	8.2	Aliphatic hydrocarbon
Alanine	5.3	5.4	Aliphatic hydrocarbon
Valine	5.5	5.7	Aliphatic hydrocarbon

$$WS_1—S_2W + —S_3^- \rightleftharpoons —S_1^- + WS_2—S_3W \quad (1)$$

Thiol/disulfide interchange facilitates conformational rearrangement of the wool proteins, leading to relaxation of molecular stress in the fiber. This property is employed in the permanent setting of wool fabrics. Another type of covalent cross-link present in wool is the isopeptide bond, formed between the side chains of lysine and either aspartic or glutamic acid (Fig. 4). Noncovalent bonds or interactions also make an important contribution to the properties of wool. These secondary bonds can occur within a single protein chain, or between different chains. They include hydrogen bonds between —CO and —NH groups in the polypeptide chains and the amino and carboxyl groups in the side chains, and also between suitable donor and acceptor groups in the amino acid side chains. Strong electrostatic interactions (ionic bonds, or "salt linkages") also occur between ionized carboxyl and amino groups in some of the side chains. Ionic bonds contribute to the dry mechanical properties of wool fibers. Hydrophobic interactions can occur between nonpolar groups in some of the side chains and these contribute to the mechanical properties of keratin fibers, particularly when wet. They are also important in wool setting.

Structure of Wool Proteins. The structure of wool proteins has been the subject of much research. Methods to solubilize, separate, and determine the amino acid sequence of these proteins have been reviewed (31,37). It is estimated that wool contains about 170 different types of polypeptides varying in relative molecular mass from below 10,000 to greater than 50,000 (37,38). Morphologically, wool fibers are biological composites, with each component having a different physical and chemical composition (Fig. 3). The groups of proteins that constitute wool are not uniformly distributed throughout the fiber, but are aggregated within the various regions.

Except for a small amount of the amino acid methionine, the sulfur in wool occurs in the form of the amino acid cystine. Only approximately 82% of clean wool consists of keratinous proteins, which are characterized by a high concentration of cystine. Approximately 17% of the fiber is protein material of relatively low cystine content (<3%); this has been termed nonkeratinous. As a result of the lower cystine content, the nonkeratinous proteins have a lower concentration of disulfide cross-links compared with the keratinous proteins in the fiber. The nonkeratinous material is, therefore, more labile and less resistant to chemical attack than the keratinous proteins. The nonkeratinous proteins are located primarily in the cell membrane complex between the cortical cells and in the endocuticle (Fig. 3). Approximately 13% of the total nonkeratinous material is also located within the cortical cells, where its distribution differs between the cells of the ortho- and paracortex.

The keratinous proteins of wool belong to three groups:

(1) low sulfur proteins, rich in amino acids that contribute to α-helix formation (glutamic acid, aspartic acid, leucine, lysine, arginine)

(2) high sulfur proteins, rich in cystine, proline, serine, and threonine
(3) high glycine, high tyrosine proteins which are also rich in serine.

The proteins derived from the rod-like intermediate filaments (microfibrils) of the cortical cells contain the helical segments of low sulfur proteins. These are surrounded by a relatively amorphous, nonfilamentous matrix, which consists principally of high sulfur and high glycine/high tyrosine proteins. It has been shown that the amino acid sequences of the helical portions are highly homologous with those of intermediate filament proteins derived from skin and other tissues. For this reason the microfibrils of wool are now generally referred to as intermediate filaments (37). Although the filament proteins of the ortho- and paracortex are similar, the orthocortex contains a higher proportion of intermediate filaments than the paracortex. The orthocortex is, therefore, richer in the low sulfur proteins that favor α-helix formation. The intermediate filaments contain a rod-like central helical domain in which the sequences show a heptad repeat, interrupted at three positions by short nonhelical segments. The ends of the polypeptides consist of nonhelical domains terminated in carboxyl and *N*-acetyl groups, respectively (37,39). The proportion of matrix (and hence of the high sulfur proteins) is greater in the paracortex than in the cells of the orthocortex (40). Furthermore, the proteins of highest sulfur content (ultrahigh sulfur proteins) are concentrated in the paracortex (41).

Wool Lipids. The lipids of wool are located mainly in the cell membrane complex. They constitute less than 1% of the fiber mass but play an important role in many properties, such as the intercellular diffusion of dyes and reagents (25,31). The free lipids are extractable with organic solvents and consist of fatty acids, fatty alcohols, sterols, sterol esters, and trace amounts of glycerides, sphinolipids, and glycolipids (26). Although phospholipid is present in the wool follicle membranes, only trace amounts of phospholipid are found in the keratinized fiber (42,43). Cholesterol and its biosynthetic precursor, desmosterol, are the main sterol components of the free lipids. In addition to the free lipids, wool contains some lipids that are believed to be covalently bound to proteins. These components are not readily removed by organic solvents, but those at the fiber surface can be released by alkaline hydrolysis under conditions where damage or modification of the fiber interior cannot occur (44). Covalently bound surface lipids represent approximately 0.025% of the fiber mass and are a distinct component of the fiber that has been termed the F-layer (44,45). This component is very important because it is responsible for the hydrophobicity of the fiber surface. The major component of the F-layer is an unusual branched-chain fatty acid (18-methyleicosanoic acid), which accounts for approximately 60% of the surface lipid material. Removal of the bound surface lipids generates a clean protein surface, which is more wettable, and has higher friction and better adhesion properties than the surface of clean untreated wool (44).

Physical Properties

Fiber Size and Shape. Wool is usually harvested from sheep by annual shearing. The fiber length is, therefore, determined largely by the rate of growth,

which in turn depends on both genetic and environmental factors. Typical merino fibers are 50–125 mm long. They have irregular crimp (curvature), with the finer fiber generally showing lower growth rates and higher crimp. The fiber surface is rough as a consequence of the outer layer of overlapping cuticle cells. By far the most important dimension is the fiber diameter. Wool fibers exhibit a range of diameters, which like fiber length is dependent on both genetics and environment. Coarse wool fibers (25–70 μm diameter) are used in carpets, while fine merino fibers (10–25 μm) are used in apparel because of their soft handle. Fibers from an individual sheep also exhibit a range of diameters. The mean diameter is the prime dictator of price; however, the distribution of diameters is also important. When worn next to the skin, the number of coarse fibers affects comfort as these fibers, rather than buckling, indent the skin and activate nerve receptors (46,47). This gives rise to a sensation of prickle and itch that has been incorrectly assumed, by some consumers, to be an allergic reaction. True allergies are rare, if they exist at all, and the irritation is mechanical and not immunological. Instruments that measure the full diameter distribution as well as fiber curvature have been developed recently (13,14). Individual fibers exhibit curvature in three dimensions; however, by measuring the circular curvature of short segments, a two-dimensional value can be obtained that correlates with the crimp frequency measured in staples. Crimp contributes to the excellent insulating properties of wool fabrics by improving their bulkiness and, hence, the amount of entrapped air.

Water Sorption. Wool is hygroscopic and able to absorb and desorb large amounts of water as the relative humidity surrounding the fiber changes. The water is believed to be associated with specific chemical groups in the amorphous regions, with polar side groups and peptide groups of the protein chains considered to be the most important (48). Debate continues, however, on the exact location of this water, its state, and the mechanism by which it enters the fiber (49–51). As a consequence of the lipid outer layer, the surface of wool is hydrophobic. It is dry to touch and not readily wet-out by liquid water. In line with other polymers having functional surfaces, the surface of wool is believed to rearrange in different environments (52). In textiles, the amount of water absorbed is generally expressed as a percentage of the dry weight. This is referred to as "regain" and is different to "water content", which is the mass of water in the fiber expressed as a percentage of the total mass of fiber plus water. A pronounced hysteresis is observed in the water sorption isotherm of wool. This is 2% higher on desorption than on absorption, at most relative humidities (53). The saturated regain of wool is about 33%, which is higher than that of most other fibers (54).

Heat is liberated when wool absorbs water; this increases comfort by helping to buffer the wearer against sudden environmental changes. The absorption of water by wool also results in other improvements to comfort during wear. At a given relative humidity, wool has similar water sorption to skin. Wool garments, therefore, act as an excellent buffer during physical activity by transporting perspiration away from the skin, thereby keeping its moisture content close to the comfort level. A new wool-containing product designed for active sportswear (SportWool^{TM}) utilizes the moisture-buffering properties of wool (CSIRO Textile and Fibre Technology Web site: http://www.tft.csiro.au; Sportwool Web site: http://www.sportwool.com). As can be seen from Table 4, most physical properties of the fiber are affected by (water) regain.

Table 4. Effect of Moisture Sorption on the Physical Properties of Wool Fibers at 25°C[a]

Table 4 Effect of Water Sorption on the Physical Properties of Wool Fibers at 25°C

Wool is sold by weight; thus, allowance for uptake of water must be made. A premium is paid for fine wools and because the diameter changes with regain, diameter measurements must be made under standard conditions of temperature and humidity.

Thermal Properties. The regular packing of α-helical polypeptide chains within the intermediate filaments forms a crystalline phase that occupies about 70% of the dry volume of the fiber (57). This phase melts irreversibly at a temperature that is both time- and regain-dependent (58). During the dyeing and finishing of wool, no melting of the fiber occurs. Care should be taken, however, when processing blends of wool and synthetic fibers that require higher temperatures. The amorphous matrix phase contains a high concentration of the amino acid cystine and is, therefore, highly cross-linked. As with other amorphous materials, a glass transition T_g has been detected in the wool fiber (59,60) which is sensitive to physical aging (61). Water acts as a plasticizer, lowering the glass-transition temperature of the dry fiber from 170°C to below zero when saturated (Fig. 5).

The glass-transition temperature is an important parameter, as the properties and performance of wool are influenced by the environmental conditions (temperature and humidity) relative to the glass transition. The insertion of temporarily set creases or pleats in wool fabric (equivalent to thermally set creases in synthetic polymer fabrics) is achieved by subjecting wool to bending strain above T_g and fixed by transition to conditions below T_g. This can be done by heating and cooling, wetting and drying, or a combination of both, eg, steam pressing. Wrinkle recovery is poorer when wrinkles are inserted above T_g and recovery is below T_g. This is likely to occur under hot and humid conditions where local wetting (perspiration) and wrinkle insertion occurs simultaneously. When the fabric moves away

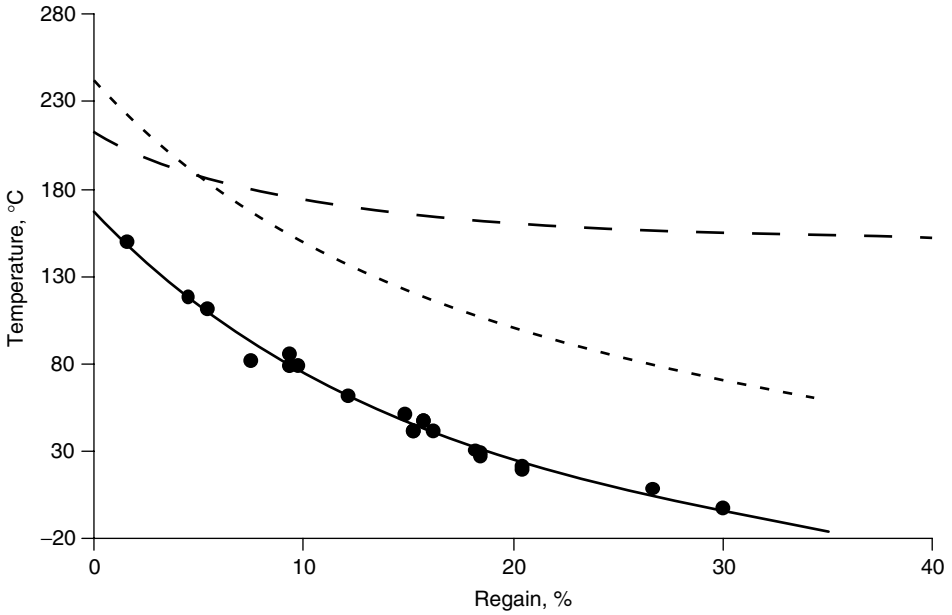

Fig. 5. Glass-transition (—) (60), indicative permanent setting temperature (----), and melting temperature (– – – –) (58) of wool as a function of regain.

from the skin, the wrinkle has insufficient time for complete recovery before the fabric dries. This causes the T_g of the fabric to rise to a temperature above that of the environment. The viscoelastic properties (59), physical aging (59), felting (62), and the water absorption isotherm of wool (50) are also influenced by the glass transition.

Tensile Properties. The tensile properties of wool are quite variable but, typically, at 65% RH and 20°C individual fibers have a tenacity of 110–140 N/ktex (140–180 MPa), a breaking elongation of 30–40%, and an initial modulus of 2100–3000 N/ktex (2.7–3.9 GPa) (54). Although wool has a complicated hierarchical structure (see Fig. 3), the tensile properties of the fiber are largely understood in terms of a two-phase composite model (63–65). In these models, water-impenetrable crystalline regions (generally associated with the intermediate filaments) oriented parallel to the fiber axis are embedded in a water-sensitive matrix to form a semicrystalline biopolymer. The parallel arrangement of these filaments produces a fiber that is highly anisotropic. While the longitudinal modulus of the fiber decreases by a factor of 3 from dry to wet (56), the torsional modulus (a measure of the matrix stiffness) decreases by a factor greater than 10 (Table 4 and Reference 66). The longitudinal stress–strain curves for a wool fiber at different relative humidities are shown in Fig. 6 (54).

Three distinct regions can be discerned, especially for fibers at higher relative humidity. Once the fiber crimp is removed, a near-linear region up to about 2% strain is obtained (pre-yield region). For the wet fiber, this is generally associated with stretching of the α-helices within the intermediate filaments. At lower (water) regain, the matrix phase plays an increasingly dominant role. Between 2 and 25%

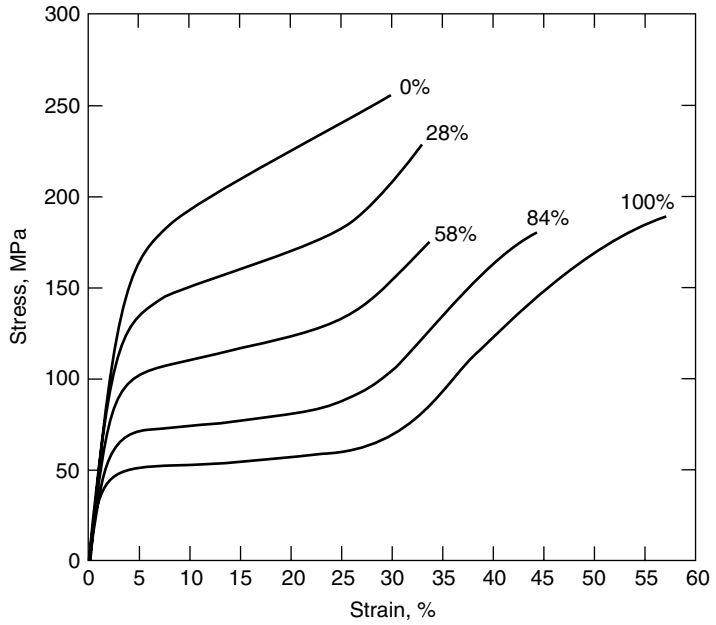

Fig. 6. Stress–strain curves of typical wool fibers at different relative humidities.

strain (yield-region) progressive unfolding of zones of α-helices to form a β-pleat configuration occurs. Very little increase in stress is observed during this stage and complete recovery is still possible, provided the fiber is allowed to relax in water. Beyond 25% strain (post-yield region), the fiber stiffens and breaks. At a molecular level, the reasons for this are still a matter of debate but include resistance to the unfolding of a stabilized region of the intermediate filaments (63,65) and the rubber-like response of the matrix (64). A recent review looks critically at the different models (67).

For a fiber immersed in water, the ratio of the slopes of the stress–strain curve in these three regions is about 100:1:10. While the apparent modulus of the fiber in the pre-yield region is both time- and water-dependent, the equilibrium modulus (1.4 GPa) is independent of water content and corresponds to the modulus of the crystalline phase (68). The time-, temperature-, and water-dependence can be attributed to the viscoelastic properties of the matrix phase.

Wool Processing

The conversion of raw wool into a textile fabric or garment involves a long series of separate processes. There are two main processing systems, worsted and woolen. A significant volume of wool is also processed on the semiworsted system, for carpet use. Some wool is processed on the short-staple (cotton) system. Details of the principal stages in the woolen and worsted systems and discussion of more recent developments can be found elsewhere (69,70).

The majority of the world's apparel wool clip is combing wool and this is processed on the worsted system. This process was so named because the combed wool spinning industry in England developed in the English town of Worsted in the fourteenth century (70). Fine, smooth yarns were produced by "spinsters" who placed the combed parallel array of fibers on top of a distaff (combed wool even today is known as top), drew the strand down to the required linear density, and inserted the twist using a spindle. Prior to the development of worsted spinning, and coexisting ever since with it, the traditional system produced yarns in which the fibers were much more disorientated. Although the texture was not as smooth, there was a high degree of bulk, and the finished woven fabrics produced coatings, blankets, and distinctive products such as tweeds and flannels. Woolen spinning is the mechanized form of the traditional system.

Besides scoured (cleaned) wool, the next saleable commodity in worsted processing is top, or combed wool. Generally the combing plant combines the processes of scouring and combing. Most often, a separate commercial enterprise which buys top from the topmaker carries out spinning. Although there are woolen sales-to-yarn spinners, particularly in the knitwear area, the production of woven woolen products in the one enterprise from raw wool is more common. The woolen process is characterized by a much higher degree of vertical integration than the worsted system.

Scouring. The first stage in wool processing is to remove the fleece impurities by scouring. The impurities consist principally of wool wax, dirt, proteinaceous contaminants, and suint. The latter is a water-soluble component, consisting mainly of potassium and other inorganic salts arising from perspiration. Scouring is carried out by washing the raw wool in an aqueous medium, a solvent medium, or a combination of the two. Aqueous scouring is used to process 99% of the world's wool. This involves washing the raw wool in aqueous solutions (neutral or slightly alkaline) of nonionic detergent or, less frequently, soap and alkali. This is followed by rinsing in water.

The process is carried out in a series of between four and seven tanks (called bowls), in which the wool is transported through the wash liquor by mechanical rakes, or by passing it around perforated drums (71,72). At the end of each bowl, the wool passes through a roller squeeze. Agitation of wool in anhydrous solvents does not cause felting, and several systems (71,73,74) have been operated to take advantage of this property, but none are still in commercial operation.

There are two broad categories of contaminants on raw wool: those that are easily removed and those that are hard to remove. The different rates of removal of these contaminants in the scouring process has led to the development by CSIRO of a new scouring technology, known as Siroscour™. This uses the principles of multistage scouring, rather than severe mechanical action, to optimize the removal of contaminants during aqueous scouring. The three separate stages which comprise the Siroscour process are a modified desuinting bowl, designed to remove as much dirt as possible; a hot scouring stage that removes the easy-to-remove contaminants; and a third stage, designed to remove the hard-to-remove contaminants. To achieve optimum performance, separate dirt and grease contaminant recovery loops are incorporated into the Siroscour process, as well as specific bowl designs for optimum scouring efficiency of Australian wools. Comparative trials have shown Siroscour to consistently produce wool of superior whiteness and

lower residual content of mineral contaminents (ash content) than other scouring systems (75).

In most situations, wastewater discharged from a scouring machine contains large quantities of wool wax and both water-soluble and water-insoluble material (organic and inorganic). The pollution load of a single modern scouring machine is equivalent to a population of 50,000 people. Disposal or treatment of the wastes to comply with environmental requirements is expensive. In the past, the least expensive approach involved biological treatment by irrigation of large land areas, or maturation in very large, shallow lagoons. The high levels of potassium present in scour effluent require 1000 ha of land for sustainable irrigation. These factors have forced scourers to install large evaporation ponds that cover many hectares. Technology has been developed that enables scourers to recover a large amount of the potassium from the scour liquor. This can be used as a potassium supplement in fertilizer.

Physicochemical methods of wastewater treatment have been investigated. These include flocculation with inorganic or polymeric flocculants, or with sulfuric acid, and also physical techniques, eg, membrane processes and solvent extraction. Few of these processes have proceeded beyond pilot-scale evaluation, however. One of the most recent processes that has proved to be commercially viable is the Sirolan CF™ technology developed by CSIRO (76). This is a chemical flocculation process that removes more than 75% biological oxygen demand, 80% chemical oxygen demand, and 99% of the suspended solids and wool wax. This is a simpler process with lower operating costs than other methods involving chemical flocculation. Sludge disposal technologies have been developed that can be used in conjunction with the Sirolan CF process. These include composting, incineration, and pelletizing (77). The centrate from the Sirolan CF process contains mainly suint salts. Plant growth trials, carried out by Agriculture Victoria and CSIRO, demonstrated that suint salts, which contain about 27% potassium, are equal or better than inorganic sources of potassium (78).

Carbonizing. Carbonizing is a process used to remove excessive amounts of cellulosic impurities, eg burrs and VM, from wool. It is carried out on loose wool, rags (79), and fabric (80). With loose wool and fabric, the wool is treated with aqueous sulfuric acid and then baked. The cellulosic matter is rapidly destroyed by the hot concentrated acid, by conversion into friable hydrocellulose, whereas wool is scarcely affected by the treatment. For dyed rags, hydrogen chloride gas is preferred as the mineral acid, because it has less effect on the colors. After acid treatment, the carbonized VM is crushed to facilitate its removal. The wool is then normally neutralized in alkali, although some mills omit this stage to facilitate subsequent dyeing under acid conditions.

Most industrial carbonizing is done on loose wool, the technology having changed little over the past 40 years. Australian carbonizers use surface-active agents to reduce fiber damage in the carbonizing process (81,82). The improved results depend on the use of high acid concentrations and rapid throughput (81).

Processing on the Worsted and Woolen Systems. The wool is dried after scouring and blended before carding. Carding individualizes the entangled fibers and reassembles them into a "sliver" weighing about 25 g/m. At the same time, up to 90% of the VM is removed. Lubrication (83) is used to minimize fiber breakage. After carding, there are three stages of gilling, to align fibers and remove

hooked fiber ends before combing. Here, the advancing beard of fibers is inserted into a circular comb, and the leading fibers are then gripped and pulled through a top comb before being reassembled, like overlapping tiles, in the output sliver. The process removes short and entangled fibers and almost all remaining VM. The waste (noil) can be carbonized and fed into the woolen system. The sliver is then given two more gillings and consolidated into top. Some combing plants also produce shrink-resist treated wool top. The current process incorporates chlorination followed by application of a polymer.

The worsted spinner converts top of about 25 g/m linear density into roving of between 200 and 2000 g/km, depending on the linear density of the yarn to be spun. The sequence of processes incorporates four or five drawing stages. The first three or four usually employ gills, whereas the last is commonly carried out on a roving frame in which the attenuated strands are rubbed or twisted to impart cohesion. For finer wool, dyed tops or after blending with synthetic fibers, it is normal to recomb the wool before the above drawing stages.

Long-staple ring spinning is similar to short-staple (cotton) ring spinning, except that the components are increased in approximate proportion to the length of the fibers. On the spinning frame, the rovings are drafted by a factor of about 20, twist is inserted, and at the same time the yarn is wound onto bobbins. The yarn on the bobbins is usually steam-set in an autoclave to reduce its twist liveliness, then wound onto packages or cones. Detection and removal of thick, thin, and colored faults can occur during winding. Following twisting into a twofold yarn and further setting, the yarns are ready for knitting or weaving. Open-end (rotor) spinning is rarely used for wool, and spinning and twisting are very costly operations, because of their low productivity: typically 40 spindles produce 1 kg/h of yarn.

In woolen processing, there are no highly efficient mechanical methods to remove VM. Generally, very clean scoured wool, combed wools, or carbonized wool must be used as inputs. Alternatively, fabrics must be carbonized. A much longer card than in worsted processing and shorter fibers are used. The web of fibers at the card delivery is split longitudinally into about 120 ends, rubbed to impart cohesion, and wound into cylindrical packages called slubbing. Twisting of these slubbings occurs on the woolen spinning frame with a draft of 1.3–1.5, to produce woolen singles yarn. This yarn can be woven without any further processing, other than a winding and clearing operation similar to that used in the worsted sequence. Woolen spinning is, thus, a very short sequence of operations compared to worsted processing. Woolen yarns, however, become economically uncompetitive with worsted yarns at relatively coarse yarn counts, because production is tied to the number of ends times their weight.

Woolen yarns cannot be spun as fine as worsted yarns, even when using the same fiber diameter. The fabric weights are greater and they have a harsher feel. For these reasons, woolen products have not been able to follow the modern trend to smoother lightweight clothing as easily as their worsted counterparts.

Setting

Setting operations form an important part of the processing of wool yarn, fabric, and garments. Yarn is set in steam to stabilize twist and prevent snarling

during winding and warping, while fabrics may be set after weaving to prevent the formation of distortions during wet processes, such as scouring and dyeing. Normally, fabrics are flat-set near the end of the finishing routine to impart dimensional stability and to confer the required handle. Finally, garments are set by steam pressing to form their desired shape, for example, to insert pleats and creases.

Two forms of set may be conferred to the wool fiber and these two forms can be distinguished on the basis of stability. Temporary set (or cohesive set as it is generally referred to in the wool industry) is imparted when wool fibers are dried, or steamed for a short time and then cooled while under strain. This set is readily lost when the fibers are gently steamed or allowed to relax in water at room temperature (84). Permanent set, as the name implies, is set that has a considerable degree of permanency. Set that remains after relaxation in water at 70°C for approximately 15 min is generally considered permanent, ie, the set is permanent to conditions in excess of those that a wool garment would normally encounter during use, eg machine washing.

At the molecular level, setting is a process of stress relaxation which results from the rearrangement of the protein macromolecules that form the fiber. Under ambient conditions of water content and temperature, the matrix regions of wool are glass-like (ie below the glass-transition temperature, see Fig. 5). When fibers are deformed under these conditions, stress relaxation is slow.

If wool is heated or becomes wet, the matrix regions become rubber-like and stress relaxation occurs much more rapidly. Cohesive or temporary setting occurs whenever the fibers are deformed under conditions where stress relaxation is high (rubbery state), and then cooled or dried to a glassy state before they are released. In the glassy state the relaxation rate is slow, so that the fiber will essentially maintain its new shape indefinitely, or until it is again wetted-out or heated to make it rubber-like.

The protein molecules, particularly those of the cuticle and matrix regions of the fiber, are stabilized by a number of covalent bonds and noncovalent interactions. The most important of these are disulfide bonds, which cross-link the peptide chains (Fig. 4). A unique feature of the wool fiber is the ability, under suitable conditions, for these disulfide bonds to rearrange and form a new cross-linked polymer network. This occurs via a mechanism involving thiol/disulfide interchange (eq. 1). Permanent setting will occur if this rearranged network, cross-linked by reformed disulfide bonds, is at equilibrium with the new shape of the fiber. The rate of disulfide rearrangement is "catalyzed" by the concentration of thiol anions in the fiber (85), as well as by the macromolecular mobility of the protein chains. Hence, the rate of disulfide rearrangement can be increased by increasing the pH, breaking disulfide bonds with a reducing agent to form additional thiol anions, or by increasing the regain or temperature to facilitate molecular mobility. In addition to the rearrangement of disulfide cross-links via thiol/disulfide interchange, other mechanisms are also involved. These include rearrangement of hydrogen bonds and the formation of new types of covalent cross-links that are formed from residues produced by breaking disulfide bonds. The new bonds include lanthionine and lysinoalanine cross-links (86). These cross-links are more stable than the disulfide bonds from which they were produced and make a significant contribution to the stability of permanently set wool fibers. In some circumstances,

hydrophobic bonds between suitably located nonpolar side chains can also contribute to the stabilization of permanent set (87). Figure 5 depicts a curve above which the temperature and regain are sufficient for imparting permanent set to wool within a few minutes. This curve is indicative only, as its actual position can vary between different wool types, previous treatments, and process conditions, because it is influenced by the thiol content and pH of the wool fiber, and also the definition of "permanent set."

During wool processing, the regain and temperature are carefully selected and controlled in order to impart either permanent or temporary set. As indicated in Figure 5, permanent setting can be achieved under wet or dry conditions (less than saturation, ie <33% regain). The most common form of wet permanent setting is continuous crabbing. This is an operation in which a wet fabric, sandwiched between a hot (up to 160°C) roller and an impermeable belt, is heated to temperatures above 100°C for up to 1 min, before being rapidly quenched in cold water. The amount of permanent set imparted in a continuous crab is less than that conferred by a traditional batch crabbing operation. The continuous method has greater productivity, however. The effectiveness depends on the pH of the wool and the treatment time and temperature. The rate of permanent setting can be increased by increasing the number of thiol groups within the fiber by impregnating the fabric with a reducing agent. Some dyeing operations can impart large amounts of permanent set to wool. This can be minimized by including in the dyebath a chemical that reacts with the thiol anions. Minimizing permanent set during dyeing is beneficial in maintaining fiber strength (88) and for maintaining yarn bulk (89).

Dry setting operations usually involve the use of steam. As is the case for wet setting, the amount of permanent set imparted in steam-setting depends on the wool pH, water content, and the time and temperature of setting. Fabrics are steam-set by decatizing. In this process, the wool fabric, interleaved with a cotton wrapper cloth, is wound onto a perforated drum, through which steam is forced. In continuous machines, the conditions are mild and little permanent set is imparted. In a batch process, in which the fabric roll is placed in a pressure vessel (autoclave), setting temperatures up to 130°C for 3–5 min are used. These conditions impart a higher degree of permanent set than continuous methods. The amount of temporary or cohesive set imparted in both batch and continuous machines depends on the temperature of the fibers when the fabric is released from the wrapper cloth. The cooler the fabric, the higher the level of cohesive set. Yarns on packages are normally cohesively set in an autoclave at temperatures up to 90°C, in order to reduce twist liveliness. A vacuum pump is used to remove air from the packages, which ensures even penetration of steam and, thus, a uniform level of set.

Normal pressing operations carried out during garment making impart only temporary set to the fibers. A number of commercial processes are used, however, to set permanent creases into wool garments (90–92). These include autoclave setting and wet or dry pressing in the presence of chemical assistants. Permanent pleats are fixed into skirts by autoclave setting at around 110°C. In the SIROSET™ process of CSIRO, for inserting permanent creases into trousers, a chemical assistant (monoethanolamine sulfite) is sprayed onto the trousers before steam-pressing.

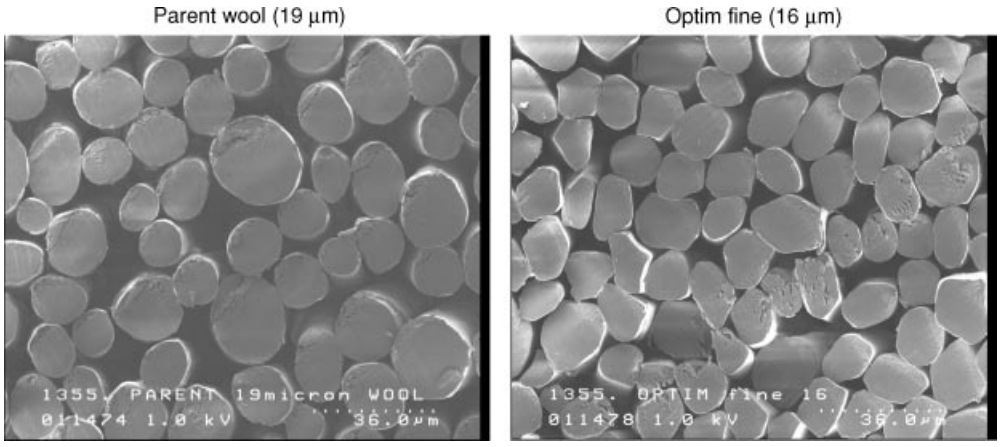

Fig. 7. Scanning electron micrograph of cross sections of normal wool and Optim fine fibers.

A New Textile Fiber from Wool. The most recent application of wool setting is in the manufacture of OPTIM^{TM} (CSIRO Textile and Fibre Technology Web site: http://www.tft.csiro.au), a new textile fiber produced from wool (93). The production process involves stretching and setting wool to create two new fiber types; Optim fine and Optim max (94). A key aspect of the continuous process is the use of false twist to maintain cohesion within a large fiber assembly during the whole operation.

In the Optim fine manufacturing process a chemical setting agent, such as sodium bisulphite, is applied to wool. A twisted assembly of the treated fibers is stretched by around 40–50% and then permanently set in the extended state. This procedure gives longer fibers of decreased diameter. Stretching and setting the fibers converts ordered intermediate filaments in the wool from an α-crystallite helical form to a β-pleated sheet structure that more closely resembles silk (95). Typically, the diameter is reduced by about 3–4 μm for a 19-μm parent wool fiber. The use of false twist to control fiber movement applies a large transverse force to the twisted assembly that changes the cross-sectional shape of the fibers so that common measures of diameter that assume a mostly circular cross section are no longer valid (Fig. 7).

Optim fine fibers are stronger and softer than the parent wool and exhibit an attractive lustre. They are used to produce fabrics with many of the aesthetic properties of silk. The modified wool is ideal for spinning into fine yarns, especially with other high value natural fibers, eg, silk, cashmere, and alpaca, where softness, lightness, and sheen are desirable attributes.

Optim max utilizes a key benefit of the manufacturing process that allows the extent of set in the fiber to be manipulated in a controlled manner. Optim max fiber is wool that has been temporarily set while stretched, so that the fiber retracts when released in hot moist conditions by about 25% in length. This fiber offers scope for innovation in yarn and fabric design. For example, when Optim max is blended with normal wool, spun into yarn, and relaxed in hank form in hot water, the Optim max fibers retract and force the normal wool fibers to buckle.

The yarn has an increased volume and this property produces increased "cover" in knitted fabric and decreased weight. When knitted to the same cover factor, a weight saving of 20–30% is possible compared with fabrics made from normal wool yarns.

Shrinkage of Wool Textiles

Two mechanisms of fabric shrinkage are observed for wool: relaxation shrinkage and felting shrinkage (22,96). Relaxation shrinkage occurs when a fabric or yarn made from any textile fiber is first immersed in water. It results from the release of temporarily set strains imparted during previous processing operations such as spinning, knitting, and fabric finishing. Relaxation shrinkage also occurs when a knitted garment or fabric is immersed in water after it has been dried while in a stretched state (for example by line drying). Felting results from the presence of cuticle cells (scales) on the wool fiber surface that point away from the fiber root and overlap like tiles on a roof (Fig. 2). The protruding scale edges result in differential friction between the with-scale and against-scale direction, which under some conditions results in irreversible migration of individual fibers toward their root ends. Felting is exploited in the "milling" of wool. This is a process of controlled, mild felting used to close up the structure of fabrics and garments. Milling is also used to produce wool felts, which are composed of a very dense matting of fibers. Felts are used for products as diverse as hats, polishing pads, table covers, and piano hammers.

Felting in garments and fabrics that leads to excessive shrinkage is, however, undesirable. It occurs when the wet material is subjected to severe mechanical action, for example, in laundering or tumble drying (22). Shrink-resist treatments are directed at preventing felting shrinkage, whereas minimization of relaxation shrinkage requires careful control during fabric finishing. Felting of loose fibers results in entanglement, whereas in fabrics fiber migration inside and between yarns reduces the fabric area, ie, shrinkage occurs. The mechanisms of felting shrinkage and its prevention have been discussed comprehensively (22). Many factors influence felting shrinkage; these include (*1*) yarn and fabric structure (woolen or worsted, knitted or woven, yarn twist level); (*2*) the method of wash-testing (pH, temperature of wash liquor, presence of detergents, electrolytes, or lubricants, and the severity of the mechanical action of the washing machine); (*3*) the properties of the fiber (elasticity, diameter, length). Recently, felting shrinkage has been related to the glass-transition temperature of wool (97). Important points to note are that products made from fine diameter wools felt more readily than those from coarse fibers, and that if a small amount of untreated wool is added to shrink-resist treated wool, the blend will felt as readily as the untreated material.

Shrink-Resistent Terminology and Testing. The term shrink-resistant is preferred to "shrinkproofed," although in recent years emphasis has switched to performance-related terms, such as hand-washable and machine-washable. A recent trend is to use the term easy-care, which for knitwear means resistance to felting shrinkage under severe conditions, including tumble drying. It also includes assessment of the fabric appearance after testing. For woven garments, this includes retention of pleats or creases as well as smooth drying performance.

All these terms are meaningless unless related to some standard testing sequence and criteria for passing the test.

Relaxation shrinkage tests usually involve mild agitation in water. Felting shrinkage is then determined after more severe agitation. Hence, in practice it may be difficult to say when relaxation ceases and felting starts. The most commonly used methods to test for felting shrinkage is to use multiple wash-test cycles in domestic-type washing machines (front loading in Europe, or top loading in the United States). The Woolmark Company (formally the International Wool Secretariat) has developed test methods for machine washability, together with performance criteria for different garment types and end uses. Woolmark test methods are widely used around the world, although in the United States AATCC methods predominate.

Development of Shrink-Resist Science and Technology. Felting of wool and its use in fabric finishing has been known for a very long time. Monge observed the differential friction effect in wool fibers in 1790 and Mercer chlorinated wool to improve dye affinity in printing in 1839, but chlorination was soon found to impart shrink-resistance (22). Chlorination was widely used during World War II to produce shrink-resistant wool socks and blankets for the military. From then on, two distinct trends in shrink-resist research and technology emerged. Firstly, better control of the reaction of chlorine or other oxidants with wool, and secondly, the use of synthetic polymers to bond adjacent wool fibers together. The reader is directed to Reference 98, which gives a good summary up to the early 1950s, and to Reference 22, which continues to the late 1970s and discusses the mechanism of felting. Recent research has been directed toward environmental aspects of the shrink-resist treatment of wool, particularly the reduction or elimination of organochlorine compounds in effluents from treatment plants. In future years, replacements for chlorination processes are likely to emerge.

Figures published by The Woolmark Company in 2002 show that approximately 40×10^6 kg of wool is shrink-resist-treated each year. This figure may include some low level chlorination treatments of fine wools, designed to prevent felting during wet processing or to improve garment appearance or dyeability. The products of these low level treatments are generally not claimed to be machine-washable. The fact that only 5–10% of all wool is shrink-resist-treated indicates that many end uses do not require an antifelting treatment. More than 90–95% of the treated wool is used in knitwear. The amount treated, however, varies markedly from country to country and also with the type of product, with those worn next to the skin, eg, underwear, being most likely to be treated. Wool can be shrink-resist-treated at various stages, from loose wool to garments. Approximately 5% is treated at the loose wool stage, mainly for use in bedding products such as futons; 80% at the top stage; very little as yarn; 10% as knitted garments; and about 5% as woven fabrics. The chlorine-Hercosett process for treating loose wool or top is by far the most important method used. In 2002 this method accounted for at least 80% of shrink-resist-treated wool.

Industrial Shrink-Resist Treatments. Mechanistically, shrink-resist treatments can be divided into degradative and additive types. Degradative treatments use an oxidizing agent to eliminate or reduce the differential friction effect of the fiber surface by modifying or removing the scales. In some cases, a polymer is also applied to the surface to mask the modified scales. The additive approach

prevents fiber migration by bonding fibers together with elastomeric polymers. Some polymer deposition processes involve a degradative chemical pretreatment, to improve the adhesion of the polymer to the fiber surface. Additive treatments must be applied after spinning (usually at the fabric stage), whereas degradative treatments can be used at any stage from loose wool through to garments.

Chlorine-Based Shrink-Resist Treatments. The principal oxidizing agent used in degradative shrink-resist treatments is chlorine. Free chlorine reacts very rapidly with wool; hence, it is difficult to treat a mass of wool fibers evenly. Two different types of chlorination methods are used commercially: continuous treatment and batch treatment. In the continuous method, top or loose wool is reacted with an aqueous solution of chlorine gas for a short time (<30 s). The batch treatment method involves a longer treatment time (5–30 min) with a less reactive chlorinating agent, such as DCCA (*N*,*N*′-dichloroisocyanuric acid). Batch treatments are mainly used on garments and fabrics but can also be applied to loose wool or tops. Generally, in both continuous and batch treatments a reactive polymer, usually cationic, is applied after the chlorination step.

The features and chemistry of chlorination shrink-resist treatments are best illustrated by consideration of the chlorine-Hercosett process for wool top (99). This process uses a dedicated plant, of which there are about 40 around the world. A web of parallel slivers is treated with water and chemicals in a series of bowls (tanks), separated by squeeze rollers. The wool is then dried. Usually, 30–40 slivers (20–30 g/m) are treated simultaneously at a speed of 5–10 m/min. Overall production rates range from 200 to 500 kg/h.

The first stage involves chlorination, either with chlorine gas dissolved in water or with sodium hypochlorite acidified with sulfuric acid. Chlorination is the most critical step of the process and modern plants incorporate features designed to achieve uniform treatment of the web. These include cooling the chlorine solution to 10–12°C, to slow down the rate of reaction with wool, and special application devices, eg, those produced by the Kroy or Fleissner companies, to rapidly contact the web with a large volume of dilute chlorine solution. The second stage of the process is a neutralization, or anti-chlor, treatment with sodium sulfite. In the third stage, the wool is treated with a cationic polyamide/epichlorohydrin polymer, usually Hercosett 57 (Hercules, Inc.). The final stage consists of treatment with a cationic softener and a lubricant to facilitate further processing, followed by drying to cross-link the polymer on the fiber surface. The reaction of chlorine with wool is complex, but the principal effect of the combination of the chlorination and neutralization stages is to remove surface lipid from the fiber. This increases the surface energy and shifts the isoelectric point of the fiber to a lower pH, by converting cystine disulfide residues to cysteic acid (sulfonic acid) groups. Some of the surface protein is also solubilized and removed, which softens the fiber cuticle. These changes allow the cationic Hercosett polymer to spread on the fiber surface. Virtually all the shrink-resistance is imparted by the chlorination step. The function of the Hercosett is to compensate for any weight loss arising from chlorination, prevent further loss of soluble protein during subsequent dyeing, and improve the shrink-resistance of any insufficiently chlorinated fibers.

Chlorine-Free Shrink-Resist Treatments. Commercially, the only other oxidizing agent used to any extent is permonosulfuric acid (PMS; $HOOSO_3H$). This is used in the form of its potassium triple salt, containing potassium sulfate and

bisulfate. It is employed in batch processes at elevated temperatures, because it reacts more slowly with wool than chlorine (100). The process sequence is similar to that used for chlorine-based treatments. It involves degradative oxidation with PMS, followed by neutralization with sodium sulfite and then application of a resin. Unlike chlorine, however, PMS does not remove the bound lipid or oxidize cystine to cysteic acid. The main product of the reaction is cystine sulfonic acid or Bunte salt groups.

Other chlorine-free shrink-resist technologies under development include plasma and ozone treatments for sliver and enzyme treatments for garments and fabrics.

Additive Shrink-Resist Treatments. The principal additive shrink-resist treatment for wool fabrics uses the polymer Synthappret BAP (Bayer AG). This is a poly(propylene oxide) polyurethane, containing reactive carbamoyl sulfonate (bisulfite adducts of isocyanate) groups, ie $-NHCOSO_3^- \ Na^+$. An aqueous solution of this polymer is padded onto woven fabrics. The polymer cross-links on drying to form flexible linkages between fibers and yarns (101). Other polymers may be applied at the same time to modify the handle.

Easy-Care Wovens

Dry-clean-only garments are increasingly becoming a turnoff to the modern consumer. Consumers now demand "total easy-care" garments that can withstand repeated machine washing and tumble drying, while maintaining their "just pressed" appearance with no more than minimal ironing. In addition to dimensional stability, wool-containing fabrics and garments must be specifically engineered so that, after laundering, seams remain flat and without pucker, the fabric remains wrinkle-free without the development of fuzz or pills, and the creases or pleats stay sharp.

To produce total easy-care garments from a blend, of wool and polyester, heat-setting the polyester component using a hot head press will generally impart sufficient set to the creases and pleats to make them stable to repeated laundering. A minimum of 20–30% polyester is needed for adequate stability. An alternative procedure that sets the entire garment is to impart temporary set to the wool component of the blend by steam-pressing the garment, followed by baking the entire garment in an oven to permanently set the polyester. The wool dries out in the oven and maintains the garment shape during setting of the polyester (102). A fabric-based treatment to prevent felting may be unnecessary, provided the polyester content is above 50% and a suitable fabric construction is used.

It is more difficult to produce pure wool total easy-care garments. The challenge is to obtain adequate permanent set rather than obtaining shrink resistance, because some wool setting processes are not stable to machine washing. The problem of set stability is further exacerbated when the garments are tumble-dried, because the tumbling action tends to flatten the creases and they become temporarily set in a distorted configuration, even if a high level of permanent set has been imparted to the garment. The application of a delay-cure polymer to the fabric, followed by curing in an oven after the garment has been made and pressed, appears to be the latest approach to producing total easy-care wool garments.

Dyeing

Commercially, wool is dyed from aqueous solutions, usually under acidic conditions. In the past, methods have been proposed for dyeing wool from organic solvents, in particular concentrated formic acid. More recently, the use of supercritical carbon dioxide has also been investigated. These solvent systems are, however, very unlikely to replace water as the preferred dyeing medium for wool, because of the relative cost of the solvent compared with water and also the specialized, expensive equipment required.

The majority of dyes used on wool are sodium salts of aromatic anions. Water solubility is usually provided by sulfonic acid groups, but in a few cases carboxyl or hydrophilic, nonionic substituents are used. In a typical wool dyeing operation, the ratio of the mass of dyestuff solution to the mass of wool ranges from approximately 10:1 to as high as 60:1, depending on the type of wool substrate and the equipment used. Wool is dyed as loose fiber, sliver, yarn, fabric, or in garment form by batch methods (103,104). In the case of fiber, sliver or yarn, the process involves pumping dye solution through the stationary substrate, whereas in fabric dyeing the material may be transported through the dye liquor or, alternatively, both liquor and fabric may be moved through the machine. Simultaneous circulation of liquor and wool substrate is also used in garment dyeing techniques. In a typical operation, the liquor is heated from around 40°C to a temperature of 98–100°C, where it is held for a period that can range from around 30 min to over 2 h. The actual time depends on the type of dye and depth of shade. Procedures have also been developed for continuously dyeing wool in loose, or sliver form and wool fabric can be dyed by a pad-batch method (105). These techniques have found only limited use, however, because they are uneconomic unless a large quantity of substrate is dyed to a single color, which is uncommon in the wool industry.

Dyeing Theory. Wool is composed mainly of a large number of different proteins, the fundamental structural units of which are α-amino acids (31). It is amphoteric in character because of the presence of basic amino groups in the side chains of lysine, hystidine, and arginine, and acidic carboxyl groups in the side chains of aspartic and glutamic acids. In an aqueous, acidic dyebath protonation of the amino and carboxyl groups results in a net positive charge on the fiber. Early workers explained the mechanism of wool dyeing in terms of electrostatic interactions between the positively charged amino groups and anionic dye molecules. The two most popular theories were the Gilbert–Rideal theory and the Donnan theory (106–108). Later studies, however, showed that the affinity and wetfastness properties of dyes on wool are largely determined by other types of interactions, namely, van der Waals' forces and interactions between hydrophobic regions in the fiber and hydrophobic parts of the dye molecules (109,110). Dyes differ markedly in their hydrophilic–hydrophobic character (105,110,111). Ionic forces are of greatest importance for dyes of relatively low molecular weight. With increasing molecular weight, van der Waals' and hydrophobic interactions become increasingly important, which is reflected in a higher affinity for the fiber and better wetfastness properties. Ionic interactions are important, however, for all wool dyes in determining the rate at which the dye is taken up by the fiber from the dye liquor. The dyeing rate can be controlled by varying the amount of acid added

to the dyebath, because this determines the size of the net positive charge on the wool, produced by protonation of amino groups.

In early studies on the uptake of dyes by wool, the fiber was treated as a cylinder of uniform composition. The main focus was on the thermodynamics of the dyeing process, in particular the situation applying when equilibrium had been attained. These studies provided little information, however, on the mechanism of the dyeing process itself. Recent work has clarified the relationship between fiber structure and the mechanism of wool dyeing (112,113).

Dyeing Mechanism. Wool fibers have a very complex morphological structure (Fig. 3). They can be considered as biological composite materials, in which the various regions are both chemically and physically different (31). Fine wool fibers contain two types of cell: those of the internal cortex and those of the external cuticle. Cortical cells, which constitute around 90% of the fiber, are spindle-shaped and are arranged in an overlapping pattern, parallel to the fiber axis. They are separated and held together by a continuous network, the cell membrane complex. This region of the fiber contains protein and also lipid material. The proteinaceous material in the cell membrane complex is relatively lightly cross-linked compared with the proteins in other regions of wool. The external cuticle cells are rectangular in shape and overlap, rather like tiles on a roof (Fig. 2). Dyes enter wool fibers at the junctions where the cuticle cells overlap and in the early stages of the dyeing process they diffuse into the interior along the lightly cross-linked network of the cell membrane complex (31,112,113). Later in the cycle, the dyes transfer, progressively, from the cell membrane complex into the cortical cells. The affinity of the dyes for wool is largely the result of their interaction with hydrophobic proteins located within the matrix of cortical cells.

Wool Dyes. The dyes used on wool can be divided into the following groups: acid dyes, chrome dyes, premetallized dyes, and reactive dyes (103,105,107,110, 111,114–116). Strictly speaking, all types of wool dyestuffs can be described as acid dyes, but in practice this term is confined to leveling acid dyes, half-milling dyes, milling dyes, and supermilling dyes (111,114). This subclassification of acid dyes arises out of the methods used for their application and their fastness properties on wool.

Levelling acid dyes (sometimes called level-dyeing or equalizing dyes) are the simplest type of dyes used on wool. They are of relatively low molecular weights (300–600) and have a comparatively low affinity for the fiber, because they interact largely by ionic attraction. They are applied at around pH 3, obtained with sulfuric acid. Under these conditions, the initial uptake of dye is usually uneven because the exhaustion rate is very rapid. As their name implies, levelling acid dyes have good migration properties and levelling occurs during the stage of the dyeing cycle when the dye liquor is held at the boil, thus producing a very even result. Levelling of the dyes is assisted by the presence of sodium sulfate in the dye bath, because the anionic sulfate ions compete with dye anions for the positively charged amino groups in the fiber. In general, these dyes are not particularly resistant to wet treatments, but are used when level dyeing is critically important.

Milling acid dyes are so named because they are more resistant than levelling acid dyes to extraction from wool during the milling process. They are of higher molecular weight (600–900) and are more hydrophobic than levelling acid dyes, which gives them a higher affinity for wool. The higher molecular weight and

lower dependence on ionic attraction means that they diffuse out of the fiber more slowly than levelling dyes, which is responsible for their higher fastness to wet treatments such as milling and laundering. Their migration properties, and hence their ability to level during application, is not as good as that of acid dyes. To obtain level results it is important to ensure that the rate of exhaustion is uniform and not too rapid. This is achieved by setting the dyebath at a higher pH (ca pH 4.5–6.0) with a weak acid, such as acetic acid, and also by the addition of a surfactant-type levelling agent, which promotes even uptake on wool. Half-milling dyes fall between levelling acid and milling dyes in molecular weight (500–600), migration properties, and wetfastness. They are applied at a pH in the range pH 4.0–4.5.

Supermilling acid dyes are similar in molecular weight to milling dyes, but contain long alkyl groups that make them more hydrophobic in character. This gives them a high affinity for wool that is virtually independent of ionic interactions with the fiber; consequently, they have very good wetfastness properties. They show good exhaustion under almost neutral (pH 5.5–7.0) dyeing conditions, but their high affinity means that they have poor migration and relatively poor levelling properties. Auxiliary products are often used to assist level application of these dyes.

Chrome dyes are acid dyes (mol. wt. 300–600) that contain groups capable of forming complexes by reaction with a metal salt, usually sodium or potassium dichromate (111,114). The chrome/dye complex has lower solubility, and hence better wetfastness, than the parent dyestuff. Reaction between the dye molecule and chromium salt can be carried out before, during or after application of the dye to the wool. Modern practice is to carry out the chroming step after dyeing. Chrome dyes are relatively cheap, and have good migration and level dyeing behavior and excellent wetfastness properties. Their popularity, except for black and navy blue shades, has declined in recent years. This is because of the need for prolonged dyeing cycles, fiber damage associated with oxidation of the fiber in the chroming step, and environmental concerns about the use of chromium salts in the textile industry.

In many applications, chrome dyes have been replaced by metal-complex dyes, which have a very high affinity for wool (111,115). In these dyes, the metal complex is preformed during manufacture of the dye, by reaction of one metal atom with either one (1:1 metal-complex dyes) or two (1:2 metal-complex dyes) dyestuff molecules that contain groups capable of coordinating with chromium or, occasionally, cobalt atoms. In general, metal-complex dyes produce duller shades than acid or milling dyes. The 1:1 metal-complex dyes are applied to wool from strongly acidic dyebaths at around pH 2. They are almost all monosulfonates (mol. wt. 400–500) and have good levelling behavior and wetfastness properties. Some degradation of the fiber can be caused by the low dyeing pH. The earliest type of 1:2 metal-complex dyes were unsulfonated; solubility was provided by nonionic polar groups, such as sulfonamide or methylsulfone. More recently, monosulfonated, disulfonated, and some carboxyl-containing types have become available. These dyes range in molecular weight from 700 to around 1000. They are applied at pH values ranging from pH 4.5 to 7.0, depending on the degree of sulfonation and molecular size of the dye.

Reactive dyes have molecular weights in the range 500–900 and usually contain two or three sulfonic acid groups (105,116). These dyes also contain groups

that react covalently with wool, which gives them outstanding wetfastness properties. They are characterized by bright colors and moderate migration and levelling properties, provided careful attention is given to ensuring that the exhaustion rate is not too rapid. This is achieved by careful control of the dyebath pH and by using special amphoteric levelling agents. Their ability to react with the fiber means that uneven uptake of these dyes is very difficult to rectify. Reactive dyes are relatively expensive and, currently, their most important application is on wools that have been treated to withstand shrinkage in machine washing. They are, however, becoming increasingly important as alternatives to chrome dyes for dyeing all types of wool. At present, reactive dyes offer the only viable alternative to chrome dyes for products where very high wetfastness properties are required.

Fiber Damage in Dyeing. When wool is dyed for prolonged times at the boil, the fiber can be damaged as a result of hydrolysis of the component proteins. Methods of dyeing wool substrates at temperatures below the boil (85–90°C) have been developed. One such method, the CSIRO Sirolan-LTD™ process employs a special chemical (Valsol LTA-N, APS Chemicals) that increases the rate of exhaustion and diffusion of dye into the fiber, thus enabling satisfactory dyeings to be obtained at temperatures below the boil (117). Wool dyed by this method suffers less degradation than wool dyed for a similar time at the boil. This leads to benefits in the processing performance of the dyed fiber and in improved quality of end products (118). Permanent setting of wool fibers during dyeing has been identified as a major factor that also contributes to deterioration of the quality of dyed wool (117). This effect is separate from hydrolytic degradation. Setting occurs via a mechanism involving thiol/disulfide interchange (eq. 1). Methods of inhibiting the permanent setting of wool fibers during dyeing have been developed (89). These involve addition to the dyebath of auxiliaries (antisetting agents such as Basolan AS, BASF) that block thiol groups and, thus, prevent thiol/disulfide interchange. Improvements in the properties of a range of products made from wool are obtained by reducing the amount of permanent set that occurs during dyeing.

Printing

Printing provides the means of transferring bright multicolor designs onto textiles. The amount of wool fabric printed is very small compared to cotton and synthetics. This is partly because the pigment printing systems widely used for cotton and synthetics have a severe adverse effect on the natural handle of wool. Furthermore, although the printing of wool using dyes maintains the natural qualities of the fiber, it requires a more complex processing sequence involving several stages, some of which are technically challenging.

The usual route for printing wool with dyestuffs is fabric preparation/print/dry/steam at 100°C (to fix dye to fabric)/wash off (to remove thickener and unfixed dye)/dry. Globally, an estimated 20 million meters per annum of high quality printed wool fabric is produced, with the center of excellence being in Northern Italy.

Fabric preparation is considered to be the most important stage for obtaining good color yields, levelness, and brightness on wool fabric (119,120). Currently, this

is done almost exclusively by an oxidative chlorination process. The most popular commercial methods use either a batch treatment with DCCA or a continuous fabric treatment with gaseous chlorine (the Kroy process). Chlorination has a profound effect on wool, especially near the fiber surface. The number of anionic groups is increased, with cystine residues oxidized to cysteic acid and accessible peptide bonds cleaved to form carboxyl groups. These reactions increase the wettability of the surface of wool, which facilitates spreading of the dye formulations. Chlorination also reduces the degree of cross-linking of wool, which increases the rate of dye diffusion into the fiber. Chlorination can have several adverse effects, however. At higher levels (4% on mass fabric of DCCA), there are problems in obtaining level treatments. Yellowing, especially after steaming, can also occur. These problems can be minimized by treating fabrics continuously in open width in a machine such as the Kroy chlorinator. With all chlorination processes, soluble protein and free oxidation products must be removed from the wool before drying. This is done by neutralization with a reducing agent, such as sodium bisulphite or sodium dithionite.

The effluent from the chlorination of wool contains adsorbable organohalogen compounds (AOX), which are now regarded as undesirable products to release into the environment, particularly in Europe. Several AOX-free methods for preparing wool for printing are currently being investigated. Plasma (121) and corona discharge (122) treatments have been investigated as potential prepare-for-print methods for wool, as they oxidize the surface of wool fibers and have the advantage of being dry processes. Although the wettability of fabrics prepared using these methods is high, the color yields of prints are significantly less than prints on chlorinated fabric and the fabric handle is inferior. An alternative approach is the CSIRO "Siroflash" process. This method involves continuous ultraviolet (UV) irradiation of dry wool fabric with the type of commercial UV source used for curing polymer films. This is followed by a conventional oxidative bleaching treatment with hydrogen peroxide (123). This process is surface-specific, giving a white fabric with good handle properties and similar color yields to DCCA treatment.

Most wool is printed directly onto the prepared fabric. Automatic flat-screen printing remains the most popular method over the rotary screen process used for most cotton printing, because of the shorter run lengths normally processed for wool fabrics. The dyestuffs most commonly used for wool printing are acid milling, metal complex, and reactive dyes. A simple dye paste is prepared using a suitable thickener, urea (to swell wool fibers during steaming), and the dyestuffs. Various additives may be included in the paste recipe, such as antifoam, glycerol to prevent screen blocking, an acid donor (to maintain a low pH), wetting agent, and a dye solvent such as thiodiglycol (120).

During the steaming stage, large aggregates of dye molecules break down into smaller entities which can then penetrate the swollen wool fibers, allowing fixation to take place. Typical steaming times are 10–15 min for reactive dyes and 30 min for acid milling and metal complex dyes. Saturated steam is essential for optimum penetration and fixation of dyes, especially for dyes of high molecular weight such as those based on copper phthalocyanine derivatives. Both continuous and batch steamers are used commercially. Chlorinated fabrics are highly prone to yellowing during steaming, which can be detrimental to printed pale shades.

The aim of washing off is to remove the thickener and any residual chemicals and unfixed dye from the fabric, without causing staining of any pale or unprinted areas. Fabrics printed with metal complex or acid milling dyes are usually washed off in water at 30–40°C, whereas reactive dyes require higher temperatures (60–80°C), with addition of ammonium hydroxide (120).

Discharge printing of wool remains popular, despite its technical difficulties (119,120). In this style of printing, a predyed fabric is printed with a reducing agent that destroys the background shade. Included in the print paste is a dye which is resistant to the discharge agent. The result is bleaching of the color in the printed areas and replacement with the illuminating color. It is often impossible to reproduce the designs and effects of discharge printing with direct printing. The reducing agents used in discharge printing are zinc, calcium or sodium formaldehyde sulfoxylate, or thiourea dioxide. The technique is limited by the choice of dyes that are resistant to the reducing agent.

Other techniques, such as resist printing, cold batch printing, and transfer printing have been applied to wool with some success, but these now occupy only a small share of the current wool printing market (119,120).

Digital inkjet printing is a recent development for printing textiles (124). It has the advantage that any design can be transferred rapidly from a personal computer onto a fabric, without the requirements to perform a color separation and make a separate screen to print each color. It is also more cost-effective for producing the short runs of printed fabric designs that are typical for wool compared with other methods. The wool fabric is prepared for printing using a conventional method, padded with a mixture of a thickening agent and urea and dried before digital printing. The padding process assists penetration of the dye into the wool fabric and avoids flushing of the prints during steaming.

Yellowing

In common with many other polymeric materials, yellowing of wool is an undesirable property that can be caused by several different mechanisms (see DEGRADATION). For wool, the most important of these are exposure to sunlight and heat.

The rate and extent of photoyellowing of wool exposed to direct sunlight is a serious shortcoming when compared with fibers such as cotton and synthetics. Photoyellowing is caused by the UV components of natural sunlight (285–380 nm), whereas exposure of wool to sunlight filtered through window glass, which absorbs most of the UV, causes photobleaching (125). Photoyellowing of wool by sunlight only occurs in the presence of oxygen and it has been proposed that it is a photo-oxidative process involving the formation of singlet oxygen (126,127). More recent work, however, has shown that in common with cotton, polyester, and nylon, wool in the wet state is capable of producing hydroxyl radicals ($OH^{\bullet}$) on irradiation with UV light at 366 nm and blue light at 430 nm (128). This reaction appears to be catalyzed by trace metals such as iron and copper. It has been proposed that the photoyellowing mechanism for wool may involve a free-radical chain reaction involving formation of hydroperoxide intermediates (as is the case for most other polymers), rather than a singlet oxygen mechanism

(128). There is now general agreement in the literature that yellow chromophores formed in irradiated wool are derived (at least in part) from tryptophan residues (129,130).

The use of some water-soluble benzotriazoles (a well-known class of UV absorber) can be effective against both photoyellowing and phototendering (see UV STABILIZERS). The effectiveness of these reagents relies on intramolecular hydrogen bonding and proton transfer, and intermolecular bonding of the compounds to wool fibers was found to be highly detrimental to their performance. Optimization of the photochemical properties of soluble benzotriazoles has resulted in a suitable formulation (Cibafast W) for use on both bleached and unbleached wool (131). Unfortunately, UV absorbers cannot be used on wool together with a fluorescent whitening agent (FWA) because they absorb the UV wavelengths necessary to excite fluorescence. FWA treatment is essential to achieve a high level of whiteness on wool, because even wool that has been bleached retains some of its natural cream color. An important problem for wool is the very rapid photoyellowing that occurs following treatment with FWAs (132). The poor lightfastness of bright white and pastel colors severely limits the range of possible shades for wool products. This is reflected in wool's limited market share in fashion and summer knitwear, sportswear, hosiery, and baby wear. Wet photoyellowing of whitened (FWA-treated) wool is extremely rapid and can cause unacceptable yellowing after a single laundering and drying cycle in direct sunlight. When wet FWA-treated wool is exposed to sunlight, hydrogen peroxide is formed (133). The rate of photoyellowing of FWA-treated wool is significantly increased by doping with hydrogen peroxide. This indicates that blocking the formation of peroxide (via the superoxide radical anion) could improve the photostability of whitened wools.

Treatment of wool with a FWA, followed by post-treatment with thiourea/formaldehyde by a pad/cure method, confers a high level of protection against photoyellowing and also improves the initial fabric whiteness (134). Unfortunately, this process is not commercially viable, partly because of environmental concerns about thiourea and formaldehyde and also because much of the benefit is lost after laundering. An alternative approach is to physically separate the FWA from the wool fiber by incorporating the whitener into a suitable polymer that can be applied as a surface treatment to wool fabrics (135). The photostability of the treated fabrics is somewhat better than for conventional FWA treatments (being similar to bleached wool) but the initial whiteness is significantly lower than that of FWA-treated wool.

Two comprehensive reviews on the photodegradation of wool keratin have been published recently by Smith (129) and by Davidson (136). There is also an excellent review dealing specifically with the problem of sunlight yellowing of wool treated with FWAs (126).

Thermal yellowing of wool can be a problem during wool processing, in particular during extended dyeing at the boil, in setting with superheated steam (decatizing), and in drying for extended times, particularly under alkaline conditions (137). The thermal yellowing of wet wool is far more rapid than for dry wool, which is similar to the behavior observed for photoyellowing. Thermal yellowing of wool during dyeing is influenced by pH, temperature, and time, chlorinated wools being especially sensitive. Yellowing during dyeing can be counteracted by adding a bleaching agent, based on sodium bisulfite or hydroxylamine sulphate, to the

dyebath (138). Addition of hydrogen peroxide to the dyebath after exhaustion of the dyestuffs can also be effective.

Bleaching and Fluorescent Whitening

The natural pale cream color of wool is due to absorption of light above 320 nm. This is the result of natural pigments and also photodecomposition products in the fiber. Reduction of the natural cream-yellow color of wool is sometimes necessary for improving the brightness of dyed shades, particularly pastel colors, and also for improving the whiteness of undyed wool fabrics. Commercially, wool bleaching is carried out using either an oxidative or a reductive system, or a combined oxidation/reduction process. Oxidative bleaching in the dyebath is also possible (138). In general, oxidative bleaching with hydrogen peroxide gives superior whiteness over reductive methods.

A batch treatment with hydrogen peroxide is used for most bleaching applications. An activator (eg an alkali) is normally added to increase the rate of bleaching. Typically, wool is bleached at pH 8–9 for 1 h at 60°C with a stabilized solution of hydrogen peroxide (0.75% w/w). It is generally accepted that, under alkaline conditions, the active bleaching species is the perhydroxy anion (OOH^-), the formation of which is encouraged by higher pH (139). Peroxide bleaching of wool under mild acidic conditions (pH 5–6) can also be carried out using a peracid activator such as Prestogen W (BASF) or citric acid (140). As wool sustains some damage in the presence of alkali, this method is useful for bleaching delicate fabrics. An undesirable side effect is the rapid decomposition of hydrogen peroxide to water and oxygen, a reaction catalyzed by transition-metal ions. A stabilizer, which sequesters these ions, is used to prevent this side reaction occurring. The most common stabilizers for alkaline wool bleaching are phosphates, particularly tetrasodium pyrophosphate. However, recent concerns over phosphates in effluents from textile treatment have led to the development of alternative stabilizers based on silicates (141). An alkaline peroxide bleaching process using the silicate-based product Stabicol BAC (Allied Colloids) has been developed (138).

Heavily pigmented fibers, such as Karakul wools, require a more severe approach known as mordant bleaching. In this method, the wool is treated with a metal salt and then with hydrogen peroxide. In the first step, the melanin pigment in the wool preferentially absorbs the metal cations; and in the second step, the cations catalytically decompose the peroxide to produce highly aggressive hydroxyl free radicals, which selectively attack and bleach the melanin (142).

The two most popular chemicals used for reductive bleaching of wool are stabilized sodium dithionite and thiourea dioxide. Most reductive bleaching of wool is carried out using stabilized dithionite (2–5g/L) at pH 5.5–6 and 45–65°C for 1 h. Thiourea dioxide is more expensive than sodium dithionite, but is an effective bleach when applied (1–3 g/L) at 80°C and pH 7 for 1 h. Whiter fabrics are produced when oxidative bleaching is followed by a reductive process—this is often referred to as "full bleaching."

To obtain a high level of whiteness, comparable to white cotton and synthetics, wool must be treated with a FWA after bleaching. The normal procedure is to carry out a full bleaching process and include the FWA in the reductive

bleaching bath. FWA-treated wool absorbs UV light and emits blue fluorescence, which makes it appear much whiter than bleached wool. Commercial FWAs for wool are usually based on a sulfonated stilbene, distyrylbiphenyl, or pyrazoline derivative.

Wool fabrics that have been bleached or treated with FWAs yellow rapidly when exposed to sunlight, especially when wet. This is a major problem when bright whites and pastel shades are required. Despite a significant amount of research into the chemistry of photoyellowing processes progress in this area has been limited (126).

Insect-Resist Treatment

Wool is a protein fiber but, because it is insoluble and highly cross–linked, it is not widely available as a food resource. Only a few keratin-digesting animals have developed specialized digestive systems that allow them to derive nutrition from the potential protein resource. These animals, principally the larvae of clothes moths and carpet beetles, perform a useful function in nature by scavenging the keratinous parts of dead animals (fur, skin, beak, claw, feathers) that are unavailable to other animals.

The principal insects that attack wool are the common clothes moth (*Tineola bisselliella*), the case-bearing clothes moths (*Tinea metonella, T. dubiella, T. translucens*, and *T. pellionella*), the brown house moth (*Hofmannophila pseudospretella*), the variegated carpet beetle (*Anthrenus verbasci*), the black carpet beetle (Attagenus piceus), and a few others. The taxonomy of the Tineid species has been comprehensively reviewed (143). These insects have different temperature sensitivities and tend to be found in different climates. Studies in Australia have shown that the native Tineids are rarely involved in domestic infestations. The introduced species, such as *T. translucens*, are the major textile pests and these are often associated with the nests of introduced urban bird species such as sparrows and swallows (144), while *T. bisselliella* is widely distributed and is common in domestic infestations.

All keratinous materials stored for long periods, including stored greasy wool in bales, animal skins, furs, and horns, are liable to attack. Strategies for protecting goods vary with the product type. Buildings used to store wool may be fumigated or sprayed periodically. Small articles of clothing may be isolated from the environment in sealed bags, often with the use of heat (sunlight), cold (refrigerated storage), or volatile repellent agents (mothballs), with varying degrees of success.

The most practical means of protecting wool textile products is treatment with an insecticide during manufacture (145). Wool products most commonly treated are carpets, furnishings, and insulation. Except for insulation, the most convenient point for treating wool goods is during dyeing, which is attractive because it avoids the needs for an additional wet processing step. Under ideal application conditions the pesticide will be adsorbed inside the highly swollen fiber. This ensures that the pesticide will have maximum resistance to desorption from the dry fiber, and also have optimum fastness to washing, dry-cleaning, and skin contact. An additional benefit of locating the pesticide inside the fiber is that there

is little contact action against nontarget pests, as the active agent is released only in the insect gut when the fiber is completely degraded.

Unfortunately, it is impossible under practical dyebath conditions to ensure 100% transfer of pesticide from dyebath to fiber. It is also extremely difficult and expensive to remove residual insect-resist agent from dyehouse effluents (146). Even if the pesticide is removed by absorption or flocculation, the fate of the adsorbed material also needs to be considered (147). As a result, there is inevitably some environmental contamination. With the current generation of insect-resist agents, discharge of residual pesticide from dyebaths is a cause of significant environmental concern in large processing centers. Insect-resist agents must have a broad spectrum of activity because of the variety of moth and beetle species that must be controlled. They must also be reasonably stable to the dyeing conditions used in their application and be durable on wool for long periods. It is also essential that the agent is relatively hydrophobic so that it exhausts effectively from the dyebath onto wool. Unfortunately, this combination of properties is likely to lead to adverse effects on aquatic insects and invertebrates. To minimize environmental damage an allowable environmental concentration for permethrin of 10 ng/L has been set in the United Kingdom (148,149). To meet this requirement, the U.K. carpet dyeing industry has introduced a range of "best practice" operational procedures. These include dyeing at low pH and high temperature, avoiding dyes and dyeing assistants that may decrease the efficiency of application of the insecticide, containing spillages, and avoiding the discharge of effluents from tape scouring machines. Additionally, a number of manufacturers are using alternative application procedures, where little or no aqueous effluent is produced (147,150–152).

Prior to the introduction of synthetic pyrethroids, insect-resist agents were based mainly on speciality materials, such as polychloro chloromethyl sulfonamido diphenyl ether (PSCDs) (Eulan U33, Eulan WA New). The production of these compounds has been discontinued, however, because of a combination of environmental toxicity (149) and cost. One speciality insect-resist agent based on sulcofuron (Mitin FF), released in 1939 (153), retains a small market share for specific applications where cost is less important and where high resistance to wet conditions is required. It has also been used on wool insulation where it also has low volatility and provides resistance to rotting (154).

The principal active agent used for insect-resist treatments since the late 1970s has been permethrin. Although other broad-spectrum agricultural insecticides (including other synthetic pyrethroids) have been examined, permethrin remains dominant as it is a nonirritant with a good human health profile, especially when strongly adsorbed into the wool fiber. Pyrethroids with a safer environmental profile, such as cycloprothrin, have also been examined (155). These, however, require higher application levels, which increases the cost of the treatment. Newer commercial insect-resist agents under development are based on lufenuron (an insect growth regulator) (147,156) and on bifenthrin (a synthetic pyrethroid). The latter agent includes a synergist to counter the resistance to synthetic pyrethroids that is being observed in Australia (147). Resistance is an inevitable result of using a single protective agent for more than two decades. Resistance to pyrethroids is common among other agricultural pests, and pyrethroid-resistant strains of the Australian carpet beetle and the case-bearing clothes moth have been found

in domestic infestations in northern Australia (157). In the future, it is unlikely that speciality insect-resist agents for the protection of wool will be developed, as the market is too small to support the testing required to demonstrate the safety of modern, biologically active agents. The focus remains, therefore, on the use of commercial insecticides for protecting wool against insect damage.

A diverse range of nonpesticidal approaches has also been studied (144). Attempts to find triggers for such behaviors as egg-laying and recognition of food were inconclusive. Although it has been long known that otherwise unrelated clothes moths and carpet beetles have developed unique reducing systems in the gut that allow them to digest wool, specific inhibitors of these systems have not yet been identified.

Flame-Resist Treatment

Wool is regarded as a naturally flame-resistant fiber, which is partly due to its high nitrogen content, high sulfur content, and high (water) regain under ambient conditions. It has a high ignition temperature (570–600°C), high limiting oxygen index (25–26%), and a low heat of combustion (4.9 kcal/g) (158). In most cases, when wool fabrics are ignited they will rapidly self-extinguish, because of the formation of a high volume, insulating ash, or char. Unlike thermoplastic materials, wool does not melt or drip when ignited. In many end uses, no additional fire-retardant treatment is needed.

If higher standards of flammability are needed, such as in aviation, furnishing fabrics, or protective clothing, durable protective treatments are available. These treatments evolved from the observation that wool treated with a chrome mordant, such as that used in chrome dyeing, has a markedly improved flame resistance (159). The chrome mordant, however, discolors undyed wool. It was shown, subsequently, that titanium or zirconium compounds give similar improvements in fire retardancy (160), with reduced discoloration of the wool. The Zirpro Process, developed by IWS (now, The Woolmark Company) has been used extensively for wool in aircraft interiors to meet FAA requirements. It is also used for protective clothing and for stage curtains and carpets in public buildings and similar areas, where high flame resistance is required by legislation (161,162). Other wool finishes (dyeing, insect-resist, shrink-resist) have been developed that are compatible with the Zirpro Process.

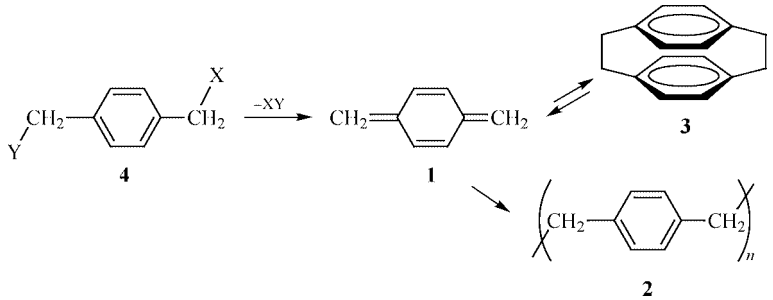
XYLYLENE POLYMERS

Introduction

In a process capable of producing pinhole-free coatings of outstanding conformality and thickness uniformity through the unique chemistry of *p*-xylylene (PX) [502-86-3] (**1**), a substrate is simply exposed to a controlled atmosphere of pure gaseous monomer. The coating process is best described as a *vapor deposition polymerization* (VDP). The monomer molecule is thermally stable, but kinetically very reactive toward polymerization with other molecules of its kind. Although it is stable as a rarified gas, upon condensation it polymerizes spontaneously to produce a coating of high molecular weight, linear poly(*p*-xylylene) (PPX) [25722-33-2] (**2**). This article emphasizes recent VDP developments. There have been several reviews of the subject (1,2), which offer a more thorough treatment of early developments in the field.



In the commercial Gorham process (3), the extremely reactive PX is conveniently generated by the thermal cleavage of its stable dimer, *cyclo*-di-*p*-xylylene

(DPX), a [2.2]paracyclophane [1633-22-3] (**3**). In many instances, substituents attached to the paracyclophane framework are carried through the process unchanged, ultimately becoming substituents of the polymer in the coating.

The process takes place in two stages that must be physically separate but temporally adjacent. Figure 1 presents a schematic of a typical parylene deposition process, also indicating the approximate operating conditions.

The PPXs formed as coatings in the Gorham process are referred to generically as the parylenes. The terms Parylene N [25722-33-2], Parylene C [9052-19-1], and Parylene D [52261-45-7] refer specifically to polymers produced as coatings by the Gorham process using the dimers DPXN, DPXC [28804-46-8], and DPXD [30501-29-2], respectively, originally marketed by Union Carbide Corp.

The parylene process has certain similarities with vacuum metallizing. The principal distinction is that truly conformal parylene coatings are deposited even on complex, three-dimensional substrates, including on sharp points and in hidden or recessed areas. Vacuum metallizing, on the other hand, is a line-of-sight coating technology. Whatever areas of the substrate cannot be "seen" by the evaporation source are "shadowed" and remain uncoated.

The *p*-xylylene species plays a central role in the coating process itself as well as in the making of the dimers which are used as feedstocks for the coating process. Polymers and dimers have both been made from precursor *p*-xylene compounds (**4**) featuring a variety of X and Y leaving groups. The conditions of the reaction determine the relative amounts of the resulting dimeric or polymeric products. Dilution is of course the key element in any procedure which offers a high yield of dimer.

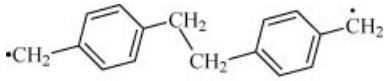
The modest commercial success the *p*-xylylene dimer based Gorham process has achieved to date is readily attributed to the fact that thermal cleavage of cyclic dimer produces the *p*-xylylene monomer in essentially quantitative yield, while at the same time producing no gaseous by-products. In a gas-to-solid coating process, any gaseous entities generated from the leaving groups X and Y, necessarily formed in volumes comparable to the volume of the monomeric *p*-xylylene

generated, would at the very least need to be exhausted through the pumping system, thereby slowing the process down. Moreover, certain of the most effective leaving groups XY, such as halogens or halogenide acids, would create a corrosion hazard both for any sensitive substrates to be coated and for the deposition equipment itself.

Gorham Process Monomers

The eight-carbon monomer PX is generated in the first stage of the parylene process by heating gaseous dimer as it passes through a high temperature zone. Its intermediacy in the process was deduced by the earliest investigators. Apprehending the unusual properties of PX is an important aid to understanding the unique features of the coating process.

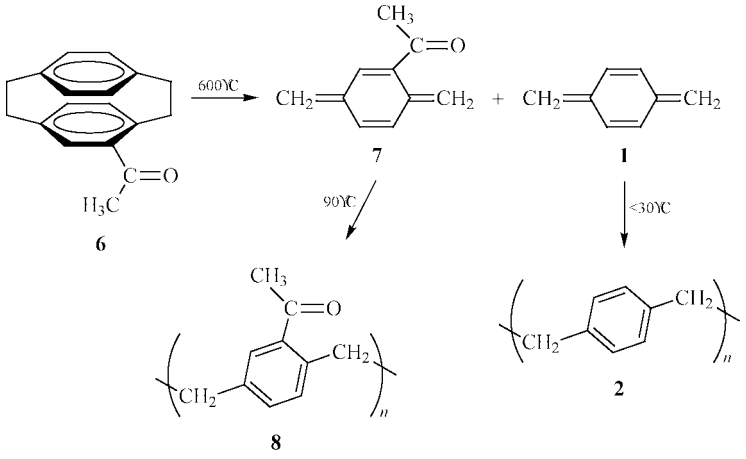
Chemical Evidence for PX Monomer. Establishing early on that PX is indeed the pyrolysis product, rather than the molecule formed by breaking only one of the original dibenzyl bonds, the dimer diradical (**5**), would prove to be an important development.



5

When the pyrolysis gases are quenched with a molar excess of iodine vapor, a yield of greater than 50% *p*-xylylene diiodide is recovered. The observation of this effect offered the first direct chemical support for the idea that DPX pyrolysis results in PX (**1**) (4).

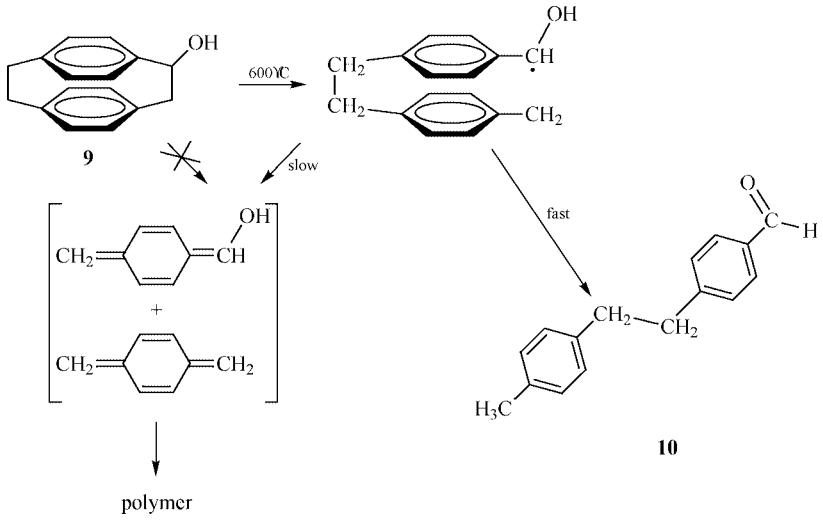
Moreover, where *ar*-acetyldi-*p*-xylylene [10029-00-2] (**6**) is pyrolyzed, by adjusting temperatures in the deposition region, it is possible to isolate two different polymeric products, ie, poly(acetyl-*p*-xylylene) [67076-72-6] (**8**) and poly(*p*-xylylene) (PPX) (**2**). This of course requires the cleavage of the original dimer into two fragments.



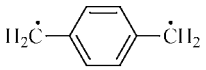
6 **7** **1** **8** **2**

Experiments with monoethyl and monocarbomethoxy di-*p*-xylylene (5) gave similar results. These experiments do not, however, shed any light on whether the rupture of the methylene–methylene bonds in the dimer upon pyrolysis is simultaneous or sequential.

Only one exception to the clean production of two monomer molecules from the pyrolysis of dimer has been noted. When α-hydroxydi-*p*-xylylene (**9**) is subjected to the Gorham process, no polymer is formed, and the 16-carbon aldehyde (**10**) is the principal product in its stead, isolated in greater than 90% yield. This transformation indicates that, at least in this case, the cleavage of dimer proceeds in stepwise fashion rather than by a concerted process in which both methylene–methylene bonds are broken at the same time. This is consistent with the predictions of Woodward and Hoffmann from orbital symmetry considerations for such [6 + 6] cycloreversion reactions in the ground state (**6**).



Monomer Properties. Despite difficulties involved in studying it owing to its great reactivity, a great deal is known about the structure of the parylene process monomer PX: the eight-carbon framework is planar (7); The molecule is diamagnetic, ie, all electron spins are paired in the ground state (spectroscopically, a singlet). Although many have ascribed its reactivity to its so-called biradical nature, the true biradical (triplet) form (**11**) of the molecule, an electronically excited state, is substantially more energetic, estimated at ca 50 kJ/mol (12 kcal/mol), and therefore cannot contribute to the monomer at equilibrium to any appreciable extent, even at pyrolysis temperatures. The PX molecule is instead a conjugated tetraolefin whose particular arrangement gives it extreme reactivity at its end carbons.



11

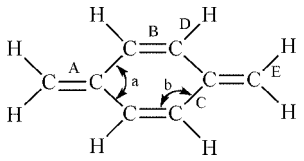


Fig. 2. Structure of PX monomer molecule from electron diffraction (9). Bond lengths: C═C A = B + 0.1381 ± 0.008; C—C, C = 0.1451 ± 0.0007 nm; C—H, D = E = 0.1116 ± 0.0035 nm. Bond angles: a = 122.2 ± 3.7°, b = 118.9 ± 1.9°.

This extreme reactivity of PX has precluded many experimental approaches that otherwise would have been useful in studying it. Most of the present structural knowledge has been gleaned from spectroscopic studies and molecular orbital calculations. A noteworthy exception is an electron diffraction study (8) in which an electron beam was directed at a stream of gaseous PX, generated much as it is in the parylene process, issuing from a nozzle in a specially constructed apparatus. The results of the study are shown in Figure 2. Although the study was unable to resolve the lengths of the two different C═C and C—H bonds, it clearly distinguished between the C—C and C═C bond lengths. Thus *p*-xylylene is experimentally demonstrated to have an olefinic geometry rather than that of an aromatic biradical.

By trapping PX at liquid nitrogen temperature and transferring it to THF at −80°C, the ^{1}H NMR spectrum could be observed (10). It consists of two sharp peaks of equal area at chemical shifts of 5.10 and 6.49 ppm downfield from tetramethylsilane (TMS). The fact that any sharp peaks are observed at all attests to the absence of any significant concentration of unpaired electron spins, such as those that would be contributed by the biradical (**11**). Furthermore, the chemical shift of the ring protons, 6.49 ppm, is well upfield from the typical aromatic range and more characteristic of an olefinic proton. Thus the olefin structure (**1**) for PX is also supported by NMR.

A particularly useful property of the PX monomer is its enthalpy of formation. Conventional means of obtaining this value, such as through its heat of combustion, are, of course, excluded by its reactivity. An experimental attempt was made to obtain this measure of chemical reactivity with the help of ion cyclotron resonance; a value of 209 ± 17 kJ/mol (50 ± 4 kcal/mol) was obtained (11). Unfortunately, the technique suffers from lack of resolution in addition to experimental imprecision. It is perhaps better to rely on molecular orbital calculations for the formation enthalpy. Using a semiempirical molecular orbital technique, which is tuned to give good values for heat of formation on experimentally accessible compounds, the heat of formation of *p*-xylylene has been computed to be 234.8 kJ/mol (56.1 kcal/mol) (12).

Successful *p*-Xylylene VDP Monomers. Within the limits mentioned above, it is frequently possible, and often desirable, to modify the *p*-xylylene monomer by attaching to it certain substituents. Limitations on such modifications lie in three areas: reactivity, performance in the coater, and cost.

Reactivity. Although the reactivity which enables the gas–solid polymerization to proceed is a characteristic of the eight-carbon *p*-xylylene tetraolefin system, it is possible to subdue that reactivity. For example, by attaching

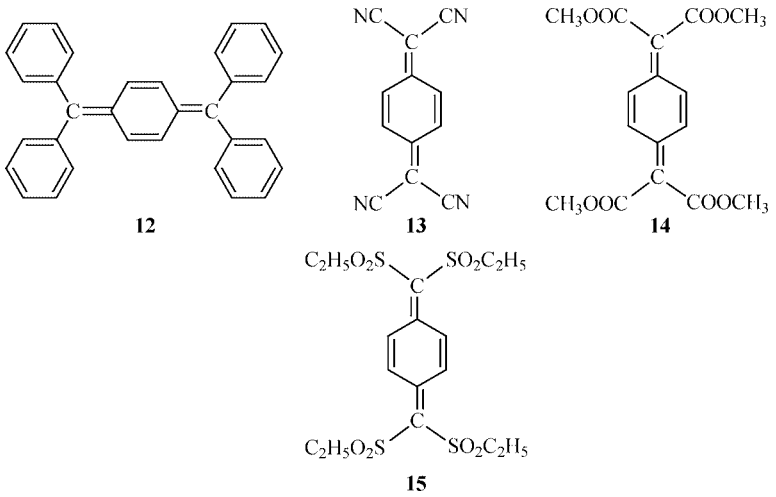

Fig. 3. Isolatable *p*-xylylene derivatives: **12**, Thiele's hydrocarbon—1904 [26392-12-1]; **13**, tetracyanoquinodimethane [1518-16-7] (TCNQ); **14**, tetrakis(methoxycarbonyl)-quinodimethan [65649-20-9]; **15**, tetrakis(ethylsulfonyl)quinodimethan [84928-90-5].

electron-withdrawing substituents to the alpha positions and thereby further delocalizing the π-electrons of the highly reactive *p*-xylylene nucleus, it is in several instances possible to prepare *p*-xylylenes that are so stable that they can be isolated and handled as normal organic compounds (Fig. 3). These sorts of substitutions must of course be avoided if the goal is to make polymer.

It is also possible to interfere with the polymerization by attaching at the alpha positions either too many groups, or groups which are too bulky. Four chlorine atoms (13) or four methyl groups (14) seem to be sufficient to hinder the production of polymer. These crowded *p*-xylylene monomers can be polymerized, but not through a VDP process.

Thus, except for electron-withdrawing or bulky substituents, at least from the standpoint of reactivity toward polymerization, modification by most other substituents is possible.

Performance in Coater. The modified monomer should perform well in commercial deposition equipment. Performance considerations include the growth rate of the coating, the uniformity of thickness of the coating over the chamber volume, and the efficiency with which the dimer is converted to useful coatings on the substrates.

An important further constraint is the fact that economic considerations in the construction of deposition equipment normally lead to a preference for an ambient-temperature deposition chamber. Control of deposition temperature is possible, but it adds to both equipment expense and operational complexity.

The vapor pressure of a parylene monomer is a prime factor in determining how rapidly a coating grows when exposed to an atmosphere of monomer at a given pressure. Vapor pressure is reduced as molecular weight increases, thereby increasing the monomer's tendency to condense and, along with it, increasing the VDP growth rate. The presence of polar functionality in the molecule further

depresses vapor pressure. But too low a vapor pressure makes it difficult to transport gaseous monomer from point to point in the deposition chamber. Hence, some optimum value of monomer volatility is expected.

The widely used Parylene C owes its popularity principally to the room-temperature volatility of its monomer. The Parylene C monomer, chloro-*p*-xylylene, has become the de facto performance standard. By comparison, the Parylene N monomer, *p*-xylylene itself, is too volatile and would perform better in a sub-ambient-temperature deposition system. The Parylene D monomer, dichloro-*p*-xylylene [85586-88-5] is too heavy, and causes distribution problems in larger deposition systems.

Cost. It is necessary to produce the feedstock from which the monomer is generated, viz, the dimer, at a cost which can be supported by the commercial application, and yet allow it to be economically competitive with all other alternative ways to achieve the same end result. This factor often, but not always, seriously limits the amount of effort that can be put into dimer synthesis and purification.

Other, Related Processes

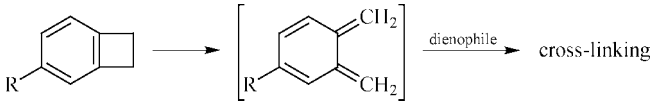
VDP processes using means other than the pyrolytic cleavage of DPX (Gorham process) to generate the reactive monomer are also known, although none are practiced commercially at the time of this writing (ca 1997).

Photopolymerization and Plasma Polymerization. The use of ultraviolet light alone (15,16) as well as the use of electrically excited plasmas or glow discharges to generate monomers capable of undergoing VDP have been explored. The products of these two processes, called plasma polymers, continue to receive considerable scientific attention. Interest in these approaches is enhanced by the fact that the feedstock material from which the monomer capable of VDP is generated is often inexpensive and readily available. In spite of these widespread scientific efforts, however, commercial use of the technologies is quite limited.

When *p*-xylene is used as the monomer feed in a plasma polymer process, PX may play an important role in the formation of the plasma polymer. The plasma polymer from *p*-xylene closely resembles the Gorham process polymer in the infrared, although its spectrum contains evidence for minor amounts of nonlinear, branched, and cross-linked chains as well. Furthermore, its solubility and low softening temperature suggest a material of very low molecular weight (17).

VDP Polyimides. Polyimide films have also been prepared by a kind of VDP (18). The poly(amic acid) layer is first formed by the coevaporation and condensation of two monomers, followed by copolymerization on the substrate. The imidization is carried out in a separate baking step (see POLYIMIDES).

***o*-Xylylene/BCB.** Thermosetting resins based on benzocyclobutene (BCB)



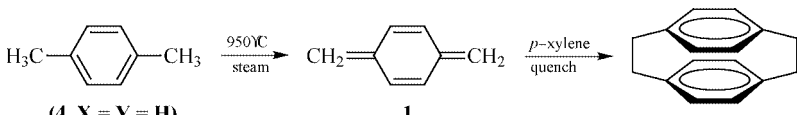
chemistry have been reported (19,20). In these condensed phase cures, the *o*-xylylene isomer is the key reactive intermediate. From the behavior of this energetically similar ortho isomer, the value of the para configuration's rendering any ring closure reaction—analogous to cyclobutene formation from the ortho isomer—geometrically forbidden can be appreciated.

Dimer

In contrast to the extreme reactivity of the monomeric PX (**1**) generated from it, the dimer DPX (**3**) feedstock for the parylene process is an exceptionally stable compound. Because of their chemical inertness, dimers in general do not exhibit shelf-life limitations. Although a variety of substituted dimers are known in the literature, at present only three are commercially available: DPXN, DPXC, and DPXD, which give rise to Parylene N, Parylene C, and Parylene D, respectively.

The unsubstituted C-16 hydrocarbon, [2.2]paracyclophane (**3**), is DPXN. Both DPXC and DPXD are prepared from DPXN by aromatic chlorination and differ only in the extent of chlorination; DPXC has an average of one chlorine atom per aromatic ring and DPXD has an average of two.

Manufacture. For the commercial production of DPXN (di-*p*-xylylene) (3), two principal synthetic routes have been used: the direct pyrolysis of *p*-xylene (**4**, X = Y = H) and the 1,6-Hofmann elimination of ammonium (HNR_3^+) from a quaternary ammonium hydroxide (**4**, X = H, Y = NR_3^+). Most of the routes to DPX share a common strategy: PX is generated at a controlled rate in a dilute medium, so that its conversion to dimer is favored over the conversion to polymer. The polymer by-product is of no value because it can neither be recycled nor processed into a commercially useful form. Its formation is minimized by careful attention to process engineering. The chemistry of the direct pyrolysis route is shown in equation 1:



(1)

First, *p*-xylene is dehydrogenated pyrolytically in the presence of steam at about 950°C to give *p*-xylylene (PX), which in turn forms di-*p*-xylylene (DPX) when quenched in liquid xylene. The xylene is recycled to the pyrolysis vessel. Yields and conversion efficiency are satisfactory. However, several engineering challenges need to be overcome, including the choice of a suitable diluent; establishing optimal residence time, vapor velocity, and operating pressure during pyrolysis; and the design and construction of novel equipment to withstand the highly corrosive reaction environment.

The Hofmann elimination route, of which many versions exist, can be carried out at much lower temperatures in conventional equipment. The PX is generated by a 1,6-Hofmann elimination of amine from a quaternary ammonium hydroxide in the presence of a base. This route gives yields of 17–19%. Undesired polymeric

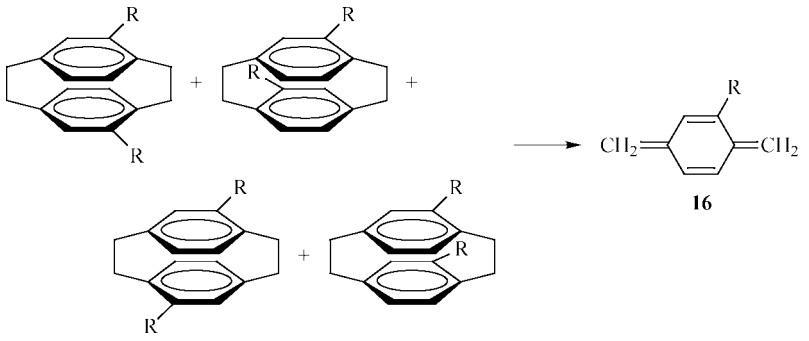


Fig. 4. Isomeric dichloro[2.2]paracyclophanes produce the same xylylene.

products can be as high as 80% of the product. In the presence of a polymerization inhibitor, such as phenothiazine, DPXN yields can be increased to 50%.

In the 1,6-elimination of *p*-trimethylsilylmethylbenzyltrimethylammonium iodide with tetrabutylammonium fluoride, yields as high as 56% have been reported (21). The starting materials are not readily accessible, however, and are costly.

The yield can be raised to 28% if the Hofmann elimination is conducted in the presence of a water-soluble copper or iron compound (22). Further improvements up to 50% were reported when the elimination was carried out in the presence of ketone compounds (23). Further beneficial effects have been found with certain cosolvents, with reported yields of greater than 70% (9).

DPXC and DPXD. The economic pressure to control dimer costs has had an important effect on what is in use today (ca 1997). Attaching substituents to the ring positions of a [2.2]paracyclophane does not proceed with isomeric exclusivity. Indeed, isomeric purity in the dimer is not an essential requirement for obtaining isomeric purity, eg, monosubstituted monomer, in the pyrolysis. Any mixture of the four possible heteronuclearly disubstituted dichloro[2.2]paracyclophanes, will, after all, if pyrolyzed produce the same monomer molecule, chloro-*p*-xylylene [10366-09-3] (**16**) (Fig. 4).

Although DPXC and DPXD prepared by the chlorination of DPXN are relatively complex mixtures, after pyrolytic cleavage the resulting mixture of monomers is considerably simpler. Thus DPXC, when pyrolyzed, gives predominantly monochloro PX, which is accompanied by small but significant amounts of PX and dichloro PX. The resulting polymer, Parylene C, consequently has an average of about one chlorine atom per repeat unit. However, it contains significant amounts of unchlorinated, as well as dichlorinated, repeat units.

DPXC and DPXD are prepared from DPXN by chlorinating to different extents. The conditions are controlled to favor aromatic ring chlorination to the exclusion of the free-radical chlorination of the ethylene bridges. However, the chlorination products are complex mixtures of the homologues DPXN, monochloro DPX, dichloro DPX, trichloro DPX, and tetrachloro DPX, and even higher homologues, as well as the several possible isomers of each.

New synthetic routes for the preparation of homologously pure dichloro DPX and tetrachloro DPX have been reported through the 1,6-Hofmann elimination of

chlorinated *p*-methylbenzyltrimethylammonium hydroxide. In the case of dichloro DPX, yields of 30% were reported (24). In the presence of ketone compounds, yields were increased to 50% (23).

Purification. Unsubstituted di-*p*-xylylene (DPXN) is readily purified by recrystallization from xylene. It is a colorless, highly crystalline solid. The principal impurity is polymer, which fortunately is insoluble in the recrystallization solvent and easily removed by hot filtration.

In purifying DPXC and DPXD, care must be taken not to disturb the homologue composition, so that product uniformity is maintained. For example, a recrystallization of DPXC from ethanol would give a higher melting, more crystalline dimer material, at the expense of a decrease in yield owing to the removal of otherwise useful isomers, but the polymer made from it would not be identical to the historical Parylene C, as defined by its preparation from the chlorination mixture. The real purification issues are the removal of insoluble residues and any components that contain aliphatic side-chain chlorine. Although ring-substituted chlorine is stable, side-chain chlorine can give rise to hydrogen chloride gas under the conditions of the parylene process, or subsequent to it, which in certain applications could initiate substrate corrosion. Fortunately, the aliphatic chlorine problem can be minimized by proper attention to process detail.

Properties. The DPXs are all crystalline solids; melting points and densities are given in Table 1. Their solubility in aromatic hydrocarbons is limited. At 140°C, the solubility of DPXN in xylene is only about 10%. DPXC is more readily soluble in chlorinated solvents, eg, in methylene chloride at 25°C its solubility is 10%. In contrast, the corresponding figure for DPXN is 1.5%.

The structure of DPXN was determined in 1953 from X-ray diffraction studies (25). There is considerable strain energy in the buckled aromatic rings and distorted bond angles. The strain has been experimentally quantified at 130 kJ/mol (31 kcal/mol) by careful determination of the formation enthalpy through heat of combustion measurements (26). The release of this strain energy is doubtless the principal reason for success in the particularly convenient preparation of monomer in the parylene process.

Polymer

The linear polymer of PX, poly(*p*-xylylene) (PPX) (**2**), is formed as a VDP coating in the parylene process. The energetics of the polymerization set it apart from

all other known polymerizations and enable it to proceed as a vapor deposition polymerization.

Thermodynamic Considerations. On the basis of the value for the enthalpy of formation of *p*-xylylene, ΔH_f^0 (PX), the enthalpy of polymerization, $\Delta H^0_{polym} = \Delta H_f^0$(PPX) ΔH_f^0(PX), can be estimated. No experimental combustion data are available for high molecular weight poly(*p*-xylylene) as it is formed in the parylene process, ΔH^0_f (PPX).

For crystalline [2.2]paracyclophane [(1,2), DPXN], a ΔH^0_f of +154.4 kJ/mol (+36.9 kcal/mol) is reported (26). The hypothetical transformation of crystalline DPXN into polymer is accompanied by the release of 129.7 kJ/mol (31.0 kcal/mol) of paracyclophane strain energy per mole of paracyclophane, and 12.6 kJ/mol (3.0 kcal/mol) per polymer repeat unit as a result of the bibenzyl hyperconjugative stabilization, which is permitted in the polymer but excluded by geometry in the dimer. Thus the standard enthalpy of formation for the hypothetical 100% crystalline poly(*p*-xylylene) is estimated to be −0.3 kJ/mol (−0.05 kcal/mol), assuming that the energies associated with crystallinity are the same in both cases. Although it might be acceptable to assume that such energies per repeat unit are similar in the crystalline polymer and crystalline dimer, Parylene N, as produced by the parylene process, is typically only about 57% crystalline. Using a value of 14.1 kJ/mol (3.37 kcal/mol) for the heat of fusion for poly(*p*-xylylene) (27), the standard formation enthalpy for Parylene N, as it is typically deposited in the parylene process, ΔH^0_f (Parylene N), is +5.7 kJ/mol (+1.4 kcal/mol).

In estimating the enthalpy of polymerization, the physical state of both starting monomer and polymer must be specified. Changes in state are accompanied by ethalpy changes. Therefore, they also affect the level of the polymerization enthalpy. The ΔH^0_f for *p*-xylylene previously mentioned is applicable to the monomer as an ideal gas. To make comparisons with other polymerization processes, most of which start with condensed monomer, a heat of vaporization for *p*-xylylene is needed. It is assumed herein that it is the same as that for *p*-xylene, 42.4 kJ/mol (10.1 kcal/mol). Thus the ΔH^0_f of the liquid monomer *p*-xylylene is 192.3 kJ/mol (46.0 kcal/mol).

The enthalpy of polymerization of unannealed (57% crystalline) Parylene N, as it is deposited, starting with liquid monomer, $\Delta H^0_{polym(lu)}$, is −186.6 kJ/mol (−44.6 kcal/mol). This is an exceptionally high value compared with those of other addition polymers, which generally fall in the −60 to −100 kJ/mol (−14.3 to −23.8 kcal/mol) range. It quantifies the vigor of the polymerization. Because the source of polymerization enthalpy is within the *p*-xylylene system, substituents affect it only to a minor extent. All parylenes are expected to have a similar molar enthalpy of polymerization. An experimental value for the heat of polymerization of Parylene C has appeared. Using the gas evolution from the liquid nitrogen cold trap to measure thermal input from the polymer, and taking advantage of a peculiarity of Parylene C at −196°C to polymerize abruptly, perhaps owing to the arrival of a free radical, a ΔH^0_{polym} of −152 ± 8 kJ/mol (−36.4 ± 2.0 kcal/mol) at −196°C was reported (28). The correction from −196°C to room temperature is estimated at −17 kJ/mol, bringing this experimental value for Parylene C closer to the calculated value for Parylene N. It is assumed that S_{polym} is 0 at 0 K (third law), 125 J/(mol · K) [30 cal/(mol · K)] at 298 K, and proportional to *T* in between—a

crude assumption, but appropriate to the current level of knowledge. Thus experiment and calculation are in harmony in quantifying the exceptional exothermicity of parylene polymerization (see THERMODYNAMIC PROPERTIES OF POLYMERS).

The thermodynamic ceiling temperature (29) T_c for a polymerization is computed by dividing the ΔH^0_{polym} by the standard entropy of polymerization, ΔS^0_{polym}. The T_c is the temperature at which monomer and polymer are in equilibrium in their standard states at 25°C (298.15 K) and 101.3 kPa (1 atm). (In the case of *p*-xylylene, such a state is, of course, purely hypothetical.) The T_c quantifies the binding forces between monomer units in a polymer and measures the tendency of the polymer to revert back to monomer. In other systems, the T_c indicates a temperature above which the polymer is unstable with respect to its monomer, but in the case of parylene it serves rather as a means of comparing the relative stability of the polymer with respect to its reversion to monomer. For computing the T_c, however, the standard entropies of polymerization are required.

The standard polymerization entropies can be estimated from the following. The standard entropy S^0 for PX as an ideal gas is computed by a group-contribution method (30) to be 310.6 J/(mol · K) [74.24 cal/(mol · K)]. The entropy of vaporization for PX is assumed to be the same as that of *p*-xylene, 104.7 J/(mol · K) [25.03 cal/(mol · K)] (31). Therefore, the S^0 for liquid PX is 205.9 J/(mol · K) [49.21 cal/(mol·K)]. Noting that the experimental specific heat C_p of PPX follows that of polystyrene over the range of 160 to 340 K (32), it can be assumed that the proportionality continues down to 0 K and that the factor 135/116 at 298 K can be applied to the known S^0 for polystyrene [$S = 128.5$ J/(mol · K) or 30.70 cal/(mol · K) (33). It follows that the S^0 for as-deposited 57% crystalline Parylene N is 149.5 J/(mol · K) [35.73 cal/(mol · K)]. Therefore, $\Delta S^0_{polym(g)} = -161.1$ J/(mol · K) [−38.50 cal/(mol · K)] and $\Delta S^0_{polym(l)} = -56.4$ J/(mol · K) [−13.4 8cal/(mol · K)].

The results of the above polymerization thermodynamics calculations for parylene are compared to similar data for typical addition polymers in Table 2. The T_c quantifies the stability of the polymer only with respect to reversion to monomer. When PPX is thermally degraded (ca 500°C), a mixture of degradation

products including hydrogen gas, *p*-xylene, toluene, and *p*-methylstyrene is observed (34), suggesting that the path taken in thermal degradation requires the cleavage of bonds other than those formed in the polymerization, very likely starting with the methylene C—H bond. Complete replacement of the methylene hydrogens in PPX with fluorine gives a polymer with substantially better stability at elevated temperatures (35).

The enthalpy liberated on the VDP of parylene is real and in an adiabatic situation causes a rise in temperature of the coated substrate. For Parylene C, 229.1 kJ/mol (54.7 cal/mol) corresponds to 1654 J/g (395 cal/g) whereas its specific heat at 25°C is only 1.00J/(g · K) [0.239 cal/(g · K)] (36). In most practical situations, however, the mass of parylene deposited is dwarfed by the substrate mass, and the heat of polymerization is dissipated within the coated substrate over the time required to deposit the coating with minimal actual temperature rise.

Polymerization Mechanism. The physical processes of condensation and diffusion must be considered along with the *p*-xylylene polymerization chemistry for a proper understanding of what happens microscopically during vapor deposition polymerization (37). These processes point to an important distinction between VDP and vacuum metallization, ie, that in the latter, adsorption is followed by a surface reorganization of the existing deposited material, and diffusion of incoming species through the bulk is nonexistent. In most parylene depositions, a coating forms from gaseous monomer under steady-state conditions.

Gaseous monomer is transported to the location within the coating where it is to be consumed to produce polymer by an initial condensation, followed by diffusion. The net flux of monomer molecules through the growth interface, ie, the outer boundary of the coating, between the gaseous and condensed phases, needed to sustain growth at a given rate can be readily calculated [for Parylene C, 10 μm/h requires $1.55 \times 10^{15}/(\mathrm{cm}^2 \cdot \mathrm{s})$]. Comparing a net flux so obtained with the flux of molecules that according to the kinetic theory of gases are striking the growth surface ($Z = PN_0/\sqrt{2\pi MRT}$) for the conditions typical of parylene deposition, a large difference (two or three orders of magnitude) is observed. For Parylene C monomer at a pressure of 1.3 Pa (10 μm Hg) and 25°C, $Z = 6.7 \times 10^{17}/(\mathrm{cm}^2 \cdot \mathrm{s})$. For each molecule that eventually enters the coating, some hundred or thousand molecules strike the growth interface. Those that condense and do not react must, of course, evaporate. The term "sticking coefficient" has sometimes been borrowed from vacuum metallization to describe this ratio of incident molecules to consumed molecules. However, the VDP situation is not adequately described by hard spheres bouncing off a growth interface. Every incident molecule spends at least some time in the polymeric coating phase beyond the growth interface before it is lost again to the gas phase.

Because most of the condensing molecules evaporate, condensation equilibrium at the growth surface can be assumed, to a good approximation. The concentration of monomer dissolved in the coating near the growth interface is, therefore, governed by Henry's law, and monomer concentration in polymer solution increases proportionately to the partial pressure of monomer in the gas phase. Furthermore, as the temperature is lowered, or as higher molecular weight monomers of lower volatility are selected, monomer concentration at the growth interface increases. In most practical situations, these Henry's law effects

Table 3. Threshold Condensation Temperatures T_{tc} for Substituted *p*-Xylylene Monomers

Monomer	T_{tc}, °C
p-Xylylene	30
2-Methyl-*p*-xylylene	60
2-Ethyl-*p*-xylylene	90
2-Chloro-*p*-xylylene	90
2-Acetyl-*p*-xylylene	130
2-Cyano-*p*-xylylene	130
2-Bromo-*p*-xylylene	130
Dichloro-*p*-xylylene	130

dominate in determining growth rates for VDP coatings by regulating monomer concentration within the coating. For each monomer, there exists a threshold condensation temperature, T_{tc}, above which the rate of growth of coating is, for all practical purposes, zero (Table 3), but this phenomenon is governed by the competition between initiation and propagation chemistries, discussed herein.

Once it is in "solution" in the coating, the monomer moves about in random directions by diffusion until it evaporates or is consumed by chemical reaction. The polymer molecules that have already grown to higher molecular weight cannot relocate appreciably owing to entanglement with their neighbors. The rate of diffusion of monomer through the polymer bulk is adequate for the participation of diffusive transport in the mechanism of VDP (ca 10^{-10} cm^2/s at room temperature). This can be confirmed in swelling-rate experiments with solvents having similar physical properties, such as *p*-xylene.

The monomer is consumed by two chemical reactions: initiation, in which new polymer molecules are generated, and propagation, in which existing polymer molecules are extended to higher molecular weight. In steady-state VDP, both reactions proceed continuously inside polymeric coating, in the reaction zone just behind the growth interface.

The first step of the initiation reaction is the coupling of two monomer molecules to form the dimer diradical (**5**). The formation of this diradical is energetically uphill, ie, the energy of two benzyl radicals is greater than that of two starting *p*-xylylene systems. The rate of destruction greatly exceeds the rate of formation. Only a trace concentration of the dimer diradical species exists at equilibrium. Further reaction of the dimer diradical with monomer gives more stable diradicals. In these subsequent transformations, a *p*-xylylene is converted into a benzene with a net stabilizing effect. At some stage of oligomerization, the resulting *n*-mer diradical becomes more stable than the *n* *p*-xylylene molecules from which it was constructed. At this point, the new polymer molecule is formed. Thus the overall order of the initiation reaction, the reaction in which new polymer molecules are generated, is some $n > 2$. Initiation chemistry requires no species other than monomer, another unusual aspect of the polymerization chemistry of *p*-xylylene.

The order *n* of the initiation reaction has an important influence on the manner in which the VDP occurs. Because monomer molecules, even in solution

at low concentration, are closer together in the condensed phase than they are in the gaseous phase, the rate of initiation is greater in the condensed phase than in the gaseous phase. The higher the order n, the more the condensed phase is favored. The order n, according to the mathematical model (37) of *p*-xylylene VDP, at the same time governs the effect of monomer pressure on growth rate at a given deposition temperature. The model predicts that growth rate should vary with the pressure raised to the power $(n + 3)/4$. Thus, if $n = 3$, the growth rate should be proportional to $p^{1.5}$. In an early attempt to determine the pressure dependence of parylene growth rate γ, an expression of $\gamma = kp^2$ was reported (38). A pressure exponent of 2 would be interpreted as an initiation order of $n = 5$. Although such a high order would favorably deemphasize "snow," consideration of the energetics of oligomeric *p*-xylylene diradicals would seem to place the order nearer to 3. Perhaps the early investigators did not anticipate a nonintegral order for pressure dependence. A more recent report (39) places n at 3 for Parylenes N and C, and 4 for Parylene D. Thus, with $n \geq 3$, the parylenes are more likely to form a continuous coating than a dust or a snow, the physical form of the product of a gas-phase polymerization. To the extent that snow is included in the formation of a coating (ie, dual-phase polymerization), haze develops.

In the propagation reaction, the monomer molecule reacts with an existing free-radical polymer chain end to make the chain one repeat unit longer. The polymer chains have two active ends, and they grow from both ends at the same time. Under normal coating conditions, the consumption of monomer by propagation must be much higher than its consumption by initiation to obtain high molecular weight polymer. In fact, the number-average molecular weight is determined by the proportion of monomer consumed by the two reactions, and is diminished by increases in deposition temperature or monomer partial pressure.

The concentration of monomer within the coating decreases approximately exponentially with distance from the growth interface. With this decrease in monomer concentration, the rates of initiation and propagation reactions also decrease. Moving back into the polymer from the growth interface, through the reaction zone where polymer is being manufactured, a region in which the polymer formation is essentially complete is gradually entered. Because initiation is of higher order in monomer concentration, it tends to occur closer to the growth interface than does propagation. Under conditions prevailing during a typical deposition, the characteristic depth of the reaction zone is a few hundred nanometers, and the maximum concentration of monomer, ie, the concentration at the growth interface, is of the order of a few tenths percent by weight. Thus the parylene polymerization takes place just behind the growth interface in a medium that is best described as a slightly swollen, solid polymer.

During the vapor deposition process, the polymer chain ends remain truly alive, ceasing to grow only when they are so far from the growth interface that fresh monomer can no longer reach them. No specific termination chemistry is needed, although subsequent to the deposition, reaction with atmospheric oxygen, as well as other chemical conversions that alter the nature of the free-radical chain ends, is clearly supported experimentally.

Polymer Properties. The single most important feature of the parylenes, that feature which dominates the decision for their use in any specific situation, is the VDP process by which they are applied. VDP provides the room-temperature

coating process and produces the films of uniform thickness, having excellent thickness control, conformality, and purity. The engineering properties of commercial parylenes once they have been formed are given in Table 4. As crystalline polymers, the parylenes retain useful physical integrity up to temperatures approaching their crystalline melting points. However, their glass-transition temperatures, T_g, the temperature spans over which the continuous amorphous phase, usually the minority phase, changes from a rigid, vitreous condition to a more flexible, rubbery condition, are probably in the vicinity of ambient temperature. In the case of PPX (Parylene N), careful measurements have established the T_g

Table 4. Typical Engineering Properties of Commercial Parylenes

to be centered at 13°C, the range over which T affects heat capacity measurements extending from 240 to 330 K (−33 to + 57°C) (27). Because they have similar backbone structures, other parylenes are expected to have similar T_gs, although no measurements taken with equal care exist. Earlier reports have quoted a somewhat higher (60–90°C) range for the entire family (5). In either case, the parylenes as prepared by their VDP process are further distinguished from conventional polymers in having been generated in a medium that is at least to some extent vitreous.

During formation, the motions of the parylene polymer chains in the vitreous medium are restricted. The properties of freshly deposited parylenes, therefore, generally differ from those that have been aged or annealed. Restricted polymer chain motion during VDP severely limits their ability to organize into crystallites, and consequently freshly deposited parylenes are metastable. With the passage of time, and sooner if heated, they will reorganize into a thermodynamically more satisfactory configuration, increasing crystallinity. Certain physical properties of freshly deposited parylenes therefore can be expected to change upon aging or annealing. Of the commercial materials, Parylene C, perhaps as a result of the asymmetry of its repeat unit, is particularly subject to modifications subsequent to its initial formation.

Mechanical Properties. Many of the mechanical properties of the parylenes are similar to those of other conventional plastics. The values in Table 4 are typical of those quoted for the parylenes, but in any particular case can vary with aging or annealing. In an outstanding instance of this effect, the 200% elongation quoted for Parylene C is the value commonly observed on the freshly

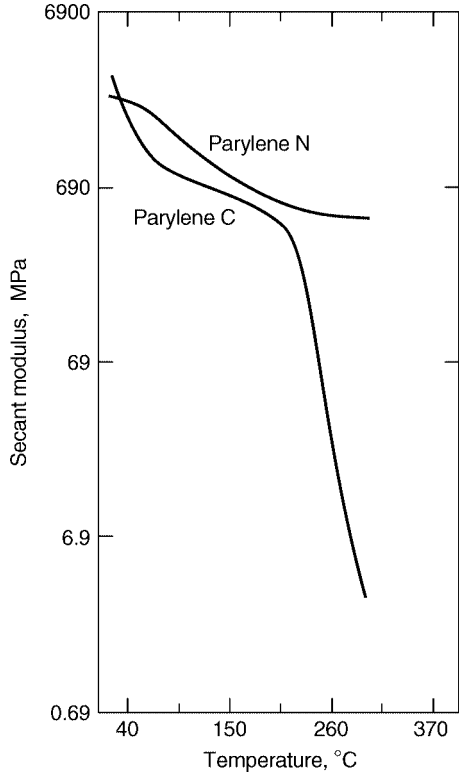

Fig. 5. Stiffness–temperature behavior of Parylenes N and C. To convert MPa to psi, multiply by 145.

deposited material. It drops dramatically as crystallinity builds. In general, an increase in crystallinity with aging or annealing results in a lowering of elongation to break and an increase in modulus and strength. The variation in mechanical rigidity of the parylenes as temperature increases is shown in Figure 5, which plots the logarithm of the secant modulus, a measure of stiffness, vs temperature. Generally, a small decrease in rigidity occurs near ambient temperature as the glass transition is traversed. Significant rigidity is then retained up to the point where the crystallites begin to melt.

It has been reported that Parylene N is deposited in a state of compressive stress (40). The inherent stress is 18 MPa (2300 psi) and is invariant with thickness. This congenital compressive stress can be removed and rendered tensile by a thermal cycle.

Electrical Properties. The bulk electrical properties of the parylenes make them excellent candidates for use in electronic construction. The dielectric constants and dielectric losses are low and unaffected by absorption of atmospheric water. The dielectric strength is quoted for specimens of 25 μm thickness because substantially thicker specimens cannot be prepared by VDP. If the value appears to be high in comparison with other materials, however, it should be noted that the usual thickness for such a measurement is 3.18 mm. Dielectric strength declines

Table 5. Dielectric Constants and Refractive Indexes of Parylenes

Parameter	Parylene N	Parylene C	Parylene D
Dielectric constant

Refractive index			
n_D line	1.661	1.639	1.669
Squared	2.76	2.69	2.79

with the square root of increasing thickness. Viewed in this light, the dielectric strength of the parylenes is good, but not outstandingly high. The bulk resistivities are advantageously high because of the purity of the parylenes, their low moisture absorption, and in particular their freedom from the trace ionic impurities present in conventional polymers as residues. Such impurities might be the residues of the catalysts necessary for their formation. The surface resistivities are advantageously high in part because of their low affinity for atmospheric water. The experimental dependence of the electrical properties on temperature is shown in Figure 6.

The question of the value of the dielectric constant of the parylenes in the gigahertz range of frequencies is often of interest to designers of high frequency circuitry. Making such measurements on low loss, low dielectric constant, thin films is experimentally difficult, and no reliable data exist as of this writing (ca 1997). Fortunately, however, an indicator is available. For nonabsorbing, nonmagnetic materials such as the parylenes, the well-known Maxwell relation applies: at any particular frequency, the square of the index of refraction equals the relative permittivity, or dielectric constant (41). The refractive indices for the parylenes at the sodium D line (589 nm), a visible wavelength that corresponds to a frequency of 510 THz (5.1×10^{14} Hz), are shown in Table 5, along with their squares and the lower frequency measurement of dielectric constant. Because by virtue of the Maxwell relation the dielectric constants of the parylenes at the much higher frequency of visible light are close to those observed by conventional means, it seems likely that when reliable gigahertz dielectric constant measurements on the parylenes become available, similar values will be obtained.

Thermal Properties and Endurance. The heat capacity or specific heat, C_p is a quantity of theoretical thermodynamic significance as well as of practical importance. It has been determined for Parylene N over the temperature range of 220 to 620 K (-53 to $+ 347^\circ$C) (27,32).

Figure 7 gives the results of an experiment in which free-standing films were exposed to constant elevated temperatures in air-circulating ovens for periods of weeks to months; the failure criterion was a 50% loss in tensile strength. Because the test is destructive, each data point (failure time at a given temperature) required many specimens. In the degradation of many polymers, including the parylenes, tensile strength is maintained until chain scission has reduced molecular weight to the point at which entanglement is no longer a factor in

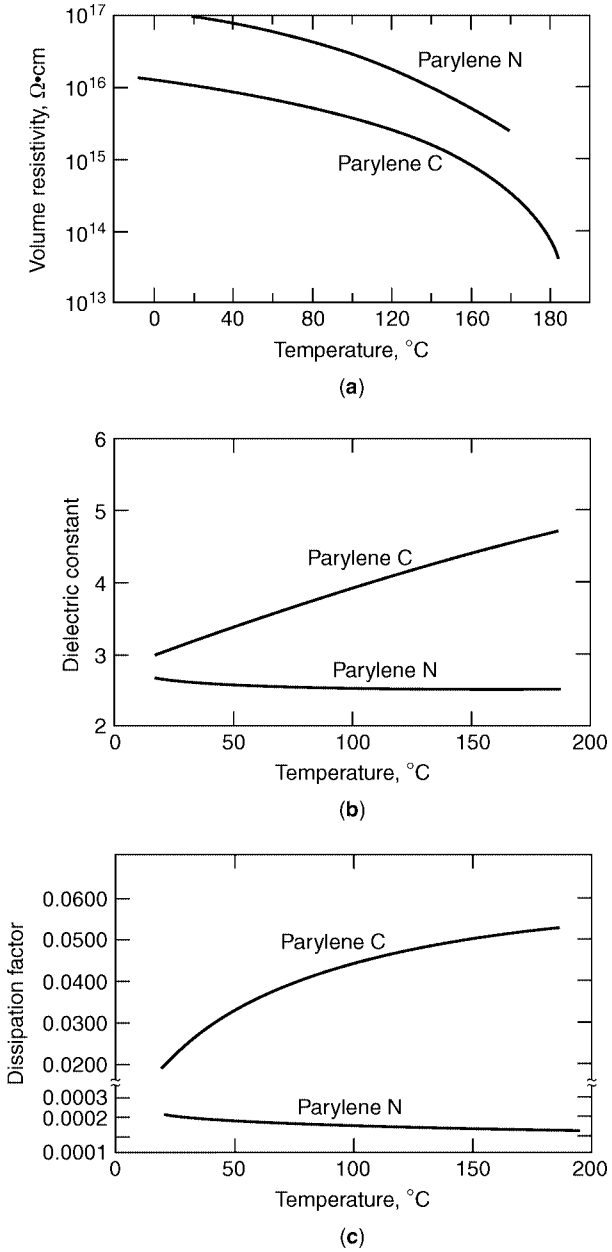

Fig. 6. Variation of electrical properties of Parylenes N and C with temperature.

determining physical properties. Beyond that point it drops abruptly. Thus despite the relatively large variance in tensile strength measurements, the 50% loss criterion allows a reasonably precise location of end of useful life on a log time scale (Fig. 8). The data of Figure 7 suggest that Parylenes N, C, and D perform in air without significant loss of physical properties for 10 years at 60, 80, and 100°C,

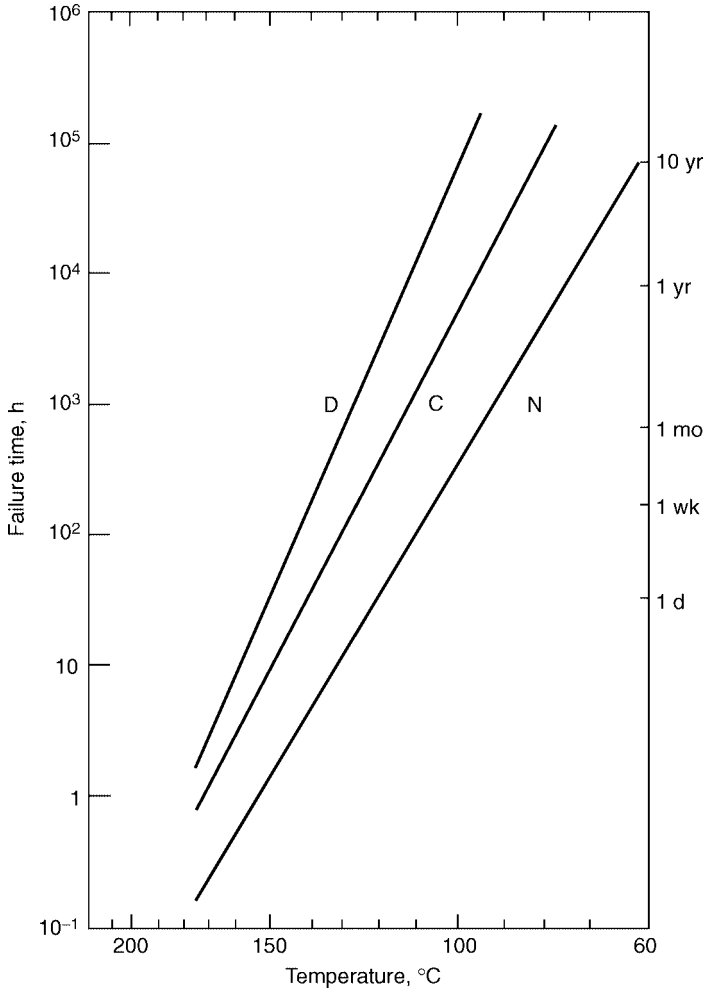

Fig. 7. Useful lifetime of Parylenes N, C, and D as a function of temperature in air. Failure = 50% loss in tensile strength.

respectively. Clearly, these data can justifiably be made to serve only as a guide for considering the parylenes for a specific application. Questions of thermal endurance tend to have no clear-cut answers. In situations where performance may be marginal, there is no substitute for retesting under conditions more directly relatable to the application.

Degradation. The most important mode of degradation for parylenes is oxidative chain scission. Significantly, hydrolytic degradation is chemically impossible. Oxidative degradation limits the use of parylenes at elevated temperatures in many common applications. Figure 9 shows the effect of exposure to elevated temperature in air or in vacuum on elongation to break, an indicator of toughness or lack of brittleness. The data are given for Parylene C, which suffers substantial change in mechanical properties as the freshly deposited material is annealed.

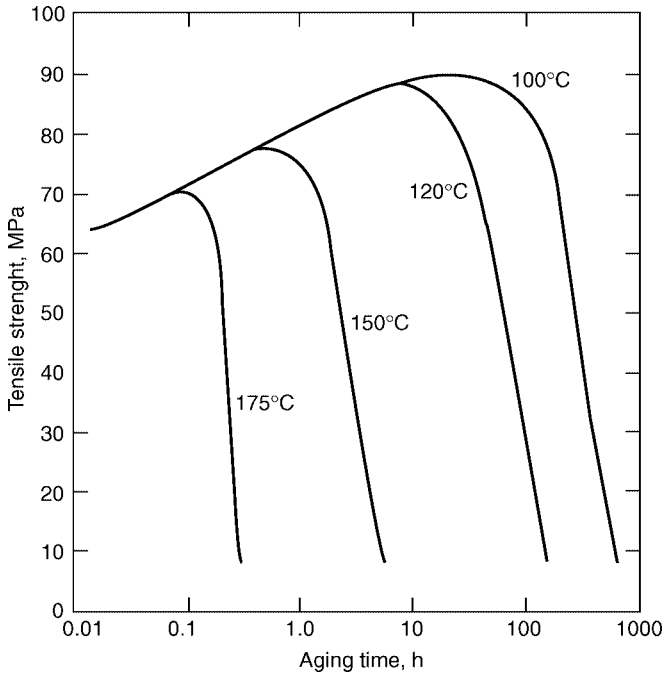

Fig. 8. Tensile strength of Parylene C on aging at elevated temperature. To convert Pa to psi, multiply by 0.145×10^3.

Aging in air at 150°C for ca 100 h causes the elongation to break to drop from its initially very high value to 0, at which point the specimen is mechanically useless. Aging in vacuum at yet higher temperatures (265°C) for a similar length of time gives a stronger, more rigid, stabilized material with 15% elongation at break, the result of annealing.

For applications where oxygen can be excluded, eg, in outer space, Figure 10 shows that 10-year-use projections exceed 200°C for Parylenes N, C, and D. Conventional antioxidants, incorporated during or after VDP, can extend the life of the parylenes at elevated temperatures (42,43).

Another factor in oxidative degradation is ultraviolet radiation, of which sunlight is a rich source. The oxidation of parylene appears to be enhanced by ultraviolet radiation. Ozone may play a mechanistic role in the ambient-temperature exposure of parylenes to ultraviolet radiation in the presence of oxygen. For the best physical endurance, exposure of the parylenes to ultraviolet light must be minimized.

Barrier Properties. The bulk barrier properties of parylenes are among the best of organic polymeric coatings. The data in Table 4 are the results of tests conducted some time ago, and certain entries seem unaccountably high, particularly the values for the permeability of Parylene N by SO_2 and H_2S. Because film damage might have been the cause of these high test values, experimental confirmation is advisable. More recent values for water transport rates in Parylene C films are available over the temperature range of 20–55°C in a comparative

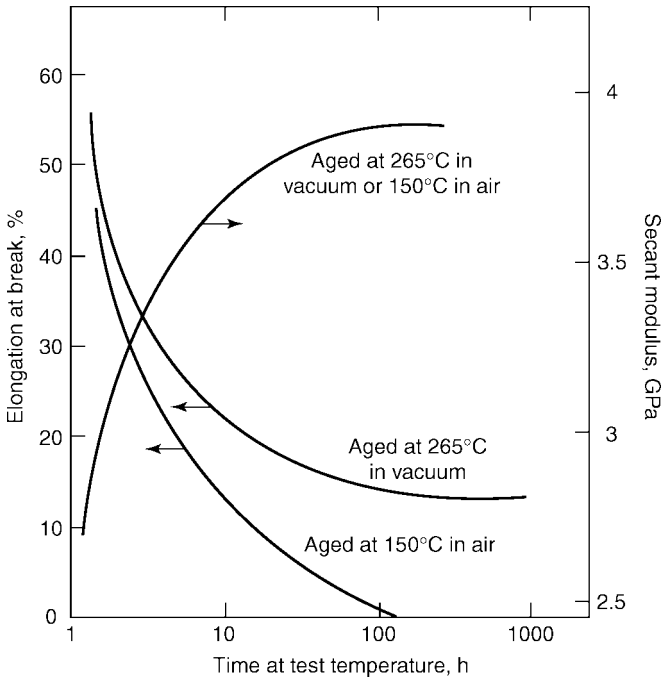

Fig. 9. Effect of temperature on the flexibility of Parylene C in air and vacuum. To convert GPa to psi, multiply by 145,000.

study which includes Mylar A and Kapton H (44). Similar information is provided for Parylene D in a study over the temperature range of 30–80°C (45).

Spectral and Optical Properties. The parylenes do not absorb visible light, and absorb only at the shorter wavelength, high energy end of the ultraviolet range (Fig. 11). Such absorption is expected for the electronic system of the parylenes' benzene ring. Films and coatings are colorless in the visible, becoming opaque to sufficiently short wavelength uv light.

The infrared transmission spectra of Parylenes N, C, and D are compared in Figure 12. Infrared spectra can be used to distinguish among sample films of the three commercial materials should a practical question of identity arise. The spectra in Figure 12 are taken on films of ca 18 μm thickness, which gives a good picture of a typical organic film in the standard infrared presentation format. It is, however, thicker than normally encountered in a typical parylene application. The amount of incident light absorbed at any given wavelength is predictably less than that indicated by the ordinate of Figure 12.
