Phenols are used as blocking agents in wire coatings. Phenol blocked isocyanates react with amines at room temperature. They are used as flexibilizing reactive additives in amine cured epoxy coatings (131).

Methyl ethyl ketone oxime (MEKO) (2-butanone oxime) [96-29-7] blocked isocyanates are more reactive than phenols. One package coatings formulated with hydroxy-functional resins cure in 30 min at 130°C. In automotive clear coats, MEKO leads to yellowing. Use of a combination of 3,5-dimethylpyrazole and 1,2,4-triazole has been recommended for clear coats that are non-yellowing (132).

The largest volume coatings with blocked isocyanates are cationic electrodeposition primers. They must be stable in water indefinitely; 2-ethylhexanol blocked isocyanates give the necessary hydrolytic stability. Many other blocking agents have been used to reduce cure temperatures; butoxyethoxyethanol is an example (133).

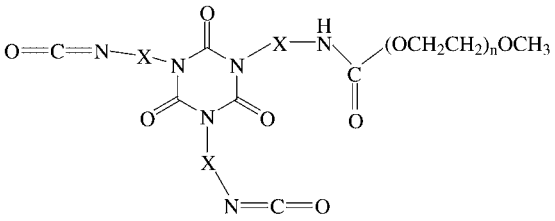
Diethyl malonate blocked diisocyanates cross-link polyols at 120°C for 30 min. The reaction with alcohols does not yield urethanes, rather transesterification occurs (134), and reaction with amines yields amides, not ureas. Storage-stable coatings can be formulated by using monofunctional alcohol in the solvent (135). Clear coats for automobiles that have both excellent environmental etch and abrasion resistance have been formulated with a combination of a hydroxy-functional acrylic resin, malonic ester blocked HDI and IPDI trimers, and an MF resin (136).

Blocked isocyanates are used in powder coatings with hydroxy-functional resins. ε-Caprolactam blocked IPDI isocyanurate has been the principal reactant. Use of caprolactam is decreasing because of the high temperatures required for curing and oven buildup. Polyol derivatives of IPDI uretdione are being increasingly used since, with cyclic amidine catalysts, they permit curing at lower temperatures than caprolactam and no volatile blocking agent is released (137).

Polyurethane moisture curing coatings cross-link by reaction of isocyanates with atmospheric water. They use isocyanate-terminated resins made from hydroxy-terminated polyesters by reacting the hydroxyl groups with excess diisocyanate. Cure rates depend on the water content of the air. At high humidity and temperature, cure is rapid, but the carbon dioxide released by the reaction of isocyanate with water can be trapped as bubbles, especially in thick films. See Reference 138 for discussion of the effects of temperature and humidity and other application considerations. Moisture curing urethane coatings are used for applications such as floor coatings, for which abrasion resistance and hydrolytic stability are important.

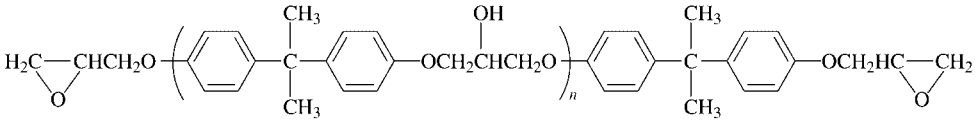
A variety of waterborne polyurethane systems have been investigated (139). Polyurethane dispersion resins (PUD) are polymers dispersed in water; both high molecular weight thermoplastic and lower molecular weight resins with reactive functional groups are available. The high molecular weight polymers are used in coatings similarly to the use of latexes. Since urethanes hydrogen bond strongly with water, they are plasticized permitting film formation with higher T_g polymers than acrylic latexes (140). They also exhibit superior abrasion resistance. hydroxy-functional PUDs can be cross-linked with MF resins or blocked isocyanates. MEKO blocked isocyanates are used with water-reducible anionic acrylic or polyester resins.

Waterborne 2K coatings have been developed. Bayer Corporation was awarded a Presidential Green Award in 2000. Waterborne 2K coatings have limited pot life. In solventborne coatings, pot life can be determined by monitoring viscosity increases; in waterborne 2K coatings, viscosity does not change as reactions occur, since the change in viscosity occurs inside aggregate particles without affecting the bulk viscosity. Coalescence is inhibited if there is too much reaction before volatiles are evaporated. Since isocyanates also react with water, an excess of isocyanate is usually required. The reaction with water results in formation of CO_2, which can lead to blistering, especially as thicker films are applied. Since TMXDI reacts more slowly with water than other isocyanates, it can be used to cross-link water-reducible acrylic resins with lower NCO/OH ratios (141). Polyisocyanate can be mixed in a water-reduced coreactant just before spraying. Spray equipment has been designed to provide in line intensive mixing of the two components (142). Hydrophilically modified polyisocyanates made by reacting a fraction of the —NCO groups of a polyisocyanate with a polyglycolmonoether are more easily mixed (143).



Hydrophilically modified polyisocyanate

Epoxy Resins. The largest volume epoxy resins are made by reacting BPA [4,4′-(1-methylethylethylidene)bisphenol] [80-05-7] with epichlorohydrin (ECH). The resins are represented by the following general formula, where the molar ratio of ECH to BPA determines the average n value.

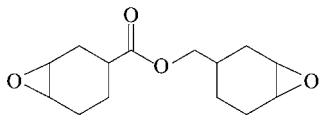


Bisphenol A epoxy resins

Resins are available, having average n values from 1.3 to 16. Viscosity increases with molecular weight. Above an average n value of 2, the resins are amorphous solids with increasing T_g. Because of side reactions, commercial resins have an $\bar{f}_n$ less than 2, commonly about 1.9. BPA epoxy resins are used in coatings in which excellent adhesion and corrosion resistance are required. A limitation of their use is poor exterior durability. Epoxy resins are also prepared by reaction of ECH with novolak phenolic resins. The resulting novolak epoxy resins have $\bar{f}_n$ of 2.2–5.5 (see EPOXY RESINS).

Epoxy-functional acrylic resins are made by using glycidyl methacrylate (GMA) as a comonomer. Epoxidized soy and linseed oils are used in making

acrylate derivatives for uv-cured resins and thermal cationic cure resins. Also available are low molecular weight cycloaliphatic diepoxy compounds such as 3,4-epoxycyclohexylmethyl 3′,4′-epoxy-4-cyclohexylcarboxylate (**2**). They are used as reactive diluents in cationic coatings and as cross-linking agents for polyols, carboxylic acids, and anhydrides.



2

Epoxy groups react at ambient temperatures with primary amines to form secondary amines and with secondary amines to form tertiary amines. Aliphatic amines are more reactive than aromatic amines. The reaction is catalyzed by water, alcohols, tertiary amines, and phenols. Reactivity is high enough to require 2K coatings. Pot life is limited to a few hours and coatings take about a week to cure at ambient temperature. Several factors control pot life, including reactive group concentrations; the structural effects of amine, epoxy, and solvents; the equivalent and molecular weights; and $\bar{f}_n$ of the reactants. As the molecular weight of a BPA epoxy resin is increased, the number of equivalents per liter of epoxy groups decreases; therefore, the reaction rate is slower. Higher solids coatings have shorter pot lives.

Many amines such as diethylenetriamine (DETA) [*N*-(2-aminoethyl)-1,2-ethanediamine] [111-40-0] are toxic. Low molecular weight diamines have the disadvantages of low equivalent weights and viscosities, which increases the risk of error in mixing stoichiometric amounts in 2K coatings and the difference in viscosity between the DETA and epoxy resin makes uniform mixing difficult. Amine adducts, BPA epoxy ($n = 0.13$) reacted with an excess of a multifunctional amine, have higher equivalent weight and lower toxic hazard. Amine Mannich bases, prepared by reacting a methylolphenol with excess polyamine, give faster curing (144). Although the functionality of the amine is reduced, the phenolic hydroxyl accelerates the epoxy/amine reaction. Another approach is to react a multifunctional amine with aliphatic mono- or dicarboxylic acids to form amine-terminated polyamides. Dimer fatty acids are widely used; they are complex mixtures, predominately C_{36} dicarboxylic acids, made by acid-catalyzed dimerization of unsaturated C_{18} fatty acids.

BPA epoxy resins and polyamides are mutually soluble in the solvents used in epoxy-amine coatings, but most are not compatible in the absence of solvents. As solvent evaporates, phase separation can occur, resulting in a rough surface, called *graininess*. Graininess can be avoided by allowing the coating to stand for an hour after the two packages are mixed. *Blushing* is the appearance of a grayish, greasy deposit on the surface of films, and incomplete surface cure. Low temperature, high humidity conditions increase the probability of blushing. Blushing decreases gloss, increases yellowing, gives poor recoatability, and may interfere with intercoat adhesion. Blushing results from formation of carbamate salts of amine by reaction with CO_2 and water (145). As with graininess, it is

often possible to minimize blushing by mixing the epoxy and amine components an hour before application.

Waterborne epoxy amine coatings are made using emulsifying agents in either or both the amine and the epoxy package. Proprietary "self-emulsifiable" epoxy resins and polyamides are available; properties approaching those of solventborne coatings can be achieved (146). Nitroalkanes form salts of amines; the salt groups stabilize epoxy-amine emulsions and allow the system to be reduced with water (147). After application, the nitroalkane solvent evaporates, freeing the amine.

BPA epoxy resins can be cross-linked with phenolic resins; both resole and novolak phenolic resins are used. The reaction is acid catalyzed. The coatings require baking, and package stability is relatively limited. Package stability is enhanced with etherified resole resins. Increased solids and high functionality are reported using butoxymethylolated BPA as the phenolic resin (148). Unpigmented epoxy-phenolic coatings are used as linings for beverage cans and for some types of food cans. Concern has been raised because of the possible endocrine disruption by free BPA, an estrogen mimic. Studies are underway to determine whether trace amounts of BPA are extracted in food or beverage cans from BPA epoxy containing can linings (149).

Carboxylic acids are cross-linkers for epoxy coatings. The literature has been reviewed in Reference 150. Reaction of a carboxylic acid and an epoxy group yields a hydroxy ester. GMA copolymers and cycloaliphatic epoxides such as 2 react more rapidly than BPA epoxies. Tertiary amines catalyze the reaction of carboxylic acids with epoxies. Triphenylphosphine is reported to be a particularly effective catalyst. With triphenylphosphine catalysis and an excess of epoxy groups, coatings can be formulated that cross-link at 25°C (151). Cyclic anhydrides are also used. See Reference 151 for a review of the literature. Reaction of anhydrides with epoxy resins can occur initially with the epoxy resin hydroxyl groups, yielding esters and carboxylic acids. The resulting carboxylic acid groups then react with epoxy groups.

Cycloaliphatic epoxies serve as cross-linking agents for polyols for films baked at 120°C. Waterborne coatings are made with caprolactone polyols and (**2**), with diethylammonium triflate as a blocked catalyst (152).

BPA epoxy resins can be cross-linked by reaction of their hydroxyl groups with MF and UF resins are used. Amine salts of a sulfonic acid are used as latent catalysts. Polyisocyanates also cross-link the hydroxyl groups of epoxy resins.

Epoxy resins undergo homopolymerization to polyethers with very strong protic acids. Acid precursors are most commonly used as initiators. There are two types: blocked acids that undergo thermal decomposition to give the free acid, and photoinitiators that release acid on exposure to uv. Suitable super acids are trifluoromethylsulfonic acid (triflic acid) (F_3CSO_3H) and hexafluorophosphoric acid (HPF_6). Only super acids are effective for homopolymerization of epoxies. Homopolymerization with α,α-dimethylbenzylpyridinium hexafluoroantimoniate as a blocked catalyst permits curing of a GMA copolymer at 120°C using (**2**) as a reactive diluent while retaining adequate pot life (153).

A large-scale use of epoxy resins is to make acrylic graft copolymers for interior linings of beverage cans (154). A solution of a BPA epoxy resin in a glycol ether solvent is reacted with ethyl acrylate (2-propenoic acid ethyl ester)

[140-88-5], styrene (ethenylbenzene) [100-42-5], and methacrylic acid (2-methyl-2-propenoic acid) using benzoyl peroxide (dibenzoyl peroxide) [94-36-0] as initiator to make a graft copolymer. The resin is neutralized with an amine such as 2-dimethylaminoethanol (DMAE) [108-01-0]. Class I MF resin is added as a cross-linker, and the system is diluted with water. Sometimes, a latex is blended with the dispersion to reduce cost.

Acrylic Resins. Acrylic resins are used as the primary binder in a wide variety of industrial coatings (see ACRYLIC ESTER POLYMERS). Their main advantages are photostability and resistance to hydrolysis. Hydroxy-functional thermosetting acrylic resins (TSA) are copolymers of nonfunctional monomers with a hydroxy-functional monomer such as 2-hydroxyethyl methacrylate (HEMA) (2-methyl-2-propenoic acid 2-hydroxyethyl ester) [868-77-9]. They are cross-linked with MF resins or polyisocyanates. An increase in solids became necessary to meet lower VOC emission requirements. The amount of non- or monofunctional resin must be kept to a very low fraction. Molecules with no hydroxyl groups would either volatilize or remain in the film as plasticizers. Molecules with one hydroxyl group terminate cross-linking reactions, leaving loose ends in the coating. Statistical methods have been used to calculate the proportions of nonfunctional molecules that would be formed during random copolymerization of monomer mixtures with differing monomer ratios to different molecular weights and molecular weight distributions (155). Esters of bulky alcohols, such as isobornyl methacrylate, as comonomers that can combine relatively low viscosity and high T_g are used (14). For most purposes the upper limit of solids that gives good properties is 45–50% NVV (nonvolatile volume). Solids can be increased by blending acrylic polyols with other low viscosity polyols, such as polyesters (156).

Carboxylic acid-functional acrylic resins are cross-linked with epoxy resins. Epoxy-functional acrylics are made using GMA as a comonomer. Such resins have been recommended for powder clear coats for automobiles (157,158). They can be cross-linked with dicarboxylic acids, such as dodecanoic acid or with carboxylic acid-functional acrylic resins. Isocyanato-functional acrylics can be prepared by copolymerizing TMI with acrylates (159); they can be cross-linked with polyols or hydroxy-functional acrylic resins. They can also be reacted with hydroxypropylcarbamate to yield carbamate-functional acrylic resins (160). Carbamate-functional acrylics can be cross-linked with Class I MF resins to give films with better environmental etch resistance than MF cross-linked hydroxy-functional acrylics while retaining the advantage of mar resistance. Carbamate-functional acrylics can also be prepared by reacting acrylic resins with urea. Trialkoxysilyl-functional acrylics can be prepared using a trialkoxysilylalkyl methacrylate as a comonomer (161). Clear coats made with them are cross-linked by moisture in the air.

VOC emissions can be reduced using water-reducible hydroxy- and carboxylic acid-functional TSA resins with acid numbers of 40–60. Solutions of amine salts of these resins in organic solvents diluted with water form stable dispersions of polymer aggregates swollen by solvent and water. In preparing a coating an amine, such as DMAE, is added; then other coating components (pigments, MF resin, sulfonic acid catalyst) are dispersed or dissolved in this solution and before application the coating is diluted with water.

The morphology of water-reducible TSA dispersions has been studied fairly extensively (162,163). The change in viscosity with dilution of amine salts of

water-reducible resins is abnormal. Initially the viscosity decreases rapidly then rises again to a peak before falling sharply to application viscosity. At application viscosity they have solids in the range of 20–30% NVW (nonvolatile weight). The height of the peak in the dilution curve is dependent on the resin and formulation, and the systems are highly shear thinning in the peak region. Another abnormality of water-reducible resins is that their pH is over 7 (commonly 8.5–9.5), even though less than the theoretical amount of amine necessary to neutralize the carboxylic acid is used (163).

Class I methyl MF resins are the most commonly used cross-linkers. Various types and amounts of amine can be used (164–166). Generally, less than the stoichiometric amount of amine is used. The lower the amine content, the lower the viscosity of the fully diluted systems. For any resin–amine combination, there is a minimum amount of amine required to give a stable dispersion at application viscosity, that is, to prevent macrophase separation. The viscosity is sensitive to amine content. The structure of the amine affects application solids, stability, and cure rate. DMAE is widely used but N-alkylmorpholines and 2,2-dimethylaminopropanol permit faster curing. The amine also affects on wrinkling during curing (164).

Polyester Resins. Polyesters for coatings are low molecular weight, amorphous, and branched, with functional groups for cross-linking. Most of the polyesters are hydroxy-terminated polyesters. They are cross-linked with MF resins or polyisocyanates. Carboxylic acid-terminated polyesters cross-linked with epoxy resins, MF resins, or 2-hydroxyalkylamides are used. In general terms, thermosetting polyesters give coatings with better adhesion to metal substrates and better impact resistance than TSAs. On the other hand, TSAs give coatings with superior water resistance and exterior durability.

Most hydroxy-terminated polyesters are made by coesterifying two polyols (a diol and a triol) and two diacids (an aliphatic dibasic acid and an aromatic dicarboxylic acid or its anhydride). The ratio of moles of dibasic acid to polyol must be less than 1 so as to give terminal hydroxyl groups and avoid gelation. Molecular weight is controlled by this ratio; the smaller the ratio, the lower the molecular weight. The molecular weight distribution $\bar{M}_n$, and $\bar{f}_n$ are all controlled by the diol-to-triol ratio. The ratio of aromatic to aliphatic dibasic acids controls T_g of the resin.

Polyols are selected on the basis of cost, rate of esterification, stability during high temperature processing, functionality, and hydrolytic stability of their esters. The most widely used diol is NPG, and the most widely used triol is TMP. A comparison of results of testing films of coatings made with a series of polyesters from several polyols is given in Reference 167. Coatings based on CHDM polyesters cross-linked with MF resins showed the best hydrolytic stability.

Aromatic acid esters hydrolyze more slowly than aliphatic esters. Esters of phthalic acid are more easily hydrolyzed than esters of isophthalic acid (IPA) (1,3-benzenedicarboxylic acid) [121-91-5]. Adipic acid (1,6-hexanedioic acid) [124-04-9] is the most widely used aliphatic dibasic acid. Dimer acids made by dimerization of drying oil fatty acids are also used.

Viscosity of polyester solutions depends on several variables: molecular weight, molecular weight distribution, T_g of the resin, and the number of functional groups per molecule. Intermolecular hydrogen bonding can be minimized by using hydrogen-bond acceptor solvents such as ketones. Synthesis of low

molecular weight polyesters with two or more hydroxyl groups on all of the molecules is relatively easy. Usually, an $\bar{f}_n$ of between two and three hydroxyl groups per molecule is used. A difunctional polyester with a narrow molecular weight distribution and an $\bar{M}_n$ of 425 is commercially available (168). Low viscosity polyester diols and triols prepared by reacting caprolactone (2-oxepanone) [502-44-3] with a polyols are available (169). These types of resins are useful in blends to increase the solids content of higher molecular weight polyester or acrylic based coatings. They are often called *reactive diluents*.

Polyesters with both hydroxyls and carboxylic acids as terminal groups are used in waterborne coatings. When reduced with water, they have abnormal viscosity dilution curves similar to those described for water-reducible acrylic resins. The most widely used are made by reacting a hydroxy-functional resin with trimellitic anhydride (TMA) (1,3-dihydro-1,3dioxo-5-isobenzofurane carboxylic acid) [552-30-7] to esterify a fraction of the hydroxyl groups, generating two carboxyl groups at each site. The ester group of partially esterified TMA is subject to hydrolysis because of the anchimeric effect of the adjacent carboxylic acid group. water-reducible polyesters are used in applications for which good storage stability and hydrolytic stability are not important, such as industrial coatings with a fast turnover.

Hydrolysis can be minimized by making powdered solid polyesters. An example of such a solid polyester is made from IPA, adipic acid, NPG, CHDM, hydrogenated BPA, and TMA (170). The resin is powdered and stored until a coating is to be made; then, it is stirred into a hot aqueous solution of DMAE to form a dispersion.

Water-thinnable polyester coatings have been formulated with low molecular weight oligomeric hydroxy-terminated polyesters (171). Up to about 20% of water dissolves in a polyester-Class I MF resin binder, reducing the viscosity to about half. This permits making solvent-free coatings.

Polyester resins for powder coating are brittle solids with a relatively high T_g (50–60°C) and so the powder coating does not sinter during storage. Terephthalic acid (TPA) and NPG are used as the principal monomers with smaller amounts of other monomers to increase $\bar{f}_n$ and to reduce T_g to the desired level. Both hydroxy- and carboxy-terminated polyesters are used. The former are most commonly cross-linked with blocked isocyanates and the latter with epoxy resins. Other cross-linkers include 2-hydroxyalkylamides and tetramethoxymethylglycoluril.

Alkyd Resins. Alkyds are synthetic drying oils (see chapter on *Drying Oils* in Reference 172) prepared from polyols, dibasic acids, and fatty acids. Alkyd Resins are lower in cost than most other vehicles and give coatings that exhibit fewer film defects during application. However, durability of alkyds is poorer than acrylics and polyesters. Oxidizing alkyds cross-link by autoxidation. Nonoxidizing alkyds are used as polymeric plasticizers or as hydroxy-functional resins, which are cross-linked by MF resins. Alkyds are classified by oil length calculated by dividing the amount of "oil" in the final alkyd by the total weight of the alkyd solids, expressed as a percentage. Alkyds with oil lengths greater than 60 are long oil alkyds; those with oil lengths from 40 to 60, medium oil alkyds; and those with oil lengths less than 40, short oil alkyds (see ALKYD RESINS).

Oxidizing alkyds are polyesters of a polyol, a dibasic acid, and drying or semidrying oil fatty acids. The rate of cross-linking increases as the number of methylene groups between two double bonds, $\bar{f}_n$, is increased, reaching a

maximum at an oil length of 60. The rate of drying also increases as the ratio of aromatic rings to long aliphatic chains increases. When the reaction is carried to near completion with excess polyol, there are few unreacted carboxylic acid groups, but many unreacted hydroxyl groups. Soybean oil and tall oil fatty acids are most often used. Dehydrated castor alkyds have fairly good color retention; they are used primarily in baking coatings.

Glycerol is the most widely used polyol because it is present in natural oils. The next most widely used is pentaerythritol (PE). At the same mole ratio of dibasic acid to polyol, more moles of fatty acid can be esterified with PE and f_n is higher.

The most widely used dibasic acid is phthalic anhydride (PA) (1,3-isobenzofurandione) [85-44-0]. The rigid aromatic rings increase the T_g of the resin. The first esterification reaction proceeds rapidly by opening the anhydride ring. The amount of water evolved is low, which also reduces reaction time. The next most widely used dibasic acid is IPA. Esters of IPA are more resistant to hydrolysis than are those of PA in the pH range of 4–8, the most important range for exterior durability.

Reduction of VOC emissions has led to efforts to increase solids content of alkyd resin coatings. Since xylene is on the hazardous air pollutants (HAP) list, its use is being reduced. Some increase in solids can be obtained by a change of solvents. Hydrocarbon solvents promote intermolecular hydrogen bonding, especially between carboxylic acids, increasing viscosity. Including some 1-butanol in the solvent gives a significant reduction in viscosity at equal solids. Decrease in molecular weight increases solids. However, making a significant reduction in VOC by this route gives an alkyd with lower functionality for cross-linking and a lower ratio of aromatic to aliphatic chains. Both changes increase the time for drying. The effect of longer oil length on functionality can be minimized by using drying oils with higher average functionality, such as safflower oil. Proprietary fatty acids with 78% linoleic acid are commercially available. Increasing the concentration of driers accelerates not only drying but also embrittlement. One can add a transesterification catalyst near the end of the alkyd cook; this gives more uniform molecular weight and a lower viscosity product, but film properties, especially impact resistance, are inferior to those obtained without transesterification catalyst. Reactive diluents have much lower viscosity than the alkyd resin and react with the alkyd during drying, reducing VOC. The use of reactive diluents is reviewed in Reference 173; 2,7-octadienyl maleate and fumarate are reported to be particularly effective.

Alkyd emulsions are used in Europe and to a lesser degree in the United States (174). The emulsions are stabilized with surfactants and can be prepared with little, if any, volatile solvent. It is common to add a few percent of an alkyd–surfactant blend to latex paints to improve adhesion to chalky surfaces and, in some cases, to improve adhesion to metals.

Oxidizing alkyds can be modified by reaction with styrene. In making styrenated alkyds, an oxidizing alkyd is prepared in the usual way and cooled to about 130°C in the reactor; then styrene and a free-radical initiator such as benzoyl peroxide are added. The ratio of alkyd to styrene can be varied; commonly 50% alkyd and 50% styrene is used. The ratio of aromatic rings to aliphatic chains is increased, and as a result, the T_g of styrenated alkyds give a “dry” film in 1 h

or less versus 4–6 h for the counterpart nonstyrenated alkyd. However, the average functionality for oxidative cross-linking is reduced because the free-radical reactions involved in the styrenation consume some activated methylene groups. As a result, the time required to develop solvent resistance is longer than for the counterpart alkyd. Styrenated alkyd vehicles are often used for air-dried primers. The topcoat must be applied almost immediately or not until after the film has had ample time to cross-link. During the intermediate time interval, application of topcoat is likely to cause nonuniform swelling of the primer, leading to lifting of the primer. The result of lifting is the development of wrinkled areas in the surface of the dried film.

Short-medium oil and short oil alkyds are made with a large excess of hydroxyl groups to avoid gelation. The hydroxyl groups can be cross-linked with MF resins. The advantage of relative freedom from film defects common to alkyd coatings is retained. Nondrying oils with minimal levels of unsaturated fatty acids are used to maximize exterior durability and color retention. Since IPA esters are more stable to hydrolysis in the pH range of 4–8 than phthalate esters, the highest performance exterior alkyd-MF enamels use nonoxidizing IPA alkyds.

Uralkyds. Uralkyds are alkyd resins in which a diisocyanate, usually TDI or MDI, replaces PA. One transesterifies a drying oil with a polyol to make a "monoglyceride" and reacts it with somewhat less diisocyanate than the equivalent amount of isocyanate. Like alkyds, uralkyds dry faster than the drying oil from which they are made, since they have a higher $\% \bar{f}_n$ and the rigidity of the aromatic rings. Two principal advantages of uralkyd over alkyd coatings are superior abrasion resistance and resistance to hydrolysis. Disadvantages are inferior color retention of the films, higher viscosity of resin solutions at the same percent solids, and higher cost. The largest use of uralkyds is in so-called varnishes. They are used as transparent coatings for furniture, woodwork, and floors ie, applications in which good abrasion resistance is important.

Epoxy Esters. BPA epoxy resins are converted to epoxy esters by reacting with fatty acids. It is not practical to esterify more than about 90% of the potential hydroxyl groups, including those from ring opening the epoxy groups. The lower useful limit of the extent of esterification is about 50%, to ensure sufficient fatty acid groups for oxidative cross-linking. Tall oil fatty acids are commonly used because of their low cost. Dehydrated castor oil fatty acids give faster curing epoxy esters for baked coatings. Epoxy esters are used in coatings in which adhesion to metal is important. Epoxy esters have good adhesion to metals and retain adhesion even after exposure of the coated metal to high humidity. An advantage of epoxy esters over alkyd resins is their greater resistance to hydrolysis and saponification. Exterior durability of epoxy ester coatings is poor.

Epoxy esters can also be made water-reducible by reacting maleic anhydride (2,5-furandione) [108-31-6] with epoxy esters prepared from dehydrated castor oil fatty acids. Addition of a tertiary amine opens the anhydride to give amine salts. Like other water-reducible resins, these resins are not soluble in water, but form a dispersion of resin aggregates swollen with water and solvent in an aqueous continuous phase. They are used in baking primers and primer-surfacers.

Phenolic Resins. Although their importance has waned, phenolic resins still have significant uses. Resole phenolics useful in coatings applications are

made by reacting monosubstituted phenols and mixtures of them with phenol with more than 1 mol of formaldehyde. They are methylol-terminated; the substituted phenols reduce cross-link density. There are two groups: alcohol-soluble, heat-reactive phenolics and oil-soluble, heat-reactive phenolics. Alcohol-soluble resole phenolics are used with an acid catalyst in interior can coatings and tank linings. To enhance flexibility and adhesion, they can be blended with low molecular weight poly(vinyl butyral). They are also blended with epoxy resins in thermosetting coatings for applications such as primers and can coatings. Oil-soluble resole phenolics are prepared by reacting a para-substituted phenol, such as *p*-phenylphenol. They are solid, linear resins with terminal methylol groups. They are used to make varnishes with drying oils.

The package stability of alcohol-soluble resole resins and their compatibility with epoxy resins can be improved by partial conversion of the methylol groups to ethers. Allyl ethers have been used with epoxy resins in interior can coatings. Low molecular weight butyl ethers are used with acid catalysts to cross-link epoxy resins and other hydroxy-substituted resins, by etherification and transetherification reactions (148).

Novolak phenolics are made with acid catalysts and ortho- or para-substituted phenols. Molecular weight is controlled by the molar ratio of phenol and formaldehyde, which is always greater than 1. The terminal phenol groups are not metholylated. Alcohol-soluble novolak phenolics derived from *o*- or *p*-cresol are used to make novolak epoxy resins. Oil-soluble novolak phenolics made with a substituted phenol, such as *p*-phenylphenol, are used with drying oils to make varnishes, such as marine spar varnish (see PHENOLIC RESINS).

Silicon Derivatives. Three classes of organic silicon derivatives are used in coatings: Silicones, reactive silanes, and orthosilicates.

Silicones are polymers with backbones consisting of —[$Si(R)_2$—O]— repeating units. They are prepared by reacting chlorosilanes with water to form silanols that condense to form siloxanes. Silicone oils made from dimethyldichlorosilane and methyltrichlorosilane are used as additives to reduce surface tension. Chemically modified silicone fluids, such as polysiloxane/polyether block copolymers, with broader ranges of compatibility have been described (175).

Polymerization of a mixture of mono-, di-, and trichlorosilanes results in a silicone resin with some unreacted hydroxyl groups. Silicone resins cross-link in 1 h at 225°C with catalysts such as zinc octanoate. The cross-linking process is reversible; hence, silicone films are sensitive to water. Ammonia and amines are especially destructive to such films (176). The coatings are repellent to liquid water, but permeable to water vapor. Most silicone resins are copolymers of methyl- and phenyl-substituted monomers; properties depend on the phenyl-to-methyl ratio. The rate of the cross-linking reaction is faster with high-methyl-substituted silicone resins. The uv resistance of high-methyl silicone resins is greater than high-phenyl ones. The exterior durability of silicone coatings is better than that of other coatings except highly fluorinated polymers (177). Coatings from methylsilicone resins have low temperature flexibility superior to those from phenylsilicones and to most other organic coatings.

High-phenyl silicones are superior to high-methyl silicones for applications requiring high temperature resistance, and far superior to other organic coatings except certain fluoropolymers. When silicones are thermally decomposed the

product is silicon dioxide, which, although brittle, can serve as a temperature-resistant coating binder. Chimney paints are made from silicone resins pigmented with aluminum flake for use at over 500°C for years. At the high service temperature, the organic substituents burn off, leaving behind a film of the aluminum pigment in a matrix of silicone dioxide, possibly with some aluminum silicate. See Reference 177 for discussion of coatings with varying heat resistance.

High solids silicone resins have been made available, which cure either by directly using zinc octonoate catalysts or by cross-linking with trialkoxysilanes using a titanate catalyst (178). Waterborne silicone resins have also been developed; one approach is to emulsify a silicone resin in water (179).

Silicone-modified alkyds are made by coreacting a silicone intermediate during synthesis of the alkyd. Silicone intermediates are low molecular weight silicone resins; frequently with the hydroxyl groups converted to methoxy groups, they react with free hydroxyl groups on the alkyd. Exterior durability of silicone-modified alkyd coatings is significantly better than unmodified alkyd coatings. The improvement in durability is roughly proportional to the amount of added silicone resin; 30% silicone resin is a common degree of modification. Silicone-modified alkyds are used mainly in outdoor air-dried coatings such as topcoats for steel petroleum storage tanks. Silicone-modified polyester and acrylic resins are used in baking coatings, especially in coil coatings for metal siding. See Reference 177 for examples of formulations and preparation of silicone-modified resins.

Waterborne silicone resins can be prepared from water-reducible acrylic and polyester resins. Also, acrylic latexes prepared with hydroxyethyl (meth)acrylate as a comonomer can be modified with silicone intermediates (178).

Reactive silanes are silanes with a substituted alkyl group and a trialkoxysilyl group. They are used in coatings in several ways; review papers are given in Reference 180. Resins with multiple trialkoxysilyl groups can be used as binders for moisture-cure coatings. For example, an isocyanate-terminated resin can be reacted with 3-aminopropyltriethoxysilane to give a resin with terminal triethoxysilyl groups. Coatings made using such resins cross-link to a polymer network after application and exposure to humid air. Part of the solvent used is ethyl alcohol, which permits reasonable pot life in the presence of water. They do not form CO_2, which can lead to film imperfections in moisture cure urethanes.

Trialkoxysilyl acrylic resins are made with a trialkoxysilylalkyl methacrylate as a comonomer (181). Coatings cure on exposure to atmospheric moisture; the reaction is catalyzed with organotin compounds or organic acids. The coatings have excellent exterior durability, resistance to environmental etching and marring, and adhesion to aluminum. Automotive clear coats are being made by combining trialkoxysilylalkyl- and hydroxy-functional acrylic resins with MF resins or blocked isocyanates (182).

Trialkoxysilylated acrylic and vinyl acetate latexes can be prepared using 3-methacryloxypropyltriisobutoxysilane as a comonomer in emulsion polymerization (115). Coatings are reported to have superior adhesion, as well as high chemical, solvent, and mar resistance.

Use of various silanes for treatment of metal surfaces is discussed in the section on Corrosion Protection.

Halogenated Resins. Halogenated polymers have low water permeability. They are used in topcoats for corrosion protection. Some are sufficiently soluble

in polyolefin plastics, and therefore they are used in tie coats to provide adhesion for topcoats. Thermoplastic vinyl chloride copolymers were formerly used on a large scale but are being phased out because of high VOC.

Dispersion grade vinyl chloride copolymers with high molecular weights are used in high solids plastisol coatings. Plastisols are polymer particles dispersed in a plasticizer. Since the T_g of the polymer is well above room temperature and polymer is partially crystalline, the polymer does not dissolve in the plasticizer at room temperature. When a plastisol is heated, the polymer dissolves in the plasticizer and the particles coalesce to a molten state. When cooled, the product is a plastic consisting of a homogeneous solution. The viscosity is reduced by addition of solvents that dissolve the plasticizer without swelling the polymer particles. Solids at application viscosities are 80% or more. A variety of stabilizing agents are used, including organotin esters such as dibutyl tin dilaurate; barium, cadmium, and strontium soaps; maleates; and oxirane compounds.

Chlorinated rubber is used in topcoats for heavy duty maintenance paints because of its low water permeability. It is also used in tie coats on polyolefin plastics. Chlorinated rubber dehydrochlorinates and requires stabilizers similar to those used with PVC. Some metal salts, especially those of iron, tend to promote degradation of chlorinated rubber and so it degrades when applied over rusty steel. Chlorinated ethylene/vinyl acetate copolymers have been developed that can be used to replace chlorinated rubber in at least some applications (183).

Polytetrafluoroethylene (PTFE) has the greatest exterior durability and heat resistance of any polymer used in coatings. However, PTFE is insoluble in solvents, and its fusion temperature is so high that coating uses are limited to applications in which the substrate can withstand high temperatures. Aqueous dispersions of PTFE are used to coat the interior of chemical processing equipment and cookware. After application, the polymer particles are sintered at temperatures as high as 425°C. PTFE has such a low surface free energy that it is not wet by either water or oils. Since its fusion temperature is lower, poly(vinylidene fluoride) (PVDF) can be used in additional applications. PVDF is used in coil coatings as a plastisol-like dispersion in a solution of acrylic resin (184). The fusion temperature of the films is reported to be 245°C. The exterior durability is outstanding but only low gloss coatings are possible. Copolymers of vinylidene fluoride (VDF) are also being used in powder coatings.

Fluorinated copolymers with functional groups such as hydroxyl groups can be cross-linked after application. Copolymers of VDF with a hydroxy-functional monomer cross-linked with a polyisocyanate give coatings with superior wet adhesion and corrosion as compared with PVDF homopolymer (185). Halofluoroethylene (CF_2=CFX)/vinyl ether copolymers have been used on steel building panels and in clear coats for automobiles (186). Vinyl ethers and CF_2=CFX form alternating polymers; functional groups can be introduced by copolymerizing hydroxy-substituted vinyl ether comonomers. Copolymers with hydroxyl groups can be cross-linked with MF resins or polyisocyanates.

Other Binders. Unsaturated polyester resins are maleic acid-containing polyesters dissolved in styrene. The resin/styrene solution is cross-linked using free-radical initiators. The polymerization is oxygen inhibited. Inhibition is minimized by incorporating some insoluble semicrystalline paraffin wax. The wax layer results in a relatively uneven, low gloss surface, suitable for some applications.

Oxygen inhibition can be minimized using coreactants that have allyl groups with styrene–unsaturated polyesters (187). Waterborne unsaturated polyester resins are prepared by reacting 2 mol of maleic anhydride with 1 mol of a mixture of low molecular weight polyalkylene glycols and diols. The resulting partial ester is further esterified with 2 mol of trimethylolpropane diallyl ether (188). Unsaturated polyester/styrene resins can be used in uv-cured coatings. A photoinitiator generates free radicals on exposure to uv radiation. High intensity radiation sources are used, which generate very large numbers of free radicals sufficiently rapidly at the surface, so that the oxygen in the air at the surface is depleted.

Gel coats are pigmented unsaturated polyester–styrene coatings; they are sprayed on the inside of a mold surface. The gel coat is then sprayed with glass fiber-loaded unsaturated polyester–styrene compound and then covered with plastic film. Many glass-reinforced plastic objects, ranging from prefabricated shower stalls to boat hulls, are made this way. Unsaturated polyesters made using neopentyl glycol, MA, and isophthalic acid provide better gloss retention than those made from propylene glycol and PA.

Various types of nitrocellulose are made, and the grade used in coatings is RS (Regular Solubility) grade with a percent nitrogen of 11.8–12.3. To reduce the handling hazard, nitrocellulose is shipped wet with ethyl or isopropyl alcohol. While nitrocellulose is not soluble in alcohol, it is soluble in mixtures of ketones and esters with alcohols and hydrocarbons. Several molecular weight grades are available. Use has dropped substantially because of the high VOC of NC lacquers; the principal remaining use is in wood finishing. These lacquers have relatively low solids but continue to be used to a significant, if decreasing, extent because they enhance the appearance of wood grain to a greater extent than any other coating. Increasingly stringent VOC emission regulations can be expected to force further reductions in use of nitrocellulose.

Acrylated oligomers are prepared from a variety of starting oligomers. Acrylated urethane oligomers tend to give coatings with a good combination of hardness and elasticity, and epoxy resin derivatives tend to give coatings with good toughness, chemical resistance, and adhesion. Any polyol or hydroxy-terminated oligomer can be reacted with excess diisocyanate to yield an isocyanate-terminated oligomer, which is reacted with hydroxyethyl acrylate to yield an acrylated urethane oligomer. The oxirane groups of epoxy resins are reacted with acrylic acid, with triphenylphosphine as a catalyst. Epoxidized soybean or linseed oil also react with acrylic acid to give lower T_g oligomers with higher functionality.

2-Hydroxyalkylamides esterify more rapidly than simple alcohols. Polyfunctional 2-hydroxyalkylamides (eg, the tetrafunctional hydroxyalkylamide derived from aminolysis of dimethyl adipate with diisopropanolamine) are cross-linkers for carboxylic acid-functional acrylic or polyester resins (189). The properties of coatings obtained by cross-linking carboxylic acid-functional acrylic resins with hydroxyalkylamides compare favorably with those obtained using MF resins as cross-linkers with the same resins. An advantage relative to MF cross-linkers is the absence of formaldehyde, which is emitted in low concentrations when MF-based coatings are baked. The cross-linking reaction is not catalyzed by acid. See Reference 190 for discussion of the mechanism of esterification. Tetra-*N*,*N*,*N*′,*N*′-(2-hydroxyethyl)adipamide is a solid used in powder coatings (191).

Acetoacetoxy-functional acrylic solution resins can be made by copolymerizing acetoacetoxyethyl methacrylate (AAEM) with other acrylate monomers (192,193). hydroxy-functional resins can be reacted with diketene or transesterified with methyl acetoacetate to form acetoacetylated resins. MF resins react with acetoacetate groups in the presence of an acid catalyst somewhat slower than with hydroxyl groups (192). There are indications of improved wet adhesion, perhaps resulting from chelating interactions with the surface of the steel. Isocyanates also react with acetoacetate groups; the cure rate is slower than with hydroxyl groups, but pot life is longer. Polyacrylates (eg,TMP triacrylate) [37275-47-1] undergo Michael reactions with acetoacetate groups at ambient temperatures, with the formic acid salt of 1,8-diazabicyclo[5.4.0]undec-7-ene as a blocked catalyst (193). Ketimines give tautomeric ketimine–eneamine cross-links that interact strongly with metal surfaces (194). A primer is reported to give excellent adhesion and corrosion resistance when applied to an aircraft grade aluminum alloy with a chromate-free pretreatment.

Polyfunctional aziridines are used as cross-linkers. Polyaziridines are skin irritants, and some individuals may become sensitized. Mutagenicity of polyaziridines is controversial; however, dilution by coating vehicles reduces their possible toxic effects (195). Polyaziridines, such as the addition product of 3 mol of aziridine to 1 mol of trimethylolpropane triacrylate, react with polyfunctional carboxylic acids to form 2-aminoester cross-links. The main uses are to cross-link carboxylic acid groups on latexes and waterborne polyurethanes. Reaction with the carboxylic acid is much faster than the reaction of the aziridine groups with water, pot lives are 48–72 h. Additional cross-linker can be added to restore reactivity.

Polycarbodiimides react with carboxylic acid and slowly enough with water so that they can be used in waterborne systems. The product of the reaction with a carboxylic acid is an *N*-acylurea. Polycarbodiimides cross-link carboxylic acid-functional resins, including aqueous polyurethane dispersions and latexes (196, 197). Cross-linking occurs within several days at ambient temperature and faster with heat.

Solvents

Most coatings contain volatile material that evaporates during application and film formation. They reduce viscosity for application and control viscosity changes during application and film formation. Selection of volatile components affects popping, sagging, and leveling and can affect adhesion, corrosion protection, and exterior durability. For a more extensive discussion see chapter on *Solvents* in Reference 172. Air pollution regulations have limited solvent usage and will become more restrictive. Most solvents used in coatings are controlled except acetone. Also some solvents are on the HAP list and there will be increasing pressure to reduce these emissions.

Solvents are selected using the general rule that like dissolves like. Three-dimensional solubility parameters are used when a change of solvent combination is required by cost changes, new toxicity information, etc. Solvents have a marked effect on the viscosity of resin solutions (see the section on Flow for discussion).

The rate at which evaporation occurs affects the time required to convert a coating to a dry film, and the appearance and physical properties of the final film. The rate of evaporation of a solvent is affected by four variables: temperature, vapor pressure, surface-to-volume ratio, and rate of air flow over the surface. When a coating is applied by a spray gun, it is atomized to small particles as it comes out of the orifice of the gun; thus, evaporation is rapid because the ratio of surface to volume is high. Rate of solvent depends on film thickness; the fraction of solvent present in a 50-μm film after a given time is greater than that remaining in a 25-μm film. The rate of air flow over the surface is a factor because the rate of evaporation depends on the partial pressure of the solvent vapor in the air at the surface. Spraying a coating with an air spray gun results in more loss of solvent than with an airless gun. Air flow effects cause nonuniform evaporation from coated objects; solvent evaporates more rapidly near the edges of a coated panel than from its center. RH has little effect on the evaporation rates of most solvents; however, it has a significant effect on the evaporation rate of water.

Rates of evaporation of solvents are related to the evaporation rate of *n*-butyl acetate [123-86-4]. Determination of relative evaporation rates requires measurement under standardized conditions. A study by Rocklin illustrates the effects of changes in conditions on relative evaporation rates (198).

When formulating baking coatings for spray application, it is common to use a mixture of fast and very slow evaporating solvents. A significant fraction of the fast evaporating solvent evaporates before the spray droplets reach the object being coated, raising viscosity and reducing the tendency of the coating to sag, while the slow evaporating solvent keeps the viscosity low enough to promote leveling and to minimize the probability of popping when the coated object is put into a baking oven.

Except in high solids coatings, the resin or other coating components have little effect on initial rate of solvent evaporation when coating films are applied. However, as solvent loss from a coating continues, a stage is reached at which the rate of evaporation slows sharply. As the viscosity of the remaining coating increases, availability of free volume decreases, and the rate of solvent loss becomes dependent on the rate of diffusion of solvent through the film to the surface, rather than on the rate of evaporation from the surface. The solids level at which the transition from evaporation rate control to diffusion rate control occurs varies widely, but is often in the 40–60% NVV range. If the T_g of the resin is sufficiently higher than the temperature of the film, the rate of solvent loss will, in time, approach zero. Years after films have been formed, there will still be residual solvent left in the film. The smaller the size of the solvent molecule, the greater its chance of finding sufficiently large free-volume holes. Even though its relative evaporation rate is higher, cyclohexane is retained in films to a greater degree than toluene because cyclohexane is bulkier. Equations have been developed that model the effect of solvent size on diffusion based on free volume of polymers (199). Solvents evaporate more slowly from high solids coatings, making it more difficult to control their sagging (see section on Sagging for discussion).

Volatile Loss from Waterborne Coatings. RH during application and drying of the coatings has a major effect on rates of volatile loss from waterborne coatings. Limited levels of organic solvents are used to modify evaporation rates; however, future regulations can be expected to reduce the levels permitted.

Evaporation of water from a drying latex paint film resembles first-stage drying throughout most of the process; it is controlled by temperature, humidity, evaporative cooling, and rate of air flow over the surface (200). After most of the water has left, evaporation slows as a result of coalescence of a surface layer through which water must diffuse. In latex paints that are to be applied by brush or roller, it is desirable to retard the development of a partially coalesced surface layer to permit lapping of wet paint on wet paint. This generally requires the presence of some slow evaporating solvent, such as propylene glycol. The presence of this solvent does not affect the initial rate of water loss, but does slow down the development of a surface skin (201). The presence of such a water-soluble solvent also facilitates the loss of coalescing solvent.

In coatings formulated water-reducible resins, the relative evaporation rate of water and solvent is affected by RH. Rocklin studied azeotropy in speeding up water/solvent evaporation in humid air (202). For example, at 40% RH, the time required for evaporation of 90% of a 20 wt% solution of 2-butoxyethanol [111-76-2] in water is 1820 s compared with 2290 s for water alone. The relative evaporation rate E of water at 0–5% RH and an air temperature of 25°C is 0.31, but at 100% RH it is 0. If a solution of 2-butoxyethanol ($E = 0.077$) in water evaporates at low RH, water evaporates more rapidly, and the remaining solution becomes enriched in 2-butoxyethanol. At high RH, 2-butoxyethanol evaporates more rapidly, and the remaining solution becomes enriched in water. At an intermediate RH, the relative evaporation rates of water and 2-butoxyethanol are equal and the composition of the remaining solution is constant. This RH is the critical relative humidity (CRH) (203). The CRH for 2-butoxyethanol solutions in water is estimated at about 80%. CRH is different in coatings; for example, CRH is 65% for 10.6 wt% (based on volatile components) 2-butoxyethanol in a coating (204). The high heat capacity and heat of vaporization of water also affect the evaporation rates of water and water-solvent blends in an oven. For example, the times for 99% weight loss of 2-butoxyethanol (bp 171°C), water, and a 26:74 blend of 2-butoxyethanol/water in a TGA when room temperature samples were put into the furnace at 150°C were 2, 2.6, and 2.5 min, respectively (205). The higher heat of vaporization of water (2260 $J \cdot g^{-1}$ at its boiling point) compared to 2-butoxyethanol (373 $J \cdot g^{-1}$ at its boiling point) slowed the rate of heating of the water and water-solvent blend enough to more than offset the expected evaporation rates based on boiling points. Such effects can be critical in controlling sagging and popping of waterborne coatings.

Water can also serve to reduce viscosity of oligomers with hydrogen-bond interactions. It has been shown that up to 20% (depending on the formulation) water can dissolve in solvent-free coatings (171).

Other Properties. Flammability depends on structure and vapor pressure. There is an upper and a lower level of vapor concentration that limits flammability or explosion. The most common cause for fires in coating factories has been static electricity. Solvent flowing out of one tank and into another tank by gravity picks up enough electrostatic charge to cause a spark; all equipment used in handling solvents and solvent-containing mixtures should be electrically grounded. There are two main types of flammability tests: open cup and closed cup; both measure a *flash point*, the minimum temperature at which solvent can be ignited by a hot wire. ASTM specifies standard conditions for both tests.

Generally, open-cup testers give results more appropriate for indicating degree of hazard of a mixture when exposed to air, as during a spill. The closed-cup flash point more nearly describes the fire hazard of a liquid enclosed in a container. U.S. Department of Transportation regulations for shipment of flammable liquids are based on closed-cup tests. Transportation costs can be substantially affected by flash points of the material being shipped. A discussion of the factors affecting flash points, including molecular interactions in blends, is given in Reference 206. Predictions of closed-cup flash points for mixed solvents can be made by computer program that requires only flash points and molecular structures of the pure components (207,208).

Density can be an important variable. Most solvents are sold on a weight basis but critical cost is the cost per unit volume. Most U.S. air pollution regulations are based on weight of solvent per unit volume of coating, which also favors use of low density solvents in formulations.

Electrostatic spraying requires control of the conductivity of the coating. The conductivity of hydrocarbon solvents is too low to permit pickup of adequate electrostatic charge. Alcohols, nitroparaffins, and amines are common solvents or additives to increase conductivity. The conductivity of waterborne coatings poses problems, such as the need to insulate the spray apparatus and relatively fast loss of charge from spray droplets.

Surface tension is a factor influencing solvent selection. Solvents affect the surface tension of coatings, which can have important effects on the flow behavior of coatings during application, as discussed in the section on Film Defects. Since surface tensions depend on temperature and concentration of resins in solution, solvent volatility can have a large effect on the development of surface tension differentials.

Toxicity and Air Pollution Regulations. All solvents are toxic at some level of exposure. The greatest potential risk comes from inhalation. Acute toxicity data indicate the level of single doses that can be injurious or lethal, and is important in cases of accidental ingestion or spills. The level of exposure that is safe for people exposed 8 h a day for long periods of time is used to set the upper concentration limits in a spray booth. Exposure over periods of years to low levels of some solvents increase the risk of cancer. For solvents that may be carcinogenic, very low levels of permissible exposure are set. The levels are frequently too low to be controlled by economically feasible methods. For example, benzene has not been used in coatings for many years for this reason. A common difficulty is to know what the level of exposure will be. Reference 209 describes an approach to assessing possible exposures when retail consumers apply coatings in a room.

In 1990 the U.S. Congress listed HAP whose use is to be reduced (210). Among those of importance in the coatings field are methyl ethyl ketone (MEK) (2-butanone) [78-93-3], methyl isobutyl ketone (MIBK), *n*-hexane, toluene, xylene, methanol, ethylene glycol, and ethers of ethylene glycol. The EPA Hazardous Air Pollutants Strategic Implementation Plan describes regulatory efforts (211). The first step was a voluntary program aimed at reducing emissions of 17 chemicals, including MEK, MIBK, toluene, and xylene, by 50% (of 1988 levels) by 1995. Mandatory HAP limits are included in EPA's Unified Air Toxics Regulations,

issued for all major categories of coatings users in 1995–1999; for an example, see Reference 212. A group of solvent producers has petitioned for removal of 2-butoxyethanol, MEK, and MIBK from the HAP list.

U.S. VOC regulations treat solvents (except water, acetone, CO_2, certain silicone fluids, and fluorinated solvents) as equally undesirable. Removal of methyl acetate and *t*-butyl acetate from the list has been requested. The EPA assessed the most advanced technology for each end use and established maximum VOC guidelines for major applications. During the 1990s, the EPA guidelines ranged from 0.23 to 0.52 $kg \cdot L^{-1}$ (1.9–4.3 $lb \cdot gal^{-1}$) for most major industrial coating operations (213). Tighter EPA guidelines are expected. EPA standards can be obtained on the internet (214).

In establishing future regulations, there is a difference of opinion as to whether all solvents should be considered as equally undesirable in the atmosphere as they are now. The present approach is simpler to enforce. However, it may well be that using less reactive solvents to replace more reactive ones would be advantageous by allowing at least some opportunity for dissipation in the atmosphere to minimize the probability of local excess ozone concentrations. In Europe, some regulations are based on the photochemical ozone concentration potential (POCP) of individual solvents. Reference 215 provides a list of POCP values and examples of reformulation of solvents to minimize POCP emissions.

An approach to VOC reduction is use of supercritical carbon dioxide as a component in a solvent mixture (216). The critical temperature and pressure of CO_2 are 31.3°C and 7.4 MPa (72.9 atm), respectively. Below that temperature and above that pressure, CO_2 is a supercritical fluid. Under these conditions, solvency properties of CO_2 are similar to aromatic hydrocarbons. A very high solids coating and supercritical CO_2 are metered into a proportioning spray gun in such a ratio as to reduce the viscosity to the level needed for proper atomization. Airless spray guns are used; it has been found that the rapid evaporation of the CO_2 as the coating leaves the orifice of the spray gun assists atomization. VOC emission reductions of 50% or more have been reported.

VOC emissions can be substantially affected by transfer efficiency in spraying coatings. When a coating is sprayed, only a part of the coating is actually applied to the object being coated. Transfer efficiency is the percentage of coating used actually applied to the product. As the transfer efficiency increases, the VOC emissions decrease. Transfer efficiency depends on many variables, particularly the type of spray equipment utilized. In some cases, regulations have been established, setting a lower limit on transfer efficiency.

In some cases, it is feasible to recover the solvent used in coatings. Solvent recovery is desirable, but feasibility is limited by low solvent concentration in the air stream, needed to stay below the lower explosive limits. VOC emissions can also be minimized by incineration. The effluent solvent-laden air stream is heated in the presence of a catalyst to a temperature high enough to burn the solvent. As with solvent recovery, this approach is feasible only when solvent concentrations are relatively high. Incineration has been found to be particularly applicable in coil coating. Most of the solvent is released in the baking oven; part of the effluent air from the baking oven is recirculated back into the oven. The amount of such recirculation is limited so that the solvent content does not approach the lower explosive limit. The balance of the effluent air is fed to the gas burners that heat

the oven. The solvent in the air is burned along with the gas; the fuel value of the solvent reduces the gas requirement.

The VOC emitted by a coating is not easily determined. Solvent can be retained in films for very long periods of time. In latex paints, coalescing solvents are used that are only slowly released from the coating. In cross-linking coatings, volatile by-products may be generated by the reaction. For example, MF cross-linking leads to the evolution of a molecule of volatile alcohol for each cocondensation reaction, and in self-condensation reactions, there can be emission of alcohol, formaldehyde, and methylal. The amount released depends on curing conditions and the amount of catalyst used. On the other hand, when slow evaporating glycol ether solvents are used in an MF cross-linking system, some of the glycol ether reacts with the MF resin and is not emitted. Amines used in "solubilizing" water-reducible coatings volatilize to different extents, depending on conditions and amine structure. With high solids 2K coatings, the amount of volatile material is affected by the time between mixing and application. Very high solids coatings use low molecular weight oligomers; particularly when baked, some oligomer may volatilize. Thus, in many cases, only approximations of potential VOC emissions can be calculated, even when the formulation of a coating is known.

It would be desirable to have a standard method for determining VOC. However, there is little agreement as to what that standard method should be. Methods for determination of VOC are available in Reference 210. Methods for determining VOC of waterborne coatings is made difficult because of the need to determine water content. A modified Karl Fischer method in which the water in a coating is azeotropically distilled before titration is most accurate and convenient (217).

Color and Appearance

Color and gloss are important to the decorative aspects of the use of coatings and, sometimes, to the functional aspects of their use. Color has three components: an observer, a light source, and an object. If a surface is very smooth, it has a high gloss; if it is rough on a scale below the ability of the eye to resolve the roughness, it has a low gloss. Color and gloss interact; changing either changes the other. Reference 218 is a monograph covering color and appearance.

Interactions of Light Sources and Observer. Color depends on the interaction of three factors: light source, object, and observer. If any factor changes, the color changes. If an object is observed under a light source with the energy distribution of a tungsten light bulb and shifts to a different illuminant, the color changes. If the chemical composition of the colorants in two coatings are the same, their reflectance spectra are identical, and the coatings match under any light source. Two coatings with different colorant compositions and different reflectance spectra can have the same color under a certain light source. However, such a pair will not match under light sources with different energy distributions. This phenomenon is called *metamerism*. In a spectral match, the two panels change color with a new light source, but it is the same change in both cases. In a metameric pair, the color is the same with one light source; the colors of both panels also change when the light source is changed, but the extent of change is different between the two panels.

Hiding. With coatings that do not completely hide the substrate, color is affected by reflectance of light through the film, reaching the substrate. Hiding increases as film thickness increases and as light scattering increases, that is, hiding is affected by the refractive index differences, particle sizes, and concentrations of scattering pigments present. Hiding increases as absorption increases. Black pigments, which have high absorption coefficients for all wavelengths, are particularly effective. Surface roughness increases hiding; a larger part of the light is reflected at the top surface, reducing the differences of reflection resulting from differences in the substrate to which a coating is applied. Preparation of a transparent coating requires that there is no light scattering within the film; therefore, the particle size of pigment particles must be very small. There are quality control tests that compare hiding of batches of the same or similar coatings, but no test is available that can provide an absolute measure of hiding (219).

Metallic and Interference Colors. Metallic coatings are widely used on automobiles. They are made with transparent colorants with nonleafing aluminum pigment. They exhibit shifts in color as a function of viewing angle. Regular high gloss paints exhibit dark colors when a panel is looked at from relatively small viewing angles and light colors when a panel is observed from large angles of view. Metallic coatings are lighter in color when viewed near the normal angle (the face color) and darker when viewed from a larger angle (the flop color). The surface must be smooth (high gloss) with no light scattering from the resin or color pigment dispersion, and the aluminum flake particles be aligned parallel to the surface of the film.

Pigments that produce colors by interference are also used in automotive coatings. Pearlescent pigments are mica flakes on which thin films of TiO_2 or iron oxide have been deposited, serving to give interference reflection of light striking the pigment surface. The hues of the coatings vary with angles of illumination and viewing. Another type of interference color pigment is composite flakes with a center layer of opaque metal sandwiched between two clear layers and thin layers of metal so that the flakes are semitransparent. Color is also affected by the angle of illumination and viewing, since the path length of light through the layers depends on the angles of illumination and viewing (220).

Color Systems. The human eye can discriminate thousands of colors. However, it is difficult for a person to tell another person what colors he/she sees. Two types of color systems are used: one that uses color samples and one that identifies colors mathematically. The visual color system used in the United States is the Munsell Color System with color chips, classified in a three-dimensional system. The dimensions of the Munsell System are hue, value, and chroma. The color chips have equal visual differences between pairs of adjacent chips. The light source must be specified. Surface roughness affects color, and so comparisons have to be made at equal gloss levels. Two sets of Munsell chips are available: one with high gloss and the other with low gloss.

The mathematical color system is the CIE Color System based on mathematical descriptions of light sources, objects, and a standard observer. Light sources are specified by their relative energy distributions, objects are specified by their reflectance (or transmission) spectra, and the observer is specified by the CIE standard human observer tables. For color analysis, the light reflected (or transmitted) from (or through) an object is measured with a spectrophotometer. The

CIE system permits accurate representation of all colors; however, mathematical differences are not visually uniform. For further discussion of color systems, see Reference 218.

Color Matching. Many pigmented coatings are color matched. The customer chooses a color for a product and a coating formulator is given a sample to match the color. Before starting the initial laboratory color match, the color matcher needs certain information:

(1) **Metamerism.**

Is a spectral (nonmetameric) match possible (using the same colorants)? If not, any match will be metameric. If the customer has been using a coating made with one or more pigments containing lead compounds and wants a lead-free coating, only a metameric match is possible.

(2) **Light sources.**

If the match is to be metameric, the customer and supplier must agree on the light source(s) under which the color is to be evaluated.

(3) **Gloss and texture.**

The color of a coating depends on its gloss and texture. Some of the light reaching the eye of an observer is reflected from the surface of the film and some from within the film. The color seen by the observer depends on the ratio of the two types of reflected light. At most angles of viewing, more light is reflected from the surface of a low gloss coating than from the surface of a high gloss coating. It is impossible to match the colors of a low gloss and high gloss coating at all angles of viewing.

(4) **Color properties.**

Colorants that meet the performance requirements have to be chosen. Does the coating need to have exterior durability, resistance to solvents, resistance to chemicals such as acids and bases, resistance to heat, or meet some regulation for possible toxicity?

(5) **Film thickness and substrate.**

Since in many cases, the coating will not completely hide the substrate, the color of the substrate and film thickness affect the color of the coating.

(6) **Baking schedule.**

Since the color of many resins and some pigments are affected by heating at high temperatures, color of a coating can be affected by the time and temperature of baking.

(7) **Tolerance.**

How close a color match is needed? Coatings for exterior siding or automobile topcoats require very close color matches. For many others, close matching is unnecessary. Overly tight tolerances raise cost without performance benefits. For coatings that are going to be produced over time with many repeat batches, the most appropriate way to set color tolerances is to have an agreed on set of limit panels.

It is desirable to use four pigments to make the original match. This provides the four degrees of freedom necessary to move in any direction in three-dimensional color space. In visual color matching, color matchers look at the sample to be matched, and from their experience select a combination of pigment dispersions that they think will permit matching the color. Computerized instrumental color matching is replacing visual color matching. Computer programs can be used to select colorants and their ratio, both to match original color in the laboratory and to provide information as to the amount of the different pigment dispersions to be added in the factory so as to match production batches. Establishing such a program requires a major effort to set up the database. The reflectance values are measured at 16 wavelengths. See Reference 218 for discussion of pigment databases. Discussion of computer color matching is beyond the scope of this article; see References 218 and 221 for reviews of computer color matching. Matching of metallic and pearlescent colors has been difficult to computerize because the colors have to match at multiple angles. Measurement of metallic and pearlescent coatings is the topic of ongoing research between instrument manufacturers, coating suppliers, and users with the ASTM; Reference 222 summarizes the approaches.

Gloss. Gloss is a complex phenomenon; for discussions of gloss see References 223 and 224. Individuals frequently disagree on gloss difference. Partly because of the difficulty of visual assessment, progress in developing useful mathematical treatments or measurements of gloss has been limited.

There are several types of gloss. *Specular gloss*, a high gloss surface reflects a large fraction of the light at the specular angle. Lower gloss surfaces reflect a larger fraction at nonspecular angles. When considering gloss, people visually compare the amount of light reflected at the specular angle with the amounts reflected at other angles. If the contrast in reflection is high, gloss is said to be high. The fraction of light reflected at a surface increases as the angle of illumination increases. Surface reflection at the specular angle increases as the refractive index of an object increases. If a surface is rough on a microscale, the angle of incidence of a beam of light is not the same as the geometric angle of the surface with

the light beam. Light is reflected at specular angles between the light beam and individual rough facets of a surface. If a surface has many small facets oriented at all possible angles, a beam of light is reflected in all directions. Such a surface is a diffuse reflector and has a low gloss.

Related to specular gloss is *distinctness-of-image (DOI) gloss*. A perfect specular reflector is a perfect mirror. If a surface has perfect diffuse reflection, no mirror image can be seen. At intermediate stages, the image is more and more blurred as the ratio of specular to diffuse reflection decreases. Often one sees both blurring and distortion.

Sheen refers to reflection of light when a low gloss coating is viewed from near a grazing angle. A high gloss coating reflects a high fraction of light whose angle is near grazing. Reflection from most low gloss surfaces is low at a grazing angle. A low gloss coating is said to have a high sheen if there is significant reflection at a grazing angle.

Haze affects gloss. When light enters a hazy film, it is scattered to some degree, causing some diffuse reflection. The contrast between the fractions of light reflected at specular and nonspecular angles is reduced.

The principal factor controlling gloss of coatings is pigmentation. Roughness of the surface varies with the ratio of PVC to the CPVC in the dry film. Reference 225 discusses the effect of pigmentation on gloss as solvent evaporates. In solventborne, high gloss coatings, the pigment concentration in the top micrometer or so of a dry film contains little, if any, pigment. This layer results from motions within a film as solvent evaporates. Convection currents are set up in the film, and resin solution and dispersed pigment particles move freely. As solvent evaporates, viscosity of the film increases, and movement of pigment particles is slowed. Movement of resin solution continues longer and so the top surface contains little pigment.

Particle size of the pigment affects gloss; if aggregates of pigment are not broken up in the dispersion process, gloss will be lower. Flocculated pigment systems have a lower CPVC, and so at the same PVC there will usually be lower gloss. However, since large particles stop moving before small ones, flocculated particles will stop moving sooner than well stabilized ones, which can lead to increased gloss in low PVC coatings. Reference 226 discuss effects of pigment particle size and clear layer thickness on specular gloss.

In some coatings, it is desirable to have a low gloss, but still a high degree of transparency. This is accomplished using a small quantity of very fine particle size silicon dioxide as a pigment. The combination of small particle size and low refractive index difference results in minimal light scattering as long as concentration is low. When solvent evaporates from such a lacquer, the SiO_2 particles keep moving until the viscosity of the surface of the film becomes high. The result is a higher than average concentration of pigment at the top of the film, reducing gloss at relatively low PVC.

Latex coatings generally have lower gloss than solventborne coatings. Latex coatings have both resin and pigment particles as dispersed phases. During drying of a latex paint film, there is not the same separation to give a pigment-free thin layer at the top of the film as in a solvent coating. Latexes with smaller particle size give somewhat higher gloss films than larger particle size latexes. Pigment-free dry films of many latexes are hazy, reducing gloss.

Gloss can change during the life of an applied film. In some cases, the surface of the film embrittles and then cracks as the film expands and contracts. Generally, this mechanical failure is progressive, and after initial loss of gloss, there is film erosion. In other cases, especially clear coats, erosion occurs first, and loss of gloss is only evident after erosion is deep enough to cause protrusion of pigment particles of the base coat. Erosion of binder in pigmented films can proceed to a stage in which pigment particles are freed from binder on the surface and rub off easily; this phenomenon is called *chalking*. Chalky surfaces have lower gloss and the color changes to a lighter color. Loss of gloss can also result from loss of volatile components after a film is exposed, causing film shrinkage and increased surface roughness (227). An excellent review of durability and gloss has been given in Reference 227.

No fully satisfactory method for measuring gloss is available, and no satisfactory rating scale for visual observation of gloss has been developed. While all people will agree as to which film is glossier if the gloss difference is large, they frequently disagree in ranking if the difference is small. Specular gloss meters are widely used, but correspondence between meter readings and visual comparisons is limited. The aperture of the slit in a gloss meter is about 2° whereas the limit of resolution of a human eye is about 0.0005° of arc. A gloss meter is, therefore, less sensitive to DOI than the eye. The distance between the aperture and a panel is fixed in a gloss meter, whereas a person can view a panel from any distance. The most widely used gloss meters measure response only at the specular angle. Those mostly used in the coatings industry make measurements at angles of incidence and viewing of 20°, 60°, and 85°. One must use the standard that has been calibrated at the selected angle. Black and white standards are available. Reflection at the specular angle is not the same from a white and a black standard with equal surface roughness because the white pigment scatters light. Normally, one first measures at 60°. If the reading is over 70, readings should be made at 20° since the precision is higher nearer the midpoint of the meter reading. It is common to read low gloss panels at both 60° and 85°. Readings at 85° may have a relationship to sheen. Readings are reproducible on carefully calibrated instruments to ±2 gloss units. This is a high percentage of error in the low gloss range.

There is confusion as to what the numbers mean. They are *not* the percentage of light reflected at the surface. They are closer to being the percentage of light reflected at that angle compared to the reading that would be obtained if a perfectly smooth surface were measured. The total reflection from a black matte surface is much higher at most angles of illumination and viewing than that from a high gloss black surface. Meter readings are lower for the same panel when the setting is 20° as compared to 60° (228). The instruments can be used for quality control comparisons of lots of the same or very similar coatings and for following loss of gloss on aging. For specification purposes other than quality control, specular gloss meters are not appropriate, and one must rely on standard visual panels.

DOI meters use the sample as a mirror. The reflection of a grid on the surface of the panel is compared visually to a set of photographic standards ranging from a nearly perfect mirror reflection to a blurred image in which the grid cannot be detected. One reports the comparison of the degree of blurring and also a qualitative statement about distortion. Correspondence with visual assessment in

the high gloss range is better than with specular gloss meters, but DOI tends to be insensitive to small differences in the low gloss range. Instruments are available to make comparisons based on optical density.

New instruments with linear diode array detectors permit multiple measurements of light reflected at small angle increments without using an aperture in front of the detector (229). Computerized instruments make multiple measurements of reflectance from small areas (approximately 100-μm diameter) over a 10-cm^2 area. This permits separation of the reflection from micro- and macroroughness, thus giving a numerical rating for gloss and a separate measurement of macro roughness, such as orange peel or texture.

Pigment Dispersion

Pigments are manufactured with a particle size distribution that gives the best compromise of properties, but the particles become cemented together into aggregates during processing. Breaking these aggregates and forming stable dispersions of optimally sized pigment particles is a critical process. Making dispersions involves three aspects: wetting, separation, and stabilization.

Dispersions in Organic Media. Wetting is essential for pigment dispersion. Wetting requires that the surface tension of the vehicle be lower than the surface free energy of the pigment. In organic media this is the case for all inorganic and most organic pigments. There can be important differences in the rate of wetting. When a dry pigment is added to a vehicle to make a mill base, it tends to clump up in clusters of pigment aggregates. For wetting to occur, the vehicle must penetrate through these clusters and into the pigment aggregates. The rate of wetting is dominantly controlled by the viscosity of the vehicle.

Processes are designed to separate pigment aggregates into individual crystals without grinding crystals to smaller particle size. Many different types of machinery are used to carry out the separation stage. Dispersion machines apply a shear stress to the aggregates suspended in the vehicle. If the aggregates are easily separated, the machinery only needs to be able to exert a small shear stress. If aggregates require a relatively large force for separation, then machinery that can apply a higher shear stress is required. Pigment manufacturers have been increasingly successful in processing and surface-treating pigments so that their aggregates are relatively easily separated. The available shear rate for a dispersion machine is set by its design. The formulator must select appropriate dispersion machinery that can transfer sufficient shear stress to the aggregates and formulate a mill base for its efficient use. Discussion of such machinery is beyond the scope of this article. Several types of machines have been discussed in Reference 230, and detailed engineering information is available from machinery manufacturers. Reference 231 deals more fundamentally with engineering aspects of some dispersion methods.

Stabilization is usually the key to making good pigment dispersions. If the dispersion is not stabilized, the pigment particles will be attracted to each other and undergo flocculation. Flocculation is a type of aggregation, but the aggregates formed are not cemented together like the aggregates in the dry pigment powder.

Flocculation can be reversed by applying relatively low levels of shear stress. Flocculation is almost always undesirable.

There are two mechanisms for stabilization: charge repulsion and entropic repulsion. In charge repulsion, particles with like electrostatic charges repel each other. In organic media, entropic repulsion is the more important stabilizing mechanism. The repelling effect of layers of adsorbed material on the surface of the particles of a dispersion prevents the particles from getting close enough together for flocculation to occur. In many dispersions of pigments in organic media, the adsorbed layer consists of resin molecules swollen with solvent. The particles are in rapid, random (Brownian) motion. As they approach each other, their adsorbed layers become crowded; there is a reduction in the number of possible conformations of molecules of resin and associated solvent in the adsorbed layers. The resulting decrease in disorder constitutes a reduction in entropy. Reduction in entropy corresponds to an increase in energy and requires force; hence, resistance to reduction in entropy leads to repulsion.

Much of our understanding of entropic stabilization of pigment dispersions comes from the seminal work of Rehacek (232). A technique has been discussed to determine the thickness and composition of the adsorbed layer on the surface of a pigment dispersed in a resin solution. It has been found that if the adsorbed layer thickness of resin plus solvent is less than 9–10 nm, the dispersion is not stable (232–234). With monofunctional surfactants, the adsorbed layer can be thinner and still protect against flocculation. It has been shown that an adsorbed layer thickness of 4.5 nm of surfactant and associated solvent was adequate (235). In contrast to the adsorbed layer of resin, which is nonuniform in thickness, the surfactant layer is comparatively uniform, and so it does not have to be as thick to provide stabilization.

Absorption plots deviate from linearity at low values of resin concentration. This results from competition between resin and solvent adsorption that depends on both the relative affinity of resin and solvent molecules for the pigment surface and the concentration of resin. At low concentrations, both solvent and resin are adsorbed on the particle surface and so the average layer thickness is insufficient to prevent flocculation. Below the start of the linear section of the curve, the low shear viscosities of the dispersions are higher than those above it, separation of pigment during centrifugation is more rapid, and the bulk of the centrifugate formed is greater. This behavior shows flocculation below the critical concentration.

With resins having several adsorption sites, the largest single factor controlling adsorbed layer thickness is molecular weight. The adsorbed layer thickness on TiO_2 dispersed in a series of BPA epoxy resins in MEK, increased from 7 to 25 nm as the molecular weight of the epoxy resin increased (233). With the lowest molecular weight resin, the layer thickness of 7 nm was insufficient. Dispersions in solutions of the higher molecular weight resins were stable. Adsorbed layer thickness is also affected by the pigment surface. A TiO_2 surface treated with alumina forms a more stable dispersion than a TiO_2 surface treated with silica in the same long oil alkyd solution (236). It was proposed that the adsorbed layer is more compact on the silica-treated TiO_2. Resin molecules that have multiple adsorbing groups have an advantage in competition with solvent molecules, but if the solvent interacts strongly with the pigment surface and the resin only interacts

weakly, the more numerous solvent molecules will "win" the contest. If the ratio of resin to solvent is just sufficient to allow adequate adsorption of resin to stabilize the dispersion, addition of more of the same solvent shifts the equilibrium, displacing part of the resin and reducing the average adsorbed layer thickness below the critical level for stabilization. The dispersion is said to have been subjected to solvent shock.

It is frequently difficult to make stable pigment dispersions in high solids coatings. Increasing the solids of organic solution coatings requires decreasing the molecular weight of the resins and reducing the number of functional groups per molecule. The low molecular weight results in thinner adsorbed layers of resin and associated solvent molecules. The reduced number of functional groups per resin molecule decreases the probability of the adsorption of resin molecules. Surfactants have been designed that are so strongly adsorbed on a pigment that, little excess over the amount sufficient to saturate the pigment surface area is needed to stabilize a dispersion. For example, phthalocyanine blue modified by covalently attaching long aliphatic side chains has been used as a surfactant with phthalocyanine blue pigment; the phthalocyanine end of the molecules of surfactant in effect joins the crystal structure of the surface of the pigment particles so that little, if any, is in solution (235). Special dispersing aids called *hyperdispersants* have been designed. The design parameters have been described in Reference 237. The most effective class of dispersant has a polar end with several functional groups and a less polar tail of sufficient length to provide for a surface layer that is at least 10 nm thick. See Reference 238 for a further review of the use of hyperdispersants.

The combination of resin (and/or dispersant), solvent, and pigment, used to make a pigment dispersion, is called a *mill base*. Higher pigment loading gives more efficient production; high loadings are possible when the viscosity of the vehicle (solvent plus resin) used in the mill base is low. Low viscosity also gives faster wetting. For maximum pigment loading, it is desirable to use the minimum concentration of resin solution that provides stability. The Daniel flow point method gives an estimate of the appropriate resin concentration to be used with a particular pigment (230).

Dispersions in Aqueous Media. Dispersion of pigments in aqueous media involves the same factors as in organic media. However, the surface tension of water is high and so there is more likely to be a problem in wetting the surface of pigment particles. In some cases, water interacts strongly with the surface of pigments; therefore, the functional groups on the stabilizers have to interact more strongly with the pigment surface to compete with water. Also, many aqueous dispersions are in latex paints, and so the systems have to be designed such that stabilization of the latex dispersion and the pigment dispersion do not adversely affect each other.

Inorganic pigments such as TiO_2, iron oxide, and most inert pigments have highly polar surfaces, and so there is no problem with wetting them with water. Most organic pigments require a surfactant to wet the surfaces. Some organic pigments are surface treated with adherent layers of inorganic oxides to provide a polar surface that is more easily wet by water. In contrast to dispersions in organic media, stabilization by charge repulsion can be a principal mechanism in aqueous media. Stability of the dispersions depends on pH, since pH affects surface charges. For any combination of pigment, dispersing agent, and water, there is a

pH at which the surface charge is 0; this pH is called the *isoelectric point* (*iep*). At *iep*, there is no charge repulsion; above *iep*, the surface is negatively charged; and below *iep*, it is positively charged. The stability of dispersions is at a minimum at *iep* $\pm$ 1 pH unit (239). The *iep* value for pigments varies, for example, 4.8 for kaolin clay and 9 for $CaCO_3$.

Entropic stabilization can also be effective. A study of stabilization of aqueous TiO_2 dispersions by anionic and nonionic surfactants concluded that a high molecular weight nonionic copolymer provided the greatest resistance to flocculation both in the dispersion and during drying of a gloss latex paint film (240). Since stabilization resulted from entropic stabilization it was not affected by changes in pH. Block copolymers with hydrophobic and hydrophilic segments made by group transfer polymerization have been recommended for stabilization of aqueous dispersions of a range of organic pigments (241).

Most latex paint formulations contain several pigments and several surfactants. The *iep* of the various pigments are different, which complicates the problem of charge stabilization. Commonly, mixtures of surfactants are used. Anionic surfactants are frequently used as one component. Polymeric anionic surfactants (such as salts of acrylic copolymers in which acrylic acid and hydroxyethyl acrylate are used as comonomers) provide salt groups for strong adsorption on the polar surface of the pigment and hydroxyl groups for interaction with the aqueous phase; nonpolar intermediate sections add adsorbed layer thickness. Polymeric surfactants are less likely to lead to performance problems in the final films than monomeric surfactants. Nonionic surfactants are frequently used along with an anionic surfactant. It is common to also add potassium tripolyphosphate, the basicity of which may assure that the pH is above the *iep* of all pigments.

Evaluation of Degree of Dispersion. Assessment of degree of dispersion is a critical need for establishing original formulations, optimizing processing methods, for quality control. Differences in degree of dispersion come from two factors: incompleteness of separation of the original aggregates into individual crystals and flocculation after separation. An effective evaluation method is by determination of tinting strength in comparison to a standard. One can check for flocculation by pouring some of the tint mix on a plate and rubbing the wet coating with a finger. If the color changes, the dispersion is flocculated. Well-stabilized dispersions have Newtonian flow properties. If a dispersion is shear thinning (and does not contain a component designed to make it shear thinning), it is flocculated. A further method of assessing pigment dispersion is by settling or centrifugation. The rate of settling is governed by particle size and difference in density of the dispersed phase from the medium. A well-separated, well-stabilized dispersion centrifuges slowly, but when settling is complete the amount of sediment is small. A well-separated but poorly stabilized dispersion settles quickly to a bulky sediment. If the pigment settles or centrifuges relatively quickly to a compact layer, the separation step is incomplete. The degree of flocculation can be calculated from rates of centrifugation (235).

One can also examine the dispersion with a microscope; one must exercise caution in preparing the samples for examination. In general, it is necessary to dilute the sample. If the sample is diluted with solvent, there is a possibility of flocculation. Electron microscope studies of the surfaces of etched dry coating films can be useful for assessing variations in dispersion (242). Flocculation gradient

technique is an accurate method for quantitative study of the degree of pigment dispersion in both liquid coatings and dry films. The method was originally developed to study TiO_2 dispersions (243). The extent of scattering of 2500-nm ir radiation by a film as a function of film thickness is measured. A plot of backscatter against film thickness gives a straight line whose gradient increases with increasing flocculation. The technique has proven useful in evaluation of flocculation of other pigments (244).

The most widely used method of testing for fineness of grind is the Hegman drawdown gauge. A sample of dispersion is placed on the steel block before the zero reading and drawn down by a steel bar scraper. One then lifts the block up and quickly looks across the drawdown sample to see at which graduation one can start to see particles projecting or streaks caused by particles being dragged along. It is said that the higher the scale reading, the "better" the dispersion. The device is not capable of measuring degree of dispersion. A major problem in making satisfactory dispersions is avoiding flocculation, but the gauge cannot detect flocculation. The particle sizes of properly dispersed pigments are small compared to the depth of the groove on the gauge. The depth on some gauges ranges from 0 to 10 mil (250 μm) in graduation units of 1.25 mil (approx 30 μm). TiO_2 pigment particles have an average size of about 0.23 μm. Aggregates of a large number of particles would escape detection. Many color pigment particles are even smaller and carbon black particles can be as small as 5 nm. It has been shown that in TiO_2 dispersions approximately 0.1% of the total pigmentation of a coating was responsible for an unacceptable fineness of grind rating (245).

Pigment Volume Relationships

Coatings formulators often work with weight relationships, but volume relationships are generally more important. A series of performance variables have been viewed to be a function of the PVC, the volume percent of pigment in a dry film (246). It has been found that many properties of films change abruptly at some PVC as the PVC is increased in a series of formulations. This PVC has been designated as CPVC. Also, *CPVC* has been defined as that pigment volume concentration where there is just sufficient binder to provide a complete adsorbed layer on the pigment surfaces and fill all the interstices between the particles in a close-packed system. Below CPVC, the pigment particles are not close-packed and binder occupies the "excess" volume in the film. Above CPVC, the pigment particles are close packed, but there is not enough binder to occupy all the volume between the particles, resulting in voids in the film. Slightly above CPVC, the voids are air bubbles in the film, but as PVC increases, the voids interconnect and film porosity increases sharply. When films are prepared from coatings with PVC near CPVC, there may not be uniform distribution of pigment through the dry film, and so parts of the film may be above CPVC and other parts below CPVC (247). Some properties start to change as soon as PVC increases so there are air voids in films, and other properties change when the PVC is sufficiently greater than CPVC and so the film begins to be porous. Coatings with flocculated pigment clusters result in films with nonuniform distribution of pigment particles, and

CPVC with flocculated pigments is lower than the CPVC with the same pigment combination that is not flocculated.

There is a controversy about the applicability of CPVC to latex paints. Reference 248 includes a review of the literature. The effect of PVC on hiding of latex paints showed that CPVC was lower in latex paint than in solvent-based paint made with the same pigment composition (249). It has been recommended that the term latex CPVC (LCPVC) be used (230). Although CPVC is approximately independent of the binder in solventborne paints, LCPVC varies with the latex and some other components of latex paints. LCPVC increases as the particle size of the latex decreases, as the T_g of the latex polymer decreases, and concentration of coalescing agent increases. A quantitative study of the effect of latex particle size on CPVC using a series of monodisperse vinyl acetate/butyl acrylate latexes with TiO_2 pigment showed that CPVC depended on the ratio of the number of latex and pigment particles and the ratio of their diameters (248). A simulation program using particle size distributions of latex and pigment and a measure of the deformability of latex particles has been developed to predict the CPVC of simple latex paints (250).

As PVC is increased in a series of coatings made with the same pigments and binders, density increases to a maximum when PVC equals CPVC and then decreases. Above CPVC the lower density of air reduces the film density. Tensile strength generally increases with PVC to a maximum at CPVC but then decreases above CPVC. Below CPVC, the pigment particles serve as reinforcing particles and increase the strength. Above CPVC, air voids weaken the film; abrasion and scrub resistances of films drop above CPVC. Stain resistance decreases above CPVC, since staining liquids can penetrate into pores. A single coat of a coating with PVC above CPVC to steel exposes the panel to humidity and rapid rusting occurs. An alkyd-based coating with PVC above CPVC to a wood substrate is less likely to blister than with a similar coating with PVC below CPVC as a result of the porosity of films above CPVC. Gloss is related to PVC. In general, unpigmented films have high gloss. The initial (low) percentage of pigment has little effect on gloss, but above a PVC of 6–9, gloss drops until PVC approaches CPVC. It is almost always desirable to make primers with a high PVC, since the rougher, low gloss surface gives better intercoat adhesion than a smooth, glossy surface. It is sometimes desirable to design a primer with PVC greater than CPVC. Adhesion of a topcoat to such a primer is enhanced by mechanical interlocking resulting from penetration of vehicle from the topcoat into pores of the primer. Many of the pores in the primer are filled with binder from the topcoat, which increases the PVC of the topcoat, resulting in loss of gloss. Such a primer is said to have poor enamel hold out. The primer PVC should be only enough higher than CPVC to provide adhesion to minimize loss of gloss of the topcoat.

PVC affects hiding; as pigmentation increases, hiding generally increases. Initially, hiding increases rapidly, but then levels off. In the case of rutile TiO_2 hiding goes through a maximum, gradually decreases with further increase in PVC, and then increases above CPVC. This increase in hiding above CPVC results from air voids left in the film when PVC is above CPVC. The refractive index of air (1.0) is less than that of the binder (approx 1.5) and so there is light scattering by the air interfaces in addition to interfaces between pigment and binder. Owing to the high cost of TiO_2, coatings are not generally formulated with a PVC of

TiO_2 greater than about 18% since incremental hiding at higher PVC is not cost efficient. (This value is dependent on the actual TiO_2 content of the TiO_2 pigment and on the stability of the TiO_2 dispersion.) In high PVC coatings, lower cost inert pigments are used to occupy additional volume. The scattering efficiency of TiO_2 is affected by the particle size of the inert pigments used with it (251). Inclusion of some inert pigment with a particle size smaller than that of TiO_2 (ie, less than 0.2 μm) increases the efficiency by acting as a so-called *spacer* for the TiO_2 particles. The increase in hiding above CPVC can be useful. Hiding of ceiling paints can be improved by formulating above CPVC. This permits hiding with one coat, which is particularly desirable in ceiling paints. The stain and scrub resistances of the paint are inferior to similar paints with PVC; less than CPVC; they are not important in ceiling paints. Tinting strengths of white coatings increase as the PVC of a series of coatings is increased beyond CPVC. The air voids above CPVC increase light scattering so that a colored paint dries with a lighter color than one with the same amount of color pigment but with a PVC below CPVC.

For any application, there is a ratio of PVC to CPVC most appropriate for the combination of properties needed. Once this ratio has been established, changes in pigment combinations for that application should be made such that this PVC/CPVC ratio is maintained. This concept is developed in detail in Reference 252.

There are large variations in CPVC, depending on the pigment or pigment combination in a coating and the extent, if any, of pigment flocculation. With the same pigment composition, the smaller the particle size, the lower the CPVC. The ratio of surface area to volume is greater for smaller particle size pigments; hence, a higher fraction of binder is adsorbed on the surface of the smaller pigment particles and the volume of pigment in a close-packed final film is smaller. CPVC depends on particle size distribution; the broader the distribution, the higher the CPVC, since broader particle size distribution of spherical, dispersed-phase systems increases packing factor. In low gloss coatings, the least expensive component of the dry film is inert pigment; to minimize cost, it is desirable to maximize inert pigment content by using inert pigments with a broad particle size distribution.

Pigment dispersion affects CPVC; CPVC of films from coatings in which the pigment is flocculated are lower than CPVC from corresponding coatings with nonflocculated pigment. Films prepared from coatings with flocculated pigment clusters have less uniform distribution of pigment, and hence, are more likely to have portions where there are local high concentrations of pigment. In one example, it is reported that CPVC decreased from 43 to 28 with increasing flocculation (253).

CPVC has been determined by many different procedures. Tinting strength is one of the most widely used. A series of white paints with increasing PVC are prepared and tinted with the same ratio of color to white pigment. Above CPVC, the white tinting strength of the coating increases because of the "white" air bubbles above CPVC. Since the density of most pigments is higher than that of binders and the density of air is lower, density maximizes at CPVC. The CPVC can be determined by filtering a coating and measuring the volume of the pigment filter cake. CPVC for a pigment or pigment combination can be calculated from oil absorption (OA), provided the OA value is based on a nonflocculated dispersion. The definitions of both OA and CPVC are based on close-packed systems with just

sufficient binder to adsorb on the pigment surfaces and fill the interstices between the pigment particles. OA is expressed as g of linseed oil per 100 g pigment; CPVC is expressed as mL of pigment per 100 mL of film. OA and CPVC are approximately independent of the binder, provided the pigment particles are not flocculated. OA values determined by a mixing rheometer, such as a Brabender Plastometer, are preferable. Although the CPVC for individual pigments can be calculated from OAs, CPVC values of pigment combinations cannot be calculated from these values alone, since differences in particle size distribution with pigment combinations affect the packing factor. The most successful equations use OA values, densities, and average particle sizes of the individual pigments (254). The equations assume that the particles are spheres, a fair assumption for many, but not all, pigments. Calculated values correspond reasonably well to experimentally determined CPVC values.

Film Defects

Many kinds of defects can develop in a film during or after application. Reference 255 is a monograph about film defects.

Leveling. The most widely studied leveling problem has been leveling of brush marks. It has been proposed that the driving force for leveling is surface tension (256). The formulator has little control over the variables except viscosity. The Orchard model (256) provides satisfactory correlation between experimental data and predictions when the liquid film has Newtonian flow properties and sufficiently low volatility such that viscosity does not change. In most cases, viscosity changes due to solvent evaporation and the equation is not applicable. It has also been proposed that surface tension differential is the principal driving force for leveling in coatings with volatile solvents (257). Wet film thickness in valleys of brush marks is less than in the ridges; when the same amount of solvent evaporates per unit area of surface, the fraction of solvent that evaporates in the valleys is larger than that in the ridges. As a result, the surface tension in the valleys is higher than that in the ridges and surface tension differential flow drives coating from the ridges into the valleys. The extent of the flow driven by surface tension differential depends on the rate of evaporation of the solvent. Solvent evaporation and leveling of water-reducible coatings has been studied (258), and it has also been shown that the forces driving leveling depend on the solvent in the formulation. Equations have been developed that model the drying process through the changes in surface tension differentials and changes in viscosity during solvent evaporation (259).

In spray application, surface roughness is called *orange peel*, which consists of bumps surrounded by valleys. Orange peel is encountered when spraying coatings that have solvents with high evaporation rates. Leveling of sprayed films can often be improved by addition of small amounts of silicone fluid that reduces surface tension. An explanation for the phenomenon has been provided (260). When one sprays a lacquer, initially the surface is fairly smooth and then orange peel grows. It has been proposed that the growth of orange peel results from a surface tension differential driven flow. The last atomized spray particles to arrive on the wet lacquer surface have traveled for a longer distance between the spray gun

and the surface, and hence, have lost more solvent, have a higher resin concentration and, therefore, a higher surface tension than the main bulk of the wet film. The lower surface tension wet lacquer flows up the sides of these last particles to minimize overall surface free energy. With the silicone fluid, the surface tension of the wet lacquer surface and the surface tension of the last atomized particles are uniformly low; there is no differential to promote growth of orange peel.

Electrostatically sprayed coatings are likely to show surface roughness. It has been suggested that the greater surface roughness results from arrival of the last charged particles on a coated surface that is quite well electrically insulated from the ground. These later arrivals may retain their charges sufficiently long to repel each other and thereby reduce the opportunity for leveling. It has also been suggested that when coatings are applied by high speed bell electrostatic spray guns, differentials in the pigment concentration within the spray droplets may result from the centrifugal forces (261). These pigment concentration differentials lead to rougher surfaces and reduction in gloss of the final films.

Leveling problems are particularly severe with latex paints. Latex paints, in general, exhibit a shear thinning and rapid recovery of viscosity after exposure to high shear rates. Because of their higher dispersed phase content, the viscosity of latex paints changes more rapidly with loss of volatile materials than the viscosity of solventborne paints. The leveling is primarily surface tension driven, since surfactants give low surface tension to latex paints, which is almost unchanged as water evaporates.

Sagging. When a wet coating is applied to a vertical surface, gravity causes it to flow downward (*sagging*). Sagging increases with increasing film thickness and decreases with increasing viscosity. The commonly used test is a sag-index blade. A drawdown, which is a series of stripes of coating of various thickness, is made on a chart and placed in a vertical position. Sag resistance is rated by observing the thickest stripe that does not sag down to the next stripe. For research purposes, a more sophisticated method, the sag balance, has been developed (262).

In spray-applied solvent solution coatings, sagging can generally be minimized while achieving adequate leveling by a combination of proper use of the spray gun and control of the rate of evaporation of solvents. Sagging of high solids solventborne coatings is more difficult to control than with conventional solids coatings. While other factors may be involved, less solvent evaporates while atomized droplets are traveling between a spray gun and the object being coated (263). A factor is the colligative effect of the lower mole fractions of solvent(s) in a high solids coatings. While this effect slows solvent evaporation from a high solids coating, it is not large enough to account for the large differences in solvent loss that have been reported. High solids coatings may undergo transition from first-stage to second-stage solvent loss with relatively little solvent loss as compared to conventional coatings (17). T_g of the solution in a high solids coatings changes more rapidly with concentration, and hence, reaches a stage of free-volume limitation of solvent loss after only a little loss of solvent. It has been found that high solids polyesters are formulated at concentrations above the transition concentration where solvent loss rate becomes diffusion controlled (264). It has also been found that the transition points occur at higher solids with linear molecules such as *n*-octane [111-65-9] versus isooctane (2,2,4-trimethylpentane)

[540-84-1], and *n*-butyl acetate [123-86-4] as compared to isobutyl acetate [105-46-4].

It is necessary to make the systems thixotropic. For example, dispersions of fine particle size SiO_2, precipitated SiO_2, bentonite clay treated with a quaternary ammonium compound, or polyamide gels can be added to impart thixotropy. The problem of sagging in high solids automotive metallic coatings can be particularly severe. Even a small degree of sagging is very evident in a metallic coating, since it affects the orientation of the metal flakes. Use of SiO_2 to impart thixotropy is undesirable, since even the low scattering efficiency of SiO_2 is enough to reduce color flop in the coatings. Acrylic microgels have been developed that impart thixotropic flow using the swollen gel particles (265). In the final film, the index of refraction of the polymer from the microgel is nearly identical with that of the cross-linked acrylic binder polymer so that light scattering does not interfere with color flop. Reference 266 discusses the rheological properties of the systems.

Hot spraying helps control sagging. The coating cools on striking the object and the viscosity increase reduces sagging. Use of CO_2 under supercritical conditions is helpful in controlling sagging, since the CO_2 flashes off almost instantaneously when the coating leaves the orifice of the spray gun, increasing viscosity. High speed electrostatic bell application permits application of coatings at higher viscosity, which helps control sagging.

Crawling, Cratering, and Related Defects. If a coating is applied to a substrate that has a lower surface free energy, the coating will not wet the substrate. The mechanical forces involved in application spread the coating on the substrate surface, but since the surface is not wetted, surface tension forces tend to draw the liquid coating toward a spherical shape. Meanwhile, solvent is evaporating, and viscosity is increasing and flow stops, resulting in uneven film thickness with areas having little, if any, coating adjoining areas of excessive film thickness. This behavior is called *crawling*. Crawling can result from applying a coating to steel with oil contamination on the surface. It is especially common in coating plastics. Crawling can also result from the presence of surfactant-type molecules in the coating, that can orient rapidly on a highly polar substrate surface. Even though the surface tension of the coating is lower than the surface free energy of the substrate, it could be higher than the surface free energy of the substrate after a surfactant in the coating orients on the substrate surface. If one adds excess silicone fluid to a coating to correct a problem such as orange peel, small droplets of insoluble fractions of the poly(dimethylsiloxane) can migrate to the substrate surface and spread on it, and the film crawls. Higher molecular weight fractions of poly(dimethylsiloxane) are insoluble in many coating formulations (175). Modified silicone fluids, such as polysiloxane–polyether block copolymers, have been developed, which are compatible with a wider variety of coatings and are less likely to cause undesirable side effects. The effect of a series of additives on crawling and other film defects has been reported (267).

Cratering is the appearance of small round defects that look somewhat like volcanic craters on the surface of coatings. Cratering results from a small particle or droplet of low surface tension contaminant, which lands on the wet surface of a freshly applied film (260). Some of the low surface tension material dissolves in the adjacent film, creating a localized surface tension differential. This low surface tension part of the film flows away from the particle to cover the

surrounding higher surface tension liquid coating. Loss of solvent increases viscosity flow, leading to formation of a characteristic crest around the pit of the crater. The user applying the coating should minimize the probability of low surface tension contaminants arriving on the wet coating surface. Spraying lubricating oils or silicone fluids on or near the conveyor causes craters. Presence of some contaminating particles cannot be avoided, and so coatings must be designed to minimize the probability of cratering. Lower surface tension coatings are less likely to form craters. Alkyd coatings have low surface tensions and seldom give cratering problems. In general, polyester coatings are more likely to give cratering problems than acrylic coatings. Additives can be used to minimize cratering. Small amounts of silicone fluid generally eliminate cratering; excess silicone must be avoided. Octyl acrylate copolymer additives usually reduce cratering. A comparison of effects of additives on the control of defects such as cratering is available (268).

In roll coating tin plate sheets, the coated sheets are passed on to warm wickets that carry the sheets through an oven. In some cases, one can see a pattern of the wicket as a thin area on the final coated sheet. The heat transfer to the sheet is fastest where it is leaning against the metal wicket. The surface tension of the liquid coating on the opposite side drops locally because of the higher temperature. This lower surface tension material flows toward the higher surface tension surrounding coating. In spraying flat sheets as solvent evaporates the coating is thickest at the edges and just in from the edge the coating is thinner than average. Solvent evaporates most rapidly from the coating near the edge, where the air flow is greatest. This leads to an increase in resin concentration at the edge and to a lower temperature. Both factors increase the surface tension there, causing the lower surface tension coating adjacent to the edge to flow out to the edge to cover the higher surface tension coating. Surface tension differential driven flow can also result when overspray from spraying a coating lands on the wet surface of a different coating. If the overspray has lower surface tension than the wet surface, cratering occurs. If the overspray has high surface tension compared to the wet film, local orange peeling results.

Floating and Flooding. Floating is most evident in coatings pigmented with two pigments. A light blue gloss enamel panel can show a mottled pattern of darker blue lines on a lighter blue background. With a different light blue coating, the color pattern might be reversed. These effects result from pigment segregations that occur as a result of convection current flows driven by surface tension differentials while a film is drying. Rapid loss of solvent from a film during drying leads to considerable turbulence. Convection patterns are established whereby coating material flows up from lower layers of the film and circulates back down into the film. The flow patterns are roughly circular, but as they expand, they encounter other flow patterns and the convection currents are compressed. As solvent evaporation continues, viscosity increases and it becomes more difficult for the pigment particles to move. The smallest particle size, lowest density particles continue moving longest. The segregated pattern of floating results. Floating is particularly likely to occur if one pigment is flocculated and the other is a nonflocculated dispersion of fine particle size. If, in a light blue coating, the white pigment is flocculated and the blue is not, one will find darker blue lines on a lighter blue background. If the blue one is flocculated and not the white, there will be lighter blue lines on a darker blue background. Floating can occur

without flocculation using a combination of pigments with very different particle sizes and densities. When a fine particle size carbon black and TiO_2 are used to make a gray coating, the particle size of the TiO_2 is several times that of the carbon black and TiO_2 has about a fourfold higher density. A larger particle size black, such as lamp black, can be used to make a gray with a lower probability of floating. As with other flow phenomena driven by surface tension differentials, floating can be prevented by adding a small amount of a silicone fluid.

In flooding the color of the surface is uniform, but different than should have been obtained from the pigment combination used. One might have a uniform gray coating, but a darker gray than that expected from the ratio of black to white pigments. The extent of flooding can vary with the conditions encountered during application, leading to different colors on articles coated with the same coating. Flooding results from surface enrichment by one or more of the pigments in the coating. The stratification is thought to occur as a result of different rates of pigment settling within the film, which are caused by differences in pigment density and size or flocculation of one of the pigments. Flooding is accentuated by thick films, low vehicle viscosity, and low evaporation rate solvents. The remedies are to avoid flocculation and low density fine particle size pigments.

Wrinkling. A wrinkled coating shriveled or wrinkled into many small hills and valleys. Some wrinkle patterns are so fine that to the unaided eye, the film appears to have low gloss rather than to look wrinkled. However, under magnification, the surface can be seen to be glossy but wrinkled. In other cases, the wrinkle patterns are broad or bold and are readily visible. Wrinkling results when the surface of a film becomes high in viscosity while the bottom of the film is still relatively fluid. It can result from rapid solvent loss from the surface, followed by later solvent loss from the lower layers. It can also result from more rapid cross-linking at the surface of the film than in the lower layers of the film. Subsequent solvent loss or cure in the lower layers results in shrinkage, which pulls the surface layer into a wrinkled pattern. Wrinkling is more apt to occur with thick films than with thin films because the possibility of different reaction rates and differential solvent loss within the film increases with thickness.

Wrinkling can occur in uv curing of pigmented acrylate coatings with free-radical photoinitiators. High concentrations of photoinitiator are required to compete with absorption by the pigment. Penetration of uv through the film is reduced by absorption by the pigment as well as by the photoinitiator. There is rapid cross-linking at the surface and slower cross-linking in the lower layers of the film, resulting in wrinkling. Wrinkling is likely to be more severe if the curing is done in an inert atmosphere rather than in air. In the latter case, the cure differential is reduced by oxygen inhibition of surface cure. uv curing of pigmented cationic coatings, which are not air inhibited, is even more prone to surface wrinkling.

Popping. *Popping* is the formation of broken bubbles at the surface of a film that do not flow out. Popping results from rapid loss of solvent at the surface of a film during initial flash off. When the coated object is put into an oven, solvent volatilizes in the lower layers of the film, creating bubbles that do not readily pass through the high viscosity surface. As the temperature increases further, the bubbles expand, finally bursting through the top layer, resulting in popping. The viscosity of the film meanwhile has increased enough so that the coating cannot flow together to heal the eruption. Popping can also result from entrapment of

air bubbles in a coating. Popping can result from solvent that remains in primer coats when the topcoat is applied. In coating plastics, solvents can dissolve in the plastic and then cause popping when a coating is applied over the plastic and then baked. Another potential cause of popping is evolution of volatile by-products of cross-linking.

Popping can be minimized by spraying more slowly in more passes, by longer flash-off times before the object is put into the oven, and by zoning the oven so that the first stages are relatively low in temperature. The probability of popping can also be reduced by having a slow evaporating, good solvent in the solvent mixture. This tends to keep the surface viscosity low enough for bubbles to pass through and heal before the viscosity at the surface becomes too high. Popping can be particularly severe with water-reducible baking enamels because of slow loss of water during baking, especially with high T_g resins. In contrast to increased probability of popping with higher T_g water-reducible coatings, popping is more likely to occur with lower T_g latex polymers. Coalescence of the surface before the water has completely evaporated is more likely with a lower T_g latex.

Foaming. During manufacture and application, a coating is subjected to agitation and mixing with air, creating the opportunity for foam formation. In formulating a latex paint, an important criterion in selecting surfactants and water-soluble polymers as thickeners is their effect on foam stabilization (269). Acetylene glycol surfactants, such as 2,4,7,9-tetramethyl-5-decyne-4,7-diol, are reported to be effective surfactants that do not increase the viscosity of the surface of bubbles as much as surfactants such as alkylphenol ethoxylates (270).

A variety of additives can be used to break foam bubbles. Most depend on creating surface tension differential driven flow on the surface of bubbles. Silicone fluids are effective in breaking a variety of foams, since their surface tension is low compared to almost any foam surface. Small particle size hydrophobic SiO_2 can also act as a defoamer and/or a carrier for active defoaming agents (270). Also, a small amount of immiscible hydrocarbon will often reduce foaming of an aqueous coating. Several companies sell lines of proprietary antifoam products and offer test kits with small samples of their products. The formulator evaluates the antifoam products in a coating with foaming problems to find one that overcomes the problem. While it is possible to predict which additive will break a foam in a relatively simple system, such predictions are difficult for latex paints because of the variety of components that could potentially be at the foam interface. The combination of surfactants, wetting agents, water-soluble polymers, and antifoam can be critical.

COEXTRUSION

Introduction

Multilayer coextrusion of thermoplastic film and sheet has developed into an important plastic fabrication process, providing large growth opportunities for the plastics industry. Coextruded multilayer plastics are challenging such traditional materials as metals, glass, paper, and textiles.

The attraction of coextrusion is both economic and technical. It is a single-step process starting with two or more plastic materials that are simultaneously extruded and shaped in a single die to form a multilayer sheet or film. Thus, coextrusion avoids the costs and complexities of conventional multistep lamination and coating processes, where individual plies must be made separately, primed, coated, and laminated. Coextrusion readily allows manufacture of products with layers thinner than can be made and handled as an individual ply. Consequently, only the necessary thickness of a high performance polymer is used to meet a particular specification of the product. In fact, coextrusion has been used commercially to manufacture unique films consisting of hundreds of layers with individual layer thicknesses less than 100 nm (1). It is difficult to imagine another practical method of manufacturing these microlayer structures.

Layers may be used to place colors, bury recycle, screen uv radiation, provide barrier properties, minimize die-face buildup, and to control film-surface properties, for example. Additives, such as antiblock, antislip, and antistatic agents, can be placed in specific layer positions. High melt strength layers can carry low melt strength materials during fabrication.

The largest market for coextruded films and sheets is in packaging applications, eg, two- or three-layer films for trash bags or five- to nine-layer structures for flexible and semirigid packages. As many as five different polymers may be used

Encyclopedia of Polymer Science and Technology. Copyright John Wiley & Sons, Inc. All rights reserved.

to obtain heat sealability, barrier, chemical resistance, toughness, formability, and aesthetics. Coextrusion is also suitable for applying thin multilayer films as coatings on substrates (2). Growing applications for coextrusion are in automotive, construction, appliance, and food packaging markets (see PACKAGING, FLEXIBLE; BARRIER POLYMERS).

Methods of Coextrusion

Coextruded films are produced by a tubular-blown film process and a flat-die, chill-roll casting process. Capital and operating costs for blown-film vs cast-film coextrusion lines are strongly dependent on product mix and utilization. Equipment suppliers provide comparative economic evaluations for specific products. Practical cast-film equipment has been discussed previously (3). Coextrusion dies are unique. Extruders used before the die and take-away equipment used afterwards are standard equipment for single-layer film manufacture of blown or cast film (see EXTRUSION).

Tubular-Blown Film Process. This process is more flexible with regard to the permissible polymer viscosity mismatch, control of film orientation balance in the transverse and machine directions through blow-up ratio, and easy randomization of film-thickness variations. Production rates are limited by flow rates per circumferential length of die (pressure drop) and cooling rates (heat transfer).

Casting Process. The flat-die, chill-roll, cast-film process is more suitable for high volume production on dedicated lines because of higher output rates obtained by wide dies and more efficient cooling on chill rolls. Cast films usually have better clarity than blown films because of rapid quenching, but uniaxial orientation can cause the film to split in the machine direction for some structures.

Coextrusion Dies

Tubular-Blown Film Dies (Circular Dies). Tubular coextrusion dies were the earliest dies used to make multilayer plastic film. Successful design requires formation of uniform concentric layers in the annular die land formed by the mandrel and adjustable or nonadjustable outer die ring. Early designs included center-fed dies that had the mandrel supported by a spider (4). Feedports arranged a concentric melt stream that was pierced by the mandrel as it flowed to the die exit, forming annular layers. Limitations of this early design were discontinuity and nonuniformity caused by spider-induced weld lines in the layers.

Another early design used stacks of toroidal distribution manifolds, so that as flow proceeded to the die exit, concentric layers were extruded on one another sequentially (5). The number of layers could be varied by changing the number of toroidal manifolds in the stack. The crosshead design of this die eliminated the spider support of the mandrel with its attendant weld-line problem.

The design most commonly used today is the multimanifold spiral mandrel tubular-blown film die (Fig. 1a). This die consists of several concentric manifolds, one within the other. The manifolds are supported and secured through the base of the die. Each manifold consists of a flow channel that spirals around the mandrel,

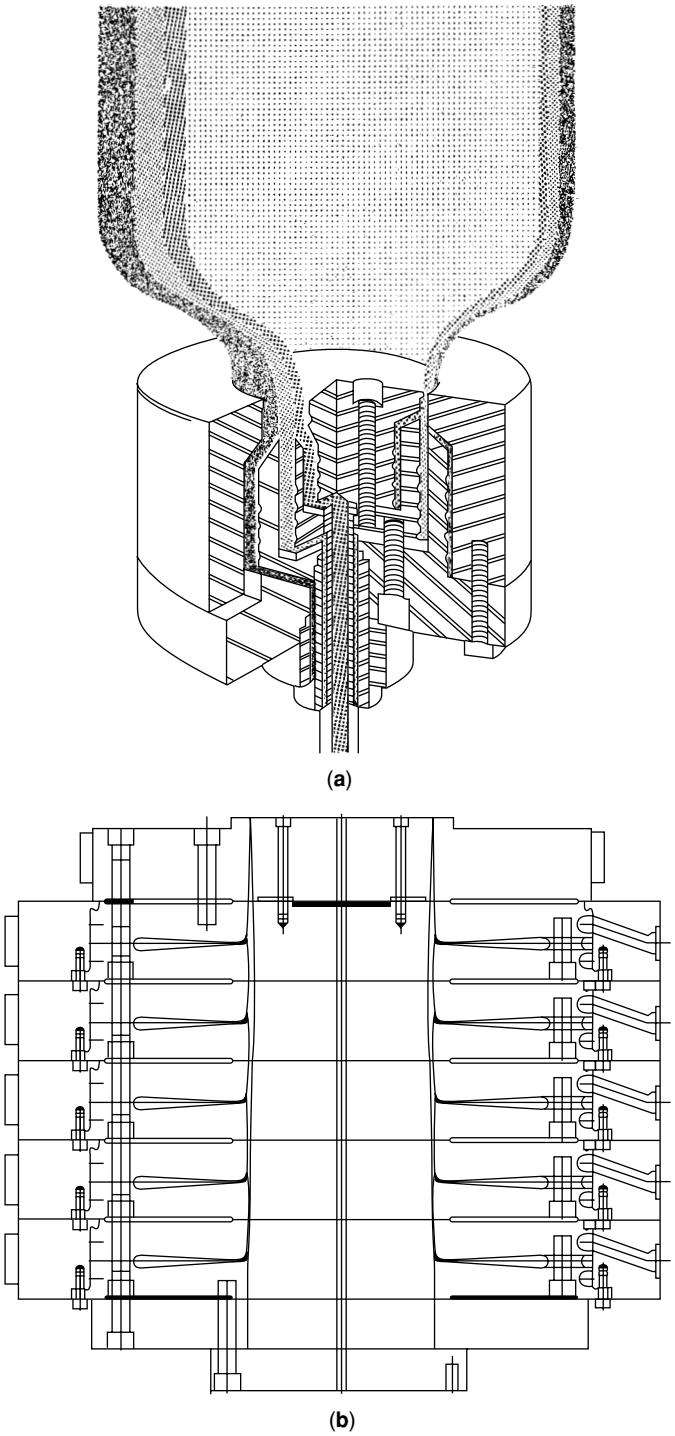

Fig. 1. (**a**) A three-layer blown film die and (**b**) a stackable blown film die.

allowing polymer to flow down the channel or leak across a land area to the next channel. This flow pattern smoothes out the flow of the polymer and minimizes any weld lines in the final film. While early designs were limited to two or three layers, dies containing seven or more layers are now offered commercially.

These dies must achieve uniform concentric flow of all layers because it is impractical to provide circumferential thickness adjustment for each layer. Most polymers are non-Newtonian, and polymer viscosity usually decreases with shear rate. Thus, rheological data obtained at the intended extrusion temperature and shear rate are needed to size manifolds and channels for layer uniformity and minimum pressure drop. Frequently, spiral mandrel manifolds, common in single-layer dies, are used to improve circumferential distribution. A well-designed spiral mandrel manifold can be helpful, but streamlining is necessary to minimize stagnation, residence time, and purging. A manifold design is only optimum for a particular polymer. Employing a polymer with significantly different properties may require a different manifold insert in the die in order to obtain satisfactory layer distribution.

Most tubular-blown film lines are designed for oscillation of the die or winder to randomize film thickness variations at the windup and avoid buildup of gauge bands, which can cause problems with film flatness. More layers complicate bearing and sealing systems in an oscillating die, but designs have now been refined to employ new sealing materials that minimize polymer leakage. New designs incorporate temperature control of individual annular manifolds to permit coextrusion of thermally sensitive polymers.

Another style of tubular-blown film die is the stackable plate die (Fig. 1b). In this style of die, each layer is spread uniformly and formed into a tube in a single plate. Plates are then stacked on top of each other and the layers are added sequentially. This style of die is becoming popular for specific applications since the number of layers can be adjusted by simply changing the number of plates in the die.

Tubular coextrusion dies are expensive, and care must be taken when disassembling and reassembling them to clean or change parts. Discussions of additional practical design, maintenance, and operating considerations have appeared (6–10).

Flat Dies (Slit Dies). Flat dies, also called slit dies because the orifice is a wide rectangular opening, are used in chill-roll, cast-film coextrusion. These dies are used almost exclusively for multilayer coextrusion with sheet thickness $>254\ \mu$m, as well as in coextrusion coating processes (2), where a multilayer web is extrusion-coated onto a substrate such as paperboard, aluminum foil, plastic foam, or textiles.

Another commercial application for flat-die coextrusion is biaxially oriented multilayer films (11) made with the tentering process to improve mechanical properties. Tentered film is biaxially oriented by stretching in the longitudinal and transverse direction, either sequentially or simultaneously, at uniform optimum temperature. In sequential stretching, the multilayer extrudate is cooled to a suitable orientation temperature on a first set of rolls and then stretched in the machine direction between a second set of rolls which is driven faster than the first set. The uniaxially stretched film then enters a tentering frame, which has traveling clips that clamp the edge of the film. The clips are mounted on two

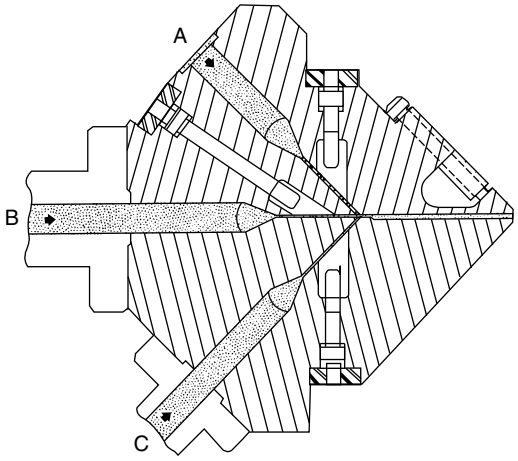

Fig. 2. Cross-sectional view of three-layer internal-combining multimanifold flat film or sheet die.

tracks that diverge inside a temperature-controlled oven increasing film width to provide transverse stretch. The film is then heat set and cooled. Simultaneous tentering frames are also used which feature accelerating clips that stretch the film longitudinally as they diverge transversely.

Two basic die types used in flat-die coextrusion systems are multimanifold dies and the feedblock/single-manifold die. A hybrid combines feedblocks with a multimanifold die.

Multimanifold Dies. For each layer, these dies have individual manifolds that extend the full width of the die. Each manifold is designed to distribute its polymer layer uniformly before combining with other layers outside the die (external combining) or inside the die before the final die land (internal combining).

External-combining dies are typically limited to two-layer coextrusion because two slit orifices must be individually adjusted with die-lip adjusting bolts. The webs are combined at the roll nip.

In principle, internal-combining dies are similar to multimanifold-tubular-coextrusion dies, except that the manifolds are flat (Fig. 2). With these dies, it is possible to regulate flow across the width by profiling an adjustable restrictor bar in each manifold to help obtain uniform distribution. However, wide dies require numerous adjusting bolts on each layer manifold along with die-lip adjustment to control final thickness; this can make them difficult to operate. Multimanifold dies have been sold, capable of coextruding five and six layers; they are expensive and require skilled operators. The principal advantage of multimanifold dies is the ability to coextrude polymers with very different viscosities since each layer is spread independently prior to combining.

A significant disadvantage of wide multimanifold dies is difficulty in coextruding very thin layers, such as thin cap (surface) layers, or thin adhesive (tie) layers used to bond two dissimilar polymers. Often these thin layers represent only 1 or 2% of the total structure thickness and are therefore extruded at a relatively low rate. With wide dies it is difficult to obtain uniformity when extrusion

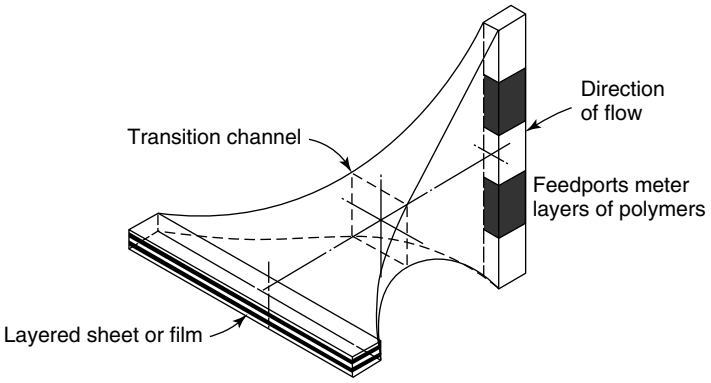

Fig. 3. The principle of the feedblock for coextruding multilayer film or sheet. Number of layers is equal to number of feedports.

rate per width is very low. Also, it is difficult to coextrude thermally- sensitive polymers such as poly(vinyl chloride) (PVC) and poly(vinylidene chloride) copolymers (PVDC) in wide dies because slow-moving material near the walls greatly increases residence time and thermal exposure.

Feedblock/Single-Manifold Dies. The feedblock method of flat-die coextrusion, originally developed and patented by The Dow Chemical Company, uses a feedblock before a conventional single-manifold die (12,13). A layered melt stream, which is prearranged ahead of the die inlet by the feedblock is extended to the width of the die as it is reduced in thickness (Fig. 3). Polymer melts from each extruder can be subdivided into as many layers as desired in the final product. Feedports arrange metered layers in required sequence and thickness proportions. A commercial feedblock/single-manifold die system is shown in Figure 4. Modular feedblock design similar to that illustrated can be used to change the number, sequence, or thickness distribution of layers by changing a flow programming module in the feedblock. Programming modules consist of machined flow channels designed to subdivide and direct flow of each material to specific locations and proportions required by the product.

The shape of the multilayer melt stream entering the die inlet can be round, square, or rectangular, as long as the feedblock is properly designed to deliver the layers to the die with constant composition (14). Some feedblock suppliers prefer round die entry design for ease of machining or retrofitting to old dies. Others prefer square or rectangular die entries for ease of design and minimization of shape change as the layer interfaces are extended to the rectangular die orifice. A thermally sensitive polymer can be encapsulated by stable polymers so that it does not contact the die walls, thus reducing residence time.

The fact that the multilayer stream at the die inlet is narrow (∼2.5–10 cm) compared to die width makes it relatively easy to meter thin surface or adhesive layers.

The versatility of the feedblock has made it the most popular flat-die coextrusion method. Large numbers of layers may be coextruded, layer structure may be readily altered with interchangeable modules, and thermally sensitive

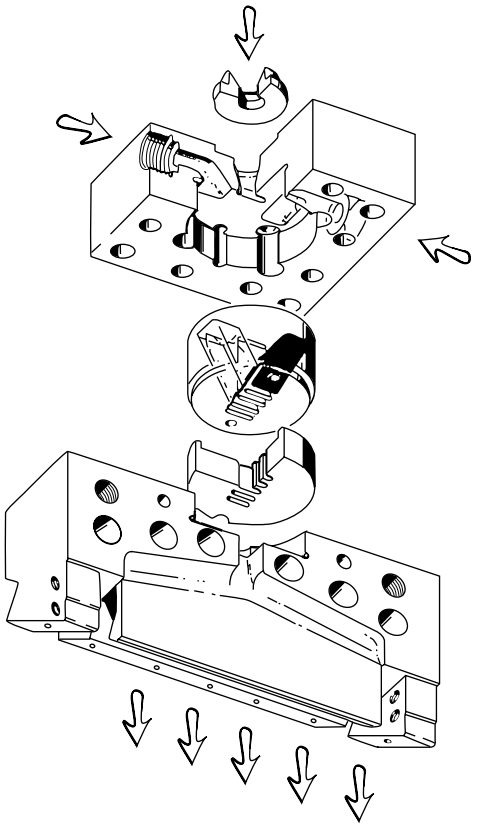

Fig. 4. Exploded view of modular feedblock and single-manifold die for three polymers forming a five-layer coextrusion.

polymers may be protected by encapsulation. It is estimated that over 95% of flat-die coextrusion systems use a feedblock.

One limitation of feedblocks is that polymer viscosities must be matched fairly closely because the combined melt stream must spread uniformly within the die. Severe viscosity mismatch results in nonuniform layers; the lower viscosity material tends to flow to the die edges. A crude rule of thumb is that polymer viscosities must be matched within a factor of 3 or 4, which is a reasonably broad range for many commercially important coextrusions. Layer uniformity may be adjusted by varying melt temperature within limits dictated by heat transfer. Increasing temperature decreases viscosity, and material moves from the center to the edges; decreasing temperature has the opposite effect. Typically, the individual polymer melt temperatures differ by as much as 30–60°C. Beyond that, heat transfer tends to nullify further adjustment by temperature variation.

Often polymers are intentionally selected with a mismatch in viscosities to avoid flow instabilities. Viscosity mismatch of a factor of 10 or more may be necessary. Layer nonuniformity expected with the mismatch is compensated by using shaped feedport geometry; that is, the layers are introduced into the die nonuniformly so that uneven flow within the die results in a satisfactorily uniform

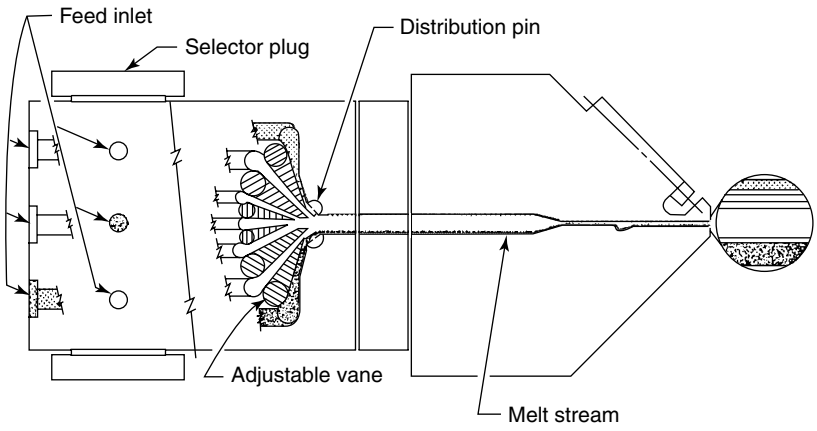

Fig. 5. Feedblock with movable vane partitions that adjust positions for different polymer viscosities and/or layer-flow rates.

final distribution. Considerable art has been developed to extend the range of viscosity mismatch that can be accommodated in a feedblock system by using compensating feedport geometry.

Some feedblocks are reportedly capable of coextruding polymers with viscosity mismatch of 100 or more (15). This style of feedblock has movable vanes that partition individual layers prior to combining (Fig. 5). The vanes may be freely floating, automatically seeking their equilibrium position on the basis of flow rates and viscosities. This self-adjusting feature can accommodate wide ranges in relative flow rates and viscosities while maintaining layer uniformity in the final product. The vanes may be rotated manually and locked into a nonequilibrium position to adjust uniformity further. Often distribution pins are used, or the vanes are profiled to compensate for nonuniform layers.

Combined Feedblock/Multimanifold Dies. Combinations of feedblocks and a multimanifold die are also used commercially. The multimanifold die can incorporate the same design principles as the feedblock, ie, vanes separating individual manifolds within the die. In a sense, the multimanifold die is a wide feedblock. A feedblock may be attached to one or more manifold inlets, as shown in Figure 6. With this system, polymers with widely different polymer viscosities and processing temperatures may be coextruded. A very viscous or high temperature polymer may be extruded through one or more die manifolds, while a thermally sensitive or much lower viscosity polymer is coextruded with adhesive layers through a feedblock feeding another manifold. Combining of all layers occurs prior to the final die land.

Rheological Considerations

Polymer rheology information is critical for designing coextrusion dies and feedblocks. The flow characteristics of the polymer must be considered when selecting materials for coextruded products (see RHEOLOGY).

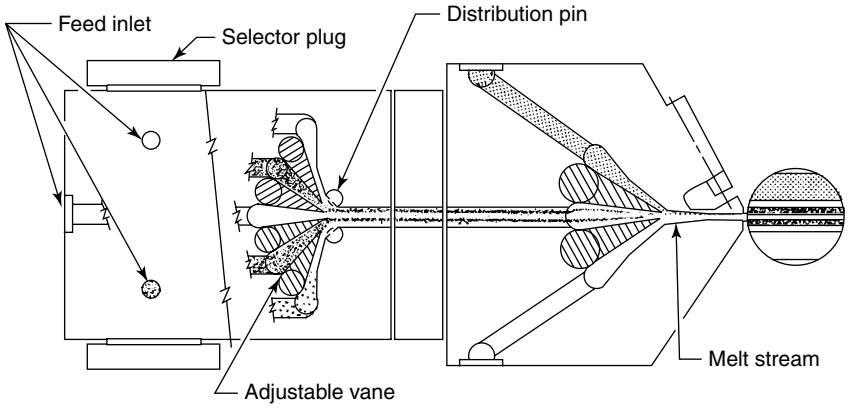

Fig. 6. Combination feedblock and multimanifold die system. Feedblock feeds center-die manifold.

The best designed die or feedblock does not necessarily ensure a commercially acceptable product. Layered melt streams flowing through a coextrusion die can become unstable leading to layer nonuniformities and even intermixing of layers under certain conditions. The causes of these instabilities are related to non-Newtonian flow properties of polymers and viscoelastic interactions.

Viscosities of non-Newtonian polymers are dependent on extrusion temperature and shear rate, both of which may vary within the coextrusion die. The shear rate dependence is further complicated in that it is determined by the position and thickness of a polymer layer in the melt stream. A polymer used as a thin surface layer in a coextruded product experiences higher shear rate than it would if it were positioned as a central core layer. There are several types of flow instabilities that have been observed in coextrusion.

Interface Distortion from Viscosity Mismatch. The importance of viscosity matching for layer uniformity was first studied in capillary flow of two polymers in bicomponent fiber production (16–19). Two polymers introduced side by side into a round tube experience interfacial distortion during flow if the viscosities are mismatched. The lower viscosity polymer migrates to regions of highest shear (at the wall) and tends to encapsulate the higher viscosity polymer. It is possible for the low viscosity polymer to encapsulate the higher viscosity polymer totally. Nature seeks the path of least resistance. The degree of interfacial distortion due to viscosity mismatch depends on the extent of viscosity difference, shear rate, and residence time.

Layer nonuniformities in feedblock fed flat dies occur for the same reason when there is a large enough viscosity mismatch. Low viscosity polymer migrates to wet the die wall. For unencapsulated layers, this migration starts in the die manifold as the layered stream spreads, resulting in increased layer thickness for low viscosity polymer at the edges of the film or sheet. If unencapsulated low viscosity polymer is a core layer, it not only becomes thicker at the edges but may even wrap around higher viscosity skin layers at the film edges.

Tubular-blown- film dies are more tolerant of viscosity mismatch because the layers are arranged concentrically, ie, there are no ends. Since streamlines

cannot cross each other, further migration cannot occur. However, good die design is required to obtain concentric layers.

Interface Distortion from Viscoelasticity. While matching the viscosities of adjacent layers has proven to be very important, the effect of polymer viscoelasticity on layer thickness uniformity is also important (20–24).

It has been shown that polymers that are comparatively high in elasticity produce secondary flows normal to the primary flow direction in a die that can distort the layer interface. This effect becomes more pronounced as the width of a flat die increases. Appropriate shaping of the die channels can minimize the effect of layer interface distortion due to elastic effects.

Coextruding a structure that contains layers of polymers with low and high levels of elasticity can cause interface distortion because of the differences in elasticity between the layers in flat dies. The effect is typically not observed in tubular dies.

Flow Instability. Interface distortion causes thickness nonuniformities, but the interface remains smooth. Other instabilities result in irregular interfaces and even layer intermixing in severe cases. These instabilities are related to viscoelasticity in non-Newtonian polymers. At low output rates, low amplitude waviness of the interface is observed, which is barely noticeable to the eye and may not interfere with the functionality of the multilayer film. At higher output rates, the layer distortion becomes more severe. If a large amplitude waveform develops in the flowing multilayer stream within the die, the velocity gradient can carry the crest forward and convert it into a fold. Multiple folding results in an extremely jumbled, intermixed interface. This type of instability has been observed in tubular-blown film dies, multimanifold dies, and feedblock/single-manifold dies.

This instability develops in the die land, and its onset can be correlated with a critical interfacial shear stress for a particular polymer system (2). The most important variables influencing this instability are skin-layer viscosity, skin-to-core thickness ratio, total extrusion rate, and die gap. Although the interfacial shear stress does not cause instability, elasticity is related to shear stress, and interfacial stress is used to correlate variables for a particular system.

Interfacial instability in a number of coextruded polymer systems has been experimentally correlated with viscosity ratios and elasticity ratios (25), and a simplified rheology review has been given (26).

This type of interfacial instability can be reduced or eliminated by increasing skin-layer thickness, increasing die gap, reducing total rate, or decreasing skin-layer polymer viscosity. These methods may be used singly or in combination. These remedies reduce interfacial shear stress, and stable flow results when it is below the critical stress for the polymer system being coextruded. Most often skin-layer polymer viscosity is decreased. In feedblock coextrusion the resultant viscosity mismatch imposed by this remedy can cause variations in layer thickness as discussed earlier. Shaped skin layer feedslots are then used to compensate.

Other types of instabilities may exist, for example, a problem has been observed in feedblock coextrusion of axisymmetric sheet (27). A wavy interface is also characteristic of this instability, but the wave pattern is more regular when viewed from the surface. The instability originates in the die, well ahead of the die land, and internal die geometry influences both the severity and pattern. For a given die geometry, the severity of instability increases with structure asymmetry and some polymers are more susceptible to unstable flow than others.

It has been suggested that this type of instability may be related to the extensional rheological properties of the polymers used in the coextruded structure (28).

No complete predictive theory exists for these complicated rheological interactions, but the accumulated experience of polymer producers, equipment suppliers, and experienced fabricators provides guidance in polymer selection.

Polymers for Coextruded Films

Polymers are chosen for individual layers to achieve special combinations of properties, eg, mechanical strength and stiffness, gas and water-vapor barrier, oil and grease barrier, heat seal, hot tack, Adhesion, optics, formability, machinability, and economics. Individual layers may be pure polymers or blends, sometimes with regrind or recycled scrap. The polymer layers are often formulated with color, antislip, antiblock, antistats, processing aids, fillers, biocides, oxygen scavengers, antifogs, flame retardants, nucleating agents, and stabilizer additives to enhance layer characteristics (29–35) (see ADDITIVES). Adhesive polymers are used as tie layers to bond dissimilar polymers that do not normally adhere to each other (see ADHESIVE COMPOUNDS).

Common polymers used in coextrusion applications are listed below with their abbreviations:

Name	Abbreviation
Low density polyethylene	LDPE
Medium density polyethylene	MDPE
High density polyethylene	HDPE
High molecular weight, high density polyethylene	HMW-HDPE
Linear low density polyethylene	LLDPE
Ultralow density polyethylene	ULDPE
Polyolefin plastomer	POP
Ethylene–styrene interpolymer	ESI
Ethylene–vinyl acetate	EVA
Ethylene–acrylic acid	EAA
Ethylene–methyl acrylate	EMA
Ethylene–ethyl acrylate	EEA
Cyclic olefin copolymer	COC
Ethylene–*n*-butyl acrylate	EnBA
Ethylene–methacrylic acid copolymer	EMAA
Ethylene–methacrylic acid salts	Ionomer
Ethylene–vinyl alcohol	EVOH
Poly(vinyl alcohol)	PVOH
Polyamide	PA
Poly(vinyl chloride)	PVC
Poly(vinylidene chloride) copolymers	PVDC
Polypropylene	PP
Polybutylene	PB
Poly(ethylene terepthalate)	PET
Glycol modified polyester	PETG
Poly(ethylene napthalate)	PEN

Name	Abbreviation
Poly(methyl methacrylate)	PMMA
Poly(hydroxyaminoether)	PHAE
Polycarbonate	PC
Polystyrene	PS
High impact polystyrene	HIPS
Acrylonitrile–methyl acrylate copolymer	AN/MA
Acrylonitrile copolymers	AN
Acrylonitrile–butadiene–styrene polymers	ABS
Styrene–butadiene block copolymer	SB

An individual polymer usually can provide several functions, but selection for each layer is determined by the key property that the polymer can contribute to the total film for a specific application.

Mechanical Properties. The coextruded film must have adequate tensile and impact strength, tear resistance, elongation, and puncture resistance for package integrity. LDPE, LLDPE, POP, HDPE, PP, nylon, ionomer, and EAA are typical resins used for toughness. Significant catalyst development has resulted in various forms of polyethylene copolymers. Ziegler–Natta catalysts produce linear copolymers with a broad short-chain branch distribution and a broad molecular weight distribution. Metallocene catalysts produce copolymers with a more homogeneous comonomer distribution and a narrower molecular weight distribution. Constrained geometry catalysts produce copolymers with a small but significant amount of long-chain branching, in addition to any short-chain branching from the comonomer, as well as with a more homogeneous comonomer distribution and a narrower molecular weight distribution. Metallocene and constrained geometry catalysts allow higher levels of comonomer and molecular tailoring for specific properties. In general, metallocene and constrained geometry catalysts have better optical properties, ESCR, impact strength, puncture strength, and tensile strength than Ziegler–Natta catalyst polymers. The lower density copolymers made possible with metallocene and constrained geometry catalysts, POP, demonstrate enhanced breathability for controlled atmosphere packaging applications. The lower density resins also have lower melting points and may be used as heat seal resins with good hot tack and seal integrity, allowing them to be substituted for EVA or ionomers. The open sites of the metallocene and constrained geometry catalysts also allow the copolymerization of different comonomers such as styrene and norbornene with ethylene. Metallocene technology has also been used for the manufacture of isotactic PP, syndiotactic PP, copolymers of PP with other olefins, and syndiotactic PS (36–45).

Most published film data is derived from monolayer film and as a first approximation, tensile strength of a coextruded film may be estimated from the percentage of each polymer present in the film according to the law of mixtures,

ie, the summation of the tensile strength per unit thickness of each layer, multiplied by its thickness, divided by total thickness. However, layer interactions can greatly influence mechanical behavior of composites. Favorable (synergistic) interactions provide mutual interlayer reinforcement (46,47), and the composite acquires better mechanical properties than expected from summation of the components as a blend (48–52). For example, when a normally brittle polymer layer is sandwiched between ductile layers which can inhibit crack propagation, the brittle layer may undergo greater deformation than is possible for it as an unsupported free film.

Unfavorable layer interactions can lead to mutual interlayer destruction, ie, failure in one layer leads to premature failure in normally ductile layers, causing catastrophic failure of an entire composite. In this case, the cracked layer acts as a notch to localize stress concentration in adjacent layers.

Layer multiplying enables structures with hundreds or thousands of layers to be produced. A layered melt stream from a feedblock is fed through layer multipliers. In each multiplier, the initial melt stream is divided vertically in two, spread horizontally, and then recombined, resulting in a doubling of the initial number of layers. Improved physical properties, mechanical, optical, barrier, and electronic, have been demonstrated. Synergistic combinations of the properties of the component polymers have also been reported. The failure mechanism of microlayered PC/SAN structures can be controlled, with layer thicknesses in the micron range demonstrating improved toughness and impact relative to conventional blends. Microlayering can also produce structures with aligned platelet fillers, demonstrating anisotropic physical, barrier, and electrical properties. Breathable films with high water vapor transition rates and good mechanical properties are obtained with a microlayered filled polypropylene/polyethylene oxide system. A number of companies have commercialized microlayer structures with unique optical properties. These structures have from 100 to 500 layers and total thickness from 1 to 2.5 mil. These films can be tuned to reflect or transmit different segments of the visible or near ir portions of the electromagnetic spectrum. Applications range from iridescent decorative films for packaging and labeling to metal free films that specularly reflect up to 98% of visible light from any incident angle for electronic display enhancement. Microlayer structures, with the ability to control the interface/volume ratio, have also been used for fundamental interdiffusion and adhesion studies (53–59).

Molecular orientation is another important factor influencing mechanical properties of coextruded films (11). Biaxial orientation can greatly improve film strength. However, uniaxial or highly unbalanced orientation causes poor transverse properties, which result in easy splitting of coextruded films in the machine direction. This tendency may occur even when a relatively thin layer responds to unidirectional orientation and propagates failure to thicker adjacent layers.

Therefore, although law of mixture calculations for multilayer films may be used for an approximate estimate of strength, it is inadequate for predicting layer interactions and ultimate film performance.

Mechanical properties measured on coextruded films include the effect of orientation during processing, as well as polymer–layer interactions. Optimization of film properties by plotting property against percentage composition of polymer combinations yields the most comprehensive picture of film performance.

Gas-Barrier Properties. Coextruded films are often used to provide a barrier to gases (oxygen, nitrogen, and carbon dioxide) and water vapor in packaging applications. PVDC, EVOH, acrylonitrile, nylon, PVC, and PET provide varying degrees of barrier to gases, flavor and aroma components, and organic fractions (60,61). A variety of nylon polymers are available including nylon-6, nylon-6,6, nylon-11, nylon-12, amorphous nylon, and MXD-6 (62) (see POLYAMIDES, PLASTICS). Coextruded films with liquid crystalline copolymers as well as with PCTFE have been reported (63–65). Poly(hydroxyaminoether) thermoplastics for barrier packaging have recently been commercialized (66). Table 1 gives comparative oxygen permeabilities for several plastics based on 25.4-μm thickness at 23°C. Various aspects of film barriers have been reviewed (67–70) (see BARRIER POLYMERS).

At steady state, gas-transmission rate through a given layer is inversely proportional to its thickness. The total transmission rate through a multilayer film may be calculated by treating the contribution of each layer as resistances in series (71). For many coextruded films the overall transmission rate is controlled by the high barrier layer, ie, the layer with lowest transmission rate. Gas-transmission rates through polymers increase with temperature. Some polymers, such as EVOH, are moisture-sensitive, and oxygen-transmission rate increases with relative humidity. Therefore, application of coextruded barrier films to packaging requires knowledge of the package environment during filling, processing, shipping, and storage. Data comparing EVOH and PVDC suggest an aggregate oxygen exposure index to evaluate barrier coextrusions under varying environmental conditions (72).

Inadequate understanding of product barrier requirements poses a package-design problem in predicting adequate shelf life from gas-transmission data.

Langmuir kinetic theory has been discussed for prediction of barrier requirements (73), but packagers still must rely on extensive shelf life testing of individual food products in candidate barrier films.

Table 2 gives water vapor transmission rates for several polymers. The ranking of polymers for water vapor transmission is different from ranking them for

[b] See listed abbreviations in "Polymers for Coextruded Films" section.

oxygen transmission. LDPE, HDPE, and PP are economical barrier polymers to water vapor. PVDC is one of the few polymers that provide an excellent barrier to both oxygen and water vapor.

Barriers to aromas and flavors are very important in packaging and cannot be predicted from common gas-barrier data. Nylon has a good aroma barrier for certain snack-food packaging (74). Flavor scalping is also important in some applications.

Oil and Grease Barrier. Oils and grease must be retained in the packaged product for product quality and must not degrade the package, its printing, or customer appeal. Nylon, EAA, and ionomers are good oil- and grease-barrier materials.

Adhesion. Successful combination of coextruded film layers has been described in terms of rheological compatibility, surface tension and melt viscosity at processing temperature, interfacial behavior at the surfaces between layers, chemical interaction between two combined materials, crystallinity, and shear compatibility between components of the composite (67). Critical factors in layer bonding are polymer functionality (chemical composition), melt temperature, time in contact at temperature, viscosity of the joining layers, layer thickness, thermal stability, orientation, quench rate, and moisture sensitivity.

No comprehensive theory exists for predicting interlayer adhesion in coextrusion (see ADHESION). Most knowledge comes from trial-and-error testing that has led to qualitative rating charts for polymer adhesion such as the one shown in Table 3. Polymer or copolymer functionality plays a strong role. Polar polymers tend to adhere to each other; adhesion is difficult between nonpolar polymers. Some polymers form covalent bonds in addition to H-bonding, acid–base, ionic, and dipole–dipole interactions (75–78).

Tie layers are used to adhere incompatible layers of dissimilar polymers. EVA, EMA, EAA, EEA, EnBA, SB, and ionomer are frequently used copolymers. The importance of tie layers for coextrusion has led material suppliers to develop new chemically modified polymers for specific applications. Tie layers also contribute physical properties, optics water barrier, modulus, thermal resistance,

[e] Chlorinated polyethylene.

and toughness. Examples include a family of Plexar resins by Equistar (79), a series of CXA resins by DuPont (80), and Mitsui's Admer adhesive resins. Greater development of extrudable adhesive polymers is expected.

Heat Seal. Heat sealability characteristics of a structure are controlled by the outer surface layers and the type of seal geometry used to form a package. Heat-seal layers must fuse and adhere to themselves and other layers. Seal strength, heat-seal temperature range, and sealability through contaminants (81) are important to high fabrication rates and package integrity. LDPE, POP, EVA (82), EAA (83), ionomer (84), and LLDPE are common seal-layer materials. LDPE is the standard multiple-purpose layer, whereas EVA has outstanding low temperature seal and seal range. EVA is frequently coextruded with HDPE to prevent the puckering that occurs when HDPE is heated to its softening point to form a heat seal. The higher softening temperature of HDPE allows use of hotter heat-seal bars. EAA, POP, and ionomers are strong and seal through contaminants (85–87). A resin's hot tack, ie, the ability of a molten seal to resist separating force,

determines the rate at which the polymer can be sealed. LDPE, LLDPE, POP, EVA, EAA, and ionomer are materials of choice.

Machinability. Packaging films must run through printing presses and package-forming machinery without marring, hang-up, wandering, or deformation. Combinations of LDPE, PP, and PET are selected for structure-fabrication needs. PC is being investigated as a high modulus layer that can provide toughness without orientation and compete with oriented PET.

Optical Properties. Many packages need sparkling clarity to display their contents (see OPTICAL PROPERTIES). Other packages have printing over nearly all of the surface area or the product must be protected from uv radiation. White, brown, and black pigmented layers are combined to protect light-sensitive products.

The gloss and haze of a coextruded structure are modified by particular layers in the structure. The total haze exhibited by a film depends on the surface haze and the internal film haze. Placing a high haze layer on the inside of a film and low haze layers on the outside surfaces improves the haze of the buried material. The outside layer controls the gloss. Modification of haze gloss may be obtained with processing conditions, processing aids, nucleating agents, and other additives. In the case of cast films, a polished roll gives a high gloss, low haze film with tack. A matte chill roll produces a dull surface.

High Temperature Dimensional Stability. Dimensional stability at elevated temperatures is important in high temperature filling, sterilization applications, and microwave oven lidding. Resistance to physical deformation under load is linked to physical distortion of the part or package. HDPE, PP, nylon, and PET are suitable for high temperature applications. Coextrusion of PC with barrier polymers is being developed for high temperature barrier packaging (88).

Economics. An advantage of coextrusion is the capability of combining layers of high performance resins with low cost resin layers to produce high performance/low cost composite structures. The use of recycled and scrap resins in buried layers further improves economy. Multilayer extrusion economic considerations have been calculated (89). The effect of recycle on film properties, eg, tensile strength, impact, and elongation, depends on the degree of compatibility of polymers in the recycle layer. Often the tie-layer polymer acts as a compatibilizer for recycle. Recycle of incompatible polymers with different refractive indexes usually causes haziness and cannot be used when excellent optical properties are required.

Aesthetics. Coextruded layers may be colored for appearance, light screening, or coding. White is used as a printing background or a cleanliness layer adjacent to the product. Colors are used to designate sterile and nonsterile surfaces; black and brown screen uv light. Coextruded film composed of over 100 layers of alternating materials with different refractive indexes produces a vivid iridescence used in decorative applications (1,90). If gloss is essential, a thin surface layer of a high gloss polymer can be coextruded to give the package sparkle for marketing appeal.

Formability. Materials with a broad softening range, such as PS and PC, can be thermoformed into deep-draw package shapes. Crystalline polymers, eg, HDPE and PP, are more difficult to thermoform, but solid-phase forming processes below the melting point are possible. Multilayer semirigid barrier containers are made by Shell's Solid Phase Pressure Forming Process and the patented Dow

Scrapless Forming Process (91–94) that is being developed by Cincinnati Milacron. An advantage of the latter process is that round containers may be made from square blanks cut from sheet without the trim scrap normally associated with sheet forming.

Applications

Flexible packaging is important in several markets. Stand-up pouches have grown significantly in the pet foods and agricultural chemical markets. In 2002, food packaging will be over half of the $9.7 billion converter sales in flexible packaging. Case ready meats, growing at 21% annually through 2002, is the fastest growing segment of the perishables market. Structures include clear antifog lidding material, high barrier films, and high abuse shrink films. High or moderate barrier materials will exhibit a 5% growth rate in flexible foodservice pouches. Dry foods markets include snacks and candy, cereals, pet food, and coffee, all of which are growing approximately 5% annually. Consumer and industrial markets include healthcare packaging growing (6% annual growth), medical disposables (8% annual growth), agricultural packaging (4% annual growth), and palletizing and unitizing (9% annual growth) (95–99). Future developments are expected to focus on high barrier coextruded films for longer shelf life and better control of product quality. Products now packaged in conventional materials such as glass and metal will be packaged in more efficient coextruded materials.

Structure design requires careful selection and planning because of the multitude of possible choices regarding material combinations, layer placement, layer thickness, etc. Often a coextruded film is further processed by lamination and coating into more complex structures to meet specific product application requirements. Theoretical design and product testing must be combined to yield the most efficient film structure for a specific application. Table 4 shows common designs that have evolved for the principal markets (100–102).

Agricultural films for mulch, greenhouse, and fumigation is illustrative. Films have been developed to capture a specific portion of the light spectrum. Films that absorb or block certain ir wavelengths and films with a specific color designed for a particular crop have been developed. Solarization films generate heat, raise soil temperature, and sterilize the soil. Light stabilizers are added to extend the life of greenhouse films on one hand while other films have been developed to minimize disposal costs at the end of the growing season. Coextruded barrier films that have 1000 times the methyl bromide barrier of a monolayer polyethylene film are also available (103).

Commercial applications for coextruded multilayer sheet began later than for films, but volume has been growing rapidly and now exceeds that of films. The largest use of coextruded sheet is in thermoformed semirigid containers. The earliest applications were two- and three-layer sheet of similar polymers, such as PS two-color drinking cups, disposable dinnerware, and dairy tubs for cottage cheese and margarine. These dairy containers had a thin gloss layer of crystal PS coextruded on HIPS for marketing appeal. Because the layers were compatible in these easily thermoformed structures, problems with trim-scrap recycle were minimal. The disposable containers were usually coextruded as three layers with

Table 4. Film Structures for Principal Markets

Markets	Typical structures[a]
Trash bags	LDPE/LLDPE/LDPE
Waste disposal	LDPE/LLDPE
	EVA/LLDPE
	LLDPE
	LLDPE/LDPE + regrind
	HDPE/regrind/LLDPE
Stretch film	LDPE/LLDPE/LDPE
	EVA/LLDPE/EVA
	LDPE/LLDPE
	LDPE/LLDPE + regrind/LDPE
Shrink Film	EVA/LLDPE/EVA
Tray wrap	LDPE/EAA
Meat packaging	
Primal, subprimal packaging	EVA/PVDC/EVA
	EVA/PVDC/EVA/ionomer
	Nylon/adhesive/EVA
	Nylon/ionomer
Bacon/luncheon/weiners	Nylon/EVA/ionomer
Flexible, formed web	Nylon/PVDC/adhesive/EVA–ionomer
	Nylon/adhesive/EVOH/adhesive/ionomer
	PVC/PVDC/EVA
	Nylon/EVOH/EVA/ionomer
Flexible, nonformed webs	PET/adhesive/EVA–ionomer
	PP/adhesive/EVA–ionomer
	PVC/PVDC/EVA
Rigid formed web	AN, MA/adhesive/EVA–ionomer
	PETG[b]/adhesive/EVA–ionomer
Cooked ham	Nylon/adhesive/ionomer
	PP/adhesive/nylon/adhesive/ionomer
Poultry	
Individual bags	LDPE/EVA
	HDPE/EVA
	HDPE/ionomer
Bulk barrier bag	EVA/HDPE/LDPE/ionomer
	HDPE/EVA
	HDPE/ionomer + PVDC coating
Snack foods	OPP, white LDPE, white HDPE/EVA–ionomer
	HDPE/adhesive/nylon/EVA
	HDPE/EVA–ionomer blend
	HDPE/ionomer/EVA
	HDPE/ionomer/nylon/ionomer
	White HDPE/brown HDPE/EVA
Cookies/crackers, bakery	HDPE/EVA
	HDPE/HDPE/EVA
	HDPE/MDPE/EVA
	PP/adhesive/EVA

Table 4. (Continued)

Markets	Typical structures[a]
Cereals	
Low barrier	HDPE/EVA
	HDPE/HDPE/EVA
	HDPE/HDPE/EVA–ionomer blend
Medium barrier	HDPE/adhesive/EVOH/adhesive/EVA
	HDPE/adhesive/nylon/adhesive/EVA
Cheese	PP/PE
	Nylon, PVDC, LDPE/ionomer
	LDPE/PVDC/LDPE/ionomer
	EVA/PVDC/EVA
	LDPE/PVDC/LDPE/adhesive/EVA
Frozen food	EVA/white LDPE/EVA
	EVA/white LLDPE/EVA
	PET/adhesive/LDPE–ionomer
Heavy-duty bags	LDPE/PVDC/LDPE
Shipping bags	LDPE/EVA
	LDPE/LLDPE/EVA
	LDPE/HDPE/EVA
	LDPE/LLDPE
	Chlorinated PE/EVA
	White LDPE/black MDPE–EVA
Medical	White LDPE/colored LDPE
	White ionomer/LDPE/colored EVA
	Plexar/nylon/LDPE/Plexar/nylon/Plexar
	PET/LDPE
	Nylon/LDPE
	LDPE/PVDC/LDPE

[b]Poly(ethylene glycol-co-cyclohexane-1,4-dimethanol terephthalate).

mixed-color scrap as a buried layer. The marketing appeal and ease of fabrication of coextruded semirigid containers quickly saturated those market applications. The principal growth area is in high barrier, semirigid food packages for long shelf life applications in competition with metal and glass for unrefrigerated storage. These advanced coextruded structures were developed in Europe during the 1970s and combine as many as five dissimilar polymers into six- to -nine layer structures (Fig. 7). A relatively thin barrier layer is coextruded with one or more bulk structural layers of HDPE, PP, or HIPS to provide package strength and rigidity. Often a thin surface layer as the interior of the package provides heat sealability for the lid stock to the container flange. In other applications, a hermetic seal is made by double seaming a metal can end onto the plastic container body. Adhesive layers bond the barrier layer to the structural layers. Often a pigmented, light barrier layer is included as an inner layer for food products that are sensitive to uv light.

Early European applications for barrier sheet were in form-fill-seal (FFS) packaging of soft cheese, fruit drinks, jams, jellies, and condiments, and high temperature-short time sterilized milk. FFS packaging (where roll stock is

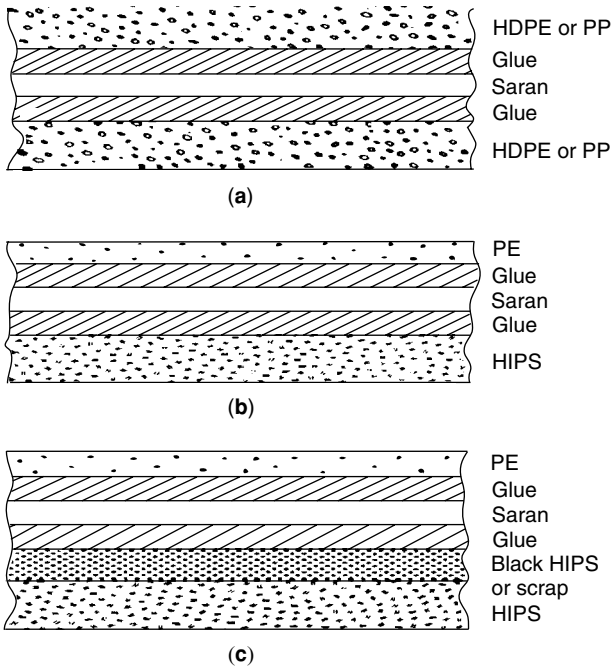

Fig. 7. Typical coextruded sheet structures used for barrier food packaging. Functional properties: (**a**) retortability, high oxygen and moisture barrier (three extruders); (**b**) heat sealability, oxygen and moisture barrier, low taste and odor transfer, thermoformability (four extruders); (**c**) oxygen and moisture barrier, uv light protection, heat sealability, thermoformability (five extruders).

converted into packages, filled with product, and sealed in the customers plant) minimizes scrap recycle. Round FFS packages have square heat-seal flanges so that most of the material is used in the package. However, the desire to use round preformed containers and to make more economical use of materials has stimulated recycling of multilayer scrap of dissimilar materials as a buried core layer. Sometimes this recycle layer is a black, pigmented uv barrier layer.

Selection of the bulk structural layers to be coextruded with the barrier polymer layer depends on package strength requirements, rigidity at minimal wall thickness, and package temperatures during product filling, thermal processing, and storage. In many FFS packaging applications, the food product is filled at ambient or low temperatures (74°C), and HIPS is chosen for its modulus and ease of forming. Most FFS machines are designed to form HIPS.

Products requiring higher fill temperatures have layers of HDPE or PP. Heat-sterilized containers heated up to 121°C employ PP, although HDPE can be used for retort temperatures up to about 112°C. HDPE has better low temperature impact properties than PP, which may be important in distribution and warehousing. HDPE and PP are more difficult to thermoform than HIPS; PP usually undergoes solid phase forming. Fillers are sometimes added to improve polyolefin stiffness and formability.

An alternative to high temperature retort sterilization of shelf-stable foods in the package is aseptic packaging in which a sterile food is packaged in a commercially sterile environment. In one technique the container is sterilized with a hydrogen peroxide solution before it is filled and sealed in a safe environment. A second technique, invented by the French company, ERCA, and licensed to Continental Packaging, uses a novel sacrificial layer to provide a sterile package interior. Continental's FFS machine, the Conoffast System, has the forming and filling stations in a safe environment. Roll stock of coextruded PP/PE/tie/PVDC/tie/black HIPS/HIPS is fed into the machine where the PP layer is separated, exposing a sterile PS layer. The barrier sheet is formed, filled, and then sealed with a second sacrificial-layer lid stock.

Formed multilayer barrier packages, eg, trays, bowls, and cans from coextruded PP/PVDC/ PP, are being developed for soups and entrees that can be stored at ambient temperatures and heated to serving temperature in a microwave oven. Coextrusions of high performance, high temperature polymers, such as polyetherimide and polysulfone, for dual-oven containers capable of withstanding conventional bake-oven temperatures of 204–232°C are being tested.

In addition to packaging markets, sheet coextrusion is applied in construction, recreational vehicle, and sanitaryware markets where weatherable or chemically resistant layers are coextruded with low cost polymers.

Continuing development of coextruded film and sheet structures from combinations of high performance polymers with low cost polymers and improved adhesive resins will expand the market opportunities for plastics in competition with other materials. Easy combination of many layers and a better understanding of synergistic behavior in multilayer film and sheet will also lead to new applications.

COLORANTS

Introduction

Colorants for plastics can be grouped into two broad categories: pigments and dyes. Pigments are organic or inorganic colored, white, or black materials. They are nearly insoluble in plastic. Dyes are intended to dissolve or go into solution in a given polymer. Physical forms for dyes and pigments can range from dry prills or powder to liquids. These forms can be used as is or can be preincorporated into compatible dispersions. The colorant supplier or concentrate supplier can manufacture predispersions. A concentrate supplier usually adds additional value-added steps such as additive packages and color matching.

The main considerations when selecting colorants usually include dispersion, migration resistance, heat stability, light stability, and cost. All are dynamic and change with concentration of the colorant, processing conditions, part thickness, and additives. Similarly, changes in properties can be expected for a single pigment type depending on supplier.

Dispersion

Dispersion relates mainly to pigment. The pigment manufacturing process usually leaves a variety of particle sizes and distributions. Primary particles are true single crystals of pigment. Nonetheless, aggregates and agglomerates are also present. These are single pigment particles that are joined together. To provide good color strength and physical properties these particles must be separated. Use of wetting agents combined with shear is the key to agglomerate and aggregate reduction.

Encyclopedia of Polymer Science and Technology. Copyright John Wiley & Sons, Inc. All rights reserved.

Migration. Migration refers to dissolved portions of a dye or pigment bleeding or blooming (1). Simply, the color is transported to the surface and can be wiped off or imparts unwanted color to an adjoining part. Dyes should be thoroughly evaluated, as they are naturally soluble. A pigments' tendency to migrate increases with the processing temperatures. When pigments are being used at the thresholds of their heat stability and/or at very low levels, caution should be observed. Plasticizers are known to facilitate migration; therefore plasticized poly(vinyl chloride) (PVC) is a good medium for evaluation.

Thermal Stability. Thermal stability of a colorant is important as thermoplastics have different melt processing temperatures and thermosets have different cure temperatures. Color changes in a pigmented or dyed polymer system usually originate from one of the following mechanisms: *Thermal decomposition* – degradation occurs if a pigment is processed above its decomposition temperature. This can be rapid as in the case of pyrazolone, Pigment Red 38; it totally decomposes at 218°C and turns brown. Decomposition can also be a slow gradual process as in the case of some quinacridones. They decompose slowly at 300–350°C. *Chemical substitution* – it is less common but can occur. In PVC some of the azomethine pigments can shift color rapidly at temperature above 160°C. The copper complex can be substituted by atoms from barium/cadmium and lead stabilizers. *Crystal shift* – polymorphous materials may undergo crystal phase transitions. Phthalo blue is a classic example. The alpha crystal can convert back to the more stable beta crystal. *Particle size or crystal growth* – pigment particles can grow in a hot solvent. As they grow a decrease in chroma and tinting strength can be observed. *Solubility* – a pigment if processed at higher than recommended temperature range can fully or partially dissolve. The fugitive material will generally change color and reduce the other properties of the colorant.

Light Stability and Weatherfastness. *Light stability and weatherfastness* are defined by the ability of a pigment or dye, in plastic, to retain its color upon exposure to sunlight and/or atmospheric impacts. If the polymer is not correctly stabilized for uv it will degrade at a rate that may negate the colorants performance. Conversely, uv stabilizers cannot greatly improve the stability of a colorant that has poor fastness properties. Lightfastness and weatherfastness are largely dependent on the particle size of a colorant. This is understandable as the job of a colorant is to absorb and reflect light. Failure of the pigment in most cases is not abrupt. A darkening of color occurs when used in masstone, and a loss of chroma and strength can be observed in the tint. The color changes layer by layer.

Cost. The broad spectrum cost for colorants is from $6.00 to $200.00/kg. Accordingly cost is as important as the above properties. Color matching and color formulation is critical. An effective colorant package should meet the needs of the application, provide a slight safety factor but not significantly exceed the properties required. As with most things, "you get what you pay for." This is also true for colorants. In most cases, the better the properties the higher the price. When comparing colorants for value, do not focus on the price alone, as this method can be misleading. Focus on the strength or amount needed for a specific application, ie "value in use."

As in many raw materials there can be large differences in properties among a pigment type. A single supplier can have a variety of Pigment Blue 15:3s. The product line can cover a range of transparency, dispersions, heat stabilities, cost,

FDA approval, shade, and physical forms. By factoring in those Pigment Blue 15:3s offered by a multitude of other suppliers the number can grow exponentially. There are many varieties of each pigment type that is discussed.

FDA Colorants. Because of the large amount of pigment used in packaging, house wares, and food-processing equipment, a colorants impact on health and safety should be considered. The U.S. Federal Government by way of the Food and Drug Administration (FDA) regulates food additives. Pigments that are used to color materials that come in contact with food are deemed to be indirect additives (2). This is based on the assumption that the pigment will extract from the plastic article and become part of the food. The FDA has published a list of sanctioned colorants. The list was introduced in Title 21 of CFR 178.3297 "Colorants for Polymers" and 175.300 for resinous and polymeric coatings. CFR 178.2600 may also be of interest when dealing with rubber articles. In very general terms, the pigments listed in these articles are suitable as components for plastic products used in producing, manufacturing, packaging, transporting, or holding food. In recent years the FDA has added new colorants or expanded usage of previously listed colorants. Some have limitations in regard to a colorants percentage and the resin to be incorporated. Current FDA regulations should be referenced for details.

Inorganic Pigments

Whites.

Titanium Dioxide. Titanium dioxide is the most common white of choice and by weight; it is actually the most widely used pigment. Product selection can be difficult as the variety can be staggering. Focus on particle size and surface coating during the selection process. Particle sizes usually range from 0.20 to 0.35 μm. Most plastic grades are manufactured to minimize reactivity. Reactive sites are masked with surface coatings of alumina, silica, and silicone fluid. This process increases dispersion and improves weatherability.

Titanium dioxide has a high Mohs' hardness and is very abrasive. Its outstanding importance is due to its light scattering properties, its FDA approval, and excellent properties. Its large particle size provides ease of dispersion, excellent heat stability, migration resistance, and lightfastness at a typical cost of less than $2.00/kg. Titanium dioxide is used in nearly all plastics to provide pastels and to adjust colors. The opacity is valued for ascetics and its ability to absorb uv radiation. In fiber, titanium dioxide pigments provide a matte finish that eliminates the undesirable oily appearance caused by translucence. *Rutile* titanium dioxide is the first choice for most plastic applications. The shade is slightly yellow. If desired, very small amounts of blue or violet can be used to provide a cooler white. *Anatase* titanium dioxide is less yellow, not highly recommended for outdoor use, blocks less uv radiation and is generally more reactive.

Zinc Sulfide. Zinc sulfide pigments were developed in 1850. They still have some use in plastic because they are less abrasive and can have a smaller particle size. However, after the introduction of titanium dioxide in the 1950s they have continually lost market share.

Zinc Oxide. Zinc oxide has lost importance as a pigment but is noteworthy for its use as an activator for accelerating vulcanization in rubber (3).

Carbon Black. Carbon blacks are not only valued as colorants but for the functional benefits they provide. They improve weatherability of plastics by blocking ultraviolet, visible, and infrared radiation. They can act as free-radical traps and provide a wide range of electrical properties. Fineness, structure, porosity, and surface chemistry are properties used in selection of a carbon black. Typical particle size is from 18 to 80 nm. Keep this in mind when considering loading levels. It can require a large quantity of resin to wet out the pigment.

For practical purposes there are two basic types of carbon black, channel and furnace. Burning enriched natural gas makes *channel black*. Channel black has become nearly obsolete with increased natural gas prices. They still find some use in plastics for FDA and special applications. *Furnace black* is produced by thermal decomposition of feedstock oil for petroleum refineries. Channel black has been all but replaced by furnace black.

Iron Oxide. Iron oxide pigments find value in plastics as they are nontoxic, chemically stable, and low in cost, and are offered in a variety of shades. They can be naturally occurring, *natural iron oxides*, or they can be synthesized, *synthetic iron oxides*. There are four basic types and thus four colors of iron oxide pigments, yellow, red, brown, and black. Synthetic iron oxides are much purer, have better tinting strength, and vary less in composition. As a consequence, they have nearly replaced natural iron oxides. Natural iron oxides still find use in cellulose and phenolics. In cases where black is required at low levels, iron oxide is often the pigment of choice. It has much lower strength than carbon black whereby larger amounts can be used. This allows for a more homogenous mixture and contributes less in weighing errors. Red, yellow, and brown can be used in most plastics. They have good durability but are dull. Use caution with the yellow (ferric hydrate) as water can be driven at temperatures above 175°C and shift the color red.

Chromium Oxide Green. Chromium oxide green is a dull olive green. It has excellent heat and weatherfastness. Its large particle size offers easy dispersion. Its reflectance is similar to that of chlorophyll, making it suitable for camouflage (3). However, its lack of tint strength and other suitable colorants in this color space exclude it from significant use.

Iron Blue. Iron Blue or Pigment Blue 27 has replaced the older names of Paris blue, Prussian blue, Berlin blue, and Toning blue, etc. It is ferric ammonium ferrocyanide [$FeNH_4Fe(CN)_6$]. It finds little use in plastics at present. It is mixed with chrome yellow to form chrome green. Chrome green offers a low cost opaque green that finds some use in polyethylene film. Caution should be used as it has little alkali resistance.

Ultramarine Pigments. Ultramarine pigments are a complex of aluminum sulfosilicate. *Pigment Blue 29* is most common though; *Pigment Violet 15* and pink *Pigment Red 259* are also available. The blue can be used in almost any polymer; the pink and violet have maximum processing temperatures of 200°C. All have poor acid resistance. Surface-treated grades do provide better acid resistance and dispersion. They do not promote shrinking or warpage and are approved worldwide for coloring of food-contact plastics. The most popular is blue. Blue has its uses in plastics but is now often replaced by phthalocyanines that have 10 times the tint strength.

Mixed Metal Oxides. The term MMO (mixed metal oxides) denotes a pigment that crystallizes in a stable oxide lattice. They are manufactured by heating combinations of metal salts to temperatures of 800–1400°C. They are regarded as solid solutions and so some prefer to call them "complex inorganic color pigments." The following are some of the colors produced: Cobalt blue – *Pigment Blue 28* ($CoAl_2O_4$) and *Pigment Blue 36* ($Co(Al,Cr)_2O_4$), cobalt green – *Pigment Green 50* ($(Co,Ni,Zn)_2TiO_4$), zinc iron brown – *Pigment Yellow 119* ($ZnFeO_4$), spinel black – *Pigment Black 28* ($Cu(Cr,Mn)_2O_4$) and *Pigment Black 22* ($Cu(Fe,Cr)_2O_4$). nickel rutile yellow – *Pigment Yellow 53* and chromium rutile yellow – *Pigment Brown 24* are commonly referred to as titanates.

Compared with organic pigments they lack clean hues and tinting strength. Compared with most inorganics they are considered expensive and hard to disperse. Nonetheless, they are indispensable in high heat applications and their weatherfastness and chemical resistance are outstanding. Use in engineering resins for automotive interior and under-the-hood application is common. MMOs are also important tools for coloring rigid PVC siding.

Lead Chromates and Lead Molybdates. Lead chromates and lead molybdates are characterized by their bright hues and good opacity. The pigments of importance are chrome yellow – *Pigment Yellow 34* and molybdate red and orange – *Pigment Red 104*. Because of the toxicity of lead and hexavalent chromium these pigments are forbidden from many uses. As a result, formulation into plastic has declined at a considerable rate. They are susceptible to acids, alkalis, and hydrogen sulfide. Surface treating of the pigments improves the weathering, chemical resistance, and heat stability. They are readily blended with each other and are often shaded with quinacridones to provide a variety of colors. Environmental regulations have caused a significant downturn in use. They are/have been replaced by high performance inorganic pigments where applicable.

Cadmium Pigments. Among the inorganic pigments, cadmium pigments are known for their bright shades. Their physical properties allow their use in most plastics. They are very heat stable, weatherfast, chemical resistant, and easy to incorporate. They also show good dimensional stability in large injection molded parts. These pigments are sensitive to overgrinding. The colors range from yellow through maroon (yellow, orange, red, bordeaux).

The pigments are cadmium sulfides and selenides. These raw materials are precipitated, dried, and calcined at 600°C (3). They usually undergo a dilute acid wash to remove impurities. Cadmium orange (*Pigment Orange* 20) is pure cadmium sulfide. Cadmium yellow (*Pigment Yellow 35*) is cadmium sulfide mixed with crystals of zinc cadmium sulfide. Cadmium red (*Pigment Red 108*) is produced in similar fashion to the yellow. Selenium powder is added to obtain the desired shade. The maroon is manufactured in the same manner as the red, selenium replacing the sulfur, at 50 mol% the shade shifts to a maroon.

Lithapones are coprecipitates with up to 60% barium sulfate. The lithapones are offered in the full color range and provide slightly better dispersion and value in use. Also available are a variety of mercury cadmiums in shades of orange, red, and maroon. They contain mercuric sulfide to replace a quantity of selenium. The advantage is slightly better economics and heat stability. Shortages of raw materials have caused increases in the price of cadmiums. Environmental

regulations have also caused a significant downturn in use. They are/have been replaced by high performance organics (eg, perylene, quinacridone, and azo condensation pigments).

Special Effect Pigments

Pearlescents. Pearlescent, nacreous, or interference pigments are designed to simulate the natural luster of pearls. Simply put, pearlescents are constructed of various layers of platy particles with differing indices of refraction. The *index of refraction* is the degree to which light slows and is bent as it passes through a substance (eg, prism). Numerous effects can be achieved by altering the incident light via reflection, refraction, and transmission.

Natural pearlesence (Guanine) is produced from the scales of herring and Atlantic salmon caught in cold waters. It does not find much use in plastics as it is more fragile, expensive, and is only available in a paste. *Bismuth oxychloride* is produced by precipitating platelet crystals from an aqueous solution of $BiCl_3$ via hydrolysis. Bismuth oxychloride pigment is the closest to natural pearl but is fragile and has relatively poor light stability.

Oxide-coated micas are produced by precipitating a metal oxide onto the surface of refined mica. Titanated micas are produced by precipitating a layer of TiO_2 from an aqueous solution of titanium tetrachloride onto a refined mica substrate. The titanium precipitates as the hydrate that is in turn converted to the oxide by calcinations at 800°C. They offer a wide range of colors, good light stability, and are generally low cost. The factors that affect luster and color are particle size, mica quality and color, and TiO_2 layer thickness. The larger particles offer more luster and transparency. The smaller particles offer more of a satin finish. The iridescent titanated micas that are produced by increasing the thickness of the TiO_2 layers are called *interference colors*. Two-tone and intensified versions of these interference colors can be produced by the addition of absorption colors. Using an absorption color that is the same as the interference color will produce a deeper colored TCM (titanium dioxide-coated mica). Using an absorption color that is different from the interference color will produce a TCM with two-tone flop effect. In a "two-tone flop effect" the color will change to two distinctly different colors when observed at different angles.

When using any of the pearls, care must be taken during incorporation. The pigment has to be wet-out but care must be taken to keep from breaking down the particles. Try to avoid twin-screw extruders unless you use a downstream feed port. If using a banburry try avoiding long cycles. This is one of a few products where mold design should be considered in the product-engineering phase as controlling flow and weld lines may be required. A variety of colors and effects can be achieved with these pearl pigments. Varying the combination and loading of pearls and traditional pigments are common practice.

Over 95% of pearls used in plastics are oxide-coated micas. The major application for plastics is polyolefin packaging. Recent interest in mass coloration for automotive parts could spur the already strong growth rate of pearls.

Metallic Pigments. Plastics can be given a metallic appearance by incorporation of very thin platelets of aluminum, aluminum–bronze, zinc, copper, and

copper–zinc alloys. The metal effect is caused by the reflection of light at the pigment surface. Larger pigment particles increase reflectance and hence brilliance. A large particle also increases *flop* (color change when viewing at an angle).

Grinding aluminum powder produces aluminum pigments. Wet milling does this best as aluminum powder forms explosive mixtures with air. The pigment suspension is usually sieved, filtered, and vacuum-dried in the case of products for plastics. Copper, gold, and bronze pigments (powdered copper–zinc alloys) are produced by dry milling. Copper is produced using 100% copper. A variety of gold shades can be achieved by adding up to 25% zinc.

Unlike most pigments used in plastics, metallics may agglomerate after a shelf life of 1 year. Proper dispersion is important. In organic colorants the objective is to deagglomerate by use of shear. However, use of high shear will tear, ball up, or fold the metallics. This will change their color and hiding power. Avoid high intensity mixers or add pigment at the end of the cycle at low speeds. Try to avoid twin-screw extruders unless you use a downstream feed port. Plate-out on calendering rollers and extruder screws have been reported. Flakes with a polymer surface treatment may reduce or eliminate the problem. Controlling flow and weld lines should be considered in mold design.

Fluorescent Pigments. There are three basic types of fluorescent pigments: A thermoplastic pigment based on a polyamide resin, a thermoplastic pigment based on a polyester resin matrix, and a pigment based on a blend of polyester and polyamide resin.

Fluorescent pigments are based on dyes that not only absorb some visible light, but also photons of higher energy form from the invisible uv region of the electromagnetic spectrum. The dyes used for the red pigments are members of the rhodamine family. The yellows are typically members of the coumarin family. There are no blue or green fluorescent dyes. These colors are achieved by blending phthalocyanines green with fluorescent yellow and phthalocyanines blue with optical brightener respectively.

The compatibility and heat stability of the pigments is important. Polyamides exhibit the highest degree of heat stability, but lack good compatibility in polyolefin. Polyester resins have excellent compatibility in olefin but lack good heat resistance. The polyester/polyamide hybrid has good heat stability and good compatibility. All lack good light stability.

Plate-out is an area of concern when processing concentrate or molding parts. At higher temperatures the components of a fluorescent pigment can undergo sublimation. The colored material will be deposited on the barrels and molds. Plate-out can be reduced by a number of methods. The combined use of absorbent agents such as barium sulfate and reactive agents such as titanate coupling agents can greatly reduce or eliminate plate-out.

Organic Pigments

Azo Pigments. Many of the red, yellow, and orange pigments used in plastics are classified as azo pigments. This classification is attributed to the fact that they contain the azo chromophore (—N=N—). Further subdivisions of azo pigment are possible. They can be labeled as metallized or nonmetallized; the

latter are most common in plastics. Manufacture of a metallized azo pigment involves four basic steps:

(1) *Diazotization*: reacting a primary aromatic amine with nitrous acid that was formed *in situ* by reacting sodium nitrite with hydrochloric acid; this forms a diazonium salt. Some common primary amines are Tobias acid, C acid, 4B acid, 2B acid, and anthranilic acid.
(2) *Coupling*: the diazonium salt is coupled to form the pigment. Common couplers are β- napthol and BON. This forms an azo dye or very unstable pigment.
(3) *Metallization*: the azo dye is precipitated as a metallized salt such as calcium, manganese, strontium, or barium. This is accomplished in the presence of anionic groups. Consequently, the sulfonic or carboxylic acid on the dye can react with metals to form an insoluble pigment.
(4) *Washing*: the suspension is then filtered and washed. This removes any unwanted impurities.

Figure 1 is an example of the process of manufacture for a metallized azo pigment, barium lithol red (**1**). Reaction with a metal salt causes the azo dye to precipitate, forming an insoluble metallized azo pigment. Most nonmetallized reds contain no anionic groups.

Azo pigments are the perfect workhorse pigments for non-high performance applications. Overall, azo pigments are low cost and have excellent tinting

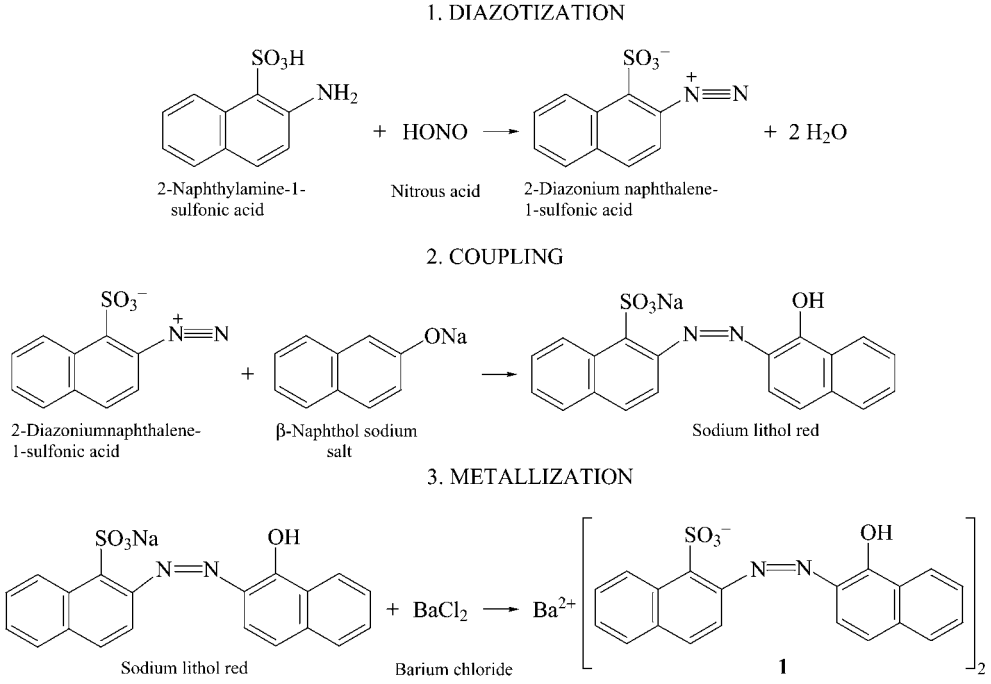

Fig. 1. Lithol red manufacture.

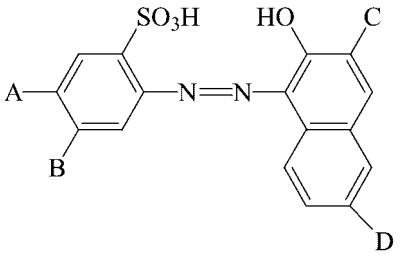

Fig. 2. A generalized representation of several red, orange, and yellow pigments. PigmentRed48.1(BariumSalt)(A = CH_3,B = Cl,C = COOH) (2); Pigment Red48.2 (Calcium Salt)(A = CH_3,B = Cl,C = COOH) (3); Pigment Red53.1(Barium Salt) (A = Cl,B = CH_3,C = H) (4); Pigment Orange46(Barium Salt)(A = Cl,B = C_2H_5,C = H) (5); PigmentRed57.1(CalciumSalt)(A = CH_3,B = H,C = COOH). (6)

strength. They have fair to good dispersion, migration, and light and heat stability properties. The following review will be focused on the most commonly used azos, as there are more azos than time for discussion allows.

Metallized Azo Reds, Oranges, and Yellows. *Pigment Red 48:1* (**2**) – Barium 2B is a strong, very yellow shade pigment with heat stability up to 260°C. Lightfastness rates a 3 on the 1–8 blue-wool scale. It has good dispersion and is used in almost all thermoplastics, excluding the engineering polymers. It has good migration in PVC systems.

Pigment Red 48:2 (**3**) – Calcium 2B is the counterpart to Barium 2B. It fills color space for a formulator by offering a clean, strong, and economical blue shade red. Physical properties are similar to Barium 2B although the Calcium 2B has slightly better light stability.

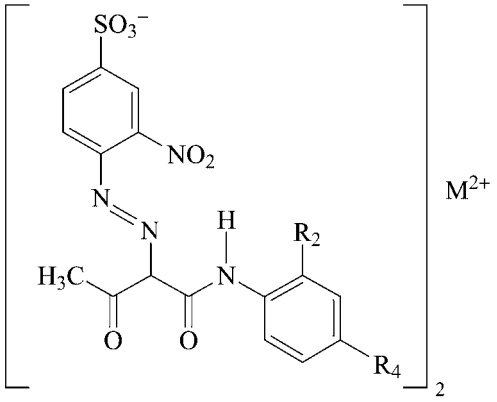
Pigment Red 53:1 (**4**) – Red Lake C is almost identical in shade to Barium 2B. Its slightly better heat stability of 288°C allows its use in ABS (acrylonitrile–butadiene–styrene) where lightfastness is not important. Caution should be used in plasticized PVC since migration can occur.

Pigment Red 57:1 (**6**) – Calcium Lithol Rubine is bluer than Ca 2B, with slightly inferior fastness properties. In Europe it replaces Ca 2B as the blue shade red of choice.

Pigment Red 60:1 – Pigment Scarlet is unique as it is laked using barium chloride and alumina hydrate. The shade is not the typical yellow shade usually offered by a Barium Lake. It is bluer, tends to be weaker but has much better physical properties than the 2Bs. Heat stability of 300°C and midrange light stability offers a pigment with properties between those of high performance pigments and the above-mentioned azos.

Pigment Orange 46 (**5**) – Clarion Red offers a brighter and yellower shade of Red Lake C. Properties are similar and caution should be used in plasticized PVC since migration can occur.

Monoazo yellow pigment lakes (Fig. 3) are synthesized by first adding the diazotizedamine to the coupler. This dye is then precipitated as an insoluble metal salt. Ordinarily they have large particle size for an organic. This offers good opacity, heat stability, and dispersion. However, the tinting strength in application is one-half that of a diarylide yellow. Major applications are low to medium



CI name	CI constitution no.	R_2	R_4	M	Shade

P.Y. 168 (**8**)	13960	Cl	H	Ca	Greenish yellow

Fig. 3. Monoazo yellow pigment takels.

performance film, fiber, and injection-molded products in olefins. They also exhibit good migration resistance in PVC. They are often used in applications in which diarylide yellows are unacceptable. *Pigment Yellow 62* (**7**) is the most common red shade yellow and Pigment *Yellow 168* (**8**) is its counterpart on the green side.

Naphthol Red. *Pigment Red 170* (Napthol red) is offered in a transparent and opaque version. Pigment's particle size of crystal form controls the opacity. The opaque version has a larger particle size. It is yellower in masstone and has better heat and light stability. Napthol red finds use in some low cost exterior applications (eg, coolers) as they have better light stability as compared with metallized azo reds.

Disazo Yellow and Red. Diarylide yellows use dichlorobenzidine (DCB) as a difunctional amine. The coupler changes, as can be seen by the generic name AAOT, AAMX, AAA, etc; hence it is the coupler that imparts the differences seen in the pigment (see Fig. 4).

Pound-per-pound, diarylide yellows cannot be out-performed for value in use. They are used in low temperature olefin and PVC application. Caution is required in plasticized PVC as migration is possible. The amine DCB is suspected to release at temperatures above 200°C in polyolefins. This is an area where discussion with your pigment supplier is recommended.

Pigment Yellow 12 (**9**) – AAA Yellow is a medium-to-red shade yellow with low heat stability. Pigment Yellow 12 finds use in rubber. Heat stability is generally too low for olefins. *Pigment Yellow 13* (**10**) – AAMX Yellow is a medium-to-red shade yellow with good opacity. *Pigment Yellow 14* (**11**) – AAOT Yellow is a very opaque medium shade yellow. *Pigment Yellow 17* (**12**) – AAOA Yellow is a slightly transparent green shade yellow. *Pigment Yellow 83* (**13**) – AADMCA Yellow is a very red shade yellow with slightly better properties than the other diarylides.

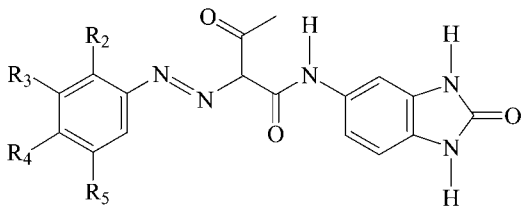
P.Y. 17 **(12)**	21105	Cl	H	OCH_3	H	H	Greenish yellow
P.Y. 83 **(13)**	21108	Cl	H	OCH_3	Cl	OCH_3	Reddish yellow

Fig. 4. Disazo yellows and reds.

Pigment Red 38 – Pyrazolone red is ideal for rubber and other low heat applications. The bright clean red masstone quickly shifts to brown or black at temperatures above 218°C. Alkali resistance is excellent. Pyrazolone red is FDA approved for use in rubber. *Pigment Orange 13* and *Pigment Orange 34* are also disazopyrazolones that find use in rubber or low temperature olefin applications. Pigment Orange 34 is slightly redder than Pigment Orange 13.

Benzimidazolone Yellow and Orange Pigments. Benzimidazolone pigments contain 5-aminobenzimidazolone group (Fig. 5). This group is common to all the pigments and hence the name. They are a very important group of pigments for plastics despite their high cost. They are not as clean and strong as diarylides. Nevertheless, they find use in a variety of applications as they have excellent lightfastness, heat stability, and migration resistance. Dispersion is fair. Some specific grades are FDA approved and others are considered low warp.

Pigment Yellow 154 (**14**) is medium-to-green shade with select codes having some FDA approval. Nevertheless, most usage is in PVC. This is due to its bleed resistance being excellent and its heat stability of 200°C being too low to find much use in olefins. *Pigment Yellow 151* (**15**) is somewhat greener than Pigment Yellow 154 (**16**) and has better heat stability (260°C). It is often used with phthalo green to provide a very yellow but stable green. *Pigment Yellow 180* (**17**) is a medium shade with select codes having some FDA approval and low warp qualities. It is stable up to 290°C in olefins and is useful in coloring engineering resins. It does not show migration in PVC. *Pigment Yellow 181* (**18**) is very red. Its heat stability is good in polyolefins and most engineering resins; however, Pigment Yellow 181 is not recommended for use in nylon. Select codes have



CI name	CI constitution no.	R_2	R_3	R_4	R_5	Shade

P.O. 36 **(19)**	11780	NO_2	H	Cl	H	Orange

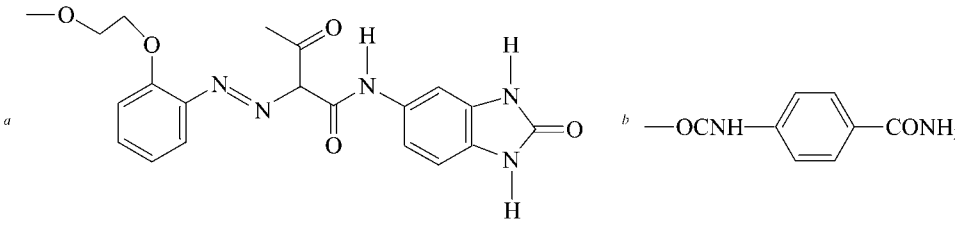

Fig. 5. Benzimidazolone pigments.

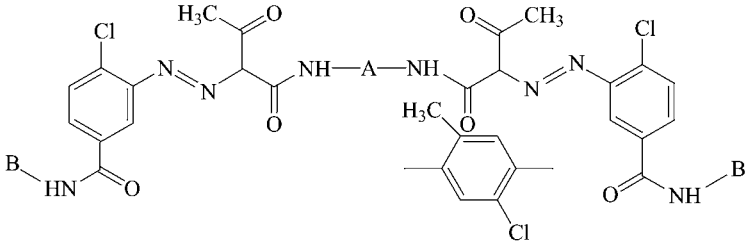
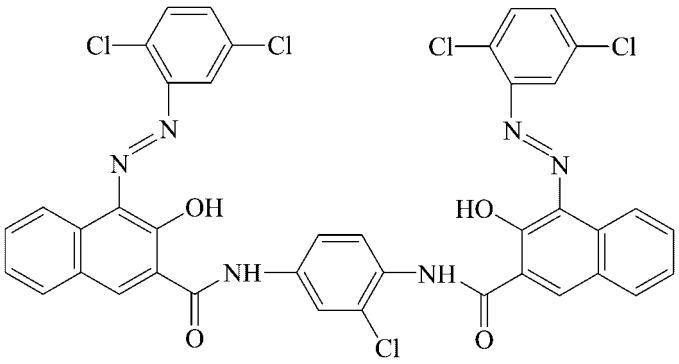
restricted FDA approval. *Pigment Orange 36* (**19**) is a reddish shade orange with very good lightfastness properties. It finds most of its use in plastisols and PVC since its heat stability is 220°C, much lower than that of the other benzimidazolones. It is often used with carbon black to create lightfast shades of organic browns.

Disazo Condensation Pigments. Disazo condensation pigments (Fig. 6) represent a multistep approach to disazo chemistry. For disazo pigments of the diarylide types both the amino groups of the DCB are diazotized simultaneously, followed by reaction with two equivalents of coupler, to form the pigment. In the category of condensation pigments the disazo components are coupled to afford monoazo carboxylic acids. In a separate stage these are converted to their respective acid chlorides. The condensation pigment then forms, in the final stage, when two equivalents of an acid chloride react with one equivalent of an appropriate diamine (**22**). By selecting the amines in the coupling or diamines in the condensation a variety of pigments can be made. The high molecular weight of these products brightens the shade and increases stability.



Structure A	Structure B	Shade	CI name	CI constitution no.
		Yellow	P.Y. 93 (**20**)	20710
		Reddish yellow	P.Y. 95 (**21**)	20034

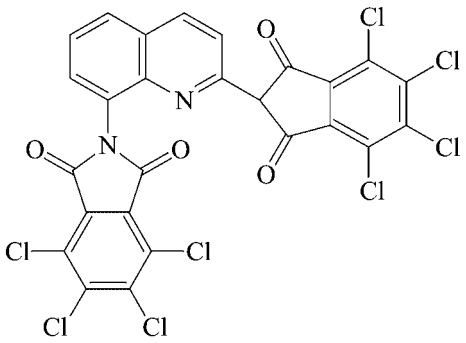
Fig. 6. Disazo condensation pigments.



(**22**)

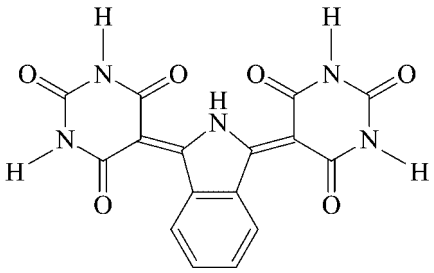
Because of the complex manufacturing process, azo condensations are expensive when compared with most organic pigments. The result is they are only used in high performance applications, the majority of that being polypropylene and polyacrylonitrile fiber. They have replaced lead and cadmium pigments where toxicity was an issue. All physical properties are excellent but shrinkage in large molded parts can be an issue. There are three important pigments for use in plastics. They are *Pigment Yellow 93* (**20**), a medium-to-green shade yellow, *Pigment Yellow 95* (**21**), a red shade yellow, and *Pigment Red 144* (**22**), a medium shade red (its CI number is 20735). Select codes of Pigment Yellow 95 have restricted FDA approval.

Miscellaneous Yellows.



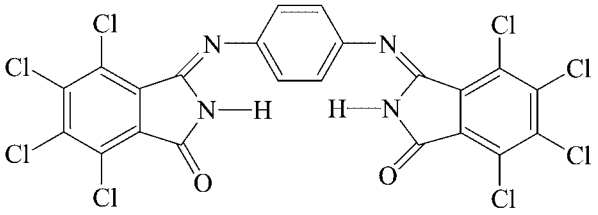
(**23**)

Pigment Yellow 138 (**23**) is a quinophthalone. It is considered slightly more opaque and weaker in tint than some of the other high performance yellows. It has good light and heat stability. The pigment is known to nucleate, which can lead to shrinkage in large parts. Select codes have restricted FDA approval.



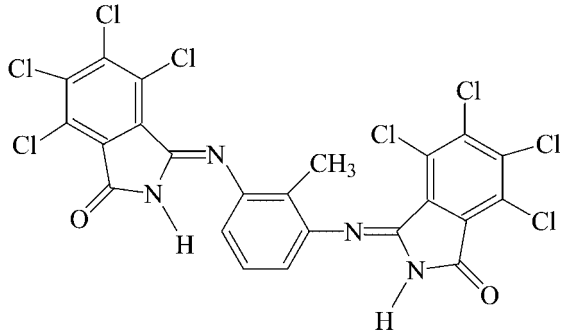
(**24**)

Pigment Yellow 139 (**24**) is a methine-type isoindoline that has a red shade.



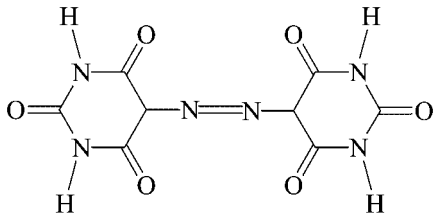
(**25**)

Pigment Yellow 110 (**25**) is an azo methine-type tetrachloroisoindolinone that has a very red shade. Pigment Yellow 110 is hard to disperse and transparent. Its good performance in PVC, heat stability in olefins of 270°C, generally good lightfastness, and the fact that select codes are FDA approved, make it worth mentioning (1).



(**26**)

Pigment Yellow 109 (**26**) is an azo methine-type tetrachloroisoindolinone. It has overall good properties and is considered a green shade yellow.



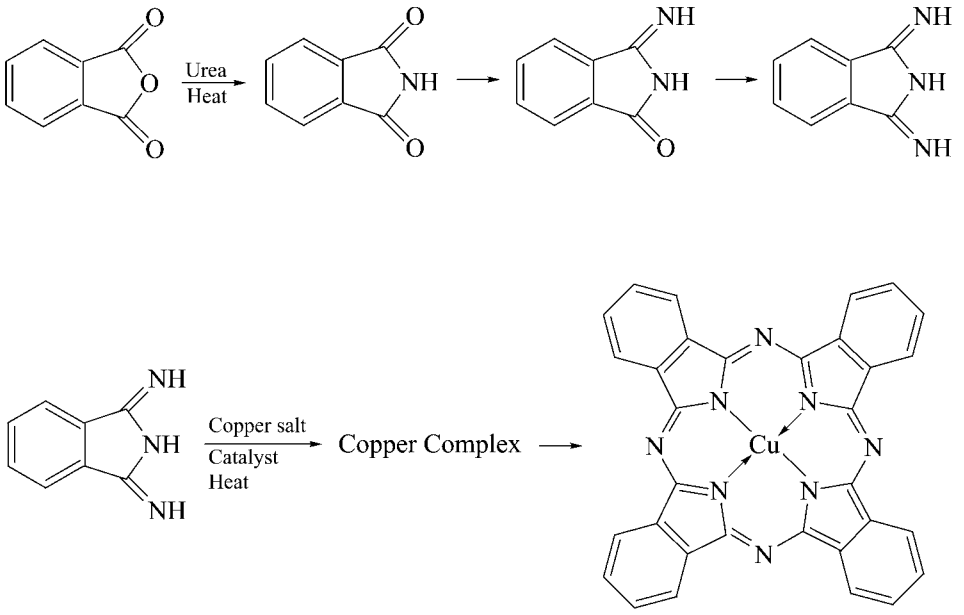
(**27**)

Pigment Yellow 150 (**27**) (Pyrimidine Yellow) is an azo/nickel complex. Its color is dull and it lacks tinting strength. It finds its importance in a good stable yellow for fiber applications. It can react with zinc sulfide.

Phthalocyanine Pigments. Presently, phthalocyanine blue and green are the most important organic pigments being used in plastics. They have bright clean shades and their physical properties are excellent. Lightfastness and weatherfastness are of automotive quality. Most can be used in all but the highest processing temperature resins. They are very high in tint strength and have excellent value in use. They are sold in high volumes and most domestic sources are FDA approved. Shrinkage in large molded parts can be an issue.

Phthalocyanines are planar molecules that comprise four isoindole moieties connected by four nitrogen atoms. This forms a 16-membered ring with the central atom being copper. Manufacture of the crude pigment is relatively straightforward (Fig. 7). Phthalic anhydride reacts with urea to form a compound that reacts at 190°C with copper salts. Molybdates and vanadates are often used as catalysts for this condensation reaction (4). This process produces crude pigment. Chemically replacing the hydrogen in the phthalo blue (**28**) with chlorine results in Pigment Green 7. Replacement of the hydrogen with bromine results in production of the yellower, Pigment Green 36.

The crude of all of these phthalos has a very large particle size and needs to be conditioned in order to make it pigmentary. Conditioning can be completed using several processes: *Salt attrition* – The crude is ground in a ball mill or a double-arm



28

Fig. 7.

mixer in the presence of salt and optionally a solvent such as diethylene glycol. This provides the green shade beta crystal in the case of blue crude. *Solvent free attrition* – The crude is ground in a ball mill in the presence of a large excess of salt, excluding the solvent; this is used exclusively for production of red shade or alpha crystal blue. *Acid pasting* – The crude is dissolved in a large excess of concentrated sulfuric acid, then reprecipitated by drown-out in iced water. *Acid swelling* – The crude is treated with a smaller amount of concentrated sulfuric acid than used in acid pasting technique. This acid-swelled paste is added to iced water to precipitate the pigment.

Phthalocyanine Blue Pigment. Phthalocyanine blue pigment (**28**) exhibits polymorphism. Although chemically the same, changes in crystal shape change the color and properties. The beta phase or green shade is more inherently stable. The alpha shade or red shade will readily convert back to the more stable green shade if not stabilized. Current methods of stabilization are essentially proprietary. They offer added heat stability and resistance to flocculation in coatings applications. Light stability remains consistent for the different crystals phases.

Pigment Blue 15 is a nonstabilized alpha crystal. It has a strong red shade and finds use in low temperature applications like rubber and PVC. Heat stability becomes a problem above 230°C.

Pigment Blue 15:1 is a stabilized or noncrystallizing alpha or red shade. Because of differing types and qualities of additives, heat stability can range from 275 to 300°C. Red shade blues are stabilized by additives or by the

addition of up to one molecule of chlorine. The chlorinated version is slightly greener in a tint and has a jet masstone as compared with the additive-stabilized Pigment Blue 15:1. In recent years, a semi-Cl version has become popular. It is a midshade and has good heat stability. Pigment Blue 15:2 is a noncrystallizing, nonflocculating red shade. It does not find much use in typical thermoplastics. Its design is for resistance to flocculation and is used in some plastisol, acrylic, and liquid color application. Heat stability is equal to that of Pigment Blue 15:1.

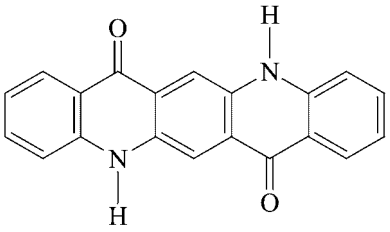
Pigment Blue 15:3 is a nonstabilized beta shade or green shade blue. The more stable beta phase crystal does not require an additive to stabilize it for heat resistance. It has heat stability up to 290°C. It is applicable for and used in almost all thermoplastics.

Pigment Blue 15:4 is a noncrystallizing, nonflocculating beta or green shade blue. Its original design was for coatings application. In spite of this, the additive used for flocculation provides excellent heat stability and accordingly Pigment Blue 15:4 finds use in very high temperature applications. Pigment Blue 15:4 often finds use in place of Pigment Blue 15:3 in engineering polymers.

Phthalocyanine Green Pigment. Phthalocyanine green demonstrates the good overall properties of phthalo blue, differing from blue in that it is not a polymorph (4). Pigment Green 7 is recognized as being more stable than its phthalo blue counterpart. This is largely due to the stabilizing factor of chlorine or bromine or both. Heat stability is the area of most improvement over blue. *Pigment Green 7* is offered in medium to blue shades of green. *Pigment Green 36* is much yellower than Pigment Green 7.

Quinacridone Pigment. Quinacridone pigments fill an important need in the coloring of plastics. They are the high performance counterparts to azo red pigments. They cover a key color space, from bright red to violet. They are exceptionally strong but can be difficult to disperse because of its especially small particle size. A few suppliers offer predispersion that limits loss through dusting and provide additional dispersion and strength, as a result, increasing their value in use. They have excellent fastness properties. They can be used in olefins for everything from packaging to fiber applications. They are also used in acrylonitrile, nylon-6, and polyester fiber. Some varieties find use in engineering resins. Quinacridones are also the pigment of choice for automotive interior and vinyl applications. Most have some FDA approval. Pigment Violet 19 is polymorphic and has two basic crystals. The beta crystal is a violet whereas the gamma crystal is a yellow shade red. The beta crystal is most stable.

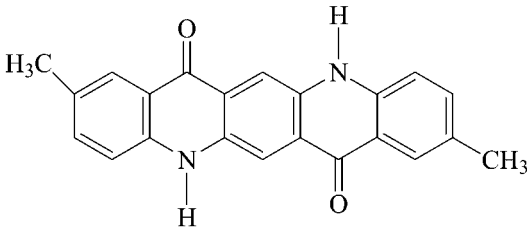
Quinacridone pigments are made by the use of two different but similar processes. They involve either the oxidation of dihydroquinacridone or the cyclization of 2,5-diarylaminoterephthalic acid. Both processes require a condensation of diethyl succinylsuccinate with an aromatic amine to form the 2,5-diarylamino-3,6-dihydroterephthalic acid diester. The diester is converted to dihydroquinacridone during ring closure at high temperatures. Subsequent conditioning leads to a quinacridone with the desired morphology. Use of 2,5-dianilinoterephthalic acid yields Pigment Violet 19 (**29**). Use of 2,5-ditoluidinoterephthalic acid yields the 2,9-dimethylquinacridone, Pigment Red 122. Use of 2,5-diparachloroanilinoterephthalic acid yields the dichloroquinacridone, Pigment Red 202 (4).



(**29**)

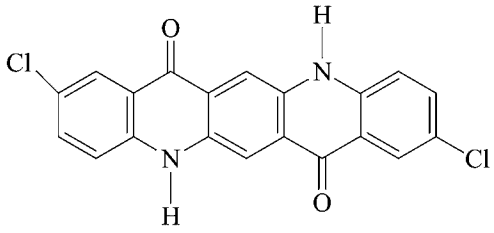
Pigment Violet 19 (Violet) (**29**) can have a variety of shades and properties. This diversity is largely dependent on the particle size and manufacturing processes. The beta crystal provides a clean violet shade. Most have FDA approval and can find use in FDA applications using extrusion coating, injection molding, and film processes. Its excellent lightfastness and heat stability make it useful in most melt-dyed fiber. Some solubility issues exist when used at very low loadings in engineering resins.

Pigment Violet 19 (Red) is also offered with variety of properties and comes in a variety of shades and opacities. The more opaque have better lightfastness and heat stability and the more transparent have excellent tinting strength. Some recently developed products can offer both. The particle size and particle size distribution are mainly responsible for the variety of products offered. Most grades are FDA approved.



(**30**)

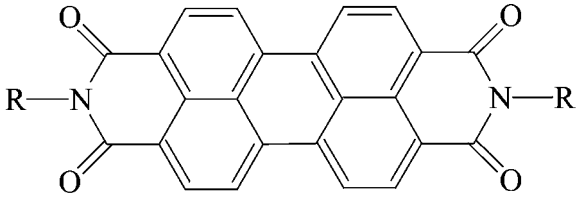
Pigment Red 122 (**30**) is the dimethylquinacridone. It is a magenta shade and is typically thought of as having better fastness properties than of the unsubstituted types. It is used in all of the above-mentioned plastic applications. Some grades are FDA approved.



(**31**)

Pigment Red 202 (**31**) is a *dichloroquinacridone*. It is also a magenta shade and is similar in properties and uses to Pigment Red 122. Pigment Red 202 was typically offered in a hard to disperse and opaque coatings grade. New, easy dispersing, high tinting strength grades are now available. Red 202 is unique in that it is the least soluble of the quinacridones. Therefore, the majority of its use is in engineering resins and other high performance applications.

Perylene Pigments.



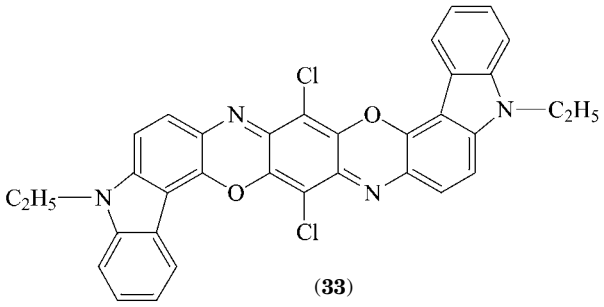
(**32**)

Perylene pigments are similar to quinacridones, given that they find use in high performance applications. Of perylenes, only three types are actively used for coloring plastics. They are Pigment Red 179 (**32**) (R=methyl), Pigment Red 149, and Pigment Violet 29 (**32**) (R=H). They are unique as compared with quinacridones in that the majority of the pigment not consumed in automotive coatings is used to color fiber. Caution should be exercised when perylenes are used in olefins that are stabilized with HALS (Hindered Amine Light Stabilizers) UV Stabilizers. At high pigment levels the stabilizers can be inactivated upon exposure to light. Perylenes are used to a lesser degree in PVC for automotive interiors.

Perylenes are chemically diimides of perylene tetracarboxylic acid. The shade change is dependent on the substitution of the imide nitrogen (4).

Pigment Red 149 is a clean, medium shade red. It exhibits high tinting strength and is very transparent. Its small particle size can cause shrinkage in large molded parts. Interestingly, its influence on shrinkage decreases with increasing temperatures. Superior migration resistance in plasticizers allows use of all types of vinyl. Pigment Red 149 can endure processing in polycarbonate because of its heat stability of 320°C. Pigment Red 149 is also used to color unsaturated polyester and other cast resins (1). *Pigment Red 179* is perylene maroon. It is a very blue shade that is very dirty and brown looking at high loadings. Most common usage is in fiber as tinted and low percentage masstone colors. At these levels it is a clean, reddish-maroon color. It is thermochromic and will change color during processing only to return to original color as it cools. *Pigment Violet 29*, a very blue shade violet, appears black at high pigment concentration. Pigment Violet 29 finds use in fiber; however, volumes are much lower than those for Pigment Red 179.

Dioxazine Pigment.

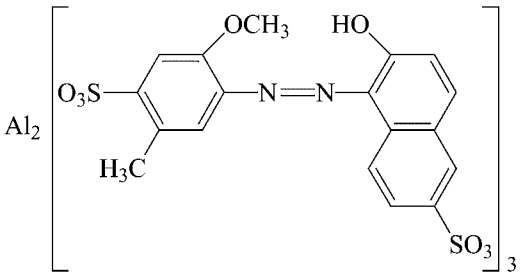


(**33**)

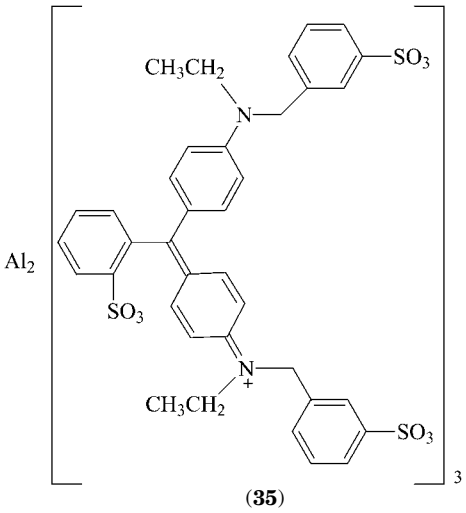
Dioxazine violet or *Pigment Violet 23* (**33**) can be used in most plastics excluding engineering resins. It is very strong in tint and can look black in masstones at normal levels. It finds most use in olefins and PVC. It is often used at low levels with TiO_2 to provide a clean pastel violet. In fiber, carbazole is often added in small quantities to blue to provide a clean red shade blue. Another use is in combination with blue as a bluing agent for whites. Use caution as decomposition can occur if processing above 250°C. Pigment Violet 23 has also exhibited solubility issues when used at very low levels. Lightfastness also requires attention since it can swing from 8 (excellent) to 3 (poor) on the blue-wool scale as pigment loadings are decreased. Carbazole dioxazine violet is manufactured by reacting chloranil with 2 mol of aminoethylcarbazole followed by oxidative cyclization.

Diketopyrrolo Pyrrole Pigment. *Pigment Red 254* is a new arrival when compared with most of the other pigments mentioned. It is offered in several different shades of medium red. The tint reductions are somewhat bluish red. Pigment Red 254 offers good color strength and has excellent fastness properties. For economic reasons it is often combined with less expensive napthols and quinacridones. This provides both a variety of shades and properties while reducing the expense of the formula.

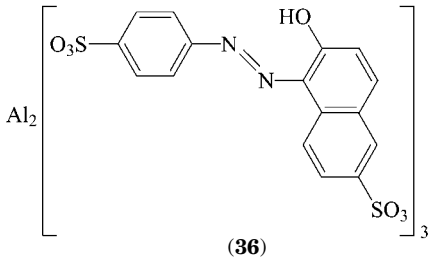
FD&C Food Lakes. FD&C lake pigments are vital to the plastics industry. They are certified by U.S. Government specifications to be of a purity and composition that allow their use as a direct food additive and colorant for certain drug and cosmetic applications. This certification makes them the pigment of choice for medical or food packaging applications (5,6). They have heat stability in the area of 250°C. Limited light stability and poor tinting strength excludes them from use in areas where their certification is not required.



(**34**)



(**35**)



(**36**)

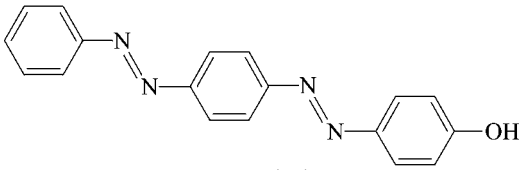
Manufacture of the food lakes requires the precipitation of food-certified dyes onto the surface of aluminum hydrate. The water of hydration present is to some extent driven off during incorporation into the plastic. Vented equipment is recommended. Over 90% of their use in plastics is in olefins for food-packaging applications. The colors available are FD&C Red 40 (**34**), FD&C Blue 1 (**35**), FD&C Yellow 5, and FD&C Yellow 6 (**36**).

Dyes. Dyes similar to pigments are listed according to their class, generic name, and Color Index (CI) name and number. The dyes are essential; without them, many transparent effects in plastics could not be achieved. Dyes are soluble in plastic, and therefore more transparent by nature than pigments. Dyes are known for poor lightfastness in tinted application. This is not as great a concern in masstone or transparent parts as failure occurs on the surface, and the color beneath is unaffected.

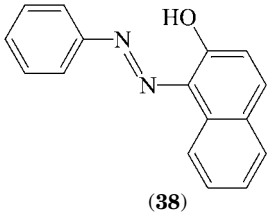
Dyes should be avoided in plasticized PVC and olefins because they tend to migrate. Plasticizers solubilize the dyes making them fugitive. In olefins, the dyes lack an affinity for aliphatic hydrocarbons and consequently migrate to the surface. Migration testing is a standard procedure unless the dye is proven in the polymer system.

Azo Dyes. Azo dyes contain the structure —N=N— similar as referred to in the Azo Pigment section. They are available in a wide range of colors. Their main uses are coloring transparent, rigid PVC, polystyrene, phenolics, and poly(methyl methacrylate). The most commonly used azo dyes are Solvent Reds 1, 24, and 26,

Solvent Yellows 14 and 72, and Solvent Black 3. Acid Orange 7 and 8, and Acid Yellow 36 find most use in phenolic resins (7) (**37**, **38**).



(**37**)



(**38**)

Anthraquinone Dyes. Anthraquinone dyes have much better heat and light stability when compared with azos. This does not come without a cost. In spite of this, it greatly expands the potential for use in exterior application. The most commonly used are *Solvent Red 111*, *Solvent Violet 13* and *3*, *Solvent Blue 12* and *59*, and *Solvent Green 3*. Usage is expanded to ABS and polycarbonate. Most recognize Solvent Red 111 for its use in automobile taillights made with poly(methyl methacrylate). Again, the acid types are mainly for phenolics. They are *Acid Blue 24* and *Acid Green 25*.

Xanthene Dyes. Xanthene dyes are an important class since they offer brilliant and fluorescent colors. Conversely they are only fair to good in heat and light stability. Useful xanthene dyes are Basic Violet 10, a fluorescent, Solvent Green 4, Acid Red 52, Basic Red 1, and Solvent Orange 63.

Azine Dyes. Azine dyes include nigrosine and induline. They have excellent heat and lightfastness. They produce very jet blacks, which are not achievable with carbon black. Nigrosenes, Solvent Black 5, and Solvent Black 7 are the largest volume dyes used in the plastics industry. Solvent *Black 5* is alcohol soluble and can be used in coloring ABS, phenolics, and polypropylene. Solvent Black 7 has higher tint strength than Black 5. Its low electrical transmission properties make it very desirable for coloring phenolic resin often used in electrical components (7).

COLORING PROCESSES

Introduction

Coloration of plastic materials is accomplished by depositing a colorant on the surface of the plastic part or incorporating the colorant into the plastic itself. Standard coating, dyeing, and printing techniques are used for surface coloration (see COATING METHODS, POWDER TECHNOLOGY; COATING METHODS, SURVEY). This article deals with colorants that are incorporated into the plastic.

The three basic forms of colorants used in plastics are raw pigments or dyes, color concentrates, and color compounds. Dyes and pigments are typically dry powders. Some pigment suppliers also offer single pigment dispersions containing only pigment and polymer. These products offer increased color strength, dispersion, and ease of use. Dyes and pigments are sold into many different levels of the supply chain.

Pigments and Dyes. The largest volume of raw pigment and dye is supplied to color houses that provide value-added products and services to molders and extruders. In turn the extruders and molders manufacture colored parts, bottles, and fibers. Some of the raw pigments and dyes are incorporated directly into finished parts via molding and extrusion; however, this is not common.

Color Concentrate. Color concentrate or masterbatch consists of a carrier resin that is highly loaded with colorants and additives. It is designed to match a reference colored sample when let down or reduced at a specified ratio, ie 25:1, 50:1 (resin/concentrate). When let down, the concentrate colors the resin as required.

Color Compound. A color compound is a system of colorants, additives, and resin that requires no letdown or addition of materials. It is ready to be processed into finished parts via molding or extrusion. A compound can be colored with dry pigment and dye or color concentrate.

Encyclopedia of Polymer Science and Technology. Copyright John Wiley & Sons, Inc. All rights reserved.

Color Houses

Color houses offer expertise in coloring of plastics. Whether a compounder or a concentrate house, they provide a high level of service to their customers. They supply a colorant and resin system that will match both the shade desired and the physical properties needed for the life of a product.

The physical form of the compound or concentrate and equipment used in manufacturing colored plastic objects can vary. Color houses can provide liquid, powdered, or pelletized systems that can be converted using all types of equipment (media mills, extruders, continuous mixers). The functions and equipment typical of a color house are detailed in the following.

Color Labs. Color matching is a complicated art and/or science. Color matchers must balance the designers' aesthetic desires with the engineers' required physical properties. This is not always an easy task. It is often difficult to achieve the color and physical properties in the desired resin. Interaction between designers and engineers provides a forum for selecting colorants and end part colors based on economics and/or performance. This improves the ability to achieve a good and reproducible color match.

Color labs are outfitted with laboratory size equipment that simulates the larger machines used for production internally and by their customers. Typical processing equipment found in the lab are small extruders, two-roll mills, banburry mills, and media mills. Small rotational, injection and blow molding machines are used to duplicate the customers' process. Instruments and computers are required for testing physical properties and color. Most labs have a computer-controlled color measuring system and a light booth to evaluate color. The spectrophotometer with computer is initially used to assist in colorant formulation and later as a quality control (QC) tool to provide certification of the quality of match to standard. The light booth provides a standardized set of conditions to visually observe color and appearance.

Product literature, provided by the pigment supplier, is kept in the color lab for reference. General information regarding cost, compatibility, FDA approval, heat stability, lightfastness, and migration resistance is used for initial colorant selection. Laboratory quantities of a large variety of colorants are kept on hand. The samples are required for physical testing, QC adjustment evaluation, and color matching.

The color lab is usually divided into two parts: color development and quality control. The color development group works closely with the sales and marketing departments. Anything, from a competitive color concentrate to bottles, films, or injection-molded parts, can be submitted to the lab for color-matching. Pantone® books or chips and other color standards are also used to specify or select targets. Specifications regarding resin, letdown ratios, weatherfastness, and price are typically submitted with the target.

In the next step, a starting formulation of colorants, additives, and resin is developed. The computer generates formulas on the basis of a database of known spectral curves of colorants. The formulas are reviewed to ensure that colorants meet heat stability, weatherfastness, and migration and chemical resistance requirements, at a cost that is competitive. Lab samples are produced, evaluated, and submitted to the customer for approval. The customer can be internal or

external. Internal, if they are manufacturing an end use product, or external, if the concentrate or compound is sold to a molder or extruder.

The QC group is focused on the evaluation of the color concentrate or compound made in the plant. Grab samples are taken during the production run. The samples (molded chips, film, fiber) are prepared and evaluated versus standards. If required, adjustments are made to fine-tune color and properties.

Incorporation of Colorants. There are a variety of points in the manufacturing process for the introduction of colorants. All involve similar steps: premixing, dispersion, and letdown. Colorants, and more specifically pigments, require more attention than other additives that can be incorporated simultaneously, eg plasticizers, antioxidants, flame retardants, fillers, and impact modifiers. This is true as the manufacturing process of pigments results in different particle sizes and particle size distributions. Primary particles (true single crystals of pigment) are uniform in size, shape, and distribution but they can combine to form aggregates and agglomerates. Aggregates and agglomerates are usually created during the drying of the pigment. The water is evaporated and the crystals come in contact with one another. Van der Waal, electrostatic, magnetic forces, and, at times, atomic bonding are responsible. Aggregates are primary pigment crystals randomly joined at their surfaces. Their interior surfaces are not available to polymer or plasticizers, and aggregates as a result are difficult to separate. Agglomerates are primary crystals joined at corners or edges with interior surfaces available. They are more readily dispersed than aggregates.

The finer the dispersion and the better the incorporation, the lower is the impact on a polymer's performance. Properties like impact and tensile strength are lowered when agglomerates or aggregates are present. Surface problems such as specks in film and injection-molded parts are also a result of poor dispersion. Poor incorporation can lead to other typical color problems of low strength and inconsistency. Processing issues such as screen pack plugging and low throughput can also be avoided if a robust process is employed.

A robust process includes several steps: wetting the pigment surfaces, breaking down aggregates, and agglomerates, and distribution of the particles in the resin. The methods to accomplish this are numerous. In general, a premix is made and milled or extruded and then is let down and extruded, calendered, or molded into a final part. Many of the processes and equipments are used in more than one phase of the coloring process.

Mixing

Mixing is usually the first step in the manufacturing of a color concentrate or compound. The goal of mixing is to achieve a homogeneous blend of polymer and colorants. In a dry or liquid mix, pigments are not fully dispersed. Remaining agglomerates preclude direct use in thin cross-section parts like film and fiber. The agglomerates are less of a problem in thick cross-section parts like injection-molded containers. In any case the undeveloped pigment provides economic motivation to process further.

High Shear Mixing Dry Powders and Resin. High shear mixing is required for achieving fiber and film quality dispersion. The shear impacts the pigment particle onto the surface of the resin and waxes. The air on the surface is

partially displaced and thus the pigment is easier to "wet out" (break down) in the dispersion phase of processing. Powdered resin and waxes are included as carriers for the colorants in this step.

High shear mixing is accomplished in a Henschel® or Hobart® type mixer. These equipment manufacturers are known throughout the food and plastic industries for jacketed kettle-type mixers with high speed impellers. The rotors have a mixing speed of up to 3600 rpm revolutions per minute. Most blends are run on low speed to slowly mix the ingredients and then at high speed to homogenize. A good vortex is required. A charge of no more than 80% of the mixer's capacity is good practice. Mixers of this type can also be used to completely flux or melt the resin and incapsulate the colorants.

Low Shear Mixing of Powders and Resin. Low shear mixing is suitable for easier dispersing inorganic pigments. These pigments have a large particle size and are in turn easy to de-agglomerate. Low shear mixing is preferred for pearlescents and metallics as these products can be destroyed in high shear environments. Dyes are suitable for low shear mixing, as they only need to be distributed evenly throughout the polymer.

Low shear mixing can be accomplished with anything from a drum tumbler to a variety of planetary mixers. Planetary mixers have low speed screws or paddles that mix the ingredients in the bin or hopper. A charge of no more than 80% of the mixer's capacity is good practice.

Mixing Liquids. Carriers like mineral oil and plastisol are typical. Mineral oil is used in a variety of liquid color application. Plastisols find use in calendered and slush-molded PVC applications. The process provides good mixing but a low level of dispersion. Some of these blends are suitable for end-use applications. Most are milled to provide a higher quality of dispersion.

A spindle or cowles mixer is used to mix colorants into liquids. The spindle is equipped with a sawtooth blade. The blade turns at 1000–5000 ft/s. Average mixing time is an hour.

Flushing. The Sigma blade mixer is used almost exclusively by pigment manufacturers. It is often referred to as a "flusher." It is named after the flush process, used by pigment manufacturers to incorporate pigment into a polymer. The goal of the process is to take the pigment while in its aqueous phase and transfer it into a plasticizer or polymer. Under temperature and shear, the pigment has a higher affinity for the polymer than water. The pigment migrates, into the polymer and the water is "flushed" (displaced) to the surface and poured off. The lid on the mixer is closed to pull vacuum and the dispersion is dried at an elevated temperature. It is allowed to cool and is cryogenically ground.

This process avoids drying of the pigment during its manufacture and thus there is no opportunity to form the "hard to disperse" agglomerates. The outcome is a highly loaded, up to 60%, pigment dispersion. It is nondusting, has excellent dispersion, and offers high throughput rates.

Concentrate houses utilize these products as single pigment concentrates or mix them with other flushes and traditional pigments to make high quality color matches for film and fiber. Flushing is also used to increase the pigment concentration in a typical dry color concentrate. With its high loading and low molecular weight carrier, flushing aids wetting of the dry color while at the same time increasing the pigment loading.

Dispersion Methods for Liquids

Milling is used to disperse pigment that is incorporated into a premix. The term "milling" is generally reserved for liquid or paste systems. There are several types of mills used to fully disperse pigment into polymer. Three-roll mills, media mills, and ball mills are the most common. They are used in making color dispersions for cast acrylics, epoxies, and plastisols.

Viscosity is the key to a good grind and/or dispersion in liquid systems. The colorant's loading and surface area are important factors. In general, higher loadings of low surface area pigment and lower loadings of a high surface area pigment are desired for a good grind. High surface area pigments can cause vehicle demand problems. Low viscosity mixes may run with little shear.

Three-Roll Mill. The three-roll mill was designed for the ink industry in order to incorporate pigment into liquid carriers. Its main use in plastics is for the manufacture of high quality plastisol dispersions and liquid colors. The typical pigment levels for these concentrates range from 25 to 50%. The pigment level is largely dependent on its surface area and the customer's requirements.

The mill is configured as a series of three rollers horizontally positioned. They are separated only by a small nip, which can be opened or closed to control the level of shear. The premix is milled and agglomerates are reduced as it is passed through the nip from roller to roller. The finished paste is scraped off the front roll. Several passes may be required to obtain a desired level of dispersion. The viscous paste is packed out in buckets.

Media Mill. The media mill, formerly designed for the ink and paint industries, is used in plastics, for the manufacture of liquid color or paste dispersions. Suitable ink or paint grade colorants along with dispersion aides are useful in solving viscosity and flocculation problems. Buehler, Netzch, and Schold are a few of the manufacturers of media mills. A premix is pumped through a cavity containing steel, ceramic, or glass shot. A variety of shot sizes are used. An impeller agitates the shot and the impact reduces agglomerate size.

Dispersion Methods and Equipment for Solids

Two-Roll Mills. Two-roll mills are key to making high quality PVC and rubber concentrates. These mills are easily cleaned. The batch process is ideal for producing small volumes; thus, a variety of colors and materials can be run without much equipment down time.

The two-roll mill rollers are parallel and horizontally mounted. The speeds and directions of rotation are different. The gap or nip between rolls can be controlled. Heat is applied or can be developed by friction. The dry premix is forced down through the gap and allowed to form a band or sheet on one of the rollers. There is little mixing, and so the banded material is usually cut and reintroduced manually to promote mixing (1). Leaving the material on the mill for a longer period of time can maximize dispersion. On occasion, the majority of the resin is added separately and allowed to band. The colorant blend is then slowly added. This can help contain the pigments and additives. The powders quickly stick to the banded resin and are incorporated as the material passes through the nip.

Banburry Mixer. The Banburry mixer is most often used to produce highly loaded concentrates for olefins and PVC. The process can be used with or without a premix. A premix is recommended when making highly loaded concentrates and/or using high surface area pigments.

The Banburry mixer is an internal, high shear compounder. Two cylindrical cavities intersect at an open feed throat that can be closed after the Banburry mixer is charged. Two intermeshing helical rotors turn at high rpm inside the cavities. A pneumatic ram seals the cavity for processing. Most are jacketed so they can be heated or cooled. Most are run cool, using shear to generate the heat to flux or melt the ingredients to form the concentrate. The fluxed material is unloaded via trapdoors in the bottom of the mixing chamber. The mix or molten mass can be fed either into an extruder and pelletized or onto a two-roll mill and sheeted out. Colors changes are rapid as the equipment is nearly self-cleaning.

Continuous Mixer. A continuous mixer is similar to a Banburry mixer but it offers the advantage of a continuous process. Residence time can be controlled by the size of the discharge unit and/or the feed rates. The continuous mixer is known for its ability to produce high volume but tends to lack in the quality of dispersion achieved in a Banburry mixer.

Extrusion

Plastics processing operations often include extrusion (see EXTRUSION).

Single Screw Extruders. The single screw extruder is the workhorse of the plastics industry. It is used to incorporate color into concentrates and compounds. It is also used to extrude rods, pipe, sheeting, film, siding, and other profiles.

An extruder consists of a hopper, a heated barrel, a screw, and a die. The hopper is used to flood-feed the colorant and plastic premix into the feed section of the screw. An alternative to flood-feeding is to starve-feed the screw by metering in a controlled flow of material. Metering is not required for a single screw and has been found to have no impact on pigment dispersion.

The feed section of the barrel can be cooled. The barrel can be heated at different temperature in different zones. The feed section of the screw is designed to convey the resin into the heated barrel, where melting takes place. The next zone is commonly referred to as the transition or compression section. The screw flights are smaller and decrease in size. External heating and heat from friction cause the melting to take place. The polymer melt is then conveyed, under pressure from the screw rotation, to the mixing and metering zones. Most extruders have a screen pack in front of the die to filter undispersed materials and trap contaminants. Typical downstream equipment consists of die face or strand pelletizing. Die face pelletizers are selected for high output extruders and “hard to run” materials.

Twin Screw Extrusion. Twin screw extruders provide more mixing and dispersion energy. In general they are more versatile as they are manufactured using segmented barrels. The different sections can be vented or used as a port to “side stuff” product into the melt stream. The length can also be changed with respect to the segments. Twin screw extruders have two screws mounted side by side. The flights of one screw are intermeshing with the grooves in the other screw. Screw designs are similar to those in a single screw extruder in that different areas

of the screws provide different functions. They differ in that they are usually modular and can be changed for a specific process or material. Screw elements are placed on a spline, as required. The elements can be for conveying, dispersing, mixing, devolatilizing, and kneading. A volumetric or gravimetric feeding system is required for a twin screw, as this type of extruder needs to be starve-fed.

Molding

Coloring may take place during a molding process.

Injection Molding. Injection molding is the process of forcing molten plastic into a mold where it is to be formed. Similar to extrusion, the process begins with delivery of the plastic to the feed hopper. The plastic is usually pelletized and is normally added directly or fed into a hopper. The hopper flood-feeds the resin directly into the feed throat. The barrel is heated and temperature profiles are established, similar to extrusion. The screw is unique in that it can move both forward and backward. As the screw turns, melted polymer is forced to the front of the barrel. It is held in place by a check valve. The pressure of the melt forces the screw backward in the barrel. When the desired shot size is reached the screw stops rotating. The valve is opened and the screw is driven forward. The plastic is forced through a nozzle into the closed mold. The melt is held under pressure by the cushion of polymer in the barrel. This allows the melt to completely fill or "pack" the mold. The mold itself is held under great pressure. After the part is allowed to cool, it is ejected. The screw starts to turn and feed fresh polymer into the barrel and the process begins again.

The screw and molding machine itself are designed for distributive mixing, and not dispersive mixing. Color concentrate is typically used for this reason. There is not enough shear to break down the agglomerates and aggregates of dry pigments. Dispersion problems and low value in use preclude dry pigment from most applications. Also, not many molders want to manage the color-matching process. By using precolored compounds or color concentrates, the color aspects are simplified and focus can be placed on molding.

Precompounded color contains all the needed ingredients required for the molded parts. It is simply added to the hopper and molded. Compounds are used when an excellent shot-to-shot consistency is required.

Concentrates require a letdown before molding. On the dry side, a typical letdown ratio is 25:1, or 25 parts of polymer mixed with 1 part of color concentrate. Viscosities or melt index of the polymers should be as alike as possible for the best mixing and color incorporation. The letdown ratio can be adjusted to achieve better economics or dispersion.

Higher the loadings lower are the conversion charges for the concentrate, and the better the economics. Lower the letdown ratio less colored pellets required, resulting in a lower probability of good mixing and color consistency.

On the liquid side, the color is let down in the feed section just above the screw or is introduced directly into the barrel. Here it quickly mixes with the polymer as it starts to soften. The liquid color is metered at a specified feed rate. This rate can be adjusted if required.

Applications for injection molding are numerous, and all but a few are colored. A few end uses are plastic containers and lids for the packaging industry, parts and components for toys, automobiles, electronics, appliances, etc.

Blow Molding. Blow molding is a process that utilizes internal air pressure to force the polymer outwards into a clamshell mold. This technique is a very practical way of molding hollow parts. Bottles for packaging are the main application; however, parts as large as plastic drums and garbage cans are made. The two types of blow molding are extrusion and injection blow molding.

Color is incorporated using the same processes as in injection molding. Pelletized and liquid color concentrate are let down into virgin resin. For injection blow molding the color is incorporated during the molding of the preform. In extrusion blow molding the color is extruded into the polymer, forming the bubble of polymer or parison. Some colorants are known to plate out and stain the mold and/or blow pin. Formulations using proper pigments and additives can prevent this occurrence. The down time required to clean the mold and blow pin is usually found unacceptable.

Extrusion Blow Molding. This is simple and economical. It can produce a variety of shapes, with fairly good control over wall thickness. The process is multistep. In the first step an extrusion of a tube of partially molten polymer is extruded down into a mold area. Then, the two halves of the mold close in on the tube of polymer. This cuts it from the extruder and captures the bubble of polymer inside. A blow pin (a hollow tube) is inserted and air is blown into the mold. The air forces the parison to fill the cavity (2). The flash or excess is then cut from the container ground and recycled when possible.

Injection Blow Molding. This is a two-step process. The first step is injection-molding a preform to be used in place of the parison in extrusion blow molding. Next the preform is placed into the blow mold. The preform can be soft, coming straight from injection molding, or it may require preheating. This is dependent on the type of process involved. The second step is the introduction of air through a core rod that is inserted into the throat of the bottle or part. Air pressures are higher than those used in extrusion blow molding.

Rotational Molding. The process of rotational molding is ideal for creating hollow parts. Polyethylene is the most common polymer used in rotational molding. Powdered plastic is introduced into a clamshell mold. Color and additives, usually a micro-pulverized blend, are added and the mold is closed. The mold is then rotated. The powder is distributed to the mold's surface by the centrifugal force. The mold is heated and a melt skin forms on the mold's surface. Spinning continues as the mold is allowed to cool. The mold is then opened, the part removed, and the process starts again.

Lack of mixing or shear makes the type of concentrate supplied to the rotational molder unique. Typical color concentrates, in the pelletized form, is ineffective for rotational molding. The pellets lack adequate surface to melt in and color a part. Commonly all colorants and additives are blended and micro-pulverized by a concentrate house. Pigment strength achieved by micro-pulverizing is not equal to that of an extruded concentrate. The molder simply adds the blend at the time the mold is filled. This ensures that the required color is achieved.

Fiber

Most fibers are created by forcing molten polymer through a spinneret to form continuous strands of polymer. This is typically accomplished using an extruder

or gear pump. A spinneret is a die that has one to several hundred holes. The tiny holes are sensitive to corrosion and clogging. Prefiltering of the molten polymer and frequent preventive maintenance to the die and filler are required. The polymer emerges in a semisolid state and solidifies in a process called spinning. This process is not the same as the "spinning" in the textile industry, where staple fibers are twisted into yarn.

Stretching and orientation is the last step. The fibers can be stretched or "drawn" while solidifying or after they have hardened. Drawing orients the molecular chains along the major axis of the fiber. This creates a much stronger yarn.

Most olefins are colored by adding color concentrates to the polymer melt during extrusion (solution-dyeing, mass-coloration, pigmentation). Other synthetic fibers are spun without color and dyed later. However, pigmentation is increasing because of the lower cost and better fastness properties. Pigmentation of nylon and polyester is experiencing rapid growth. No additional process water is required and no effluents are produced, as is the case in dye systems. Inventory flexibility is reduced with pigmented fibers.

Coloration can also be added in the condensation process before polymerization. In the case of polyester, this can mean the colorants are exposed to temperatures reaching 290°C for 5–6 h. Only a few high performance pigments can withstand these conditions.

The methods of spinning are (*a*) Melt, (*b*) Wet, and (*c*) Dry (3).

Melt Spinning. This is used with thermoplastics like polypropylene, polyamide, and polyesters. The polymer is blended with dry, pelletized concentrate or flush containing the additives required to color and stabilize the fiber. The mix is extruded and forced through a screen pack to remove agglomerates. The polymer is then pressed through spinnerets. The small strands of polymer descend vertically through a cooling chamber and are stretched and wound. The fibers can be spun in different shapes (round, pentagonal, octagonal, etc) to achieve a variety of appearances and properties.

Excellent dispersion is needed where pigments are used. After processing, remaining pigment agglomerates must not exceed 5 μm. Larger particles (pigments or additives) can lower the tensile strength and often cause failure as the fiber is stretched. With this in mind, dry pigment should be avoided. Pigment preparations, flushes or concentrates, are required.

Wet Spinning. This is used to spin a filtered viscous polymer that has been dissolved in a solvent. The spinnerets are submerged and the fibers are forced into a chemical coagulation bath. The filaments precipitate from solution and solidify. This is termed wet spinning as the fibers are formed in a chemical bath. Acrylic, rayon, and spandex are produced with this type of spinning.

In wet spinning a pigment's heat stability is of less concern than in melt spinning, but solvent resistance is required.

Dry Spinning. In dry spinning, the polymer is dissolved in a solvent, filtered, and forced through spinnerets. The fibers are then, by use of vacuum, pulled through an oxygen-free heated chamber. The polymer solidifies as the solvent evaporates. The filaments do not come in contact with a liquid and thus there is no need for drying. Solvent recovery is easy. Acetate, acrylic, and spandex fibers can be produced using dry spinning.

COMPOSITES, FABRICATION

Introduction

In the last half of the twentieth century, the processes used for fabrication of parts made from composite materials evolved from operations relying on manual labor to manufacture by automated equipment controlled from sophisticated microprocessor systems. Early pioneers combined fiber and resin raw materials and formed them into a finished structure by hand lay-up or spray-up on open molds. The parts were cured at ambient temperature.

As the value of fiber-reinforced polymers became apparent and accepted in electrical applications, recreation products, and corrosive environments, these synthetic materials began to penetrate virtually every other market worldwide, from automotive and marine to primary structural elements of aircraft and bridges. Such widespread growth in product applications mandated corresponding growth in materials technology, design approaches, and fabrication processes.

For convenience, terms frequently encountered in composite fabrication are defined below:

Angle of winding (wind angle)	The angle the roving band is laid with respect to the mandrel axis of rotation
Closed-end vessels	Parts that have much smaller diameters or totally closed domes at the ends
Debulking	A process in which air is squeezed out of a prepreg laminate in order to promote adhesion
Doff	Roving package
Fiber payout	Transfer of rovings from delivery system to product line

Encyclopedia of Polymer Science and Technology. Copyright John Wiley & Sons, Inc. All rights reserved.

Overtravel	The additional carriage or eye travel beyond the ends of the part mandrel that is necessary to provide laydown of the fiber mandrel
Mat	Chopped or random reinforcement material cut to the contour of a mold, usually impregnated with resin just before or during the molding process
Peel ply	The outside expendable layer of a laminate, which is removed to improve bonding of additional layers
Prepregs	Reinforcements in the form of a cloth impregnated with thermosetting resin advanced in cure only through the B-stage. The term also covers fabrics such as jute and rayon, which have been impregnated with a thermoplastic resin, eg, vinyl or ABS
Roving	A form of reinforcing fiber glass comprised of 8–120 (and usually 60) single strands gathered into a bundle, and treated with a coupling agent to promote adhesion of the glass to the plastic matrix
Tape	A form of reinforcement similar to mat and broad goods, cut in 7.5- to 30-cm widths, and of flexible consistency for laying onto a mold. Tapes are generally prepregs and are supplied with backing paper to prevent loss of integrity prior to use
Tow	Term used instead of roving to designate fiber strands when referring to graphite or boron reinforcements in the fiber strand form
Wet systems	Composite fabrication processes and equipment that incorporate reinforcement impregnation as part of the process, just before the raw material die entry or mold contact

Product and Machine Design

Before a fabrication process can be determined for producing a new product, and production equipment designed and built, the designer must know something about the product. In the formative years of composites fabrication, traditional procedures allowed each discipline to proceed independently, with little consultation between design and manufacturing. The result has too often been equipment that did not operate efficiently. Product and process optimization are only achieved through cooperative design, planning, and manufacturing.

An integrated approach is necessary to achieve the best results in product automation and economics. Cooperative effort among all disciplines is required from the start of a project.

Although it is not necessary for the machine designer to be familiar with every detail of manufacture, it is important to have certain basic data, such as environment, load paths, throughput rates, economic constraints, and configuration information.

Structural analysis is recommended to determine specific property requirements of the product application. Hybrid materials—for example, combining carbon fiber with glass fiber in areas of high stress—can often satisfy strength and

weight specifications at reasonable cost. An over-designed composite part that uses more material or higher cost materials than necessary cannot compete with wood, steel, and other established materials. However, a well-designed part can be commercially competitive, especially when installation, maintenance, and life-cycle costs are considered.

In general, the resin matrix of a composite product provides corrosion and weather resistance and other physical characteristics, and the reinforcing fiber imparts strength characteristics such as stiffness and impact resistance.

Fiber type, form, and orientation (fiber architecture) comprise the main considerations when choosing reinforcements. In a part that will be carrying little or no structure loads, chopped or continuous strand mat with random fiber orientation is sufficient. However, in a part that will see primary or secondary structural loads, fiber orientation is critical and departures from the optimum can result in drastic property reduction. Fiber architecture can be tailored for specific requirements, with parallel longitudinal (0°) strands carrying tension loads, circumferential (90°) strands providing compression and impact strength, and helical (commonly $\pm 33^\circ$ or $\pm 45^\circ$) strands handling torque stresses. This design principle is comparable to the way that civil engineers use steel-reinforcing bar in a concrete structure.

Responding to the challenge of achieving optimum fiber architectures, material producers have devised innovative braided, woven and nonwoven, and stitched fabrics that are being used today even in bridge decks, beams, and other primary structural elements.

The difficulty of making complex arrangements to direct oriented fibers into automated equipment is the primary reason why hand lay-up and other labor-intensive processes are still prevalent in the composite industry. However, this is not to say that complex arrangements are impossible; fiber architecture in nearly every conceivable configuration has been achieved on automated equipment. Appropriate design and arrangement of supply spools and folding tooling for pultrusion equipment, multiaxis controls on filament-winding and tape-placement equipment, and other devices make complex laminate schedules feasible.

The most common composite-reinforcing materials are fiber glass, carbon fibers, aromatic polyamide (aramid), and boron. The term composite is used throughout to include glass fibers and other so-called advanced composite materials (see COMPOSITE MATERIALS & COMPOSITE MATERIALS, FIBER-MATRIX INTERPHASES). Reinforcement selection is based on intended usage, and property values established for these materials can be used as guidelines. Although most machines accommodate all reinforcements, designers who know the type of reinforcement to be used can take unique characteristics such as high modulus into consideration.

In addition to the common roving strands, raw material is available in many other forms, such as preimpregnated (prepreg) and wet systems, mats (paper and nonwovens), woven specialties with knit and braided reinforcement, multiple-ply broad goods, core materials as they apply to automation, fillers, extenders, and additives (films, coatings, plating, etc). The characteristics of the reinforcement must be familiar to the machine designer.

Matrix selection is another important design consideration; resin chemistry can accommodate nearly every conceivable product application. Running speed,

cure rates, and final properties vary widely with resin, catalyst, additive, and fillers. Advance consultation with the supplier is recommended.

In addition to wet systems, where reinforcements are resin-coated during the process, more convenient prepregs are available that can be used for many applications. Suppliers assist in the selection of preimpregnated materials, which are available as unidirectional, woven, and nonwoven tape, tow, mat, and so forth.

Although thermosets are the standard composite matrices, recent advances in thermoplastic technology may change this situation.

The diversity of products that can be fabricated on automated equipment is fast expanding as suppliers increase the flexibility of raw materials, and designers and manufacturers gain experience with integrated designs.

Methods and Processes

Open contact molding in one-sided molds, typically spray-up and hand lay-up, is still common for fabricating large nonstructural parts such as boat hulls, recreational vehicle panels, and bathware. To reduce emissions of volatile organic compounds (VOCs) during processing, vacuum-assisted resin transfer molding (VARTM) systems can be used, which cover even very large parts with a vacuum bag before resin is applied (see Figs. 1 and 2).

However, VARTM systems are still highly labor-intensive, and as the industry matured, it sought to develop methods and processes that reduce labor and increase production rates.

Fig. 2. One-piece bridge deck made by SCRIMP process. Courtesy Hardcore Composites, New Castle, Del.

An early move toward automation and mass production was the invention of preform machines that sprayed chopped-glass strands onto a three-dimensional air screen that approximated the shape to be molded. The preformed glass mat was placed in a matched metal die in a compression molding press and liquid resin was added to form the product. Today, resin transfer molding (RTM) and resin injection molding (RIM) preform die-molding processes are used to mass-produce small and mid-size parts with two finished sides, notably automobile bodies, truck cabs, and even small boat shells.

Recent variations on preform technology include prefabricated preforms that are replacing wood as stringers for framing boat hulls (1). The preformed stringers are installed in an open hull mold, wet-out and co-cured with the hull skin laminate. In another development, prefabricated panels in a structural sandwich configuration can be purchased as a custom "kit" to build an original boat design (2). And in the late 1990s, a process was patented that lays up an entire boat hull preform, injects resin to wet-out the part, and compression molds the whole hull (with two finished sides) in matched composite molds (3) (see Figs. 3 and 4).

Sheet molding compounds (SMCs) that sandwich chopped fiber glass between two layers of resin paste are also used extensively to compression mold parts for the electrical, transportation, and other high volume industries. Automakers are exploring the use of carbon-fiber-reinforced SMC for body panels and other exterior parts because of the material's high strength and stiffness-to-weight ratio (4).

Bulk molding compounds (BMCs) are used for injection molding, which is a fast, high volume closed process. A BMC is a thermoset resin formulation containing 15–20% chopped fiber glass. A metered measure of the thick compound is dropped into the injection-molding machine and is forced by a ram or screw-type plunger through the machine's heated barrel. The compound liquefies as it

approaches its cure temperature and the liquid flows along channels into forming cavities in the mold, where it quickly cures. Nearly 2000 small parts can be produced per hour.

A thermoplastic version of BMCs, long fiber-reinforced thermoplastics (LFRT) are gaining ground in the automotive market because of their superior impact resistance and recyclability compared to that of thermoset compounds. Another significant advantage is that thermoplastics emit no VOCs during processing and so do not require the expensive environmental equipment and procedures required for fabricating thermoset parts. LFRT compounds can be processed by "plasticising" equipment in a process similar to injection molding, using a reciprocating screw extruder to move the material forward under low pressure, with low shear. This heats and "plasticates" the material, melting and mixing the compound. The screw pushes the hot charge out and drops it onto a cold tool, where it solidifies in the mold. The screw then retracts to pick up another charge. The material flows easily and so large parts can be made on smaller presses and at

Fig. 5. Twintex (Vetrotex) long fiber reinforced thermoplastic (LFRT) fabric—made by commingling woven fiber glass with polypropylene fibers—is preformed for manufacture of automotive bumper beams. Courtesy of Plastic Omnium, Paris.

lower pressure than other compression-molding systems such as SMCs. In a recent LFRT innovation, a commingled fiber glass and polypropylene woven fabric has been developed (see Fig. 5). In one successful product application, the fabric is being used to produce high volume, low weight structural bumper beams in Europe and the United States (5).

While many of these are automated methods and processes with economic advantage in high and low volume production, in most cases they produce nonstructural or semistructural parts using chopped or randomly oriented fibers. To meet the needs of the burgeoning infrastructure market for composite primary structures, fully automated and controlled processes using continuous fiber reinforcements must be used.

Pultrusion. The pultrusion process makes structural profiles of any shape continuously from composite materials (6–9), just as they would be extruded in aluminum. It is a one-step process that converts raw stock into finished product at rates up to 4.5 m/min.

Reinforcements are drawn into the system, impregnated with resin, and simultaneously formed and cured in a heated die; radio frequency or induction energy can be used to supplement curing (10–12).

The graphs shown in Figures 6, 7, 8, 9 illustrate the heat–pressure–time (line speed) interactions taking place inside a 90-cm long die during curing (13). The temperature profiles of Figure 6 show that the die temperature must be lower at the inlet to prevent pre-gel, and also at the exit to prevent hot-cracking. Preheating permits a more gradual die heat profile and avoids skinning. As can be seen from Figure 7, superimposing material temperature on the die heat profile shows inversion of the heat–flux relationship. First, the material absorbs heat from the die, then the die cools the cured profile. In Figure 8, material viscosity

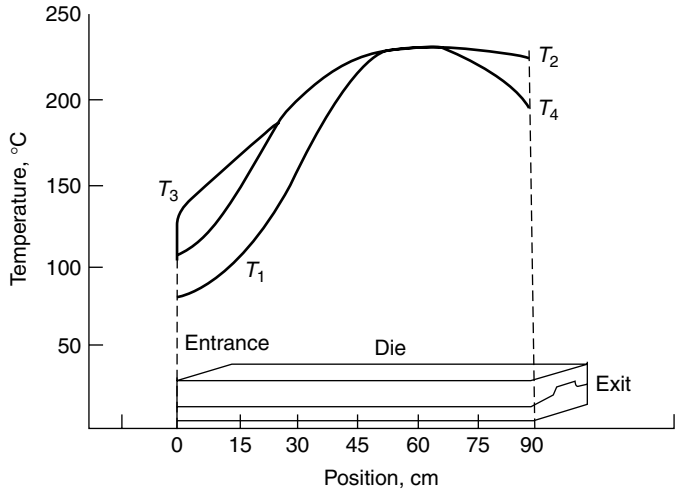

Fig. 6. Die temperature profiles. T_1, start-up; T_2, steady-state; T_3, with preheat; and T_4, cool-down.

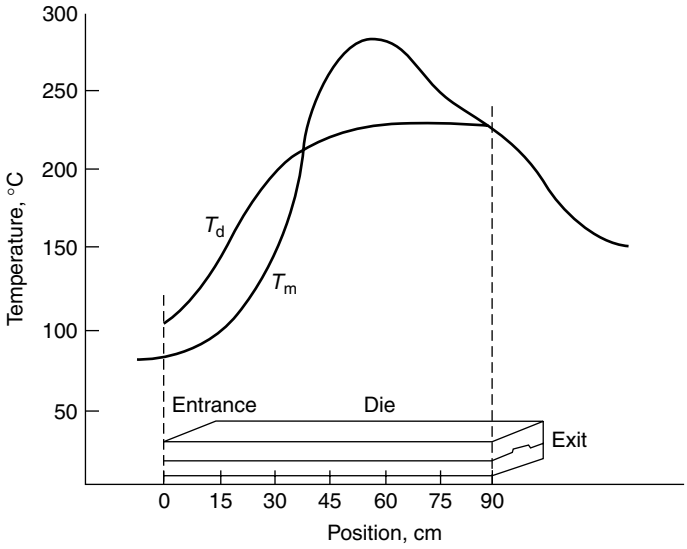

Fig. 7. Die (T_d) and material (T_m) temperatures.

is superimposed on temperature curves. Viscosity at the die inlet must be high enough to prevent porosity formation inside the die.

Pultrusion Machines. A typical pultrusion machine is shown in Figure 10. Reinforcements are impregnated by one of the available devices, in this case a pass-through-type wet-out tank, before passing through squeeze-out bushings. All the energy required to cure the resin system can be supplied by a radio frequency (r-f) generator. The process is run fast enough to bring the material into

the forming die just before gelation. The die, 75–120 cm long, is heated to prevent it from becoming a heat sink that would draw heat from the package. The cured product leaving the die proceeds downstream through the pullers, which gives rise to the term pultrusion. Unlike extrusion, in which the material is forced through a die with pressure, pultrusion pulls material through the die. As the stock leaves

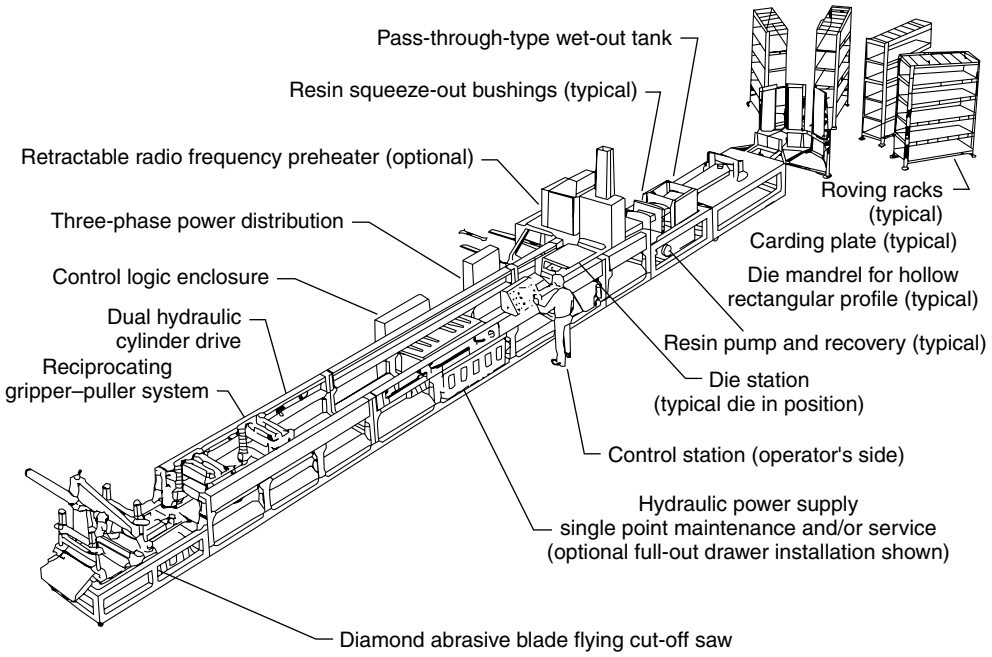

Fig. 10. Typical pultrusion machine.

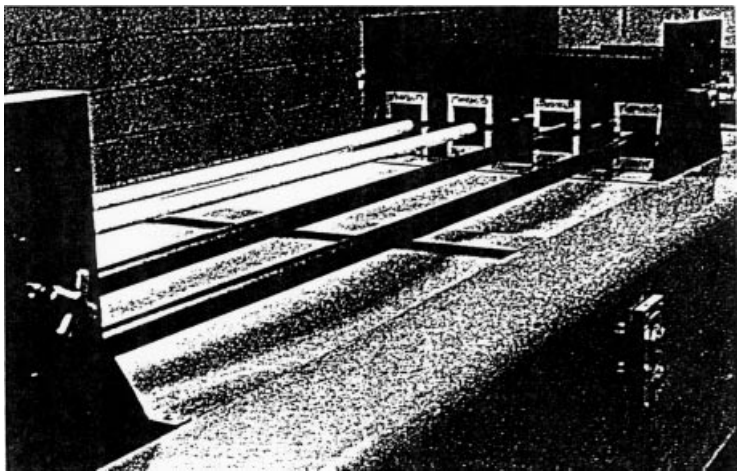

Fig. 11. Reciprocating clamp-puller system. Courtesy of Pultrusion Technology, Inc.

the pulling mechanism, a flying saw cuts it to length. Reciprocating clamp-puller systems with multistream capability, such as the equipment shown in Figure 11, are commonly employed.

Product center-line control is an often overlooked but necessary feature in pultrusion processing. This control can be conveniently provided by hydraulic jackscrews, which can change the height of the bottom platen (see Fig. 12).

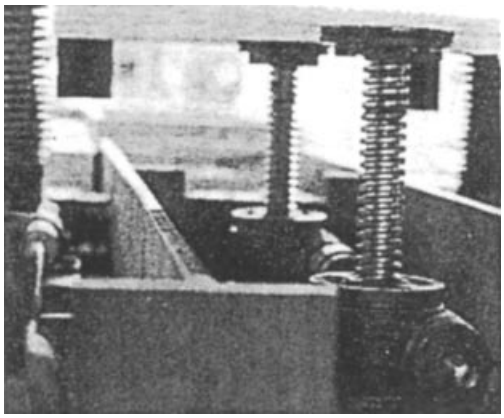

Fig. 12. Product center-line control. Courtesy of Pultrusion Technology, Inc.

Center-line control can also be obtained by shimming of tools on the bottom platen. Center-line height must be compatible with the height of the cutoff saw.

The trend in the United States to reduce air pollution has driven pultrusion manufacturers to reduce styrene emissions by enclosing the resin tank. This led to the development of the so-called injection die pultrusion, in which dry reinforcements are pulled into a heated die and resin is continuously injected through special ports directly into the closed die (14). An added benefit is that the dry preform retains its fiber orientation better than a wet package as it enters the die, and the die retains the fibers in position during resin injection. The result is reported to be a stronger part with more reliable and repeatable structural integrity.

Capacity. The capacity of pultrusion equipment is steadily increasing and the future market for pultruded product may be in profiles much larger than anything possible with traditional materials such as aluminum or rolled steel sizes. The Goldsworthy Pulmaster is designed to produce profiles up to 90 cm wide and 60 cm high.

The potential of automated composite fabrication is further illustrated by the pultrusion of residential building panels up to 2.6 m wide and 10–15 cm deep, with internal ribbing. A full-length panel can be tilted up on a building in any desired length, limited only by available means of transportation. Such large panels can be made because pultrusion is not a pressure operation, and size is limited only by the size of surrounding structure. Competitive processes, such as the steel rolling and aluminum extrusion, require very high pressures, and sizes are correspondingly limited.

Very large profiles are difficult to cut off. To reach the center of a 90 cm $\times$ 60 cm profile, a diamond saw, 19 m in diameter, is required. For the 90 cm $\times$ 45 cm capacity machine, two saws are used.

Fiber Orientation. Contrary to common belief, pultrusion is not limited to unidirectional reinforcements, but can bring reinforcing fibers into the profile in any needed orientation.

The development of inline winding wheels, which wrap roving around formed packages before they enter the die, and other material in-feed equipment enables

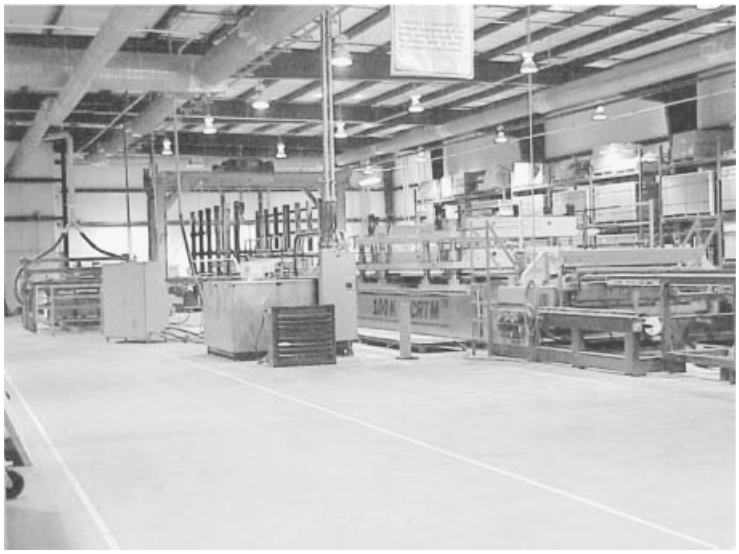

Fig. 13. Clean injection die pultrusion process and equipment is producing structural elements such as beams for bridge decks and one-piece 224-cm by 297-cm floor panels for semitruck cab and sleeper. Courtesy of Glasforms Inc.

pultrusion of fibrous reinforcements in virtually every axial orientation. Fiber forms from continuous strand mat to sophisticated stitched, multiaxial fabrics are being pultruded in both conventional and injection die processes. These systems have produced primary structure for load-bearing building panels, transmission towers, bridge decks, and even bridge beams (see Figs. 13, 14, 15).

Square tubing is made on the equipment shown in Figure 16, which includes longitudinal reinforcement of pure roving, three plies of random continuous fiber mat for omni-directional plies, and a circumferential overwind. Random mat is fed into a folding shoe that convolutely folds the mat around the mandrel, while longitudinal fiber is brought in from supply racks and the circumferential ply is applied by the rotating wheel.

Nearly any construction can be achieved. Tooling fabricated for round tubing with 6.25-mm wall starts with an inside ply of polyester wall mat, a ply of random glass fiber, and a ply of longitudinal fibers. Because of the thickness of the wall, this package is taken through an impregnating bushing; two additional plies of random glass mat are added, and the package wrapped with plies of pure circumferentials by a winding wheel. Another ply of random mat is added, following which a $+45^\circ$ ply and a -45° ply are added by large winding wheels. Another impregnating bushing wets out this last group of plies. The package then enters the r-f system, where the energy is introduced. More plies can be added. The product proceeds through the pullers in the usual manner.

Production Rate. Throughput speed depends largely on the resin system. A vinyl ester system at 1.2–1.5 m/min is used for the round tubing. Polyester and vinyl ester systems have been developed that permit a production rate of ca 4.5 m/min with pure unidirectional reinforcement. However, when an off-axis

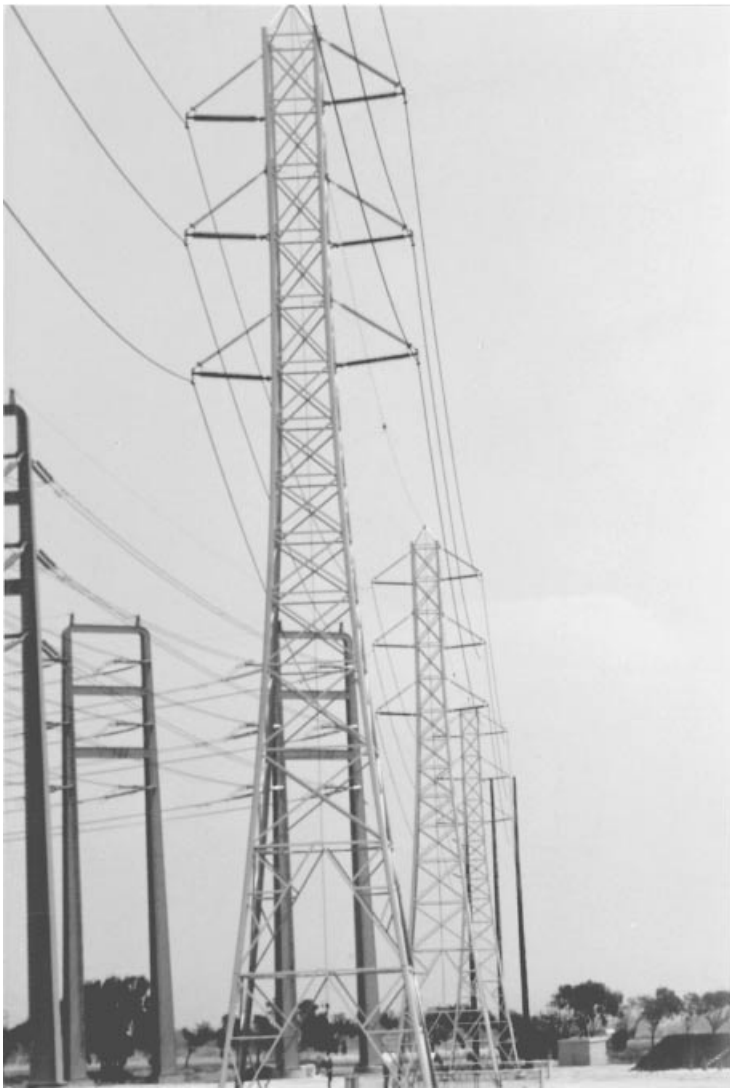

Fig. 14. Composite transmission towers energized at Southern Calif. Edison power generation station; the entire tower was constructed from pultruded structural elements. Courtesy of Goldsworthy & Assoc.

reinforcement such as mat is added, viscous shear forces increase exponentially with velocity, and at speeds of 2–3 m/min the reinforcements tear.

Radio-frequency heat is recommended only for glass-reinforced stock. For graphite or conductive fiber reinforcement, inductive heating is applied. The mass can be instantly heated through by one of these techniques.

Curved Configuration. Since there is no way to bend pultrusions after curing, curved pultrusion must be made in the desired configuration. The roving is drawn off supply racks in the usual manner, impregnated, passed through an r-f

Fig. 15. Pultruded transmission tower elements are joined by patented fastenerless interlocking system. Courtesy of Goldsworthy & Assoc.

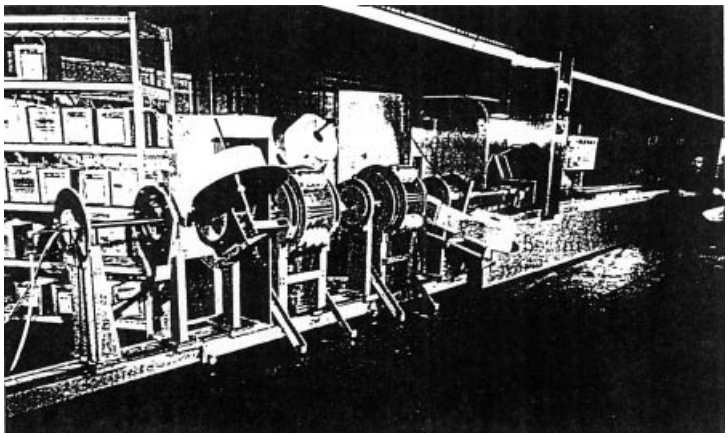

Fig. 16. Pultrusion machine tooled for square tubing. Courtesy of Goldsworthy Engineering Inc.

generator, and brought between a fixed and a rotating die. The preheated stock is pulled through the system by a curved die located on the face of a rotating curved quadrant, pulling the part continuously through the orifice formed by the fixed and rotating dies (15). Goldsworthy Engineering developed this curved pultrusion process and built prototype equipment for NASA for making graphite hat-section stiffener rings for the space shuttle.

Filament Winding. Filament winding allows control of fiber volume and orientation, utilizing continuous filaments, thereby maximizing laminate strength. The reinforcement, its alignment, and the resin matrix are determined during the design, according to process requirements. The winding process

parameters can be calculated from the product geometry and the wind angle for each layer. The angle of rotation required through certain portions of the mandrel is calculated, and circuit pattern, band width, and the number of circuits needed are determined. This is an iterative process; several variables are interdependent. After test winds, winding parameters are often changed; this process is repeated to give full optimization.

Nongeodesic winding, though more complex, utilizes the same theory. A friction factor is introduced into the fiber-path motion function, allowing the winding to be located out of its geodesic pattern; the matrix resists side slip. Tension and resin viscosity greatly influence the degree and speed of winding such patterns without resorting to mechanical resistance to side slippage.

Traditionally, the pattern was based on the fiber tension; winding proceeded along geodesic paths irrespective of structure. Innovative filament-placement techniques, however, deviate widely from the geodesic path, and may lead to winding of very complex structures.

This innovative technique was made possible by two developments: computer control and the winding on nonuniform mandrel surfaces. For instance, it would be possible in one operation to wind an aircraft fuselage with interruptions to the pure geodesic path such as doublers around doors and transparencies.

Filament winding was originally used to fabricate tanks and pipes; early equipment consisted of little more than converted lathes, with a reciprocating feed eye winding a helical pattern onto a rotating mandrel. This created the impression that helical winding of pipes and tanks is necessary, when in fact, other winding patterns are equally effective.

Winding can be accomplished on a horizontal (Figs. 17 and 18) or vertical (Fig. 19) tooling face. Employment of mechanical or computer-controlled filament-winding machines depends on equipment cost, part geometry, and usage, ie, dedicated to a single task or adaptable for a broad range. Capital equipment costs are significantly lower for mechanical machines, which, however, require time-consuming calculations and hardware changes.

If large quantities of simple parts are to be produced, a mechanical winding machine offers advantages. Programming consists of coordinating the motion

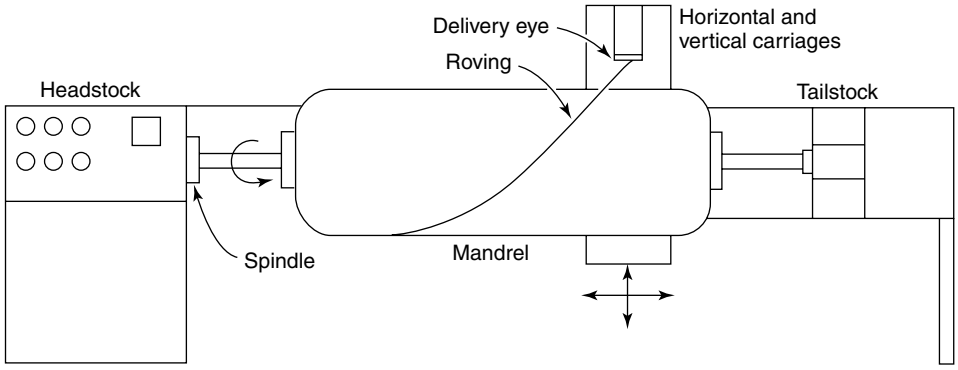

Fig. 17. Horizontal filament winding machine. Courtesy of Engineering Technology, Inc.

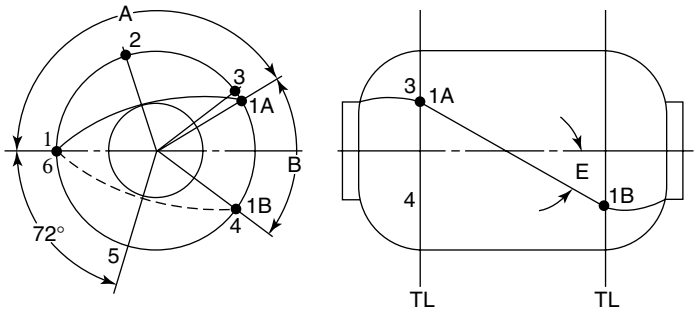

Fig. 18. Helical winding pattern. Courtesy of Engineering Technology, Inc.

between spindle and carriage by selecting a drive-gear ratio and determining the carriage drive sprocket and chain length.

Computerized programmable equipment is usually more cost effective where a variety of parts are to be produced or where part configuration is complex, such as a wind turbine blade. Sophisticated software for filament winding such as FGX Windows developed by Entec Composite Machines (Salt Lake City, Utah) allows the manufacturer to create patterns to wrap a pressure vessel, as an example, before winding begins. Filling in a simple menu defines the part geometry, and the computer uses this database to calculate a fiber path for the part and establish the

(1) wind angle throughout the path,
(2) friction values, which indicate if the fiber might slip anywhere on the part,
(3) thickness buildup on the part, and
(4) data to help with the analysis of the composite part.

It can also set band advance parameters. Small changes in the fiber path often drastically modify the way the fiber is distributed over the mandrel surface and a band advance module makes it easier to control these changes. By changing the band advance parameters in the computer, the operator can see what the result will be before winding begins. Winding simulations show how the final winding pattern will look on the part.

Equipment. A typical early filament-winding machine with rudimentary computer controls is the lathe-type winder illustrated in Figure 20, utilizing rotating mandrel and traversing carriage.

Another type is known as the orbital, or racetrack winder, where the winding heads move completely around the mandrel, as shown in Figure 21. It is used primarily for rocket motor cases and where polar winding is desired; high speed is attainable.

In the tumble-type winder (Fig. 22), the mandrel is tumbled end over end during a polar wind, whereas the feed eye is traversed and the mandrel rotated in the normal lathe-type fashion for helical or circumferential winds. This type is widely used for high volume commercial products such as water-softener tanks and pool filter tanks.

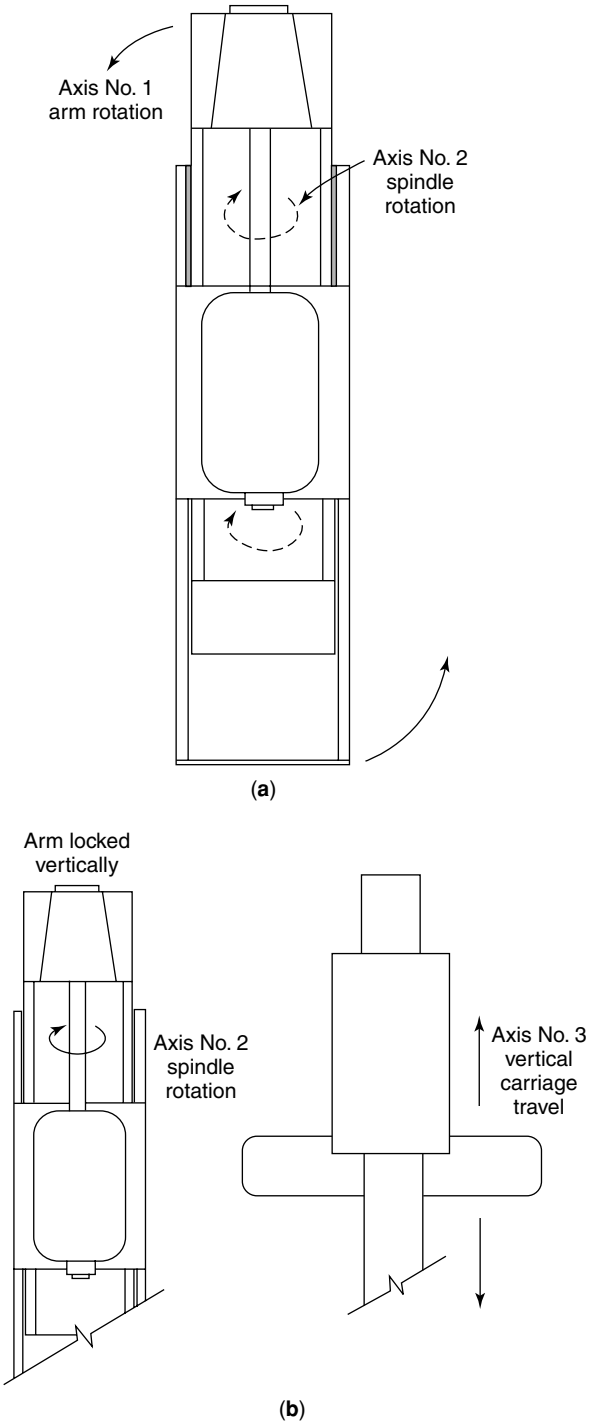

Fig. 19. Winding on a vertical mandrel; (a) longitudinal; (b) circumferential. Courtesy of Engineering Technology, Inc.

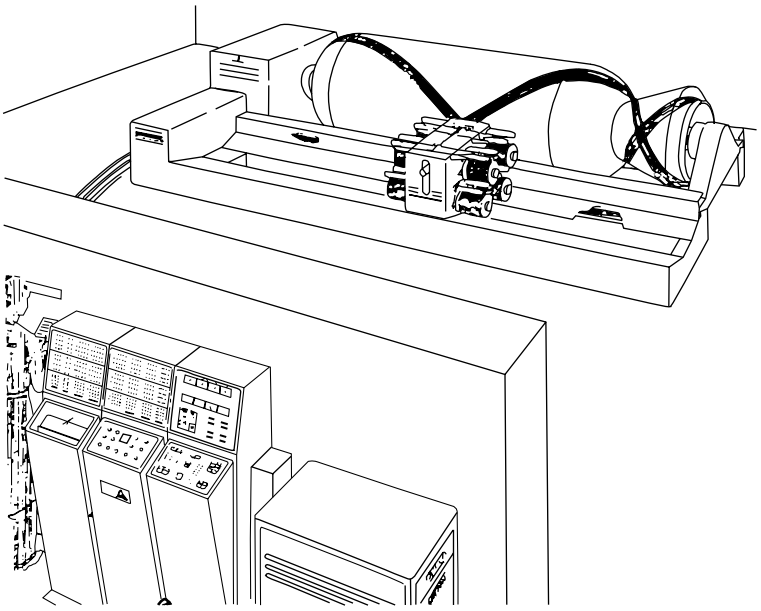

Fig. 20. Typical lathe-type filament-winding machine.

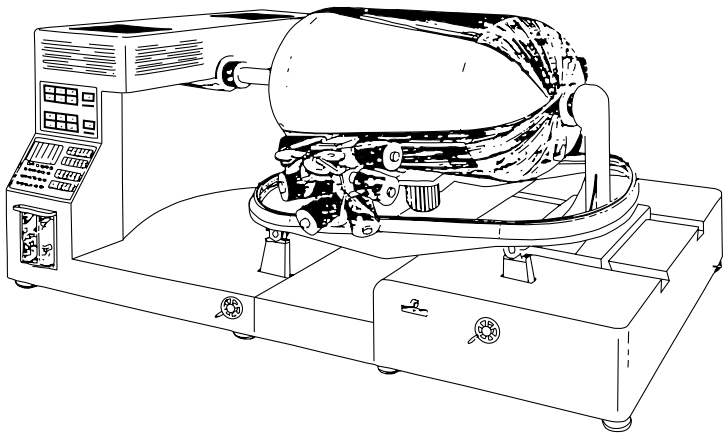

Fig. 21. Typical racetrack-type filament-winding machine.

Whirling-arm filament winding is illustrated in Figures 23 and 24. Polar wind is accomplished by means of the C-shaped arm, which supplies filaments from feed eyes at both extremities. While whirling on its horizontal axis, the arm winds on the polar axis of the mandrel, which is circumferentially indexed at appropriate intervals. During polar wind, the horizontal winding arm is retracted;

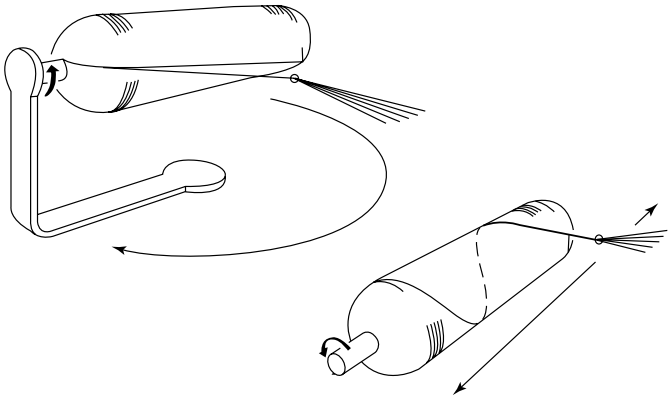

Fig. 22. Tumble-type winder.

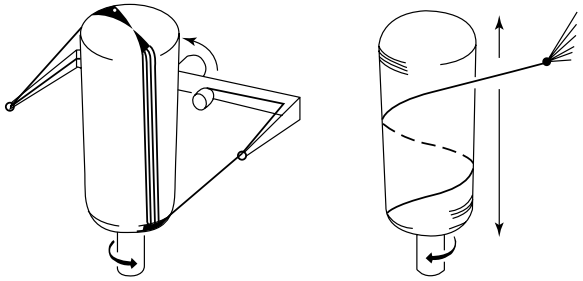

Fig. 23. Whirling-arm-type winder.

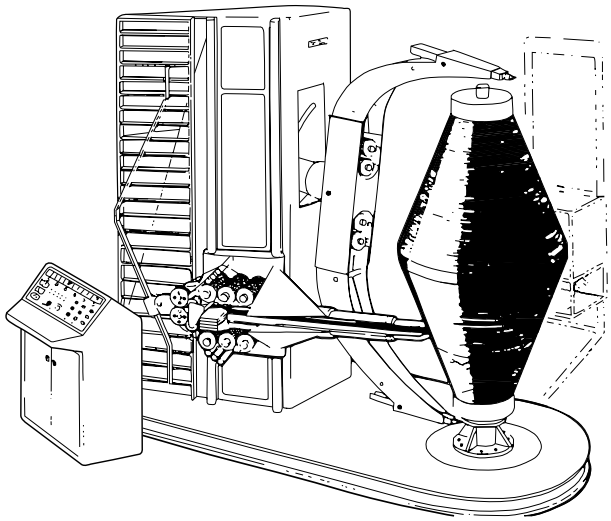

Fig. 24. Typical whirling-arm-type filament-winding machine.

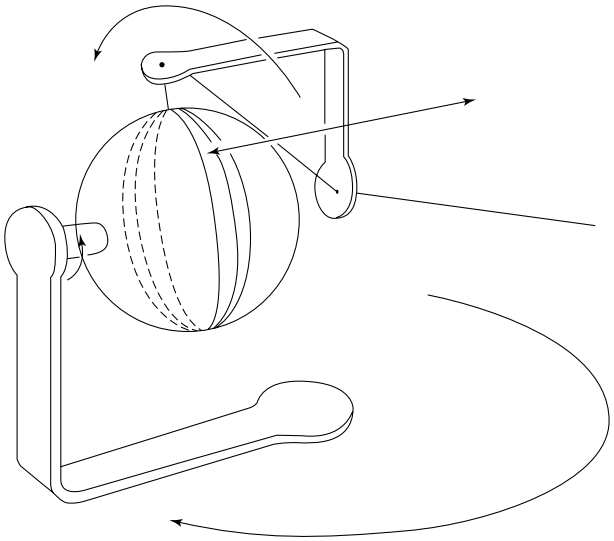

Fig. 25. Spherical winder.

when the polar wind is completed, the horizontal arm extends and reciprocates vertically to effect helical or circumferential winds while the mandrel rotates.

Although filament winding is most commonly employed on curved surfaces of rotation, it is also possible to wind on flat-sided surfaces. A flat-sided whirling-arm winding machine was built in the early 1960s for winding high strength instrument cases (16). All six faces of the tool had to be wound, and rather than using normal support mandrels, the tool was flipped into position by means of hydraulically operated tables.

Spherical winding is most difficult (Fig. 25). Before the advent of the computer, most machines were digitally controlled.

Contact-type balls, such as basketballs, volleyballs, and soccer balls, are filament wound. Although a totally random wind must be effected, it must be controlled; because it is necessary to wind all over the ball, there is no way of holding onto it or driving it. The required controlled random pattern can be obtained by suspending the rubber bladder on an air column and changing product rotational speed and thereby direction of wind by air jetting the column.

In a ring winder (Fig. 26), the winding head rotates around and traverses a passive mandrel. This type originated for the filament winding of massive structures, for example, a 45-m windmill blade. It is clearly a formidable task to support and rotate such a structure. The ring-winder design allows the mandrel to remain passive while the rotating ring-feed-eye assembly reciprocates along its length, laying a helical pattern. Steady rests stationed along the length of the part are hydraulically lowered by the carriage and raised behind it.

Tape Laying. Tape-laying equipment utilizes an automated tape-laying head to place the tape contiguously on a pattern table or mold in such a way

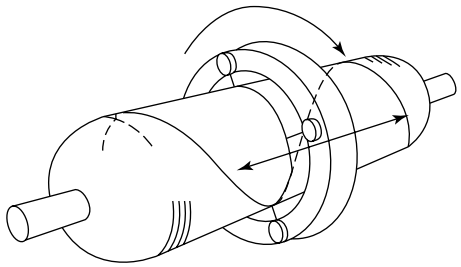

Fig. 26. Ring-type winder.

that each tape lies within a specified distance of any previous tape course with no overlap. Precise sequential-layer orientation (cross-plying) is mandatory for strength; taper can be achieved by step-back buildup (17). The raw materials used at present are graphite, aramid fiber, or glass reinforcements in the form of unidirectional or woven tape. Widths range from 2.5 to 30 cm. The tape is usually impregnated with an epoxy-based resin system.

Early automated tape laying imitated manual operations to lay 7.5-cm unidirectional tape on a flat table. All manufacturers at first produced 7.5-cm tape, and tape-laying machines were built accordingly. Tape sizes were then extended to 15 and 30 cm, then back to 2.5 cm. Today most machines have two heads: one for 2.5-cm, and another for 15-cm tape.

This progress resulted from the fact that if tape of any width is laid over a compound curvature, one edge of the tape travels farther than the other. Hand lay-up in the manufacture of aircraft structures established the tradition of using unidirectional tape for flat patterns, which in most cases were draped in the tooling to form simple curved parts. As the need to produce parts with compound curvature became apparent, manual methods were adapted to machinery, although they usually incorporate guided adjustments that the machine does not imitate, leaving ripples at the long edge.

A typical early tape-laying head is illustrated in Figure 27. As this device was built without computer control, optical devices were utilized to sense the edge of the tool, accelerate machine motion, set shear to the right angle, and trim the tape (17). At that time, the head was usually built separately and then attached to an existing machine. For example, a head built by Goldsworthy Engineering was used by Lockheed with a profiler as the host machine; the lay-up is trimmed after the machine is in place.

The first machine to use 30-cm tape fabricated weapon bay doors for the B1 bomber. A government contract limited the expenditure by the prime contractor (Rockwell), but without any sacrifice in accuracy. Requirements were met by a manually operated machine with automatic width indexing, with other motions initiated by the operator.

Computer Control. The Army's desire to test an all-purpose, multiaxis tape placement machine led to the next step forward, an automatic machine built in 1974 for helicopter rotor blades for the Army Aviation Systems Command (AVSCOM) (19). This was the first 6-axis minicomputer-controlled tape-laying

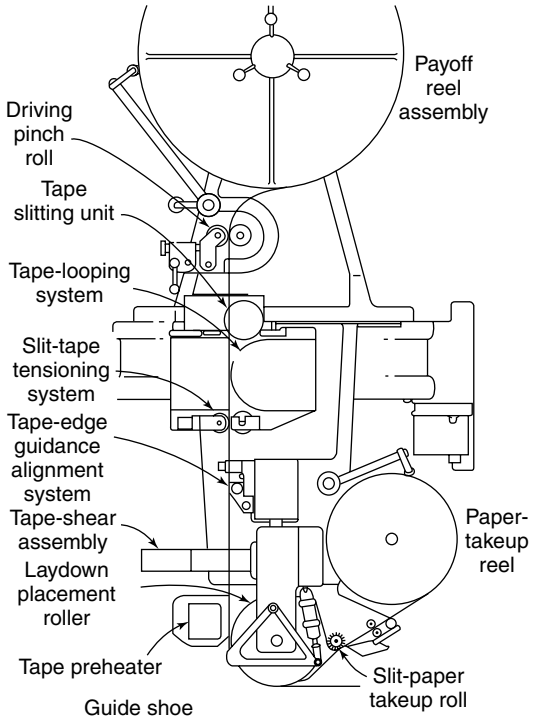

Fig. 27. Typical early tape-placement head.

machine. The entire gantry, including the *Y*-axis structure, was built from composites. At first, army personnel strenuously objected because of the established use of iron machine tools. However, an essential element of tape-laying machines is rapid *X*-axis travel, and it was vital to control the structure at the desired speeds. The composite gantry provided this capability.

The machine was actually an 8-axis machine, with two steady rests to support the blade tooling. Extreme compound curvatures existed in the transition area between the air-foil section of the blade and the hub section. For conformity with these extreme compound curvatures, the tape head had the capability of splitting the 7.5-cm tape into 24 individually tensioned 0.31-cm tapes.

In the first composite blade to be laid up, the spar was built up on the machine, honeycomb put in place to form the section of the blade aft of the spar, and the skin wound over it. In effect, this structure became a mandrel in place.

This machine was an excellent tool for developing the techniques of spar making, skin lay-ups, and attachment of helicopter rotor blades; it pointed the way to specialty production machinery (see Figs. 28 and 29).

Production Design. These machines were adequate in the airframe industry for prototypes and testing, but large structural components require production tape-laying machines. These presented certain problems, of which the most pressing was that the tape, lacking integrity, must be guided by the backing paper. If

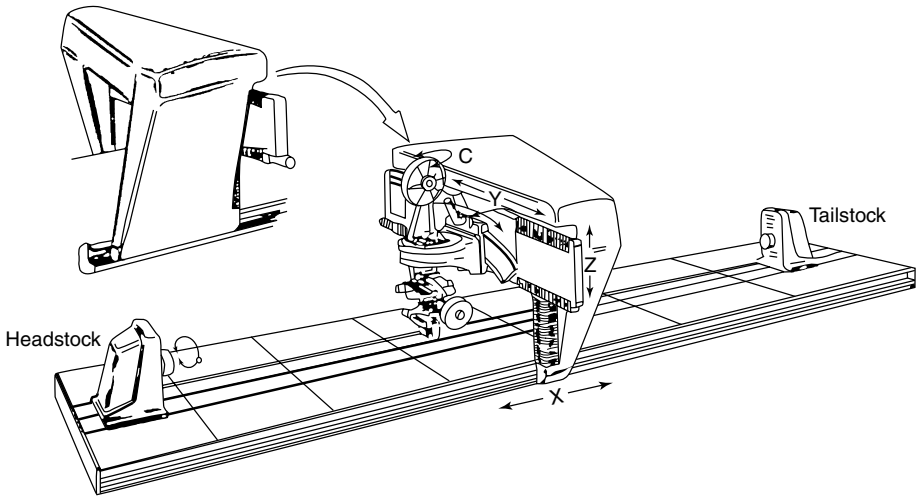

Fig. 28. Original 8-axis automated tape lay-up system (ATLAS). Courtesy of Goldsworthy Engineering, Inc.

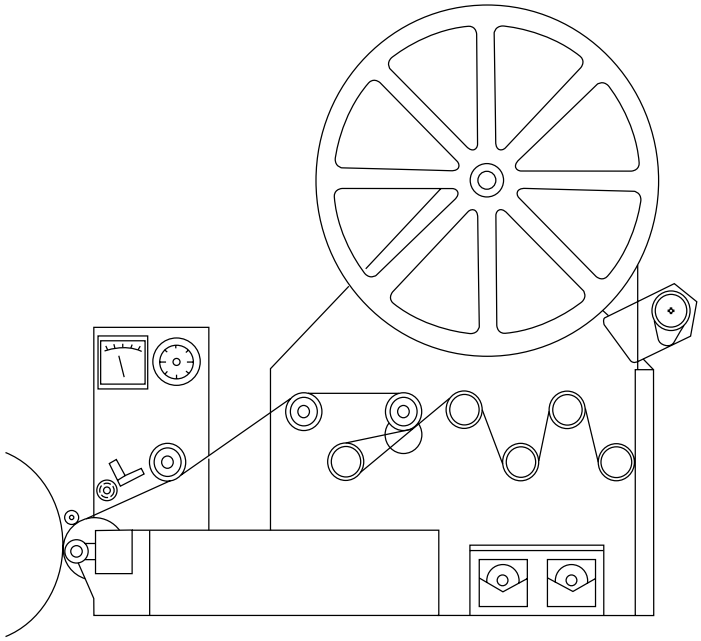

Fig. 29. Tape-wrapping head. Courtesy of Cincinnati Milacron, Inc.

tape and paper are separated, tape control is therefore lost. It follows that a device is required that will shear the tape to the proper trim angles without shearing the backing paper. A number of devices were developed to perform this difficult task; their success rate has been about 93%. Unfortunately, a 7% failure rate is

disastrous since even one uncut filament destroys the integrity of the entire system by pulling it up when the head lifts; the damage must be repaired manually before resuming production. In other words, even a low failure rate destroys the automated functioning of the machine.

High angle cuts present a similar problem. The long tapering tail on one side of the cut needs to be pressed down, and the other side picked up.

To overcome these and other difficulties, Goldsworthy Engineering developed a two-phase system (Fig. 30): tape preparation is accomplished in phase I, and lay-up in phase II.

In the preparation phase designated ACCESS (Advanced Composite Cassette Edit–Shear System), the supply spool is interfaced with CAD system software specific to the part to be produced. The material from the supply spool is measured, cut lengthwise, angled on both ends, and transferred to new backing paper in order to be spaced to compensate for long tails. Defective material is removed. Voids, cut failure, and high angle problems during lay-down are thus eliminated. The cut tape on its new backing paper is rewound on a new supply spool, and the "composite cassette" installed on the tape-laying machine for the second lay-up phase of the system. The second phase is termed ATLAS II (Automated Tape Lay-up System, second version).

This ACCESS/ATLAS II system offers several important advantages: 100% shear dependability, properly spaced tails, preinspected and edited tape, and elimination of all waste motion from the tape-laying machine. The result is higher production rates.

However, the most important feature of the ACCESS/ATLAS II is that it is the only tape lay-up machine that will lay compound contours. The reason it can do this is that the ACCESS system cuts the tape lengthwise into narrow strips. As the ATLAS machine dispenses the cut tape from the cassette along the contour of the tool, both edges of the tape travel the exact same distance. This contrasts sharply with standard tape-laying where typically 3-in. to 12-in. wide patterns are laid down; as the tape follows the contour of the tool, the tape edges must travel unequal distances, creating folds and wrinkles in the tape.

The only other alternative for automated lay-up of compound curvatures is fiber placement, which lays individual tows on the part.

Fiber Placement. Fiber placement machines can separately dispense, cut, and restart each tow during placement on the mandrel.

Cincinnati Machine (Cincinnati, Ohio), Automated Dynamics (Schenectadm, New York), Ingersoll Milling Machine (Rockford, Illinois), and other machine manufacturers are building multiaxis fiber-placement systems for building complicated parts and primary structures in a wide range of sizes. Computer numerical controls (CNC) on Cincinnati's Viper Fiber Placement System steer thermoset prepreg tow and slit tape over curves and into hollows to make a variety of complicated shapes for such things as engine inlet ducts, cowlings, side-skin panels, small fuselage sections, and spars for rotor blades and rotor grips on helicopters (see Figs. 31 and 32).

Pulforming. The curved-pultrusion process developed for the NASA shuttle stiffener rings led to so-called pulforming. In this process, as in pultrusion, primary reinforcing fibers are drawn through a tank for resin impregnation and then through a die. Pulforming may be curved or straight with machines that

produce profiles of changing volume and changing shape or constant volume and changing shape.

Changing Volume and Shape. An example is the composite hammer handle made continuously on straight pulforming equipment (20). Volume is changed

as follows: a BMC in the form of extruded rope on a supply spool is fed through a monitoring device that measures length to provide the desired volume. The length is cut and crimped around a single traveling roving strand at uniform intervals. The result resembles a string of beads proceeding downstream. A blivet press traveling at line speed forms the BMC pieces into the shape of the changing volume. Further downstream, all primary reinforcing fibers come together to encapsulate the center fiber with the formed BMC. Film is convolutely folded and ultrasonically welded around the package, creating a roll, which passes through a shrink tunnel; this tightens the film to produce a very controlled package.

The package next enters a split female die, which travels at line speed downstream and is closed with a C-press, which injects the die into a belt-clamping system that butts a whole stream of the dies together. The dies are heated as they traverse the clamping area; when they reach the end, the dies open, releasing cured stock, and return to the upstream C-press end of the die section. Operation is thus effected continuously. The part is cut to length with a flying saw.

Constant Volume and Changing Shape. The automatic machine pictured in Figure 33 was developed to make automotive leaf springs (21,22). Reinforcing materials from supply racks pass through an impregnating tank, are heated in an r-f generator, and enter the die cavity, which is at the convergence of a

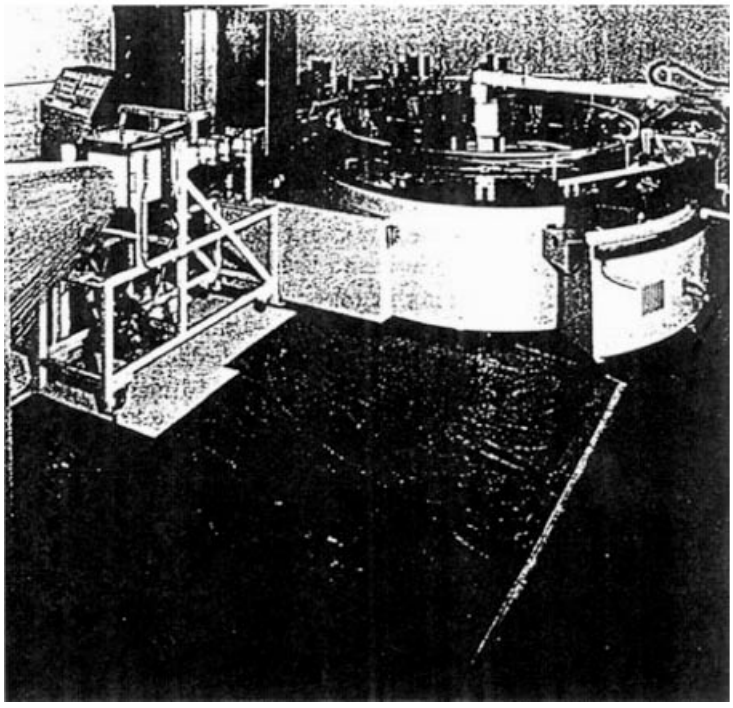

Fig. 33. Pulformer curved pultrusion machine; constant volume–changing shape. Courtesy of Goldsworthy Engineering, Inc.

stainless-steel belt and the rotating die. The die cavity is in the shape of the spring to be produced. The stainless-steel belt is clamped to the die face and runs continuously with it, thereby closing the fourth side of the die. Curing of the part is finished along that belt; it is then peeled out of the die cavity and guided into the path of the flying saw. At present, such machines are controlled by standard switch and relay logic; future machines will utilize programmable controllers. Production rate, depending on specific configuration, is approximately two springs per minute. Springs produced by pulforming are much cheaper than steel springs.

Specialty Machines. Machinery can usually be designed to accommodate any reinforcing fiber and resin system on the market today. Since the goal is the lowest possible cost, the industry usually employs roving or tow as the cheapest raw material, and thermoset polyesters and vinyl ester resins, rather than epoxies, for the highest running rates.

Most of the machines described here are flexible as to fibrous form; however, very high modulus fibers, such as carbon graphite, can create problems. If designers know that high modulus fibers are to be used on prospective equipment, they can plan accordingly.

The specialty machinery described below was designed for a variety of applications and demonstrates the flexibility of automated composite production equipment.

Plywood. Composite-faced plywood equipment for the truck and container industry continuously applies a bidirectional glass facing to both sides of standard plywood (3 m × 1.2 m), producing an endless laminate-faced plywood panel 3 m wide. An automatic saw cuts it to the desired length, the standard being 12 m × 3 m (23–25).

The plywood is stacked at the entrance of the machine, where it is automatically elevated, separated, and butted at the edges, then driven into the system. Cross-ply glass is applied with a large winding wheel, holding about 80 doffs of roving, which rotates around the plywood as it proceeds at a controlled rate. Longitudinal rovings are added by feeding roving through carding racks above and below the product stream just ahead of an opposed belt laminator. Resin is poured onto the upper and lower surfaces of the product just upstream of the longitudinal roving contact point, wetting cross and longitudinal fiber as it enters the opposed belt laminator. The package proceeds through the laminator and is cured, trimmed, and cut to length.

Sporting Goods. A continuous-taper tube-winding machine is used to manufacture graphite–epoxy golf clubs (26). Stock is filament wound using ten stacked winding wheels; speed is individually controlled in such a way that angle of wind and tape can be varied for production of flexible or stiff shafts. Steel mandrels are centerless ground to the taper requirement; the small end of one mandrel is indexed into the large end of the other, and the mandrels can pass continuously through the machine.

Insulation. A reinforced foam machine designed for McDonnell Douglas may be the most complex automated composite fabrication equipment ever built (27). Its purpose was to produce a 70 cm × 22.5 cm three-dimensionally reinforced, urethane foam log continuously, to be used for insulating tankers transporting liquefied natural gas. This equipment probably holds a record number of ends of reinforcing material handled on a single machine. A supply rack feeds 3500 ends

of glass fibers into the system for X and Y reinforcement; additional creels in the center section supply 1500 ends of *Z*-direction fiber.

Military Equipment. Filament-winding machines are used to wind wet filament on 155-mm artillery projectiles, five shells at a time on a 3-min cycle. The steel casings are automatically loaded horizontally onto a continuous chain- and spud-conveyor system. The casings are oriented vertically under a row of winding heads, which move into position for winding and then withdraw. At the next station the filament is severed, while the conveyor brings a new bank of shells into position. The wound shells are cured in an r-f oven and removed at the end of the machine.

During the Vietnam war, a machine was designed to transport water, gas, and jet fuels to the front. Rolled steel or aluminum tanks were bulky, awkward, and required seam welding, a skilled operation. A pultrusion machine was installed in a standard 12-m highway trailer, and a composite tank constructed on-site (28).

After the foundation was poured, a continuously pultruded tongue-and-groove profile resembling hardwood flooring was produced in the length required for the tank wall (ca 1560 m). An unusual feature was that two streams of two-sided, bondable Tedlar were fed in with glass roving reinforcements, to create an impermeable barrier. The profile was fed into an erection machine that wound and zippered it continuously together while injecting epoxy bonding. With unskilled labor, the prototype tank (6 m in diameter and 3 m high) was erected in about 4.5h and then grouted into the foundation.

Under the auspices of the Air Force Materials Laboratory, Air Force Wright Aeronautical Laboratories (AFWAL), several primary airframe manufacturers such as Grumman Dynamics have spent several years in research and development of automated integrated composite laminating centers, commonly termed "factory of the future."

Grumman's integrated laminating center (ILC), for example, fills the need for more fully automated fabrication of gently contoured composite structures from unidirectional tape (29). Elimination of manual operation significantly cuts costs of airframe components such as the 56-ply covers of the F-14A horizontal stabilizer (utilizing 7.5-cm wide boron–epoxy tape), and hybrid boron graphite–epoxy B-1 stabilizers. In the late 1970s, Grumman teamed with AFWAL to develop mechanized equipment for fabricating severely contoured, integrally stiffened, complex structures for high performance aircraft. For the Automated Integrated Manufacturing System (AIMS) (Fig. 34), three modules were integrated with the ILC, ie, a contour ply handler, broad-goods prepreg dispenser, and trans-laminar stitcher. Computerized air-passage contour database; computerized detail design of flat ply patterns, templates, and curing tools; and computer-generated nesting pattern for automatic laser trimming are included.

Automotive Applications. Another example of low cost production is provided by a machine continuously manufacturing automotive drive shafts. A hybrid drive shaft is produced with glass fiber in the $\pm 45^{\circ}$ directions to take torsional loads and graphite as longitudinal fiber for stiffness. An endless stream of mandrels is fed through the machine; steel end fittings are inserted and later welded to universal joint spiders. Winding wheels apply glass fiber, and longitudinal graphite fibers are fed in at the next station. Circumferential fibers are added last. The mass is cured by induction heating.

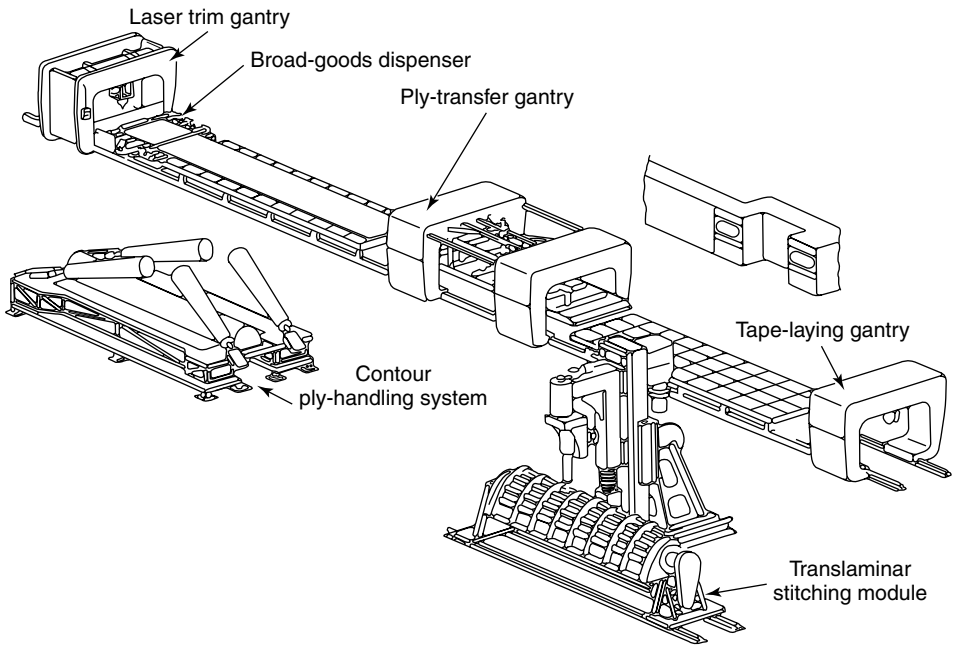

Fig. 34. Factory of the future: Grumman's Automated Integrated Manufacturing System (AIMS). Courtesy of Grumman Aerospace Corp.

Other automotive applications include pulformed leaf springs, bumpers, door frames, and others.

Aircraft. A "pin winder" built for Bell Helicopter for making blade spars is shown in Figure 35. Carrying impregnated S-glass, the carriage moves along the tooling bed, rotating 180° at each end. The beam is computer-controlled for vertical *Z*-axis motion; the feed eye moves in a plane but any path is possible.

Interest has recently grown in the fabrication of structural aircraft components from composites, but it must be understood that neither economic nor performance benefits are realized by designing a metal airplane and building it from composites.

A 2.4-m full-scale test section of a geodesic aircraft fuselage is shown in Figure 36. The entire fuselage section is filament wound. Although during World War II thousands of Wellington bombers were built with geodesic structures, they are troublesome with metal. However, a geodesic pattern is probably the simplest design for composite aircraft structures. By a straightforward procedure, the structure is wound first, and then the skin. The test section shown in Figure 36 was for a pressurized airplane, and therefore required bulkheads at both ends; these usually create severe stress problems. Problems also arise in the filament winding of end sections. They were solved by winding across the pressure bulkhead and keeping it in tension with the structure being stiffened. The wound skin was cured in a female die to form aerodynamic surfaces. A peel ply was wound with the skin in the geodesic pattern, leaving a clean surface after stripping. Both

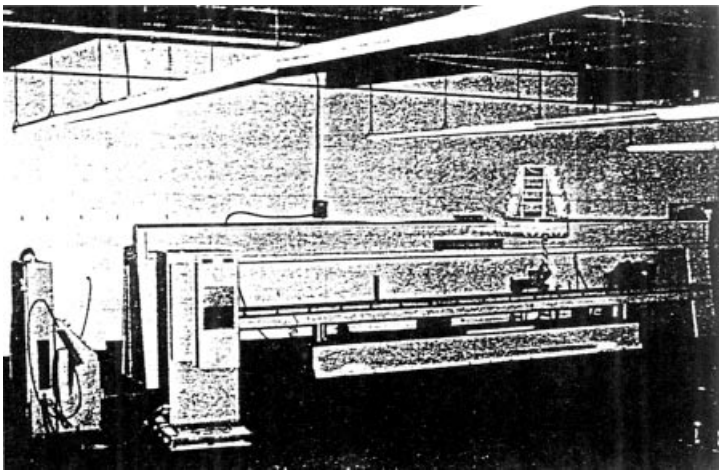

Fig. 35. Helicopter spar "pin winder." Courtesy of Goldsworthy Engineering, Inc.

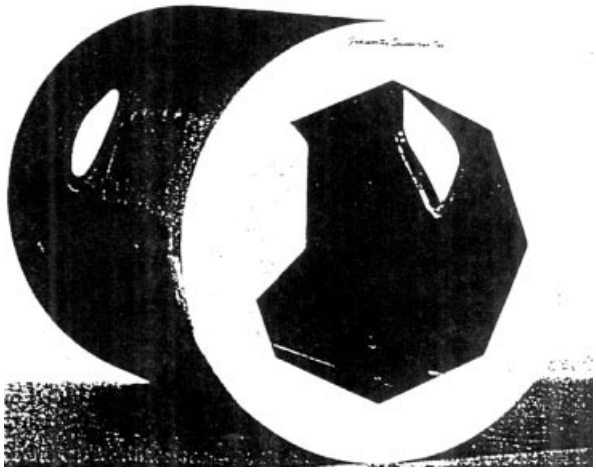

Fig. 36. Geodesic aircraft fuselage. Courtesy of Goldsworthy Engineering, Inc.

diamond and round windows were wound into the test section, the former because they were compatible with the geodesic structure.

Composites in Orbit. A ribbon-forming machine was developed for the NASA SSPS (satellite solar power system) program (Fig. 37). The $0 + 45 - 45 - 0$ graphite–thermoplastic matrix ribbon formed would be installed in a cassette in a machine in the cargo bay of the space shuttle. In orbit, the machine would process the ribbon into a triangular truss beam (see Fig. 38). The graphite-reinforced, polysulfone matrix ribbon is formed and welded into the triangular closed beam. The intercostals are continuously wound or welded on the beam to form a truss. Prototype equipment was built in the Goldsworthy Engineering laboratory, and a triangular truss beam is on display at NASA Huntsville, Alabama.

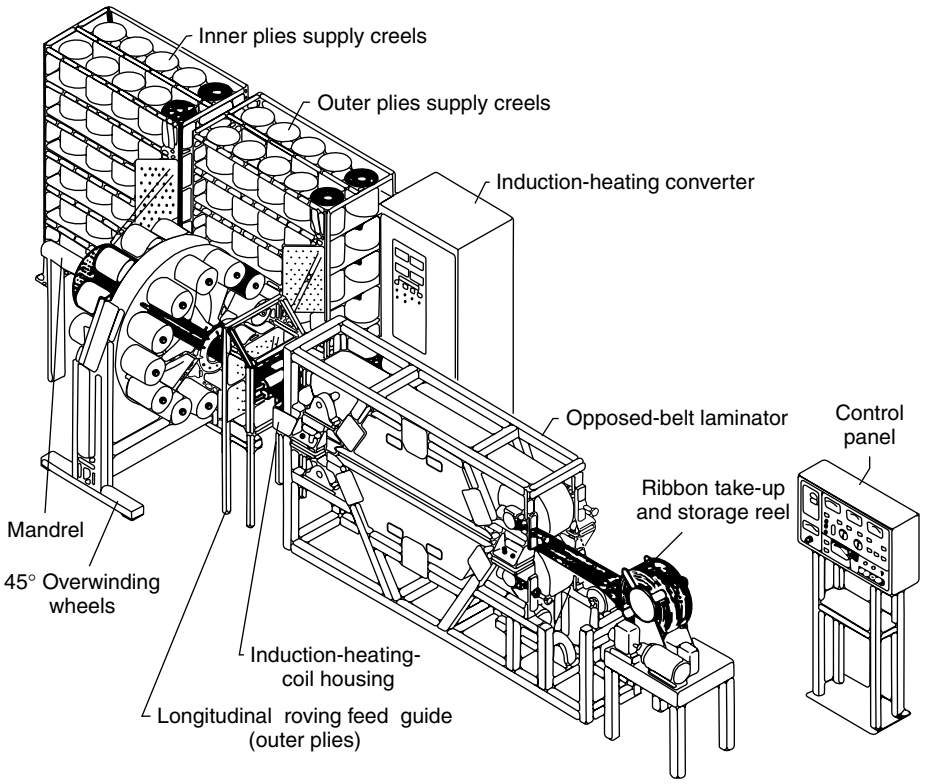

Fig. 37. Earthbound ribbon-forming beam machine; thermoplastic matrix-graphite fiber $(0 + 45 - 45 - 0)$.

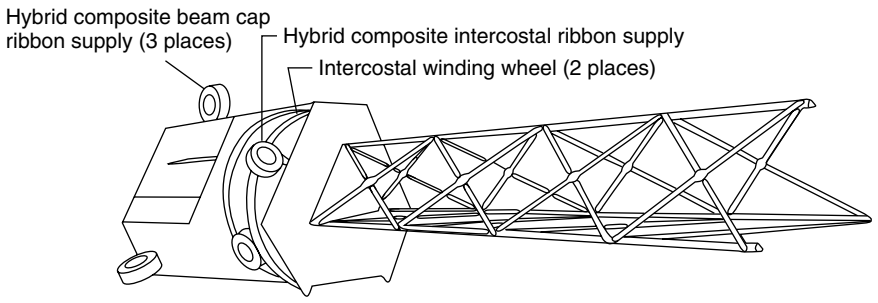

Fig. 38. Beam machine: continuously wound and welded intercostal version.

Thermoplastics. Thermoplastic matrix composites represent a new and intensively researched area. They offer promise in significantly improved properties and faster processing, as well as reduced cost in most cases.

Thermoplastic matrices, by definition, require no cure cycle. They are heated until they flow or permanently deform, pushed into their new shape, and cooled. Elimination of cure cycles reduces processing cycle times.

Compression molding and filament winding are already commercially viable and production processes and equipment are in service, manufacturing a variety of parts such as automotive bumper beams and sports equipment, notably basketball backboards, and snowboards.

Continuous processes such as pultrusion still represent a challenge to processors because the very high melt viscosities of thermoplastic matrices, compared to the low thermoset viscosities, limit the throughput rate severely as high hydraulic shear forces are generated in the dies and forming tools. These forces can damage the reinforcement and generate high pull loads unless line speeds are kept to a few centimeters per minute.

However, fluidized bed powder matrix application and derivative processes may solve these problems. Ideally, processors would like to see a material with the properties of polyetheretherketones (peek), poly(acrylene sulfides) (qv), polysulfones, and similar engineering thermoplastics with melt viscosities below 1 Pa·s (=cP).

Other processes like tape laying also show great promise in the application of thermoplastic matrices. Present tape-laying operations, even when machine performed, require several "debulk" cycles plus the normal multihour cure cycle. Capability for heating under pressure and debulking may make it possible to have a complete trim-ready wing skin at the end of the lay-up operation, without debulk or cure cycles.

Clearly the potential here, both in the tougher, higher temperature physical properties available from thermoplastics, and in the near instantaneous processing, will increase research and investment in thermoplastic matrix-processing of composites. It is possible that in 10–20 years thermoplastics will be the dominant form of matrix. Much depends both on the progress of research and applications and the competitive response of the thermoset manufacturers (18).

Standards and Specifications

Specifications and standards pertaining to reinforced plastics-composites fall into one of the following classifications (30):

(1) Standards developed and published primarily by ASTM and ANSI committees.
(2) Codes set by users such as building officials, American Petroleum Institute (API), American Water Works Association (AWWA), etc.
(3) Design data generated by commercial and government research.

Table 1 is a guide to the major organizations that write standards for composites and the agencies that specify those standards in codes and handbooks, shown by composite markets and product applications.

Table 1. Guide to Organizations and Agencies that Specify Standards for Composites in Codes and Handbooks

Market	Major product applications	Standards[a] in Codes and Handbooks: Major organizations	Standards[a] in Codes and Handbooks: Major governing agencies (US)
Housing construction	Bathware	ANSI, ASTM	International Code Council (ICC, incl. ICBO, BOCA & SBCCI)
Infrastructure construction	Highway	ACI, AASHTO, ACPA[b]	AASHTO, State DOTs, U.S. Army Corps of Engineers
	Pilings	ASTM, ACI, PCI[c], AWPI[d], AISC[e]	AASHTO, PCI FHWA, DOTs, ACI, U.S. Army Corps of Engineers, other government agency handbooks
	Power/utility	ASCE, ANSI, NEMA, IEEE	Individual power/utility companies, EPRI
Corrosion-resistance	Pipe and tank in chemical plants, petroleum refineries, and wastewater facilities	ASTM, API, NACE, AWWA, ANSI, ASME, UL	Chemical Plant And Petroleum Refinery Code. Local regulations. AWWA controls building codes for drainage pipes & underground water pipes.
Electrical	Line tools	ASTM, NEMA, IEEE	OSHA
	Cable trays	ASTM, UL, NEMA, IEEE	Uniform Building Code
Automotive	Exterior structural & nonstructural body panels, interior, under-the-hood	SAE, ASTM, ISO, DIN (Germany)	OEMs

Economic Aspects

The composites industry has usually been perceived as providing specialty parts at premium prices. Today, however, composites are being reclassified from "specialty" to "commodity" industry. The growth of composite product development has resulted in lower prices without loss of properties, such as light weight, high stiffness, and corrosion resistance. Composites are now often cheaper than traditional materials—especially when installation costs, maintenance costs, and life cycle are factored in—and may become the economic barometer of the country, similar to steel in an earlier era.

This change is accelerated in times of energy crises, which typically results in a sharp price increase of traditional materials. Energy requirements are given in Table 2. In general, those for composite materials and processing are lower than those for steel and aluminum.

Table 2. Energy Requirements for Traditional Raw Materials and Composites[a]

Material	MJ/kg[b]
Traditional metals	
Steel, sheet	29
Aluminum sheet	175
Die cast	90
Glass fiber	
Roving	43
Chopped strand mat	52
Chopped strands	44
Woven roving	46
Yarn	63
Resins	
Polyester	92
Epoxy	167
Phenolic	82
Polyamide	190
Polycarbonate	146
Composite compounding	
BMC[c], 18% glass–52% filler	44
SMC[d], 30% glass–35% filler	54
Polyamide–30% glass	153
Polycarbonate–30% glass	126
Polypropylene–30% glass	107
Composite products	
Contact-molded	82
Sprayed-up	80
Hot-press-molded	88
SMC	60
Pultruded	58
Filament-wound	80

Cost Savings Example. Leaf springs provide a clear example of cost savings that are possible with composites. Composite springs weigh only a fifth as much as steel and perform far better. In a fatigue test, a steel spring fails at 35,000–50,000 cycles, whereas the composite spring survives 500,000 or even 5×10^6 cycles with no sign of failure. The cost savings extend beyond material cost to weight reduction and every aspect of production and performance. For example, the steel spring requires skilled labor in a multiple-step process, whereas the composite spring is made on automatic machinery.

Environmental Advantages. With respect to expensive safety and pollution-control devices, composites have a marked advantage. A steel-spring plant presents a variety of hazards and serious pollution problems, whereas composites fabrication is conducted at a console. Emissions of styrene and other VOCs have been significantly reduced through closed processing and improved resin chemistries and take-off systems that vent remaining EPA allowable emissions outside the plant.

Quality Assurance Techniques

Quality assurance techniques for composite products fall into two categories: process control and product evaluation.

Raw material control is, of course, critical to all manufacturing processes and is assumed in this article.

This type of manufacturing confronts problems not found elsewhere, such as process variables and determining the size and degree of a fault area in large composite pieces. Still another problem is that faults in composite materials do not propagate as in more traditional materials and are harder to locate. As a result, in-process quality assurance is of much greater importance than in traditional manufacturing. Some defects can be corrected while the process is under way; others can be detected only in the end product and therefore corrective action must wait until another cycle (see also COMPOSITES, TESTING).

A recently patented system that holds promise for nondestructive evaluation of a composite product is the Reverse Geometry X-ray from Digiray Corp. in Danville, Calif.(see Fig. 39). RGX is a motionless, portable system of computed tomography that relays a digital image through layers of a composite structure directly into a computer. As an example, the system can inspect aircraft, spacecraft, and aerospace structures without the costly removal of wings, helicopter, or wind-tunnel blades. Digital recording media replaces expensive x-ray photographic film and the system is said to eliminate the "fogging" of the image that is typical of conventional x-ray technology.

One of the most important features of digital inspection is speed. Because everything is done digitally there is no need to develop plates like in the old days. The result is that inspections which used to take days now only take hours. Also for record-keeping, everything is stored digitally and can be retrieved and shared at any time during the life of the component.

Traditional methods of inspection are summarized below.

Tape-Laying Process. The automated tape-laying process assumes the correct size, angle of cut, material constituency, and order of progression on the

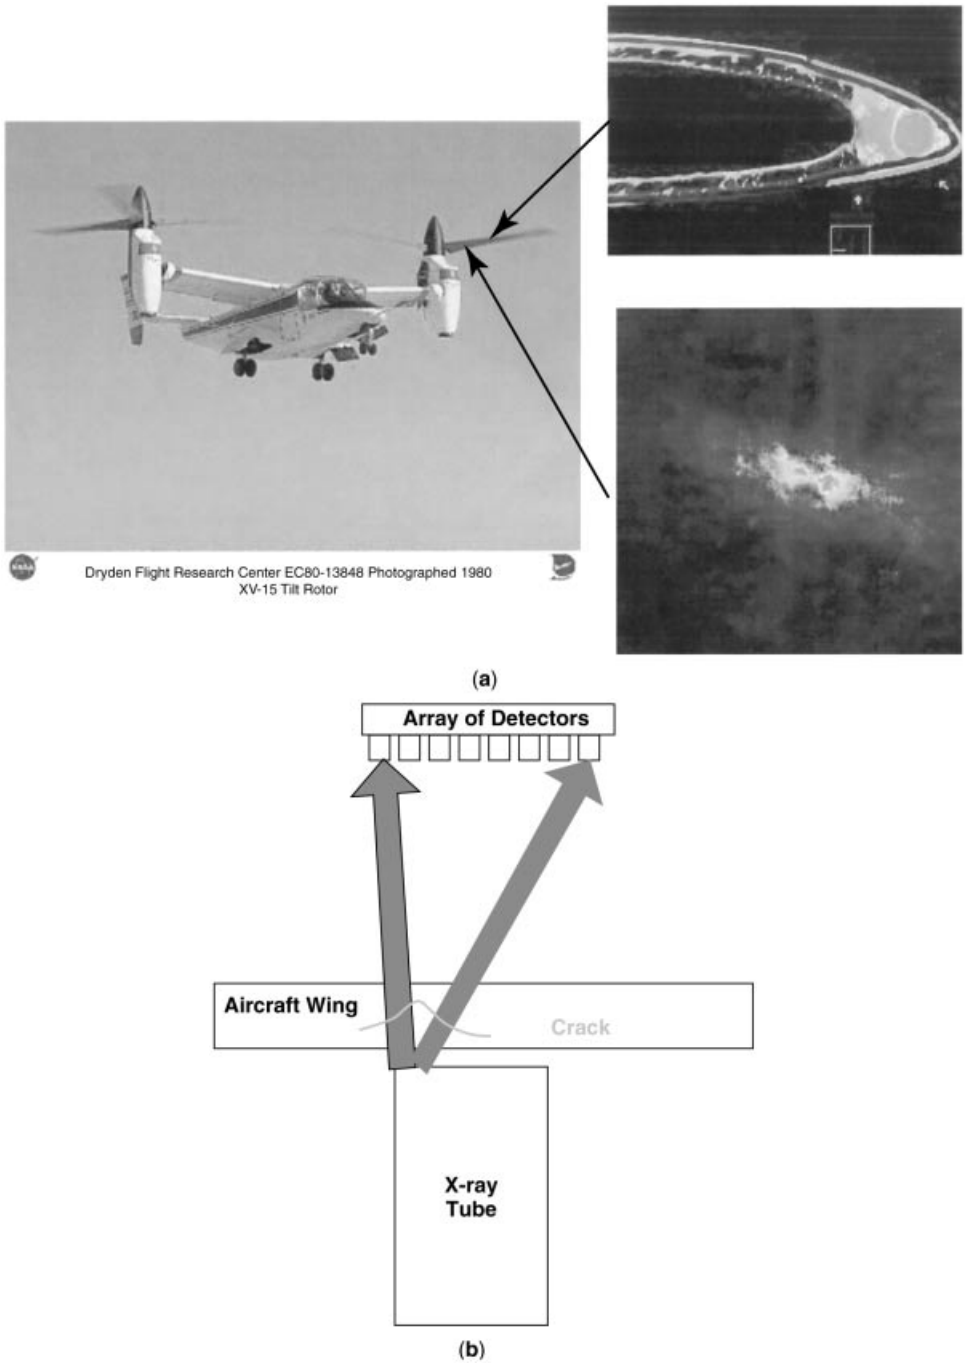

Fig. 39. Digiray Reverse Geometry x-ray technology (Source: Digiray). (**a**) Impact damage on the rotor blades of XV-15 tiltrotor (experimental development vehicle for V-22); (**b**) Schematic of setup for scan through a wingbox; (**c**) Hardware setup on wingbox of Boeing 707.

(c)

Fig. 39. (Continued)

roll of the prepreg tape supplied by a programmed tape magazine. It can be termed an intermediate process, since the product is moved to another process center for thermal development of properties.

Defects in orientation, tape width, length, ply thickness, angle of cut, or smoothness are found mainly by visual inspection. An extremely high accuracy and control are required of the tape supply magazine and its programming.

Detection of defects is easier after thermal processing. Pressure and temperature must be monitored closely, usually by self-correcting mechanisms and without manual adjustment. After thermal processing, the part may be subjected to appropriate nondestructive testing, as described later.

The size, complexity, and value of the processed part may limit testing to "on-site" techniques. Thorough visual inspection usually reveals significant surface defects, such as porosity, scratches, deficiency or surplus of resin, tape misorientation, and wrinkles.

Hardness of peripheral regions should be tested. The impressions or indentations made by instruments such as the Barcol tester are considered destructive testing, although many materials recover fully.

Separate specimens are used for destructive analysis and evaluation with regard to fiber fraction, void content, porosity, and mechanical properties.

Pultrusion. In contrast to tape laying, pultrusion requires almost continuous monitoring to ensure continuous flow and optimum product properties. Curing of the resin matrix is critical, ie, gelation must be reached before the stock leaves the curing die. The degree of cure is checked by dielectric inspection. As marginal conditions are discovered, heating corrections to ensure gelation and continuity of flow through the dies can be made. This is true for polyesters and even more for epoxy resins, which require more time to gel.

The mandatory visual inspection can detect discoloration, crazing, surface fractures, pitting, bubbles, porosity, voids, finish inconsistencies, and surplus or deficiency of resin.

The pultruded part is evaluated by ultrasonic C-scan or ir scanning. Uniform fiber dispersion and even coating by the matrix resin are the main requirements.

Pulforming. Pulforming resembles pultrusion, except that the products can be straight or curved and may have constant volume and changing shape or changing volume and shape.

During pulforming, complications due to changes in cross-sectional shape and volume of the developing part require that close attention be paid to shrink rate and surface uniformity. The proper timing of resin gelation with respect to entry into the pulforming dies is determined by dielectric inspection of the degree of cure.

The surface is inspected visually during processing, but as in pultrusion, ultrasonic C-scan or ir scanning are valuable techniques. Uniform dispersion of the fibers and evenness of the resin coating are essential.

Both pultrusion and pulforming may benefit from inspection by flash x-ray or cineradiography, with associated good visual display.

Filament Winding. In filament winding, many factors influence the product, including mandrel stiffness and surface finish, winding speed, resin precure, filament alignment and tension, and temperature control.

The three winding methods include wet winding, in which the roving passes from a spool through the impregnating bath and onto the mandrel; dry winding with preimpregnated B-staged roving fed directly onto a heated mandrel or first through a softening oven; and postimpregnation, in which the roving is dry wound onto the mandrel and the resin applied by brushing, pressure, or vacuum. All methods require close control of fiber and resin properties.

The filaments are applied to the mandrel by circumferential or helical winding; both require uniform filament tension, even resin coating, correct filament patterns, and temperature control throughout.

The importance of inspection during winding may be reduced by computerized control. Visual inspection can detect filament out of position and uneven resin distribution, indicating variation in tension.

With the completion of filament winding, the testing of the wound and cured part encounters other difficulties. The correlation of standard test results with final performance poses a major problem. Since the filaments are wound in a curve, tensile tests of detached specimens are not directly relatable to material requirements. Recently, special test specimens have been developed for use with standard ASTM methods.

Nondestructive tests applicable to filament-wound parts include ultrasonic C-scan and radiographic and visual inspection.

Advantages and disadvantages of nondestructive methods are given in Table 3.

Outlook. Continuous-flow processes, eg, for composite pipe, are adequately controlled by continuous scanning. With the improvement of such systems as ir scanning and cineradiography and self-correcting loop-feedback controls, continuous processing machines will gain in scope. For noncontinuous processes,

Table 3. Nondestructive Test Methods for Wound Filaments

Method	Advantages	Disadvantages
Penetrant inspection	Good detection of defects or discontinuities open to the surface	No graphic record in normal operation
	Familiarity and reliability	Not always portable
Holographic interferometry	Good definition of material integrity, especially subsurface	Expensive
	Good graphic record	Not always applicable
		Not portable
Radiographic inspection	Good definition of material integrity, surface, and subsurface	Radiation hazard
	Good graphic record Detects almost every type of defect	Time-consuming
		Expensive
		Not always portable
Ultrasonic C-scan	Good definition of material integrity, surface, and subsurface	Expensive
	Choice of techniques for specific applications	Requires liquid coupling agent that is not always practical
		Not always portable
Visual, aided or unaided	Convenient	No graphic record
	Inexpensive	Limited to surface conditions
	Wide scope	
Infrared scanning	As accurate as ultrasonic techniques	Still under development as standard equipment
	Good graphic record	
	Portable	
	No coupling agent required	
Dielectric inspection	Can determine degree of cure on moving material	Still under development as standard equipment

functional design criteria obtained from field use may facilitate the control of low volume composite products. Automated composite-fabrication systems and their quality control methods are at the frontiers of composite technology.

CRITICAL PHASE POLYMERIZATIONS

Introduction

A supercritical fluid (SCF) can be defined as a substance or mixture which has both a temperature and pressure that exceed its critical temperature (T_c) and critical pressure (P_c), and a density at or above its critical density (1) (Fig. 1). Near this critical point, the density, transport properties (such as diffusivity and viscosity), and other physical properties (such as dielectric constant and solvent strength) can be varied in a continuum from gas-like to liquid-like, with relatively small changes in temperature or pressure. The tunability of SCFs makes them very attractive as solvents for polymerization reactions.

The first example of polymerization in an SCF and the most commercially significant till this time is the high pressure synthesis of low density polyethylene (PE) (2). In this process, ethylene from a recycle stream and a makeup source are compressed to 250 MPa (2500 bar) in a tubular reactor at 250°C. The free-radical reaction is initiated with either peroxide or traces of oxygen. The polymer produced has an average molecular weight higher than 100,000 g/mol that is soluble in the ethylene monomer at the process conditions. Polyethylene is precipitated and collected in a separator downstream of the reactor section by reducing the pressure of the solution to 35 MPa (350 bar), thus changing the solvent quality of ethylene.

In an effort to reduce emission of volatile organic compounds, to completely phase out the use of chlorofluorocarbons (CFCs), and to reduce the generation of aqueous waste streams generated in the polymer industry, scientists have turned to the use of supercritical carbon dioxide ($scCO_2$). In the 1990s, CO_2 has proven to be a suitable alternative solvent for critical phase polymerization reactions (3). It has an easily accessible critical point with a T_c of 31.1°C and a P_c of 7.38 MPa

(73.8 bar) (4). Within this region, scCO_2 exists as a low viscosity medium with a tunable density (Fig. 2). It is nontoxic, nonflammable, relatively inexpensive, naturally abundant, and generally regarded as safe. Because CO_2 is an ambient gas, it can be separated from the polymer by depressurizing the reaction vessel, resulting in a dry polymer product. CO_2 is also inert toward free radicals and cations, which lessens chain-transfer reactions. These aspects make CO_2 very attractive

for use in synthesis of industrially important polymers. Numerous examples exist of both chain-growth and step-growth polymerizations using CO_2 as a reaction medium. This article focuses on the utilization of liquid and scCO_2 as a reaction medium for polymer synthesis.

Knowledge of two important issues is important when CO_2 is used as a polymerization solvent: solubility and plasticization. CO_2 is a nonpolar solvent and should generally dissolve anything that dissolves in hexane. This concept is valid for many low molar mass compounds that have appreciable vapor pressures; however, it fails in the case of polymers that have negligible vapor pressures (5). In fact, the only polymers that show good solubility in CO_2 under mild conditions [$<100^{\circ}$C, <35 MPa (<350 bar)] are amorphous fluoropolymers, siloxanes (6,7), and polyether carbonates (8). CO_2 has a very low polarizability per unit volume (27.6×10^{-25} cm^3) (9) and a low dielectric constant (1.01–1.67) (10), making its solvating power similar to that of a fluorocarbon oil. Because of structural symmetry, CO_2 lacks a dipole moment; however, it does have a strong quadrapole moment that contributes to its solubility parameter. This quadrapole moment along with the Lewis acidity of CO_2 allows it to participate in specific solute–solvent interactions that allow certain polymers to have enhanced solubilities in CO_2. Experiments conducted using Fourier transform infrared spectroscopy reveals that CO_2 is capable of having Lewis acid–base type interactions with polymers that have electron-donating functional groups such as carbonyls (11). Amorphous fluoropolymers have an especially high solubility that is attributed to specific interactions such as the formation of weak CO_2–fluoropolymer complexes or favored clustering of the CO_2 near the more polar C—F bonds of the polymer. High resolution ^{1}H and ^{19}F nmr studies confirm that such interactions do exist, thus causing magnetic shielding of the fluorine nuclei (12,13).

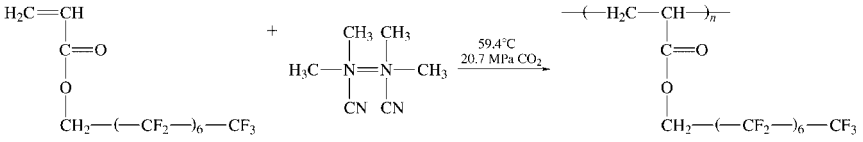
The unique solubility characteristics of CO_2 limit the types of polymerization techniques that can be successfully employed. While amorphous fluoropolymers may be synthesized homogeneously in CO_2, most other polymers are insoluble in CO_2 and must be made via heterogeneous processes such as precipitation, dispersion, and emulsion techniques or via mass polymerizations swollen by CO_2.

The plasticization of polymers by CO_2, which causes a decrease in the glass-transition temperature (T_g) of the polymer, is another important feature that must be taken into account. This plasticization facilitates the occurrence of important effects that are essential to polymer synthesis. Plasticization of the polymer allows enhanced diffusion of monomer and initiator into the polymer phase which often results in increased polymerization rates in heterogeneous polymerizations, removal of residual monomer, solvent, or catalyst from the polymer, and the formation of blends by polymerization within a CO_2-swollen host polymer. An important emerging issue is the role that CO_2 plays in manipulating the loci of reactants such as monomer/comonomer/initiator partition coefficients. Each of these topics is discussed in this chapter.

Chain-Growth Polymerizations in CO_2

Homogeneous Polymerizations. Fluoropolymers are used in many technologically demanding applications because of their balance of high

performance properties. Several significant impediments to the synthesis of commercially important fluoropolymers exist including their general insolubility in most solvents, the undesirable effect of chain transfer of fluoroolefin radicals to most hydrogen-containing solvents (hence the extensive use of CFC solvents), and their high hydrophobicity (which necessitates the use of specially fluorinated surfactants when synthesized in water). Preparing these amorphous low melting materials in $scCO_2$ can circumvent the environmental concerns for CFCs and can avoid the ensemble of problems associated with their synthesis in water. The feasibility of utilizing liquid and $scCO_2$ as a solvent for homogeneous solution polymerization of high molar mass amorphous fluoropolymers by using thermal free-radical initiation has been demonstrated (14–16). Several fluorinated acrylates have been polymerized using this methodology to give high yields of polymer. For example, poly(1,1-dihydroperfluoroctyl acrylate) (PFOA) (50 w/v) was polymerized using 2,2′-azobis(isobutyronitrile) (AIBN) as the initiator at 59.4°C and 20.7 MPa (207 bar) CO_2 for 48 h (eq. (1)).



(1)

The results from a uv spectroscopy study revealed that the decomposition rate of AIBN in CO_2 is 2.5 times slower than those observed in more viscous solvents (15). This was attributed to the difference in dielectric constants of the solvents. In contrast, higher initiator efficiencies were observed in CO_2, relative to other solvents, as a result of a decreased solvent cage effect in the supercritical phase due to the inherently low solvent viscosity. Other fluorinated acrylates, methacrylates, and perfluoroalkyl derivatized styrenes have been homogeneously polymerized or copolymerized in CO_2 (17–19). The free-radical propagation kinetics of styrene, methyl methacrylate, and butyl methacrylate in CO_2 has been evaluated using a pulsed laser polymerization (PLP) (20–22). The propagation rate was found to be slightly lower than that in the bulk, which indicates that CO_2 does not interfere with the chain-growth process. Homogeneous free-radical polymerizations have also been used to synthesize telomers of 1,1-difluoroethylene (23). The perfluoroalkyl iodides prepared in this manner had both controlled molecular weights and relatively narrow molecular weight distributions.

Precipitation Polymerizations. A variety of polymers have been synthesized in CO_2 by free-radical precipitation polymerization. In the earliest studies, the free-radical polymerization of ethylene in CO_2 using either gamma radiation or AIBN initiation was investigated (24–26). Other patents (27,28) disclosed the polymerization of several vinyl hydrocarbon monomers in liquid and $scCO_2$. Homopolymers of vinyl chloride, acrylonitrile, acrylic acid, vinyl acetate, 2-hydroxyethylacrylate, and some *N*-vinylcarboxamides as well as PS/PMMA and PVC/PVAc random copolymers have been made. The polymerization reactions resulted in polymers with gravimetric yields ranging from 15 to 97% and viscosity average molecular weights (M_v) ranging from 1.2×10^4 to 1.6×10^6 g/mol depending on the monomer and the reaction conditions used. More recently, the free-radical polymerization of high molecular weight poly(acrylic acid)

($M_n = 1.5 \times 10^5$ g/mol) has been achieved in $scCO_2$ despite the fact that the polymer precipitates from solution at molecular weights greater than 1000 g/mol (29,30). The molecular weight of the polymer could be controlled by either adding ethyl mercaptan as a chain-transfer agent or by manipulating the temperature and pressure parameters for the reaction. High performance fluoropolymers have also been synthesized in CO_2 by free-radical precipitation polymerization. Homo- and copolymers of tetrafluoroethylene (TFE) have generated particular interest, since it was discovered that TFE can be handled more safely as a mixture with CO_2 (31). In 1995, homopolymerizations (32) of TFE and copolymerizations (33,34) of TFE with hexafluoropropylene (HFP) or perfluoropropyl vinyl ether (PPVE) yielding high molecular weight polymers ($>10^6$ g/mol) in good yield were reported. Copolymerization of TFE and perfluoroalkyl vinyl ether monomers in CO_2 occurs with virtually no β-scission, implying that propagation of terminal vinyl ether-containing radicals is more favorable in CO_2 than in traditional solvents. A system for the continuous polymerization of various monomers in $scCO_2$ has been developed (35). Continuous precipitation polymerization of vinylidene fluoride and acrylic acid can occur in an intensely agitated continuous stirred tank reactor (CSTR). Rates of polymerization of vinylidene fluoride in the CSTR are significantly higher than the average rates of batch polymerization, under similar conditions. CO_2 has also been employed as a solvent in precipitation polymerizations of cross-linked polymers, using high levels of divinylbenzene cross-linker (36). The AIBN-initiated reactions were performed at 65°C for 12 h in 31 MPa (310 bar) CO_2 and yielded spherical particles without the use of surfactants. Multifunctional monomers such as trimethylolpropane trimethacrylate and ethylene glycol dimethacrylate were also investigated (37). These reactions produced well-defined polymer monoliths with pore diameters ranging from 20 to 8000 nm (see the "Porous Polymer Synthesis" section). A clear advantage to the use of CO_2 in each of these precipitation reactions is that the products are easily isolated from the depressurized reaction vessels as dry, solvent-free materials.

Dispersion and Emulsion Polymerizations. The relative insolubility of many industrially important polymers in $scCO_2$ necessitates the use of heterogeneous polymerization techniques conducted with added stabilizers. Conventional heterogeneous dispersion polymerizations of unsaturated monomers are performed in either aqueous or organic dispersing media, with the addition of interfacially active agents to stabilize the colloidal dispersion that forms (38,39). Successful stabilization of the polymer colloid during polymerization results in the formation of high molar mass polymers with high rates of polymerization. A similar analogy applies to dispersion polymerization in CO_2 where stabilization can be accomplished with the aid of nonionic homopolymers, block copolymers, and reactive macromonomer surfactants (40) (Fig. 3). Typically, a free-radical dispersion polymerization in $scCO_2$ starts as a one-phase, homogeneous system such that both the monomer and the polymerization initiator are soluble in the polymerization medium. As the reaction progresses, the resulting growing polymer phase separates into primary particles that are stabilized by amphiphilic materials so as to prevent particle flocculation and aggregation. Polymer colloids produced by dispersion polymerizations in CO_2 are usually stabilized by a steric mechanism as compared with an electrostatic mechanism that is common to colloidal stabilization in aqueous environments because of the low dielectric constant of CO_2. Steric stabilization of a colloidal dispersion is usually imparted by

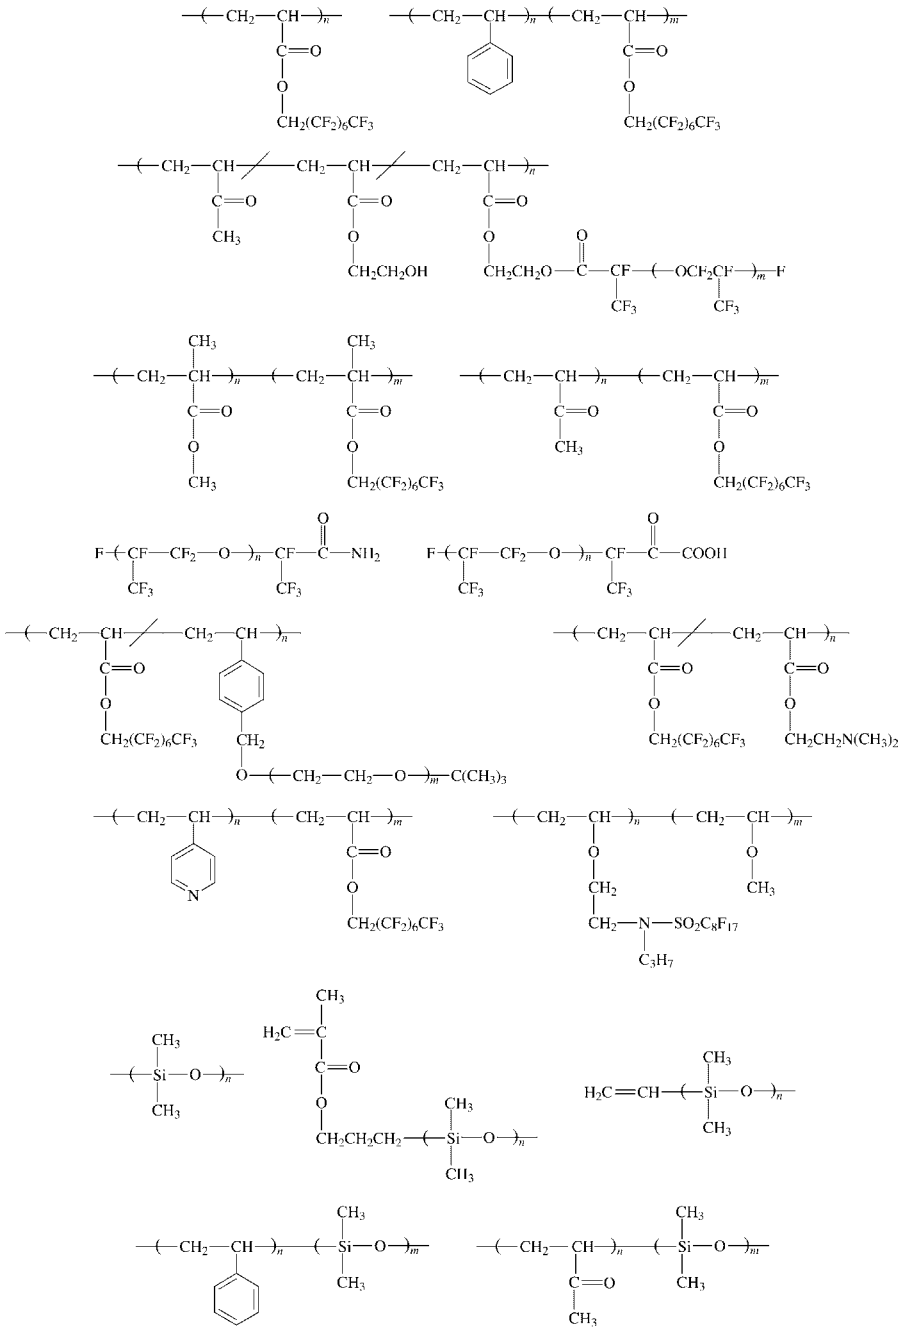


Fig. 3. Surfactants for CO_2.

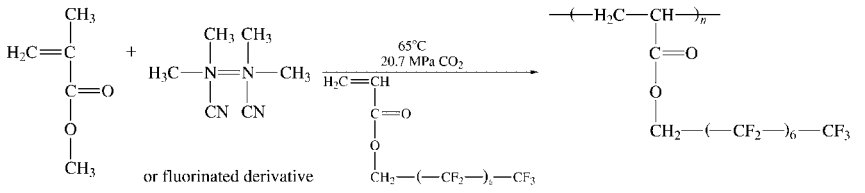
amphiphilic macromolecules that become adsorbed onto the surface of the dispersed phase. These macromolecules contain an anchoring segment that attaches to the particle usually by physical adsorption and stabilizing moieties that are soluble in the continuous phase. The stabilizer prevents aggregation of particles by coating the surface of each particle and imparting long-range repulsions between them.

A substantial number of studies on the dispersion polymerization of lipophilic monomers in CO_2 have focused on methyl methacrylate (MMA). The first success in this area exploited the amphiphilic nature of the homopolymer PFOA as a stabilizer (40) (eq. (2)).



(2)

MMA was polymerized heterogeneously to very high conversions (>90%) and high degrees of polymerization (>3000 g/mol) in $scCO_2$. These polymerizations were conducted at 65°C and 20.7 MPa (207 bar) CO_2 with AIBN or fluorinated derivatives of AIBN as initiators and PFOA ($M_n = 1.1 \times 10^4$ or 2.0×10^5 g/mol) as the surfactant. The reactions resulted in kinetically stable dispersions of micrometer-sized particles with a narrow size distribution. In contrast, reactions that were performed without PFOA as a stabilizer resulted in precipitated polymer with an unstructured, nonspherical morphology. Several other monomers were also polymerized by dispersion polymerization methods in CO_2 (Table 1).

Table 1. Summary of Dispersion and Emulsion Polymerizations in CO_2

Monomer(s)	Stabilizers	Reference
Acrylamide	Amide end-capped PFPE	41
2,6-Dimethylphenylene oxide	PFOA, PFOA-based random copolymers, PS-*b*-PFOA	42
Divinylbenzene and ethylvinylbenzene	Fluorinated methacrylate–PMMA block copolymer	37
Methyl methacrylate	PFOA	40,43,44
	PDMS macromonomer	(45,46)–(47)
	Fluorinated graft or block copolymers	48

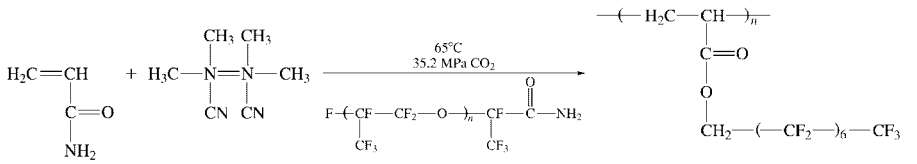
	Carboxylic acid terminated PFPE	52
Vinyl acetate	PFOA, PDMS, PDMS macromonomer, PVAc-b-PDMS and PVAc-b-PFOA	53
Vinyl acetate and ethylene	PDMS, PVAc-*b*-PFOA	53
1-Vinyl-2-pryrrolidinone	PFOA	54
Acrylonitrile	PFOA, PS-*b*-PFOA	55

Typical emulsion polymerizations utilize oil-soluble monomers dispersed in an aqueous media with a water-soluble initiator, whereas "inverse" emulsions employ water-soluble monomers dispersed in an organic medium containing an oil-soluble initiator. The insoluble polymer particles that result from these reactions are stabilized as colloids in solution by repulsive forces imparted by a small molecule ionic surfactant and/or an amphiphilic macromolecular stabilizer (56,57). These reactions produce high molecular weight, spherical polymer particles with sizes typically smaller than 1 μm. Since most common monomers are highly soluble in CO_2, there are very few examples of CO_2-based emulsion polymerizations. However, acrylamide is a rare example of a vinyl monomer that has a low solubility in CO_2 at moderate temperatures and pressures. The AIBN-initiated water-in-oil or "inverse" emulsion polymerization of acrylamide has been attempted at 65°C in 35.2 MPa (352 bar) CO_2 (41,58) (eq. (3)).



(3)

Reactions performed with an amide end-capped perfluoropolyether (PFPE) appeared to form a milky-white latex, but produced polymers with conversions and molecular weights similar to those polymers precipitated in reactions without a stabilizer. More inverse emulsion studies are expected with the utilization of surfactants that have the ability to form water in CO_2 microemulsions. Several researchers have demonstrated that various amphiphilic surfactants like the graft copolymer PFOA-*g*-PEO (59), an ammonium carboxylate PFPE $[(OCF_2\text{-}CF(CF_3))_n(OCF_2)_m]OCF_2COO^-NH_4^+$ (60), and the hybrid hydrocarbon–fluorocarbon $C_7F_{15}CH(OSO_3^-Na^+)C_7H_{15}$ (61) are able to stabilize water-in-CO_2 microemulsions. In principle, these same surfactants could be used to form microemulsions of water and water-soluble monomers in CO_2 for inverse emulsion polymerizations.

***In Situ* Synthesis of Polymer Blends.** The ability of $scCO_2$ to plasticize most polymers enables the synthesis of polymer blends that are not easily accessible by other methods. Supercritical CO_2 can be used to swell a CO_2-insoluble polymer matrix and subsequently infuse CO_2-soluble monomers and initiators into the matrix for polymerization. In one system, poly(chlorotrifluorethylene) (PCTFE), poly(4-methyl-1-pentene) (PMP), high density polyethylene (HDPE), nylon-6,6-poly(oxymethylene), and bisphenol A polycarbonate (PC) were each swollen with CO_2 and infused with styrene monomer and either AIBN or *tert*-butyl perbenzoate initiators (62,63). Polymerization was thermally initiated within the polymer matrix either in the presence of CO_2 or N_2 to generate a polymer blend. Mass uptakes of up to 118% based on the original mass of the polymer were observed. In the case of PCTFE, extraction of polystyrene from the matrix and subsequent gpc analysis showed high molecular weight polymer ($M_n > 1 \times 10^5$ g/mol) in the blend. Transmission electron microscopy and energy dispersive x-ray analysis were used to demonstrate that the polystyrene exists as discrete phase-segregated regions

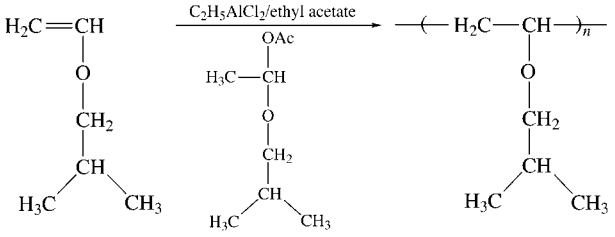
throughout the matrix polymer. Thermal analysis results revealed that radical grafting reactions are not significant. Other materials including PS/PE composites (64) and FEP/PS blends (65) can be synthesized by related routes. In a similar study this strategy has been used as a route to polymer surface modification. Styrene (with and without various cross-linkers) was infused into three polymer substrates (PTFE, PCTFE, and FEP), polymerized, and subsequently sulfonated in order to provide surface modified semi-interpenetrating networks (66). An increase in wettability of the modified fluoropolymer matrices was shown using water contact angle measurements.

Cationic Polymerizations. Homogeneous and heterogeneous cationic polymerizations of various monomers in liquid and $scCO_2$ have been performed (Table 2). Several different catalyst systems were employed in these polymerizations, all of which proved to be effective. The early experiments conducted using monomers such as isobutylene (67) and formaldehyde (70–72) normally resulted in a low yield of low molecular weight products. Nonetheless, proof of concept for the use of CO_2 as an effective solvent for cationic chain-growth reactions was achieved. Other polymers based on different substituted alkenes (73), vinyl ethers (74,75) (eq. (4)), and oxetanes (75) (eq. (5)) have been synthesized.

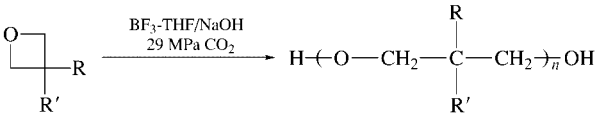
Table 2. Summary of Cationic Polymerizations in CO_2[a]

Monomer (s)	Catalyst System	Reference
Isobutylene	$AlBr_3$/ethyl bromide (cosolvent)	67
	$TiCl_4$/isopropyl chloride	67
	2-(2,4,4-trimethylpentyl) chloride (TMPSCl)/$TiCl_4$/methyl chloride	68
Isobutylene/styrene	TMPSCl/$TiCl_4$/methyl chloride	69
Ethyl vinyl ether	$SnCl_4$ or BF_3-$O(C_2H_5)_2$	28
Formaldehyde	Acetic acid or trifluoroacetic acid	70,71–72
3-Methyl-1-butene	Water/$AlCl_3$/methyl chloride	73
4-Methyl-1-pentene	Water/$AlCl_3$/methyl chloride	73
Isobutyl vinyl ether (IBVE)	Acetic acid adduct of IBVE	74,75
	$C_2H_5AlCl_2$	
	$C_2H_5OOCCH_3$ (Lewis base deactivator)	
2-(*N*-propyl-*N*-perfluorooctyl-sulfonamide ethyl vinyl ether (FVE)	Acetic acid adduct of FVE	74,75
	$C_2H_5AlCl_2/C_2H_5OOCCH_3$	
Bis(ethoxymethyl)oxetane	BH_3-THF/NaOH[b]	76
3-Methyl-3′[1,1-dihydrohepta-fluorobutoxy)methyl]-oxetane	BH_3-THF/NaOH	76
FVE/methyl vinyl ether	Acetic acid adduct of FVE $C_2H_5AlCl_2$/ $C_2H_5OOCCH_3$	76
Styrene	$TiCl_4$[c]	77

[a] reactions are homogeneous unless noted.
[b] heterogeneous precipitation reaction.
[c] heterogeneous dispersion reaction.



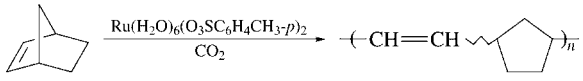
(4)



R = R′ = $-CH_2OCH_2CH_3$ or R = $-CH_3$; R′ = $-CH_2OCH_2CF_2CF_2CF_3$ (5)

Fast reaction kinetics generated by the high reactivity of carbocations is a major benefit in cationic polymerizations. However, this same reactivity leads to unwanted side reactions such as chain transfer to monomer and early chain termination by abstraction of acidic hydrogen atoms beta to the carbocation. CO_2 has several features that make it a suitable solvent for cationic polymerization reactions. It is relatively inert toward the carbocationic propagating species and is not incorporated into the polymer backbone (75). CO_2 as a solvent mimics the typical nonpolar solvents that are conventionally used by affecting the equilibrium between contact pairs and solvent-separated pairs. This in turn affects the activation energy for chain transfer and termination reactions. To minimize the limitations of cationic polymerizations, lower reaction temperatures (typically -70°C to -30°C) as well as controlled polymerization techniques are used. Living cationic polymerization methods that involve the stabilization of the cationic propagating species with a nucleophilic counterion or an added Lewis base have been developed and allow well-defined polymer and block copolymers to be prepared (75).

Transition-Metal-Catalyzed Polymerizations. Metal-catalyzed polymerizations (76) have been performed in scCO_2 (77,78). The ring-opening metathesis polymerization (ROMP) of norbornene has been performed with CO_2 and CO_2/methanol mixtures using a $Ru(H_2O)_6(O_3SC_6H_4CH_3\text{-}p)_2$ catalyst as the initiator (78) (eq. (6)).



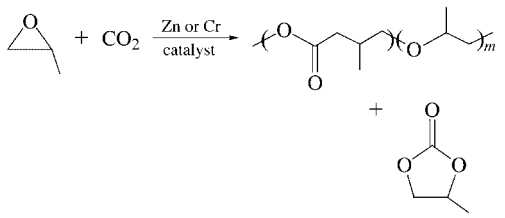
(6)

These reactions were carried out at 65°C and 6–34.5 MPa (60–345 bar) CO_2 and yielded polymers with conversions, molecular weights, PDIs, and polymer microstructures similar to those obtained in other solvent systems. Addition of methanol as a cosolvent to the polymerization medium accomplished several things: it enabled the ruthenium catalyst that was insoluble in neat CO_2 to be solubilized in the CO_2/monomer mixture; it allowed for increased rates of

polymerization yielding similar conversions in a shorter period of time compared to polymerizations done in pure CO_2; and it strongly affected the cis–trans ratio of the polymer microstructure by favoring the trans carbene propagating species (76,79). Both a ruthenium-based Grubbs catalyst (80) and a molybdenum-based Shrock catalyst (81) have shown even greater activity in the ROMP of norbornene, producing high molecular weight polymer (10^5–10^6 g/mol) in good yields (up to 97%) at milder reaction conditions [25–45°C and 11 MPa (110 bar) CO_2]. The ruthenium catalyst was also used to polymerize cis-cyclooctene in 50% yield and a molecular weight of 10^5 g/mol.

An insoluble rhodium catalyst [(nbd)Rh(acac)] has been used to synthesize polyphenylacetylene in the presence of liquid and $scCO_2$ (82). The catalyst is solubilized in the reaction mixture by addition of a perfluoroalkyl-substituted triphenylphosphine ligand. Polyphenylactylene formed in good yields (60–75%) had a molecular weight of about 4×10^4 g/mol for THF soluble fractions, and molecular weight distributions in the range of 8–10.

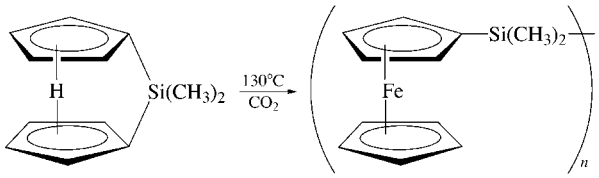
A number of metal-catalyzed polymerizations have utilized CO_2 as both a solvent and as a reagent in the reactions. Precipitation copolymerization of either propylene oxide (83) or cyclohexene oxide (84) with CO_2 in $scCO_2$ has been catalyzed using heterogeneous zinc catalysts. Copolymerizations of CO_2 and propylene oxide formed PCs with a molecular weight of about 10^4 g/mol and incorporation of CO_2 at greater than 90% (eq. (7)). A small percentage of propylene carbonate by-product was also observed.



(7)

The cyclohexene oxide reactions yielded polymers with $M_w = 3.8 \times 10^5$ g/mol and 91% CO_2 incorporation. Catalyst efficiencies for these two systems were low to average (3–400 g of polymer per gram of Zn), possibly because of the insolubility of the zinc complexes in the CO_2/monomer mixture (85). Molecular weight distributions were also very broad (PDI = 2.4–27). A partially fluorinated porphyrin complex was found to be soluble in CO_2, and CO_2/monomer mixtures catalyzed the polymerization of cyclohexene oxide and CO_2 (in the presence of a base) forming polymer in good yields with high degrees of carbonate linkages (90–97%) (86). This system demonstrated substantially higher catalyst efficiencies (up to 3900 g of polymer per gram of Cr) than other systems and very narrow molecular weight distributions (PDI < 1.4).

Thermal Ring-Opening Polymerization. The thermal ring-opening polymerization of a silicone-bridged [1]-ferroceneophane in $scCO_2$ was performed at 20.7 MPa (207 bar) and 75–130°C (87) (eq. (8)). The polymer molecular weights were of the same order of magnitude as the polymers prepared by the solvent-free methods, but were uniformly lower ($M_w = 2.87 \times 10^5$ vs 5.2×10^5 g/mol).



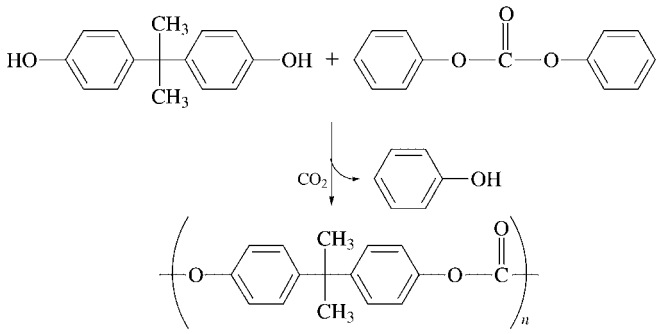
(8)

In addition to the lower molecular weights, the PDIs of the polymers made in CO_2 were broader (3.0–5.1 vs 1.5). Increasing the monomer concentration by 75% for the same reaction increased the M_w of the polymer to 5.9 × 105 g/mol and decreased the PDI to 2. This synthesis represents a comprehensible way to make organometallic polymers from highly strained precursors without dealing with the limitations imposed by melt-phase (88,89) or polycondensation routes (90).

Step-Growth Polymerizations in CO_2

Melt-Phase Condensation Polymerizations. Many condensation polymerizations are performed in the melt phase to produce high molecular weight material without the need for organic solvents. These polycondensation reactions are driven by the removal of small molecule condensates such as water, methanol, and phenol. Current industrial processes require high temperatures and high vacuum to allow the removal of the condensate molecule from the polymer melt phase. The drawback to this method is that the high molecular weight polymers produced have high viscosities that make polymer processing difficult and costly, as well as limit the molecular weight of the polymer. CO_2 is capable of acting as a plasticizing agent for the polymer melt phase, thus increasing the free volume of the melt and decreasing the viscosity of the melt for greater processability. Using CO_2 also facilitates the driving force for polycondensation reactions. Plasticization of the polymer melt phase provides a greater surface area for condensate removal, and solubilization of the small molecule condensate in CO_2 assists in carrying it out of the reactor. This enhancement in condensate removal results in greater mobility of chain ends, leading to higher reaction rates and higher molecular weight products. This strategy has been pioneered by DeSimone to synthesize polymers by step-growth methods, including polycarbonates, polyesters, and polyamides.

Melt polymerization of bisphenols (bisphenol A, bisphenol P, bisphenol AF, and bisphenol Z) with diphenyl carbonate in CO_2 with several catalysts have been achieved (91,92). Polymers with number-average molecular weights ranging from 2.2×10^3 to 1.1×10^4 g/mol ($M_w = 4.5 \times 10^3$ to 2.7×10^4) were obtained over a range of reaction temperatures (180–250°C) and CO_2 pressures [20.7–24.1 MPa (207–241 bar)]. Reaction conditions were chosen to ensure efficient removal of solubilized condensate (phenol) without extracting the reactants (diphenyl carbonate). Polycarbonate synthesis from bisphenol A and diphenyl carbonate catalyzed by tetraphenylphosphonium tetraphenyl borate were also performed in $scCO_2$ (93) (eq. (9)).



(9)

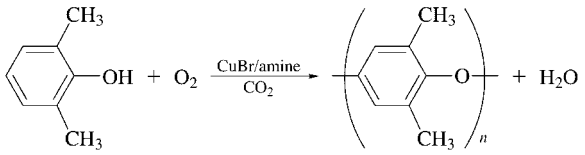
Polymers with high molecular weights (M_n up to 1.3×10^4 g/mol) were obtained at 270°C and 29.6 MPa (296 bar) CO_2. In this technique a slight excess of diphenyl carbonate is required because of monomer extraction. Supercritical CO_2 has also been used to induce crystallization of PC prepolymer beads for solid-state polymerization (94). The amorphous PC beads ($M_w = 2500$ g/mol) were rendered 19% crystalline by treatment with $scCO_2$ and were subsequently polymerized at temperatures from 180 to 240°C yielding polymers with molecular weights as high as 1.4×10^4 g/mol.

Poly(ethylene terephthalate) (PET) is commonly prepared by melt-phase polycondensation reactions. Bis(hydroxyethyl) terephthalate (BHET) was converted to PET under a variable flow (2–10 mL/min) of CO_2 at 20.7 MPa (207 bar) (95). Molecular weights were obtained over the range 3×10^3 to 6.3×10^3 g/mol and increased significantly with flow rate and/or reaction time. These values are low compared to normal molecular weights obtained in commercial processes (approx. 2×10^4 g/mol) and may be attributed to the decreased solubility of the ethylene glycol condensate in CO_2 compared with phenol in the polycarbonate system.

Polyamides have also been synthesized in the melt phase in the presence of CO_2 by the nylon salt route (96). A 1:1 salt of hexamethylenediamine and adipic acid was heated at 220°C for 2 h and then at 280°C for 3 h in 20.7 MPa (207 bar) CO_2 producing nylon-6,6 with molecular weights up to 2.45×10^4 g/mol.

Oxidative Coupling. The synthesis of polypyrrole, an organic conducting polymer known for its good thermal stability, has been extended to SFCs. Polypyrrole was synthesized in supercritical fluoroform and in $scCO_2$ from pyrrole that is generated *in situ* by decarboxylation of 2-carboxypyrrole and a chemical oxidant [either $FeCl_3$ or $Fe(CF_3SO_3^-)_3$] (97). $Fe(CF_3SO_3^-)_3$ was more soluble in CO_2 and gave higher yields compared to $FeCl_3$ (50–60% vs. 87% yield). These yields are still lower than those obtained from control reactions run in toluene (92%). Unlike the globular structure normally obtained when polypyrrole is prepared in traditional solvents, these polymers possess a different morphology with fibers ranging from 100 to 200 nm in diameter and several micrometers long.

Poly(2,6-dimethylphenylene oxide) (PPO) is synthesized via oxidative coupling in a CO_2 continuous phase (43). The reactions proceed at 34.5 MPa (345 bar) and at either room temperature or 40°C for 20 h using a CuBr/amine/O_2 catalyst system (eq. (10)). PPO with yields as high as 83% and Mn up to 1.7×10^4 g/mol were precipitated. Small molecule amines (pyridine and dimethylethylamine) and CO_2-soluble polymeric amines (block copolymers of FOA and either 4-vinylpyridine or DMAEA) were used in the reaction.



(10)

The pyridine proved to be the most effective amine for the system. Although the polymeric amines produced milky white latexes and served to stabilize the PPO as a colloid, no increase in yields or molecular weight associated with dispersion polymerizations were observed.

Porous Polymer Synthesis. Supercritical CO_2 is an attractive solvent for the preparation of porous polymers since conventional processes often require large volumes of "porogenic" organic solvents that tend to become trapped in the polymer matrix. Microcellular polyurethane foams have been synthesized in $scCO_2$ by treating a range of diisocyanates with various propylene oxide and ethylene oxide polyols (98). Phase separation was found to lead to the generation of a polymer-rich phase and a CO_2-rich phase that became porous upon removal of CO_2. Another example of the synthesis of porous polymers is the direct formation of aerogels by sol–gel polymerization of alkoxysilanes in $scCO_2$ (99). A "water-free" sol–gel polymerization technique is utilized in order to account for the low miscibility of water and CO_2 (100). In this technique, alkoxysilanes such as tetramethoxysilane (TMOS) and 1,4-bis-(triethoxysilyl) benzene (BESP) can react with anhydrous formic acid at 35–40°C in the presence of 41 MPa (410 bar) $scCO_2$ for up to 12 h. Opaque white silica aerogels were obtained in nearly quantitative yields (after aging for 12–18 h). The silica gels contained pores larger than those found in gels made in traditional solvents and had interconnected particles 100–200 nm in diameter. Surface areas of silica gels (260–308 m^2/g) were similar to gels formed in ethanol or formic acid. BESP aerogels had surface areas lower than those prepared by aqueous sol–gel polymerizations in organic solvents (471–586 m^2/g vs 1000–1600 m^2/g) (101). A technique has been developed that exploits the selation of CO_2 to form well-defined macroporous materials based on acrylate monomers (IOZ) and by using suspension polymerization methods (103).

Conclusion

The many examples cited in this article suggest that CO_2 is a viable alternative solvent for numerous polymerizations. The use of CO_2 provides not only environmental advantages over traditional solvents but also performance advantages. And its tunable properties allow it to be used as a continuous phase in a variety of both step-growth and chain-growth polymerization techniques with control heretofore unattainable with conventional solvents. The rapid growth of CO_2 technology in the past ten years has provided fundamental knowledge that will undoubtedly enable the preparation of more advanced materials in the future.

CYCLOHEXANEDIMETHANOL POLYESTERS

Introduction

1,4-Cyclohexanedimethanol (CHDM) is an important commercial cycloaliphatic diol that is used in a variety of important commercial polyesters. It is produced by the catalytic hydrogenation of dimethyl terephthalate (DMT) (1). CHDM can exist as the cis or trans isomer; however, most commercial high volume production CHDM is a mixture of isomers with an approximately 70/30 trans/cis ratio. This isomer ratio plays an important role in determining the final properties of polyesters containing CHDM by influencing the ability of chains to pack efficiently. Structure **1**, trans (axial, axial) enchainment, and structure **2**, cis enchainment, schematically illustrate the differences in these structures. Most CHDM containing polyesters are based on the 70/30 (trans/cis) mixture and the stereochemistry of CHDM is maintained during the polycondensation.

The amount of CHDM incorporation as a comonomer also has a large effect on the crystalline nature of the backbone since it is so dissimilar in size and shape to other common diols (2). Poly(ethylene terephthalate) (PET) containing low levels of CHDM (less than 5 mol%) has enjoyed widespread use in stretch blow molded carbonated soft drink containers, where the CHDM modifies strain hardening during stretching, which therefore serves to widen the processing window. When incorporated into a terephthalic acid (TPA) based polyester at higher levels, the absolute level of CHDM can regulate whether the polyester is a high melting crystalline material or a tough clear amorphous composition. In general, when CHDM is copolymerized with other aliphatic diols with common diacids such as TPA, it increases the T_g of the backbone as well as rendering the backbone more resistant to hydrolysis. The flexible character of the CHDM unit is also known to impart enhanced impact and toughness to polyesters. The origin of these effects has been studied and a recent report correlates these properties to secondary relaxation modes arising from the CHDM structure (3).

The most important commercial polyesters containing CHDM are based on TPA and ethylene glycol (EG). Isophthalic acid (IPA) can also be used as a comonomer with TPA. The polyester of CHDM with TPA is poly(1,4-cyclohexylenedimethylene terephthalate) (PCT), which melts at 300°C. When this structure is modified with an acid such as IPA, the abbreviation PCTA (acid-modified PCT) is used. PCT polyesters with glycol modification of up to 50 mol% EG are abbreviated as PCTGs. Likewise, PET polyesters with up to 50% CHDM content are called PETGs. The abbreviations of PETG, PCTG, and PCTA are generally reserved for compositions that contain enough of the comonomer to render the backbone slow to crystallize or amorphous. This article discusses the chemical characteristics and properties of the important commercial crystalline and amorphous examples of polyesters based on CHDM.

Crystalline Polymers Based on CHDM

The primary crystalline polymer based on CHDM is the terephthalate, PCT. PCT was originally developed for fiber applications but has since found wider utility as a reinforced polymer for injection molding and (when copolymerized with a small amount of IPA) as a material for crystallized food packaging trays. The key property of PCT, which sets it apart from other thermoplastic polyesters in these latter applications, is melting point.

When made with the normal 70/30 trans/cis CHDM isomer ratio, the melting point of PCT is about 290°C. The melting point varies substantially with isomer ratio, however, as shown in Table 1 (4).

Table 1. Effect of trans/cis Isomer Ratio on Melting Point of PCT

% trans	T_m, °C
100	315
70	290
50	275
0	250

For comparison, the melting point of poly(butylene terephthalate) (PBT) is 225°C and that of PET is in the range of 250–260°C.

Crystallization of PCT is relatively rapid, but because of its higher T_g (90°C) the maximum rate of crystallization occurs at a higher temperature than is typical of other crystalline polymers such as PET (T_g about 70°C) or PBT (T_g about 35°C).

The bulky in-chain CHDM moiety results in several other important differences between PCT and crystallizable polyesters such as PET. The amorphous density is significantly lower, 1.195 g/cm^3 for PCT compared to 1.334 g/cm^3 for PET. PCT also exhibits a strong sub-T_g molecular relaxation, which results in a relatively low modulus at room temperature (155 MPa vs 240 MPa for PET) and improved toughness in the amorphous state. As an example of the latter phenomenon, the notched Izod impact strength of amorphous PCT is greater than 1000 J/m, while that of amorphous PET is less than 100 J/m.

The CHDM isomer ratio also has an effect on gas barrier properties, with better barrier properties resulting from higher cis levels. Because of the higher local free volume contributed by the CHDM structure, the diffusivity through PCT is generally higher than that through denser structures like PET (5). However, the magnitude of this effect is strongly dependent on the isomer ratio, as shown in Table 2. A recent patent (6) discloses that PCT with a 93/7 cis/trans ratio containing 50% 2,6-naphthalene dicarboxylic acid has a permeability of 2.68 (cm^3·mil)/(100 in.^{2} · 24 h · atm).

Preparation of PCT is best accomplished from DMT using standard transesterification catalysts such as titanium compounds. Because of the high melting point of the polymer, final polyesterification temperatures must be high (greater than 300°C at typical commercial trans/cis ratios) (7). PCT prepared in the melt phase can be crystallized and then solid phase polymerized to obtain even higher molecular weights.

If PCT is modified with relatively high levels of comonomer, substantially amorphous materials result (as described later). However, it is possible to maintain crystallinity at lower levels of modification. For example, replacing up to about 10 mol% of the terephthalate units with isophthalate results in a polymer with reasonable crystallization rates and ultimate degrees of crystallinity.

One might expect that replacing the terephthalate unit in PCT with naphthalene dicarboxylate would make an interesting high temperature polymer. This polymer cannot be successfully prepared, however, because its melting point is above its degradation temperature. Reduction of the melting point by

[a] To convert nmol/(m·s·GPa) to (cm^3·mil)/(100 in.^{2}·24 h·atm), divide by 2.

copolymerization (for example either with terephthalic acid or isophthalic acid) eliminates this problem (8).

Crystalline polyesters from CHDM and aliphatic diacids are possible, but generally are of little interest because of low melting points and low glass-transition temperatures. Cyclic aliphatic diacids offer some potentially attractive possibilities since the melting points are not so depressed. For example, the polyester of CHDM with the high trans isomer of 1,4-cyclohexane dicarboxylic acid has a melting point similar to that of PBT (7).

Processing of Crystalline PCT-Based Polymers. Melt processing of the high-melting PCT-type polymers must be done carefully, owing to a relatively small window between the melting point and the temperature at which degradation rates become significant. The degradation is both thermal and hydrolytic in nature. While it may be argued that the PCT structure is inherently more hydrolytically stable than other polyesters such as PET, the higher processing temperature compensates by accelerating the rate. Thus drying of the polymer or formulation before processing is recommended. Dessicant drying at temperatures up to about 125°C is commonly used.

Degradation results in color formation, loss of molecular weight, and deterioration of critical mechanical properties such as toughness.

Injection Molding Applications. PCT forms the basis of a family of reinforced, crystalline plastics for injection molding. As mentioned previously, the high melting point of the polymer is a key property, as this results in high heat-deflection temperatures (HDT) in glass-fiber-reinforced formulations. Good toughness, flow into the mold, and rapid crystallization are also important attributes in these applications.

Formulations for injection molding typically contain 30–40 wt% glass fiber or a mixture of glass fiber and mineral filler. Stabilization packages to improve processing stability and additives to enhance crystallization rate are also incorporated. These products may or may not be flame-retarded, depending on the application area, with HDTs ranging from about 250°C to about 260°C. This level of heat resistance makes PCT-based plastics suitable for high temperature applications such as electronic connectors, where high soldering temperatures are encountered. Typical competitive materials in this market include poly(phenylene sulfide), with an HDT of about 260°C, and high temperature polyamides, with HDTs in the range of 270–280°C. Other properties of a typical 30% glass-reinforced, flame-retarded grade of PCT are shown in Table 3.

Table 3. Properties of 30% Glass-Reinforced Flame-Retarded PCT

Flame-retarded grades are widely used for various computer connectors and circuit board components. Representative applications are edge card connectors, grid arrays, and memory modules. Non-flame-retarded grades find use in automotive (under the hood) applications, typically connectors and related parts. As higher temperature soldering techniques become more common in the automotive industry, the use of high temperature plastics such as PCT is expected to increase.

It is also possible to formulate unreinforced PCT with crystallization aids and tougheners to provide a material similar in some respects to supertough nylon. PCT provides advantages in dimensional stability and lower moisture sensitivity compared to the polyamide-based products.

Extrusion Applications. A well-established application for extruded unreinforced PCT (copolymerized with isophthalate) is in the preparation of crystallized, thermoformed trays for foods. Crystallized PET is widely used for this application, but where higher temperature performance is needed the PCT-based polymer may be chosen. Such trays are formed from extruded sheet, using a hot mold to promote crystallization. Isophthalate-modified PCT polymers are approved by the Food and Drug Administration for high temperature food contact use.

The good hydrolytic stability of PCT-based polymers leads to applications for monofilament in paper machine belts. Monofilament is extruded from high molecular weight polymer, drawn, and crystallized, then woven into a screen. Such belts are found in the drying section of paper machines, where there is a combination of high moisture and high temperature. Because of their hydrolytic stability, PCT-based polymers provide much longer service life in this application than PET-based.

Amorphous Polyesters, CHDM-Modified PET and PCT

The size and shape of CHDM render it as an effective diol for modifying crystallinity in polyesters. The decrease in crystallization rates for low levels of CHDM incorporation into PET is shown in Figure 1, where the half-times (measured by dsc) for crystallization vs temperature in the melt are plotted. When copolymerized with EG and TPA, the middle composition ranges, from approximately 70/30 CHDM/EG to 20/80 CHDM/EG, have very slow crystallization rates and do not show crystallization peaks when scanned by dsc at 20°C/min and thus are amorphous polyesters. These compositions can be processed into clear, transparent sheets and molded articles.

As the composition is varied from a PETG composition to a PCTG composition, several general property trends are noted. These are illustrated in the schematic in Figure 2.

Increasing CHDM level leads to an increase in toughness, as measured by impact and increasing elongation-to-break values, a decrease in tensile modulus, and increases in T_g and HDT. A comparison of the physical and mechanical properties for a PETG composition of approximately 70 EG/30 CHDM and a PCTG composition of approximately 60 CHDM/40 EG is shown in Table 4.

Preparation of Amorphous PETGs and PCTGs. In general, amorphous PETG and PCTG polyesters can be made by standard melt-phase polycondensation processes, starting either with DMT or TPA. One significant difference

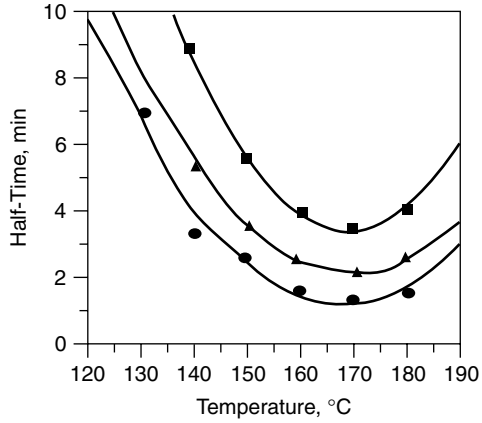

Fig. 1. Plot of crystallization half-time in minutes as determined by dsc versus temperature in degree Celsius. ● PET; ▲ PET–1.5% CHDM; ■ PET–3.5% CHDM.

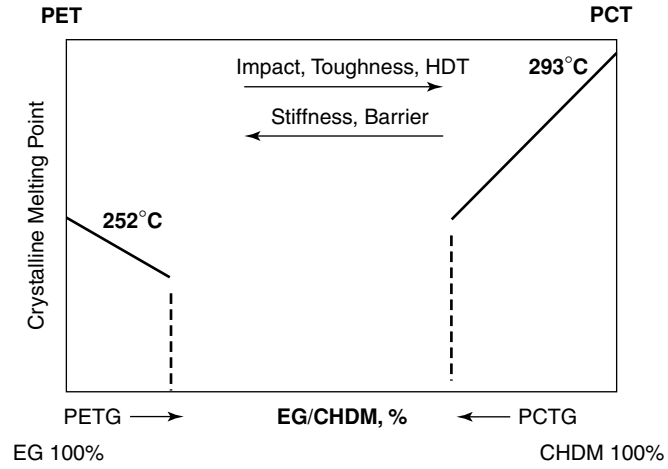

Fig. 2. Schematic showing the general properties and amorphous regions for PETG and PCTG polyesters.

in the preparation of amorphous copolyesters compared to crystalline copolyesters is the need to achieve the required degree of polymerization directly in the melt-phase process. Crystalline polyesters are readily solid-state polymerized to high degrees of polymerization, thus avoiding any problem with melt viscosity in the large-scale finishing reactors used for the melt-phase processes. However, the slow crystallization rates for amorphous copolyesters prohibit converting to a crystalline state, which is required to avoid the fusing of pellets or powders used in the solid-state processes.

Processing and Applications of PETGs and PCTGs. The amorphous nature of both PETG and PCTG permits them to be processed into clear transparent sheets and articles. PETG has found large volume application in extruded

heavy gauge sheet products, blister packages, etc. It offers better toughness than acrylic-based sheet products and better chemical resistance than polycarbonate products (9). The higher CHDM-containing copolyesters are often preferred for applications in medical devices where resistance to lipid solutions and property retention after gamma and ethylene oxide sterilization are important (9).

Acid-Modified PET and PCT Amorphous Copolyesters. Some of the performance benefits of PCT vs PET include improved toughness, hydrolysis resistance, electrical properties, color, and clarity. However, because of the high melting point of PCT (typically ∼290°C), this polyester must be processed at temperatures in excess of 300°C. This results in a very narrow processing range for PCT in order to avoid degradation (10). Incorporation of relatively low levels of a modifying diacid, such as IPA, into PCT yields PCTA compositions which are less crystalline and have lower melting points but which retain the good toughness characteristics and other beneficial properties of PCT. As the isophthalate level in the PCTA is increased, the melting point decreases and the processing window increases. IPA is also used in low levels as a modifier for PET. It provides a slight improvement in barrier properties and also allows for a slightly lower processing temperature. Higher levels of IPA modification of PET can further improve the barrier properties but lead to significant loss of toughness and heat resistance of molded containers. In contrast, PCT can be modified using high levels of IPA to yield PCTA compositions with outstanding properties. Above about 20% isophthalate incorporation, the poly(1,4-cyclohexylenedimethylene terephthalate-*co*-isophthalate) copolyesters are tough, amorphous thermoplastics, which are easy

to process. These amorphous materials can be processed at 230–280°C, much lower than the temperatures in excess of 300°C required for unmodified PCT. They can be injection molded to form tough, transparent parts and can be extruded into sheet, pipe, and profiles as well. The properties of a typical amorphous PCTA which has a composition of about 70 mol% TPA and 30 mol% IPA are shown in Table 4 and are very similar to those of amorphous PETG and PCTG. One advantage of amorphous PCTA compositions over analogous amorphous PETG and PCTG materials (with EG as the modifier) arises from the superior hydrolysis resistance of the PCTA. This manifests itself in the ability to melt process the PCTA with minimal or no drying, whereas PETG and PCTG require more extensive drying to avoid excessive loss in molecular weight during processing (11). Acids other than IPA have been investigated as modifiers for PCT and have been shown to give different performance attributes; however, no other PCTA compositions are commercially available.

DENDRONIZED POLYMERS

Introduction

Practically all dendrimers (1–5) known today have cores with a few functional groups to which the corresponding number of dendrons (dendritic wedges) are attached. The fact that these dendrons are connected to one another by a small, almost dot-like molecule results in considerable steric congestion around the core. This congestion is a unique structural feature and has led one to view dendrimers, specifically those of high generation, as molecular boxes or containers (6,7) and as entities that assume a spherical shape to which a "surface" can be assigned. The term surface may, of course, only be applied with care. Since their discovery some 20 years ago, dendritic macromolecules have stimulated an almost explosive research effort and many synthetic, analytical, and application-related issues have been addressed (1–5). Even industrially applicable syntheses were developed (8–11). During this stormy process, research has virtually exclusively focused on dendrimers with small cores, in spite of a U.S. patent entitled "Rod-like Dendrimer" in 1987 (12,13). There the dendrimers are like (**1**) with polymeric cores and are proposed as being useful in the production of molecular composites and as crystallinity modifiers for polymeric materials. It took some years more before first (published) steps were undertaken to obtain these dendrimers (14,15). It is immediately apparent that they not only complement dendrimers with small cores under structural aspects but as a consequence of the structural differences they should also have unique properties. A simple reason for this slow development may be that in the beginning of dendrimer research spherical dendrimers were simply considered a more appropriate and perhaps more important target. As judged by the increasing number of publications, this view is presently undergoing a rapid modification. Another reason may be seen in a reluctance to begin

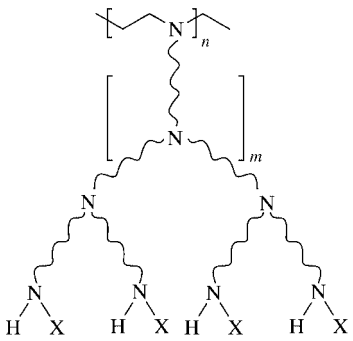
working on a seemingly more complex area than small core dendrimers where chemists are already being confronted with considerable synthetic and analytical difficulty.



X = H, X = $CH_2CH_2CO_2^{\ominus}$ $Na^{\oplus}$

1

This article tries to draw a comprehensive picture of what has been done in the field of dendrimers with polymeric cores, putting emphasis on synthetic issues, on accurate molecular weight determination, and, finally, on the aggregation behavior of these intriguing macromolecules both in the bulk and at solid and fluid interfaces. First attempts to manipulate individualized dendronized polymers on surfaces are also described. The article starts with a small chapter summarizing some of the ideas why these make up a challenging project and where these unusual molecules are expected to have impact on the natural sciences.

The macromolecules treated here may be considered as either dendrimers with polymeric cores or alternatively dendronized polymers (or polymers with appendent dendrons) depending on whether one sees them from the vantage point of an organic or macromolecular chemist (Fig. 1). The first view is somewhat puzzling, because dendrimers are normally considered monodisperse, which they certainly are not (16), whereas polymeric dendrimers are intrinsically polydisperse. At best the polymeric core may have a narrow molecular weight distribution. Not considered here are polymers which do not carry dendrons at every repeat unit (r.u.) but at a few ones only, eg, at both termini (17–22), as well as works on

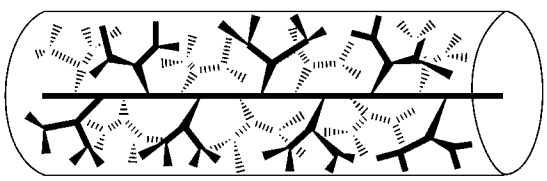


Fig. 1. Design of a dendronized polymer whose dendritic layer is so densely packed around the backbone that it is stretched out and a molecular cylinder with a "surface" is generated.

surface coatings with dendrons or hyperbranched molecules (23–28). The references to dendrimers with dot-like cores are kept at a minimum and the reader is referred to pertinent reviews, monographs (1–5,29), and other articles. Reviews on dendronized polymers are available (30–32). Attempts to stiffen polymer chains by attaching flexible, straight oligomers to each repeat unit which lead to the interesting class of bottle-brush-like polymers (33–41) are not covered in this article because of space limitations.

Dendronized Polymers

Dendronized polymers are formally comb polymers (42), with the combs' teeth being dendrons. What makes them so unique that one does not normally refer to them as such? Mainly it is the complex interplay of dendron size, distance between dendrons, and backbone flexibility/rigidity, together with several interactions (eg, dendron/dendron, dendron/backbone, solvent/dendron). All these factors sum up to a slower decrease of density on going from the interior to the exterior than in common comb polymers where the teeth are linear chains. This unusual density profile, which for spherically shaped dendrimers has been controversially discussed (43–46), leads to new and rather fascinating properties of otherwise conventional polymers. The first issue to mention here is their shape and its dependence on the substitution with dendrons. Depending on the dendrons' structure, size, and attachment density along the backbone, conventional polymer backbones such as polyacrylate or polystyrene can attain conformations all the way from random-coil to fully stretched linear: A flexible, cooked spaghetti-like polymer can be converted into a rigid (high bending modulus) rod just by proper substitution with large dendrons. This stiffening of the backbone is caused by steric repulsion between the pendent dendrons. For this reason the whole matter is referred to as shape-control by implementation of steric strain. In this sense steric strain may be compared to hydrogen bonding and π,π-stacking as the main shape-determining factors in proteins or DNA. In the extreme case, which will be described later, the dendritic layer around the polymer backbone is so dense that a macromolecule can turn into a molecular cylinder with defined dimensions: Its length is determined by the degree of polymerization and its diameter is roughly two times the dendron extension. In this case the dendrons spread away from each other to keep steric repulsion between them at a minimum.

Dendronized polymers can, however, also be designed so that there is an attractive interaction between dendrons that leads to shape control. This requires two features: (*1*) dendrons with mesogenic properties and (*2*) their loose attachment to the backbone which leaves the dendrons sufficient freedom to find the optimum packing. This kind of shape control driven by the dendrons' mesogenic properties can lead to highly ordered materials in the solid state as will be described later.

Let us come back to rigid polymers with a tightly packed dendritic layer around the backbone. What is the importance of such cylindrical objects (Fig. 2 and 3). Contrary to conventional polymers, their diameter is of the order of a few nanometers rather than tenths of a nanometer. As a consequence, the rigidity is so high that the persistence length of an individual chain can be a few tens of

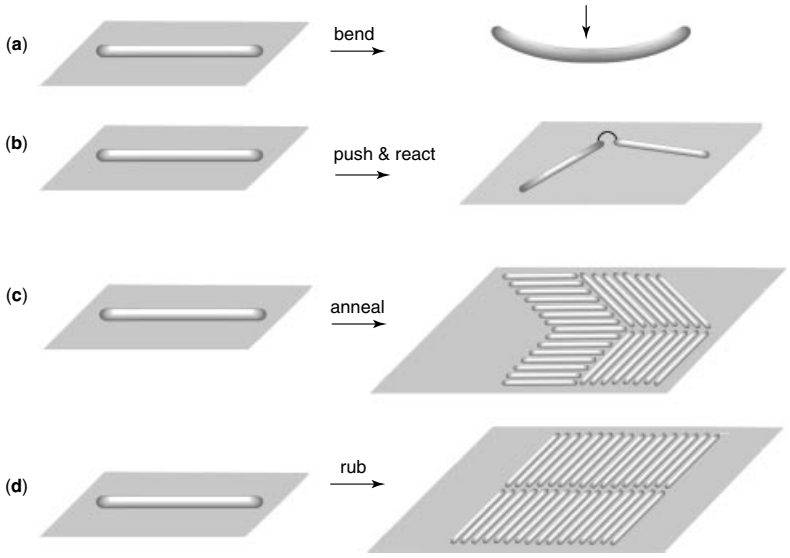

Fig. 2. Characterization, manipulation, and assembly of rigid dendronized polymers: (**a**) determination of bending moduli of individual macromolecules in dependence of factors like nature of backbone, generation of the attached dendrons, and the dendrons' molecular structure; (**b**) manipulation of individualized macromolecules on surfaces in order to use them for covalent nanoconstructions, eg, by inducing linkages photochemically; (**C**) Self-assembly of ordered arrays; and (**d**) generation of large oriented areas by rubbing or one-dimensional flow for applications, eg, in polarizers, polarized emitters, or as templates in LC-applications.

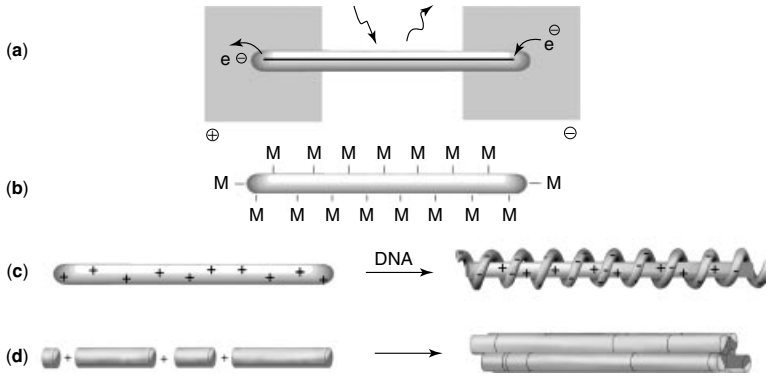

Fig. 3. Further potential applications of rigid dendronized polymers: (**a**) Use of conjugated polymers with dendritic shells for photoluminescence or charge carrier transport. The black line indicates a conjugated backbone. (**b**) Usage as nanometer-sized supports for catalysis when surface charged with catalytically active centers (m). (**c**) Generation of hybrid materials by, eg, wrapping of positively charged dendronized polymers with DNA, which is a negatively charged polyelectrolyte. (**d**) Amphiphiles with a lengthwise segregation of the polar and nonpolar domains (left) should possibly self-aggregate into supercylinders (right) which during growth can accept amphiphiles of different lengths and nevertheless be monodisperse regarding the diameter.

nanometers. Thus, exceptionally high bending moduli can be expected, despite the fact that the polymers are still single stranded (Fig. 2a). Dendritic rods could therefore potentially be used for constructions on the nanometer scale very much like an architect builds frames for houses, bridges, etc from plywood (Fig. 2b). The first steps in this direction would be to isolate individual rods, determine their dimensions, and move them about. The high modulus results in a strong tendency of these rods to form large ordered two-dimensional arrays in which the individual rods are packed parallely to each other like tree trunks of a raft, the only difference being that the dendritic trunks have a length distribution (Fig. 2c). Please note that the designs in this figure do not account for this. Rubbing or one dimensional flow may be used to orient the rods over large areas (Fig. 2d). Such large parallel-ordered arrays of nanometer scale objects on surfaces are interesting for a number of applications, eg, as polarizers, polarized emitters, or orienting surfaces in liquid crystal displays. Shielding comes into play when the backbones are electrically conducting or when they fluoresce (Fig. 3a). In the former case dendritic cylinders can be used to contribute to the important question of charge transport along an individual molecular wire. Because of their rigidity and the mere size, single cylinders could be placed between nano electrodes, the current be measured and correlated with one and only one molecular wire (Fig. 3a). The dendritic layer would just act as an insulating shell which, at the same time, provides some mechanical stiffness, a relevant issue for device fabrication. Insulation by dendritic layers can also help prevent fluorescence quenching in bulk phase, since conjugated backbones have a strong tendency to aggregate, which almost automatically results in quenching. Indeed, this spoils the potential utility of conjugated polymers as light emitters. Finally, the dendritic layer could possibly be used to harvest and channel energy to the backbone.

Apropos tree trunks and cylindrical surface: This may also be a starting point to think about dendritic rods as supports with defined curvatures to which catalytically active components could be attached (Fig. 3b). In a way, cylinders of the size discussed here bridge the gap between homogeneous and heterogeneous catalysis. They may combine the respective advantages of both. Attachment of catalytically active groups to the surface at more or less constant distances may well provide candidates, eg, for applications in flow reactors. Spherically shaped dendrimers equipped with transition-metal complexes have already been successfully employed for such purposes (47–50).

The fact that the tobacco mosaic virus also has a cylindrical shape at first glance may appear as a somewhat artificial link to the biosciences, but this striking similarity may nevertheless help initiate thought about the potential biological importance of dendritic rods and derivatives thereof. Spherically shaped dendrimers have already been used as gene vectors. Positively charged poly(amido amine) (PAMAM) dendrimers (51), for example, render DNA more compact through coulombic interactions, which facilitates cell membrane transfection (52,53). First experiments indicate a similar aggregation behavior between the cylinders' positive surface charges and the negatively charged phosphates of DNA (Fig. 3c). This could influence endocytosis and endosome formation, which are important matters during transfection.

Another important application of dendritic cylinders is as amphiphiles. Common amphiphiles like dodecylsulfonate can form micelles, bilayers, and other

interesting and sometimes even commercially relevant supramolecular aggregates (54). These amphiphiles normally are a few nanometers long and have diameters of a few tenths of a nanometer. If it were possible to decorate the surface of a dendronized polymer with one hydrophilic and one hydrophobic block segregated perpendicularly to the backbone, giant amphiphiles would result, which may lead to a big jump in the size of the corresponding aggregates. Alternatively, if it were possible to decorate the cylinders not cross- but lengthwise, the resulting amphiphiles (Fig. 3d) would have the unique polarity distribution of some ion channel membrane proteins and could be used for coatings to switch surface polarities to their opposite, or for various applications as colloids. These latter amphiphiles should also exhibit a rather unique aggregation behavior in which a defined number of linear sequences of the individual amphiphilic constituents (Fig. 3d, left), regardless of their respective chain length, form an indefinitely long super cylinder with monodisperse diameter (Fig. 3d, right). Such aggregates would exhibit an unprecedented mechanical stiffness when compared with the many known cylindrical self-aggregates from small (tenth of nanometer) amphiphiles (55).

Last but not least, the issues of synthesis and structural analysis ought to be mentioned. Before entering into all the exciting options mentioned above, dendronized polymers need to be synthesized and sufficiently characterized on both the organic chemistry and polymer level. Without going into details the main synthetic problems include (*1*) steric repulsion and thus incomplete reactions, (*2*) autocatalytic decomposition of sensitive dendrons because of their exceptionally high functional group density, (*3*) high molar mass and sometimes high molar mass difference of reactants which makes it difficult to meet correct stoichiometry, and (*4*) purification of high molar mass reactants. These factors may appear almost trivial but can brew together to a seething mixture which renders a controlled synthesis quite an endeavor and challenge. Additionally, the size of the molecules involved makes the tools of organic chemistry absolutely insufficient. Additional methods like small-angle neutron scattering (sans), scanning force microscopy (sfm), x-ray diffraction (qv), matrix-assisted laser desorption ionization time of flight (MALDI-TOF) mass spectrometry need to be employed to really prove what one proposes to have.

Synthesis

There are two principally different synthetic routes to dendronized polymers (Fig. 4). In the first, the polymer which becomes the core in the final product serves as starting material. Its anchor groups are used to convergently attach a dense sequence of dendrons (attach-to route, route A). In the second, monomers already carrying dendrons are subjected to polymerization or polycondensation (macromonomer route, route B). The intrinsic problems of both routes become more serious and limiting, the more sterically demanding the dendrons are. An obviously critical issue associated with route A is achieving complete coverage of the backbone anchor groups with dendrons. Even if a very efficient coupling chemistry is available, a large dendron excess may be required to drive the reaction to completion. This excess may, in turn, make it difficult to purify the product. If

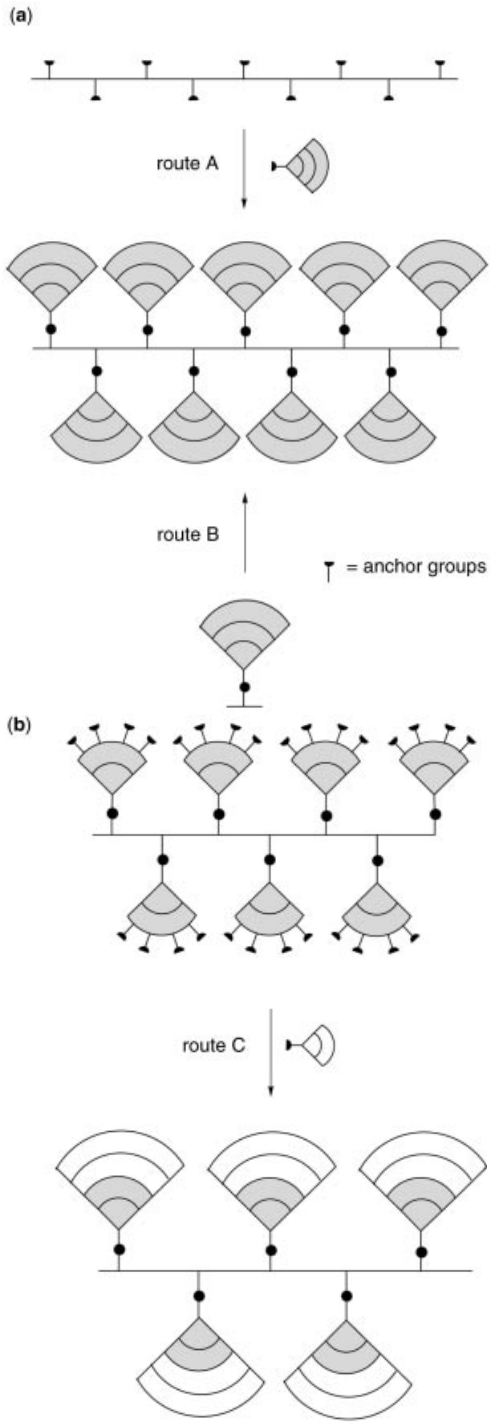

Fig. 4. Routes A and B (**a**) and C (**b**) to dendronized polymers. They may be referred to as attach-to route (A), macromonomer route (B), and mixed route (C). The dendrons shown are of generation 3 (routes A and B) and generation 2 and 4 respectively (route C).

large dendrons are to be attached, steric hindrance also comes into play for two reasons: (*1*) the shielding of unreacted anchor groups on the backbone by dendrons already attached in close proximity and (*2*) the dendron's conformation, which may lead to a self-shielding of the functional group at the focal point through which the attachment ought to take place. Both factors lead to a decrease in the rate of attachment, if they do not suppress the process entirely. This decrease of rate can favor side reactions which may not just involve themselves or the solvent but also the already attached dendrons.

The problems associated with route B also have something to do with steric hindrance. Here the critical point is the steric demand of both monomer and chain end. Incoming monomer will only be connected to the chain end if steric hindrance is not too high. Otherwise this process will be slowed or even rendered impossible. Depending on the kind of polyreaction applied, this may lead to termination of the reactive chain end and/or to side reactions of the monomer, like loss of coupling functionality as in some polycondensations or auto-initiation specifically in radical polymerizations. From this discussion it can be extracted that the basic problems for both routes are incomplete coverage (route A) and low molecular weight dendronized polymer (route B). Of course, intermediate solutions may also be applicable and have actually been developed to some ripeness during the last 3–4 years. If for some reason, eg, a fourth generation macromonomer does not polymerize (which in fact is normally the case) and the alternative attempt to attach a G4 dendron to a polymer also does not work (which is so in all reported cases), route C may offer the solution. Here a polymer which already carries second or third generation dendrons is converted to a higher generation one by attaching a second or first generation dendron. This of course requires the existence of functional groups at the surface of the starting polymer and the availability of a very efficient attachment chemistry whose efficiency must be quanti fiable.

Besides synthetic hurdles there are also analytical ones. Dendronized polymers tend to have repeat units with considerable molecular weight. Repeat units with 1, 2, or even 3 kDa are no exception. Such high molar masses sometimes render structural characterization difficult because the proportion of backbone to dendron atoms becomes so unfavorable that nmr spectroscopy reaches its limits. For example, sometimes the degree of attachment (coverage) simply cannot be determined with sufficient accuracy because the signal intensity of the unreacted anchor groups is too weak for comparison with reference signals in the spectrum. The nmr characterization may occasionally be further complicated by large differences in the relaxation times of backbone and dendron nuclei. Thus, nmr signal integrals are rendered unreliable if a sufficient pulse delay time is not applied. Another problem with dendronized polymers is their molar mass determination. Gel permeation chromatography (gpc) is a quick and easy method to roughly estimate the molar mass of a polymer (56). This estimation can only be reasonably used as long as the hydrodynamic volumina of the polymer under consideration and the polymer used for calibration purposes, typically polystyrene, are in the same range. The hydrodynamic volume of dendronized polymers strongly deviates, however, from parent polystyrene, and gpc results should be treated with care. Additionally, facile aggregation of these dendrimers is sometimes encountered, which leads to further complications. Other methods of molar mass

determination like light scattering have to be used and measures taken to avoid aggregation.

Looking back over what has happened regarding synthesis of dendronized polymers since 1992, when work (14,15) began in this field, one has to arrive at the conclusion that the attach-to route (route A) is inferior to the alternative macromonomer approach (route B). There is no reported route A case in which a complete coverage of a polymeric core with dendrons of higher generation than G2 was achieved. Additionally the polymeric cores used [mostly of the poly(*para*-phenylene) (PPP)-type] did not have very high molar masses. For route B, however, many high molar mass G2 cases, a few G3 ones, and a low molar mass G4 case are known. Furthermore, a high molar mass G4 polymer was reported recently. Since the mixed solution (route C) also has proven to be a successful alternative in certain situations, this article concentrates on route B and gives some insight into what has been accomplished along the lines of route C. For a treatment of route A representatives, however, the reader is referred to a pertinent review (30).

Overview of Macromonomer Approach. Synthesis of dendronized polymers from macromonomers (route B) has been developed broadly in recent years. A reason for this is the advantage that polymers, if they can be obtained at all by this method, necessarily carry the predetermined number of dendrons at the backbone. The above questions of dendron perfection and coverage degree in divergent and convergent syntheses do not play a role. This only holds true, of course, if the dendrons are compatible with the polymerization conditions and do not degrade, a prerequisite which is fulfilled in many of the cases reported. The polymerization procedures used may be divided into (*a*) radically initiated and transition-metal catalyzed chain-growth and (*b*) step-growth polymerizations (polycondensations). Figure 5 gives an overview of the macromonomers' structures reported to date and groups them into the subclasses *a* and *b* depending on the respective type of polyreaction. Fréchet-type dendrons (57) are drawn in an abbreviated form, which is explained in Figure 6. Monomers are polymerized by radical polymerization [**2** (15), **3** (58), **4** (59), **5** (60), **6** (61), **7** (62), **8** (63), **9** (64), **10** (61), **11** (55), and **12** (65)], insertion polymerization [**13** (66)], ring-opening metathesis polymerization (ROMP) (67) [**14** (68,69)], Suzuki polycondensation (SPC) (70,71) with **17** [**15** (72) and **16** (73)] and **24** [**20** (74), **21** (75), **22** (76), and **23** (76)], polyaddition with **19** under polyurethane formation [**18** (77)], Heck coupling of **25** with **26** (78,79), Sonogashira/Hagihara-type coupling of **27** with **28** (80), and, finally, Yamamoto reaction of **29** (81). Dendronized oligomers with enediine repeat units were also prepared (82).

Some features of the dendronized polymers obtained from the macromonomers of Table 1 will become important later in this article and are therefore emphasized in the following: (*1*) Most of the macromonomers carry G1 or G2 dendrons. Exceptions are only (**12**) (G3), (**16**) (G3), (**18**) (G3 and G4), (**23**) (G4), (**25**) (G3), and (**27**) (G3 and G4); (*2*) Many dendrons are of the benzyl ether type whose terminal phenyl rings are either unsubstituted or have one to three long alkoxy or fluoroalkoxy chains. The corresponding polymers are important for a variety of reasons but are unreasonable candidates, of course, whenever chemical modification becomes an issue; (*3*) This is where dendrons (**7**), (**8**), (**10**), (**11**), and potentially also (**13**) come into play which carry protected

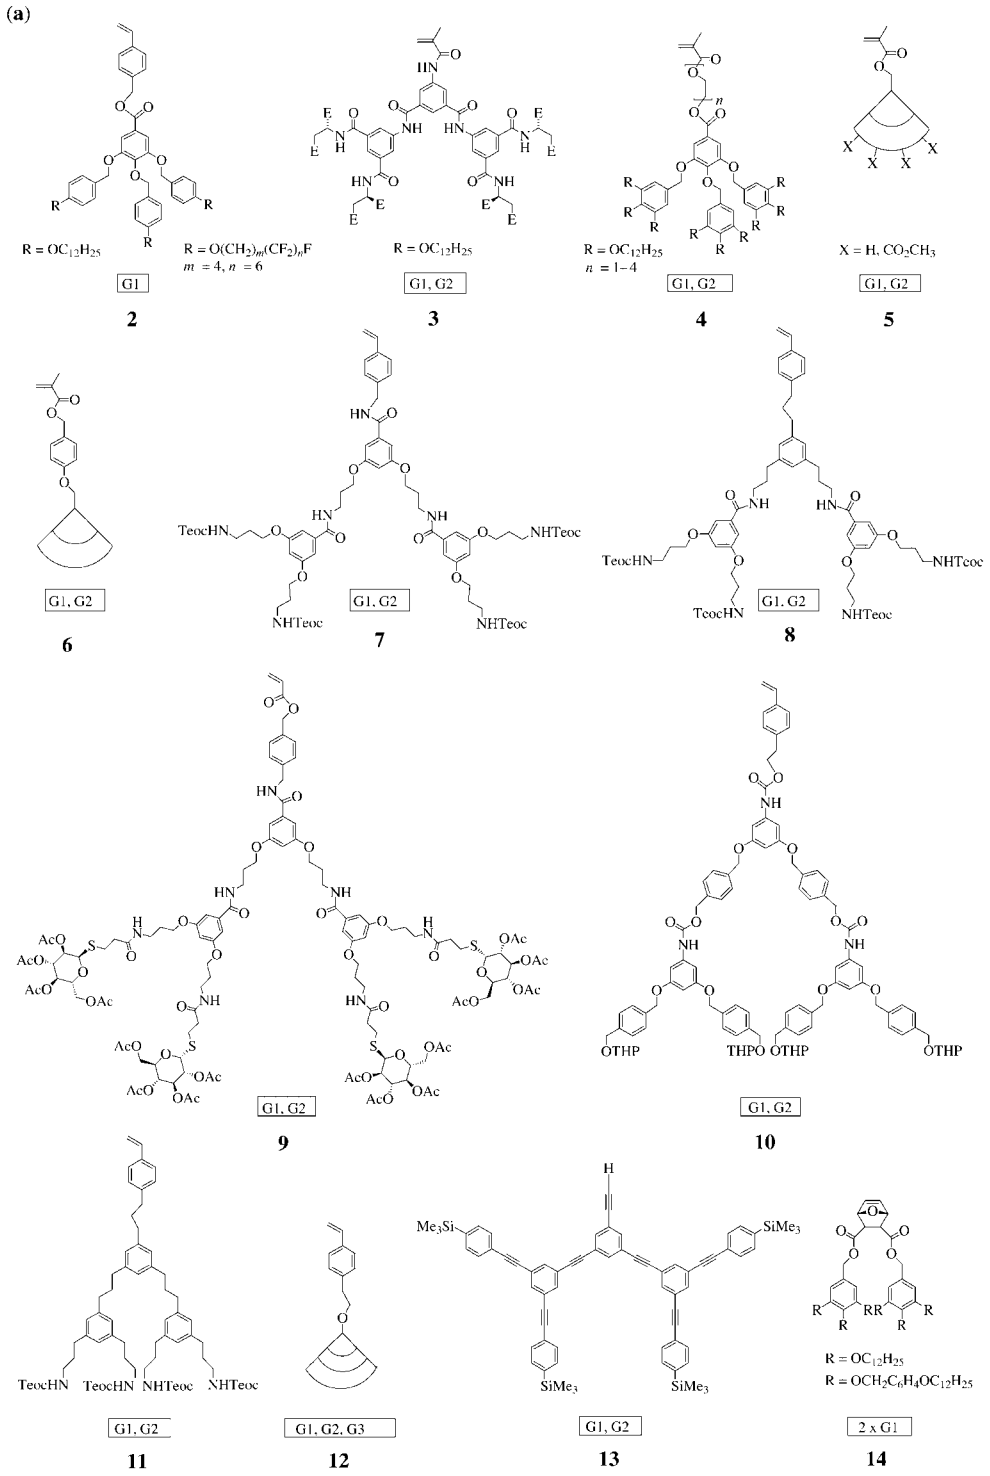

Fig. 5. Structures of macromonomers to obtain dendronized polymers by chain-growth (**a**) and step-growth procedures (**b**).

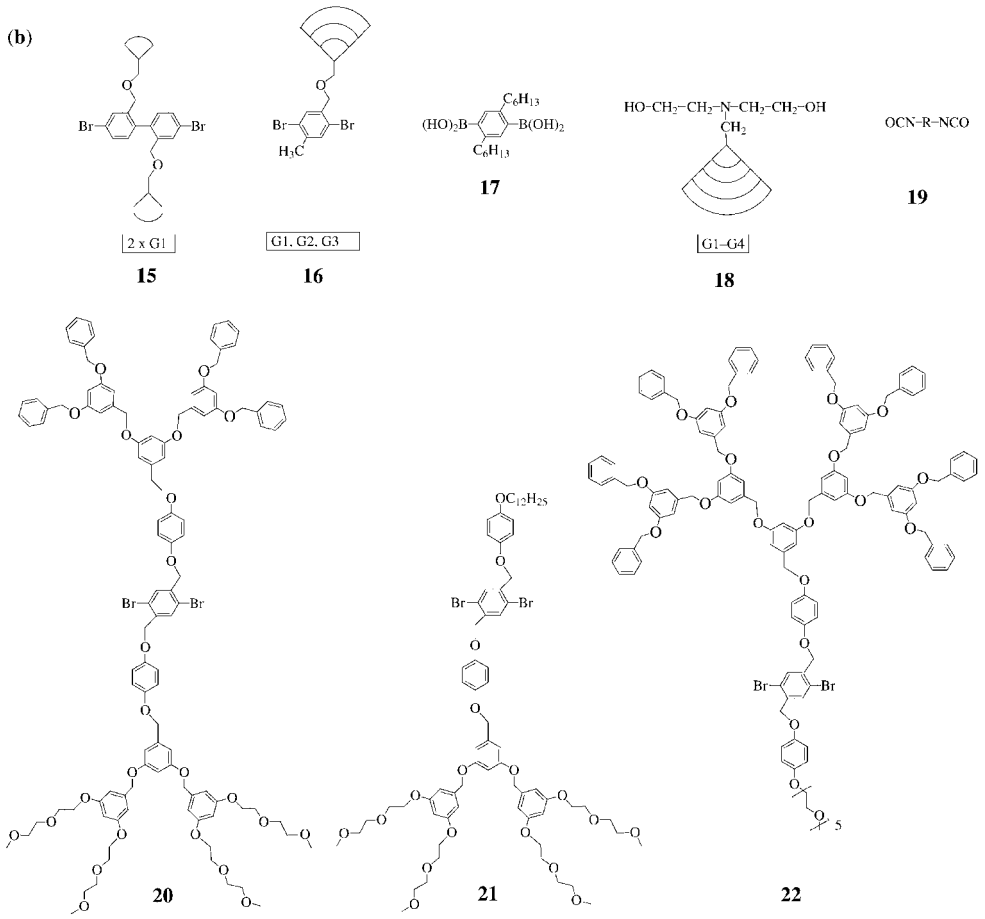

Fig. 5. (Continued)

functional groups [hydroxy, amino, trimethylsilyl (TMS)] in the periphery. The corresponding polymers are the starting point for the important aspect of surface modification; and finally (*4*) dendron (**8**) (G2) has one nonpolar and two polar branching units, and dendron (**11**) (G2) is completely nonpolar except for its terminal protected amine groups. These structural features stay in context with considerations regarding dendronized polymers with specific polarity patterns which will become an important matter in future but will not be discussed in this article.

Monomer (**23**) (G4) requires a special comment: The attempt to subject this G4 monomer to SPC met with a trivial but nonetheless serious synthetic difficulty (76) which is typical for related polycondensations in which two monomers with grossly different molar masses are to be reacted with one another in the strictly required exact 1:1 stoichiometry. The molar mass difference between the two components (**23**) and (**24**) is so considerable (**23**: 3540 g/mol; **24**: 246 g/mol) that it is difficult to meet in practice this requirement. For that purpose, monomer

(**23**) was prepared on the 20-g scale as analytically pure material. This enabled one to do SPC on a relatively large scale ensuring sufficient stoichiometry control. In a series of optimization experiments, conditions were finally found which gave the corresponding polymer **P23/24** (G4) with $P_n = 25$ and $P_w = 125$ according to gpc on the gram scale (76). Presently, fractions of this material with $P_n = 10$, 75, 150, and 300 (gpc) are being investigated by sans in order to determine their true molar mass. Though it is still unclear as to what the actual molar mass of this polymer is, this data clearly shows that SPC works even for sterically enormously loaded G4 monomers. This is in contrast to vinyl-type macromonomers. No such

Table 1. Molar Masses of Dendronized Polymers P7 and P12 Determined by gpc and sans

	$M_w \times 10^{-3}$		
Polymer	(gpc)[a]	(sans)	M_w (sans)/M_w (gpc)

monomer carrying a G4 dendron has yet been found to undergo radically initiated polymerization.

Finally, it should be pointed out that apart from common organic reactions, the concentration of the reaction medium plays an absolutely important role in the polymerization of vinyl macromonomers. This may go as far as that below certain (very high) concentrations polymerization is not only slowed down but rather rendered impossible. This matter has been treated in some detail (33,34,55).

Route C and Cylinder "Surface" Modification. Both the "mixed" route (route C) and controlled surface modifications of dendritic nanorods are challenging goals for synthesis and many application related issues. The former allows to increase the dendritic layer around a backbone whenever needed and other synthetic routes (A and B) fail. The latter is an important option to engineer properties in various directions by attaching to one and the same polymer the different groups considered relevant for a certain application. For both cases it is obviously necessary to have accessible surface functions to which either another dendritic fragment or the modifying groups can be attached. Some experiments along these lines have been undertaken. The essential steps are

(1) Synthesis of monomers with protected functional groups in the periphery. The protection is required for compatibility with the polymerization conditions.
(2) Polymerization of these monomers and complete deprotection of the peripheral functional groups of the resulting polymer. The resulting deprotected polymer needs to be soluble.
(3) Derivatization of the deprotected polymer with the desired dendritic or other functional units.

Step *1* has been solved at least for up to generation 2. Monomers (**7**), (**8**), (**10**), and (**11**) in Figure 5 are good examples. These monomers have all been polymerized to the corresponding high molar mass materials **P7**, **P8**, **P10**, and **P11** (step *2*) and their functional groups deprotected. For the use of the somewhat uncommon trimethylsilyl(ethyloxy)carbonyl (Teoc) protecting group, see Reference 62. Figure 7 shows ^{1}H nmr spectra of monomer (**7**) (G2), the corresponding polymer **P7** (G2), and its deprotected counterpart. The deprotection can obviously be driven to completion. This aspect has also been quantified for many G3 and even G4 polymers, and deprotection was found to be virtually 100% in all cases. This is important because the remaining protected functional groups are an integral part of the polymer and cannot be removed by purification as in common organic chemistry. Step *3* has mainly been developed for the "mixed" route even though the knowledge gained here should be fully transferable to all kinds of surface modifications. Figure 8 shows an example in which high molar mass polymer **P11** (G2) was first converted into its G3 analog (polymer **A**) by deprotection of its Teoc protected amine groups with trifluoro acetic acid and subsequent reaction of the amines with the active ester G1 dendron **30**. Polymer **A** was then subjected to the same sequence of deprotection (to give **B**) and dendronization with (**30**) to give polymer **C**. The degree of deprotection was determined by

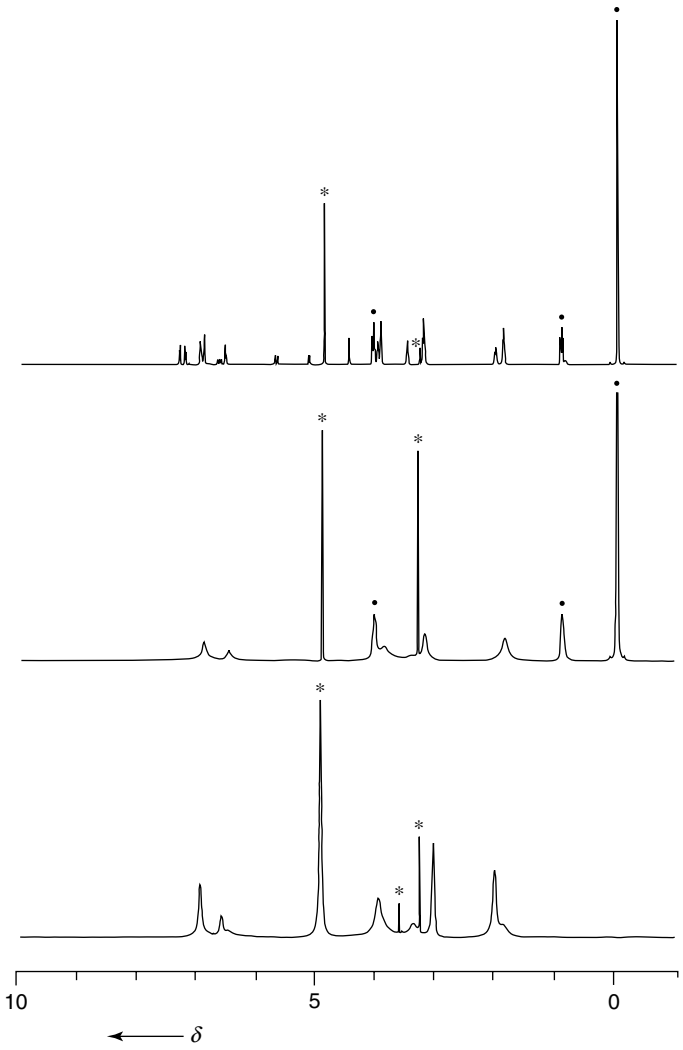

Fig. 7. ^{1}H nmr spectra of monomer (**7**) (G2), the corresponding polymer **P7** (G2), and its deprotected counterpart (from top to bottom) to illustrate the structure control during polymerization and the degree to which deprotection of the polymer can be achieved. Signals of the Teoc protecting group (full dots) and the solvent are marked (asterix).

rigorous application of 500-MHz nmr spectroscopy and that of the dendronization by applying Sanger's reagent, 2,4-dinitrofluorobenzene, and quantitative uv absorbance measurements. This reagent upon reaction with amines gives intensely yellow derivatives whose formation can be accurately quantified when its uv absorbance is compared with model compounds. Under broadly varied conditions and with the help of control experiments it was made sure that each amine group of polymer **B** which had not reacted with the G1 dendron (**30**) had in fact done so with the Sanger reagent (83). With a series of experiments it was proven that the

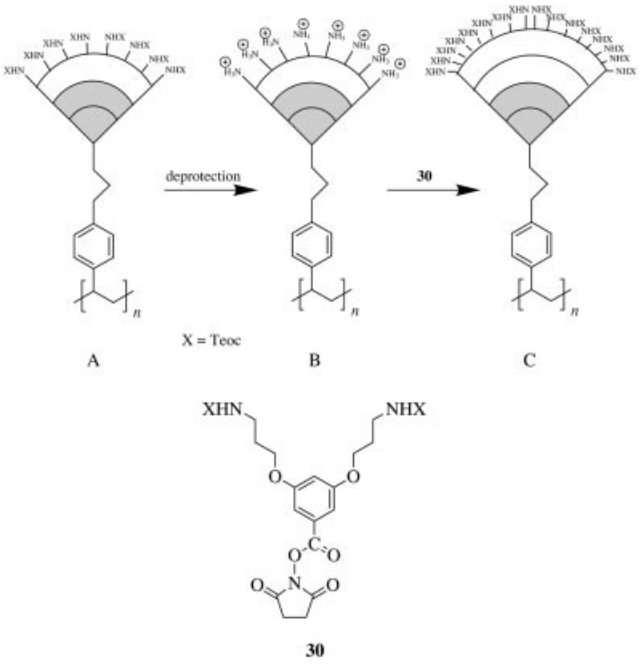

Fig. 8. Route C used to convert a third generation dendronized polymer (**A**) with terminal amine groups into the corresponding fourth generation derivative **C**. The sequence involves complete deprotection of **A**'s protected amine termini and reaction of the resulting polyelectrolyte **B** with the first generation dendron (**30**). Compound (**30**) has an active ester focal point functionality which proved to react extremely efficiently with polymer **B**'s amines.

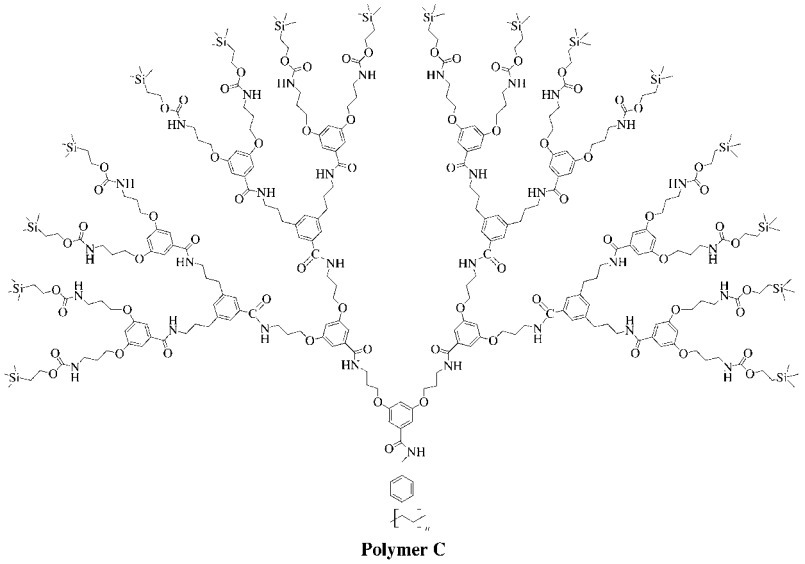
conversions of the dendronization of **B** furnishing polymer **C**, whose structure is given in detail, can easily be driven beyond 99.3% (84).



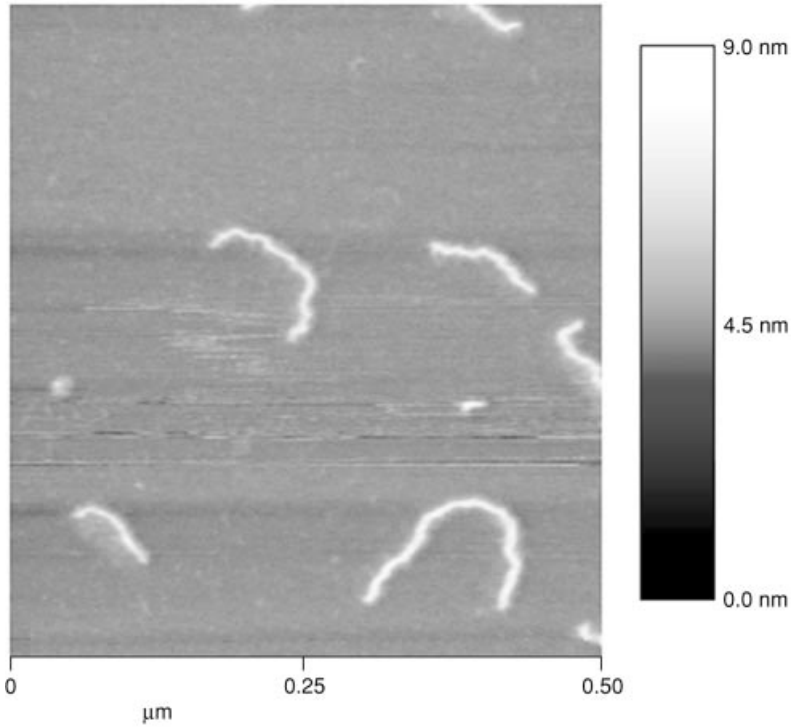


Fig. 9. Tapping mode sfm height image of a G4 polystyrene (**C**) on mica to visualize the length of individual chains.

These very high conversions were found for high molar mass polymers **A** which had degrees of polymerization between approximately 400 and 800. Figure 9 illustrates this point by showing a tapping mode sfm image of polymer **C** on mica. Even though a statistical evaluation of the length is not yet available, it can be seen that some chains reach considerable lengths of up to 250 nm. This equals 1000 r.u.'s assuming the backbone attains an all-trans zigzag conformation, which may not even be the case. This astounding result not only underlines the effectiveness of the route C dendronization protocol but also shows the power of amide formation between surface amines and activated ester components like (**30**). This latter aspect opens an avenue to all kinds of surface modifications based on this chemistry. All what is required is to use active esters which carry sugars, amino acids, catalytically active sites, etc. An alternative way to get to modified dendronized polymers is to polymerize modified dendronized monomers, for example, monomer (**9**) (G1 and G2) which gives sugar-coated polymer **P9** (64).

Molar Mass Determination. In practically all cases the molar masses of dendronized polymers were obtained from gpc versus polystyrene standard. As pointed out above, this is not an appropriate method for such polymers. The values reported (32,40,85) should therefore be treated at best as rough guesses (see below) and a direct comparison of different polymers is impossible. This refers also to polymers with the same backbone but different generation dendrons. Despite the

importance of an accurate molar mass determination of dendronized polymers, a systematic study on this matter is not yet available. The most extended one is one where gpc molar mass of five polymers obtained from monomers (**7**) (G1), (**7**) (G2), (**12**) (G1), (**12**) (G2), and (**12**) (G3) are compared with those obtained from sans (86). Both fractions and representative samples of these polymers were employed. Table 1 summarizes the results. In all cases the sans data are higher than those from gpc and the factor by which gpc underestimates the real molar masses varies between 1.6 and 3.9. A qualitative explanation for this finding is to be seen in the much larger mass per unit length of dendronized polymers than the calibration standard polystyrene. The true molar mass should therefore be higher than the gpc molar mass. There is, however, an opposing effect which has to do with the chain stiffening of the polymer chain imposed by the spatially demanding substituents. This leads to an increased hydrodynamic volume, causing the gpc molar mass to become larger than the actual one. For the cases of Table 1, the latter effect obviously does not overcompensate the former. Whether this will still be the case even for polymers with G4 substituents awaits to be seen. The sans measurements also revealed that polymer (**12**) (G3) is a rigid rod whose persistence length is of the order of the contour length.

The degree of polymerization (P_n) of polymer **P16/17 (G3)**, a representative of a step-growth polymer (Fig. 5b) obtained from monomers (**16**) (G3) and (**17**), was also investigated carefully in order to learn about the effectiveness of step-growth procedures [here SPC (70,71)] in the case of sterically demanding monomers. Its P_n could not be directly determined because of unsurmountable problems with aggregation. Through some chemical modification, however, an average $P_n = 110$ was finally obtained. According to Carother's equation (87), this P_n results when each coupling step proceeds with a conversion of 99.1%. From a synthetic point of view, this result is truly remarkable. It shows the enormous potential of SPC even for cases where steric congestion is considerable.

Some Aspects of the Molecular Structure. As discussed above, one objective for research of dendronized polymers was to use the decoration with dendrons as a means to stiffen the backbone to the point that it is fully stretched linear. This should be reached when the appendent individual dendrons are evenly distributed around the backbone and tightly packed at van der Waals distance. This fully stretched conformation will also be reached, of course, at a somewhat less tight situation, provided solvent molecules are sucked into the dendritic layer through osmotic effects. Both cases lead to a rigid rod with a cylindrical envelope; however, only in the first case this shape would be practically independent from the surrounding medium, whereas in the second, the dendritic layer would collapse under conditions where the solvent diffuses out (eg, in vacuum). The question of tightness of packing is an essential one for synthesis. Generally speaking, the synthesis becomes more difficult, the less spatial mobility the reaction partners have to attain the mechanistically required relative conformation in the transition state of the reaction (here, growth step). To evaluate the feasibility of a certain polymerization on grounds of sterics, it would be ideal to have a detailed picture of the spatial changes around the reaction center on going along the reaction coordinate. Since it is practically impossible to obtain this with a reasonable amount of computational effort, only some molecular dynamics (MD) calculations of final products were performed. Additionally, some polymers were visualized by

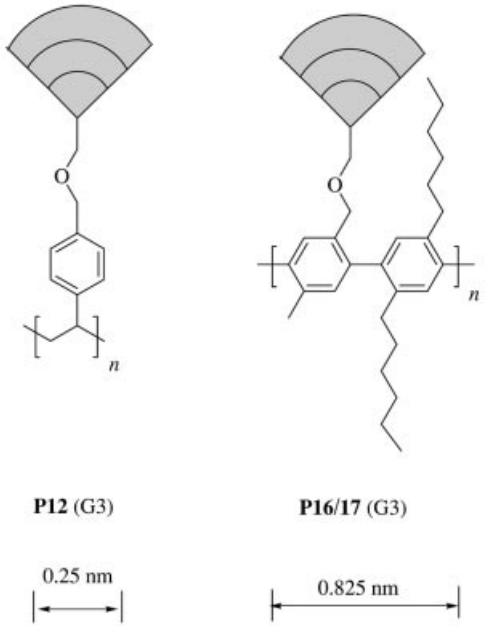

Fig. 10. The lengths of repeat units of polymers **P12 (G3)** (0.25 nm) and **P16/17 (G3)** (0.825 nm) to qualitatively assess the average distance between attached dendrons.

computer-generated 3-D images in order to help the synthetic chemist to assess whether or not a macromonomer undergoes polymerization.

MD simulations were performed in vacuo with polymers **P12 (G3)** (88) and **P16/17 (G3)** (89), which carry both of the same G3 dendrons but differ by the average distance between the dendrons' anchor groups [**P12 (G3)**: 0.25 nm, **P16/17 (G3)**: 0.825 nm] and the flexibility of the backbone (Fig. 10). Unfortunately, solvent molecules could not be considered because of the enormous number of atoms already contained in the polymers. Figure 11 shows the minimum conformations obtained. While the dendritic layer of **P12 (G3)** is quite compact, that of **P16/17 (G3)** is much more open and loose. The diameters of **P12 (G3)** and **P16/17 (G3)** are on average approximately 4.4 nm and 2–4 nm, respectively. This difference in compactness is certainly to a large extent due to the difference of the average distance of the dendrons' anchor groups at the backbones, but the backbones' different stiffnesses also play a role here. While the contour length of **P16/17 (G3)** of the starting conformation upon equilibration remains practically constant, that of **P12 (G3)** is reduced by some 30% when the minimum conformation is reached. This shows that the dense appearance of the latter polymer can be partially attributed to some backbone coiling. It is reasonable to assume that it is exactly this small space still available which rendered the polymerizations feasible. Considerations regarding preaggregation of polymerizable dendrons into ordered cylindrical arrays prior to polymerization through the aggregate (85) do not seem to be applicable here.

Figure 12 shows computer-generated structures of **P16/17** (G1) through **P16/17** (G4). Though these structures are not fully energy minimized, it is quite

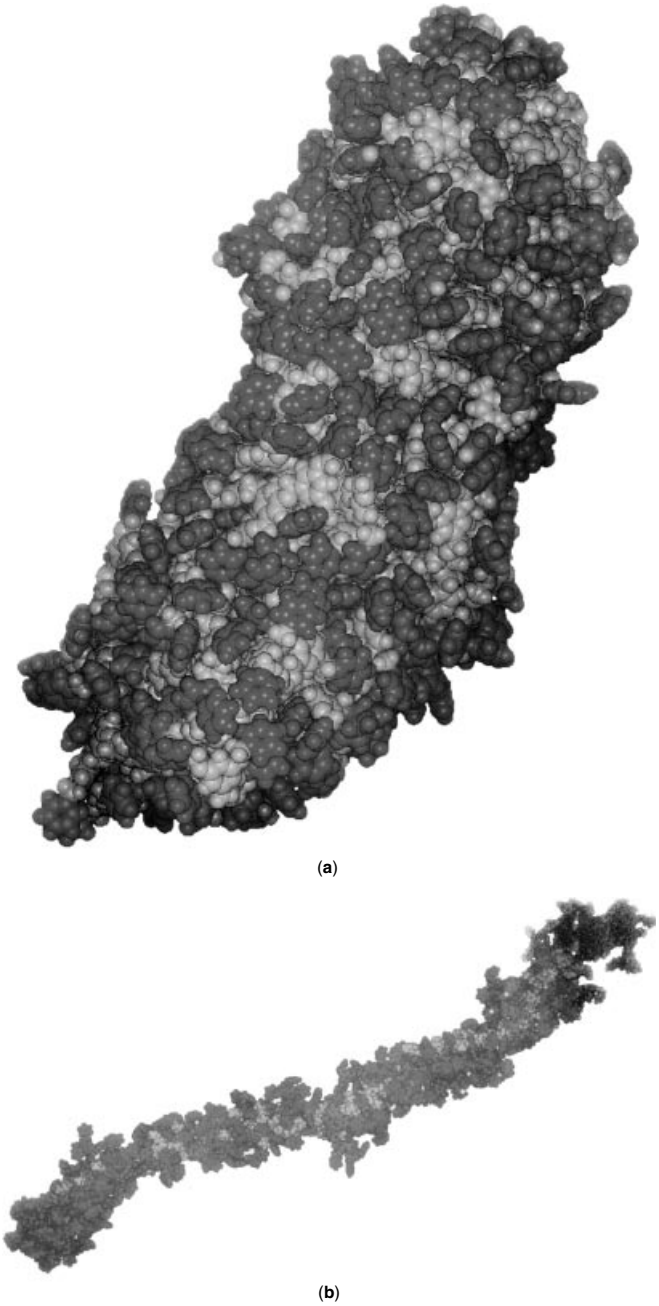

Fig. 11. Molecular dynamics (MD) simulations of dendronized polymers **P12 (G3)** (**a**) and **P16/17 (G3)** (**b**). **P12 (G3)** has 50 r.u's and the structure shown was obtained after 300 ps. End-to-end distance 9.1 nm, average diameter 4.4 ($\pm$0.2) nm. The backbone atoms are kept in *yellow*, the terminal benzene rings in *red*, all other atoms in *green*. **P16/17 (G3)** has 40 r.u.'s and a contour length of 33 nm. The backbone and the hexyl chain atoms are in *yellow*, the terminal benzene rings in *red*, and all other atoms in *green*. The diameter fluctuates between approximately 2 and 4 nm.

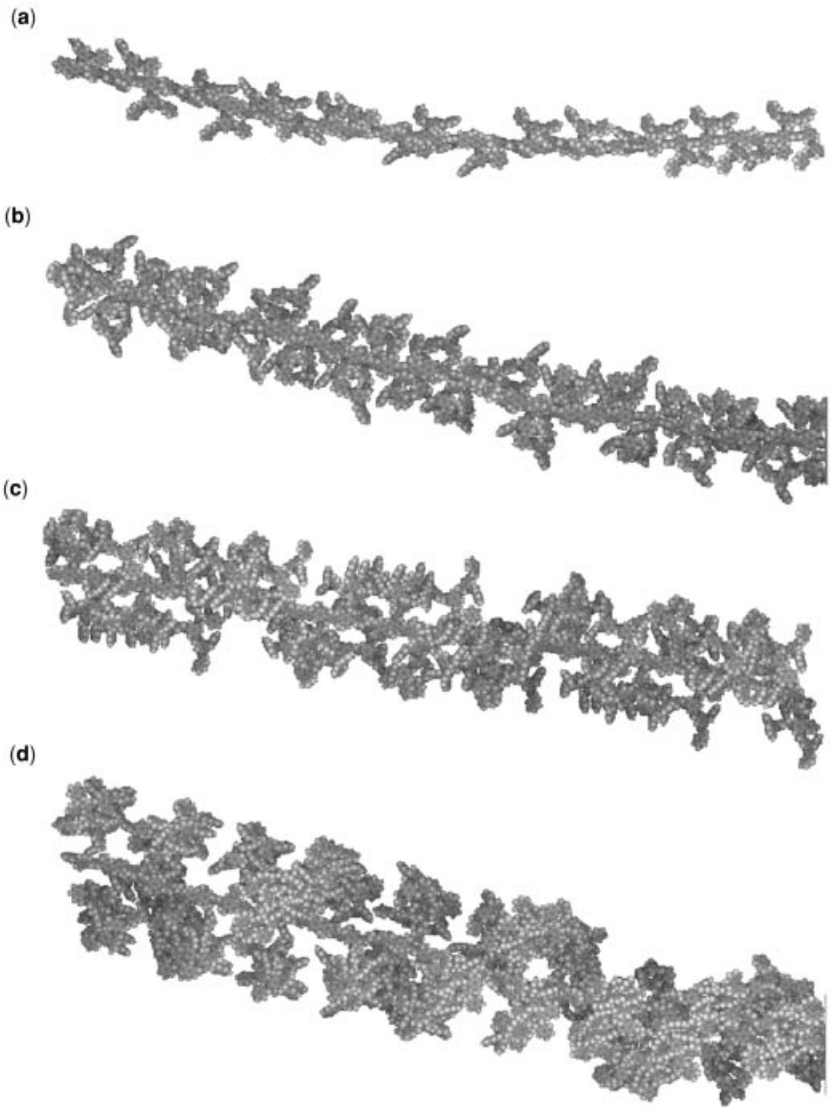

Fig. 12. Computer-generated images of dendronized polymers **P16/17** (G1) to **P16/17** (G4) (**a**–**d**).

obvious that there is space between consecutive dendrons even for the G4 case. This space, together with the surprisingly successful polymerization of monomer (**16**) (G3) supported the idea to also try SPC with monomer (**16**) (G4).

Behavior in the Bulk

The bulk properties have been investigated for polymers **P2** (G1 and G2) (59), **P4** (G2) (59,90) (**P2**, **P4**: R = $OC_{12}H_{25}$), **P18/19** (G4) (77), and **P25/26** (78). All four

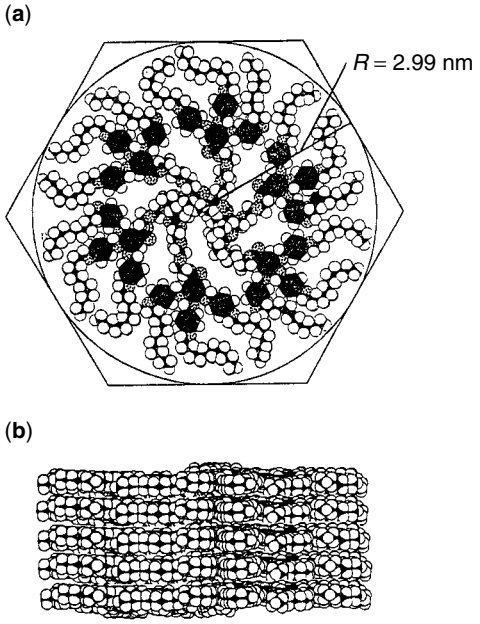

Fig. 13. Schematic representation of a supramolecular cylinder of dendronized polymer **P2** (G1) (R = $OC_{12}H_{25}$, $n = 3$) in the Θ_h mesophase: (**a**) top view of a cylinder containing 6 repeat units in a stratum with the alkyl tails melted to match the average column radius determined by x-ray scattering experiments, (**b**) side view of a cylinder containing 30 repeat units of the polymer assembled with melted alkyl tails. Reproduced with permission from Ref. 15.

structures have flexible backbones with a noncompact sequence of dendrons. In the first two cases and in the last one, the dendrons have liquid crystalline properties, whereas in the third they do not. Polymer **P2** (G1) self-assembles into a tubular supramolecular structure exhibiting enantiotropic columnar hexagonal (Θh) phases. These phases are characterized by differential scanning calorimetry, wide-angle and small-angle x-ray scattering, thermal optical polarized microscopy, and molecular modeling (15). The structure model proposes the stratum of the column to be formed by the backbone and the linking segments melted and segregated in the center of the column and their melted dendrons radiating toward the column periphery (Figs. 13 and 14). When a second generation dendron is used as in **P2** (G2) and **P4** (G2), an additional interesting feature is observed (59). As the degree of polymerization increases, the dendrimer's shape shifts from spherical to cylindrical. This is accompanied by the backbone going from random-coil to the extended conformation. This phenomenon provides the unique possibility for molecular engineering of polymer shapes, backbone conformation, and properties and is a way to show the interplay and impact of the above-mentioned interactions. Spherical and extended architectures of these dendrimers are basically proven by x-ray diffraction and can also be visualized by an sfm investigation using bilayers on a mica substrate. For a G1 polymer with closely related structure (not shown), a second columnar liquid crystalline phase was observed (90). For a polymer coated

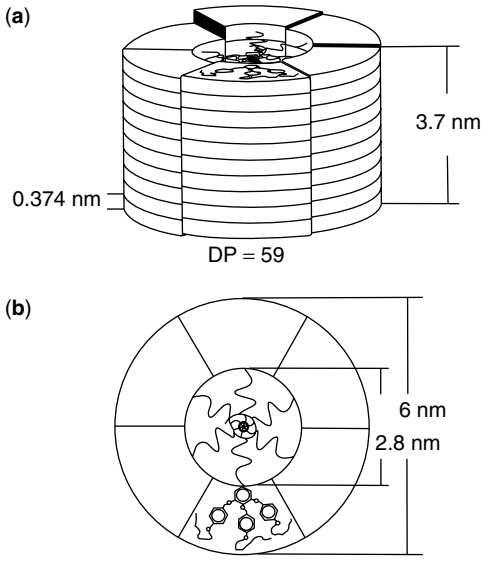

Fig. 14. An idealized representation of the supramolecular cylinder self-assembled from a single chain of dendronized polymer **P2** (G1) (R = $OC_{12}H_{25}$, $n = 3$) in the hexagonal columnar phase, assuming one single backbone per cylinder, drawn to proportion with existing data: (**a**) a tilted side view, (**b**) top view. Reproduced with permission from Ref. 15.

with two tapered units per side chain (not shown), a hexagonal columnar liquid crystalline superlattice was observed (91).

Though polymer **P18/19** (G4) does not show any liquid crystallinity, it nevertheless forms supramolecular structures in the bulk (77). This was concluded from x-ray diffraction patterns obtained from Si plates coated with this polymer and monomer (**18**), respectively. A series of Bragg peaks for the polymer showed the existence of an ordered structure. Based on MD calculations and additional small-angle x-ray scattering experiments, this structure was proposed to be body-centered cubic.

Polymer **P25/26** self-orders in solvent-cast films, with the backbones parallel to the substrate and a strong solvent dependence of the degree of ordering (78). Spacings of 2.2–2.6 nm are observed by x-ray diffraction, indicating interdigitation of the dendritic side chains. **P25/26** also forms thermotropic nematic liquid crystalline phases. With optical microscopy, Schlieren textures are observed for thin films cast from solution.

Assembly and Manipulation at Surfaces

Dendronized polymers can self-assemble on surfaces into highly ordered layers, which renders them into a material attractive for various applications. The assembly process can be investigated on the molecular scale using the sfm. In addition, the sfm may be used to manipulate single macromolecules on solid substrates in order to generate assemblies, which would not form spontaneously.

The behavior of the dendronized polymers at interfaces is determined not only by intra- and intermolecular forces but also by interfacial forces. The latter (92) include the van der Waals force, which is important on the nanometer scale and which is due to the difference in the dielectric properties of the two adjacent phases. This force is always attractive, and therefore favors a high molecular segment density at the interface, which in turn favors 2-D crystallization, since crystals exhibit usually higher densities than less ordered phases. Counteracting is the influence of entropy: Immobilizing flexible molecules in 2-D crystals at interfaces reduces entropy, since the molecules lose both translational as well as conformational entropy. For the adsorption from a liquid mixture, this favors the adsorption of the *largest* molecules, since the loss of translational entropy is counted per particle, wherear the van der Waals energy gained is proportional to the mass. Entropy effects also favor the adsorption of the most *rigid* molecules, since they lose the least conformational entropy. As a result, the large and rigid rods will be preferably adsorbed from a liquid molecular mixture. In addition, there are short-range chemical forces, which are specific for the particular chemical species at the interface and may be attractive or repulsive. Well-known consequences of these forces are epitaxial layering on crystalline substrates and the ordering of amphiphilic molecules at the water–air interface. Moreover, there are electrostatic forces for charged species.

In the following, the behavior of two classes of dendronized polymers at interfaces will be discussed: those with one type of dendrons (homophilic systems) and others with a hydrophobic and a hydrophilic dendron at each repeat unit (amphiphilic systems).

Homophilic Systems. Dendronized polymers can be observed by sfm either in ordered ultrathin films or as individual molecules on solid supports. SFM (93,94) is a powerful tool for investigating morphology, molecular packing, and molecular dynamics at surfaces with a resolution on the molecular scale. Both, synthetic and biological polymers (87,95,96) as well as spherical dendrimers have been studied (97–99). Of particular interest for rather soft organic materials is the operation in the "intermittent contact" or "tapping" mode (94), which minimizes sample wear during imaging.

Ultrathin layers of homophilic dendrimers can be prepared by solution casting (slow layer formation) or spin coating (fast layer formation) from organic solvents. SFM images of **P12 (G3)** were obtained for thin (in the range of 20–30 nm) solution casted layers on highly oriented pyrolytic graphite (HOPG) (Fig. 15) (88). They reveal a remarkably high degree of order: One observes domains which consist of periodic arrays of rows (Fig. 2c) with a periodicity of $D = 5.0 \pm 0.5$ nm. For comparison, MD simulations (Fig. 5a) and sans measurements reveal rod diameters of $D = 4.4 \pm 0.2$ nm and $D = 5.1 \pm 0.5$ nm, respectively. These numbers are very similar to the distances between the rows, suggesting that the rows can be attributed to molecules, which are predominantly oriented parallel to the surface. They are grouped in anisotropic domains, whose sizes vary between 20 and 200 nm (parallel to the director axis) and between 20 and 100 nm (perpendicular to the director axis). However, a reliable correlation of individual chain lengths with domain size is not possible, since, despite the high resolution of the image, only the chain ends at the grain boundaries can be clearly identified, while those in the interior may be obscured if two dendrimers with the same director axis

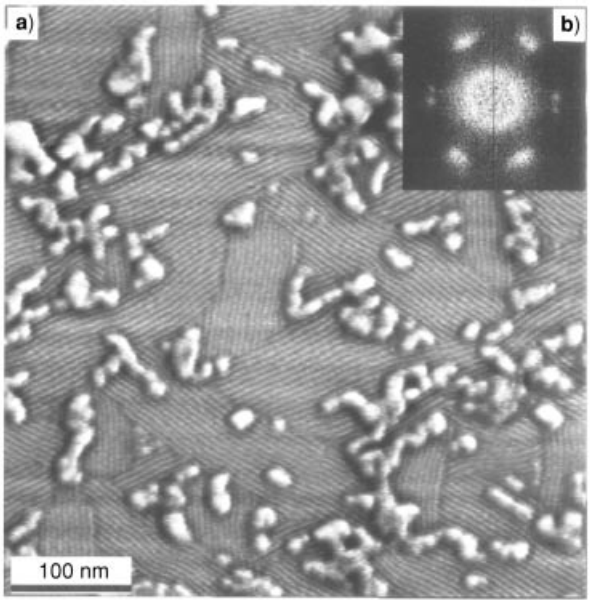

Fig. 15. Tapping mode phase contrast sfm image of an ultrathin layer of **P12 (G3)** on highly oriented pyrolytic graphite (HOPG) (50). The rows are attributed to molecules, which are predominantly oriented parallel to the surface as well as to each other. Their orientation within the surface plane reflects also the threefold symmetry of the substrate, as indicated by the Fourier-Transform in the inset.

are in tight contact and oscillate somewhat along this axis (88). Large-scale sfm images show that the films exhibit terraces with height differences δh between adjacent terraces of 4.2 ± 0.2 nm. This is close to 5.0 nm $\times$ cos $30^\circ = 4.3$ nm, which one would expect for a model of closely packed cylinders of a diameter of 5 nm (Fig. 16).

Interestingly, the different domains in Figure 13 exhibit three molecular orientations at $60^\circ \pm 8^\circ$ relative to each other, indicating that even in a layer of a thickness of the order of five monolayers, the top layer reflects the threefold symmetry of the graphite substrate. While this symmetry is stable in time, reorientations by 120° do occur. The case of a similar dendronized polymer, **P16/17 (G3)**, is demonstrated in Figure 17 (89).

The results described above show that the ultrathin layers of the described dendronized polymers offer the possibility to orient the polymeric backbones along substrate axes, and to access molecular dimensions in arrays by sfm imaging. In order to follow the assembly process on the molecular scale, it is desirable to prepare submonolayers with isolated single molecules on the surface. A convenient preparation for this is spin-coating HOPG from a dilute solution. SFM images of **P14** (2$\times$G1) (100–102) (Fig. 18a) reveal single molecules stretched out on the surface with sharp kinks of typically 120°, which reflect again the symmetry of the substrate. The sharpness of the kinks indicates that this polymer is quite flexible. Upon annealing, compact monolayer islands can form (Fig. 18b), revealing that the flexibility of the chains allows the formation of very sharp bends. SFM images

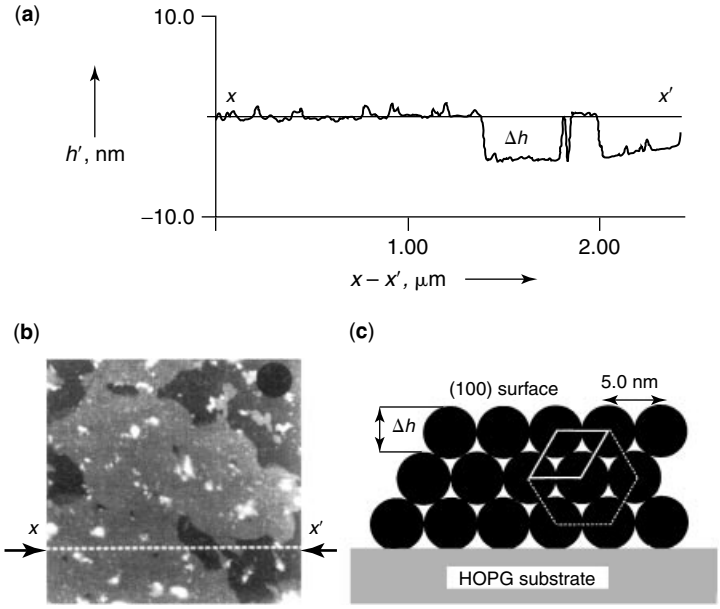

Fig. 16. Tapping mode sfm of ultrathin films of **P12 (G3)** on HOPG and a packing model (97). (**a**) Cross-sectional profile along x-x′ as indicated in (**b**). The height difference between adjacent terraces has the dimension of a monolayer ($\Delta h = 4.2 \pm 0.2$ nm), (b) Large-scale ($2.4 \times 2.4\ \mu m^2$) sfm image of molecular terraces, (c) Schematic model of close-packed molecularly defined cylinders in ultrathin films of **P12 (G3)** on HOPG. From Ref. 88.

may also be used to determine the distributions of contour lengths. They revealed that **P14** (2×G1), ie, a polymer with a spatially not very demanding side group, appeared to be at least two times shorter than the contour length as expected on the basis of size exclusion chromatography and static light scattering. This was attributed to a disordered helix-like conformation of the polymeric backbone, and can be contrasted to the case of **P4** (G1) with a spatially more demanding side group, whose contour lengths agreed fairly well with the expectation (100–102). On one hand, it shows that bulky dendrons force the backbone into extension. On the other hand, there is a degree of freedom for less bulky dendrons, namely the conformation of the flexible polymer backbone, which may be used to control the contour length of the dendronized polymer (eg, by contraction through helix formation).

Polymers at surfaces may also be manipulated with the sfm (Fig. 2). An example for the manipulation of dendronized polymers by rubbing (Fig. 2d) with the sfm is shown in Figure 19, which has been obtained as follows: First a rather low molecular weight fraction (of the order of 10 r.u.'s on average according to gpc with polystyrene standard) of **P16/17** (G4) was spin-coated to give a monolayer on HOPG. The result is an apparently disordered surface. Scanning with the sfm tip, however, orients the molecules almost prefectly uniformly in the whole scan window which can be 1 μm^2 or more (104), limited apparently only by the domain size of the underlying HOPG, which is typically of the order of 10 μm, but can also vary.

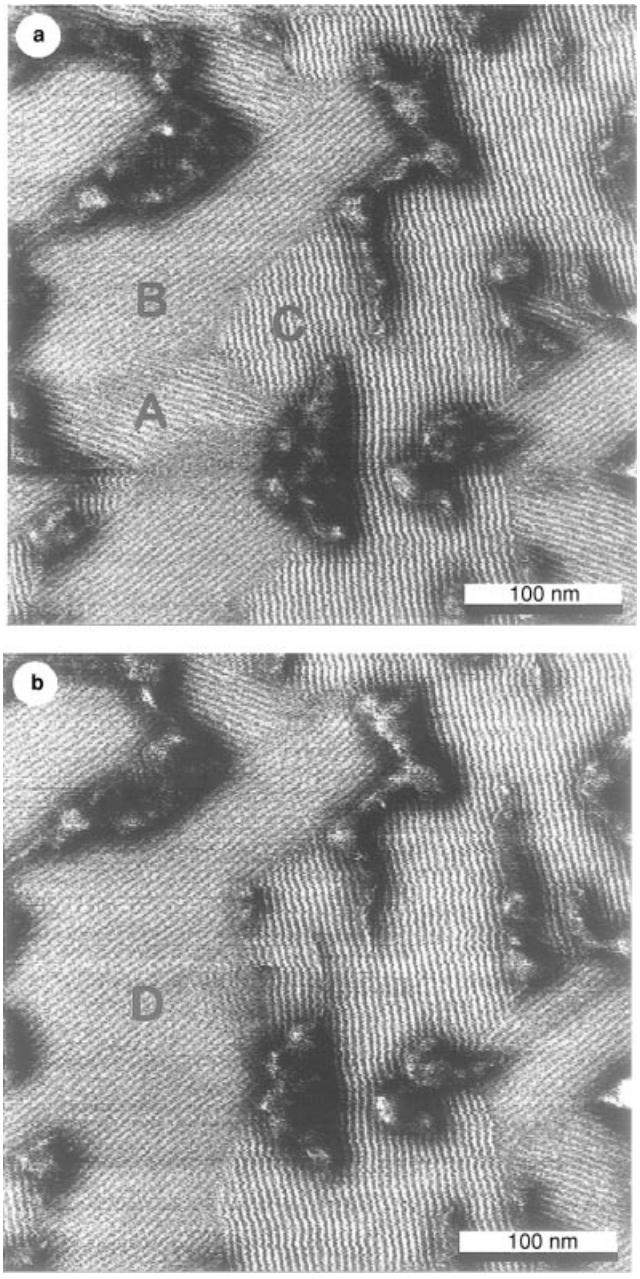

Fig. 17. Tapping mode phase contrast sfm images of an ultrathin film of **P16/17 (G3)** on HOPG (89). The rows are again attributed to molecules, which are predominantly oriented parallel to the surface as well as to each other. Their orientation within the surface plane reflects also the threefold symmetry of the substrate (three molecular orientations denoted A, B, and C in panel **a**). Images (**a**) and (**b**) have been recorded at the same position at an interval of 10 min. Domain A reorients in the same direction as domain B, resulting in a new domain D.

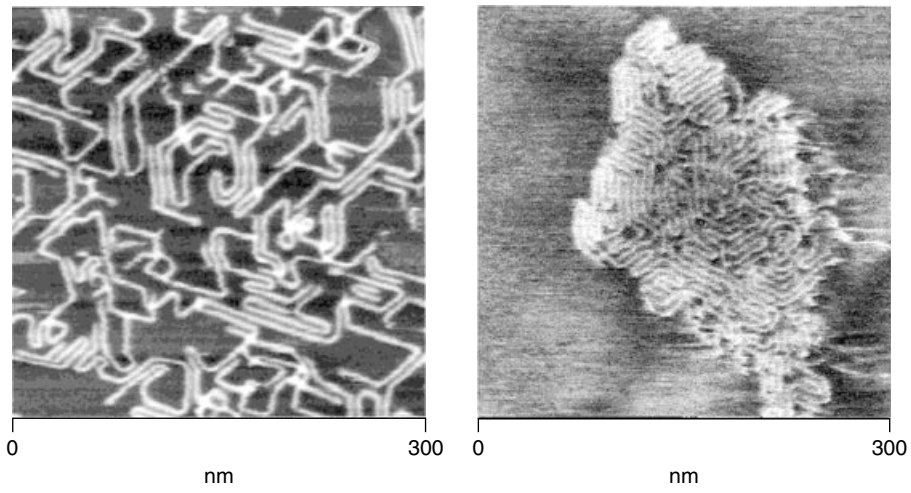

Fig. 18. Tapping mode sfm height images of **P14** (2×G1) with a theoretical $P_n = 100$ on HOPG prepared by spin casting from a solution in THF (102): (**a**) as prepared, (**b**) after annealing at 100°C for 24 h. The molecular orientations reflect the symmetry of the substrate; the molecules are flexible enough to let them be frequently bent by 120°. The strong tendency for the single molecule to align along lattice axes of the substrate has been attributed to the orientation of the pendent alkyl chains (103). Upon annealing, compact, domains are formed.

But not only layers can be manipulated by the sfm tip, also single macromolecules can be moved across the surface (Fig. 2b). Figure 20 (left) shows an sfm image of **P7** (G2) with two C12 chains per terminal amine group (not shown) on HOPG. The alkyl chains cause the backbones again to orient preferentially according to the threefold symmetry of the substrate, and the flexibility of the backbone allows sharp kinks to form. Figure 18b shows the same area after one molecule has been moved to the left by sliding the sfm tip at stronger interaction with the substrate along a path indicated by the red arrow. The image reveals that the macromolecule also bent because of its flexibility.

Such manipulations should be better defined for polymers with higher rigidity. Since Coulomb-charges along the backbone should stiffen the macromolecule, polyelectrolytes, similar to the polymers with bulky dendrons **P12 (G3)** and **P16/17** (G4), should be promising candidates to manipulate them one by one with the sfm tip, and to determine single molecule properties, like persistence lengths and Young's or bending moduli (Fig. 2a).

Amphiphilic Systems. Amphiphilic dendronized polymers may lead to amphiphilic cylinders which, depending on the surrounding medium, could segregate lengthwise into two different halves (Figs. 3d, Fig. 21). This structural motif is rather unique. In nature it can be found in some ion channel membrane proteins, which means that amphiphilically dendronized polymers are of interest as models for such proteins (105–108). They may also serve as novel and giant constituents of self-aggregated assemblies and should show interesting behavior at interfaces. A good candidate is a dendronized polymer, whose repeating units are equipped with two sterically demanding substituents, one of which being hydrophobic and

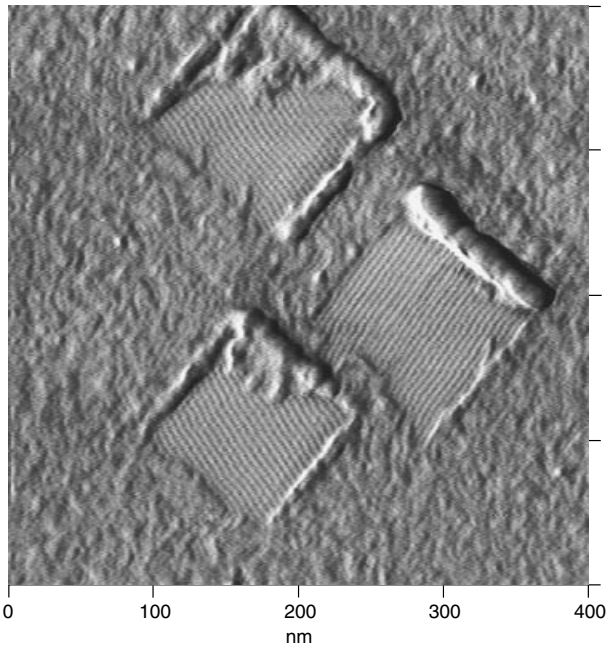

Fig. 19. Tapping mode phase contrast sfm image of a monolayer of oligomeric **P23/24** (G4) after scanning three areas with the sfm (104). It reveals that upon scanning the molecules are perfectly oriented along one of the three symmetry axes of the substrate.

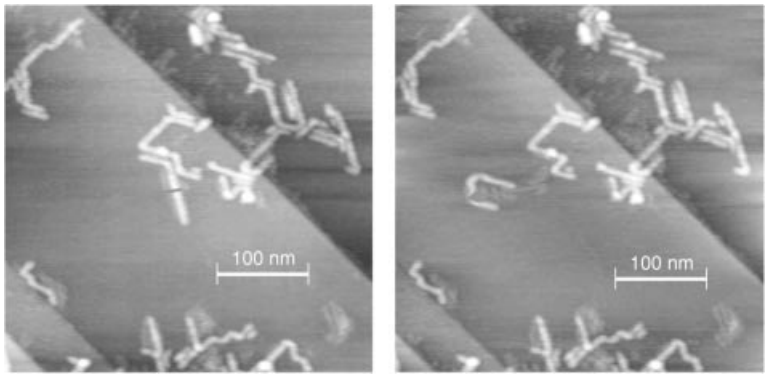

Fig. 20. Manipulation of individualized **P7** (G2) with two C12 chains per terminal amine group on HOPG by switching from an sfm tapping mode imaging modus to manipulation by approaching the tip to the sample and moving along the path of the red arrow. (**a**) image before and (**b**) image after manipulation. From Ref. 104.

the other hydrophilic (62). This area was entered with three differently equipped PPPs **P20/24**, **P21/24**, and **P22/24**, which differ in the relative spatial demand of their polar and nonpolar substituents.

There are different ways to prepare ultrathin layers from amphiphilic polymers: One is to form Langmuir monolayers at the water–air interface followed by

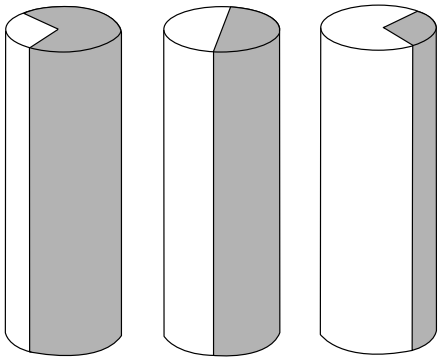

Fig. 21. Representations of amphiphilically equipped dendritic cylinders with varying spatial demands of polar and nonpolar domains. The lengthwise segregation of these domains is interesting for surface modifications and for attaining unprecedented aggregates in solution.

transfer to solid substrates using the Langmuir–Blodgett technique. Another is spin coating as for the homophilic systems.

Amphiphilic dendron-based molecules have been investigated at the air–water interface and stable Langmuir monolayers were found for some of these systems (109–114). In one study (115), the behavior of the hydrophobic Fréchet-type dendrons (Fig. 6) carrying hydrophilic ethyleneoxy (EO) chains at their focal point was studied at this interface by systematically varying the dendron size (G3 to G5) and chain length. Longer hydrophilic chains increased the stability of the Langmuir films for G3 and G4 by roughly 3.1 and 4.1 mN/m (=dyn/cm), respectively, per additional EO unit. On going from the lower to the higher generations, the shape of the dendrons changes from vertically elongated to more flat. The collapse pressures ranged from approximately 6 mN/m for G3 with one EO group to 25 mN/m for G3 with six EO groups.

Langmuir monolayers of monomer 20 and polymer **P20/24** have been prepared at the air–water interface (74), exhibiting surface pressure-area isotherms at room temperature, which reveal stable monolayers. The monolayers of 20 exhibit very good reversibility for compression, decompression, and repeating cycles, with an area per molecule of about 0.73 nm^2 per molecule at 20 mN/m. This is consistent with a monolayer structure, in which the four EO chains per water-soluble dendron are close-packed and oriented perpendicularly to the monolayer, thereby defining a minimum area per molecule. In comparison, polymer **P20/24** exhibits a 10% larger area per repeat unit (0.82 nm^2/r.u.) upon the first compression with a hysteresis in the first decompression and a shift to a more reversible isotherm, and a smaller area per repeat unit in the second cycle (0.77 nm^2/r.u.). The good agreement between the areas per molecule of monomer (**20**) and per repeat unit of polymer **P20/24** indicates a structure of the polymer monolayer, in which the rod-like polymer molecules are oriented with their long axes within the monolayer plane and close-packed. Moreover, the hydrophylic ethyleneoxide chains are on that side of the polymer which faces the water subphase, while the more hydrophobic dendron faces the air side of the polymer. This picture is supported by a control experiment using a closely related polymer in which the hydrophilic

dendron of **P20/24** is replaced by another G2 Fréchet dendron (structure not shown). Under the same conditions this polymer does not form a stable monolayer at the air–water interface.

Also, polymers **P21/24** and **P22/24** with their corresponding monomers (**21**) and (**22**) were investigated at the air–water interface (75). Except **P22/24** they all form stable monolayers on the Langmuir trough, which can be transferred by the Langmuir–Blodgett (LB) technique to mica. While the transferred films of (**21**) and (**22**) are unstable, **P21/24** forms stable, rather smooth monolayers, whose morphology remains unchanged for at least a week. The fact that both monomers are stable on water but not on mica reflects the discrepancy of the space demand of the hydrophilic and hydrophobic parts. Since the polymer **P21/24** is stable on mica, the covalent attachment of the amphiphilic repeat units can stabilize an LB-layer. On the other hand, the fact that **P22/24** does not form a stable monolayer, not even on water, indicates that this polymer with its amphiphilic misbalance does not behave like an amphiphile under these conditions.

A quantitative comparison of the collapse pressures of the Curtis–Hawker amphiphiles (114) with the ones described here cannot be made. There are substantial structural differences even if this comparison is restricted to the monomers (**20**), (**21**), (**22**). Additionally, the Curtis–Hawker amphiphiles have EO chains with terminal (polar) hydroxy functions whereas the monomers have (non-polar) methoxy groups instead. The collapse pressures are, however, in a similar range.

Usually, no molecular scale resolution sfm images were obtained for the LB-layers, contrary to the analogous homophilic systems prepared by spin coating. Therefore, spin coating has been employed as an alternative preparation method for the amphiphilic systems also (104). Figure 22 displays an sfm image of a

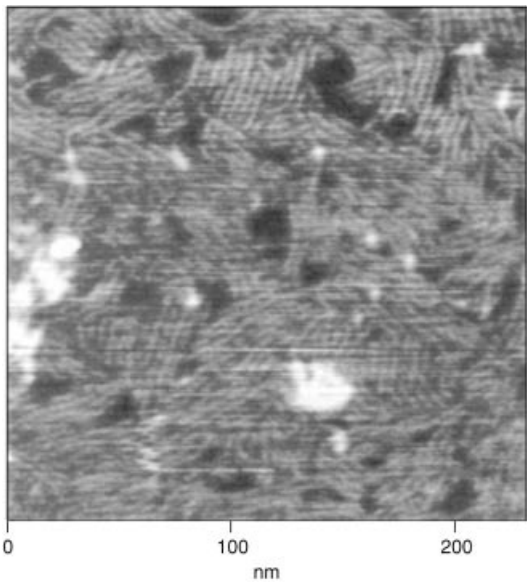

Fig. 22. Molecular resolution tapping mode sfm height image of spin-coated amphiphiles **P20/24** on HOPG. From Ref. 104.

spin-coated monolayer of **P20/24** on HOPG, which reveals rather straight rods. Again, their orientation within the plane is not random but it reflects the threefold symmetry of the substrate. Within the experimental error, the length distribution of the rods agrees with their determination by size exclusion chromatography. However, the distance between the rods is 4.4 ± 0.5 nm, which is larger than what one would expect for close-packed molecules. A possible explanation is a well-defined aggregation of the amphiphilic rods, eg, into dimers, which exhibit hydrophobic surfaces in contact with both the rather hydrophobic substrate and the ambient.

Optical Properties

Dendronized polymers may exhibit interesting optical and electrical properties which should at least be briefly mentioned here. Poly(phenyleneethynylene)s are among the few conjugated polymers which are interesting candidates for blue light-emitting diodes (116,117). A problem which hampers the use of these polymers in commercial devices is luminescence quenching of the excited state because of intimate contact between the backbones. Wrapping of such a backbone by a dendritic layer, which itself does not quench the luminescence, can be a solution (80). Over a wide concentration range, the quantum yield of the luminescence of **P27/28** (G4) was nearly 100%, contrary to the case of **P27/28** (G3 or G2) where it drops below 40% (Fig. 23). Additionally, upon 278-nm excitation of the dendritic substituents of **P27/28** (G4) in tetrahydrofuran (THF), the observed fluorescence was 11 times more intense than that of the lower generation analogs under identical conditions. In this case, the dendritic layer harvests the uv photons, channels them to the backbone which then emits with high efficiency in the blue Light-emitting diode.

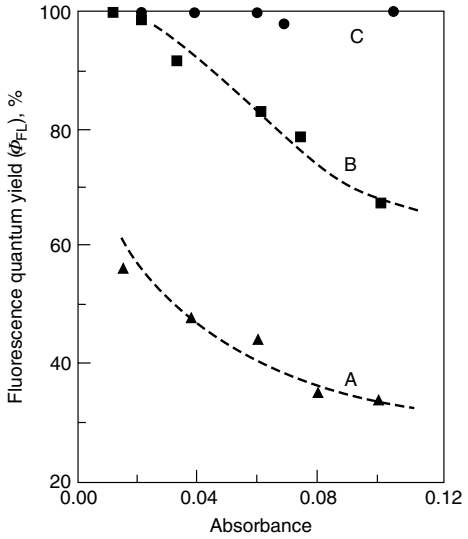

Fig. 23. Fluorescence quantum yields of **P27/28** (G2) (A), **P27/28** (G3) (B), **P27/28** (G4) (C) upon excitation of the conjugated backbone in THF with absorbances of 0.01–0.1 at the excitation wavelength $\lambda = 425$ nm under Ar at 20 °C. From Ref. 80.

The same idea of isolating active backbones from one another and, thus, exploiting their intrinsic undisturbed properties, were also followed (78,79,81). In Reference 81, polymers **P29** ($n = 0,1$) were prepared and it was shown that the attachment of bulky substituents does not influence the electronic characteristics of the backbone. No increase of the dihedral angle between consecutive repeat units was observed. The emission maximum ($\lambda_{exc.} = 380$ nm) of a drop-casted film of **P29** ($n = 1$) was virtually unchanged and no sign of aggregation behavior was found. **P29** ($n = 1$) was incorporated into a device which produces blue emission with an onset voltage below 4 V. On very similar experiments with **P25/26**, an enhancement in solid-state photoluminescence by a factor of 4 because of the intermolecular separation of the chromophores by the attached dendrons was found (78,79).

Summary and Outlook

High molecular weight dendronized polymers are synthetically accessible. If certain prerequisites are taken into account, even the sterically demanding macromonomers (**12**) (G3), (**16**) (G3), and (**23**) (G4) can be employed, which widens the scope of both radically initiated polymerizations as well as Suzuki polycondensation. The successful synthesis of polymers like **P12 (G3)**, **P23/24** (G4), and **C** (G4) allows investigation of the impact of the dendritic decoration on the backbones' coiling behavior and addresses the important question of whether or not steric congestion can be used as a tool to force molecules into a certain shape, which is more or less independent of the surrounding medium (in solution, adsorbed on surfaces, spread at solid–liquid interfaces, and in the solid state). SFM and sans measurements as well as MD simulations reveal that, eg, polymer **P12 (G3)** is quite stiff and can be viewed as a cylindrically shaped molecular object with a defined diameter of approximately 5 nm and a persistence length on the length scale

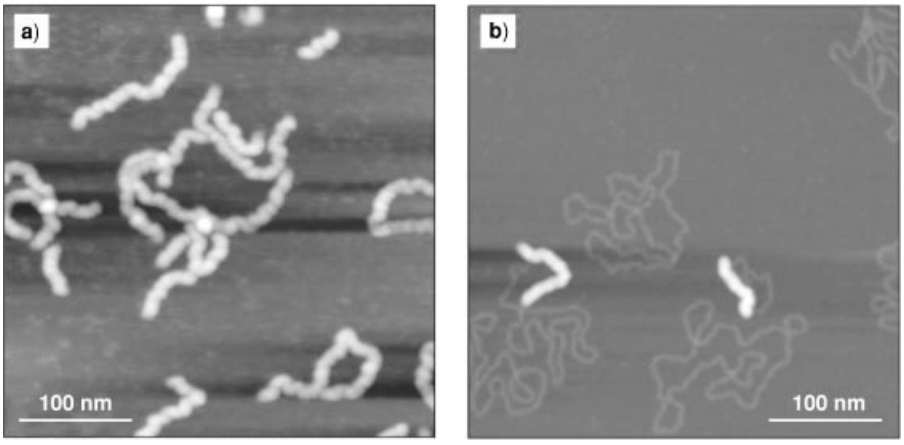

Fig. 24. Tapping mode sfm height images of (**a**) unprotected and quaternized (charged!) polymer **C** (G4) on mica and (**b**) the same when complexed with plasmid DNA. The brighter and wider features in (**b**) are attributed to the aggregate between the two oppositely charged polyelectrolytes while the other features represent neat DNA. From Ref. 118.

of a few tenths of a nanometer. One may even be inclined to assign a "surface" to this polymer. Driven by the idea of generating molecular nanoobjects with functional surfaces just by polymerizing appropriately equipped monomers, first steps were made to decorate these surfaces with both functional and polar/nonpolar groups in order to engineer properties and explore possible fields of application. Research on nano-objects of the described kind is a truly interdisciplinary enterprise, and progress depends upon tight cooperation between synthetic chemists, experimental physicists, and theoreticians. Some future directions will be (*1*) to develop synthesis to the point where several rigid objects with various surface functionalities are available and their length distributions are somewhat better under control, (*2*) to isolate individual very rigid cylinders on surfaces and determine quantitatively molecular properties like bending moduli, (*3*) to move them about on surfaces for patterning and construction purposes, and (*4*) to start investigations into their properties along the lines described under "Dendronized Polymers." Figure 24 gives, as an example, a taste of what is presently being investigated in the directions indicated in Fig. 3c. Complex formation of the kind described here is possible. Figure 24a shows an sfm image of unprotected and quaternized (positively charged) polymer **C** (G4) spin-coated on mica. Figure 24b shows the same polymer complexed with (negatively charged) DNA after complexation in solution and subsequently spin-coated on mica. The image reveals both neat DNA and complexes of the dendronized polymer with DNA, which are a little thicker than the neat polymer (118).

DENTAL APPLICATIONS

Introduction

The dental industry has taken great advantage of polymer science to design materials. Materials used in the oral cavity or external prostheses have very specific requirements, ie, these materials must have physical, chemical, biological, and aesthetic requirements, not always fulfilled by currently available materials. A host of requirements must often be met, including adequate strength, resilience, wear or abrasion resistance, dimensional stability for both fabrication and use, translucency or transparency to provide a match of the natural tissue replaced, good color stability, resistance to the oral environment, show tissue tolerance and low toxicity, and exhibit ease of fabrication into a needed dental device. Since few resins fulfill all the mentioned requirements, the search for improved dental materials has been limited to a few classes of polymeric materials. The various types of monomers and polymers used in dentistry are discussed, along with brief attention given to new areas of promise for preparing better materials.

The largest volume of polymeric materials used in dentistry is in prosthetic applications. Polymeric materials are also important in operative dentistry, being used to produce composite resins, dental cements, adhesives, cavity liners, and as a protective sealant for pits and fissures. Elastomers are employed as impression materials. Resilient prosthetic devices are often fabricated to restore external soft-tissue defects. Mouth protectors are fabricated to prevent injury to teeth, as well as prevent head and neck injuries. Other polymer applications include fabricating patterns for metal castings and partial denture frameworks, impression trays, orthodontic and periodontal devices, space maintainers, bite plates, cleft palate obdurators, and oral implants. Polymeric materials may also be used to fabricate an artificial tongue, when disease results in its loss.

Encyclopedia of Polymer Science and Technology. Copyright John Wiley & Sons, Inc. All rights reserved.

The discovery of vulcanized rubber in 1839 gave rise to the first polymeric dentures, followed by celluloid dentures about 1870, and subsequent use of vinyl chloride copolymers, phenol–formaldehyde resins, and polystyrene. Acrylic-based resins gained rapid acceptance after 1937, and are being greatly used today. Their main disadvantages are related to shrinkage because of the free-radical polymerization of methyl methacrylate, poor abrasion resistance, and fracture toughness. Other polymers, such as epoxy resins, polystyrene, polyesters, polycarbonates, polysulfones, vinyls, silicones, polysulfides, and polyethers, have been explored or used to some degree.

The various dental polymers discussed in this article include impression materials, dentures and denture liners, artificial teeth, crown and bridge materials, mouth protectors, maxillofacial materials, restoratives (consisting of glass polyalkenoates or glass-ionomers and composites), adhesives, and sealants. Specifications and standards for dental materials are also briefly mentioned in the text.

Impression/Duplicating Materials

Impressions must accurately show the dimensions, surface detail, and relationship of teeth and soft oral tissues. Materials used to accomplish this task include rigid gels of the reversible hydrogen-bonding type, irreversible alginate hydrocolloids, and elastomers such as silicones, polysulfides, and polyethers. Duplicates of original casts, used to fabricate partial or complete dentures, are made from duplicating materials.

Agar (Reversible Hydrocolloids). Agar, a galactose sulfate or mucopolysaccharide (sulfonic acid ester of a galactan complex), is a long-chain polymer having a molecular weight of about 150,000. The material forms a colloid with water, with the solutions being liquid at $\geq 70^{\circ}$C and setting to a gel at 30–50°C. Strong hydrogen bonding causes the molecule to form a helical structure, which uncoils on heating. On cooling, the gel forms and reproduces the shape of the oral tissues. These materials can be used several times, but prolonged heating causes degradation. While agar is the main constituent, it is by no means the main constitutent by weight. For example, a typical formulation consists of about 85.5% water, 12.5% agar, 1.7% potassium sulfate, 0.1% alkyl benzoate, and trace amount of pigments. Fillers, such as zinc oxide and a hard wax or clay, are often used to modify the formulations. Borax or calcium metaborate may be used to control the pH, increase viscosity, toughness, and resiliency. These materials were developed to make accurate impressions, even of undercut areas. The agar used in duplicating uses has a composition similar to the agar impression material, but with a higher water content. ANSI/ADA Specifications No. 11 (1997) applies to agar-based impression materials.

Alginates (Irreversible Hydrocolloids). The reactive component in these materials is the sodium or potassium salt of anhydro-*o*-D-mannuronic acid (alginic acid), isolated from brown seaweed (algae). A typical formulation consists of about 18% sodium or potassium alginate, 14% calcium sulfate dihydrate, 2% sodium phosphate, 10% potassium sulfate, 56% diatomaceous earth filler, and 4% sodium silicofluoride. When mixed with controlled amounts of water, the soluble

hydrocolloid is converted to insoluble calcium alginate, ie, and an acid–base reaction leads to matrix cross-linking. In the sol–gel conversion, calcium cations form salt-bridges with the carboxylate anions, forming ionic cross-linking. The material can only be used once. The addition of sodium tripolyphosphate or tetrasodium pyrophosphate retards rapid precipitation of gel. Addition of a fluorosilicate completes the precipitation of the insoluble alginate, after adequate working time has elapsed. Besides diatomaceous earth filler, zinc oxide may be used to improve strength and yield a material with a smooth, nontacky surface. Alginates, used most frequently to make impressions, are inexpensive, easy to manipulate, and comfortable for the patient. But, alginates deteriorate rapidly on storage at $\geq 50^{\circ}$C and once set they must be kept in 100% relative humidity to prevent shrinkage. In addition, they are the least accurate of the impression materials. Both reversible and irreversible hydrocolloids have been used at the same time in a laminating technique. ANSI/ADA Specification No. 18 (1992) sets the requirements for fast and slow setting alginate impression materials.

Synthetic Elastomers. Synthetic elastomers, such as polysulfides, silicone, and polyethers, exhibit much better dimensional stability than the hydrocolloids. They are mainly used in crown and bridge applications or for impressions of dentate patients. These polymers are used at a temperature above their glass-transition temperature (T_g). The viscosity of the materials used is influenced by both the working temperature above T_g and the length of the polymer chains, as well as by fillers and other additives. The formulated materials are liquids or pastes at room temperature, which transform into a solid by covalent bonding between the long-chain molecules. The process of forming chemical bonds creates a three-dimensional organic matrix. The chemistry of the impression materials is described separately, followed by a brief comparison of their properties. ANSI/ADA Specification No. 19 (1982) sets requirements for the elastomeric-type impression materials.

Polysulfides. The starting materials have molecular weights of about 2000–4000 and can be formulated to yield a wide range of physical and chemical properties. In the two-component (paste) system, the base material is a viscous polysulfide liquid prepolymer having terminal and pendant mercaptan (SH) groups, such as a Thiokol LP-2 rubber, commonly called thiols (see Fig. 1). Titanium dioxide (TiO_2), calcium sulfate, calcium carbonate, silica, or alumina is used as fillers, to extend, reinforce, or harden the product. Dibutyl phthalate, tricresyl phosphate, or tributyl citrate is added as modifiers or diluents to improve mixing and flow properties. The paste may also contain sulfur and oleic or stearic acid, which act as a retarder to control the set. The SH groups are oxidized by lead dioxide or copper hydroxide supplied as a separate part of the formulation. When the accelerator (oxidizer) is added to the base (polysulfide) paste an exothermic reaction occurs, bringing about a 3–5°C rise in temperature, depending on the

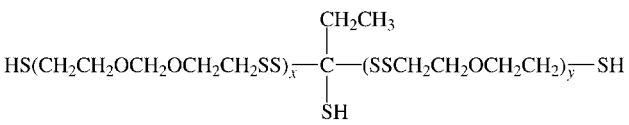

Fig. 1. Polysulfide oligomer.

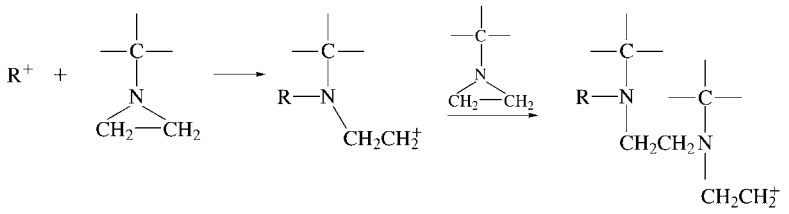

Fig. 2. Polyether impression material reaction.

amount of sulfur used. The exothermic reaction is accompanied by a rapid increase of molecular weight and elimination of water, caused by formation of the chain-extending and cross-linking —S—S— bonds. Besides being sticky and having a disagreeable odor, polysulfides [$R(SH)_x$] are difficult to mix and exhibit relatively poor elastic recovery when stressed. In undercut areas, they may not provide accurate reproduction of oral structures. When properly used they exhibit good tear resistance and acceptable stability.

Polyethers. These impression materials were developed in Germany in the 1960s. The reactive oligomer used is a polyether having cyclic imine (ethyleneimine) residues, which undergo ring opening and subsequent cross-linking via a cationic initiator, as shown in Figure 2. The two-part formulation contains the imine functionalized polyether, silicate filler, and a glycol ether plasticizer as one paste, and the cationic initiator (such as an alkylester of benzene sulfonic acid), a silicate filler, and a plasticizer as the second paste (1). Adding a polyester diluent or thinner controls the rheological properties and working time. Mixing is moderately easy and dimensional changes in air are low (<0.1%) over several hours, as no products are released during curing. The elastic recovery and reproduction of detail are excellent. These materials have a much higher modulus of elasticity than silicones or polysulfides, making them more difficult to remove from the mouth. Polyether impression materials tear readily and have an equilibrium water sorption of about 14%. Dimensional stability in water is poor, necessitating storage in a dry environment.

Silicones. Two types of silicones are used in impression materials: addition (Fig. 3) and condensation (hydrosilylation) (Fig. 4). Both are based on using poly(dimethylsiloxane), with the two having different end groups and different curing mechanisms. Addition siloxanes are a two-paste system, with one paste

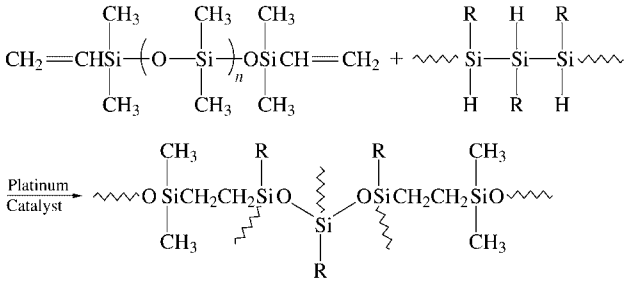

Fig. 3. Addition silicone structure/reaction.

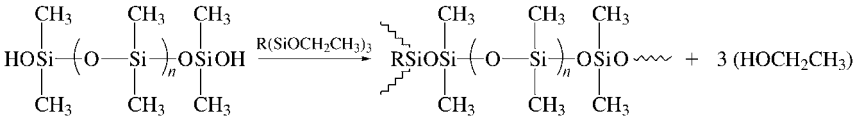

Fig. 4. Condensation silicone structure/reaction.

containing a low molecular weight silicone having terminal vinyl groups (Fig. 3) and reinforcing filler and the other paste consisting of the hydrogen-terminated silanol oligomer, filler, and chloroplatinic acid catalyst. Mixing the pastes gives a cross-linked elastomer. No volatiles are given off during polymerization—a definite advantage—compared to the condensation type, which eliminates ethyl alcohol.

The condensation-type silicone impression materials are based on hydroxyl-terminated poly(dimethylsiloxane), ie, viscous liquids of structure (Fig. 4). Colloidal silica or micronized metal oxides, having 5–10 μm particle size, are added to prepare a paste which is cross-linked with an alkyl silicate containing 50% ethoxy groups, such as tetraethyl orthosilicate (TEOS). Organic tin activators, such as stannous octoate or dibutyltin dilaurate (2), are used at the 1–2% level.

The chief uses of silicone impression materials are for crown and fixed partial dentures. These systems may be used in a wide range of impression techniques. They are relatively easy to mix, producing high tensile strength materials having good elastic properties, along with permanent-set values of about 1% at 40% strain. But, they tear at relatively low extension.

Communicable diseases have caused concern in handling of impression materials, meaning impressions are not generally accepted by dental laboratories unless they are disinfected. However, disinfection must be accomplished without distorting the impression. Reversible and irreversible hydrocolloids, as well as polyether impressions, should be avoided if they are to be disinfected, since they lack the required stability. A guide for disinfecting impression materials may be found in the ADA Council on Dental Materials, Equipment and Instruments (COMEI, 1988 and 1992).

Impression Materials Merits. Elastomeric impression materials reproduce surface details very accurately, provided low viscosity formulations are used. Since these materials are generally hydrophobic, they will not properly wet out the surface of the tooth with saliva present. Contact angle studies of water on the elastomeric impression surfaces for polyether, polysulfide, and addition silicones show angles of 49.3°, 82.1°, and 98.2°, respectively, indicating that polyethers work best where saliva cannot be excluded. The setting process for polysulfides is highly susceptible to temperature and humidity, influencing working and setting times. Condensation silicones may also show erratic setting, because of inadequate mixing and possibly some hydrolysis of TEOS. The setting behavior of addition silicones and polyethers is the most consistent. Condensation silicones are dimensionally less stable than polysulfides, addition silicones, or polyethers. The contraction or shrinkage of condensation silicones, upon cooling from mouth temperature (37°C) to room temperature, is ca 0.35%, compared to 0.20% for the polysulfides. This shrinkage is essentially caused by release of alcohol generated

during the condensation reaction. However, condensation silicones are cleaner to handle than polysulfides (3).

Elastomer Thermal and Mechanical Properties. Comparing stiffness of the polysulfide (PS), condensation silicone (CS), addition silicone (AS), and the polyether (PE) elastomeric impressions, the ranking would be as follows: PS < CS < AS < PE. The permanent set or resistance to deformation on removal would be as follows: PS > PE > CS > AS. Tear strength would be approximated as follows: PS $\ggg$ PE > AS and CS. Polymerization shrinkage for the elastomers is of the order PE = AS < PS < CS. The materials may thermally contract on removal from the oral cavity, with PE = 320, PS = 270, and AS = CS = 200 ppm/°C.

Denture Resins/Prosthetic Materials

A variety of polymeric materials have been studied or used for preparing dentures, including epoxy resins, cellulose nitrate, rubber or vulcanite, phenol–formaldehyde, vinyl acrylics, polystyrene, polycarbonates, and polysulfones, but acrylics have become the materials of choice. It happens that compression-molded, cross-linked acrylic dentures are as dimensionally stable and useful as the dentures made with special resins (4).

Denture wearers demand an accurate fit and natural appearance. The fit is very important, since chewing efficiency of artificial dentures is substantially lower than that of natural teeth. Besides being easy to fabricate, an ideal denture material would have high strength, stiffness, hardness, and toughness, ie, be fracture resistant, have low density, good dimensional stability, show resistance to oral fluids, have an absence of odor or taste, be resistant to bacterial growth, have good thermal conductivity, show good retention to other polymers, porcelain, and metals, be radiopaque, be easy to repair, easy to clean, have good storage life, and be inexpensive to make. Significant challenges remain to produce the ideal denture material.

To achieve needed comfort, dentures must be custom-made. To form the customized denture, in which the artificial teeth are embedded, a wax pattern is used. The wax pattern is inserted in a plaster or dental stone in a split mold flask. After removal of the wax, the surface of the resulting mold cavity is painted with a separating medium, usually an aqueous alginate solution, followed by the addition of the acrylic resin. The separating medium aids in removal of the cured acrylic from the mold.

Acrylic denture materials are made by free-radical (addition) polymerization, using methyl methacrylate (MMA) monomer. In the process, the MMA becomes poly(methyl methacrylate) (PMMA). The resins are available in either heat- or cold-cured formulations. A cross-linking monomer, such as ethylene glycol (Fig. 5)

Fig. 5. Dimethacrylate monomers/reactive diluents. EGDMA (R = CH_2CH_2); DEGDMA (R = $CH_2CH_2OCH_2CH_2$); TEGDMA (R = $CH_2CH_2OCH_2CH_2OCH_2CH_2$).

or diethylene glycol dimethacrylate (Fig. 5), is included with the MMA mixture to improve the mechanical properties. The dimethacrylates are covalently bonded at various points along the PMMA chains, forming a cross-linked matrix. Visible light-cured versions have also become available, with the chemistry akin to that of composite restoratives.

Heat-Cured Methacrylate Formulations. These resins consist of granular PMMA powder blended with liquid MMA, along with a cross-linking monomer, as shown in Figure 5 (EGDMA or DEGDMA). After mixing and heating, the monomer–polymer dough forms a rigid plastic. The powder component is mostly granules of PMMA, along with benzoyl peroxide initiator (BPO, 0.5–1%), titanium/zinc oxide pigments and opacifiers, dibutyl phthalate plasticizer, and acrylic- or nylon-type reinforcing fibers. The liquid component contains the inhibited MMA, along with a cross-linker (Fig. 5, DEGDMA). The blends, normally consisting of about two to three parts of PMMA and one part of monomer by volume, are packed with pressure into the mold, having the properly positioned teeth. The MMA is normally inhibited with the methyl ether of hydroquinone (MEHQ) or butylated hydroxytoluene (BHT). Small amounts of other acrylic monomers, plasticizers, and 1–5% of a cross-linking agent may be employed. The polymeric granules may also have methyl acrylate in the backbone or be plasticized by ethyl or butyl methacrylate or ethyl acrylate to increase solubility in the monomer syrup. Particle size and molecular weight distribution of the PMMA controls the solubility of the polymer and the working consistency of the mixture. Traces of poly(acrylic acid) or soluble starch suspension agents may remain in the polymer, preventing wetting of the beads by the monomer. The residual initiator content of the polymer beads may be at the level to obviate the need of further BPO to be added to the mix.

Most dentures are fabricated from the heat-cured formulations with the polymerization rate increasing directly with temperature, proportional to the square root of the initiator concentration. The half-life temperature ($t_{1/2}$, °C) for BPO at 72°C is 10 h (5). The customary curing cycle of the fully mixed powder/liquid blend is about 90 min at 65°C. Post-curing is usually done at 100°C for 60 min so as to produce a more fully cured denture with low porosity. After cooling, the denture is separated from the embedding material, trimmed, and polished. Red fibrous materials and beads of varying translucency are added in small amounts prior to curing so as to simulate the appearance fo natural oral-tissue.

Autopolymerizing Resins. Room temperature (RT) curing, initiated by a suitable redox (oxidizer–reducer) combination, is a simple modification of the heat-cured formulations. In such formulations tertiary aromatic amines, such as *N*,*N*-dihydroxyethyl-*p*-toluidine or *p*-*N*,*N*-dimethylaminophenethanol (6), are added at about the 0.3–0.8% level to the monomer, which is subsequently blended with a polymer containing 2% BPO. The rate and degree of polymerization depends on both the type and concentration of initiator (BPO) and activator (amine), as well as the particle size of the PMMA powder. Techniques for preparing the molding are very similar to the procedure described for heat-cured dentures. In this procedure, the freshly mixed monomer–polymer blends are more limited in use because of the handling characteristics of the formulations, ie, the polymerization is slightly delayed upon mixing. The rise in temperature depends on the mass of material and the powder/liquid (P/L) ratio used. Since polymerization occurs from inner to

outer portions of the mass, temperatures within the bulk portion of the casting are higher than those at the surface. The cured dentures are usually not very porous, since monomer evaporation is limited. The bulk of the polymerization takes place within 30–45 min, but may continue for hours. The denture flask is therefore held under pressure for several hours so as to ensure complete curing. Room-temperature cured materials usually contains about 3–5% free monomer, compared with only 0.2–0.5% found in heat-cured materials. Thus, this method of curing is not as efficient as the heat-cured process, since the product produced has less cross-linking density and a lower T_g than the heat-cured materials. The latter factors also make these RT-cured materials more susceptible to creep, eventually creating distortion in the denture. The larger the amounts of free monomer present in the final product, the greater the propensity for warpage to occur. Materials generated by using amines in the curing have poorer color stability upon aging. Blue dye, a ultraviolet absorber (7), may be added to the formulation to mask color shift. Production of high dimensional accuracy is one of the main advantages of RT-cured resins, resulting from lower curing temperature leading to reduction of stresses in the matrix. Differences between thermal expansion of the denture resin and the plaster mold may result in undesired dimensional changes when the mold is subjected to a wide temperature range during processing. Dentures cured at RT have better dimensional accuracy (8,9) than heat-cured dentures. However, both are clinically acceptable.

Low Viscosity, Chemically Cured Resins. The pour and cure acrylic resins are blends of high molecular weight polymer powder mixed with monomer and other additives to achieve a pourable viscosity. The mixture is usually poured through sprues into a hydrocolloid-based mold, with polymerization conducted under pressure for about 30 min at RT (10). This procedure for preparing dentures is inferior to heat- and cold-cured acrylics. However, it is an excellent technique for denture duplication. Polymerization shrinkage is a problem for this type of system, possibly causing posterior teeth to be displaced in the resilient mold and out of the desired occlusal pattern (11). Methods have been developed to improve the latter, by increasing the bond of acrylics to denture teeth (12). This technique requires great attention to detail in order to produce clinically acceptable prostheses.

Visible Light-cured Resins. Employing high intensity visible (blue) light to bring about free-radical polymerization (curing) of the denture resins holds great promise (13). A photopolymerizable formulation in this case could consist of a urethane dimethacrylate–acrylic polymer combination, reinforced with a microfine silica filler. Thus, the materials produced have more in common with a composite restorative material than with the commonly used denture-based resins. The matrix produced is a highly cross-linked acrylic, having an interpenetrating polymer network (IPN)-type structure. MMA is not used in the urethane dimethacrylate (Fig. 8) cross-linked IPN matrix, filled with colloidal silica and acrylic polymer beads. Akin to composite restoratives, the formulation makes use of the camphorquinone–*tert*-amine initiator system. With the exception of brittleness, the cured materials have properties as good or better as the denture materials made by the methods described earlier. This technique shows good potential for expanded use.

Mixing/Working Properties. For denture resins certain aspects are important to note. First, great care needs to be taken to use the correct P/L ratios,

usually about 2.0/1.0 wt% or 1.6:1.0 vol%. Too much powder will result in underwetting of the beads, leading to production of a weak structure. Conversely, too much monomer will produce excessive shrinkage. All ingredients must be thoroughly mixed to achieve the best results. A separating medium must be used to prevent adhesion of the resin to the mold surface. Control of porosity and prevention of processing stress are also two areas of concern. Polymerization shrinkage and escape of volatiles can generate porosity.

Concerning shrinkage, volume reduction of about 20% for the monomer is minimized by using polymer (PMMA) powder, cutting shrinkage to about 5–8%. It is very important that this contraction is not translated into the high linear-type contraction, which on the basis of volumetric shrinkage should be about 1.5–2.0%, but is actually in the range of about 0.20–0.5%. The observed change is probably due to thermal contraction, caused by temperature changes, and not to actual polymerization shrinkage. The resin becomes very rigid once the temperature of the reaction descends below the T_g of the material, at which point the curing contraction will have essentially been completed. From this point onwards thermal contraction contributes to dimensional changes of the denture material. Because of the latter, cold-cured dentures should have a better fit, since the processing temperature is considerably lower, ca 60°C, compared to heat-cured dentures at ca 100°C. Thus, it is very important to pack the viscous mix in the mold in sufficient quantity to create pressure, facilitating removal of voids and helping to cut down on curing contraction. In all systems, polymerization generates an exotherm, which might elevate to the point of causing monomer vaporization and creating porosity. Thus, temperatures of cure should be controlled to avoid gaseous porosity and pressure maintained to eliminate contraction porosity. Dimensional changes also give rise to internal stress, which if allowed to relax may lead to warpage, crazing, and distortion of the denture. The use of acrylic teeth, rather than porcelain teeth, eliminates differential shrinkage, helping to reduce strain. Craze development is another problem that may develop in dentures as a result of strain relief, polishing, presence of alcohol, and differential contraction due to the type of teeth used. Cross-linking helps reduce craze formation. A brief summary of the denture materials' properties is shown in Table 1.

Biocompatability. PMMA is highly biocompatible, with very few patients showing any type of allergic reaction. Adverse reactions are usually caused by leachable monomers. Cold-cured formulations may be a problem, since they tend to have more residual, free monomer. Post-curing of the denture helps lower free monomer content, but may also cause some denture distortion.

Dimensional and Mechanical Properties. Even though the denture is placed on soft tissues, there is still great need for the denture to have dimensional stability. The denture must fit as accurately as possible to promote retention of the denture to the mucosa. As shown in Table 1, there is a considerable variation in mechanical properties, depending on composition, processing technique, and environment factors. Room-temperature cured resins have lower strength and stiffness, with about the same elastic modulus as heat-cured materials. Polymerization shrinkage of the monomer–polymer dough is about 6–7%. Linear shrinkage is about 0.5% across the posterior aspect, under normal denture processing. Water sorption, about 1–2 wt%, partially compensates for the shrinkage. Linear shrinkage of 0.3–0.4% is clinically insignificant, since the tissue on which the

Table 1. Physical Properties of Denture-Based Materials[a]

Property	Poly(methyl methacrylate)	Vinyl acrylics
Compressive strength MPa[b]	76	70–76
Tensile strength, MPa[b]	48–62	51–60
Flexural strength, MPa[b]	83–117	69–110
Elastic modulus, MPa[b]	3.8×10^3	2.3×10^3
Elongation, %	1–2	7–10
Impact strength, N·m[c]	1050	3150
Transverse strength, MPa[b]	41–55	41–55
Knoop hardness (KHN)	15–23	14–20
Coefficient of linear thermal expansion per °C	81×10^{-6}	71×10^{-6}
Heat-distortion temp., °C	160–195	130–170
Polymerization shrinkage[d], %	6–7	6–7
Water sorption, 24 h, %	0.3–0.4	0.07–0.4

[a]Partially taken from Ref. 14.
[b]To convert MPa to psi, multiply by 145.
[c]To convert N·m to ft·lbf, multiply by 0.74.
[d]Linear shrinkage of commercial dentures is ca. 0. 12–0.97%.

denture rests adjusts to such changes (14,15). Some cross-linked resins contain 2-hydroxyethyl methacrylate (HEMA), which promotes higher water sorption, lowering dimensional stability. Fillers reduce the thermal expansion of the dentures, providing higher impact strength. However, they are difficult to polish, tend to stain, and may collect debris and imbibe bacteria at the surface.

It has been clearly shown that radiopaque materials are needed (16,17) for visualization of aspirated or swallowed denture fragments. This is accomplished with additives such as barium sulfate, barium fluoride, barium or bismuth glasses, and halogenated organic compounds. The physical properties of the materials are significantly affected by large quantities of these additives. ANSI/ADA specifications or requirements for radiopaque materials for denture-based polymers have been described (18).

While commercial denture materials are reasonably strong and show good flexibility, improved fracture resistance and fatigue strength are still sought. Seeking to improve such things as fracture toughness, impact and transverse strength, tensile strength, etc, various types of fiber (glass, carbon, Kevlar, and polyethylene) reinforcement have been found to significantly improve many of the aforementioned properties (19). Glass fiber reinforced composite resins have also been introduced as a replacement for metal framework in crown and bridges or fixed partial dentures as per recent clinical studies (20). Yet, research is still needed to develop improved materials, pointed toward reducing the need for denture repair (21). ANSI/ADA Specification No. 12 sets the requirements for denture-based Resins.

Polymeric Teeth for Dentures. Acrylic resin denture teeth were introduced in the late 1930s. About 60% of all preformed artificial teeth used in dentures, at least in the United States are produced from acrylics or vinyl acrylic resins. The chemistry used is based on the well-known MMA polymerization

technology. Poor wear, crazing, blanching, fracturing, etc, found in earlier acrylic teeth, has been overcome by better methods of fabrication, improved formulations, and use of higher cross-linking density. The molding technique for preparing the teeth must be highly controlled, with respect to particle size, molecular weight, and residual initiator. Further, the mix flow properties and curing cycle must be highly controlled. Mechanical retention serves, to some degree, to anchor the teeth in the chemically activated denture-based resins. However, a combination of mechanical and chemical bonding is used to retain the teeth (22).

Polycarbonates and polyslfones have also been explored for producing molded teeth. Compositions containing very finely dispersed spheres of pyrogenic silica as reinforcing fillers, urethane dimethacrylate (Fig. 8) resin, highly cross-linked IPNs, and the fabrication of layered teeth with an exterior made up of a 2,2-bis-*p*(2′-hydroxy-3′-methacryloxypropoxy)-phenylpropane (BisGMA)-based resin have also been explored (23). All formulations employ pigments to provide a natural appearance. Other additives/modifiers are also used to achieve a more natural appearance.

Acrylic teeth, with compressive strength of 76 MPa (11,000 psi), abrasion resistance, elastic modulus of 2700 MPa (3.9×10^5 in.$^{-2}$), elastic limit of 55 MPa (8000 psi), Knoop hardness (KHN) range of 18–20 kg/mm^2, and good abrasion resistance, have physical properties which are lower than those of metal alloys used for dentures and those of human enamel or dentin. For example, dentin and enamel have an ultimate compressive strength of 297 and 384 MPa, respectively, and ultimate tensile strength of 105.5 and 10.3 MPa, respectively. Furthermore, the low modulus of elasticity in plastic teeth reduces the clicking sound often exhibited by denture wearers. Compared to porcelain teeth, acrylic teeth have less resistance to creep, higher water sorption, greater fracture toughness, better resistance to thermal shock, and bond to the denture base. In contrast, porcelain teeth display better dimensional stability and increased wear resistance. A study of plastic teeth opposite plastic teeth or opposite smooth porcelain teeth has been published (24). Plastic teeth are covered by ANSI/ADA Specification No. 15.

Denture Repair Resins. Fractured dentures are readily repaired with materials similar to the RT- or cold-cured denture resins. Repairs are achieved with little to no dimensional change. However, the strength of the repaired denture may be substantially less than the original prosthesis (25). ANSI/ADA Specification No. 13 (1999) sets the requirements for cold-cured repair resins.

Denture Liner Materials. There are three groups of these materials: hard and soft liners and tissue conditioners. It is often necessary to refit the denture because of the changes in the denture-bearing tissue. To meet this need a hard relining material can be employed, using an RT- or cold-cured acrylic resin at the dentist's office, or by sending the denture to a laboratory to be repaired with a heat-cured acrylic resin. Soft liners weaken the strength of the heat-cured resins, since they can reduce the thickness of the denture base and allow diffusion of monomer or solvent into the base. The cold-cured formulations are basically of two types: a two part PMMA powder blended with MMA monomer, containing the plasticizer di-*n*-butyl phthalate or poly(ethyl methacrylate), PEMA powder, blended with liquid butyl methacrylate (BMA) monomer. The BPO–amine redox initiator system is used for curing. The use of PEMA and BMA works best where

the patients may be sensitive to PMMA or MMA. However, the use of PEMA and BMA creates a liner with a lower T_g, which may create dimensional problems. The liners must show good adhesion to the denture, allow recovery from deformation, provide a good cushioning effect, have good wetability, be relatively resistant to oral fluids, not support bacterial growth, not impair denture function, and be easily cleaned. At present, a material awaits discovery for fulfilling all of these requirements. Polyphosphazine fluoroelastomers have been formulated and cured with peroxides (26), showing that systems may be found to eliminate some of the deficiencies found in currently available liners.

Soft liners were developed to eliminate the use of MMA directly against soft tissue. Also, there are patients who are not able to tolerate a hard relining surface, even though the denture fits well. The soft liner is more comfortable and provides a means of absorbing masticatory forces via the highly resilient material placed between the denture and the soft oral tissue. In addition, soft liners may be used to reduce tissue inflammation caused by worn out or ill-fitting dentures. Polymers with a T_g slightly above the mouth temperature exhibit a rubbery behavior in the oral cavity. A variety of materials have a T_g low enough to be useful as soft liners, including silicones and acrylics. PMMA is also useful when plasticized to obtain the required T_g. Fortunately, acrylic monomers are available which produce polymers with a wide range of T_g, starting with PMMA at 105°C, PEMA at 65°C, and poly(*n*-butyl methacrylate) (PBMA) at 20°C. They are all useful for producing soft liners. The soft liners are generally supplied as powder-liquid kits or ready-to-use sheets. Materials currently available are usually plasticized acrylics. All formulations contain fairly high molecular weight acrylate or methacrylate polymers or copolymers, derived from ethyl, *n*-propyl, *n*-butyl, etc, monomers and a liquid or solvent, such as ethyl alcohol or ethyl acetate, a plasticizer, such as dibutyl phthalate, and a polymerizable monomer. The T_g of the material is set to $\leq$47°C. The materials adhere well to denture-based resins. But, they have poor elasticity and harden upon aging because of the loss of the plasticizer (27–30). More hydrophilic liners have been formulated by using HEMA or other copolymers (28). However, HEMA-based resins may soften and swell excessively due to water sorption, leading to undersirable functional changes.

Silicone liners are similar in composition to the previously described elastomeric impression materials, which are produced by condensation polymerization. Systems for the relining application may be either a one-component system, which cures in the presence of moisture or heat, or a two-component system, containing base and catalyst. Both types generally have poor adhesion to the denture surface, and can readily support bacterial growth.

Tissue Conditioners. These products alleviate discomfort from soft-tissue injury or inflammation. Tissue conditioners are soft materials applied temporarily to the denture fitting surface, allowing better distribution of stress. They exhibit viscous flow under pressure, forming a very soft cushion between the hard denture and the soft tissue. In terms of softness, the material must not be too soft or flow to the extent that it will be displaced from between the denture and the mucosa. These materials may consist of PEMA powder mixed with a solvent (such as ethyl alcohol) and a plazticizer (such as *n*-butyl phthalate and *n*-butyl glycolate) (31,32). The alcohol swells the PEMA beads, rapidly promoting diffusion of the plasticizer into the polymer, yielding a plasticized gel. Alcohol and plasticizer are

slowly leached out from the applied gel, which may cause the material to become too rigid. The liner must be replaced every few days to retain properties, until the patients supporting tissues return to normal state.

Crown and Bridge Temporary Resins. Materials used in this area are usually based on methyl or ethyl methacrylates and BisGMA-acrylics mixtures (20), or even an ethyleneimine-terminated monomer (33). The formulations are supplied as a two-component paste, composed of monomers and polymerization initiator. Used for interim tooth coverage, these materials are not as strong as other acrylics. However, they exhibit good flow, low exotherm, and low curing shrinkage. They maintain the correct biting relationship, stop teeth drifting, and protect the prepared tooth against fracture, while waiting for the permanent prosthesis to be delivered.

Polymeric materials are also used for fixing veneers on crown and bridges. Polymers used for this application include acrylics, vinyl acrylics, and dimethacrylates, as well as silica- or quartz-microfilled composites. After placing on the metallic substrates of the prostheses, the materials are heat or light cured. These materials are easy to fabricate, and can be readily matched to the color of the tooth structure. The acrylic facings have poor adhesion to the metals, being retained only by curing the monomers into mechanical undercuts designed into the metal substrate. They have less mechanical strength, less color stability, poorer abrasion, etc, than normal dental composites, along with deforming more under bruxism. With the advent of porcelain fused to metal crowns and bridges, restoratives with polymeric veneers are less frequently used.

Mouth Protectors. The widespread growth of contact sports has accelerated the use of mouth guards (34,35). Guards may be produced from natural rubber, poly(vinyl chloride), poly(vinyl acetate-*co*-ethylene), or polyurethane materials. Customized guards are often fabricated from poly(vinyl acetate-*co*-ethylene) blanks, soft acrylic dough, liquid rubber latex, polyurethane, and laminated thermoplastic (36,37). Over the counter protectors usually fit poorly, in contrast to dimensionally stable and comfortable, customized mouth protectors.

Maxillofacial Prosthetic Materials

A large number of polymers, including latexes, vinyl plastisols, silicone elastomers (heat or RT vulcanized), and polyurethanes, may be formulated into materials for facial prostheses (38–41). The materials should be biocompatible, easy to fabricate, easy to clean, feel like real skin, translucent, stable to heat, light, and cleaning solutions, and sufficiently resilient to prevent tearing. It should be possible to modify the formulation to match skin color. No material meets all these requirements.

Latexes. These materials do not have the strength and color stability to be very useful for this application. In addition, they may cause an allergic reaction. However, a recent terpolymer derived from *n*-butyl acrylate, MMA, and methyl methacrylamide, can be formulated with colorants to provide a superior latex, compared to earlier materials.

Vinyl Plastisols. These materials have some utility in maxillofacial prostheses. The formulations are viscous liquids, made up of small vinyl particles dispersed in a plasticizer, along with colorants. They are heated to generate the

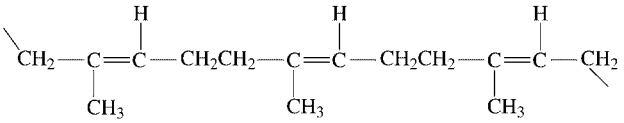

Fig. 6. Gutta-percha structure.

desired materials. The loss of plasticizer and lack of stability decreases the use of these materials.

Silicones. These materials have some only recently been used to produce maxillofacial prostheses. Both the RT- and heat-vulcanized materials may be used. Heat-vulcanized formulations are supplied as a semisolid or putty-like material, which requires the addition of colorants. The molded material is cured under pressure at 180°C/30 min. The heat-cured materials exhibit better strength and color stability than the RT-cured materials.

Polyurethanes. This is the most recent material used in maxillofacial applications. Fabrication requires accurate proportioning of the components. The isocyanate and polyol are blended, placed in a suitable mold, and allowed to cure at room temperature. Colorants and other additives are also used in the formulations. Even though the fabricated prosthesis has a natural feel and appearance, the final product is still relatively unstable.

Root-Canal Sealants

A variety of materials have been used to hermetically seal the root canal, preventing ingression of oral fluids into the canal. One natural material used is gutta-percha (Fig. 6), a rubber obtained from the Taban tree. This material has been used in endodontics for over a hundred years. Rubbers are polymers of 2-methyl-1,3-butadiene (isoprene), having two possible conformations, ie, a cis and trans form, with the trans form being gutta-percha. These rubbers are hardened by vulcanization, achieved by blending and heating with a few percent of sulfur, which causes cross-linking. A typical formulation used in a root canal has about 19–22% gutta-percha, 59–75% zinc oxide filler, 1–17% heavy metal salts, and 14% wax plasticizer. The material softens at about 60–65°C and melts in the vicinity of 100°C, providing a temperature range to soften, deform, and condense the material into the prepared root-canal space. Other materials used for endodontically treated, fractured teeth are based on zinc oxide-eugenol, epoxy resin, polyvinyl resin, calcium hydroxide resin based formulations, and glass-ionomers formulations.

Other Uses

Patterns for gold-inlay castings can be prepared from acrylics. Castings made this way are not superior to castings produced from a wax pattern, accounting for the lack of interest in this technique. Some dental laboratories use epoxy die

materials for fabrication of casts. Autopolymerizing resin formulations are used to make custom impression trays, with such resins containing substantial quantities of fillers to increase the rigidity of the materials. PMMA or other thermoplastics are used to prepare occlusal night guards. Other areas of dentistry make extensive use of polymers in retainers, splints, temporary space maintainers, and bite plates.

Restorative Materials

Filling Materials. Resins used to formulate dental composites/restoratives were initially derived from the free-radical polymerization of doughs made from PMMA beads blended with MMA monomer (42–46). Many studies have focused on improving these materials, by addition of cross-linking monomers and reinforcing fillers (45), with much of the early work done at the National Bureau of Standards. Earlier, the polymer industry had previously shown that epoxy resins, based on bisphenol A, were excellent matrix resins for a variety of composites. However, epoxies exhibited poor ambient polymerization characteristics under conditions useful in the oral cavity. Knowing the latter, as well as the need to have a new monomer which would be both free-radical polymerizable with less shrinkage in composites, Bowen (47,48) made the discovery that the diepoxide derived from bisphenol A and epichlorohydrin could be treated with methacrylic acid to form a unique hybrid monomer, well known today as BisGMA (45,47,48). Alternatively, the BisGMA monomer may also be produced by reaction of bisphenol A with 2 mol of glycidyl methacrylate. The synthetic path to the bulky, thermosetting dimethacrylate, BisGMA, launched a new era for development of composites used in dentistry. BisGMA (Fig. 7) has two chiral carbon atoms (denoted by an asterisk) with the dimethacrylate diastereomers helping to make the BisGMA mixture a viscous syrup. Compared with the PMMA–MMA doughs, the BisGMA-based formulations, combined with inorganic reinforcing fillers and suitable polymerization initiators, made available composite fillings with lower polymerization shrinkage, improved mechanical properties, reduced water sorption, a more attractive coefficient of thermal expansion, better esthetics, and more acceptable biocompatibility (44,45). A good review of dental composite resins has been published (49).

Dental Composite Restoratives. Polymeric restoratives have three major components: an organic resin matrix, an inorganic filler modified with a coupling agent, and a suitable polymerization initiator system. The formulation used to produce the organic matrix, or continuous phase, is made up of free-radical polymerizable monomers. The monomer mostly used in the formulations for both anterior and posterior resins is BisGMA (Fig. 7), or alternatively formulated with

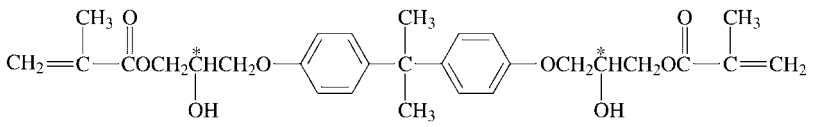

Fig. 7. BisGMA structure(s).

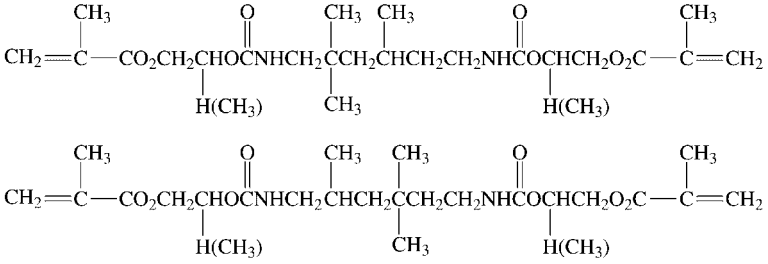

Fig. 8. Monomers structures in urethane dimethacrylate mixture.

a urethane dimethacrylate monomer (Fig. 8). A variety of fillers may be used to make up the reinforcing phase. Fillers may consist of silanized quartz, glass or various ceramics, with silanization affording the coupling mechanism. A prepolymerized resin containing pyrogenic silica may also be used to reduce polymerization shrinkage. Various polymerization initiators or activator–initiator combinations are known to be useful to achieve curing. Inhibitors are required to prevent polymerization during storage. Sealants used in dentistry have similar compositions, but are more lightly filled or possibly unfilled. Composites used in dentistry can come in various forms, ie, a one- or two-part formulation, a uniform paste, a powder–liquid, a paste–liquid, or a paste–paste formulation.

Polymerization. Methacrylate-based restoratives are free radical not radicals polymerized by redox systems or photochemically by visible light, using photoinitiators or photoinitiator–photosensitizer combinations with only the visible light range (400–500 nm) allowed for curing. Redox initiation systems may consist of such things as BPO/*tert*-amines, hydroperoxides-thioureas, peroxides with ascorbic acid or derivatives, and BPO/*tert*-amine with synergistic promoters, eg, polythiols (4,50–52). A commonly used combination for redox use is the BPO/*N*,*N*-dihydroxyethoxy-*p*-toluidine system. The combination of α-diketones, such as camphorquinone (CQ), with a tertiary amine, such as *N*,*N*-dimethylaminoethyl methacrylate (DMAEMA) (52), are particularly useful for visible light-curing (VLC) (53,54). With light activation, CQ and DMAEMA form an "exciplex" with the "exciplex" subsequently producing a DMAEMA-based radical, which initiates the polymerization. VLC resins provide the dentist a significant control over the restorative hardening process. Further, the porosity and surface tackiness, owing to air inhibition, are lower in the VLC-cured materials compared with that of the redox formulations. But, properly mixed redox formulations polymerize much more uniformly, especially in areas of great bulk, compared to the VLC formulations. When using VLC systems to fill deep cavities, a layering technique must be used to ensure adequate polymerization.

Monomers or Matrix Phase. Although BisGMA is widely used in commercial dental composites, other types of dimethacrylates have also been studied or developed for use as alternatives to BisGMA (55–76). Because of the high viscosity of BisGMA, a variety of dimethacrylates have been found to be useful as reactive diluents or polymerizable modifiers to provide suitable viscosities for high filler loading, with diethylene glycol and triethylene glycol dimethacrylates (Fig. 5) being good examples. Studies on the kinetics and the nature of the network

formation in the dimethacrylate polymerizations have been given significant attention (77–83), with the types of monomers used and the degree of carbon–carbon double bond conversion achieved determining the T_g obtained (49). There is growing interest in varying the polymerization stages, ie, using a "soft start" stage, as a way to improve the resin properties.

Resins have also been designed to utilize multifunctional methacrylate prepolymers, derived from the chain-extending reaction of BisGMA with a diisocyanate, such as 1,6-hexamethylene diisocyanate, combined with a diluent monomer (64,65). Incorporating urethane residues in the matrix, which enhances toughness, gained great acceptance in Europe, with an example being the monomer derived from the reaction of HEMA with a branched aliphatic diisocyanate (Fig. 8).

Many experimental dimethacrylates have been explored for reduction of shrinkage and water sorption in composites, seeking to improve such things as dimensional stability, creep resistance, fracture toughness, wear resistance (66,84–95). The goal is to formulate a better alternative to the commonly used amalgam. Some of these have been prepared from nonhydroxylated homologues of BisGMA, having lower viscosity (66). In one case, a multimethacrylate prepared from esterification of a low molecular weight styrene–allyl alcohol copolymer was shown useful in reducing shrinkage or polymerization contraction stress in BisGMA/TEGDMA neat resin blends (96,97).

A variety of fluorine-containing monomers and polymers have been prepared and examined to produce hydrophobic dental composites with low water sorption, high contact angles, reduced margin leakage, and resistance to surface staining (67–73). One such formulation consisted of 75 wt% octafluoro-1,1,5-trihydropentyl methacrylate and 25 wt% of a nonhydroxylated homologue of BisGMA (66–68). But, the polymerization shrinkage and strength deficiencies were not improved. Also, the volatility of the nonbulky fluorinated-monomer component was a problem. In contrast, a stronger hydrophobic composite was prepared from a low surface-energy matrix resin consisting mainly of a highly fluorinated multifunctional methacrylate prepolymer, ie, PFMA (70–73,98). The viscosity of this formulation was comparable to that of BisGMA, along with solubility in a variety of diluent monomers. The dimethacrylate derivative of a fluorinated triethylene glycol, having low viscosity, was recently examined as a reactive diluent, showing some promise to improve the performance properties of an ethoxylated bisphenol A dimethacrylate (BisEMA)-based composite (99–101).

Elimination of polymerization shrinkage has been under study for some time (74,75). In the early work, a blend of a BisGMA-based resin and a solid spiroorthocarbonate (SOC), which also polymerizes by a free-radical, ring-opening mechanism, was cured to give thermosets with very low volume shrinkage (75). Following the latter study, a great variety of compositions have been designed for ring opening, expanding polymerizations, focused on eliminating or reducing the shrinkage as well as improving the physical and mechanical properties of composites. The focus has mainly been on SOC and SOC-type monomers with epoxy resins (102–113). This concept has not, to date, produced marketable dental restoratives.

More recently, the possible use of liquid crystalline monomers (114), hyperbranched polymers (115,116), inorganic–organic hybrid monomers (117–120), and sol–gel technology (121) has started to be examined for preparing improved

composites. The use of multimethacrylate substituted hyperbranched polymers looks to be a particular attractive path to explore for generating composites with significantly lower shrinkage, since low viscosity, high molecular weight entities can be formulated into the monomer–polymer mixture. Also, the *in situ* generation of a nanocomposite, where the inorganic component is truly distributed at the molecular level in the cured composite, may satisfy the great need for preparing restoratives with both low shrinkage and significantly improved wear resistance.

Reinforcement Phases. After introduction of quartz filler in the late 1950s, many types of reinforcing fillers have been studied or used in dental composites. In addition to quartz, fused or colloidal silica, and other inorganic fillers, finely divided, organic prepolymenized composite particles are also useful as a dispersed phase. This is especially true for microfilled and hybrid composites (122–124). Fillers serve to increase hardness and compressive strength, and significantly reduce shrinkage of the restoratives. Filler technology has brought many improvements to currently used composites. But, in order for the composites to have acceptable mechanical properties, it is critical for the resin matrix and filler to have a strong interfacial bond. A breakdown at the interface, followed by load application, will not allow the stresses developed to be effectively distributed throughout the material. Bonding is achieved by the use of coupling agents, incorporated into the formulation at the surface of the filler. Vigorous efforts have been focused on maximizing filler volume or obtaining highly loaded composites, which exhibit much better stress-bearing capability.

Physical Properties. Table 2 shows some physical properties of unfilled (neat) resins and filled composites. Microfilled composites generally have inferior properties compared to conventional or the more recent hybrid restoratives, with

Table 2. Physical Properties of Resin Restoratives

Property	Unfilled PMMA	Microfilled composite	Conventional and filled hybrid composite
Inorganic content[a], wt%		33–51	70–80
Compressive strength, MPa[b]	55–78	225–350	250–400
Knoop hardness (KHN)	15	5–30	50–60
Tensile strength, MPa[b]	14–28	30–55	50–90
Modulus of elasticity, GPa[c]	1.9–2.3	3.2–6.0	8.0–20.0
Linear coefficient of thermal expansion, 10^{-6} °C	92	50–70	20–40
Water sorption, mg/cm^2	1.70–2.03	0.94–2.20	0.50–0.70
Polymerization shrinkage, vol%	5.2–8.0	1.0–1.8	1.2–5.3
Thermal conductivity[d,e] W/(m·K)	2.4	6.3–8.4	1.5–4.0

[a]The volume (weight) of the filled systems varies from about 30 to 77% (50–85%). Traditional, small particle filled, micro-filled, and hybrid composites have fillers ranging in size, respectively, from 8–12, 1–5, 0.04–0.4, to 0.6–1.0 μm.
[b]To convert MPa to psi, multiply by 145.
[c]To convert GPa to psi, multiply by 145,000.
[d]Thermal conductivity of enamel and dentin, respectively, is 0.87 and 0.59 W/(m·K).
[e]Composite restoratives are good insulators.

the exception of polishability. By definition, hybrids (blends) have a combination of colloidal and fine particles as filler, at approximately 60–65 vol% with the fillers ranging in size from 8–12, 1–5, 0.04–0.4, to 0.6–1.0 μm. The higher volume ratio of polymer to inorganic filler, ie, low filler content, of the microfilled resins leads to lower modulus of elasticity, greater thermal dimensional changes, less resistance to indentation, and higher water sorption. Requirements for dental composites are covered by ANSI/ADA Specification No. 27.

Dental Cements. Polymeric matrices used in formulating cements are similar to those used in methacrylate-based composites and sealants. BisGMA or some other dimethacrylate is blended with monomers such as MMA, along with fillers and other additives, to make the formulated adhesive useful in the oral cavity. They may be of the VLC type and/or chemically cured type. They may also contain additives such as inorganic fluoride salts, which may result in reducing recurrent decay.

Polyelectrolyte-Based Restoratives. Alginates, previously described under Impression Materials, were the first ionic polymers to be employed in dental applications. But, polyelectrolytes derived from poly(acrylic acid), various co- and terpolymers of acrylic acid, and other alkenoic acids (ie, itaconic acid and maleic acid) are used in aqueous solutions for formulating polyelectrolyte-based cements. These materials are also known as *glass polyalkenoates* or more commonly *glass-ionomers* (GIs) (125–135). Several articles present the chemistry associated with GIs (136–139). Cements based on glass ionomers adhere well to enamel but only weakly to dentin.

Glass Polyalkenoate Cements. Polyalkenoate cements, which evolved from the zinc phosphate cements, were formulated with an organic polyacid and subsequently called zinc polyacrylate cements (127). Zinc oxide was the basic powder component, with smaller amounts of magnesium or tin oxide and, optionally, small quantities of silica, calcium hydroxide, stannous fluoride, and other salts. The acid component was an aqueous solution of poly(acrylic acid), having about 30–50% solids, with the polymer having an average molecular weight of 30,000–50,000. Copolymers of acrylic and other alkenoic acids, eg, itaconic, maleic, and aconitic acids, were subsequently used to make shelf stable aqueous solutions with lower viscosity, providing a cement with better properties. A series of acid–base reactions brings about hardening or setting of the cements, with ionic-type cross-linking achieved by the ionized carboxylate groups forming a complex (salt-bridge) with the divalent metal cations, producing a highly, ionically cross-linked, hydrophilic matrix. Free powder embedded in the stiff polymeric hydrogel or matrix acts as a normal reinforcing agent. Other types of additives are incorporated into the formulations to improve certain properties. Cements of this type, which have an opaque appearance due to the high concentration of zinc oxide, adhere well to tooth structure and base metals, enabling them to be used as bases under permanent fillings and to cement prefabricated restorations and orthodontic appliances. The properties of various cements are given in Table 2. A family of non-aqueous polycarboxylate cements may also be formulated, with such systems displaying excellent hydrophobic and energy-absorbing properties. Chain-extending, acid-base reactions of dimer and trimer acids with various basic powders may be used (140). The water-based cements are covered by ANSI/ADA Specification No. 96 (1994).

Table 3. Physical Properties of Resin Restoratives

Property	Unfilled PMMA	Microfilled composite	Conventional and filled hybrid composite
Inorganic content, wt%		33.2–50.9	70.4–80.2
Compressive strength, MPa[a]	55–76	221–330	127–350

[a]To convert MPa to psi, multiply by 145.
[b]To convert GPa to psi, multiply by 145,000.

More translucent glass polyalkenoate- or polyelectrolyte-based cements (GI) were developed by using similar aqueous solutions of polyacids, such as poly(acrylic acid), poly(acrylic acid-*co*-itaconic acid), poly(acrylic acid-*co*-maleic acid), etc, and ion-leachable calcium fluoro aluminosilicate type glass powders (126,128,135). The matrix in this conventional-type GI is formed by acid-base reactions involving the di- (Ca^{2+}) and trivalent ($A1^{3+}$) cations, binding carboxylate groups in ionic cross-links (salt-bridges), producing a stiff hydrogel into which partially reacted glass particles are embedded (136–138). Glass-ionomers, similar to the zinc polycarboxylate cements, exhibit good adhesion properties. Glass-ionomer cements may be used as a cosmetic filling materials and for the repair of cervical erosions because of good adhesion and semitranslucent nature. In the area of mechanical strength, GI-based cements are superior to zinc phosphate and zinc polycarboxylate, approaching the dental silicate cements in compressive strength and modulus of elasticity (Table 3). Other polyelectrolytes have also been explored as polymeric acids for formulating GIs, with poly(vinyl phosphonic acid) being an example (141,142). The vinyl phosphonic acid polymer formulations were too acidic to allow suitable working and setting times (142). Experimental cements have also been described for taking advantage of the reaction of an aqueous solution of phytic acid and myoinositol hexakisphosphate with zinc oxide or alumino-silicate glass powders (143). In such a formulation, a polyelectrolyte network matrix is formed by ionic chain extension and cross-linking reactions involving leachable multivalent cations and the organophosphoric acid groups.

Acrylic acid copolymers were recently modified with *N*-acryloyl- or *N*-methacryl-oylamino acids, such as *N*-methacryloyl-glutamic acid (MGA), providing a possible path to improved, conventional GIs (144–148). The copolymers studied had the carboxylic acid groups tethered at various distance off the copolymer backbone, with the acid groups having a range of pK_a or dissociation constants (149,150). The AA—IA—MGA copolymer having an 8:1:1 monomers ratio looked particularly attractive to use in formulating conventional GIs, as shown by statistically designed experiments. The study showed that an 8:1:1 (AA:IA:MGA)

copolymer gave the highest compressive strength (148). Raman spectroscopy studies showed that tethering the acid groups various distances off the copolymer backbone influences the level of salt-bridge formation (149). This type of modification was also shown to enhance the adhesion of the GI to tooth structure, improve fracture toughness, and enhance fluoride release. All the improvements were attributed to greater availability of the carboxylic acid groups to ionize and form salt-bridges. The copolymers with pendant amino acid residues have also been developed for preparing VLC formulations (146,150).

The monomer *N*-vinylpyrrolidinone (NVP), 1-vinyl-2pyrrolidinone, has been explored for modification of poly(acrylic acid-*co*-itaconic acid), providing a path to new polyelectrolytes for formulating GIs (151–155). For these copolymers, the optimum monomer ratios and molecular weights, to give good mechanical properties, were determined by statistical design of experiments. Formulations containing NVP residues were also developed for VLC applications. Clearly, new polyelectrolytes can be prepared for formulating improved GIs.

VLC Glass-Ionomers. Presently, the GI formulations used in the United States are either the free-radical, VLC, redox initiated, or a combination of VLC and redox initiation types (128,136–139). These are water-soluble polylectrolytes having both pendant carboxylic acid groups and free-radical polymerizable moieties, such as methacrylate residues. These hybrid-type formulations, which are more composite-like, are also referred to as resin modified glass-ionomers (RMGIs) (138,156–158). The two-component formulations, with one being an aqueous solution of the polyelectrolyte (acidic polymer), initiators, and reactive monomers and the second the basic glass powder consisting of calcium fluoro-aluminosilicate, are mixed, placed in the cavity, and exposed to visible light. Hardening occurs in two ways: formation of a free-radically cross-linked organic matrix and salt-bridge formation. A combined VLC, redox, and salt-bridge reaction in the same formulation appears to work best (157,158). The VLC GIs are less technique sensitive, cure in shorter time, may be finished at the time of placement, are more plastic in nature, have better adhesion to tooth structure, and reduce microleakage better than the conventional GI formulations (159). All in all, the RMGI modifications made the GI family of restoratives significantly stronger than the conventional GIs, leading to recommendations that these materials could be used in Class V and Classes I and II restorations in primary teeth.

Compomers. Glass-ionomers have evolved along with composite resin technology to produce a new family of materials for restoratives, now commonly called *compomers* (160–166). To some degree, compomers offer the advantages of both GI and composites in one material. Starting from the first resin modified cements (160,161) work, compomers were first introduced to the market in 1995. The term polyacid modified composite more readily describes the chemistry of compomers. These formulations consist of an organic and an inorganic phase, with the inorganic phase having some level of fluoride-containing, basic or reactive glass particles. The organic phase also contains carboxylic acid functionalized monomers and initiators. On exposure to light, free-radical polymerization occurs to give the cured resins. Water sorption of the cured organic matrix facilitates an acid-base reaction, bringing about further hardening due to formation of some ionic-type cross-linking. Water diffusion also facilitates the release of fluoride ions to the tooth structure. The physico-mechanical properties of GIs, compomers, and

composite restoratives have recently been compared (167), with this and other efforts showing that the mechanical properties of compomers, as well as their resistance to wear, are significantly better than both conventional- and VLC-type GIs. The compressive strength and diametral tensile strength for compomers is in the range 280–460 MPa and 52–62 MPa, respectively, with polymerization shrinkage in the range of 2.0–3.0%, and the coefficient of thermal expansion (ppm/°C) being in the range 12–41. The reported coefficient of thermal expansion for coronal tooth structure is about 11 ppm/°C. Clearly, research on compomers suggests that there are still others ways to be discovered for improving the handling characteristics and compensating for polymerization shrinkage in the design of dental restoratives.

Sealants

A variety of sealants have been explored or developed (168), with many people having one or more applications of a sealant. Sealants are vital for promotion of adhesion, which significantly reduces caries formation (169–177). Pit and fissure sealants are covered under the American Dental Association (ADA) Acceptance Program. These materials are used to seal high caries-susceptible pits and fissures of the deciduous and permanent molars, and also to seal microspaces between the tooth and restorative materials, enabling these materials to adhere firmly both to prepared cavity walls and to other restoratives. They provide dental pulp protection and protection from secondary caries formation.

Most dental sealants are resinous materials derived from free-radical polymerizable monomers, but GI dental cements (discussed earlier) also have some use as sealants. Sealing with resinous materials or GIs is part of modern preventive technology, where the sealants used for this purpose are called *preventive dental sealants* (PDS). Dental caries that occur around restorations are called secondary caries. Sealing the microspaces with adhesive resinous materials is effective in controlling secondary caries; here we call these adhesive materials the *restorative dental sealants*.

A brief history and state-of-the-art ion enamel and dentin bonding was published in 1995 (178). Recent advancements in synthetic chemistry and polymer science of dental sealants are now briefly reviewed or discussed, including those designed for various clinical uses, directed toward prolonging the lifetime service of natural teeth.

Preventive dental sealants, used to seal the susceptible areas of teeth, are classified into pit and fissure sealants and smooth surface sealants. From a material science perspective, pit and fissure sealants can be further classified into resin sealants and GI cements. Preventive dental sealants are usually placed onto molar teeth of young children who are at high risk for caries development.

Pit and Fissure Sealants. Resin sealants consist of a free-radical polymerizable monomer mixture, having a viscosity low enough to penetrate easily into narrow pits and fissures, capable of being cured to a hard and durable sealing material. BisGMA, urethane dimethacrylate, and other methacrylates are very popular as monomers for resin sealants, along with other monomers, to lower

mixture viscosity to enhance penetration ability, which is interesting to note. The highly active, anerobically cured cyanoacrylate monomers have also been evaluated for sealant applications (179). Etchants, such as phosphoric acid, citric acid, or other acidic solutions, are applied to the enamel pit or fissure area prior to application of the sealant, to provide the required tooth bonding to the nonadhesive resin (179–181). This so-called *acid etching* changes the enamel surface to a microrugged structure, which fosters better penetration of the sealant into the fissure and results in stronger adhesion between the sealant and the tooth surface (182). Acidic monomers have been developed for use in the sealant formulations to further enhance the penetration and adhesion. Polymerization of the sealants is initiated chemically with BPO/amine or sulfinate (redox combinations) or visible (blue) light irradiation, where the formulation contains CQ as the photosensitizer. These sealants may be one- or two-component formulations. One-component, photopolymerizable sealants can be cured very rapidly (<60s) by exposure to visible light, with two-component, self-curing sealants taking significantly longer time to harden or cure after mixing (183).

Glass-ionomer cements, where the chemistry was described earlier in the text, are widely used as sealants. Uses of this type of hydrogel (184) vary with the dental treatment, where low viscosity pastes, which exhibit fast setting, characterize the cements for pit and fissure sealing. In this process a glass powder and an aqueous polymer solution are mixed in given proportions and packed into pits and fissures without prior acid etching of the tooth surfaces. The cement paste cures within a short time through the salt-bridge formation between poly(acrylic acid) (185), or acrylic acid copolymers with maleic and itaconic acids (6), and Ca^{2+} and Al^{3+} cations leaching out from the glass powder. Poly(acrylic acid) undergoes ionic interaction with calcium ions on the enamel surface, producing bond strengths of 2–4 MPa. Fluoride ion released from these compositions helps prevent caries formation, improving the acid resistance of surrounding dental enamel (186).

Smooth surface sealants are used to prevent bacteria, staining, and physical damage to susceptible teeth. Cured sealants are directly exposed to the oral conditions, and therefore strong adhesion to enamel and dentin, good physical properties, good wear resistance, chemical stability, biological stability, and thin-film formation are required. Glass-ionomer cements fail to meet these requirements because of insufficient physical properties. Instead, highly cross-linked resin sealants, reinforced with ultrafine silica particles, are used.

Shear bond strengths of composite restoratives on enamel, etched with 30–40% phosphoric acid solutions are typically in the range of 18–25 MPa (182). In comparison, bonding to dentin is a much tougher challenge because of its organic constituents, fluid-filled tubules, and intrinsic compositional variation (187). However, substantial progress has been made to facilitate minimal invasive restorative therapy, by design of new bonding techniques/agents. First, it was discovered that resin penetration into the acid etched (conditioned) dentin, which is critical to achieve good bonding, is influenced by dentinal conditions (moist or dry) and by the type of solution used (188,189). There is great correlation of the bond strength received with the permeability and dentin penetration depth (189–191). The elusive goal, not yet totally reached, is to have a simplified application

method for a dentin bonding system which will produce a very durable bond with total elimination of future microleakage (192–194). Composite resin polymerization shrinkage is the main reason for marginal gaps and stress at interfaces, leading to microleakage (192,195). Thermo- and load-cycling studies are essential for determining or predicting the dentin-restoration bond longevity (196,197). Apart from using simple acid etching, the evolutionary development of surface-active comonomers with both hydrophilic and hydrophobic moieties, as part of the primer system, has made a very significant impact on improving bonding to dentin (198–201). The work on self-etching primers, to improve the understanding of what it takes to bond well to dentin, also played a very important role in the design of improved dentin bonding systems (202–206). For specific information on some of the most recent, commercial enamel and dentin bonding systems, see literature on Excite (Ivoclar AG or Vivident), Single Bond (3M Dental Products), One Step (BISCO), Prime Bond (Dentsply/DeTrey), and Optibond Solo (Kerr Sybron).

Dental Restorative Sealants. Dental amalgams are mixed and condensed into molar teeth cavities, hardened by the amalgamation process. The amalgam has no chemical interaction with the cavity wall, and irregular microspaces are produced along the interface between them. Amalgam sealant and amalgam bonding agents are used to seal the microspace and control the incidence of secondary caries around the amalgam restoration. Chemical composition of this sealant or bonding agent may be as follows: a monomer such as diethylene glycol dimethacrylate (Fig. 5) or a comonomer such as methacryloxyethyl phthalate (MEP). Other formulation additives may be *tert*-butyl hydroperoxide initiator, *o*-sulfobenzimide accelerator, and hydroquinone inhibitor.

This sealant is composed of only one liquid, which remains uncured before application, but cures quickly once applied to amalgam. Because of *tert*-butyl hydroperoxide and *o*-sulfobenzimide, polymerization occurs anaerobically when it is cut off from air and it contacts the copper in the amalgam. When placed between two glass plates at 25°C, it takes more than 10 min to cure. However curing occurs within 2 min between a glass plate and the amalgam. The MEP (207) monomer is used to enhance penetration of the sealant into micro spaces and achieve adhesion to both arnalgam and tooth surface. This sealant achieves amalgam–enamel bonding by about 1.0 MPa and bonds amalgam–dentin by about 2.6 MPa without acid etching. Examples of two amalgam bonding agents illustrate the latter, brief discussion.

Amalgam Restorative Sealants. These adhesives are of two types: adhesive resin cements and bonding agents originally developed for composite restorations. One commonly used adhesive resin cement is Amalgambond (Sun Medical Co., Japan), which consists of PMMA powder and MMA monomer, containing 4-methacryloxyethyl trimellitate anhydride (4-META) and tributylborane oxide (TBB-O) as a catalyst. TBB-O is activated by the water on the surface of adherents and promotes graft polymerization of MMA onto collagen in dentin, promoting strong adhesion (201,207,208).

Panavia 21 (Kuraray Co., Japan) is an adhesive cement, characterized by the use of 10-methacryloyloxydecyl dihydrogen phosphate (MDP). This cement consists of a primer and a composite paste. The primer is a monomer solution containing MDP, which develops strong adhesion to enamel and dentin. The

cement paste is a mixture of polymerizable monomers, including MDP, and inorganic filler, with polymerization/curing caused by the catalyst BPO/*text*-amine/sulfinate. Strong adhesion to tooth substances and amalgam is achieved. Panavia has a shearbond strength, in MPa, of 20 to dentin, 37 to enamel, 15 to amalgam, and 47 to Ni–Cr alloy.

Composite Restoration Sealants. Systems used in this case consist essentially of dimethacrylate mononers, such as BisGMA, homologues of BisGMA, urethane dimethacrylate, and silanated inorganic fillers, as discussed in the section on Composite Resins. The sealants used for restorations (called *bonding agents*) are applied onto the cavity walls prior to the placement of composites and bond the two substances tightly.

Bonding Agent Chemistry. Composite bonding agents are a mixture of polymerizable monomers or a solution of monomers in volatile solvents, which cures through free-radical polymerization on the cavity walls or between cavity walls and composite restorations. Liquid monomers, such as MMA, HEMA (207,209,210), other erythritol methacrylates, and ethylene glycol dimethacrylate, exhibit strong adhesion to dry teeth. The well-known Gluma adhesive system is made up of water, HEMA, and glutaraldehyde (211). When the teeth cavity walls are wet, application of acidic monomers is common for getting reliable adhesion, even when using a water-free adhesive primer (189). Monomer composition is selected for a balance of hydrophilicity and hydrophobicity, physical properties of the cured polymers, adhesion to composite restorations, curing time, and so on. Polymerization catalysts used are similar to those for pit and fissure sealants.

Pretreatment of cavity walls with bonding agents is a must for composite restorations. A typical procedure for restoration with composites, using a light-cured bonding agent and a light-cured composite is as follows: (*1*) cavity preparation, (*2*) washing and air drying, (*3*) acid etching of the cavity wall, (*4*) application of the bonding agent and visible light irradiation, (*5*) composite restoration filling and visible light irradiation, and (*6*) finishing and polishing. Researchers have improved this procedure by using acidic monomer in the bonding agent as the acid for etching. Combining the etching and bonding agents reduces the number of steps and gives higher bonding strength to the dentin.

Dental Adhesives (For Alloys and Ceramics)

Various materials such as polymers, alloys, ceramics, and composites are used to restore or replace tooth structure. It is vitally important for these materials to be bonded securely to the tooth surface. Lack of bonding between the materials and tooth will induce secondary dental caries or restoration detachments. Recent dental adhesive techniques are based on chemo-mechanical bonding between the adhesive and adherend.

Surface conditioning before applying adhesives effectively increases the surface bonding area and enhances the strength of the bonding agent. The enamel is commonly etched with an aqueous solution of phosphoric acid or other acids. Most current enamel bonding systems employ phosphoric acid in various concentrations and viscosities as an etchant (169,170).

Casting alloys in dentistry are categorized into base metals and noble metals. Base metals include cobalt–chromium (Co–Cr), nickel–chromium (Ni–Cr), and titanium (Ti) alloys, while noble metals include gold (Au), silver (Ag), and palladium (Pd) alloys. Mechanical methods, such as air-abrading with 50–200 μm alumina, are the most common way to prepare the alloy surface. Electrolytic etching creates micro-mechanical retention on the alloy surface. Other types of surface modification include electroplating, silica coating, and ion-coating.

Dental ceramics consist mainly of metal oxides of silicon, aluminum, potassium, and sodium. Etching with an aqueous solution of hydrofluoric acid roughens the ceramic surface.

The roughened, adherend surface is treated with a primer for chemical bonding. Because the composition of dental adhesives is based on methacrylate monomers, the primers for chemical bonding also contain functional monomers. The functional monomer usually consists of a polymerizable methacrylate or vinyl group, a hydrophobic intermediate spacer, and a functional group capable of bonding to the adherend surface. Functional groups effective for bonding base metal alloys are the acid anhydride, carboxylic acid, and phosphoric acid groups. Thiol derivatives are used to prime noble metal alloys. The dental ceramic surface is primed with silane couplers activated in acids, such as carboxylic acid monomers, ferric chloride, and/or a tri-*n*-butylborane derivative (TBB) (212,213). Silane couplers are also used for surface modification of filler particles included in dental composites (214).

After surface preparation, the restorative material is bonded to the tooth structure with auto-polymerizing adhesive resin. One prerequisite for dental adhesives is an ability to cure in the mouth; that is why methacrylate-based polymer materials are used in dentistry. Initiation systems are BPO–*t* amine or TBB (201). Monomers used are MMA or bifunctional methacrylate monomers. The needed optical opacity (215,216) is achieved by various inorganic and metal compounds incorporated into the formulations.

Acid anhydride or acidic monomers, such as 4-methacryloxyethyl trimellitate anhydride (4-META), 4-methacryloxyethyl trimellate (4-MET), 4-(3-methacryloyloxypropoxy carbonyl) phthalic anhydride (MPRPA), and 4-(4-methacryloyloxybutoxycarbonyl) phthalic anhydride (MBPA), prepared by condensing hydroxyalkyl methacrylates and trimellitic anhydride acid chloride, are very important coupling agents. The phosphoric acid derivative, MDP is synthesized from methacrylic acid, 1,10-decanediol, and phosphorus oxychloride. These very useful, functional (polymerizable) monomers are added to the primer or liquid part of the adhesive.

The MMA-based adhesive system, 4-META/MMA–TBB resin formulation, has three components: initiator, monomer liquid, and powder. The initiator is partially oxidized TBB (TBB-O). The monomer liquid contains 5% 4-META in MMA. The powder is finely pulverized PMMA, with a number-average molecular weight of about 100,000. The original MMA–TBB resin without 4-META is a transparent, unfilled resin. Bonding to enamel and base metal alloys is improved by addition of 4-META monomers to the liquid part. A primer containing 0.5% 6-(4-vinylbenzyl-*n*-propyl)amino-1,3,5-triazine-2,4-dithol (VBATDT) in acetone is used to bond noble metal alloys. Mercaptan (SH) groups on the VBATDT monomer bond to noble metals and copper on the alloy surface. The ceramic surface is treated with a

two-part liquid primer before applying 4-META resin. One liquid contains 4% γ-methacryloxypropyl trimethoxysilane (γ-MPTS), while the other liquid contains 5% 4-META (or 4-MET) in MMA or 0.5% ferric chloride in ethanol. The γ-MPTS is activated by mixing with 4-META (or 4-MET) or ferric chloride to silanate the dental ceramic surface. The use of MMA polymer (PMMA)-coated titanium oxide (217) makes 4-META/MMA–TBB-O resin optically opaque.

Shear bond or tensile tests determine the dental adhesive bond strength, with thermocycling in water effectively evaluating the bond durability. The monomer VBATDT is effective for bonding Ag–Pd alloy, while 4-META is suitable for Ni–Cr alloy and titanium. For Ni–Cr alloys, the chromium content influences bond durability. Ferric chloride combined with a silane coupler significantly improves the bond strength of 4-META/MMA–TBB-O resin joined to dental porcelain.

Ceramic restoratives are often bonded directly to the tooth surface with adhesive resins, reducing the amount of healthy tooth reduction needed in clinical treatment. Resin-bonded fixed partial denture or resin-bonded ceramic restoration methods are often employed. Adhesive resins are also used for bonding orthodontic brackets, amalgam restoratives, and many other metal and ceramic materials.

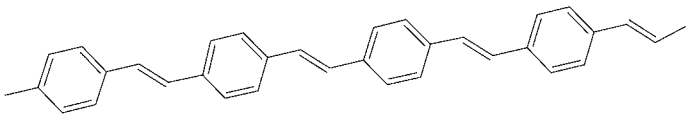
DIACETYLENE AND TRIACETYLENE POLYMERS

Introduction

Polydiacetylene (1–5) and polytriacetylene along with polyacetylene are the only known linear conjugated polymers (6). Conjugated polymers are distinguished from traditional polymers in that they contain alternating π-bonds along the polymer backbone. This structural feature imparts useful electronic and optical properties for the development of advanced materials. The linearly conjugated polymers are distinguished from the other conjugated polymers [eg, poly(phenylene vinylene) (**1**)] because the linearly conjugated polymers do not have branch points along the network of π-bonds. Polydiacetylene (**2**), polytriacetylene (**3**), and polyacetylene (**4**) are also the first three members of a series of linearly conjugated polymers with an increasing number of alkyne groups that terminates with polycarbyne.



Poly(phenylene vinylene)

Polydiacetylene

Polytriacetylene

Polyacetylene

The polydiacetylenes and polytriacetylenes differ from polyacetylene because preorganization of the diacetylene and triacetylene is required for a successful polymerization (7). This remarkable observation was first recognized (8,9) in 1969 and marks the beginning of modern polydiacetylene and polytriacetylene chemistry. In a few cases, this topochemically controlled polymerization occurs from a crystal of the monomer to a crystal of the polymer, giving rare examples of macroscopic single polymer crystals (9).

The study of polydiacetylenes has been an active area of research. From 1969 there have been 3301 publications concerned with the preparation and study of polydiacetylenes, and 2713 of these have been published since 1986.

Polydiacetylenes

Preparation of the Diacetylene Monomers. Although a few interesting methods have appeared (10), the oxidative coupling of monosubstituted acetylenes, using copper salts (11,12) (Hay or Eglinton reaction conditions), continues to be the most common route to symmetrical diacetylenes (eq. 1). For unsymmetrical and symmetrical diacetylenes the Cadiot–Chodkiewicz coupling reaction, along with its modifications, has proven useful. When the traditional copper coupling methods fail, some success has been had, mediating this reaction with transition metals such as palladium (13).

(1)

Preparation of Polydiacetylene. The preorganization for the 1,4-polymerization of diacetylenes has been discussed previously (7,14,15). Successful polymerization occurs when the diacetylenes have a translational repeat distance (d) of about 0.49 nm and an angle (π) of about 45° with respect to the translational direction and van der Waals contact (R_v) of the polydiacetylene functionalities (Fig. 1). If these structural parameters are met then the C1 and C4 carbon atoms of adjacent diacetylenes will be in a position for a topochemically controlled polymerization. Because the 0.49 nm translational repeat distance (d) of the monomer is about the same as the repeat distance in the polymer, the polymerization process can occur with little disruption of the reactant packing.

A number of diacetylenes have been reported to undergo a solid-state polymerization to give polydiacetylenes. However, one of the more exciting aspects of the diacetylene polymerization, shown in Figure 1, is the ability of some diacetylene single crystals to polymerize to give single crystals of the polymer. Although there is a difference in the quality of the x-ray data, 16 examples of polymer single crystals have been reported (16,17). Eleven of these were reported before 1986 whereas only five have been reported after this date. Given the large number (508) of diacetylenes that have been reported in the Cambridge Structural Database (CSD), only a very small percentage possess the structural parameters to undergo

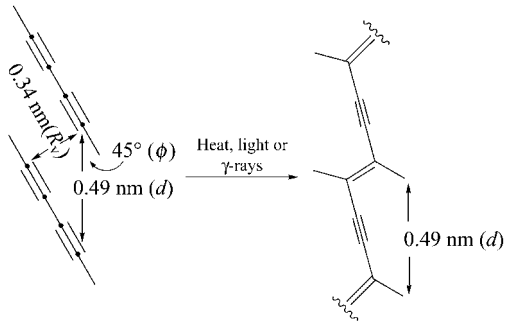

Fig. 1. Topochemical requirements for the 1,4-polymerization of diacetylenes.

a crystal-to-crystal polymerization. Clearly, diacetylenes, by themselves, show no tendency to self-assemble with the required structural parameters shown in Figure 1. The organization of diacetylenes in the solid state for a topochemically controlled polymerization would appear to be an excellent candidate for crystal engineering (18) or supramolecular synthesis. However, there has been little effort devoted to the application of crystal design methods (19) to the preparation of diacetylene crystals suitable for a topochemical polymerization.

The most critical structural parameter shown in Figure 1 is the transitional repeat distance d of the diacetylene. The ideal value for d is about 0.49 nm. This is a necessary structural parameter for a topochemically controlled polymerization. If this structural condition is achieved and the diacetylene functionalities close pack then a simple calculation demonstrates that the angle will be about 45° and the 1–4 carbons of the diyne will be in close contact.

Inspection of the known crystal-to-crystal polymerizations reveals two packing themes for establishing a d value of about 0.49 nm. The diacetylene monomers contain either an aromatic ring or amide functionality. Parallel translated aromatic rings is a common self-assembly for aromatic compounds. This assembly produces a translational repeat distance between 0.46 and 0.54 nm (20), which includes the required d of 0.49 nm. The difficulty of using the π-stacking to establish a desirable d for polymerization, in a directed supramolecular synthetic scheme, is that there are three other common assemblies of aromatic rings that are not suitable for polydiacetylene polymerizations. The π-stacking of aromatic rings is not a reliable supramolecular interaction. Nevertheless, π-stacking has been observed for the organization of diacetylenes for a topochemically controlled polymerization. One notable example that has often been studied is PTS (polyhexadiyne-1,6-diol-bis-*p*-toluene sulfonate; Fig. 2) (21).

A variation of this theme, the use of parallel translated aromatic rings as a supramolecular synthon (19), has been exploited as a possible route to the *cis*-polydiacetylene, an isomer of the *trans*-polydiacetylene shown in Figure 1. The required supramolecular structure was achieved using the benzene–hexafluorobenzene interaction (22), which stacks the aromatic rings almost on top of each other. This arrangement places the terminal carbon atoms of adjacent diynes into close contact for a polymerization to the *cis*-polydiacetylene.

Hydrogen bonded amides are commonly used by nature for supramolecular assembly. The translational repeat of amides (23) is within the range of the

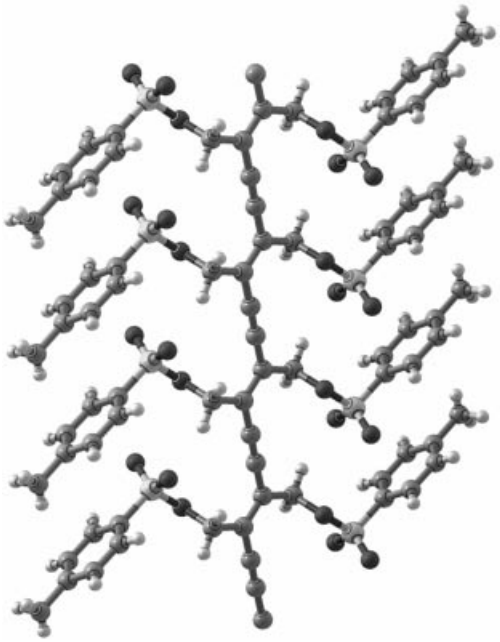

Fig. 2. Crystal structures of PTS showing the π-stacking of aromatic rings to establish the required translational distance for a topochemically controlled polymerization.

0.49 nm shown in Figure 1. This hydrogen bond motif is persistent and has often been used to organize diacetylenes for a topochemical polymerization. Because of its solubility in common organic solvents one of the better known examples of a polydiacetylene is derived from the symmetrical 4-BCMU [5,7-dodecadiyne-1,12-bis(butylcarboxymethylurethane); Fig. 3] (3). Because of the ability of the urethane functionality to self-assemble according to Figure 1 and the relative ease of synthesis (24) (Fig. 4), the poly *n*-BCMUs have been a popular class of compounds to study (25). By varying the nature of the alkyl ester, this class of potentially polymerizable diynes can be further extended (26).

It has been observed that with *N*-phenyl urethanes the conformation of the alkyl link between the diacetylene and urethanes can have an effect on the polymerization. When the alkyl group contained an even number of carbon atoms (four or six) the polymerization occurred as anticipated but failed with an odd number of carbon atoms (five). Although the association of all of these urethanes was the same, the low energy molecular conformations of this latter compound do not allow for close contact of the 1,4 atoms of adjacent diacetylenes shown in Figure 1. This observation demonstrates the importance to consider both intermolecular and intramolecular interactions in the design of a supramolecular synthetic strategy.

Polydiacetylenes with aromatic rings attached to the polymer backbone has been a challenge to synthetic chemistry. These compounds are of interest because of the known abilities of aromatic systems to interact with the delocalized π-system to produce new materials with interesting properties. For example, it has been argued that aromatic rings extend the π-system to give materials with

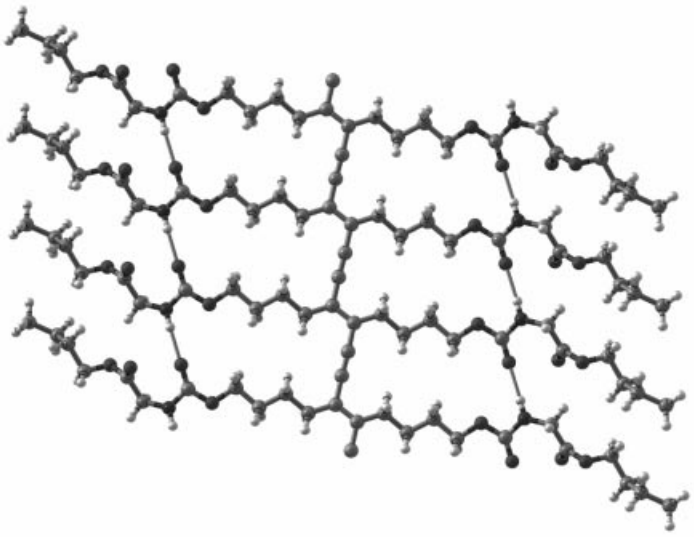

Fig. 3. Crystal structures of BCMU showing the hydrogen bonding of the carbamate functionality to establish the required translational distance for a topochemically controlled polymerization.

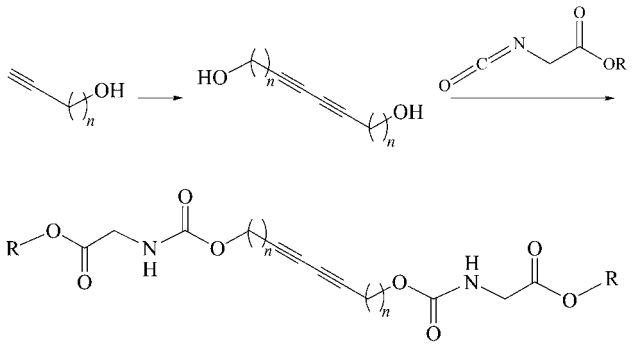

Fig. 4. Preparation of *n*-BCMUs. R = *n*-butyl.

enhanced nonlinear properties. Because of the tendency of aromatic rings to stack in parallel planes, diacetylenes with aromatic rings attached to the dialkyne functionality sometimes have favorable parameters for a topochemical polymerization (27). However, the reluctance of diaryl-substituted diacetylenes to polymerize is well known and is believed to be due to the development of unfavorable nonbonded interactions between the aromatic rings along the reaction trajectory.

In order to prepare polydiacetylenes with aromatic rings directly attached to the polymer backbone an interesting strategy has been employed. The aromatic ring is attached to one position of the diyne and a functionality for proper self-assembly (Fig. 1) is attached to the other position of the diyne. A carbamate functionality has commonly been used to provide the proper supramolecular structure (Fig. 5). Advantages of this scheme are that the reduced nonbonded interactions

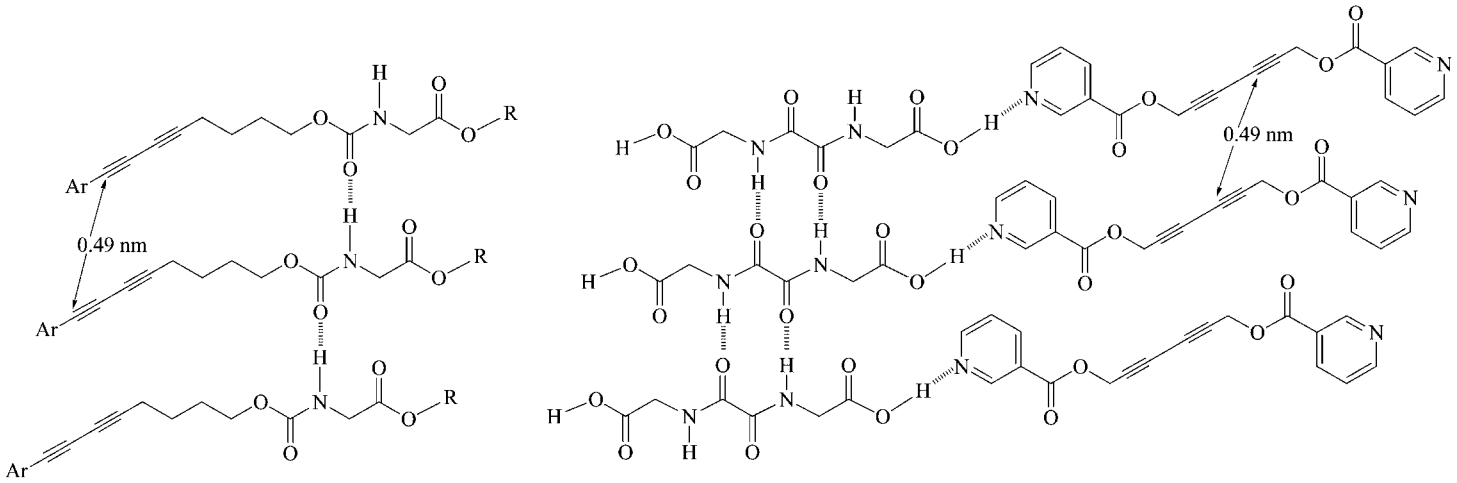

Fig. 5. The use of carbamates and host–guest chemistry to organize diacetylenes for a topochemically controlled polymerization.

between the aromatic rings will facilitate polymerization and a choice of carbamates analogous to the *n*-BCMUs may impart favorable solubility properties to the polydiacetylenes. A disadvantage of this scheme is that the molecular synthesis of the monomers becomes more tedious. This strategy has been applied to the synthesis of a number of interesting polydiacetylenes (28) and will undoubtedly continue to be important in the future.

A different but related strategy to the polymerization of diacetylenes has been to use host–guest chemistry. One molecule, the host, provides the required molecular scaffold and the other, the guest, contains the diacetylene functionality. Reliable functionalities for producing the molecular repeat distance *d* (Fig. 1) are ureas or, better, oxalamides (29). The carboxylic acid–pyridine interaction has been used to assemble the host and the guest.

The practical goal of the above studies is to prepare different polydiacetylenes with different properties. This is done by using synthetic chemistry to alter the nature of the substituents on the diacetylene monomer that can produce a polydiacetylene with different properties. A major problem with this approach is that a change in the substituent can change the solid-state packing and can produce a diacetylene without the proper structural parameters for a topochemically controlled polymerization. Rather than modifying the monomer an alternate strategy is to modify the polymer. This elegant approach has led to some new azo and tricyanovinylated polydiacetylenes with interesting properties. Postmodification of polydiacetylene polymers will undoubtedly prove to be an effective method for the production of advanced polymers.

The structural parameters required for a topochemically controlled diacetylene polymerization can be achieved by organizing the diacetylenes into layers. Advantages of layered materials are that they are anisotropic and can more readily be adapted to traditional fabrication methods than single crystals. Layered diacetylene structures can be constructed using a number of methods such as Langmuir–Blodgett films (30), membranes (31), liquid crystals (32), and SAMs (33). Layers meet the translational spacing requirement shown in Figure 1. If the head groups are spaced at about 0.49 nm and the chains containing the diacetylene functionality associate within the van der Waals radii, then the diacetylenes will be properly oriented for polymerization. Topochemically controlled diacetylene polymerization has been observed in a number of layered structures. Amphiphilic molecules frequently contain a polar, hydrogen bonding head group, such as a carboxylic acid or amide, to establish the required 0.49 nm translational spacing. If the hydrocarbon chains close pack then carbon atoms 1 and 4 of the diacetylene functionality will be in close contact for a 1,4-diacetylene polymerization.

Related to the above approach for the preparation of polydiacetylenes is the recent report of forming single polydiacetylene nanowires of 10,12-nonacosadiynoic acid on a graphite surface. The polymerization of single arrays of this diacetylene were initiated and terminated using the probe of a scanning tunneling microscope (STM). This technique has the interesting possibility of interconnecting nanostructures by using polydiacetylene nanowires (34).

The use of monolayers to achieve the supramolecular structural parameters for a topochemical polymerization is a powerful strategy that will undoubtedly prove to be useful for the preparation of sensors (35) and devices (36) that exploit the diacetylene-conjugated polymeric backbone (Fig. 6).

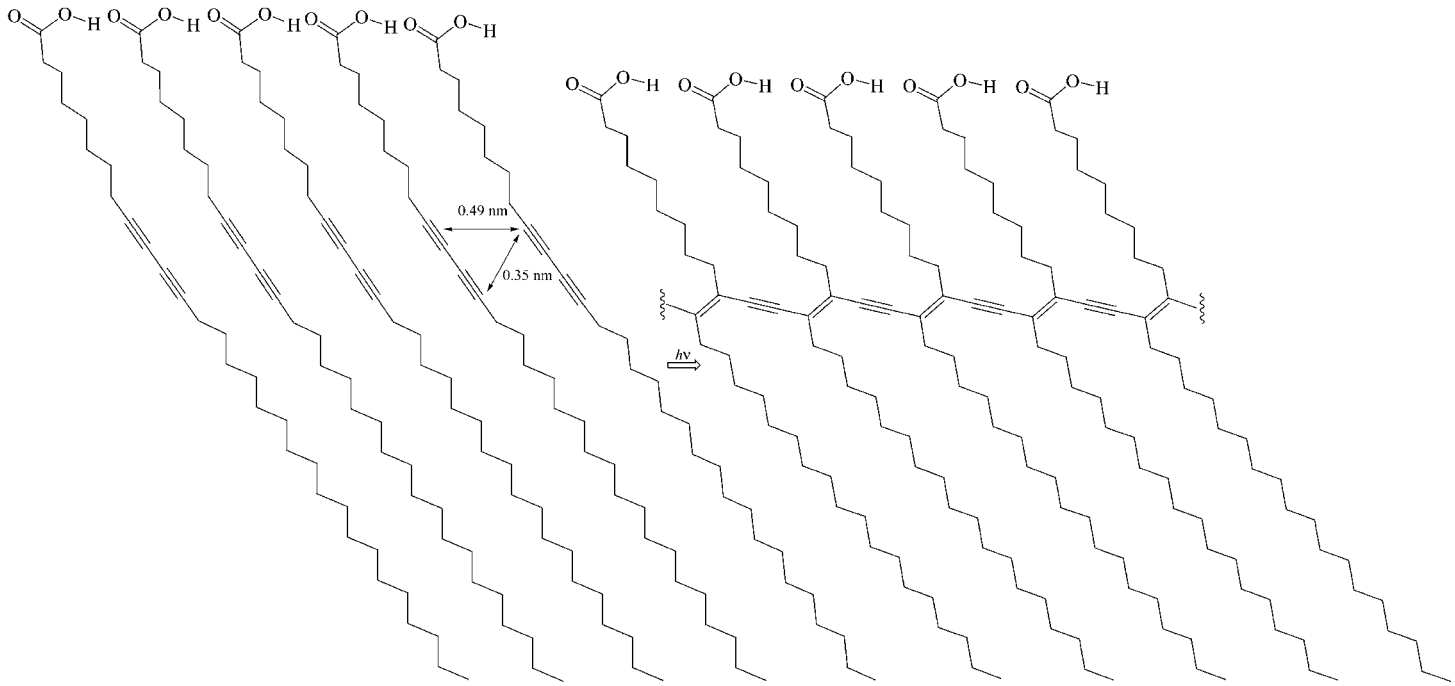

Fig. 6. A lipid monolayer with the diacetylene functionalities properly oriented for a topochemically controlled polymerization.

Properties of Polydiacetylenes. Among the interesting properties displayed by conjugated polymers such as polydiacetylenes, nonlinear optical response and electrical conductivity have attracted the most attention (37). In addition, polydiacetylenes display chromism that is induced by environmental conditions. Interestingly, the chromism (blue to red to yellow) of polydiacetylenes has been known for a long time but its orgins are still controversial (25). The color changes have generally been attributed to a decrease of the effective conjugation length of the polymer backbone. The changes in the effective conjugation length can be affected by changes in the conformation of the polymer backbone. Polymer conformational changes can be the result of a number of different actions involving polymer associations or the interactions of the substituents on the polymer backbone.

Whatever its origin, the chromism of polydiacetylenes has been the basis of interesting sensor development. Amphiphilic diacetylenes are known to form vesicles that can be polymerized to colored polydiacetylenes. If a specific ligand is attached to the vesicle then binding to receptor can induce a color change due to a conformational change of the polymer backbone (38). For example, sialic acid binds to the influenza virus lectin, hemagglutinin. A polydiacetylene liposome with sialic acid attached undergoes a color change from blue to red when exposed to the influenza virus. These impressive sensors are acting in an analogous, although primitive, manner to a biological membrane.

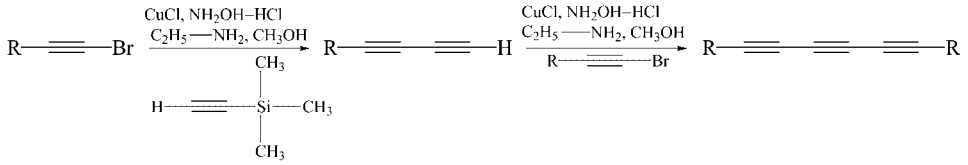
A robust polydiacetylene/silica composite has recently been prepared that undergoes a color change in response to thermal, chemical, and mechanical stimuli (39). This new hybrid material holds considerable promise for the fabrication of new devices.

Probably the most studied and exciting property of polydiacetylenes is their nonlinear optical properties (40). Polydiacetylenes are one-dimensional molecular quantum wires. Along the polymer backbone of the polymer the polydiacetylenes are effectively centrosymmetric and have only odd order nonlinearities such as 3. PTS has the largest known off-resonant nonlinear refractive index (41,42). This property makes the polydiacetylenes exciting candidates for the preparation of optical devices such as waveguides (43). The development of polydiacetylenes that can be deposited as oriented noncrystalline thin films would be desirable. However, an advantage of organic materials is that their properties can be fine-tuned using organic synthesis.

One of the interesting aspect of conjugated polymers is their ability to behave as electrical conductors (44) (see ELECTRICALLY-CONDUCTING POLYMERS). The metallic appearance of many polydiacetylene crystals suggests they would be good candidates as electrical conductors. However, these organic materials are insulators with conductivities less than 10^{-10}. Polyacetylene also shows low conductivity in the solid state but it is dramatically altered by doping. Because of the similarity of polydiacetylene to polyacetylene it was anticipated that doping would enhance the conductivity of polydiacetylene. Although increases in conductivity have been observed, it is not as large as has been observed for polyacetylene (4). One of the problems that appears is the inability of the dopant to penetrate the polydiacetylene materials because of their high crystallinity.

Polytriacetylenes

Preparation of the Triacetylene Monomers. Triacetylenes are most commonly prepared using the Cadiot–Chodkiewicz coupling reaction (11,12). Using this method each triple bond is added in a separate step.



Preparation of Polytriacetylene. Soon after the early understanding of the diacetylene polymerization was reported (8,9), attempts were made to polymerize a triacetylene to produce a polytriacetylene (45). However, these early attempts as well as more recent efforts (7) were not successful. The difficulty of the topochemically controlled polymerization is the organization of the triacetylene monomer with a translational repeat distance of about 0.74 nm.

The first oligomers with the backbone structure of polytriacetylene were actually prepared by the oxidative coupling of ene diynes (Fig. 7) (46). An advantage of oligomers is that they can usually be prepared with a defined length, making them excellent models for conjugated polymers. The triacetylene oligomers prepared by oxidative coupling have been proven to be remarkably stable and are promising candidates for second hyperpolarizabilities (47).

Polytriacetylenes have recently been prepared by a topochemically controlled polymerization of a triacetylene. This was accomplished using the host–guest strategy (Fig. 8). A vinylogous amide was used to establish the required translational repeat distance and γ-rays were necessary to induce the polymerization (48).

The pyridine host can be removed from the polytriacetylene by washing with acid and the polytriacetylene can be dissolved in base. The optical and Raman spectra are in accord with those that have been observed for the oligomers.

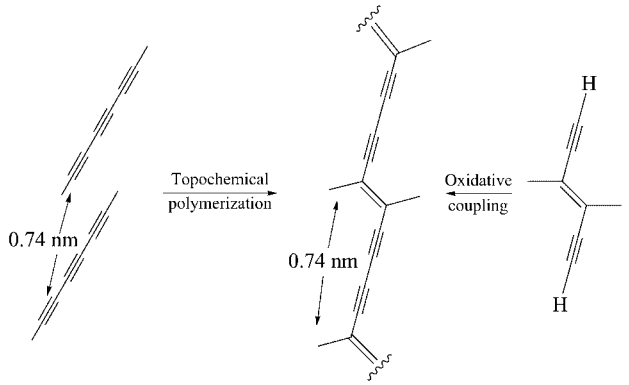


Fig. 7. Two strategies for the preparation of polytriacetylene.

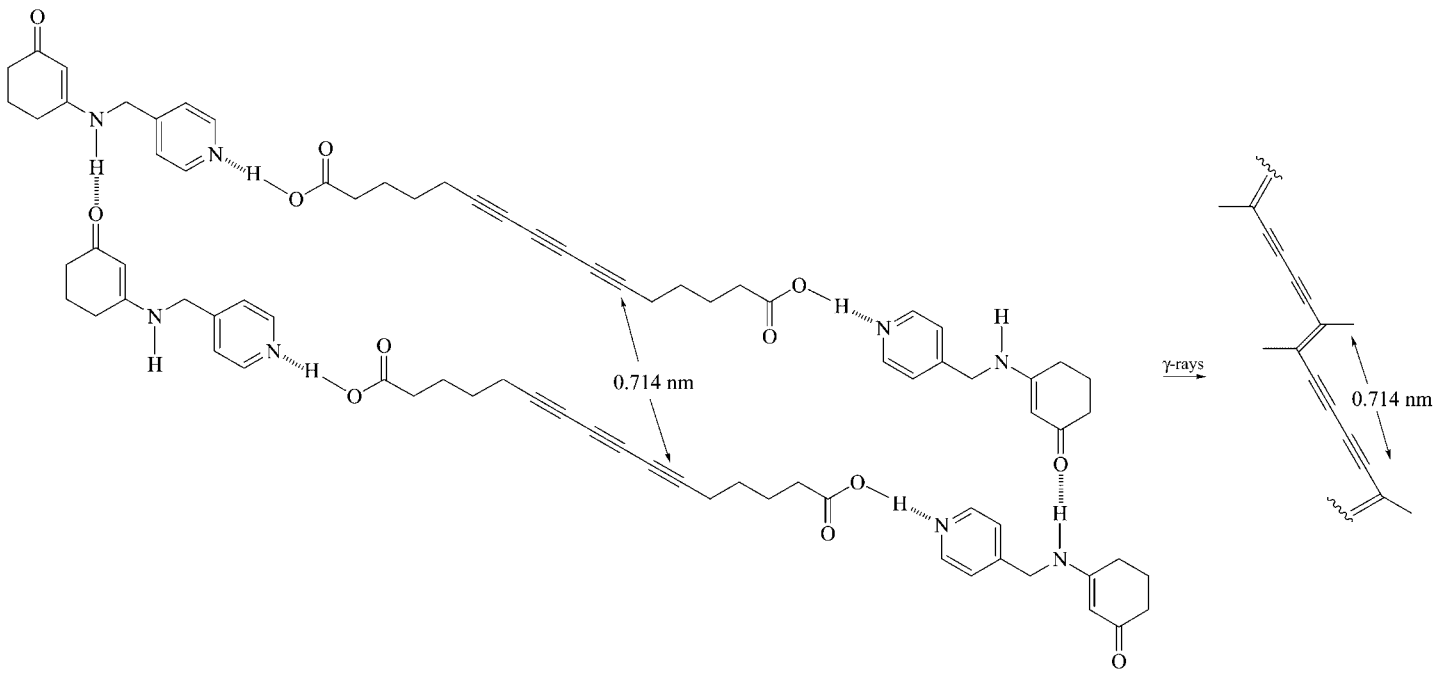

Fig. 8. The host–guest strategy for the preparation of polytriacetylenes.

Properties of Polytriacetylenes. Most of what is known about the properties of polytriacetylene has been determined from studies on the oligomers prepared by oxidative coupling of ene diynes (46). It has been determined that the effective conjugation length of the polymer is about 10 monomer units; that is, most properties of polytriacetylenes will be expressed in oligomers containing 10 monomer units. These oligomers display high environmental stability and excellent solubilities in common solvents. These properties facilitate their study and possible development into devices.

The solution optical gap for polytriacetylenes has been estimated to be $E_g =$ 2.3 eV. This is comparable to $E_g = 2.3$ eV for polydiacetylenes (49).

Their second hyperpolarizabilities (47) have been studied using third-harmonic generation and degenerate four-wave mixing. These studies suggest interesting macroscopic hyperploarizability (7) for properly prepared bulk materials.

The polydiacetylenes and the newer polytriacetylenes are clearly exciting families of conjugated polymers. Because these polymers are highly organized and their properties can be controlled by organic synthesis they offer considerable potential for the development of advanced materials. Their major disadvantage is their preparation. The preparation of a given polymer requires two major steps. Preparation of the monomers, followed by their organization in the solid state for a topochemically controlled polymerization. This latter step, the control of supramolecular structure, is particularly challenging. If the preparation of advanced materials is to ever be a rational process, it is important that the scientific community meet this challenge.

ELASTICITY, RUBBER-LIKE

Introduction

Elasticity is the reversible stress–strain behavior by which a body resists and recovers from deformation produced by a force (1). This behavior is exhibited by rubber-like materials in a unique and extremely important manner. Unlike metals or glasses, they can undergo very large deformations without rupture (and are thus similar to liquids) and then can come back to their original shape (as do solids). This exceptional ability was investigated in 1805 (2,3), well before the concept of polymers as long-chain molecules was established in the 1920s. It was observed that a rubber gave off heat upon stretching and, when submitted to a constant load, became shorter as temperature was increased. Later, Kelvin (4) derived the thermodynamic laws of elasticity, and more careful experiments were performed by Joule (5). Many books and review papers have been published on the subject (6–36).

Deformation and Mechanical Testing

When a body is submitted to external stress or pressure, it undergoes a change in shape or volume. Mechanical testing of rubber involves application of a force to a specimen and measurement of the resultant deformation or application of a deformation and measurement of the required force. The results are expressed in terms of stress and strain and thus are independent of specimen geometry. Stress is the force f per unit original cross-sectional area A, and strain the deformation per unit original dimension. The units of stress are Newtons per square meter (N/m^2 or Pa); strain is dimensionless. The ratio of stress to strain is called the

Encyclopedia of Polymer Science and Technology. Copyright John Wiley & Sons, Inc. All rights reserved.

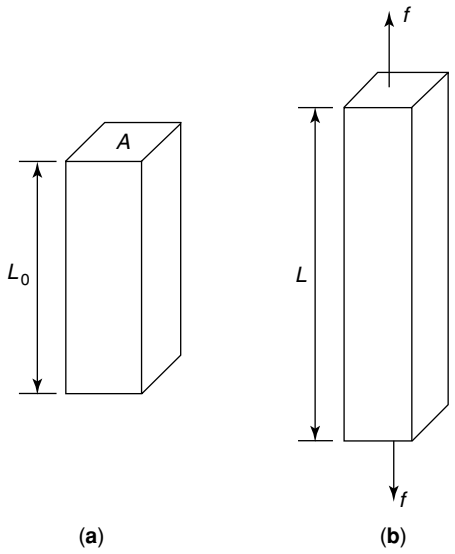

Fig. 1. Uniaxial extension of a bar-shaped sample. (a) No load; (b) tensile load. A = area; f = force; L_0 = original length; L = length.

modulus. A material is Hookean when its modulus is independent of strain (typical of a metal spring or wire); elastomers are Hookean only in the range of very small deformations.

The simplest deformations are isotropic compression under hydrostatic pressure, uniaxial extension (or compression), and simple shear. They are used to determine the bulk modulus K, Young's modulus E, and shear modulus G, respectively (37–44). Elastomer testing for commercial applications is highly dependent on the method, the conditions (eg, strain rate, temperature), and the shape of the samples. Therefore, mechanical tests have been standardized for uniformity and simplicity by the American Society for Testing and Materials (ASTM) (45).

Isotropic Compression. The volume of a sample decreases from V_0 to V when submitted to a hydrostatic pressure p. The bulk modulus is the ratio of this pressure to the volume change per unit volume $\Delta V/V_0$:

$$K = p/(\Delta V/V_0) \tag{1}$$

where $\Delta V = V_0 - V$; K is the reciprocal of the compressibility and can be determined by direct measurement of compressibility (46) or velocity of longitudinal elastic waves (sound) or by theoretical calculations (39).

Uniaxial Extension. A rubber strip of original length L_0 is stretched uniaxially to a length L, as illustrated in Figure 1. The stretch and elongation are $\Delta L = L - L_0$ and $\lambda = L/L_0$, respectively. The strain ϵ (also known as the relative deformation, linear dilation, or extension) and the elongation or extension ratio λ are related by

$$\epsilon = \Delta L/L_0 = \lambda - 1 \tag{2}$$

The lengthwise extension is in general accompanied by a transverse contraction. The ratio of the change Δw in width per unit width w_0 to the change in length per unit length is called *Poisson's ratio* (47):

$$\nu_p = (\Delta w/w_0)/(\Delta L/L_0) \tag{3}$$

Ideal rubbers and liquids deform at constant volume, for which ν_p is equal to 0.5. Poisson's ratio for real elastomers may be experimentally determined by applying extensometers in the transverse and axial directions of a sample. Approximate values of ν_p thus determined are 0.33 for glassy polymers, 0.4 for semicrystalline polymers, and 0.49 for elastomers. *Young's modulus E* is the ratio of normal stress f/A to corresponding strain ϵ:

$$E = (f/A)/\epsilon \tag{4}$$

Generally, stress–strain curves deviate markedly from a straight line, as illustrated in Figure 2. The Young's modulus at small deformation is the slope tan θ of the stress–strain curve at the origin (initial tangent modulus). It can be measured in flexure or by tensile experiments (48).

Tension testing of a vulcanized elastomer also permits the determination of the tensile strength, which is the maximum stress applied during stretching a specimen to rupture; the corresponding rupture strain is called the maximum extensibility (49–52). Typical values are given in Table 1 (14). Dumbbell and ring specimens can be used.

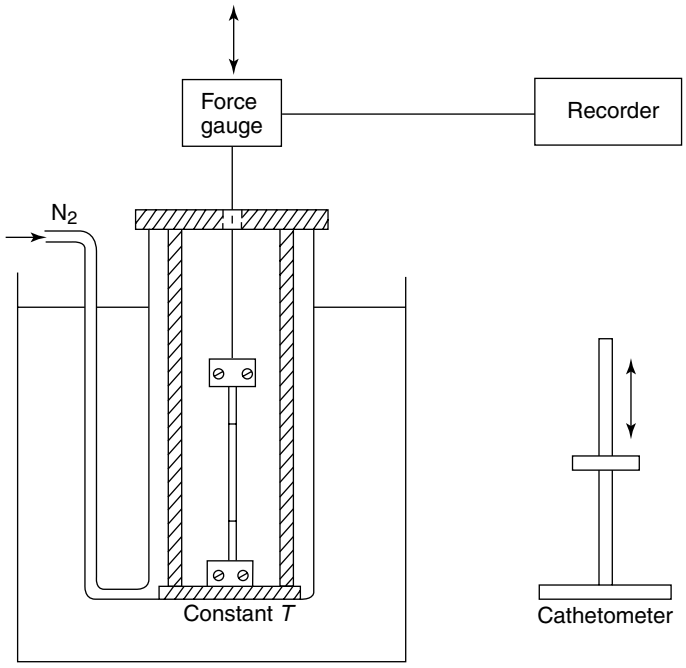

Fig. 3. Schematic diagram of a typical apparatus used to measure elastomer stress as a function of strain (21). T = Temperature.

A typical apparatus used to measure the equilibrium stress of an elongated network as a function of strain and temperature is shown in Figure 3 (21). The rubber strip is held between two clamps and maintained under a protective atmosphere of nitrogen. The sample length, required to characterize its deformation, is obtained by means of a cathetometer or traveling microscope (the central test section of the sample is delineated by ink marks applied before loading). Values of the force are obtained from a calibrated stress gauge, the output of which is displayed as a function of time on a standard recorder. Measurements are made at elastic equilibrium; the influence of temperature can also be studied. Another example of a stretching device is an automatic stress relaxometer (53).

Simple Shear. Simple shear, illustrated in Figure 4, is a deformation in which the height H and surface A of the sample are held constant. The shear

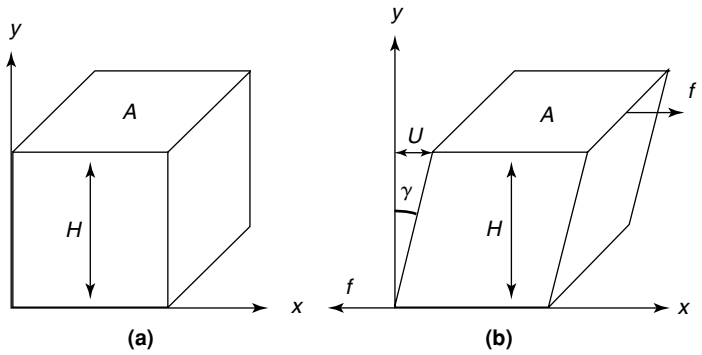

Fig. 4. Simple shear of a rectangular sample. (a) No deformation; (b) simple shear. A = area; H = height; f = force; U = linear displacement.

modulus or rigidity G is expressed by the relations

$$G = (f/A)/(U/H) = (f/A)\tan\gamma \simeq f/\gamma A \tag{5}$$

where γ is the shear strain and f/A the shear stress. As in the case of Young's modulus, the shear modulus (41,42) is a material constant if stress and strain are directly proportional. If they are not, the *shear modulus* at small deformation is employed; it is defined as the slope at the origin of the stress–strain curve. The shear modulus is generally measured on a cylindrical specimen and a tension-testing machine.

Typical values of moduli and Poisson's ratios for metals, ceramics, and polymers are given in Table 2 (39). Moduli of rubbers are strikingly low, and even those of other types of polymers are of the order of one tenth of those of metals. However, compared at equal weights, ie, ratio of modulus to density ρ, polymers (except rubbers) compare favorably.

Relationships between Moduli and Poisson's Ratio. On the basis of the theory of elasticity of isotropic solids, the moduli and Poisson's ratio are interrelated (54) as follows:

$$E = 2G(1+\nu_p) = 3K(1-2\nu_p) \tag{6}$$

For elastomers, the Poisson's ratio is nearly 0.5, and thus $E \simeq 3G$.

Conditions for Rubber-like Elasticity

Long, Highly Flexible Chains. Elastomers consist of polymeric chains which are able to alter their arrangements and extensions in space in response to an imposed stress. Only long polymeric molecules have the required exceedingly large number of available configurations.

It is necessary that all the configurations are accessible; this means that rotation must be relatively free about a significant number of the bonds joining neighboring skeletal atoms.

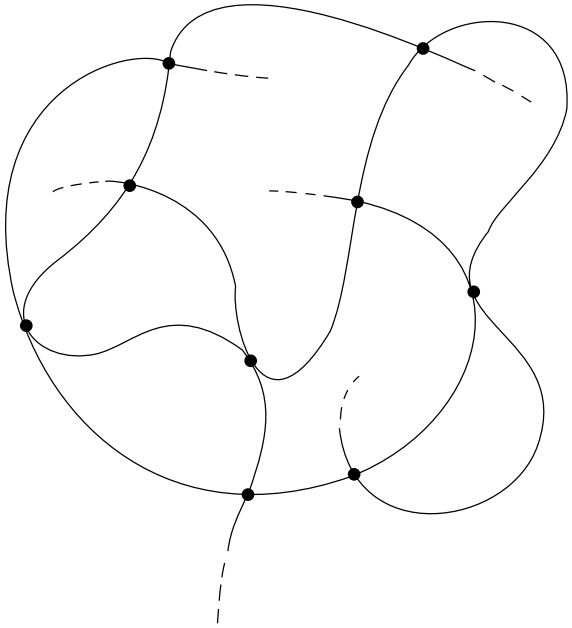

Fig. 5. Segment of an elastomeric network.

Network Structure. Chains must be joined by permanent bonds called cross-links, as illustrated in Figure 5. The network structure thus obtained is essential so as to avoid chains permanently slipping by one another, which would result in flow and thus irreversibility, ie, loss of recovery. These cross-links may be chemical bonds or physical aggregates, eg, glassy domains in multiphase block copolymers (55,56).

At the end of the cross-linking process, the topology of the mesh is composed of the different entities represented in Figure 6 (16,57–59). An elastically active junction is one joined by at least three paths to the gel network (60,61). An active chain is one terminated by an active junction at both its ends. Rubber-like elasticity is due to elastically active chains and junctions. Specifically, upon deformation the number of configurations available to a chain decreases and the resulting decrease in entropy gives rise to the retractive force.

Weak Interchain Interactions. Apart from the effects of the cross-links, the molecules must be free to move reversibly past one another, that is, the intermolecular attractions known as secondary or van der Waals forces, which exist between all molecules, must be small. Specifically, extensive crystallization should not be present, and the polymer should not be in the glassy state.

Differences between Elastomers and Metals

Elastomers and metals differ greatly with regard to deformation mechanisms (26, 62,63). Metals and minerals are formed of atoms arranged in a three-dimensional crystalline lattice, joined by powerful valence forces operating at relatively short

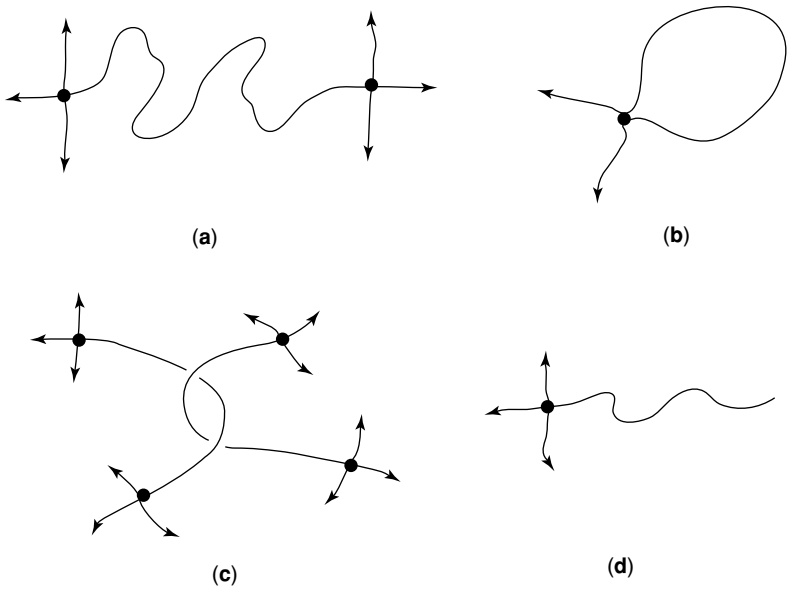

Fig. 6. Structural features of a network. (a) Elastically active chain; (b) loop; (c) trapped entanglement; (d) chain end.

range. Deformation of such materials involves changes in the interatomic distance, which requires large forces; hence the elastic modulus of these materials is very high. After a small deformation, slippage between adjacent crystals occurs at the yield point, and the deformation increases much more rapidly than the stress and becomes irreversible or plastic. The primary effect of stretching a metal short of this yield point is the increase ΔE_m in energy caused by changing the distance d of separation between metal atoms. The sample recovers its original length when the force is removed, since this process corresponds to a decrease in energy. Heating increases oscillations about the minimum of the asymmetric potential energy curve and thus causes the usual volume expansion.

Stretching of elastomers does not involve any significant changes in the interatomic distances, and therefore the forces required are considerably lower. The number of available configurations for a network chain is reduced in the deformation process. After suppression of the stress, the specimen recovers its original shape, since this corresponds to the most disordered state. Thus the retractive force arises primarily from the tendency of the system to increase its entropy toward the maximum value it had in the undeformed state. At high elongations, stress–strain curves turn upward, a behavior very unlike that of metals. The number of available configurations is drastically reduced in this region, and chains reach the limits of their extensibility. For polymers with regular structures, crystallization may also be induced. Further elongation may then require deformation of bond angles and length, which requires much larger forces.

At constant force, heating increases disorder, forcing the sample in the direction of the state of disorder it had at a lower temperature and smaller deformation. The result is therefore a decrease in length.

Extension of Elastomers and Compression of Gases

The extension of elastomers and the compression of gases are associated with a decrease in entropy. Thus, similar behavior is expected in regard to (adiabatic) deformation and heating. The work of deformation of a gas is $dW = -pdV$, where p is the pressure and V the volume. For an elastomer it is $dW = f\,dL$, where f is the force and L the length; the term $-pdV$ is not taken into account, since there is only a negligible change in rubber volume during stretching. These observations can be used to explain Gough's experiments by making use of classical thermodynamic principles (64).

Statistical Distribution of End-To-End Dimensions of a Polymer Chain

Before treating the statistical properties of a network, the statistics of a single chain must be considered, mainly to establish the relationship between the number of configurations and the deformation (12,16,65–72). A polymeric chain is constantly changing its configuration by Brownian motion. Statistical methods and idealized models permit calculation of the average properties of such a chain.

The Freely Jointed Chain. This type of idealized chain consisting of n links of length l is represented in Figure 7, where r is the end-to-end distance. When the chain is completely extended, $R = nl$. The chain may assume many configurations, each associated with an end-to-end distance r_i. In statistics, it is equivalent to consider a molecule at different times or an assembly of N molecules at the same time. An average quantity describing the assembly is the mean-square end-to-end distance $\overline{r^2}$ defined by

$$\overline{r^2} = \frac{1}{N}\sum_{i=1}^{N} r_i^2 \tag{7}$$

where r_i is the end-to-end distance of the ith chain. The vector $\boldsymbol{r}_i$ is the sum of the link vectors $\boldsymbol{I}_j$:

$$r_i = \sum_{j=1}^{n} I_j \tag{8}$$

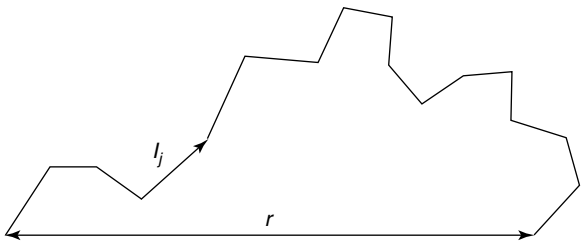

Fig. 7. Ideal chain formed with n links of length l. r = End-to-end distance, $\boldsymbol{I}_j$ = link vector.

and $r^2{}_i$ is the scalar product of r_i with itself:

$$r_i^2 = \sum_{j=1}^{n} I_j^2 + 2\sum_{k<j} I_k \cdot I_j \tag{9}$$

If the chain is assumed to be freely jointed and volumeless, any two links can assume any orientation with respect to each other. Therefore the second term of equation (9) is zero and

$$r_i^2 = nl^2 \tag{10}$$

The mean-square end-to-end distance of a freely orienting chain is deduced from equations (7) and (10) (73–76) as follows:

$$\overline{r^2} = nl^2 \tag{11}$$

Another interesting quantity is the probability that a chain has a given end-to-end distance (77–81). This is called the Gaussian distribution function

$$W(x,y,z)\mathrm{d}x\mathrm{d}y\mathrm{d}z = W(x)\mathrm{d}x\,W(y)\mathrm{d}y\,W(z)\mathrm{d}z = (b/\pi^{1/2})^3 \exp(-b^2r^2)\mathrm{d}x\mathrm{d}y\mathrm{d}z \tag{12}$$

where $r^2 = x^2 + y^2 + z^2$, and $b^2 = 3/2\overline{r^2}$. This generalization is valid only for small extensions of a relatively long chain (82). Equation (12) gives the probability that if one extremity of the vector r is fixed at the origin of the coordinates, the other lies in the volume $\mathrm{d}x\ \mathrm{d}y\ \mathrm{d}z$ centered around the point (x, y, z). What is more interesting is the probability for a chain to have its end in a spherical shell of radius r and thickness $\mathrm{d}r$ centered at the origin, irrespective of direction. This is the radial distribution

$$W(r)\mathrm{d}r = (b/\pi^{1/2})^3 \exp(-b^2r^2)4\pi r^2\mathrm{d}r \tag{13}$$

which is illustrated in Figure 8 (3). The maximum occurs at $r = (2nl^2/3)^{\frac{1}{2}}$. The mean-square end-to-end distance is the second moment of the radial distribution function

$$\overline{r^2} = \int_0^\infty r^2 W(r)\mathrm{d}r \Big/ \int_0^\infty W(r)\mathrm{d}r \tag{14}$$

which yields the result of equation (11)

$$\overline{r^2} = 3/2b^2 = nl^2 \tag{15}$$

The Gaussian distribution (eq. (12)) was obtained in the aforementioned treatment with the assumption that chains are far from their full extension. Moreover, the Gaussian distribution function predicts zero probability only for $r = \infty$ instead of for all r in excess of that for full chain extension, and does not adequately

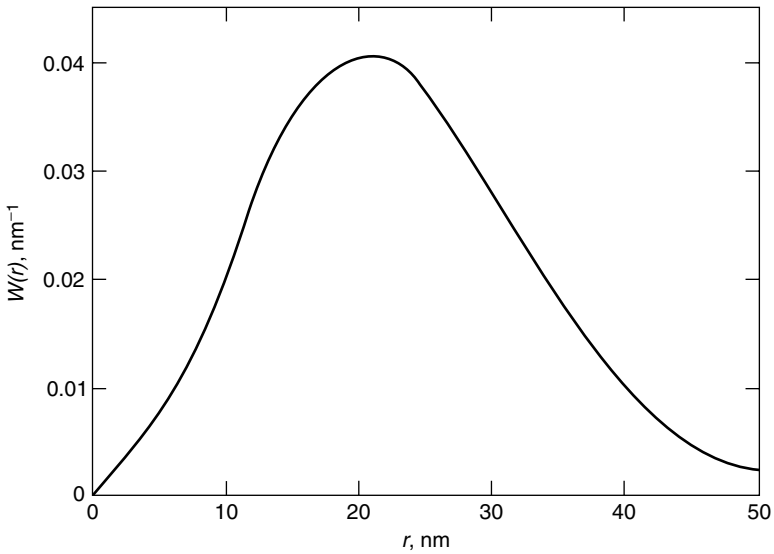

Fig. 8. Radial distribution function $W(r)$ of the chain displacement vectors for chain molecules consisting of 10^4 freely jointed segments, each of length $l = 0.25$ nm; $W(r)$ is expressed in nm^{-1} and r in nm (3). Courtesy of Cornell University Press.

take into account the significant geometric and conformational differences known to exist among different types of polymer chains (83). The distribution obtained from a more general treatment is of the more complicated form (84–86) shown as follows:

$$W(r)\mathrm{d}r = \text{const.} \times \exp\left(-\int_0^r \mathcal{L}^{-1}(r/nl)\mathrm{d}r/l \right) 4\pi r^2 \mathrm{d}r \tag{16}$$

where $\mathcal{L}^{-1}$ is the inverse Langevin function and

$$\mathcal{L}(u) = \coth u - 1/u \tag{17}$$

Equation (16) can be expanded in the series

$$W(r)\mathrm{d}r = \text{const.} \times \exp\{-n[(3/2)(r/nl)^2 + (9/20)(r/nl)^4 + (99/350)(r/nl)^6 + \cdots]\} 4\pi r^2 \mathrm{d}r \tag{18}$$

and the Gaussian distribution (eq. (13)) recovered for $r \ll nl$. A comparison of the Gaussian and inverse Langevin distributions for $n = 6$ is shown in Figure 9 (7).

Chain with Bond-Angle Restrictions. Although the chain in the aforementioned treatment was assumed to be freely jointed, a real polymer chain has fixed bond angles θ. Therefore, the second term in equation (9) is no longer zero. The scalar product of two vectors $\boldsymbol{I}_i \cdot \boldsymbol{I}_j$ is $l^2 \cos^{|j-i|}\theta$. It can be shown (9,73,74) that

$$\overline{r^2} \simeq nl^2(1 - \cos\theta)/(1 + \cos\theta) \tag{19}$$

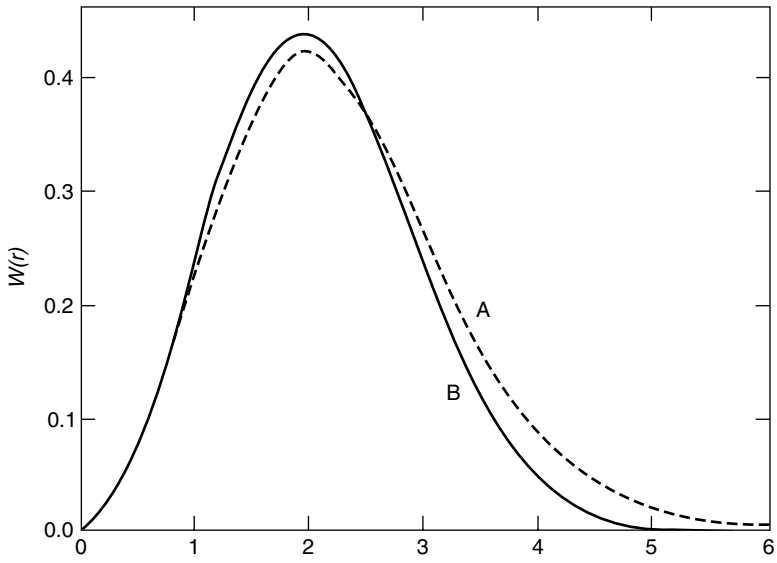

Fig. 9. Distribution function $W(r)$ for a six-link random chain, with length $l = 1$ in arbitrary units: A, Gaussian limit; B, inverse Langevin function (7). Courtesy of Oxford University Press.

In the particular case of a tetrahedrally bonded chain, $\theta = 109.5^\circ$ and $\overline{r^2} = 2nl^2$, twice the value for a freely jointed chain. Thus, a real chain is quite different from this ideal representation. Nevertheless, any flexible real chain can be represented by a simple model which is the statistical equivalent of a freely jointed chain (87,88). The two conditions are that the real and freely jointed chains have the same mean-square end-to-end distance and the same length at complete extension:

$$\overline{r^2} = \overline{r_e^2} = n_e l_e^2 \tag{20}$$

and

$$R = R_e = n_e l_e \tag{21}$$

Thus, only one model chain is equivalent to the real one, obeying the same Gaussian distribution function and composed of n_e segments of length l_e given by

$$n_e = R^2/\overline{r^2} \tag{22}$$

$$l_e = \overline{r^2}/R \tag{23}$$

Chain with Bond-Angle Restrictions and Hindered Rotations. The angle of rotation ϕ of a single bond around the axis formed by the preceding one may be restricted by steric interferences between atoms. When n is large and the average value of $\cos\phi$, ie, $\overline{\cos\phi}$, is not too close to unity, the following relationship can be established (89,90):

$$\overline{r^2} = nl^2\left(\frac{1-\cos\theta}{1+\cos\theta}\right)\left(\frac{1+\overline{\cos\phi}}{1-\overline{\cos\phi}}\right) \tag{24}$$

When the rotation is not hindered, ie, when $\overline{\cos\phi} = 0$, equation (24) is equivalent to equation (19).

The conformations of polymer chains may be generated by a Monte Carlo simulation method. The dimensions of linear chains, unperturbed by excluded-volume interactions, have been measured in various solvents by light scattering, x-ray small-angle scattering, and dilute-solution viscosity measurements. They are reported most comprehensively in the *Polymer Handbook* (91,92). A powerful tool to investigate chain conformations in unswollen and swollen melts and networks is small-angle neutron scattering (sans) (67,93–97).

The Equation of State for a Single Polymer Chain. The variation in the Helmholtz free energy is the negative of the work of deformation in isothermal elongation

$$\mathrm{d}A = -\mathrm{d}W = f\,\mathrm{d}r \tag{25}$$

with

$$\mathrm{d}A = \mathrm{d}U - T\mathrm{d}S \tag{26}$$

The tensile force f on a polymer chain for a given length r is

$$f = \left(\frac{\partial A}{\partial r}\right)_T = \left(\frac{\partial U}{\partial r}\right)_T - T\left(\frac{\partial S}{\partial r}\right)_T \tag{27}$$

In freely jointed and freely rotating model chains, no rotation is preferred; therefore, the internal energy is the same for all the conformations. Then,

$$f = -T\left(\frac{\partial S}{\partial r}\right)_T \tag{28}$$

The entropy is given by the Boltzmann relation

$$S = \mathrm{k}\ln\Omega \tag{29}$$

where k is the Boltzmann constant, and Ω, the total number of configurations available to the system, is proportional to $W(r)$ (eq. (13)). Calculation of the force gives

$$f = 2kTb^2r \tag{30}$$

$$f = 2kTr/\overline{r^2} \tag{31}$$

Thus, f is directly proportional to the absolute temperature and to r, which means the chain acts as a Hookean spring with modulus $3kT/\overline{r^2}$. The use of a non-Gaussian distribution for Ω leads to (71,85,86)

$$f = (kT/l)\mathcal{L}^{-1}(r/nl) \tag{32}$$

Classical Thermodynamics of Rubber-like Elasticity

In experiments concerning the relationships between length, temperature, and force, usually the change in force with temperature at constant length is recorded (53,98–101). It is therefore necessary to extend the thermodynamic treatment of the elasticity. Moreover, the force is not purely entropic, and the energetic contribution carries useful information on the dependence on temperature of the average end-to-end distance of the network chains in the unstrained state (21,102). It is therefore important to know how to deduce these quantities from a thermoelastic experiment.

The change in internal energy during stretching an elastic body is

$$\mathrm{d}U = \mathrm{d}Q - \mathrm{d}W \tag{33}$$

where $\mathrm{d}Q$ is the element of heat absorbed by the system and $\mathrm{d}W$ the element of work done by the system on the surroundings. In a reversible process,

$$\mathrm{d}Q = T\mathrm{d}S \tag{34}$$

where S is the entropy of the body. The work $\mathrm{d}W$ can be expressed as the sum

$$-\mathrm{d}W = -p\mathrm{d}V + f\mathrm{d}L \tag{35}$$

where p is the equilibrium external pressure, $\mathrm{d}V$ the volume dilation accompanying the elongation of the elastomer, and f the equilibrium tension. Thus,

$$\mathrm{d}U = T\mathrm{d}S - p\mathrm{d}V + f\mathrm{d}L \tag{36}$$

At constant pressure, the enthalpy change is

$$\mathrm{d}H = \mathrm{d}U + p\mathrm{d}V = T\mathrm{d}S + f\mathrm{d}L \tag{37}$$

A deformation $\mathrm{d}L$ at constant pressure and temperature induces a retractive force

$$f = \left(\frac{\partial H}{\partial L}\right)_{T,p} - T\left(\frac{\partial S}{\partial L}\right)_{T,p} \tag{38}$$

Expression 38 is one of the forms of the thermodynamic elastic equation of state. Measurements of stress at constant length as a function of temperature have been

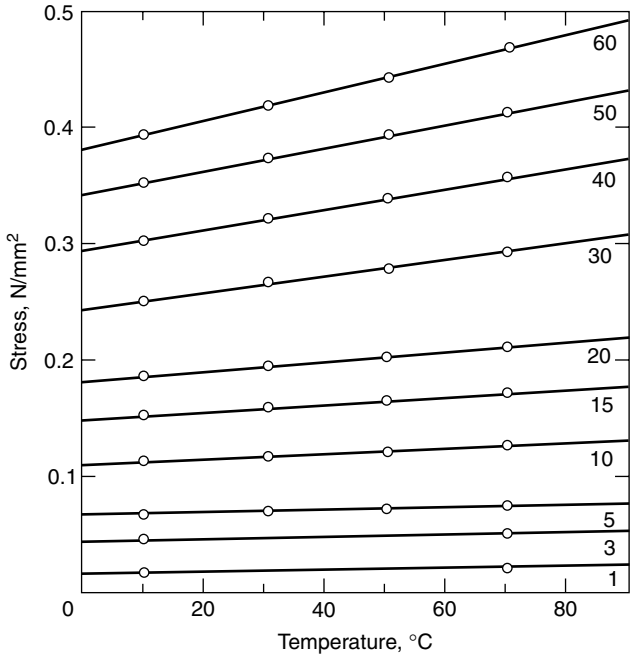

Fig. 10. Stress–temperature curves for sulfur-vulcanized natural rubber (99,103). Courtesy of the American Chemical Society.

performed (see Fig. 10) (97,103–105). All the curves appear to be straight lines; the slope increases with increasing elongation, but for very small elongations, the slopes can be negative. This phenomenon, called the thermoelastic inversion, is due to the volume expansion occurring in any elastomer. The condition of constant length does not correspond to constant elongation as well, since the sample's unstrained reference length changes with temperature. The inversion is suppressed by correction of the original length (11).

The energetic and entropic contributions to the force in the intramolecular process of stretching the chains can be obtained in experiments where there is no other energetic contribution resulting from changes in (intermolecular) van der Waals forces. Therefore, these experiments must be performed at constant volume. A basic postulate of the elasticity of amorphous polymer networks is that the stress exhibited by a strained polymer network is assumed to be entirely intramolecular in origin. That is, intermolecular interactions play no role in deformations at constant volume and composition.

An equation similar to equation (38) is obtained for the elastic force measured at constant volume:

$$f = \left(\frac{\partial U}{\partial L}\right)_{T,V} - T\left(\frac{\partial S}{\partial L}\right)_{T,V} \tag{39}$$

The variation in the Helmholtz free energy has the following expression:

$$dA = -SdT - pdV + fdL \tag{40}$$

The second derivative obtained by differentiating $(\frac{\partial A}{\partial L})_{V,T}$ with respect to T at constant V and L is identical with that obtained by differentiating $(\frac{\partial A}{\partial T})_{V,L}$ with respect to L at constant V and T:

$$-\left(\frac{\partial f}{\partial T}\right)_{V,L} = \left(\frac{\partial S}{\partial L}\right)_{V,T} \tag{41}$$

Thus, equation (39) can be written as

$$f = \left(\frac{\partial U}{\partial L}\right)_{T,V} + T\left(\frac{\partial f}{\partial T}\right)_{V,L} \tag{42}$$

The energetic and entropic components of the elastic force, f_e and f_s, respectively, are obtained from thermoelastic experiments using the following equations:

$$f_e = \left(\frac{\partial U}{\partial L}\right)_{T,V} = f - T\left(\frac{\partial f}{\partial T}\right)_{V,L} \tag{43}$$

$$f_s = -T\left(\frac{\partial S}{\partial L}\right)_{T,V} = T\left(\frac{\partial f}{\partial T}\right)_{V,L} \tag{44}$$

An example of thermoelastic data is given in Figure 11 (99). The change in entropy with elongation up to 350% is responsible for more than 90% of the total stress at room temperature, whereas the contribution of internal energy is less than 10%. Thus, the restoring force is due almost entirely to the tendency of the extended rubber molecules to return to their unperturbed, random conformational states. Above 350%, crystallization appears. This is a specific feature of stereoregular rubbers, such as natural rubber which is capable of crystallization. Data concerning most of the polymers studied in this manner are reviewed in References 21 and 106.

Statistical Treatment of Rubber-like Elasticity

A network is an ensemble of macromolecules linked together, each of them rearranging its configurations by Brownian motion. Classical thermodynamics explains the behavior of elastomers with regard to force, temperature, pressure, and volume, but does not give the relationship between the molecular structure of the network and elastic quantities such as the moduli. Therefore, statistical mechanics was introduced in the 1940s (16,86,87,107–109), and its theoretical predictions were tested (110–112). Because of the complexity of network structures, two models based on affine and phantom networks were studied. The cross-linking points

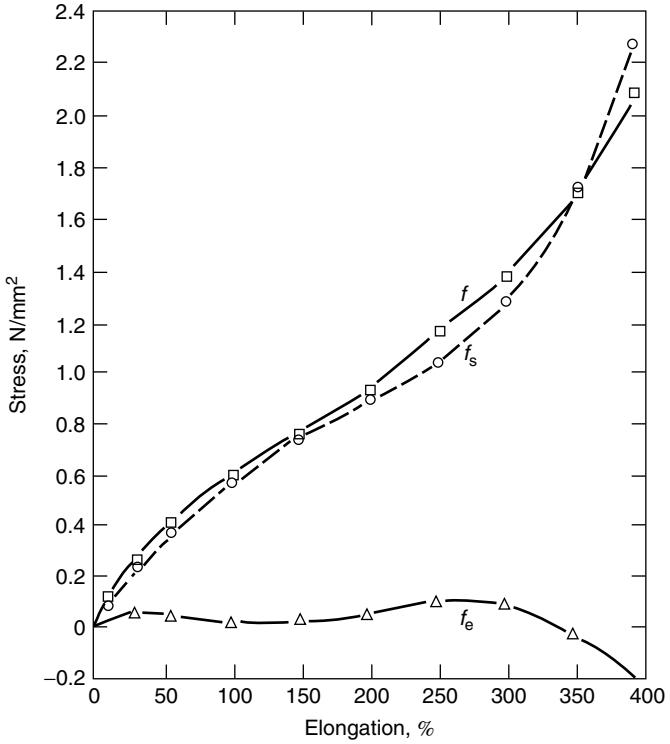

Fig. 11. Plot of the energetic (f_e) and entropic (f_s) contributions to the stress at 20°C for sulfur-vulcanized rubber (99). N/mm^2 = MPa; to convert MPa to psi, multiply by 145. Courtesy of the American Chemical Society.

of the affine network are fixed, whereas those of the phantom network can undergo fluctuations independent of their immediate surroundings. The effects of the macroscopic strain are transmitted to the chains through these junctions at which the chains are multiply joined, with the internal state of the network system specified in terms of the positions of the cross-linkages. Deformation transforms the arrangements of these points. The system is represented by the vectors $\boldsymbol{r}_i$, each of which connects the two ends of a chain. For a given end-to-end vector $\boldsymbol{r}_i$, the number of available configurations is directly proportional to the probability $W(r_i)$ or relative number of configurations. Representation of $W(r)$ by a Gaussian function according to equation (13) fails as r approaches the maximum extension r_{max}. Experimental evidence of deviations from the Gaussian theory have been reported (24,113–116) and non-Gaussian theories based on an expression for $W(r)$ similar to equation (16) have been developed (84,85,117–119). These theories have the disadvantage of containing parameters that can be determined only by comparisons between theory and experiments, specifically ν, the number density of chains in the network, and n, the number of statistical links.

The tensile force is expressed by

$$f/A_0 = (1/3)\nu kTn^{1/2}\left[\mathcal{L}^{-1}(\lambda n^{-1/2}) - \lambda^{-3/2}\mathcal{L}^{-1}(\lambda^{-1/2}n^{-1/2})\right] \tag{45}$$

where

$$\mathcal{L}^{-1}(t) = 3t + (9/5)t^3 + (297/175)t^5 + \cdots$$

and A_0 is the cross-sectional area of the unstrained sample. The number n of random links may be obtained by birefringence and stress–strain measurements, and from this result, an estimation of the number of monomer units in the equivalent-random link (of the Kuhn–Grün theory) of the polymeric chain (120). Another approach to a non-Gaussian theory utilizes information provided by rotational isomeric state theory on the spatial configurations of chain molecules (83), including most of those used in elastomeric networks. Specifically, Monte Carlo calculations (121–123) based on the rotational isomeric state approximation are used to simulate spatial configurations followed by distribution functions for the end-to-end separation r of the network chains (124).

The theory in the Gaussian limit has been refined greatly to take into account the possible fluctuations of the junction points. In these approaches, the probability of an internal state of the system is the product of the probabilities $W(r_i)$ for each chain. The entropy is deduced by the Boltzmann equation, and the free energy by equation (26). The three main assumptions introduced in the treatment of elasticity of rubber-like materials are that the intermolecular interactions between chains are independent of the configurations of these chains and thus of the extent of deformation (125,126); the chains are Gaussian, freely jointed, and volumeless; and the total number of configurations of an isotropic network is the product of the number of configurations of the individual chains.

Affine Networks. Diffusion of the junctions about their mean positions may be severely restricted by neighboring chains sharing the same region of space. The extreme case is the affine network where fluctuations are completely suppressed, and the instantaneous distribution of chain vectors is affine in the strain. The elastic free energy of deformation is then given by

$$\Delta A_{\text{el}}(\text{aff}) = (1/2)\upsilon kT(I_1 - 3) - (\upsilon - \xi)kT \ln(V/V_0) \tag{46}$$

where I_1 is the first invariant of the tensor of deformation

$$I_1 = \lambda_x^2 + \lambda_y^2 + \lambda_z^2 \tag{47}$$

The quantities λ_x, λ_y, and λ_z are the principal extension ratios, which specify the strain relative to an isotropic state of reference having volume V_0; V is the volume of the deformed specimen, and υ is the number of linear chains whose ends are joined to multifunctional junctions of any functionality $\phi > 2$. (The *functionality of a junction* is defined as the number of chains connected to it.) The cycle rank ξ (102) represents the number of chains that have to be cut to reduce the network to an acyclic structure or tree (127). The cycle rank is the difference between the number of effective chains ν and effective junctions μ of functionality $\phi > 2$:

$$\xi = \nu - \mu \tag{48}$$

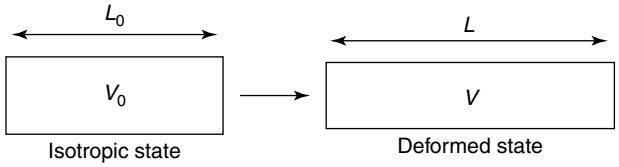

Fig. 12. Simple extension of an unswollen network prepared in the undiluted state (99). Courtesy of the American Chemical Society.

For a perfect network of functionality ϕ,

$$\xi = (1 - 2/\phi)\nu \tag{49}$$

Simple Extension. The most general case is an extension with change in sample volume, as illustrated in Figure 12. The strain along the direction of stretching is given by λ_x as

$$\lambda = \lambda_x = L/L_0 \tag{50}$$

Since the volume changes from V_0 to V,

$$\lambda_x \lambda_y \lambda_z = V/V_0 \tag{51}$$

Because there is symmetry about the x axis, $\lambda_y = \lambda_z$. Combining equations (50) and (51) leads to

$$\lambda_y = \lambda_z = (V/\lambda V_0)^{1/2} \tag{52}$$

The force f is the derivative of the free energy with respect to length; specifically,

$$f = \left(\frac{\partial \Delta A}{\partial L}\right)_{T,V} = (1/L_0)\left(\frac{\partial \Delta A}{\partial \lambda}\right)_{T,V} \tag{53}$$

Using equation (46),

$$f = (\nu kT/L_0)\left[\lambda - V/\left(V_0 \lambda^2\right)\right] \tag{54}$$

It is also possible to deduce the expression for the force as a function of the extension α measured relative to the length $L_v{}^i$ of the unstretched sample when its volume is fixed at the same volume V as occurs in the stretched state:

$$\alpha = L/L_v^i = \lambda L_0/L_v^i \tag{55}$$

and

$$L_0 = L_v^i (V/V_0)^{-1/3} \tag{56}$$

Equation (54) is then transformed to

$$f = \left(vkT/L_v^i\right)(V/V_0)^{2/3}(\alpha - 1/\alpha^2). \tag{57}$$

Energetic Contributions. Equation (57) can be used for the molecular interpretation of the ratio f_e/f. Thus, equation (43) can be rewritten as

$$f_e = f - T\left(\frac{\partial f}{\partial T}\right)_{V,L} = -fT\left(\frac{\partial \ln(f/T)}{\partial T}\right)_{V,L} \tag{58}$$

or

$$\frac{f_e}{f} = -T\left(\frac{\partial \ln(f/T)}{\partial T}\right)_{V,L} \tag{59}$$

The derivative of f at constant volume and length, thus at constant α, can be obtained from equation (57), with the result

$$f_e/f = (2/3)T(\mathrm{d}\ln V_0/\mathrm{d}T) = T\left(\mathrm{d}\ln \overline{r_0^2}/\mathrm{d}T\right) \tag{60}$$

since V_0 is the volume of the isotropic state so defined that the mean square of the magnitude of the chain vectors equals $\overline{r_0^2}$, the value for the free unperturbed chains.

The intramolecular energy changes arising from transitions of chains from one spatial configuration to another are, by equation (60), directly related to the temperature coefficient of the unperturbed dimensions. It is interesting to compare the thermoelastic results for polyethylene (128), $f_e/f = -0.45$, and poly(dimethylsiloxane) (129), $f_e/f = 0.25$. The preferred (lowest energy) conformation of the polyethylene chain is the all-trans form, since gauche states at rotational angles of $\pm 120^\circ$ cause steric repulsions between CH_2 groups (83). Since this conformation has the highest possible spatial extension, stretching a polyethylene chain requires switching some of the gauche states, which are, of course, present in the randomly coiled form, to the alternative trans states (106,130). These changes decrease the conformational energy and are the origin of the negative type of ideality represented in the experimental value of f_e/f. (This physical picture also explains the decrease in unperturbed dimensions upon increase in temperature. The additional energy causes an increase in the number of the higher energy gauche states, which are more compact than the trans ones.) The opposite behavior is observed in the case of poly(dimethylsiloxane) (26). The all-trans form is again the preferred conformation; the relatively long Si—O bonds and the unusually large Si—O—Si bond angles reduce steric repulsion in general, and the trans conformation places CH_3 side groups at distances of separation where they are strongly attractive (83,129,131). Because of the inequality of the Si—O—Si and O—Si—O bond angles, however, this conformation is of very low spatial extension. Stretching a poly(dimethylsiloxane) chain therefore requires an increase in the number of gauche states. Since these are of higher energy, this explains the fact that deviations from ideality for these networks are found to be positive (106,129,130).

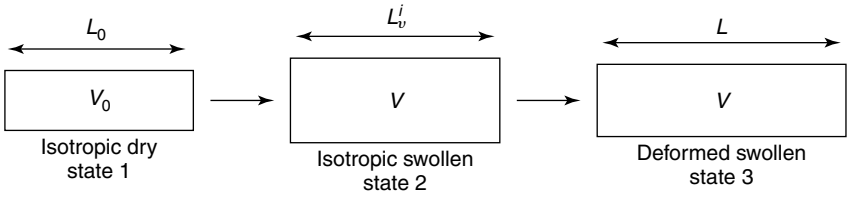

Fig. 13. Simple extension of a swollen network.

Simple Extension of Swollen Networks. The force required to deform an elastomeric sample, from state 2 to state 3 in Figure 13, is given by equation (57), in which $\alpha = L/L_v^i$ is the extension ratio for the isotropic swollen state relative to the deformed swollen state. The ratio V_0/V is the volume fraction v_2 of polymer in the swollen system, and A_0 is the cross-sectional area of the dry sample, which is generally measured before the experiment. The area of the swollen sample is given by

$$A_v^i = A_0(V/V_0)^{2/3} \tag{61}$$

Equation (56), of course, still holds, and $L_0A_0 = V_0$. In an experiment, the force f is measured as a function of elongation. Under these conditions,

$$f/A_0 = (\nu kT/L_0A_0)v_2^{-1/3}(\alpha - 1/\alpha^2) \tag{62}$$

Hence, the quantity $[f*] \equiv v_2^{1/3}/A_0(\alpha - 1/\alpha^2)$ should be a constant, independent of the degree of swelling, and be equal to $\nu kT/V_0$. As shown later $[f*]$ is commonly plotted versus $1/\alpha$ to determine deviations from theory (112,132,133).

Simple Extension of Networks Cross-linked in the Diluted State. The polymer is dissolved, cross-linked, and dried. The stress–strain measurements are carried out on the dry network, as illustrated in Figure 14. Equation (57) also holds for this case. If A_v^i is the cross-sectional area of the undeformed dry specimen, the force per unit undeformed area is

$$f/A_v^i = (\nu kT/V)(V/V_0)^{2/3}(\alpha - 1/\alpha^2) \tag{63}$$

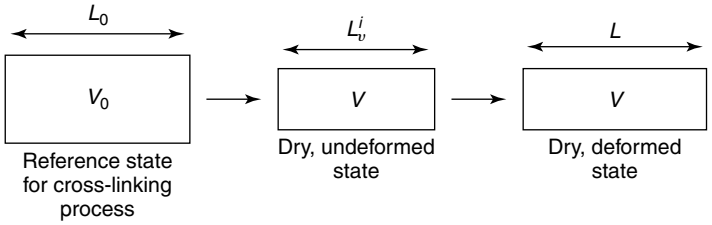

Fig. 14. Simple extension of an unswollen network cross-linked in the diluted state ($V_0 > V$).

which is $(V/V_0)^{2/3}$ times the tension of a network cross-linked in the dry state (111,134).

The Affine Shear Modulus. For $V = V_0$, equation (54) becomes

$$f/A_0 = (\nu kT/V_0)(\lambda - 1/\lambda^2) \tag{64}$$

Making use of equation (2) gives $\lambda = 1 + \epsilon$. For small values of ϵ, $\epsilon \ll 1$, equation (64) may be written as

$$f/A_0 = 3(\nu kT/V_0)\epsilon \tag{65}$$

The tensile modulus E_{aff} is three times the shear modulus G_{aff}, since Poisson's ratio for elastomers is close to 0.5. Specifically,

$$E_{\text{aff}} = 3\upsilon kT/V_0 = 3G_{\text{aff}} \tag{66}$$

and hence,

$$G_{\text{aff}} = \upsilon kT/V_0 \tag{67}$$

If υ/V_0 is the molar number density of chains [equal to ρ/M_{c} for a perfect network, where ρ is the elastomer density and M_{c} is the molecular weight between cross-link points (in g/mol)], then

$$G_{\text{aff}} = \upsilon RT/V_0 \tag{68}$$

where R is the gas constant. In the remaining material, υ is a molar quantity unless it is followed by the Boltzmann constant k.

For an affine perfect network,

$$G_{\text{aff}} = \rho RT/M_c \tag{69}$$

As a numerical example, the affine shear modulus of a perfect poly (dimethylsiloxane) tetrafunctional network of density $\rho = 0.97$ g/cm^3 and $M_{\text{c}} =$ 11,300 g/mol is $G_{\text{aff}} = 0.212 \times 10^6$ N/m^2. However, imperfections such as chain ends exist in typical networks, as illustrated in Figure 6. The following correction can be made to account for this circumstance (16). Before the cross-linking reaction, it is assumed that υ_{m} chains of length $\overline{M}_n$ are present in the melt, with $\upsilon_m = \rho/\overline{M}_n$. Each chain has two ends, thus there are $2\rho/\overline{M}_n$ chain ends. After the cross-linking process, there are υ_0 chains of length M_{c}, $\upsilon_0 = \rho/M_{\text{c}}$, along with the $2\rho/\overline{M}_n$ chain ends. Therefore the number of chains that are elastically effective is

$$\upsilon = \rho/M_{\text{c}} - 2\rho/\overline{M}_{\text{n}} = (\rho/M_{\text{c}})(1 - 2M_{\text{c}}/\overline{M}_{\text{n}}) \tag{70}$$

This correction is small for $M_c \ll \overline{M}_n$, which is frequently the case.

Phantom Networks. In this idealized model, chains may move freely through one another (135). Junctions fluctuate around their mean positions because of Brownian motion, and these fluctuations are independent of deformation. The mean square fluctuations $\overline{\Delta r^2}$ of the end-to-end distance r are related to the mean square of the end-to-end separation of the free unperturbed chains $\overline{r^2}$(102,136,137) by

$$\overline{\Delta r^2}/\overline{r^2}_0 = 2/\phi \tag{71}$$

The fluctuation range ($\overline{\Delta r^2} = \overline{r_0^2}/2$ for a tetrafunctional network) is generally quite large and of considerable importance. The instantaneous distribution of chain vectors $\boldsymbol{r}$ is not affine in the strain because it is the convolution of the distribution of the affine mean vector $\boldsymbol{r}$ with the distribution of the fluctuations $\Delta\boldsymbol{r}$, which are independent of the strain. The elastic free energy of such a network is

$$\Delta A_{\mathrm{el}}(\mathrm{ph}) = (1/2)\xi kT(I_1 - 3) = (1/2)(\nu - \mu)kT(I_1 - 3) \tag{72}$$

In simple extension, the equivalent of equation (62) is now

$$f/A_0 = (\nu - \mu)kTV_0^{-1}v_2^{-1/3}(\alpha - 1/\alpha^2) \tag{73}$$

and the shear modulus is given by

$$G_{\mathrm{ph}} = (\upsilon - \mu)RT/V_0 \tag{74}$$

For a perfect network of functionality ϕ, equation (49) holds, and therefore,

$$G_{\mathrm{ph}} = (1 - 2/\phi)\upsilon RT/V_0 \tag{75}$$

$$G_{\mathrm{ph}} = (1 - 2/\phi)\rho RT/M_{\mathrm{c}} \tag{76}$$

The relationship between affine and phantom moduli is then

$$G_{\mathrm{ph}} = (1 - 2/\phi)G_{\mathrm{aff}} \tag{77}$$

For example, G_{aff} is twice G_{ph} for a perfect tetrafunctional network.

Comparisons With Experimental Results. Stress–strain measurements in uniaxial extension can be compared with the prediction of an affine Gaussian network (eq. (64)), as illustrated in Figure 15 (113). The Gaussian relationship in the affine limit is valid only at small deformations. The best fit is obtained using $G_{\mathrm{aff}} = 0.39$ MN/m^2 (56.6 psi) (7); deviations occur when $\lambda > 1.5$. The experimental curve may nevertheless be well represented by adjusting the parameters of the non-Gaussian stress–strain relationship (eq. (45)) (84,117,138). These disagreements between experiments and the simple predictions of statistical mechanics have led some workers to develop a phenomenological theory of rubber-like elasticity.

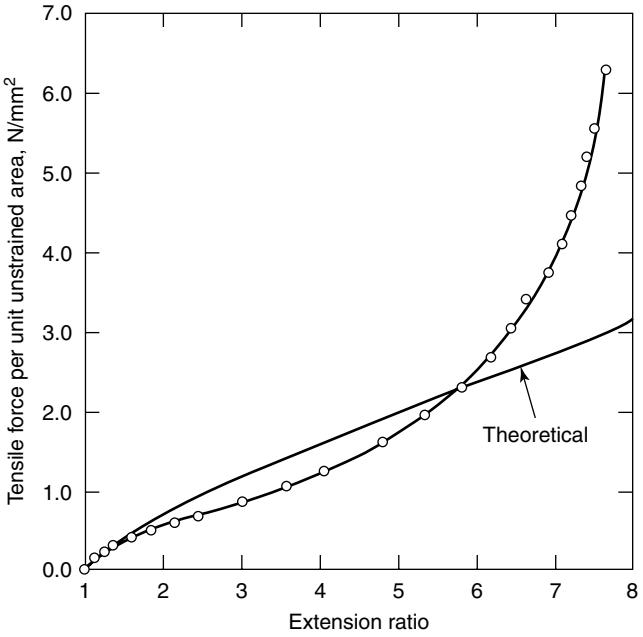

Fig. 15. Stress–strain isotherms in simple elongation; comparison of experimental curve (open circles) with theoretical prediction (eq. (64)) (113). To convert N/mm^2 to psi, multiply by 145. Courtesy of The Royal Society of Chemistry.

Phenomenological Theory. Continuum mechanics is used to describe mathematically the stress–strain relations of elastomers over a wide range in strain. This phenomenological treatment is not based on molecular concepts, but on representations of observed behavior (132,139–143). The main goal is to find an expression for the elastic energy W stored in the system (assumed to be perfectly elastic, isotropic in its undeformed state, and incompressible), analogous to the free energy of the statistical treatment. The condition of isotropy in the unstrained state requires that W be symmetrical with respect to the three principal extension ratios λ_x, λ_y, λ_z. A rotation of the material through 180°, ie, a change of sign of two of the λ_i ($i = x, y, z$), does not alter W (144). The three simplest even-powered functions satisfying these conditions are the strain invariants I_1, I_2, and I_3 defined as

$$I_1 = \lambda_x^2 + \lambda_y^2 + \lambda_z^2$$

$$I_2 = \lambda_x^2\lambda_y^2 + \lambda_y^2\lambda_z^2 + \lambda_z^2\lambda_x^2 \tag{78}$$

$$I_3 = \lambda_x^2\lambda_y^2\lambda_z^2$$

The most general form of the strain–energy function, which vanishes at zero strain, for an isotropic material is the power series

$$W = \sum_{i,j,k=0}^{\infty} C_{ijk}(I_1 - 3)^i (I_2 - 3)^j (I_3 - 1)^k \tag{79}$$

In equation (79), the experimental results obtained at sufficiently small strains are well represented with two nonzero terms, C_{100} and C_{010}:

$$W = C_{100}(I_1 - 3) + C_{010}(I_2 - 3) \tag{80}$$

In uniaxial extension, the so-called Mooney–Rivlin equation is obtained (17):

$$f\upsilon_2^{1/3}/A_0 = 2(C_1 + C_2/\alpha)(\alpha - 1/\alpha^2) \tag{81}$$

A convenient and standard way to treat stress–strain data is to plot the reduced force

$$[f*] \equiv f^* \upsilon_2^{1/3}/(\alpha - 1/\alpha^2) \tag{82}$$

versus $1/\alpha$, where $f*$ is the nominal stress f/A_0 and υ_2 the volume fraction of polymer in the network, if swollen (Fig. 16).

In this scheme, the affine and phantom networks are represented by horizontal lines (eqs. (62) and (73)) from equations $[f*] = \upsilon RT/V_0$ and $[f*] = (\upsilon - \mu)RT/V_0$, respectively. It has been reported that C_2 decreases as υ_2 decreases, whereas C_1 is approximately constant, as illustrated in Figure 16 (112). In view

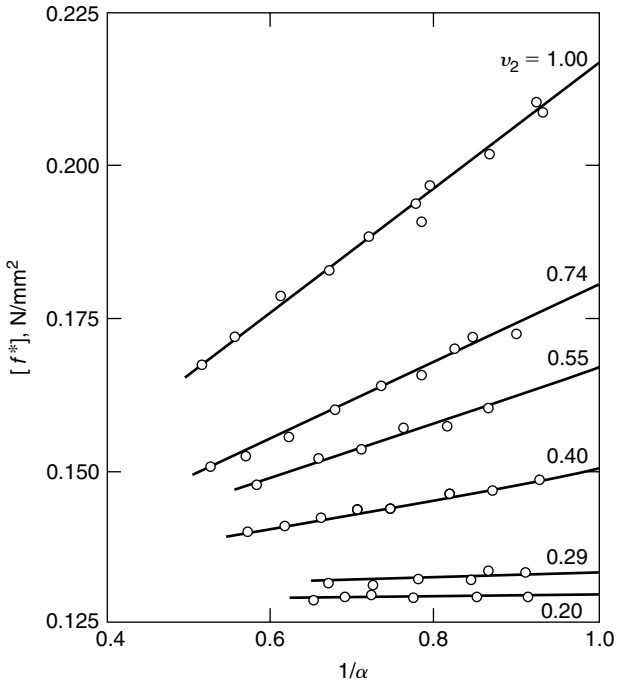

Fig. 16. Plot of $[f*]$ versus $1/\alpha$ for a natural rubber vulcanizate swollen in benzene to demonstrate the influence of υ_2 on C_2 (114). To convert N/mm^2 to psi, multiply by 145. Courtesy of The Royal Society of Chemistry.

of experimental results on swollen networks (69,114,145,146), the following form of the strain energy per unit volume of dry network is to be preferred:

$$W/V_0 = C_1(I_1 - 3) + C_2(I_2 I_3^{-1+m/2} - 3) \tag{83}$$

The reduced force can be deduced (145) as $[f*] = 2C_1 + 2C_2 v_2^{(4/3)-m} \alpha^{-1}$. The parameter C_1 of the swollen network is equal to C_1 of the dry network, whereas C_2 (swollen) is equal to C_2 (dry) $v_2^{(4/3)-m}$. Experimentally, m was found to be 0 or $\frac{1}{2}$ (145). The constant C_1 increases with the cross-linking density of the rubber (114,147), and $2C_1 + 2C_2$ is approximately the shear modulus at small deformation (148). Although there have been many attempts (149–155), a molecular explanation of C_1 and C_2 has been achieved only recently, as is described later.

The experimental error range is of great importance. A 1% error in the determination of λ has a tremendous effect on the Mooney curve when $1/\alpha > 0.9$; this part of the curve is therefore highly unreliable (156).

Statistical Theory of Real Networks. Affine and phantom networks are extreme limits. Stress–strain measurements in uniaxial extension have revealed that the behavior of real networks is between these limits. A theoretical attempt has been made to account for this dependence of $[f*]$ on $1/\alpha$ in terms of a gradual transition between the affine and phantom deformations (102,157), and a molecular theory has been formulated (102,158–161). In this model, the restrictions of junction fluctuations due to neighboring chains are represented by domains of constraints. At small deformations, the stress is enhanced relative to that exhibited by a phantom network. At large strains, or high dilation, the effects of restrictions on fluctuations vanish and the relationship of stress to strain converges to that for a phantom network. In a later theoretical refinement, the behavior of the network is taken to depend on two parameters. The most important is κ which measures the severity of entanglement constraints relative to those imposed by the phantom network. Another parameter ζ takes into account the nonaffine transformation of the domains of constraints with strain. Topological and mathematical treatment leads to the expression

$$[f*] = f_{\text{ph}}(1 + f_{\text{c}}/f_{\text{ph}}) \tag{84}$$

where f_{ph} is the usual phantom modulus and $f_{\text{c}}/f_{\text{ph}}$ is the ratio of the force due to entanglement constraints to that for the phantom network. A specific expression for $f_{\text{c}}/f_{\text{ph}}$ in uniaxial extension is

$$f_{\text{c}}/f_{\text{ph}} = (\mu/\xi)\left[\alpha K\left(\alpha_1^2\right) - \alpha^{-2} K\left(\alpha_2^2\right)\right]/(\alpha - 1/\alpha^2) \tag{85}$$

where $\alpha_1 = \alpha v_2^{-1/3}$, $\alpha_2 = \alpha^{-1/2} v_2^{-1/3}$, and μ/ξ is the ratio of the number of effective junctions to the cycle rank. For a perfect network, $\mu/\xi = 2/(\phi - 2)$. The function $K(x^2)$ is given by

$$K(x^2) = B[\dot{B}\,(B+1)^{-1} + g(\dot{g}\,B + g\,\dot{B})(gB+1)^{-1}] \tag{86}$$

with

$$g = x^2[1/\kappa + \zeta(x-1)]$$

$$\dot{g} = 1/\kappa - \zeta(1 - 3x/2)$$

$$B = (x-1)(1+x-\zeta x^2)/(1+g)^2$$

$$\dot{B} = B\left[(2x(x-1))^{-1} - 2\,\dot{g}\,(1+g)^{-1} + (1-2\zeta x)[2x(1+x-\zeta x^2)]^{-1}\right]$$

It is interesting to note that junction fluctuations increase in the direction of stretching but decrease in the direction perpendicular to it. Therefore the modulus decreases in the direction of stretching, but increases in the normal direction since the state of the network probed in this direction tends to be more nearly affine. The curve of $[f*]$ versus $1/\alpha$ is sigmoidal. The parameters κ and ζ of poly(dimethylsiloxane) networks are determined in Figure 17 (155); the intercept of the sigmoidal curves is the phantom modulus. This Flory–Erman theory has been compared successfully with such experiments in elongation and compression (155,162,162–166). It has not yet been extended to take account of limited chain extensibility or strain-induced crystallization (167).

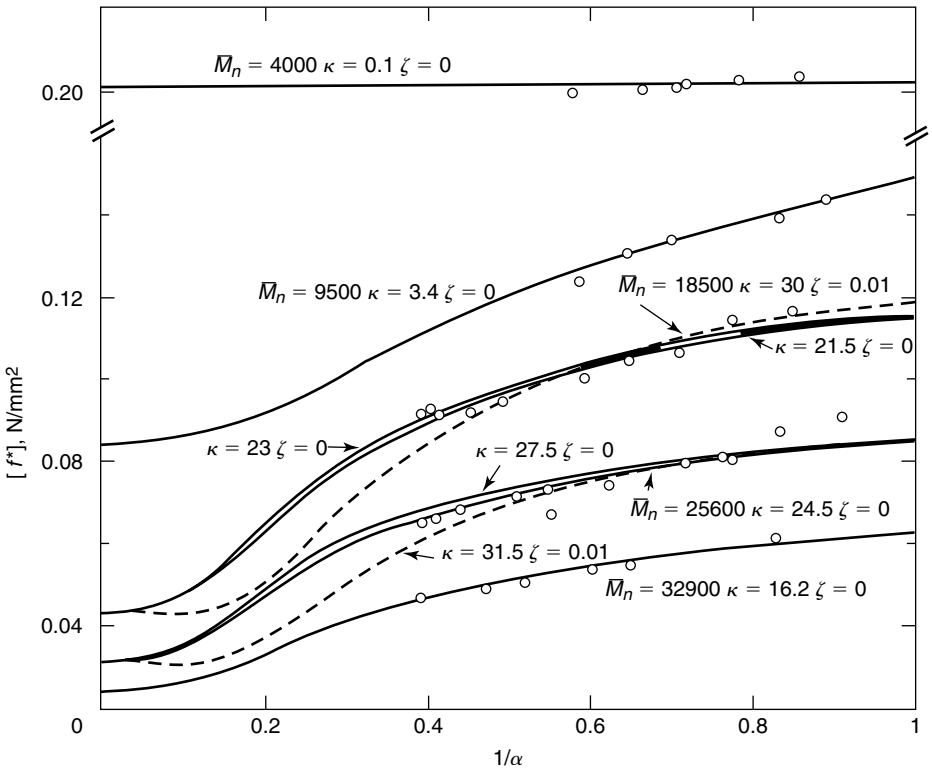

Fig. 17. Determination of the parameters κ and ζ of the Flory–Erman theory for perfect trifunctional poly(dimethylsiloxane) networks (155). To convert N/mm^2 to psi, multiply by 145. Courtesy of Springer-Verlag.

Predictions for the Parameters κ and ζ. The parameter ζ is not far from zero, which is to be expected since the surroundings of junctions cause their deformation to be nearly affine with the macroscopic strain. The primary parameter κ is defined as the ratio of the mean-square junction fluctuations in the equivalent phantom network, ie, in the absence of constraints, to the mean-square junction fluctuations about the centers of domains of entanglement constraints (in the absence of the network) in the isotropic state. Thus in a phantom network, the absence of constraints leads to $\kappa = 0$. In an affine one, the complete suppression of fluctuations is equivalent to $\kappa = \infty$. It has been proposed that κ should be proportional to the degree of interpenetration of chains and junctions (165). Since an increasing number of junctions in a volume pervaded by a chain leads to stronger constraints on these junctions, κ was taken to be

$$\kappa = I\left(\overline{r_0^2}\right)^{3/2}(\mu/V_0) \tag{87}$$

where I is a constant of proportionality, $(\overline{r_0^2})^{3/2}$ is assumed to be proportional to the volume occupied by a chain, and μ/V_0 is the number of junctions per unit volume. The mean-square unperturbed dimension $\overline{r_0^2}$ can be taken proportional to M_c (95), the molecular weight between cross-links, and μ/V_0 to M_c^{-1} for a perfect tetrafunctional network; therefore $\kappa \simeq M_c^{1/2}$ (93,155,165).

Swelling Equilibrium. The isotropic swelling of a cross-linked elastomer by a liquid has two important opposing effects: the increase in mixing entropy of the system because of the presence of the small molecules, and the decrease in configurational entropy of the network chains by dilation. Therefore, an equilibrium degree of swelling is established, which increases as the cross-linking density decreases (168–170). The free energy change ΔA for this process is usually assumed to be separable into the free energy of mixing, ΔA_m, and the elastic free energy ΔA_{el},

$$\Delta A = \Delta A_m + \Delta A_{el} \tag{88}$$

although questions have been raised with regard to this separability (171,172). The contribution ΔA_m has been calculated with the help of a lattice model (173, 174). The other contribution ΔA_{el} is given in the later Flory–Erman theory (161) by

$$\Delta A_{el} = \Delta A_{el}(\text{ph}) + \Delta A_c \tag{89}$$

where $\Delta A_{el}(\text{ph})$ is given by equation (72); ΔA_c is the additional term which accounts for the constraints and is given by

$$\Delta A_c = \mu kT/2 \sum_{i=x,y,z} \{[1 + g(\lambda_i)]B(\lambda_i) - \ln[(B(\lambda_i) + 1)(g(\lambda_i)B(\lambda_i) + 1)]\}. \tag{90}$$

The λ_i are the principal extension ratios, and g and B have been defined in equation (86).

The chemical potential of the solvent in the swollen network is

$$\mu_1 - \mu_1^0 = N\left(\frac{\partial \Delta A_{\mathrm{m}}}{\partial n_1}\right)_{T,p} + N\left(\frac{\partial \Delta A_{\mathrm{el}}}{\partial \lambda}\right)_{T,p}\left(\frac{\partial \lambda}{\partial n_1}\right)_{T,p} \tag{91}$$

where n_1 is the number of moles of solvent, and the isotropic extension ratio λ is

$$\lambda = \lambda_x = \lambda_y = \lambda_z = [(n_1 V_1 + V_0)/V_0]^{1/3} = v_2^{-1/3} \tag{92}$$

where V_1 is the molar volume of the solvent and V_0 the volume of the dry network. At swelling equilibrium, $\mu_1 = \mu_1^0$. Hence, the standard expression for ΔA_{m} (3) leads to

$$\ln(1 - v_{2m}) + v_{2m} + \chi v_{2m}^2 = -\left(\frac{\partial \Delta A_{\mathrm{el}}}{\partial \lambda}\right)_{T,p}\left(\frac{\partial \lambda}{\partial n_1}\right)_{T,p} (\mathrm{RT})^{-1} \tag{93}$$

where v_{2m} is the volume fraction of polymer at swelling equilibrium. The interaction parameter χ_1 may be determined, for example, by vapor pressure or by osmometry measurements (145,175–178). It depends on the concentration of polymer in the polymer–solvent system (175). Using the Flory–Erman expression for the elastic energy and assuming the parameter κ to be independent of swelling (isotropic swelling does not change the relative topology of the network), equation (93) (with the left-hand side abbreviated as H) becomes

$$H = -(\xi/V_0)V_1 v_{2m}^{1/3}\left[1 + (\mu/\xi)K\left(v_{2m}^{-2/3}\right)\right] \tag{94}$$

The molecular weight M_{c} between cross-links of a perfect network is then obtained by combination of equations (48),(49), and (94), with $v/V_0 = \rho/M_{\mathrm{c}}$:

$$M_{\mathrm{cr}} = (2/\phi - 1)\rho V_1 v_{2m}^{1/3}\left[1 + (\varphi/2 - 1)^{-1} K\left(V_1 v_{2m}^{-2/3}\right)\right]/H \tag{95}$$

where the subscript r is employed here for real networks.

For a network deforming affinely, $\kappa = \infty$, $K(\lambda^2) = 1 - \lambda^{-2}$, and

$$M_{\mathrm{ca}} = -\rho V_1 v_{2m}^{1/3}\left(1 - 2v_{2m}^{2/3}/\phi\right)\Big]/H \tag{96}$$

For a phantom network, $\kappa = 0$, $K(\lambda^2) = 0$, and

$$M_{\mathrm{cp}} = (2/\phi - 1)\rho V_1 v_{2m}^{1/3}/H \tag{97}$$

Determination of the Degree of Cross-linking by Stress–Strain Measurements and by Swelling Equilibrium

Characterization of network structures is often the main objective of theoretical and experimental works in the field of rubber elasticity (179–183). Simple experiments such as swelling equilibrium have been extensively used. However, most of the experimental swelling results on cross-linked polymers have been interpreted using the Flory–Rehner expression for an affinely deforming network (6,184–186).

The modern theory of real networks now permits a more accurate determination of network structures through use of equations (84),(87), and (95) (187–204). Stress–strain measurements can be analyzed as shown in Figure 17. The phantom modulus thus determined leads to ν and M_c through equations (75) and (76) (189). Swelling equilibrium data are similarly analyzed through equation (94), with the parameter κ given by equation (87) (189).

If M_c and κ have been determined previously from stress–strain measurements, then the interaction parameter χ_1 may be calculated through equation (95) (187,190).

Entanglements

Entanglements have been introduced in the later Flory–Erman theory as constraints that restrict junction fluctuations. Another viewpoint considers entanglements to act as physical cross-links, being based, in part, on the observation that linear polymers of high molecular weight exhibit a storage modulus $G'(\omega)$, which remains relatively constant over a wide range of frequencies ω (205). This plateau modulus G_N^0 is independent of chain length for long chains and is insensitive to temperature. Since it varies with the volume fraction of polymer in concentrated solutions, it could be due to pair-wise interactions between chains (20), and a universal law has been proposed for the dependence of G_N^0 on the chemical structure of the polymer (206). During the cross-linking process, some of such interactions or entanglements could be trapped in the network and act as physical junctions. This conclusion has been tested by irradiation cross-linking of already deformed networks (207–209), and then measuring the dimensional changes.

In the simplest phenomenological approach for rubber-like elasticity of trapped entanglements at small deformation (210,211), the shear modulus is taken to be the sum of two terms:

$$G = G_c + G_e T_e \tag{98}$$

where G_c is the contribution of the chemical cross-links. Taking into account the restrictions of junction fluctuations, as in the Flory theory, leads to

$$G_c = (\upsilon - h\mu)RT \tag{99}$$

in which the empirical parameter h was introduced (153). Its value, between 0 (affine) and 1 (phantom), characterizes the nature of the networks at small deformation; h can also be expressed as a function of the Flory parameters κ and ζ (155,212). The additional contribution $G_e T_e$ is said to arise from permanently trapped (interchain) entanglements in the network. The modulus G_e is thought to have a value close to G_N^0, and T_e, the "trapped entanglement factor," is the probability that all of the four directions from two randomly chosen points in the system, which may potentially contribute an entanglement, lead to the gel fraction.

The idea of entanglements acting as physical junctions was originally developed in the literature to explain deviations from the predictions for affine networks (185,213). The possibility of a contribution at equilibrium caused by trapped entanglements has been tested with model networks, ie, those prepared in such a way that the number and functionality of the cross-links are known. A

typical, highly specific reaction used for this purpose is the end-linking of functionally terminated polymer chains. Specific examples would be hydroxyl-terminated or vinyl-terminated chains of poly(dimethylsiloxane), $-[Si(CH_3)_2O]_x-$, end-linked with an organic silicate or silane (214,215). A considerable body of published data has, in fact, been interpreted as proving the existence of a trapped-entanglement contribution in this kind of network (216–222). Typically, the network characteristics, eg, number of chains and junctions, extent of cross-linking reaction p, trapped entanglement factor T_e, and effective functionality ϕ_e, were calculated by the branching theory after measurement of the network sol fraction. The main assumption of this probabilistic method is that the sol fraction, after subtraction of the amount of nonreactive species as determined by gel permeation chromatography analysis (218), is composed only of primary reactive chains (223). On the contrary, however, the sol fraction is a complicated mixture of reactive, unreactive, reacted, and unreacted molecules. For example, simulation of nonlinear polymerizations has shown that about half of the sol molecules are (reacted) cyclics (224). Their presence indicates that the value of the extent of the cross-linking reaction, formerly calculated with the assumption that the sol fraction is composed of nonreacted reagents, has to be significantly increased. As a result, many model networks can be considered as nearly perfect. This casts some doubt on the results interpreted as showing an entanglement contribution at equilibrium. If these networks are considered as perfect, such a contribution does not seem to be important (155,225). Entanglement contributions have been reported for polybutadiene (153) and ethylene–propylene copolymer (154) networks prepared by radiation-induced cross-linking. Again some doubt exists on the method used to characterize the network structure.

Molecular models treating entanglements as interstrand links that are free to slip along the strand contours have been developed (226–228) and tube models have been investigated (229,230). These approaches have been reviewed in Reference 27.

The question of entanglements is still controversial. It has been postulated (160) that an entanglement cannot be equivalent to a chemical cross-link. Contacts between a pair of entangled chains are transitory and of short duration owing to the diffusion of segments and associated time-dependent changes of configurations. Such trapped entanglements as previously described are possibly of minor importance in equilibrium stress measurements.

ELECTRONIC PACKAGING

Introduction

Organic polymers are widely used as structural materials and as processing aids in the electronics industry. The widespread use of polymeric materials in electronics is due to the ease in which desired engineering properties can be designed into materials by the manipulation of polymer structures and formulary compositions. In addition, the wide range of fabrication processes by which polymers can be formed into finished articles and the frequently lower fabrication costs of polymers compared to metals or ceramics have contributed to ubiquitous use of polymers in electronic assemblies.

The Electronic Packaging Hierarchy. Electronic packaging is broadly defined as the physical interconnection of electronic and electromechanical components to provide an enclosed system that provides for power and signal distribution, allows heat dissipation, and protects the components from the environment (1). Efficient construction and configuration of an electronic system is obtained through the packaging hierarchy (1) shown in Figure 1.

The first level of assembly begins with assembling one or more integrated semiconductor devices or "chips," each of which may contain millions of transistors fabricated in multiple layers of active devices, insulating layers, and metal interconnection layers (2), into a discrete module or *first level package*. The goals of first level packaging are to provide reliable electrical connections between the devices on one or more chips and the external metal conductors on the package, protect the delicate chip from the environment, and provide electrical and mechanical connection to the next level of assembly. High humidity, salts, certain gases such as the oxides of nitrogen and sulfur, radiation, static electrical discharges, and mechanical shock are all common environmental stresses that are harmful to

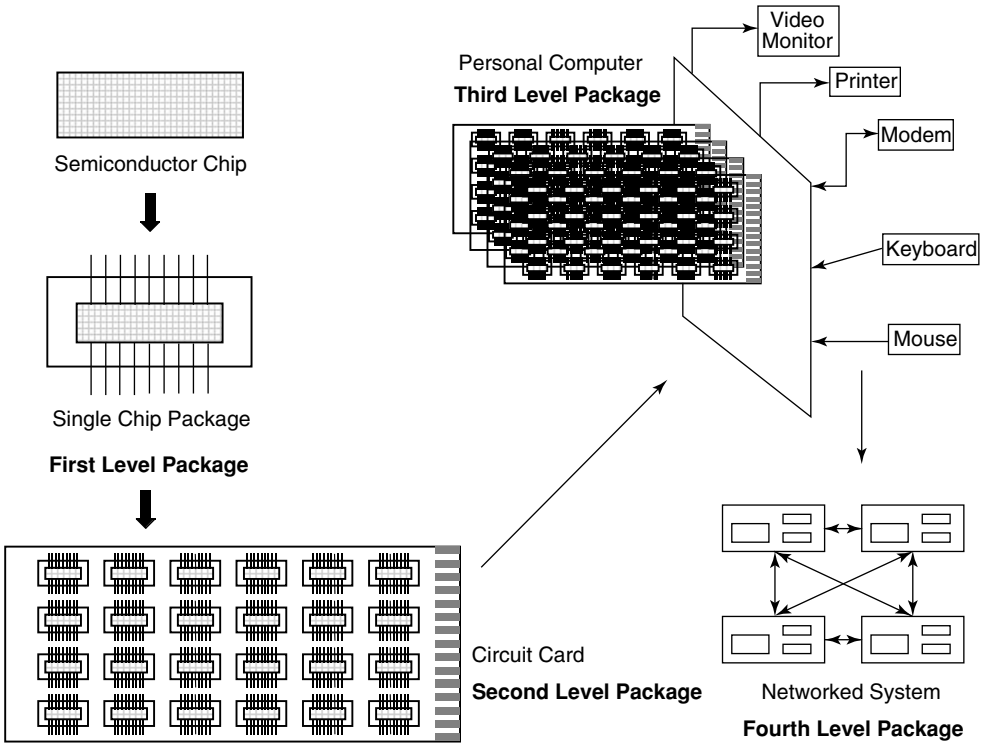

Fig. 1. The electronic packaging assembly hierarchy.

integrated circuits. First level packages are attached to a substrate or *second level package* bearing metal conductors that provide interconnections between the first level components. The most familiar example of second level packages is the ubiquitous fiber glass-epoxy laminate circuit board found in a wide range of consumer electronics and computer systems. Second level packages often have a defined, modular function such as memory cards, disk drive controller cards, and video cards. In other instances, the second level package is a system and is mounted in a protective case to produce a modular component that is used directly, for example, an automotive ignition module or the electronics of a consumer product such as a cellular telephone. A group of second level packages are frequently assembled on a larger card, termed a "motherboard" or "backplane" and the resulting assembly is housed in a cabinet or case. This assembly produces a *third level package* that provides electrical interconnection between cards and other board or cabinet mounted components such as power supplies and disk drives and provides connectivity to input devices, such as a keyboard and mouse, to output devices, such as printers and video monitors, and to input–output devices such as modems. An easily recognizable third level package is a personal computer. *Fourth level packages* are obtained through interconnection of third level systems to provide more complex systems such as the familiar office network or large mainframe computer system.

Electronic packaging makes use of a wide variety of polymer material classes to fulfill a diverse range of engineering uses. Table 1 provides a segmentation

of commonly used polymeric materials by engineering use and polymer class (3,4).

Polymers in First Level Packages

One of the most common and recognizable first level packages is the plastic dual in-line package (DIP) as shown in Figure 2. This package provides a convenient case example for further discussion of the polymers and polymer processing used in first level electronic packaging.

The sequential assembly (Fig. 3) of a DIP (1) begins by attaching the chip, which often bears a top-side polymeric passivation or *stress buffer coating*, to a metal lead frame substrate by using a *die attach adhesive* formulation. A linear array of aluminum alloy contacts or bond pads are arranged along the periphery of the chip. Typical bond pads are squares with dimensions in the 50–200 μm range and are the termini for the internal chip wiring. The bond pads are connected to contact points on the lead frame by 25–50 mm diameter gold or aluminum wire using ultrasonic, thermocompression, or thermosonic bonding (5). The wire-bonded lead frame-chip assemblies are then loaded into cavity molds and a molten, *encapsulation resin* composition is transferred into the mold under heat and pressure. Assembly is completed by applying lead finish plating, marking component identifying information on the package, singulating the packages, forming the leads into the required geometry by precision bending, and final packing for shipment to the second level package assembler. The single-chip plastic package appears in a variety of sizes and pin counts, depending upon the chip size, the number of leads required to connect the chip, and the amount of space allocated on the circuit board for the package (Fig. 4). For example, the DIP was designed for insertion into plated-through holes on a circuit board while the

packages shown in Figure 4 were designed for surface mounting to a circuit board. Surface mounting technology, or SMT, allows internal board space to be used for routing connections and reduces the board size by eliminating the space needed for the plated-through holes. Package size reduction is a major industry trend and is driven by the space constraints imposed by personal electronic products such as cellular phones, laptop computers, and personal digital assistants. This trend has resulted in the recent development of several new package types with the

goal of obtaining package geometries that are as close as possible to the size of the chip itself. These technologies are collectively know as chip scale packaging or CSP (6).

Stress Buffer Coatings. The top or device surface of semiconductor chips is frequently coated with a polymeric passivation coating that acts as a protective stress buffer layer (Fig. 2b). While stress buffer coatings (SBCs) are applied in the last steps of the wafer fabrication process, they have been shown to provide several important benefits to packaged device yield and reliability (8–10) and are considered herein as packaging materials. The SBC protects the chip from mechanical damage during package assembly and provides a relatively soft and ductile material on the chip that prevents chip cracking from the shear stresses that occur during encapsulant molding. The SBC also provides a mechanism for distributing stress over the surface of the chip and greatly reduces chip failures due to locally high stresses. Shear stress at the chip surface can cause movement or sliding of the underlying metal lines chip, cracking in silicon oxide and silicon nitride passivation layers, and parametric shifts in the electrical characteristics of the chip (8). The incidence of stress-related failure modes are frequently higher in larger chips and packages because of the larger distances over which thermal stress can be developed. As a consequence, most current memory and logic devices use SBCs to improve the yield of packaged devices and to lower lifetime failure rates. Finally, SBCs provide a barrier to alpha-particle radiation, which can lead to soft errors (11) in the device.

Stress buffer coat films require film mechanical properties that result in strong, tough films that resist mechanical damage but are soft enough to absorb stress. Successful materials generally have an elastic modulus in the range of 2–4 GPa (290,000–580,000 psi), a yield strain of 5–10%, and a tensile failure strain of 25% or greater. The use of low modulus materials runs a risk of wire bond breakage due to creep. Film thermal stability is important in that the materials must be dimensionally stable at the process temperatures frequently required in latter process steps and must not outgas volatiles during these operations. This thermal stability requirement leads to a need for materials with a glass-transition temperature T_g of 260°C or greater, with some assembly processes requiring T_gs greater than 350°C. Silicon is a low expansion material with a coefficient of thermal expansion (CTE) of 3.2 ppm/°C. Because polymers typically have CTEs that are higher than the CTE of silicon, there is a significant CTE mismatch between the chip and the stress buffer coat, resulting in tensile coating stress that is large enough to bend or bow the chip. The extent of bow is largely determined by the thickness ratio of the coating to the chip, the magnitude of CTE mismatch, the coating thermal history, the elastic modulus of coating and substrate, and by the extent of in-plane coating shrinkage during cure (12). In general, the CTE of the SBC should be matched as closely as possible to the CTE of the package components with which it is adhered. The adhesion of the SBC to the chip must be exceptionally good so that delamination does not occur during package assembly or during the operational lifetime of the package. Finally, the SBC chemistry must promote adhesion to the encapsulating resin so that adhesion failures do not occur at the SBC–encapsulant interface.

Stress buffer coats are applied to semiconductor devices by two commonly used methods. The first method is termed “glob-top coating” and involves

dispensing a drop of polymer solution or neat resin formulation onto the chip after wire bonding. Multiheaded syringe systems that dispense material on many parts at once are commonly used for this purpose. The dispensed material is heated to cure the resin and to remove solvents. The second method is to apply the coating at the wafer level using standard wafer fabrication spin coating equipment. Materials applied at the wafer level by spin coating have largely replaced glob-top coating in the manufacture of many device types including large memory and logic devices, with small power devices remaining as the major application for drop-on coatings. This trend is due to the greater throughput of the spin coating process where hundreds of chips are processed at once on a single wafer and to the reduction in device mechanical damage that is obtained by applying the top coat prior to processing the wafers into packages.

Materials for Stress Buffer Coatings. Stress buffer coating formulations have been prepared using polymers from several classes including polyimides, polybenzoxazoles, polybenzocyclobutenes, and polysiloxanes. Polyimides are the most commonly used buffer coat materials, and commercial formulations are available from several suppliers. Polyimides offer several advantages as SBCs including high thermal stability, good dielectric properties, good chemical resistance, and excellent film mechanical properties. The adhesion of formulated polyimide materials to silicon oxide and silicon nitride is excellent as most materials feature chemical modifications designed to promote adhesion to these surfaces. Two types of modification strategies are used to improve adhesion: modification of the polymer backbone by incorporating siloxane-containing monomers or by adding adhesion-promoting additives such as aminosiloxanes. In addition, the processability of formulated polyimide products has greatly improved over the last 10 years and materials are available that have been optimized for high throughput on current semiconductor factory tool sets and process methods. Finally, commercial materials are available with low trace metal and halogen content demonstrating the maturity of the supply chain in providing electronic grade materials. As a class, polyimides have relatively high moisture absorbance which limits their use in some applications where stable dielectric properties or low tolerance for absorbed moisture are important considerations.

Structure–Property Relationships in Polyimides. Electronic polyimides are obtained from the polymerization of aromatic or aliphatic diamines with aromatic dianhydrides or derivatives of the dianhydrides. Table 2 provides selected physical properties of several structurally diverse polyimides derived from the monomer units shown in Figure 5. The thermal and mechanical properties of polyimide films are readily modified in a designed approach by selecting the dianhydride–diamine pairs needed to provide the desired film properties. An additional degree of property optimization may be obtained through the copolymerization of one or more dianhydrides with one or more diamines. In general, the selection of rigid monomers provides materials with a high modulus and high T_g and a low CTE while selection of monomers with flexible spacer groups, such as ether linkages, between the imide bearing aromatic rings provides materials with a lower modulus and lower T_g and a higher CTE, with copolymers demonstrating properties predicted by the rule of mixtures. While most aromatic polyimides are

not soluble in common solvents and must be processed using soluble precursors, solvent-soluble materials can be prepared using monomers that contain several flexible linkages, have strongly dissymmetric structures, or have bulky pendent groups.

Polyimide SBCs can be grouped into four classes based on both the chemistry of their precursors and the processing strategy used to pattern their coatings. These classes are polyamic acids, solvent-soluble polyimides, solvent-developed, photosensitive materials, and aqueous-base developed, photosensitive materials.

Polyamic Acids. Polyamic acids are commonly prepared by the step-growth polymerization of one or more aromatic dianhydrides and one or more aromatic or aliphatic diamines in *N*-methylpyrrolidinone (NMP) solvent to yield 15–25% solids solutions which are typically used without isolation of the polymer. While numerous polyamic acids have been reported in the literature (18,19), only a few are in common use in stress buffer formulations as many of the monomers reported in the literature are not available in commercial quantities. Special care must be taken to use the purest materials available so that the product is free of metallic and organic contaminants, especially surface-active materials, that may cause coating defects or lead to poor adhesion. The polymer molecular weight may be controlled by conventional methods, either by adjusting the stoichiometry of the reactants (20) or by using monofunctional anhydrides or amines to limit chain growth. Molecular weight control is of great importance because the mechanical properties and thermal stability of the cured film are functions of molecular weight (21) and because the thickness of the spin-coated film depends on both the viscosity and the solids loading of the polymer solution. The need for

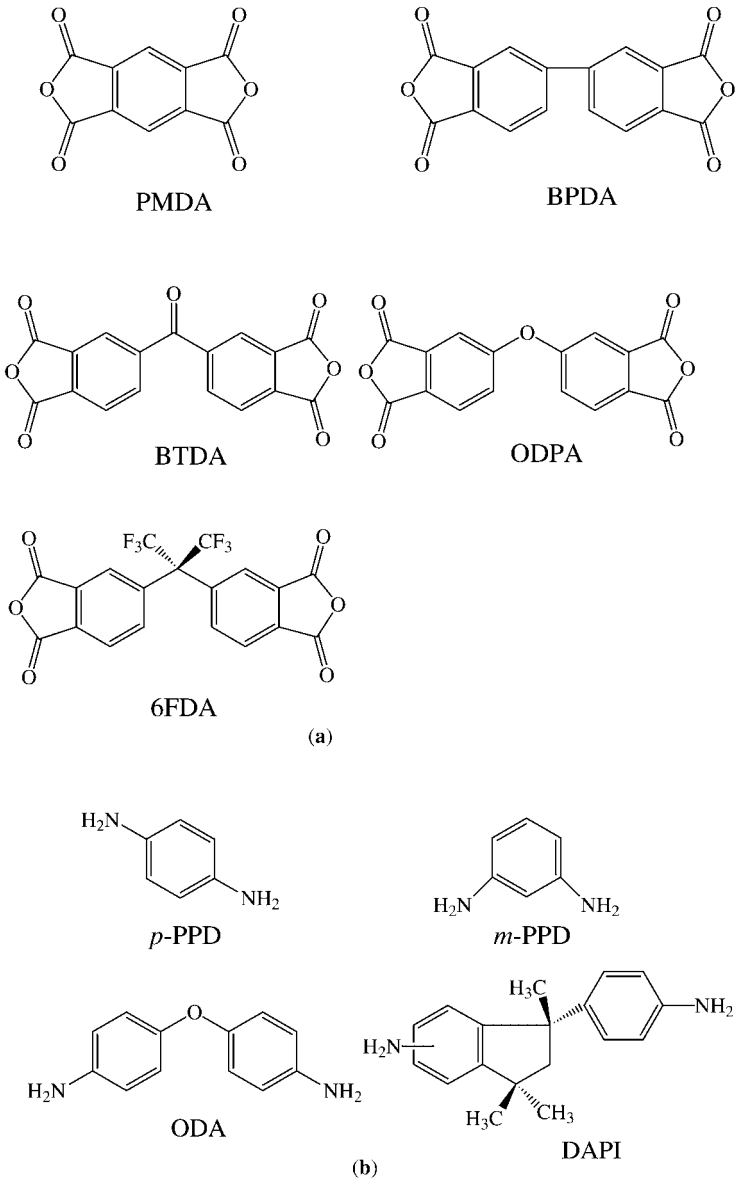

Fig. 5. The chemical structures of some common aromatic dianhydride (**a**) and aromatic diamine (**b**) monomers used in the synthesis of electronic-grade polyimides.

control of these parameters is demonstrated by Figure 6 which shows plots of spin coat film thickness vs solution solids content and the relationship between solids content and viscosity obtained from measurements on a PMDA–ODA polyamic acid solution. Prior to use, polyamic acid solutions must be filtered to remove particulate matter to prevent film defects that will cause problems in subsequent processing.

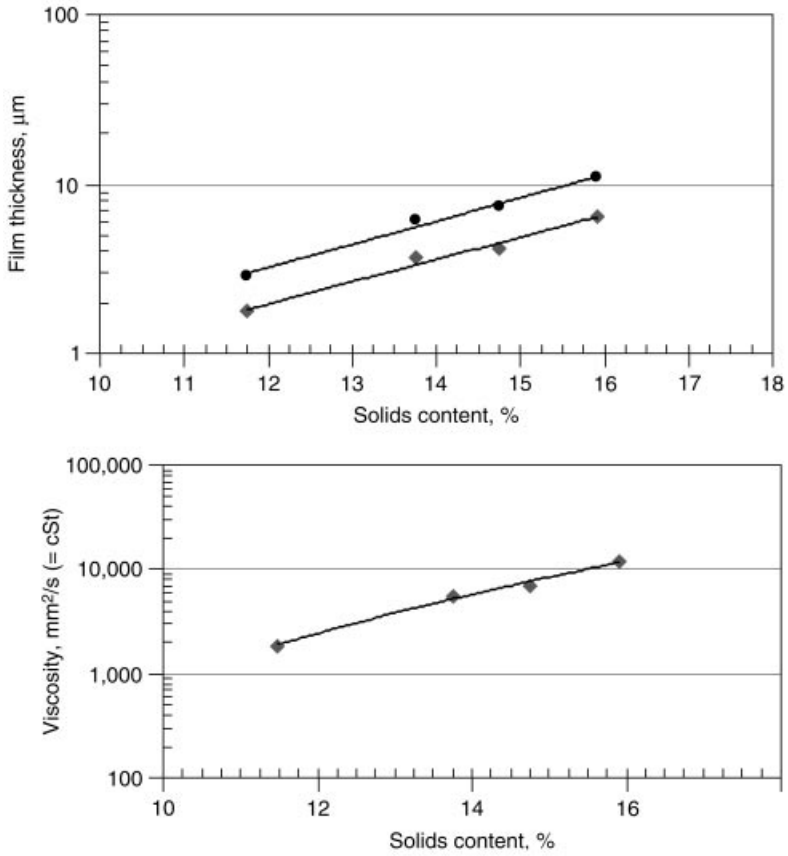

Fig. 6. (**a**) Relationship between film thickness and solution solids content. (**b**) Relationship between solution viscosity and solution solids content.▪, Cured thickness;▫, Soft baked thickness. Data are from a PMDA–ODA polyamic acid solution.

The polyamic acid film is prepared by spin-coating the solution on a wafer and then baking the wet film at 85–150°C on a hot plate to yield a tack-free film that can be handled by automated wafer handling equipment without perturbing the coating thickness. Imidization or "curing" of the polyamic acid film to form a polyimide film is completed by heating the polyamic acid to temperatures ranging from 250 to 400°C in a nitrogen atmosphere, resulting in cyclodehydration and evaporation of solvent (Fig. 7).

In order to permit wire bonding, openings must be patterned through the SBC so that metallurgical contact can be made with the aluminum pads on the device. The required openings are readily patterned in polyamic acid films using a photolithographic, bilayer patterning and base etch process (22,23) (Fig. 8). In this process, the polyamic acid solution is dispensed onto the center of a rotating silicon wafer using a metering pump. After dispensing is complete, the wafer is accelerated to a higher speed and then held at constant speed for 20–30 s. The wafer is then moved to a programmable hot plate and "soft-baked" at temperatures ranging from 85 to 150°C to yield a tack-free film with a coating thickness and etch

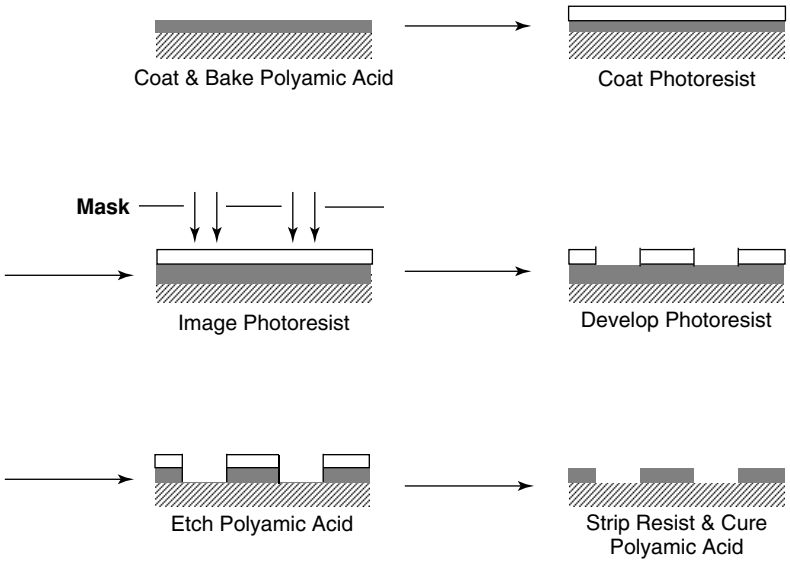

Fig. 8. Bilayer process for patterning polyamic acid films.

rate defined by the soft bake time and temperature program. This process results in a coating of defined thickness and, if the process is optimized, film thickness variation is less than 2% of the film thickness. The dried and partially imidized polyamic acid film is then coated with a resist layer formed by spin coating and baking a diazonapthaquinone-novalac photoresist film (24) on the polyamic acid film. The photoresist is imaged by exposure to uv light through a photomask (25). Treatment of the exposed resist with an aqueous hydroxide base solution such as tetramethylammonium hydroxide develops the latent resist image and yields a positive-tone relief image of the mask. The development process is then allowed to continue, resulting in an isotropic etch that transfer the resist relief image into the

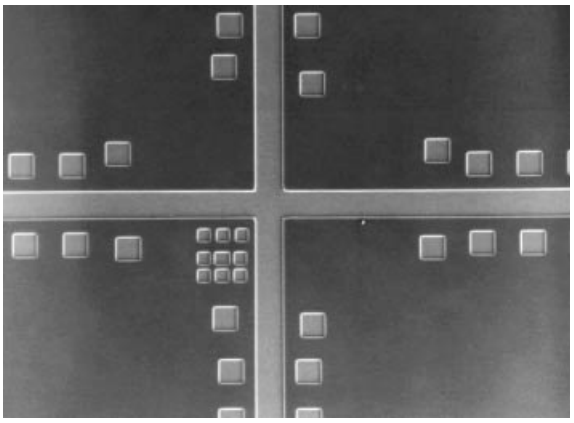

Fig. 9. A stress buffer coat pattern formed in PMDA–ODA polyamic acid using the bilayer process shown in Figure 8. Courtesy of Arch Chemicals, Inc.

polyamic acid film by solubilizing the polyamic acid through the combined effects of soluble salt formation and chain hydrolysis. Next, the photoresist film is removed by dissolving the resist in a solvent, such as acetone, that is compatible with the polyamic acid film. The process is completed by heating the film at 300–400°C, which completes the imidization reaction and removes the water of imidization and residual solvent. Figure 9 shows a photograph of a patterned film where the small square features are bond pad openings and the large open lines or "dicing streets" are formed to allow passage of the diamond saw blade used to singulate chips from the wafer without blade fouling from adhered polymer.

The polyamic acid patterning process described above has been used for many years. However, the process has several drawbacks. First, the number of process steps involved reduces process throughput, produces a significant amount of waste, and increases the possibility of process defects. Second, pattern resolution is limited to a maximum feature width that is about 50% of the polyamic acid film thickness. Third, processing polyamic acid films greater than 10 μm in thickness is difficult owing to thickness uniformity in spin-coating polyamic films to film thicknesses greater than 10 μm in one coating operation and to chipping of the resist etch mask during long etch times which causes defects in the pattern. Finally, the process etch rate is sensitive to the bake temperature and time used to set the polyamic acid film which can cause reproducibility problems in etch rate. In consequence, the dimensional tolerances of the pattern are affected resulting in a deviation, or bias, from the mask dimensions.

Electronic grade polyamic acid products are available from several supplies including Arch Chemicals, Inc., HD Microsystems, and Toray Industries. Commercial materials are generally formulated to provide reproducible coating thickness over a certain range of coating thickness or spin speeds.

Solvent-Soluble Polyimides. Materials in this class are also termed "preimidized polyimides" because the film-forming polymer is a polyimide rather than a polyimide precursor such as a polyamic acid. Thus, the curing process for these materials involves only removal of solvent. In some instances, a high

temperature post-cure above T_g can be used to cross-link the polymer and impart increased resistance to solvents. The best known examples are polyamide-imides prepared by the step condensation of 4,4′-methylenebis(phenyl isocyanate) with trimellitic acid (26), polyimide–siloxanes, and polyimides derived from trimethylphenyl diaminophenylindane (DAPI) monomers (15,27,28). Use of these materials for stress buffer applications is generally restricted to glob-top applications. However, the materials may be spin-coated and patterned using a hard mask etch process. The hard mask process is an extension of the bilayer process in which a layer of oxygen plasma etch-resistant material, such as aluminum or silicon dioxide, is coated on the cured polyimide film prior to applying the photoresist. The resist is applied and imaged as usual resulting in a positive relief image over the hard mask. Next, the hard mask is patterned using a plasma or wet chemical etchant that is selective for the hard mask material. The process is completed by transferring the pattern into the polyimide film using a oxygen reactive ion etch process followed by removal of the resist and hard mask. This process is seldom used as it is even more time consuming and expensive than the bilayer process. However, the process has an important advantage in that it can be used to define very high aspect ratio structures and it is generally applicable to a wide variety of polymers. Commercial examples of solvent-soluble polyimide include the Durimide™ 32 and Durimide™ 200 series materials (Fig. 10) available from Arch Chemicals, Inc. (29).

A compilation of commercially available nonphotosensitive stress buffer coat materials is shown in Table 3 (29–34). Table 4 provides selected physical data for some of the materials shown in Table 3.

Solvent-Developed Photosensitive Materials. Many of the limitations of the bilayer polyamic acid process have been overcome through the use of photosensitive polyimides (9). Formulated photosensitive products have been developed that result in improved process capability resulting in increased pattern resolution, improved soft bake time and temperature process latitude, and improved lithographic process latitude and throughput while maintaining desired film physical properties. Moreover, the film patterning process requires fewer steps

resulting in reduced costs and increased yields. Consequently, photosensitive materials are rapidly replacing polyamic acids as SBC materials.

Two approaches for the synthesis of photosensitive polyimide precursors are in common use today. The first approach was pioneered at Siemens (35–37) and is based on polyamic acid esters wherein the ester group is a radiation cross-linkable group such as 2-hydroxyethylmethacrylate (Fig. 11). Materials based on the ester chemistry are often described as "covalent-type" photosensitive polyimides. The second approach, developed by Toray Industries, involves combining a polyamic acid solution with a tertiary amine bearing radiation cross-linkable groups (38) (Fig. 12). The tertiary amine forms a salt with the polyamic acid and the resulting ionic interactions are of sufficient strength to provide solubility discrimination in the imaging process. Materials based on the amine salt chemistry

are commonly referred to as "ionic-type" photosensitive polyimides (39). The ionic approach provides the additional advantages of a simple synthesis starting from polyamic acids. Material suppliers have made steady improvements during the last 15 years, resulting in formulations with improved lithographic performance and final film properties (40–42).

Following exposure to uv light, both the covalent- and ionic-type materials undergo photoinitiated radical cross-linking reactions between the ester groups. This reaction provides the differential solubility between the exposed and unexposed area of the film that is necessary for forming relief images (Fig. 13). The photoinitiated cross-linking reaction of a 2-hydroxyethyl methacrylate polyamic ester bearing a ^{13}C label at the methacrylate β-carbon has been studied using a solids nmr method (43). The nmr spectra showed that the percentage of methacrylate groups reacted varied with exposure dose and processing conditions.

Photosensitive precursor polymers are formulated in a suitable solvent such as *N*-methylpyrrolidinone or γ-butyrolactone with a radical photoinitiator and a variety of additives such as glycol acrylates to improve image contrast and photospeed; functionalized silane coupling agents to improve adhesion of silicon and silicon nitride; photosensitizers to improve photosensitivity; substituted phenolic stabilizers to improve formulation working life and storage stability; and leveling agents to improve coating quality and uniformity.

The single-layer imaging process for photosensitive polyimides is represented in Figure 14, which, in comparison to Figure 8, clearly shows the simplification of the patterning process compared to the polyamic acid etch process. Because the solubility of the exposed film is less than the solubility of the unexposed film, the relief image is a negative image of the mask. In contrast to the bilayer polyamic acid etch process, the single-layer photosensitive process readily provides images with a pattern aspect ratio of 2:1, and if care is taken, resolution can be extended to an aspect ratio of 3:1. Because of their decreased

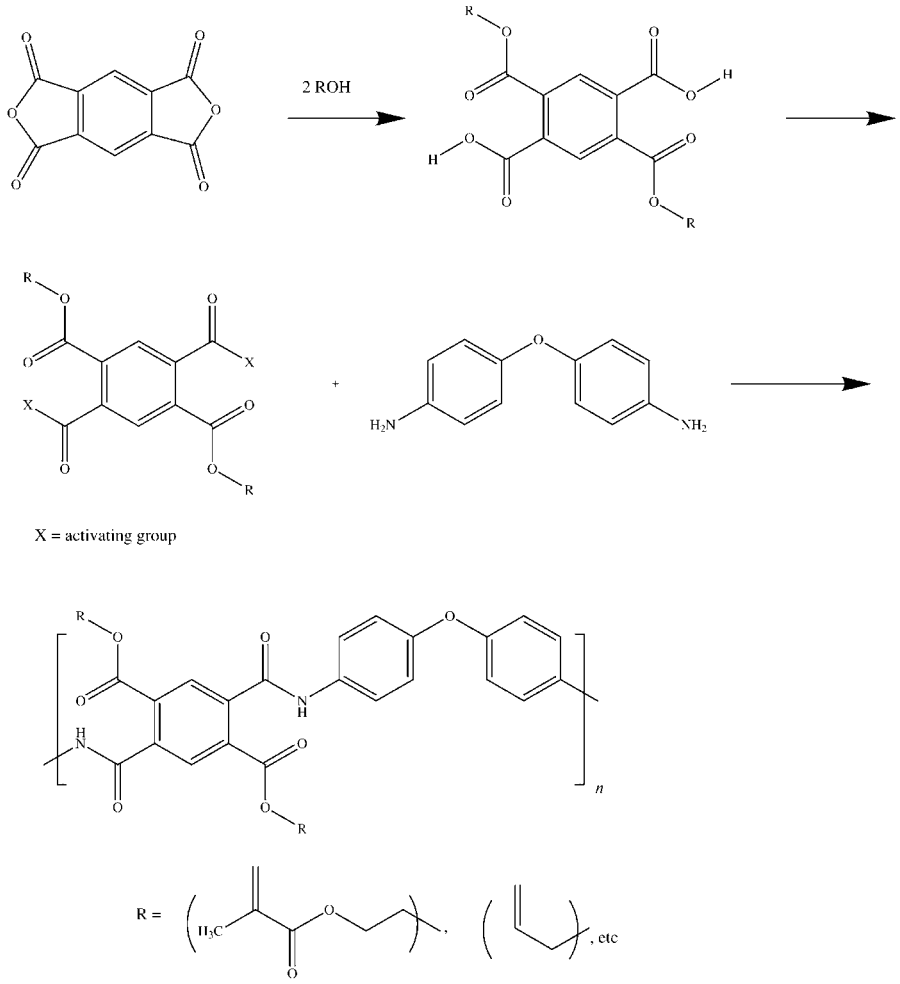

Fig. 11. Synthesis of a covalent-type photosensitive polyimide precursor based photoreactive polyamic esters.

hydrogen bonding compared to polyamic acids, photosensitive polyamic esters are particularly suited to the processing of thick films as their solutions have lower viscosities than polyamic acids at equivalent molecular weights and solids loading. Thus, high solids content solutions that are suitable for casting thick films can be formulated at viscosities suitable for spin coating. Robust patterning processes have been demonstrated in 50-μm thick films which yield 25-μm thick films after curing (44). Recently, detailed characterization studies on the lithographic process latitude of covalent-type materials processed using modern, stepper exposure tools have been reported (45,46). Figure 15 shows some examples of relief structures patterned in a photosensitive polyamic ester film. The process is completed by curing the imaged polyamic ester at 300–400°C in an inert atmosphere, which results in imidization with the loss of the photoreactive groups as volatile products (Fig. 13). The imaged film shrinks by 40–50% in thickness

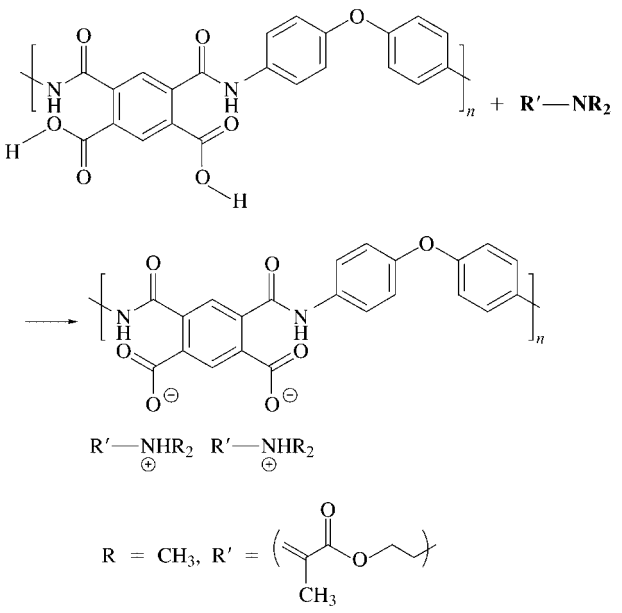

Fig. 12. Synthesis of an ionic-type photosensitive polyimide precursor based on tertiary amine-polyamic acid salts containing photoreactive groups.

during the curing process, leading to cured film aspect ratios ranging from 1.0 to 1.5.

Autophotosensitive, preimidized polyimides (Fig. 16) represent a third approach to negative tone materials and are based on the inherent photosensitivity of polyimides containing benzophenone tetracarboxylic dianhydride (BTDA) derived segments together with ortho-alkyl-substituted diamine segments (47). The photochemical basis for imaging is believed to be radical cross-linking initiated by a benzophenone ketyl radical to yield cross-linked photoproducts (48,49). The most interesting feature of these materials is that they do not require formulation with the photoinitiators, photosensitizers, contrast enhancing agents, and stabilizers commonly found in the additive packages used in the formulation of covalent- and ionic-type materials. Accordingly, films prepared from autophotosensitive materials show substantially less shrinkage during cure than do covalent or ionic materials (26). However, autophotosensitive materials have not been extensively used in SBC applications because of their low photosensitivity and long developing times as compared to covalent and ionic materials. Commercial examples of autophotosensitive materials are the Probimide® 400 series from OCG Microelectronic Materials and the Ultradel® 7500 series from Amoco.

A separate group of negative tone materials based on the thermal polymerization of benzocyclobutenes (BCB) has been developed by the Dow Chemical Co. (50,51) and have been used as SBCs (52). The chemistry is based on the *in situ* generation of reactive, ortho-quinodimethane dienes that undergo facile polymerization to form a thermoset network (Fig. 17). The physical properties of the materials can be tailored by modification of the connecting group X. One such modified

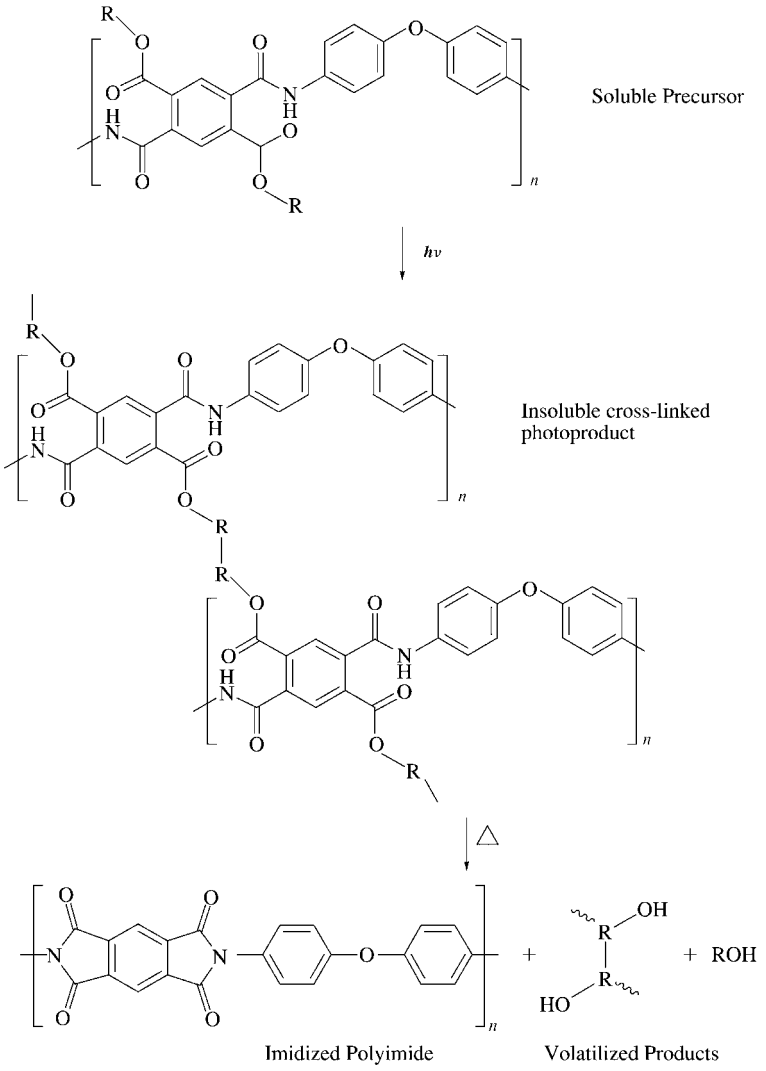

Fig. 13. Photochemical cross-linking of a covalent-type photosensitive polyimide precursor.

monomer is divinylsiloxane-bis-benzocyclobutene (DVS-bis-BCB). Photosensitive formulations are obtained by combining B-staged, or partially polymerized DVS-bis-BCB, with aromatic bisazide compounds in solvent. Such formulations can be spin-coated and are processable using the negative tone process described in Figure 14. Processing of the patterned films is completed by heating to convert the photocross-linked, B-staged film into the cured thermoset. BCB derived films have attracted much interest in electronic packaging owing to their low dielectric constants and low moisture uptake. The BCB materials are marketed under the trade name Cyclotene®.

Aqueous-Developed Materials. During the last 5 years, aqueous developable materials have been introduced as a new class of photosensitive SBCs. Development of these materials is an area of intense current activity and is driven by industry needs for materials with improved cost of ownership and improved compatibility with semiconductor factory process strategies and materials. One of the drawbacks of most negative tone materials is that they require organic solvents for image development. Organic solvents impose a significant cost penalty on semiconductor factories for several reasons. First, high purity, electronic grade solvents are expensive to purchase. Second, standard process equipment must be modified to allow the safe use of solvent sprays, and the modified equipment is not generally usable for other coating processes such as positive photoresists. Many factories must obtain VOC emission permits to use solvent-processed materials.

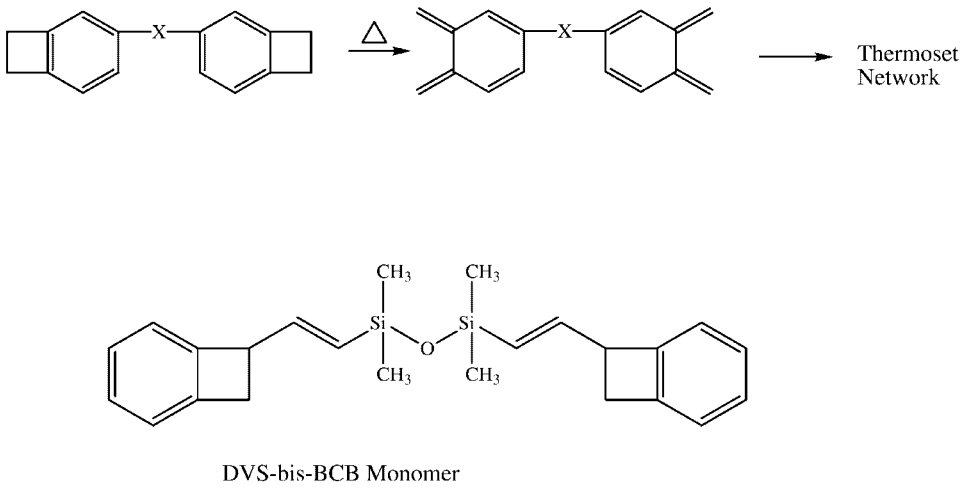

Fig. 17. The benzocylcobutene cure reaction and the structure of DVS-bis-BCB monomer.

Finally, factories must collect and segregate spent solvent waste as a separate waste stream and thus incur additional cost. These cost of ownership issues are substantially decreased through the use of aqueous, metal-ion free developers based on tetramethylammonium hydroxide which are the semiconductor industry standard for developing positive photoresists.

Both negative and positive tone aqueous developable materials have been introduced. Negative tone materials have been derived from the covalent-type polyamic ester precursors through the use of additives that enhance solubility of the unexposed film in aqueous developers (53). Positive tone materials are based on either polyamic ester precursors containing carboxylic acid (54) or phenolic oxygen substituents (55,56) or on aromatic poly(ortho-hydroxyamides) as precursors to polybenzoxazoles (57,58), a class of high temperature stable, heterocyclic polymers with thermal and mechanical film properties similar to polyimides (Fig. 18). In both approaches, the acid–base reaction of the phenolic or carboxylic

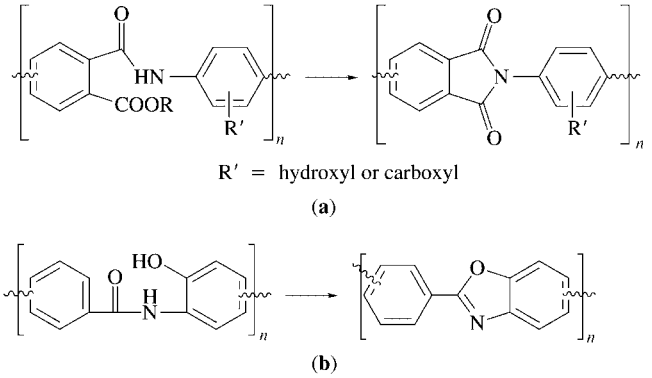

Fig. 18. Generic structures of positive tone, aqueous processable precursors for polyimide (**a**) and polybenzoxazole (**b**) based materials.

substituents with base provides the mechanism for solubilizing the precursor in an aqueous developer. When formulated with diazonaphthaquinone-containing photoactive compounds (DNQ-PACs), the resulting formulations function as positive photoresists. The DNQ-PAC inhibits the solubility of the precursor polymer in base. When the DNQ-PAC is exposed to uv light, the DNQ moeity undergoes a formal Wolff rearrangement to form a ketene as the primary photoproduct which undergoes reaction with environmental water to form an indene carboxylic acid derivative (59). The indene carboxylic acid photoproducts increase the dissolution rate of the exposed film relative to the unexposed film. Thus, the photolithographic contrast of the system is obtained from the dissolution rate difference between the unexposed and exposed films (Fig. 19). Processing this class of materials retains the cost and simplicity benefits of the single-layer process used for solvent-developed negative tone materials and adds the benefit of positive tone imaging, which results in higher image resolution and a decreased sensitivity to pattern defects due to particles on the surface of the film (60).

Commercial photosensitive SBC formulations are available from several suppliers and provide a range of materials differentiated by wavelength photosensitivity, chemistry type, and film properties. A list of commercial photosensitive SBC formulations is shown in Table 5 (29,30,32,61–63). Table 6 shows a compilation of selected film physical property data selected from those listed in Table 5.

Die Attach Adhesives. After completion of SBC processing, the finished wafers are electrically tested and nonfunctional chips are marked for discard. It is a common occurrence that the wafer and fabrication packaging facilities are separate factories or even different companies and cassettes of wafers are routinely shipped from the wafer fabrication plant to the packaging plant for assembly. At the packaging plant, the wafers are first thinned using a grinding and polishing process that removes bulk silicon from the backside of the wafer. Substantial thickness reduction is necessary to allow assembly into the thin packages commonly used in board assembly. For example, a 200-mm wafer 725 μm thick is commonly thinned to a thickness of 250 μm and sometimes to as thin as 80 μm (64). The

SBC layer provides both protection and support during the thinning process. The thinned wafer is then mounted, with their active device side up, onto a tacky adhesive release tape fixed in a steel ring. The mounted wafer is then singulated or "diced" into chips using a high speed diamond wet saw. To allow for the cutting kerf, the blade passes between device boundaries known as "saw streets" that were established during wafer fabrication (see Fig. 9). In high volume factories, the processes of wafer thinning and singulation are highly automated assembly line operations.

After dicing, the chips are removed from the release tape using a vacuum tool, which then places the die onto the metal lead frame to which has been applied die attach adhesive material in the form of a paste or film. Most die attach adhesives in use today are formulated products based on epoxies, thermoplastic polyimides, or thermoplastics such as bismaleimides, polysulfone, polyphenylene sulfide, and polyesters. The polymers may be used separately or as blends. Die attach adhesives usually contain inorganic metal or metal oxide fillers that impart electrical and/or thermal conductivity to the adhesive bond, thus creating an electrical connection to the lead frame and improving package heat dissipation by allowing better heat transfer from the device to the lead frame. High speed, automated dispense equipment is used to dispense and place the adhesive with a

high degree of accuracy with a cycle time of 2 s per chip placement (65). The lead frames are then loaded into magazines and placed in ovens to cure the adhesive. Typical curing cycles are 1 h at 150°C for epoxy-based formulations and 30 min at 150°C followed by 30 min at 275°C for polyimide-based formulations. Rapid or "snap" curing materials are now available that can be cured in one minute and can thus allow integration of the adhesive cure process into the dispense line.

In addition to excellent adhesion, critical design considerations for die attach adhesives may be segregated into those involving processability, thermal properties, electrical properties (insulating or conductive), and thermal conductivity. The viscosity, thixotropic index, and working life are important parameters with respect to the dispense method used. Dispense methods include needle dispensing, stamping or pin transfer, and screen or stencil printing. Needle dispensing is the most common method and allows uniform deposition of material at high speeds. The glass-transition temperature, thermal stability, shear strength, modulus, and fatigue resistance of the cured adhesive determine the strength and stress characteristics of the bond. The choice of filler material determines electrical and/or thermal conductivity, and formulations are available with metallic fillers, such as silver and gold, to provide electrical conductivity, or with mineral oxides that provide thermal conductivity but are electrically insulating. Curing conditions are chosen to optimize the bond strength and physical properties of the adhesive while providing maximum efficiency of assembly. The most commonly used materials are silver-filled conductive epoxies. Because of steady improvements, manufacturers provide materials with optimized physical properties and processing characteristics. In recent years, low modulus materials have been developed for use with larger chips and great attention has been given to developing formulations with fast or "snap" cure chemistry that increase throughput through the assembly line by allowing adhesive cure to be integrated into the adhesive dispense line. A list of die attach materials and their formulation type is shown in Table 7 along with selected physical property data.

Encapsulation Resins. Encapsulation is the general process of surrounding the wire bonded chip with an electrically insulating material that protects the circuit from the environment, provides mechanical support for the chip lead frame assembly, and assists in conducting heat out of the package. Plastic encapsulation materials are in widespread use throughout the microelectronic industry and the majority of plastic packages are encapsulated using formulated epoxy molding compounds in a transfer molding process. In the molding process, lead frames are loaded into cavity molds and the mold halves are pressed together in a molding press. The molding compound charge is heated in a transfer pot until it is sufficiently soft to be transferred under pressure through the mold runners and gates into the cavities. The mold compound is then held for a short period of time in the heated mold to allow curing to proceed. The mold halves are then separated and the molded lead frames are ejected and loaded into magazines for post-curing in a batch oven for 1–4 h at 175°C. The objective of post-curing is to complete resin cure such that the optimal thermomechanical properties of the resin are obtained. Parameters that are critical to the success of the process include mold pressure, compound viscosity, transfer pressure, mold temperature, and the geometry of the mold.

additives		Reduce crack initiation	
		Reduce CTE	

[a]From Ref. 69.

Modern epoxy molding compounds are multicomponent formulations whose exact compositions are highly proprietary. However, most materials are variations on the general composition (69) shown in Table 8. Commercial formulation are carefully formulated to provide materials that adhere strongly to all interfaces; have thermal and mechanical properties optimized to minimize stress arising from thermal expansion mismatch between the encapsulant, lead frame, and chip; have low moisture absorbance; have low shrinkage during molding; and have processing characteristics that provide for good moldability and short post-cure times.

Early resin materials used in mold compound formulations were silicones, phenolic resins, and bisphenol-A or bisphenol-F epoxies. Because of shortcomings in performance, these materials have been displaced by epoxy phenol or cresol novalac resins (ECN resins) and by the biphenyl- and tris(triphenylmethane)-type epoxies (70) (Fig. 20). The high cross-link density of ECN-based materials results in low moisture absorption rate and higher thermal stability than

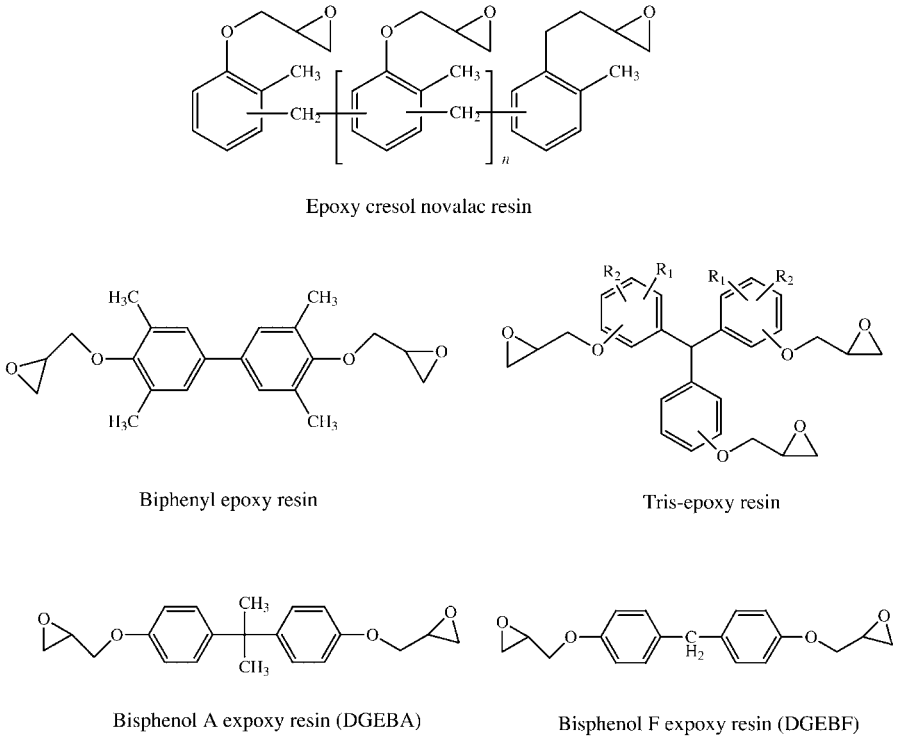

Fig. 20. General structures of epoxy resins used in semiconductor mold compounds.

bisphenol A epoxies. The choice of curing agent and cure accelerator not only determines the structure of the cured resin but also affects viscosity and reactivity. Anhydrides and amines are the most commonly used curing agents. *Accelerators* are catalysts that control the composition gel and cure times and can, as the case of Lewis acid catalysts, promote linear polymerization to form polyether linkages and thus modify the modulus of the resin by decreasing the number of network crosslinks.

Filler materials are used to modify resin properties and are essential components in obtaining desired encapsulant properties (71). The preferred filler material is ground, fused quartz which has a CTE of 0.5 ppm/°C. A silica filler loading of 68–70% reduces the CTE of the neat resin from 40–50 ppm/°C to 20–24 ppm/°C. Improved resins and spherical filler technology has allowed an increase in loading up to 85%, resulting in reduction of CTE to 10–15 ppm/°C. Decreased CTEs provide improved thermal stability and thermal-shock resistance during wide temperature fluctuations. Additional benefits of increased filler loading are increased thermal conductivity, reduced moisture absorbance, and reduced shrinkage during molding. While generally increasing the encapsulant elastic modulus, fillers decrease the flexural and tensile strength and do not usually provide significant enhancement to T_g or to package heat distortion properties. Filler size, shape, and loading determine the rheology of the molten encapsulant. Filler materials are treated with adhesion promoters to increase the adhesion of the resin to

the filler, resulting in improved encapsulant mechanical strength and decreased moisture absorption. Commonly used adhesion promoters include organosilanes and organotitanates. Stress-relief additives, such as silicones and acrylonitrile–butadiene elastomers, are often added to reduce the elastic modulus, improve toughness and flexibility, and lower the compound CTE (72). The final components added to the mold compound formulation are mold-release agents that aid in releasing the molded packages from the mold; flame retardants to reduce flammability; and coloring agents, generally carbon-black, that reduce device visibility and serve to distinguish one device type from another. Table 9 shows a listing of some commercial semiconductor molding compounds with selected physical data (73–76).

ELECTROOPTICAL APPLICATIONS

Introduction

The term *electrooptic* can have widely different meanings. In the broadest sense, it can imply any change produced in an optical beam by application of an electrical field from either a low frequency (dc to millimeter wave) field or another optical (micrometer wave) field. Change of the index of refraction of the material through which an optical beam is transiting can influence the (velocity of the) propagating optical beam. Such change of index of refraction can be accomplished by altering either the electron distribution or the nuclear configuration of a material. The associated optical phenomena are referred to as Kerr and Pockels effects (1–15) and have been known since the nineteenth century.

However, altering an optical beam by electrically controlled mechanical movement of a mirror (particularly as in micro-electro-mechanical-systems, MEMS) is also referred to as an electrooptic operation. Indeed, even greater confusion arises by usage of the terms electrooptic and all-optical signal processing in the telecommunications industry. Electrooptic is taken to refer to converting optical signals to electrical signals, carrying out signal processing in the electrical (electronic) domain, and then converting back to the optical domain. Thus, techniques such as bubble jet (Hewlett Packard/Agilent) and MEMS (Texas Instruments) optical switching at network nodes are referred to as all-optical signal processing by telecommunication engineers while an optical physicist would reserve the term all-optical switching for the dynamic Kerr phenomenon (switching of one optical beam by another).

A review of electrooptical applications in the broadest sense is out of the question. It would involve treatment of topics ranging from modulated lasers (direct modulation) to light-emitting diodes (LEDs), to liquid crystalline materials,

Encyclopedia of Polymer Science and Technology. Copyright John Wiley & Sons, Inc. All rights reserved.

not to mention MEMS, thermooptic, and bubble jet technologies currently used in telecommunications. Moreover, the literature is enormous. Over 1000 reviews and texts have appeared on the subject of liquid crystalline electrooptic materials alone. In this article, a narrow view of electrooptic phenomena, materials, and applications is taken and focus is upon the "electronic" Pockels effect, with emphasis on the phenomenon realized using polymeric or dendritic materials rather than inorganic or organic single crystals. The term *electronic* refers to changes in refractive index associated purely with electric-field-induced change of the electron distribution of a material (in contrast to changes in nuclear configuration associated with molecular reorientation). Moreover, there is a focus upon π-electron organic chromophores rigidly embedded in polymeric or dendritic supramolecular matrices. Currently, commercially utilized materials exploiting the electronic Pockels effect are inorganic crystalline materials such as lithium niobate. Although the most commercially viable organic electrooptic (defined in the broader sense) materials are liquid crystalline materials (16–58), electronic Pockels effect organic materials are receiving increased attention because of the possibility of exceptional (greater than 100 GHz) bandwidth performance. Although potential applications of such materials range from telecommunications to information processing, to defense, to transportation, and to display industries, the telecommunications and defense industries are particularly important drivers of development of electrooptic materials with greater bandwidths. Electronic Kerr materials (59–67) have the potential for even greater bandwidth and the possibility of convenient all-optical signal processing; however, to the present time electronic Kerr coefficients have not been large enough to be commercially viable for telecommunication applications. Mott–Hubbard transition-metal oxide and halide systems with charge-transfer gaps and low hydrogen-density organic materials such as the fullerenes and chromophore-containing dendrimers may hold future promise for all-optical switching at telecommunication wavelengths (eg, 1.55 μm) because of their large two-photon absorption coefficients (third-order optical nonlinearities) and their low optical loss. Inorganic Kerr materials such as titanium sapphire are currently used for mode-locked lasers and other applications.

Other reasons for heightened interest in organic electronic electrooptic materials include large electrooptic coefficients (greater than 50 picometers/volt (pm/V) at telecommunication wavelengths). Large electrooptic coefficients permit voltages from semiconductor electronics to drive electrooptic devices without the introduction of amplifiers. Amplifiers are undesirable because of their bandwidth limitations, noise figures, weight, bulk, and cost. Indeed, a major reason for increased commercial interest in organic electrooptic materials is that drive voltages of less than 1 V can be realized with simple broadband device structures (68,69). Such drive voltages permit lossless telecommunication links to be achieved and even permit realization of gain in electrical-to-optical-to-electrical signal transduction. Another attractive feature of organic electrooptic materials is facile integration with semiconductor electronics and silica fiber optics (70–74). In this article, both the state of development of organic electrooptic materials and the principles that define material performance are reviewed.

The reader is referred elsewhere for reviews of organic photorefractive materials (75–86) and of photochromic and optomechanical materials (87). Electronic electrooptic chromophores (such as charge transfer azobenzenes) have frequently

been used for such applications, but the response times of these phenomena and their conceptual basis are quite different from the phenomenon and applications discussed here. (See also CHROMOGENIC POLYMERS; LIGHT-EMITTING DIODES).

General Theoretical Principles

At the molecular level, the change in electron distribution (polarization) with application of an electrical field is given by

$$p_i = p_{0i} + \alpha_{ij}E_j + \beta_{ijk}E_jE_k + \gamma_{ijkl}E_jE_kE_l + \cdots \tag{1a}$$

where p_{0i} is the permanent polarization of the molecular site "i" and E stands for the local electric field strength. The tensors α, β, and γ are the molecular polarizability and molecular first and second hyperpolarizabilities. For macroscopic or bulk materials, the polarization equation is

$$P_i = P_{0i} + \chi^{(1)}_{ij}E_j + \chi^{(2)}_{ijk}E_jE_k + \chi^{(3)}_{ijkl}E_jE_kE_l + \cdots \tag{1b}$$

It is assumed that the electric fields in equations (1a) and (1b) have frequencies that are outside the domain of both electronic and lattice resonances of the system. If only one electric field is applied and it is in the form of a square wave pulse (of amplitude E_0), or an a-c field ($E_0 \cos \omega t$), or a d-c field (of amplitude E_0), then equations (1a) and (1b) lead to the following expression for refractive index n:

$$(1/n^2) = (1/n_0^2) + rE_0 + RE_0^2 + \cdots \tag{2}$$

where n_0 is the refractive index in the absence of the electric field. The linear and quadratic terms correspond to the Pockels and Kerr effects, respectively. The Pockels effect is observable only for noncentrosymmetric materials; the electrooptic coefficient r is related to the molecular first hyperpolarizability β and the noncentrosymmetric order parameter $\langle \cos^3 \theta \rangle$ by

$$r = 2\mathrm{Nf}(\omega)\beta\langle \cos^3\theta \rangle / n^4 \tag{3}$$

where N is the chromophore number density and $f(\omega)$ is a local field factor accounting for the dielectric nature of the medium (host material). The electrooptic coefficient r is related to the drive voltage required to effect electrical-to-optical signal transduction (with a Mach Zehnder interferometer) by

$$V_\pi = \lambda d/(n^3 \mathrm{rL}\Gamma) \tag{4}$$

V_π is the voltage required for a π phase shift of light passing through the arm of the Mach Zehnder modulator to which an electric field has been applied. The optical wavelength of the transiting light is given by λ, d is the gap between the electrodes used to apply the electric field, L is the interaction length of the

electrical and optical fields (electrode length in the simplest case), and Γ is a modal overlap integral. Equation (3) is greatly oversimplified as we have neglected the vectorial nature of the interaction of the fields, but this equation is frequently applicable to poled polymer materials.

From equations (2) and (3), it is readily seen that optimizing the drive voltage performance of electrooptic materials is a matter of optimizing β, N, and $\langle\cos^3\theta\rangle$. We shall proceed to discuss the optimization of these parameters and the status of organic electrooptic materials, but before we do this, it is important to indicate what additional material properties must be achieved for commercial viability. These can be briefly summarized as follows: (*1*) fast response time or high operational bandwidths, (*2*) low optical loss including both material loss and insertion (optical mode mismatch) loss, (*3*) good stability including thermal and photochemical stability, (*4*) good mechanical properties, (*5*) good processability and ease of integration with disparate materials such as silica fibers, semiconductors, and metals, and (*6*) low production cost. For polymers to displace alternative technologies such as modulated semiconductor lasers, lithium niobate electrooptic modulators, or gallium arsenide (GaAs) electroabsorptive modulators, they must exhibit competitive or superior performance characteristics in all material categories. Thus, in the following paragraphs, we consider auxiliary properties as well as electrooptic activity.

Electrooptic Activity

It is clear that optimizing electrooptic activity involves optimizing the molecular hyperpolarizability β of organic chromophores. Quantum mechanics has provided effective guidance for the improvement of molecular nonlinear optical (electrooptic) activity by several orders of magnitude in the past 10 years (88–97). If chromophores are aligned into a noncentrosymmetric (acentric) lattice by electric field poling and if the interactions among chromophores are neglected, then the order parameter becomes (in the high temperature approximation) $\langle\cos^3\theta\rangle = \mu F/5kT$, where μ is the chromophore dipole moment, F is the applied electric poling field felt by the chromophores, k is the Boltzmann constant, and T is the poling temperature (Kelvin). In this approximation, macroscopic electrooptic activity would be expected to increase as $\mu\beta$. As can be seen from Figure 1, $\mu\beta$ values have been systematically improved over the past decade from the value of the 1990 state-of-the-art material Disperse Red (DR). Indeed, if current chromophores could be organized into a pure chromophore lattice with perfect acentric order, $\langle\cos^3\theta\rangle = 1.0$, then electrooptic coefficients in excess of 1000 pm/V could be achieved. Such electrooptic coefficients would permit true millivolt drive voltages to be routinely employed. Such materials would greatly exceed the performance of lithium niobate ($r = 31$ pm/V, $V_\pi = 5$–6 V) and would likely displace liquid crystalline materials in applications such as spatial light modulation and optical switching. However, while the DR chromophore of Figure 1 exhibits an electrooptic coefficient of 10–15 pm/V and V_π voltages of 12–20 V, the FTC chromophore exhibits a surprising low electrooptic coefficient of 35–50 pm/V and V_π voltages of 3–5 V. Clearly, a problem existed/exists in translating large molecular electrooptic activity into usably large macroscopic electrooptic activity.

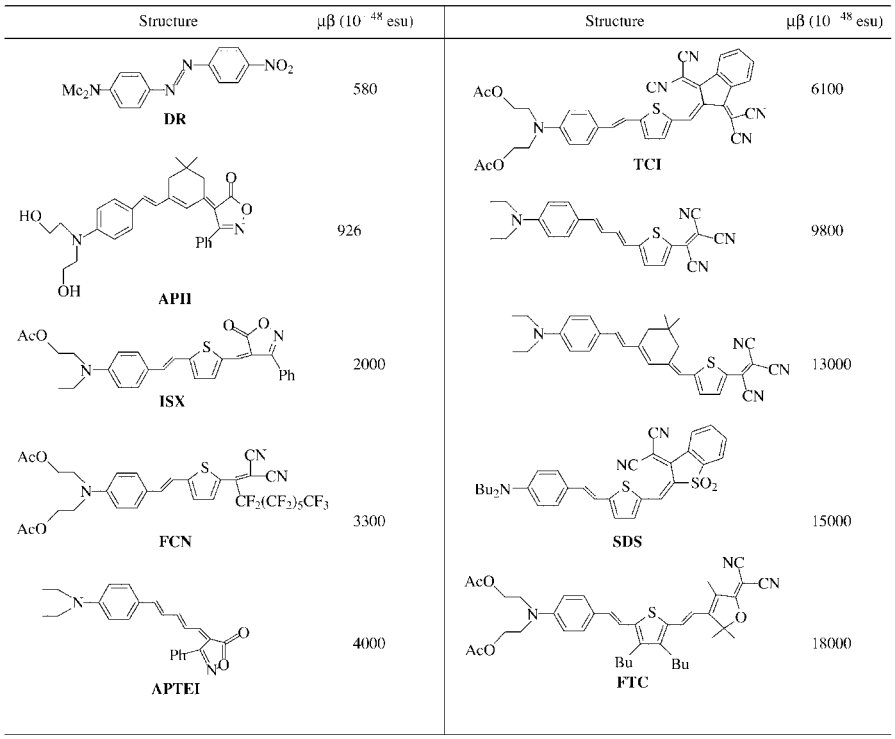

Fig. 1. The variation of $\mu\beta$ (dipole moment-first hyperpolarizability product) with chromophore structure is shown.

As is illustrated in Figure 2, the problem is now understood to derive from intermolecular electrostatic interactions among chromophores opposing the poling field in introducing the acentric order required for electrooptic activity (68,98–102). The same interactions oppose introduction of acentric order by sequential synthesis, self-assembly techniques where surface forces are used in place of a poling field to guide the assembly of chromophores into an acentric lattice (103). In this latter case, intermolecular electrostatic interactions cause the chromophores to tip away from the normal to the surface in their assembly. The problem has been successfully modeled using both equilibrium statistical mechanical methods and kinetic Monte Carlo methods, with both approaches specifically treating the many-body, long-range, spatially anisotropic interactions among chromophores. The intermolecular electrostatic interaction potential functions of equilibrium statistical mechanical and Monte Carlo methods are found to be very similar and approximate the potential function introduced by Piekara in the 1930s (104). Theoretical calculations explain a great many additional experimentally observed features including the relatively weak dependence of maximum achievable electrooptic activity upon electric poling field strength and phenomena such as concentration and electric-field-dependent phase separation. The theoretical rationalization of the dependence of achievable electrooptic activity upon the electronic and molecular structure of chromophores and the processing conditions (applied poling field

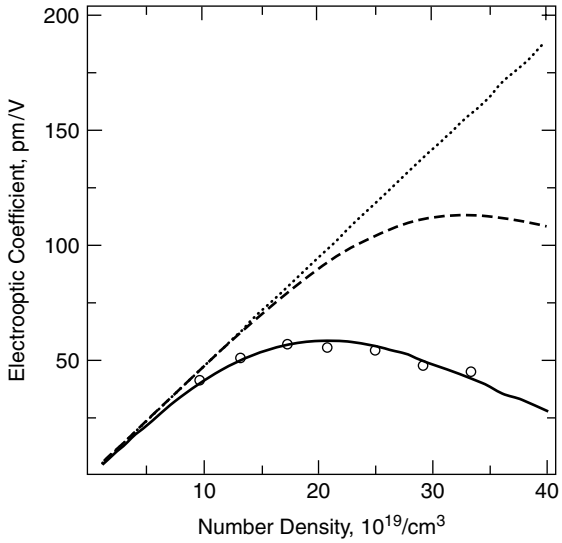

Fig. 2. The experimental and theoretically predicted dependence of electrooptic coefficient for the FTC chromophore (see Fig. 1) in poly(methyl methacrylate) (PMMA) upon chromophore number density (concentration in PMMA) is shown. Theoretical results are shown for various shape approximations and for the neglect of intermolecular electrostatic interactions (the ideal gas model). ------ Gas model; – – Sphere; —Prolate ellipsoid; ○ Experimental.

strength, dielectric constant of the host polymer matrix, chromophore concentration, temperature, etc) has provided both good and bad news. The bad news is that it will always be impossible to realize more than a fraction of the potential electrooptic activity represented by a given chromophore structure. Electrooptic coefficients of a few hundred pm/V may be obtainable, but values of 1000 pm/V or greater will be unobtainable with high dipole moment chromophores unless some other force (eg, ionic) is used to overwhelm the effect of dipole–dipole interactions. The good news is that theory provides guidance to quick optimization of electrooptic activity for a given chromophore/polymer system. The concentration (number density) of chromophores leading to maximum electrooptic activity is predicted by theory with high accuracy. Moreover, theoretical results argue that the shape of chromophores should be altered from their normal prolate ellipsoidal shape to a more spherical shape. This is readily accomplished by adding inert substituent (alkyl or alicyclic) groups to the waist of chromophores (68). An even more promising route is that of dendrimer synthesis including dendrimer structures where more than one chromophore is incorporated into the dendrimer. Very simply, steric forces are used to prevent chromophores from achieving centric order driven by dipole–dipole interactions. An example of an early version multichromophore dendrimer, which has led to electrooptic coefficients of 60 pm/V at 1.55 μm telecommunication wavelength, is shown in Figure 3 (105).

Theoretical guidance has permitted polymeric electrooptic materials to be fabricated that exhibit electrooptic coefficients in excess of 100 pm/V (68,106) at telecommunication wavelengths. With these materials, V_π voltages of less than 1 V have been achieved. This has been, without question, a very important

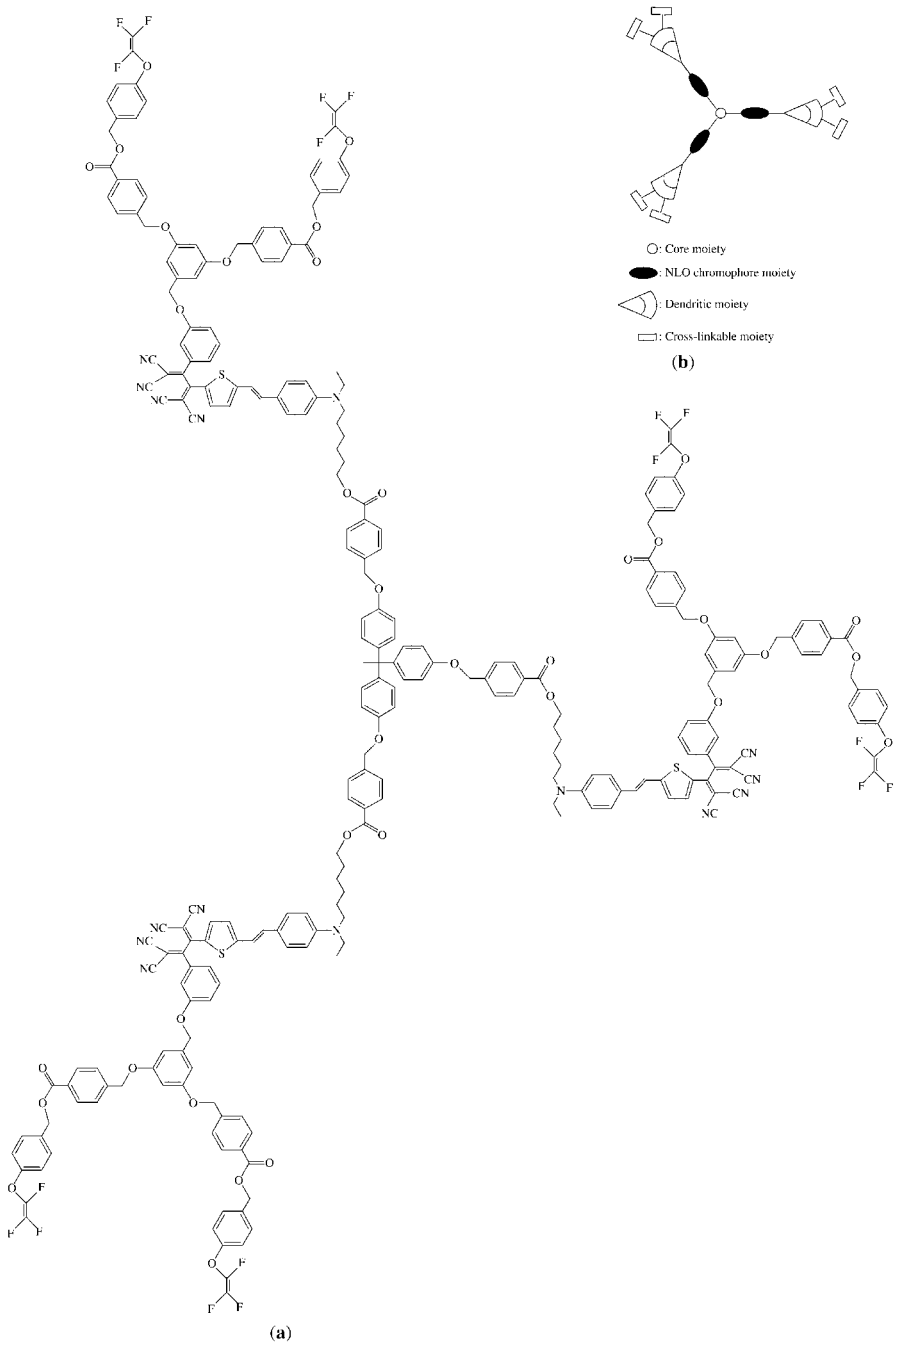

Fig. 3. (a) An early version multichromophore dendrimer (105) is shown. This cross-linkable dendrimer yields an electrooptic coefficient of 60 pm/V at 1.55 μm wavelength that is stable under testing at 85°C for 1000 h. (b) Schematic representation. $M_w = 4664$; Chromophore density: 33 wt%.

result stimulating considerable interest from both large and small companies in the telecommunications and defense fields. V_π voltages on the order of 1 V permit low cost complementary metal oxide semiconductor (CMOS) and high speed electrochemical luminescent circuits to be used without amplifiers. Moreover, such low voltages are important for the realization of transparent (low loss) communication links. Indeed, the realization of deep optical modulation with low electrical drive voltage can lead to gain in electrical-to-optical-to-electrical signal transduction. In satellite telecommunication applications, the elimination of low noise amplifiers is important for the reduction in launch weight as well as for reducing noise and cost. The practical (commercial) importance of the advances in electrooptic activity rests upon two issues: (*1*) Can electrooptic activity be further improved and by how much? (*2*) Can large electrooptic activity be achieved in conjunction with all of the other required properties? The answer to the first question is very likely positive. Indeed, it is clear that electrooptic activity will be further improved by at least another factor of 2. The answer to the second question will become clear from the following paragraphs.

Bandwidth

The bandwidth (response time or highest frequency component of data that can be handled) of devices fabricated from electrooptic materials is determined by the index of refraction n and dielectric constant ε of the materials from which the devices are fabricated. For polymeric organic electrooptic materials, $\varepsilon = n^2$ approximately. This means that low frequency electrical and high frequency optical waves propagate with the same velocities in a material. This in turn means that long interaction lengths can be employed, which leads to low drive voltage requirements. For example, 3-cm electrodes were used to achieve sub 1-V V_π values for polymeric modulators (68). For organic materials, voltage-length products are currently of the order of 1–3 V·cm. The typical index of refraction values ($n = 1.55$–1.70) and dielectric constant values ($\varepsilon = 2.4$–3.0) for polymeric organic materials have permitted electrooptic device bandwidths of 113 GHz to be demonstrated using simple device structures (107–110). Pulsed measurements establish that the intrinsic material bandwidth response is of the order of 350 GHz (essentially defined by the phase relaxation time of the π-electron system). Device bandwidth-length product values could conceivably be as high as 350 GHz·cm with polymeric organic electrooptic materials; however, the difficulty of transmitting electrical signals with frequency components above 120 GHz through metal electrodes makes this a difficult objective to achieve. The low dielectric constants of organic materials also lead to very favorable power requirements (eg, typical P_π values are on the order of 4 dB). Crystalline organic materials achieve acentric order by exploiting ionic interactions to overwhelm the chromophore π-electron dipole interactions that favor centric order. These ionic interactions lead to higher index of refraction and dielectric permittivity values, eg, 2.5 and 7.0 respectively.

For lithium niobate, dielectric constants are of the order of 28 while index of refraction is of the order of 2.2. The bandwidth-length product is 10 GHz-cm and the voltage-length product is 5 V-cm. By clever engineering (minimizing the

time spent by electrical waves in high dielectric lithium niobate), lithium niobate devices have been demonstrated to approximately 90 GHz. Commercial devices are available from Lucent with bandwidths of 30 GHz, V_π voltages of 6 V (1550 nm), insertion loss of 6 dB, and temperature stability to 70°C. The high dielectric constant of lithium niobate results in high power dissipation, ie, $P_\pi >$ 32 dB currently. While high frequency operation is possible with devices fabricated from lithium niobate, more sophisticated device engineering is required. Moreover, such bandwidth is accomplished with sacrifice of drive voltage. The high intrinsic bandwidth afforded by polymeric organic materials was early on recognized as one of the greatest advantages of such materials. The fact that the high bandwidth of organic electrooptic materials is now accompanied by low drive voltage requirements argues for the serious commercial consideration of these materials.

GaAs electroabsorptive modulators offer the possibility of high bandwidth (50 GHz) and low drive voltage (1–2 V). However, these materials exhibit substantial chirp. It is impossible to change absorption without also changing index of refraction. Moreover, GaAs devices are plagued by high insertion loss (9–12 dB). Lithium niobate modulators seem to be the currently preferred alternative to GaAs modulators for high frequency (10–30 GHz) applications.

Modulated lasers, thermooptic switches, liquid crystalline modulators, bubble jet switches, and MEMS devices suffer even greater bandwidth limitations. The introduction of wavelength division multiplexing (WDM) has taken some of the bandwidth pressure off of purely time division multiplexing (TDM) approaches to handling telecommunication throughput. However, bandwidth is likely to remain a serious issue for future telecommunication systems, and thus the bandwidth performance organic and inorganic electrooptic materials will remain an issue of active concern.

Optical Loss

One of the most attractive advantages of lithium niobate is exceptionally low optical loss (material loss of 0.2–0.4 dB/cm and device insertion loss of 3–6 dB at telecommunication wavelengths). Optical loss has been a problem with polymer materials until recently when a better understanding of factors leading to both material and insertion optical loss has permitted significant improvement in loss values (to material loss values of as low as 0.2 dB/cm and insertion loss values as low as 4 dB at telecommunication wavelengths). Material optical loss can be associated with either absorption loss or loss due to scattering. Absorption loss can arise from either (or a combination of) interband electronic absorption or C—H (or N—H, O—H) vibrational overtone absorption at 1.3 or 1.55 μm wavelengths. Wavelength-dependent interband absorption is easily assessed by techniques such as photothermal deflection spectroscopy. Appropriate chromophore design can keep optical loss due to interband absorption below 1 dB/cm even at 1.3 μm wavelength. Such loss is probably not a significant factor at 1.55 μm telecommunication wavelength. Vibrational absorption at 1.3 and 1.55 μm wavelengths is a much more serious problem. As with the production of low loss silica fiber, the answer to the problem of intrinsic optical loss is to get the hydrogen out of

the material. Without such reduction in hydrogen content, optical loss in organic materials is typically limited to approximately 1 dB/cm at 1.3 μm wavelength and somewhat higher values at 1.55 μm wavelength. With organic materials, reduction in hydrogen content typically means using partially fluorinated materials or materials constructed with functionalities, such as the cyanurate ligand, that do not contain hydrogen (when the carbon positions are substituted). Using cyanurate and fluorinated dendrons, optical loss values as low as 0.2 dB/cm have been obtained for electrooptic dendrimer materials. Fluorination of polymer materials frequently involves unwanted changes in processability; for example, changes in solubility in spin-casting solvents. Dendrimer synthesis has been demonstrated to provide a convenient means of reducing optical absorption loss without paying a price in material processability.

Scattering losses induced by processing have been a much more insidious problem in the fabrication of low loss organic waveguide structures. Scattering losses can arise from several sources. One of the most obvious is material inhomogeneity associated with spin casting. Any phase separation leads to disastrously high loss values. Strong dipole–dipole interactions among chromophores can drive phase separation. Fortunately, such interactions can be attenuated by appropriate derivatization of chromophores. Such derivatization also improves the entropy of mixing (and hence the solubility) of chromophores in spin casting solvents. Electric field poling and the concurrent cross-linking of materials to lock-in poling-induced electrooptic activity can also lead to optical loss (71,100,106,111–113). Two types of optical loss are typically associated with electric field poling. The first arises from electric-field-induced surface damage. This is simply a form of dielectric breakdown and can be avoided by keeping corona poling field strengths below damage thresholds. It is important to keep in mind that the harder (more cross-linked) the polymer lattice, the higher the damage threshold. Thus, electric field poling and lattice hardening are typically carried out using a stepped temperature/electric field protocol (71,100,112,114–116). The second type of poling-induced scattering loss is associated with introduction of inhomogeneity in the material as the result of electric field poling. Such inhomogeneity can arise from an electrophoretic effect or from poling-induced birefringence. If defects (such as dust particles) exist that are not influenced by the poling field, then poling can enhance the index difference between these defect regions and the electrooptic material leading to enhanced scattering loss (117). Lattice hardening (cross-linking) chemical reactions can also be a source of material inhomogeneity that leads to increased scattering loss. This is particularly true with thermosetting reactions such as urethane chemistry where a variety of oligomeric structures can exist and grow at different rates (111). Some of these structures can become incompatible and phase separate. Moreover, some cross-linking chemistries, such as urethane chemistry, are susceptible to atmospheric moisture. The reaction with water from the atmosphere can upset the one-to-one stoichiometry of lattice hardening reactions leading to the buildup of incompatible components and phase separation. The occasionally observed cloudy appearance of polyurethane electrooptic polymers is typically indicative of problems with atmospheric moisture. However, when sources of optical loss associated with electric field poling and lattice hardening are taken into account, optical loss values on the order of 1 dB/cm are readily obtained (71,100,106,111–113).

Optical loss can also arise from fabrication of buried channel waveguide structures by reactive ion etching (RIE) techniques and by the deposition of cladding layers where the solvent employed in spin casting the cladding layer causes solvent pitting of the electrooptic film layer. Both of these loss mechanisms can be controlled by lattice hardening of the electrooptic material and by control of processing conditions. Control of the kinetic energy of reactive ions in RIE (118,119) can keep optical loss values due to waveguide wall roughness to insignificant values (0.01 dB/cm). Cladding layers pose an unanticipated problem for the utilization of organic-electrooptic materials. While cladding materials have been utilized that make no problematic contribution to optical loss, problems in device operation can frequently be traced to cladding materials rather than to the electrooptic materials. Conducting cladding materials can be particularly problematic. In general, one wants the electrical conductivity of the cladding material to be higher than that of the electrooptic material so as to drop the poling field across the cladding layer. However, if the cladding material has significant optical loss, the penetration of the propagating optical field into the cladding layer will result in unwanted attenuation of the transiting beam. The cladding material can also undergo photochemical damage and may do so even when the electrooptic material does not show damage. This can manifest in time-dependent loss of mode confinement when no change in electrooptic modulation efficiency is observed. A more subtle problem that can arise with conducting cladding materials is that of photoconductivity (or optical power-dependent conductivity). Electrooptic chromophores are very polarizable materials and can inject charge into a conducting medium (71,112). Thus, an optical power-dependent conductivity of the cladding material can result if that material is susceptible to accepting charge and transporting that charge. Such effects are typically observed only at high power levels in devices such as high frequency oscillators based on electrooptic modulator technology. Of course, optical fields must be kept away from lossy metal electrodes. Again, if care is taken in the design and execution of device structures, loss from waveguide fabrication, cladding deposition, and electrode deposition can be kept to insignificant values, and overall active waveguide loss values of 1 dB/cm can be routinely achieved.

The greatest loss issue to be faced in the commercial implementation of organic electrooptic devices is that of mode mismatch loss when coupling silica fiber and polymeric electrooptic modulator waveguides. For 1.3 μm telecommunication wavelength operation, silica optical fiber waveguides are cylindrical with spherical cross-sectional core diameters on the order of 10 μm, while the cross-sectional shapes of polymeric electrooptic modulator waveguides are elliptical with heights of 1–2 μm. Butt coupling of such active and passive waveguides leads to optical loss on the order of 4 dB per transition. The coupling problem is readily addressed using spherical lens or tapered transitions (70,71,112,120). A tapered transition such as shown in Figure 4 reduces coupling loss to a few tenths of a decibel. Thus, total insertion losses of 4–5 dB have been obtained for polymeric materials exhibiting material loss on the order of 1 dB/cm. Tapered transition structures can be fabricated by employing offset, gray scale, and shadow ion masking techniques (70), which are to be discussed later. Such lithographic techniques are also useful for constructing sophisticated 3-D circuits (70).

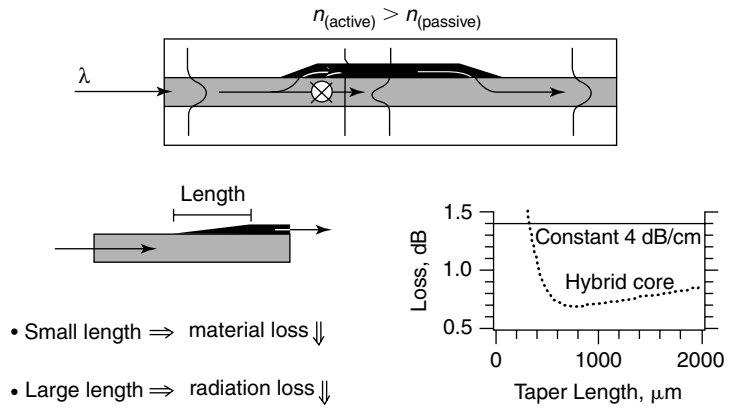

Fig. 4. A low loss polymeric electrooptic modulator transition structure is shown. The optimum taper length is defined by the trade-off between acceptable radiation loss and material loss.

Stability

For electrooptic materials (eg, liquid crystalline materials) based on index of refraction changes associated with molecular reorientation, one wants facile reorientation to permit fast switching times. Organic photorefractive materials also exhibit enhanced response when molecular reorientation contributes to observed index changes. In contrast, reorientation destroys the electric-field-poling-induced electronic electrooptic activity of chromophore-containing polymeric materials. When one speaks of thermal instability of electronic electrooptic activity for organic materials, one is referring to reorientational (molecular rotational) dynamics that destroy poling-induced acentric order. There are two general approaches to improving the stability of poling-induced order. One is to place chromophores in polymer materials, such as polyimides or polyquinolines, characterized by high glass-transition temperatures. This may be accomplished either by physically dissolving chromophores in polymers to produce composite materials or by covalently coupling chromophores to polymer lattices (71,112,121–134). The stability will be defined by both the segmental flexibility of the polymer backbone (the glass transition temperature) and the number (and positioning) of covalent bonds coupling the chromophore to the polymer lattice. The stability of poling-induced acentric chromophore order (electrooptic activity) can be readily assayed by monitoring second harmonic generation (another phenomena related to $\chi^{(2)}$) as a function of heating the sample (see Fig. 5) (135). This is a nonlinear optical analogue of thermal gravimetric analysis except that molecular reorientation rather than material decomposition accounts for the loss of second-order nonlinear optical activity. As shown in Figure 5, thermal stability of electrooptic activity is increased with cross-linking. When dynamic thermal stability is increased to temperatures such as 170°C as shown in Figure 5, then long-term stability is typically observed for periods of several thousand hours even when devices are operated at 100°C. Segmental flexibility of polymers is one of the most serious problems with relaxation

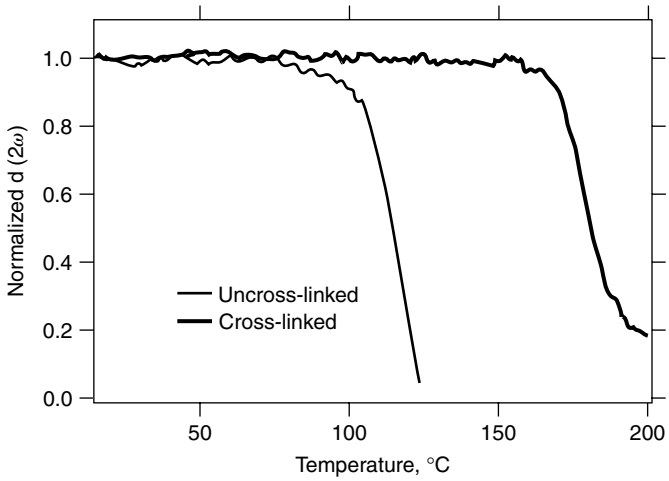

Fig. 5. Second harmonic generation is shown as a function of temperature for heating at a rate of 10°C per minute for two samples. The uncross-linked sample (chromophore is attached covalently by one end to a PMMA backbone) starts to lose second-order optical nonlinearity (acentric chromophore order) before 100°C. The cross-linked sample corresponds to both ends of the chromophore being covalently coupled to the polymer lattice. For this sample, thermally stable second-order optical nonlinearity is observed until nearly 170°C.

of poling-induced acentric order. Dendrimer materials appear to have distinct advantages for enhancing the thermal stability of poling-induced electrooptic activity. Not only can the covalent bonds and steric interactions of dendrimers hold chromophores away from each other (inhibiting centric ordering) but dendrimer structures can also oppose thermal relaxation. The dendrimer material of Figure 3 is observed to exhibit stable electrooptic activity for 1000 h at 85°C. Greater thermal stability should be achieved by greater attention to the flexibility of dendrons and by better control of cross-link density. In comparison, the thermal stability of lithium niobate devices is typically listed as 90°C while gallium arsenide devices are specified as stable to 80°C.

Preliminary studies of the stability of organic electrooptic materials to high energy (gamma ray) radiation and particles (protons) carried out by Lockheed Martin (Palo Alto) and by researchers at the Air Force Research Laboratory (Wright Patterson Air Force Base) suggest that space application of polymeric electrooptic materials should proceed without problems.

Photochemical stability is more difficult to assess. Lithium niobate is specified as having optical power handing capabilities to 250 mW while gallium arsenide is specified as having a maximum power handling capability of 30 mW. However, such power handling capability is typically specified for packaged materials where oxygen has been excluded. The photochemical stability of organic materials is dramatically affected by the presence of oxygen. Exclusion of oxygen typically improves photochemical stability by several orders of magnitude. The addition of oxygen (radical) scavengers can also improve photochemical stability (136). Photochemical stability can also improve

with lattice hardening (100) although this will depend upon the porosity of the polymer lattice, which may not always correlate simply with cross-link density. Unfortunately, controlled evaluation of photochemical stability under conditions appropriate for commercial applications have not been carried out for polymeric electrooptic materials; thus, photochemical stability remains the most serious question concerning the commercialization of organic electrooptic materials.

Mechanical Properties

Polymeric electrooptic materials have the advantage of being conformal and of exhibiting effective bonding to a variety of surfaces. Moreover, by control of cross-link density, the mechanical properties of polymeric electrooptic materials can be controlled. Electrooptic device operation can be carried out over a wide range of temperatures. Eventually, different coefficients of thermal expansion may cause delamination problems upon thermal cycling over wide temperature ranges, but such problems have not been noted to the present. A unique feature of polymeric systems is that good mechanical properties are obtained for lightweight materials. Weight is an issue in satellite telecommunication and reconnaissance systems. Regarding weight issues in satellite telecommunications and reconnaissance operations, the low drive voltage requirements of polymeric electrooptic devices permit the elimination of low noise amplifiers, which in turn results in substantial weight reduction. Thus, the weight issue is not the relative weights of lithium niobate and polymeric electrooptic materials but the relative weights of total systems fabricated from these materials. Also, the critical weight saving comes from using photonic (optical fiber) versus electrical (coaxial) cables.

Processing and Integration

Polymeric materials are amenable to facile processing by RIE (70,71,112,119,120) and photolithographic techniques (71,112,137). Use of offset, gray scale, and shadow ion lithographic masks and RIE has permitted implementation of vertical waveguide transitions and the fabrication of 3-D circuits permitting the ready integration of passive and active optical waveguide components (70,71). Polymeric electrooptic materials are also very compatible with semiconductor processing, and electrooptic circuitry has been fabricated on top of very large-scale integration (VLSI) semiconductor chips (71,112). Indeed, through use of planarizing polymers, electrooptic modulators have been vertically integrated (in high density) with VLSI chips. Integration has been accomplished without the perturbation of the performance characteristics of either electronic or optical (electrooptic) circuitry. One of the advantages of polymeric electrooptic materials is this ready integration with semiconductor electronics and the ability to fabricate a large number of modulator waveguides on a single chip. With lithium niobate, such integration is not possible and connection to electronic circuitry is typically made by wires and flip chip bonding. By use of tapered transitions and

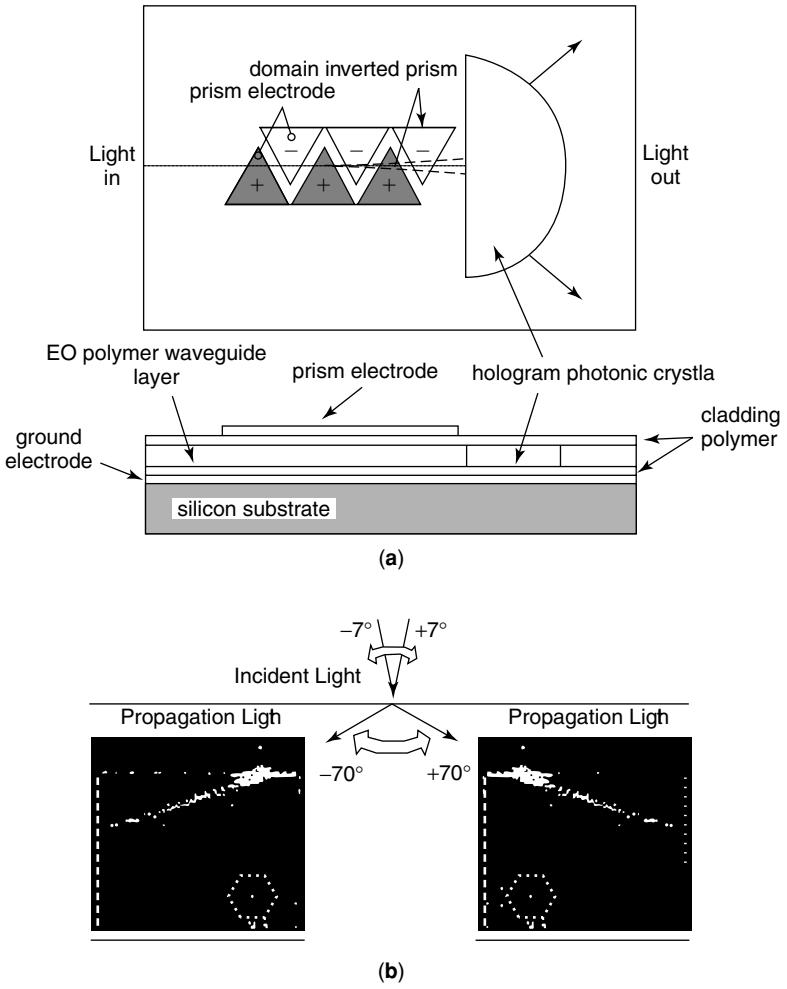

Fig. 6. Large-angle beam steering is shown for a device based on a polymeric electrooptic material (a cross-linkable version of the CLD chromophore discussed in Ref. 68). (a) EO waveguide prism introduces a small deflection angle to initialize the beam scanning. The half-circle 2-D photonic crystal region is embedded into the waveguide so that the deflection angle is "amplified" as the light passes through the crystal region. 3-D scanning can also be provided if a 3-D structure is built. (b) The experimental observation of the angle sensitivity.

spherical lens, electrooptic waveguides have been coupled to silica fiber optics. Again, coupling can be achieved in a more straightforward manner than with lithium niobate.

An example of sophisticated device development is shown in Figure 6. Large-angle (-70° to $+70^\circ$) beam steering is demonstrated by implementing a series of cascaded electrooptic prisms, which initiate beam steering and feed light into a photonic band gap lattice (138,139). The photonic band gap lattice is fabricated by holography in a photopolymer material (see Fig. 7). Beam steering is accomplished with more than an order of magnitude lower drive voltage than required using

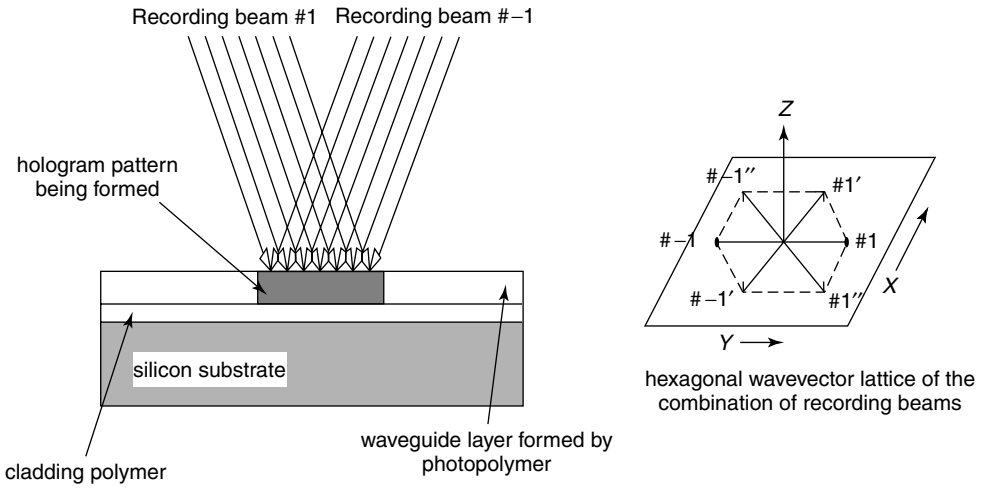

Fig. 7. The holographic production of the polymeric photonic band gap lattice used in the beam steering device of Figure 6 is shown.

lithium niobate materials. Through the cascaded prism electrodes, the deflection angle is given for steering of a TM polarized beam by

$$\theta = n_0^2 r_{33}(V/\mathrm{d})(L/h) \tag{5}$$

where L and h are the length and width of the prism array, respectively. V is the applied driving voltage and d is the electrode spacing. The electrooptic coefficient in the direction of the driving field is r_{33}, while n_0 is the voltage independent index of refraction. In the present example, L/h is approximately 80 with $L = 16$ mm and $h = 200$ μm. The model used to arrive at equation (4) is based only upon the total phase retardation across the wave front. The deflection angle thus depends only on the overall dimension of the prisms, since the accumulated phase difference across the wave front is independent of how the deflector is subdivided into individual prisms, as long as the interfaces between adjacent prisms are straight lines.

Devices

The most simple device configurations utilizing electrooptic materials are shown in Figure 8 (122). These include the Mach Zehnder and birefringent modulators and the directional coupler. As configured in Figure 8, the first two devices are amplitude modulators. A somewhat higher drive voltage is required for the birefringent modulator than for the Mach Zehnder modulator. This is because the V_π voltage of the Mach Zehnder relates directly to the principle component (r_{33}) of the electrooptic coefficient. The V_π voltage of the birefringent modulator relates to the difference between the major and minor components

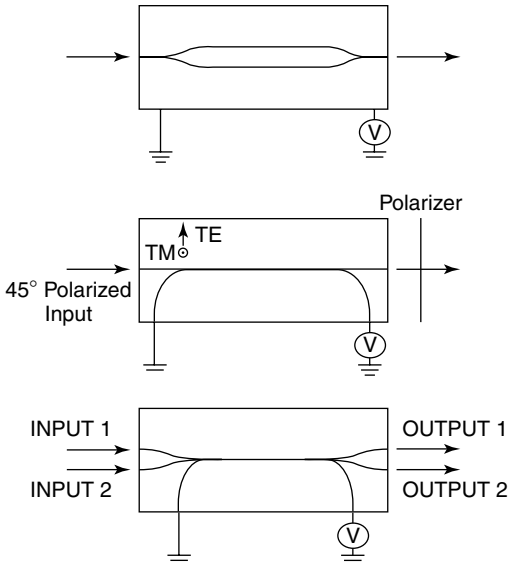

Fig. 8. Mach Zehnder interferometer (top), birefringent modulator (middle), and directional coupler (bottom) device configurations are shown.

$(n_3^3 r_{33} - n_1^3 r_{13})$. A still higher drive voltage is required for the directional coupler, and the relationship to material electrooptic activity is somewhat more complex (122).

We have already shown a large-angle spatial light modulator based upon organic electrooptic and photonic band gap materials (Figs. 6 and 7). Such beam steering without moving parts is relevant for holographic optical data storage, switching in all optical networks, advanced laser radar (ladar), photonic phased array antennas, optical sensors, and laser printers. Spatial light modulation exploiting electronic electrooptic activity has not only the advantage of greater speed but also avoids instability due to overshoot associated with the momentum of mechanical beam steering (MEMS) devices. The fact that such beam steering can be accomplished with application of driving voltages in the range of volts rather than kilovolts (as is the case for lithium niobate) is also a very attractive feature. For fiber optic switching, spatial light modulation has the advantage that a large number of fiber channels can be selectively addressed using only one electrode. Overall, electrooptic beam steering offers a simplified operating scheme, low driving voltage, high switching speed, small size, and low cost.

Ultra high bandwidth analogue-to-digital (A/D) conversion has been accomplished utilizing polymeric electrooptic materials in several different device configurations. Analogue-to-digital conversion employing a cascaded series of Mach Zehnder modulators has been discussed elsewhere (112). Analogue-to-digital conversion can also be accomplished by time stretching (140). In this application, a femtosecond pulse is stretched (by a dispersive medium) to match the length of an incoming data stream containing high frequency information. The data stream is transduced as an amplitude modulation (by a polymeric electrooptic modulator)

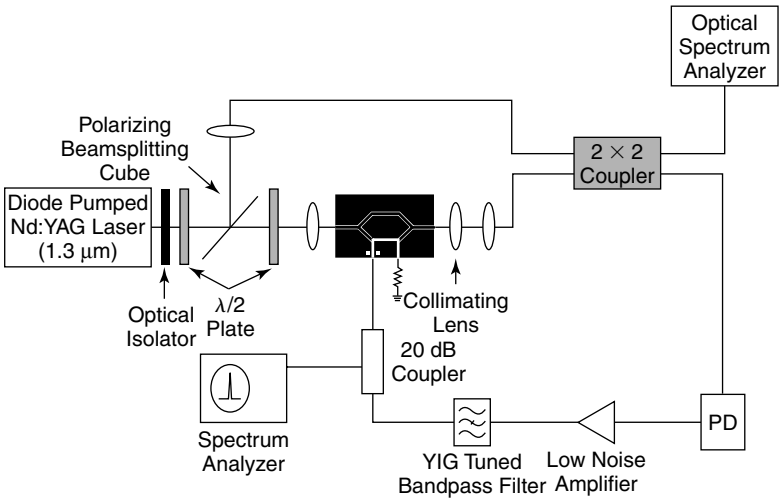

Fig. 9. A broadband, ultrastable oscillator based on polymeric electrooptic materials is shown.

onto the optical pulse. The pulse is then further time stretched to a length compatible with conventional A/D converters. The pulse is then converted to an electrical signal by a diode detector and A/D conversion is effected. Such time stretching permits A/D conversion at rates of 100 Gbit/s.

Another prototype device, which has been demonstrated by researchers at Pacific Wave, is that of a high frequency oscillator (see Fig. 9). In this oscillator, the stability of the oscillator is determined by the length (Q) of the optical circuit (loop) and can thus be very high indeed.

A variety of phased array systems have been fabricated based on polymeric electrooptic materials (141,142). One configuration is based on the photonic phase shifter shown in Figure 10. This provides a very linear phase shift as a function of control d-c voltage. Optical signals of controlled phase are thus sent to various radiating antenna elements. The optical signals are converted to radiofrequency signals by diode detectors.

High frequency (including secured communication by frequency hopping) telecommunication applications are receiving considerable attention (143). As can be seen in Table 1, the bandwidth limitation of current electronic components is the limiting factor to achieving increased bandwidth performance with polymeric electrooptic materials. In Figure 11, a device configuration capable of 130-GHz bandwidth operation is shown.

Other demonstrated prototype devices include optical gyroscopes (144), broadband acoustic spectrum analyzers (145), 1×2 Y-fed directional couplers (146) and polarization-insensitive electrooptic modulators (147,148). For long-haul telecommunication applications, it is difficult to maintain polarization control; thus, a need exists for polarization-insensitive modulators. Indeed, polarization insensitivity was one of the advantages claimed for gallium arsenide electroabsorptive modulators. By using different poling schemes, overall polarization insensitivity has been achieved for polymeric modulators (147,148).

Table 1. The Bandwidth Characteristics of Various Electrical Interfaces

Modulator type	Electrical interface	Bandwidth, GHz	Technology availability	Reliability	Cost
Traditional	K-coax	0–40	Simple, commercial	Proven	Low
M-Z modulators	V-coax	0–65	Simple, commercial	Proven	Low
	W-coax	0–110	Ongoing at TACAN	R&D	Low
	WR-15	50–75	Complicated, customer	R&D	High
	WR-10	75–110	Complicated, customer	R&D	High

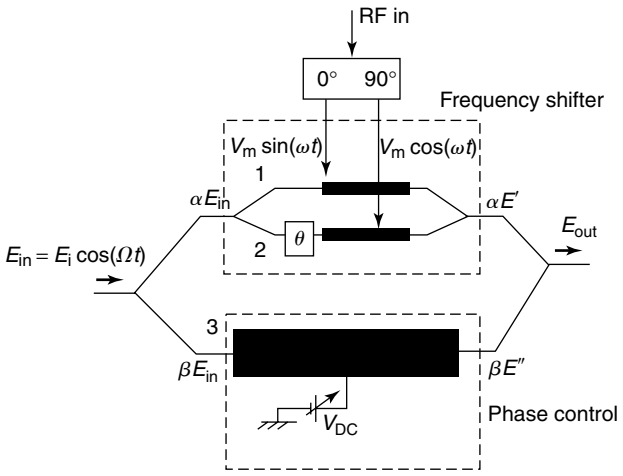

Fig. 10. A schematic representation of a photonic radiofrequency phase shifter is shown.

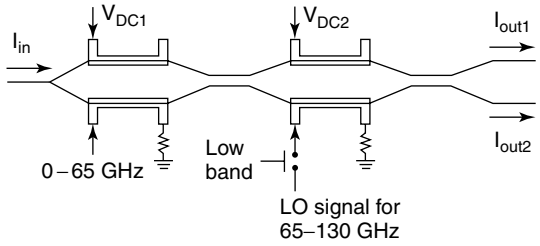

Fig. 11. A 130-GHz telecommunications device is shown.

Commercialization and Cost

As with lithium niobate, the cost of devices based on polymeric electrooptic modulators is in the packaging rather than in the materials. A Lucent lithium niobate modulator sells for approximately $6000. Polymer modulator vendors such as Pacific Wave Industries (Los Angeles, California) are quoting comparable prices. The low material cost is associated with the fact that modulator devices are thin-film

devices and a chip containing 6–100 modulators requires very little polymeric electrooptic material.

A number of small companies such as Lumera (Bothel, Washington), Pacific Wave Industries (Los Angeles, California), Radiant Research (Austin, Texas), IP-ITEK/TACAN (Carlsbad, California), KVH Industries (Tinley Park, Illinois), etc are exploring the commercialization of electrooptic devices based on polymeric materials. Lockheed Martin has pursued research in polymeric electrooptic materials for more than a decade and continues to be a leader in the field. Lucent has recently resumed research on polymeric electrooptic materials. A number of telecommunication companies including Nortel, Agilent, Cisco, and JDS-Uniphase are currently evaluating polymeric electrooptic technology to determine the viability of R&D and commercial activity in this area.

The market for inorganic electrooptic and electroabsorptive modulators is currently in the hundreds of millions of dollars per year with wait times of several months for delivery of lithium niobate modulators. The perceived need for greater bandwidth in the telecommunications industry is likely to drive demand even higher.

Future Prognosis

Provided that no unexpected problems arise that would inhibit the commercialization of polymeric electrooptic technology, the prognosis is very good. The greatest uncertainty involves whether or not organic electrooptic materials will exhibit adequate photochemical stability over many years of in-field operation. Preliminary studies suggest that exclusion of oxygen and hermetic sealing will yield devices capable of exhibiting photochemical stability over many years for exposure to optical fields at telecommunication wavelengths and powers. Almost certainly, electrooptic coefficients will continue to be improved. New and improved chromophores are being synthesized with great regularity (149). Devices operating with sub 1-V V_π values should become commonplace. Utilization of photonic band gap materials and controlled coupling to resonated structures should permit further reduction in drive voltage requirements (possibly even to microvolt levels); such reduction is, of course, at the expense of some reduction in response time (bandwidth). Low drive voltage requirements, together with high bandwidth capabilities and the ease of integration with semiconductor electronics and silica transmission fibers, should be a powerful driver for the deployment of polymeric electrooptic technology in telecommunication, defense, transportation, and display industries. However, the extent of utilization of polymer electrooptic technology in the telecommunication industries will depend upon perceived bandwidth needs. If low cost alternatives to high information throughput with reduced bandwidth requirements (such as expanded use of WDM technology) become popular, limited bandwidth technologies such as thermooptic, liquid crystalline, MEMS, and modulated laser technologies may continue to dominate sales in the telecommunications area. However, even if deployment is slow in telecommunications, defense industries should find use for the exceptional capabilities of polymeric electrooptic materials for applications such as radar, electronic counter measure, sensor, and display systems. Other

niche applications including biomedical sensors, analytical instrumentation, and high frequency test equipment are likely to develop.

The main limitation to general deployment of organic electrooptic materials is that they have been optimized to this point in time for applications at telecommunication wavelengths. Inorganic materials such as lithium niobate are still the materials of choice for applications at visible wavelengths. Such inorganic modulators are likely going to continue to dominate the laboratory market for modulators to be used with research laser systems.

Nomenclature

p_i	ith component of the molecular polarization vector in the presence of electrical fields
p_{0i}	ith component of the permanent polarization of the molecule
E	the local electric field strength
F	the local electric poling field strength
α	molecular polarizability tensor
β	molecular first hyperpolarizability tensor
γ	molecular second hyperpolarizability tensor
P_i	ith component of the bulk polarization vector in the presence of electrical fields
P_{0i}	ith component of the bulk polarization vector in the absence of external fields
V	applied voltage
$\chi^{(1)}_{ij}$	first-order electric susceptibility tensor
$\chi^{(2)}_{ijk}$	second-order electric susceptibility tensor
$\chi^{(3)}_{ijkl}$	third-order electric susceptibility tensor
n	refractive index in the presence of an applied electric field
n_0	refractive index in the absence of an applied electric field
r	Pockels coefficient or electrooptic coefficient
r_{33}	electrooptic coefficient in the direction of the applied field (principal element)
r_{13}	electrooptic coefficient orthogonal to the applied field direction (minor element)
R	Kerr factor
E_0	applied electric field amplitude
N	number density
$f(\omega)$	local field factor
$\langle\cos^3\theta\rangle$	acentric order parameter
V_π	applied voltage required to produce a phase shift of π
λ	wavelength of light
d	electrode gap
L	interaction length of electrical and optical fields in material
Γ	modal overlap integral
θ	beam deflection angle

ELECTROOPTICAL APPLICATIONS

Introduction

The term *electrooptic* can have widely different meanings. In the broadest sense, it can imply any change produced in an optical beam by application of an electrical field from either a low frequency (dc to millimeter wave) field or another optical (micrometer wave) field. Change of the index of refraction of the material through which an optical beam is transiting can influence the (velocity of the) propagating optical beam. Such change of index of refraction can be accomplished by altering either the electron distribution or the nuclear configuration of a material. The associated optical phenomena are referred to as Kerr and Pockels effects (1–15) and have been known since the nineteenth century.

However, altering an optical beam by electrically controlled mechanical movement of a mirror (particularly as in micro-electro-mechanical-systems, MEMS) is also referred to as an electrooptic operation. Indeed, even greater confusion arises by usage of the terms electrooptic and all-optical signal processing in the telecommunications industry. Electrooptic is taken to refer to converting optical signals to electrical signals, carrying out signal processing in the electrical (electronic) domain, and then converting back to the optical domain. Thus, techniques such as bubble jet (Hewlett Packard/Agilent) and MEMS (Texas Instruments) optical switching at network nodes are referred to as all-optical signal processing by telecommunication engineers while an optical physicist would reserve the term all-optical switching for the dynamic Kerr phenomenon (switching of one optical beam by another).

A review of electrooptical applications in the broadest sense is out of the question. It would involve treatment of topics ranging from modulated lasers (direct modulation) to light-emitting diodes (LEDs), to liquid crystalline materials,

Encyclopedia of Polymer Science and Technology. Copyright John Wiley & Sons, Inc. All rights reserved.

not to mention MEMS, thermooptic, and bubble jet technologies currently used in telecommunications. Moreover, the literature is enormous. Over 1000 reviews and texts have appeared on the subject of liquid crystalline electrooptic materials alone. In this article, a narrow view of electrooptic phenomena, materials, and applications is taken and focus is upon the "electronic" Pockels effect, with emphasis on the phenomenon realized using polymeric or dendritic materials rather than inorganic or organic single crystals. The term *electronic* refers to changes in refractive index associated purely with electric-field-induced change of the electron distribution of a material (in contrast to changes in nuclear configuration associated with molecular reorientation). Moreover, there is a focus upon π-electron organic chromophores rigidly embedded in polymeric or dendritic supramolecular matrices. Currently, commercially utilized materials exploiting the electronic Pockels effect are inorganic crystalline materials such as lithium niobate. Although the most commercially viable organic electrooptic (defined in the broader sense) materials are liquid crystalline materials (16–58), electronic Pockels effect organic materials are receiving increased attention because of the possibility of exceptional (greater than 100 GHz) bandwidth performance. Although potential applications of such materials range from telecommunications to information processing, to defense, to transportation, and to display industries, the telecommunications and defense industries are particularly important drivers of development of electrooptic materials with greater bandwidths. Electronic Kerr materials (59–67) have the potential for even greater bandwidth and the possibility of convenient all-optical signal processing; however, to the present time electronic Kerr coefficients have not been large enough to be commercially viable for telecommunication applications. Mott–Hubbard transition-metal oxide and halide systems with charge-transfer gaps and low hydrogen-density organic materials such as the fullerenes and chromophore-containing dendrimers may hold future promise for all-optical switching at telecommunication wavelengths (eg, 1.55 μm) because of their large two-photon absorption coefficients (third-order optical nonlinearities) and their low optical loss. Inorganic Kerr materials such as titanium sapphire are currently used for mode-locked lasers and other applications.

Other reasons for heightened interest in organic electronic electrooptic materials include large electrooptic coefficients (greater than 50 picometers/volt (pm/V) at telecommunication wavelengths). Large electrooptic coefficients permit voltages from semiconductor electronics to drive electrooptic devices without the introduction of amplifiers. Amplifiers are undesirable because of their bandwidth limitations, noise figures, weight, bulk, and cost. Indeed, a major reason for increased commercial interest in organic electrooptic materials is that drive voltages of less than 1 V can be realized with simple broadband device structures (68,69). Such drive voltages permit lossless telecommunication links to be achieved and even permit realization of gain in electrical-to-optical-to-electrical signal transduction. Another attractive feature of organic electrooptic materials is facile integration with semiconductor electronics and silica fiber optics (70–74). In this article, both the state of development of organic electrooptic materials and the principles that define material performance are reviewed.

The reader is referred elsewhere for reviews of organic photorefractive materials (75–86) and of photochromic and optomechanical materials (87). Electronic electrooptic chromophores (such as charge transfer azobenzenes) have frequently

been used for such applications, but the response times of these phenomena and their conceptual basis are quite different from the phenomenon and applications discussed here. (See also CHROMOGENIC POLYMERS; LIGHT-EMITTING DIODES).

General Theoretical Principles

At the molecular level, the change in electron distribution (polarization) with application of an electrical field is given by

$$p_i = p_{0i} + \alpha_{ij}E_j + \beta_{ijk}E_jE_k + \gamma_{ijkl}E_jE_kE_l + \cdots \tag{1a}$$

where p_{0i} is the permanent polarization of the molecular site "i" and E stands for the local electric field strength. The tensors α, β, and γ are the molecular polarizability and molecular first and second hyperpolarizabilities. For macroscopic or bulk materials, the polarization equation is

$$P_i = P_{0i} + \chi^{(1)}_{ij}E_j + \chi^{(2)}_{ijk}E_jE_k + \chi^{(3)}_{ijkl}E_jE_kE_l + \cdots \tag{1b}$$

It is assumed that the electric fields in equations (1a) and (1b) have frequencies that are outside the domain of both electronic and lattice resonances of the system. If only one electric field is applied and it is in the form of a square wave pulse (of amplitude E_0), or an a-c field ($E_0 \cos \omega t$), or a d-c field (of amplitude E_0), then equations (1a) and (1b) lead to the following expression for refractive index n:

$$(1/n^2) = (1/n_0^2) + rE_0 + RE_0^2 + \cdots \tag{2}$$

where n_0 is the refractive index in the absence of the electric field. The linear and quadratic terms correspond to the Pockels and Kerr effects, respectively. The Pockels effect is observable only for noncentrosymmetric materials; the electrooptic coefficient r is related to the molecular first hyperpolarizability β and the noncentrosymmetric order parameter $\langle \cos^3 \theta \rangle$ by

$$r = 2\mathrm{Nf}(\omega)\beta\langle \cos^3\theta \rangle / n^4 \tag{3}$$

where N is the chromophore number density and $f(\omega)$ is a local field factor accounting for the dielectric nature of the medium (host material). The electrooptic coefficient r is related to the drive voltage required to effect electrical-to-optical signal transduction (with a Mach Zehnder interferometer) by

$$V_\pi = \lambda d/(n^3 \mathrm{rL}\Gamma) \tag{4}$$

V_π is the voltage required for a π phase shift of light passing through the arm of the Mach Zehnder modulator to which an electric field has been applied. The optical wavelength of the transiting light is given by λ, d is the gap between the electrodes used to apply the electric field, L is the interaction length of the

electrical and optical fields (electrode length in the simplest case), and Γ is a modal overlap integral. Equation (3) is greatly oversimplified as we have neglected the vectorial nature of the interaction of the fields, but this equation is frequently applicable to poled polymer materials.

From equations (2) and (3), it is readily seen that optimizing the drive voltage performance of electrooptic materials is a matter of optimizing β, N, and $\langle\cos^3\theta\rangle$. We shall proceed to discuss the optimization of these parameters and the status of organic electrooptic materials, but before we do this, it is important to indicate what additional material properties must be achieved for commercial viability. These can be briefly summarized as follows: (*1*) fast response time or high operational bandwidths, (*2*) low optical loss including both material loss and insertion (optical mode mismatch) loss, (*3*) good stability including thermal and photochemical stability, (*4*) good mechanical properties, (*5*) good processability and ease of integration with disparate materials such as silica fibers, semiconductors, and metals, and (*6*) low production cost. For polymers to displace alternative technologies such as modulated semiconductor lasers, lithium niobate electrooptic modulators, or gallium arsenide (GaAs) electroabsorptive modulators, they must exhibit competitive or superior performance characteristics in all material categories. Thus, in the following paragraphs, we consider auxiliary properties as well as electrooptic activity.

Electrooptic Activity

It is clear that optimizing electrooptic activity involves optimizing the molecular hyperpolarizability β of organic chromophores. Quantum mechanics has provided effective guidance for the improvement of molecular nonlinear optical (electrooptic) activity by several orders of magnitude in the past 10 years (88–97). If chromophores are aligned into a noncentrosymmetric (acentric) lattice by electric field poling and if the interactions among chromophores are neglected, then the order parameter becomes (in the high temperature approximation) $\langle\cos^3\theta\rangle = \mu F/5kT$, where μ is the chromophore dipole moment, F is the applied electric poling field felt by the chromophores, k is the Boltzmann constant, and T is the poling temperature (Kelvin). In this approximation, macroscopic electrooptic activity would be expected to increase as $\mu\beta$. As can be seen from Figure 1, $\mu\beta$ values have been systematically improved over the past decade from the value of the 1990 state-of-the-art material Disperse Red (DR). Indeed, if current chromophores could be organized into a pure chromophore lattice with perfect acentric order, $\langle\cos^3\theta\rangle = 1.0$, then electrooptic coefficients in excess of 1000 pm/V could be achieved. Such electrooptic coefficients would permit true millivolt drive voltages to be routinely employed. Such materials would greatly exceed the performance of lithium niobate ($r = 31$ pm/V, $V_\pi = 5$–6 V) and would likely displace liquid crystalline materials in applications such as spatial light modulation and optical switching. However, while the DR chromophore of Figure 1 exhibits an electrooptic coefficient of 10–15 pm/V and V_π voltages of 12–20 V, the FTC chromophore exhibits a surprising low electrooptic coefficient of 35–50 pm/V and V_π voltages of 3–5 V. Clearly, a problem existed/exists in translating large molecular electrooptic activity into usably large macroscopic electrooptic activity.

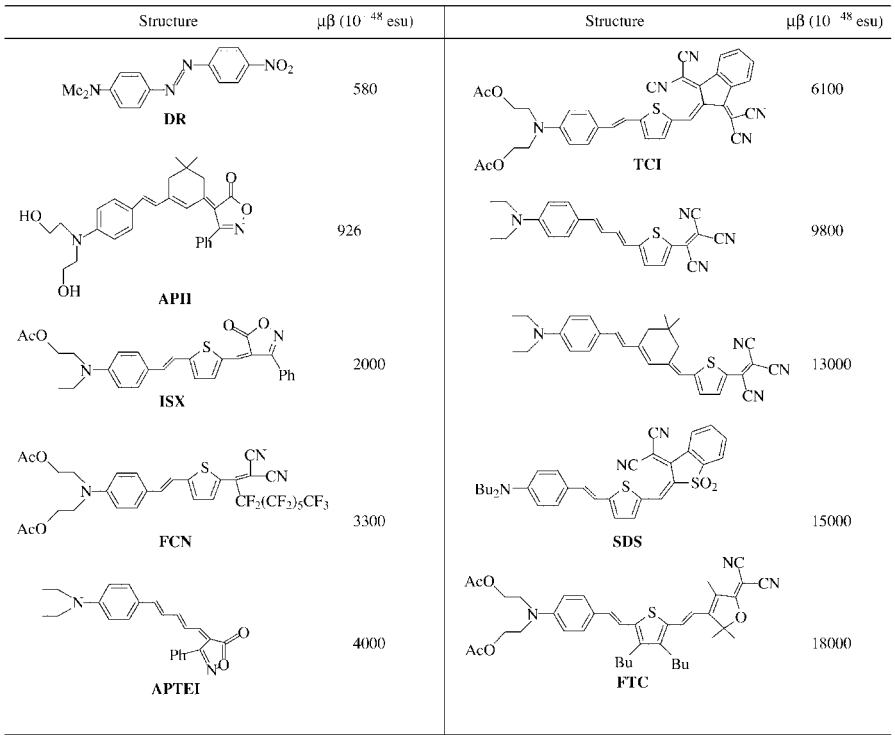

Fig. 1. The variation of $\mu\beta$ (dipole moment-first hyperpolarizability product) with chromophore structure is shown.

As is illustrated in Figure 2, the problem is now understood to derive from intermolecular electrostatic interactions among chromophores opposing the poling field in introducing the acentric order required for electrooptic activity (68,98–102). The same interactions oppose introduction of acentric order by sequential synthesis, self-assembly techniques where surface forces are used in place of a poling field to guide the assembly of chromophores into an acentric lattice (103). In this latter case, intermolecular electrostatic interactions cause the chromophores to tip away from the normal to the surface in their assembly. The problem has been successfully modeled using both equilibrium statistical mechanical methods and kinetic Monte Carlo methods, with both approaches specifically treating the many-body, long-range, spatially anisotropic interactions among chromophores. The intermolecular electrostatic interaction potential functions of equilibrium statistical mechanical and Monte Carlo methods are found to be very similar and approximate the potential function introduced by Piekara in the 1930s (104). Theoretical calculations explain a great many additional experimentally observed features including the relatively weak dependence of maximum achievable electrooptic activity upon electric poling field strength and phenomena such as concentration and electric-field-dependent phase separation. The theoretical rationalization of the dependence of achievable electrooptic activity upon the electronic and molecular structure of chromophores and the processing conditions (applied poling field

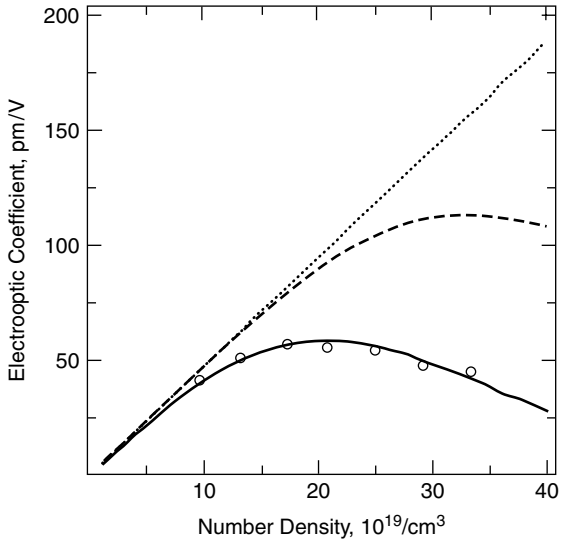

Fig. 2. The experimental and theoretically predicted dependence of electrooptic coefficient for the FTC chromophore (see Fig. 1) in poly(methyl methacrylate) (PMMA) upon chromophore number density (concentration in PMMA) is shown. Theoretical results are shown for various shape approximations and for the neglect of intermolecular electrostatic interactions (the ideal gas model). ------ Gas model; – – Sphere; —Prolate ellipsoid; ○ Experimental.

strength, dielectric constant of the host polymer matrix, chromophore concentration, temperature, etc) has provided both good and bad news. The bad news is that it will always be impossible to realize more than a fraction of the potential electrooptic activity represented by a given chromophore structure. Electrooptic coefficients of a few hundred pm/V may be obtainable, but values of 1000 pm/V or greater will be unobtainable with high dipole moment chromophores unless some other force (eg, ionic) is used to overwhelm the effect of dipole–dipole interactions. The good news is that theory provides guidance to quick optimization of electrooptic activity for a given chromophore/polymer system. The concentration (number density) of chromophores leading to maximum electrooptic activity is predicted by theory with high accuracy. Moreover, theoretical results argue that the shape of chromophores should be altered from their normal prolate ellipsoidal shape to a more spherical shape. This is readily accomplished by adding inert substituent (alkyl or alicyclic) groups to the waist of chromophores (68). An even more promising route is that of dendrimer synthesis including dendrimer structures where more than one chromophore is incorporated into the dendrimer. Very simply, steric forces are used to prevent chromophores from achieving centric order driven by dipole–dipole interactions. An example of an early version multichromophore dendrimer, which has led to electrooptic coefficients of 60 pm/V at 1.55 μm telecommunication wavelength, is shown in Figure 3 (105).

Theoretical guidance has permitted polymeric electrooptic materials to be fabricated that exhibit electrooptic coefficients in excess of 100 pm/V (68,106) at telecommunication wavelengths. With these materials, V_π voltages of less than 1 V have been achieved. This has been, without question, a very important

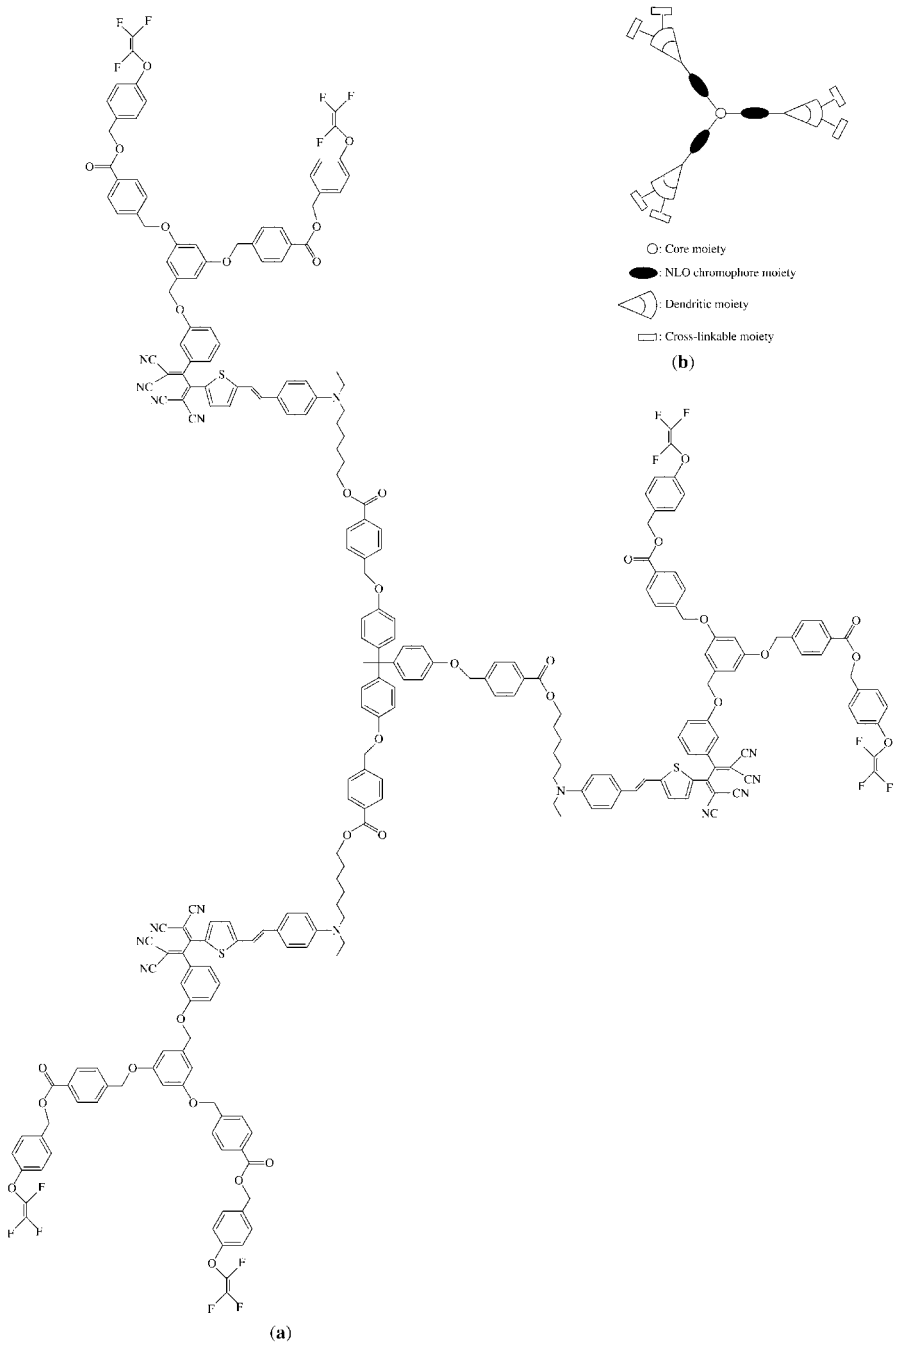

Fig. 3. (a) An early version multichromophore dendrimer (105) is shown. This cross-linkable dendrimer yields an electrooptic coefficient of 60 pm/V at 1.55 μm wavelength that is stable under testing at 85°C for 1000 h. (b) Schematic representation. $M_w = 4664$; Chromophore density: 33 wt%.

result stimulating considerable interest from both large and small companies in the telecommunications and defense fields. V_π voltages on the order of 1 V permit low cost complementary metal oxide semiconductor (CMOS) and high speed electrochemical luminescent circuits to be used without amplifiers. Moreover, such low voltages are important for the realization of transparent (low loss) communication links. Indeed, the realization of deep optical modulation with low electrical drive voltage can lead to gain in electrical-to-optical-to-electrical signal transduction. In satellite telecommunication applications, the elimination of low noise amplifiers is important for the reduction in launch weight as well as for reducing noise and cost. The practical (commercial) importance of the advances in electrooptic activity rests upon two issues: (*1*) Can electrooptic activity be further improved and by how much? (*2*) Can large electrooptic activity be achieved in conjunction with all of the other required properties? The answer to the first question is very likely positive. Indeed, it is clear that electrooptic activity will be further improved by at least another factor of 2. The answer to the second question will become clear from the following paragraphs.

Bandwidth

The bandwidth (response time or highest frequency component of data that can be handled) of devices fabricated from electrooptic materials is determined by the index of refraction n and dielectric constant ε of the materials from which the devices are fabricated. For polymeric organic electrooptic materials, $\varepsilon = n^2$ approximately. This means that low frequency electrical and high frequency optical waves propagate with the same velocities in a material. This in turn means that long interaction lengths can be employed, which leads to low drive voltage requirements. For example, 3-cm electrodes were used to achieve sub 1-V V_π values for polymeric modulators (68). For organic materials, voltage-length products are currently of the order of 1–3 V·cm. The typical index of refraction values ($n = 1.55$–1.70) and dielectric constant values ($\varepsilon = 2.4$–3.0) for polymeric organic materials have permitted electrooptic device bandwidths of 113 GHz to be demonstrated using simple device structures (107–110). Pulsed measurements establish that the intrinsic material bandwidth response is of the order of 350 GHz (essentially defined by the phase relaxation time of the π-electron system). Device bandwidth-length product values could conceivably be as high as 350 GHz·cm with polymeric organic electrooptic materials; however, the difficulty of transmitting electrical signals with frequency components above 120 GHz through metal electrodes makes this a difficult objective to achieve. The low dielectric constants of organic materials also lead to very favorable power requirements (eg, typical P_π values are on the order of 4 dB). Crystalline organic materials achieve acentric order by exploiting ionic interactions to overwhelm the chromophore π-electron dipole interactions that favor centric order. These ionic interactions lead to higher index of refraction and dielectric permittivity values, eg, 2.5 and 7.0 respectively.

For lithium niobate, dielectric constants are of the order of 28 while index of refraction is of the order of 2.2. The bandwidth-length product is 10 GHz-cm and the voltage-length product is 5 V-cm. By clever engineering (minimizing the

time spent by electrical waves in high dielectric lithium niobate), lithium niobate devices have been demonstrated to approximately 90 GHz. Commercial devices are available from Lucent with bandwidths of 30 GHz, V_π voltages of 6 V (1550 nm), insertion loss of 6 dB, and temperature stability to 70°C. The high dielectric constant of lithium niobate results in high power dissipation, ie, $P_\pi >$ 32 dB currently. While high frequency operation is possible with devices fabricated from lithium niobate, more sophisticated device engineering is required. Moreover, such bandwidth is accomplished with sacrifice of drive voltage. The high intrinsic bandwidth afforded by polymeric organic materials was early on recognized as one of the greatest advantages of such materials. The fact that the high bandwidth of organic electrooptic materials is now accompanied by low drive voltage requirements argues for the serious commercial consideration of these materials.

GaAs electroabsorptive modulators offer the possibility of high bandwidth (50 GHz) and low drive voltage (1–2 V). However, these materials exhibit substantial chirp. It is impossible to change absorption without also changing index of refraction. Moreover, GaAs devices are plagued by high insertion loss (9–12 dB). Lithium niobate modulators seem to be the currently preferred alternative to GaAs modulators for high frequency (10–30 GHz) applications.

Modulated lasers, thermooptic switches, liquid crystalline modulators, bubble jet switches, and MEMS devices suffer even greater bandwidth limitations. The introduction of wavelength division multiplexing (WDM) has taken some of the bandwidth pressure off of purely time division multiplexing (TDM) approaches to handling telecommunication throughput. However, bandwidth is likely to remain a serious issue for future telecommunication systems, and thus the bandwidth performance organic and inorganic electrooptic materials will remain an issue of active concern.

Optical Loss

One of the most attractive advantages of lithium niobate is exceptionally low optical loss (material loss of 0.2–0.4 dB/cm and device insertion loss of 3–6 dB at telecommunication wavelengths). Optical loss has been a problem with polymer materials until recently when a better understanding of factors leading to both material and insertion optical loss has permitted significant improvement in loss values (to material loss values of as low as 0.2 dB/cm and insertion loss values as low as 4 dB at telecommunication wavelengths). Material optical loss can be associated with either absorption loss or loss due to scattering. Absorption loss can arise from either (or a combination of) interband electronic absorption or C—H (or N—H, O—H) vibrational overtone absorption at 1.3 or 1.55 μm wavelengths. Wavelength-dependent interband absorption is easily assessed by techniques such as photothermal deflection spectroscopy. Appropriate chromophore design can keep optical loss due to interband absorption below 1 dB/cm even at 1.3 μm wavelength. Such loss is probably not a significant factor at 1.55 μm telecommunication wavelength. Vibrational absorption at 1.3 and 1.55 μm wavelengths is a much more serious problem. As with the production of low loss silica fiber, the answer to the problem of intrinsic optical loss is to get the hydrogen out of

the material. Without such reduction in hydrogen content, optical loss in organic materials is typically limited to approximately 1 dB/cm at 1.3 μm wavelength and somewhat higher values at 1.55 μm wavelength. With organic materials, reduction in hydrogen content typically means using partially fluorinated materials or materials constructed with functionalities, such as the cyanurate ligand, that do not contain hydrogen (when the carbon positions are substituted). Using cyanurate and fluorinated dendrons, optical loss values as low as 0.2 dB/cm have been obtained for electrooptic dendrimer materials. Fluorination of polymer materials frequently involves unwanted changes in processability; for example, changes in solubility in spin-casting solvents. Dendrimer synthesis has been demonstrated to provide a convenient means of reducing optical absorption loss without paying a price in material processability.

Scattering losses induced by processing have been a much more insidious problem in the fabrication of low loss organic waveguide structures. Scattering losses can arise from several sources. One of the most obvious is material inhomogeneity associated with spin casting. Any phase separation leads to disastrously high loss values. Strong dipole–dipole interactions among chromophores can drive phase separation. Fortunately, such interactions can be attenuated by appropriate derivatization of chromophores. Such derivatization also improves the entropy of mixing (and hence the solubility) of chromophores in spin casting solvents. Electric field poling and the concurrent cross-linking of materials to lock-in poling-induced electrooptic activity can also lead to optical loss (71,100,106,111–113). Two types of optical loss are typically associated with electric field poling. The first arises from electric-field-induced surface damage. This is simply a form of dielectric breakdown and can be avoided by keeping corona poling field strengths below damage thresholds. It is important to keep in mind that the harder (more cross-linked) the polymer lattice, the higher the damage threshold. Thus, electric field poling and lattice hardening are typically carried out using a stepped temperature/electric field protocol (71,100,112,114–116). The second type of poling-induced scattering loss is associated with introduction of inhomogeneity in the material as the result of electric field poling. Such inhomogeneity can arise from an electrophoretic effect or from poling-induced birefringence. If defects (such as dust particles) exist that are not influenced by the poling field, then poling can enhance the index difference between these defect regions and the electrooptic material leading to enhanced scattering loss (117). Lattice hardening (cross-linking) chemical reactions can also be a source of material inhomogeneity that leads to increased scattering loss. This is particularly true with thermosetting reactions such as urethane chemistry where a variety of oligomeric structures can exist and grow at different rates (111). Some of these structures can become incompatible and phase separate. Moreover, some cross-linking chemistries, such as urethane chemistry, are susceptible to atmospheric moisture. The reaction with water from the atmosphere can upset the one-to-one stoichiometry of lattice hardening reactions leading to the buildup of incompatible components and phase separation. The occasionally observed cloudy appearance of polyurethane electrooptic polymers is typically indicative of problems with atmospheric moisture. However, when sources of optical loss associated with electric field poling and lattice hardening are taken into account, optical loss values on the order of 1 dB/cm are readily obtained (71,100,106,111–113).

Optical loss can also arise from fabrication of buried channel waveguide structures by reactive ion etching (RIE) techniques and by the deposition of cladding layers where the solvent employed in spin casting the cladding layer causes solvent pitting of the electrooptic film layer. Both of these loss mechanisms can be controlled by lattice hardening of the electrooptic material and by control of processing conditions. Control of the kinetic energy of reactive ions in RIE (118,119) can keep optical loss values due to waveguide wall roughness to insignificant values (0.01 dB/cm). Cladding layers pose an unanticipated problem for the utilization of organic-electrooptic materials. While cladding materials have been utilized that make no problematic contribution to optical loss, problems in device operation can frequently be traced to cladding materials rather than to the electrooptic materials. Conducting cladding materials can be particularly problematic. In general, one wants the electrical conductivity of the cladding material to be higher than that of the electrooptic material so as to drop the poling field across the cladding layer. However, if the cladding material has significant optical loss, the penetration of the propagating optical field into the cladding layer will result in unwanted attenuation of the transiting beam. The cladding material can also undergo photochemical damage and may do so even when the electrooptic material does not show damage. This can manifest in time-dependent loss of mode confinement when no change in electrooptic modulation efficiency is observed. A more subtle problem that can arise with conducting cladding materials is that of photoconductivity (or optical power-dependent conductivity). Electrooptic chromophores are very polarizable materials and can inject charge into a conducting medium (71,112). Thus, an optical power-dependent conductivity of the cladding material can result if that material is susceptible to accepting charge and transporting that charge. Such effects are typically observed only at high power levels in devices such as high frequency oscillators based on electrooptic modulator technology. Of course, optical fields must be kept away from lossy metal electrodes. Again, if care is taken in the design and execution of device structures, loss from waveguide fabrication, cladding deposition, and electrode deposition can be kept to insignificant values, and overall active waveguide loss values of 1 dB/cm can be routinely achieved.

The greatest loss issue to be faced in the commercial implementation of organic electrooptic devices is that of mode mismatch loss when coupling silica fiber and polymeric electrooptic modulator waveguides. For 1.3 μm telecommunication wavelength operation, silica optical fiber waveguides are cylindrical with spherical cross-sectional core diameters on the order of 10 μm, while the cross-sectional shapes of polymeric electrooptic modulator waveguides are elliptical with heights of 1–2 μm. Butt coupling of such active and passive waveguides leads to optical loss on the order of 4 dB per transition. The coupling problem is readily addressed using spherical lens or tapered transitions (70,71,112,120). A tapered transition such as shown in Figure 4 reduces coupling loss to a few tenths of a decibel. Thus, total insertion losses of 4–5 dB have been obtained for polymeric materials exhibiting material loss on the order of 1 dB/cm. Tapered transition structures can be fabricated by employing offset, gray scale, and shadow ion masking techniques (70), which are to be discussed later. Such lithographic techniques are also useful for constructing sophisticated 3-D circuits (70).

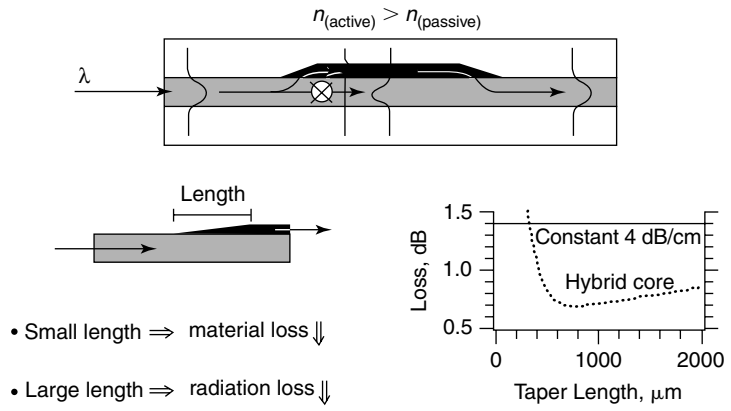

Fig. 4. A low loss polymeric electrooptic modulator transition structure is shown. The optimum taper length is defined by the trade-off between acceptable radiation loss and material loss.

Stability

For electrooptic materials (eg, liquid crystalline materials) based on index of refraction changes associated with molecular reorientation, one wants facile reorientation to permit fast switching times. Organic photorefractive materials also exhibit enhanced response when molecular reorientation contributes to observed index changes. In contrast, reorientation destroys the electric-field-poling-induced electronic electrooptic activity of chromophore-containing polymeric materials. When one speaks of thermal instability of electronic electrooptic activity for organic materials, one is referring to reorientational (molecular rotational) dynamics that destroy poling-induced acentric order. There are two general approaches to improving the stability of poling-induced order. One is to place chromophores in polymer materials, such as polyimides or polyquinolines, characterized by high glass-transition temperatures. This may be accomplished either by physically dissolving chromophores in polymers to produce composite materials or by covalently coupling chromophores to polymer lattices (71,112,121–134). The stability will be defined by both the segmental flexibility of the polymer backbone (the glass transition temperature) and the number (and positioning) of covalent bonds coupling the chromophore to the polymer lattice. The stability of poling-induced acentric chromophore order (electrooptic activity) can be readily assayed by monitoring second harmonic generation (another phenomena related to $\chi^{(2)}$) as a function of heating the sample (see Fig. 5) (135). This is a nonlinear optical analogue of thermal gravimetric analysis except that molecular reorientation rather than material decomposition accounts for the loss of second-order nonlinear optical activity. As shown in Figure 5, thermal stability of electrooptic activity is increased with cross-linking. When dynamic thermal stability is increased to temperatures such as 170°C as shown in Figure 5, then long-term stability is typically observed for periods of several thousand hours even when devices are operated at 100°C. Segmental flexibility of polymers is one of the most serious problems with relaxation

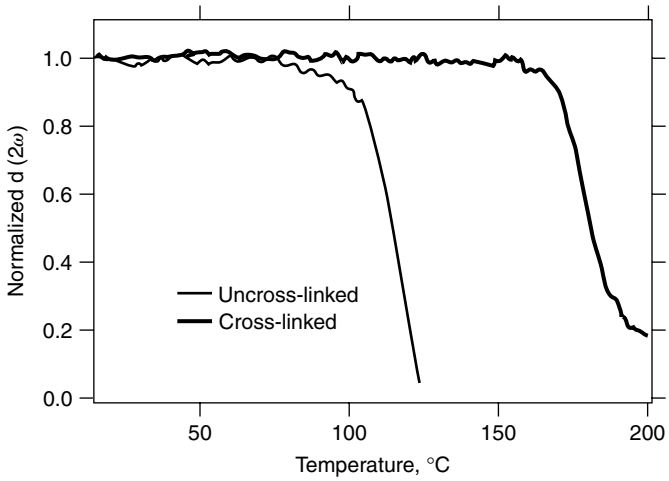

Fig. 5. Second harmonic generation is shown as a function of temperature for heating at a rate of 10°C per minute for two samples. The uncross-linked sample (chromophore is attached covalently by one end to a PMMA backbone) starts to lose second-order optical nonlinearity (acentric chromophore order) before 100°C. The cross-linked sample corresponds to both ends of the chromophore being covalently coupled to the polymer lattice. For this sample, thermally stable second-order optical nonlinearity is observed until nearly 170°C.

of poling-induced acentric order. Dendrimer materials appear to have distinct advantages for enhancing the thermal stability of poling-induced electrooptic activity. Not only can the covalent bonds and steric interactions of dendrimers hold chromophores away from each other (inhibiting centric ordering) but dendrimer structures can also oppose thermal relaxation. The dendrimer material of Figure 3 is observed to exhibit stable electrooptic activity for 1000 h at 85°C. Greater thermal stability should be achieved by greater attention to the flexibility of dendrons and by better control of cross-link density. In comparison, the thermal stability of lithium niobate devices is typically listed as 90°C while gallium arsenide devices are specified as stable to 80°C.

Preliminary studies of the stability of organic electrooptic materials to high energy (gamma ray) radiation and particles (protons) carried out by Lockheed Martin (Palo Alto) and by researchers at the Air Force Research Laboratory (Wright Patterson Air Force Base) suggest that space application of polymeric electrooptic materials should proceed without problems.

Photochemical stability is more difficult to assess. Lithium niobate is specified as having optical power handing capabilities to 250 mW while gallium arsenide is specified as having a maximum power handling capability of 30 mW. However, such power handling capability is typically specified for packaged materials where oxygen has been excluded. The photochemical stability of organic materials is dramatically affected by the presence of oxygen. Exclusion of oxygen typically improves photochemical stability by several orders of magnitude. The addition of oxygen (radical) scavengers can also improve photochemical stability (136). Photochemical stability can also improve

with lattice hardening (100) although this will depend upon the porosity of the polymer lattice, which may not always correlate simply with cross-link density. Unfortunately, controlled evaluation of photochemical stability under conditions appropriate for commercial applications have not been carried out for polymeric electrooptic materials; thus, photochemical stability remains the most serious question concerning the commercialization of organic electrooptic materials.

Mechanical Properties

Polymeric electrooptic materials have the advantage of being conformal and of exhibiting effective bonding to a variety of surfaces. Moreover, by control of cross-link density, the mechanical properties of polymeric electrooptic materials can be controlled. Electrooptic device operation can be carried out over a wide range of temperatures. Eventually, different coefficients of thermal expansion may cause delamination problems upon thermal cycling over wide temperature ranges, but such problems have not been noted to the present. A unique feature of polymeric systems is that good mechanical properties are obtained for lightweight materials. Weight is an issue in satellite telecommunication and reconnaissance systems. Regarding weight issues in satellite telecommunications and reconnaissance operations, the low drive voltage requirements of polymeric electrooptic devices permit the elimination of low noise amplifiers, which in turn results in substantial weight reduction. Thus, the weight issue is not the relative weights of lithium niobate and polymeric electrooptic materials but the relative weights of total systems fabricated from these materials. Also, the critical weight saving comes from using photonic (optical fiber) versus electrical (coaxial) cables.

Processing and Integration

Polymeric materials are amenable to facile processing by RIE (70,71,112,119,120) and photolithographic techniques (71,112,137). Use of offset, gray scale, and shadow ion lithographic masks and RIE has permitted implementation of vertical waveguide transitions and the fabrication of 3-D circuits permitting the ready integration of passive and active optical waveguide components (70,71). Polymeric electrooptic materials are also very compatible with semiconductor processing, and electrooptic circuitry has been fabricated on top of very large-scale integration (VLSI) semiconductor chips (71,112). Indeed, through use of planarizing polymers, electrooptic modulators have been vertically integrated (in high density) with VLSI chips. Integration has been accomplished without the perturbation of the performance characteristics of either electronic or optical (electrooptic) circuitry. One of the advantages of polymeric electrooptic materials is this ready integration with semiconductor electronics and the ability to fabricate a large number of modulator waveguides on a single chip. With lithium niobate, such integration is not possible and connection to electronic circuitry is typically made by wires and flip chip bonding. By use of tapered transitions and

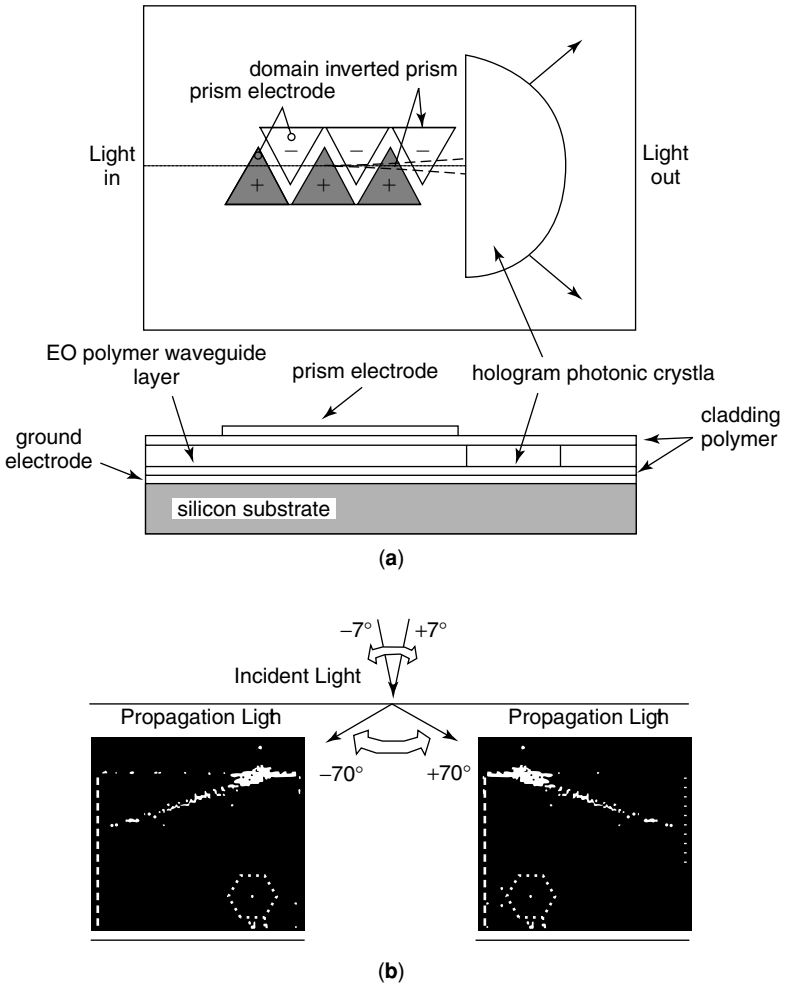

Fig. 6. Large-angle beam steering is shown for a device based on a polymeric electrooptic material (a cross-linkable version of the CLD chromophore discussed in Ref. 68). (a) EO waveguide prism introduces a small deflection angle to initialize the beam scanning. The half-circle 2-D photonic crystal region is embedded into the waveguide so that the deflection angle is "amplified" as the light passes through the crystal region. 3-D scanning can also be provided if a 3-D structure is built. (b) The experimental observation of the angle sensitivity.

spherical lens, electrooptic waveguides have been coupled to silica fiber optics. Again, coupling can be achieved in a more straightforward manner than with lithium niobate.

An example of sophisticated device development is shown in Figure 6. Large-angle (-70° to $+70^\circ$) beam steering is demonstrated by implementing a series of cascaded electrooptic prisms, which initiate beam steering and feed light into a photonic band gap lattice (138,139). The photonic band gap lattice is fabricated by holography in a photopolymer material (see Fig. 7). Beam steering is accomplished with more than an order of magnitude lower drive voltage than required using

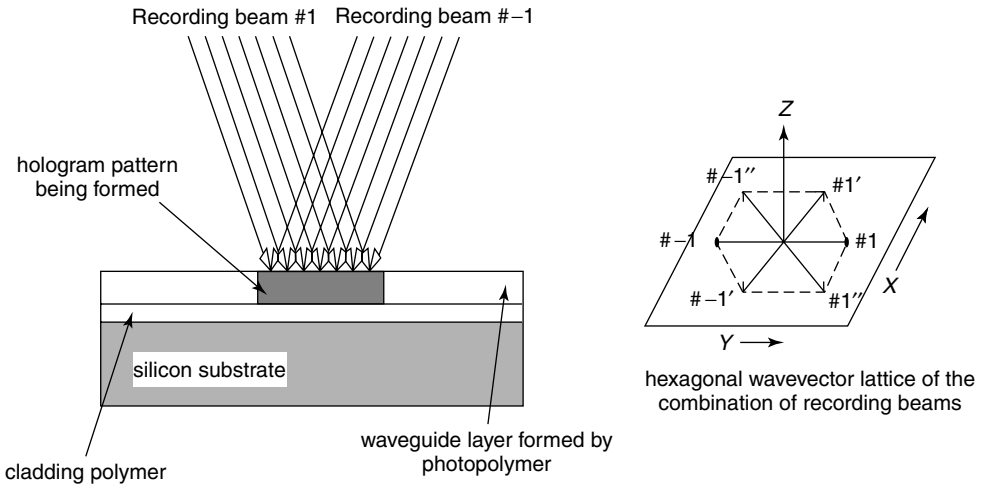

Fig. 7. The holographic production of the polymeric photonic band gap lattice used in the beam steering device of Figure 6 is shown.

lithium niobate materials. Through the cascaded prism electrodes, the deflection angle is given for steering of a TM polarized beam by

$$\theta = n_0^2 r_{33}(V/\mathrm{d})(L/h) \tag{5}$$

where L and h are the length and width of the prism array, respectively. V is the applied driving voltage and d is the electrode spacing. The electrooptic coefficient in the direction of the driving field is r_{33}, while n_0 is the voltage independent index of refraction. In the present example, L/h is approximately 80 with $L = 16$ mm and $h = 200$ μm. The model used to arrive at equation (4) is based only upon the total phase retardation across the wave front. The deflection angle thus depends only on the overall dimension of the prisms, since the accumulated phase difference across the wave front is independent of how the deflector is subdivided into individual prisms, as long as the interfaces between adjacent prisms are straight lines.

Devices

The most simple device configurations utilizing electrooptic materials are shown in Figure 8 (122). These include the Mach Zehnder and birefringent modulators and the directional coupler. As configured in Figure 8, the first two devices are amplitude modulators. A somewhat higher drive voltage is required for the birefringent modulator than for the Mach Zehnder modulator. This is because the V_π voltage of the Mach Zehnder relates directly to the principle component (r_{33}) of the electrooptic coefficient. The V_π voltage of the birefringent modulator relates to the difference between the major and minor components

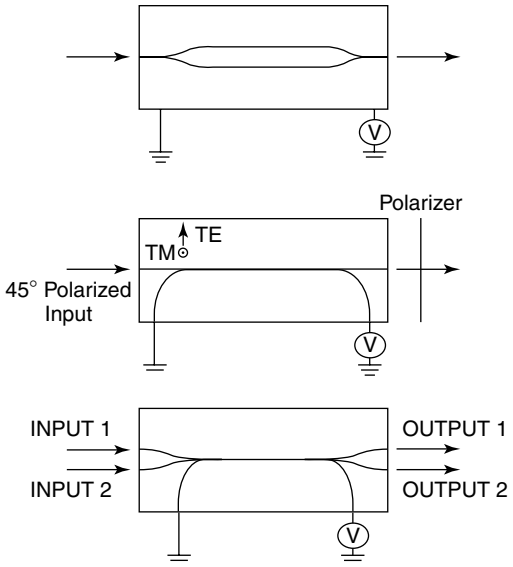

Fig. 8. Mach Zehnder interferometer (top), birefringent modulator (middle), and directional coupler (bottom) device configurations are shown.

$(n_3^3 r_{33} - n_1^3 r_{13})$. A still higher drive voltage is required for the directional coupler, and the relationship to material electrooptic activity is somewhat more complex (122).

We have already shown a large-angle spatial light modulator based upon organic electrooptic and photonic band gap materials (Figs. 6 and 7). Such beam steering without moving parts is relevant for holographic optical data storage, switching in all optical networks, advanced laser radar (ladar), photonic phased array antennas, optical sensors, and laser printers. Spatial light modulation exploiting electronic electrooptic activity has not only the advantage of greater speed but also avoids instability due to overshoot associated with the momentum of mechanical beam steering (MEMS) devices. The fact that such beam steering can be accomplished with application of driving voltages in the range of volts rather than kilovolts (as is the case for lithium niobate) is also a very attractive feature. For fiber optic switching, spatial light modulation has the advantage that a large number of fiber channels can be selectively addressed using only one electrode. Overall, electrooptic beam steering offers a simplified operating scheme, low driving voltage, high switching speed, small size, and low cost.

Ultra high bandwidth analogue-to-digital (A/D) conversion has been accomplished utilizing polymeric electrooptic materials in several different device configurations. Analogue-to-digital conversion employing a cascaded series of Mach Zehnder modulators has been discussed elsewhere (112). Analogue-to-digital conversion can also be accomplished by time stretching (140). In this application, a femtosecond pulse is stretched (by a dispersive medium) to match the length of an incoming data stream containing high frequency information. The data stream is transduced as an amplitude modulation (by a polymeric electrooptic modulator)

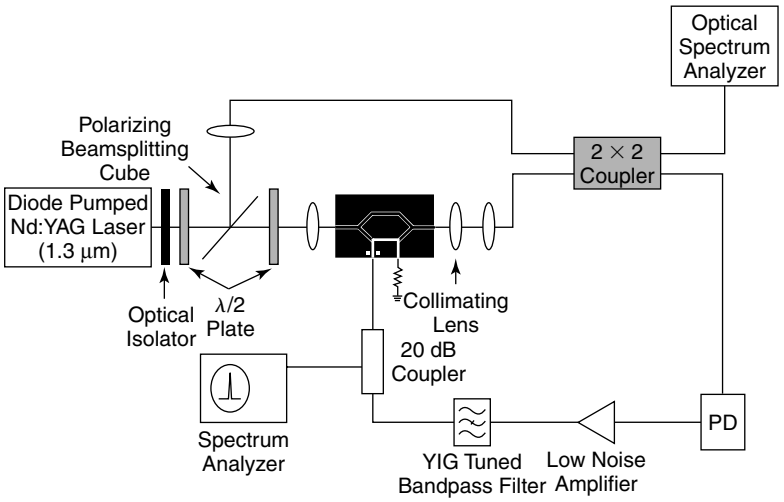

Fig. 9. A broadband, ultrastable oscillator based on polymeric electrooptic materials is shown.

onto the optical pulse. The pulse is then further time stretched to a length compatible with conventional A/D converters. The pulse is then converted to an electrical signal by a diode detector and A/D conversion is effected. Such time stretching permits A/D conversion at rates of 100 Gbit/s.

Another prototype device, which has been demonstrated by researchers at Pacific Wave, is that of a high frequency oscillator (see Fig. 9). In this oscillator, the stability of the oscillator is determined by the length (Q) of the optical circuit (loop) and can thus be very high indeed.

A variety of phased array systems have been fabricated based on polymeric electrooptic materials (141,142). One configuration is based on the photonic phase shifter shown in Figure 10. This provides a very linear phase shift as a function of control d-c voltage. Optical signals of controlled phase are thus sent to various radiating antenna elements. The optical signals are converted to radiofrequency signals by diode detectors.

High frequency (including secured communication by frequency hopping) telecommunication applications are receiving considerable attention (143). As can be seen in Table 1, the bandwidth limitation of current electronic components is the limiting factor to achieving increased bandwidth performance with polymeric electrooptic materials. In Figure 11, a device configuration capable of 130-GHz bandwidth operation is shown.

Other demonstrated prototype devices include optical gyroscopes (144), broadband acoustic spectrum analyzers (145), 1×2 Y-fed directional couplers (146) and polarization-insensitive electrooptic modulators (147,148). For long-haul telecommunication applications, it is difficult to maintain polarization control; thus, a need exists for polarization-insensitive modulators. Indeed, polarization insensitivity was one of the advantages claimed for gallium arsenide electroabsorptive modulators. By using different poling schemes, overall polarization insensitivity has been achieved for polymeric modulators (147,148).

Table 1. The Bandwidth Characteristics of Various Electrical Interfaces

Modulator type	Electrical interface	Bandwidth, GHz	Technology availability	Reliability	Cost
Traditional	K-coax	0–40	Simple, commercial	Proven	Low
M-Z modulators	V-coax	0–65	Simple, commercial	Proven	Low
	W-coax	0–110	Ongoing at TACAN	R&D	Low
	WR-15	50–75	Complicated, customer	R&D	High
	WR-10	75–110	Complicated, customer	R&D	High

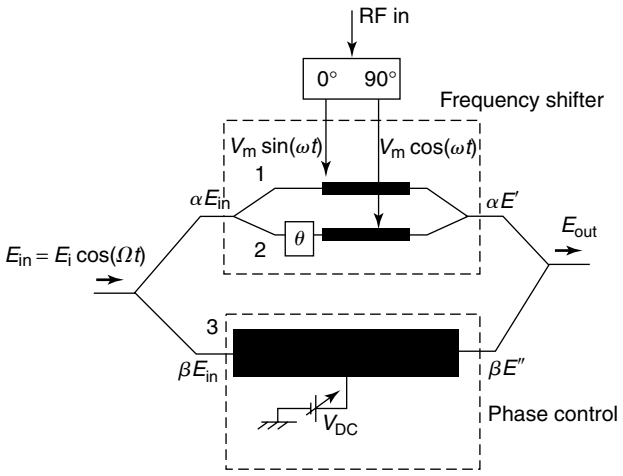

Fig. 10. A schematic representation of a photonic radiofrequency phase shifter is shown.

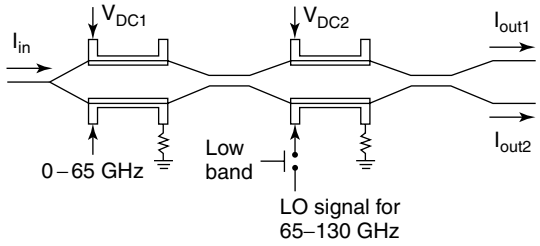

Fig. 11. A 130-GHz telecommunications device is shown.

Commercialization and Cost

As with lithium niobate, the cost of devices based on polymeric electrooptic modulators is in the packaging rather than in the materials. A Lucent lithium niobate modulator sells for approximately $6000. Polymer modulator vendors such as Pacific Wave Industries (Los Angeles, California) are quoting comparable prices. The low material cost is associated with the fact that modulator devices are thin-film

devices and a chip containing 6–100 modulators requires very little polymeric electrooptic material.

A number of small companies such as Lumera (Bothel, Washington), Pacific Wave Industries (Los Angeles, California), Radiant Research (Austin, Texas), IP-ITEK/TACAN (Carlsbad, California), KVH Industries (Tinley Park, Illinois), etc are exploring the commercialization of electrooptic devices based on polymeric materials. Lockheed Martin has pursued research in polymeric electrooptic materials for more than a decade and continues to be a leader in the field. Lucent has recently resumed research on polymeric electrooptic materials. A number of telecommunication companies including Nortel, Agilent, Cisco, and JDS-Uniphase are currently evaluating polymeric electrooptic technology to determine the viability of R&D and commercial activity in this area.

The market for inorganic electrooptic and electroabsorptive modulators is currently in the hundreds of millions of dollars per year with wait times of several months for delivery of lithium niobate modulators. The perceived need for greater bandwidth in the telecommunications industry is likely to drive demand even higher.

Future Prognosis

Provided that no unexpected problems arise that would inhibit the commercialization of polymeric electrooptic technology, the prognosis is very good. The greatest uncertainty involves whether or not organic electrooptic materials will exhibit adequate photochemical stability over many years of in-field operation. Preliminary studies suggest that exclusion of oxygen and hermetic sealing will yield devices capable of exhibiting photochemical stability over many years for exposure to optical fields at telecommunication wavelengths and powers. Almost certainly, electrooptic coefficients will continue to be improved. New and improved chromophores are being synthesized with great regularity (149). Devices operating with sub 1-V V_π values should become commonplace. Utilization of photonic band gap materials and controlled coupling to resonated structures should permit further reduction in drive voltage requirements (possibly even to microvolt levels); such reduction is, of course, at the expense of some reduction in response time (bandwidth). Low drive voltage requirements, together with high bandwidth capabilities and the ease of integration with semiconductor electronics and silica transmission fibers, should be a powerful driver for the deployment of polymeric electrooptic technology in telecommunication, defense, transportation, and display industries. However, the extent of utilization of polymer electrooptic technology in the telecommunication industries will depend upon perceived bandwidth needs. If low cost alternatives to high information throughput with reduced bandwidth requirements (such as expanded use of WDM technology) become popular, limited bandwidth technologies such as thermooptic, liquid crystalline, MEMS, and modulated laser technologies may continue to dominate sales in the telecommunications area. However, even if deployment is slow in telecommunications, defense industries should find use for the exceptional capabilities of polymeric electrooptic materials for applications such as radar, electronic counter measure, sensor, and display systems. Other

niche applications including biomedical sensors, analytical instrumentation, and high frequency test equipment are likely to develop.

The main limitation to general deployment of organic electrooptic materials is that they have been optimized to this point in time for applications at telecommunication wavelengths. Inorganic materials such as lithium niobate are still the materials of choice for applications at visible wavelengths. Such inorganic modulators are likely going to continue to dominate the laboratory market for modulators to be used with research laser systems.

Nomenclature

p_i	ith component of the molecular polarization vector in the presence of electrical fields
p_{0i}	ith component of the permanent polarization of the molecule
E	the local electric field strength
F	the local electric poling field strength
α	molecular polarizability tensor
β	molecular first hyperpolarizability tensor
γ	molecular second hyperpolarizability tensor
P_i	ith component of the bulk polarization vector in the presence of electrical fields
P_{0i}	ith component of the bulk polarization vector in the absence of external fields
V	applied voltage
$\chi^{(1)}_{ij}$	first-order electric susceptibility tensor
$\chi^{(2)}_{ijk}$	second-order electric susceptibility tensor
$\chi^{(3)}_{ijkl}$	third-order electric susceptibility tensor
n	refractive index in the presence of an applied electric field
n_0	refractive index in the absence of an applied electric field
r	Pockels coefficient or electrooptic coefficient
r_{33}	electrooptic coefficient in the direction of the applied field (principal element)
r_{13}	electrooptic coefficient orthogonal to the applied field direction (minor element)
R	Kerr factor
E_0	applied electric field amplitude
N	number density
$f(\omega)$	local field factor
$\langle\cos^3\theta\rangle$	acentric order parameter
V_π	applied voltage required to produce a phase shift of π
λ	wavelength of light
d	electrode gap
L	interaction length of electrical and optical fields in material
Γ	modal overlap integral
θ	beam deflection angle

EMULSION POLYMERIZATION. See HETEROPHASE POLYMERIZATION.

ENGINEERING THERMOPLASTICS, OVERVIEW

Introduction

The development of plastic materials is one of the most successful stories of the twentieth century. In the sixties, plastics represented a small fraction of the total annual consumption of materials, but 20 years later they surpassed metallic materials (mostly iron-based) in terms of consumed volume. At the end of the century, plastics reached the astonishing total amount of 150 million metric tons produced per year. Of this amount, 70% is comprised by the so-called commodity plastics (HDPE, LDPE, PP, PVC, and PS), 11% by thermoset resins, 7% by elastomers, and 12% by engineering thermoplastics.

The definition of engineering plastics is rather arbitrary. In the last edition of this encyclopedia they were defined as *thermoplastic resins, neat or filled, which maintain dimensional stability and most mechanical properties above 100°C and below 0°C*. In such a definition, engineering plastics are obviously intended as engineering thermoplastics and the terms are used interchangeably. They encompass plastics that can be formed into parts suitable for bearing loads and able to withstand abuse in thermal environments traditionally tolerated by metals, ceramics, glass, and wood. A more general definition defines *engineering plastics* as those *high performance materials that provide a combination of high ratings for mechanical, thermal, electrical, and chemical properties*. This article adopts this latter definition, with the following three restrictions: (*1*) thermoplastics considered here are generally produced on an industrial scale; (*2*) with some exceptions, their predominant application is as solid parts or films, not fibers or cellular materials; and (*3*) sophisticated derivations of commodities, like reinforced PP, UHMWPE, etc, widely used in engineering applications are excluded. Following

these guidelines, Table 1 was compiled; occasionally, copolymers, blends, and reinforced polymers are included. The materials have been arbitrarily grouped by considering the most representative heteroatom present in their chemical structure. These materials are discussed in general in this article and in more detail in articles devoted to the various polymers. Cross references are provided.

The selection of polymer families treated here is somewhat arbitrary. For instance, fluoropolymers are more functional materials than engineering materials, and acrylic resins suffer enough thermal instability to be considered by some authors as outside the border of engineering plastics. However, PTFE (together with some copolymers) and PMMA have been considered because of their notoriety and some specific engineering applications.

Table 1 categorizes polymeric materials as *engineering polymers* (lower performance) or *high performance polymers;* the borderline between the two groups is rather vague. Relatively good indicators for such a classification are the selling price and/or the amount produced per year. Polymers can be either amorphous or partially crystalline, depending on their molecular structure and conditions of formation of the solid phase (polymerization and/or thermal history). The amorphous or semicrystalline nature of each material is reported in Table 1 as the form predominantly used in applications. A polymer is considered semicrystalline when it develops a detectable crystalline phase upon nonaccelerating cooling of the melt (see SEMICRYSTALLINE POLYMERS; CRYSTALLIZATION KINETICS). However, in particular conditions a polymer normally crystalline appears amorphous. For example, PET, is crystalline by slow cooling of the melt, but by rapid quenching it is amorphous. Crystalline and amorphous polymers are distinguished by several different properties, and the most evident of them is light transmission: crystalline polymers are opaque, whereas amorphous polymers are transparent (see AMORPHOUS POLYMERS). Finally, Table 1 collects the acronyms which are assigned to the various polymers through the text, as well as the Chemical Abstract Service Registry Number (CASRN). In the case of polymers, the assignment of more than one CASRN to the same material is frequent.

Table 2. Relationships between Polymer Properties and Morphology

Property	Crystalline	Amorphous
Light transmission	High	None to low
Solvent resistance	High	Low
Lubricity	High	Low
Dimensional stability	High	Low
Mold shrinkage	High	Low
Resistance to dynamic fatigue	High	Low
Facility to form high strength fibers	High	None
Thermal expansion coefficient	High	Low
Melting temperature	Sharp	Absent
Dependence of properties on temperature	High	Low

In Table 2, the qualitative dependence of some properties of polymeric materials as a function of their morphological state is reported. Such properties are determined directly or indirectly by the different response of chains to solicitations (chemical, thermal, and so on) when they are in an ordered arrangement or in a random one. Totally crystalline (100%) polymers are impossible to obtain because of the unavoidable presence of chain folds; further, the crystallinity degree can change under the effect of thermal, mechanical, or chemical operations.

History of Development

The development of engineering thermoplastics began in the thirties and is still continuing. The first patent on polyamide (nylon) was obtained by Carothers in 1931. Before the second World War, acrylic and polyester resins were discovered, as well as styrene-based copolymers (ABS) and PTFE. The latter was brought to full production in 1950 as Teflon by DuPont. In the same year, polycarbonates were introduced by General Electric and acetal resins by Celanese. In the period of 1960–1980, most of the actual high performance polymers were developed, among them were polyimides, PES, PPS, PEEK, and PEI, as well as other engineering resins such as PPO and PBT. At that time, the potential of development of novel engineering plastics was overestimated, and when it was realized that the volume growth was not so fast, the introduction of new families slowed down. Several factors contributed to this change of attitude, from the growing of costs necessary for the introduction of a new material, to a lower demand of materials studied for structural applications, and finally to the competition of tailored grades of existing polymers (also commodity plastics, like PP), new blends, and reinforced materials. Furthermore, the time from the invention of a new polymer structure to the achievement of the industrial stage remained quite high (10–12 years), in spite of the experience accumulated in such processes. Thus, from an originally forecasted 25% of the whole plastics market, engineering plastics cover only 10% roughly. It remains true that the growth rate is higher than that of commodities, but this expands their total fraction only very slowly. In Figure 1, the chronological development of commercial thermoplastic polymers is sketched, taking into account commodities nearer to engineering polymers (in properties) (1,2). The figure shows that most of the engineering thermoplastics were

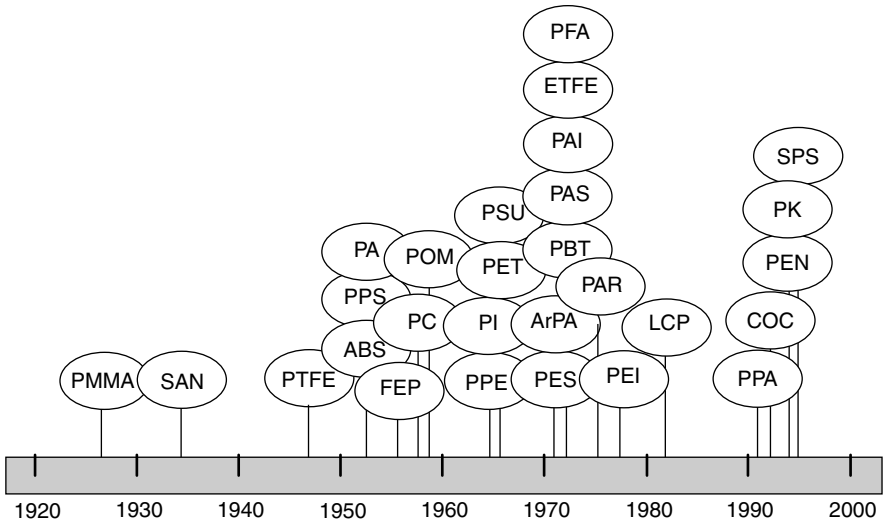

Fig. 1. The historical development of synthetic thermoplastic resins. The reported years indicate the presumed entry in the market. See Table 1 for an explanation of acronyms.

introduced industrially in the 1950–1980 period. The new flourishing in the nineties was partly enhanced by some particular events, like the development of metallocene catalysts, which rendered convenient the fabrication of new materials like sPS and COCs, and the availability of the monomer for PEN.

Table 3 reports for each polymer family the most important producers and corresponding trade names, with the aim of helping the reader to identify materials. Some books are dedicated to this task (3–5), which is complicated by ongoing mergers and selling of operations, resulting in changed connections between producers and trade names.

Properties of Thermoplastics

Some material properties are intrinsic to the chemical substance under investigation; others depend on the processing operation, which confers a shape and orientation to the material. Because some processing is often necessary to prepare testing specimens, intrinsic properties can be difficult to measure. Some properties acquire relevance only when the final article is manufactured and strictly depend on the specific use of the article. Properties have been distinguished as performance, maintenance, or aesthetic properties (1); however, this classification is extremely subjective. Herein, mainly intrinsic and processing properties are considered, divided into four conventional groups: physical, electrical, thermal, and mechanical. Several of such properties change remarkably depending on the morphology (amorphous or semicrystalline materials) or for the presence of fillers and reinforcing fibers. It is impossible to report the properties of all the grades present on the market; it was estimated that more than 5300 grades of engineering plastics were offered by producers in 1997 (6). Thus, the more representative of them are described in discussions of specific polymers. In Table 7, the most

Table 3. Producers and Trade Names of Engineering Thermoplastics

Material[a]	Trade Name	Manufacturer
COC	Topas	Ticona
	Apel	Mitsui Petrochemical
	Zeonex[b], Zeonor[c]	Nippon Zeon
	Arton	JSR
sPS	Questra	Dow
	Xarec	Idemitsu
POM	Delrin	DuPont
	Hostaform, Celcon	Ticona

representative properties are reported, together with the proper SI units and, if existing, the respective standard measurement method. Several books describe the methods in more detail (2,3,7).

Physical Properties. Physical properties include density, properties connected to their combustion tendency (flammability and oxygen index), optical properties (refractive index and yellow index), and the ability to absorb water. Density ρ, ie, the mass per unit volume, depends on the nature of atoms present in the chemical structure and the way molecules (chains) pack together. Polyolefins, composed of C and H only, have densities in the range 0.85–1; organic polymers

containing heteroatoms rarely have densities higher than 2. Conformations and crystalline phases strongly influence density. Crystalline phases are generally more dense than amorphous phases, an average ρ_c/ρ_a ratio of 1.13 ± 0.08 has been determined (1).

The Limited Oxygen Index (LOI) test determines the minimum oxygen fraction in an oxygen/nitrogen mixture able to support combustion of a candle-light sample under specific test conditions. The LOI test is necessary but not sufficient for determining the burning behavior of polymers in real conditions. For this task, specific flammability tests have been established on an empirical basis. The most widely used test is UL94, elaborated by Underwriters Laboratories, rating the

ability of a material to extinguish a flame once ignited (8). In decreasing order, the UL94 degrees are V-0, V-1, V-2, and HB, based on a specific specimen thickness. Only a few high performance polymers, like polyetherimides, have been classified as inherently nonflammable (ie, V-0); other polymers can reach a good classification after the addition of specific additives, ie, flame-retardants, in the material formulation.

The refractive index n measures the deviation of light when passing through matter and is expressed as $\sin(i)/\sin(r)$, where i and r are the angles of incident light and refracted light, respectively. It is closely linked to molecular structure of polymers and contributes to their optical properties, like clarity, haze, birefringence, color, transmittance, and reflectance. Most of engineering plastics considered here are opaque and/or inherently colored, with the exceptions of PC, PMMA, and COC. For them, when used in optical applications, the yellow index (YI) is relevant. Yellow index indicates the degree of departure of an object color from colorless or from a preferred white toward yellow and is determined from spectrophotometric data.

Water absorption indicates the increase of weight of a polymer after immersion in water under specified conditions of temperature and time. Generally, it is referred to 24 h at room temperature (23°C) and is expressed as a percentage with respect to the initial weight. If water is absorbed by a polymer, drying is required before processing operations because the presence of water at high temperature results in uncontrolled degradation of the material and consequently poor performance. This is the case of PET and other polyesters. Some polymers like polyamides absorb water from air humidity and hold water molecules rather firmly by hydrogen bonding. Absorbed water causes a slow variation of properties like electrical characteristics, mechanical strength, and dimensions. For this reason, polymers or specific grades insensitive to water must be employed in moist environments.

[c] To convert MPa to psi, multiply by 145.
[d] To convert J/m to lbf·ft/in., divide by 53.38.

Electrical Properties. Electrical properties include dielectric constant, dielectric strength, dissipation factor, and volume resistivity. All of them depend on temperature and water absorption.

The (relative) dielectric constant is the ratio of the capacitance of a condenser formed by two metal electrodes separated by a suitable layer of the material considered and the same separated by dry air. The dielectric strength measures the dielectric breakdown resistance of a material under an applied voltage. The applied voltage value just before breakdown is divided by the specimen thickness. Thus, because the result depends on thickness, this value must be specified. The

dissipation factor, also called loss tangent, measures the tangent of the difference angle between 90° (ideal angle for a perfect dielectric material) and the true angle at which an alternating current leads the voltage. It is equivalent to the ratio of current dissipated into heat and current actually transmitted. The volume resistivity is the electrical resistance of a unit cube of a given material when an electrical potential is applied to two opposite faces of the cube.

Thermal Properties. Thermal properties include some transitions like melting temperature and glass transition transition temperature, the heat-deflection temperature (HDT), specific heat capacity, thermal conductivity, coefficient of thermal expansion, and upper working temperature.

The melting temperature T_m is the temperature at which a solid becomes a liquid (or, on cooling, at which a liquid solidifies). For polymeric materials, T_m is often a temperature range rather than a single value; however, its point value should represent the maximum temperature at which crystallites exist. Amorphous polymers do not exhibit a T_m. The glass-transition temperature T_g is the temperature at which a solid, rigid, and brittle polymer becomes rubbery by loosening remarkably its rigidity. Mechanical properties are also reduced at T_g, and other properties like volume, thermal expansion coefficient, and specific heat capacity change noticeably. Being kinetic in nature, T_g occurs over a temperature range (depending, for instance, on cooling rate) and is hardly visible in some polymers. HDT measures the temperature at which a specimen is deformed a specific amount (eg, 0.25 mm) under a given load (usually, 0.45 or 1.82 MPa), applied in a three-point arrangement. HDT is also called DTUL (deflection temperature under load) and should not be interpreted as a safe temperature for continuous operation (which is usually somewhat lower). The specific heat capacity represents the amount of heat necessary to increase the temperature of a unit mass of a substance by one degree. Depending on its definition at constant pressure or at constant volume, it is indicated as c_p or c_v, respectively. Thermal conductivity represents the amount of heat conducted per unit of time through a unit area of a material of unit thickness having a difference of one degree between its faces. The thermal expansion coefficient represents the change in volume (or length) accompanying a temperature unit variation and is of great importance in molding operations of plastic articles, having mold shrinkage as a practical effect. The upper working temperature is a purely empirical indication at which a given plastic can be expected to perform safely and satisfactorily. It is generally lower than HDT.

Mechanical Properties. Mechanical properties include tensile properties (modulus and strength), flexural properties (modulus and strength), compressive strength, elongation at break, impact resistance, hardness, and friction coefficient. Other relevant properties are creep and fatigue but it is difficult to find comparative data among materials.

The tensile modulus (also elastic, or Young's modulus) E is the stress-to-strain ratio within its proportional limit for a material under tensile loading (in practice, the initial slope of the stress–strain curve). The tensile strength represents the maximum tensile stress observed when the specimen is being pulled. It may or may not coincide with the ultimate strength, ie, the tensile stress at specimen failure. In tough materials it can be equal to the yield stress. The flexural modulus is the stress-to-strain ratio within its proportional limit for a material

under bending load conditions. It measures the stiffness of a material. The flexural strength is the ability of a material to flex without permanent deformation or breaking. The elongation at break is equal to tensile strength at failure multiplied by 100. It is expressed as a percent of the original length of the specimen. The impact strength (or impact resistance) represents the ability of a material to resist physical breakdown when subjected to a rapidly increasing force and is accepted as a comparison guide for toughness (see IMPACT RESISTANCE). It depends strongly on the type of test used. The most widely used test in the field of plastics is Izod; the Charpy test is less common. The Izod test requires specimens of thickness from 3.18 to 12.7 mm, preferentially notched following the test method prescriptions. A weighted pendulum arm released from a fixed height strikes the specimen in a specified way. The Izod impact energy is measured by dividing the energy lost by the pendulum (presumably absorbed by the specimen) by the specimen thickness. Hardness, defined as the resistance of a material to local deformation, is connected in a complex way to mechanical properties, elasticity, and plasticity. Hardness cannot be defined unambiguously and depends strongly on the test adopted for its determination. It is usually characterized by the combination of three parameters, ie, scratch resistance, abrasion resistance, and identation under load. For the identation test, different Shore and Rockwell scales are in use, Rockwell M and Rockwell R being the most popular for engineering plastics (2). The scale depends on the combination of load and indentor dimensions. The friction coefficient represents the resistance of surfaces of solid bodies in contact with each other to sliding or rolling. It is represented as $k = F/w$, where F is the force necessary to move one surface with respect to the other one, and w the load exerted on them.

Rheological Properties. Rheological properties (qv), describing the deformation of materials under stress and concerning their flow properties, must be considered in all processing techniques for the fabrication of plastic articles. In order to give operators necessary rheological information, melt viscosity vs shear plots are commonly included in Data Sheets provided by plastics producers. Here only a few properties connected to rheology are considered, ie, intrinsic viscosity (IV) and melt-flow index (MFI).

Intrinsic viscosity measures the capability of a polymer in solution to increase the viscosity of the solution itself. Because IV increases with molecular mass, it is an indication of this last property. The MFI (or simply melt index) measures the isothermal resistance to flow through an extrusion plastometer commonly referred to as melt indexer. Practically, the amount of matter forced by a given load to pass in 10 min through a standard die is determined. Melt-flow index can be considered as a single-point test (ie, resistance to flow at a single shear rate). Every plastics processing technology operates at a defined MFI range as follows (2): 5–100 g/10 min for injection molding, 5–20 g/10 min for rotational molding, 0.5–6 g/10 min for film extrusion, and 0.1–1 g/10 min for blow molding and profile extrusion.

Chemical Resistance. Chemical resistance is less rigidly defined than the properties discussed previously. Measurement methods include immersion in selected vapors or liquids of a test specimen, then determining the variation of mechanical properties after and before treatment. Optical properties are also considered, particularly in the case of transparent materials. The test results are generally indicated as excellent, good, fair, or poor, or are given other arbitrary

scale units. Chemical agents are chosen in order to simulate possible real situations: strong and weak acids, alkalis, saline solutions, hydrocarbons (aliphatic or aromatics), oils and greases, alcohols, aldehydes, ketones, etc. Engineering plastics are generally difficult to dissolve in most solvents. Strictly correlated to chemical resistance is weathering resistance, where a combination of a particular environment, temperature, time, and uv irradiation is considered, also with cyclic experiments.

Processing of Thermoplastics

Processing of thermoplastic materials can be classified into four main categories: extrusion, post-die processing, forming, and injection molding (9–11).

In an extruder, the polymer is melted and pumped into a shaping device called a die, through which the material is forced to assume a particular shape. The pumping action is done by a single-screw or by a twin-screw device, the configuration of which is essential for a suitable result. Extruders are very often used at the end of the polymerization reactor in order to obtain polymer pellets by chopping an extruded strand. Extruders are also currently used to mix in the proper additives for the polymer, to obtain intimately mixed polymer blends, to devolatilize the material from the monomers or solvent residues, and in some special cases as a chemical reactor (reactive extrusion). For example, polyetherimide is prepared at the industrial level by reactive extrusion. Depending on the extrusion die geometry, final articles can also be obtained, including sheets, films, pipes, rods, and profiles of various geometries (T, double T, C, and so on). Coating on wires can be done, as well as coextrusion of two or more layers.

Post-die processing includes a number of operations carried out at the exit of the extruder die in a free-surface way. Examples of such processes are fiber spinning, film blowing, and sheet forming. The shape and dimensions of the extrudate material are determined by the rheological properties of the melt, the die dimensions, the cooling conditions, and the take-up speed (relative to the extrusion rate).

Forming processes use a mold to confer the final form to the article. Blow molding is widely used in the manufacture of bottles or other containers for liquids, widely using engineering polymers like PET and PC. Essentially, an extruded cylindrical parison is inflated with a gas until it fills the mold cavity. A good equilibrium between the melt strength of the resin under low shear conditions (parison stability) and the flow properties under high shear conditions (blowing) are essential for obtaining a satisfactory result. In thermoforming, a polymer sheet is heated to a temperature above its T_g (or sometimes above T_m) and then pressed into the female part of the mold by means of a suitable plug or by vacuum pulling. Simple-shape articles such as trays can be obtained. In compression molding, an amount of polymer is heated at the proper temperature and then squeezed by means of the male part of the mold into the mold cavity.

Injection molding is the most commonly used processing technique for engineering thermoplastics. Typically, the polymer pellets are melted and the melt pulled forward by means of a screw as in extrusion, so filling a mold under appropriate pressure. The shape of the mold, the number and relative location of the injection devices, and the mold cooling rate determine, together with the intrinsic properties of the material, the final quality of the molded articles. Very complex

article shapes can be obtained by this technique. A viscosity of the resin around 10,000 Pa·s and a shear rate of 100 s^{-1} are needed for a convenient operation.

The main problem in injection molding is shrinkage, caused by the volume changes during transition from the melt to the solid. The typical shrinkage of semicrystalline polymers during processing is around 1–4%, compared to 0.2–0.8% for amorphous polymers (11). To reduce the problem, crystallinity could be maintained low, but this is to the detriment of mechanical properties. A compromise should be used. For polymers which crystallize slowly, like PET, it is preferable to allow the polymer to reach the maximum crystallization degree by the use of nucleating agents. If the shrinkage amount is different in different volume portions of the fabricated part, warpage of the part itself can be observed.

Interpolymer Competition

The properties of engineering thermoplastics span a wide range, and there are many overlapping situations among resins. To select the right polymeric material for a specific application is a hard job because the forest of commercial polymers has become so crowded. Books have appeared to guide the materials engineer in the selection of thermoplastic materials, with the help of a dedicated software (6).

Four main groups of technical considerations must be made in order to make the right choice, ie, mechanical, electrical, environmental, and appearance. In addition, two other elements are important, ie, cost and specifications (eg, imposed by a government body or by a corporation). The environmental considerations include the operating temperature, the chemical environment, the weathering exposure, and humidity degree. The appearance includes style, shape, color, transparency, and surface finish of the fabricated object. Mechanical and electrical considerations must include both short-time and long-time values, and also the effects of environment on such properties. Also, appearance can vary under service conditions. The necessary information must be provided by different actors, that is, the material supplier, the processor, the processing equipment supplier, and the product designer/producer.

Depending on the particular application, numerous properties should be considered during the selection of the best candidate. Further, every property has a different importance, and thus a different weight on the final choice. Property values reported here are representative; several of them vary over a wide range depending on several factors, like the nature and amount of fillers, the possible occurrence of copolymerization, etc. Also, some data are not available in the current literature and others are difficult to describe with just one figure. This is particularly true for rheological data reported in data sheets as flow curves viscosity vs temperature curves, etc. Similar difficulties arise for creep curves (related to long-term mechanical resistance) and shrinkage and warpage of fabricated parts, strongly dependent on the geometry and thickness of the part itself. The internet has made it easier to access data about polymer grades actually produced (Table 8).

In the final selection of the best material for the fabrication of a specific object, a compromise is generally made by choosing the material which shows an optimized balance of the most relevant properties. In addition to some particular

properties, like transparency and the question of processability (which involves complex issues as rheology, shrinkage, and surface finishing), in most of the applications of engineering thermoplastics, the following characteristics and properties are considered: price, mechanical properties, thermal properties, electrical properties, and chemical resistance.

Price. The price of a thermoplastic resin is basically determined by the cost of preparation, which in turn strongly depends on the cost of reagents (monomers, catalysts, etc), the complexity of the manufacturing process, and the dimension of production plants. Aliphatic polyketones, for instance, are made from very cheap raw molecules as ethylene, propylene, and CO; their cost is determined by the need for expensive catalysts, based on Pd complexes, and the relatively complex production plant. On the other hand, PEN, which can easily be prepared in the same reactors used for PET, suffers from the difficult availability of its basic monomer dimethyl 2,6-naphthalene dicarboxylate. Most engineering polymers contain aromatic monomers, which are difficult to synthesize and polymerize, with slow and sophisticated mechanisms (condensation, substitution, oxidative coupling).

Roughly, commodities are priced at US$0.5–1/kg, engineering polymers in the range of US$1–5/kg, and high performance polymers the range of US$5–50/kg. The current prices fluctuate following market conditions and can be found as a price range, for most materials, in technical journals like Plastics Technology. In Figure 2, the prices of engineering thermoplastics are reported as a function of annual production volume, confirming, with a few exceptions, the inverse relationship between the two parameters. The price is reported in U.S. cents per

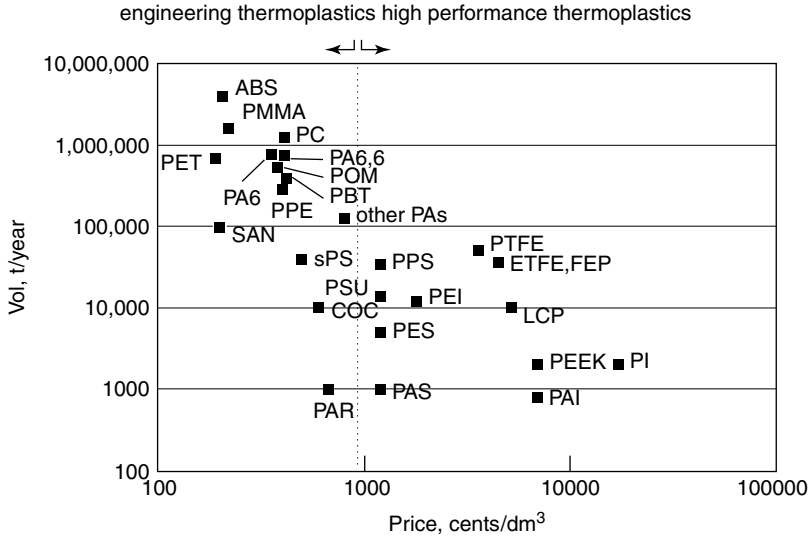

Fig. 2. Production volumes and prices for volume units for thermoplastics considered in this compilation. The dashed line represents an arbitrary border between engineering and high performance thermoplastics. In some cases, reinforced resins have been considered, ie, PPS: 10% glass fibers (GF); PSU, PA11: 30% GF; PAS: 40% GF. Acronyms are those listed in Table 1.

volume unit, more significant than the corresponding price per mass unit. The unfilled materials have a density ranging from 1.02 g/mL for COCs to 2.18 g/mL for PTFE. However, the density of most engineering thermoplastics falls around 1.15–1.45 g/cm^3. The price/volume relationship does not work when a low volume material can be produced in a captive way in a plant used also for producing a higher volume polymer. This is the case of polyarylates, some aliphatic polyamides, and polysulfones.

Mechanical, Thermal, and Electrical Properties. The most representative mechanical properties are elastic (or tensile) modulus, tensile strength, flexural modulus, and toughness. Flexural modulus is particularly interesting, because it represents the stiffness of the material; unfortunately, data are not available for all materials. However, because flexural modulus values are mostly of the same order of magnitude of tensile modulus values, the latter can be used for comparison purposes. Toughness is approximately described by Izod impact strength. Figure 3 reports elastic moduli and Izod strengths of engineering thermoplastics. Data ranges are particularly wide for toughness data. The figure shows that for any application, a wide number of combinations of stiffness and toughness is available in the field of engineering thermoplastics. Further, reinforcing practice with fibers, minerals, or other fillers is largely applied in order to enhance the mechanical and thermal properties. Most of the materials treated here are offered in the market in a large number of reinforced grades. Such a practice also influences the cost of the material, and this is particularly relevant when the cost of the matrix is higher than the cost of the filler. Figure 4 shows the increase of modulus values that can be obtained by adding glass fibers to several polymers.

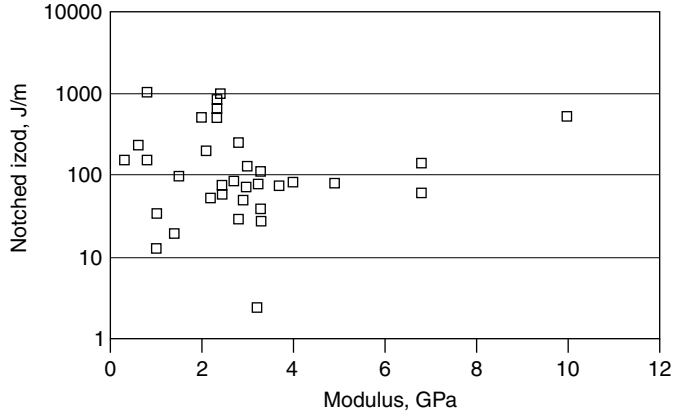

Fig. 3. Modulus vs notched Izod of engineering thermoplastics. To convert J/m to ft·lbf/in., divide by 53.38. To convert GPa to psi, multiply by 145,000.

Heat-deflection temperature does not correspond to the practical use temperature; however, it has been widely used in the plastics industry to compare the physical response of materials to temperature at a single–load level. In Figure 5, HDT vs tensile strengths at two different loads are reported. Both groups of data roughly show a proportional trend that can be ascribed to the fact that in many cases the molecular structure of the chain influences, in the same sense, the mechanical and thermal properties.

The electrical properties of engineering thermoplastics are generally excellent. In specific applications, like cable and wire coatings, electrical or electronic parts, etc, demanding values are requested. On the other side, electrical conductivity can be increased by adding particular fillers like metallic powders.

Chemical Resistance. Chemical resistance belongs to environmental considerations because the accidental or expected exposure of a material to the action of chemicals or solvents can have relevant short-and long-term influence

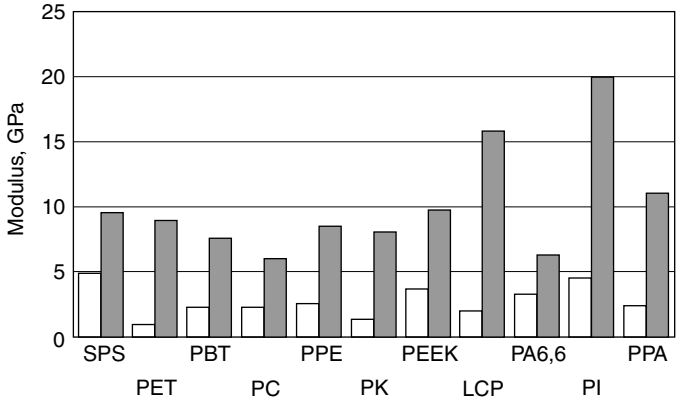

Fig. 4. Modulus increases obtained by reinforcing thermoplastic matrices with glass fibers. GF contents are at 30 wt%, but those of PC and PK are at 20 wt%. PPE values are referred to a PPE–PS blend. To convert GPa to psi, multiply by 145,000.

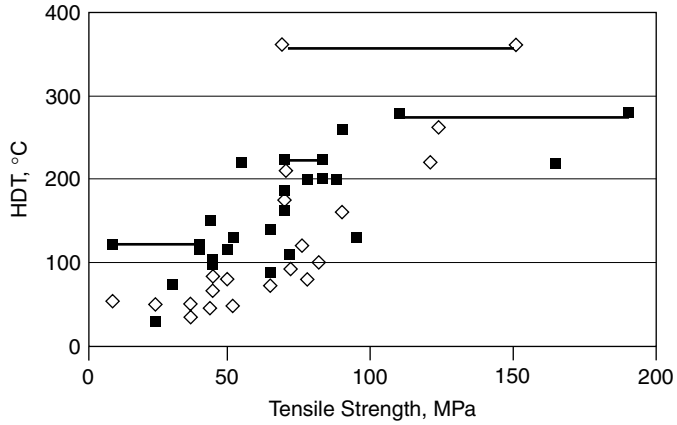

Fig. 5. Tensile strength vs HDT of engineering thermoplastics. Full squares represent HDT values obtained at 0.45 MPa, empty rhombi at 1.8 MPa. Horizontal bars between two tensile strength values represent a range. To convert MPa to psi, multiply by 145.

on the other properties. Table 9 summarizes the resistance of polymers against the most common families of chemicals and solvents. As expected, fluoropolymers show the best response against the whole range of chemicals considered. Chemical resistance values reported in the table are indicative because they can be significantly affected by exposure length and temperature. In practice, chemical resistance testing under end-use conditions is suggested.

The Future

Thermoplastic materials have now pervaded every important aspect of the human life, from food management (through packaging) to clothing (through synthetic fibers), ground and air transportation, office equipment, health (medical instruments and devices, artificial prostheses), entertainment (audio and video reproduction components), sports goods, and so on. Applications of thermoplastic materials, both commodities and engineering thermoplastics, will continue to expand at the expense of other materials like glass, metals, wood, and ceramics. Moreover, the time between the laboratory synthesis of a new polymer and its industrial production remains high (12), thus discouraging the introduction of new materials. The expected expansion of the engineering thermoplastics market is of the order of 12% per year in the next three years (13). Interestingly, the most significant threat to engineering polymers comes from some commodities, like polypropylene, which in some reinforced (but also unreinforced) grades reach the performance of some engineering materials.

More About Engineering Thermoplastics. Many of the individual resins mentioned in this overview are covered in articles devoted to them. Cross references are provided in Table 1. A list of related articles is as follows: ACETAL RESINS; ACRYLIC ESTER POLYMERS; ACRYLONITRILE AND ACRYLONITRILE POLYMERS (SAN and ABS); ETHYLENE-NORBORNENE COPOLYMERS; LIQUID CRYSTALLINE POLYMERS, MAIN-CHAIN; METHACRYLIC ESTER POLYMERS;

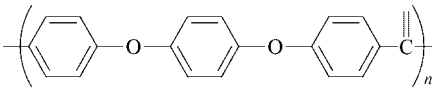
Poly(ether ketone) resins are discussed in the next section.

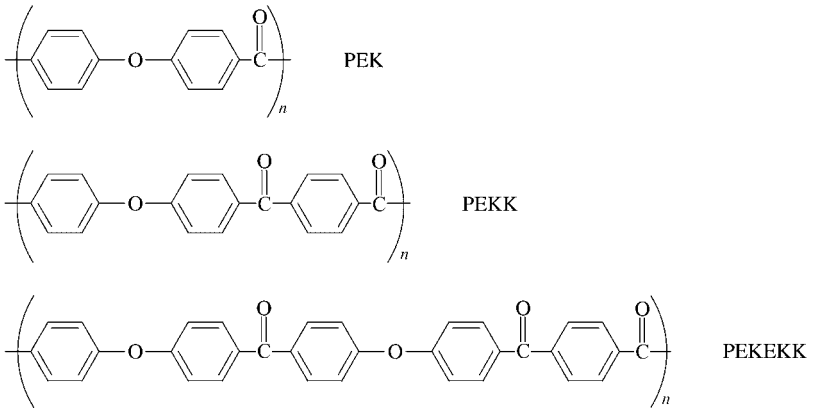
Poly(ether ketones)

Poly(ether ketones) include a variety of aromatic high performance polymers characterized by the presence of ether bridges and ketone groups in the main chain, linking together arylene groups. Currently, the only product manufactured worldwide is Victrex PEEK, launched by ICI in 1978 and produced annually in an

amount of about 2000 tons (14). PEEK has the following chemical structures and is believed to be produced by polycondensation of 4,4′-difluorobenzophenone and a potassium salt of bisphenol (15).



The reaction is carried out at high temperature (up to 300°C) in a high boiling solvent like diphenylsulfone. It is produced in batches, with rather high production cost. Similar products, bearing various sequences of ether and ketone groups bridging together arylene rings can be synthesized in similar ways, eg, PEK, PEKK, and PEKEKK (15). Some of these structures have been commercialized.



The first polymer of this group (PEK) was commercialized by Raytheon in the 1970s under the trade name Stilan. Equivalent materials were commercialized by Hoechst Celanese and Amoco, whereas PEKEKK and PEKK were commercialized by BASF and DuPont, respectively. Their T_g values are in the range of 150–165°C, and T_m values are in the range of 370–390°C. PEEK has a pale amber color and is usually semicrystalline and opaque. It has excellent thermal, mechanical, and tribological resistance and is insoluble in most solvents, with the exception of strong protonating acids like concentrated H_2SO_4 and HF. It is also soluble above 220–230°C in benzophenone and chloronaphthalene. Properties of PEEK are reported in Table 10.

A review (16) and a book (17) on the chemistry and properties of poly(ether ketones) have been published. PEEK is present in the market also in reinforced grades (glass or carbon fibers) as well as in yarns or in powder for coatings. Fibers are marketed by ICI under the trade name Zyex. PEEK found application in the transport, teletronics, and aerospace sectors, with the fabrication of injection-molded engineering components and circuit boards. PEEK materials have also found a place in medical technologies. For this purpose, their biological and toxicological safety has been certified (14).

ENZYMATIC POLYMERIZATION

Introduction

Enzymes catalyze not only all *in vivo* biosynthetic reactions in living cells for maintaining "life" but also many *in vitro* reactions of natural and unnatural substrates under selected reaction conditions. Enzymatic catalysis for organic synthesis possesses advantages such as much acceleration of reaction rate, operation under mild conditions, and high stereo-, regio-, and chemoselectivities of reactions in comparison with those of chemical catalysts. Such characteristic properties have brought about an extraordinarily rapid increase in interest in the area of biotransformations (1–5).

All naturally occurring polymers are produced *in vivo* by enzymatic catalysis. Recently, *in vitro* synthesis of polymers through enzymatic catalysis ("enzymatic polymerization") has been extensively studied (6–14); highly selective polymerizations catalyzed by enzymes have been developed to produce various functional polymers in response to increasing demands of structural variation of synthetic targets for polymers in material science.

This article deals with recent advances in enzymatic polymerizations. We define *enzymatic polymerization* as "chemical polymer synthesis *in vitro* (in test tubes) via nonbiosynthetic (nonmetabolic) pathways catalyzed by an isolated enzyme." Enzymes are generally classified into six groups. Table 1 shows typical polymers produced with catalysis by respective enzymes. The target macromolecules for the enzymatic polymerization have been polysaccharides, poly(amino acid)s, polyesters, polycarbonates, polyaromatics, vinyl polymers, etc. Here, enzymatic polymerizations are described according to the polymer structure. In many cases, enzymatic polymerization enables the synthesis of polymers, which otherwise are difficult to prepare. Enzymatic polymerization often provides an environmentally

benign process, where starting materials and products are within the natural material cycle; this is in the context of "green polymer chemistry" (13,14).

Polysaccharides

Polysaccharides are among the most important biopolymers as are proteins and nucleic acids in nature. They are regarded as three important families of natural biomacromolecules. As to the enzymatic polymerization for polysaccharides, hydrolases and transferases are reported to catalyze their synthetic reactions.

Hydrolases. It is generally accepted that an enzymatic reaction is virtually reversible, and hence, the equilibrium can be controlled by selecting the reaction conditions. Based on this view, hydrolases, enzymes catalyzing a bond-cleavage reaction by hydrolysis, have been developed as catalyst for the reverse reaction of hydrolysis, leading to polymer production by a bond-forming reaction (9,12).

It is believed that using a glycosidase for the glycosylation process is one of the most promising methodologies for selective construction of a glycosidic linkage under appropriate conditions, since chemical approach requires complicated procedures including a regioselective blocking and deblocking of a hydroxy group in the sugar moiety to achieve regioselectivity, and furthermore, complete stereocontrol of the glycoside bond-formation has not often been achieved by chemical catalysts.

Enzymatic formation of a glycosidic bond is realized by combined use of a glycosyl donor and a glycosyl acceptor. The former is to be activated by an enzyme to give a glycosyl-enzyme intermediate which can be attacked by a hydroxy group of the acceptor, forming a glycosidic bond between the donor and the acceptor. The repeated glycosylations are expected to produce polysaccharide molecules.

Glycosyl fluorides, sugar derivatives whose anomeric hydroxy group is replaced by a fluorine atom, are known to be recognized by glycosidases. Cellulose is one of the most important biomacromolecules, which is the most abundant organic substance on the earth (12). Thus, in 1991, the first *in vitro* synthesis of cellulose via nonbiosynthetic pathway has been achieved by an enzymatic polymerization of β-cellobiosyl fluoride as substrate for *Tricoderma viride* cellulase, an extracellular hydrolytic enzyme of cellulose (Fig. 1) (15–21). The polymerization was performed in an aqueous organic solvent in order to make the desired

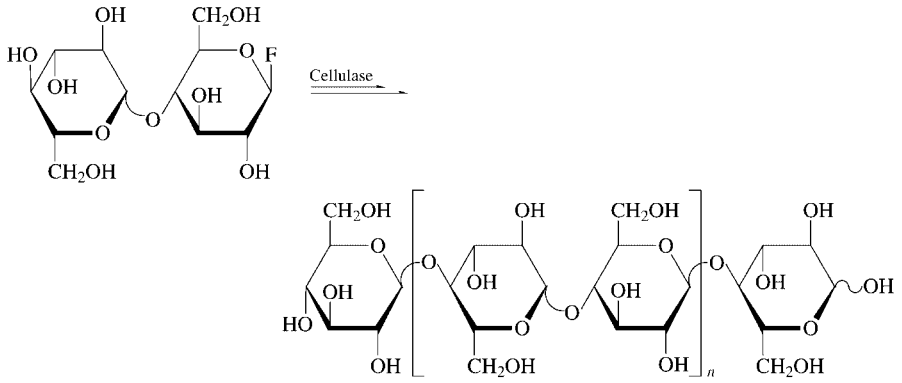

Fig. 1. *In vitro* synthesis of artificial cellulose via cellulase catalysis.

polycondensation predominant in comparison with the competitive hydrolysis reaction. A mixed solvent of acetonitrile/acetate buffer (pH 5) (5:1) gave the best results in terms of the yield of water-insoluble "artificial cellulose." The enzyme promoted transglycosylation of the cellobiosyl moiety toward the 4′-hydroxy group of another monomer eliminating hydrogen fluoride. In this polymerization, regio- and stereoselectivities were perfectly controlled.

The cellulase-catalyzed polycondensation of new cellobiosyl fluoride derivatives, 6-*O*-methyl and 6′-*O*-methyl-β-cellobiosyl fluorides, have been examined (22,23). The 6-O-methylated monomer was polymerized using the purified enzyme in a regio- and stereoselective manner to give a novel cellulose derivative having a methyl group alternatingly at the 6-position, which can never be realized by the conventional modification of natural cellulose, ie, methylation of cellulose. On the other hand, the 6′-O-methylated monomer gave a mixture of low molecular weight oligomers. The difference of the polymerization behavior can be explained by the steric repulsion between the methyl group of the monomers and the active site of the cellulase catalyst.

The process of the artificial cellulose was visually analyzed by using transmission electron microscopy (24). Cellulose formation was detected as early as 30 s after the initial stage of the reaction in the aqueous acetonitrile. The electron diffraction pattern of the product showed the typical pattern of the crystal structure of thermodynamically stable cellulose II with antiparallel orientation between each glucan chains. When the purified cellulase (39 kDa) was used, cellulose microfibrils with an electron diffraction pattern characteristic of metastable cellulose I with parallel orientation, an allomorph of natural cellulose, were first observed in an artificial process (25). Based on these results, a new concept of *choroselectivity*, selectivity concerning the relative ordering of the polymer chain direction, in polymerization chemistry has been proposed (26–28).

In some cases, the enzymatic polymerization afforded spherulites of artificial cellulose II, composed of single crystals with the molecular axis orientated perpendicular to the plane (29). Both positive- and negative-type spherulites were observed by polarization optical microscopy. By changing the reaction parameters,

the size, growth and formation/degradation rate, and number of spherulites could be controlled.

α-Amylase catalyzed the polycondensation of α-D-glucosyl fluoride in an aqueous solution to produce maltooligosaccharides (mainly pentamer) (30). α-D-Maltosyl fluoride was also polymerized by α-amylase catalyst in an aqueous methanol, yielding a maltooligosaccharide with degree of polymerization (DP) up to 7 (31). Enzymatic transglycosylation of α-D-maltosyl fluoride with a cyclodextrin using pullulanase or isoamylase as a catalyst produced a branched cyclodextrin, 6-*O*-α-maltosylcyclodextrin (32,33).

Synthetic xylan was synthesized by a cellulase-catalyzed polymerization using β-xylobiosyl fluoride as a substrate (34). The enzymatic polymerization proceeded in a perfect regio- and stereoselective manner to produce powdery artificial xylan, which is insoluble in any organic solvent. Xylan, one of the most important components of hemicellulose in plant cell walls, normally contains 4-*O*-methylglucuronic acid or L-arabinose as a minor unit in the side chain. On the other hand, the artificial xylan consists exclusively of a xylopyranose moiety connected through a $\beta(1\rightarrow4)$ glycosidic bond.

The first synthesis of a cellulose–xylan hybrid polymer, a novel polysaccharide having a glucose–xylose repeating unit, has been achieved by the xylanase-catalyzed polymerization of β-xylopyranosyl-glucopyranosyl fluoride (Fig. 2) (35, 36). Identification of the enzyme fraction promoting the polymerization showed that endoxylanase was highly efficient for production of the hybrid polymer.

Cellulase-catalyzed polycondensation of 4-thio-β-cellobiosyl fluoride produced hemithiocellodextrins having 4-thiocellobiosyl repeating units linked by $\beta(1\rightarrow4)$ oxygen linkages (37). A water-soluble oligomer with DP up to 20 was obtained in an aqueous acetonitrile.

Chitin is the most abundant organic macromolecules in the animal field found in invertebrates (12). The *in vitro* synthesis of this important biomacromolecule has been achieved for the first time by enzymatic ring-opening polyaddition of a chitobiose oxazoline monomer (Fig. 3). Chitinase, a hydrolysis enzyme of chitin, regio- and stereoselectively induced the polymerization of the monomer in a basic buffer (38–41). It is postulated that the monomer is preferable as a

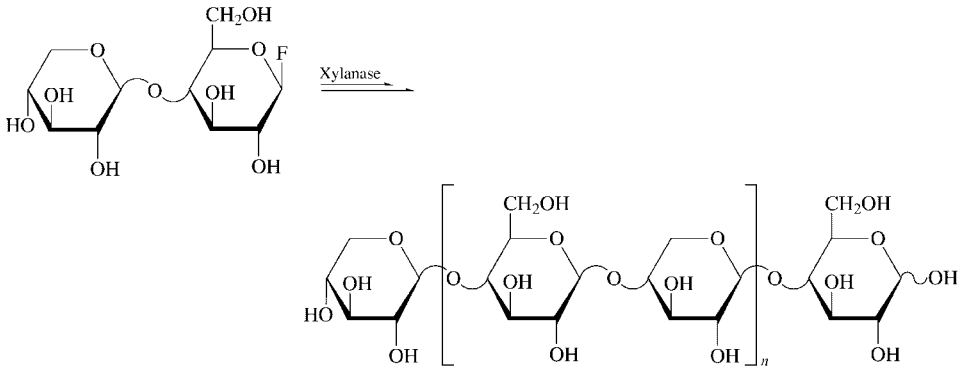

Fig. 2. Enzymatic synthesis of cellulose–xylan hybrid polymer.

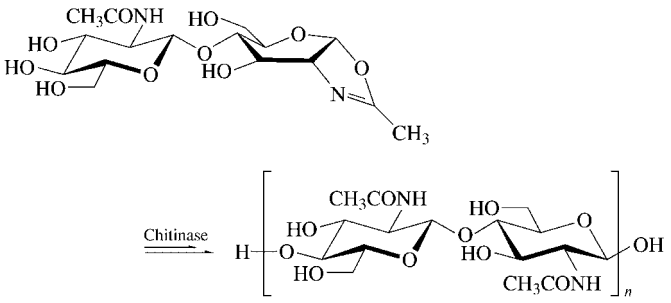

Fig. 3. *In vitro* synthesis of artificial chitin via chitinase catalysis.

substrate because it can be recognized by the active site of chitinase readily due to the oxazoline structure resembling that of the transition state of the chitin hydrolysis with chitinase as revealed by a later work (12,42). Thus, the monomer is regarded as a "transition state analogue substrate" for chitinase. From x-ray diffraction and nmr analysis, the product was found to show crystal structure of α-chitin. A oxazoline monomer from *N*-acetyl glucosamine was also polymerized at high substrate concentration to give chitooligosaccharides.

The visualization of high ordered structure formation during the enzymatic synthesis of artificial chitin has been investigated (43). Plate-like single crystals of α-chitin were first formed and gradually shaped into ribbons by the rapid growth along the a axis with the crystalline thickness being ca 10 nm. The α-chitin ribbons then aggregated to form bundle-like or dendritic assemblies as the ribbon concentration in solution increased. They grew up to spherulites by splaying and branching. This artificial chitin spherulite, in which a number of α-chitin ribbons radiated from a common center, is completely different from the helicoidal textures composed of α-chitin microfibrils known as a typical three-dimensional organization of chitin (see CHITIN and CHITOSAN).

A cellulose–chitin hybrid polymer, a nonnatural polysaccharide having a glucose unit and an *N*-acetyl glucosamine unit alternatingly in the main chain, was synthesized by chitinase-catalyzed polyaddition of a disaccharide oxazoline monomer in an aqueous solution (44).

Sugar-chain elongation from di-*N*-acetylchitobiose as initial substrate to hexamer and heptamer of chitooligosaccharide was efficiently induced through lysozyme catalysis in an acetate buffer containing 30% ammonium sulfate at 70°C. The high concentration of ammonium sulfate resulted in a remarkable increase of the hexamer and heptamer productions. In this reaction, a sugar-elongation from the dimer to trimer was the rate-limiting step in the overall process of transglycosylation (45).

Transferases. Phosphorylase catalyzes polymerization of α-D-glucose-1-phosphate in the presence of primer, leading to *in vitro* synthesis of amylose (Fig. 4) (46). By utilizing phosphorylase catalysis, various amylose derivatives such as linear-, star-, and comb-shaped amylose polymers were synthesized (47). The chain length could be controlled by a simultaneous start for all chains using a primer with a minimum length of four glucosyl residues. This method was

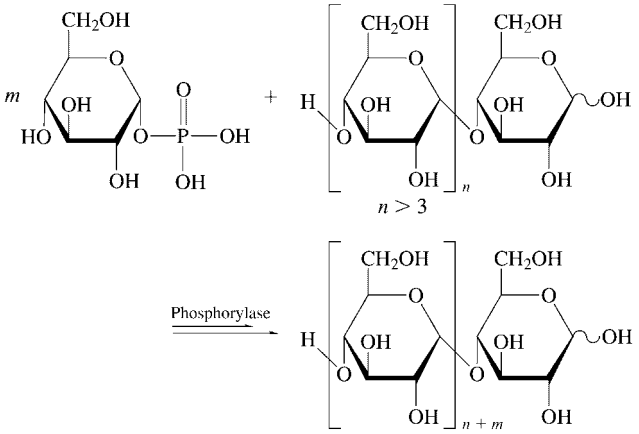

Fig. 4. Phosphorylase-catalyzed synthesis of amylose.

applied to production of styryl-type amylose macromonomer (48), amylose-*graft*-poly(dimethylsiloxane) (49), amylose-*graft*-poly(L-glutamic acid) (50), amylose-*block*-polystyrene (51), amylose-*block*-poly(ethylene oxide) (52), and amylose-containing silica gel (53,54). Amylose-polytetrahydrofuran (PTHF) inclusion complex was synthesized by the phosphorylse-catalyzed polymerization in the presence of PTHF (55).

Cyclodextrin-$\alpha(1\rightarrow4)$glucosyltransferase (CGTase) catalyzes formation of cyclodextrins from starch. By use of immobilized CGTase (silica gel support functionalized with glutardialdehyde), α-glucosyl fluoride was transformed in high yields, predominantly into cyclodextrin and maltooligomers as by-products (56). α-Maltosyl fluorides substituted at the 6- or 6′-position with H, F, Br, OCH_3, and $OCOCH_3$ have been tested as substrates for CGTase (57). Among these substrates, only 6′-*O*-CH_3 and 6′-*O*-$COCH_3$ monomers were polymerized to give the cyclic compounds, indicating that the affinity of substrates toward the catalytic site of CGTase (*Bacillus marcerans*) greatly affected the specificity of the cyclization.

Poly(amino acid)s

Biosynthesis of artificial polypeptides has been achieved by the expression of target proteins in living cells with a gene recombination technique; polypeptides with precise control of the chain length, sequence, and stereochemistry have been synthesized by genetic engineering. On the other hand, it is well known that amino acid derivatives are subjected to protease-catalyzed coupling reaction, yielding functional peptide compounds (58). In using amino acid esters as monomer, poly(amino acid)s are obtained.

Papain catalyzed the polymerization of L-methionine methyl ester hydrochloride to give water-insoluble oligomer with DP = 8–10 (59–61). The resulting water-insoluble oligomer was converted to water-soluble sulfoxide and sulfone derivatives by treatment of DMSO or hydrogen peroxide. Esters of phenylalanine,

threonine, and tyrosine were also subjected to the protease-catalyzed oligomerization (62).

Polymerization of L-glutamic acid diethyl ester hydrochloride took place in the presence of papain or α-chymotrypsin as catalyst to give the corresponding oligomer composed of 5–9 glutamic acid residues (63,64). An nmr analysis showed that the product consisted exclusively of α-peptide linkage (65). Diethyl L-aspartate was polymerized by alkanophilic protease from *Streptomyces* sp. to give poly(ethyl α,β-L-aspartate) with weight-average molecular weight (M_w) up to 3600 (66). The ratio of α-linkage was about 88%, independent of the enzyme concentration.

In order to enhance the molecular weight, protease was modified by mutation technique to show high catalytic activity in an aqueous *N*,*N*-dimethylformamide (DMF) solution. A subtilisin mutant (subtilisin 8350) derived from BPN′ (subtilisin from *Bacillus amyloliquefaciens*) via six site-specific mutation (Met 50 Phe, Gly 169 Ala, Asn 76 Asp, Gln 206 Cys, Tyr 217 Lys, and Asp 218 Ser) induced the polymerization of L-methionine methyl ester in the aqueous DMF to produce poly(methionine) with DP up to 50 (67). The increase of the molecular weight is due to the improvement of the product solubility and minimization of the enzymatic peptide cleavage under the high concentration of DMF. Another mutant (subtilisin 8397) showing higher stability in DMF, the same as 8350 except that there is no change for Tyr 217, has been applied as the catalyst for the polymerization of single amino acid, dipeptide, and tripeptide methyl esters (68).

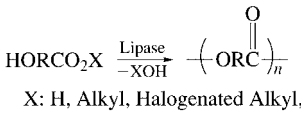
A different type of peptide hydrolase, dipeptidyl transferase (dipeptidylpeptide hydrolase), catalyzed the polymerization of dipeptide amide in an aqueous solution. In the case of glycyl-L-phenylalaninamide, trimer was formed in 78% yield (69). The polymerization of glycyl-L-tyrosinamide produced the corresponding oligomer with DP up to 8 (70).

Protease was used as catalyst for polymer modification. Phenylalanine residues at the side chain of methacrylamide polymers were coupled with alanine *t*-butyl ester by α-chymotrypsin catalyst in water–chloroform solvent (71). Up to 35% peptide-bond formation was achieved for 7 days at room temperature. Polyamide synthesis was performed by cellulase-assisted polycondensation of chiral fluorinated compound having carboxylic acid and amino groups (72).

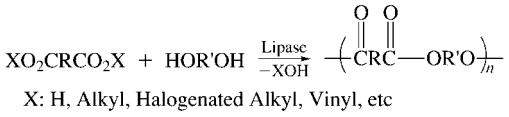
Polyesters

Syntheses of aliphatic polyesters by fermentation and chemical processes have been extensively studied in a viewpoint of biodegradable materials. Recently, another approach of their production has been performed by using an isolated lipase or esterase as catalyst via nonbiosynthetic pathways under mild reaction conditions. Lipase and esterase are enzymes which catalyze hydrolysis of esters in an aqueous environment in living systems. Some of them can act as a catalyst for the reverse reactions, esterifications and transesterifications, in organic media (1–5). These catalytic actions have been expanded to enzymatic synthesis of polyesters. Figure 5 represents three major reaction types of lipase-catalyzed polymerization leading to polyesters (6–14,73).

Polycondensation of Oxyacids or Their Esters



Polycondensation of Dicarboxylic Acids or Their Derivatives with Glycols



Ring-Opening Polymerization of Lactones

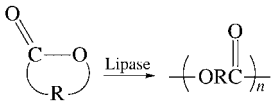


Fig. 5. Typical routes of polyester production using an isolated enzyme as catalyst.

Polymerization of Oxyacids and Their Esters.

Oxyacids. In 1985, a lipase-catalyzed polymerization of 10-hydroxydecanoic acid was reported. The monomer was polymerized in benzene using poly(ethylene glycol) (PEG)-modified lipase soluble in the medium to give an oligoester with DP more than 5 (74).

Ricinoleic acid, 12-hydroxyoctadecanoic acid, 16-hydroxyhexadecanoic acid, and 12-hydroxydecanoic acid were polymerized by lipase from *Candida cylindracea* (lipase CC) or *Chromobacterium viscosum* as a catalyst at 35°C in water, hydrocarbons, or benzene (75). The molecular weight of the polymers was ca 1×10^3. Oligomerization of ricinoleic acid proceeded in the presence of lipase CC immobilized on ceramics (76).

In the polycondensation of 10-hydroxydecanoic and 11-hydroxyundecanoic acids, a large amount of lipase CC catalyst (10 weight fold for the monomer) afforded the corresponding polyesters with relatively high molecular weight (77, 78). From the latter monomer, the polymer with M_w of 2.2×10^4 was formed in the presence of activated molecular sieves.

Porcine pancreas lipase (PPL) polymerized 3-hydroxybutyric and 12-hydroxydodecanoic acids in anhydrous hydrophobic solvents (79). The molecular weight of the polymer from the former was low (ca 500), whereas the polymerization of the latter at 75°C produced the polymer with molecular weight of 3×10^3. A cellulase-assisted polymerization of chiral fluorinated compound having carboxylic acid and phenolic groups produced the aromatic polyester (72).

Enzymatic synthesis of a methacrylamide-type polyester macromonomer was reported (80,81). In the polymerization of 12-hydroxydodecanoic acid in the presence of 11-methacryloylaminoundecanoic acid using lipase CC or *Candida antarctica* lipase (lipase CA) as catalyst, the polymerizable group was quantitatively incorporated into terminal of the polymer chain.

By using characteristic catalysis of lipase, regio- and enantioselective polymerizations of oxyacids have been achieved. Lipase CA catalyzed regioselective

polymerization of cholic acid, in which the hydroxy group at 3-position was regioselectively acylated to give the oligoester with molecular weight less than 1×10^3 (82). An optically active oligoester was obtained by the enantioselective polymerization of racemic 10-hydroxyundecanoic acid catalyzed by lipase CC. The resulting polymer was enriched in the (S) enantiomer with 60% enantiomeric excess (ee) and the (R)-enriched unreacted monomer with 33% ee was recovered (83). In the polymerization of racemic lactic acid catalyzed by lipase CA at 50°C (84), nonamer was detected in the product by MALDI-TOF mass measurement. A hplc analysis showed that the D-enantiomer possessed higher enzymatic reactivity.

Oxyacid Esters. The polymerization of ethyl glycolate using PEG-modified esterase from hog liver and lipase from *Aspergillus niger* (lipase A) gave oligo(glycolic acid) with DP up to 5 (85). PPL catalyzed the polymerization of methyl esters of 5-hydroxypentanoic and 6-hydroxyhexanoic acids (86). In the polymerization of the latter in hexane at 69°C for more than 50 days, the polymer with DP up to 100 was formed. Relationships between solvent type and polymerization behaviors were systematically investigated; hydrophobic solvents such as hydrocarbons and diisopropyl ether were suitable for the enzymatic production of high molecular weight polymer. Polycondensation of various hydroxyesters, ethyl esters of 3- and 4-hydroxybutyric acids, 5- and 6-hydroxyhexanoic acids, 5-hydroxydodecanoic acid, and 15-hydroxypentadecanoic acid, proceeded by *Pseudomonas* sp. lipase catalyst to give the corresponding polyesters with molecular weight of several thousands (87).

A symmetrical hydroxy diester, dimethyl β-hydroxyglutarate, was enantioselectively polymerized by lipase catalyst to produce a chiral oligomer (dimer or trimer) with 30–37% ee (88). The enantioselective polymerization of ε-substituted-ε-hydroxy esters took place in the presence of PPL catalyst, yielding optically active oligomers (DP < 6) (89). The enantioselectivity increased as a function of bulkiness of the monomer substituent. Optically active polyesters with molecular weight more than 1×10^3 were obtained by the copolymerization of the racemic oxyacid esters with methyl 6-hydroxyhexanoate.

Lipase-Catalyzed Polymerization of Dicarboxylic Acids or Their Derivatives. Enzymatic synthesis has been achieved via various combinations of dicarboxylic acid derivatives and glycols. As to the diacid monomer, dicarboxylic acids, activated and nonactivated esters, cyclic acid anhydrides, and polyanhydrides were enzymatically reacted with glycols under mild reaction conditions.

Dicarboxylic Acids. Immobilized *Mucor miehei* lipase (lipase MM) catalyzed polycondensation of adipic acid and 1,4-butanediol by using a horizontal two-chamber reactor in the presence of molecular sieves as dehydrating agent (90). A low dispersity polyester with DP=20 was obtained by the two-stage polymerization.

The polymerization of dicarboxylic acids and glycols proceeded by using lipase CA catalyst in a solvent-free system, despite the initial heterogeneous mixture of the substrates (91–94). The polymerization behaviors strongly depended on the chain length of both monomers (93). The polymerization under reduced pressure increased the molecular weight of polyesters. The detailed studies in the combination of adipic acid (A) and 1,4-butanediol (B) showed that the propagation took place by the reaction of the preliminary adduct (AB) with a hydroxy-terminated species (92).

For the solvent-free polycondensation, a small amount of adjuvant was effective for the polymer production when both monomers were solid at the reaction temperature (93). In the polymerization of adipic acid and 1,6-hexanediol, loss of the enzymatic activity was small during the polymerization, whereas less than half of the activity remained in using glycols with methylene chain length less than 4 (94). An attempted experiment allowed the polyester production from adipic acid and 1,6-hexanediol in 200-kg scale. This solvent-free system has a good potential as an environmentally friendly practical synthetic process of polymeric materials owing to the mild reaction conditions without using organic solvents and toxic catalysts.

A dehydration polymerization of dicarboxylic acids and glycols took place by lipase catalyst even in water (95,96). This catalysis of lipase is quite specific since a dehydration reaction in an aqueous solution is generally disfavored by water, which is in equilibrium with starting materials because of the law of mass action. Hydrophobic monomer combinations gave the polyesters in good yields.

Lipase CA catalyzed the polymerization of adipic acid and glycerol to give the oligomeric products (97). The presence of molecular sieves improved the molecular weight.

The molecular weight increase was achieved using vacuum system, which removed the resulting water molecules during the polymerization (98,99). An aliphatic polyester with M_w of 4.2×10^4 was obtained from sebacic acid and 1,4-butandiol using lipase MM catalyst in diphenyl ether at 37°C for 7 days under the reduced pressure. The molecular weight was much larger than that obtained under ambient pressure. The polymerization of isophthalic acid and 1,6-hexanediol at 70°C produced the corresponding aromatic polyesters with M_w of 5.5×10^4 (100).

Dicarboxylic Acid Diesters. Since unactivated esters, typically alkyl esters, show low reactivity toward lipase catalyst, the polycondensation with glycols was often performed under vacuum to produce polyesters of high molecular weight. Lipase MM-catalyzed polycondensation of diethyl sebacate and 1,4-butanediol under vacuum produced the polymer with M_w more than 2×10^4 (98).

There is, of course, an equilibrium between the monomers and polymer in the lipase-catalyzed polycondensation of dialkyl esters and glycols. In the lipase CC- or MM-catalyzed polymerization of dimethyl succinate and 1,6-hexanediol in toluene, adsorption of methanol by molecular sieves or elimination of methanol by nitrogen bubbling shifted the thermodynamic equilibrium (101). When dicarboxylic acid dialkyl esters and α,ω-alkylene glycols were used as monomers, cyclic oligomers were formed from any monomer combinations examined (102). The yield of the cyclics depended on the monomer structure, initial concentration of the monomers, and reaction temperature. The ring-chain equilibrium was observed and the molar distribution of the cyclic species obeyed the Jacobson–Stockmayer equation.

Activated esters of halogenated alcohols, such as 2-chloroethanol, 2,2,2-trifluoroethanol, and 2,2,2-trichloroethanol, have often been used as substrate for enzymatic synthesis of esters (4), owing to the increase of the electrophilicity (reactivity) of the acyl carbonyl and the avoidance of significant alcoholysis of the products by decreasing the nucleophilicity of the leaving alcohols.

Polymerization of bis(2,2,2-trichloroethyl) alkanediaoates with glycols proceeded by PPL catalyst in anhydrous solvents of low polarity to produce the

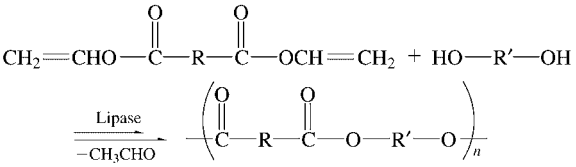

Fig. 6. Lipase-catalyzed polycondensation of divinyl esters and glycols.

polyesters with molecular weight of several thousands (103,104). The oligomer formation was observed in the polymerization of bis(2-chloroethyl) succinate and 1,4-butanediol using *Pseudomonas fluorescens* lipase (lipase PF) as catalyst (105).

Vacuum method was applied to shift the equilibrium forward by removal of the activated alcohol formed (98,99,106,107). In the polycondensation of bis(2,2,2-trifluoroethyl) sebacate and aliphatic diols, lipases CC, MM, PPL, and *Pseudomonas cepacia* lipase (lipase PC) produced the polymer with M_w more than 1×10^4. Among the enzymes examined, lipase MM showed the highest catalytic activity (106). As to solvents, diphenyl ether and veratrole were suitable for the production of the high molecular weight polyesters under vacuum. In the PPL-catalyzed reaction of bis(2,2,2-trifluoroethyl) glutarate with 1,4-butanediol, the increase of the molecular weight was attained by periodical vacuum using veratrole or 1,3-dimethoxybenzene as less-volatile solvent (107).

In lipase-catalyzed transesterifications, enol esters have been used as acyl agents (4), since the leaving unsaturated alcohol irreversibly tautomerizes to an aldehyde or a ketone, leading to the desired product in high yields. Bis(enol ester)s were reported to be much effective for the enzymatic synthesis of polyesters under mild reaction conditions (Fig. 6) (108); the polymerization of divinyl adipate and 1,4-butanediol proceeded by lipase PF at 45°C, and adipic acid and diethyl adipate did not afford the polymeric materials under the similar reaction conditions.

Various lipases (lipases CA, MM, PC, and PF) catalyzed the polycondensation of divinyl adipate or divinyl sebacate with α,ω-glycols with different chain length (109,110). A combination of divinyl adipate, 1,4-butanediol, and lipase PC afforded the polymer with number-average molecular weight (M_n) of more than 2×10^4. The polymerization behaviors of the lipase-catalyzed polymerization of divinyl adipate and 1,4-butanediol have been widely investigated (111–114). During the polymerization, the hydrolysis of the terminal vinyl ester took place, resulting in the significant limitation of the formation of the polyester with high molecular weight. A mathematical model describing the kinetics of this polymerization was proposed, which effectively predicts the composition (terminal structure) of the polyester.

Another irreversible approach was performed by using bis(2,3-butanedione monoxime) alkanedioates as diester substrate (115). The polymerization with α,ω-alkylene glycols by lipase MM produced the polymer with M_n up to 7.0×10^3.

An enantioselective polymerization of racemic substrates took place through lipase catalysis, yielding optically active oligoesters and polyesters. The polymerization of bis(2-chloroethyl) 2,5-dibromoadipate with excess of 1,6-hexanediol using lipase A catalyst produced optically active trimer and pentamer (116).

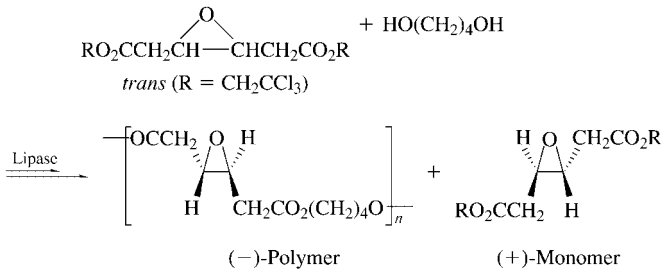

Fig. 7. Enantioselective polymerization of epoxy-containing diester with 1,4-butanediol.

PPL-catalyzed polymerization of bis(2,2,2-trichloroethyl) *trans*-3,4-epoxyadipate with 1,4-butanediol enantioselectively proceeded in anhydrous diethyl ether to give an optically active polyester with molecular weight of 5.3×10^3 (Fig. 7) (117). The molar ratio of the diester to the diol was adjusted to 2:1 so as to produce the (−) polymer with enantiomeric purity of >96%.

Polymerization of divinyl esters with triols regioselectively took place by lipase CA catalyst to give the soluble polymers with M_w of more than 1×10^4 (118,119). MALDI-TOF MS analysis confirmed the presence of a linear polyester with hydroxy substituents. An nmr analysis of the product obtained from divinyl sebacate and glycerol in bulk at 60°C showed that 1,3-diglyceride was a main unit and the branching unit (triglyceride) was contained in the resulting polymer. The regioselectivity of the acylation between primary and secondary hydroxy groups was 74:26. By choosing the reaction conditions, the polymer consisting exclusively of 1,3-acylated unit of glycerol was formed.

Lipase CA catalyzed the regioselective polymerization of sugar alcohols such as sorbitol and mannitol with divinyl sebacate to give polyesters containing sugar group in the backbone (120). Some proteases show an esterase activity, especially in their catalytic activity for regioselective acylation of sugars. By utilizing this property, protease-catalyzed synthesis of sugar-containing polyesters was demonstrated (121). Polycondensation of sucrose with bis(2,2,2-trifluoroethyl) adipate using an alkaline protease from *Bacillus* sp. as catalyst proceeded to give the polymer ($M_n=1.6\times10^3$), which was claimed to have ester linkages at the C-6 and C-1′ positions on the sucrose (Fig. 8). In using divinyl adipate as diester monomer, the molecular weight reached 1.1×10^4 (122).

Another approach of enzymatic synthesis of sugar-containing polyesters was demonstrated (123). Lipase CA-catalyzed reaction of sucrose or trehalose with an excess of divinyl adipate produced 6,6′-diacylated product having vinyl esters at both ends, which was employed as monomer in the enzymatic polycondensation with various glycols, yielding linear polyesters with M_w up to 2.2×10^4.

Unsaturated ester oligomers were synthesized by lipase-catalyzed polymerization of diesters of fumaric acid and 1,4-butanediol (124). Mild reaction conditions did not induce isomerization of the double bond to give all-trans oligomers showing crystallinity, whereas the industrial unsaturated polyester having a mixture of cis and trans double bonds is amorphous (125). The enzymatic polymerization of bis(2-chloroethyl) fumarate with xylylene glycol produced the unsaturated oligoester containing aromaticity in the backbone (126).

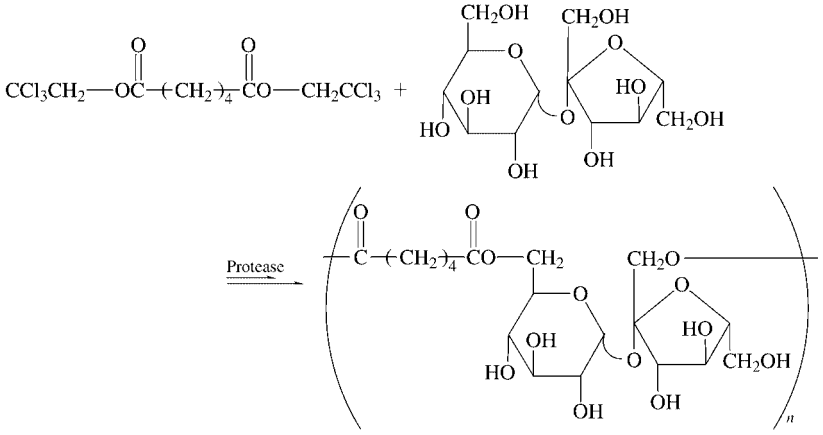

Fig. 8. Enzymatic synthesis of sucrose-containing polyester.

An unsaturated polyester possessing exclusively cis structure was synthesized by lipase CA-catalyzed polymerization of dimethyl maleate and 1,6-hexanediol in toluene (127). During the polymerization, formation of cyclic oligomers was observed. The cycles were semicrystalline, whereas the linear polymer was amorphous. In the lipase CA-catalyzed copolymerization of dimethyl maleate and dimethyl fumarate with 1,6-hexanediol, the content of the cyclization was found to mainly depend on the configuration and concentration of the monomers (128).

Polyesters containing an aromatic moiety in the backbone were synthesized by lipase CA-catalyzed polymerization of dicarboxylic acid divinyl esters and glycols under mild reaction conditions. Divinyl esters of isophthalic acid, terephthalic acid, and *p*-phenylene diacetic acid were enzymatically polymerized with α,ω-alkylene glycols to give the polymers with molecular weight of several thousands (129). Aromatic polyesters were also synthesized from methyl esters of terephthalic and isophthalic acids with 1,6-hexanediol in the presence of lipase CA (130). In using methyl isophthalate as monomer, macrocyclic compounds were formed as by-product. Protease from *Bacillus licheniformis* catalyzed the oligomerization of esters of terephthalic acid with 1,4-butanediol (131). Lipase-catalyzed synthesis of aromatic polyesters was achieved by the polymerization of divinyl esters with xylylene glycols (129,132).

Enzymatic synthesis of fluorinated polyesters was demonstrated (133). Fluorinated diols such as 2,2,3,3-tetrafluoro-1,4-butanediol and 2,2,3,3,4,4-hexafluoro-1,5-pentanediol were used as glycol substrate and polymerized with divinyl adipate using lipase CA catalyst. The enzymatic synthesis of polyester was also achieved in supercritical fluoroform solvent by the polymerization of bis(2,2,2-trichloroethyl) adipate and 1,4-butanediol (134). The molecular weight increased as a function of the pressure.

Anhydrides. Ring-opening poly(addition-condensation) of cyclic acid anhydrides with glycols proceeded through lipase catalysis (135). The polymerization of succinic anhydride with 1,8-octanediol proceeded using lipase PF catalyst at room temperature to produce the polyester with M_n of 3×10^3.

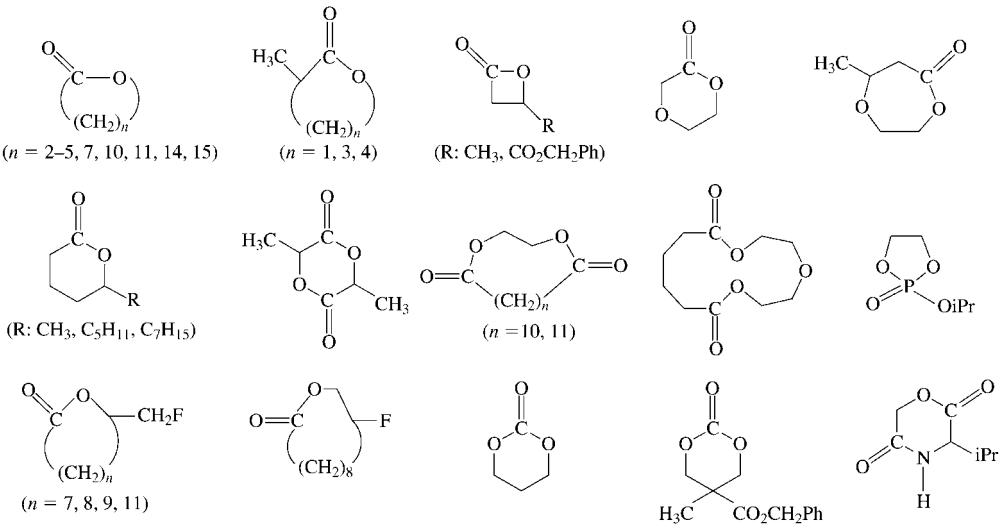

Fig. 9. Cyclic monomers polymerized by lipases.

Polyanhydrides were effective as diacid substrate for enzymatic synthesis of polyesters (136). The reaction of poly(azelaic anhydride) and 1,8-octanediol took place by lipase CA catalyst to give the corresponding polyester with molecular weight of several thousands. In the reaction of poly(azelaic anhydride) and glycerol, a highly branched polyester was obtained.

Oxiranes such as benzyl glycidate and glycidiyl phenyl ether were polymerized with succinic anhydride in the presence of PPL at 60 or 80°C (137,138). The reaction of succinic anhydride with serine residue of the lipase catalyst produces a carboxylic acid moiety, which might act as acid catalyst for ring-opening of oxirane.

Ring-Opening Polymerization of Cyclic Esters. Polyester syntheses have been achieved by enzymatic ring-opening polymerization of cyclic esters with various ring-sizes. Figure 9 summarizes cyclic monomers so far polymerized through lipase catalysis.

Lactones. Small-size (four-membered) lactone derivatives have been reported to be polymerized through lipase catalysis. The polymerization of β-propiolactone (β-PL) proceeded by using *Pseudomonas* family lipases as catalyst in bulk to give a mixture of linear and cyclic oligomers (139). By employing a very small amount of lipase CC (0.5 versus for the monomer), high molecular weight poly(β-PL) was formed (140).

Ring-opening polymerization of racemic α-methyl-β-propiolactone using lipase PC catalyst proceeded enantioselectively to produce an optically active (S)-enriched polymer (141). The highest ee value of the polymer was 0.50. An nmr analysis of the product showed that the stereoselectivity during the propagation resulted from the catalyst enantiomorphic-site control.

β-Butyrolactone (β-BL) was enzymatically polymerized to give poly(β-hydroxybutyrate) (PHB), which is a polyester produced *in vivo* by bacteria for an energy-storage substance. PPL-catalyzed polymerization of β-BL in bulk at

room temperature produced PHB with molecular weight around 1×10^3 (142). In the polymerization at high temperature (80 or 100°C), PHB with higher molecular weight was obtained by lipase CC, PF, or PPL catalyst (143,144). A significant amount of the cyclic PHB fraction was formed and the content of the cycles increased with increasing the monomer conversion. Enantioselective polymerization of β-BL was achieved by using thermophilic lipase to give (R)-enriched PHB with 20–37% ee (145).

PHB depolymerase is an enzyme catalyzing hydrolysis of PHB and its catalytic site is a serine residue, the same as lipase. The polymerization of β-BL proceeded using two types of PHB depolymerase with or without substrate-binding domains (SBD) as catalyst (146). The SBD-lacking PHB depolymerase showed higher catalytic activity.

Chemoenzymatic synthesis of biodegradable poly(malic acid) was demonstrated by lipase-catalyzed polymerization of benzyl β-malolactone, followed by the debenzylation (147). The molecular weight of poly(benzyl β-malolactone) increased by the copolymerization with a small amount of β-PL (17 mol% for the monomer) (148).

Five-membered unsubstituted lactone, γ-butyrolactone, is not polymerized by conventional chemical catalysts. However, oligomer formation from γ-butyrolactone was observed by using PPL or *Pseudomonas* sp. lipase as catalyst (87,142).

Medium size lactones, δ-valerolactone (δ-VL, six-membered) and ε-caprolactone (ε-CL, seven-membered), were subjected to lipase-catalyzed polymerizations. Lipases CC, PF, and PPL showed high catalytic activity for the polymerization of δ-VL (149,150). The molecular weight of enzymatically obtained poly(δ-VL) was relatively low (less than 2×10^3).

ε-CL was enzymatically polymerized by various lipases of different origin, lipases CA, CC, PC, PF, and PPL (86,149–157). Among them, lipase CA was the most active toward the ε-CL polymerization; a very small amount of lipase CA (less than 1 wt% for ε-CL) was enough to induce the polymerization (151). Under appropriate reaction conditions, the molecular weight reached more than 4×10^4 (157). In the lipase CA-catalyzed polymerization in organic solvents, cyclic oligomers were mainly formed, whereas the main product in the bulk polymerization was of linear structure (155).

The detailed kinetics of the ε-CL polymerization showed that termination and chain transfer did not occur and the monomer consumption followed a first-order rate law under appropriate conditions, indicating that the system provided controlled polymerizations where the molecular weight was a function of the monomer to initiator stoichiometry (152,153,156).

Effect of reaction medium has been systematically investigated in the lipase CA-catalyzed polymerization of ε-CL (157). Solvents having $\log P$ values from -1.1 to 0.49 showed low propagation rates; on the other hand, solvents with $\log P$ values from 1.9 to 4.5 efficiently induced the polymerization, leading to high molecular weight polymer. The monomer-to-solvent ratio also affected the polymerization behaviors.

Enzymatic hydrolytic degradation of poly(ε-CL) in toluene also took place using lipase CA catalyst to give oligomers with molecular weight of less than 500 (158). After the removal of the solvent from the reaction mixture, the residual

oligomer was polymerized in the presence of the same catalyst of lipase. From these data is proposed a basic concept that the degradation–polymerization could be controlled by presence or absence of the solvent, providing a new methodology of plastics recycling.

Substituted medium size lactones were polymerized by lipase catalyst. Ring-opening polymerization of α-methyl-substituted six- and seven-membered lactones (α-methyl-δ-valerolactone and α-methyl-ε-caprolactone, respectively) proceeded using lipase CA catalyst in bulk (159). As to (*R*)- and (*S*)-3-methyl-4-oxa-6-hexanolides (MOHELs), lipase PC induced the polymerization of both isomers. The apparent initial rate of the S isomer was seven times larger than that of the R isomer, suggesting that the enantioselective polymerization of MOHEL took place through lipase catalysis (160).

Poly(1,4-dioxane-2-one) is a biocompatible polymer with good flexibility and tensile strength for medical applications. Metal-free poly(1,4-dioxane-2-one) with M_w up to 4.1×10^4 was synthesized by lipase CA-catalyzed ring-opening polymerization of 1,4-dioxan-2-one (161).

Lipase-catalyzed ring-opening polymerization of nine-membered lactone, 8-octanolide (OL), has been reported (162). Lipases CA and PC showed the high catalytic activity for the polymerization.

Four unsubstituted macrolides, 11-undecanolide (12-membered, UDL) (163, 164), 12-dodecanolide (13-membered, DDL) (164,165), 15-pentadecanolide (16-membered, PDL) (163,164,166,167), and 16-hexadecanolide (17-membered) (168), were subjected to the lipase-catalyzed polymerization. An nmr analysis showed that the terminal structure of the polymer obtained in bulk was of carboxylic acid at one end and of alcohol at the other terminal.

The bulk polymerization of PDL using lipase CA or MM as catalyst produced the corresponding polyester with high molecular weight up to 3.4×10^4 (167). The polymerization behaviors (rate of the monomer consumption and molecular weight of the polymer) depended on the water content in the reaction system. Enzymatic ring-opening polymerization of macrolides (UDL, DDL, and PDL) proceeded even in an aqueous medium (169).

The enzymatic polymerization of lactones is explained by considering the following reactions as the principal reaction course (Fig. 10) (160,163,170,171). The key step is the reaction of the lactone with lipase involving the ring-opening of the lactone to give the acyl-enzyme intermediate (enzyme-activated monomer, EM). The initiation is a nucleophilic attack of water, which is probably contained in the enzyme, onto the acyl carbon of the intermediate to produce ω-hydroxycarboxylic acid ($n=1$, the shortest propagating species). In the propagation stage, the intermediate is nucleophilically attacked by the terminal hydroxyl group of a propagating polymer to produce a one-unit-more elongated polymer chain. This is a *monomer-activated mechanism* in contrast to an active chain-end mechanism, the widely known polymerization mechanism.

Macrolides have virtually no ring strain, and hence, show similar reactivities with acyclic fatty acid alkyl esters in the alkaline hydrolysis and lower anionic ring-opening polymerizability than ε-CL. However, polymerization of the macrolides using lipase PF catalyst proceeded much faster than that of ε-CL. This specific polymerizability by lipase catalyst was quantitatively evaluated by Michaelis–Menten kinetics (160,168,170–172). For unsubstituted lactones in the

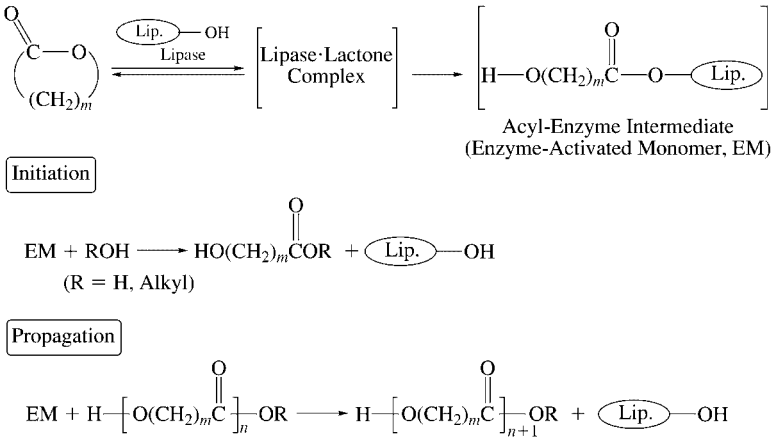

Fig. 10. Postulated mechanism of lactone polymerization catalyzed by lipase.

range of ring-size from 7 to 17, linearity was observed in the Hanes–Woolf plot for the formation of the acyl-lipase intermediate, indicating that the polymerization followed Michaelis–Menten kinetics. $V_{\max(\text{lactone})}/K_{\text{m(lactone)}}$ and $V_{\max(\text{lactone})}$ values increased as a function of the ring-size; on the other hand, $K_{\text{m(lactone)}}$ values were not so different from each other. These data imply that the enzymatic polymerizability increased as the ring-size increased, and the large polymerizability of macrolides through lipase catalysis is mainly due to the large reaction rate ($V_{\max}$), but not to the binding abilities, ie, the ring-opening reaction process of the lipase–lactone complex to the acyl-enzyme intermediate is the key step of the polymerization.

Fluorinated lactones in the ring-size from 10 to 14 were enantioselectively polymerized using lipase catalyst (173). The lipase CA-catalyzed polymerization of 10-fluorodecan-9-olide (10-membered) produced the optically active polymer with positive rotation. Interestingly, the corresponding oxyacid gave an optically inactive polyester.

Enzymatic synthesis of aliphatic ester copolymers was achieved by lipase-catalyzed polymerization of two lactones. The copolymerization of δ-VL and ε-CL catalyzed by lipase PF produced the corresponding copolymer having random structure of both units (174). In the copolymerization of OL with ε-CL or DDL, random copolyesters were also formed (162), suggesting the frequent occurrence of transesterifications between the polyesters. On the other hand, the copolymer from ε-CL and PDL was not statistically random (166).

Polyesters with high optical purity were synthesized by the lipase CA-catalyzed copolymerization of racemic β-BL with ε-CL or DDL (175). (S)-β-BL was preferentially reacted with DDL to give the (S)-enriched optically active copolymer with ee of β-BL unit = 69%. δ-CL was also enantioselectively copolymerized by the lipase catalyst to give the (R)-enriched optically active polyester with ee up to 76%.

Frequent occurrence of transesterification between polyesters chains was expanded to synthesis of random ester copolymers by the lipase-catalyzed

polymerization of lactones in the presence of poly(ε-CL) (176). Intermolecular transesterifications between poly(ε-CL) and poly(PDL) also took place through lipase catalysis.

Ester copolymers were synthesized by lipase-catalyzed copolymerization of lactones, divinyl esters, and glycols (177). The ^{13}C nmr analysis showed that the resulting product was not a mixture of homopolymers, but a copolymer derived from the monomers, indicating that two different modes of polymerization, ring-opening polymerization and polycondensation, simultaneously take place through enzyme catalysis in one pot to produce ester copolymers.

Immobilized lipase showing high catalytic activity toward the enzymatic synthesis of polyesters was demonstrated (178). Only a small amount of immobilized lipase PF adsorbed on a Celite was effective for the polymerization of lactones. The catalytic activity was further enhanced by the presence of a sugar or PEG at the immobilization. Surfactant-coated lipase efficiently catalyzed the ring-opening polymerization of lactones in organic solvents, in which the modified enzyme was soluble (179).

Enzymatic synthesis of end-functionalized polymers such as macromonomers and telechelics has been achieved by initiator and terminator methods. An alcohol could initiate the ring-opening polymerization of lactones by lipase catalyst ("initiator method"). In the lipase CA-catalyzed polymerization of DDL using 2-hydroxyethyl methacrylate as initiator, the methacryloyl group was quantitatively introduced at the polymer terminal, yielding the methacryl-type polyester macromonomer (180). In the lipase-catalyzed polymerization of ε-CL in the presence of functional alcohols (181), end-functionalized poly(ε-CL) as well as the cyclic by-product was formed.

Polyesters bearing the sugar moiety at the polymer terminal was synthesized by lipase CA-catalyzed polymerization of ε-CL in the presence of alkyl glucopyranosides (182–184). In the initiation step, the primary hydroxy group of the glucopyranoside was regioselectively acylated. Poly(ε-CL) monosubstituted first generation dendrimer was synthesized using lipase CA as catalyst. The monoacylation of the initiator took place at the initial stage (185).

Polymeric hydroxy group also initiated the enzymatic ring-opening polymerization of ε-CL (186). The polymerization was performed using thermophilic lipase as catalyst in the presence of hydroxyethyl cellulose (HEC) film to produce HEC-*graft*-poly(ε-CL) with degree of substitution from 0.10 to 0.32.

Single-step synthesis of polyester macromonomers was achieved by lipase-catalyzed polymerization of lactones in the presence of vinyl esters acting as terminator ("terminator method") (187,188). A methacryl-type poly(DDL) macromonomer was obtained using vinyl methacrylate (12.5 or 15 mol% based on DDL) and lipase PF as terminator and catalyst, respectively. By the addition of divinyl sebacate, the telechelic polyester having a carboxylic acid group at both ends was synthesized.

Cyclic Diesters. Cyclic diesters were subjected to the lipase-catalyzed ring-opening polymerization. Lactide, cyclic dimer of lactic acid, was polymerized by lipase PC in bulk at high temperature (80–130°C) to produce poly(lactic acid) with M_w up to 2.7×10^5 (189,190). Protease (proteinase K) also induced the polymerization of lactide; however, the catalytic activity was relatively low.

Ring-opening polymerization of cyclic diesters obtained from diacid and glycol, ethylene dodecanoate, ethylene tridecanoate, and 1,4,7-trioxa-cyclotridecane-8,13-dione, took place through lipase catalysis (191,192). The former two monomers were polymerized by lipase CA, PC, or PF catalyst (191). The enzyme origin affected the polymerization behaviors; the polymerization of these bislactones using lipase PC catalyst proceeded faster than that of ε-CL and DDL, whereas the reactivity of these cyclic diesters was in the middle of ε-CL and DDL in using lipase CA.

***In Vitro* PHA Polymerase-Catalyzed Polymerization to PHA.** *Alcaligenes eutrophus* has been used for industrial production of poly(hydroxyalkanoate)s (PHAs). PHA is prepared from acetyl CoA in three steps and the last step is the chain growth polymerization of hydroxyalkanoate CoA esters catalyzed by PHA polymerase, yielding PHA of high molecular weight, which has been *in vitro* examined, leading to synthesis of PHAs with well-defined structure. This synthetic process obeys the biosynthetic pathways (see POLY(3-HYDROXYALKANOATES)).

The growing polymer chain was covalently attached to a highly conserved cysteine residue (Cy319) of the polymerase (193). The granules of the precipitated polymer were quickly formed when the purified polymerase was exposed to (*R*)-hydroxybutyryl CoA (HBCoA) (194,195). The artificial PHB granules were spherical with diameters of up to 3 μm, significantly larger than the native ones.

The polymerization of the CoA monomers of (*R*)-hydroxyalkanoate was of chain growth in a living fashion; each molecule of the polymerase initiated and catalyzed the formation of one molecule of the polymer (196–198). By utilizing this property of polymerase, random and block copolyesters were synthesized. The resulting polymer had high molecular weight ($>10^6$). In the polymerization of racemic HBCoA, only the *R* monomer was polymerized. Furthermore, the presence of the *S* monomer did not reduce the polymerization rate of the *R* isomer. These data indicate that the *S* monomer does not act as competitive inhibitor for the polymerase.

Recombinant PHA synthase from *Chromatium vinosum* showed different catalytic behaviors in comparison with that of *A. eutrophus* (199). In combination of this synthase with purified propionyl-CoA transferase of *Clostridium propionicum*, a two-enzyme *in vitro* PHB biosynthesis system was established, which allowed the PHB synthesis from (*R*)-hydroxybutyric acid as substrate (200).

Hydrolase-Catalyzed Modification of Polymers. Terminal hydroxy group of poly(ε-CL) was reacted with carboxylic acids using lipase CA catalyst to give end-functionalized polyesters (181). Lipase MM catalyzed the regioselective transesterification of the terminal ester group of oligo(methyl methacrylate) with allyl alcohol (201).

The lipase-catalyzed acetylation of high molecular weight methacrylic polymers containing racemic hydroxy groups in the side chain was achieved with a maximum conversion of 40% (202,203). The optical rotation was low (up to -1.2°), suggesting a low enantioselectivity of this esterification. The enzymatic transesterification of amylose film with vinyl caprate in the isooctane solution containing solubilized subtilisin Carlsberg produced an amylose derivative regioselectively acylated at the C-6 position (204).

Enzymatic epoxidation of polybutadiene was demonstrated (205). Lipase CA catalyzed the oxidation of polybutadiene using hydrogen peroxide as oxidizing agent in the presence of acetic acid.

Polycarbonates

Polycondensation. Oligocarbonate with molecular weight of less than 1×10^3 was formed by lipase CC-catalyzed polycondensation of carbonic acid diphenyl ester with bisphenol A (206). Diethyl carbonate was polymerized with 1,4-butanediol by lipase CA catalyst (207,208). The successive two-step polymerization, the prepolymerization under ambient pressure, followed by the polymerization under vacuum (0.5 mm Hg), produced poly(tetramethylene carbonate) with M_w of more than 4×10^4.

Activated dicarbonate, 1,3-propanediol divinyl dicarbonate, was used as new monomer for enzymatic synthesis of polycarbonates (209). Lipase CA catalyzed the polymerization with α,ω-alkylene glycols under mild reaction conditions and the M_w value reached 8×10^3. Aromatic polycarbonate was enzymatically obtained from the activated dicarbonate and xylylene glycol (132).

Ring-Opening Polymerization. 1,3-Dioxan-2-one, six-membered cyclic carbonate, was polymerized in the presence of lipase catalysts (210–212). Under mild reaction conditions ($\leq$70 °C), lipase CA efficiently catalyzed the polymerization to give the corresponding polycarbonate with M_n more than 1×10^4 (211,212). No ether bond was observed in the nmr spectrum of the product, indicating that elimination of carbon dioxide did not occur during the enzymatic polymerization. The polymerization in the presence of a small amount of PPL (0.1 or 0.25 wt% for the monomer) at 100°C produced the high molecular weight polymer ($M_w = 1.6\times10^5$) (210).

The enzymatic polymerization of 5-methyl-5-benzyloxycarbonyl-1,3-dioxan-2-one produced the corresponding polycarbonate (213). Lipases PF and CA showed high catalytic activity for the polymerization. Debenzylation by catalytic hydrogenation led to the water-soluble polycarbonate with pendent carboxyl group.

Lipase CA catalyzed the polymerization of cyclic dicarbonates, cyclobis(hexamethylene carbonate) and cyclobis(diethylene glycol carbonate), to give the corresponding polycarbonates (214). The enzymatic copolymerization of cyclobis(diethylene glycol carbonate) with DDL produced a random ester-carbonate copolymer. Enzymatic synthesis of poly(ester-carbonate) was also achieved by the copolymerization of 1,3-dioxan-2-one and lactide (215). The PPL-catalyzed copolymerization at 100°C produced the copolymer with M_w higher than 2×10^4.

Besides polyesters and polycarbonates, lipase-catalyzed synthesis of polymers from cyclic monomers has been reported. 3(*S*)-Isopropylmorpholine-2,5-dione, six-membered depsipeptide, was polymerized by lipase PC and PPL catalysts to give poly(ester-amide) (216,217). High temperature (100 or 130°C) was required for the polymerization, yielding biodegradable poly(depsipeptide) with maximum $M_n = 3\times10^4$. During the polymerization, the racemization of the valine residue took place. PPL-catalyzed synthesis of poly(phosphate) was demonstrated (218). The ring-opening polymerization of ethylene isopropyl phosphate,

five-membered cyclic phosphate, took place at 40–100°C to give the polymer with molecular weight of ca 1×10^3.

Polyaromatics

In living cells, various oxidoreductases play an important role in maintaining the metabolism of living systems. So far, peroxidase containing Fe-active site, laccase containing Cu-active site, tyrosinase (polyphenol oxidase, Cu-active site), bilirubin oxidase (Cu-active site), etc, have been reported to act as catalyst for oxidative polymerization of phenol and aniline derivatives and for polymer modification via oxidative coupling.

Enzymatic Oxidative Polymerization.

Polyphenols. For enzymatic oxidative polymerization of phenol derivatives, peroxidase has been often used as catalyst. Catalytic cycle of peroxidase is shown in Figure 11. Peroxidase catalyzes decomposition of hydrogen peroxide at

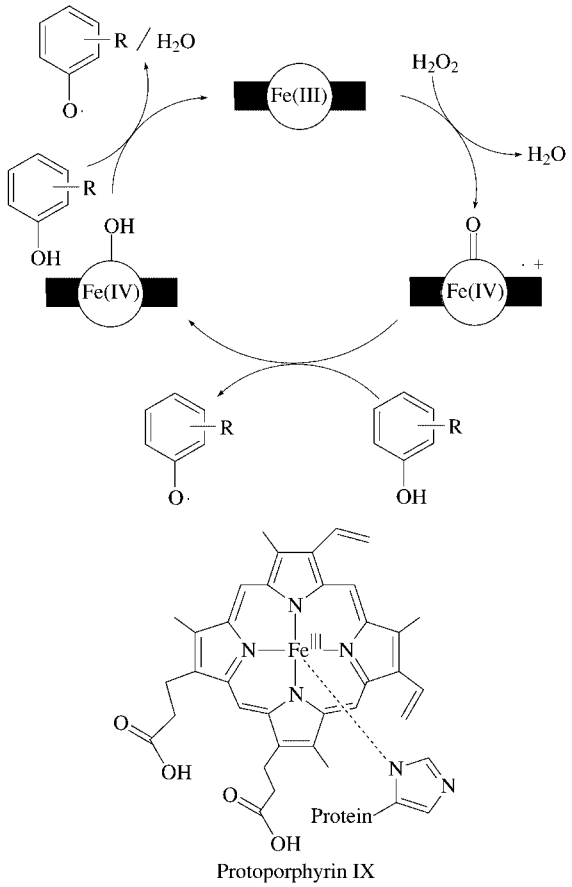

Fig. 11. Catalytic cycles of peroxidase for polymerization of phenols.

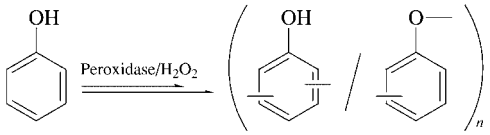

Fig. 12. Peroxidase-catalyzed oxidative polymerization of phenol.

the expense of aromatic proton donors in living cells. In some cases, the peroxidase-catalyzed oxidation of these donors, eg, phenols, yields water-insoluble polymeric materials, which had not been characterized yet.

In 1987, enzymatic synthesis of a new class of polyphenols has been first reported. An oxidative polymerization of *p*-phenylphenol using horseradish peroxidase (HRP) as catalyst was carried out in a mixture of water and water-miscible solvents such as 1,4-dioxane, acetone, DMF, and methyl formate to give powdery polymeric materials (219). The reaction medium composition greatly affected the molecular weight, and the highest molecular weight (2.6×10^4) was achieved in 85% 1,4-dioxane.

In the case of phenol, the simplest and most important phenolic compound in industrial fields, conventional polymerization catalysts afford an insoluble product with noncontrolled structure since phenol is a multifunctional monomer for oxidative polymerization. On the other hand, the peroxidase catalysis induced the polymerization in an aqueous organic solvent to give a powdery polymer consisting of phenylene and oxyphenylene units showing relatively high thermal stability (Fig. 12) (220–224). HRP and soybean peroxidase (SBP) were active as catalyst for the polymerization in the aqueous 1,4-dioxane (220–222). However, the resulting polymer showed low solubility; the polymer was partly soluble in DMF and dimethyl sulfoxide, and insoluble in other common organic solvents. The solubility was much improved by using a mixed solvent of buffer and methanol, producing the DMF-soluble polymer with molecular weight of 2100–6000 in good yields. Furthermore, the unit ratio (regioselectivity) could be controlled by changing the solvent composition; the polymer in the range of the phenylene unit from 32 to 66% was obtained (223,224).

So far, various phenol derivatives have been polymerized through peroxidase catalysis in the aqueous organic solvent (225–227). For the case of a combination of *p*-*n*-alkylphenols and HRP, the polymer yield increased as the chain length of the alkyl group increased from 1 to 5 (228,229). Polymer formation was observed in using all cresol isomers by HRP catalyst (230). The polymer was obtained in a high yield from *p*-*i*-propylphenol, whereas ortho and metaisomers were not polymerized under the similar reaction conditions. Poly(*p*-*n*-alkylphenol)s prepared in the aqueous 1,4-dioxane showed low solubility toward common organic solvents, and the molecular weight was in the range of several thousands. On the other hand, soluble oligomers with molecular weight less than 1000 were formed in using an aqueous DMF as solvent (231).

Enzymatically synthesized polyphenols showed biodegradability (232), although the degradation rate was not high. Antioxidant effects of the polymers obtained from various phenols through the enzyme catalysis were evaluated (233). Pronounced improvement for the autooxidation of tetralin was observed.

As to meta-alkyl substituted phenols, the soluble polyphenols were obtained by HRP or SBP catalyst in the aqueous methanol (234). Enzymatically synthesized poly(*m*-cresol) had glass-transition temperature (T_g) of higher than 200°C. The enzyme origin strongly influenced the polymer yield; HRP could readily polymerize the monomer having a small substituent, whereas in the case of large substituent monomers, the high yield was achieved by using SBP as catalyst.

The enzymatic reaction kinetics on the HRP-catalyzed oxidation of *p*-cresol in aqueous 1,4-dioxane or methanol showed that the catalytic turnover number and Michaelis constant were larger than those in water (235). Numerical and Monte Carlo simulations of the peroxidase-catalyzed polymerization of phenols were demonstrated (236). The simulations predicted the monomer reactivity and polymer molecular weight, leading to synthesis of polymers with specific molecular weight and index. In an aqueous 1,4-dioxane, the formation of monomer aggregate was observed (237), which might elucidate the specific polymerization behaviors in such a medium.

Effects of the monomer substituent and substituted position on the initial reaction rate in the HRP-catalyzed polymerization of substituted phenols were examined (238). Substrates with the electron-drawing group or ortho-substituted substrates showed low polymerizability. Lactoperoxidase also showed catalytic activity for the polymerization of phenols.

Four interfacial systems, micelles, reverse micelles, a biphasic, and Langmuir trough systems, have been examined for preparation of the enzymatic synthesis of polyphenols. In the polymerization in micelle solution consisting of surfactant and buffer, the obtained polymer from *p*-phenylphenol had narrow molecular weight distribution in comparison of that in the aqueous 1,4-dioxane (239).

HRP and *p*-ethylphenol were encapsulated in the reverse micelle, which was a ternary system composed of isooctane, water, and bis(2-ethylhexyl) sodium sulfosuccinate (AOT). The introduction of hydrogen peroxide into the system induced the polymerization to produce the polymer particles in the diameter range from 0.1 to 2 μm quantitatively (240–242). Similar particles were obtained by pouring the solution of enzymatically prepared polyphenol into a nonsolvent containing AOT (243).

HRP-catalyzed polymerization of *p*-alkylphenols proceeded in a biphasic system consisting of two mutually immiscible phases (isooctane and water) (226). The molecular weight increased as a function of the carbon number of the alkyl group.

Enzymatic polymerization of phenol derivatives in a monolayer form was demonstrated (241,244,245). A monolayer was formed from *p*-tetradecyloxyphenol and phenol at the air–water interface in a Langmuir trough, which was polymerized by HRP catalyst in the subphase. The polymerized film could be deposited on silicon wafer with a transfer ratio of 100% for the Y-type film. The monolayer thickness determined by Eppipsometric and AFM was 27.8 Å.

Poly(2,6-dimethyl-1,4-oxyphenylene) [poly(phenylene oxide), PPO] is widely used as high-performance engineering plastics, since the polymer has excellent chemical and physical properties, eg, a high T_g (ca 210°C) and mechanically tough property. PPO was first prepared from 2,6-dimethylphenol monomer using a copper/amine catalyst system (246,247). 2,6-Dimethylphenol was also polymerized through HRP catalysis to give the polymer consisting of exclusively 1,4-oxyphenylene unit (248). On the other hand, a small amount of Mannich-base

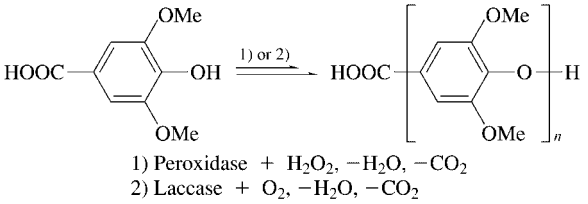

Fig. 13. Enzymatic synthesis of PPO derivative from syringic acid.

and 3,5,3′5′-tetramethyl-4,4′-diphenoquinone units are contained in commercially available PPO. The polymerization also proceeded in the presence of laccase derived from *Pycnoporus coccineus* under air without the addition of hydrogen peroxide.

HRP, SBP, and laccase catalysis induced a new type of oxidative polymerization of 4-hydroxybenzoic acid derivatives, 3,5-dimethoxy-4-hydroxybenzoic acid (syringic acid) and 3,5-dimethyl-4-hydroxybenzoic acid. The polymerization involved elimination of carbon dioxide and hydrogen from the monomer to give PPO derivatives with molecular weight up to 1.8×10^4 (Fig. 13) (110,249–251).

Polymerization of *p*-alkoxyphenols regioselectively proceeded by HRP catalyst to give PPO (252). Peroxidase-catalyzed synthesis of poly(catechol) was achieved and the iodine-labeled polymer showed low electrical conductivity in the range of 10^{-6}–10^{-9} $S\cdot cm^{-1}$ (253).

Thiol-containing polyphenol was synthesized by peroxidase-catalyzed copolymerization of *p*-hydroxythiophenol and *p*-ethylphenol in reverse micelles (254). CdS nanoparticles were attached to the copolymer to give polymer–CdS nanocomposites. By a similar procedure, polyphenol–iron oxide composites were synthesized (242). The reverse micellar system was also effective for the enzymatic synthesis of poly(2-naphthol) showing a fluorescence characteristic of the naphthol chromophore (255). nmr, ir, and uv analyses showed the formation of the polymer with quinonoid structure.

Bilirubin oxidase (BOD), a copper-containing oxidoreductase, catalyzed the oxidative polymerization of 1,5-dihydroxynaphthalene to give the polymer showing low solubility (256,257). The polymerization proceeded regioselectively to produce the polymer film having a long π-conjugated structure. This monomer was also polymerized by HRP catalyst (258). The polymerization in the presence of porous silicon (PS) wafer produced the polyphenol–PS composite showing optoelectronic properties.

Bisphenol A was polymerized by SBP catalyst to give a soluble polymer with molecular weight of several thousands in good yields (259). Interestingly, the polymer was subjected to thermal curing at 150–200°C. 4,4′-Biphenol was polymerized by HRP catalyst in an aqueous 1,4-dioxane to give the polymer showing high thermal stability (260).

The mechanistic study of the HRP-catalyzed oxidative polymerization was performed by using nmr spectroscopy (261,262). In the initial stage of the polymerization of 8-hydroxyquinoline-5-sulfonate, the oxidative coupling took place at carbons of the 2-, 4-, and 7-positions of the monomer. Polymerization and copolymerization of 8-hydroxyquinoline also took place through HRP catalysis (263).

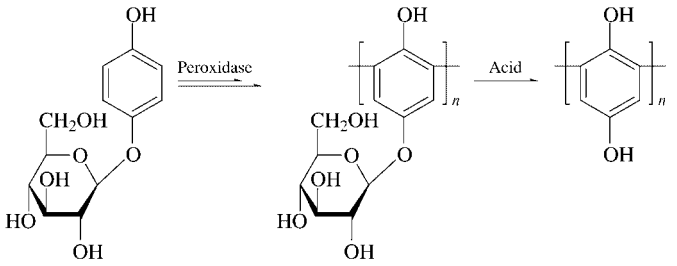

Fig. 14. Chemoenzymatic synthesis of poly(hydroquinone).

Peroxidase catalysis induced the oxidative polymerization of glucose-β-D-hydroquinone (arbutin) in a buffer to produce a water-soluble polyphenol (264). The acid treatment of the polymer led to the quantitative deglycosylation of the polymer, yielding poly(hydroquinone) soluble in polar organic solvents (Fig. 14). The resulting polymer was used as a mediator for amperometric glucose sensors (265). Another route for chemoenzymatic synthesis of poly(hydroquinone) from 4-hydroxyphenyl benzoate was demonstrated (266), whose structure was different from that obtained from arbutin. Enzymatically synthesized phenolic copolymer containing fluorophore (fluorescein or calcein) was applied as array-based metal-ion sensor (267).

A polynucleoside with unnatural polymeric backbone was synthesized by SBP-catalyzed oxidative polymerization of thymidine 5′-*p*-hydroxyphenylacetate (268). Chemoenzymatic synthesis of a new class of poly(amino acid), poly(tyrosine) containing no peptide bonds, was achieved by peroxidase-catalyzed oxidative polymerization of tyrosine ethyl esters, followed by alkaline hydrolysis (269). The amphiphile higher alkyl ester derivatives were also polymerized in micellar solution to give the polymer showing surface activity at the air–water interface (270). The polymerization was monitored by the quartz crystal microbalance (271).

HRP catalysis induced a chemoselective polymerization of a phenol derivative having methacryloyl group (272). Only the phenol moiety was polymerized without involving vinyl polymerization of methacryloyl to give a polymer having the methacryloyl group in the side chain (Fig. 15). The resulting polymer was subjected to thermal and photochemical curings (273).

A phenol with an acetylenic substituent in the meta position was also chemoselectively polymerized to give the polyphenol having the acetylenic group (274). The resulting polymer was converted to carbonized polymer in a much higher yield than enzymatically synthesized poly(*m*-cresol).

Cardanol, a main component obtained by thermal treatment of cashew nut shell liquid, is a phenol derivative mainly having the meta substituent of a C-15 unsaturated hydrocarbon chain mainly with one to three double bonds. A new cross-linkable polymer was synthesized by the SBP-catalyzed polymerization of cardanol (110,251,275). The polymerization in an aqueous acetone produced oily polymeric materials having the carbon–carbon unsaturated group in the side chain. The curing by cobalt naphthenate gave the cross-linked film with high gloss surface. The hydrogenated cardanol derivative was also oxidatively polymerized by HRP (276).

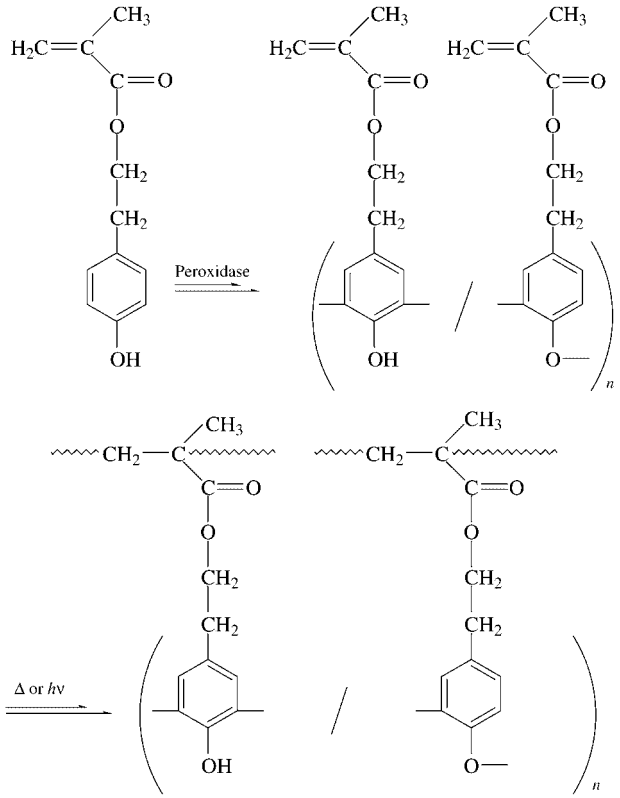

Fig. 15. Chemoselective polymerization of a phenol derivative having a methacryloyl group.

Fluorinated phenols, 3- and 4-fluorophenols and 2,6-difluorophenol, were subjected to peroxidase-catalyzed polymerization, yielding fluorine-containing polymerizations. During the polymerization, elimination of fluorine atom partly took place to give the polymer with complicated structure (277).

Morphology of the enzymatically synthesized polyphenol was controlled under the selected reaction conditions. Monodisperse polyphenol particles in the submicron range were produced by HRP-catalyzed dispersion polymerization of phenol using poly(vinyl methyl ether) as stabilizer in an aqueous 1,4-dioxane (278–280). The particle size could be controlled by the stabilizer concentration and solvent composition. Thermal treatment of these particles afforded uniform carbon particles. The particles were also formed from *m*-cresol and *p*-phenylphenol.

Bienzymatic system (glucose oxidase + HRP) was used as catalyst for the polyphenol synthesis. This system induced the polymerization of phenol in the presence of glucose without the addition of hydrogen peroxide to produce the polymer in a moderate yield (281). Hydrogen peroxide was formed *in situ* by the oxidation of glucose catalyzed by glucose oxidase, which acted as oxidizing agent for the polymerization.

In vitro synthesis of lignin, a typical phenolic biopolymer, was claimed by the HRP-catalyzed terpolymerization of lignin monomers, *p*-coumaryl alcohol, coniferyl alcohol, and sinapyl alcohol (14:80:6 mol%) in an extremely dilute aqueous solution at pH 5.5 (282). Dialysis membrane method was applied to the polymerization of coniferyl and sinapyl alcohols, yielding insoluble polymeric materials (283). In the HRP-polymerization of coniferyl alcohol in the presence of a small amount of lignin component, the molecular weight distribution became much broader than that in the absence of lignin (284).

Peroxidase-catalyzed polymerization behavior of coniferyl alcohol has been compared with that by laccase (285). Peroxidase oxidized the substrate faster than laccase in the presence of hydrogen peroxide. As to the laccase-catalyzed polymerization, the oxidation rate and reaction mechanism depended on the enzyme origin.

Enzymatic polymerization of soluble lignin fragments (lignin oligomer) was demonstrated. In the polymerization catalyzed by HRP, or polyphenol oxidase (potato), brown precipitates were formed (286). The increase of the molecular weight was observed in the laccase-catalyzed treatment of the lignin oligomer (287).

Peroxidase-catalyzed grafting of polyphenols on lignin has been attempted by HRP-catalyzed polymerization of *p*-cresol with lignin in the aqueous 1,4-dioxane or reverse micellar system. (288–290). The monomer was incorporated into lignin by the oxidative coupling between the monomer and the phenolic moiety of lignin.

Low molecular weight coal (4 kDa) was polymerized by HRP or SBP catalyst in a mixture of DMF and buffer (291). The resulting product was partly soluble in DMF and the DMF-soluble part had a larger molecular weight than that of the starting substrate.

A novel system of enzymatic polymerization, ie, a laccase-catalyzed cross-linking reaction of new "urushiol analogues" for the preparation of "artificial urushi," has been demonstrated (Fig. 16) (292,293). Single-step synthesis of the urushiol analogues was achieved by using lipase as catalyst. These compounds were cured in the presence of laccase catalyst under mild reaction conditions without the use of organic solvents to produce the cross-linked polymeric film with high gloss surface and good elastic properties. Catechol derivatives directly

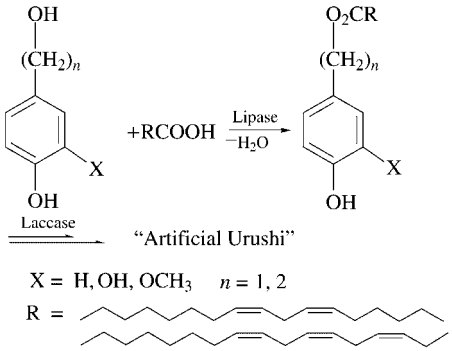

Fig. 16. Laccase-catalyzed curing of urushiol analogues to "artificial urushi."

connecting an unsaturated alkenyl group at 4-position of the catechol ring were also cured by laccase to give the cross-linked polymeric film showing ideal dynamic viscoelasticity (294).

Polyanilines. Oxidoreductases also catalyze oxidative polymerization of aromatic amines. HRP induced the polymerization of aniline. In the HRP-catalyzed polymerization under neutral conditions, the polymer with complicated structure was obtained in low yields (295). The resulting polymer showed good third-order nonlinear optical properties (296).

On the other hand, the polymerization using sulfonated polystyrene (SPS) as template produced the electroactive form of polyaniline (297–299). The resulting polymer was soluble in water and the conductivity reached 5×10^{-3} S·cm^{-1} without doping. Besides SPS, a strong acid surfactant, sodium dodecylbenzenesulfonic acid, provided suitable local template environments leading to the formation of conducting polyaniline. Aniline was also polymerized by BOD catalyst to give the polyaniline film, which was electrochemically reversible in its redox properties in acidic solution (300).

HRP-catalyzed oxidative polymerization of *o*-phenylenediamine in a mixture of 1,4-dioxane and phosphate buffer produced a soluble polymer consisting of an iminophenylene unit (301). From para and meta isomers, the polymer with well-defined structure was not obtained (302). Enzymatic polymer formation was observed from *p*-aminobenzoic acid (303), *p*-aminophenylmethylcarbitol (304), 2,5-diaminobenzenesulfonate (305), and *p*-aminochalcones (306). Cytochrome *c* catalyzed oxidation of *o*-phenylenediamine to give oligomeric products (307). Monolayer of aniline/*p*-hexadecylaniline prepared by LB technique at the air–water interface was polymerized through HRP catalysis to give polymeric monolayer (244,245).

A new class of polyaromatics was synthesized by peroxidase-catalyzed oxidative copolymerization of phenol derivatives with anilines. In case of a combination of phenol and *o*-pheneylenediamine, ftir analysis showed the formation of the corresponding copolymer (308).

Polymer Modification by Oxidoreductases. Tyrosinase (polyphenol oxidase, a copper-containing monooxygenation enzyme) was used as catalyst for modification of chitosan. The enzymatic treatment of chitosan film in the presence of tyrosinase and phenol derivatives produced a new material of chitosan derivative (309). During the reaction, unstable *o*-quinones were formed, followed by the reaction with chitosan to give the modified chitosan. In the enzymatic treatment of *p*-cresol with a low concentration of chitosan (<1%), the reaction solution was converted into a gel (310).

The similar treatment in the presence of chlorogenic acid produced the modified chitosan soluble under both acidic and basic conditions (311). On the other hand, the tyrosinase-catalyzed reaction of 3,4-dihydroxyphenylethylamine (dopamine) provided water-resistant adhesive properties to chitosan (312). A chitosan derivative modified with hydroxy or dihydroxybenzaldehyde was cross-linked by tyrosinase to give stable and self-sustaining gels (313). Phenolic moiety of a synthetic polymer, poly(*p*-hydroxystyrene), was also subjected to tyrosinase-catalyzed oxidation (314).

Peroxidase-catalyzed treatment of soy proteins (315) and wheat gliadins (316) was demonstrated, in which tyrosine residues of the protein were subjected

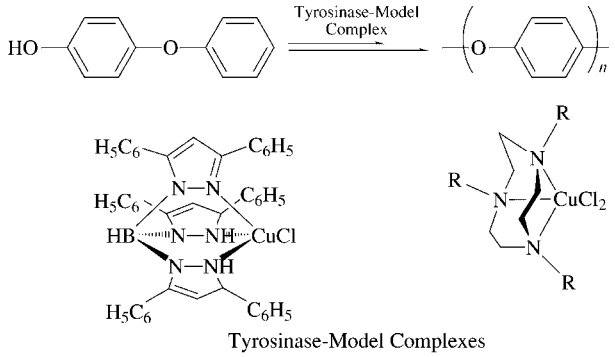

Fig. 17. Regioselective polymerization of 4-phenoxyphenol catalyzed by a tyrosinase-model complex to unsubstituted PPO.

to the enzymatic oxidative coupling, yielding a network of peptide chains. The treatment increased the tensile strength of the materials. In the oxidative polymerization of bovine pancreatic ribonuclease A catalyzed by lignin peroxidase, the coupling between tyrosine residues was confirmed (317).

Oxidative Polymerization Catalyzed by Enzyme-Model Complexes. Metal complexes containing a catalytic site of enzymes or its modified moiety have been used as catalyst for oxidative polymerizations. Regioselective oxidative polymerization of 4-phenoxyphenol was achieved by using tyrosinase model complexes as catalyst, leading to crystalline 2,6-unsubstituted PPO (318–321) (Fig. 17). The complex also catalyzed the regioselective polymerization of 2,5-dimethylphenol to give the crystalline PPO derivative with melting point higher than 300°C (322). From *o*- and *m*-cresols, polymers consisting mainly of 1,4-oxyphenylene unit were also formed (323,324).

Catalytic site of peroxidase is a heme, which is rapidly oxidized in its free form to hematin. *p*-Ethylphenol was polymerized using hematin as catalyst in an aqueous DMF (325). Iron-*N*,*N*′-ethylenebis(salicylideneamine) (Fe-salen) also can be regarded as model complex of peroxidase. Fe-salen catalyzed an oxidative polymerization of various phenols such as 2,6-dimethylphenol, bisphenol A, cardanol, and urushiol analogues (251,293,326–329). The polymerization of 2,6-difluorophenol by Fe-salen produced a crystalline fluorinated PPO derivative (330).

Vinyl Polymers

Some oxidoreductases have been reported to induce polymerization of vinyl monomers. HRP, xanthin oxidase, alcohol oxidase, chloroperoxidase, and laccase could catalyze the polymerization of acrylamide and hydroxyethyl methacrylate (331,332). Glucose oxidase mediated the initiation of vinyl polymerization in the presence of Fe^{2+} and dissolved oxygen (333).

A novel initiating system for vinyl polymerization, HRP/hydrogen peroxide/β-diketone, was demonstrated (334–336), in which the catalytic action of HRP generates carbon radical, a real initiating species, from hydrogen

peroxide and β-diketone through an oxidoreductive pathway. A combination of laccase and organic peroxide initiated the polymerization of acrylamide in the presence of lignin, yielding lignin-*graft*-polyacrylamide (337).

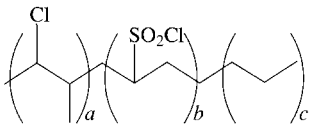
ETHYLENE POLYMERS, CHLOROSULFONATED

Introduction

Chlorosulfonated polyethylene (CSM) [68037-39-8] describes a group of curable, halogenated olefin polymers, first introduced to the rubber industry by E. I. du Pont de Nemours and Co. in 1951 (1–5) under the trade name of Hypalon. They contain pendant chlorine and sulfonyl chloride groups and vary in consistency from soft and elastomeric to hard and plastic. The chemical structure may be represented by



Typical ratio a::b::c = 31:1:108

Although the base resin is usually polyethylene, other base resins, ie, polypropylene (6), ethylene propylene copolymers (7), and polymers containing additional functionality (ie, vinyl acetate, acrylic or methacrylic acid, and maleic anhydride graft) have been chlorinated and chlorosulfonated commercially. This family of polymers is widely used in rubber and adhesive industries because of the valuable properties that can be achieved when properly compounded and vulcanized.

Chlorosulfonated olefin polymers may be prepared in polymer melts (8), as slurries in a nonsolvent medium (9,10), or in a fluidized bed (11), but are usually prepared by the interaction of ethylene polymers or copolymers with

chlorosulfonating agents in a homogeneous solution. Substitution of chlorine atoms onto the polymer chains interrupts the regularity of the chain structure so that the crystalline polymer becomes semiplastic to elastomeric and eventually hard and brittle as the substitution level increases. Introduction of the sulfonyl chloride group provides a cross-linking site for vulcanization with conventional rubber technology. These polymers are known for advantages in combined heat and oil resistance compared with most other synthetic elastomers. They also offer good mechanical toughness and are superior in color retention, weatherability, flame resistance, abrasion resistance, and resistance to corrosive chemicals. In addition, it can be made to adhere well to metal and most fabric reinforcements. Chlorination of the polymer, to sufficient levels, also provides for solubility in common solvents, and the sulfonyl chloride group or other functionality offers unique advantages in specific adhesion to various substrates. This combination provides for tough, abrasion-, chemical-, and oil-resistant coatings and adhesives. The properties of these polymers vary widely with the selection of the base resin, chlorine and sulfonyl chloride content, or other functionality.

Olefin polymers containing only pendent chlorine groups may also be prepared using this procedure. The properties are very similar to those of CSMs in appearance and properties; however, the lack of sulfonyl chloride group makes them more difficult to cure and less flexible in compounding techniques.

Polymer Properties

Polyethylene. Chlorosulfonated polyethylene is one of a few examples of a class of polymers, which is formed by chemical substitution on the backbone chain of a preformed polymer. In addition, starting from one specific polyethylene, a whole new series of polymers result, whose properties depend on the degree and randomness of chlorine substitution. So, it is not surprising that the properties of the modified polymer also depend, to a large extent, on those of the precursor olefin resin.

Polyethylene is a saturated hydrocarbon and shows, in general, properties expected for high molecular weight paraffin. As such, it exhibits very low chemical reactivity at low temperatures, but impurities, such as residual catalyst fragments, may cause oxidative or free-radical attack, particularly at elevated temperatures. Oxidative attack is prevented by the addition of small amounts of antioxidants, ie, hindered phenol or alkyl phosphites. An excess of these residual antioxidants may inhibit the chlorosulfonation reaction. The structure and morphological aspects of polyethylene are tied to the synthesis technology. A large variety of synthesis processes are used in polyethylene manufacture, including high pressure polymerization in supercritical ethylene (known as “free-radical” or “high pressure” process) and solution-, slurry-, or gas-phase polymerization using Ziegler-type catalysts (known as “low pressure” or “linear” process) (12). Control of the properties is achieved by controlling molecular weight, molecular weight distribution, and density. This is accomplished by choice of catalyst, reactor configuration, and temperature profile. These structural properties are then carried over into those of the resulting chlorosulfonated polymer, since neither chain scission nor cross-linking

takes place during the chlorosulfonation process. Molecular weight and molecular weight distribution of the polymer chains then have great influence on mechanical and rheological properties of the polyethylene resin as well as the modified polymer. The average molecular weights of commercial polyethylenes may vary from about 500 for polyethylene waxes to $>10^6$ for ultrahigh molecular weight polyethylene grades.

The presence, shape, and length of side branches as well as the distribution of branches along the molecular chain also significantly modify physical properties of solid polyethylene polymers and their melts.

Depending on the catalyst system and polymerization conditions employed, a wide variation in the degree and type of chain branch is observed. In high pressure, free-radical polymerization (low density polyethylene, LDPE), these branches may be linear or branched and may vary in length from 1 to 8 (short-chain branching) or up to several thousand carbon atoms (long-chain branching). The broad molecular weight distribution in these polymers is mostly because of the varying length of chain branches. In low pressure, catalytic polymerization, polymer chains are essentially absent of branching and are termed as linear or high density polyethylene (HDPE) (13).

Alternatively, significant short-chain branching may be introduced deliberately by copolymerization of ethylene with α-olefins, ie, butene, hexene, octene, etc. Branching is controlled by the type of catalyst, α-olefin type, and composition. Metalathene polymerization catalysts give a more select distribution of branching than Ziegler catalysts. (13) These polymers are called linear low density polyethylene (LLDPE).

According to ASTM D1248, polyethylene resins are divided into various classifications based on properties. Two of the most easily measured characteristics of polyethylene are melt index and density. The density determines the type of resin and melt index determines the category. However, the shape of molecular weight distribution curve has an important bearing on the properties of both the polyethylene and the resultant chlorinated polymer. The molecular weight distribution is usually referred to as the polydispersity index or weight to number-average molecular weight ratio. Polyethylene resins are generally categorized as narrow, intermediate, or broad based on these indices, but the distribution may also be bimodal and/or skewed toward the high or low portions of the distribution curve (13). The shape function of the distribution curve may be determined by several methods; however, it is most easily determined by gel-permeation chromatography (gpc). Polydispersity index can be readily calculated from gpc data, but is also indicated by the melt flow ratio (MFR), which is the ratio of two melt indexes determined at different melt pressures. The range of MFR may vary from 25 to 150 for commercial polyethylene resins. Another term often used to describe molecular weight distribution is *stress exponent*, which is defined as the slope of the melt flow ratio curve over a specified range.

Because of its exceptional symmetry, the polyethylene molecule fits so readily into a crystalline lattice, in spite of its lack of molar cohesion, that its tendency is to crystallize into spherulite structures on relaxation rather than revert to a disordered state. However, the degree and type of chain branching that interrupts the geometrical regularity of the polyethylene molecular structure causes a local

reluctance to form crystallites so that both crystalline and amorphous regions may be present. The density of the polyethylene is a function of the degree of crystallinity. For HDPE, this crystallinity reaches levels of about 80%. The crystallinity of LLDPE is usually below 40–45% (13). So, the size, structures, and level of the crystallites for a given polymer depend on the degree, type, and uniformity of branching.

In order to convert these crystalline polymers into elastomers it is necessary to eliminate most of these areas of crystallinity. This may be accomplished by increasing the concentration of α-olefin comonomer as in the case of ethylene–propylene elastomers; however, these polymers are similar to polyethylene in chemical properties.

Chlorosulfonated Polyethylene. The process of modifying polyethylene with randomly spaced chlorine atoms represents a change in entropy conditions. Although adding chlorine to the polymer chain greatly increases its polarity and thus its molar cohesion, the increase in bulk, because of its large volume, prevents temporary chain alignment by external tension, thus reducing the entropy factor. As chlorine attachments to the chain are made, the adjacent chain segments, not held in place by crystallites, begin to exhibit rapid local Brownian motions, typical of molecules in the liquid state as may be seen in the polyethylene melt. This rapid internal Brownian movement, together with the slow external Brownian movement, or movement of entire polymer chains, due to high molecular weight, creates the captive liquid or rubbery state.

Incorporation of chlorine atoms onto the polyolefin backbone then causes sufficient molecular irregularity to break up crystalline chain segments of the base resin. As the chlorine content is increased, the crystallites gradually disappear and, eventually, the thermoplastic material becomes amorphous and behaves as an elastomer because of the inherent flexibility of the polyethylene chain. Chlorosulfonated polyethylene resins made in slurry or fluidized beds generally have a more blocky chlorine distribution, both intramolecularly and intermolecularly, so that the same degree of amorphous characteristic is not always achieved. The increase in molar cohesion, by the addition of chlorine atoms, increases the polymer solubility parameter, and thus decreases its miscibility with paraffinic and aromatic oils. So, as chlorine content of the polymer increases, resistance to swelling effect of oil increases.

The added pendant chlorine groups create intermolecular friction, due to their polar nature, binding chains together, particularly at high substitution levels, in a rigid network, reducing free volume, increasing short-range entanglement, and thereby increasing the brittle point. The glass-transition temperature (T_g), which is closely related to the brittle point, is then a function of the chlorine content ranging from -35 to -40°C at about 15–20% chlorine to $>80^\circ$C at chlorine levels above 65%. The low chlorine polymers retain some of the polyethylene crystallinity and thus yield products that are thermoplastic. At the higher chlorine substitution extremes polymer properties are achieved, which may be generally associated with relatively high temperature rigid plastic material. In between these extremes range a whole series of materials with intermediate properties, which depend on the level of chlorination and the randomness of the chlorine placement along the chain. In the range of 25–35 % chlorine, there is a series of polymers along a more random chlorination line, whose transition

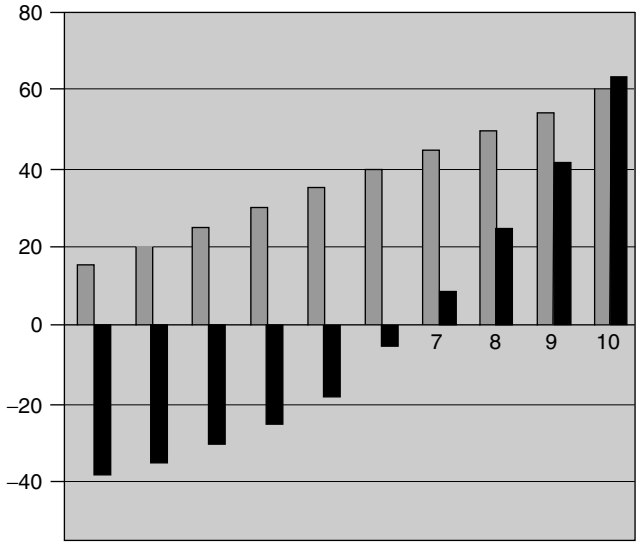

Fig. 1. Chlorine content vs T_g for CSM with random chlorine substitution. ▒ Chlorine %; ■ T_g, °C.

temperature occurs in the range of −20 to −30°C. Glass-transition temperatures in this range represent materials that behave like elastomers. The glass-transition temperature of a chlorinated polyethylene polymer may be estimated by considering that it is a copolymer of ethylene and vinyl chloride. It then follows the relationship (14)

$$T_g = \Sigma M_i T_{gi}$$

where M_i is the mole fraction of the ith component, T_g the glass-transition temperature of the copolymer in Kelvin, and T_{gi} the glass-transition temperature of the homopolymer of the ith component, ie,

$$T_g = M_1 T_{g1} + M_2 T_{g2}$$

where T_{g1} is the glass-transition temperature of polyethylene (−80°C), M_1 the mole fraction of ethylene, T_{g2} the glass-transition temperature of poly(vinyl chloride) (75°C), and M_2 the mole fraction of poly(vinyl chloride).

At higher chlorine levels, where vicinal chlorine groups may occur, one may also include a term for poly(vinylidine chloride) (T_g = 226°C). The relationship of glass-transition temperature to chlorine content for a CSM with random chlorine substitution is shown in Figure 1.

The optimum chlorine content for an amorphous elastomer is the minimum amount required to destroy the crystalline segments. This optimum level depends on the number and types of crystallites in the polyethylene precursor, the randomness of chlorine distribution along the chain, and chain-to-chain distribution. So, for HDPE, the optimum chlorine level for elastomeric properties is at about 35%

with even distribution along the chain. For low density base resin, the optimum chlorine level is about 28–30%.

The flow behavior of CSM polymers under manufacturing and finished product processing conditions is of primary practical importance in their commercial acceptance. These properties are functions of the starting polyethylene parameters and the chlorine content and distribution. For molten polymers and for elastomers, viscosities differ with deformation conditions, and elastic effects accompany the flow properties. Hence, both polymer melts and elastomers are generally viscoelastic and greatly influenced by polymer chain lengths and by the distribution of chain lengths within the whole polymer. Melt index, as described earlier, is a low average shear viscosity measurement (avg. shear rate $= 4\ s^{-1}$) measured at 190°C. It serves the polyethylene industry as an imperical measure of processing control parameters. It is not a fundamental quantity, however, and its meaning is often ambiguous, but its measurement is convenient and well entrenched in the industry as a prediction of processing characteristics. Although it is considered to be mostly responsive to the weight-average molecular weight of the polyethylene, in most cases it is not because it is measured in the non-Newtonian region of the flow curve. The shape and slope of the curve in this region are strongly effected by the molecular weight distribution and this effect can be overriding.

For the same reason of convenience and low cost, Mooney viscosity (avg. shear rate $= 1.6\ s^{-1}$), usually measured at 100°C, is an imperical control for the rubber industry. It, too, is not a fundamental quantity and is usually measured in the non-Newtonian part of the flow curve.

The Mooney viscosity of CSM is also related to the weight-average molecular weight of the starting polyethylene and the chlorine content. However, differences in molecular weight distribution, and especially in the shape function of the distribution curve, become an even more important factor in determining the final chlorosulfonated polymer bulk viscosity and shear sensitivity.

Quantitizing the effect of these parameters is difficult because of the many different possibilities in the shape function of the base resin molecular weight distribution curve. When the distribution curve is monomodal and log normal, the breadth of the molecular weight distribution is a function of the slope of a line formed by measurement of melt flow at increasing load or shear rate. Extrapolation of this slope defines a shear rate for measuring a base resin viscosity, which correlates with Mooney viscosity of the chlorinated product.

Although both base resin and chlorinated product viscosities are related to molecular weight, a higher shear rate is needed in the latter case to account for the lower measuring temperature for Mooney viscosity. Substitution of chlorine atoms onto the polymer chain increases polymer bulk and polarity, resulting in greater chain entanglement and resistance of chains to flow past one another causing viscosity increase at a predictable rate. Using these parameters, ie, extrapolated melt viscosity and chlorine content, one can predict the final product Mooney viscosity assuming log normal distribution and random chlorination (15).

$$\eta_\gamma = 3.5 + 1.06(0.56 \ln 86 + 2.66 \ln f)/f$$

$$M_v = \eta_\gamma[(-1.7 + 5.9(\%Cl)]$$

where η_γ is the polyethylene viscosity at a shear rate which corrects for measuring temperature differences between Mooney viscosity and melt index of polyethylene under standard conditions, f is the slope of melt index vs shear rate, and M_v the Mooney viscosity of the chlorinated product at 100°C.

A more general approach for a polydisperse case uses an adaptation of a model relating molecular weight distribution of the polyethylene to shear dependence. This method concerns the relationship of elastic properties of polyethylene melts to molecular weight. It postulates that bulk viscosity η_γ is a function of a specific molecular weight average $M_w{}^*$ in the same manner that zero shear viscosity is a function of weight-average molecular weight (16).

$$\eta_\gamma = K(M_w^*)_a \quad \text{when} \quad \eta_0 = K(M_w)_a$$

Where K and a are empirical constants depending on the nature of the polymer and temperature. Then,

$$M_W^* = \sum_{i=0}^{i=c-1} W_i M_I + M_c \sum_{i=c}^{\infty}$$

where W_i is the weight fraction associated with molecular weight M_i and M_c is the critical molecular weight associated with the largest polymer molecule undergoing Newtonian flow at γ, and therefore must be determined for each shear rate of interest.

For CSM, at a given chlorine content, the relationship of molecular weight to viscosity is

$$\text{Log}\,\eta(\gamma) = -13{,}8615 + 3.4\text{Log}\,M_w$$

where $\eta(\gamma)$ is the bulk viscosity of CSM at 100°C in kPa's and $M_w{}^*$ is the molecular weight average of the polyethylene used to manufacture the CSM.

To convert $\eta(\gamma)$ to CSM Mooney viscosity ($\gamma = 1.6\ s^{-1}$), $\eta(\gamma) = 1.2894 \times$ Mooney viscosity.

As expected, the viscosity of the polymer increases with increasing molecular weight. The effect diminishes, however, until a critical molecular weight is reached where chains become so long that they fail to undergo complete relaxation at a given shear rate and the additive effect on viscosity becomes negligible. Polymer chains longer than the critical molecular weight influence the whole polymer viscosity as though they were of critical molecular weight. And chain entanglements become unimportant to flow behavior if molecular weight $> M_c$. Thus, as chain length, and the weight-average molecular weight, increases in the distribution curve, its contribution to viscosity is increased until the critical molecular weight is reached. Beyond that point chains contribute to viscosity as though they were at the critical molecular weight. This gives added weight to contributions of low molecular weight fractions as confirmed by experience. This relationship gives added flexibility to design of chlorosulfonated polymers for specific application without viscosity penalties.

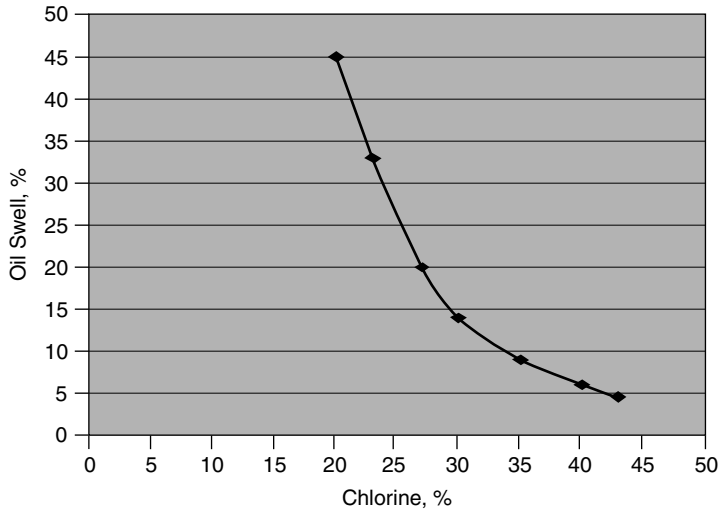

Fig. 2. General relationships of oil swell and chlorine content on a cured linear-based CSM.

To further interpret the results, the distribution curve may be divided into three segments, ie, low, medium, and high, and a polydispersity index, M_w/M_n, calculated for each segment (17).

$$M_w = \Sigma H_i M_i / \Sigma H_i \quad \text{and} \quad M_n = \Sigma H_i / \Sigma H_i M_i$$

where H is the height of the segment and M is the mass.

This model has, in fact, been found to give the most comprehensive relationship between polyethylene composition and Mooney viscosity of the resultant CSM polymer. CSM polymers are generally categorized on the basis of base resin type, ie, LDPE, HDPE, LLDPE or functionalized polyolefin, chlorine content, and Mooney viscosity.

The chlorine atoms on the polymer backbone not only provide elastomeric properties but also give useful improvement in chemical and mechanical properties. The chlorine atoms attached to the chain form centers of high cohesive energy, which prevents infusion of oil, oxygen, acids etc from reaching the main chain. Thus, oil, chemical, flame, and weather resistance improves with increasing chlorine level. Conversely, heat resistance, low temperature flexibility, and electrical resistance become poorer. When the chlorine atoms are more evenly spaced along the chain, they are more effective and, thus, more efficient. Therefore, a CSM with a homogeneous chlorine distribution would be expected to have better resistance to low temperature brittleness and oil resistance than one with blocky distribution, all other conditions being equal. Figure 2 shows the general relationships of oil swell and chlorine content on a cured linear-based CSM, made under homogeneous chlorinating conditions.

Table 1 shows a description of commercial CSM polymers produced by DuPont Dow Elastomers under the trade name of Hypalon Acsium and Hypalon CP. Toya Soda of Japan also offers similar but not all grades.

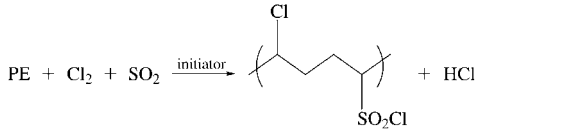
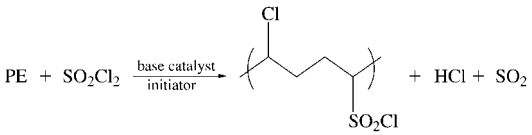
Preparation

Chlorosulfonated polyolefins are prepared by interaction of the base resin with chlorine and either sulfur dioxide (18) or sulfuryl chloride in the presence of a radical initiator (19). Sulfuryl chloride may be used alone as a chlorosulfonating agent, but must be accompanied by a catalytic amount of pyridine or other organic base. It has been proposed that the function of the organic base is to catalyze decomposition of the sulfuryl chloride molecule to form SO_2 and Cl_2. However, the chlorosulfonation rate with base-catalyzed sulfuryl chloride is 5–10 times faster than that with gaseous chlorine and sulfur dioxide. So it is possible that the mechanism is more complex. In the latter case, the ratio of sulfonyl chloride to chlorine substituted onto the polymer backbone is, to some extent, a function of the amount of organic base added. The reaction temperature (lower reaction temperatures that result in higher sulfur utilities) also affects it (19).





The chlorination reaction and the chlorosulfonation reaction are usually carried out simultaneously in homogeneous solution, but may be carried out in stages; that is, the resin may be partially chlorinated with elemental chlorine and then chlorosulfonated to the desired composition with a chlorosulfonating agent (20).

Many solvents have been used in laboratory preparations of CSM, eg, chloroform, chlorobenzene, trichloroethane, tetrachloroethane (21), trichlorofluoromethane, fluorobenzene (22), and carbon tetrachloride. Mixed solvents, ie, chlorobenzene and carbon tetrachloride, have also been used to achieve certain desired properties such as low temperature flexibility (23).

For practical applications, the solvent used in the reaction must dissolve the base resin and the final product, be inert to chlorination, and easily be separated from the finished product without polymer degradation. The degree of compatibility of the solvent with the base resin and the various stages of finished product may also substantially affect the chlorine distribution and thus the physical and mechanical properties of the final product.

When a highly compatible solvent is used, the solvent surrounds each segment with an "envelope" of solvating molecules, which prevents contact with other segments and other chains. The individual chain is then in a relatively elongated condition, and the solvent can flow freely around the various chain parts. When the chlorinating agent is dissolved in the solvent, equal exposure of all chains and chain segments to molecular chlorine attack is afforded and therefore a more selective chlorine distribution along the chain and between chains results.

In a solvent with poor compatibility, the chains are irregularly folded into tight coils, and considerable amounts of solvent can be immobilized by the entangled segments of the polymer. At a concentration where chains would still be separate and discrete in a good solvent, they would have associated into networks of relatively large size in a poorer solvent. These shapes and dimensions hinder attack of chlorine in hidden segments and chains, leading to a more blocky distribution of chlorine atoms substituted along the chain and among the polymer chains. In addition, as the polymer concentration is increased, chain-to-chain bridging takes place much more readily in the tightly coiled chains so that the bridged chains respond as though they are much higher in molecular weight. The rate of increase in viscosity with concentration is then distinctly greater in a poorer solvent. The higher viscosity causes the formation of larger gas bubbles during chlorine gas addition and interferes with the mass transfer of chlorine from the bubble to the main body of solution. Under this condition, a higher concentration of chlorine at the bubble interface causes overchlorination of polymer chains in that area compared to the remainder of the reaction mass. Thus, optimum conditions for a homogeneous chlorine distribution are low solution viscosity, good mixing, high reaction temperature, and a reaction solvent most compatible with the polymer.

The effect of solvent compatibility on chlorine distribution may be illustrated by comparison of reaction in fluorobenzene, an excellent solvent for both polyethylene and the chlorinated product, and in carbon tetrachloride, a poorer

solvent. Blocky chlorine distribution may be shown by comparison of ΔH values; infrared absorption at 715 and 730 cm^{-1} and by nmr determination of γ, or greater protons. Chlorinated polymers prepared in fluorobenzene show about 1/3 as many γ, or greater hydrogens as those prepared in carbon tetrachloride under the same reaction conditions, indicating more selective distribution in the former case.

In commercial solution processes, carbon tetrachloride has been the solvent of choice, in spite of its solvency limitations. It is desirable because it easily dissolves the polyolefin reactants as well as the chlorosulfonated finished product. It is also stable under reaction conditions; it is inert to chlorination and its boiling point is low enough to facilitate isolation of the polymer from solvent by evaporation at temperatures low enough to prevent decomposition of the chlorosulfonated product. In addition, it has always been readily available and reasonably priced. However, because carbon tetrachloride is toxic and a suspected carcinogen and because it is postulated that it can take part in reactions that deplete atmospheric ozone, it has been the subject of increasingly stringent controls. Consequently, the use of carbon tetrachloride on a large scale has become increasingly undesirable for both safety and environmental reasons. Its continued use requires that careful and stringent containment is maintained (24). Trichloroethane or fluorobenzene have been suggested as safe and environmentally friendly alternatives (24), but have higher boiling points, thus difficult to remove from the polymer and not completely unreactive to chlorine. Chloroform, because of its very low ozone depletion potential, is considered environmentally acceptable, but it is toxic and a suspected carcinogen and it undergoes some chlorination to carbon tetrachloride under reaction conditions. Therefore, it too requires restricted containment.

Commercial processes consist of dissolving the base resin, usually polyethylene, at a temperature above its Vicat softening point, in a glass-lined, stirred kettle, fitted with an agitator and at least one condenser. For HDPE, the dissolving temperature is at least 98°C, but dissolution rate increases with temperature. The chlorosulfonating agents together with a free-radical initiator, usually 2,2′-azobisisobutyronitrile, are added continuously during reaction. The heat of reaction, 54–145 J/g (13–35 cal/g), depending on reactants used, is removed from the reaction mass by condensing the solvent vapors and returning the cooled reflux liquid to the reaction mass. The temperature of the cooled reflux may affect composition control as it affects the solubility of sulfur dioxide, ie, lower reflux temperatures and/or reaction temperatures, at a given reaction pressure, favor higher sulfonyl chloride incorporation.

When the desired chemical composition is reached, as determined by infrared analysis, the by-product HCl and unreacted SO_2 are removed by sparging with an inert gas, ie, nitrogen, decreasing reactor pressure to atmospheric, pulling a vacuum on the system, or combinations of these. Adding a small amount of an aromatic epoxy resin then stabilizes the product. This resin reacts with residual HCl remaining in the degassed solution as well as that, which may be formed upon product storage. It also functions to prevent oxidative decomposition of the sulfonyl chloride group during storage.

The usual method for removing the solvent from the cement is by means of steam-heated drum dryers, wherein a heated solution of the polymer is introduced into the nip of rotary drum dryers and solvent is removed by evaporation. As the solvent evaporates at the drum surface, a thin film of polymer is deposited, which continues to dry as the drum rotates. The dried film is doctored from the drum surface with a knife blade; gathered into a rope and cut into small chips. It is then dusted with talc, to prevent massing, and then packaged.

Processing of Chlorosulfonated Polyethylene

As with most other elastomers, unvulcanized CSM is unsuitable for all but a few applications. In order to make useful materials having the desired processing characteristics, ultimate finished product properties, or cost control, it is usually necessary to incorporate several compounding ingredients to improve their mechanical and chemical behavior. These include vulcanizing agents, accelerators, accelerator activators, specific retarders, age resisters, processing aids, reinforcing pigments, inert fillers, coloring dyes and pigments, and other special-purpose materials, ie, blowing agents, abrasives, etc.

After the compounds have been properly mixed and shaped into blanks for molding, or calendered, extruded, or fabricated into a composite item, they must be vulcanized by one of many processes. During this vulcanization process, the polymer chains are cross-linked into three-dimensional structures, transforming the soft, weak, plastic-like material into a strong elastic product.

In most elastomers the reactive site for cross-linking is carbon–carbon double bonds either in the backbone of the polymer chain or, as in the case of EPDM elastomers, on the side chains. Vulcanization of these polymers usually involves reacting sulfur or sulfur compounds with the double bond at elevated temperatures to form sulfide or polysulfide cross-links. Metal oxides, ie, zinc oxide and organic sulfur bearing accelerators (ie, thiuram polysulfides), are added to speed up the curing process. For CSM, the major cross-linking site is the sulfonyl chloride group, which offers a variety of cross-linking reactions. The most commonly used cross-linking systems for CSM may be grouped into four general classes: sulfur donor, ionic, organic (Maleimide), and peroxide. Although they may be fundamentally different, these systems may also be viewed as the extreme end points of a broad band of possible cure recipes. Consequently, practical curing systems may incorporate various combinations of different types of vulcanizing agents offering a synergistic effect in optimizing desired properties of a given final product for a specific application.

CSM cure chemistry usually involves a cross-linking agent, an activator, an accelerator, and often an activator/retarder for processing safety. Acid acceptors must also be added to neutralize the by-products HCl and SO_2, which may evolve in the vulcanizing environment. The acid acceptors may also be involved in forming a part of the cross-linking mechanism.

The cure system most widely employed for CSM is based on sulfur and its derivatives, sometimes referred to as the sulfur or sulfur donor cure. Unlike

elastomers, ie, natural rubber, which contains unsaturation, CSM may not be cured with elemental sulfur alone, or with sulfur and a metal oxide, eg, lead oxide or magnesium oxide, even at extended cure times. However, several sulfur bearing organic compounds, eg, dipentamethylene thiuram hexasulfide ("Tetrone A"), thiuram disulfide ("Thiuram M" or "Methyl tuads"), and tetramethylthiuram disulfide ("TMTD"), have been found to give low level CSM cures when used alone. When combined with PbO or MgO, high states of cure may be achieved. Addition of finely divided elemental sulfur further enhances the state of cure. Lead compounds have become increasingly restricted in rubber stocks because of health hazards. Hydrotalcite (magnesium aluminum hydroxy carbonate) has no serious health issues and has been found to perform in the same manner as PbO in CSM compounds by trapping chlorides (25). Its use has been accepted by most of the rubber industry.

Incorporation of elemental sulfur, activated by metal oxide, into the curing recipe allows further polysulfidic cross-links through the small amount of unsaturation formed by SO_2 decomposition to further enhance the cross-link density. Benzothiazyl disulfide (MBTS) is often added in practical sulfur recipes. It functions as a retarder–activator, ie, it improves processing safety (scorch) while increasing cross-link density. The mechanism probably involves assisting in the decomposition of the polysulfide at a controlled rate. When optimum heat resistance is desired, nickel dibutyl dithiocarbamate (NBC) is often added. This material does not act as an antioxidant, which is normally added to compounds for heat aging resistance. Several mechanisms have been proposed for its effectiveness but it probably reacts with any residual sulfonyl chloride group, which survives curing conditions, causing their elimination and the formation of a stable alkyl chloride in the polymer chain. This reaction prevents further cross-linking during heat aging from the polymer radical and oxygen, which eventually causes brittleness.

The Maleimide cure of CSM is also widely used particularly when low compression set is needed along with good heat resistance. It can also give tight cures with flexible cross-links, which are important for dynamic applications. The fact that it can give heat resistance equivalent to the best mixed oxide (MgO + PbO) cures without the use of lead, and that it can be used in light colored applications has added substantially to its importance. The major disadvantage is the sensitivity of uncured compounds to moisture, causing poor bin stability. Water opens the Maleimide ring, which voids its use in the cross-links. Mixing in additional Maleimide may reactivate a stock, containing Maleimide, which has been exposed to moisture for an extended time and, therefore, rendered inactive.

The Maleimide cure system is similar to the sulfur donor system in that it involves the decomposition of the sulfonyl chloride cure site. In this case, however, the Maleimide (meta-toluene-bis-maleimide, HVA-1 or meta-phenylene-bis-maleimide, HVA-2) rather than sulfur, is involved in the cross-links, and there is no evidence of a metal ionic bond. The reaction is usually initiated with an amine involving either an amine-catalyzed decomposition of the sulfonyl chloride group or a path of radical anions. The most recently developed initiators, which have been found to give a balanced combination of

excellent processing safety and cross-link density, are a butyraldehyde/aniline condensation product (known as "Antox" special or "Vanax" AT) and *N*,*N*′-diphenylpropylene diamine (GFI), all secondary amines. These amines are antioxidants and therefore readily oxidized, which makes them less stable, particularly at elevated temperatures and in the presence of the sulfonyl chloride group (a strong oxidizing agent) and leads to decomposition. In completing the cross-linking reaction, the polymer radical, thus formed, interacts with the Maleimide.

Since SO_2 is released quantitatively in this cross-linking reaction, it is necessary to include an SO_2 absorbing ingredient in the compound. For this reason calcium hydroxide is usually added. Other SO_2 absorbers, eg, 1,3-bis (hydroxymethyl) urea, which are not too volatile, may be used as well.

Peroxide cures are used in cross-linking CSM as well as many other elastomeric and nonelastomeric polymers. It is used in CSM when very low compression set is needed along with excellent heat aging and oil resistance. Its disadvantages include limited amount and types of plasticizers, requirement of high amounts of acid acceptors, and high cure temperatures.

Hydrogen chloride, evolved at curing temperatures, inhibits the cross-linking reaction. Therefore, sufficient quantities of an acid acceptor must be added to the recipe to neutralize the HCl. Magnesium oxide is the most effective acid acceptor because it does not react with the sulfonyl chloride group to cause scorch, but its miscibility with the CSM polymer is poor. Therefore, relatively large amounts are required for an efficient cure. This increases the cost and the compound viscosity, which is already high due to the absence of plasticizer. Addition of a small amount of pentaerythratol complexes with the MgO greatly improves its solubility in the polymer mass and therefore significantly reduces the amount of MgO required.

Peroxide cures are usually temperature specific, and higher than normal curing temperatures are usually required to achieve adequate properties. Addition of a small amount of a co-agent, triallyl cyanurate or HVA-2, helps to activate the cure by forming a complex with the peroxide.

Typical vulcanizable compounds will, in addition to the curatives, contain certain plasticizers, fillers, processing aids, pigments, etc.

CSM does not crystallize upon elongation, but some reinforcement is developed through polar and hydrogen bonding effects. Thus, vulcanizates containing no filler may still develop significant tensile strength upon extension. Additional reinforcement may be achieved with certain carbon blacks and silicates. Surface reinforcing furnace blacks give the best balance of properties and are widely used as general-purpose fillers. Weathering of CSM with as little as three parts of carbon black is outstanding. Mineral fillers may be used to take advantage of CSM's nondiscoloring characteristics. Among mineral fillers, finely divided calcium carbonate gives the best heat resistance, and the best electrical properties and water resistance is obtained with calcined clay. Titanium dioxide may be used when white or pigmented end products are desired. The color of CSM products containing titanium dioxide does not fade. Flammability performance is improved by the addition of hydrated silica and alumina Table 2.

The linear low density based CSM polymers have excellent dynamic properties over a broad temperature range. The pendent alkyl groups on the linear

backbone reduce the crystallinity of the base resin and allow rubbery products at lower chlorine levels than linear-based polymers. High strength polymer products are produced with the heat and oil resistance near those of linear-based CSM, but with low hysteresis, high resilience, high complex modulus, low damping, and good flexibility at low temperatures. When properly compounded and cured, these resins produce tan δ values of 0.06–0.13 at 100°C, dynamic ratio (E′/tan δ) of 50–70, and a brittleness temperature of −75°C. Gehman T50 values are −30 to −40°C (26).

Economic Aspects

Production of chlorosulfonated polymers has declined somewhat in recent years because of the increased competition from polymers with similar properties.

Annual worldwide production of all products is now about 40,000 tons. The primary producer, with about 85% of world capacity, is DuPont Dow Elastomers, Inc., a joint venture of E.I. du Pont de Nemours & Co. Inc. and The Dow Chemical Co., with a single plant in the United States. The remaining capacity is provided by Toyo Soda Manufacturing Limited, with one plant in Japan. DuPont Dow Elastomers products are sold worldwide under the trade names of Hypalon, Acsium, and Hypalon CP. Products similar to several grades of Hypalon products are made by Toya Soda and sold under the trade names of CSM-CP and CSM-Ts. The material cost variability is related mostly to the petroleum costs. Prices generally range from $3 to $6 per kilogram.

Health and Safety Factors

Hypalon, Acsium, and Hypalon CP grades contain small amounts of carbon tetrachloride residue, normally <0.2%, and traces of chloroform. These chemicals are toxic and carcinogenic and carry time-weighted average exposure limits of 5 ppm. They are both regulated under the Occupational Safety and Health Act as air contaminants. These contaminants diffuse from the product at measurable rates if the product is not massed. So it is advisable to provide adequate ventilation to keep concentrations at safe levels. Toya Soda chlorosulfonated products, CSM-CP and CSM-Ts, may contain up to 0.5% trichloroethane and small amounts of tetrachloroethane. Both products contain <1% epoxy resin as stabilizer. These resins are regulated at <1% level in some European countries. Significant amounts of sulfur dioxide and hydrogen chloride as well as traces of carbon oxy sulfide (COS) may be evolved during compounding in internal mixers.

Disposal of Hypalon, Acsium, Hypalon CP, CSM- CP and CSM-Ts grades should be in an approved landfill. Incineration is not recommended because of the possible evolution of toxic gases. Additional information is available from DuPont Dow Elastomers concerning these or other potential hazards when handling Hypalon products.

Uses

CSM products are classed as specialty elastomers but enjoy use in a broad spectrum of industrial, automotive, construction, coatings and miscellaneous applications. The applications for CSM depend only in part to its combination of oil resistance and heat resistance. CSM is much more resistant to corrosive or oxidizing chemicals, including ozone, than are CR or nitrile rubbers. It is tougher than silicone and EPDM rubbers. It has good electrical insulation properties, which are not as good as EPDM but better than many other elastomers. CSM also has excellent radiation resistance needed in nuclear power applications and is also color-stable and highly weather-resistant. Good flame resistance is obtained with high chlorine grades of CSM. Chlorinated plasticizers, brominated resins, and antimony trioxide synergists are commonly used as additives. Mineral fillers,

excluding carbonates are preferred and hydrated alumna is frequently used when smoke suppression is important.

In industrial hose, CSM is particularly useful because of its combination of heat, oil, and chemical resistance and its outstanding ozone and weather resistance. It is also preferred because of the frequent need for stable bright colors. Hypalon 4085 and Hypalon 610 are often used in these applications because their high compound Mooney viscosity prevents hose collapse or "flat spotting" during curing.

In the electrical industry, CSM may be used as a protective jacketing or sheathing over elastomers having superior insulation resistance but poor weatherability. It also finds considerable usage as an integral insulator for up to 600 V. This combination of insulation resistance plus the long-term ozone resistance makes it useful for high quality applications. In these cases, the lower viscosities of LD999 and Hypalon 40 are preferred for faster and smoother extrusions.

In the automotive industry, Hypalon 40 grades are used for fuel hose, power steering hose, brake hose covers, vacuum tubing, and spark plug wire covers and boots. The new Acsium grades are finding use in high performance timing belts and accessory drive belts and in brake hose covers (26). Low permeability to moisture and refrigerants make high chlorine grades qualify for air conditioning hose and tubes. Chlorinated and chlorosulfonated maleic anhydride grafted polypropylene is used as a primer for polypropylene bumpers.

Low chlorine CSM grades, based on linear polyethylene, eg, Hypalon 45, have sufficient crystallinity to produce adequate tensile strength and elongation for uncured applications. They are generally compounded with white or light-colored pigments and calendered into film for use as unsupported membranes. Tensile strength of these sheets range from 9 to 12 MPa and Graves tear strength of the order of 50–60 kN/m. These types are also used as binders for magnetic door strips and signs because of its ability to accept very high loading and specific adhesion to magnetic metal powders, as well as its excellent weatherability.

Hypalon CP grades are similar to CSM but have additional functionality, ie, esters, acids, or maleic anhydride grafts, which set them apart for specific applications. They add value as modifiers for adhesives, coatings, and inks because of their low solution viscosity and increased solubility and compatibility. Hypalon CP 826 promotes adhesion to polypropylene and finds use as a primer coating for automobile bumpers.

A variety of miscellaneous end uses take advantages of CMS's oil resistance, colorability, and weather and ozone resistance. Grades based on LDPE find use in numerous coating applications such as awnings, gas hose, escalator handrails, and rubber boats. CSMs are also used for curb pump hose, mining cable jackets, and appliance wire jackets. Grades based on ethylene vinyl acetate polymers are used for traffic paints and marine paint.

ETHYLENE POLYMERS, HDPE

Introduction

Polyethylene (PE) is the most widely used plastic throughout the world, and high density PE (HDPE) is the most widely used type of PE. HDPE has generally been taken to mean the product of ethylene polymerization having density greater than about 0.935 (or 0.94). It includes ethylene homopolymers and also copolymers of ethylene and alpha-olefins such as 1-butene, 1-hexene, 1-octene, or 4-methyl-1-pentene. Other types of PE include low density PE (LDPE), made through a free-radical process, and linear low density PE (LLDPE).

An analysis of commercial usage of the world's major plastic types is shown in Table 1. In terms of amount consumed, PE dominates the other types. Table 2 lists the U.S. usage of the various types of PE. In comparison to the other types of PE, HDPE is by far the most versatile. HDPE consumption in the United States accounted for about 6.95 billion kilograms per year in 1999, or almost half of total U.S. production of all PE types. Figure 1 shows how the demand for HDPE in the United States has developed historically since its invention in 1951.

History of PE

Early Work. The history of HDPE (and polyolefins in general) actually began in the 1890s with the synthesis of "polymethylene" from the decomposition of diazomethane. Between 1897 and 1938, numerous reports of such polymers appeared in the literature (1–6). Catalysts such as unglazed china, amorphous boron, and boric acid esters were used for the decomposition. The empirical formula of such products was found to be CH_2. Later reproductions of work (3,6) established

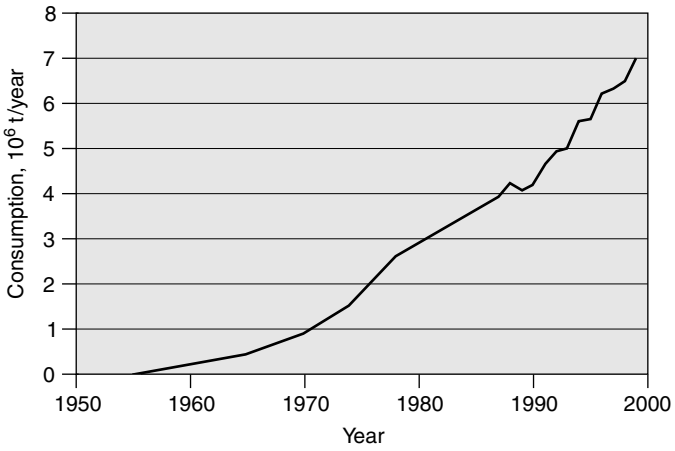

Fig. 1. HDPE consumption in the United States.

that the polymethylene thus obtained was a high molecular weight linear polymer having a melting point of 134–137°C and a density of 0.964–0.970 g/cm^3 (7). Thus, it can be stated that although no commercial use was initially made of it, HDPE was discovered long before the well-known LDPE was introduced (8,9).

In another early approach Pichler (10) and Pichler and Buffleb (11) described during 1938–1940 the preparation of high molecular weight (M_n = 23,000) polymers from the hydrogenation of carbon monoxide over ruthenium and cobalt

catalysts. The reported melting point of 132–134°C and density of 0.980 g/cm^3 indicate again that linear HDPE was obtained.

Free-Radical Process. The first commercial PE was developed by Imperial Chemical Industries from 1932 to 1938 using a free-radical process (12). Ethylene was polymerized at high pressure (142 MPa or 1400 atm) and at about 180°C. It was discovered by accident that oxygen impurity could serve as the initiator. An ICI British patent filed in 1936 (13) disclosed pressures of ca 50–300 MPa (500–3000 atm), temperatures of 100–300°C, the necessity of removing heat to control temperature, and the necessity of controlling the oxygen content of the ethylene used.

The PE produced at this time had a melting point of 115°C and a density of 0.91–0.92 g/cm^3. In 1940, Fox and Martin (14) found by infrared analysis that there were more methyl groups in the polymer than could be accounted for by the end groups of a linear chain. Thus the importance of chain branching was recognized, and subsequent studies of branching led to a better understanding of its effect on mechanical properties and polymer morphology. This material is called low density PE (LDPE) and is still in high commercial demand today. Further work on the free-radical process extended the pressure. Larcher and Pease (15) disclosed PE with densities of 0.95–0.97 g/cm^3, melting points above 127°C, and branching of less than one side chain per 200 carbon atoms.

Transition-Metal Catalysts. Today's "low pressure" catalytic processes, from which HDPE now comes, were discovered in the early 1950s. The term "low pressure" refers to operating pressures of generally 1.4–6.9 MPa (200–1000 psig), in contrast to the ICI free-radical process. Patent applications were filed by Standard Oil of Indiana (16), in 1951, by Phillips Petroleum (17) in early 1953, and by Ziegler and co-workers (18) in late 1953.

The Standard Oil patent (16) describes a supported reduced molybdenum oxide or cobalt molybdate on alumina, with the ethylene preferably contacting the catalyst in an aromatic solvent to affect the polymerization. Operating temperatures of 100–270°C were disclosed and the molecular weight could be varied from very high to low such as those of greases.

At about the same time (1951) it was discovered that supported chromium oxide catalysts would also polymerize ethylene at low pressures to produce high molecular weight polymers (17). Reaction temperatures were in the range of 60–190°C. Polymer characteristics, particularly, molecular weight and molecular weight distribution, could be varied by reactor temperature, pressure, and activation temperature of the "Phillips catalyst."

Shortly thereafter, yet another transition-metal catalyst (Ziegler catalyst) capable of polymerizing ethylene at low pressure was discovered in Germany (18). This approach used a transitional metal halide, or other complex, activated by an aluminum alkyl cocatalyst. Transition-metal compounds of Groups IVa through VIa (Ti preferred) were claimed.

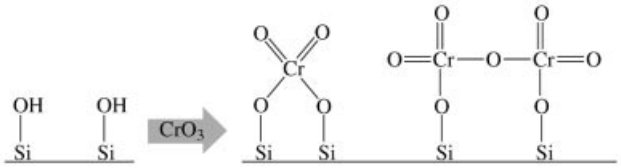
Although the Standard Oil discovery came first, commercialization was slow (19,20). Three plants were eventually built between 1961 and 1971, but the process had poor economics and was soon scrapped. In contrast, the Phillips and Ziegler discoveries were both commercialized rapidly and still exist today in more advanced forms. At Phillips, the first plants were brought on stream in 1955 and 1956. However, Phillips management concluded that no one manufacturer could

develop the full market potential of the Phillips HDPE and therefore decided to license the process. By 1956, nine companies in seven countries became licensees (21–24). Ziegler also began to license his patent, following the discovery that good activity could be obtained by use of titanium halides in combination with aluminum alkyls. However, the patent included only catalyst knowledge, and each licensee had to develop a process. The first Ziegler plant was brought on stream in late 1956 by Hoechst. A second one was built in 1957 by Hercules. By 1960 U.S. production of HDPE via the Phillips process had reached over 91,000 t annually, while 32,000 t came from the Ziegler process.

Today HDPE is still made almost entirely through chromium or Ziegler systems. The two systems produce different types of polymer, which is useful for different applications. The Phillips catalyst generally produces broader molecular weight distributions than that of typical Ziegler catalysts.

Catalysts Used for HDPE Production

Chromium Catalysts. The Phillips chromium catalyst, which perhaps accounts for about half of the total HDPE production, is usually made by impregnating a chromium compound onto a porous, high surface area oxide carrier, such as silica, and then calcining it in dry air at 500–900°C (25). This latter activation step converts the chromium into a hexavalent surface chromate, or perhaps dichromate, ester. Because each Cr atom is individually attached to the surface, the support is not inert but exerts a strong influence on the polymerization behavior of the site.



The first step in the development of polymerization activity occurs when these hexavalent surface species are then reduced by ethylene in the reactor to a lower valent active precursor, probably Cr(II) (25–28). Because Cr(VI) is tetrahedrally coordinated, and the reduced species can be octahedral, the resultant expansion of the coordination sphere creates a high level of coordinative unsaturation which plays a role in the polymerization mechanism. Thus, the reduced species chemisorbs olefin readily. However, this same trait makes the catalyst very sensitive to small levels of polar impurities in the feed streams, such as alcohols, water, amines, etc (29,30). Commercial catalysts usually contain about 1.0 wt% Cr, but only a small fraction of this, perhaps 10–20% or even less, is actually active for polymerization (25,27,30).

The second step in the development of polymerization activity is an alkylation reaction in which the first chain begins growing on the reduced chromium species. Exactly how this reaction occurs has been unclear. Several possibilities have been suggested over the years, but no clear answer has yet been established (25,31–35). Recent studies suggest that initial adsorption of olefin on Cr(II) sites may cause an oxidation to an alkylated Cr(IV) site as the active polymerization

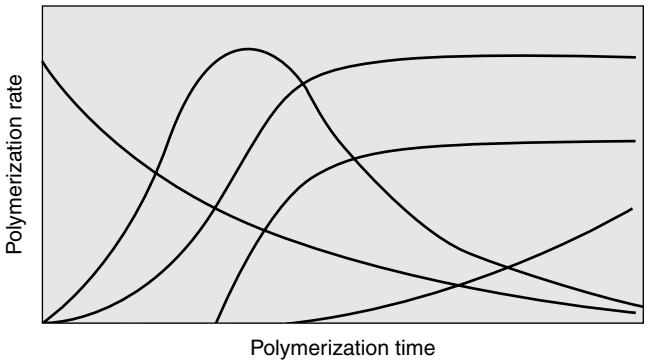


Fig. 2. Kinetic profiles of Cr-based catalysts.

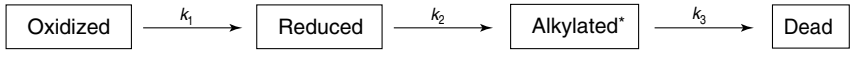

$$[C^*] = k_1 k_2 \left[\frac{e^{-k_1 t}}{(k_2 - k_1)(k_3 - k_1)} + \frac{e^{-k_2 t}}{(k_1 - k_2)(k_3 - k_2)} - \frac{e^{-k_3 t}}{(k_1 - k_3)(k_2 - k_3)} \right]$$

species (34,35). These two initial steps, reduction followed by alkylation, cause the catalyst to display an induction time. That is, the onset of polymerization occurs gradually after a delay which can last from a few minutes to over an hour depending on reaction conditions (25,27).

Alternatively, the reduction step can also be accomplished before the catalyst contacts ethylene in the reactor, by exposure to carbon monoxide at 350°C (25,27). In this case the reduced species has definitely been identified as Cr(II) (28,36–40). This catalyst behaves much like its Cr(VI)/silica parent when introduced into the reactor, producing similar polymer at similar activity in most cases. However, the onset of polymerization often occurs more rapidly when the catalyst is prereduced, since one step is omitted (25,27).

Once the polymerization reaction has developed, a decay in activity can also sometimes be observed because of a chemical instability of the active species. Thus, the kinetic profile of the polymerization reaction can be defined as a series of three consecutive reactions: (*1*) reduction, (*2*) alkylation, and (*3*) decay. Each step in the series has its own dependency on ethylene concentration, temperature, and catalyst composition. Figure 2 shows some typical kinetic profiles that are often obtained and that can be produced by varying the individual rate constants of the three steps (41).

Metal alkyl cocatalysts, such as alkyl boron, aluminum, zinc, lithium, etc, can also be added to the reactor as a way of enhancing the activity of the catalyst. Such agents act by accelerating the reduction step, by alkylating the chromium, or by scavenging minor amounts of poisons such as water and oxygen. These agents are sometimes used commercially for specific resin types, although they are not essential and in most cases are not used (41,42).

In another, less common, variation of the catalyst, lower valent organochromium compounds can be deposited onto an already calcined support to produce very active catalysts (43–51). These compounds react with surface hydroxyls to become attached to the support, often losing one or more ligands. Examples

include bisarene Cr(0), allyl Cr(II), and Cr(III), beta-stabilized alkyls of Cr(II) and Cr(IV), and biscyclopentadienyl Cr(II). The latter example has been used commercially to great extent. Such catalysts often develop activity more rapidly than the chromium oxide catalysts, being already reduced and in some cases already alkylated. The remaining organic ligands can also change the polymer obtained in certain ways.

The most common support used commercially is silica and silica–titania. However, silica–alumina, alumina, and aluminophosphates can also be used (52,53). Adding titania to the recipe enhances activity and broadens the molecular weight distribution not because the titanium itself is active, but because it influences the chromium (54). It is believed that some chromium sites become attached to the titania, which thus indirectly influences the polymerization reaction through electronic effects. Likewise, adding alumina, magnesia, boria, and other oxides have unique effects. Aluminum phosphate is particularly interesting in that it is isoelectronic and isostructural with silica, but of course the surface chemistry is quite different, containing such diverse groups as P—OH, P=O, and Al—OH (41,52,53,55). Thus, changing the support can be a way of varying polymer characteristics.

Ziegler Catalysts. Titanium chloride based Ziegler catalysts are also widely used throughout the HDPE industry. These catalysts generally produce a narrower molecular weight distribution than that obtained from chromium oxide catalysts. Figure 3 shows this typical distinction. Because of this, the Ziegler catalysts are often used for different applications compared to chromium oxide.

While chromium oxide species may vary considerably in their local environment because of the heterogeneous nature of an amorphous oxide carrier, Ziegler species are often thought to be more uniform, occupying certain places in a microcrystalline environment (56–58). Frequently, donor compounds, such as ethers,

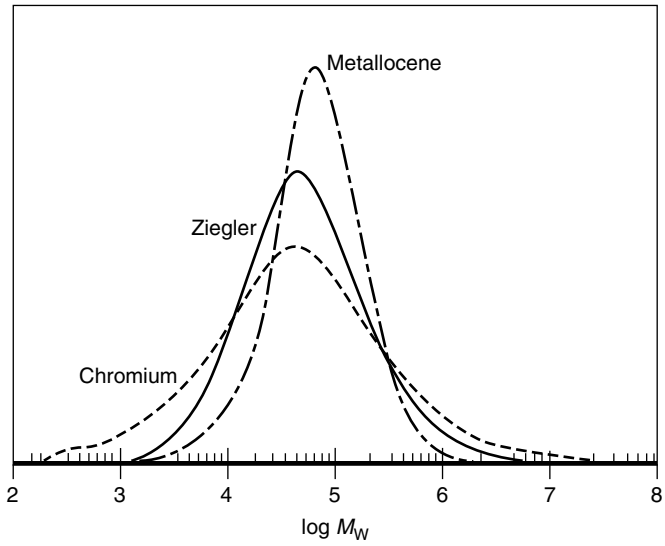

Fig. 3. Molecular weight distribution (gpc curves) of resins derived from metallocene, Ziegler, and chromium oxide based catalysts.

esters, and silane alkoxides, are added to neutralize or modify certain undesirable sites (59).

The early commercial Ziegler catalysts were based on titanium(III) chloride, often ball milled or otherwise treated to provide higher surface area. In about 1968, Hoechst introduced the so called high activity Ziegler catalysts, in which the titanium was dispersed in a magnesium chloride lattice, into which it fitted nicely (60–62). In this way the polymer yield per titanium atom was increased by 10-fold or more.

The transition-metal compound, usually a titanium(III) or titanium(IV) chloride, is transformed into the active catalytic species upon reaction with an aluminum alkyl cocatalyst. During this reaction the active metal becomes alkylated, and ethylene is inserted into the metal–alkyl bond. Often the active site is considered to be a bridging complex between the transition metal and the alkyl aluminum compound, in which one or two ligands are shared between the two metals.

In some cases, broadening has been achieved by using vanadium, zirconium, or other metal halides in the recipe, either alone or in combination with titanium (63–65). In other cases, broadening has been achieved by providing two distinctly different chemical environments for the titanium (66), or in the process by passing the Ziegler catalyst through two or more reaction zones (67).

Metallocenes and Other Single-Site Catalysts. One type of Ziegler catalyst, based on cyclopentadienyl titanium or zirconium halides (which provided only marginal activity using aluminum alkyls as cocatalysts) received an extreme enhancement in activity in the mid-1970s with the discovery of methylaluminoxane (MAO) cocatalyst (68,69). Unlike traditional aluminum alkyl cocatalysts, MAO is far more capable of ionizing the transitional metal compound (57,70–73).

$$Cp_2ZrCl_2 + CH_3Al^{2-} \longrightarrow Cp_2ZrCH_3Cl \longrightarrow Cp_2ZrCH_3{}^{+}MAO{-}Cl^{-}$$

Since that time other ionizing agents have also been developed, which are capable of activating these “metallocene” compounds (74,75).

Metallocene catalysts differ from the traditional catalysts in that the site is derived from a singular molecular species with defined ligands, unlike the heterogeneous character of chromium or Ziegler species. This accounts for the ultranarrow molecular weight distribution of the polymer obtained (see Fig. 3). Although usually described as single-site catalysts, it is nevertheless clear on closer inspection that many of these catalysts do not entirely fit the description because the ionization agent is still part of the active site. MAO, the partial hydrolysis product of trimethylaluminum, is also capable of providing a complex and varied site environment.

Metallocene catalysts are at present just entering the market in certain specialty applications, accounting for perhaps less than 1% of all HDPE sales. However, the greater degree of control offered by metallocenes, and the ability to combine different metallocenes into one catalyst, offers the ability for the first time to truly tailor polymer architecture. Thus, it seems likely that future advancements in single-site chemistry will have a profound impact on the HDPE market. The influence of metallocenes on the LLDPE market has been somewhat greater to date (see LLDPE). This has been mostly due to their ability to evenly distribute branching over the molecular weight distribution. The result has been improved film performance over traditional Ziegler systems.

Within the past 5 years, other types of new organo transitional metal compounds have also been reported, which can be activated by ionizing agents like MAO (76–78). Some of these compounds, such as Brookhart's nickel diimine complex, offer the possibility of producing highly branched ethylene homopolymers that have never before been possible from low pressure systems. Thus, although no commercial polymers are presently made from these systems, it seems likely that these new catalyst developments will have a strong influence on the future direction of HDPE markets.

Polymerization Mechanism and Reactor Control

Molecular Weight and Molecular Weight Distribution. Once an active site has been formed, through reduction and alkylation of chromium oxide species, and once polymerization has been initiated, two reactions—propagation and termination (or chain transfer)—occur simultaneously and competitively. These catalysts are not "living" systems, in which the polymer chain grows indefinitely. Rather, the length of the chain formed is determined by the rate of propagation relative to the rate of termination. On average in a commercial process, the lifetime of a chain on an active site is typically a small fraction of a second, say 0.1 s or less. Since the lifetime of the catalyst in the reactor is usually 1–2 h, this means that each site produces many chains before being discharged from the reactor.

For active chromium species on the Phillips catalyst, the rates of propagation and termination are thought to be characteristic of the local geometry and ligand field surrounding each site on the heterogeneous silica surface. Thus, different sites tend to produce polymers of different average molecular weight, and the overall molecular weight distribution of the polymer reflects the site heterogeneity of the catalyst. This connection allows the molecular weight distribution to be controlled by varying the composition and heat history of the catalyst.

The Schultz–Flory distribution has usually been considered as the simplest model for representing the molecular weight distribution expected from a polymerization catalyst (79). It assumes that each site is identical and that the probability of termination is not dependent on the length of the growing chain. Thus if the probability of propagation is considered to be p, and of termination to be $(1-p)$, then the probability of producing a chain n units long would simply be $F(n) = p^n(1-p)$. This distribution produces a breadth of molecular weight distribution, or polydispersity (weight average/number average), of 2.0. In reality, typical chromium catalysts produce much broader molecular weight distributions, with polydispersity values of 4–20. This is taken as an indication of multiple site environments on these catalysts. Indeed this is also evident by the fact that the molecular weight changes (increases) as the activity develops with time. Those sites which come on stream first produce the lowest molecular weight. Some metallocene and other single-site catalysts, however, do approach the narrow theoretical Schultz–Flory distribution of 2.0.

The propagation step, usually first order in ethylene concentration (80), is thought to occur through the insertion of coordinated ethylene into the metal–alkyl bond (56–58). Termination, or chain transfer, can occur through several different mechanisms. Two of the most common reactions are shown in Figure 4

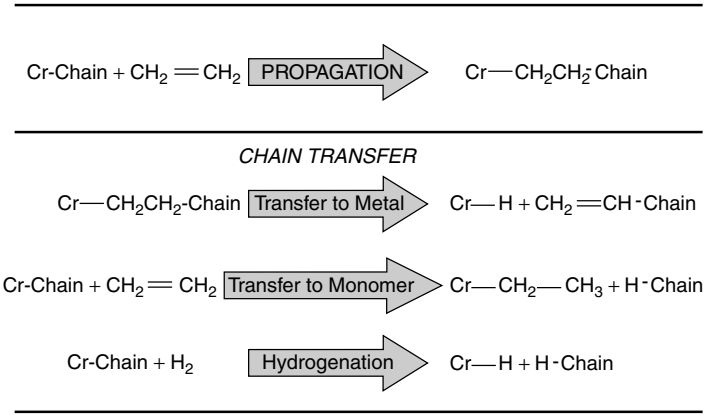

Fig. 4. Steps of polymerization.

as beta-H elimination (*1*) to monomer and (*2*) to the metal. Both reactions leave a vinyl group on one end of the chain and a methyl on the other. In the former case, the transfer step is dependent on ethylene concentration, while in the latter case it is not. On many Ziegler and metallocene catalysts the primary transfer mechanism is to monomer, so that the molecular weight is unrelated to ethylene concentration (since both propagation and transfer are first order in ethylene). However, on chromium oxide catalysts transfer to metal also becomes significant, and this fact is used to control product molecular weight during commercial manufacture. When ethylene concentration in the reactor is increased, the molecular weight also increases (25).

Hydrogen can also be added to the reactor to control molecular weight for most catalyst systems. When deuterium is used in place of hydrogen, the prominent chain end-group $-CH_2D$ is observed (27). Metallocene and Ziegler catalysts are more sensitive to hydrogen than most chromium oxide systems. In the latter case, adding hydrogen to the reactor also tends to narrow the molecular weight distribution, because the high molecular weight producing sites seem to be most sensitive. Metal alkyls can also sometimes terminate chains through alkyl exchange. Aluminum, zinc, and boron alkyls have been reported to do this for some catalyst systems. For chromium oxide catalysts there are indications that boron alkyls are particularly potent and the process may even be catalytic (81). Again, some sites seem to be more affected than others, which can be used to produce special polymer effects (82).

Fracturing. On silica supported catalysts, such as the Phillips chromium oxide system and some Ziegler catalysts, the active sites are attached to the internal surface of pore walls. Within a minute or so after polymerization begins, these pores become clogged with polymer. At this point, the silica particle begins to fracture into perhaps a billion smaller fragments because of the internal pressure created by polymer generation (25,83,84). This fracturing process only occurs on certain high porosity (and thus friable) silicas which are specially prepared for use as polymerization catalyst supports. Otherwise, fracturing does not take place and the catalyst has little or no activity. These fragments, which may be as small as 0.1 μm, then become engulfed in polymer, and unless the polymer is made in a

solution process, these subparticles are loosely held together by entwined polymer into a larger polymer particle which replicates the shape of the original catalyst particle. Each ton of catalyst produces some 2000–10,000 tons of polymer (or more) before being discharged from the reactor. Each catalyst particle thus produces a polymer particle of about the same shape, but many thousands of times its own mass. The catalyst is left in the polymer as a minor impurity.

Polymer Structure

General Structure. Commercial HDPE is a predominantly linear polymer with the chemical composition roughly of polymethylene, $(CH_2)_n$. Its name reflects the principal method of production: ethylene polymerization by transition-metal catalysts. At least one end group of each chain contains a methyl group, and depending on the method of manufacture, the other end group is also a methyl or a vinyl group. Some general properties are shown in Table 3.

The weight-average molecular weight (M_w) of typical commercial HDPE grades can vary from 20,000 to over 1,000,000, depending on the application. The molecular weight distribution of commercial HDPE polymers can range from very narrow, for metallocene derived polymers, to very broad, for grades made from chromium oxide catalysts. A convenient measure of the molecular weight breadth is the polydispersity, or the ratio of the weight-average molecular weight to the number-average molecular weight (M_w/M_n). Experimentally, the molecular weight distribution is measured by gel-permeation chromatography (gpc).

Short-Chain Branching. Although described as high density, commercial HDPE can actually vary in density from 0.975 down to 0.935. HDPE contains a crystalline phase and an amorphous phase, and the measured density directly reflects the percentage of each. Typical homopolymer is normally about 94% crystalline and has a density of 0.960–0.965. Higher densities can be achieved by low molecular weight and slow cooling.

Crystallinity is disrupted, and density therefore lowered, if branching is added to the otherwise linear polymer backbone. This is typically accomplished by copolymerizing alpha-olefins in small amounts with the ethylene. 1-Butene, 1-hexene, 1-octene, and 4-methyl-1-pentene are the comonomers most commonly used commercially, producing respectively ethyl, butyl, hexyl, and isobutyl branches. On a weight basis, comonomer is usually added in an amount less than 5% of the total composition. Figure 5 shows the relationship between density and comonomer content.

Rheology and Long-Chain Branching. Molten HDPE is a non-Newtonian fluid at temperatures of 140–200°C. Its effective viscosity is reduced sharply, up to several thousand times, when the melt-flow speed is increased. The viscosity of the polymer is also a function of its molecular weight. Non-Newtonian behavior of the melt at low shear rates allows correlation of melt viscosity with molecular weight. The reason for this behavior is disentanglement of polymer coils at high shear rate and their partial orientation in the flow direction.

By convention, the most convenient and generally accepted representation of melt viscosity is the "melt index", which is the amount of polymer flowing through a standard capillary viscosimeter at 190°C under a 2.16-kg load for 10 min (ASTM

Table 3. Properties of Three Typical Commercial HDPE Grades

Method D1238 condition 190/2). The melt index is inversely connected with molecular weight.

In addition to the so called short-chain branches (ethyl, butyl, hexyl, etc from copolymerization of alpha-olefins), many HDPE grades also contain a very small

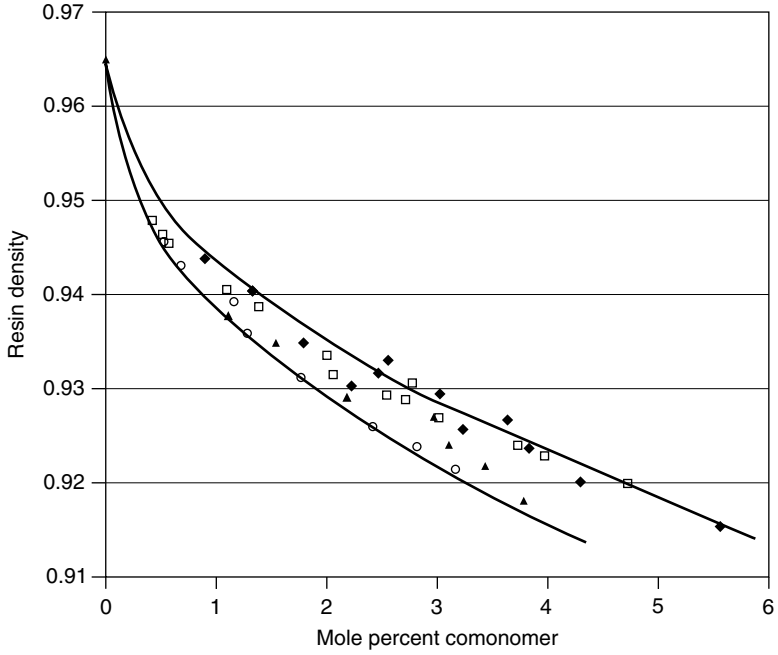

Fig. 5. Resin density vs comonomer content. ◆ 1-Butene; □ 1-hexene; ▲ 1-octene; and ○ 4-methyl pentene.

amount (perhaps less than 1 branch per 10,000 carbons) of long-chain branches. These branches are defined as being long enough to affect the rheology of the polymer, that is longer than about 130 carbons (85).

The viscosity of HDPE melt is strongly temperature dependent and can be described by an exponential dependence similar to the Arrhenius equation. The activation energy of the viscous flow of HDPE melt is usually 25–30 kJ/mol, but it increases with increasing long-chain branching (LCB) up to 40 kJ/mol, or even higher. This is one main method of determining the extent of LCB in a particular resin. Another method is to compare the measured (extrapolated) zero-shear viscosity to a value expected from a linear polymer of the same molecular weight.

Although LCB occurs infrequently in commercial HDPE, it has a profound effect when it does occur on the polymer flow behavior. Control of LCB is therefore critical in the manufacture of HDPE grades because it affects the suitability of the resin for film, blow molding, sheet, injection molding, and many other applications. Some applications require the presence of LCB, whereas in other applications it is a detriment (86,87). For example, LCB causes orientation in film, decreased die swell in blow molding, and greater melt strength in sheet, geomembranes, and blow molding. However, it also usually has a negative effect on environmental stress-crack resistance (ESCR), when compared at molecular weights to yield equivalent processing.

Long-chain branching in HDPE grades is thought to have its origin in the copolymerization of vinyl end groups. Upon termination of a chain, chromium oxide catalysts typically leave one vinyl group on one end of that chain, which can then be copolymerized into another growing chain, as shown in Figure 6 (25,88). This fact would explain why most Ziegler resins, which contain few vinyl end groups, also exhibit little LCB. The details of how this happens in a slurry process, where polymer chains crystallize out as solids as they are formed, are still debated. One thought is that chains are frozen out of solution almost instantaneously as they are formed so that reincorporation of vinyl end groups would most likely occur on a neighboring (and not the original) site as the tail of the incorporated chain is still mobile. This would explain why the degree of LCB can be controlled on a chromium oxide catalyst, by varying the chromium–chromium separation distance (ie, the chromium loading). Figure 7 shows how the activation energy of the polymer, which reflects the degree of LCB, is affected by chromium loading on the catalyst.

Other origins of LCB have also been identified. It has been observed that at the typically high molecular weight used in extrusion grade resins, LCB content is

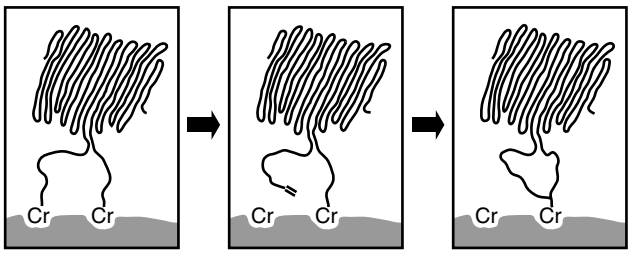

Fig. 6. Long-chain branch formation through reincorporation of vinyl end groups.

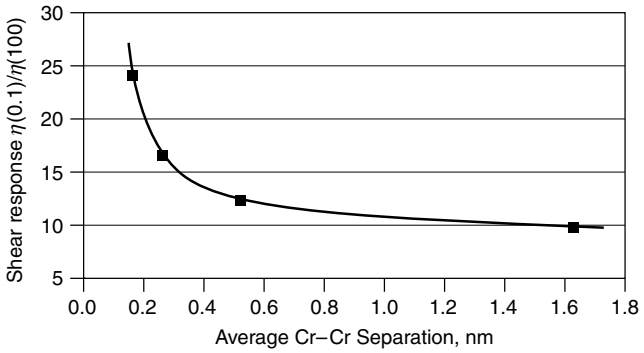

Fig. 7. Dependence of long-chain branching (as measured by shear response) on chromium loading.

highly dependent on the pore volume of the catalyst, even when the chromium site density is held constant. The effect is also seen in some silica-supported Ziegler resins of high molecular weight. When the porosity of the silica catalyst base is very low, high levels of LCB are seen in the resin. The exact reason for this behavior is unknown. One possible explanation is that long polymer chains entangled in small catalyst pores (where they were formed) of catalyst fragments resist melt flow much like true LCB, provided the relaxation time of these "knots" is longer than the relaxation time permitted by the molding process.

More recently, extreme LCB-like behavior has also been observed from certain metallocene-derived polymers (89,90). Reincorporation of vinyl end groups is again a possible method of origin. However, if true, it is hard to explain why some metallocenes are so much more potent than others at creating LCB, and why solution polymers or solution catalysts exhibit similar LCB levels to that of samples made in slurry mode. Direct activation of polymer C—H bonds by some catalysts has also been proposed as another avenue to the formation of LCB (91). "Chain walking" is known to happen on nickel-based catalysts (92) although it is unknown whether this also happens on zirconium-based systems. Recently, still another potential mechanism of LCB formation has also been advanced in this laboratory, although not proven. It is suggested that on some catalysts two alkyl chains may be simultaneously associated with one site through a bridging aluminum. If true, one chain terminated through beta-H elimination could be easily incorporated into the other on the same site as LCB (M.P. McDaniel and M.D. Jensen, Results from Phillips Petroleum Company Research Department).

Morphology. The only stable local chain conformation of HDPE at low temperature is the flat zigzag chain configuration with C—C bond length of 0.154 nm, and C—C—C bond angle of 112° (93). This local chain conformation also prevails in the melt and solution. The principal crystalline form of linear PE is orthorhombic, like the linear paraffins, with theoretical density of 1.00 g/cm^3. A second crystalline form is pseudomonoclinic with theoretical density of 0.965 g/cm^3. The former is typical of most articles made of HDPE, while the latter forms during low temperature stretching and orientation of films, and is thus always present in HDPE film. It is stable only below 50°C; annealing at 80–100°C restores the orthorhombic form.

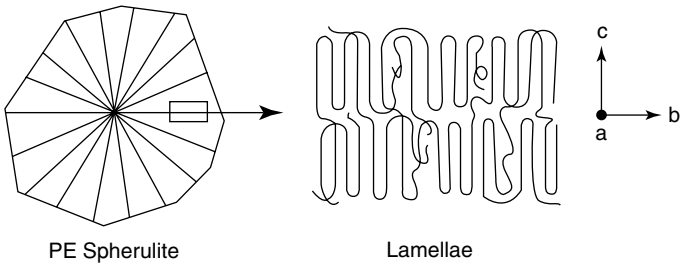

Fig. 8. Structure of HDPE spherulite.

The principal morphological units of PE crystallizing under typical conditions from the melt are spherulites, very small anisotropic spheres (ca 1–5 μm) visible under high magnification with polarizers (Fig. 8). The spherulites form as a result of a complex crystallization process of macromolecules. Their structural subunits are "rays," thin rod-like fibrils spreading in all directions from the center to the periphery and frequently branching, thus filling the spherulite body. The fibrils consist of lamellae (crystallites). Spherulites are characteristic only where HDPE crystallized slowly from the melt. In rapid crystallization, intertwined lamellae or rod-like structures are formed (94). During crystallization, polymer chains fold many times. When HDPE is crystallized from solution, this folding is tight, but when crystallized from the melt, the chain packing organization is much looser (95).

HDPE crystallizes very rapidly. Articles such as films, filaments, pipes, and injection-molded articles exhibit some degree of molecular and crystal orientation. This orientation develops either spontaneously during melt flow and crystallization, or is introduced deliberately by stretching. The degree of orientation can be measured by x-ray, polarization spectroscopy, acoustical methods, or birefringence.

When films or filaments are stretched uniaxially below the melting point, the *c*-axis of the crystals is always oriented parallel to the stretching direction, as is typical for all semicrystalline polymers. The degree of orientation increases with the stretching ratio and can approach 100% (96). A similar orientation is developed during the crystallization of a strongly oriented PE melt, such as during capillary melt flow or solid-state extrusion. Under these conditions, both crystalline and amorphous phases are nearly perfectly oriented in the flow direction (97). When a polymer melt is slightly stretched at the outset of crystallization, a condition typical in the production of blow-molded parts, the resulting solid films exhibit a significant orientation of the *a*-axis of the crystal in the machine direction (98).

Polymer Properties

Mechanical Properties. Polyethylene properties can be made to vary over a wide range, by controlling the molecular weight, the molecular weight distribution, the degree of branching, the type and placement of branching, the end group moieties, the extent of LCB, and by adding certain fillers, flow enhancers, etc. It is no surprise then that hundreds of different grades of HDPE exist for as many

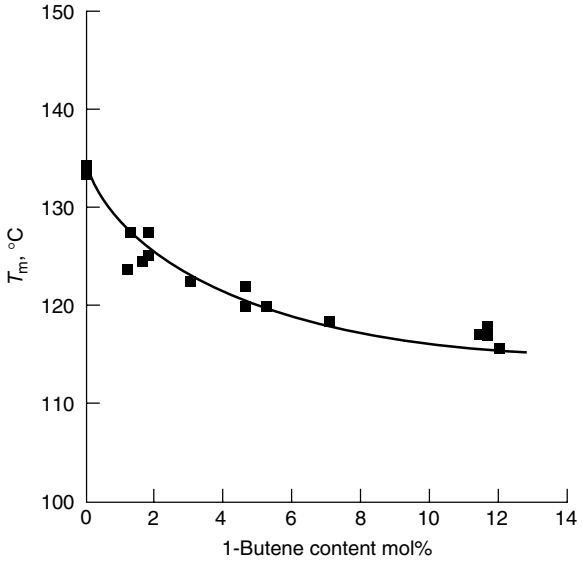

Fig. 9. Melting point of HDPE as a function of 1-butene content.

different applications, each of which require widely different properties. Such important final end-use properties include the stiffness of the polymer, the gloss or clarity, the impact, puncture or tear resistance, chemical resistance, electrical insulation properties, molding characteristics, and tensile properties, to name only a few. Table 3 lists some of the most important polymer properties for three typical commercial HDPE grades.

Measurements of highly crystallized HDPE samples give melting points of 133–138°C. The melting point is a function of both molecular weight and of branch content. In linear PE, the decrease in molecular weight from ca 1,000,000 to 40,000 is accompanied by a decrease in melting point from 137 to 128°C. The change in melting point with branch content is shown in Figure 9.

HDPE is a very good insulator and is therefore widely used for wire and cable encapsulation. Polymer density and molecular weight affect electrical properties very little. HDPE is only slightly permeable to organic compounds, both in liquid and gas phases. Permeability to water and inorganic gases is also low.

Forced elongation of an HDPE sample into a film or rod is accompanied by structural and mechanical changes (Fig. 10) At low deformations (ca 0.5% of sample length), spherulites elongate elastically. Further strain results in a partial break of bridges between crystallites in lamellae, slippage of the lamellae in rays constituting spherulites, ray splitting, and other irreversible mechanical changes. These processes can be regarded as a succession of partial "meltings" of the morphological features of HDPE under mechanical stress.

At some point, called the yield point, these transformations accumulate, causing a significant change in sample appearance. A "neck" develops, which is an area consisting of highly oriented bundles of polymer molecules. With further elongation, the initial morphological structures (spherulites, rays) are disassembled and the growth of the oriented polymer area continues. The primary mechanism

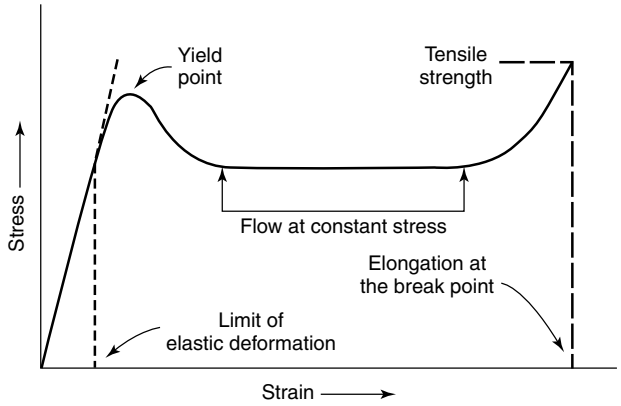

Fig. 10. Idealized stress–strain curve for HDPE.

of this transformation is slippage of lamellae with respect to one another and crystallite reorientation. This process develops in the boundary layer between the unchanged part of the sample and the neck, and continues in the neck, causing further strain. As a result, the sample elongates at nearly constant stress until all material in the samples becomes highly oriented. Subsequently, the oriented structure adsorbs additional small strain at increased stress and finally beaks. This ultimate stress is defined as the tensile strength.

Molecular weight has a large effect on this behavior. Low molecular weight HDPE is brittle and breaks at low strain (ca 10%) without neck development. In the range of 80,000–1,200,000, typical for commercial HDPE, the neck always develops. The yield point of such polymers is nearly constant. However, increasing molecular weight is accompanied by decreasing elongation at the breakpoint, from ca 1200–1500% to 200–300%, and by significant increase in tensile strength, from ca 35–40 MPa (5075–5800 psi) to ca 60 MPa (8700 psi). Finally, HDPE with molecular weight greater than 1,500,000 does not develop a neck but elongates by 200–400%. Tensile strength of such polymers is very high, ca 60–70 MPa (8700–10,150 psi).

Molecular weight also significantly affects impact strength. Low molecular weight samples are brittle, but with increasing molecular weight, impact–stress resistance can become very high.

An increase in branching reduces crystallinity and is accompanied by significant modification of mechanical characteristics. An increase in branching is accompanied by an increase in elongation at breakpoint and a significant drop in tensile strength.

It is generally accepted that the mechanical strength of a polymer sample is determined by the number of intercrystallite links, that is, polymer chains anchored in adjacent crystallites and binding them (Fig. 11). These links are the weakest elements of the polymer structure. Special developments in processing allow a significant increase in the number of the intercrystallite links. The technology employed is either low temperature (ca 100°C) extrusion of solid HDPE at high pressure [ca 200–300 MPa (29,000–43,500 psi)] or continuous casting of film from a dilute solution. Such films are highly stretched (up to 40 times), usually

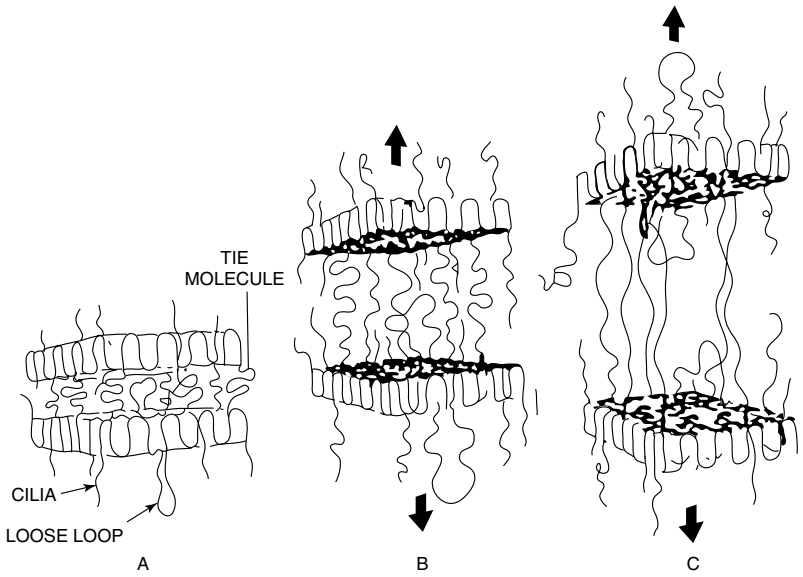

Fig. 11. Role of intercrystallite links in resin failure.

transparent, and almost perfectly oriented in both phases. They exhibit ultrahigh modulus [up to 100 GPa (1.45×10^7 psi)] and very high tensile strength of ca 500–600 MPa (72,500–87,000 psi).

One type of PE that has an increased number of intercrystallite links, and thus improved physical properties, is called bimodal polymer. These polymer grades are usually made of two components—a low molecular weight homopolymer blended with a high molecular weight branched copolymer. In this combination, having branches on the longest chains selectively places these chains in the amorphous phase, which thus increases the probability that they will function as intercrystallite links. Much of PE research today is aimed at producing more efficient methods of manufacturing such bimodal polymers.

Another important property that is influenced by molecular weight, by branching, and by intercrystallite links is load-bearing ability or resistance to creep. This property is of particular importance in applications in which the applied stress is continuous or frequent and represents an appreciable (though not necessarily large) fraction of the tensile strength. Even though the tensile strength of linear PE decreases considerably as density is decreased, the load-bearing ability of the polymer is greatly improved at densities decreasing from 0.960 to 0.950 g/cm^3. Not only is time to failure increased greatly, but deformation is decreased.

Chemical Resistance. Linear PE is predominantly saturated linear hydrocarbon, and thus in general it exhibits low chemical reactivity. High crystallinity and low permeability to most chemicals reduce the reactivity of solid HDPE even further. HDPE is stable to alkaline solutions and solutions of salts, including oxidizing agents such as $KMnO_4$ and $K_2Cr_2O_7$. It does not react with organic acids, HCl, or HF. Concentrated HNO_3 (ca 50%) does nitrate the polymer, even at room temperature.

HDPE is not soluble in any known solvent at room temperature, although several solvents (ie, xylenes) have a swelling effect. However, certain binary solution mixtures including CS_2 dissolve HDPE at as low as 30–40°C. Above 80°C HDPE dissolves in many aliphatic and aromatic hydrocarbons and their halogen-substituted derivatives. Solvents most frequently used include xylenes, tetralin, decalin, o-dichlorobenzene, 1,2,4-trichlorobenzene, and 1,2,4-trimethylbenzene. These solvents are employed for the determination of molecular weights from solution–viscosity data or by gpc.

An important measure of chemical resistance which is often used in household and industrial containers is environmental stress-crack resistance (ESCR). Many variations of the test are known and used, such as ASTM D1693, Conditions A and B. In these tests, the plastic part, a molded bar, a bottle, or a tube, etc, is placed under a standardized stress usually at elevated temperature, and exposed to a surface active agent. For example, one test uses 10% surfactant in aqueous solution at 60°C. The time needed for the sample to break is then recorded. The surfactant is thought to aid in the relaxation and disentanglement of chains.

Degradation. HDPE is relatively stable to heat because of the high bond energy of the single C—C bond. However, above about 290–300°C, chemical processes in an inert medium begin to result in breakage and cross-linking of chains. This reaction is similar to thermocracking of linear hydrocarbons. Near 500°C in an inert atmosphere, HDPE is rapidly pyrolized to a mixture of low molecular weight alkanes, alkenes, and dienes.

Oxygen is quite aggressive toward the C—H bonds of these macromolecules at the usual melt processing temperatures (200–300°C). This type of degradation is also a combination of radical reactions, resulting in a reduction of molecular weight, formation of oxygen-containing groups such as hydroxyl, carbonyl, and low molecular weight by-products such as water, aldehydes, and ketones. The initiation of oxidation can be enhanced by transition-metal impurities in the polymer from catalyst residues. For this reason it is important to achieve high activity from the catalyst, leaving only a few ppm of transition metal in the polymer. The conditions of commercial pelletization and molding favor thermooxidative degradation, and therefore oxygen is preferably excluded if possible. Protection is also nearly always afforded by the addition of an antioxidant package as well, which can include hindered phenols, phosphites, and other specialized agents added in the concentration of 0.01–1.0%.

Exposure of the molded HDPE articles to sunlight and air also attacks the polymer over time, especially at wavelengths less than 400 nm. Photooxidation resembles thermooxidation in that it is a complex chain of radical transformations. Such exterior aging of the polymer results in development of surface cracks, brittleness, changes in color, and a deterioration of mechanical and dielectrical properties. Photooxidation degradation is prevented by small amounts of light stabilizers, such as 2–4% carbon black or, for colorless articles, esters of salicylic acid or derivatives of benzotriazole or benzophone and others in the 0.1–0.5% range.

Chemical reactions of HDPE not involving oxidation include fluorination, chlorination, and sulfonation. Sometimes molded articles, such as fuel tanks, are given such a surface treatment to increase diffusional resistance.

Manufacturing Processes

Many diverse commercial technologies exist for the manufacture of HDPE, developed by many different companies worldwide. However, they can be divided into three fundamental types: (*1*) solution processes, (*2*) slurry processes, and (*3*) gas-phase processes. In recent years, hybrids and combinations of these three basic forms have also been widely used.

Solution Processes. The earliest commercial HDPE plants used a solution process in which the polymer dissolves in a hydrocarbon solvent as it is formed. Cylcohexane was commonly used as solvent at 120–150°C. Initially catalyst productivity was low, but the solution process allowed a filtration or centrifugation step in which catalyst residue could be removed. Later, as catalyst productivity improved, this step could be omitted in some processes. Low molecular weight polymers are made more easily in the solution process because of the lower solution viscosity. Although most of the earlier solution processes have been shut down due to poor economics, more recent improved designs, such as those developed by DuPont, Dow, and others, are still in production today and considered competitive (98–104).

For example, the DuPont process is reported to operate at a temperature in excess of 150°C and a pressure of about 8 MPa (1160 psi). Residence time in the reactor is short, on the order of 5–10 min and polymer concentration relatively high, up to 35% for low molecular weight grades. The sensible heat of the reaction mixture is employed to flash concentrate the solution from which the product is recovered in a devolatilizing extruder. Terminating agents and stabilizers are added in the extruder. Vapor from the flash step is condensed, cooled, and returned to the reactor. Residual hydrocarbon is removed in the extrusion step and purified for recycle to the polymerization.

The advantages of this process are a relatively small reactor and short residence time which allows fast transition between grades and easy control of some polymer properties. Because of the higher reactor temperature, higher alpha-olefins can be more easily used in the solution process than in other processes, and thus ethylene 1-octene copolymers are common from this technology. The longer side chains derived from 1-octene (versus 1-hexene or 1-butene) are thought to improve some resin properties. The solution process is also easily adaptable to multiple reactor schemes in order to tailor the molecular weight distribution.

Further development of the solution polymerization concept has led to molten PE as a medium for ethylene polymerization. Installations typically used for free-radical ethylene polymerization at high pressure are converted to accommodate catalytic ethylene polymerization. Stirred autoclaves operating at 30–200 MPa (4350–29,000 psi) and 170–350°C are convenient (105,106). Residence time is very short, typically less than 1 min.

Slurry Processes. If the hydrocarbon liquid described above is deliberately chosen to be a bad solvent for PE, and the temperature is lowered so that the polymer does not swell or melt in the hydrocarbon, the resultant process is called slurry technology because the polymer is produced as a suspended powder. In slurry systems the hydrocarbon non-solvent is called the diluent. Two major types of slurry systems are widely used throughout the worldwide HDPE industry:

(*1*) light hydrocarbon loop reactor processes and (*2*) heavier hydrocarbon stirred tank reactor processes.

Phillips Petroleum Co. originally developed the loop slurry process in the late 1950s for its chromium oxide catalyst, and Phillips has continued to develop the loop technology up to the present on an ever larger scale. The preferred diluent is isobutane, which was chosen to allow maximum reactor temperature without polymer swelling. This was necessary because the early chromium catalysts tended to produce lower melt index polymer (higher molecular weight) than optimum for the new extrusion market. Higher reaction temperatures permit higher melt index polymer to be produced. Initially, many hydrocarbon diluents were tested, and the degree of polymer swelling caused by each diluent was found to be related to the ratio of CH_3 to total carbons in the hydrocarbon (107). Thus, for example, pentane was inferior to isopentane, and neopentane, which has the highest CH_3/C ratio of any hydrocarbon, permitted the highest reactor temperature without swelling. However, isobutane, which permits a top reactor temperature of 113°C, was considered as a close second and more economical.

The choice of light diluents and high reactor temperatures also means relatively higher operating pressures. Thus a pipe-loop reactor was considered a convenient way to accommodate operating pressures of up to 5.5 MPa (800 psig). The reactor is equipped with an impeller which drives a concentrated slurry of polymer and isobutane rapidly around the jacketed loop at 5–12 m/s. Today's loop reactors can run up to 50% solids (by weight), typically in the temperature range of 80–110°C. Residence time is 0.5–1.5 h and conversion is high per pass (95–98%) (99).

The initial development of a slurry process for Ziegler-based catalysts did not face the same problems as scientists at Phillips. Since Ziegler catalysts are much more sensitive to hydrogen, molecular weight control does not rely on precise control of high reactor temperatures, as it did for the chromium oxide based loop slurry process. Therefore, lower reactor temperatures and heavier hydrocarbons were possible, and there was no need to go beyond a stirred tank. Hoechst developed the first such process, but Montedison, Mitsui, Solvay, and others have also developed similar processes.

In the Hoechst process, for example, hexane is used as the diluent (108,109). Hexane, ethylene, alpha-olefin, catalyst components, and hydrogen are continuously fed into a stirred reactor for polymerization. The slurry is then transferred into a smaller reactor for post-polymerization, after which the total charge is separated by a centrifuge into a liquid stream (which is returned to the initial reactor) and solid polymer. The wet polymer is steam-stripped from the solvent, dried, and pelletized. The stripped hexane is purified and recycled. Although stirred tanks are most common, loops can also be used in this fashion. In some schemes, a portion of the recycle diluent from the centrifuge is returned to the reactor, and a portion is fed to recycle purification for wax removal. This step removes some of the lowest molecular weight polymer, which dissolves in the diluent.

Gas-Phase Processes. Unlike solution or slurry processes, the original gas-phase polymerization processes employed no hydrocarbon diluent. Union Carbide introduced the first gas-phase technology in 1968, and other firms soon developed the approach still further, such as Naphtachimie, British Petroleum, BASF, and Amoco (110–114). In this technology, solid catalysts are used for ethylene polymerization or its copolymerization with light comonomers in the

gas phase. The system can be agitated by mechanical devices, such as horizontal paddles or screws, but more often by a gas stream of ethylene which fluidizes the PE particle bed.

A typical fluidized bed reactor has a length-to-diameter ratio of ca 7 and a disengagement zone at the top. Uniform fluidization is achieved by ethylene flow through a distribution plate at the reactor bottom, and rapid circulation is needed to remove heat. Conversion is about 2% per pass. Unreacted ethylene enters the disengagement zone, separates from the entrained polymer particles, and is filtered, cooled, compressed, and recycled. A catalyst is continuously fed to the reactor without diluent, and polymer particles are continuously removed from the bed through a system of valves. Reactor temperatures of 70–100°C are common, with pressure of 1.4–3.5 MPa (200–500 psig).

Polymerization of ethylene is quite exothermic (3.4×10^6 J/kg) and since the heat capacity of gas is much lower than that of liquid, removal of the heat of polymerization can be problematic compared to solution and slurry processes. This was usually accomplished by lowering the activity of gas-phase catalysts by say 50–75% to reduce the rate of local heat generated. To compensate, the residence time was then extended to several hours. As a result of these differences, gas-phase processes tend to have a much larger polymer inventory in the reactor. The gas-phase approach is also more rigid in its catalyst requirements. The kinetic profile of a catalyst for a gas-phase process should preferably have a steady activity lasting 2–3 h. The particle size for consistent fluidization is also sometimes important, and smaller particles are preferred for heat removal.

The fluidized bed gas-phase process offers some advantages and disadvantages compared to the slurry processes. Since there is no diluent, it makes low density resins well, without swelling. The lack of diluent also simplifies the operations and equipment to some degree. On the other hand, transitions are extremely slow and there is usually a large inventory which can greatly increase the off-specification rate during transitions. Gas-phase units are sometimes also more sensitive to poisons in the feedstocks, and more sensitive to fouling. Once a reactor has "logged," cleanup can be longer and more difficult for a gas-phase reactor.

In recent years the fluidized bed processes have been improved through the addition of liquid hydrocarbons into the polymer bed (115,116). These evaporate, adsorbing heat from the bed more effectively than gas alone, and are then condensed in the recycle stream and reused. The result of this "condensed mode" or "super condensed mode" approach is increased production rates from the same reactor, or greater tolerance for higher activity catalysts. Of course, it reverses some of the benefits of pure gas phase, since it is a step back toward hydrocarbon diluent. Nevertheless, this innovation has greatly improved operations and production of the gas-phase process, instilling new life into the technology.

Bimodal Reactor Technology. In a modification of the original stirred tank slurry process, Hoechst, Nissan, Mitsui, and others developed cascade reactor systems to make bimodal resins with improved properties (67,117,118). Under these processes, multiple reactors are aligned in series, parallel, or a combination of series and parallel, so that a Ziegler catalyst is exposed to more than one set of reaction conditions during its lifetime. In this way low molecular weight homopolymer can be produced in combination with high molecular weight copolymer, the

so-called bimodal resin combination. This technique was originally developed to counteract the limitation of Ziegler catalysts, which unaided, tend to make a narrow molecular weight distribution which is not useful for many extrusion applications. However, this type of broadening also allows the branching to be selectively placed into the high molecular weight portion of the distribution.

In later years, other reactor arrangements have also been developed to produce bimodal resins. Other variations include combining two loops in series (Solvay, Fina, and others), two gas-phase reactors in series (Union Carbide), and loop/gas phase (Borealis).

Multiple reactor processes have some advantages and disadvantages over single reactor arrangements of similar capacity. They produce some unusual resins that (at the time of this writing) cannot be exactly duplicated by any other means, such as high molecular weight film resins. However, they are also more complicated and more expensive to build and run, and they are much less flexible in what can be made. Many HDPE researchers believe that new single-site catalyst advances will eventually make bimodal reactor technology obsolete.

Commercial Applications of HDPE

Its low melting point and high chemical stability facilitate the processing of HDPE by many conventional techniques. Some of the most common applications include injection molding, blow molding, blown and cast film, pipe and tubing, and wire and cable coating. Table 4 indicates the approximate current breakdown in the United States by end use.

Injection Molding. In this technique molten HDPE is injected into a metal mold at 200–260°C and 70–140 MPa pressure (690–1380 atm). The mold is then cooled and opened and the solid article, which is now in the shape of the mold, is removed. Usually resins with a narrow molecular weight distribution are preferred

Table 4. U.S. Usage of HDPE by Application

Market	Annual usage, 10^6 t	Market share, %
Extrusion		
Film (up to 12 mil)[a]	1.06	15.6
Sheet (over 12 mil)[a]	0.35	5.1
Pipe and conduit, corrugated	0.30	4.3
Pipe and conduit, noncorrugated	0.58	8.5
Other extruded products	0.21	3.1
Rotomolding	0.07	1.0
Injection Molding	1.08	15.7
Blow Molding	2.23	32.5
Resellers and Compounders	0.85	12.4
All other uses	0.12	1.8
Total	*6.85*	*100*

1 mil = 0.025% mm.

for injection-molding applications, because broader distributions are more likely to leave orientations frozen into the articles upon cooling because of the slower relaxation time. Such frozen orientations can lead to warpage of the article upon cooling. For this reason most injection-molding resins are prepared from Ziegler catalysts. Because of the narrow molecular weight distribution, which tends to resist flow at high shear, and because of the need to completely fill sometimes intricate molds, injection-molding resins generally have lower average molecular weights than are needed for other applications. Injection-molding resins generally include the melt index range of 3–80. A wide diversity of articles are made from injection-molded HDPE including cups, pails, toys, housewares, auditorium seats and chairs, crates, food containers, etc. (see INJECTION MOLDING).

Blow Molding. Blow molded articles account for the largest single use of HDPE. The technique is used for rapid processing of large quantities of articles of relatively simple configuration, such as bottles and simple containers. A molten tube of HDPE, called a parison, is extruded through a die and then enclosed by a doubly split metal mold (Fig. 12). The parison is blown by air pressure to conform to the internal configuration of the mold into the formed article, much as glass is blown into bottles. When the melt leaves the die, it swells and the parison diameter increases, especially with HDPE of high molecular weight and at high extrusion rates (see BLOW MOLDING).

In the initial phase of blow molding, the molten tube is extruded at high pressure and rate through a small die gap and the tube thus formed is free-hanging in the mold. Thus, low viscosity at high shear is preferred to enhance extrusion, but to resist sagging in the mold, high zero-shear viscosity is preferred. Thus this combination is achieved by using broader molecular weight distribution resins of relatively high molecular weight (melt index 0.1–0.5). Chromium catalysts are ideal for producing blow-molding resins.

Another important characteristic of blow-molding resins is the degree of "parison swell" and "die swell." The former is the extent to which the molten tube tends to flare out during the extrusion step. An excessively high degree of flare can cause the tube to extend beyond the mold cavity, while too little flare can sometimes cause incomplete filling of the mold structure. Die swell is a measure of how much the tube wall expands as it exits the die under high pressure. The die gap must be adjusted to take die swell into account in order to produce the desired wall thickness. Molders prefer to set this parameter midway and not have to

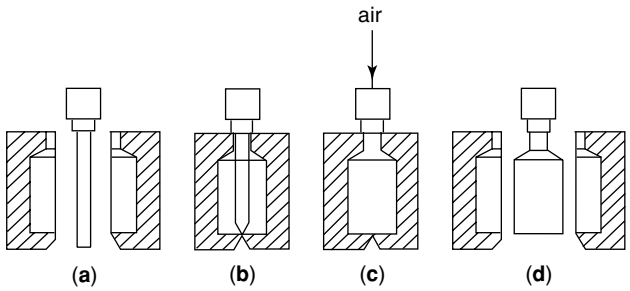

Fig. 12. HDPE blow molding processing steps: (**a**) extrusion of parison, mold is open; (**b**) mold is closed; (**c**) air is blown into parison; and (**d**) mold is opened for removal of article.

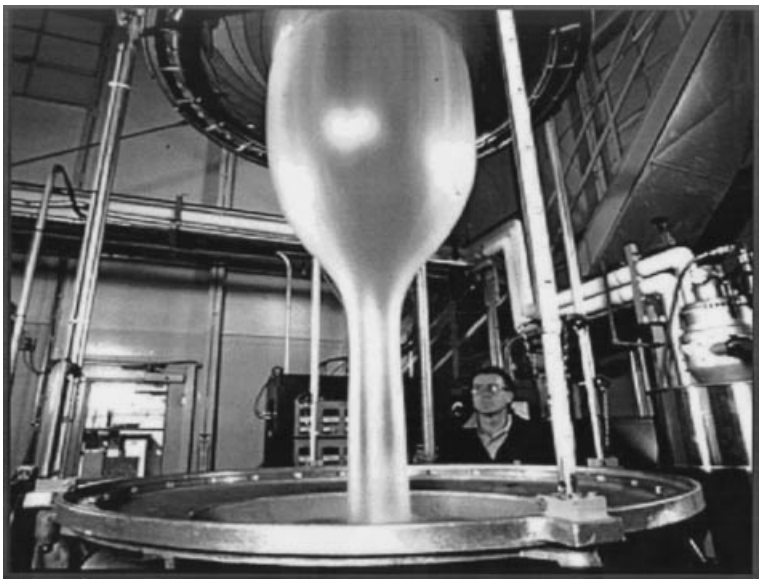

Fig. 13. HDPE film blowing.

readjust it from one resin lot to another. The degree of swell in these resins is highly influenced by the degree of LCB in the resin. A certain minimum level of LCB is required for most resins. This is another reason that chromium oxide catalysts lend themselves well to blow-molding applications. LCB content can be adjusted easily by varying chromium loading, activation temperature, or cocatalyst level.

Blow molding is widely used to form bottles for food packaging, detergents, oil, and other household materials, industrial drums, fuel tanks for automobiles, toys, and a wide assortment of other articles.

Blown Film. The impermeability, stiffness, and higher softening temperature of HPDE make it useful for certain film applications (Fig. 13). A continuous roll of blown film is produced by extrusion of HDPE melt through a die with a circular slit of ca 0.6–1.5 mm; the diameter of the ring can typically be as large as 80–100 cm. The extruded thin-walled tube rises vertically and is filled with air, thus expanding the tube to a certain size. Usually the ratio of the tube diameter to the die diameter is about 4:1, allowing for the formation of a film trunk up to 4 m in diameter. The film, 0.007–0.125 mm thick, is air-cooled and rolled. Bags can be made from the rolled hollow film tube, or it can be split into one continuous sheet for wrapping and other uses. In coextrusion, two different types of plastic are simultaneously extruded through a single die with two concentric circular slits, giving a layered film. This can be done to achieve special physical properties or permeability resistance.

Chromium-based catalysts can be used quite widely for production of HDPE film grades but some of the best HDPE films, in terms of mechanical properties and extrusion rates, are bimodal resins made from Ziegler catalysts passing through two or more reaction zones. Most recently, metallocene resins have been used to produce extremely high clarity resins, despite the high density. Applications of HDPE films include food packaging, grocery and merchant bags, and drum liners.

The thickest blown film made from HDPE, sometimes called sheeting, ranges in gauge from 0.5 to 3.0 mm and is used in geomembranes. Geomembrane blowing operations typically produce a sheet 6.9 m wide (22.5 ft), with the bubble rising eight stories into the air, weighing 2.5 tons. Geomembrane sheeting is used to protect the environment by lining pits and covering landfills. For example, sewage ponds and spillover sumps near oil and chemical storage tank areas are first lined with geomembrane to prevent seepage into the groundwater. Reservoirs to hold drinking water are also lined with geomembrane in some regions to prevent loss. Leaching pads used in mining operations, irrigation canals, evaporation ponds, and industrial waste lagoons are other applications of geomembrane. In this type of service, toughness is extremely valued to avoid penetration by rocks, tree roots, etc. Thus, high molecular weight and a significant amount of branching is preferred in the polymer. The blowing operation favors resins with high melt strength, which is imparted by high levels of LCB. Chromium catalysts are commonly used for this type of blown film.

Thermoforming. Thermoforming is a process in which the resin is extruded into flat sheets of perhaps 2–13 mm after which that sheet is softened by heat and then stamped or pulled by vacuum into a large mold. Thermoformed sheet is widely used for trays, pans, for lining the beds of pickup trucks or other vehicles, for flooring, and a wide variety of other articles. Thermoforming resins typically require stiffness, toughness, and good melt strength, all of which are achieved from chromium oxide catalysts at 0.05–0.2 melt index.

Pipe and Tubing. Pipes (diameter >1 cm) and tubing (diameter <1 cm) are produced by passing HDPE melt through a die with a circular channel, forming a thick tube. Immediately after leaving the die, the molten tube enters a vacuum calibrator, where it is forced against sizing rings and cooled. Extrusion and drawdown (ratio of the cross-sectional area of the die opening to the tube wall) are adjusted with the help of mechanical pulling devices. For pipe manufacture, die openings are large, resistance to polymer flow is low, and drawdown does not exceed 1.1. Pipes with diameter ca 1.5 m are made commercially.

HDPE pipe is used in low pressure applications for transporting potable water, gas, acids, liquid hydrocarbons, oils, salt water, and other chemicals and solvents. Long-term load bearing, or "creep," tests are essential to determine the life of PE pipe under pressure. HDPE pipe withstands pressures in short-term burst tests that are several times greater than long-term burst pressures because of the creep phenomenon. Broad molecular weight distribution resin, as obtained from chromium oxide catalysts, are ideal for most pipe applications. The introduction of superior, bimodal type, pipe resins in recent years has extended HDPE pipe applications.

Wire and Cable Insulation. Excellent electrical properties and moisture resistance make linear PE ideal for wire and cable coatings. Use includes power, communications, and control applications. Continuous coatings can be extruded directly onto wire at high speed, followed by cooling in a bath. The lubricity and high abrasion resistance of the coating aid in conduit installations. Copolymers of 0.935–0.945 g/cm^3 density and ca 1 melt index are commonly used because of the good balance of toughness, ESCR, and extrudability. Polymers of medium-to-broad molecular weight distribution are preferred because of high coating speeds

and good surface finish. Addition of about 2.5% small particle carbon black greatly increases weather resistance.

Filament. In the production of monofilament, extruded strands are quenched, reheated, then pulled to draw ratios of 10:1. The tensile strength of finished filament is 345–690 MPa (50,000–100,000 psi) due to the high degree of orientation. Cord and rope are used in sporting goods and utility purposes. Larger PE rope is used in marine applications where it has a clear advantage over nylon, since HDPE floats and does not adsorb water. Ribbon yarn, made from split film, finds applications in carpet backing, some fabrics, bags, and in binding of multiwire cable together. A large market for these products is especially found in Asia and South America. Owing to its chemical inertness, linear PE is used for monofilament gauze for tissue reinforcement in surgery. Ziegler resins are particularly well suited to these applications, although chromium oxide derived resins are also common.

Rotomolding. Larger items, such as tote boxes, fuel tanks, and water storage tanks are often made by a rotational molding operation. Usually HDPE powder or pellets are introduced into a mold cavity which is then heated and rotated evenly. As the polymer melts, it coats the inside surface of the mold uniformly. The mold is then cooled while still under rotation to prevent sagging or other imperfections. Sometimes organic peroxide is added so that upon heating the plastic, a cross-linking reaction takes place in which the molecular weight and viscosity of the plastic dramatically increases. The mold is then separated and the article removed. Tanks up to 37.8 M^3 (10,000 gal) are made in this way. Rotomolding applications require good flow under zero-shear conditions. Narrow molecular weight distribution resins, as provided by Ziegler or metallocene catalysts, are preferred for rotomolding applications.

Health and Safety of HDPE

HPDE is generally inert and lacking in any toxicity, which accounts for its widespread use in food packaging. It is also used in prosthetic devices, in surgery, hip or knee joint replacements, etc.

HDPE can present some health hazard during its combustion, pyrolysis, or during thermocutting, when smoke, fumes or toxic decomposition products can be formed. Irritation of the skin, eyes, and mucous membranes of the nose and throat are possible. In some cases this irritation has been traced to traces of acrolein or formaldehyde from thermooxidative decomposition. However, other large-scale fire testing of foamed PE under actual conditions did not reveal significant acrolein formation and demonstrated that PE presents no worse hazard than cellulosic materials. Still other studies indicate that maximum evolution of irritants occurs from smoldering combustion at 300–400°C.

ETHYLENE POLYMERS, LDPE

Introduction

Low density polyethylene (LDPE) was the first thermoplastic polyolefin used commercially. It was discovered serendipitously in 1933 and was quickly utilized for electrical cable sheathing for radars during the war. LDPE, along with high density polyethylene (HDPE) and linerar low density polyethylene(LLDPE), offers an unparalleled combination of low cost, ease of fabrication into a variety of end uses, and balance of physical properties. Polyethylene has displaced paper, metal, wood, and other materials of construction. LDPE is unique in its polymerization process. Free-radical-initiated polymerization is used to make LDPE, as compared to transition-metal catalysis for HDPE and LLDPE. The free-radical process leads to the unique molecular structure of LDPE: large amounts of long-chain branching. The long-chain branching imparts unusual rheological behavior in both shear and extension. LDPE is used in a variety of applications, such as film, coating, molding, and wire and cable insulation. One of the reasons for its wide range of utility is its thermal stability and low toxicity.

Monomer and Comonomers for LDPE

Ethylene [74-85-1] is the monomer used to make LDPE [9002-88-4]. The predominant method of manufacture of ethylene is high temperature cracking of natural gas or crude oil. Some properties of ethylene are collected in Table 1. The principal method for the industrial preparation of ethylene is thermal cracking of hydrocarbons. Small amounts of comonomers, such as vinyl acetate [108-05-4], methyl acrylate [96-33-3], or ethyl acrylate [108-88-5], can be added to modify

the properties of the polymer. Vinyl acetate is made by the oxidative addition of acetic acid to ethylene in the presence of a palladium catalyst. The acrylates can be commercially manufactured from acetylene, but the preferred route is by the oxidation of propylene oxide. A few of the pertinent physical properties of these monomers and more detailed descriptions of their manufacture can be found in the articles on Vinyl Acetal Polymers and Acrylic Ester Polymers and Methacrylic Ester Polymers.

Properties of LDPE

LDPE Homopolymer. LDPE, discovered by ICI in 1933 (1,2), quickly found war-time utility in high frequency cables for ground and airborne radar equipment. After the war, the balance of chemical inertness, thermal and environmental stability, ease of processing, physical properties, stiffness, and optical properties made this polyolefin polymer useful in a variety of applications. A detailed and exhaustive compilation of molecular, physical, and chemical data on LDPE can be found in the *Polymer Data Handbook* (3).

With the commercialization of HDPE in the early 1950s (see article on ETHYLENE POLYMERS, HDPE) and LLDPE in the 1960s (see article on ETHYLENE POLYMERS, LLDPE), there was cannibalization of LDPE markets and applications by these new polymers. Despite some predictions of the demise of LDPE due to the better properties and lower cost of LLDPE and HDPE, LDPE remains the resin of choice in many applications. The most unique structural difference between LDPE and HDPE/LLDPE is the presence of large amounts of long-chain branching in the molecule (Fig. 1). This branching leads to rheological and property behaviors which cannot be matched by the other polymers. Today, LDPE is still used in a variety of film, coating, wire and cable, and molding applications. The physical and extrusion properties of LDPE depend on the molecular weight, molecular weight distribution (MWD), frequency of short-chain branches, and frequency and length of the long-chain branches. Some typical molecular properties for LDPE are found in Table 1. A comparison of blown film properties between LDPE and LLDPE is

Table 1. Typical Properties of LDPE[a]

Property	Value	Method
Molecular weight	70,000–120,000	gpc
Melt index, g/10 min	0.2–50	ASTM D1238
Density at 20°C, MPa g/cm^3	0.920–0.935	ASTM D1505
Vicat softening point	80–96°C	ASTM D1525
Tensile strength, MPa[b]	9–15	ASTM D638
Tensile elongation at rupture, %	150–800	ASTM D638
Hardness, Shore D	40–60	ASTM D676
Dielectric constant @ 1 MHz	2.3	ASTM D1531
Dissipation factor @ 1 MHz	0.0001	ASTM D1531
Low temperature brittleness F_{50}, °C	< -76	ASTM D746

[b] To convert MPa to psi, multiply by 145.

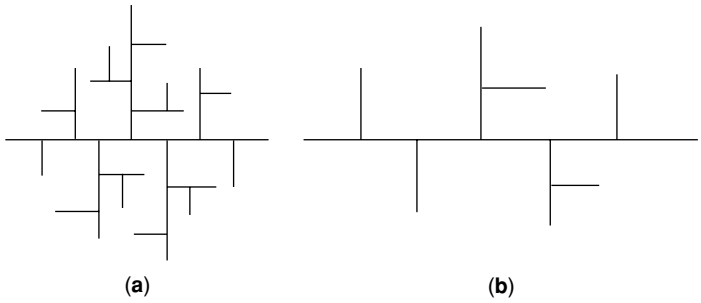

Fig. 1. Long-chain branching in fractions with M_n 200,000 from polyethylenes with melt index 1.7 and density 0.918–0.919 g/cm^3: (**a**) autoclave product with 20 long branches; (**b**) tubular product with 7 long branches. Short-chain branches are not shown.

found in Table 2. A comparison on injection-molding properties between LDPE and LLDPE is found in Table 3.

LDPE Copolymers. A variety of comonomers can be added to the polymerization of ethylene to make copolymers. The free-radical polymerization mechanism of LDPE production allows for the copolymerization of polar comonomers. At this time, the incorporation of polar comonomers is unique to LDPE. The transition metals used to catalyze HDPE and LLDPE production are generally poisoned by polar comonomers and therefore, only copolymers containing alpha-olefins like 1-butene, 1-hexene, and 1-octene can be made. Because the polar copolymers can be made only by the LDPE process, they command a premium in the market. The most common comonomers (and their corresponding copolymers) are vinyl acetate (EVA), methyl acrylate (EMA), ethyl acrylate (EEA), and acrylic acid

Table 2. Blown Film Property Comparison[a] between HP-LDPE and LLDPE

Property	ASTM test method	HP-LDPE	HP-LDPE	LLDPE	LLDPE	LLDPE
Melt index, g/10 min	D1238	2.5	0.2	1.0	1.0	1.0
Density, g/cm^3	D1505	0.921	0.923	0.918	0.918	0.918
Comonomer		None	None	Butene	Hexene	Octene
Dart drop, N/mm (=dyn/cm)	D1709	29	71	39	77	97

[b]To convert kJ/m to ft·lbf/in., multiply by 18.73.
[c]To convert MPa to psi, multiply by 145.

Table 3. Injection Molded Property Comparison of LDPE and LLDPE

Property	ASTM test method	LDPE	LDPE	LLDPE	LLDPE
Melt index, g/10 min	D1238	24	38	21	105
Density, g/cm^3	D1505	0.923	0.923	0.924	0.929
Tensile strength, MPa[a]	D638	8.3	8.9	8.3	12.5
Dishpan impact[b] at −20°C, J		12	7	41	4
Failure mode		Brittle	Brittle	Ductile	Ductile
Low temperature brittleness[c] F_{50}, °C	D746	−39	−25	< −76	−58
ESCR[d] F_{50}, h	D1693	<1	–	150	<2

[a]To convert Mpa to psi, multiply by 145.
[b]Industry test done on standard molded plastic dishpan. Parts of various weights dropped on dishpan until failure.
[c]Test method has been found useful for specification purposes, but does not necessarily indicate the lowest temperature at which the material may be used.
[d]At 50°C, 100% Igepal, no slit.

[79-10-7] (EAA). The presence of the comonomer decreases crystallinity and imparts more flexibility and softness to the final articles. Increasing levels of these comonomers imparts better adhesion to other materials. This superior adhesion of LDPE copolymers to other materials like metal, foil, cardboard, and paper is unmatched by other polyolefins and remains a unique property of LDPE. Comonomer contents as high as 20 wt% of EVA, EMA, and EEA can be used in various extrusion and molding applications. Films made from EVA, EMA, or EEA tend to have good low temperature properties and very good sealability. Because of the good sealability and broad sealing latitude, these materials are often used in coextruded structures as a seal layer. Copolymers containing acrylic or methacrylic acid have very good toughness and stress-crack resistance, but impart corrosivity to the polymer. In general, these products are used in coextruded or laminated structures. Comonomer levels from 20 to 40 wt% can also be made in the LDPE process. These copolymers are used in coating and adhesive applications.

Ionomers. Copolymers of acrylic or methacrylic acid can be converted into the sodium or zinc salts of the acids. These ionomers(qv) show strong ionic bonding, such that the properties are similar to LDPE of very high molecular weight (4). However, the ionic bonds are weakened at extrusion temperatures so that the ionomers process under similar conditions of LDPE homopolymers of normal molecular weight. Because of their polar nature, ionomers are paintable and commonly used to adhere to aluminum and metal or laminate to nylon.

Polymerization Reactors

LDPE is also known as “high pressure, low density” or HPLD, because it is exclusively made by the high pressure process. LDPE is produced under high pressures (81–276 MPa) and high temperatures (130–330°C) with a free-radical initiator, such as peroxide or oxygen. The polymerization mechanism is a free-radical

reaction that leads to the formation of long-chain branches, which can be as long as the main polymer backbone (5). The free-radical mechanism also leads to the formation of short-chain branches, typically one to five carbon atoms long (6). These short-chain branches normally seen in LDPE include 1,3-diethyl and 2-ethylhexyl side chains as well as the most common butyl branches. LDPE also contains lesser amounts of amyl branches while hexyl branches are rare. Most of the methyl branches occur when propylene is added to the reactor as a chain-transfer agent. The polymerization is carried out in tubular or stirred autoclave reactors (7).

The rate-limiting factor in LDPE production is heat removal from the reactor. The heat of polymerization of ethylene is very high, at about 3.35 kJ/g. For comparison, the heat of reaction of styrene is only about 0.657 kJ/g. There are basically two ways to dissipate the heat during the polymerization: through the walls of the reactors and by the unreacted ethylene, which is cooled and returned to the reactor. Since the LDPE polymerization occurs at very high pressures, the reactor walls must be very thick and external cooling is not very efficient. This is especially true for the autoclave reactor. The tubular reactors can benefit from cooling jackets, which is one of the factors accounting for the fact that only large tubular reactors are being built today. Older small autoclave and tubular reactors of 100–150 kta (kta $= 10^3$ t/year) cannot economically compete with new 400–500 kta low pressure "mega-reactors" being built for HDPE and LLDPE. The new high pressure tubular reactors of 350 kta, which are being installed now, will be able to compete with the HD and LLDPE units as well as offer the unique polymer properties that customers value.

In both the tubular and autoclave reactors, the control of molecular weight can be accomplished by reaction pressure, temperature, or the addition of chain-transfer agents or telogens. However, reaction pressure and temperature also affect the MWD and the amount of short- and long-chain branching. Therefore, it is desirable to use chain-transfer agents for the primary control of molecular weight so that pressure and temperature can be used for MWD and branching control.

There are subtle differences in the structure of the LDPE resins made from the tubular and autoclave reactors. The biggest difference is in the type and level of long-chain branching. As was seen in Figure 1, the autoclave reactor gives rise to shorter, more 'bushy' long-chain branching than does the tubular reactor. This is due to the higher level of backmixing in each stage of the reactor. The free radicals have more opportunity to react and terminate with other polymer molecules in the autoclave. In the tubular reactor, there is relatively little backmixing since the reaction flow is carrying the polymer down the tube as it is reacting. Therefore, once a long-chain branch is started, it is likely to continue to grow rather than interact with another polymer molecule to terminate.

The effects of these subtle differences in long-chain branching are difficult to measure (see the section on Analytical and Test Methods). Spectroscopically, the long chains are indistinguishable from the polymer backbone. The differences are also very minor in the rheology of the polymer. There are a few extrusion and physical property differences that are created by the different types of long-chain branching. Autoclave resins tend to have better see-through clarity than tubular reactors, due to the smaller spherulites formed during the crystallization process.

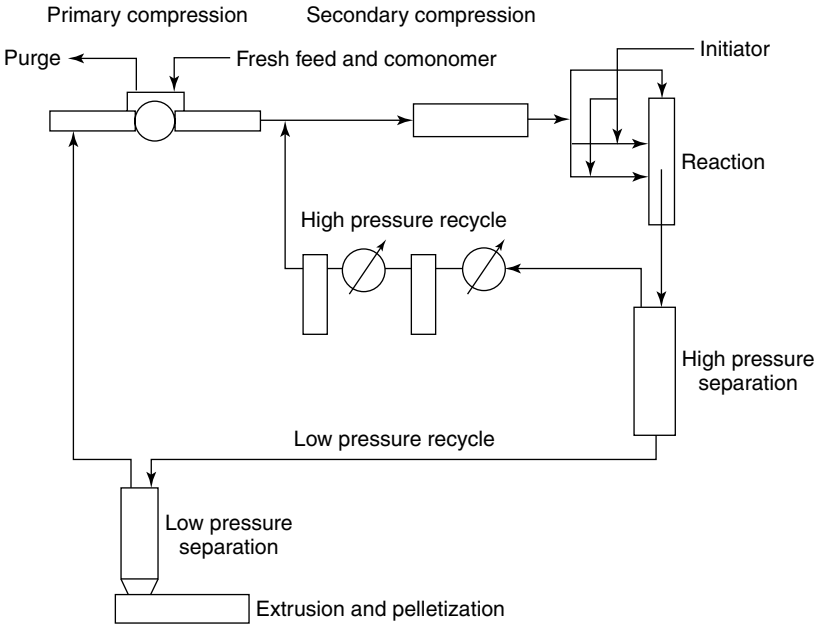

Fig. 2. Autoclave reaction process and recycle system.

Autoclave resins also exhibit better drawdown and neck-in in the extrusion coating process.

Stirred Autoclave Reactor. The stirred autoclave reactor (Fig. 2) generally has a (proprietary) stirrer running the length of a cylindrical vessel with a length to diameter ratio of 4:1 to 18:1. There are baffles in the reactor to divide it into multiple reactor zones, with independent temperature control and initiator injection points. The stirrer provides backmixing in each stage, but practically no mixing between stages. Product molecular weight, MWD, and branching are controlled by the temperatures in each zone and the placement of the initiator injection. Pressure is held constant by using a modulating valve. Because of the high pressures used, generally about 210 MPa, the reactor walls are very thick and severely limit heat removal from the vessel. Therefore, unreacted ethylene is used to remove the heat of polymerization from the reactor. This limits the conversion per pass of ethylene to about 22%. In some cases, conversion may be even lower, if unusual product characteristics are desired.

Tubular Reactor. Tubular reactors (Fig. 3) are basically long, thick-walled pipes from 0.5 to 1.5 km long, arranged as elongated coils, with cooling jackets. The use of cooling jackets allows more efficient heat removal than in the autoclave reactor and hence, higher conversion of ethylene per pass. Typical conversion rates for tubular reactors are in the 35% range. In contrast to the autoclave reactor, where reaction pressure is held constant, pressure in the tubular reactor varies. Pressure is controlled by a cycle valve that opens periodically. This generates pressure waves and surges in the reactor. These surges are actually beneficial to the process in that they help keep the walls cleaned of polymer buildup and

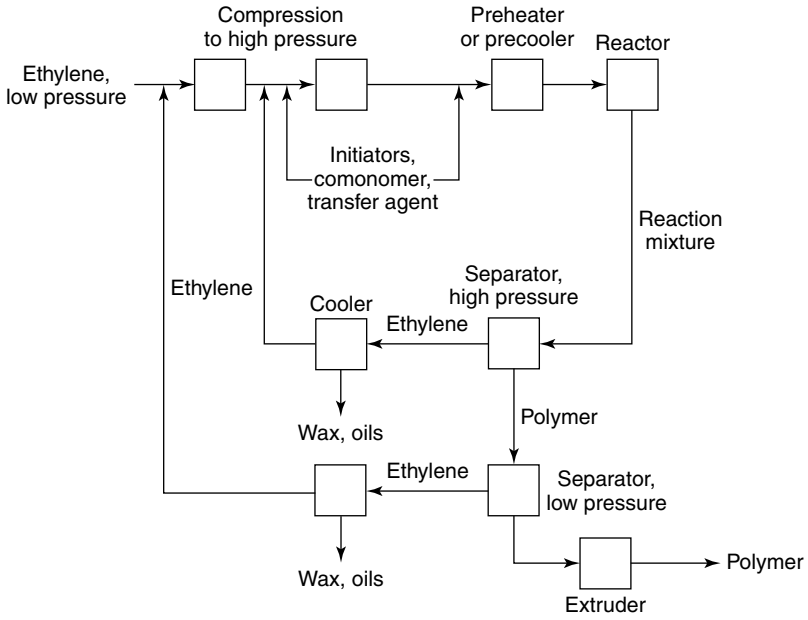

Fig. 3. Tubular reaction process.

help optimize heat transfer to the cooling jacket. Ethylene can either be added in the front or in the front with one or more additional side feed entries. Initiators, peroxide or oxygen, can also be introduced in multiple places down the tube. Thus, multiple reaction zones can be created, which can be used to control the properties of the final product.

Post Reactor Process. Since only a portion of the ethylene fed to the reactor is converted to polyethylene, recovery and recycling of the unreacted ethylene (and other monomers, if present) is necessary to improve the economics of the process. The recycle system generally comprises two sections: a high pressure separator and a low pressure separator. When the polymer first exits the reactor, it is still at very high pressures and temperatures and contains a lot of entrapped ethylene gas. The high pressure separator first partitions the polymer from the gases and low molecular weight waxes. The gases and waxes are then separated and cooled. The cool gas stream is combined with fresh feeds and fed to the secondary compressor.

Meanwhile, the polymer stream from the high pressure separator is fed to the low pressure separator. Although considerable ethylene has already been removed from this stream, further recovery is still possible. This recovered gas is fed to a multiple stage compressor to get it back to feed pressure and then fed to the secondary compressor with the gas from the high pressure separator. Small purges (less than 2%) of the feed from the multiple stage compressor may be taken to control the buildup of inert gases, such as methane and ethane.

The molten polymer coming out of the low pressure separator is then mixed with stabilizers and processing additives and fed to a pelletization process. An

extruder or a melt pump can be used to force the polymer through a die with multiple holes. The polymer strands are cut under water and the water/pellet slurry fed to a centrifugal drier. The pellets can be loaded directly into hopper cars or can be stored in silos and loaded at a later time.

Polymerization Mechanism

Initiation. A free radical is generated from the thermal decomposition of a peroxide or by an as-yet unknown mechanism in the case of oxygen. The free radical then reacts with ethylene to start a growing polymer chain.

$$I\cdot + CH_2{=}CH_2 \rightarrow I{-}CH_2{-}CH_2\cdot \tag{1}$$

$$R_i = k_i[I] \tag{2}$$

The choice of initiator is made on the basis of the type of reactor, the residence time in each zone, the desired reaction temperature, and initiator cost. A principal factor in choosing an initiator is the half-life. The longer the half-life of the initiator, the higher the degree of polymerization, but the higher the cost of the peroxide. Table 4 gives some common initiators, half-lives, and costs.

Chain Propagation. Chain propagation proceeds by radical reaction with ethylene or comonomer molecules. In the case of ethylene homopolymerization, the mechanism and kinetics are straightforward.

$$R{-}CH_2{-}CH_2\cdot + CH_2{=}CH_2 \rightarrow R{-}CH_2{-}CH_2{-}CH_2{-}CH_2\cdot \tag{3}$$

$$R_p = k_p[R\cdot]P_e \quad \text{or} \quad R_p = k_p[R\cdot][E] \tag{4}$$

where P_e is the ethylene pressure and E is ethylene.

Table 4. Peroxide Initiators for LDPE Polymerization

Peroxide	CAS No.	Half-life (1 min) temperature[a], °C	Cost[b] $/gram
t-Butyl peroxypivalate	[927-07-1]	123	
Dioctanoyl peroxide	[762-16-3]	127	
t-Butyl peroxyisobutyrate	[109-13-7]	130	
Dibenzoyl peroxide	[96-36-0]		0.084
t-Butyl peroxyisopropylcarbonate	[2372-21-6]		0.141
t-Butyl peroxybenzoate	[614-45-9]	170	0.075
Dicumyl peroxide	[80-43-3]		0.101
Di-*t*-butyl peroxide	[110-05-4]	191	0.084
t-Butyl hydroperoxide	[75-91-2]	260	0.205

[a]Refs. 8 and 9.
[b]Aldrich Catalog, 2000–2001 Edition.

When comonomers are involved, the propagation step becomes more complicated. When comonomer is present, the growing chain can react with an ethylene molecule (M_1) (eq. (5), which is the same as eq. (3) with M_1 representing the ethylene molecule) or a comonomer molecule (M_2) (eq. (6)), and those reactions may have very different rate constants. Likewise, if the growing chain does react with a comonomer, the comonomer radical end can now react with another comonomer (eq. (7)) or with ethylene (eq. (8)).

$$R{-}CH_2{-}CH_2\cdot + M_1 \rightarrow R{-}CH_2{-}CH_2{-}M_1\cdot \tag{5}$$

$$R{-}CH_2{-}CH_2\cdot + M_2 \rightarrow R{-}CH_2{-}CH_2{-}M_2\cdot \tag{6}$$

$$R{-}M_2\cdot + M_2 \rightarrow R{-}M_2{-}M_2\cdot \tag{7}$$

$$R{-}M_2\cdot + M_1 \rightarrow R{-}M_2{-}M_1\cdot \tag{8}$$

Each of these reactions has its corresponding rate reaction (eqs. (9), (10), (11), (12)).

$$R_{11} = k_{11}[R{-}M_1\cdot][M_1] \tag{9}$$

$$R_{12} = k_{12}[R{-}M_1\cdot][M_2] \tag{10}$$

$$R_{22} = k_{22}[R{-}M_2\cdot][M_2] \tag{11}$$

$$R_{21} = k_{21}[R{-}M_2\cdot][M_1] \tag{12}$$

Determining the individual propagation constants is not easy. However, if one defines reactivity ratios of the propagation constants (eqs. (13) and (14)), then the reactivity ratios can be determined by measuring the rates of disappearance of M_1 and M_2 (eq. (15)) in a controlled experiment.

$$r_1 = k_{11}/k_{12} \tag{13}$$

Table 5. Reactivity Ratios for Comonomers with Ethylene

Comonomer	r_1	r_2	Pressure, MPa[a]	Temperature, °C	Reference
Propylene	3.1 ± 0.2	0.77 ± 0.05	103–172	130–220	10, 11
1-Octene	3.1 ± 0.1	NA[b]	138	130	10, 11
Vinyl acetate	1.07 ± 0.06	1.09 ± 0.2	101	90	12, 13
Vinyl chloride	0.24 ± 0.07	3.6 ± 0.3	101	90	12, 13
Methyl acrylate	0.042 ± 0.004	5.5 ± 1.5	138	130–152	12
Methyl methacrylate	0.2	NA	207	160–220	12
Carbon monoxide	0.15	0.0	92	130	14

[b]NA = not available.

$$r_2 = k_{22}/k_{21} \tag{14}$$

$$\mathrm{d[M_1]/d[M_2]} = \{[\mathrm{M_1}]/[\mathrm{M_2}]\} \times \{(r_1[\mathrm{M_1}] + [\mathrm{M_2}])/([\mathrm{M_1}] + r_2[\mathrm{M_2}])\} \tag{15}$$

Between 1945 and 1970, ethylene was copolymerized with many comonomers and the reactivity ratios measured (8–12). Table 5 lists some common comonomers and their reactivity ratios.

The reactivity ratios can be used to predict how the comonomer will be distributed in the final polymer. If the product of r_1 and r_2 approaches unity, then the monomer and ethylene are randomly distributed. If r_1 equals r_2, then the concentrations of the comonomer and ethylene in the polymer is the same as their concentrations in the feed. If one reactivity ratio is higher than the other, then the copolymer contains more of that comonomer than is in the feed. If the product of r_1 and r_2 is less than one, the monomers tend to alternate along the chain. If r_1 is higher than unity, then the amount of ethylene in the copolymer is greater than in the feed. If both ratios are less than 1, then certain feed compositions yield a copolymer of the same composition. If the product of r_1 and r_2 is greater than unity, then block copolymerization is favored. This has not been established in free-radical polymerization.

For example, in Table 3, it is seen that the r_1 and r_2 ratios for EVA are nearly one. Therefore, the ethylene and EVA are randomly distributed along the polymer chain, and the concentration of EVA in the copolymer is approximately the same as in the feed.

Short- and Long-Chain Branching. LDPE is a unique polymer with respect to the high amount of long-chain branching in the polymer. The long-chain branch is a direct result of the free-radical polymerization mechanism. A free radical at the end of a growing polymer chain can abstract a hydrogen from the middle of another polymer chain. This terminates the first polymer molecule and creates a new radical growth point in the middle of the second polymer chain. This is known as intermolecular chain transfer.

$$\mathrm{R'CH_2R''} + \mathrm{R\cdot} \rightarrow \mathrm{RH} + \mathrm{R'C\cdot HR''} \tag{16}$$

$$R_{\mathrm{trp}} = k_{\mathrm{trp}}[\mathrm{R}\cdot][\mathrm{P}] \tag{17}$$

where P is the polymer.

Short-chain branching is created by intramolecular chain transfer. A free radical at the end of a growing chain can abstract a hydrogen from within the same chain (backbiting) to end up with the free radical on an internal carbon atom. When polymerization continues from that internal radical, a short alkyl branch is formed. Statistically, abstraction of the hydrogen from the fifth carbon atom back is favored, and the resulting branch is a butyl group. However, backbiting can also occur on the third, fourth, and sixth carbon atoms back, forming ethyl, propyl, and amyl branches.

$$\mathrm{RCH_2CH_2CH_2CH_2CH_2}\cdot \rightarrow \mathrm{RC}\cdot\mathrm{H{-}C_4H_9} \tag{18}$$

$$\mathrm{RC}\cdot\mathrm{H{-}C_4H_9} + \mathrm{CH_2{=}CH_2} \rightarrow (\mathrm{R})(\mathrm{C_4H_9})\mathrm{RHCH_2CH_2}\cdot \tag{19}$$

$$R_{\mathrm{b}} = k_{\mathrm{b}}[\mathrm{R}\cdot] \tag{20}$$

Termination. There are a variety of competing mechanisms by which the growth of a polymer chain can be stopped. The dominant mechanisms are determined by the polymerization conditions and the concentrations of chain-transfer agents present.

Termination by Coupling. Two growing polymer chains can react together to form one long polymer molecule or can disproportionate to form two inert chains.

$$\mathrm{R{-}CH_2{-}CH_2}\cdot + \mathrm{R{-}CH_2}\cdot \rightarrow \mathrm{R{-}CH_2{-}CH_2{-}CH_2{-}R \; or \; RCH_3 + R{-}CH{=}CH_2} \tag{21}$$

$$R_{\mathrm{t}} = k_{\mathrm{t}}[\mathrm{R}\cdot]^2 \tag{22}$$

Termination by Chain Transfer with Ethylene. The growing polymer chain can react with ethylene, and instead of the ethylene inserting into the growing chain, a radical transfer reaction can take place to form vinyl end group.

$$\mathrm{RCH_2CH_2}\cdot + \mathrm{CH_2{=}CH_2} \rightarrow \mathrm{RCH{=}CH_2} + \mathrm{CH_3CH_2}\cdot \; \mathrm{or} \; \mathrm{RCH_2CH_3} + \mathrm{CH_2{=}CH}\cdot \tag{23}$$

$$R_{\mathrm{tre}} = k_{\mathrm{tre}}[\mathrm{R}\cdot]P_{\mathrm{e}} \tag{24}$$

Termination by Chain Transfer with Chain-Transfer Agents or Solvents. Polyethylene radicals are very reactive and will react with solvents or other trace

Table 6. Common Chain-Transfer Agents and Their Constants

Agent	Transfer constant	Reference
Methane	0.0002	15
Ethane	0.0006	15
Propane	0.0030	16
Ethanol	0.0075	17
Propylene	0.0122	17
Hydrogen	0.0159	17
Acetone	0.0168	17
Isobutylene	0.021	15
2-Butene	0.038	17
1-Butene	0.047	17
Propionaldehyde	0.33	18

contaminants in the reactor to terminate one chain and begin another. Chain-transfer agents or telogens, such as propane, propylene, hydrogen, and isobutylene, can be added to the reaction to facilitate control of molecular weight.

$$RCH_2CH_2\cdot + SH \rightarrow RCH_2CH_3 + SH\cdot \tag{25}$$

$$R_{trs} = k_{trs}[R\cdot][S] \tag{26}$$

Chain-transfer constants for some common chain-transfer agents, as well as impurities found in feedstocks, are found in Table 6. As resin producers are striving to increase production rates and aim-grade polymer yield, reaction models are being used to predict polymer properties and accelerate transitions. Analytical devices are being used to measure the impurities in the incoming and recycled ethylene streams and the corresponding chain-transfer constants applied to calculate the molecular weights being made in the reactor. Therefore, these chain-transfer constants are more than just of academic interest.

Termination by β-Scission of Polymer Radicals. Internal polymer radicals, formed by either intra-or intermolecular chain transfer (see eqs. (16) and (18)), can undergo chain cleavage to form a terminated polymer chain and a new radical.

$$RCH_2C\cdot R'CH_2R'' \rightarrow R\cdot + CH_2{=}CR'CH_2R'' \text{ or } R''\cdot + RCH_2CR'{=}CH_2 \tag{27}$$

$$R_\beta = k_\beta[R\cdot] \tag{28}$$

Kinetics. The average molecular weight of LDPE can be expressed as the degree of polymerization(DP). The DP is equal to the rate of propagation (eq. (4)) divided by the sum of all the rates of termination (eqs. (22),(24),(26), and (28)).

$$DP = k_p[R\cdot]P_e/\{R_t = k_t[R\cdot]^2 + k_{tre}[R\cdot]P_e + k_{trs}[R\cdot][S] + k_\beta[R\cdot]\} \quad (29)$$

If one makes the simplifying assumption that, at steady state, the rate of initiation for a polymer radical is the same as the rate of termination (eq. (30)), then one can solve for the value of [R·].

$$k_i[I] = k_t[R\cdot]^2 \quad (30)$$

$$[R\cdot] = k_i^{1/2}[I]^{1/2}/k_t^{1/2} \quad (31)$$

Substituting for [R·] in equation (29), one gets the following:

$$DP = \{k_p P_e/k_t k_i[I]\} + \{k_P/k_{tre}\} + \{k_P P_e/k_{trs}[S]\} + \{k_P P_e/k_\beta\} \quad (32)$$

These factors can be either measured directly or calculated from other known relationships.

Processing of Polymers

LDPE can be processed by most standard plastics processes. In fact, since LDPE was the first large volume polyolefin commercialized, many plastics fabrication processes were designed around the rheological properties of LDPE. For example, blown film lines were developed to accommodate the shear thinning of LDPE during melting and extrusion and the strain hardening of LDPE in the bubble forming parts of the process (19). Therefore, when LLDPE was introduced to the film market in the late 1970s, significant retrofitting of blown film lines was necessary to handle the very different rheology of LLDPE.

Shear thinning and strain hardening are rheological phenomena that occur during extrusion and extensional deformation, respectively (20). The long-chain branching in LDPE affects these two behaviors significantly. The differences between LDPE and LLDPE in shear thinning and strain hardening are illustrated in Figures 4 and 5. *Shear thinning* is the term used to describe the flow behavior of a polymer in a melt-extrusion process. Shear thinning polymers exhibit a decrease in viscosity as the output rate is increased or as they are forced through narrower die gaps. The presence of long-chain branching, and in some cases, the broader molecular weight distribution of LDPE versus LLDPE both contribute to a greater degree of shear thinning for LDPE. The result is that under extrusion conditions, the viscosity of an LDPE resin is much lower than that of an LLDPE resin of the same molecular weight. The commonly accepted reason for the difference in melt viscosity is that the LDPE molecule, containing long-chain branches, is much more compact and 'spherical' in nature than the LLDPE molecule of the same weight. The LDPE molecules flow past each other more easily than the linear, entangled LLDPE molecules. This means that the LDPE resin will extrude at lower temperatures and requires less power per pound of resin. As a result of

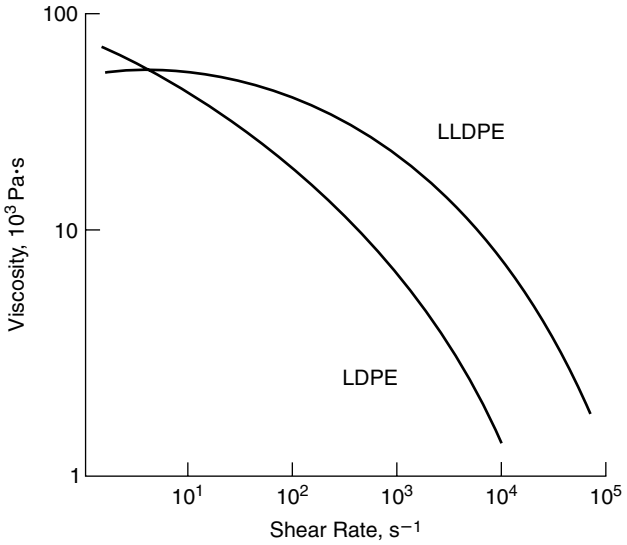

Fig. 4. Viscosity behavior under shear for LDPE and LLDPE.

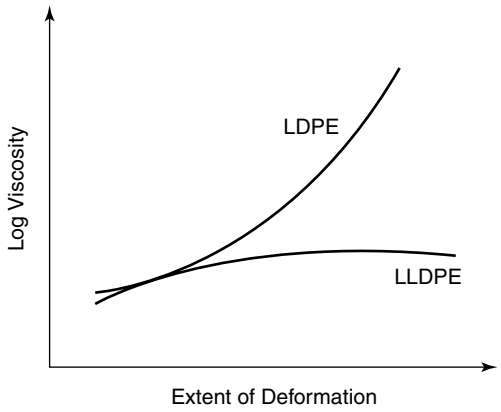

Fig. 5. Viscosity behavior under extension for LDPE and LLDPE.

this extrusion behavior, film extruders designed for LDPE were commonly underpowered for LLDPE extrusion and larger motors had to be added to convert them to efficiently extrude LLDPE.

The strain hardening effect is most clearly seen in blown film extrusion. A polymer that exhibits strain hardening will become more rigid as it is drawn to a greater extent or drawn at faster rates. An LDPE resin typically strain hardens to a greater degree than an LLDPE resin. As the polymer melt is formed into a bubble and drawn down to its final thickness, the strain hardening behavior of LDPE gives the bubble rigidity and stability to withstand the cooling air being blown on it. LLDPE, on the other hand, has a much 'softer' bubble, which is easily deformed by cooling air. The difference in extensional behavior is analogous to the

difference between pulling on a rubber band versus pulling on bubble gum. The rubber band will extend and pull, but the more you pull it, the more resistance is felt. Bubble gum can be easily pulled; it develops very little resistance to the stretching force. Because of the highly stable bubble, gauge uniformity is excellent with LDPE. On the other hand, the softer LLDPE bubble can be drawn to thinner gauges and is more forgiving of imperfections and gels that would cause the LDPE bubble to tear off or break. It is commonly accepted that the strain hardening behavior of LDPE is the result of long-chain branches.

The common methods of processing LDPE are blown and cast film extrusion and coextrusion, extrusion coating, blow molding, injection molding, rotomolding, and wire extrusion. Explanations for these processes can be found in other articles in the Encyclopedia.

Economic Aspects

Despite threats from other polyolefins, such as HDPE, LLDPE, and *m*-LLDPE, LDPE remains a viable, high volume polymer (Table 7) (21). During the 1980s, no new LDPE capacity was added because of the assumption that low cost LLDPE would replace LDPE in most applications. However, while LLDPE did displace LDPE in many areas and did absorb most of the overall growth in the North American film market, LDPE remains the resin of choice in some applications and markets (Table 8) (21,22). The overall growth of LDPE demand remains very low (0–1% annually), and there is relatively little growth in LDPE capacity. The picture for LDPE in the rest of the world is not much different in terms of growth (Table 9) (21,23,24). LLDPE took longer to be accepted by the rest of the world because the supply was mainly located in North America for several years while LDPE was locally available. LDPE is still favored in many areas of the world because of its easy film processing. In many countries, film blowing equipment is

old and has been designed to handle the rheology of LDPE. Substituting LLDPE causes significant production rate penalties on film lines. Many film fabricators had resorted to blends of LDPE with small amounts of LLDPE to improve film toughness without sacrificing extrusion rates.

Looking forward, continued substitution of LLDPE and HDPE for LDPE will take place. As older film extrusion equipment is replaced or retrofitted to handle LLDPE, the consumption of LDPE will decrease. The two attributes of LDPE which, as of today, have not been satisfactorily met with LLDPE are the long-chain branching and the flexibility and properties of polar comonomer

containing copolymers. But even these attributes are under attack with new technology. Some metallocene catalysts, which give very narrow molecular weight and narrow comonomer distribution LLDPE, also show the presence of long-chain branching (25). When the type and level of long-chain branching can be controlled by these catalysts, applications such as extrusion coating will be vulnerable to LLDPE substitution. Another category of new polyethylene catalysts is based on late transition metals, such as Fe and Ni. These catalyst systems give the promise of the ability to incorporate polar comonomers (26).

Pricing in the polyethylene market is extremely volatile. Because of the significant economies of scale, when new ethylene and polyethylene capacity is added, it is in very large increments. This overwhelms the regular, but modest, growth in consumption so that a large imbalance in supply versus demand occurs when the new plant starts up. When there is an overabundance of supply, prices are very low as all producers struggle to keep their facilities sold out. This condition lasts a few years until the demand catches up to the supply and prices start to rise. However, as soon as prices start increasing, new capacity is announced and the cycle starts all over. Typical low density pricing in North America will vary from US$600/ton to over US$1100/ton through the cycle (27).

Specifications and Standards

There are about 10 manufacturers of LDPE in North America. The top six include Equistar Chemicals, LP, The Dow Chemical Co., Exxon Mobil Corp., Chevron Phillips Chemical Co., DuPont, and Westlake Polymer Corp. Each company has their own trade names and specific grade slates for various applications. Data sheets and MSDSs are available from each supplier and many have them available on their web sites. A typical product data sheet will cover resin characteristics such as melt index and density, as well as 'typical' final product properties, such as film tear and tensile and impact strength. The tests will identify the ASTM test methods and the data sheet will usually have the conditions under which the test samples were made. There will also be an indication of the FDA and food contact status of the resin and the applications for which the resin is suited.

A majority of the LDPE used in North America is shipped in 82-ton rail cars. Other common forms of shipment are 18-ton bulk trucks, 500-kg boxes, and 25-kg bags. In general, no special safety labels are needed for LDPE products. In other parts of the world, the most common mode of shipment is in 25-kg bags.

Analytical and Test Methods

The most important tests for LDPE are those that measure the molecular characteristics of the resin: molecular weight, molecular weight distribution, and density. Since long-chain branching is unique to LDPE, a short description of the analytical test methods used to measure it is given. However, because of the difficulty and lack of precision of the tests, measurement of long-chain branching is not

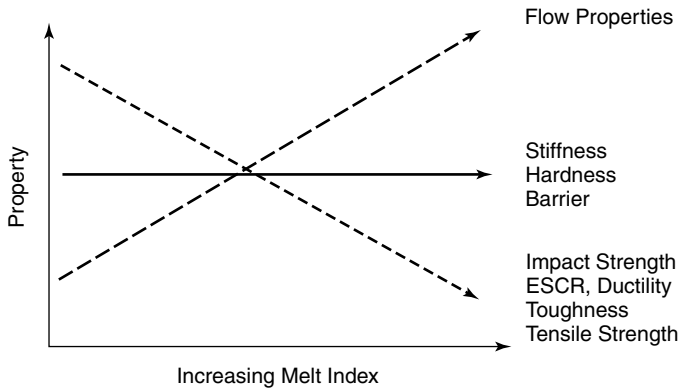

Fig. 6. Effect of molecular weight on LDPE properties.

commonly done as a quality control test. The measurement and reporting of gels, or film imperfections, are covered.

Melt Index. The melt index of a polymer is a measurement that is inversely related to molecular weight. ASTM D1238 is typically used for this test. A small amount (less than 10 g) of LDPE is melted and forced through a small orifice under constant load. The weight of polymer extruded in 10 min under 298 kPa pressure at 190°C is called the melt index. If a pressure of 2982 kPa is used, the measurement is called the flow rate (FR) or melt-flow rate (MFR). Typical LDPE melt indices range from 0.2 to over 100 g/10 min. In general, the lower melt index resins are used for film and blow molding and wire and cable applications while the higher melt index resins are used for extrusion coating and injection-molding applications. Low melt index resins have higher molecular weight than high melt index resins. The higher the molecular weight, the better the strength properties of the final products, but the more difficult the extrusion behavior (Fig. 6).

Flow Rate Ratio. The FR ratio is used as a rough estimate of the MWD of a resin. Molecular weight distribution can be measured directly by gel permeation chromatography, but this is a time-consuming, technically challenging measurement that is not commonly found in quality control laboratories. Melt-flow ratio measurements are easily done, since the MFR of a resin is the flow index of the sample divided by the melt index of the sample.

Melt-flow ratios for LDPE resins can range from very narrow [20] to very broad [100], and can be controlled by reactor conditions and reactor type. Resins with narrow MWD give stronger products but are more difficult to extrude than resins with broad MWD.

Density. ASTM D1505 is used to measure polymer density. A small sample (1–5 g) of powder or pellet is molded in a carefully prescribed manner and dropped into columns with alcohol/water gradients of different viscosities. The position of the sample in the column is compared with standards of known density, and the density of the test sample is determined.

Density is a measure of the crystallinity of the polymer. Polymer crystallinity affects such product properties as stiffness, rigidity, environmental stress-crack

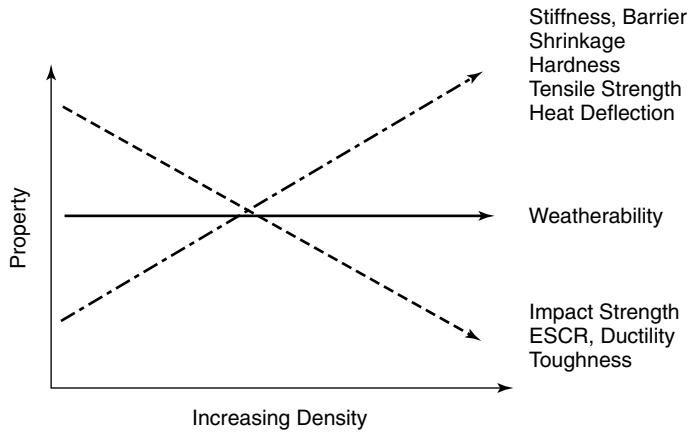

Fig. 7. Effect of density on LDPE properties.

resistance (ESCR), and barrier properties (Fig. 7). The lower the crystallinity, and hence the density, the more limp and flexible the material is. A 0.918-g/cm^3 density LDPE product has better ESCR and worse barrier properties than a product with a density of 0.930 g/cm^3.

Long-Chain Branching. The number of long-chain branches per 1000 carbon atoms on the main backbone of LDPE can range from 0.4 to over 10. Long-chain branching has been a very difficult feature to quantify. The variations in the lengths and locations and branch points for the long-chain branches make comparison of data and standardization of samples difficult. Qualitatively, the presence of long-chain branching can be surmised by looking at intrinsic viscosity as a function of molecular weight. Linear polymers give a linear response of intrinsic viscosity as a function of molecular weight. If the intrinsic viscosity of a resin with long-chain branching is plotted on this same graph, it will fall below the line for the linear polymers. However, the quantitative information on the amount and length of the long-chain branching has been difficult to extract from this method. The ^{13}C nmr analysis has been used to quantify the number of long-chain branches (28,29); however, there are some limitations to this method as well. In ^{13}C nmr, any branch longer than six carbon atoms is considered a long branch (30). Combinations of methods, such as ^{13}C nmr plus sec (size exclusion chromatography) (31,32) and sec plus intrinsic viscosity (33), are being developed to overcome the deficiencies of single-method determinations.

Gels. While gels are neither a physical property nor a reported attribute of LDPE, the gel level is a critical quality variable for LDPE film resins. Gels are physical defects which can affect the appearance, but more importantly, the performance of LDPE film. There are many forms of gels, ranging from arrowheads, pinpoint gels, black specks, and fish-eyes. Gels can be caused by many factors. Gels can be formed in the reactor by poor mixing in a reactor zone. If polymer builds up on the reactor wall, it can cross-link to form high molecular weight gels or even black specks. The compounding or pelletizing step can also cause cross-linking and gels if not cleaned and operated properly. Most resin manufacturers

will run a film quality test on LDPE resin to ensure that the gel level is low in the product before certifying it as prime material.

However, gels can be caused in the material after it has left the resin producer. Extraneous materials, like dirt, fibers, or contamination with other polymers, can occur during shipment or unloading at the fabricator. In addition, gels can be created during extrusion into film by improper film blowing conditions or inadequate maintenance and cleaning of film blowing equipment.

Gels can be analyzed by a variety of techniques to determine their origin. A simple melting point can determine if the gel is polymeric or cross-linked. Infrared spectroscopy can determine the nature of the polymer to determine if cross-contamination with another material has occurred. Conducting the melting point under a microscope can reveal if there is a solid core to the gel which might indicate a foreign contaminant. Electron microscopy can hone in on the gel and measure the presence of any metal that might indicate barrel or screw wear or totally foreign materials like bolts or nails. Because gels are an important quality issue and can be caused by a variety of mechanisms, resin producers have developed sophisticated analytical methods to identify the gels so that improvements can be made in resin production and handling to prevent them.

The reason gels are a critical quality factor with LDPE film is that they can cause problems in film extrusion and in film performance. If the gels are large enough, they can actually cause the bubble to break during the blown film process. "Bubble tear-offs" are a serious problem for the film fabricator because it causes down time and loss of product quality. If the gels are not large enough to cause problems during the extrusion process, they can still cause problems for film quality. In extrusion coating, for example, the presence of small gels in the very thin layer of polyethylene can cause pinhole leaks in the coating and destroy the barrier performance of the material. In wire and cable applications, the gel can form a weak spot in the wire coating, which will be the initiation point for electrical failure.

Health and Safety Factors

The majority of homo- and copolymer LDPE is supplied in small pellet form and is consider a material with low toxicity, low reactivity, and low flammability. However, during movement of the pellets in a conveying system, fines and dust can be created as the pellets come in contact with the piping system. If these fines build up in the system, the potential for a dust explosion exists. In addition, polyolefin powders are supplied for certain applications, such as rotomolding or coating. These polyolefin powders also pose fire and explosion safety concerns. Polyolefin dust is defined as a combustible material in the "Standard for the Prevention of Dust Explosions in the Plastics Industry" (NFPA 654). Concentrations of polyolefin powder as low as 0.02 kg/m^3 can burn, releasing sufficient heat to produce a self-propagating reaction that can result in an explosion (34). This explosive concentration is dependent on the particle size of the powder and also on the type and concentration of any additives used in the polymer. The material supplier should always be consulted for advice on handling dust and powders from LDPE.

Polyolefin dust is currently classified as a nuisance material. Polyolefin materials have a long history of safe use and are not thought to produce irreversible change in lung tissue or produce significant disease or toxic effects when exposure is kept under reasonable control. The Occupational Safety and Health Administration (OSHA) and the American Conference of Governmental Industrial Hygienists (ACGIH) have established permissible exposure limits of 15 and 10 mg/m^3 of air, respectively, for total nuisance dust, and 5 mg/m^3 for the respirable fraction.

Food Contact. Homopolymer LDPE is a relatively inert, nontoxic and benign polymer, which is used extensively in a variety of food contact and medical applications. Copolymers containing EEA, EMA, EVA, and other comonomers can also be used selectively in food contact applications. The resin supplier should be asked for specific information on FDA compliance for each particular resin, as the type of polymer, the amount of comonomer, and the type and level of additives

and stabilizers all play a part in determining the FDA compliance of a specific resin.

Environmental Impact. In recent years, there has been quite a bit of adverse publicity around the use of plastics and the impact of plastic litter on the environment. The decision of fast food restaurants to discontinue the use of expanded polystyrene clamshell hamburger containers is one example of how plastics growth and use can be changed by public opinion. Many states have considered or passed regulations specifying the amount of recycled plastic that must be incorporated into new plastic articles. This has had a direct impact on the polyethylene industry, including LDPE, because polyethylene is one of the more recyclable plastics being used today. However, the recycling effort has been

hampered by the higher cost of collecting, separating, and cleaning the polyethylene containers compared to the cost of virgin polymer.

Photo- and biodegradable plastics have been offered as possible solutions to the litter problem. LDPE copolymers containing carbon monoxide have been produced by Union Carbide Chemical and Plastics Co., Inc. (35) and The Dow Chemical Co. These photodegradable copolymers have been used to make beverage can carriers or rings but have not been widely used in other commodity applications because of the unique physical properties. Currently, the search for biodegradable LDPE has not led to a commercially successful product. Blends of LDPE and starch-like fillers improve the biodegradation of LDPE, but at a significant sacrifice of physical properties (36). A new degradable/compostable technology has been developed, such that the degradability can be triggered by heat, light, and/or stress. Products made by this technology are being currently marketed in Europe and South America (37).

Plastic pellets inadvertently lost from plastic production and warehouse facilities pose a threat to fish and wildlife. Therefore, the U.S. EPA (Environmental Protection Agency) has classified plastic pellets as "significant materials.". The finding of even one pellet in a storm water run-off without a permit is now subject to federal regulatory action with the potential for substantial fines and penalties. As a result, the plastics industry has launched Operation Clean Sweep, an initiative to prevent the accidental release of pellets into the environment. Specific recommendations for handling polyolefins to prevent resin loss into the environment have been developed by the Society for the Plastics Industry (38).

From a polymerization process standpoint, fugitive hydrocarbon emissions, mainly ethylene, are the biggest environmental concern. Much progress has been made in controlling these emissions by recovering and recycling gas from various points in the process. Using advanced process control software and better

instrumentation, runaway reactions or "decomps" have been significantly reduced. These "decomps" are typically vented to the atmosphere and so this improved control has resulted in fewer hydrocarbons being released. On a positive side, many polymerization units capture the heat of polymerization from the reaction and use that to generate low pressure steam. This reduces the need for electrical power to run the process.

Uses

Film and Sheet. The film and sheet market is the largest application for low density polyethylene, consuming about 50% of the total North American demand (Table 8). Packaging applications include pallet and shrink wrapping, heavy-duty sacks, and food packaging. Nonpackaging applications comprise refuse bags, storage bags, agricultural film, and industrial sheeting. The film market has been the primary focus of LLDPE manufacturers, and LLDPE now accounts for over 50% of the low density film market (Table 7). At one time, garbage bags, grocery sacks, garment bags, stretch film, and food packaging films were made from 100% LDPE, but because of the outstanding physical properties of LLDPE, these markets have largely been converted to LLDPE or LLDPE-rich blends of LDPE. There are still a few film applications where LDPE remains the resin of

choice: shrink wrap, clarity films, etc. The advantages of LDPE in film are ease of extrusion, clarity, and low taste and odor. Typical resins used for film have melt indices from 0.2 to 6 and densities from 0.917 to 0.930 (Tables 10, 11, 12).

Extrusion Coating. In extrusion coating, LDPE is used as a thin coating on another material, such as paper, aluminum foil, paperboard, or another polymeric material. The final structure is used for snack food packaging, juice boxes, milk, or other food containers. The LDPE can serve as an adhesive, moisture barrier, seal layer, printing surface, or barrier to tearing. Typically, resins with melt indices from 4 to 10 and densities from 0.920 to 0.930 are used in this application (Tables 13, 14, 15). This is one market where LLDPE has not made significant penetration. The unique long-chain branching characteristics of LDPE, especially that produced in autoclave reactors, has not been duplicated by LLDPE manufacturers. This long-chain branching gives LDPE the combination of neck-in and drawdown necessary for successful high speed extrusion coating.

Wire and Cable. Radar sheathing cable was one of the first commercial uses for LDPE. Currently, about 10% of LDPE production is used in wire and cable applications. The cleanliness of LDPE insofar as its lack of gels or inorganic catalyst residues is a key advantage in high energy wire sheathing. The ease of extrusion is also another advantage of LDPE, as wire coating lines run at very high speeds. Many resin producers offer wire and cable resin, which has been pre-compounded with a variety of colors, including black (Table 16). Some wire and cable manufacturers prefer to add color themselves. Typical resins used for wire and cable are very similar to film resins in the melt index and density ranges employed (Table 17).

Injection Molding. This market, which includes lids, buckets, toys, freezer containers, has seen significant penetration by LLDPE. LLDPE offers advantages in product properties such that higher melt index products can be used without sacrificing product performance. The use of the higher melt indices allows the fabricator to increase production speed and reduce costs. The markets where LDPE

is still used are those in which some clarity is desired, such as caps and closures (Table 18).

Blow Molding. HDPE is the preferred resin for blow molding because of its combination of rigidity and barrier properties. LDPE is less commonly used, but does offer advantages in applications where clarity, flexibility, and excellent ESCR are required. Typically, low melt index resins are used for blow molding applications (Table 19).

ETHYLENE POLYMERS, LLDPE

Introduction

Linear low density polyethylene (LLDPE) was first commercialized in the late 1970s by Union Carbide and Dow Chemical. Since that first introduction, LLDPE has seen the fastest growth rate in usage of the three major polyethylene families—low density polyethylene (LDPE), LLDPE, and high density polyethylene (HDPE)—and now comprises approximately 25% of the annual production of polyethylene around the world, approaching 13 million metric tons. Conventional LLDPE differs from LDPE by having a narrower molecular weight distribution and by not containing long-chain branching. LLDPE is made by the copolymerization of ethylene and α-olefins. Significant research and development efforts were conducted throughout the 1980s to tailor LLDPE properties by controlling molecular weight distribution and comonomer distribution. In the early 1990s, the LLDPE industry was revitalized with the introduction of several new product families, including novel single-site-catalyzed very low density polyethylenes (VLDPE) called plastomers (Exxon, 1991, and Dow, 1993), super-hexene LLDPE (Mobil, 1993), and metallocene-catalyzed LLDPE(mLLDPE) for commodity applications (Exxon, 1995) (see SINGLE-SITE CATALYSTS). Work continues by resin companies around the world on new classes of LLDPE for a variety of applications.

Molecular Structure and Properties

Comonomer Type and Content. Although practically any α-olefin from C_3 to C_{20} can be used as comonomer for LLDPE, the four most commonly used are 1-butene, 1-hexene, 4-methyl-1-pentene, and 1-octene. Approximately 40% of

Table 1. Comonomer Content and Density Ranges for Commercial LLDPE Resins

Family	Common name	Comonomer, mol%	Crystallinity, %	Density, g/cm^3
Medium density	MDPE	1–2	55–45	0.940–0.926
Low density	LLDPE	2.5–3.5	45–30	0.925–0.915
Very low/ultra low density	VLDPE/ULDPE	>4	<30	<0.915
Very low density (single-site catalyzed)	Plastomer	≤25	0–30	≤0.912

LLDPE made uses 1-hexene as comonomer, approximately 35% uses 1-butene, and approximately 25% uses 1-octene. Only a small fraction is made using 4-methyl-1-pentene. Hexene and butene copolymers are more prevalent because they are less expensive than octene and because they are commonly used in the gas-phase process, which accounts for most of the global LLDPE production. For LLDPE, density is strongly controlled by comonomer content. Conventional LLDPE basically covers the density range of 0.915–0.940. Within that density range, and also lower density ranges, there are common product family subsets. Table 1 shows comonomer content and subsequent density ranges for commercial LLDPE.

Chain Structure. LLDPE comprises linear molecules of ethylene and α-olefins and can be generally represented by the formula $-CH_2-CH_2-CH_2-CH-(C_{n-2}H_{2(n-2)+1})$, where n is the number of carbon atoms in the α-olefin. In LLDPE above 0.915 g/cm^3 density, most of the branching due to comonomer is randomly distributed along the polymer backbone, although there may be some adjacent comonomer units. Single-site-catalyzed resins have comonomer much more uniformly distributed along the polymer backbone than do conventional LLDPE resins. A conventional gas-phase hexene copolymer LLDPE at 0.918 g/cm^3 density has approximately 18 branches per thousand carbon atoms while a single-site-catalyzed gas-phase hexene copolymer LLDPE at the same density has 11–12 branches per thousand carbon atoms. In the single-site-catalyzed resins, the hexene is more randomly distributed along the backbone, shortening the average backbone sequence length for crystallization, and therefore less comonomer is needed to achieve the same density.

Most LLDPE chains have at least one methyl ($-CH_3$) group at one chain end. Other chain ends can be a methyl group from termination from chain transfer, or a vinyl group ($CH_2=CH=$) or vinylidene group ($CH_2=C\!\!<$) from termination from β-hydride transfer (1).

Generally speaking, LLDPE resins do not contain long-chain branching. However, certain families of plastomers may contain more than 0.01 long-chain branches per thousand carbons (2).

Composition. A representative schematic of the structural differences between LDPE, LLDPE, and single-site-catalyzed LLDPE is given in Figure 1.

LDPE contains a mixture of long-chain branching and short-chain branching. LLDPE contains only short-chain branching, but that branching is not uniformly distributed through the molecular weight. LLDPE made using Ziegler–Natta catalysts tends to have more comonomer in the lower molecular weight fraction and less in the high molecular weight fraction (3,4). A temperature rising elution

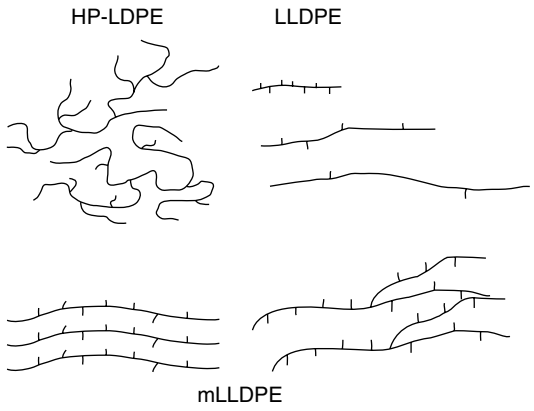

Fig. 1. Structural differences between LDPE, LLDPE, and single-site-catalyzed LLDPE.

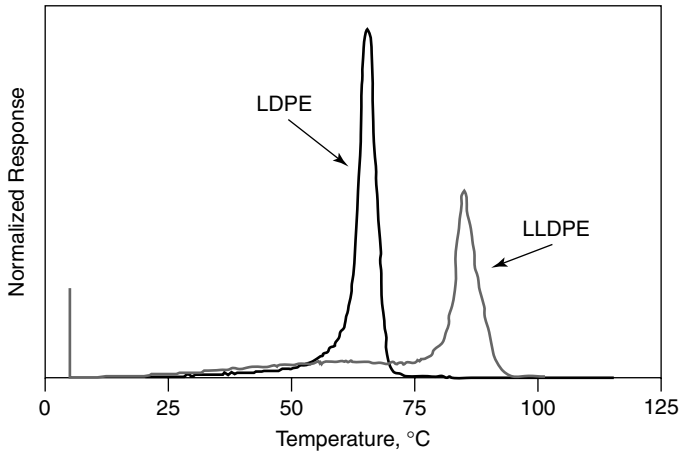

Fig. 2. LDPE and LLDPE TREF comparison.

fractionation (TREF) plot for LDPE at 0.919 g/cm^3 and LLDPE at 0.918 g/cm^3 is shown in Figure 2.

As you can see, the peak elution temperature for the LDPE is much lower and the peak is much narrower than that for the LLDPE. This indicates that the LLDPE is more compositionally heterogeneous than the LDPE.

The first commercially available single-site-catalyzed polyethylenes were very low density resins called plastomers (5,6), which had high levels of comonomer and were very homogeneous. Later, commercial commodity grade mLLDPEs were not quite as homogeneous as the plastomers, but were still more homogeneous than LLDPE (7–9). Figure 3 shows a TREF plot of an LLDPE at 0.918 g/cm^3 density and an mLLDPE at 0.917 g/cm^3 density, both produced in the gas phase. Also included is a plastomer at 0.900 g/cm^3 density produced in a slurry reactor.

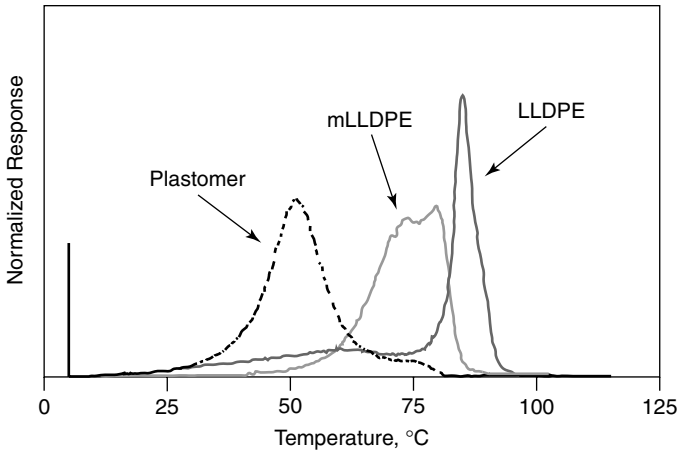

Fig. 3. TREF profiles for LLDPE, mLLDPE, and plastomer.

A polymer that has branching more uniformly distributed along the polymer backbone will have shorter sequence lengths for polymer crystallization. Shorter sequence lengths result in thinner crystals that dissolve and elute at lower temperatures than thicker crystals. The mLLDPE has a lower peak elution temperature than LLDPE at the same density, indicating that mLLDPE is more compositionally homogeneous. The plastomer has a peak elution temperature of approximately 50°C and a very narrow peak indicating that the resin is very compositionally homogeneous.

Molecular Weight. Commercially available LLDPE resins can have weight-average molecular weights from less than 20,000 to over 200,000. *Melt index*, a measure of polymer flow through a specified die for a given time, is often used as an estimator of polymer molecular weight and is inversely proportional to weight-average molecular weight. An approximate correlation of weight-average molecular weight and melt index for LLDPE is shown in Figure 4.

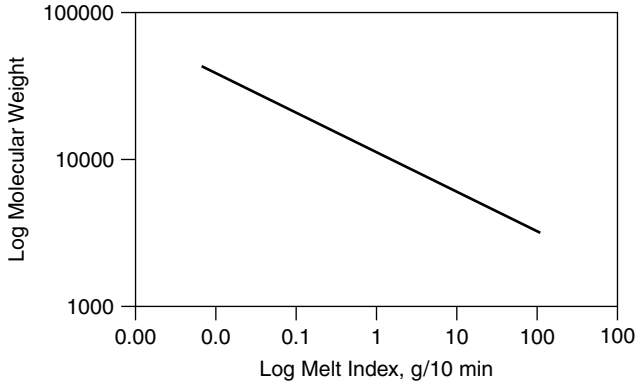

Fig. 4. Molecular weight/melt index correlation for LLDPE.

Table 2. Melt Index and Molecular Weight Data for LDPE and Several LLDPEs

Property	HP-LDPE	Gas-phase LLDPE	Gas-phase mLLDPE	Plastomer	
				Slurry	Solution
Melt index I_2, g/10 min	1.0	1.0	1.0	1.1	1.0
MIR I_{21}/I_2	60	33	17	21	31
M_n, g/mol	22,000	28,000	44,000	46,000	40,000
M_w, g/mol	104,000	107,000	102,000	99,000	82,000
PDI, M_w/M_n	4.7	3.8	2.3	2.2	2.1

Over the range shown, the relationship between molecular weight and melt index is linear but will not be completely linear over a broader range. Commercially available film grade LLDPE resins can range from 0.2 g/10 min to over 5 g/10 min melt index. Injection-molding grades vary in melt index from approximately 10 g/10 min to greater than 125 g/10 min. Table 2 shows measured molecular weights and melt-flow properties for several LDPEs and plastomers at nominal 1 g/10 min melt index.

Molecular weight distribution plots for the resins in Table 2 are given in Figures 5 and 6.

Depending on the standards used for calibration of the molecular weight fractionation technique, LLDPE has a molecular weight polydispersity index (PDI, M_w/M_n) between 3 and 4.5 with melt index ratios (MIR, I_{21}/I_2) of 20–35. LDPE has PDI usually greater than 5 and contains long-chain branching. Therefore, although the LDPE and LLDPE resins shown have similar weight-average molecular weights and melt indices, their MIR (I_{21}/I_2) values are significantly different. The higher MIR for LDPE indicates greater sensitivity to shear caused by the broader PDI and long-chain branching.

The single-site-catalyzed mLLDPE and slurry plastomers have much narrower molecular weight distributions and therefore have much lower MIR values

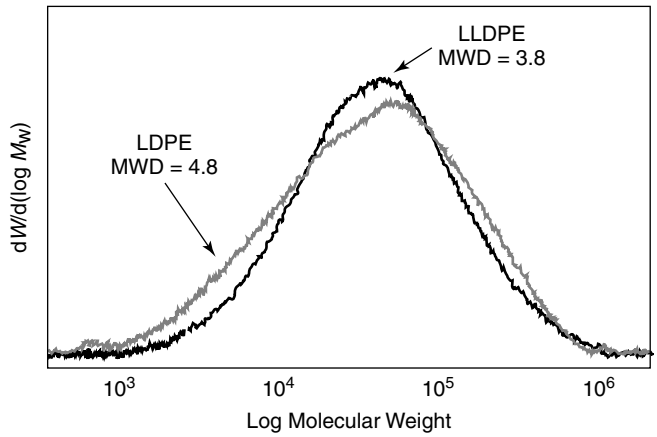

Fig. 5. Molecular weight distribution plots for LDPE and LLDPE.

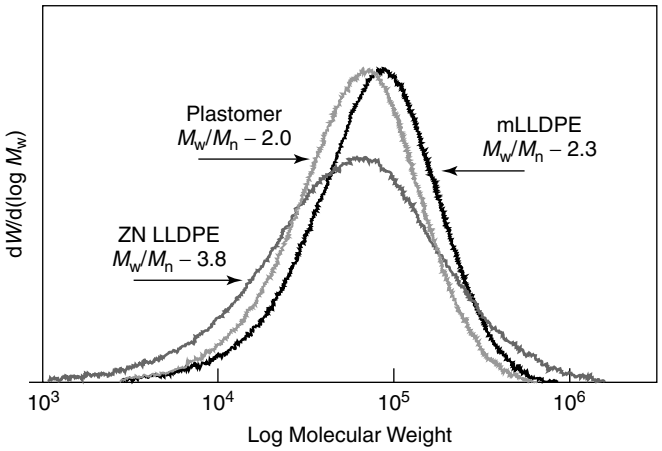

Fig. 6. Molecular weight distribution plots for LLDPE, mLLDPE, and a plastomer.

than LLDPE. The plastomer produced in solution phase has trace levels of long-chain branching that make it more sensitive to shear, giving it a higher MIR than the linear plastomer. A narrower PDI for the single-site-catalyzed resins means a smaller low molecular weight fraction commonly called hexane extractables, which can be a limiting factor for LLDPE use in food contact applications.

There is a relatively small volume of LLDPE resins made using chrome-based catalysts that have much broader PDI, 10 and higher, and MIR values of 70 and higher. Chrome-based LLDPEs are mostly used in wire and cable coatings, blow molding, and some film applications.

Chemical Properties. LLDPE is a saturated hydrocarbon and is generally unreactive. The most reactive parts of the polymer molecule are tertiary carbons at short-chain branch points and double bonds at chain ends. LLDPE is stable in alcohols, alkaline solutions, and saline solutions. It is not attacked by weak organic or inorganic acids. Reactions with concentrated sulfuric acid (H_2SO_4, >70%) at elevated temperatures can result in the formation of sulfo-compounds. LLDPE can be nitrated with concentrated nitric acid (HNO_3). Fuming nitric acid is also used in analytical techniques to etch away amorphous polyethylene. At room temperature, LLDPE is not soluble in low molecular weight solvent although very low molecular weight and very low density fractions may be extracted. At higher temperatures, LLDPE can be dissolved in certain aromatic, aliphatic, and halogenated hydrocarbons including xylenes, tetralin, decalin, and chlorobenzenes.

Physical Properties. All polyethylene above 0.86 g/cm^3 density is semicrystalline. The basic crystalline structure for most commercial LLDPE is chain-folded lamellae (Fig. 7). The body of the crystal consists of polymer backbone segments, and the surfaces are a collection of chain folds, loose cilia, and tie chains (chains incorporated into more than one crystal). When crystallized isothermally, it has been found that 95% of the lamellae in a given sample are within 5% of the same thickness (10). There is some debate over the mechanism of chain folding and of the subsequent fold loops. The most likely model includes adjacent reentry, loose adjacent reentry, and nonadjacent reentry. Short-chain branch length

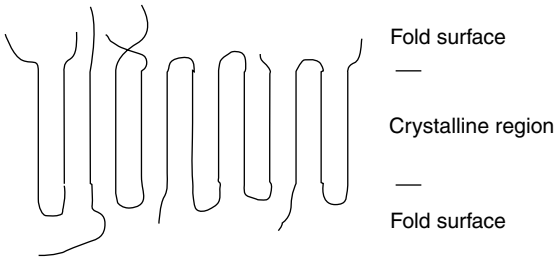

Fig. 7. Schematic of chain-folded lamellar structure.

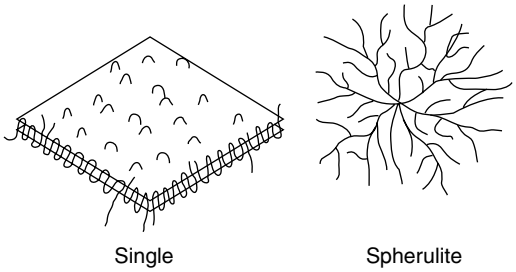

Fig. 8. Single crystal and spherulitic structures.

plays an important role in determining backbone flexibility for chain folding and subsequently fold loop size. Longer short-chain branches sterically hinder chain folding and therefore cause longer fold loops and increased numbers of tie chains. It has been found that a minimum sequence length of 14 carbons is needed for ready incorporation into a crystal lattice (11). The most stable crystalline form for polyethylene is orthorhombic with unit cell dimensions of $a = 7.42$ Å, $b = 4.94$ Å, and $c = 2.55$ Å. Research has shown that the chain axis is inclined at an angle of 30–45° to the crystal surface (12,13).

From very dilute solution ($\leq$0.1% weight or volume) single, lozenge-shaped crystals are formed (Fig. 8). They have similar relative dimensions as a sheet of paper, Angstroms thick and microns in lateral dimensions. Cooled from an unstressed melt, LLDPE forms spherulitic structures, also shown in Figure 8. Spherulites form from a defect or nucleation site and are essentially ribbon-like lamellae radiating out from a central point. They begin as sheaf-like structures and grow into spherical shapes. Regions between lamellae are amorphous chain segments and tie chains (14,15). The tie chain density between lamellae plays a dominant role in determining mechanical properties.

It is now widely accepted that LLDPE will form row nucleated, a.k.a. "shish-kebob", structures when crystallized in a melt subjected to a deviatoric stress, such as film extrusion (16–21). As given in Figure 9, a core of linear higher density polymer forms in the direction of stress (machine direction in film applications), and lamellae grow radially. Space between lamellae is filled with amorphous chain segments and tie chains. Some plastomers below 0.89 g/cm^3 density will form a fringed micellar morphology because of the very short backbone sequence length between branch points (22,23).

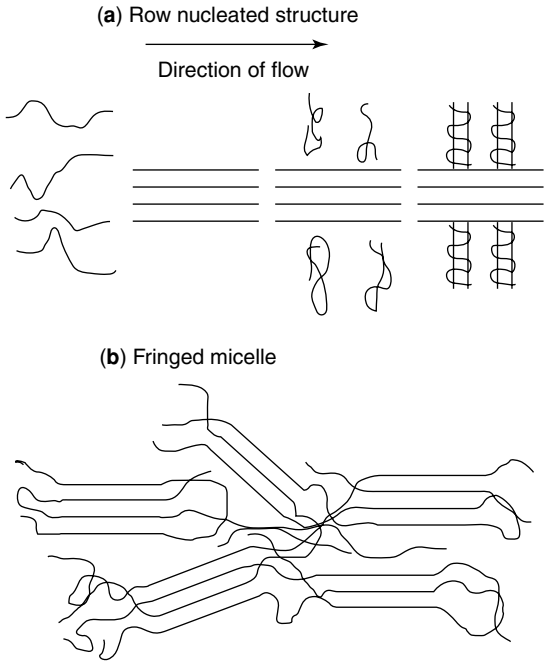

Fig. 9. (**a**) Row nucleated and (**b**) fringed micelle structures.

Polymer crystals are rarely perfect and can include chain ends, voids, and at times short-chain branches. As it is generally concluded that the ethyl branch from butene comonomers can be incorporated into the crystal lattice (24–28), this may explain why longer comonomers give LLDPEs with improved properties. Hexene and octene comonomers are more likely to produce large fold loops or tie chains that improve toughness. Quick quenching from the melt also provides less perfect crystals and may allow longer branches to be included in the crystal lattice (29).

As mentioned earlier, LLDPE has a heterogeneous composition and a higher density fraction with minimal branching. Because of this higher density fraction and its thicker crystals, the maximum melting peak in the relatively broad melting range of LLDPE usually falls between 122 and 128°C and is somewhat independent of comonomer-type. Even nonuniform VLDPE resins can have a melting point above 120°C. LDPE has thinner crystalline lamellae than LLDPE and therefore has a lower melting point as shown in the differential scanning calorimetry (dsc) profiles in Figure 10. Homopolymer LDPE usually has a melting point between 105 and 115°C.

Because of its lower melting point, LDPE has been preferred over LLDPE for many heat-sealing applications. mLLDPE and plastomers are more compositionally homogeneous than LLDPE. Shorter backbone sequence lengths for crystallization results in thinner crystalline lamellae and therefore lower melting points (Fig. 11).

mLLDPE produced in the gas phase and several produced in the slurry phase have peak melting points of 115–118°C. Plastomers have peak melting

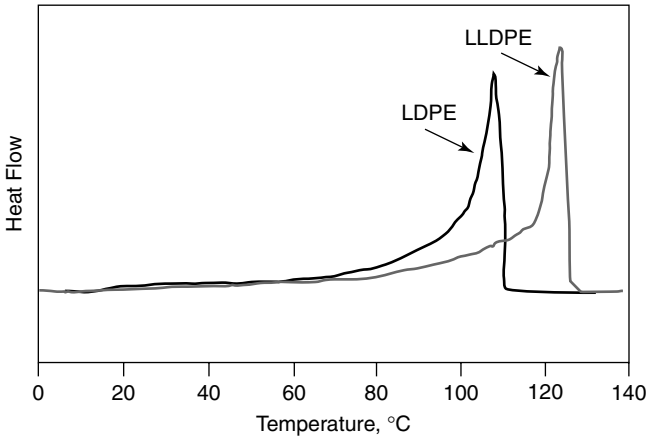

Fig. 10. The dsc melting profiles for LDPE and LLDPE.

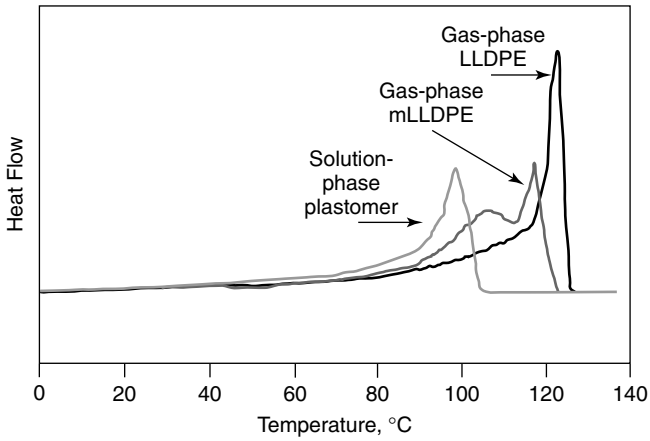

Fig. 11. The dsc melting profiles for LLDPE, mLLDPE, and a plastomer.

temperatures below 100°C. Lower melting points make single-site-catalyzed LLDPEs ideal for use as heat seal layers in many applications. Figure 12 shows heat seal strengths for LLDPE and mLLDPE, both at 0.917 g/cm^3 density, and a 0.900 g/cm^3 density plastomer produced in a high pressure reactor. All have nominal 1 g/10 min melt index. The single-site-catalyzed resins have lower seal initiation temperatures and generally have higher hot tack strengths, which allows for shorter dwell time and faster line speeds.

As with all polymers that are at least partially amorphous, polyethylene has a glass-transition temperature T_g where the transition from brittle solid to viscoelastic material occurs. There is still disagreement as to the actual T_g for polyethylene and researchers have proposed different temperatures of $-30 \pm$

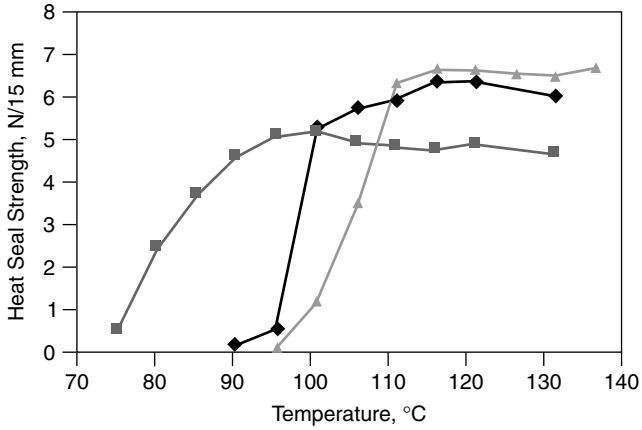

Fig. 12. Heat seal strength comparison for LLDPE, mLLDPE, and plastomer. To convert N/15 mm to ppi, divide by 2.625. –△ LLDPE–; –◇ mLLDPE–; –■ Plastomer–.

15°C (30,31), −80 ± 10°C (32), and −128 ± 5°C (33,34). Above the melting point, polyethylene is a viscous liquid.

Polyethylene has a dielectric constant of 2.3 at 1 kHz which makes it suitable for use as wire and cable housing.

Mechanical Properties

Effects of Density. Decreasing the α-olefin comonomer content increases the amount of crystallinity in LLDPE. Increasing the amount of crystallinity increases the density of the polymer and has a significant effect on polymer properties. As crystallinity increases, LLDPE becomes stiffer and in general, less tough. Table 3 shows the effect of increasing density in LLDPE blown films.

Only a seemingly small increase in density, 0.005 g/cm^3, can dramatically alter mechanical properties. Dart impact and puncture resistance are significantly reduced while tensile yield and modulus increase. For resins produced using the same catalyst and process, more crystallinity means more, larger light-scattering bodies in the film and a rougher film surface causing film haze to increase and surface gloss to decrease. At the relatively low strain rates used to test film tensile properties, density alone does not significantly affect ultimate properties such as tensile strength or elongation at break.

Effects of Comonomer and Compositional Uniformity. Table 4 shows blown film mechanical properties for an LDPE, two gas-phase LLDPEs, and one gas-phase mLLDPE, all at the same nominal melt index and density.

The first two resin columns show general film property differences between LDPE and LLDPE. LLDPE has higher tensile strength than LDPE. Modulus is higher in LLDPE resins allowing for downgauging without sacrificing stiffness. LDPE films have higher machine direction (MD) tear at low blow-up ratios (BUR) while LLDPE films have higher machine direction tear at higher BUR. Transverse

direction (TD) tear is significantly higher in LLDPE. LLDPE has better dart impact strength than LDPE, although 0.25 g/10 min melt index LDPE will have dart impact strength approximately equal to 1 g/10 min melt index butene copolymer LLDPE. In general, LDPE has better optical properties, lower haze, and higher gloss than LLDPE. LLDPE, blended with a small amount of LDPE, 5–25 wt%, has dramatically improved optical properties. Improved mechanical properties in LLDPE are often related to microstructure, ie, increased tie chain density (36,37),

although there has been some work to suggest LLDPE contains a dispersed soft phase that leads to improved impact and fracture properties (38).

In general, as side-chain branch length increases from methyl to ethyl to butyl (C_3 to C_4 to C_6 comonomer), mechanical properties improve. While comparisons between butene and hexene copolymer LLDPEs are relatively straightforward, it is difficult to compare them with the effects of octene comonomer on properties. Butene and hexene copolymers are usually made in the gas phase while octene copolymers are usually made in solution phase. Differences in polymerization medium and catalyst can create subtle, yet significant, differences in molecular weight distribution and compositional homogeneity that make it difficult to sort out the effects of comonomer alone on mechanical properties. Generally speaking, there is little difference in mechanical properties in films made from hexene and octene copolymer LLDPEs. When produced in the same process, hexene and octene copolymer LLDPEs have nearly equivalent mechanical properties that are significantly better than those for butene copolymer LLDPE (39).

Butene copolymer LLDPE has the poorest balance of mechanical properties of the commercially available resins. Replacing even a small amount of butene comonomer with a longer α-olefin can improve toughness properties (40). A butene copolymer LLDPE and hexene copolymer LLDPE, both made in the gas phase, are compared in Table 4. Even at thinner gauge, the hexene copolymer LLDPE has improved tensile, tear, and impact properties relative to the butene copolymer LLDPE.

Also included in Table 4 is a gas-phase process hexene copolymer mLLDPE. The mLLDPE has a narrow molecular weight distribution and is more compositionally homogeneous compared to a conventional LLDPE. A narrower molecular weight distribution gives improved tensile properties but lower tear resistance. Greater compositional uniformity produces smaller crystals resulting in lower tensile modulus, significantly improved impact strength, and lower film haze.

Properties for blown films made from two different plastomers are shown in Table 5. The plastomer made in the high pressure process has better overall toughness and optical properties than the plastomer made in the solution process.

Effects of Molecular Weight and Molecular Weight Distribution. Molecular weight has the largest effect on tensile properties. Table 6 shows that for resins of equal density, higher molecular weight (lower melt index) translates into higher tensile strength. There is no major effect on yield strength or MD tear resistance, but TD tear resistance and dart impact strength are improved.

Effects of molecular weight distribution in mLLDPE have been discussed previously. Subtle changes in molecular weight distribution can also have a significant effect on LLDPE properties. Super-hexene LLDPE resins produced in the gas phase have slightly narrower molecular weight distributions, 3.5 compared to approximately 4 for conventional LLDPE, and slightly improved compositional homogeneity. The combination of molecular weight distribution and composition can lead to dart impact strengths improved over 250% and MD tear resistance improved over 30% compared to conventional LLDPE of similar melt index and density (42,43).

LLDPE resins with broad molecular weight distributions made using chrome-based catalysts find application in blown films and some molding applications (44). Because of broader molecular weight distribution, they tend to be more

sensitive to orientation and therefore have less balanced properties compared to a conventional Ziegler–Natta-catalyzed LLDPE. The broad molecular weight distribution is a benefit in blow molding for having higher melt strength (for less sag) and higher environmental stress-crack resistance (ESCR) than LLDPE of similar molecular weight.

Effects of Orientation. Molecular orientation plays a significant role in determining physical performance of a finished article. In particular, film properties can be affected by processing conditions and their subsequent effects on

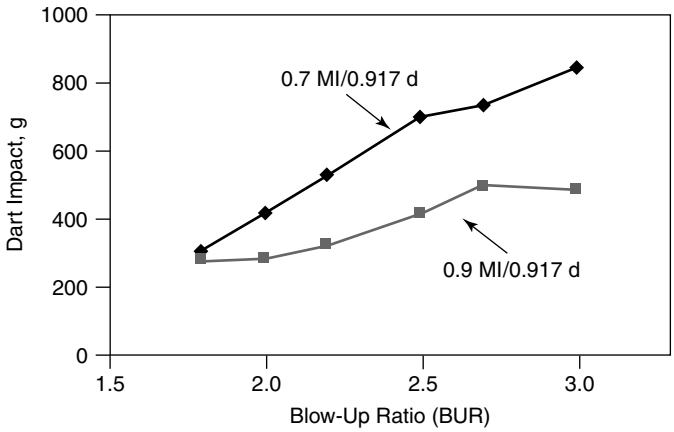

Fig. 13. Effects of blown film orientation on two LLDPEs.

molecular orientation. In general, polyethylene blown and cast films have predominant molecular orientation in the MD (41). LDPE films usually have more MD orientation than LLDPE films because of greater strain hardening behavior. Blow-up ratio (BUR) is a blown film process parameter used to control orientation. As BUR increases, molecular orientation in the MD is decreased and LLDPE blown film mechanical properties become more balanced. Impact strength is especially affected by changes in orientation. Figure 13 shows the effect of increasing BUR. In this example, output rate is held constant, BUR is increased, and line speed is reduced to maintain constant film gauge.

Catalysts for LLDPE Production

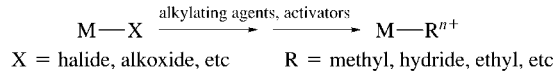
Central to the discovery and development of LLDPE has been transition-metal catalysis. However, because a given catalyst may be most useful for a different class of polyethylene or several classes, the following discussion will at times touch on other topics such as high density polyethylene (HDPE) or even polypropylene. Emphasis will be given to commercialized systems.

Almost two decades after ICI's commercialization of free-radical-polymerized LDPE in the 1930s, transition-metal catalysts proved capable to produce unbranched "linear low" density polyethylene (LLDPE) and linear "high density" polyethylene (HDPE), which had significantly different properties. Remarkably, the discovery occurred nearly simultaneously in three different research groups, using three different catalyst systems. First was Standard of Indiana's reduced molybdate on alumina catalyst in 1951 (46) followed by Phillips with chromium oxide on silica ("chromox") catalysts (47) and Ziegler's titanium chloride/alkylaluminum halide systems (48) in 1953. Only the second two were widely commercialized. This linear polyethylene is tougher than its predecessor and gave rise to entirely new markets, which are now larger globally than any other polymer. All these systems were characterized by low ethylene pressures (hundreds

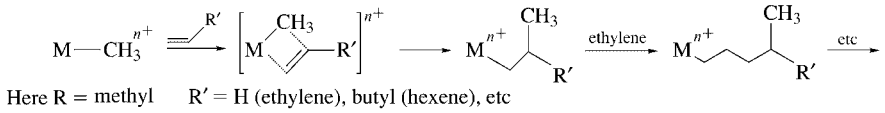
of psi vs tens of thousands for HPLDPE), broadened molecular weight distributions, the absence or strong reduction of the long-chain branches characteristic of high pressure polyethylene, and the ability to incorporate α-olefins including the production of polypropylene.

The following decades saw generations of refinements to the Ziegler system, the advent of vanadium catalysts, some "single-sited," mainly for the production of ethylene–propylene–diene-modified "rubber" copolymers (EPDM), the discovery of organochromium catalysts for HDPE, and the introduction of slurry loop and gas-phase heterogeneous process technology. In the early 1980s, the field was again revolutionized by Kaminsky's discovery of the methylalumoxane (MAO) activator that led to single-site behavior and phenomenal activities for metallocene catalysts. Others, particularly Exxon and Fina, soon showed that variation of the metallocene structure leads to variation in and exquisite control of catalyst–polymer properties. While MAO has an undetermined polymeric structure, it was shown that discrete "noncoordinating" anions which could stabilize metallocene cations produced equally active catalysts. Bercaw's linked cyclopentadienylamide ligands were shown by Dow ("constrained geometry catalysts") and Exxon to give high activity when bound to titanium (see as given later). While these two catalyst systems, metallocene and "constrained geometry," long seemed unique in giving defined, single-site polyethylene, the 1990s have given rise to numerous nonmetallocene catalyst systems, some of which may be commercially viable in LLDPE applications. The uniting feature of these metal-catalyzed systems is the hypothesis that a metal–carbon bond is formed into which olefins can repeatedly insert, creating polymers by a chain-growth mechanism.

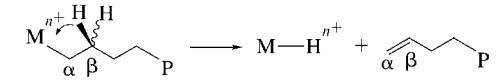
Mechanism of Metal-Catalyzed Polymerization. While the detailed mechanism of chain propagation may vary from system to system, most if not all are now believed to proceed by the Cossee–Arlman (49) mechanism in which an olefin monomer undergoes a concerted insertion into a metal–polymer chain bond via a 4-center transition state. Several fundamental steps describe the process. Initiation/Activation occurs when a metal center is transformed so that it is bonded to a group via carbon. A metal–carbon bond capable of inserting an olefin is created at the (usually cationic) metal center:



Propagation occurs when olefins insert into the metal–carbon bond, extending the chain. In the following the Cossee–Arlman transition state is shown:



Spontaneous termination of the chain occurs when a hydrogen on the beta carbon of the chain migrates to the metal creating a metal hydride, which can reinitiate, and a chain with an unsaturated end.



P = polymer chain

Chain transfer can occur to hydrogen, aluminum alkyls, or possibly even monomers, ending chain growth and initiating a new chain. Deactivation occurs by reaction with poisons or thermal decomposition of the catalyst center.

Standard of Indiana Catalyst. The first "low pressure" polyethylene catalyst invented (46), the Standard of Indiana catalyst system, saw relatively little commercial practice. Their 1951 patent discloses reduced molybdenum oxide or cobalt molybdate on alumina for ethylene polymerization, preferably in aromatic solvents. Later, work concerning the use of promoters was also disclosed.

Phillips Chromox Catalyst. Impregnation of chromium oxide into porous, amorphous silica–alumina followed by calcination in dry air at 400–800°C produces a precatalyst that presumably is reduced by ethylene during an induction period to form an active polymerization catalyst (47). Other supports such as silica, alumina, and titanium-modified silicas can be used and together with physical factors such as calcination temperature will control polymer properties such as molecular weight. The precatalyst can be reduced by CO to an active state. The percent of metal sites active for polymerization, their oxidation state, and their structure are the subject of debate. These so-called chromox catalysts are highly active and have been licensed extensively by Phillips for use in a slurry loop process (Fig. 14). While most commonly used to make HDPE, they can incorporate α-olefins to make LLDPE. The molecular weight distributions of the polymers are very broad with PDI > 10. The catalysts are very sensitive to air, moisture, and polar impurities.

Ziegler Catalysts. For his work in the discovery of a new class of highly active catalysts for polymerization of ethylene, propylene, and dienes, Karl Ziegler shared the 1963 Nobel Prize in Chemistry with Guilio Natta whose contributions were predominantly related to polypropylene. Today, these catalysts together with the Phillips catalyst are responsible for the majority of the world's polyethylene production. Loosely defined, Ziegler catalysts are polyethylene catalysts derived from transition-metal halides and main group metal alkyls (46,50–53). In modern

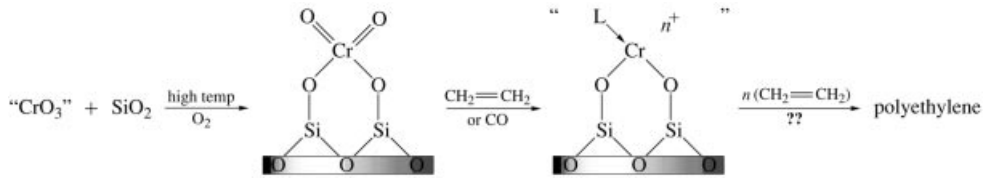


Fig. 14. Phillips' chromox catalyst. (Here "??" indicates that the actual mechanisms are as yet unknown.)

usage this generally means titanium (and sometimes vanadium) chlorides with aluminum alkyls or alkylchlorides. Numerous large research and commercialization efforts have progressed titanium-based systems through five or six generations, particularly for isospecific propylene polymerization. Most early systems used titanium halides with aluminum metal or aluminum alkylhalides to produce some form of crystalline $TiCl_3$, usually the alpha form, often with Al in the lattice. The Ti centers could be in +3, +4, and even +2 oxidation states. Aluminum alkyl cocatalyst was required for activity. In the next generation, large increases in activity were achieved by dispersing the titanium centers over crystalline $MgCl_2$, and this is now standard commercial practice. Modifiers, internal donors, external donors, and cocatalysts have been used to produce smaller $MgCl_2$ crystals, higher surface areas, poison undesired sites, control oxidation states, enhance activity, and otherwise change the catalyst performance. Silica or other porous supports are usually used to introduce the catalyst into heterogeneous processes. As with most heterogeneous systems (eg, organochrome and chromox catalysts) there are multiple active sites which may only be a fraction of the total metal centers. The exact structure and number of active sites is usually a topic of debate because of the problem of extremely active catalysts: they must be used in extremely low concentration and usually cannot be detected directly at "real world" conditions. Multiple sites lead to polyethylene chains with varying structures from chain to chain, though the typical molecular weight PDIs of 3.5–6 for Ziegler catalysts are still much narrower than the chromox catalysts. Some producers (eg, Dow and Nova) use these catalysts in solution, but most of the LLDPE volume comes from supported catalysts because of their use in the heterogeneous gas-phase processes extensively licensed by Union Carbide and British Petroleum. These catalysts are substantially less sensitive to air and moisture than chromium-based systems. Polyethylene molecular weight can be reduced by the addition of H_2, and α-olefin comonomers are copolymerized in order to lower the polymer's density.

Organochrome Catalysts. Like the Phillips chromox catalysts, the organochromium catalysts introduced by Union Carbide in the 1970s required an oxide support. Both disilyl chromates, $(R_3SiO)_2CrO_2$ (Fig. 15), and chromocenes, $(C_5H_5)_2Cr$ (Fig. 16), are believed to bond to an oxo functionality on the support ultimately leading to Cr^{2+} species. How these form the active species and its nature remain unproven. These catalysts have been licensed extensively in slurry-phase and gas-phase processes, but only for HDPE production because of negligible comonomer incorporation ability. Molecular weight distributions are broad, and hydrogen lowers molecular weight by chain transfer. These systems are very sensitive to impurities as with the Phillips catalyst.

Metallocene Catalysts. Although some commercial solution catalysts (eg, vanadium halide/alkyl aluminum EPDM systems) exhibited single-site behavior (eg, PDI = 2) earlier, metallocenes ushered in well-understood, finely tunable single-site polymerization capability on a far broader scale. Metallocenes are molecular transition-metal compounds containing the flat cyclopentadienyl ring bound "side-on" to the metal center. Shortly after their discovery in the 1950s, it was known that metallocenes could polymerize or oligomerize olefins in the presence of aluminum alkyl cocatalysts. By the 1970s, it had been found that small amounts of water increased the system's activity (48,54,55). Around this time, it was shown that unactivated, neutral Group 3 metallocenes could

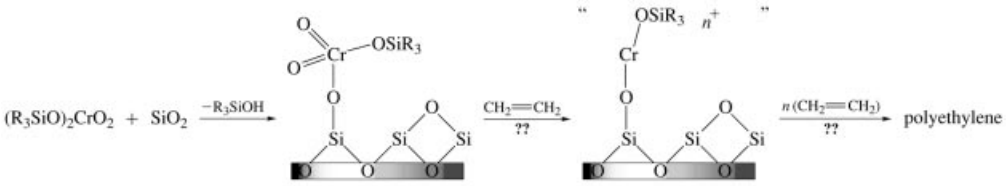

Fig. 15. Disilyl chromate catalyst. (Here "??" indicates that the actual mechanisms are as yet unknown.)

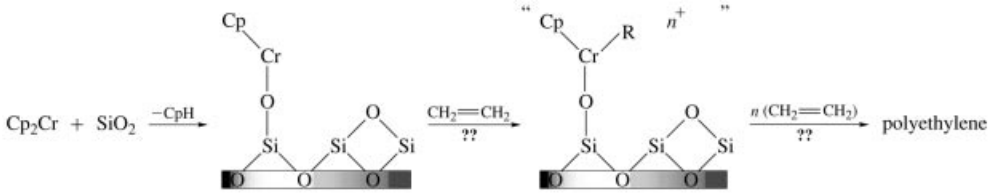

Fig. 16. Chromocene catalyst. (Here "??" indicates that the actual mechanisms are as yet unknown.)

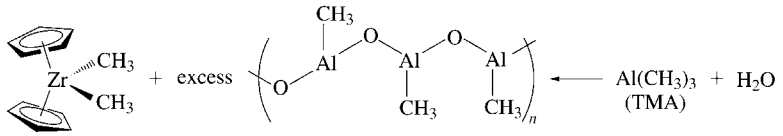
polymerize olefins to high molecular weight with narrow molecular weight distributions (56,57). Despite these many works demonstrating most of the major characteristics of the current state-of-the-art polymerization catalysts, the critical breakthrough came in the activator.

MAO—The Kaminsky Activator and Single-Site Catalysis. In 1976, Kaminsky, Sinn, and co-workers discovered that water-treated trimethylaluminum activates metallocenes orders of magnitude better than previous systems (48,54,55,58). This finding has revolutionized this field of ethylene and α-olefin polymerization, laying the foundation upon which all further advances were built. The key activator, known as methylalumoxane (MAO), is generally formed by the reaction of less than one water with one $Al(CH_3)_3$ to create polymeric structures $(CH_3AlO)_n(Al(CH_3)_3)_n$ thought to contain chains, rings, three-dimensional cage structures, and unreacted trimethylaluminum (TMA). Typically formed in toluene, the original MAO has a tendency to form gels.



methylalumoxane, "MAO"

Versions incorporating, eg isobutyl groups (MMAO), have differing properties such as hydrocarbon solubility and less gelation. The optimal activator will vary from system to system. Despite the multisited structure of MAO, many MAO-activated metallocenes give polymers with narrow molecular weight distributions (PDI = 2.0) and narrow comonomer distributions, behavior characteristic of only a

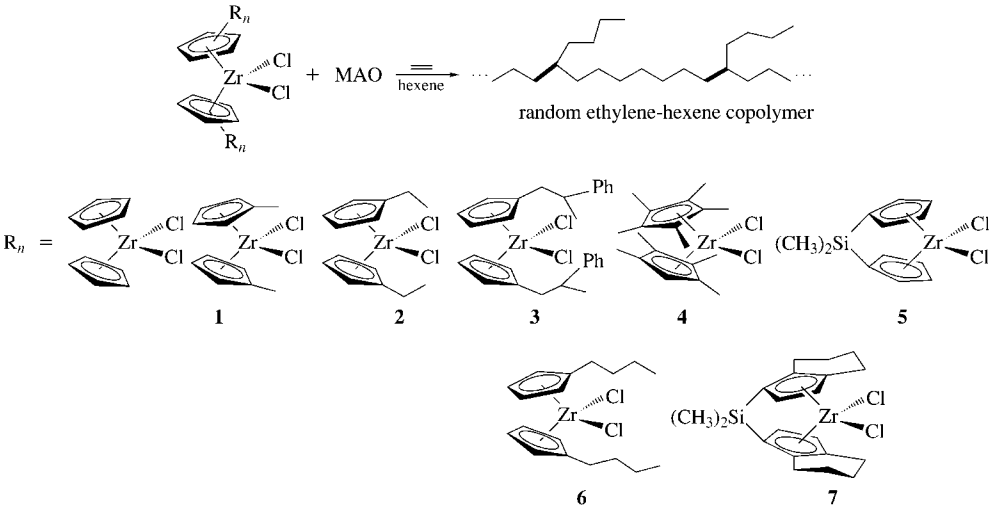


Fig. 17. Substituted metallocene catalysts. The identity of R_n controls polymer molecular weight and density, which in turn controls polymer properties. $R_n = H$ or see other examples. (**1**), (**2**), (**3**), (**4**), (**5**) from the patent (59). Many further derivatives were later disclosed, notably, (**6**) and (**7**).

single active structure. The contrast with multi-sited Ziegler and chrome systems lead to the use of single-site catalysis to describe these systems.

Metallocene Commercialization—The Significance of Substitution. The parent metallocenes used by Kaminsky and co-workers are rarely used commercially, so it is fair to say that the breakthrough was not completed until the recognition that subtle variations in the metallocene molecular structure dramatically change the catalyst performance and polymer characteristics (Fig. 17). Welborn and Ewen of Exxon lead in this discovery, leading to base patent coverage in the field (59). Patents and articles on metallocene derivatives now number into the thousands. Ewen as well as Brintzinger and Kaminsky, Spaeleck and co-workers at Hoechst, Weymouth (60,61), and many others advanced the mechanistic insights into these systems by studying tacticity control in polypropylene.

Noncoordinating Anions—Alternative, Discrete Activators. Elucidation of the nature of the active species in MAO/metallocene catalyst systems was the subject of intensive research efforts with contributions coming from many laboratories. It would be artificial to attribute credit to any one group for solving the mystery, but it was the discoveries by Jordan (62) and by Turner and Hlatky of Exxon (63) that most clearly established the current view. They demonstrated that metallocene cations possessing stable, noncoordinating anions (NCAs) such as tetraarylborates were extremely active for olefin polymerization and were single-sited in nature (Fig. 18). This strongly implied that MAO functions by abstracting an anionic ligand from a neutral metallocene to form a metallocene cation and an MAO anion. Indeed, it was shown that a neutral aryl borate could abstract a methyl group to form a metallocenium—anion pair with high activity (64). Because of the known structure of these activators vis a vis MAO, these are often referred to as discrete activators. These activators are commercially viable,

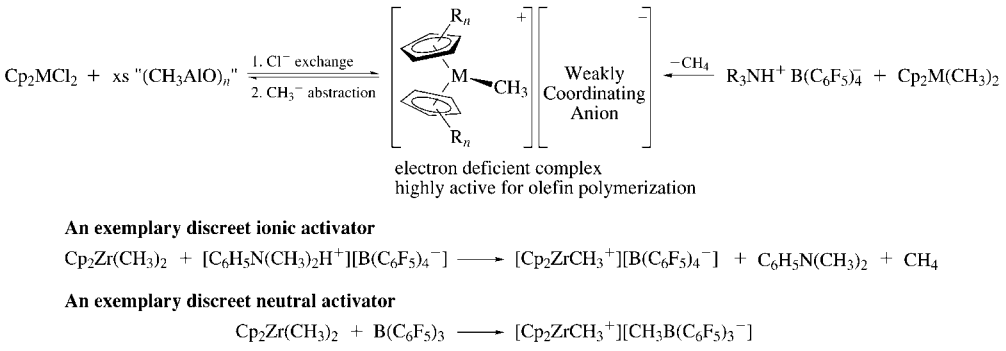

Fig. 18. Noncoordinating ionic catalysts.

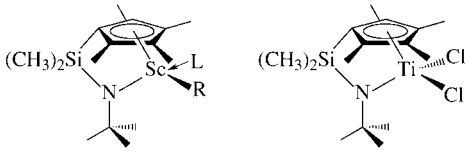
often yielding greater activity than MAO with the cost advantage that large molar excesses are not needed as with MAO. Conversely, such systems are often very sensitive to impurities, whereas excess MAO acts as an impurity scavenger.

The CPSiNR Ligand for Constrained Geometry Catalysts. Biscyclopentadienylmetal complexes were not the only single-site catalysts for olefin polymerization. Monocyclopentadienyl complexes often showed activity, but generally were not competitive catalysts except when linked to a bulky amido group. Thus, Bercaw's Group 3 metal system CpSiNR ligand (**8**) was placed on titanium (**9**) by workers at Dow (65) and Exxon (66) and was found to produce very active catalysts with attractive features. The open structure leads to very good comonomer incorporation and has high molecular weight capability. Both companies filed patents in the U.S. and World offices within days of each other resulting in interferences and court actions over catalyst, activator, and polymer, which were recently settled after more than a decade. Dow proceeded with commercialization of the system dubbing them constrained geometry catalysts because of the bridge between the cyclopentadienyl and amide ligands.



8 **9**

Commercialization of Single-Site Catalysts. In commercial practice, mono and biscyclopentadienyl (mono Cp bis Cp) catalysts show sensitivity to oxygen, water, and polar functionality more comparable to that of chrome catalysts. Depending on catalyst molecular structure, molecular weight capability and comonomer incorporation level vary over a tremendous range beyond the capabilities of other commercial catalysts. Comonomer incorporation is usually more facile and more evenly distributed throughout the chain than in the older conventional systems in addition to less chain-to-chain molecular weight and comonomer

variation. Bis Cp catalysts are very sensitive to chain termination by H_2, while mono Cp amide (constrained geometry) catalysts are more like titanium Ziegler systems in this regard. The systems are supported on silica when used in slurry-phase or gas-phase processes, and both MAO and NCA activation are practiced. Although the major components of these catalysts—metal complex, MAO, discrete activators—are inherently more expensive than conventional catalyst raw materials, volume manufacture and high activity have reduced costs to acceptable levels when combined with premiums commanded by the polymer products.

Though not well known, the commercial use of metallocenes for polymerization began in 1985 with Uniroyal's sale of "Trilene" low molecular weight polyethylene products. Exxon began production of metallocene VLDPE in a high temperature and pressure unit in 1991 under the EXACT trade name. These metallocene polymers are characterized by very narrow molecular weight and comonomer distributions, which lead to high strength and uniformity. Several years later, Dow introduced constrained-geometry-catalyst-produced polymers using a high temperature solution process to make VLDPE and LLDPE. These polymers generally emphasized easier processability relative to the bis metallocenes. Then in 1994, Exxon launched commercial metallocene products from the low pressure, low temperature, very large-scale UNIPOL™ gas-phase process. Metallocene polypropylene was introduced by Exxon and Hoechst the following year, and 1996 saw the sale by Exxon of metallocene polymers produced in slurry loop reactors. With the DuPont/Dow solution process to produce EPDM polymers, all major processes and polyethylene/polypropylene polymer types were being produced by single-site catalysts. While many commercialization announcements have been made up to 2000, relatively few producers beyond those mentioned earlier have initiated full commercial production. However, strong demand, production of specialty products like cyclic copolymers, the recent sale of single-site catalyst licenses, and the announcement of new nonmetallocene single-site catalysts suggest that these new technologies are finally coming into their own after more than a decade of development.

Other Ligand-Based or Single-Site Catalysts. The term single site is misleading because the polymers of these systems, including metallocenes, sometimes have broad molecular weight distributions indicative of multiple catalyst sites. Some prefer the term ligand-based catalysts to denote that the catalysts come from discrete molecular precursors (of exactly defined ligand sets) even though in the active system the metal complex may have been partially converted to multiple new species. The mono Cp and bis Cp complexes long seemed unique as commercially useful ligand-based catalysts, but that picture is changing. As metallocene catalysts have risen in profile during the 1990s, and MAO and discrete activators have become widely available enough, nonmetallocene ligand-based catalysts have been discovered to warrant reviews (67,68). Figure 19 depicts exemplary nonmetallocene systems, several of which may be near commercialization. Noteworthy are the nickel- and palladium-based "Versipol" catalysts of DuPont and the University of North Carolina that make hyperbanched polymers (69,70). Also, pyridyl bisimine ligand-based iron catalysts have been disclosed (71–73) and may be used in the near future for HDPE production. Nova has recently announced forthcoming products from ligand-based systems. With Stephan's titanium bisphosphaimine systems for example, they

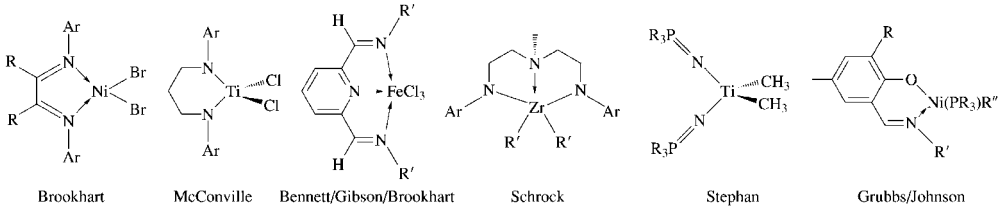


Fig. 19. Other ligand-based single-site catalysts.

collaboratively disclose performance comparable to the constrained geometry catalysts of Dow and Exxon under commercial reaction conditions (74). Given the current state of the technology, it seems very likely that advances in conventional, metallocene, and nonmetallocene catalyst systems will continue to drive LLDPE product and process performance to new levels for decades to come.

Low Pressure Manufacturing Processes and Capacities

Gas-Phase Process. The gas-phase process is considered to be the most versatile low pressure process for producing polyethylene because it can make the broadest product portfolio in terms of molecular weight and density. It had been used since the 1960s to make HDPE and in 1977, Union Carbide built the first gas-phase plant for LLDPE production. Subsequently, British Petroleum and Himont developed alternative gas-phase processes for producing LLDPE. As a result of its versatility, it is the most widely licensed technology worldwide for linear low density production. A simplified schematic of the Union Carbide Unipol process is shown in Figure 20.

In this process, purified ethylene and comonomer are continuously fed into a fluidized bed reactor. Catalyst in dry form is added directly into the bed. The gas recycle stream serves several purposes—fluidizes the polymer particles, provides polymerization raw materials, and removes heat of polymerization. Reactor temperatures are usually below 100°C to prevent resin stickiness and pressures are approximately 2 MPa (300 psi).

The gas stream fed to the bottom of the reactor is the only source of cooling for reactor temperature control. Reactor temperature is a function of polymerization rate. At one time, output rates were limited to prevent high reactor temperatures and resin stickiness. To increase cooling capacity of the gas stream and therefore increase production rates, the recycle stream can be cooled below reactant dew point forming a liquid–gas mixture that is returned to the reactor, which operates above the dew point of the recycle stream. Evaporation of liquids in the recycle stream absorbs heat from the reactor allowing for greater production rates (75). This is commonly referred to as "running in condensed mode." Nonreactive hydrocarbons such as *n*-hexane or isopentane in quantities up to approximately 30 wt% of the recycle stream can also be used as condensing agents allowing for production rates near twice design reactor capacity (76).

Residence time for polymer in the reactor can be several hours. This is one disadvantage to the gas-phase process as grade changes can take hours to

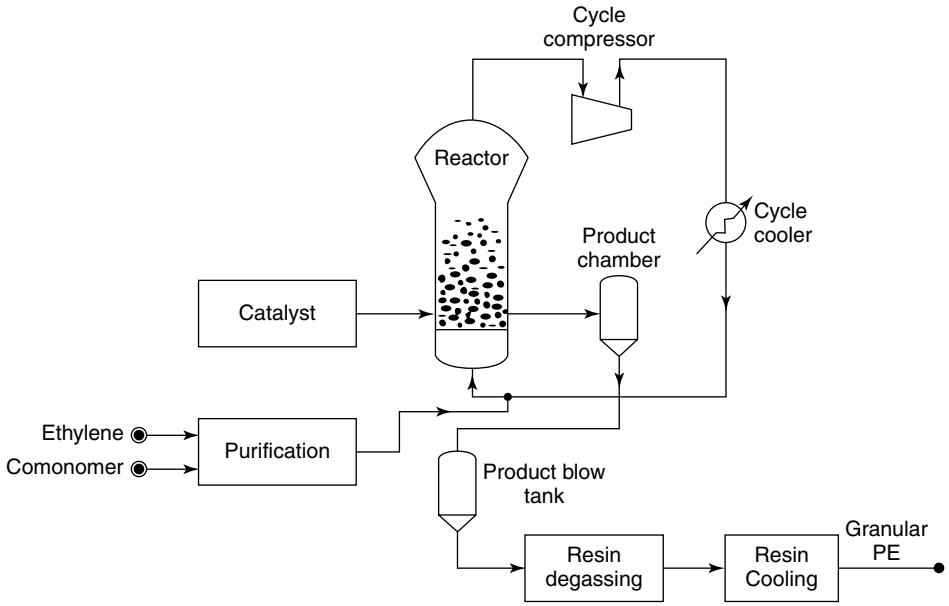

Fig. 20. Schematic of UNIPOL gas-phase polymerization process.

complete. Granular polyethylene is periodically removed from the reactor and sent via pressurized lines to a purge bin where residual catalyst is neutralized and residual monomers are removed. Resin is then conveyed to a pelleting process.

Solution Process. The solution-phase process is also very versatile. Because of short residence times in the reactor, product changes can be made in less than an hour at commercial production rates. A schematic of a solution-phase polymerization process is shown in Figure 21.

Ethylene and comonomer are purified and dissolved in a solvent. An activated catalyst is added to that solution, which is then fed to a stirred reactor. The temperature of the feed stream controls reactor temperature, which is a major determinant of polymer molecular weight. Reactor temperatures are usually 170–250°C with pressures of 4–14 MPa (500–2000 psi). The solution is then fed to a secondary, trimmer reactor where further polymerization takes place. Chelating agents are injected into the solution to neutralize active catalyst. A high pressure flash vessel is used to remove monomer and about 90% of the solvent. A secondary devolatilization step is required to completely remove solvent. Granular polymer is then conveyed for pelletization.

Two limiting factors in solution-phase polymerization are cost of operation and polymer molecular weight. Solvent recovery steps are very energy intensive and add to production costs. Also, the production of high molecular weight resins is limited because of the very high viscosity of the resultant solution. Advantages include short reactor residence time that allows for very quick product transitions (77).

Slurry Process. While the slurry polymerization process is more often associated with production of HDPE, improved catalyst technology has allowed

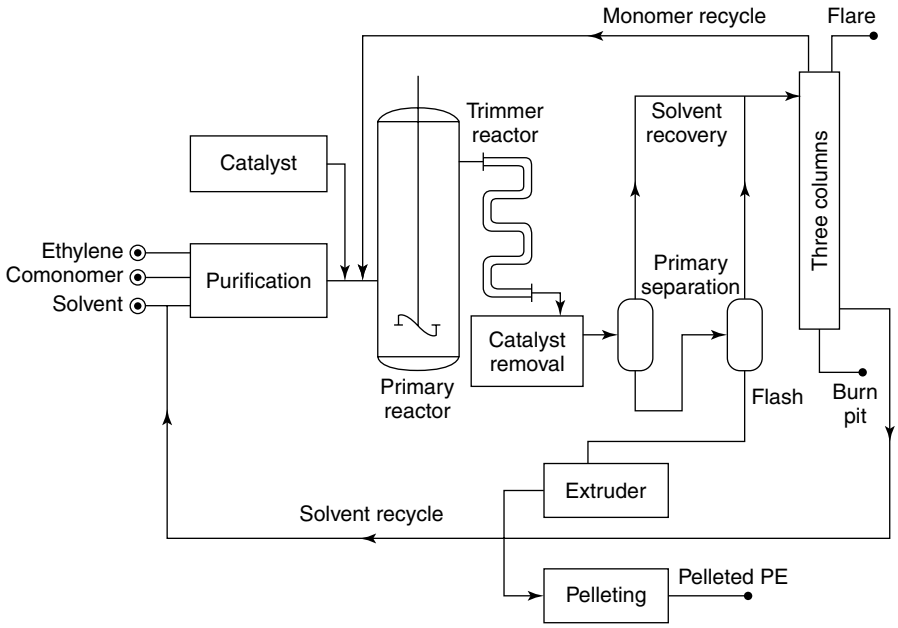

Fig. 21. Schematic of solution-phase polymerization process.

the production of LLDPE and mLLDPE resins. In the slurry process, monomer is dissolved in a diluent in which the polymer product is insoluble. Polymerization occurs below the melting point of the polymer product that forms as suspended particles. An example schematic of a slurry-phase polymerization process is shown in Figure 22.

Ethylene and comonomer are purified, then dried and fed with recycled diluent with a catalyst slurry to a double loop continuous reactor. Polymer forms as discrete particles on catalyst grains and is allowed to settle briefly at the bottom of settling legs to increase concentration from about 40% in main loop to 50–60% in the product discharge (77). Reactor temperatures are usually 70–110°C and reactor pressures are between 3 and 5 MPa (450 and 720 psi). Diluent and residual monomers are flashed off for recycle and polymer is conveyed for pelletization. Production of low density polymers was not practicable due to solubility of low density/low molecular weight polymer molecules in the diluent, but the use of chromox catalysts that produce broad molecular weight LLDPE and metallocene catalysts that produce mLLDPE have broadened the product portfolio for slurry-phase polymerization.

In order to more finely control polymer molecular architecture in LLDPE, much research and development effort has been spent on developing staged reactor technology. There are currently commercial systems in staged gas phase (Union Carbide) (78,79), staged slurry/gas phase (Borealis) (80), and staged solution phase (Nova) (81). Each of these processes allows for control of molecular weight distribution and location of comonomer, ie in high molecular weight or low molecular weight fractions.

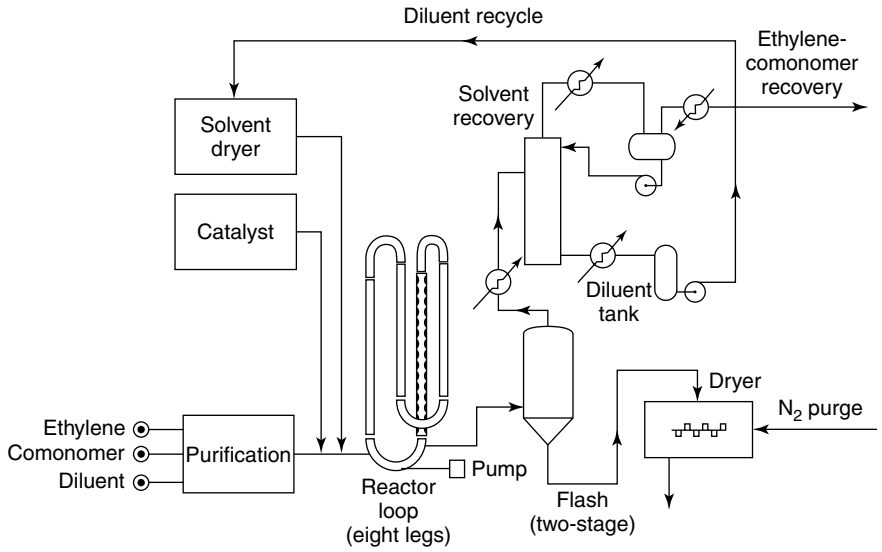

Fig. 22. Schematic of slurry-phase polymerization process.

Processing of LLDPE

Rheology. Every process used to convert LLDPE into a finished product involves melting. Therefore, polymer viscosity is a very important resin parameter that must be considered when selecting a resin for use. LLDPE melts in the normal processing range of 150–300°C exhibit non-Newtonian (shear thinning) behavior as their apparent viscosity is reduced when melt-flow speed is increased (82–85). Figure 23 shows a plot of dynamic melt viscosity for LDPE, gas-phase

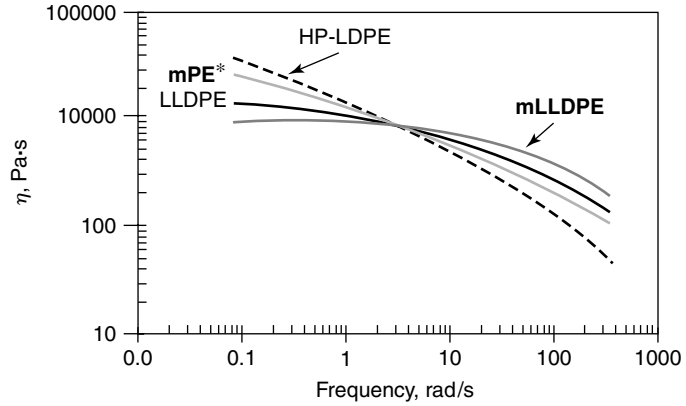

Fig. 23. Melt viscosity data for LDPE, LLDPE, and mLLDPE all normalized to1 g/10 min melt index. Also shown is new type of easy-processing metallocene-catalyzed polyethylene, mPE*. To convert Pa·s to P, multiply by 10.

LLDPE and gas-phase mLLDPE, all normalized to 1 g/10 min melt index. At very low shear rates, LDPE has the highest viscosity, caused by a broad molecular weight distribution and long-chain branching. LLDPE has a broader molecular weight distribution than mLLDPE and therefore has higher viscosity at very low shear rates. As you approach the shear rates commonly associated with extrusion, 100–1000 rad/s, those trends are reversed. The broad molecular weight distribution and long-chain branching seen in LDPE cause it to have a greater response to shear. As a result of increased shear thinning relative to LLDPE and mLLDPE, the melt viscosity of LDPE at higher shear rates is significantly lower than that of the linear resins. The LLDPE resin has lower shear viscosity than the mLLDPE because of its broader molecular weight distribution. Higher viscosities will translate to higher extrusion pressures, higher temperatures, and greater energy consumption.

Because melt viscosities for LLDPE and mLLDPE are so much greater than that for LDPE at the higher shear rates experienced during extrusion, market penetration has been limited in some applications and geographical areas where LDPE processing equipment dominates. Several resin companies are working to develop metallocene-catalyzed resins that are compositionally homogeneous but have slightly broader molecular weight distributions or trace levels of long-chain branching. This gives the resins improved mechanical properties relative to LLDPE, but with lower viscosities and easier extrudability (86–88). An example of this type of resin is shown in Figure 23. A relatively new type of metallocene-catalyzed polyethylene, here noted as mPE*, is shown to have higher melt viscosity than LLDPE at very low shear rates because of a slightly broader molecular weight distribution and trace levels of long-chain branching. Because of its broader molecular weight distribution and long-chain branching, it demonstrates greater shear thinning behavior than LLDPE allowing for use in older equipment designed for LDPE extrusion.

Figure 24 shows extensional viscometry results for 1 g/10 min melt index LDPE, LLDPE, and mLLDPE. LDPE, with its broader molecular weight

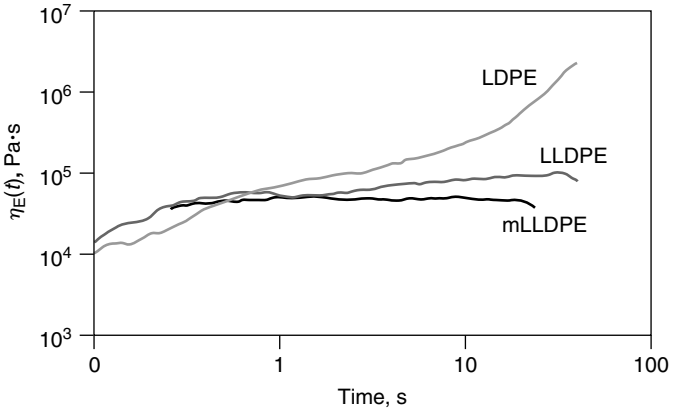

Fig. 24. Extensional rheology data for LDPE, LLDPE, and mLLDPE. To convert Pa·s to P, multiply by 10.

distribution and long-chain branching, shows appreciable strain hardening behavior relative to the linear resins. LLDPE has greater extensional viscosity than mLLDPE because of broader molecular weight distribution. Lower extensional viscosity translates to poorer bubble stability in the blown film process, but lack of strain hardening allows linear resins to be drawn down to thinner gauges than LDPE of equivalent melt index.

Film Extrusion. Approximately 77% of the LLDPE produced globally is processed into film. The most common techniques for producing film are blown film extrusion and cast film extrusion. Both involve extrusion prior to film forming.

In the extrusion process, resin pellets are gravity fed into a heated barrel. Pellets are conveyed down the barrel by a screw that first compacts and then melts the pellets through shear-induced heat. The last section of the screw, also known as the metering section, ensures a homogeneous melt and uniform output. Because of its narrower molecular weight distribution and higher shear viscosity, LLDPE extrudes differently than LDPE. At equivalent melt index, LLDPE is expected to have higher extrusion pressures and temperatures than LDPE. At equivalent temperatures and pressure, LLDPE has better pumping characteristics than LDPE, ie pounds per hour per screw rpm (89). Higher resin viscosity for LLDPE means greater power consumption than LDPE.

To compensate for extrusion differences between LDPE and LLDPE extrusion, screw designs have changed. LLDPE screws have lower compression ratios (channel depth in feed section/channel depth in metering section). Barrier screws, which have additional flights to separate the melt pool from solids bed during melting, were developed to accommodate the different melting behaviors of LLDPE. Extrusion temperatures for LLDPE range from 180 to 300°C with pressures ranging from 15 to over 40 MPa. LLDPE resins, and especially mLLDPE resins, often incorporate fluoropolymer processing aids, such as Dynamar™ products from Dyneon. Fluoropolymer processing aids coat the barrel to reduce shear and therefore pressures and temperatures, and also coat die lips to eliminate melt fracture and die lip buildup. Metallocene-catalyzed resins can be extruded on any line used by LLDPE with the understanding that there may be higher extrusion temperatures and pressures as a result of narrower molecular weight distributions in the mLLDPE compared with conventional LLDPE (90).

In blown film extrusion, molten resin is forced through an annular die. Commercial-scale diameters range from 15 to 120 cm. There are four main components to a blown film die—mandrels, inner lip, outer lip, and body. The mandrel and body distribute polymer flow around the die. Most commercial mandrels have several spirals to more uniformly distribute melt flow and minimize gauge variation (91). Die lips define the die gap. Commercial die gaps for LLDPE blown film extrusion range from 1.5 to 2.5 mm compared to die gaps for LDPE processing, which range from 0.5 to 1.0 mm. Wider die gaps are needed to eliminate melt fracture in LLDPE caused by higher viscosity. After exiting the die, the molten tube of polymer is generally pulled upward by a set of nip rolls, although in some cases it is pulled horizontally or downward. As film thickness is reduced, the tube expands because of internal bubble pressure and forms a tube of larger diameter. The ratio of final bubble diameter to initial die diameter is the BUR. Blow-up

ratios in commercial processes range from 1.5 to over 4 and are largely determined by product end use. Film cooling is aided by air rings that supply air flow around the molten tube. Because of lower extensional viscosity, LLDPE can be drawn to thinner gauges than LDPE but is more prone to bubble instabilities. Dual-lip air rings that provide Venturi-type air flows around the bubble are used to stabilize the bubble in addition to providing cooling. The tubes are drawn down to final film thicknesses of 0.007–0.25 mm. Maximum line speeds approach 240 m/min. Film rolls up to 4 m in diameter are collected on cardboard cores. Many lines have in-line converting for producing articles such as trash bags as the film is being produced.

Cast film extrusion involves extruding molten polymer through a flat die, usually with a coat-hanger design. Commercial die widths can range from 150 to over 600 cm. Die gaps for LLDPE film extrusion are 0.5–0.8 mm. The molten sheet of film is usually extruded downward, but in some cases is extruded horizontally. Within inches after exiting the die, the film is deposited onto a rotating chilled or heated roller. The roller can be polished smooth, have a matte finish, or be embossed with a repeating pattern. Film edges are usually trimmed, chopped, and refed into the system as flaky material called "fluff" or "regrind." Film gauges range from 0.007 to 0.125 mm. Film rolls up to 4 m in diameter are collected on cardboard cores. Cast film processes can be run at much higher rates (over 600 m/min) than blown film processes.

Injection Molding. LLDPE is processed by injection molding to produce complex shapes from children's toys to household containers. Polymer pellets are fed to a single-screw extruder and melted at approximately 160–240°C temperatures. The polymer melt is injected into a mold at 35–130 MPa. Higher viscosity resins, ie, higher molecular weight or narrower molecular weight distribution, will require higher pressures. Molds are usually made in two halves, one fixed and one movable. When the mold halves are together, at least one machined cavity will be formed into which molten resin is injected. Cooler mold temperatures decrease cycle time and increase toughness, but can increase molded-in stress. Higher mold temperatures produce high surface gloss. Filling times for very small molds range from 0.2 to 0.8 s and for larger, more complex molds from 3 to 6 s. After the mold is filled, it is held under pressure than cooled rapidly. Cycle time depends on polymer viscosity, density, and part requirements. LLDPE injection-molding cycle times range from 10 to 30 s (92). Plastomers can be injection molded on equipment designed for flexible polyvinyl chloride with only minor adjustments in processing conditions—colder dies, faster injection speeds, and hot runners (93).

Blow Molding. Bottles and drum liners are common LLDPE blow-molded articles. In the blow-molding process, a thick-walled tube of film called a parison is extruded vertically downward. The parison will have the correct dimensions, weight, and position relative to the mold to produce the finished product. After the parison is extruded, two mold halves with a machined cavity will close around it sealing the bottom of the tube, and the parison is then inflated by pressurized air. Air pressure is usually low, between 0.3 and 0.7 MPa. The molten resin takes the shape of the mold and is cooled to the solid state. The pressurized air is released, the mold is opened, and the part is ejected. Two areas of concern are polymer swell and melt strength. Swell is caused by shrinkage in the process direction

from elastic recovery of the melt. Melt strength of the polymer must be sufficient to support the weight of the extruded parison and prevent excessive "sag," which occurs when the parison reaches some critical length and its weight causes an abrupt increase in speed. Both parameters can be controlled by process conditions and selection of polymer molecular weight (94,95).

Rotational Molding. Rotational molding is used to produce a variety of polymer parts from small to large and from simple to complex. Instead of resin pellets, finely granulated polymer powders are used. Rotational molds are filled with the exact weight of the part to be formed. They are then heated and simultaneously rotated in two perpendicular planes. Tumbling powder sticks to the heated mold and forms a uniform coating on the interior mold surface. Rotation speeds should be relatively low to prevent strong centrifugal forces that can cause uneven thicknesses. After heating, rotation continues and the mold is cooled. The part is removed after the cooling step (96,97). The impact strength of the product is strongly dependent on the internal air temperature of the mold. Lower internal temperatures lead to inadequate sintering of articles, increased void content, and poor crystalline microstructure (98).

Extrusion. Additional extrusion applications of LLDPE include pipe, tubing, sheet, and insulated wire. Pipe and tubing are extruded through annular dies similar to blown film dies. Small diameter products, less than 10 mm, are considered to be tubing while larger diameter products are referred to as pipes (99). Sheet is produced on flat dies and is usually classified as having thickness greater than 0.254 mm. Wire coatings are made by passing a conductor through the hollow center of an annular die and coating with molten polyethylene.

Economic Aspects

LLDPE is made in every continent except Antarctica. It currently makes up approximately 25% of all polyethylene demand and has the greatest growth rate of the major product families (100) as Table 7 shows.

Usage of metallocene-catalyzed resins is predicted to grow at over 24% from 2000 to 2005 as manufacturing processes become more robust, more companies begin to produce these resins, and resin pricing becomes more competitive with commodity grades (100). Consumption in 2005 is expected to be near 3000 kton.

Table 8 shows global allocated LLDPE production capacities by country and process (101). It must be noted that capacity determination is difficult as

many processes can be used to make LLDPE and HDPE. The values shown indicate capacity used solely for LLDPE and mLLDPE production. Total LLDPE–HDPE swing capacity is approximately 25.3×10^3 kton (101). The countries with the largest LLDPE capacity are the United States, Saudi Arabia, and Japan. In the United States, LLDPE is produced by Chevron, Dow, Eastman,

Equistar, ExxonMobil, Huntsman, Montell, Phillips, Union Carbide, and Westlake. Commercial mLLDPE is available from Dow, ExxonMobil, and Phillips. Globally, it is estimated that there are eleven commercial suppliers of metallocene-catalyzed polyethylene (102).

Ethylene is produced primarily from "cracking" ethane or naphtha. Regions such as the Middle East, Western Canada, and Malaysia have cost advantages over other regions because of plentiful supply of ethane and low alternative values. Countries such as Japan and Korea have much higher ethylene production costs because of poorer plant economics (smaller scale) and expensive naphtha feedstock (82). U.S. pricing for ethylene in mid-2000 is approximately \$0.55–0.60/kg. α-Olefins are commonly produced by distillation of hydrocarbons, ethylene oligomerization, catalytic dehydrogenation of alkanes, and wax cracking. Mid-2000 U.S. pricing for butene is approximately \$0.57–0.66/kg and pricing for hexene and higher is approximately \$1.25–1.35/kg (103).

Raw materials comprise the greatest fraction of the cost to produce LLDPE. Raw materials include ethylene, α-olefin, hydrogen, catalyst, and additives. Depending on geographical region, raw materials (at cash cost) are approximately 60–75% of total production costs (100). Utilities, including power, cooling water, steam, and fuel, are approximately 5–15% of total LLDPE production costs. Overhead makes up the balance and includes physical structures, staffing, and shipping. Actual costs can vary significantly by reactor technology, environmental costs, and product mix. Frequent product or catalyst changes can significantly increase production costs by reducing the amount of prime material available for sale.

LLDPE pricing will vary according to comonomer, application, and sales volume. As of the middle of the year 2000, U.S. pricing for butene copolymer LLDPE ranged from \$0.79 to \$0.84 per kilogram for film grade resins. Hexene copolymer LLDPE film resins are \$0.06–0.09/kg higher, octene copolymer LLDPE film resins are \$0.08–0.11/kg higher, and metallocene-catalyzed volume film grades are \$0.08–0.13/kg higher. Pricing is nearly equivalent for general-purpose injection-molding grades and as much as 10% higher for lid grades. Rotomolding powders can be 50–100% greater than butene copolymer LLDPE film grades. Pricing for plastomers ranges from approximately \$1.40 to over \$2.00 per kilogram.

Shipment and Specification

In the United States, bulk resin can be delivered by rail in hopper cars in quantities of 70–100 t. Smaller bulk quantities of 15–20 t can be delivered by hopper truck. Very small quantities and samples are usually delivered in large cardboard boxes called gaylords that contain 450–650 kg of resin. Globally, much resin is packaged in 25-kg sacks.

Polyethylene is categorized by physical property for specification into groups, classes, and grades as described in ASTM D4976-98. Group 1 resins are branched and Group 2 resins are linear. Class defines density and is divided as Class 1, low density resins, from 0.910 to 0.925 g/cm^3, Class 2, medium density resins, from 0.926 to 0.940 g/cm^3, Class 3, high density resins, 0.941 to 0.960 g/cm^3, and

Class 4, high density resins, 0.961 g/cm^3 and above. Polymer melt-flow rate at 190°C using 2.16-kg weight is specified by grade. Grade 1 is a melt-flow rate of greater than 25 g/10 min, Grade 2 is greater than 10–25 g/10 min, Grade 3 is greater than 1–10 g/10 min, Grade 4 is greater than 0.4–1 g/10 min, and Grade 5 is 0.4 g/10 min or less. There are also specifications for electrical requirements, flammability requirements, weatherability requirements, and mechanical properties such as tensile strength, flexural modulus, and crack resistance, but these are not widely used in most commercial LLDPE applications.

Wire and cable resins are also categorized for color by class according to ASTM D1248-98. Class A contains no pigments, Class B contains white or black pigment, Class C contains not less than 2% carbon black, Class D is uv-resistant with colored pigment.

Analytical and Test Methods

Molecular Weight and Distribution/Rheological Properties. Methods of measuring number-average molecular weight (M_n) include ebulliometry (freezing point depression or melting point elevation), membrane osmometry, and vapor-phase osmometry. Weight-average molecular weight (M_w) can be quantified by light scattering and ultracentrifugation [M]. Both number-average and weight-average molecular weight and therefore polydispersity of LLDPE (M_w/M_n) can be measured simultaneously by high temperature gel permeation chromatography (gpc) using *o*-dichlorobenzene or 1,2,4-trichlorobenzene as solvents, ASTM D6474-99. In this method, a dilute polymer solution is passed over a porous inert material. Low molecular weight species follow a tortuous path through the system allowing the high molecular weight materials to elute first. Viscosity methods are also employed to measure molecular weight, ASTM D1601-99 and D2857-95.

Other methods for solvent fractionation are by precipitation method where a ratio of solvent and nonsolvent is incrementally adjusted from solvent-rich to nonsolvent-rich. In this technique, the higher molecular weight fractions will be precipitated first. A reverse technique is solvent gradient elution where a liquid mixture of increasing solvent power is used to remove the lowest molecular weight materials first (10).

Molten polymer flow through a specific die is often used as a quick estimation of polymer molecular weight. Such a measurement is called melt index. Melt index (also called melt-flow rate by some resin producers) for LLDPE is commonly measured according to ASTM D1238-99 using the 190/2.16 method (190°C and 2.16-kg load). Notation is shown as I_2 and this number is inversely proportional to molecular weight as long as the polydispersities of the resins compared are the same and there is no long-chain branching. A measure of polydispersity, or molecular weight distribution, can be obtained by measuring melt flow at higher stresses, 190/10 (I_{10}) or 190/21.6 (I_{21}). Ratios of the different rates, I_{21}/I_2 (known as melt index ratio, MIR) and I_{10}/I_2, correlate very well with M_w/M_n for linear polymers.

Density. LLDPE density is commonly measured using a flotation method in a density gradient column as described in ASTM D1505-98. In this technique, a glass column is filled with a liquid that provides a density gradient from top (lower density) to bottom (higher density) which is marked using calibrated glass beads. The most common liquid used for LLDPE is an isopropanol–water mixture that provides for a density range of 0.79–1.00 g/cm^3. Specimens are dropped into the column and their final resting place is then extrapolated into a resin density. One of the most important aspects of this test is sample preparation, which is done by slow cooling compression molded plaques (ASTM D1928-96). It is very important that the specimen be free of voids and have a thermal history that is consistent with prior samples for accurate comparison.

Polymer density can also be determined using ultrasonic techniques (ASTM D4883-99), and specific gravity (ASTM D792-98).

Structure and Composition. Knowing LLDPE comonomer content and distribution is an important part of predicting polymer properties. Carbon-13 nuclear magnetic resonance (nmr) is commonly employed to identify comonomer type, quantity incorporated, and distribution along the polymer backbone. ASTM D5017-96 provides for standard test method for this analysis. Branching can also be detected by infrared (ir) methods. The method described in ASTM D2238-92 (1999) quantifies methyl group absorption at 1378 cm^{-1}. Infrared analysis is also used to determine vinyl and trans unsaturation in polyethylene (ASTM D6248-98) and vinylidene unsaturation (ASTM D3124-98).

Amount of crystallinity in LLDPE can be quantified using x-ray diffraction (xrd), ir, dsc, and density. The xrd methods usually involve subtracting the amorphous contribution from the x-ray diffraction pattern. ir uses ratios of absorptions from crystalline and amorphous components. dsc uses enthalpy of fusion ΔH_f for a sample compared to the equilibrium heat of fusion ΔH_f° which for polyethylene is between 276 and 301 J/g. Percent crystallinity is given as $X = (\Delta H_f/\Delta H_f^\circ) \times 100\%$. An ASTM standard is given in D3417-99. Density measurements can also give percent crystallinity values X by using $1/\text{density} = X/d_{cr} + (1-X)/d_{am}$, where d_{cr} is usually accepted as 1.00 g/cm^3 and d_{am} is 0.852–0.862 g/cm^3.

Compositional Uniformity. Temperature rising elution fractionation is the preferred technique for measuring compositional uniformity in LLDPE and metallocene-catalyzed resins (104–110). In a typical TREF experiment, a small portion of polymer is dissolved in a heated solvent such as 1,2,4-trichlorobenzene. An inert support is added to the solution that is then cooled at a prescribed rate, eg 1.5°C/h. Polymer fractionation occurs when chains with little to no comonomer crystallize from solution at temperatures higher than those chains that contain more comonomer. After cooling, the inert support is placed in a column and a progressively heated solvent is then passed over the solvent to wash away the crystallized polymer. In this heating step, the lower density fractions, ie those with more comonomer, are eluted at lower temperatures than higher density fractions with little comonomer. Concentration of the elute is detected using an ir detector and is plotted as a function of temperature (Figs. 2 and 3). Crystallization from solution can be affected by both comonomer content and molecular weight. A light-scattering detector can be used in conjunction with the ir detector to measure molecular weight of the eluted fractions. While very informative, the process is very time and labor consuming.

Thermal methods using dsc have been developed to give somewhat the same qualitative information as TREF, but without solvent and in a less labor-intensive manner (111,112). The dsc melting profiles can be used to approximate comonomer content and distribution.

Low molecular weight, low density fractions may migrate to whatever comes into contact with the LLDPE. For food-contact applications, these materials are called hexane extractables. FDA procedure 21 CFR177.1520 calls for immersing a sample in *n*-hexane at 50°C for 2 h and measuring weight loss in the sample. For food contact during cooking, hexane extractables levels need to be below 2.6 wt% and for general noncooking contact hexane extractables levels need to be below 5.5 wt%.

Mechanical Properties of LLDPE. There are literally hundreds of test specifications written for LLDPE mechanical properties testing for all sorts of end-use applications. Since more than 60% of LLDPE consumed is used in film applications, common methods for film testing will be discussed here.

Tensile properties of thin (<1.0 mm) LLDPE films are determined using ASTM D882-97. Strips of film are pulled at controlled strain rates while load cells measure the forces required. Initial strain rates for properties such as ultimate tensile strength and elongation are usually 10 mm/(mm·min) while tensile modulus is tested at 0.1 mm/(mm·min.) ASTM D638-99 is used for thicker sheeting and molded samples from 1.0- to 14-mm thickness.

Tear properties can be determined in a variety of ways. The most common tear test is the Elmendorf test (ASTM D1922-94a). In this test, a weighted pendulum propagates a tear in a specimen. The energy lost by the pendulum while propagating the tear is related to tear strength. In another tear propagation test (ASTM D1938-94), otherwise known as a trouser-leg tear test, a tensile tester is used to propagate a tear through a specimen that resembles a pair of trousers. ASTM D1004-94a is a test method that uses a tensile tester to measure the force to initiate a tear in film. The energy required to both initiate and propagate a tear is determined using ASTM D2582-93.

Impact properties are very important in many film applications. ASTM D1709-98 is the most common technique used to determine impact resistance because of test simplicity and low equipment costs. In this test, a weighted dart with a smooth hemispherical head is dropped from a prescribed height onto a circular diaphragm of film. If the sample does not break, weight is added to the dart. If the sample breaks, weight is removed. At least 10 breaks and 10 failures are recorded to give a good statistical average. Another dart impact test, D4272-99, determines the total energy impact of a film by measuring kinetic energy loss of a dart that passes through the film.

Optical properties are important in many packaging applications. Specular gloss is a measure of the shiny appearance of films. In this test, a beam of light is reflected off of a film surface at a specified angle. It is measured using ASTM D2457-97 at three angles, 20° for high gloss films, 45° for intermediate and low gloss films, and 60° for intermediate gloss films. Film haze is a measure of film clarity. In this test (ASTM D1003-97), the wide-angle light scattering properties of a film are quantified as a percentage of light diffused.

Health and Safety

Resin manufacturers usually provide health and safety information through Material Safety Data Sheets (MSDS) that discuss resin handling and storage, toxicity, combustibility, disposal, labeling, and FDA status.

LLDPE resins are relatively inert and do not constitute hazards for skin contact and ingestion with normal handling (113,114).

Polyethylene is flammable and may give off toxic gases during combustion. Fires may be extinguished with water, carbon dioxide, or dry chemical units. Respiratory and eye protection is required for fire fighters.

Polyethylene may be disposed of by landfill or incineration. In landfill, polyethylene will not degrade unless exposed to sunlight. It is not expected to evolve gases or leechates to pollute water sources.

Most polyethylene is acceptable for use in food contact applications. In some cases of plastomers, resins containing as much as 50% comonomer are acceptable (115). FDA compliance is based mainly on levels of migratable low molecular weight, low density olefins called hexane extractables and various additive levels. A letter of compliance or other certification should be received from the appropriate resin supplier before actual use.

LLDPE Applications

Annual global production of LLDPE is approximately 13.6 million tons. Of that amount, approximately 77% is used in film applications (100). With that proportion, it is not surprising that much of the research and development that is conducted at resin suppliers is on the film market. LLDPE is supplanting LDPE in many film applications because of its improved strength properties, downgauging potential, and cost.

Film Applications. Over 3.4 billion kilograms of LLDPE were consumed in North America for film applications. Trash bags, including retail and institutional markets, is the largest North American market for LLDPE film (over 0.64 billion kilograms). Compared to LDPE, LLDPE offers better puncture resistance, tear resistance, impact, and tensile properties along with the ability to downgauge. LLDPE has better tear resistance balance and puncture resistance than HDPE. The consumer retail trash bag market has two major market thrusts: (*1*) bags with high dart impact and tear strengths but relatively low modulus and (*2*) bags with high stiffness but minimal impact and tear resistance. A significant portion of the retail market consists of blown coextrusion capabilities to meet these challenging requirements. LLDPE melt index range for this market is approximately 0.5–1 g/10 min and density range is 0.917–0.928 g/cm^3. mLLDPE resins tend to be used as layers in coextrusions or as blend components to improve the properties of less expensive resins.

Pallet wrap stretch film is the second largest North American market for LLDPE film. It consumes over 0.545 billion kilograms of LLDPE annually. Pallet wrap stretch film is used to unitize loads to prevent shifting during shipping. It is also used as a protective film and as a tamper indicator. Film

properties required for pallet wrap stretch film include high elongations, high tensile strength, high holding force, puncture resistance, tear resistance, and high cling. Stretch films must have adequate cling so that they will adhere to themselves after application to prevent unwinding and loss of holding force. The most widely used process is cast coextrusion with three, five, and seven layers now common. Approximately 40% of the stretch film capacity is produced via blown film monolayer and coextrusion. The stretch film market has two main product areas: (*1*) machine film and (*2*) handheld film. Machine film is applied by an automated unit that prestretches the film from 150 to over 300% and then applies the film under tension to a load which sits on a turntable. Handheld film is applied manually by a worker walking around a load and is usually stretched less than 200%. Common LLDPE melt indices in this market range from 1 to 4 g/10 min and most resins have a density of 0.917 or 0.918 g/cm^3. mLLDPE has made a significant market penetration in stretch film by offering improved puncture resistance and greater holding force. Blends of LLDPE and mLLDPE are used to optimize properties and reduce costs (116,117). Plastomers are being used as cling layers for consistent cling without the use of additives such as polyisobutylene.

The third largest LLDPE film application in North America is industrial liners, greater than 250 million kilograms per year. Industrial liners are used inside cans, drums, cardboard boxes and the like to prevent spillage, contamination, moisture, and ease of container reuse. Important film attributes are puncture resistance, tear strength, and tensile strength. Common LLDPE melt indices are 0.5–2 g/10 min with densities of 0.917–0.930 g/cm^3. mLLDPE finds little application here because of higher raw material costs.

Other areas where mLLDPE is making an impact are heavy-duty shipping sacks, food packaging (especially fresh produce packaging) (117–120), and breathable films for personal care use, eg diaper backsheet. Plastomers find application as modifiers in LLDPE and ULDPE to improve impact strength, low temperature toughness, and sealability (121).

ULDPE and VLDPE resins find application in low temperature applications, such as ice bags, where lower density offers greater toughness. They are also used as sealing layers, replacing low density copolymers such as vinyl acetate, and as blend components to improve toughness.

LDPE is still the preferred resin for extrusion coating. Because of the narrow molecular weight distribution of LLDPE (and also of metallocene-catalyzed polyethylenes), the resins are more difficult to extrude and have greater "neck-in" than LDPE.

Injection Molding. Injection molding is the second largest product area for LLDPE consuming approximately 8% of the global LLDPE produced. Injection-molded articles include trash cans, pails, food containers, lids, and closures. LLDPE has mechanical properties advantages over LDPE in environmental stress crack resistance, reduced warpage and shrinkage, and low temperature toughness (122). LLDPE is preferred for use over polypropylene in low temperature applications. An example of LLDPE improved properties is given in Table 9 comparing a butene copolymer LLDPE and LDPE of similar melt index and density.

Metallocene-catalyzed resins have not yet had a substantial impact on the marketplace. Primary advantages for metallocene-catalyzed resins compared to

[c]NM = not measured.

conventional Ziegler–Natta-catalyzed LLDPE are improved impact strength, less brittleness at higher melt indices, and less odor and taste transfer. Plastomers are seeing some use as a replacement for poly(vinyl chloride) in injection-molded articles (124). Plastomers are also used as impact modifiers in molded polypropylene automotive parts (125).

Rotational Molding and Blow Molding. Rotational molding accounts for approximately 5% of LLDPE consumption and blow molding accounts for approximately 0.5%. Rotational-molded articles include storage tanks, shipping containers, recreational equipment, and outdoor furniture. LLDPE has higher impact

resistance and stress-crack resistance than LDPE and HDPE. Table 10 lists two LLDPE resins compared to an HDPE sample. Metallocene-catalyzed resins are finding application in rotational molding primarily because of reduced cycle times, reduced energy consumption, a wider processing window (127), and greater impact strength than conventional LLDPE. Improved flexibility and stress-crack resistance make LLDPE ideal for some blow-molded bottle applications. Table 11 details the improved escr compared to HDPE.

Wire and Cable Insulation. LLDPE use in wire and cable insulation makes up approximately 1% of LLDPE consumption. Cable insulation requires flexibility, toughness, abrasion resistance, low brittleness temperature, and good dielectric properties. LLDPE offers a better balance of flexibility and toughness than LDPE or HDPE. LLDPE-coated wire and cable is used in numerous low and medium voltage applications. Metallocene-catalyzed resins are finding use in wire and cable jacketing because of improved abrasion resistance, flexibility, and low temperature toughness (125,128).

Pipe and Tubing. Extrusion of pipe and tubing accounts for a very small fraction of LLDPE consumption. LLDPE offers higher burst strength, environmental stress crack resistance, and higher heat-distortion temperature than LDPE. Plastomer grades have been used to replace plasticized polyvinyl chloride in medical tubing applications (129).

ETHYLENE–ACRYLIC ELASTOMERS

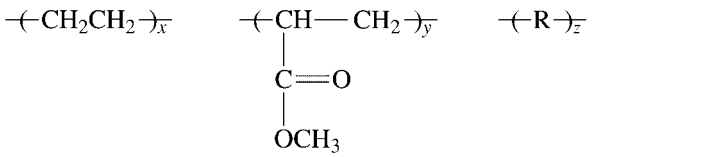
Introduction

Ethylene–acrylic is a term used to describe a family of acrylic elastomers that was first introduced commercially in 1975 under the trademark Vamac by DuPont. The original elastomer was the result of an intensive research effort to develop an oil-resistant polymer with greater heat resistance than that of nitrile or polychloroprene rubbers, at a moderate cost well below that of silicones and fluoroelastomers. Ethylene–acrylic elastomers are best known for their excellent heat and oil resistance, but they also possess a good balance of compression set resistance, flex resistance, physical strength, low temperature flexibility, and weathering resistance. Special compounded attributes include uniquely temperature-stable vibrational dampening properties and the ability to produce flame-resistant compounds with combustion products having an exceptionally low order of smoke density, toxicity, and corrosiveness. Because of this balance of properties, ethylene–acrylic elastomers have found ready acceptance in many high performance applications, especially in the automotive market (1–4).

Polymer Properties

Polymer Composition. Ethylene–acrylic elastomer terpolymers are manufactured by the addition copolymerization of ethylene [74-85-1] and methyl acrylate [96-33-3], in the presence of a small amount of an alkenoic acid to provide sites for cross-linking with diamines (5).

Encyclopedia of Polymer Science and Technology. Copyright John Wiley & Sons, Inc. All rights reserved.



In the early 1990s, DuPont commercialized a new family of copolymers of just ethylene and methyl acrylate, which do not include a cure-site monomer. These dipolymers are cured with peroxides.

The polymerization process yields a random, amorphous terpolymer or a random, amorphous dipolymer (no cure-site monomer). The polymer backbone is fully saturated, making it highly resistant to ozone attack even in the absence of antiozonant additives. The fluid resistance and low temperature properties of ethylene–acrylic elastomers are largely a function of the methyl acrylate to ethylene ratio. As the methyl acrylate level increases, the polymer becomes more polar and has better fluid resistance to aliphatic hydrocarbon oils. Also, as the methyl acrylate level increases, the glass-transition temperature (T_g) of the polymer increases slightly. There is a trade-off between oil resistance and low temperature performance.

Commercial Forms. Four different base polymers of Vamac ethylene–acrylic elastomers are commercially available (Table 1). Until 1990, existing grades of ethylene–acrylic elastomers were based on a single-gum polymer, Vamac G, defined as a terpolymer of 55% methyl acrylate, ethylene, and a cure-site monomer (6). In 1991, a higher methyl acrylate terpolymer, Vamac GLS, was introduced. The composition of this polymer was specifically chosen because it significantly increased the oil resistance of the polymer while minimizing the loss in low temperature flexibility (7).

A new family of peroxide-cured dipolymers was introduced in 1991. The peroxide cure provides copolymers that cure faster and exhibit good compression set properties without a post-cure. The removal of the cure-site monomer has made the polymer less susceptible to attack from amine-based additives. By varying the methyl acrylate level in the dipolymer, two offerings in this family have been synthesized, Vamac D and its more oil-resistant counterpart, Vamac DLS (7).

Curing. Carboxyl cure sites are incorporated in the ethylene–acrylic terpolymer to permit cross-linking with primary diamines (1,8). Guanidines are added to accelerate the cure. If faster cure is desired for the terpolymers, one can use the combination of diamine and peroxide to approximately double the cure rate (9,10) as measured by tc(90). Dipolymers are cured only with peroxides.

Table 1. Vamac Ethylene–Acrylic Elastomer Polymers

Commercial designation	Monomers[a]	Methyl acrylate level	Type of cure system
Vamac G	E/MA/CS	Average	Amine
Vamac GLS	E/MA/CS	High	Amine
Vamac D	E/MA	Average	Peroxide
Vamac DLS	E/MA	High	Peroxide

[a]E is ethylene; MA, methyl acrylate; and CS, proprietary cure-site monomer.

Table 2. Heat Resistance Profile

Temperature of continuous exposure, °C	Approximate useful life of >50% absolute elongation
121	24 months
149	6 months
171	6 weeks
177	4 weeks
191	10 days
200	7 days

Heat Resistance and Aging Properties. The main features of ethylene–acrylic elastomers are heat (175°C by ASTM D2000) and oil resistance. At elevated temperatures, ethylene–acrylic elastomers age by an oxidative cross-linking mechanism, resulting in eventual embrittlement, rather than reversion. A general heat resistance profile is shown in Table 2.

As shown, ethylene–acrylic elastomers will function for more than 24 months at 121°C, or 6 weeks at 171°C continuous service. Exposures up to 190–200°C can be tolerated, although service life at these temperatures is measured in days rather than weeks. When immersed in service fluids, the oxidative process is often slowed down leading to longer actual service life.

Ethylene–acrylic elastomers are highly resistant to the damaging aspects of weather, ie, sun, water, oxygen, and ozone. Vulcanizates have shown little change in tensile properties and no visible signs of surface deterioration after exposure to the elements in Florida for 10 years. Samples under 20% tensile strain (static) displayed no cracks after one week's exposure to 100 ppm ozone in air, a concentration 100 times greater than is usually specified in qualifying tests.

Fluid Resistance. Ethylene–acrylic elastomers are well suited for applications requiring continuous exposure to hot aliphatic hydrocarbons, a class that includes most lubricants derived from petroleum (11). Volume swell data in Table 3 illustrate the good resistance of ethylene–acrylic elastomers to most common automotive lubricants and hydraulic fluids and to ASTM oils at elevated temperatures. The higher methyl acrylate polymer, Vamac GLS, exhibits approximately one-half the volume swell in these fluids of Vamac G. Low swell in motor oils and transmission fluids indicates usefulness for service as various seals, gaskets, and cooler hoses for transmission and engine oil and seals for wheel and crankshaft bearings. Recently, the synthetic motor oil is gaining attention because of its significantly longer service life between oil changes. Both Vamac G and Vamac GLS exhibit low volume swell and excellent retention of properties in the synthetic oils. Although resistance to water and glycol is excellent, some antifreeze-additive packages can cause excessive stiffening of the terpolymer vulcanizates. Ethylene–acrylic elastomers should not be selected for service in continuous contact with gasoline, brake fluid, highly aromatic fluids, or polar solvents such as esters and ketones.

Mechanical Properties. Typical properties of ethylene–acrylic elastomers, like those of other compounded rubbers, vary widely with formulation and also polymer grade. Among compounding ingredients, reinforcing fillers and plasticizers as well as type and amount of curing agents exert the greatest influence.

Table 3. Fluid Resistance

Medium	Time, h/Temp, °C	Volume swell, %	
		Vamac G	Vamac GLS
ASTM #1 oil	70/150	+5	+2
ASTM #2 oil	70/150	+24	+10
IRM 903 oil	70/150	+50	+25
Service fluid 105	1008/150	+22	+10
Motor oil-5W/30	168/150	+19	+9
Motor oil-5W/30	1008/150	+20	+10
Synthetic motor oil-5W/30	1008/150	+10	+4
ATF fluid	168/150	+25	+14
ATF fluid	3000/150	+32	+20
Power steering fluid	168/150	+15	+5
Fuel B	168/23	+73	+57
Kerosene	168/23	+31	
Unleaded gasoline	168/23	+68	
Water	504/100	+6	
Ethylene glycol	504/100	+4	

A typical compound based on Vamac G and Vamac GLS with pertinent vulcanizate properties is shown in Table 4. Note that while Vamac GLS has improved oil resistance versus Vamac G, its low temperature flexibility is about 2–5°C higher than that of the Vamac G compound.

Low Temperature Properties. Medium hardness compounds of average methyl acrylate, ie, Vamac G, without a plasticizer typically survive 180° flex test at −40°C. This type of performance is good for a heat-resistant polymer. Low temperature properties can be greatly enhanced by the use of ester plasticizers (12). Careful selection of the plasticizer is necessary to preserve the heat resistance performance of the polymer. At equivalent plasticizer levels, compounds made from the high methyl acrylate grades lose a few degree celsius in flexibility, compared to compounds made with the average methyl acrylate levels.

Flame Resistance and Smoke Suppression. Ethylene–acrylic elastomers are not inherently resistant to burning. Through compounding, the rate of burning can be retarded and the amount of smoke generated can be suppressed. An important feature of ethylene–acrylic elastomers is their ability to respond to the addition of hydrated alumina (13). This polymer/filler combination provides vulcanizates with good flame resistance, freedom from corrosive gases, and most importantly in many judgments, an unusually low smoke density.

Dynamic Mechanical Properties. Ethylene–acrylic elastomers have a high capacity for dampening that is uniquely insensitive to temperature changes between −10 and 160°C. Damping characteristics at room temperature, as indicated by loss tangent (tan δ), are similar to those of butyl rubber, which is noted for its damping properties. Ethylene–acrylic elastomers differ from butyl and other elastomers, however, by their ability to maintain a high loss tangent as temperature is raised to 160°C. This loss tangent remains virtually unchanged after six months aging in air at 150°C. Damping properties of ethylene–acrylic elastomers are also relatively insensitive to compound variations (14,15).

Table 4. Vulcanizate Properties of Vamac G and Vamac GLS in Black Loaded Compound[a,b]

Property	Vamac G	Vamac GLS
Physical properties at RT		
100% Modulus, MPa[c]	5.3	6.2
Tensile strength, MPa[c]	15.1	16.0
Elongation at break, %	290	273

Processing

Mixing. Ethylene–acrylic elastomers are processed in either an internal mixer with an upside down process for large-scale production or a rubber mill for smaller scales. In either case, it is important to keep the compound as cool as possible and to avoid overmixing. Ethylene–acrylic elastomers require no breakdown period prior to addition of ingredients. Mixing cycles for a one-pass mix are short, typically 2.5–3.5 min. When compounds are mixed in a rubber mill, care should be taken to add the processing aids up front with additives. Normal mill mixing procedures are followed otherwise.

Extrusion and Calendering. Most compounds of ethylene–acrylic elastomers have low nerve and yield smooth extrusions or calendered sheets. To improve collapse resistance in hoses, compounding techniques should be used to maximize compound viscosity. This includes using a higher viscosity terpolymer, a higher structure carbon black, or fumed silica. The extruder temperatures should be kept quite low. A suggested starting temperature gradient would go from 50 to 65°C, with 75°C at the die. Extruded hose is usually vulcanized by exposure to high pressure steam in an autoclave. Other applications, such as wire insulation and jacketing, are subjected to fast, continuous, high pressure steam vulcanization. Vulcanization at atmospheric pressure produces highly porous vulcanizates and is not recommended.

Molding. Parts can be produced from ethylene–acrylic elastomers using compression, transfer, or injection-molding techniques. Because the viscosity of these polymers is usually lower than the typical rubber used in the industry, compounds of ethylene–acrylic elastomers have a tendency to trap air during molding, especially in a compression mold. This situation can be avoided with adequate venting of the mold, the use of an effective mold lubricant, the use of compounding techniques to maximize compound viscosity, good preforming techniques, and proper mold temperatures. The low viscosity of ethylene–acrylic elastomers makes them especially good for injection molding.

Mold temperatures vary between 150 and 200°C, depending on the molding methods and part size. Parts can be molded in 1.5–10 min depending on the configuration and thickness of the part, the mold temperature, and the desired state of cure at demolding. Since most ethylene–acrylic parts are post-cured, it is sometimes possible to demold partly cured articles and complete vulcanization in the post-curing oven.

Post-Curing. Whenever production techniques or economics permit, it is recommended that compounds based on terpolymer grades be post-cured for optimum properties. Relatively short press cures can be continued with an oven cure in order to develop full physical properties and maximum resistance to compression set. Various combinations of time and temperature may be used, but a cycle of 4 h at 175°C is the most common. The post-cure step increases modulus, greatly improves compression set performance, and stabilizes the initial stress–strain properties. During the post-cure step, the chemical cross-link is converted from an amide linkage to a more stable imide linkage. Peroxide-cured dipolymer compounds need not be post-cured.

Adhesion. Commercially available one- or two-coat adhesive systems produce cohesive rubber failure in bonds between ethylene–acrylic elastomer and metal (16). Adhesion to nylon, polyester, or aramid fiber cord or fabric is greatest when the cord or fabric have been treated with carboxylated nitrile rubber latex.

Additional information on processing compounds of ethylene–acrylic elastomers can be found in References 17,18–19.

Economic Aspects

The market for ethylene–acrylic elastomers was greater than 5000 t/year in 2000. The growth rate for ethylene–acrylic elastomers has been greater than 10% in the 1990s. Over 50% of ethylene–acrylic elastomers are sold in Europe.

Several new products are under development (10), including a higher viscosity terpolymer. These new products, when commercialized, will expand the serviceability of the ethylene–acrylic elastomers and also improve their processability.

Uses

The favorable balance of properties of ethylene–acrylic elastomers has gained commercial acceptance for these elastomers in a number of demanding applications, especially in the automotive industry and in wire and cable jacketing.

Approximately 80% of ethylene–acrylic elastomers are used in automotive applications with hose and tubing as the single largest end use. The recent steady increases in automobile operating temperatures make ethylene–acrylic a prime candidate for under-the-hood applications. Applications include oil and transmission seals, O-rings and gaskets, high velocity CVJ boots, spark plug boots, torsional dampers, and extruded sponges (20,21). Hose applications include transmission and engine oil cooler hoses, air conditioning hose, power steering hose, and turbo charger hose.

Industrial applications include pipe seals, hydraulic system seals, dampers for machinery and high speed printers, and motor lead wire insulation. The fact that the polymer contains no halogens along with certain unique compounding techniques for flame resistance prompts the selection of ethylene–acrylic as jacketing material on certain transportation/military electrical cables, and in floor tiles.

ETHYLENE–NORBORNENE COPOLYMERS

Introduction

Copolymers made from α-olefins and cyclic olefins have been known for nearly 50 years (1,2). Ethylene–norbornene (Et–Nb) copolymers are specifically described in the patent literature as long ago as 1973 (3), with further patent filings since then (4–6). The general class of thermoplastic cyclic olefin copolymers (COCs) includes products from Mitsui Chemicals (7), Japan Synthetic Rubber (8), Nippon Zeon (9), and Ticona (10). Some of these products are manufactured by ring-opening metathesis and others by addition polymerization. Only the COCs made by Ticona, a division of Celanese AG, under the trademark Topas, are Et–Nb copolymers. These products, for which Ticona started up a 30,000-t plant in September 2000 (11), are described in this article.

Properties

Ethylene–norbornene copolymers are made by the direct addition of ethylene and norbornene, using metallocene catalysts. Although regularly alternating copolymers have been made with semicrystalline characteristics, all Et–Nb products presently available are completely amorphous random copolymers, varying only in melt flow and glass-transition temperature (T_g). The bridged ring structure of norbornene makes the resins quite stiff, and their completely amorphous nature ensures high transparency. In general, the resins are stiff, strong, glass-clear, and water-white. They have low elongation at break, negligible moisture absorption and transmission, very low dielectric loss, and low density. The glass-transition

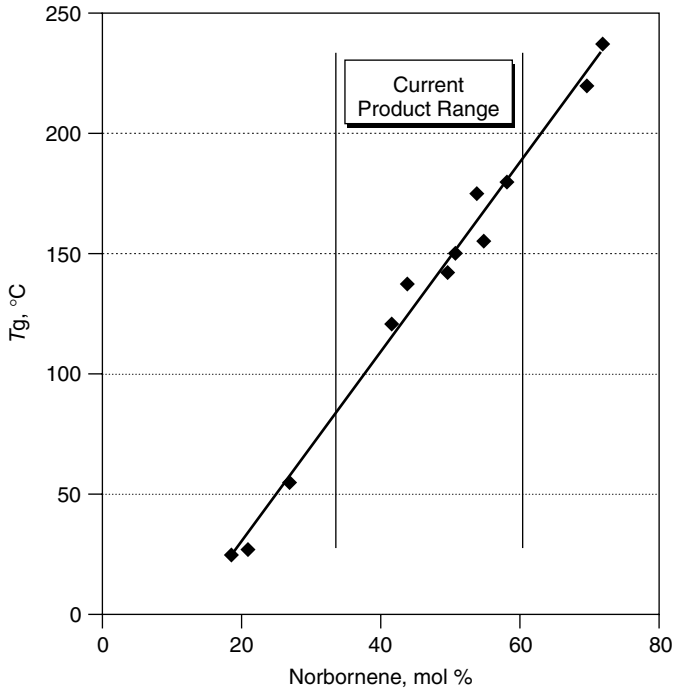

Fig. 1. Effect of norbornene content on T_g.

temperature increases linearly with norbornene content, as shown in Figure 1. The commercially available products range in T_g from about 65°C to about 180°C. Subject to some limitations, conventional thermoplastic processing methods may generally be employed with all of these products.

Because of the bulkiness of norbornene, Et–Nb copolymers remain amorphous down to very low levels of norbornene, where a clear elastomeric polymer is obtained. In the current commercial range of products, all grades on offer exhibit high rigidity, with tensile (Young's) modulus values ranging from 2600 to 3200 MPa. Specific gravity values fall in a narrow spread from 1.00 to 1.02, and light transmission is around 92%. Typical values for a range of physical properties are shown in Table 1 for the announced commercial grades of Topas COC resins (12). These materials have excellent chemical resistance to aqueous fluids (acids and bases) and many polar solvents (alcohols and ketones), but are attacked by nonpolar solvents (hexane, toluene, oleic acid, and methylene chloride) and some oils and fats. The chemical resistance of the copolymers may be summarized as follows (13).

The commercially important properties of Et–Nb copolymers include low density, high transparency and low color, high moisture barrier and low moisture absorption, low optical distortion, excellent feature replication, resistance to polar solvents, high purity, shatter resistance, good biocompatibility, extremely low dielectric loss, high temperature capability, and compatibility with polyethylenes. The resins also have the low shrinkage and warpage typical of amorphous polymers.

Table 1. Properties of Et–Nb Copolymers, Commercial Grades of Topas

Property	8007	5013	6013	6015	6017

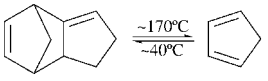
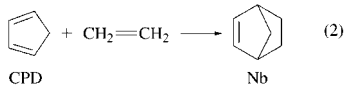
FDA Drug and device master file numbers respectively are DMF 12132 and MAF 1043. All grades, save only the highest temperature one, comply with U.S.P. Class VI requirements. The FDA has issued a regulation, 21 CFR 177.1520, for Et–Nb copolymers in dry food contact (14). The 80°C T_g grade complies with food contact requirements under conditions of use C through H, while the 140°C and 160°C T_g grades comply under conditions of use A through H. A Food Contact Substance Notification, FCN 000075, became effective on August 22, 2000 for the polymers in direct food contact with all food types as films, sheets, and articles made therefrom (15). The afore mentioned properties, usually in various combinations, are the drivers for current and developing applications for Et–Nb copolymers.

Manufacturing

Although, strictly speaking, Et–Nb products are copolymers of ethylene and norbornene, the manufacturing process starts with ethylene and a high purity dicyclopentadiene (DCPD) stream. The DCPD is cracked at a temperature in excess of 160°C to yield cyclopentadiene (CPD) (eq. (1)), which reacts with ethylene to give norbornene (bicyclo[2.2.1]-2-heptene) via Diels–Alder condensation (eq. (2)). Cyclopentadiene boils at 42°C, whereas norbornene melts at 47°C.

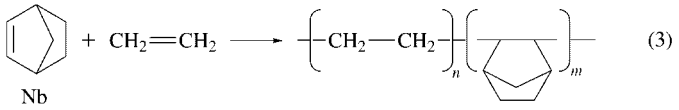


DCPD CPD (1)



(2)

The norbornene product then reacts in solution with ethylene to form the copolymer, using a zirconium metallocene procatalyst/methylaluminoxane cocatalyst system (eq. (3)).



(3)

Subsequent removal of catalyst and solvent yields a very pure polymer.

Processing

Many processing methods have been employed with Et–Nb copolymers. These include injection molding, injection and coinjection blow molding, compression molding, cast film and sheet extrusion and coextrusion, blown film extrusion and coextrusion, tubing extrusion and coextrusion, extrusion compounding, film solvent casting, mono- and biaxial (tenter) orientation of film, and thermoforming of film and sheet. In co-extrusion and coinjection molding, a tie layer is normally required except for polyethylenes and high ethylene copolymers. Unless the parison is quite small, presently available polymer grades do not have sufficient melt strength for extrusion blow molding. Typical starting conditions for molding and extrusion are given in Tables 2 and 3 where the higher temperatures apply to polymers of higher T_g. For processes involving a free surface, such as extrusion or blow molding, an external processing aid should be dusted on the polymer pellets to obtain the best product esthetics. For both extrusion and molding, low compression screws are recommended. A special screw design for film extrusion is shown in Figure 2 (16). In both extrusion and molding, it is important that the forming surface be maintained near the T_g of the polymer grade being processed. For higher T_g grades, this requires oil-heated tooling for molding and oil-heated take-off rolls for film casting. Manufacture of blown films requires a shorter tower and a lower nip than those that are used in conventional olefin processing.

Post-processing assembly procedures such as lamination, machining, or diamond turning, and joining by solvent, friction, and ultrasonic bonding have all been satisfactorily demonstrated with Et–Nb copolymers. Machining lubricants should be water-based and should contain no oil. Also, relatively slow speeds and shallow cuts should be used to avoid cracking the part.

Applications

Rigid and flexible packaging are currently the leading uses for Et–Nb copolymers. This category includes both film and container applications in pharmaceutical, medical and diagnostic, and food packaging end uses. Pharmaceutical blister packaging requires high moisture barrier, transparency, and thermoformability.

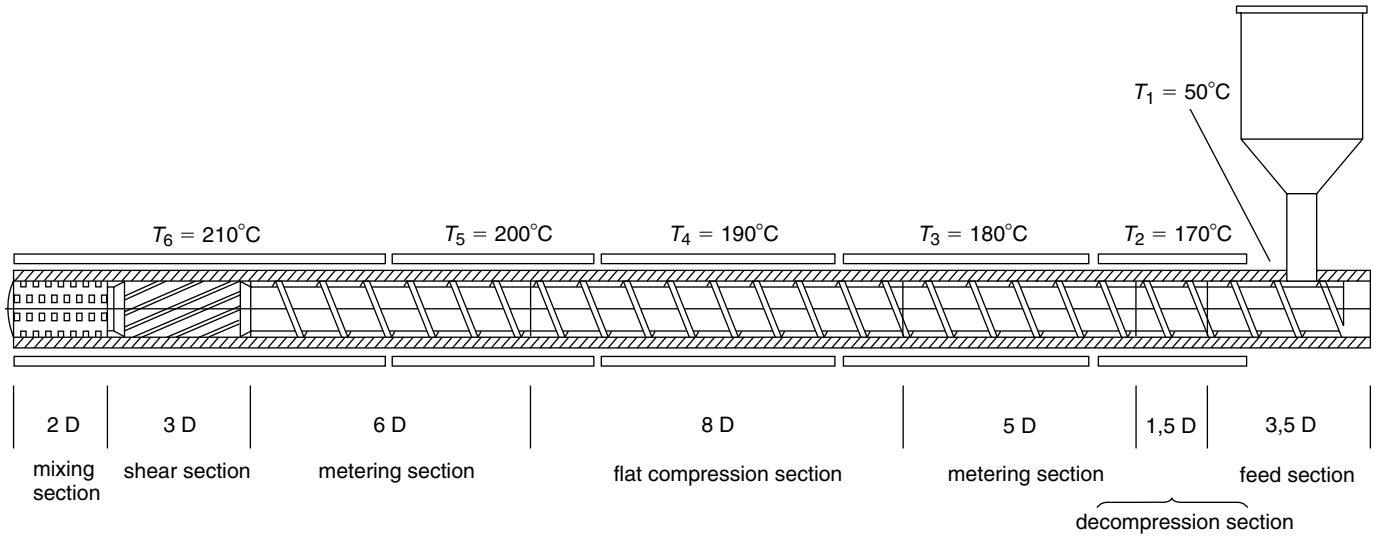


Fig. 2. Special screw design for film extrusion.

Table 2. Injection-Molding Conditions for Et–Nb Copolymers

Feed Zone	<80°C
Barrel Zone 1	230°C–270°C
Barrel Zone 2	245°C–290°C
Barrel Zone 3	260°C–300°C
Barrel Zone 4	270°C–300 °C
Nozzle	270°C–300°C
Melt	260°C–310°C
Max barrel residence	<15 min
Injection pressure	50–110 MPa[a]
Hold pressure	30–50 MPa[a]
Back pressure	0.7 MPa[a]
Screw speed	50–150 rpm
Injection speed	Moderate to fast (2–10 cm/s)
Mold temperature	110°C–150°C
Nozzle type	Open
Screw suckback	None or minimum
Cushion	Small
Screw type	Low compression
Screw turn on inject	No
Ram speed	Moderate to fast

Table 3. Extrusion Conditions for Et–Nb Copolymers

L/D ratio	>25
Compression ratio	2.0–2.5
Casting roll	Close to HDT of polymer (50°C–70°C up to 160°C–175°C)
Feed Zone	<50°C
Zone 1	210°C–240°C up to 255°C–275°C
Zone 2	220°C–250°C up to 275°C–300°C
Zone 3	230°C–270°C up to 275°C–300°C
Zone 4	230°C–270°C up to 275°C–300°C
Die	230°C–270°C up to 275°C–300°C
Melt	230°C–270°C up to 290°C–310°C

These requirements are met with a multilayer structure containing a thicker central layer of the copolymer with thin outer layers of polypropylene (17). Such film structures are made by lamination or coextrusion, respectively using appropriate adhesive or tie layers. Other uses for these films include packaging of personal care and consumer products as in, for instance, blister bottles.

Medical and diagnostic packaging applications include syringes, vials, and tubes made by injection or injection blow molding (18,19). Here the key properties include moisture barrier, transparency, shatter resistance, bioinertness, and ability to undergo terminal steam- or gamma-sterilization. Cuvettes and micro-titer (multiwell) plates are other important diagnostic/analytical uses for the copolymers (20,21). Resistance to dimethyl sulfoxide is an important attribute in these applications, as are clarity and transparency, especially in the near uv region. Low shrinkage and dimensional stability provide the ability to mold very flat

three-dimensional structures that can be accurately and consistently positioned in automated analytical equipment.

Food packaging uses may include both mono- and multilayer films, primarily using the copolymer in a blend with polyethylene (22). Suitable blend components include low density, linear low density, and plastomer polyethylenes as well as ethylene vinyl alcohol copolymers. These blends exhibit improved stiffness, reduced friction and blocking, and improved hot tack and ultimate seal strength performance over the respective unmodified polyethylenes, with no loss, or even an improvement in clarity and oxygen permeation. Uses for the blends are in packaging of fresh-cut produce and standup pouches.

Biaxially oriented cast films have been shown to have improved mechanical properties, with modulus increased 1.5 times, tensile strength 2.5 times, and elongation 20 times (23). Films have been drawn down to about 7 μm using draw ratios between 3:1 and 4:1 in machine and transverse directions. These films can be metallized on both sides and because of their extremely low dielectric loss and higher temperature capability, can provide superior capacitor performance in a smaller package.

High transparency, low birefringence, and high Abbé number combine with low moisture absorption to make the Et–Nb copolymers extremely suitable for precision optical applications as well as more mundane uses where temperature or solvent resistance issues preclude the use of other materials such as polycarbonate or polymethyl methacrylate. Superior reproduction of surface features also makes the resins suitable for production of diffraction optics. Current applications include lenses for use in light-emitting diodes, compact disc (CD) readers, and automotive rain sensors. Light guides capable of resisting higher temperatures such as are experienced during wave soldering are another current optical application (24).

Work in the mid-nineties showed that excellent audio CDs could be made from a high flow Et–Nb copolymer. However, cycle times comparable to those obtainable with CD-grade polycarbonate were not achieved. As optical storage media standards move to higher and higher data density, renewed interest has arisen in COC resins for such applications, based on their excellent feature replication, superior birefringence, and higher transparency to the lower wavelength lasers required to read the smaller pits accurately. Et–Nb copolymers are candidates for these high data density applications (25).

The two key control parameters available in manufacture of the copolymers are T_g and molecular weight. This capability has been exploited to produce a new class of toner binder resins for electrophotographic printing (26). The new binder resins offer significant performance benefits over existing materials especially where high process speed or improved image quality is required. Control of T_g allows precise matching to the fuser temperature requirements of specific printer designs. The single-site metallocene catalysts used in manufacture of the Et–Nb resins allow a narrow molecular weight distribution with a polydispersity index (M_w/M_n) of close to 2.0. This enables undesirable oligomer content to be kept to a minimum and also facilitates design of appropriate bimodal molecular weight compositions to meet the requirements of different printing processes, especially in regard to providing a large antioffset window. The high clarity and colorlessness of the base copolymer resin provide high color fidelity in the finished print. Making toner binder resins of very low molecular weight ensures good pigment

dispersability and also facilitates grinding the finished toner into relatively uniform small and approximately spherical particles.

The Et-Nb copolymers presently on the market are all neat polymers. No compounds of these resins are commercially available at this time. However, glass-fiber-reinforced formulations have been developed (27), as have impact-modified and flame-retarded compositions (28). The glass-reinforced formulations had high flow and the ability to fill long thin sections. Complex three-dimensional parts showed very little warpage, reflecting the low shrinkage of the base resin. Reinforcement with glass fibers significantly increased notched impact strength. Improvements in tensile strength and modulus were on a par with those obtainable with polypropylene. Flame-retarded compositions were based on halogenated and nonhalogenated flame-retardant packages, and yielded both V-0 and V-2 performance.

As the unique property profiles of cyclic olefin polymers and copolymers, and particularly those of Et-Nb copolymers, become more widely known and understood, new applications and most likely, new formulations will continue to develop. This process will undoubtedly be furthered by any cost improvements obtainable via scale economies in production of the base resin, for which the U.S. developmental price in 2001 ranges between $5.70/kg and $6.60/kg at truckload quantities.

EXTRUSION

Introduction

The main function of an extruder is to develop sufficient pressure in the material so as to force the material through the die. The pressure necessary to force a material through the die depends on the geometry of the die, the flow properties of the material, and the flow rate. Basically, an *extruder* is a machine capable of developing pressure. In other words, an extruder is a pump. A *plastics extruder* is a pump for plastic materials. However, this is not to be confused with a *plasticating extruder*, which is a machine that not only extrudes but also plasticates, or melts, the material. A plasticating extruder is fed with solid plastic particles and delivers a completely molten plastic to the die. On the other hand, a machine that extrudes molten plastic without melting it is called a *melt-fed extruder*.

Extruders Types

Extruders are the most common machines in the plastics processing industry. Extruders are used not only in extrusion operations, but also in most molding operations, for instance injection molding and blow molding. Essentially every plastic part has gone through an extruder at one point or another; in many cases, more than once.

Single Screw Extruders. In the plastics industry, there are three main extruder types: the screw extruder, which is the most common; the ram extruder; and the drum or disk extruder, which is the least common. In a screw extruder a screw rotates in a cylinder; the rotation of the screw creates a pumping action (see Fig. 1).

Encyclopedia of Polymer Science and Technology. Copyright John Wiley & Sons, Inc. All rights reserved.

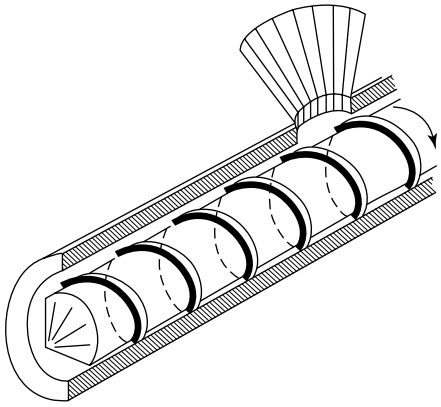

Fig. 1. A single screw extruder.

Twin Screw Extruders. A screw extruder can have one screw or more than one screw. An extruder with one screw is called a single screw extruder; it is the most common machine in the plastics processing industry. An extruder with more than one screw is called a multiscrew extruder. The most common multiscrew extruder is the twin screw extruder; it has two screws.

Co-Rotating Twin Screw Extruders. There are several types of twin screw extruders. In most twin screw extruders, the screws are located side by side. If both screws rotate in the same direction, the extruder is called a *co-rotating twin screw extruder* (see Fig. 2).

Co-rotating twin screw extruders used for compounding run at high screw speed, typically between 200 and 500 rpm. Some of the newer very high speed twin screw extruders are capable of running at speeds over 1000 rpm, as high as 1600 rpm.

Counter-Rotating Twin Screw Extruders. If the screws of a twin screw extruder rotate in opposite direction, it is called a *counter-rotating twin screw*

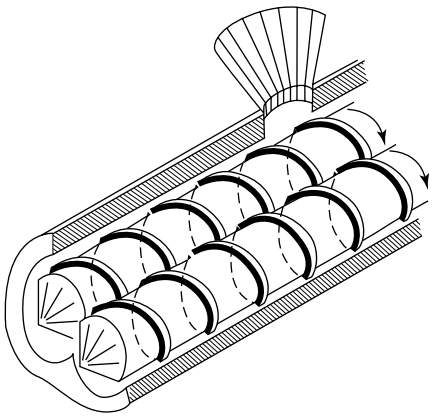

Fig. 2. A co-rotating twin screw extruder.

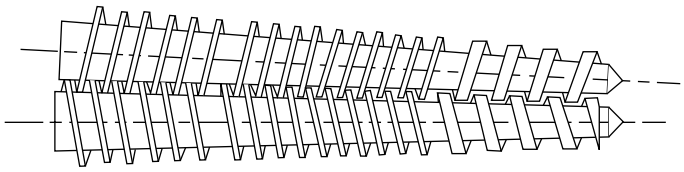

Fig. 3. Conical twin screw extruder.

extruder. Twin screw extruders can run at high or low speed, depending on the application. High speed extruders run at around 200–500 rpm and even higher; they are primarily used in compounding. Low speed extruders run at about 10–40 rpm and are used mostly in profile extrusion applications.

Most twin screw extruders for profile extrusion are counter-rotating extruders. This is because counter-rotating extruders tend to have better conveying characteristics than co-rotating extruders. Most twin screw extruders have parallel screws, but some extruders have conical screws where the screws are not parallel (see Fig. 3). Another distinguishing feature of twin screw extruders is the extent that the screws intermesh. The screws can be fully intermeshing (Fig. 4a), partially intermeshing (Fig. 4b), and nonintermeshing (Fig. 4c).

Most twin screw extruders are intermeshing. The advantage of nonintermeshing twin screw extruders is that they can have a very long length without problems with metal-to-metal contact between the screws. The *L/D* ratio can be 100:1 and higher. The *L/D* of intermeshing twin screw extruders is generally limited to values less than 60:1. A disadvantage of current nonintermeshing twin screws is that they have limited dispersive mixing capability; however, newer dispersive mixing technologies may negate this limitation (see section on The CRD Mixer and Figs. 63, 64, 65).

Ram Extruders. In a ram extruder a piston forces the material through the die (see Fig. 5). Ram extruders have very good conveying characteristics and can develop very high pressures. The drawback of ram extruders is that they have low melting capacity. Therefore, they are not used very often for normal plastics. There are some unusual plastics, however, that are often processed on a ram extruder, such as the so-called *intractable plastics* that cannot be processed on normal extruders. Examples of such plastics are PTFE and ultrahigh molecular weight (UHMW) PE. These plastics do not melt like normal plastics and are formed by sintering. Continuous products can be made on a ram extruder; the line speeds are quite low though, in the range of 25–75 cm/h (10–30 in./h).

Components of an Extruder

The Extruder Screw. The heart of the extruder is the extruder screw. This is a long cylinder with a helical flight wrapped around it (see Fig. 6). The screw is so important because conveying, heating, melting, and mixing of the plastic are mostly determined by the screw. The stability of the process and the quality of the extruded product are very much dependent on the design of the screw. The screw rotates in a cylinder that fits closely around it.

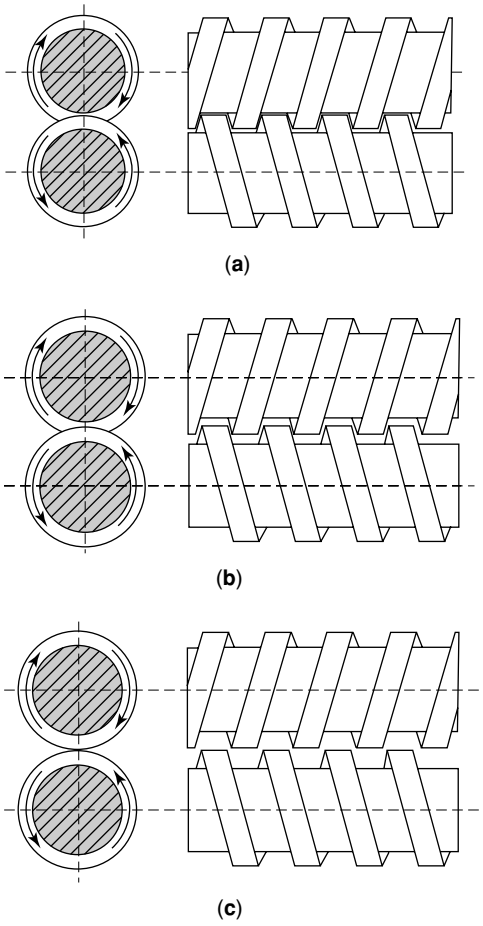

Fig. 4. Counter-rotating screws: (**a**) fully intermeshing; (**b**) partially intermeshing; and (**c**) nonintermeshing (tangential).t

The Extruder Barrel. The cylinder is called the extruder barrel. The barrel is a straight cylinder usually equipped with a bimetallic liner; this liner is a hard, integral layer with high wear resistance. In most cases, the wear resistance of the barrel should be better than that of the screw. The reason is that the screw is much easier to rebuild and replace than the barrel. Bimetallic barrels usually cannot be rebuilt.

The barrel may have a vent opening through which volatiles can be removed from the plastic (see Fig. 7), a process called *devolatilization*. An example is the removal of moisture from a hygroscopic plastic. An extruder with a vent port should use a special screw geometry to keep the plastic melt from coming out of the vent port; such a screw is called a two-stage screw (see Fig. 7).

The Feed Housing. The feed housing is connected to the barrel; it contains the feed opening through which the plastic material is introduced to the extruder. The feed throat usually has water-cooling capability because the feed

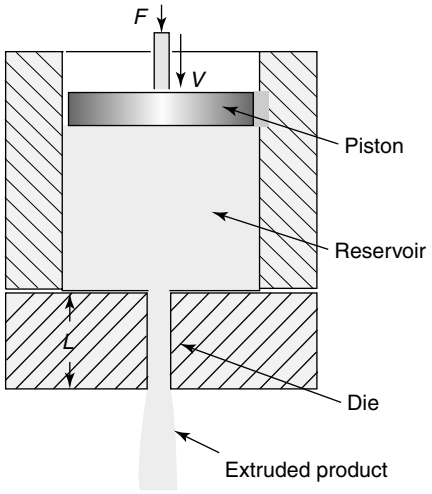

Fig. 5. Schematic of a ram extruder.

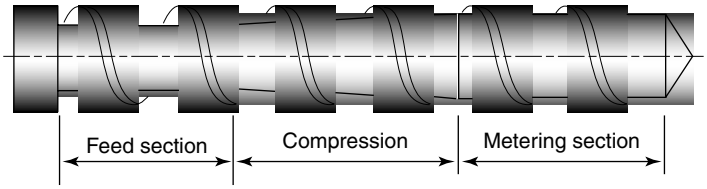

Fig. 6. A single flighted extruder screw.

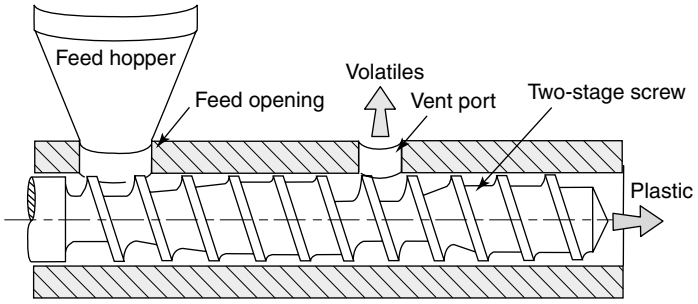

Fig. 7. A vented extruder barrel with a two-stage screw.

throat temperature is kept low enough to keep the plastic particles from sticking to the wall. To improve the intake capability of the feed throat, the feed opening can be offset as shown and have an elongated shape. The length of the feed opening should be about 1.5 times the diameter of the barrel and the width about 3/4 times the diameter, as shown in Figure 8.

Some extruders do not have a separate feed throat, but the feed opening is machined right into the extruder barrel. There are both advantages and

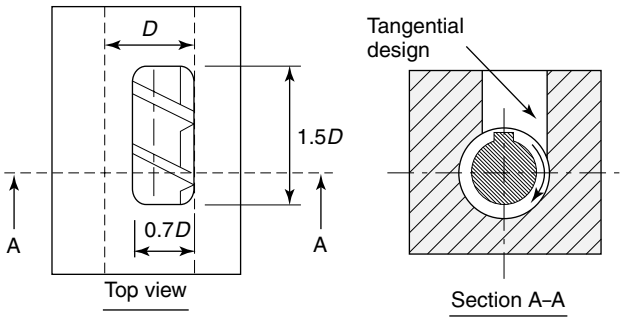

Fig. 8. Preferred geometry for feed opening in the feed throat.

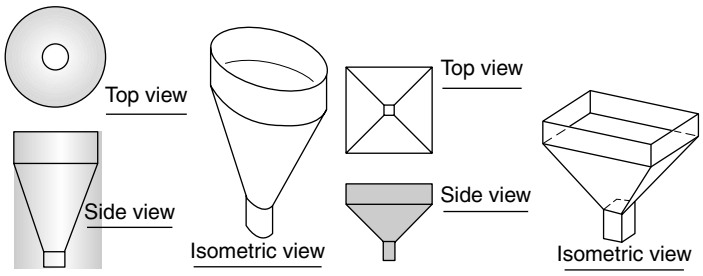

Fig. 9. Good hopper design (left) and poor hopper design (right).

disadvantages to such a setup. The advantages are lower cost, fewer parts, and no problems with alignment of the barrel to the feed throat. Disadvantages are that it is more difficult to create a thermal barrier between the hot barrel and the cold feed throat region, and good cooling of the feed throat region is more difficult.

The Feed Hopper. The feed throat is connected to the feed hopper and the extruder barrel. The feed hopper holds the plastic pellets or powder and discharges the material into the feed throat. The hopper should be designed to allow a steady flow of material through the hopper. Steady flow is best achieved with a circular hopper with a gradual transition in the conical section of the hopper (see Fig. 9). For difficult bulk materials, special devices, such as vibrating pads, stirrers, wipers, and even crammer screws, can be used to promote steady flow through the hopper so as to force the material to the discharge (see Fig. 10).

Barrel Heating and Cooling. The extruder barrel typically has both heating and cooling capability. Heating is usually done with electrical band heaters located along the length of the extruder. Induction and radiation heating are not commonly used; fluid heating is used in some rubber extrusion operations and on some older plastic extruders.

Most extruders have at least three temperature zones along the length of the barrel. Long extruders may have eight temperature zones or more. Each zone has its own heating and cooling capability and at least one temperature sensor to measure the zone temperature. The temperature is usually measured in the barrel. The die may have one or several temperature zones depending on its complexity.

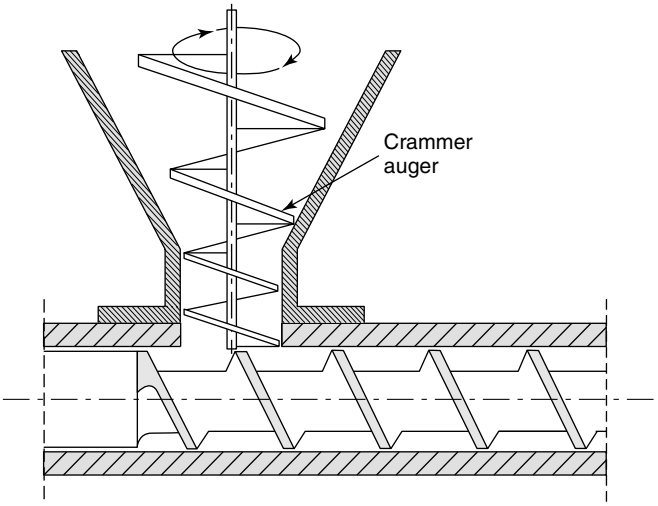

Fig. 10. Example of crammer feeder.

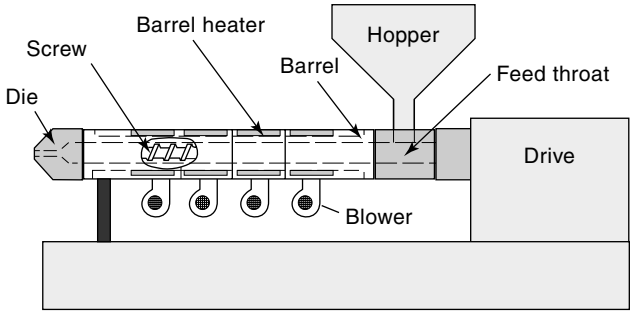

Fig. 11. Extruder with barrel heaters and blowers for cooling.

Some dies have more then 10 temperature zones. Dies have heating capability, but usually do not have cooling.

The barrel has to be cooled if the internal heat generation in the plastic raises the barrel temperatures above the set point. This is likely to occur when extruding high viscosity plastics and when running at high screw speeds. Cooling on single screw extruders is usually done with air. Blowers are placed under the extruder barrel and temperature zones are partitioned, so that one blower cools only one temperature zone (see Fig. 11).

Water cooling can be used as well, particularly if large amounts of heat must be removed. The extrusion process normally runs best when the screw supplies most of the energy needed in the process, so that little additional heating or cooling needs to be done through the barrel. As a result, air cooling is sufficient for most extrusion operations using single screw extruders. Since water cooling removes heat more quickly, it can be more difficult to maintain good temperature control

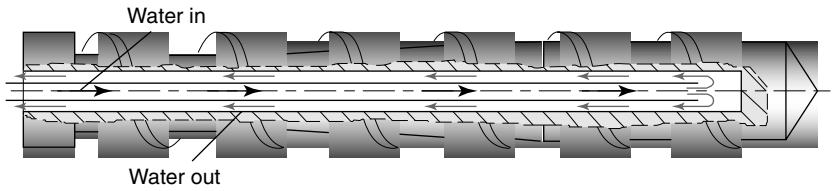

Fig. 12. Circulating a heat transfer fluid through the screw.

with water cooling. Oil cooling can be used as well; in fact, oil can be used both for heating and cooling.

With barrel cooling active, it is important to realize that even if the temperature is at its one word, the actual melt temperature is above the one word. With barrel cooling on, the heat flows from the plastic through the barrel to the outside. In this situation, the highest temperature occurs in the plastic. Even if the barrel temperature is at one word, the plastic temperature can be substantially higher. When a large amount of cooling is done in a particular part of the extruder the actual plastic temperature will be substantially above the barrel temperature set point. Therefore, barrel cooling should be minimized as much as possible.

Screw Heating and Cooling. The screw of an extruder is usually neither heated nor cooled; such a screw is called a *neutral screw*. However, it is possible to either heat or cool the screw by coring the screw (making it hollow) and circulating a heat transfer fluid through the hollow section (see Fig. 12). The screw can also be heated by a cartridge heater. The heater's electrical power has to be supplied through a slip ring assembly at the drive end of the screw. If the cartridge heater is equipped with a temperature sensor, the power to the heater can be controlled to maintain a constant temperature.

The Breaker Plate. The breaker plate is located at the end of the barrel. It is a thick metal disk with closely spaced holes.

The main purpose of the breaker plate is to support a number of screens located just ahead of the breaker plate. The other function of the breaker plate is to stop the spiraling motion of the melt as it comes off the screw. The breaker plate forces the melt to flow in a straight-line fashion into the die. It is possible to incorporate mixing capability into the breaker plate; this allows the breaker plate to act as a static mixer. Such a mixer was developed by The Madison Group in cooperation with Rauwendaal Extrusion Engineering. This mixing breaker plate (MBP) has many tapered channels that split the flow and expose the plastic melt to elongational flow. This promotes both distributive and dispersive mixing. An example of the MBP is shown in Figure 13. Different pattern can be machined into the MBP and several MBPs can be stacked together to enhance the mixing action.

The screens are used to trap contaminants so that they do not end up in the extruded product. Usually, several screens are stacked together, starting with a coarse screen, followed by increasingly finer screens, and then a coarse screen again right up against the breaker plate. The plastic melt thus flows through screens with increasingly smaller openings. The last coarse screen acts merely as a support for the finer screen. The collection of screens is called the *screen pack*.

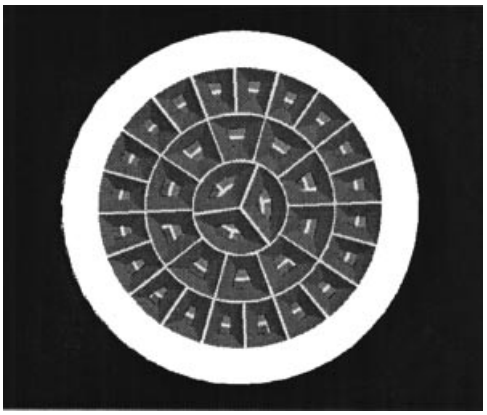

Fig. 13. Example of a mixing breaker plate.

The Screen Pack. The screen pack is not only used to trap contaminants, but in some cases the restriction of the screen pack is increased to increase mixing in the extruder. This works to some degree; however, the mixing can be improved more efficiently by adding mixing sections to the extruder screw. The most common filters are wire mesh screens. The mesh number of the screen represents the number of wires per inch (25 mm). The higher the mesh, the more wires per inch and the smaller the openings of the screen.

Figure 14 shows the relationship between the mesh value of the screen and the micron rating. The micron rating indicates what size particles the screen is able to trap. The higher the mesh, the lower the micron rating and, therefore, the

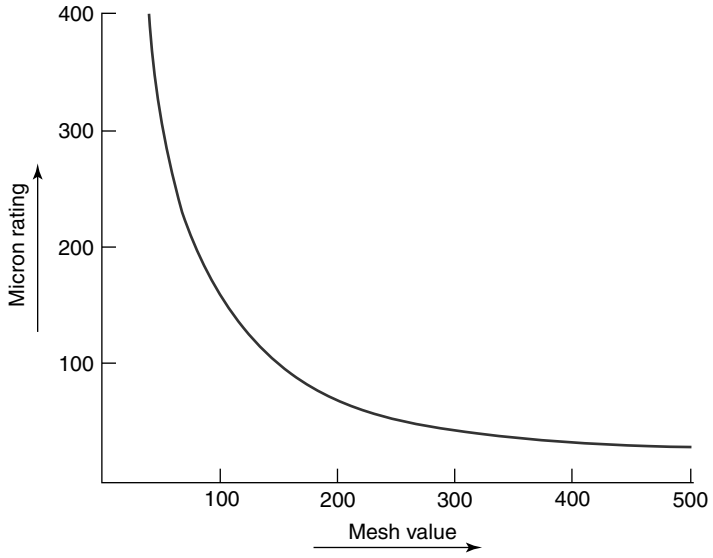

Fig. 14. The micron rating vs the mesh value for wire mesh screens.

Table 1. Comparison of Different Filter Media

	Wire mesh square weave	Wire mesh Dutch twill	Sintered metal powder	Random metal fibers

Permeability	Very good	Poor	Fair	Good
Price	Low	Fair	High	High

finer the screen. A typical screen pack can consist of a 20-mesh screen, followed by a 40-, 60-, and 80-mesh screens, with a final 20-mesh screen for support against the breaker plate.

There are a number of different filter materials. Wire screens are the most common. Several types of wire screens are available, such as the square mesh with plain weave and the square mesh with Dutch twill. There are also depth filtration media, such as sintered metal powder and random metal fibers. Advantages and disadvantages of different filter materials are shown in Table 1.

Other filter materials used in some cases are plates with small holes and filters made up of sand. Plates with small holes are useful in filtering out coarse contaminants and, for that reason, are used for prefiltration. Sand is inexpensive and because of the large volume, sand filters can operate for long periods before they have to be changed. A drawback of sand is that the filtration action is not uniform. Also, the run-in period for sand filters can be long and the installation is complicated.

Screen Changers. In some cases, screens have to be replaced at short intervals, for instance, every 2 h. This may happen when the plastic contains a substantial level of contaminants. In such a situation, it can be advantageous to use a *screen changer*, which is a device that allows a quick change of the screens. Some screen changers allow the extruder to keep running while the screens are changed; these are called *continuous screen changers*. Screen changers are useful when pressure increases rapidly at the screens. Screen changers can be manual or automatic. In many automatic screen changers, the screens are changed when the pressure drop across the screens reaches a preset value.

There are various types of screen changers, including manual screen changers, hydraulic screen changers, semicontinuous screen changers, screen changers with a continuous moving screen, and rotary-type screen changers. Manual screen changers are used on smaller extruders, up to about 120 mm or 4.5 in. They use a slide plate design with two circular screen blocks; one is in the melt flow at all times. When the pressure builds up to a certain level, the operator uses a hand lever to insert a new screen into position. At the same time, the dirty screen is pushed out of position so that it can be removed and replaced with a clean screen pack.

Hydraulic screen changers use a hydraulic ram to push the block containing a new screen into the melt stream (see Fig. 15). They can be used with larger extruders. Semicontinuous screen changers allow the screen to be changed without stopping the melt flow. In most units, trapped air is prevented from going into the melt stream by a bleed valve. Even if the entrapped air can be eliminated

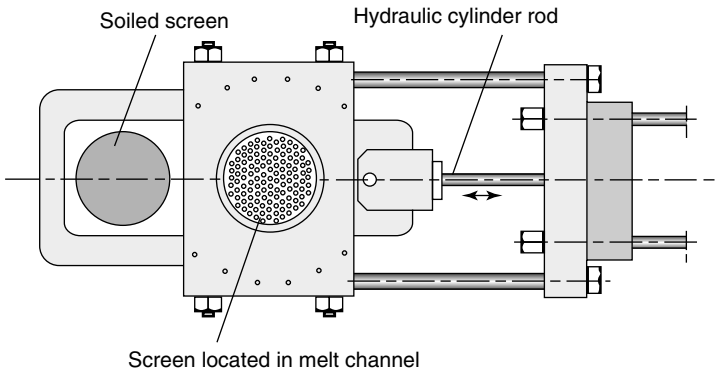

Fig. 15. Typical slide plate screen changer.

completely, there may still a pressure spike when a new screen is moved into position.

In screen changers with a continuously moving screen, a continuous band of screen material passes across the melt flow at a speed determined by the pressure difference across the screen. The rotary screen changer uses a moving wheel with 10–16 kidney-shaped cavities containing the screens. Each cavity moves slowly through the melt stream. This is similar to the continuously moving screen, except that in the rotary screen, the screen itself is not continuous because of the webs between the cavities. The webs, however, are relatively thin, so that at all times at least 90% of the channel is occupied by the screen. Rotary screen changers use separate screen inserts that are changed by the operator. The advantage of the screen changer with the continuously moving screen and the rotary screen is that pressure disturbances during screen changes are minimized.

The Extrusion Die. The die is placed at the discharge end of the extruder. Its function is to form the flowing plastic into the desired shape of the extruded product. Dies can be categorized by the shape of the product that they produce. Annular dies are used to make tubing, pipe, and wire coating. Slit dies are used to make flat film and sheet. Circular dies are used to make fiber and rod. Profile dies are used to make shapes other than annular, circular, or rectangular. Dies are also named by the product that they produce. So, we talk about tubing dies, flat film dies, blown film dies, etc.

The inlet channel of the die is usually designed to match the exit of the extruder. If the die entrance does not match the extruder exit, an adapter can be used between the extruder and the die. The three main elements of the die flow channel are the inlet channel, the manifold, and the land region (see Fig. 16).

The flow channel of the die should be designed such that the plastic melt achieves a uniform velocity across the die exit. The shape of the land region of the die corresponds to the shape of the extruded product. An example of an in-line tube or pipe die is shown in Figure 17. The material flows into the die from the extruder; then it flows around a torpedo.

The torpedo is supported by spider legs that have a streamlined shape to achieve smooth flow around the support legs. From the torpedo, the plastic melt

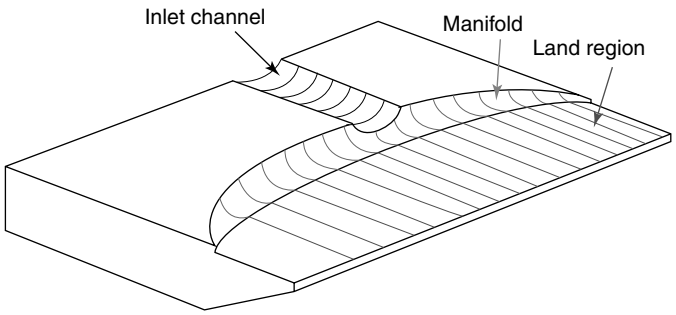

Fig. 16. The three main elements of an extrusion die.

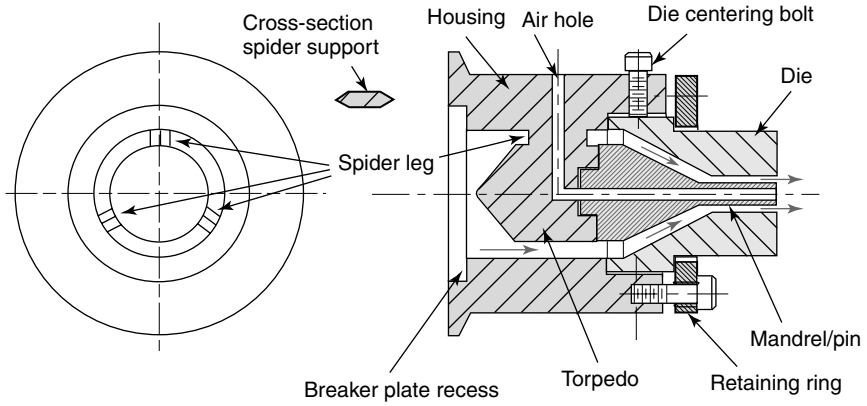

Fig. 17. Example of in-line tubing or pipe die.

flows to the tip and die where it is shaped into an annulus, so that a tube-shaped product emerges.

The size and shape of the land region are not exactly the same as the extruded product. There are several reasons for this: draw down, cooling, swelling, and relaxation. Because of the several variables affecting the size and the shape of the extruded plastic, it is often difficult to predict how exactly the size and shape of the plastic changes as it leaves the die. As a result, it is also difficult to predict how the die flow channel should be shaped to achieve the desired shape of the extruded product. This is an important reason why die design is sometimes still largely based on experience rather than on engineering calculations. With the advent of improved numerical techniques and commercial die flow analysis software, this situation is improving; however, die design is still often a trial and error process.

Coextrusion Dies. Another type of die used in the extrusion industry is the coextrusion die. This type of die is used to make a multilayered product in one step. There are two main coextrusion systems: the feed block system and the multimanifold system. In the feed block system, the different plastic melt streams are combined in a feed block and then fed into a regular single manifold extrusion die (see Fig. 18).

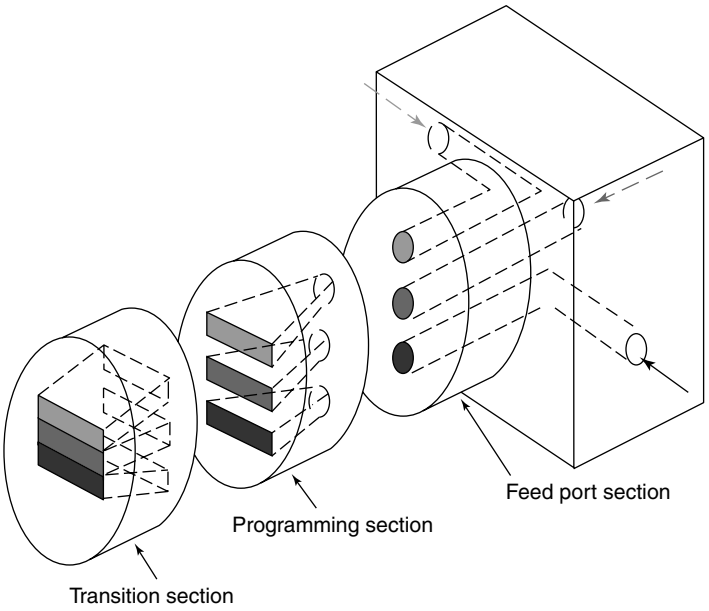

Fig. 18. Example of a feed block system.

In the multimanifold system, the different plastic melt streams enter the die separately and each material has its own manifold. The different melt streams combine close to the die exit to make the multilayered product (see Coextrusion).

The Extruder Drive. The screw drive is usually an electric motor that supplies the power to turn the screw. The nominal speed of the motor is typically around 1800 rpm, while a typical maximum screw speed is about 100 rpm. As a result, a speed reducer is needed between the motor and the screw. Various motors can be used for extruders. DC motors are most common up to the 1990s; nowadays, AC motors are starting to be used more frequently. Older extruders often use a DC brush motor with tachometer feed back. This yields a speed regulation of about 1% of full speed. One-percent regulation may be acceptable for some products, but it may not be good enough for high precision operations, such as medical tubing, particularly when the extruder operates at low speed. For example, if an extruder has a maximum screw speed of 100 rpm and a DC brush motor with tachometer feed back, the screw speed can vary as much as 1 rpm (see Table 2).

However, if the screw speed is reduced to 10 rpm, the screw speed can still vary as much as 1 rpm. This 1-rpm variation now represents 10%. Obviously, this

Table 2. Screw Speed Variation at Different Screw Speeds

Screw speed, rpm	Screw speed variation, rpm	Screw speed variation, %
100	1	1
10	1	10

would be too much for a high precision extruded product. Fortunately, nowadays we have drives with better speed control. For example, there are brushless DC drives with a speed regulation of about 0.01% of full speed. Drives with similar speed control are digital DC brush drives and variable frequency AC vector drives. Servo drives can achieve speed regulation that is considerably better than 0.001% of full speed.

Coupling between Motor and Gearbox. When we have a direct coupling between the motor and the gear reducer, we call this a *direct drive* (see Fig. 19). Some extruders have a belt transmission between the motor and the gear reducer; these are called *indirect drives* (see Fig. 20). Advantages of direct drives are no chance of slippage, energy efficiency, and fewer parts. The disadvantage of a direct drive is that it may be more difficult to change the reduction ratio. Advantages

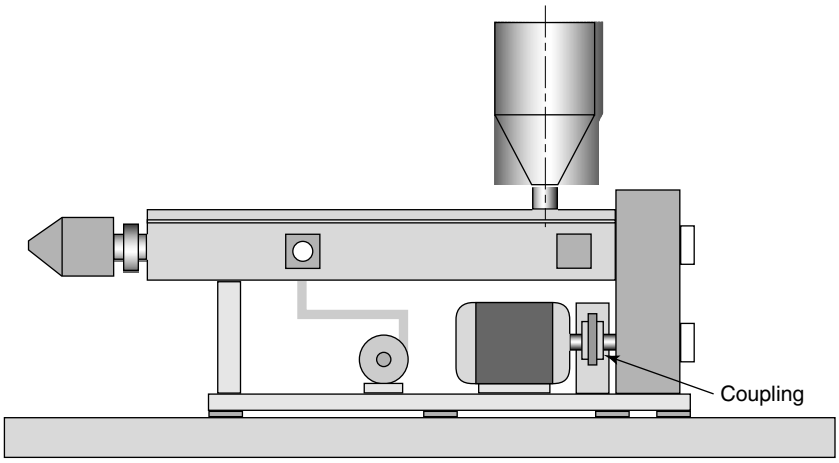

Fig. 19. Example of extruder with direct drive.

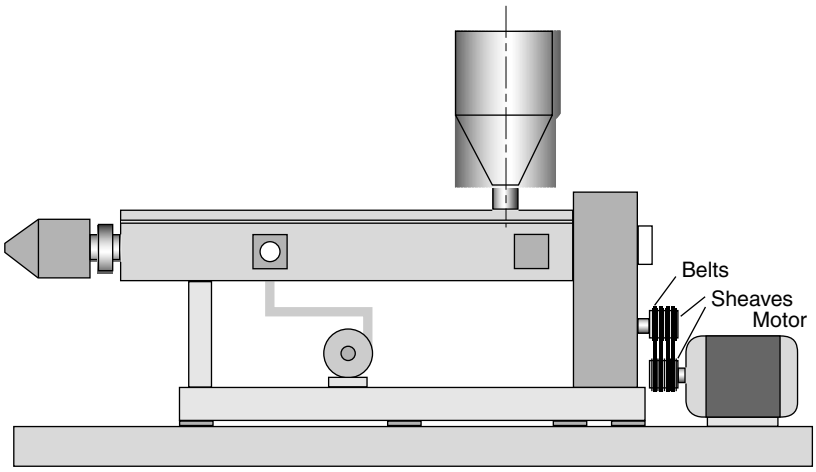

Fig. 20. Example of an extruder with indirect drive.

of indirect drives are ease of changing the reduction ratio and more freedom to position the motor. Disadvantages of indirect drives are chance of slippage, energy loss in the belts, and more parts that can wear out and fail.

Even though direct drives appear to be more attractive, many extruders are made with indirect drives. An example of an extruder with an indirect drive is shown in Figure 20.

The Speed Reducer. A speed reducer is necessary because the speed of the motor is much higher than the speed of the screw. Typical reduction ratios range from 15:1 to 20:1; they can be as low as 5:1 and as high as 40:1. The most common reducers with extruders are gear reducers using spur gears. A popular spur gear is the herringbone gear. The V-shaped tooth design practically eliminates axial loads on the gears.

Important issues with gear reducers are the reduction ratio, energy efficiency, power transmission capability, cost, and backlash of the gearbox. Backlash is basically the slop in the gears. If the screw speed is maintained at a constant value, backlash is not a big issue. However, if the screw speed is changed quickly, as is done in some advanced control schemes, then the backlash should be minimal to maintain good speed control and to avoid rapid wear of the gears.

Gear boxes can be made with a quick-change gear provision. This allows a quick and easy change of the gear ratio. A quick-change gear provision can improve the flexibility and versatility of an extruder. Changing the gear ratio on a regular gearbox is a precision job and is quite time consuming. Most gear boxes in the industry are not quick-change gear boxes.

Thrust Bearing Assembly. Thrust bearings are necessary because the extruder screw has to develop substantial pressure to overcome the flow resistance of the die. Typical diehead pressures range from 7 to 28 MPa (about 1000 to 4000 psi). The melt pressure at the end of the screw causes a thrust force on the screw, pushing it in the direction of the drive. The thrust bearings are necessary to take up the thrust load acting on the screw. A 150-mm (6-in.) extruder running at a head pressure of 35 MPa (about 5000 psi) experiences an axial thrust of about 620 kN (about 140,000 lbf). The thrust bearing assembly may be connected to the gear reducer or it may also be part of the gearbox itself.

The ability of the thrust bearings to handle the thrust load on the screw is reflected in the *B-10 life* of the thrust bearings. The B-10 life is the number of hours that 9 out of 10 identical bearings last at a certain load and speed. The B-10 life for the extruder thrust bearings is usually given at a head pressure of 35 MPa (5000 psi) and a screw speed of 100 rpm. If an extruder is operated 24 h a day, the B-10 life should be at least 100,000 h to get a useful life of more than 10 years out of the thrust bearing.

The Gear Pump. Extruders have some limitations, including the fact that high output stability is difficult to achieve. This is important in high precision extrusion operations such as fiber spinning or medical tubing extrusion. The best output variation that can be obtained in a regular extruder is about 1%. To improve the output stability, a gear pump can be added to the extruder; it is placed between the extruder and the die. The gear pump consists of two intermeshing counter-rotating gears.

Material entering the gear pump is trapped in the space between two teeth and moves forward in a circular path with the gears. At the point where the gears

start to intermesh, the plastic melt is forced out of the gears and to the discharge of the pump. The action of a gear pump is similar to that of a bucket brigade. The "buckets" are filled at one end and emptied at the other end. If each bucket has the same volume and is filled completely, precise control of the flow rate can be achieved.

The conveying of plastic melt in the gear pump is by forced conveying rather than by drag as is the case in the extruder. As a result, good output stability is easier to achieve with a gear pump than without one. Another advantage of the gear pump over the extruder is that it generates pressure more efficiently. As a result, gear pumps make sense in the following applications:

(1) high precision extrusion where the output variability must remain less than 1%
(2) operations where the extruder does not have sufficient pressure generating capability, for instance, a vented extruder that has to operate at high barrel pressure

There are some operations where the use of gear pumps can create problems. One is when a plastic containing abrasive fillers or other abrasive ingredients is extruded. This causes wears of the gear pump and reduces its pumping accuracy. Another potential problem can occur when a gear pump is used with a plastic that is susceptible to degradation. In many gear pumps, the plastic melt is used to lubricate the gears. This means that a small fraction of the plastic spends a long time in the gear pump, as much as 15 min or longer. The long residence time in the gear pump combined with the high temperatures can cause degradation.

Complete Extrusion Lines

In addition to the extruder, upstream and downstream equipment is needed to produce a useful product. The main elements of an extrusion line are resin handling system, drying system, extruder, post-shaping or calibrating device, cooling device, take-up device, and cutter or saw. The main types of extrusion lines are tubing and pipe extrusion lines, film and sheet extrusion lines, extrusion compounding lines, and profile extrusion lines. Besides these four main types there are quite a few more, such as fiber spinning lines, extrusion blow molding machines, and integrated sheet and thermoforming lines.

Tubing and Pipe Extrusion Lines. Dies for tubing and pipe were discussed earlier. Small diameter tubing (less than 10 mm) is usually made with a free extrusion process; this is a process without a sizing or calibrating unit. Large diameter tubing and pipe is made with a sizing device just downstream of the die. The purpose of the sizer or calibrator is to solidify the plastic to a thickness sufficient to transfer the stresses acting on the product while maintaining the desired shape and dimensions. The main components of a typical tubing extrusion line are shown in Figure 21.

This line does not use a sizing unit and thus, would be used for small diameter tubing. The gear pump may or may not be used depending on the precision

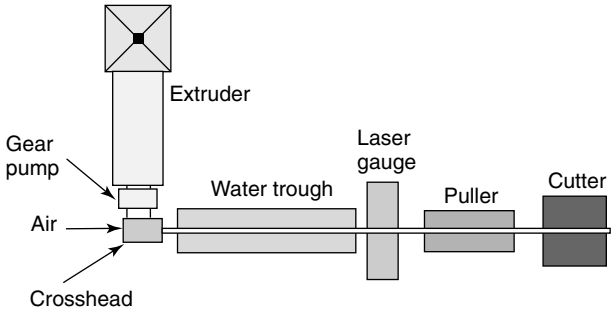

Fig. 21. Components of a typical tubing extrusion line.

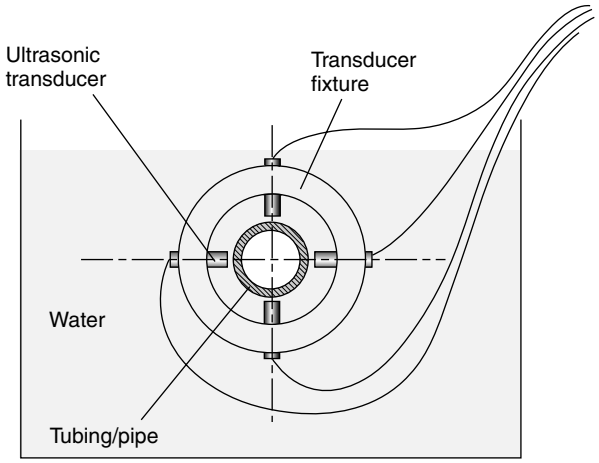

Fig. 22. Ultrasonic wall thickness gauge.

required in the extrusion process. The internal air pressure of the tubing is controlled to achieve the correct values for the outside diameter and wall thickness. The diameter is often measured with a laser gauge to allow close monitoring and control. The diameter and the wall thickness are primarily determined by the extruder output, the puller speed, and the internal air pressure. Closed loop control systems are available that automatically set the appropriate screw or gear pump speed, the puller speed, and internal air pressure. After the puller, the tubing may be cut or reeled up on a spool. In some lines, the wall thickness is measured directly; this can be done with ultrasonic sensors positioned around the circumference of the tubing or pipe as shown in Figure 22.

Film and Sheet Lines Using the Roll Stack Process. There are no significant differences between the extrusion of flat film and sheet. The main components of a sheet line are the extruder, the roll stack, the cooling section, the nip roll section, and the winder (see Fig. 23). The roll stack contains three rolls that are often referred to as polishing rolls. They are used to exert pressure on the sheet and to impart the surface conditions of the rolls to the plastic sheet. If a smooth surface is required, smooth rolls are used. If a textured surface is needed,

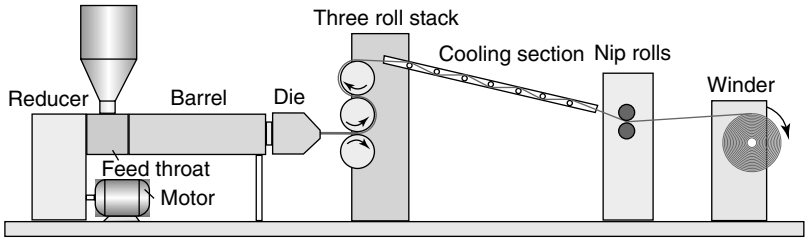

Fig. 23. Components of a sheet or flat film extrusion line.

a textured surface is used on the roll. The roll texture is the negative of the texture required on the sheet. It is possible to produce a sheet with one textured surface and the other smooth by using a smooth and textured roll next to each other.

Figure 23 shows the plastic sheet going up along the center roll and making an S-wrap around the center roll and top roll; this is called "upstack" operation. Sheet lines can also run in the "downstack" mode, where the material makes an S-wrap around the center roll and bottom roll. The rolls do not have to be in the vertical position; they can be in a horizontal position or any angle between vertical and horizontal. In fact, in some roll stacks, the angle is adjustable.

The rolls are normally cored so that the temperature of the rolls can be controlled. This is usually done with circulating hot oil. It should be possible to adjust the temperature of each roll separately. The cooling section consists of a number of rolls positioned in a frame; the sheet runs over and under the rolls to keep the sheet flat. At the end of the cooling section are the pull rolls or nip rolls; these are rubber rolls that pull the sheet from the roll stack to maintain a certain tension in the sheet. After the nip rolls, the sheet is led to the winder that rolls the sheet on a core. Many different winders are available; some winders automatically transfer the sheet to a new core when one package is full.

Film Lines Using Chill Roll Casting. Thin films are often cast on a chill roll rather than extruded into a roll stack. The main components of a cast film line are the extruder, the film die, the chill roll unit, the thickness gauging system, the surface treatment unit, and the winder.

The film is extruded downward onto the chill roll. The initial contact between the film and the chill roll is established by the use of an air knife. The air knife produces a thin stream of high velocity air across the width of the chill roll, and the air stream pushes the film against the roll surface, as shown in Figure 24.

From the chill roll unit the film is led to a thickness-gauging unit where the thickness of the sheet is measured across the width of the film. Most thickness gauges for film and sheet have a scanning measuring head that traverses across the film back and forth to measure thickness both along the length and across the width of the film.

After the thickness-gauging unit, the film passes through a surface treatment unit. Such a unit is incorporated if surface treatment of the film is required. This is usually done to improve adhesion, for instance, for a subsequent printing or laminating operation. The most important adhesion promoters are flame treatment, corona-discharge treatment, ozone treatment, and primers. From the

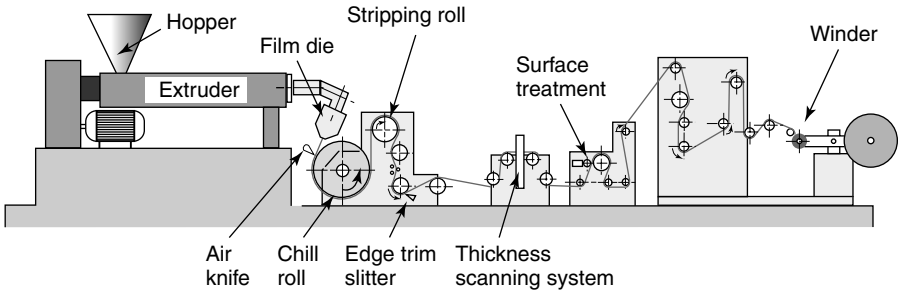

Fig. 24. Components of a cast film extrusion line

treatment unit, the film is led to the winder unit. Just as with sheet extrusion, many different types of winders are available.

Combination of Materials. The requirements of many products, particularly in packaging applications, are such that a single plastic cannot meet all of them. To meet the requirements, often two or more materials have to be combined. There are a number of techniques to combine different materials; some of the more important ones are coextrusion, coating, and lamination.

Coextrusion. *Coextrusion* is a commonly used technique to combine two or more plastics passing through a single extrusion die. There are two major coextrusion techniques: the feed block system and the multimanifold system. In the feed block system the different plastics are combined in the feed block module (see Fig. 18) and then enter into a regular extrusion die with a single inlet, manifold, and outlet.

The advantage of the feed block system is that it is simple, inexpensive, and allows many layers to be combined. The main drawback is that the flow properties of the different plastics have to be quite close to avoid interface distortion. This limits the choice of materials that can be combined through feed block coextrusion.

In the multimanifold system each plastic has its own entrance and manifold in the coextrusion die. The different melt streams are combined just before they exit the die, so that minimum interface distortion can occur. The advantage of the multimanifold system is that plastics with widely different flow properties can be combined. As a result, there is a wide choice of materials that can be combined through this extrusion technique. The disadvantage is that the design of the die is more complicated and therefore more expensive.

Figure 25 shows a multimanifold sheet or film die. This die has two inlets, two manifolds, and a single outlet. The flow of the upper layer can be adjusted by flexing the choker bar, using the adjustment nuts. The two plastics combine at the entrance to the land region; this is the last parallel section of the die flow channel. The flow in the land region can be adjusted with the flex lip adjustment bolts. These bolts are located along the width of the die exit with a spacing of about 25–40 mm (1.0–1.5 in.) and allow local adjustment of the die gap. Some newer sheet and film dies have a flexible membrane to allow adjustment of the flow. Many multimanifold dies are possible, including flat film and sheet dies, tubing and pipe dies, blown film dies, and profile dies.

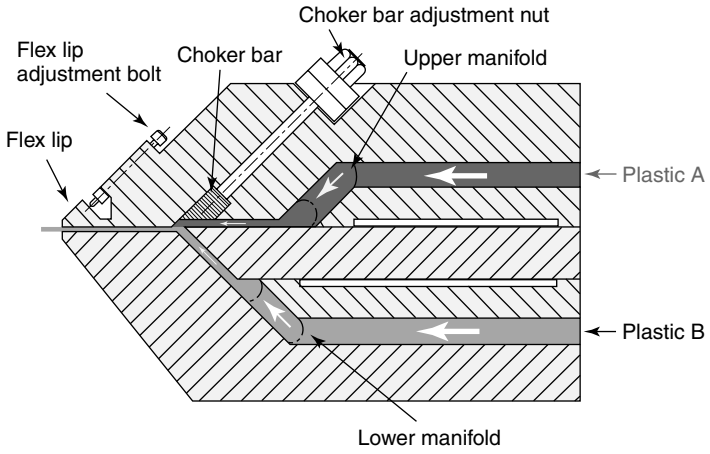

Fig. 25. Example of a multimanifold sheet die.

Extrusion Coating. In extrusion coating, a molten layer of plastic film is combined with a moving solid web or substrate. The substrate can be paper, paperboard, foil, plastic film, or fabric; the substrate can also be a multilayer product. A schematic of an extrusion coating operation is shown in Figure 26.

Extrusion Lamination. Extrusion lamination involves two or more substrates, such as paper and aluminum foil, combined by using a plastic film as the adhesive between the two substrates (see Fig. 27). The webs may be preheated or surface treated to improve bonding with the plastic film.

The extruded sheet or film can be laminated with a film on one side or both sides. The laminate can be paper, foil, mesh, or a number of other materials. With lamination many different structures of sheet or film products can be made. The laminate is unrolled from a payoff, combined with the film, and

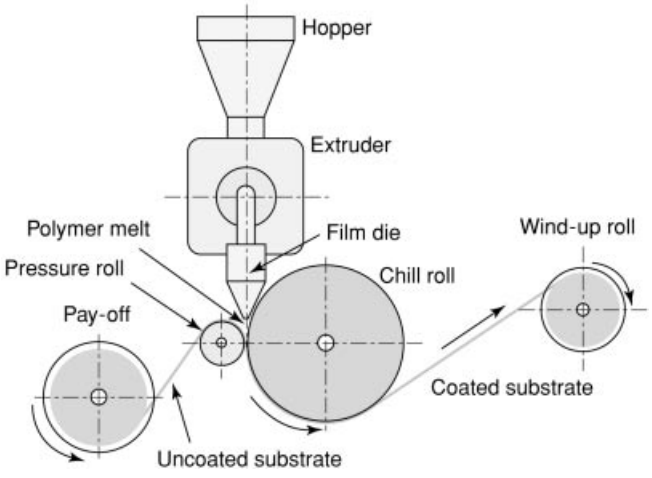

Fig. 26. Schematic of extrusion coating operation.

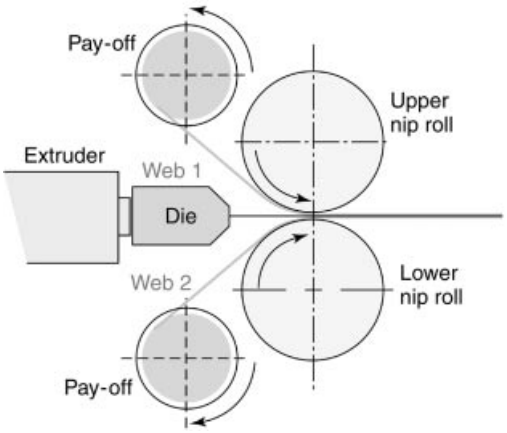

Fig. 27. Schematic of extrusion lamination.

immediately led into a set of nip rolls. After lamination, the film is handled as a regular film.

Blown Film Lines. A blown film line is quite different from a flat film line. In a blown film line, a tubular film is extruded vertically upwards as shown in Figure 28. Air is introduced to the inside of the tube; as a result, the tube expands to a bubble with a diameter larger than the diameter of the die. The ratio of the bubble diameter to the die diameter is called the *blow-up ratio*. Typical blow-up ratios used in LDPE film extrusion for packaging are in the range of 2.0–2.5:1.

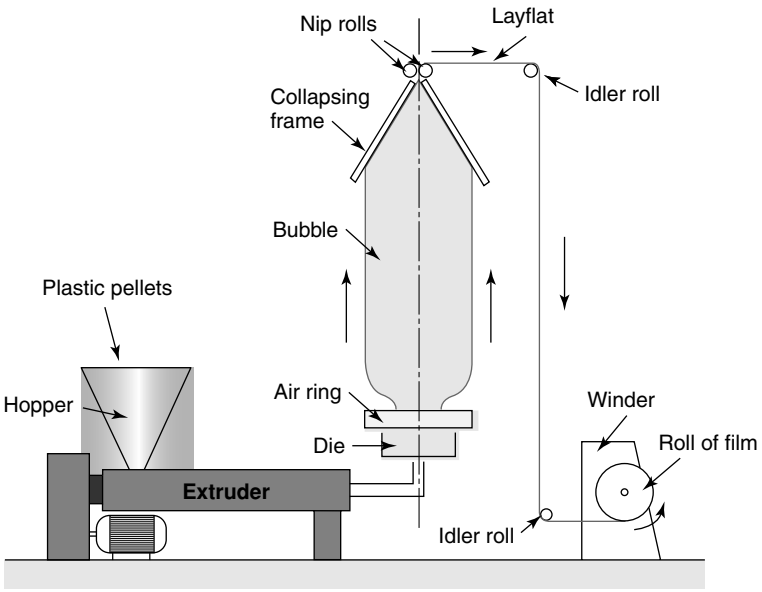

Fig. 28. Schematic of blown film line.

When the bubble has cooled sufficiently, it is flattened in a collapsing frame and pulled through a set of nip rolls to its top. From there, the layflat film is guided over several idler rollers to the winder where it is rolled up over a core.

One advantage of the blown film process is that it can produce not only tubular products (bags) but also flat film, simply by slitting open the tube. In some blown film processes the plastic is extruded downwards to produce films with special properties.

Extrusion Compounding Lines. Compounding lines come in many shapes and sizes. Compounding can be done on single screw extruders, twin screw extruders, reciprocating single screw compounders, batch internal mixers, and continuous internal mixers. The configuration of the line is determined, among other things, by the ingredients to be combined in the compounding extruder. The downstream equipment typically consists of a pelletizing system (see Fig. 29). The polymeric components are usually added through the first feed port. Fillers are often added to a downstream feed port at a point where the plastic has melted already; this arrangement reduces wear on the extruder that might be caused by the filler. High levels of filler are often added by a twin screw stuffer, particularly when the filler has a low bulk density. With high levels of filler, there is often a substantial amount of entrained air; this is removed through the vent port. The vent port is often connected to a vacuum pump; a high level of vacuum improves the removal of volatiles from the plastic.

Some pelletizers cut extruded strands cooled in a water bath; these are called strand pelletizers. Dicers cut extruded sheet rather than strands. The pellets from a dicer have a uniform cubic or octahedral shape. Other pelletizers cut the material right at the die exit; these are called die face pelletizers. These cutting systems can be dry die face pelletizers, water ring pelletizers, and under water pelletizers.

In dry die face pelletizers, the molten plastic is cut at the die face. The pellets are hurled away from the die face by the rapid motion of the cutter knives usually into a water slurry. In water ring pelletizers, the centrifugal action of the cutter hurls the pellets into a snail's cage of water whirling around the perimeter of the cutter housing. The slurry flows to a centrifugal dryer. In underwater pelletizers, the molten plastic is extruded directly into water and cut immediately by a multiple knife cutter. The die may need special heating capability to avoid die plate freeze-off. The start-up procedure for underwater pelletizers often requires careful sequencing of plastic flow, cutter rotation, and inlet water flow rate to avoid die freeze-off or agglomeration.

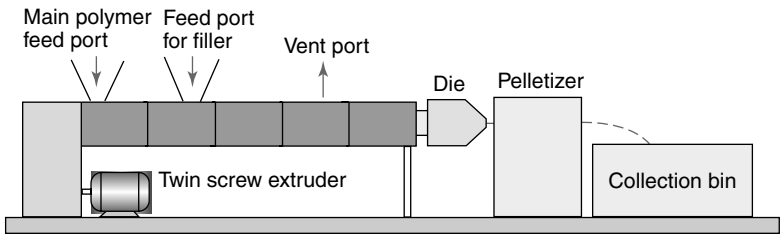

Fig. 29. Typical extrusion compounding line.

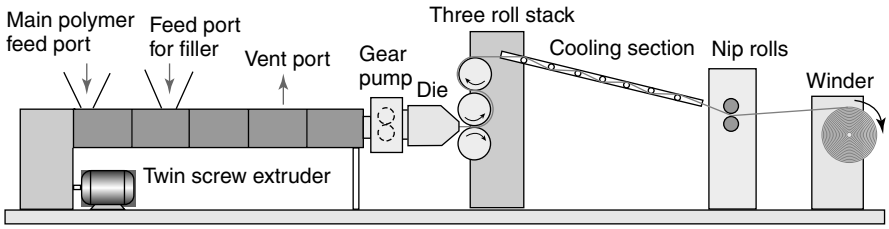

Fig. 30. Extrusion compounding line with in-line shaping.

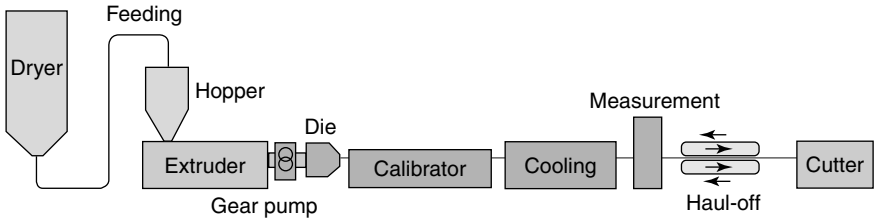

Fig. 31. Components of a profile extrusion line.

Compounding extruders can also be combined with direct forming systems downstream. In many cases, a gear pump is placed at the discharge end of the extruder to generate the diehead pressure and to control the throughput. An example of a combination compounding/sheet extrusion line is shown in Figure 30.

The plastic is introduced to the first feed port of the compounding extruder, the filler is introduced to the second feed port, and the volatiles and air entrapment are removed from the vent port. A gear pump is placed between the compounding extruder and the sheet die. The sheet is fed to a roll stack and from there it is handled as in a normal sheet line, as discussed earlier.

Profile Extrusion Lines. Many extrusion lines are used for the production of profiles. Profile lines also come in many shapes and forms. A typical extrusion line consists of an extruder, a die, a calibrating unit, a cooling unit, a measurement device, a haul-off, and a coiler or cutter or saw (see Fig. 31). A gear pump may be used if the dimensional tolerance of the extruded product is quite small. On some profile lines a film or foil is laminated to the extruded profile. Extruded profiles have an enormous range of shapes and sizes.

Extrusion Tasks: Inner Workings of an Extruder

In a plasticating extruder, a number of tasks are performed that are each critical to the proper functioning of the extruder. These tasks or functions are solids conveying, melting or plasticating, mixing, melt conveying, degassing, and shaping or forming.

Degassing is not done on all extruders; some extruders are equipped with a vent port. The vent port allows volatiles or gasses to escape from the plastic melt. Degassing is also referred to as devolatilization. The functions listed above are

interdependent. For instance, a change in the forming region affects the other functions. The forming region is the extrusion die. So, if the die temperature in lowered, this affects melt conveying, melting, mixing, solids conveying, and degassing if a vented extruder is being used.

To understand how an extruder works, it is important to know what happens in the different functional zones in an extruder. The starting and end points of each functional zone depend on the machine geometry, the plastic properties, and the operating conditions. For instance, melting starts where the plastic temperature first exceeds the melting point. This point can shift when barrel temperatures or screw speed are changed.

On the other hand, the geometrical sections of the screw are fixed by the screw geometry. The feed section is the first deep flighted section of the screw and this is where solids conveying occurs. However, the solids conveying zone may end before or after the end of the feed section. The same is true for the melting in the transition section of the screw and the melt conveying in the metering section of the screw. The boundaries of the screw sections are fixed, but the boundaries of the functional zones can shift with plastic properties and operating conditions.

Solids Conveying

Solids conveying occurs both in the feed hopper and along the first several diameters of the screw. The solids conveying in the feed hopper results from the weight of the material. The conveying mechanism at work in the hopper is called *gravity induced conveying*. The material flows down the feed hopper into the feed throat and from there, into the screw channel. The conveying along the screw results from frictional forces acting on the plastic. This conveying mechanism is called *drag induced conveying*, and is the mechanism in the solids conveying zone, the melting zone, and melt conveying zone.

Gravity Induced Conveying. The flow in the feed hopper can be quite complicated. A number of things can go wrong in this section of the machine. For instance, if the bulk material consists of small and large particles, the small particles can separate from the larger particles, causing nonuniform flow from the hopper. This, in turn, causes instabilities in the extruder resulting in output variation.

Some bulk materials are very difficult to handle; for instance, post consumer reclaim (PCR) usually has a wide particle size distribution and a low bulk density. As a result, special extruders have been developed to handle this bulk material efficiently. These machines can have larger diameters in the feed section than in the metering section; they may also use crammer feeders to achieve steady flow of material into the extruder. In some cases, a grooved feed section is used to improve the feeding of low bulk density material.

Important bulk properties are bulk density, compressibility, internal coefficient of friction, external coefficient of friction, particle size and particle size distribution, and particle shape and particle shape distribution.

The bulk density is the density of the material, including the air voids between the particles. The density of a material is the mass per unit volume. The bulk density of pelletized material is usually around 60% of the regular density.

If the bulk density is less than about 30% of the actual density, conveying the bulk solid can become quite problematic and special design features may be necessary to ensure consistent flow. The compressibility is the change in bulk density when pressure is applied. A high compressibility indicates a bulk material that compacts readily under pressure. Highly compressible materials are difficult to handle and susceptible to various flow problems in feed hoppers.

The *internal coefficient of friction* is the friction between the plastic particles themselves. The *external coefficient of friction* is the friction between the plastic particles and another surface, such as the barrel surface. For efficient conveying in the feed hopper, it is required that both the internal and external frictions should be low. For efficient conveying along the extruder screw, it is required that the barrel friction to be high and the screw friction should be low; this is discussed later.

The design of the feed hopper can have a strong effect on the flow in the hopper. This is particularly true for difficult bulk flow materials. Stagnation should be avoided in the flow through the hopper. As a result, a circular hopper is better than a hopper with a square or rectangular cross section (see under The Feed Hopper). Also, the converging region of the hopper should expose the material to a gradual compression; otherwise, unstable flow results. If the compression of the material is too rapid, the flow may stop altogether. This can happen when the bulk material is susceptible to *bridging*. This is a condition where a natural bridge is formed in the material strong enough to support the material above it. When bridging occurs, the flow can stop completely.

Various devices can be used in the feed hopper to promote steady flow. Sometimes stirrers are used to gently mix the material. The stirrer may be equipped with a blade to wipe the material off the hopper wall. This can be beneficial if the material has a tendency to stick to the wall. When the material is susceptible to bridging, vibrating pads may placed against the hopper to create a vibrating action to dislodge any bridges that could form. When the bulk material is very difficult to handle, a crammer feeder may be used. This is a conveying screw placed in the hopper that forces the material to the discharge by the rotation of the screw (see under The Feed Hopper).

A special feed hopper design to minimize flow problems was developed by Johanson (1). The geometry of this hopper transitions from a circular cross section to an oval cross section and back to a circular cross section; it is called the diamondback hopper (see Fig. 32).

The solids conveying into the extruder is also affected by the design of the feed opening. For difficult bulk flow materials, it has been found that an elongated feed opening improves feeding (see also under The Feed Housing). Also, feeding can be improved by offsetting the opening in the direction of the movement of the screw flight in the top position, as shown in the figure. By offsetting the feed opening, a more or less tangential feed opening is created that increases the action of the screw flight in pushing the feed material into the extruder barrel.

Drag Induced Conveying. Once the bulk material drops into the screw channel, it starts moving along its length as a result of frictional forces acting on the plastic. To understand conveying in screw extruders, it is important to know which frictional force is responsible for the forward movement of material and which force is holding the material back. Since the material moves forward as a

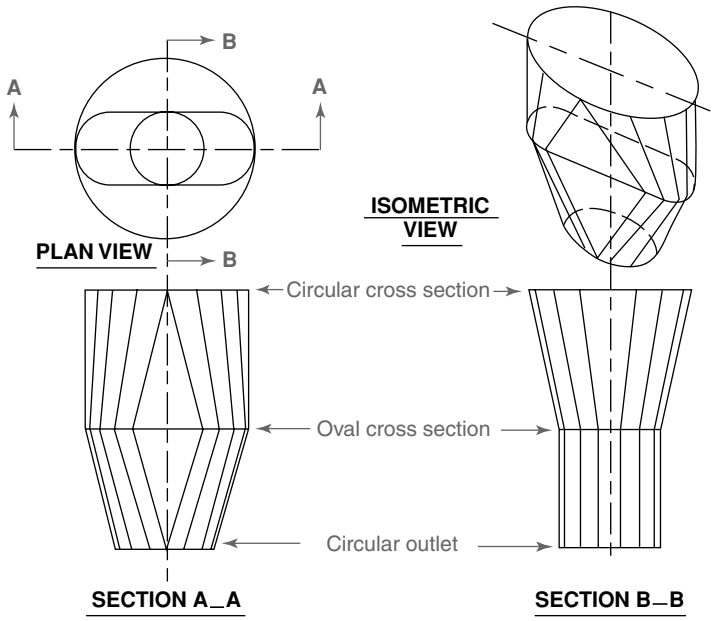

Fig. 32. The diamondback feed hopper (U.S. Pat. 4958741).

result of the rotation of the screw, it would seem that the friction between the plastic and the screw moves the material forward.

Even though this seems like a plausible argument, this is not what really happens. It is the frictional force at the barrel that is responsible for moving the material forward. To understand this, consider an extruder with a barrel coated with a zero friction material. In this case, the material drops down into the screw channel and, once in there, only moves with the screw, around and around. Without friction at the barrel, there is no forward movement of the material.

Another analogy is a rotating threaded shaft with a nut on the shaft that is free to rotate with the shaft. In this situation, the nut stays in the same position on the shaft rotating with the shaft, but not moving forward. If the nut is kept from rotating with the shaft, the nut starts to move along the length of the shaft. If the extruder screw is considered as being the threaded shaft and the plastic as being the nut on the shaft, then it becomes clear why the friction at the barrel is responsible for moving the material forward (see Fig. 33). In fact, barrel friction is a necessary condition for forward transport. If there is no barrel friction, then there can be *no* forward conveying.

Starve Feeding. Starve feeding is a method of feeding the extruder where the plastic is metered directly into the extruder at a rate below the flood feed rate. This means that the plastic drops directly into the screw channel without any buildup of plastic in the feed hopper. With starve feeding, the screw channel is partially empty in the first few diameters of the extruder. Thus, if one looks into the feed opening, one should be able to see the screw flight and part of the root of the screw.

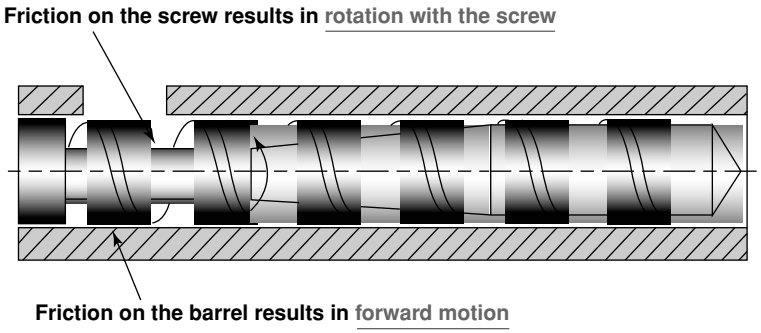

Fig. 33. Driving force and retarding force in conveying along the extruder screw.

When the screw channel is partially filled, there is no pressure development in the plastic. Without pressure development, there is very little frictional heating and mixing. In effect, starve feeding reduces the effective length of the extruder. Thus, a 25 *L*/*D* extruder might have an effective length of only 21*D* with the first four diameters partially filled with material. Starve feeding may be beneficial if the extruder is longer than necessary for the plastic being processed. However, if the length of the extruder is marginal, starve feeding most likely results in poor extruder performance.

Starve feeding is commonly used on high speed twin screw extruders; in fact, most high speed twin screw extruders run starved. Starve feeding is less commonly used with single screw extruders, because it is beneficial only in some cases. Starve feeding can be useful to reduce the motor load of the extruder, to reduce the temperature buildup in the plastic melt, and to add several ingredients simultaneously through one feed port using several feeders.

In mixing and compounding starve feeding can be very useful because it reduces the chance of agglomeration of the filler. As a result, mixing and compounding operations frequently use starve fed extruders. A number of workers have reported dramatic improvement in dispersive mixing when comparing flood fed to starve fed extruders.

Grooved Feed Extruders. The driving force for the conveying process is the frictional force at the barrel surface, as discussed earlier. The frictional force can be affected by adjusting the barrel temperature in the first one or two temperature zones. However, the effect of barrel temperature is usually small. Another method of increasing barrel friction is to machine grooves into the barrel surface; this has a strong effect on the feeding characteristics of the extruder. The grooves typically run in the axial direction, with a length of several screw diameters. The barrel around the grooved section has to be cooled to avoid plastic from melting in the grooved section; the plastic can degrade if melt collects in the grooves.

A relatively new development is the adjustable grooved feed extruder (AGFE). This extruder has a grooved feed section with a mechanism that allows adjustment of the groove depth (2). This makes it possible to adjust the solids conveying efficiency to match the characteristics of the plastic and the screw geometry. The adjustment to the grooves can be made while the extruder is running.

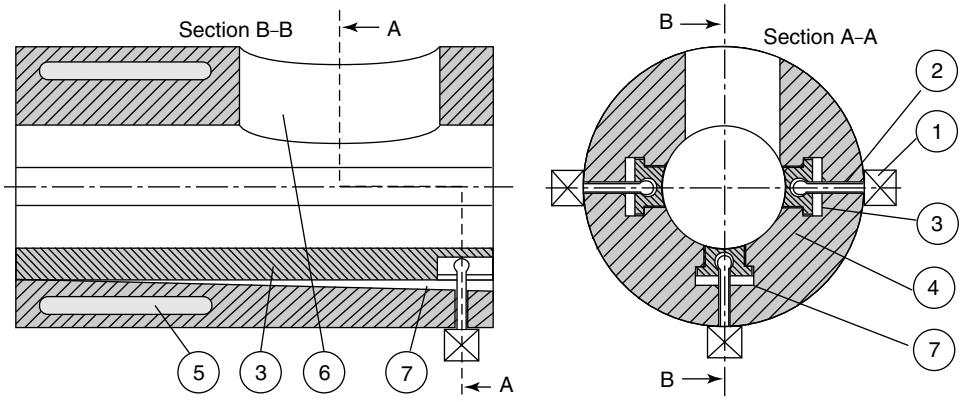

Fig. 34. Grooved feed section with adjustable groove depth.

As a result, it is possible to set the groove depth to achieve the minimum pressure fluctuation at the discharge end of the extruder. The AGFE allows a level of control and versatility not possible with conventional extruders. Figure 34 shows a schematic representation of the AGFE with the grooves shown in the zero depth position. Actuators can pull the keys into the housing to increase the groove depth. This allows continuous adjustment of the grooved depth between zero and maximum depth.

There are a number of advantages associated with grooved feed extruders, including

(1) The output of grooved feed extruders is less dependent on discharge pressure (see Fig. 35); as a result, the stability of the extrusion process tends to improve.
(2) The output of grooved feed extruders tends to be higher than that of smooth bore extruders.
(3) Grooved feed extruders allow extrusion of some very high molecular weight plastics, such as very high molecular weight PE. These materials cannot be processed on conventional smooth bore extruders.

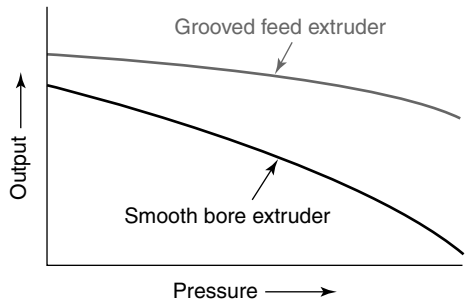

Fig. 35. Output vs discharge pressure for grooved feed vs smooth bore extruder.

With the conventional grooved feed extruder there are some disadvantages as well, such as

(1) The grooved barrel section has to be cooled well enough to avoid premature melting of the plastic in the grooves; this reduces energy efficiency and adds to the complexity of the extruder.
(2) The stresses that occur in the grooved region can be quite high, making the grooves susceptible to wear. The grooves have to be made out of a wear-resistant material to avoid high rates of wear.
(3) The pressures that occur in the grooved section can be quite high, in the range of 70–140 MPa (10,000–20,000 psi). The barrel has to be designed to withstand these high pressures.
(4) The screw design rules for grooved feed extruders are quite different from the rules for smooth bore extruders. Thus, grooved feed extruders require special screw designs. The use of conventional screw designs in grooved feed extruder can lead to a number of problems, such as overheating of the plastic and screw wear.
(5) With a grooved barrel section, the motor load increases and with it, the torsional load on the extruder screw.

It should be remembered that conveying can be improved not only by increasing the barrel friction, but also by reducing the by screw friction. This can be done by screw design, by screw temperature, and by the screw material. Screw design features that reduce screw friction are single flighted geometry (avoid multiple flights), large flight flank radius, and large helix angle. These features are illustrated in Figure 36.

Reducing screw friction can often be achieved by internal screw heating. This can be done by coring the screw and circulating a heat transfer fluid inside the screw, usually oil. Another method of heating the screw is to put a cartridge

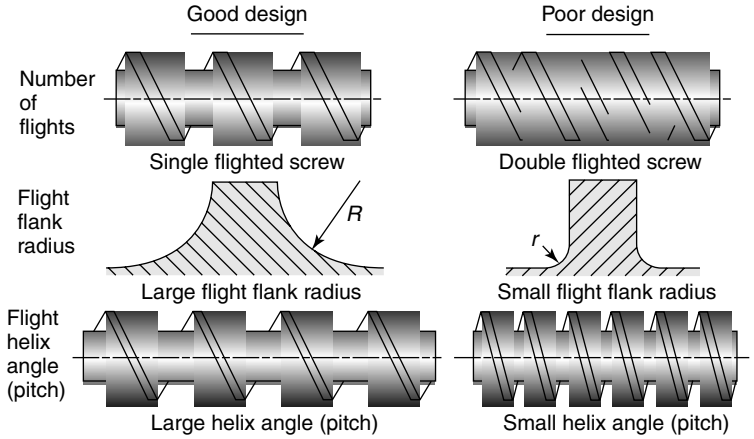

Fig. 36. Measures to reduce screw friction by screw design.

heater inside the screw. Power to the heater can be supplied through a slip-ring assembly at the shank of the screw. Finally, the surface friction of the screw can be reduced by applying a coating to the screw or a surface treatment. The following coatings and surface treatments have been used PTFE impregnated nickel plating, PTFE/chrome plating, titanium nitride, boron nitride, tungsten disulfide (WS2), and catalytic surface conversion (eg J-Tex). The advantage of a low friction coating extends beyond improved conveying along the screw. It reduces the tendency of the plastic to hang up or build up on the screw surface and makes it easier to clean the screw. These coatings can also be used for extrusion dies, particularly the inside surfaces of the die channel in contact with the plastic melt. The advantages here are reduced pressure drop in the die, improved surface quality of the extruded product, and reduced tendency of material to build up at the die exit. The last problem is often referred to as *die drool* or *beard formation*.

Melting

Melting in the extruder starts when the plastic temperature reaches the melting point. There are two types of melting that occur in screw extruders.

Contiguous Solids Melting. In the first type of melting, the solid particles are compacted and form a solid plug that spirals along the length of the screw channel. Between the solid bed and the barrel a thin melt film is located. Most of the melting occurs at the interface between the solid bed and the melt film. The newly melted material collects in the melt film, but is dragged away to the melt pool that is pushed against the active flight flank (see Fig. 37). This type of melting is called contiguous solids melting (CSM) and is most often observed in single screw extruders.

Dispersed Solids Melting. In the second type of melting, the solid particles are dispersed in a melt matrix (see Fig. 38). The solid particles decrease in size until they have melted completely. This type of melting is called dispersed solids melting (DSM) and is observed in high-speed twin screw extruders and reciprocating single screw compounding extruders. The melting in DSM is substantially more efficient than in CSM. The axial length from the start to end of melting in

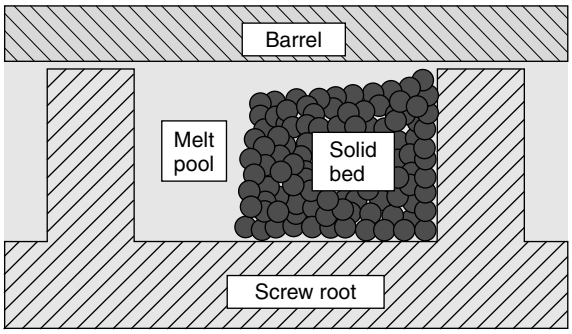

Fig. 37. Contiguous solids melting in single screw extruders.

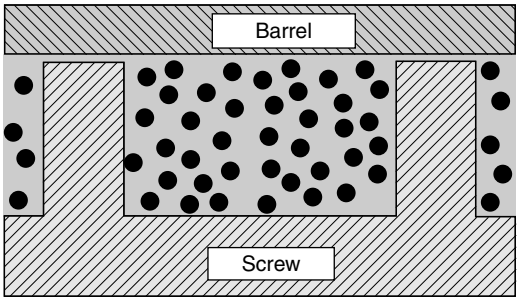

Fig. 38. Dispersed solids melting in single screw extruders.

twin screw extruders is usually about 1–2 screw diameters. On the other hand, in single screw extruders, the melting length is usually 10–15 diameters.

This is an important difference between single and twin screw extruders. In single screw extruders the solids conveying and melting zones extend about 15–20 diameters. This means in a 25 *L*/*D* extruder, there is not much length left for melt conveying, mixing, and degassing. In fact, if degassing is to be done, the extruder length is generally increased to 30–35 diameters. In a twin screw extruder, the solids conveying and melting zones may extend only 5–6 screw diameters. If the twin screw extruder is 30*D* long, it means that most of the length of the extruder is still available to do mixing, degassing, chemical reactions, etc. This makes the twin screw extruder a more versatile machine than the single screw extruder. As a result, the twin screw extruder is often the machine of choice for demanding processing tasks.

The theory of CSM melting was developed by Tadmor (3) in the early 1960s. The theory of DSM was not developed until much later (4). From the quantitative description of the CSM melting, we can determine how plastic properties, processing conditions, and screw geometry affect melting. There are two important sources of heat in the melting process. One is the heat from the barrel heaters conducted through the barrel, then through the melt film into the solid bed. The other source of heat is the viscous heating in the melt film. The amount of viscous heating is determined by the viscosity of the material and the shear rate in the melt film.

The melting mechanism in contiguous solids metting is called *drag induced melt removal*. This refers to the action in the melt film. The melted material added to the melt film is dragged away to the melt pool by the rotation of the screw. As a result, the melt film can remain thin, which is critical to maintaining a high melting rate. If the newly melted material is not dragged away, the melt film thickness will increase as melting progresses and the melting efficiency will drop off rapidly. This is why single screw extruders melt much more efficiently than ram extruders and this is why larger injection molding machines use screw extruders rather than ram extruders.

From this description of melting it is clear that the thickness of the melt film is an important parameter in the melting process. A thin melt film is important in maintaining high melting efficiency. With a thin melt film, there is high viscous

heat generation in the melt film and the barrel heat has to travel only a short distance through the melt film to reach the solid bed. The initial melt film thickness is primarily determined by the flight clearance. The larger the flight clearance, the thicker the melt film. As a result, to achieve efficient melting, it is important to keep the flight clearance small. A worn screw or barrel results in a large flight clearance, and this generally has a negative effect on melting and therefore on the overall extruder performance.

Clearly, when we increase the barrel temperature, more heat is available from the barrel heaters to melt the plastic. On the other hand, a higher barrel temperature increases the melt temperature in the melt film. This, in turn, reduces the viscosity of the melt film and the viscous heat generation. Therefore, a higher barrel temperature increases the barrel heat, but reduces viscous heat generation. If the reduction in viscous heat generation is larger than the increase in barrel heat, then the net effect is a reduction in the melting rate. This may seem somewhat counter intuitive; however, this is certainly possible when one considers that at high screw speeds, most of the heat introduced to the plastic is by viscous heating.

The helix angle of the screw flight can have a considerable effect on the melting efficiency, as shown in Figure 39. We see that the axial length required to complete melting decreases when the helix angle increases. It is interesting to see that the highest melting efficiency occurs at a helix angle of 90°. Such a helix angle may be good for melting, but it certainly would not be good for efficient conveying. Remember that a 90° helix angle means that the screw flight is parallel to the axis of the screw. Clearly, the forward conveying capability of the screw is zero when the helix angle is 90°. To achieve both good conveying and good melting we should select a helix angle that gives us not only good melting but also good conveying. Usually a helix angle in the range of 20–30° satisfies both demands.

The use of multiple flights can also improve melting, as shown in Figure 39, because the average melt film is thinner than in a single flighted screw (see Fig. 40). A drawback of multiple flights is that it reduces solids conveying and melt conveying. So, a double flighted screw may improve melting, but at the same time may cause problem in solids conveying and melt conveying. As a result,

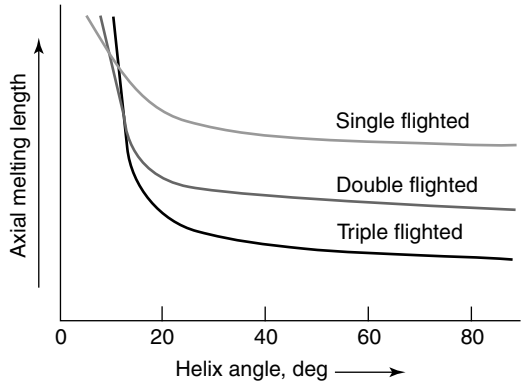

Fig. 39. The effect of the number of flights on the melting length.

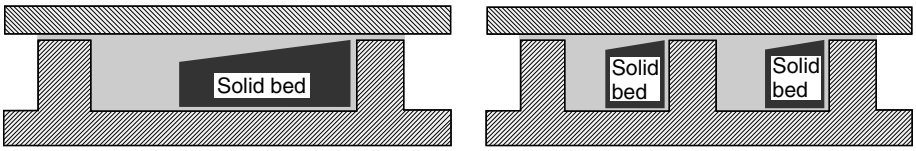

Fig. 40. Melting in a single flighted screw (left) and double flighted screw (right).

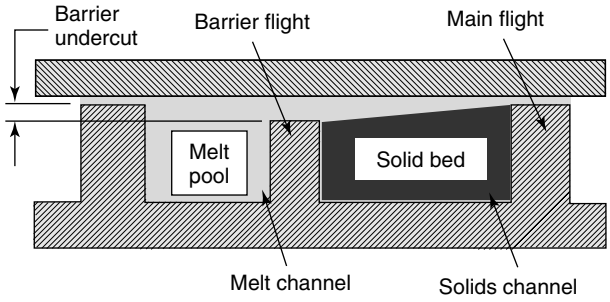

Fig. 41. Cross section of a barrier screw.

a multiflighted screw makes sense if the extrusion is clearly limited by melting capacity.

It is also important to realize that the advantage of a multiflighted screw to melting does not apply to a barrier screw. A barrier screw has two flights: a main flight and a barrier flight. The purpose of the main flight is to separate the solid material from the melted material (see Fig. 41). Thus, the barrier flight effectively separates the solid bed from the melt pool. Because the barrier screw has only one solid bed, its melting capability is about the same as a single flighted screw without a barrier flight.

One variable that affects the melting in an extruder is the temperature at which the plastic is introduced to the extruder. By preheating the plastic in the feed hopper or before, the amount of heat that has to be added to melt the plastic in the extruder is reduced and as a result, melting occurs earlier in the extruder. When it is suspected that an extrusion problem is related to melting, preheating is a method of diagnosing the problem.

The barrier screw has the following advantages:

(1) The barrier screw achieves more stable extrusion than a simple conveying screw.
(2) With a barrier screw, there is virtually no chance of unmelted material beyond the barrier section. However, this is not true for all barrier screw designs.
(3) There is a certain amount of dispersive mixing that occurs as the plastic melt flow over the barrier flight into the melt channel.

Next to these advantages, there are the following disadvantages:

(1) Barrier screws are no better in performance than nonbarrier screws designed with mixing sections.
(2) Barrier screws are more expensive than nonbarrier screws, particularly when purchased from an original equipment manufacturer (OEM).
(3) Because the solid material is restricted to the solids channel, the barrier screw is inherently more susceptible to plugging. This occurs when melting cannot keep up with the reduction in the size of the channel in the compression section of the screw, resulting in the solid material getting stuck in the screw channel. This creates a momentary obstruction to flow and leads to surging. Surging is a variation in extruder output.

Melt Conveying

Melt conveying starts when the melting is completed in the extruder. Strictly speaking, melt conveying starts when melting starts, because it is the melting zone where both solids conveying and melt conveying take place, with the amount of solid material gradually decreasing and, at the same time, the amount of melted material gradually increasing. However, the *melt conveying zone* is defined as the region where all the plastic is completely melted.

The mechanism of melt conveying is viscous drag. In other words, the viscous forces acting on the plastic melt are responsible for the forward conveying of the melt. In the melt conveying zone, the viscous force at the barrel is responsible for forward conveying, while the viscous force at the screw is a retarding force. As a result, melt conveying is improved by reducing the barrel temperature and increasing the screw temperature. Interestingly, screw heating in the melt conveying zone makes more sense than barrel heating. Internal screw heating is not used much in the extrusion industry; the obvious reason is that barrel heating is much easier than internal screw heating.

The optimum screw geometry for melt conveying can be determined from extrusion theory. The optimum helix angle is dependent only on the degree of non-Newtonian behavior of the plastic melt; it can be determined from the following expression:

$$\text{optimumhelixangle[degrees]} = 13.5 + 16.5(\text{powerlawindex})(1) \qquad (1)$$

The optimum helix angle for melt conveying decreases as the power law index decreases; in other words, when the plastic is more shear thinning. A similar expression can be derived for the optimum depth of the channel in the melt conveying zone. The optimum depth depends on the viscosity, the pressure gradient, and the power law index. When the plastic becomes more shear thinning, the channel depth should be reduced to maintain good melt conveying.

Melt Temperatures. Because of the low thermal conductivity of the plastic melts, the temperatures in the melt conveying zone can vary substantially. Local temperatures are difficult to measure because it hard to put a probe in the

screw channel while the screw is rotating. Melt temperatures can be predicted from extrusion theory using numerical techniques. A popular technique for this purpose is finite element analysis (FEA). With this technique the flow patterns and temperature distribution can be predicted.

In Figure 42 we show the temperature distribution in the screw channel by looking at a cross section of the screw channel. The temperatures are shown in colors; different colors represent different temperatures, just like the weather map on the back page of USA Today. The temperature scale is shown on the right-hand side of the figure. The lower surface of the picture is the root of the screw; the upper surface is the extruder barrel. The barrel is maintained at 175°C and the screw surface is considered insulated (adiabatic). It can be seen in the figure that the highest melt temperatures occur in the mid-region of the channel, while the outside region of the channel remains at a lower temperature.

The reason for this temperature distribution is the way the plastic melt flows along the screw channel. This flow can be illustrated by unrolling the screw channel and by looking it as a straight trough see Fig. 43 and the barrel as a flat plate.

If the flow is viewed relative to the screw, then the barrel moves in tangential direction, v_b, making an angle ϕ with the channel. Angle ϕ is the helix angle of the screw flight. A fluid element close to the barrel surface flows in the direction of the channel until it gets to the pushing side of the flight. At this point, the element moves downward and then crosses the screw channel. When the element gets to the trailing side of the flight, the element moves up again close to the barrel surface and the element starts moving in the direction of the barrel again. This pattern repeats itself numerous times as long as the regular flight geometry is maintained.

If the flow is viewed in the cross section of the screw channel (see Fig. 44), then the material moves to the pushing side of the flight at the top of the channel. This flow results from drag flow. At the bottom of the channel, the material moves toward the trailing side of the channel. This is a pressure flow resulting from the fact that the pressure at the pushing side of the flight is higher than at the trailing side of the flight. If the leakage flow through the flight clearance is negligible, the

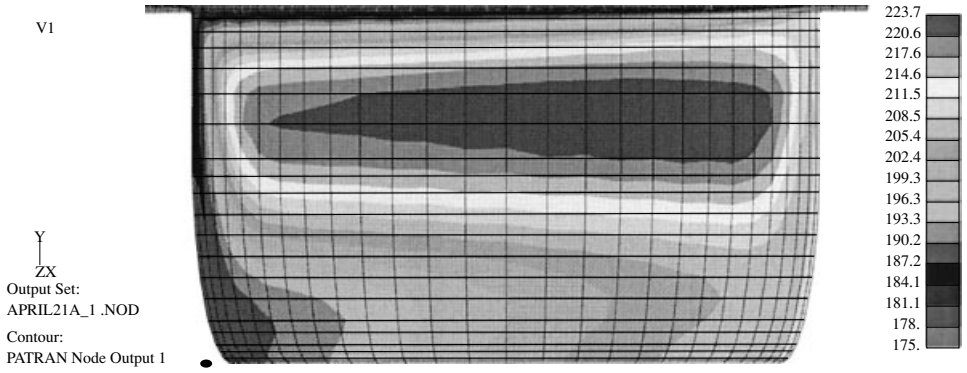

Fig. 42. Predicted melt temperatures in the screw channel.

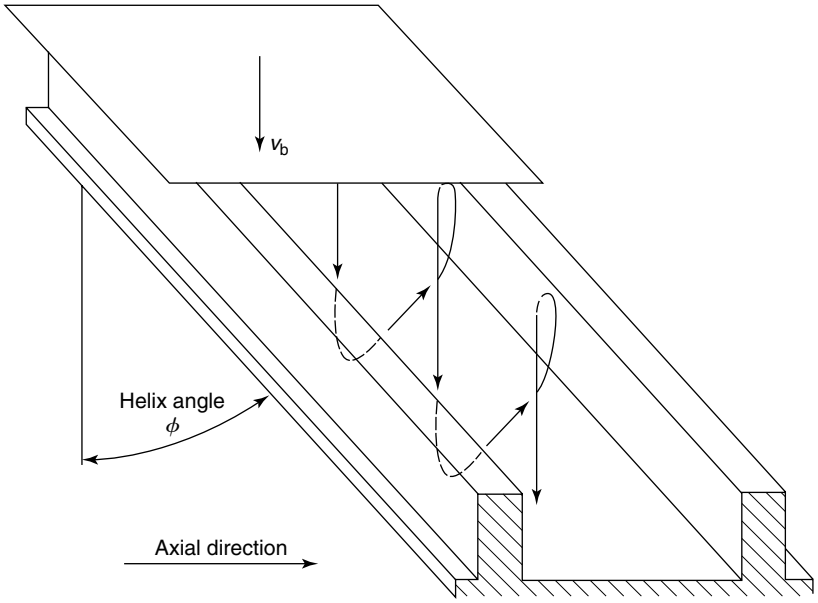

Fig. 43. Flow along the unrolled screw channel.

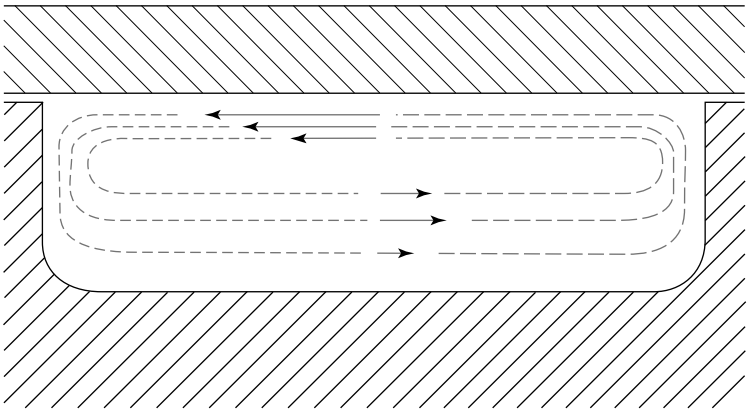

Fig. 44. Recirculating flow in the cross section of the screw channel.

amount of material flowing to the pushing flight flank is the same as the amount of material flowing to the trailing flight flank. Thus, a recirculating flow is obtained as shown in Figure 44. There are also small velocity components in the normal direction close to the flight flanks. At the pushing flight flank, the normal flow is downward, toward the root of the screw; at the trailing flight flank, the normal flow is upward, toward the barrel. The normal flow also results from pressure differences. For instance, the pressure at the top of the pushing flight flank is higher than at the bottom of the flight flank, which is why the flow is downward in this region.

The fluid is sheared as it flows along the screw channel and as a result, there is viscous heat generation in the plastic melt. The actual temperatures that occur at different points in the screw channel are determined not only by viscous heating, but also by how efficiently this heat can be removed. If the barrel is cooled, the melt flowing close to the barrel surface can exchange heat efficiently and hence cool down efficiently. When this outer layer moves along the screw surface, it remains relatively cool even if the screw is insulated.

However, the situation is quite different for the inner layer. Because this layer is trapped in the inner recirculating region, it never gets close to the barrel. As a result, this layer has very limited opportunity for removed of its heat; the outer layer of plastic melt essentially insulates the inner layer. This explains why the temperature in the inner region of the screw channel tends to be higher than in the outer region. In Figure 42, the temperature in the center region is about 60°C higher than the barrel temperature. Thus, it is clear that considerable melt temperature differences can occur in the screw channel.

If these temperature differences are carried to the end of the screw, the melt discharged into the die is not thermally homogeneous. This leads to flow problems in the die and distortion of the extruded product. It is important, therefore, to try to keep these nonuniform melt temperatures from reaching the end of the screw. The most efficient method to do this is by incorporating mixing elements into the design of the screw. Mixing sections are not only important when different plastics are mixed, but also when a single plastic is extruded so that a thermally homogeneous melt at the end of the screw is achieved.

Mixing

Mixing takes place both in the melting zone as well as the melt conveying zone of the extruder. The solid plastic typically moves in plug flow, which means that there is no relative motion between the solid plastic particles. As a result, there is little or no mixing in solids conveying. This means that complete mixing does not start until all the plastic has melted. For this reason, mixing is to be viewed only in the melt conveying zone of the extruder.

Distributive Mixing. The extent of distributive mixing can be determined from the total shear deformation of the plastic melt in the melt conveying zone. The total shear deformation is also called the *total shear strain*; it is determined by the product of the shear rate and the length of time that the fluid is exposed to the shear rate. For instance, if the plastic melt is exposed to a shear rate of $100\ s^{-1}$ for 15 s, the resulting shear strain is $100 \times 15 = 1500$. The units of shear strain are dimensionless. The shear rate is determined by the velocity profiles in the extruder.

Mixing in single screw extruders is determined mostly by the two main velocity components in the screw channel. These are the velocity in the direction of the channel (z-direction) and the velocity in the cross-channel direction (x-direction) (see Fig. 45).

There is also a velocity component in the third direction (y-direction) parallel to the flight flank. This velocity component is usually very small and therefore, can usually be neglected. The velocities in down-channel direction depend on the

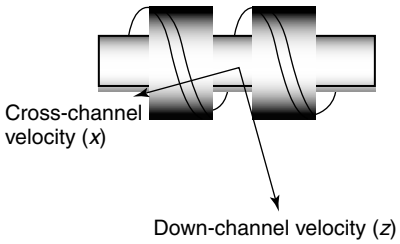

Fig. 45. The two main flow components in a single screw extruder.

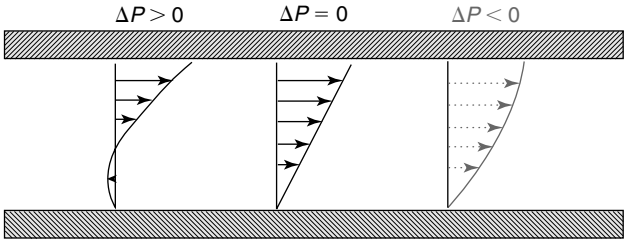

Fig. 46. Down-channel velocity profiles for three pressure conditions.

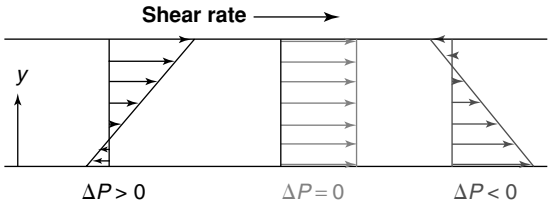

Fig. 47. Down-channel shear rates for three pressure conditions.

pressure gradient; this can be positive, zero, or negative. When the pressure gradient is positive, pressure is increasing along the melt conveying zone; when the pressure gradient is negative, pressure is decreasing along the melt conveying zone. Down-channel velocity profiles for different values of the pressure gradient are shown in Figure 46.

The cross-channel flow is shown in Figure 44. At the top of the channel, the material flows to the left by drag flow and at the bottom of the channel, the material flows to the right by pressure flow. The shear rate can be determined from the velocity profile; the shear rate is equal to the slope of the velocity profile. This slope of the velocity profile is also called the velocity gradient. From the down-channel velocities, we can determine the down-channel shear rates; these are shown in Figure 47.

When the pressure gradient is positive, the shear rates increase toward the barrel surface, when the pressure gradient is zero the shear rate is constant, and when the pressure gradient is negative the shear rates decrease toward the barrel surface. The same approach can be used to determine the cross-channel shear rate

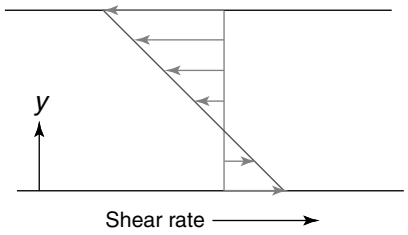

Fig. 48. Cross-channel shear rate vs normal distance.

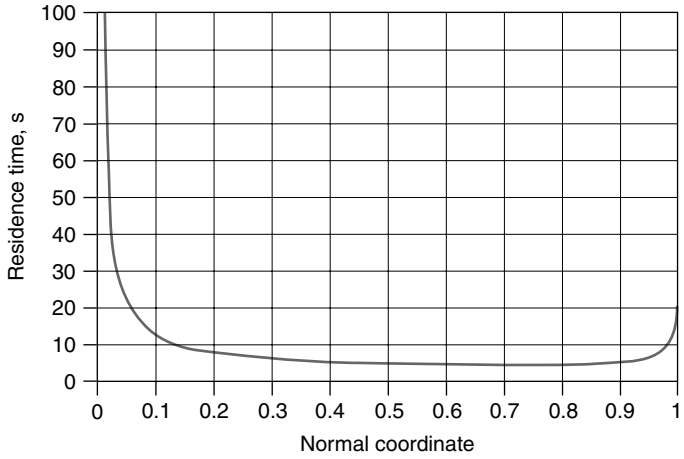

Fig. 49. Residence time vs normal distance (dimensionless).

from the cross-channel velocities. The cross-channel shear rate profile is shown in Figure 48.

In the bottom of the channel, the fluid is exposed to positive shear rates and in the top of the channel, the fluid is exposed to negative shear rates. This has important consequences for the mixing that occurs in screw extruders.

The residence time as a function of the normal distance is shown in Figure 49. The vertical axis shows the residence time $t(y)$ and the horizontal axis shows the normal distance y. The screw surface corresponds to $y=0$ and the barrel surface corresponds to $y=1$.

It is clear from this figure that fluid elements in the center region of the channel have the shortest residence time. The residence time increases toward the screw and barrel surfaces and becomes very long at the barrel and screw surfaces. From Figure 49 it is clear that particularly on the screw there is a relatively thick layer of plastic melt that has a very long residence time relative to the material in the center of the channel. Unfortunately, this increases the chance of material building up on the screw surface and causing problems with degradation.

The total cross-channel shear strain can be determined by adding the shear strain in the upper portion of the channel to that in the lower portion of the

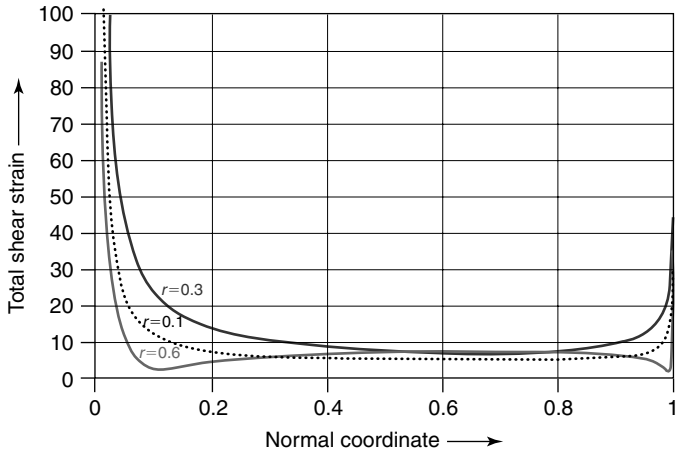

Fig. 50. Total shear strain vs normal distance (dimensionless) at various r_d values.

channel. The total down-channel shear strain can be found the same way. The total shear strain is obtained by adding the cross- and down-channel shear strains. The total shear vs normal distance for several values of the throttle ratio r_d is shown in Figure 50. The *throttle ratio* is the ratio of the pressure flow to drag flow. When $r_d = 0$, we have pure drag flow (pressure flow is zero). When $r_d = 1/3$, the drag flow is three times the pressure flow; this is a fairly common situation in single screw extruders.

The total strain depends strongly both on the normal distance and on the throttle ratio. Fluid elements close to the barrel wall experience a high level of shear strain and thus, will be well mixed. Elements further away from the wall, as well as elements close to the wall, experience a lower level of strain and will not be well mixed.

The shear strain in the center region increases with the throttle ratio. When the throttle ratio is one-third or greater, the shear strain reaches a minimum when close to the wall; this corresponds to the location where the down-channel shear strain approaches zero. Mixing is improved by increasing the throttle ratio or choking the extruder. This can be done by increasing the restriction at the end of the screw, for instance, by increasing the number of screens in the screen pack. Such an increase in mixing, however, is at the expense of output. Since reduced output increases residence time and plastic melt temperatures, there is an increased chance of degradation. Therefore, increasing the restriction of the screen pack is often not the most efficient way of improving mixing.

The nonuniform cross- and down-channel shear strains result in nonuniform mixing in the screw channel. Unfortunately, poor mixing ability is typical of single screw extruders with straight conveying screws, ie without mixing sections. The best method to really improve mixing in single screw extruders is to incorporate mixing sections. Mixing sections are also useful in reducing the large variations in melt temperature that can occur in screw extruders. If a melt with nonuniform melt temperatures is discharged into an extrusion die, several problems can occur, when affects the quality of the extruded product.

There are certain characteristics that are desirable for mixing sections in general. These are

(1) The mixing section should have minimum pressure drop, preferably by having forward pumping capability.
(2) The mixing section should have streamlined flow; dead spots should be avoided.
(3) The mixing section should wipe the barrel surface completely; thus, circumferential grooves should be avoided.
(4) The mixing section should be operator friendly; it should be easy to assemble, install, run, clean, and disassemble.
(5) The mixing section should be easy to manufacture and reasonably priced.

In addition to the general characteristics desirable for mixing sections, there are some specific characteristics important for distributive mixing:

(1) The plastic melt should be subjected to significant shear strain, and
(2) The flow should be split frequently with reorientation of the fluid elements.

Splitting and reorientation is critical to achieving efficient distributive mixing, because mixing can improve exponentially by splitting and reorientation. Distributive mixers can be divided into some main groups: cavity mixers, pin mixers, slotted flight mixers, variable channel depth mixers, and variable channel width mixers.

Based on the important characteristics of mixers we can compile the various distributive mixers and list how they perform with respect to different criteria. This is shown in Table 3; the ranking is based on a five-point system: 5 is very good, 1 is very bad.

The last column in Table 3 is the most important when it comes to distributive mixing effectiveness. The Dulmage, Saxton, CTM, TMR, and CRD all do very well in this category. The Saxton and CRD mixers combine good mixing with low cost,

Table 3. Comparison of Various Distributive Mixers[a]

Mixers	Pressure drop	Dead spots	Barrel wiped	Operator friendly	Machining cost	Shear strain	Splitting, reorientation
Pins	2	2	3	4	5	2	4
Dulmage	4	4	2	4	4	4	5
Saxton	4	4	5	4	4	4	5
CTM	1	3	2	1	1	4	5
TMR	1	3	4	3	2	4	5
CRD	4	4	5	4	3	4	5
Axon	4	4	4	4	5	4	3
Double wave	4	4	4	4	2	4	2
Pulsar	4	4	4	4	3	3	2
Strata-blend	4	3	4	4	3	3	2

[a]The ranking is based on a five-point system: 5 is very good, 1 is very bad.

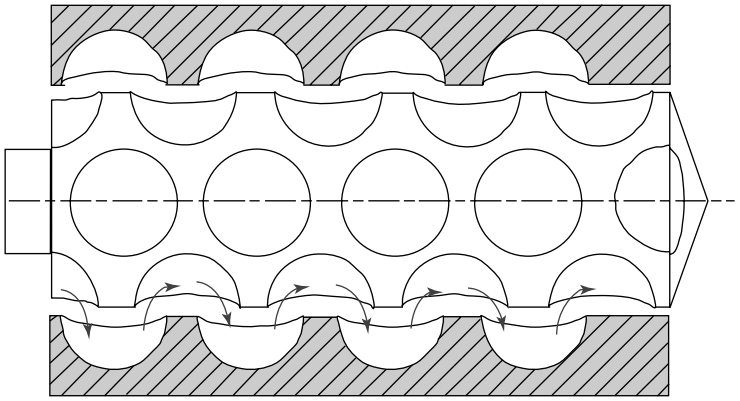

Fig. 51. Cavity transfer mixer.

good streamlining, ease of use, and low pressure drop. The CRD mixer also has dispersive mixing capability; it will be discussed in the next section.

Cavity Mixers. One of the well-known cavity mixers is the cavity transfer mixer (CTM). It consists of a screw section and a barrel section, both containing hemispherical cavities (see Fig. 51).

As the plastic melt travels through the mixer, the material is frequently cut and reoriented. This action gives the mixer good mixing capability. There are a few practical issues, however, that make the CTM a less than ideal mixer. It has no forward pumping capability; thus, the CTM is a pressure consuming mixing device that will reduce the extruder output and increase the temperature buildup in the plastic melt. With the hemispherical cavities, the streamlining is not very good; this can be a problem in product changeover and with thermally sensitive materials. Other drawbacks of the CTM are high cost, difficult installation and cleaning, and the fact that the barrel is not completely wiped during processing.

Another cavity mixer is the Twente mixing ring (TMR) developed by Semmekrot at Twente University in Enschede, the Netherlands. It is similar to the CTM, but it has a freely moving mixing ring with circular holes instead of a barrel with cavities (see Fig. 52). This removes a number of the disadvantages of the CTM; the TMR is easier to install, easier to clean, and the barrel is completely wiped.

Pin Mixers. Pin mixers have been in use for many years and come in many shapes and sizes. Often the pins are circular, but other shapes can be used as well, eg, square, rectangular, and diamond-shaped. Two examples of pin mixing sections are shown in Figure 53.

Pins achieve a moderate level of splitting and reorientation, and as a result, give a moderate improvement in mixing. One drawback of pins is that they create a restriction to flow and, thus, reduce extruder output. The greater the number of pins, the more the output goes down. Another drawback of pins is that they tend to create regions of stagnation, particularly at the corner of the pin and at the root of the screw.

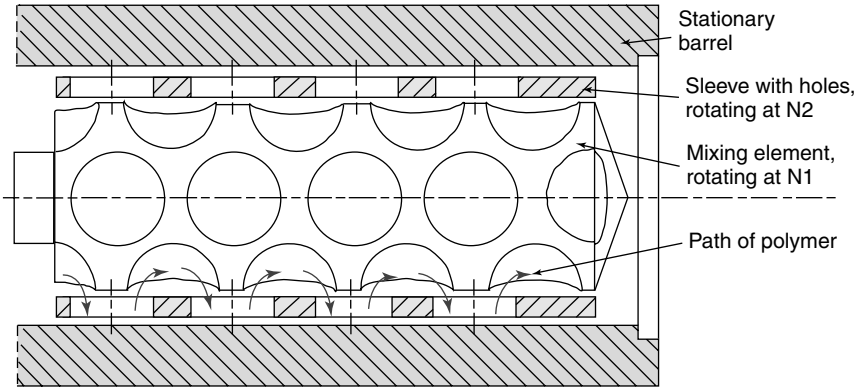

Fig. 52. Twente mixing ring, N1 > N2.

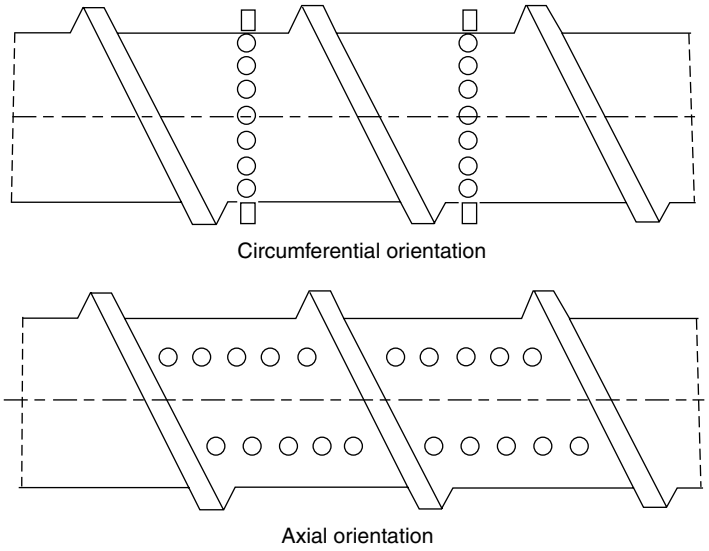

Fig. 53. Examples of pin mixing sections.

Slotted Flight Mixers. There are a great number of slotted flight mixers. Examples of slotted mixers are the Dulmage (Fig. 54) and the Saxton mixing sections (Fig. 55).

Both these mixers have frequent splitting and reorientation, resulting in effective mixing action. Because of the forward orientation of the flights, there is some forward pumping capability. Thus, good mixing can be combined with high output capability. The drawback of the Dulmage mixer is that it has circumferential slots, which means that the barrel is not completely wiped by the mixing section.

Variable Depth Mixers. In these mixers, the channel depth of the mixer is varied to obtain improved mixing. One variable depth mixer is the double wave screw (see Fig. 56).

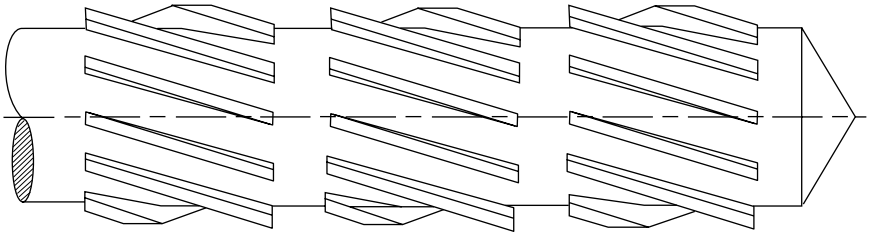

Fig. 54. The Dulmage mixing section.

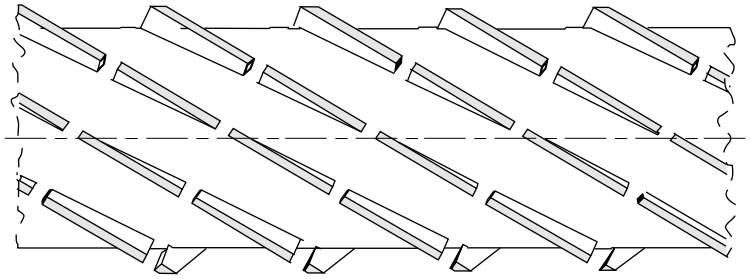

Fig. 55. The Saxton mixing section.

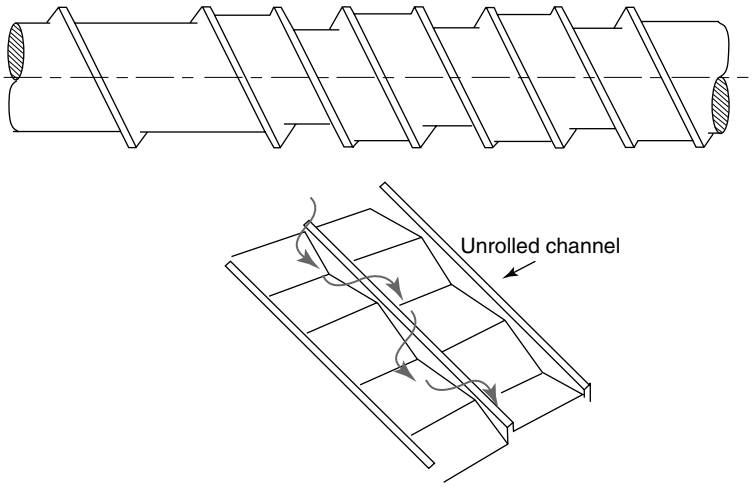

Fig. 56. Double wave screw.

The channel depth varies periodically in each channel in such a way that when one channel decreases in depth, the other increases and vice versa. In this mixer there is no strong mechanism for flow splitting and reorientation. Thus, the mixing capability of this mixer is moderate. Other variable depth mixers are the Pulsar and Strata-blend mixing sections (see Fig. 57). These do not achieve efficient flow splitting and reorientation.

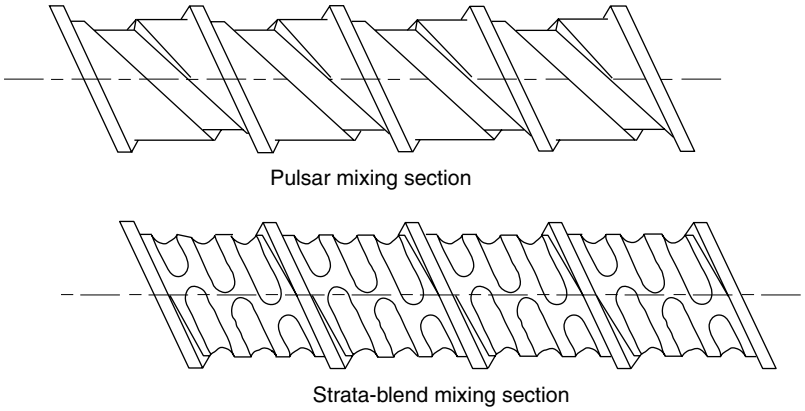

Fig. 57. Pulsar mixer and Strata-blend mixer.

Dispersive Mixing. For dispersive mixing the following characteristics are desirable:

(1) The mixing section should have a region where the material is subjected to high stresses, preferably elongational stresses.
(2) The high stress region should be designed such that the exposure to high shear stresses occurs only for a short time, while exposure to elongational stresses is maximized.
(3) All fluid elements should pass through the high stress regions many times to achieve efficient dispersive mixing action.
(4) All fluid elements should pass through the high stress regions the same number of times for uniform mixing.

A comparison of dispersive mixers is shown in Table 4; the ranking is based on a five-point system: 5 is very good, 1 is very bad.

There are several types of dispersive mixing sections: blister rings, fluted mixing sections, and planetary gear extruders.

Table 4. Comparison of Dispersive Mixers for Single Screw Extruders[a]

Mixer	Pressure drop	Dead spots	Barrel wiped	Cost	Number passes	Type of flow
Blister	1	3	2	5	1	Shear
Egan	2	5	5	4	1	Shear
LeRoy/Maddock	2	2	5	4	1	Shear
Zorro	5	5	5	3	1	Shear
Helical LeRoy	5	5	5	4	1	Shear
Planetary gear	3	5	5	2	Multiple	Shear
CRD	5	5	5	4	Multiple	Elongation

[a]The ranking is based on a five-point system: 5 is very good, 1 is very bad.

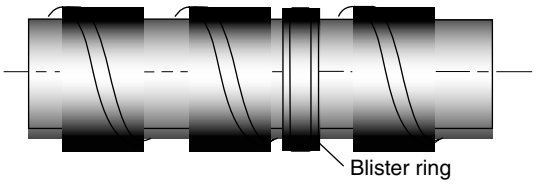

Fig. 58. Blister ring.

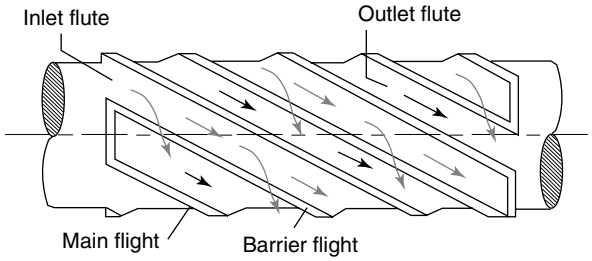

Fig. 59. Egan mixing section.

Blister Ring. The blister ring is simply a circumferential shoulder on the screw with a small clearance between the ring and the barrel (see Fig. 58). All material must flow through this small gap where it is exposed to high shear stresses. Since no forward drag flow occurs in the blister ring, relatively high pressure drops occur across the blister ring. The stress level in the gap is not uniform; therefore, the mixing action is not uniform.

Fluted Mixing Sections. These mixers have inlet and outlet flutes separated by barrier flights. For the material to exit the mixer it has to pass through the narrow gap of the barrier flights; this is where the mixing action takes place. One of the earliest fluted mixers was the Egan mixing section developed by Gregory and Street. The flutes in this mixer have a helical orientation (see Fig. 59).

Another fluted mixer is the Union Carbide mixer (UC mixer) developed by LeRoy and popularized by Maddock. It has straight flutes as shown in Figure 60. Because of the straight flutes, the LeRoy mixer has no forward pumping capability and thus, tends to have high pressure drop. It is typically machined with a ball mill; as a result, the flutes have a semicircular cross section. This tends to result in inefficient streamlining at the entry and exit of the flutes. Despite these shortcomings, the LeRoy mixer is probably the most commonly used mixer in single screw extruders.

It is important to design mixing sections to have a low pressure drop; this is particularly true for dispersive mixers. High pressure drop reduces output, increases melt temperatures, increases residence time, and increases the chance of degradation. Higher melt temperatures reduce the melt viscosity and the stresses in the melt in the mixing section. As a result, higher temperatures reduce dispersive mixing. Since high pressure drop causes high temperatures, high pressure drop should be avoided. For this reason a helical LeRoy mixer is better than the straight LeRoy mixer.

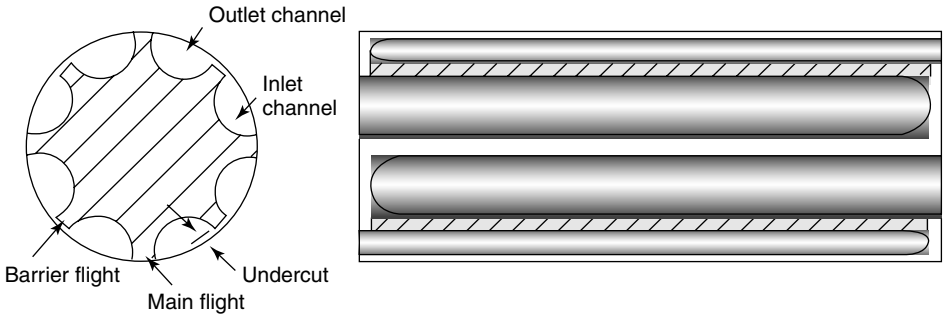

Fig. 60. LeRoy mixing section.

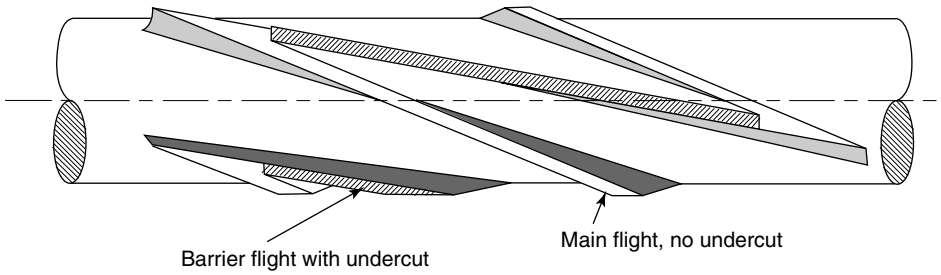

Fig. 61. Zorro mixing section.

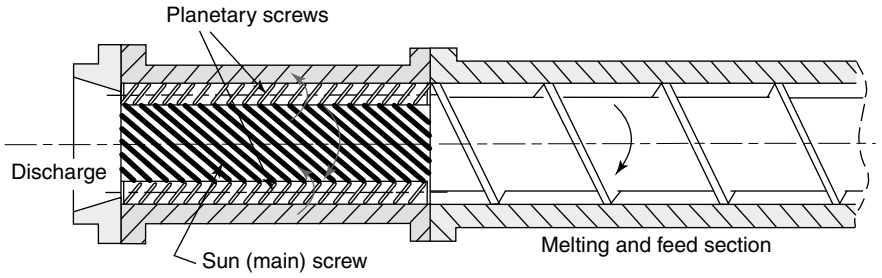

Fig. 62. Schematic of planetary gear mixer.

To promote good streamlining, the helix angle of the barrier flight can be made larger than that of the main flight. This makes the entry channel wide at the entrance and the exit channel wide at the exit. To minimize hang-up, the channels should taper to zero depth at the end of the entry channels and the start of the exit channels. A commercial version of this mixer is the Zorro mixing section (see Fig. 61).

Planetary Gear Mixers. Planetary gear mixers have six or more planetary screws that revolve around the circumference of the main screw. The planetary barrel section must have helical grooves corresponding to the helical flights on the planetary screws. The planetary barrel section is generally separate, with a flange-type connection to the other barrel section (see Fig. 62).

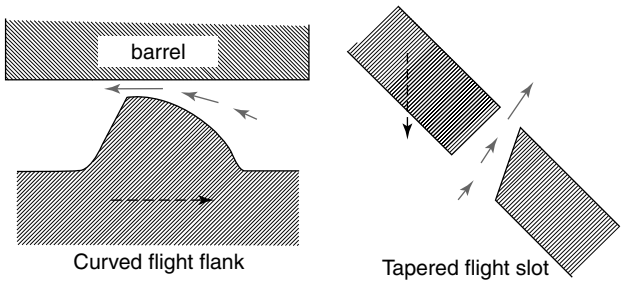

Fig. 63. Various flight geometries that form a wedge-shaped lobal region.

These machines are commonly used in Europe; they are used less in the United States. Some of the benefits of planetary gear mixers are, good homogeneity of the melt at low temperature level, uniform shear exposure, high output per screw revolution, low production cost per unit throughput, self-cleaning action for easy material change, and good dispersive and distributive mixing of various additives.

These characteristics make the planetary gear extruders well suited for processing heat-sensitive materials such as rigid and flexible PVC. They are also used to process blends (eg, PVC and ABS), plastic foams, powder coatings, epoxy, polyester, acrylic, polyurethane, chlorinated polyethylene, etc.

The CRD Mixer. Current dispersive mixers have two important drawbacks. One, they rely mostly on shear stresses to disperse materials rather than elongational stresses; dispersion is more effective in elongational flow than in shear flow. Two, the material passes over the high stress region only once. Advantages of elongational flow over shear flow are

(1) Lower viscous dissipation resulting in lower melt temperatures;
(2) Action of greater forces on agglomerates and droplets;
(3) More efficient deformation of agglomerates and droplets;
(4) Dispersion of gels in elongational flow but not in shear flow.

New mixing technology developed by Rauwendaal eliminates these disadvantages of existing dispersive mixers (5). The CRD mixer uses a slanted pushing flight flank to create a wedge-shaped lobal region, as shown in Figure 63. To create effective distributive mixing, multiple flights are used with many slots. The slots are tapered so that material flowing through the slot is accelerated and exposed to elongational deformation.

The wedge shapes create strong elongational flow. The CRD (6) mixer uses multiple mixing flights with a relatively large flight clearance to ensure that all fluid elements pass through the high stress region several times. There are also a large number of tapered slots to make sure that all fluid elements pass through the slots several times. In addition, there are two wiping flights with slots to make sure that the barrel surface is completely wiped by the mixer and to keep the mixer centered within the barrel. A picture of an actual CRD8 mixer is shown in Figure 64.

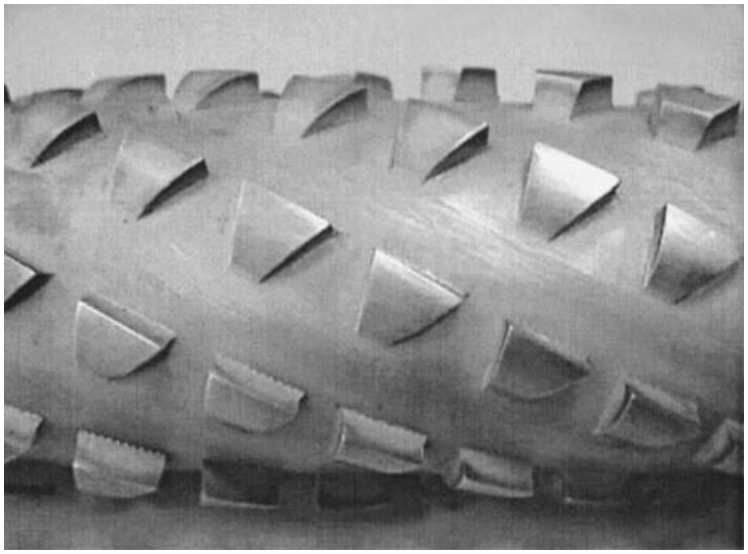

Fig. 64. CRD8 mixer with separate wiping flights. Copyright Rauwendaal Extrusion Engineering, Inc.

The mixing and wiping flights have a positive helix angle; this gives the mixing forward pumping capability. As a result, the mixer does not compromise extruder output. It also allows the mixer to be quite long. A typical length of the CRD mixer is six to eight screw diameters; this results in excellent mixing. Because of the large clearance of the mixing flights, it is necessary to use wiping flights to avoid a stagnant film at the barrel surface and improve pumping. The slots generate efficient distributive mixing in the CRD mixer to randomize the fluid elements and ensure that all elements pass through the high stress regions several times. Separate wiping flights can be avoided by incorporating wiping segments along the dispersive mixing flights.

The CRD mixer has also been applied to twin screw extruders, blow molding, and injection molding machines. A special version of the CRD mixer has been developed that combines a nonreturn valve (NRV) at the end of an injection molding screw with a CRD mixer. This CRD–NRV takes up the same space as a regular NRV, and as a result, offers a quick and convenient method to improve the mixing capability of injection molding machines. Figure 65 shows a slide-ring-type CRD–NRV; the slide ring has internal mixing pins that split the flow and accelerate the plastic melt. The conical nosepiece has tapered circular holes that cause splitting and acceleration as well. As a result, the plastic melt is exposed to three splitting, acceleration, and reorientation events as it passes through the CRD–NRV.

Even though the CRD–NRV is designed for injection molding machines the same principle can be used in conventional extruders. In this case there is no axial motion of the slide ring; however, there will still be a difference in rotational speed between the slide ring and the rest of the screw. The velocity difference will enhance the mixing action.

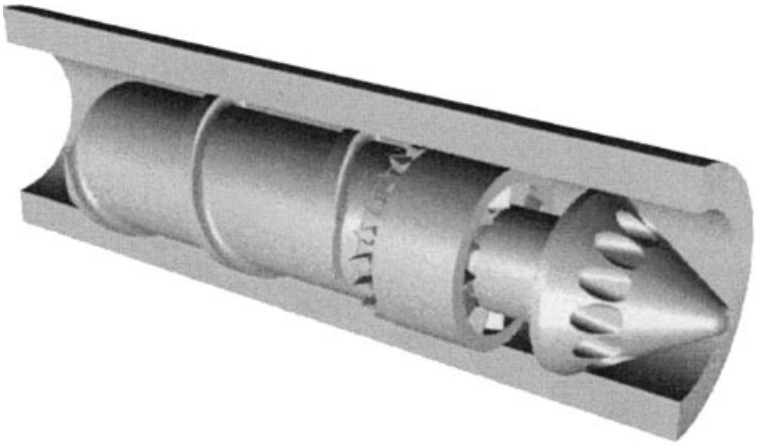

Fig. 65. CRD–NRV used in injection molding.

The following are the benefits of the CRD mixer:

(1) Better dispersive and distributive mixing than existing mixers;
(2) Reduced barrel pressure and melt temperature fluctuation resulting in better output stability and dimensional control;
(3) Reduced die lip buildup, and better and more consistent product appearance;
(4) Lower viscous dissipation and reduced power consumption resulting in lower melt temperatures (less degradation);
(5) Higher extruder output because of pumping action of the mixer; and
(6) The CRD mixer can disperse gels; shear-based mixers cannot disperse gels.

Degassing

Degassing is done on a vented extruder; this is an extruder with a vent port in the barrel. A special screw design has to be used in a vented extruder to make sure that there is a zero pressure region under the vent port. Degassing is needed when the plastic contains volatile components at a level high enough to cause problems. Generally, volatiles cause voids or surface defects in the extruded product.

Degassing is often used in extrusion of hygroscopic materials; these materials have an equilibrium moisture content higher than the level that can be tolerated in extrusion, which is about 0.1% for most plastics. For some plastics, this level is quite a bit lower. Table 5 lists hygroscopic plastics with their equilibrium moisture contents and the allowed moisture content.

With such materials we have two choices: predry the plastic or remove the moisture at the vent port. Drying plastics is usually a very slow process; it can take from 4 to 40 h. Devolatilization in the extruder is much more rapid because of the high temperatures involved. As a result, it can be advantageous to remove the moisture by venting rather than by predrying. In some cases drying and venting

Table 5. Equilibrium and Allowable Moisture Content for Various Plastics

Plastic	Equilibrium moisture content, %	Allowable moisture content, %
CA	2.2	<0.05
CAB	1.3	<0.05
ABS	1.5	<0.10
PA6	3.0	<0.10
PA66	2.8	<0.10
PC	0.19	<0.015
PBTP	0.2	<0.03
PMMA	0.8	<0.10
PAN	0.4	<0.10

are done at the same time, particulary in high output extrusion operations. Many hygroscopic plastics contain too much moisture to remove the required amount of moisture through a single vent port. In this case some predrying has to be done or an extruder can be used with two vent ports rather than one.

It should be noted that there are some hygroscopic plastics that are not good candidates for venting. Some plastics degrade rapidly when the plastic is exposed to high temperatures in the presence of moisture; an example is polyester. This moisture-induced degradation is called hydrolysis. Venting such material to remove moisture invariably results in considerable degradation of the plastic. As a result, polyester is usually dried before extrusion, rather than having the moisture removed during extrusion through the vent port. Other plastics susceptible to hydrolysis are polyamide (nylon), polycarbonate, and polyurethane.

Vented extruders require a special screw design to keep the vent port region at zero pressure; such a screw is called a two-stage screw. The zero pressure region is achieved by following a shallow metering section before the vent port with a deep flighted extraction section underneath the vent port. A short compression section and a second metering section or pump section follow this extraction section. Figure 66 shows the geometry of a two-stage extruder screw.

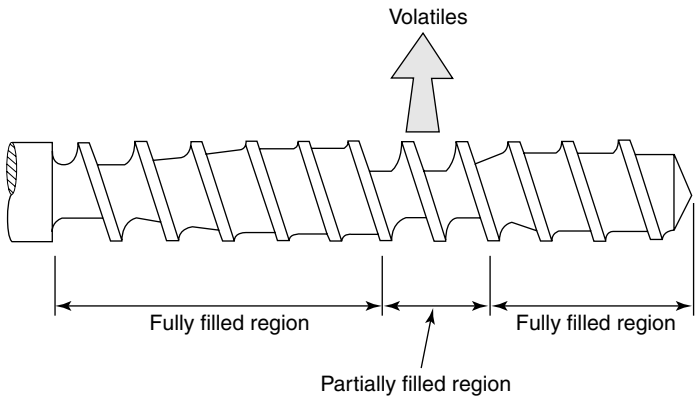

Fig. 66. A two-stage extruder screw used for devolatilization.

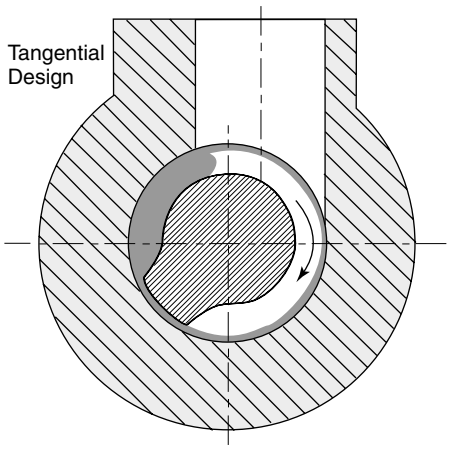

Fig. 67. Cross section of a tangential vent port region showing the rolling bank.

The feed section, the first compression section, and the first metering section make up the first stage of the screw. The extraction section, the second compression section, and the pump section make up the second stage of the screw. For the proper functioning of the screw, it is important that the conveying ability of the pump section be greater than the metering section. The metering section should be the rate controlling part of the screw; it should act as a dynamic choke. If this is the case, the extraction section of the screw is only partially filled and venting occurs properly. If this is not the case, the extraction section completely fills and molten plastic escapes through the vent port; this is referred to as vent flow.

It is critically important that the screw channel under the vent port is only partially filled with plastic; this is true for single as well as twin screw extruders. Figure 67 shows a cross section of a partially filled screw channel. The vent opening has a tangential design; this is beneficial in minimizing accumulation of plastic melt in the vent port.

There is a rolling bank of plastic melt at the leading side of the screw flight. Only when this condition is fulfilled can one be sure that no pressure is generated in the vent port region. If pressure does build up in the vent port region, the plastic melt flows out through the vent port, causing vent flow. This is a common problem in vented extruders.

Vent flow occurs when the conveying rate of the second stage cannot keep up with the first stage. This happens when the first stage is supplying more material than the second stage can handle. This condition can result from incorrect screw design. Vent flow can also occur when a high restriction die is used at the end of the extruder. The diehead pressure is generated only in the second stage of the screw because the extraction section is pressureless. As a result, a higher diehead pressure reduces the pumping capacity of the second stage while the pumping capacity of the first stage is not affected. As the diehead pressure increases, it will reach a point where the pumping capacity of the second stage decreases to that of the first stage. This is the critical diehead pressure for vent flow. If the diehead pressure increases above this value, vent flow occurs. The critical diehead pressure

for vent flow depends on the screw design, the flow properties of the plastic, and the operating conditions.

Die Forming

The shaping of the molten plastic occurs in the extrusion die. As the plastic flows through the die, it adopts the shape of the flow channel. Thus, the exit geometry of the die flow channel is shaped like the required shape of the extruded product. The exit region of the die flow channel is called the *land region*. The land region for a pipe or tubing die has an annular shape; for a flat film or sheet die, it has the shape of a slit. One of the most important objectives in die design is to distribute the melt in the flow channel such that the material exits from the die with a uniform velocity. With certain extruded shapes, it can be quite difficult to achieve a uniform exit velocity across the die.

Size and Shape Changes. The land region of the die does not have exactly the same shape and dimensions as the extruded product because there are a number of factors that change the shape and dimensions of the plastic as it emerges from the die. The main factors are drawdown, extrudate swell, cooling, and relaxation. Drawdown occurs because the take-up speed has to be higher than the velocity of the plastic at the die exit to maintain a tension in the plastic between the die and the take-up. This tension is necessary to keep the plastic from sagging. In some operations, the drawdown only reduces the size of the extrudate a few percent; in other cases, the size change can be quite large, as much as a factor of 2 or 3. Drawdown can change the shape of the product if the product has a noncircular shape.

Extrudate swell is the expansion of the plastic as it leaves the die; it is often called die swell, even though this term is not accurate; it is the material coming out of the die that swells, not the die itself! The swelling of the extrudate occurs primarily because of the elastic nature of the plastic melt. Even though plastic melts are usually considered viscous materials, they are not purely viscous but actually visco-elastic. This means that plastic melts behave both in a viscous and an elastic manner. The elastic component is responsible for most of the swelling of the extrudate. The swelling is the result of the relaxation of the strain imparted to the plastic in the die and perhaps even upstream of the die.

The swelling of the melt is determined by the die design, the flow properties of the plastic, the flow rate, the temperatures, and the drawdown between the die and the take-up. If the drawdown is large enough, there may not be any visible expansion of the material coming out of the die. In this case, the size reduction resulting from drawdown overrides the swelling of the extrudate. A problem with the swelling is that it is generally not uniform; this is illustrated in Figure 68.

With a square flow channel, swelling occurs more at the centers of the sides than in the corners. This nonuniform swelling results from the fact that the shear rates in the corners are lower than at the centers of the sides. Another reason for the distortion of the extruded product is that the flow velocities in the corners are lower than along the sides. This is illustrated in Figure 69; since the velocity field is symmetrical, only the upper left quadrant is shown.

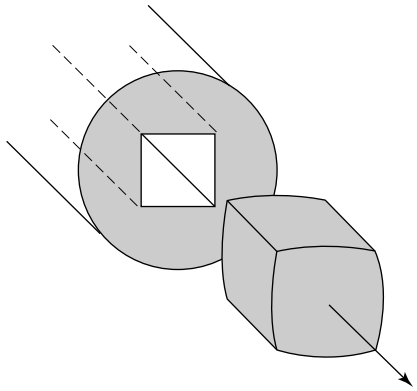

Fig. 68. Swelling of the melt coming out of a die with a square flow channel.

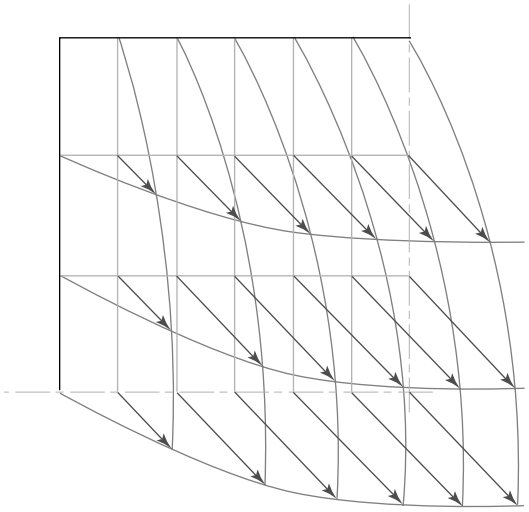

Fig. 69. Velocities in a square flow channel.

As a result, the material in the corners is drawn down more than the material along the sides. Reducing the land length in the corners can enhance flow in the corners; this is typically done by back relieving the die. An example of back relieving the corners is shown in Figure 70.

Cooling increases the density of the plastic and therefore reduces the size of the extruded product. Semicrystalline plastics shrink more upon cooling than amorphous plastics because crystalline regions have a higher density than amorphous regions. Cooling usually does not result in a uniform size reduction. In thick parts, shrink voids can form upon cooling because the outer wall cools and solidifies first. Later the inner layers cool, but they are restrained from shrinking because of the solidified outer wall. As a result, the plastic tends to shrink to the outside, leaving a shrink void in the center, as shown in Figure 71.

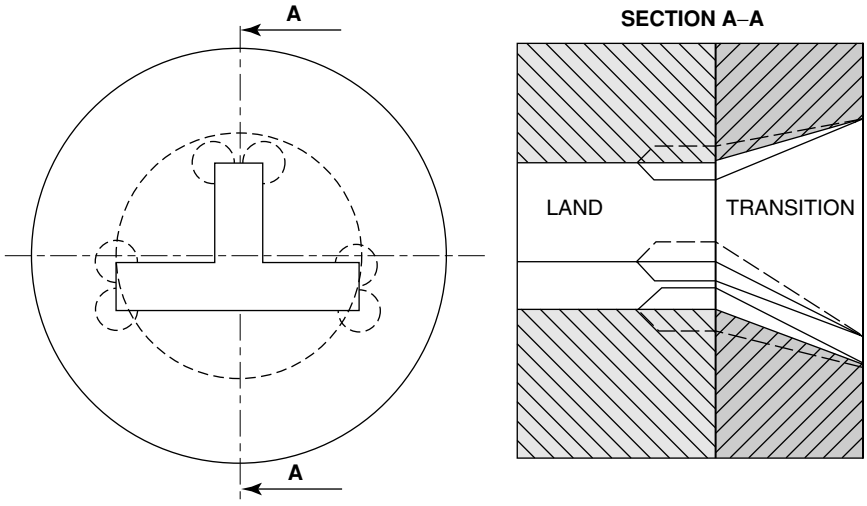

Fig. 70. An example of back relieving the corners of a T-shaped profile.

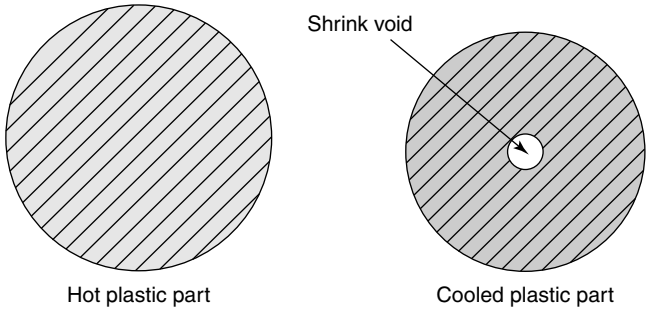

Fig. 71. Formation of a shrink void upon cooling.

Relaxation is the gradual reduction of internal stresses resulting from changes within the material. The stresses can result from the flow in and before the die. Die swell is the result of these stresses. Stresses are also induced after the die exit. The stresses resulting from drawdown are often the dominant stresses induced in the extrusion process. The relaxation processes are strongly temperature-dependent and occur rapidly at high temperatures, particularly above the melting point. At low temperatures however, relaxation occurs only slowly. If drawdown occurs at sufficiently low temperatures, the orientation can relax only partially and a high level of orientation remains in the extruded product. Several commercial processes take advantage of this, such as cold drawing of synthetic fibers.

If nonuniform stresses occur within an extruded product, relaxation of these stresses can lead to warping of the product. An example is shown in Figure 72.

The orientation in the thin legs of the profile tends to be higher than in the thick section. As a result, relaxation in the thin legs is higher than in the thick section, with a correspondingly larger reduction in length. With more length

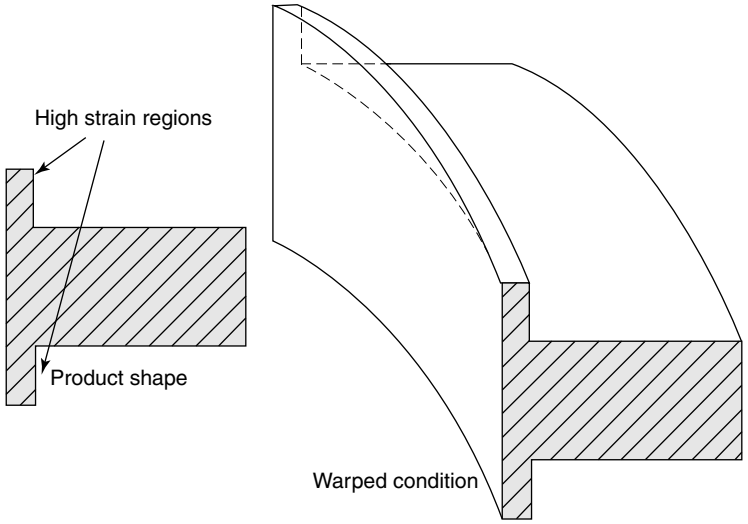

Fig. 72. Warp as a result of nonuniform relaxation in a T-profile.

reduction on the side of the legs (left side), the profile bows with the legs at the concave side as shown. The results of relaxation may not be immediately noticeable. Often the extruded profile appears perfectly straight when first produced. Warpage may not be seen until after the product has spent several days in the warehouse or worse, after it has been sitting in a customer's plant for some time.

Tubing and Pipe Dies. Extrusion dies can be categorized based on the shape of the product produced. Thus, we can distinguish annular dies, slit dies, rod dies, and profile dies. Annular dies are used to make tubing, pipe, blown film, and wire coating. Tubing is a small diameter (less than about 25-mm outside diameter) annular product; it is usually flexible. Pipe is a large diameter annular product (usually with a diameter greater than 25 mm) and is rigid in most cases. Both tubing and pipe are most often used to transport fluids; as a result, they can be exposed to substantial internal pressures. Blown film can have a very large diameter, up to 10 m (30 ft), but the wall thickness is quite small, in the range of 5–250 μm (0.002–0.010 in.). Wire coating and cable jacketing is the extrusion of a layer of plastic over a core. In wire coating, the core is conducting wire; in cable jacketing, the core is a bundle of coated wires.

Annular dies can be either in-line or crosshead. As the name implies, the entrance channel of the in-line die is in-line with the exit channel. This geometry is preferred if it is important to have uniform stresses in the extruded product. A schematic of an in-line die is shown in Figure 73.

Looking at the cross section, the melt enters from the left, then flows around the torpedo, and then though the annular space between the tip and the die. The torpedo is supported by a number of spider legs with a streamlined cross section to minimize hang-up of material. The tip is attached to the torpedo and the die is pressed against the housing by a retaining ring that is bolted against the housing.

A crosshead die is shown in Figure 74. The melt is split around the flow splitter or helicoid, then flows over a shoulder to the tip and the die. The tip is

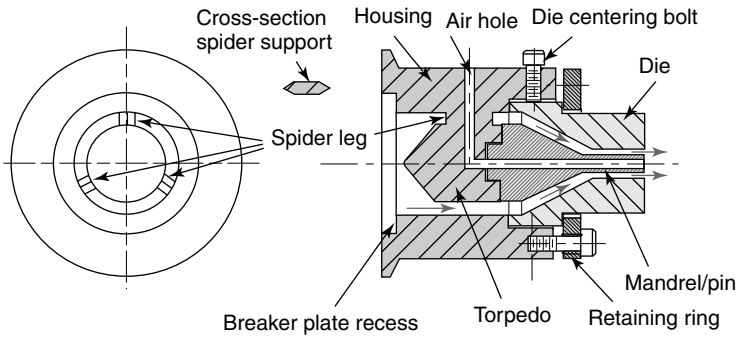

Fig. 73. Schematic of an in-line annular die.

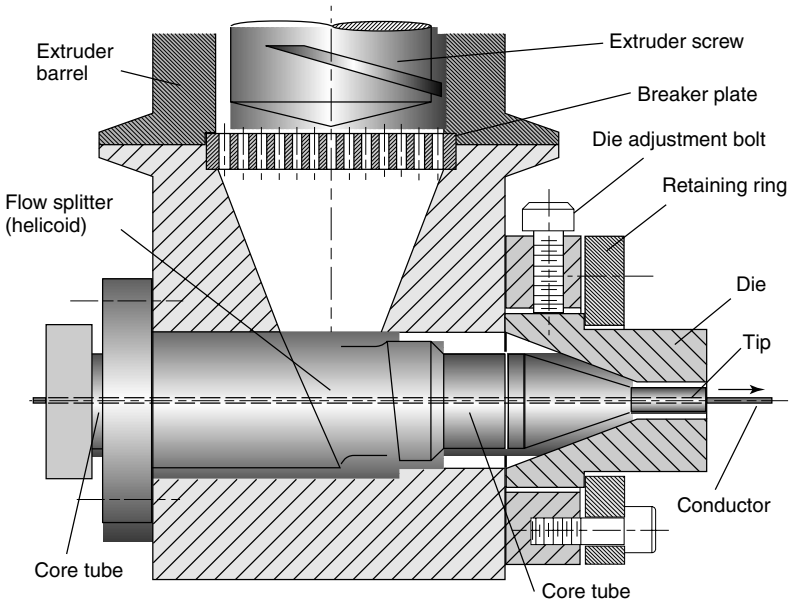

Fig. 74. Example of a crosshead die.

attached to the core tube that can be moved axially. This allows axial adjustment of the tip relative to the die. The die can be adjusted vertically and horizontally by two sets of die adjustment bolts; this allows adjustment of the concentricity of the extruded tube.

Crosshead dies are also used for wire coating. In this case, a conductor moves through the core tube and tip, often at high speed. As the conductor exits from the tip, it is coated with molten plastic in a continuous fashion. Very high line speeds can be achieved in wire coating, as high as 3000 m/min (about 10,000 ft/min).

It should be noted that the dies shown here are some simple examples of annular dies. There is an enormous variety of designs; however, at this point only the main types and features are covered. For instance, in the die assemblies shown, the die can be moved relative to a fixed tip to adjust concentricity. It is also possible to design the die assembly such that the tip can move relative to a

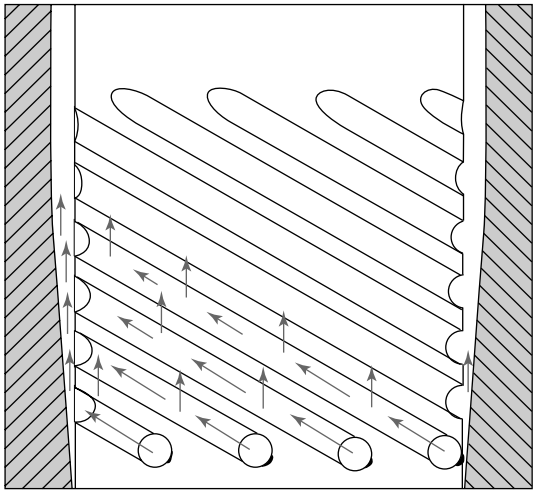

Fig. 75. Spiral mandrel die.

fixed die to adjust concentricity, for instance, by moving the core tube in the back section of the die assembly.

In some annular dies the concentricity adjustment is done automatically. In order to do this, the wall thickness has to be measured downstream of the die along the circumference of the product or in at least four positions. In most cases, the wall thickness is measured using ultrasound. Automatic adjustment is done in some pipe extrusion operations where excess material usage because of poor concentricity could be quite costly.

A special die geometry that was developed for blown film extrusion is the spiral mandrel die, shown in Figure 75. The plastic melt is usually fed through a central channel, then led through radial channels that come out in helical channels in the mandrel. The helical channels are deep initially but they gradually become shallower. At the same time the clearance between the mandrel and the housing increases. As a result, the initial flow is largely a helical flow; however, there is a gradual increase in annular leakage flow with a corresponding reduction in helical flow. At the end of the spiral mandrel section, the flow is a pure annular leakage flow.

The following are the advantages of the spiral mandrel die:

(1) Weld lines are largely eliminated.
(2) Good flow distribution is eliminated.
(3) The helical flow induces some circumferential orientation which increases the hoop strength of the extruded product.
(4) The flow through the spiral mandrel section can be readily modeled, which is helpful in design and optimization.

Even though spiral mandrel dies are primarily used in blown film, they have obvious advantages in tubing and pipe extrusion. Both tube and pipe are often

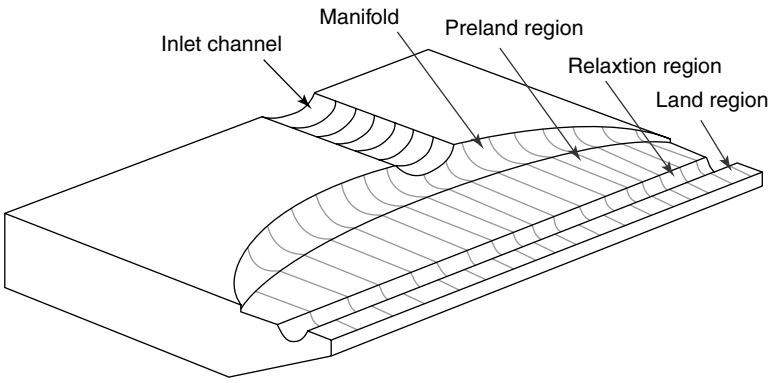

Fig. 76. Main sections of the flow channel of a flat film or sheet die.

pressurized internally in normal product use. With internal pressurization, it is important to have high hoop strength and make sure that weld lines are avoided as much as possible. Since spiral mandrel dies increase hoop strength and reduce weld line problems, they are an attractive option for almost any annular product exposed to a high internal pressure during its end-product use.

Flat Film and Sheet Dies. Dies for flat film and sheet have the same general shape, although there are many differences in the geometrical details. The main sections of the flow channel of a sheet die are the inlet channel, the manifold, the preland section, the relaxation section, and the land section. The main sections of the flow channel are shown in Figure 76.

The inlet channel connects with the discharge of the extruder on one end; on the other end it connects with the manifold section. The function of the manifold is to evenly distribute the flow from the inlet across the manifold outlet. From the manifold, the melt flows to the pre-land, through the relaxation section, and then to the land section. There are a number of different manifold designs, such as the T-die, the coat hanger die, and the horse shoe die. The T-shaped manifold of the T-die does not yield well-streamlined flow; however, the geometry works for low viscosity plastics that are not susceptible to degradation. Another advantage of the T-die is that it is not susceptible to clam shelling, which is the separation of the die lips resulting from the internal pressure of the plastic melt in the die (see Fig. 77).

The coat hanger die has a manifold shaped like a coat hanger (see Fig. 76). The manifold has a complicated shape and is not easy to design or machine. The advantage of the coat hanger manifold is that it produces streamlined flow and it is not susceptible to clam shelling. Coat hanger dies have been made in widths as large as 10 m (30 ft).

The horseshoe die has a manifold with a rectangular cross section (see Fig. 78). It can be designed such that the distribution of flow is independent of the degree of shear thinning of the plastic melt. In fact, it is the only manifold geometry that has this characteristic. The drawback is that the horseshoe die is susceptible to clam shelling. As a result, this die is not typically used for dies wider than 1 m (40 in.).

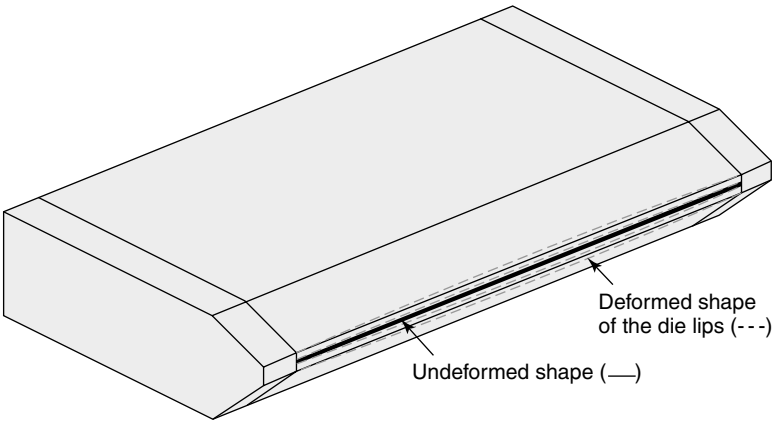

Fig. 77. Illustration of clam shelling.

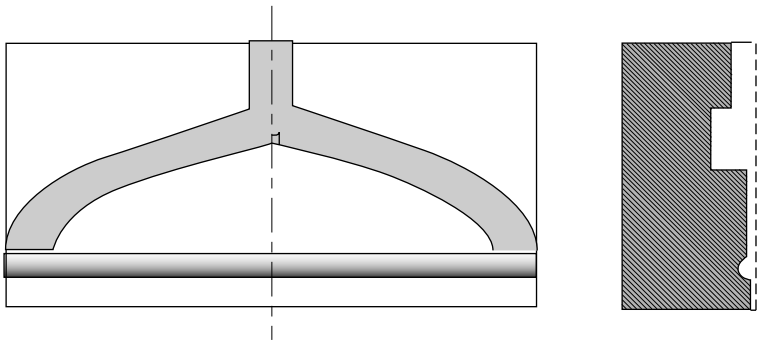

Fig. 78. Horse shoe manifold.

Profile Dies. Profile dies come in many different shapes and sizes. The term profile die is used for dies that extrude shapes other than rectangular, annular, or circular. There are two main types of profile dies: the plate die and the fully streamlined die. The plate die, shown in Figure 79, uses a plate with a cavity shaped to produce the required extruded product. This plate is attached to the end of a section with a large flow channel. The advantage of the plate die is that it is easy to make. On the other hand, the flow is not streamlined and dead spots are likely to occur.

The streamlined die, shown in Figure 80, has a flow channel that gradually changes to the exit geometry of the die. As a result, the velocities gradually increase as the plastic melt moves through the die. There is little chance of hang-up in this geometry. Therefore, the streamlined die is more appropriate for long runs and for plastics with limited thermal stability. The disadvantage of the streamlined die is that it is more difficult to manufacture and therefore more expensive.

There are many profile dies that have a geometry between the plate die and the fully streamlined die; these could be called partially streamlined dies. Because of the enormous variety of profile dies, it is not possible to cover this subject

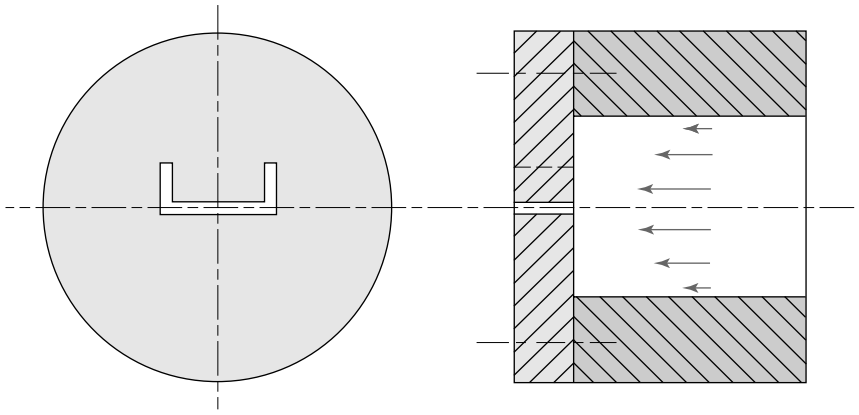

Fig. 79. Example of plate die.

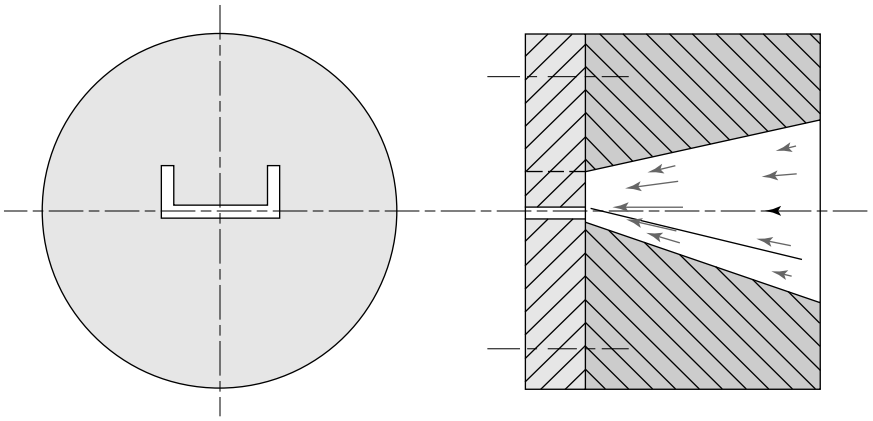

Fig. 80. Example of streamlined die.

comprehensively. For more information, the reader is referred to Michaeli's book on die design (7).

FILMS, ORIENTATION

Introduction

Molecular orientation provides a wide range of improved properties for thermoplastic films. Most often, molecular orientation results in significantly higher physical properties such as tensile strength and modulus. Orientation may improve thermal properties of a film by increasing the crystallinity. Optical properties are influenced by orientation. Films with high clarity to high opacity may result from orientation. The polarization and reflective responses of films are also impacted by orientation. Enhanced electrical properties, such as increased dielectric constants or piezoelectric properties, may result from orientation. Orientation begins with a cast web suitable for stretching. This web may be stretched in one direction, two directions sequentially, or two directions simultaneously.

Cast Web Considerations

Extrudate Uniformity. The quality of the cast web has a great influence on subsequent orientation steps. While in the extruder, the polymeric melt needs to become homogeneous. Thermal gradients, poor blending of additives or polymeric blends, and entrapped gases may result in imperfections in the cast web. During orientation, these imperfections may lead to high stress concentrations and fracture of the film. Selection of the proper extrusion system, screw design, temperature profiles, venting, and homogenizing equipment will improve the orientation capability of the cast web.

Orientation of multilayer films is a common practice. The various melt streams either flow together in a feedblock prior to entering the die or in a

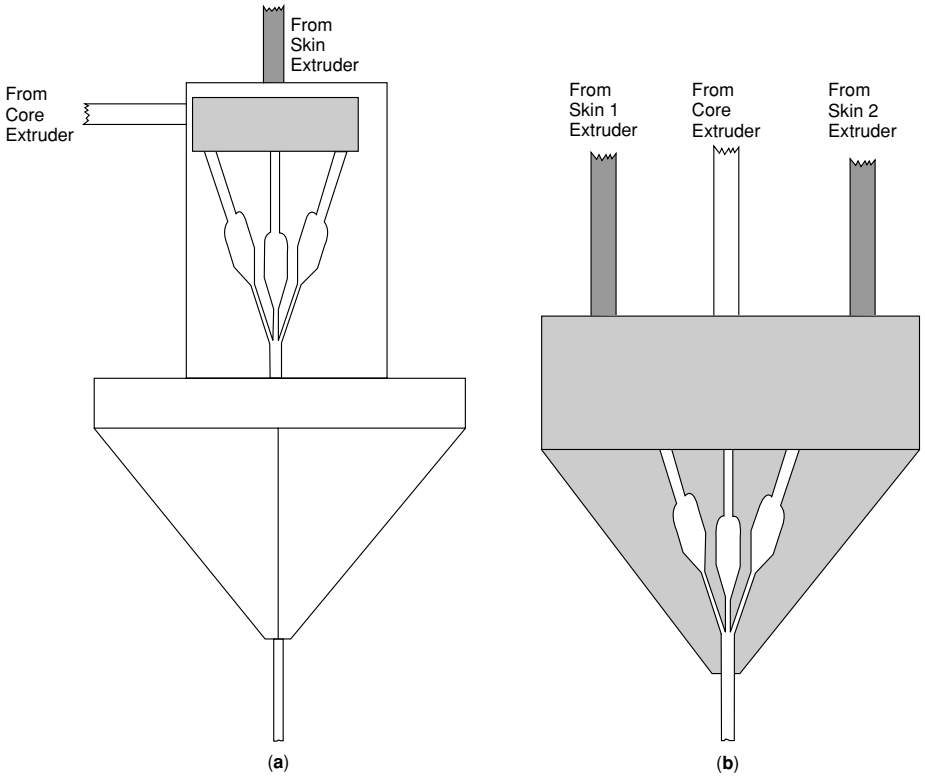

Fig. 1. (**a**) Feedblock and (**b**) die combining melt streams.

multicavity die (Fig. 1). As the layers flow together, viscosity and speed matches are critical. If the layers do not have a good match, interfacial instabilities occur. These flow effects produce minor to severe thickness variations in the extrudate. These variations are typically very localized. During the orientation process, significant stress concentration may be generated around these thickness variations, resulting in fracture of the film.

Quench. Cooling the melt to solidify the viscous extrudate is an important process parameter. Depending on the orientation process, the melt quenching process may be very different. The two primary extrudate geometries are a flat sheet and a tube. Most often, heat needs to be removed from the extrudate as quickly as possible. For semicrystalline polymers with a relatively slow crystallization kinetics, like PET, PEEK, or PPS, rapidly quenching the melt results in a molecular amorphous state. For semicrystalline polymers with a relatively fast crystallization kinetics, like polyethylene, polypropylene, or nylon 6, rapidly quenching the melt allows for the growth of smaller spherulites.

The flat sheet extrudate emerges from the die and falls on a rotating drum or continuous belt (see Fig. 2). The rotating drum or chill wheel cools the melt as quickly as possible. The internal flow design of the chill wheel must provide a uniform cooling surface to the melt. If there are zones of different temperatures, the extrudate will cool at different rates. This could lead to areas of

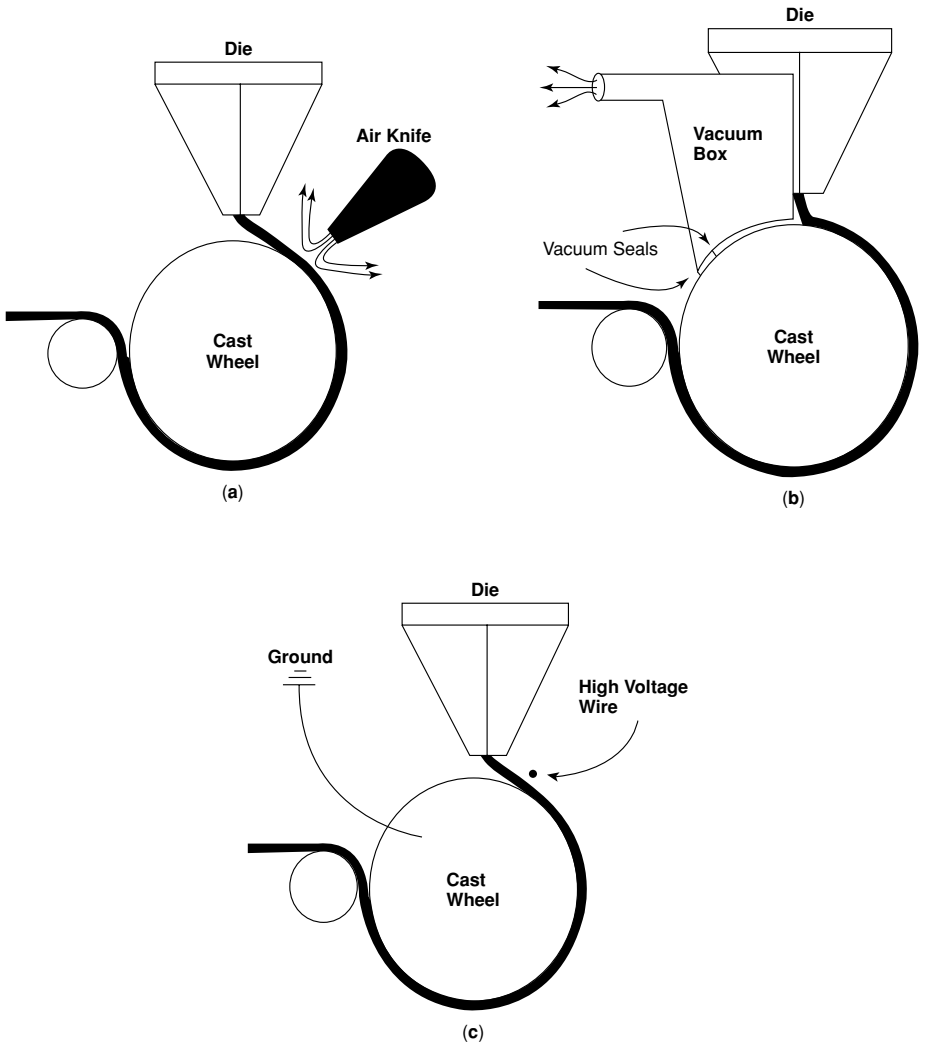

Fig. 2. (**a**) Air knife quenching, (**b**) vacuum box quench, (**c**) electrostatic pinning, (**d**) nip roll quench, and (**e**) water bath.

the cast web with different levels of crystallinity or spherulite size. The chill wheel's surface topography will impact the quench rate and smoothness of the final film.

At high line speeds found in industrial applications, air entrapment between the melt and chill wheel can greatly retard the cooling of the melt. Cooling the melt at different rates in small zones may lead to nonuniform stretching and may even result in fracture of the web during orientation. There are several methods available to improve the heat transfer from the melt into the chill wheel. A slot with high pressure air may be directed at the melt just after it hits the chill wheel. This "air knife" process presses the melt against the chill wheel to increase the heat

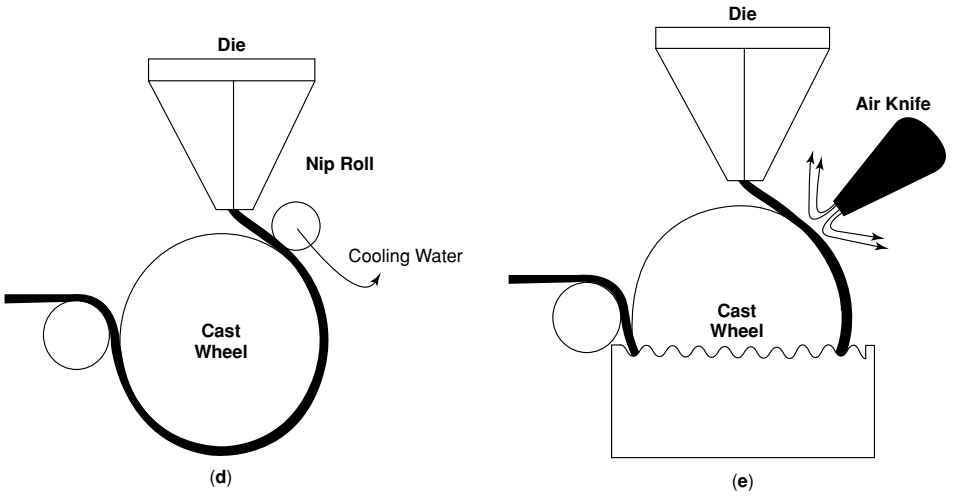

Fig. 2. (Continued)

transfer. The location, angle of incidence, and air flow are the major parameters to consider. Improper tuning of the air knife may result in a cast web with excessive flutter and resultant caliper variations. Uniform pressure or air flow across the entire melt curtain will lead to a uniform cast web.

A second method of pressing the melt against the chill wheel is through electrostatic forces (1). Passing a high voltage through a wire suspended just above the melt produces charged particles which are attracted to the ground, ie, the chill wheel. Electrostatic pinning may work better for some materials or thinner cast webs. Deposits on the wire over time will reduce its effectiveness. Continually feeding new wire will help eliminate this source of variability in the process.

A third approach to improve the heat transfer to the chill wheel is to remove the air between the melt and chill wheel. By applying a vacuum between the die and melt, a more intimate contact between the melt and chill wheel occurs. The vacuum box needs to have seals on the edge of the die in order to produce a strong enough vacuum. Uniformity of the vacuum across the melt curtain will result in a more uniformly quenched cast web. Too high a vacuum will result in the melt curtain being pulled backwards. This could result in the melt developing scratches in it by being dragged across the lip of the die. Ideally, the vacuum should be adjusted to have the melt drop straight away from the die.

A fourth method of assuring good contact to the chill wheel is to mechanically nip the melt against the chill will. This nip roll may also have to be cooled. The surface of the nip usually needs to have some flexibility in it. The cast web may not be perfectly flat and a nip roll will need to press on the entire surface of the melt. High temperature rubber sleeves on the nip roll are most often used, but these may result in producing a rough surface.

The chill wheel may also be partially submerged in a bath to provide additional cooling from the second surface of the extrudate. The flow in a water

bath must be adjusted with care. Continually circulating the water will increase the effectiveness of the quench. High pressure water jets can help keep pressure on the web against the chill wheel. These jets can also deform the surface of the cast web. If they are at the wrong angle, the web could be pulled away from the chill wheel, reducing the quench rate. If this technique is used, the chill wheel needs to be dried off by the time it rotates to the point where melt is again placed on it. If it is too wet, steam bubbles may form creating serious nonuniformities in the cast web. A nip roll or air knife has been used to accomplish the drying of the roll. Combination of both may be required in high speed operations.

When extruding a tube through an annular die there are two kinds of orientation processes available, blown film process and tubular film process. Blown film conducts the orientation in the melt state. The tube is rapidly pulled away from the die by a nip at the top of a tower. Air is pumped through the annular die to inflate the tube and to provide additional cooling. The molecular orientation produced in blown film is quite low compared to solid-state orientation. The molecules are above their melt and have very fast relaxation times. One often refers to the frost line in a blown film process. This is the point where the melt crystallizes. The polymeric web goes through a clear to hazy transition at this point. Further molecular orientation in the web in this stage of the process typically does not occur.

In the tubular film process, or double bubble process, the extruded tube encompasses a cooled mandrel and is pulled away by a nip (Fig. 3). The mandrel should not impart scratches in the tube. This first "bubble" is usually quenched as rapidly as possible for the same reasons in flat film. Controlling the air pressure inside the first bubble is another handle used to determine the quench rate. A water bath on the outside of the tube provides additional cooling of the extrudate. Water flow around the tube is very important. Too great an impingement against the melt may result in surface defects. A tube quenched in this manner will allow subsequent orientation to occur in the solid state at significantly lower temperatures, resulting in higher molecular orientation.

Melt-State Orientation—Blown Film

The blown film process, as shown in Figure 4, orients the molecules while they are in the melt state. Inflating the melt bubble provides the orientation. The air pressure in the bubble is maintained to achieve a certain "blow up ratio," the ratio of bubble diameter to the die diameter. The strain rates are relatively low and relaxation times are very fast. The subsequent molecular orientation obtained via this process falls between the high levels of orientation obtained by stretching in the solid state and very low levels obtained in standard casting operations. The orientation occurs during elongational flow of the melt. Although elongational flow is much more effective at orientation than shear flow, this process has limitations.

There are many methods to increase the amount of orientation frozen in during the blown film process. Systems have been developed to approach

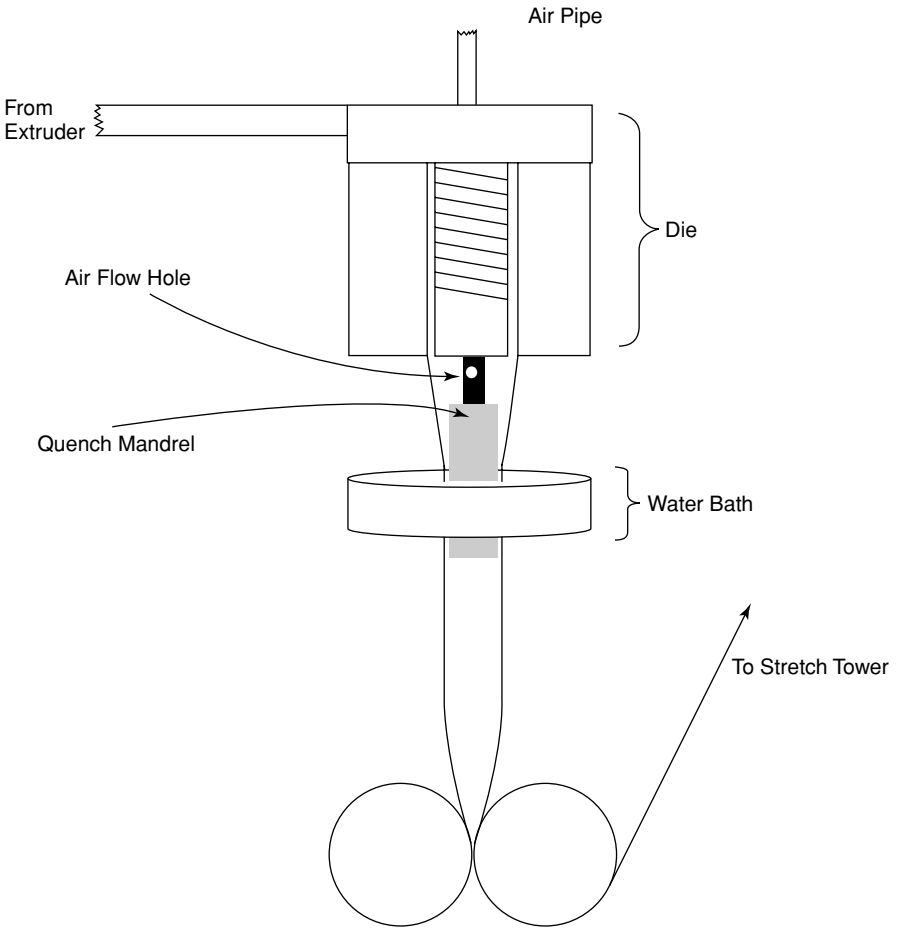

Fig. 3. Tubular film quenching.

quenching a blown film tube from both internal to the bubble and external to the bubble. The faster the quench, the greater molecular orientation is obtained. Internal devices (2,3) can cool the film preferentially, locking in molecular orientation. Externally cooling the blown film bubble in multiple stages (4–6) will allow greater orientation to occur in the tube. Operation of the primary air cooling ring has a dramatic impact on final properties (7). Attempts to separate the machine direction stretching from the transverse direction have shown some promise (8).

Choice of materials, as in any process, is a major consideration. Most resin suppliers and equipment vendors have laboratory to pilot-scale equipment that can screen various resins. Blends of similar resins can also be useful in obtaining greater orientation in the blown film process (9).

There been attempts to generate off-axis orientation in blown film. Rotation of some component of the annular die may impart diagonal orientation (10,11).

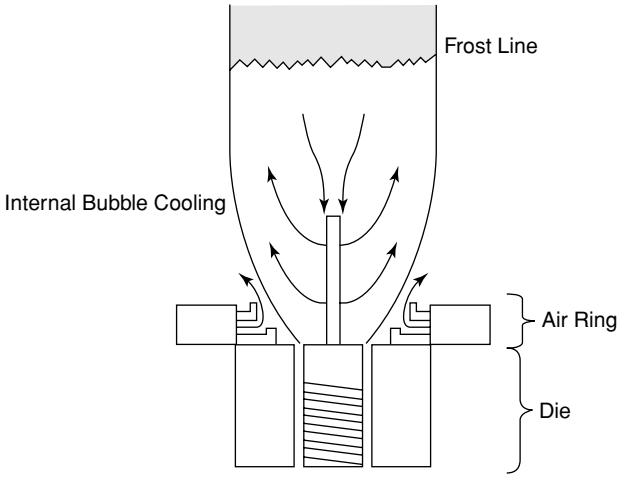

Fig. 4. Blown film process, quench air ring, and internal bubble cooling.

Solid-State Orientation—Monoaxial Orientation

Machine Direction. There are applications in which improvements in properties are required in only one direction. Most often, this high strength axis is in the machine direction (12). Equipment that stretches a film in the machine direction can be called machine direction orienter or length orienter. Uniform heating of the unoriented web is achieved by wrapping the web around a series of heated rolls. These preheat rolls need to have very smooth surfaces to ensure good heat transfer to the web and to prevent scratching the film. These rolls may be driven rolls or idler rolls. Another method to heat up the web uses ir radiation (13). It is also possible to immerse the cast web in a temperature-controlled bath to bring it up to temperature prior to orientation (14).

For a crystallized semicrystalline polymer, the web is heated to below, but near, the melting point. Amorphous polymers will only need to be heated to slightly above their glass-transition temperatures (T_g).

The web passes through an inlet nip, over the preheat rolls and enters the stretch section (Fig. 5). A high speed nip pulls the film in the machine direction. The amount of orientation in the film will be determined by the strain rate, stretch temperature, amount of stretch, and how quickly the film is cooled. Stretching between two rolls is a very high strain rate process in industrial settings, often of the order of 5000%/s. The level of orientation attainable is quite high.

Selection of the polymeric material plays an important role in the efficiency of this process. One needs to consider the molecular weight, the molecular weight distribution, and even the additive package. High loadings of some stabilizers may plate out on the equipment and interfere with consistent heat transfer.

Subsequently, a second or even more (15) machine direction stretching stations may be used. The web may have to be further heated before it is stretched a second time. This process can produce higher molecular orientation in films than

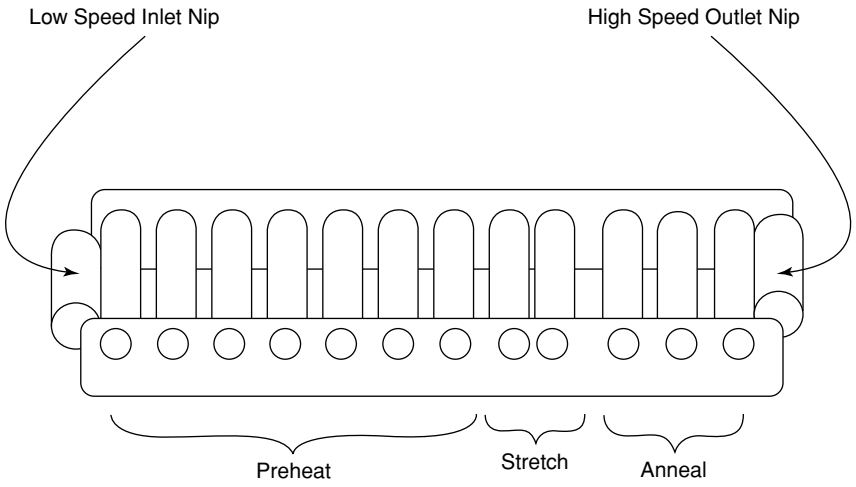

Fig. 5. Machine direction orientation unit.

a single-stage stretch. It is possible to heat-treat the stretched film at this point to allow some relaxation in the material. This will assist in maintaining greater dimensional stability as the film ages.

The width of the film reduces during the machine direction orientation. As the gap between the low speed roll and high speed roll increases, this width reduction increases. One approach to minimize the width reduction is to shorten the stretch gap. Another approach is to pin the web against the rollers with high-pressure air (16).

This machine direction stretching process is also used as the first orientation step in sequential biaxial film manufacture.

A second major machine direction orientation process involves a very high pressure nip (see Fig. 6). Input cast webs are cold-rolled or compression-rolled

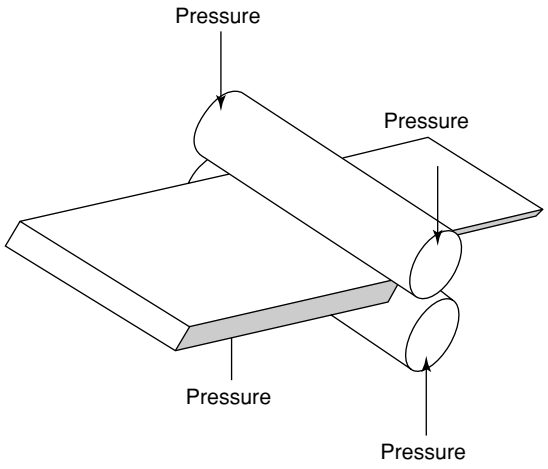

Fig. 6. Compression rolling process.

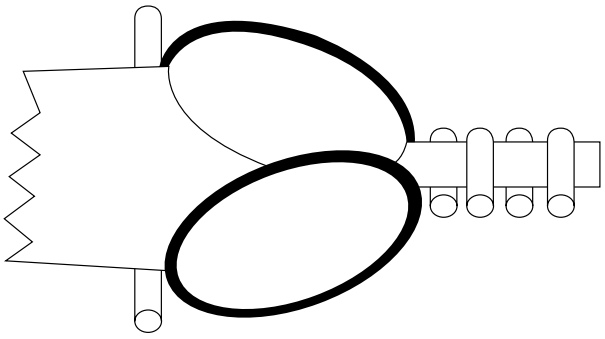

Fig. 7. Disc orienter.

to impart molecular orientation. Prior to entering the nip, a coating (17) or surface treatment (18) may be applied to the cast web. This surface treatment helps lubricate the film while in the high pressure nip. The cast web may enter the high pressure nip anywhere from room temperature to below the melt point. The temperature typically is above the glass-transition temperature of the material. Pressures on the cylinder arms can be of the order of 1,000,000 psi for some industrial applications. The thickness of the polymeric film can be reduced from 5 to 95% (19).

As with the drawing process above, it is possible to incorporate several compression rolling stages in line (20). Combination of a length orienter and a compression rolling station (21) may lead to triaxial orientation morphology. Molecular orientation from this type of process can be exceedingly high. This level of orientation leads to properties of films that are not commonly attained through standard length orientation draw stations.

Transverse Direction. In the case where the cross direction requires the improved properties, there are several ways to generate such films. Large discs (22) with a groove in the perimeter are tilted with respect to each other. At the discs' closest spacing, each edge of the web is secured to the perimeter of the divergent discs by a belt. At this point, the web must be preheated to its orientation temperature. This can be accomplished by running the web over a number of heated rolls just prior to clamping the web onto the diverging discs.

As the discs rotate, the web is stretched in the cross direction. At some point around the discs, the belt holding the web to the perimeter is peeled away and the transverse-oriented film continues down the process line (Fig. 7). If the forces required to stretch the film are quite large, this technique may not work. The film may be pulled out from under the belt.

Stretching the film only in the transverse direction may also be accomplished by using a tenter (23). The tenter process uses clips on a chain (Fig. 8). The clips grab each side of the cast web and transport the web through an oven. Once the film is heated to the orientation temperature, the rails that the chains ride on diverge. This method alone is seldom employed in practice.

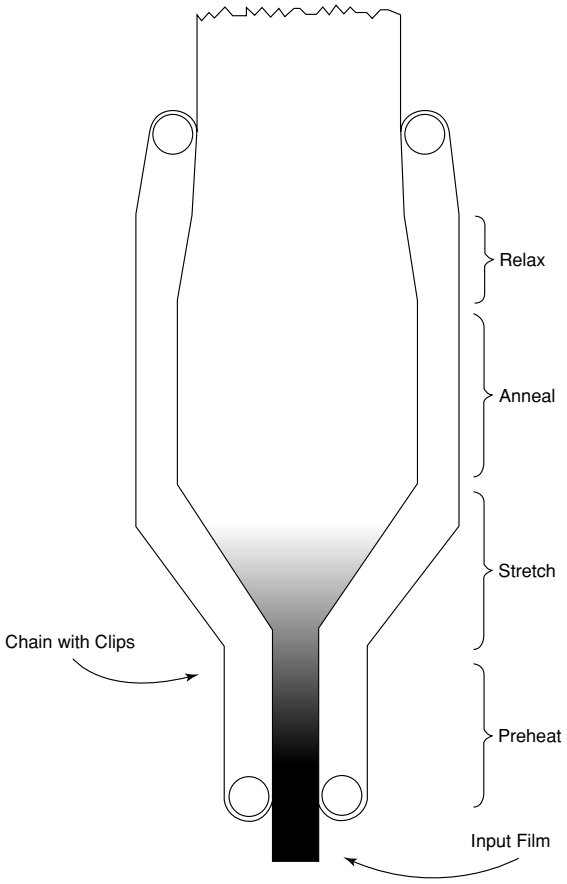

Fig. 8. Standard tenter frame.

Solid-State Orientation—Biaxial Orientation

Orienting the film in both the machine and transverse direction has produced many significant products. Biaxial orientation can be achieved in many different methods. In sequential orientation, the web is stretched first in one direction, usually the machine direction, and then in a second direction. The other main method of biaxial orientation is simultaneous biaxial stretching—stretching the film in both directions at the same time. The simultaneous orientation process has two major processes, one is based on a flat film approach and the second processes the web in a tube.

Sequential Biaxial Orientation. The standard process for sequential biaxial orientation is machine direction orientation followed by transverse orientation. This is a continuous process. The machine direction stretch occurs similar to the process described in the monoaxial section (Fig. 5). However, a second draw station is typically not present in this process. In the pure monoaxial orientation case, the process often tries to maximize the molecular orientation in the

web. This would lead to difficulties in the sequential biaxially oriented process. The orientation in this first step must be low enough such that the molecular structure of the film will support transverse direction stresses. Films stretched highly in the machine direction tend to split when pulled in the transverse direction.

The second stretch occurs in a tenter (Fig. 8). Often the temperature will need to be higher for the second stretch. A long distance in the oven is required to heat the web to the orientation temperature. The rate of divergence of the rails will impact the final properties of the film in the transverse direction. Once the stretch has been completed, the rails are often brought slightly closer together to relax the film. In this section, additional annealing may increase the crystallinity in the film for semicrystalline materials that are quenched to an amorphous state at the chill wheel.

Reversing the order of sequential stretching (24) is possible. The orientation in the first stretch is usually limited. By reversing the order, this allows the machine direction orientation to be second and hence greater than if it were done first.

A third stretching operation may also be performed. This is done to generate greater orientation in the film (25,26).

Simultaneous Biaxial Orientation. There are two predominate systems available to do this, tubular and flat film. In the tubular process (see Fig. 9), also referred to as the double bubble process, a continuous tube is extruded and quenched. Typically, an interior cooled mandrel is hung from the die inside the tube. The surface of the mandrel may greatly influence the interior surface of the tube. Care must be taken not to impart scratch lines in the melt as it is pulled down over the mandrel. Air pressure in this primary tube is very critical. The melt needs to be held out over the mandrel but not too far away. A water bath on the external side of the tube helps quench the tube rapidly. A nip pulls the tube from the die and acts to isolate the casting bubble from the air pressure in the stretching bubble (27).

Going through a nip can be very difficult for a tube. Cracks in the edge or localized stretching in the crease can negatively impact the film produced. There are several proprietary methods used to reduce this area of concern. The tube is often reinflated and transported to the top of a stretching tower. At the top of the tower, the tube is again nipped. This inlet nip again helps isolate pressures from the stretching and casting bubbles. Once through the inlet nip, the tube will descend through a heater section to the bottom of the tower.

Heaters will soften the tube and the tube is inflated with air. The initial filling of the tube with air requires good timing by the operator. As air is pumped into the expanding tube, the operator pulls the tube away faster than the top nip supplies cast tube. Once the inflated bubble reaches the bottom of the stretch tower, a second nip closes. This second nip seals the air in the tube. The second nip runs at a speed greater than the first and provides the machine direction orientation. The amount of air pumped into the tube before the second nip closes is one of the primary factors in the transverse direction stretch ratio. Other process variables that contribute to the transverse stretch ratio are the web temperature and machine direction stretch ratio. Pressure in the tube may be increased by narrowing the frame used to collapse the bubble.

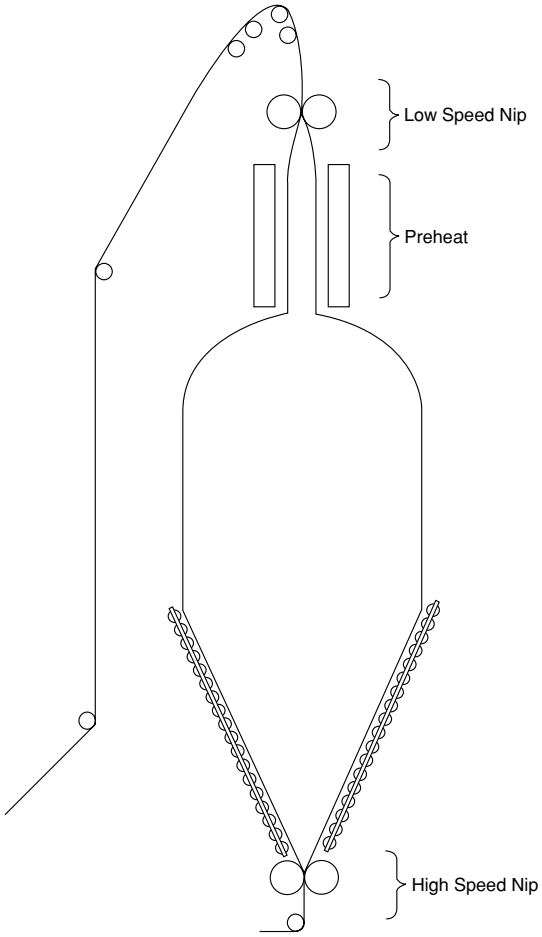

Fig. 9. Tubular orientation process.

Biaxial stretching of the tube occurs in one temperature zone, which can be limiting to the ultimate molecular orientation achieved in both directions. Another limitation to this method is gradual deflation of the stretch bubble over time. There are a few proprietary methods to maintain a constant air pressure in the stretching tube to extend the run time of this process. Continuous operation of a tubular bubble for over a week is very possible.

After the tube has been biaxially stretched, the film needs to be annealed. This process can be done in several ways (Fig. 10). The most common is to insert into the tube a set of parallel bars. These bars have air flowing out on their outer surfaces that allow the film to slide over them. These bars are in an oven or ir-heating chamber. As the tube reaches the end of the annealing zone, it is split open and sent to the winder.

Alternately, a third bubble may be inflated and passed through an oven to anneal the tubular film. This method may be preferred if excessive heat is required to anneal or crystallize the material. Shrink forces for some polymeric

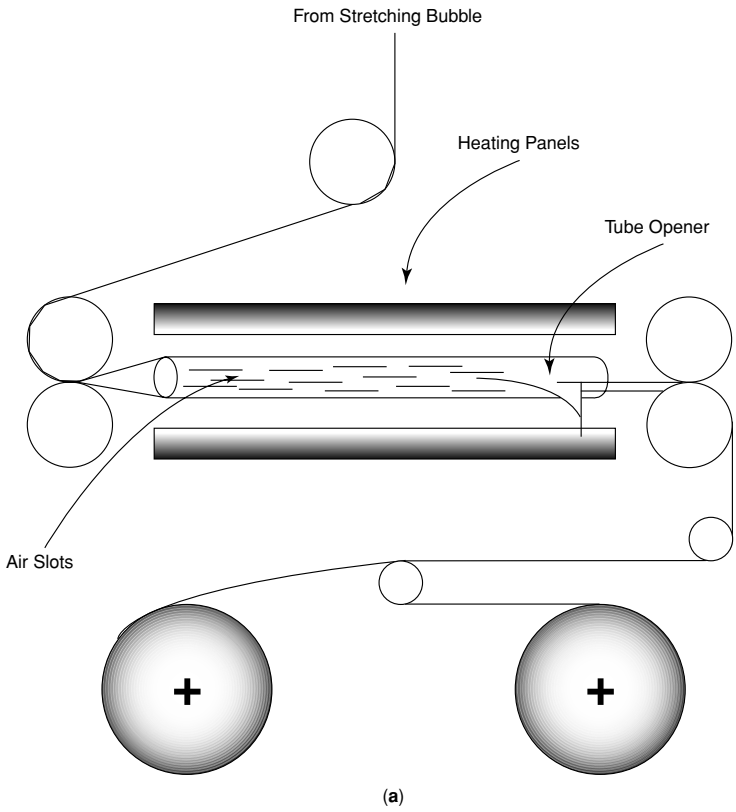

Fig. 10. Tubular annealing process: (**a**) air rails and (**b**) triple bubble.

systems may be too great to pull the tube over the annealing bars mentioned above.

One of the features of tubular film process is the roll formation obtained. It is common to rotate the tube or collapsing frame. This will distribute caliper variations in the film across the wound up roll. Soft areas and hard bands may be eliminated in the output roll with this process. This process requires low labor content as compared to larger flat film lines. As all the film is uniformly stretched, the yield of this process may be very high.

In the flat film biaxial process there are several methods available to simultaneously stretch a web (28,29). The throughput on the film line can be significantly greater with the flat film process as compared to the tubular process. With flat film processes, there is more flexibility in the temperature profile during the stretching process than that found in the tubular process. This can help attain greater levels of orientation in the film.

Common to the various processes, clips grab the edge of the cast web. These clips must allow the web to be pulled in both directions. This type of clip requires special designs as compared to the transverse direction only style clips. The geometry of the clip footprint and its surface shape are key characteristics.

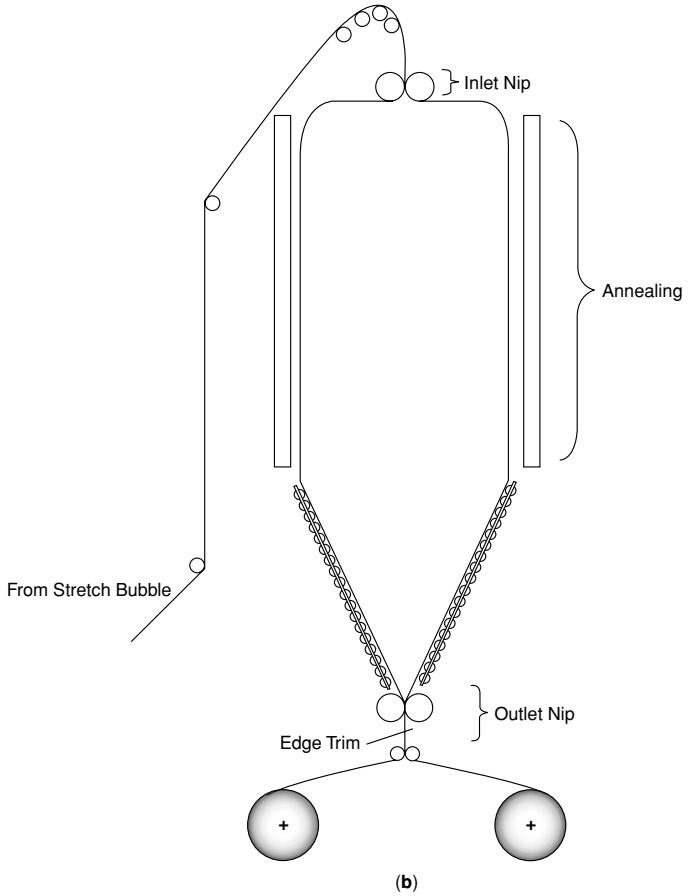

Fig. 10. (Continued)

The main difference between the flat film methods is how the clips are accelerated through the tenter. In one commercial process, the clips ride in a screw (30). As the pitch of the screw increases, the clips accelerate in the machine direction (Fig. 11). The clips may be passed from one screw to another. This type of process has large constraints on the machine direction orientation. Once the screw is machined, the machine direction stretch ratio is fixed. Changing from one screw to another can demand excessive time. A machine direction orienter prior to the inlet of the tenter oven may be used with this type of tenter (31). This permutation of this process will allow for changing the overall machine direction stretch ratio without changing the screws.

Another type of simultaneous stretching may be accomplished with a pantograph type stretching process (32). This expandable frame rides on the tenter rails (Fig. 12). The clips are initially packed close together by a drive sprocket at the entrance to the tenter oven. After transporting the web through the preheat zone, the pantograph is expanded in the machine direction at

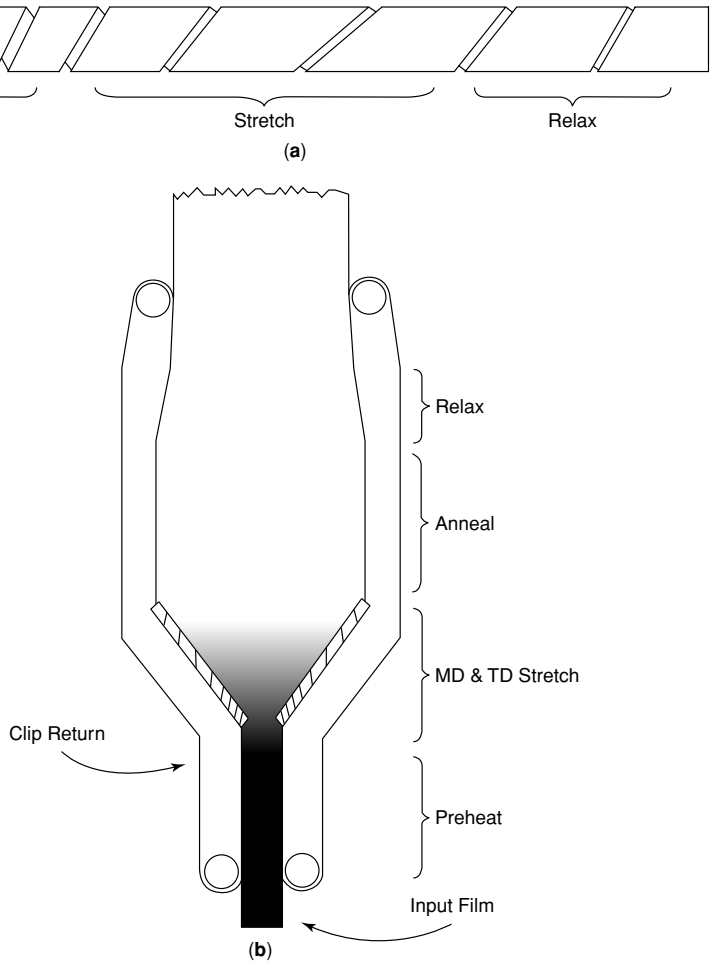

Fig. 11. Screw for screw orientation process: (**a**) stretching screw and (**b**) simultaneous biaxial tenter frame.

the same time the rails diverge. This produces a simultaneous orientation to the polymeric film. A drive sprocket at the end of the tenter maintains the separation of the clips for transport back to the tenter entrance. A third sprocket drive collapses the expanded pantograph between it and the inlet drive sprocket.

Determination of where and by how much the pantograph expands may be controlled by an additional rail or shoe that will squeeze the pantograph causing it to expand.

Most recently, a linear synchronous motor-based process (33) has been developed. The commercialized process (34) has been run successfully on several full production lines. Multilayer polyester and polyolefin films are commercially made via this latest technology. This process uses a magnetic wave to propel the

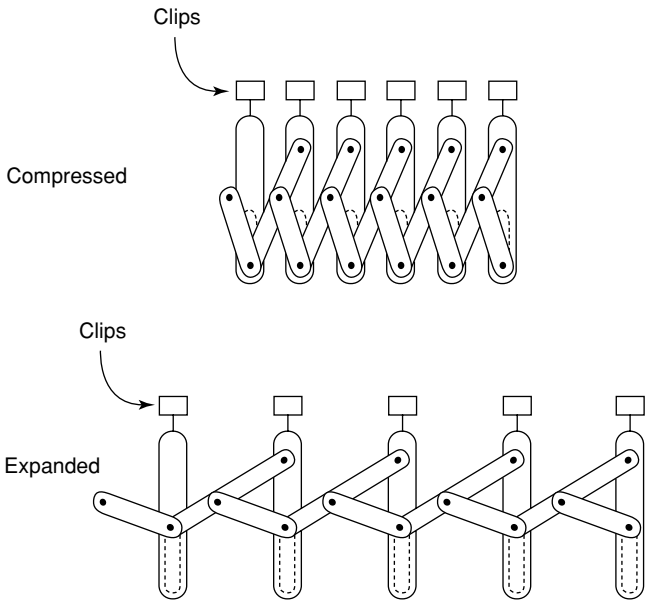

Fig. 12. Pantograph simultaneous biaxial orientation process.

clip through the oven. Once the film has been preheated, it enters the stretch section of the oven. As the rails the clips ride on diverge, the magnetic wave will accelerate the clip in the machine direction. Strain rates in the machine direction are typically of the order of 400%/s. This process allows for significant flexibility in the machine direction orientation as compared with the previous technologies.

Each clip frame assembly, as shown in Figure 13, has permanent magnets attached to its top and bottom. The linear motor consists of fixed stators. A moving magnetic wave is produced when the stator windings are energized by a three-phase electric current. This wave interacts with the magnets on the clip frame to push or pull it through the tenter (see Fig. 14). As the frequency of the power supply is changed, the speed of the magnetic wave is proportionally changed as well. Control of the ac current supply to each stator allows for programming various accelerations as well as the total amount of machine direction stretch (35). The stretch forces required by some materials or thicker webs may pose a problem for this process. If the stretch force exceeds the force the magnetic wave can impart on the clips, the clips will slip the wave. This can lead to nonuniform stretching or in the extreme case, a lack of clips at the tenter inlet.

The main feature of this type of process is the very high level of flexibility attainable in the machine direction stretch. The strain profile may be linear, exponential, logarithmic, or stepped. The amount of stretch can easily be programmed to occur in a given temperature zone in the oven. Changing the machine direction stretch ratio can easily be programmed. It takes just

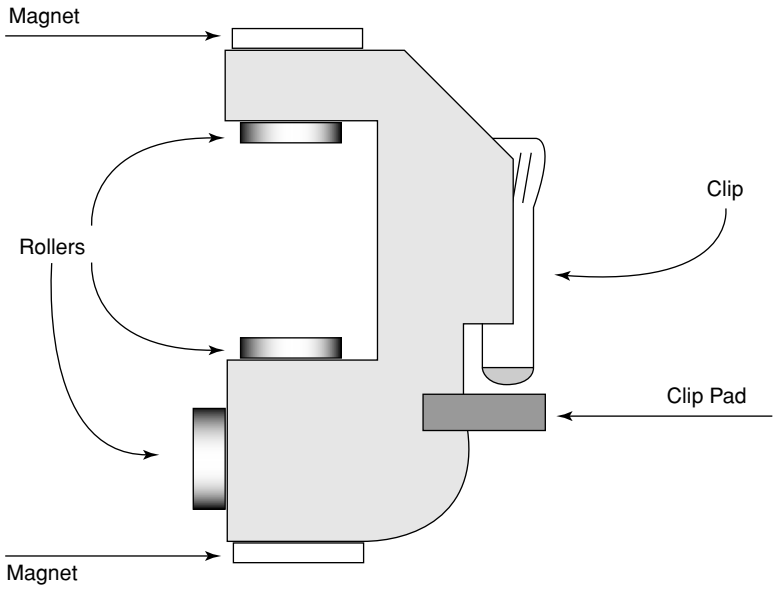

Fig. 13. Linear motor clip assembly.

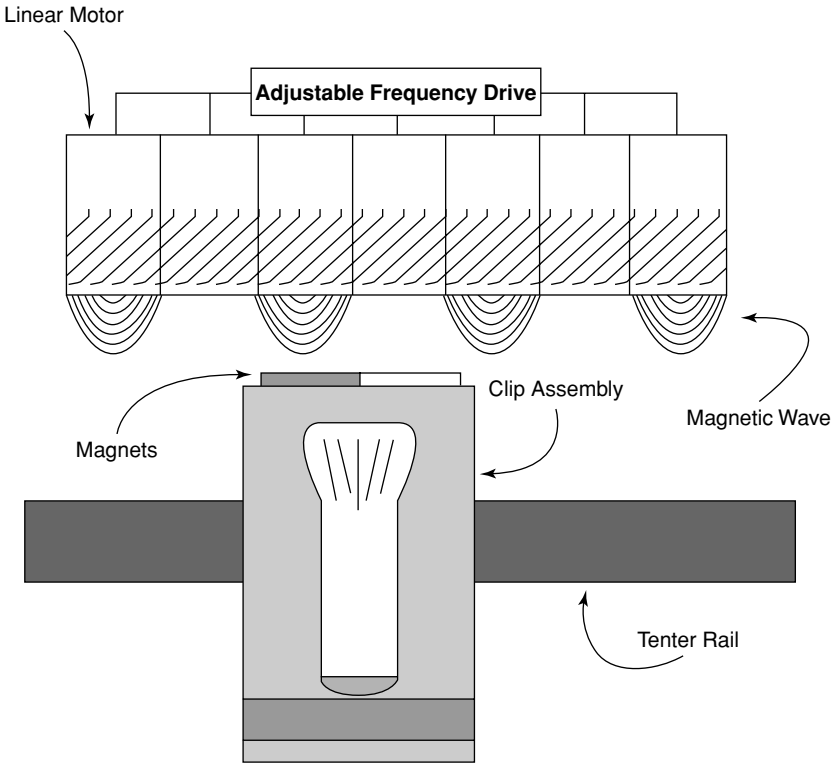

Fig. 14. Magnetic wave propulsion system.

minutes to make slight to moderate changes in the machine direction stretch profile.

A concern for these simultaneous biaxial orientation processes relates to the clips separating from each other. As the clips separate in the oven, the edge of the web between the clips tends to bow in. This can result in lower yields. At the very edge of the web, the film is oriented purely in the machine direction. The orientation in the film changes in going from the edge toward the centerline. The breadth of this transition region can be controlled with process parameters and material properties.

FLUOROCARBON ELASTOMERS

Introduction

Fluorocarbon elastomers are fluorine-containing, cross-linked amorphous polymers with a carbon–carbon backbone. They are designed for demanding service applications in hostile environments characterized by broad temperature ranges and contact with industrial chemicals, oils, or fuels.

Military interest in the development of fuel- and thermal-resistant elastomers for low temperature service created a need for fluorinated elastomers. In the early 1950s, the M.W. Kellogg Co., in a joint project with the U.S. Army Quartermaster Corps, and 3M Co., in a joint project with the U.S. Air Force, developed two commercial fluorocarbon elastomers. The copolymers of vinylidene fluoride (CF_2=CH_2) and chlorotrifluoroethylene (CF_2=CFCl) became available from Kellogg in 1955 under the trademark of Kel-F (1–3), and a polymer based on poly(1,1-dihydroperfluorobutyl acrylate) was marketed in 1956 as 3M brand fluororubber 1F4 (4). The poor acid-, steam-, and heat-resistance of the latter limited its commercial use (see also VINYLIDENE FLUORIDE POLYMERS).

In the late 1950s, the copolymers of vinylidene fluoride and hexafluoropropylene (CF_2=$CFCF_3$) were developed on a commercial scale by 3M (Fluorel) and by DuPont (Viton) (5–7). In the 1960s, terpolymers of vinylidene fluoride, hexafluoropropylene, and tetrafluoroethylene (CF_2=CF_2) were developed (8) and commercialized by DuPont as Viton B. At about the same time, Montedison developed copolymers of vinylidene fluoride and 1-hydropentafluoropropylene as well as terpolymers of these monomers with tetrafluoroethylene marketed as Tecnoflon polymers (9,10) (see also PERFLUORINATED POLYMERS).

Encyclopedia of Polymer Science and Technology. Copyright John Wiley & Sons, Inc. All rights reserved.

In the 1960s and 1970s, DuPont introduced polymers containing perfluoro (methyl vinyl ether), CF_2=$CFOCF_3$. With tetrafluoroethylene and a cure-site monomer, it gives a perfluoroelastomer, and when it is used as a comonomer with vinylidene fluoride and/or tetrafluoroethylene, improved low temperature properties are obtained (11,12).

Peroxide cure-site monomers, typically iodine- or bromine-containing fluorolefins, have also been polymerized with the above monomers for improved steam- and amine-resistance (13–20).

Copolymers of propylene and tetrafluoroethylene were introduced in the early 1980s by Asahi Glass Co., Japan (21–26). 3M introduced bisphenol/onium cured copolymers of vinylidene fluoride, tetrafluoroethylene, and propylene in the late 1980s (27–30).

The principal commercial fluorocarbon elastomers are given in Table 1.

Of the approximately 10,000 t consumed worldwide per year, ca 40% is used in the United States, 30% in Europe, and 20% in Japan, and 10% APAC (excl. Japan); 2000 prices were $44–$4000/kg.

Properties

The characteristics of vulcanizates prepared from commercially available fluorocarbon elastomer gumstocks are given in Table 2.

Thermal Stability. The retention of elongation after thermal aging is an indication of the thermal stability of fluorocarbon elastomers. As shown in Figure 1, fluorocarbon elastomers are far superior to hydrocarbon elastomers. A more severe test at 205°C shows that a typical molding compound retains 90% of initial elongation after 1 year. Retention of tensile strength is another important characteristic of fluorocarbon elastomers. Figure 2 demonstrates the effect of long-term heat aging on a typical O-ring compound made from vinylidene fluoride–hexafluoropropylene copolymer; 90% of the initial tensile strength is retained after

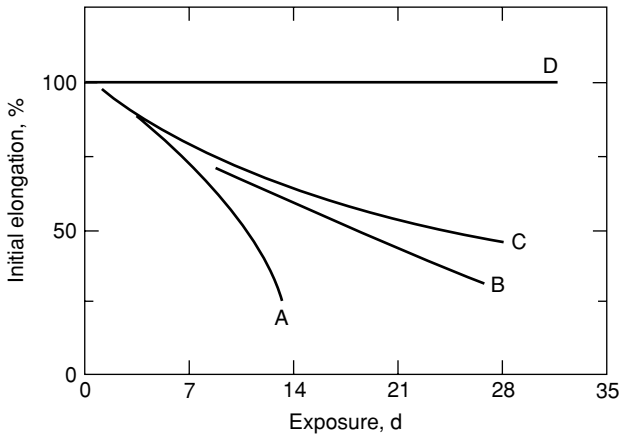

Fig. 1. Elongation retention of vulcanized elastomers at 150°C: A, nitrile; B, ethylene–propylene–diene monomer (EPDM); C, acrylate; D, fluorocarbon (31).

1 year at 205°C. Perfluoroelastomers [copolymers of tetrafluoroethylene and perfluoro (alkyl vinyl ethers)] are more thermally stable yet. Some of these polymers are stable up to 320°C.

Chemical Resistance. The resistance of fluorocarbon elastomer compounds to chemicals is given below:

(1) *Excellent resistance, may be used without reservation*, eg, automotive fuels and oils, hydrocarbon solvents, aircraft fuels and oils, hydraulic fluids, and certain chlorinated solvents.

Table 2. Properties of Fluoroelastomers

Property	ASTM test method	Value/description
Physical properties		
Tensile strength, MPa[a]	D412	9–20
100% modulus, MPa[a]		2–16
Elongation at break, %		100–500
Hardness, Shore A	D2240	45–95
Compression set, %	D395[b]	
70 h at 25°C		9–16
70 h at 200°C		10–30
1000 h at 200°C		50–70
Specific gravity of gumstock	D297	1.80–2.04
Low temperature flexibility,[c] °C		
T_g	E1356	0 to −30
TR10	D1329	0 to −30
Brittle point,[c] °C	D2137	−18 to −50
Thermal degradation temperature, °C	E1131	400–550
General characteristics		
Gas permeability		Very low
Flammability		Self-extinguishing or nonburning[d]
Radiation resistance		Good to fair
Abrasion resistance		Good and satisfactory for most uses
Weatherability and ozone resistance		Outstanding[e]

[a]To convert MPa to psi, multiply by 145.
[b]Method B for 5-mm O-ring.
[c]Highly dependent on material grade.
[d]When properly formulated.
[e]Unaffected after 200-h exposure to 150-ppm ozone.

(2) *Good to excellent resistance, gum and compound must be chosen with care*, eg, highly aromatic solvents, polar solvents, water and salt solutions, Aqueous acids, dilute alkaline solutions, oxidative environments, and amines.

(3) *Not recommended, to be used only with perfluoro and TFE/propylene elastomers*, eg, ammonia, strong caustic, 50% sodium hydroxide above 70°C, and, certain polar solvents, eg, low molecular weight ketones, esters, and ethers.

However, Viton Extreme (32) is resistant to ammonia, strong caustic, and certain polar solvents.

In the past 10 years fluoroelastomers containing 70–72% fluorine have been introduced. These highly fluorinated elastomers are resistant to the new oxygenated fuels now used in the automobile industry and meet the stringent permeation requirements (33–35) (see Fig. 3).

Compression-Set Resistance. Fluorocarbon elastomers are used in the sealing industry because of their resistance to compression set under extreme

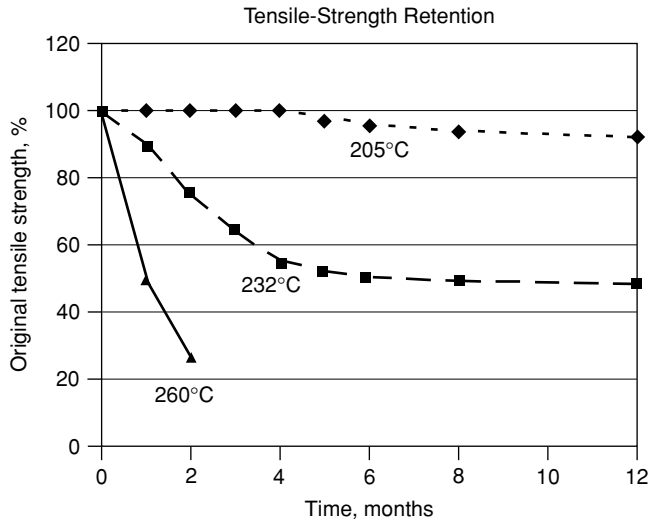

Fig. 2. Tensile-strength retention in continuous service for fluorocarbon elastomers, compound 1 (see Table 5).

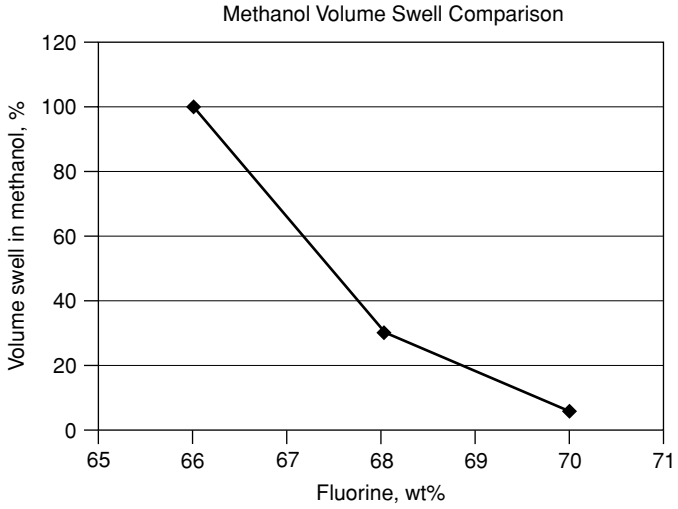

Fig. 3. The percent volume swell in methanol for 7 days at 21°C compared with the weight percent of fluorine in fluorocarbon elastomers: 66%, dipolymer of vinylidene fluoride–hexafluoropropylene; 68% and 70%, terpolymers of vinylidene fluoride–hexafluoropropylene–tetrafluoroethylene.

conditions. Plots of compression set vs time are shown in Figure 4 for compounds prepared especially for compression-set resistance (O-ring grades).

Manufacture

The elastomers listed in Table 1 are typically prepared by high pressure, free-radical, aqueous emulsion polymerization (5,8,36,37). The initiators are organic or

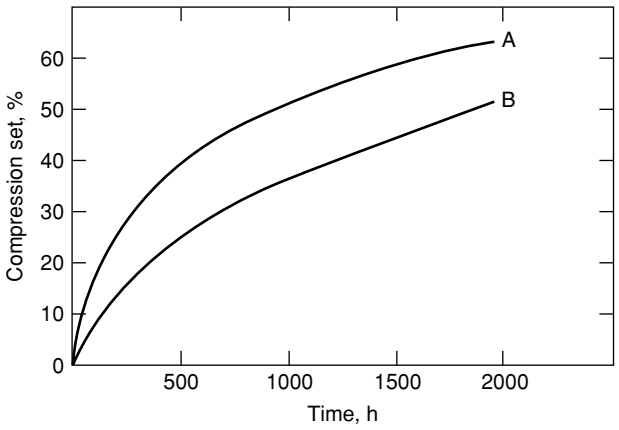

Fig. 4. Compression-set values of fluorocarbon elastomers at 200°C (ASTM D 395), 3.5-mm O-rings: A, compound 1 (see Table 5); B, compound 2 (see Table 5).

inorganic peroxy compounds, such as ammonium persulfate, and the emulsifying agent is usually a fluorinated acid soap. The temperature ranges from 30 to 125°C and the pressure from 0.35 to 10.4 MPa (50–1500 psi). The molecular weight of the polymer is controlled by the ratio of initiator to monomer or choice of chain-transfer agent, or both. Typical chain-transfer agents are ethyl acetate, methanol, acetone, diethyl malonate, and dodecylmercaptan (38–40). A typical polymerization recipe is given in Table 3.

The aqueous emulsion polymerization is conducted by batch, semicontinuous, or a continuous process (Fig. 5). In a simple batch process, all the ingredients are charged to the reactor, the temperature raised, and the polymerization run to completion.

In a semicontinuous process all the recipe ingredients are added to the reactor and the vessel is pressurized with the monomers. The reaction is started and the consumed monomers are continuously replenished in order to maintain constant reactor pressure.

In a continuous process (37), feeding of the ingredients and removal of the polymer latex are continuous. The discharge of latex from the reactor is controlled by a pressure-control or relief valve. The polymer latex is coagulated into a crumb

Table 3. Typical Fluorocarbon Elastomer Polymerization Recipe

Component	Grams
Vinylidene fluoride	61
Hexafluoropropylene	39
Diethyl malonate	0.13
Ammonium persulfate	0.35
Ammonium perfluorooctanoate	0.90
Potassium phosphate, dibasic	0.85
Water	225

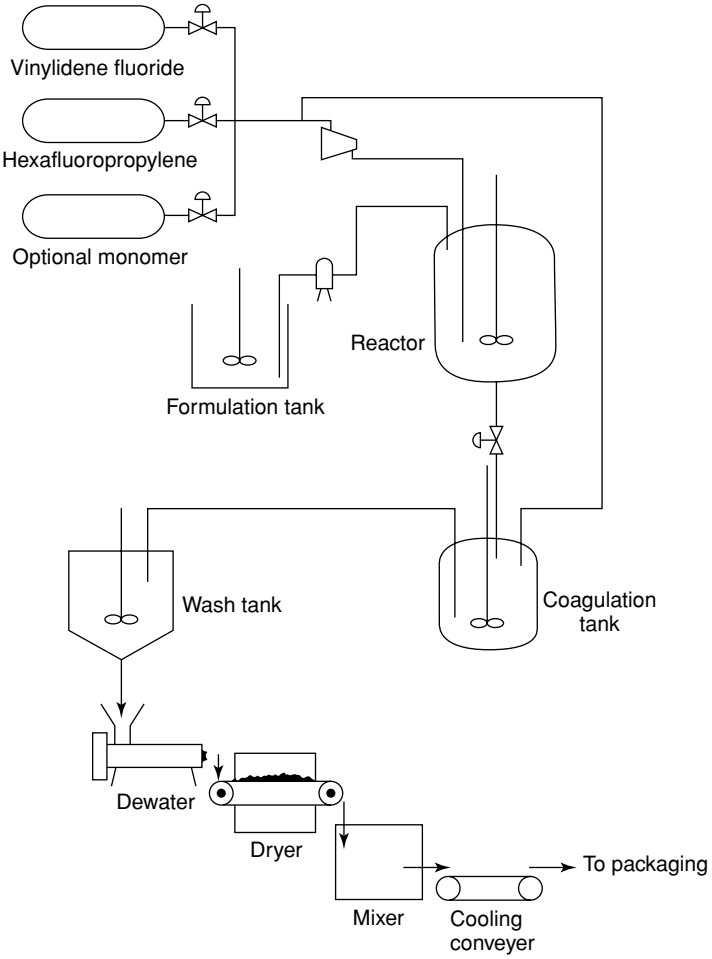

Fig. 5. Production of fluorocarbon elastomers.

by adding salt or acid, a combination of both, or by a freeze-thaw process. The crumb is washed, dewatered, and dried.

Most fluorocarbon elastomer gums contain a cure system, and, in the final step, the cure additives are incorporated in a two-roll mill, in an internal mixer, or in a mixing extruder. The cure system comprises an organic onium cure accelerator, such as triphenylbenzylphosphonium chloride, and a bisphenol cross-linking agent, such as hexafluoroisopropylidenediphenol. These cure systems improve compression-set performance and processing safety and accelerate cure cycles.

For complete formulation, reinforcing fillers and metallic oxides are added, the latter as acid acceptors (41–46). Raw gums contain no curative, and cure ingredients such as diamines, bisphenols, or peroxides (47) must be added in addition to formulation (compound) ingredients. Diamines were the first commercially important curing agents; they give good thermal resistance but poor scorch resistance. Bisphenol/onium cure systems yield very low compression set and good processing

safety. Peroxide cure systems improve steam and water resistance and give fair compression-set resistance; no water is produced during cure.

Processing

Compounding. Compared with the large number of ingredients required in a conventional rubber recipe, fluorocarbon elastomer compounding seems simple (Table 4) (see RUBBER COMPOUNDING).

O-Rings. In O-ring applications, the primary consideration is resistance to compression set. The choice of a fluorocarbon elastomer gum is based on gum viscosity, cross-link density, and cure system. Formulations are given in Table 5 (compounds 1 and 2).

Long-term compression-set resistance is described in Figure 4. Values are reduced by using gumstock of higher viscosity at comparable cross-link densities. Compression-set resistance also depends on the cure system. The bisphenol/onium cure system offers the lowest compression-set resistance, as shown in Table 6.

Table 4. Typical Fluorocarbon Elastomer Compound

Molded Articles. In the compounding of molded articles, the most important physical property of the vulcanizate is elongation to break. Compression set is a secondary consideration. Since complex shapes are often required, compound flow is also important. These objectives are best met by using a gum with the lowest initial viscosity and a low cross-link density to permit high elongation compared with O-ring formulations.

Comparison of viscosities and properties of a molding compound (see Table 7) with an O-ring compound (see Table 5) shows differences in elongation due to lower cross-link density. Special formulations give even higher elongations and exceptionally high tear strengths in the press-cure state. Fillers (48) are of special importance for water- and acid-resistant compounds. The supplier may make specific recommendations to meet the properties required.

Extruded Articles. In an extruded article, the most important parameters are scorch safety and flow characteristics (49). The bisphenol/onium cure system provides the best scorch resistance. Gum viscosities and process aids affect flow characteristics. Typical formulations for extrusion-grade fluorocarbon elastomers are given in Table 8.

Formulation. Gum viscosity affects vulcanizate properties, especially compression set. Gums are available with Mooney viscosity (ML 1 + 10, large rotor, at 121°C) values of 0–160. A range of 20–60 gives the optimum combination of flow and physical properties. Mooney viscosity is commonly measured in a Mooney viscometer apparatus (ML = large rotor, MS = small rotor) after preheating the sample for 1 min, followed by heating at 121°C for 10 min, and then taking a reading (these values may vary). Mooney scorch (MS) is determined with a small rotor. Higher viscosities can cause excessive heat buildup during mixing,

without improvement in physical strength. Compound viscosity depends on gum viscosity and filler type and loading. A range of 25–60, as measured by MS (121°C), is preferred.

Compound stability and safety are strongly affected by ingredients and cure systems.

The data in Table 6 clearly show the effect of cure system on scorch stability and processing, as determined by standard testing techniques (MS at 121°C). The most workable formulations are compounded with raw gums containing the bisphenol/onium cure systems. These cure systems offer maximum processibility safety.

Mixing. Fluorocarbon elastomers may be compounded by any standard rubber technique. Open mills may be used, since most commercial gums mix well, except very low viscosity gums, which stick to the rolls, and high viscosity gums, which are very tough.

Internal mixing, commonly referred to as Banbury mixing, is widely used with fluorocarbon elastomers. Gumstocks and compounds that are particularly successful fall in the viscosity ranges discussed earlier. A typical internal mix cycle takes 6–8 min with a drop temperature of 100–125°C. The formulations given in Tables 5 and 8 are both well suited to internal mixing.

Preforming. Formulations are easily preformed at cool barrel temperatures with a screw- or piston-type extruder (Barwell). Gums must be in the proper viscosity range and scorching must be avoided.

For routine calendaring operations, warm rolls (40–90°C) are recommended for optimum sheet smoothness. Process aids, such as low molecular weight polyethylene wax, are often used and sheets of 0.5- to 1.3-mm thickness are normally produced.

Molding. Compression molding is generally used to economize on material. Flow requirements are minimal and high viscosity resins may be used.

Little preforming is required for transfer molding, which is used for the production of very small parts. However, this technique often requires excessive amounts of material. Flow requirements are high, but fluorocarbon elastomers are available that can be used with this technique.

Injection molding is increasingly used in the rubber industry and fluorocarbon elastomers are well suited for this technique. Viscosity and cure rheology are very important because of high shear and fast cures (50–54). Molding at 180–200°C allows operations of 5 min or less, depending on part size.

Extrusion. Extrusion techniques are used for tubing, hose, O-ring cord, preforms, and shaped gaskets; typical extrusion conditions are 70–85°C for barrel temperature and 95–110°C for head temperature. The extruded forms are cured in a steam autoclave at 150–165°C. Special grades of peroxide–curable fluorocarbon elastomers may be vulcanized by hot air.

Postcuring. Postcuring for a period of 16–24 h at 200–260°C develops maximum physical properties, eg, tensile strength and compression-set resistance.

Specifications

Commercially available fluorocarbon elastomers meet automotive specifications in the HK section of ASTM D2000 and SAE J200. ASTM D1418 specifies designations of composition; fluorocarbon elastomers are designated FKM, FEPM, or FFKM in the case of perfluoroelastomers.

Some fluorocarbon elastomers meet the O-ring specifications, such as AMS 7276, AMS 7280A, AMS 7259, and MIL-83248 Amendment 1 Type II, Class I and II.

Certain grades and formulations are approved under the Code of Federal Regulations, 21, Food and Drugs, Part 177.2600, for articles intended for contact with food. Elastomer suppliers provide assistance in formulating for specified uses.

Test Methods; Health and Safety

The fluorocarbon elastomer raw gums are tested for Mooney viscosity (ASTM D1646) and specific gravity (ASTM D297). When compounded as described above, the stocks are tested for Mooney cure (ASTM D1646), Mooney scorch (ASTM D1646), and vulcanization characteristics (ASTM D2084 and D5289). The vulcanizates are evaluated with respect to original physical properties (ASTM D412, D2240, D1414), aged physical properties (ASTM D573), compression set (ASTM D395), and fluid aging (ASTM D471). Low temperature properties include low temperature retraction TR10 (ASTM D1329), torsional modulus (ASTM D1053), and brittle point (ASTM D2137).

Under normal handling conditions, fluorocarbon elastomers are nontoxic and nonirritating. Safe handling procedures are provided by manufacturers upon request.

Uses

About 45% of U.S. fluorocarbon elastomer consumption is in ground transportation. Typical components include engine oil seals, fuel system components such as hoses and O-rings, and drive-train seals. Growth in this area is expected to continue, considering the increased demands from higher engine temperatures, alcohol-containing fuels, and improved lubricants. Other industries include petroleum and petrochemicals, pollution control, and industrial hydraulic and pneumatic applications. These areas are more dependent upon general industrial production and overall energy demands, and will show slower growth than the automotive segment.

Consumption in Europe and Japan depends more upon the automotive industry. However, with the recent concern about acid rain, the European market is expected to show increased interest in fluorocarbon elastomers for pollution-control applications. In Japan, fluorocarbon elastomers are used for general manufacturing, eg, copiers. Petroleum applications are of little interest outside the United States. The aircraft industry uses less than 10% of the total fluorocarbon elastomer consumed.

Perfluoroelastomer parts are primarily used in the chemical processing industry and are finding increased applications in semiconductor manufacturing equipment, because of their high purity, extreme chemical inertness, and unrivaled thermal stability.

FRACTOGRAPHY

Introduction

Fractography is the visualization, description, and interpretation of a fracture or a fracture surface, often in order to establish structure–property relationships. Artifact-free visualization and as accurate a description as possible are a prerequisite for interpreting a fracture surface and using it to reveal information about material properties, such as composition, deformation under load, and the failure mechanism.

The failure of a plastic part is governed by the interaction of its physicochemical structures, by the processing parameters, by the environmental conditions, such as moisture, temperature, chemical influences, and high-energy radiation, as well as by the mechanical stresses, which themselves are determined by their nature (tensile, compressive, shear, flexure), their combination and magnitude, and their rate and duration. While environmental factors may be viewed as relatively constant during the failure process, local mechanical stress changes. A description of the state of the material and the environment is offset by a visible change in the failure process over the course of time.

Any assessment of this kind of damaging process must pay special attention to these changes. It is therefore vital to find characteristics that help to interpret this process. This is the primary objective of fracture surface analysis, or fractography.

A number of standardized test methods are available for assessing the material structure and the mechanical properties of a plastic. Similarly, chemical and thermal damage, and the state of processing may be determined, eg, from an examination of the crystalline structure, of orientations, and of internal stresses. However, in contrast to fractography, these methods yield very little information about the failure process itself.

Encyclopedia of Polymer Science and Technology. Copyright John Wiley & Sons, Inc. All rights reserved.

The fractography of polymers has been based on metallurgical experiences. (References 1 and 2 and the reported review therein are documents for these roots.) Especially the analytical way of how to observe, describe, measure, and interpret a fracture surface could be adapted for and applied to polymers (3–13). However, it is necessary to take into account the more complex deformation behavior of polymers.

A fracture is an undesirable separation of a formerly whole functional element into two or more parts. The cause of the fracture may lie in wrong material selection, material defects, or the operating conditions. However, the nucleation of the fracture will begin at a minute inhomogeneity in the material. This defect can be on the surface or inside the observed part, depending on the local internal and external stress conditions leading to the failure, and may not always be in evidence.

The fracture surfaces of polymers offer many features, from which the causes may be discerned. The fracture surface often (especially with brittle materials) shows certain characteristic regions. A relatively smooth area—the so-called mirror—with the nucleating inhomogeneity in its center is due to slow-crack growth. The mirror is surrounded by a boundary called the mist, which is slightly rougher. Beyond the mist a relatively rough region of hackles is observed, finally followed by bifurcation or branching of the crack (6). The roughness increases from the center to the periphery. The smaller the stress [also the longer the time and the higher the temperature (7)], which initiated the crack, the larger is the radius of the mirror. Distinguishing the different regions can become difficult, as their geometrical extensions depend on the fracture conditions and the extent of brittle deformation behavior of the material. Therefore, depending on the micromechanical deformation mechanisms of the specific polymer under the specific loading conditions, shear bands or crazes may be observed (see also MICROMECHANICAL PROPERTIES).

Fractures propagate in different directions, either simultaneously or with a time lag. The above-mentioned boundaries deviate from circular shapes, if the propagation rate of the crack is dependent on the direction in the plane of the crack.

Optical Microscopy

A first impression of the fracture surface is obtained by conducting a macroscopic analysis with the unaided eye or a stereomicroscope. It has been suggested that the fracture diagram be annotated with arrows showing the direction of the fracture travel when fractures are being analyzed. This will yield an overall picture of complex fracture propagation (Fig. 1). In order that the object being assessed may be described objectively, no preliminary information should be available. Aspects that should be taken into account during the macroscopic analysis are summarized in Table 1.

Optical microscopy is a simple and inexpensive method to obtain the overall view of the fracture surface. By applying the reflected light mode information on the origin of the fracture, the crack propagation direction, location of arrest lines can be gained. Also, in the transmission mode, it is

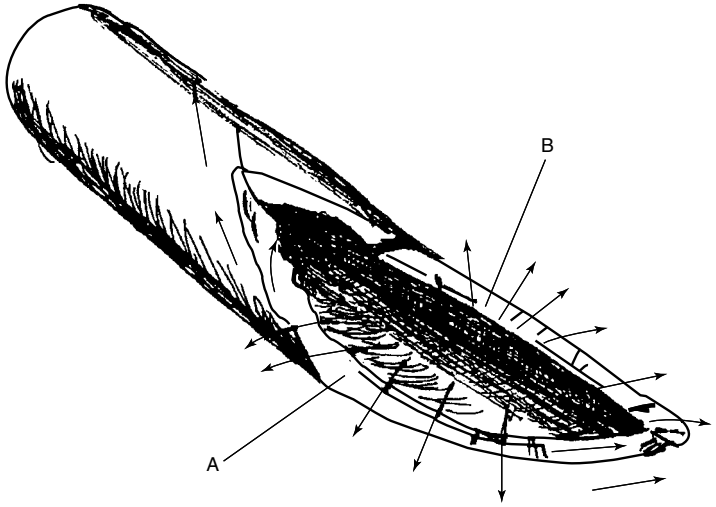

Fig. 1. Determination of fracture propagation in a pipe (original drawing by H. Klingele).

possible to reveal events and processes occurring beneath the surface, such as yield zones and damage zones at the crack tip. For further details see MICROSCOPY.

An optical microscope often has an insufficient depth of field for conducting a microscopic examination of surfaces, especially fracture surfaces. The depth of field of the optical microscope is approximately 100 times smaller than the depth of field of the scanning electron microscope (SEM) at the same magnification (14). At a magnification of 1000 the depth of field amounts to 0.5 μm for the optical microscope (15) and 50 μm for the SEM. It is for this reason, and the greater possible magnification, that the SEM is used.

A new method to overcome the disadvantage of an insufficient depth of field in conventional light microscopy is confocal scanning light microscopy (16). The different scanning techniques and light sources of this method basically have the aim to obtain several images at different heights, with only a narrow band of the surface in sharp focus, and then to combine the in-focus details of the images at different heights in one image. This partial combination of images is realized by means of computer image processing techniques.

Scanning Electron Microscopy

Polymers consist of macromolecular, chain-like base elements that are composed primarily of carbon and hydrogen. The diameter (physical sphere of influence) of a hydrogen atom is 0.24 nm and that of a carbon atom is approximately 0.38 nm. The resolution of an SEM is roughly 10 nm and that of an optical microscope is 1000 nm. Concrete visualization of atoms is therefore impossible in both cases. Not even a 0.4 nm thick and 6 μm long polyethylene chain can be visualized by

Table 1. Macroscopic Analysis (Selection)

Area	Aspects
Details of damaged part	Dimensions (eg, including section thickness)
	Design details (eg, melt accumulation, sharp edges)
	Production detail (eg, gating point)
	Coloring
	Coatings
Type of damage	Fracture, crack, deformation, corrosion, wear, discoloration... (or signs of fatigue, aging, shrinkage, distortion, creep, impact)
Extent of damage	Brittle or ductile fracture
	Length and number of cracks
	Degree of deformation
	Depth of corrosive attack or wear
Position, origin of damage	Damage at corners, edges, apertures, domes, abrupt changes in section thickness, ribs, radii, or in the gate area
	Position relative to gating point
Surface features	Mold grooves
	Grooves from machining
	Flow lines
	Crack-initiating notches, eg, through weld lines
	Surface treatment
	Thermal exposure, melt structures (partial)
	Coatings, liquid or paste-like media
	Discolorations
	Inhomogeneities
	Sink marks
	Processing traces (streaks, burner)

SEM. Individual atoms and molecules cannot be used to provide satisfactory explanations of structural and especially fracture phenomena as they are neither deformed individually nor destroyed. Failure processes therefore need to be explained in terms of the behavior of the superstructures.

In scanning electron microscopy, electrons emitted by an electron gun (primary electrons) are focused by means of Wehnelt cylinders and electromagnetic lenses onto the sample surface, which they scan line by line (Fig. 2). The secondary and back-scattered electrons emitted by the sample are captured by detectors and presented in the form of brightness modulation on, eg, a monitor. The secondary electrons come from a surface layer up to 10 nm thick, while the back-scattered electrons usually originate from deeper layers.

The imaging contrast comprises the material contrast, which varies with the atomic number of the elements in the sample; the topographical contrast, which varies with the orientation of the sample surface toward the direction of the incident primary electrons; and the orientation contrast, which varies with the relative position of the sample surface to the electron detector. While the material contrast obtained via the back-scattered electrons is of subordinate

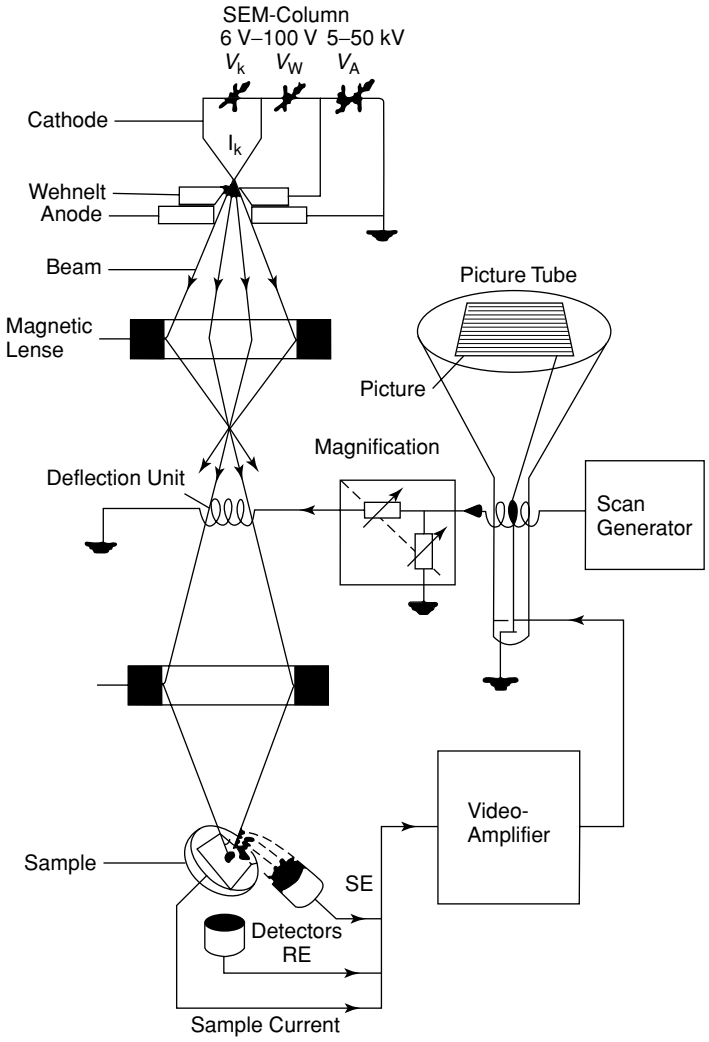

Fig. 2. Basic structure and mode of action of the scanning electron microscope.

importance in the case of pure polymers, the topographical contrast generated by the secondary electrons contributes to a brighter visualization of edges and tips, and the orientation contrast contributes to the plastic character of the SEM micrographs.

The sample surfaces, eg, fracture surfaces measuring several square millimeters, of plastics are viewed under a magnification of 20–20,000 in SEM under a vacuum. These surfaces can be recorded digitally or as a monochrome photograph.

The great depth of field evident in SEM micrographs stems primarily from the fact that an optical lens system is not necessary for building up the image. Consequently, electrons from various depths are able to reach the detector.

The detectors used for identifying materials in SEM are of the energy-dispersive and wavelength-dispersive types. However, in most cases failure analysis does not rely predominantly on the detailed knowledge of the materials contents. Similarly, for failure analysis the topographical details of the fracture surface usually do not have to be cleared up to the scale available via the atomic force microscope (see also SURFACE ANALYSIS and ATOMIC FORCE MICROSCOPY).

Sample Preparation

For optical microscopy of fracture surfaces usually little or no surface preparation is necessary. However, because plastics have poor electrical conductivity, for SEM examinations the sample surface generally needs to be coated with a conductive layer that prevents charging and heating. The energy carried into the sample can melt the polymer or vaporize low molecular contents locally and change the fracture surface irreversibly, making its interpretation impossible. On the other hand, to ensure artifact-free imaging, the applied layer itself must not have any visible structure and must be so thin that the structures on the surface are not hidden.

The surfaces under test are vacuum coated with carbon or metals. The standard equipment for this is a sputter device that ignites a glow discharge in an air or argon atmosphere at 5–20 Pa (0.05–0.2 mbar). The gas ions dislodge cathode material, which then condenses on the sample surface. The cathode is mostly made of gold, but also possible are chromium, carbon, and, because it yields a superior coating, gold–palladium. The sample itself is bonded firmly to the holder with a conductive adhesive.

Very bulky samples may be dipped in or sprayed with a metal coating. Another preparative method is to mold the sample surface, eg, in silicone rubber, and to make a replica. However, there is a possibility of artifact formation here.

Nowadays, there are so-called low-voltage scanning electron microscopes available that frequently eliminate the need to apply a conductive coating to the polymer and can permit fracture surface analyses to be performed.

While on the topic of sample preparation, it should also be mentioned that the imaging contrast of phase morphologies can be enhanced by staining the surface by means of contrasting agents, such as OsO_4 for ABS and RuO_4 for PE/PP blends, as well as by etching. Further information on these pretreatments may be found in References 17–20–21.

Classification of Fracture Modes and Examples

Load Fracture. Thermoplastics, thermosets, and elastomers deform in different ways. In the case of ductile thermoplastics, as the load increases, the tangled, thread-like macromolecules become stretched, aligned, and in some cases will glide apart. The stretched areas will recoil like a spring, and this will be most pronounced at the highly stressed fracture site, which additionally warms up on

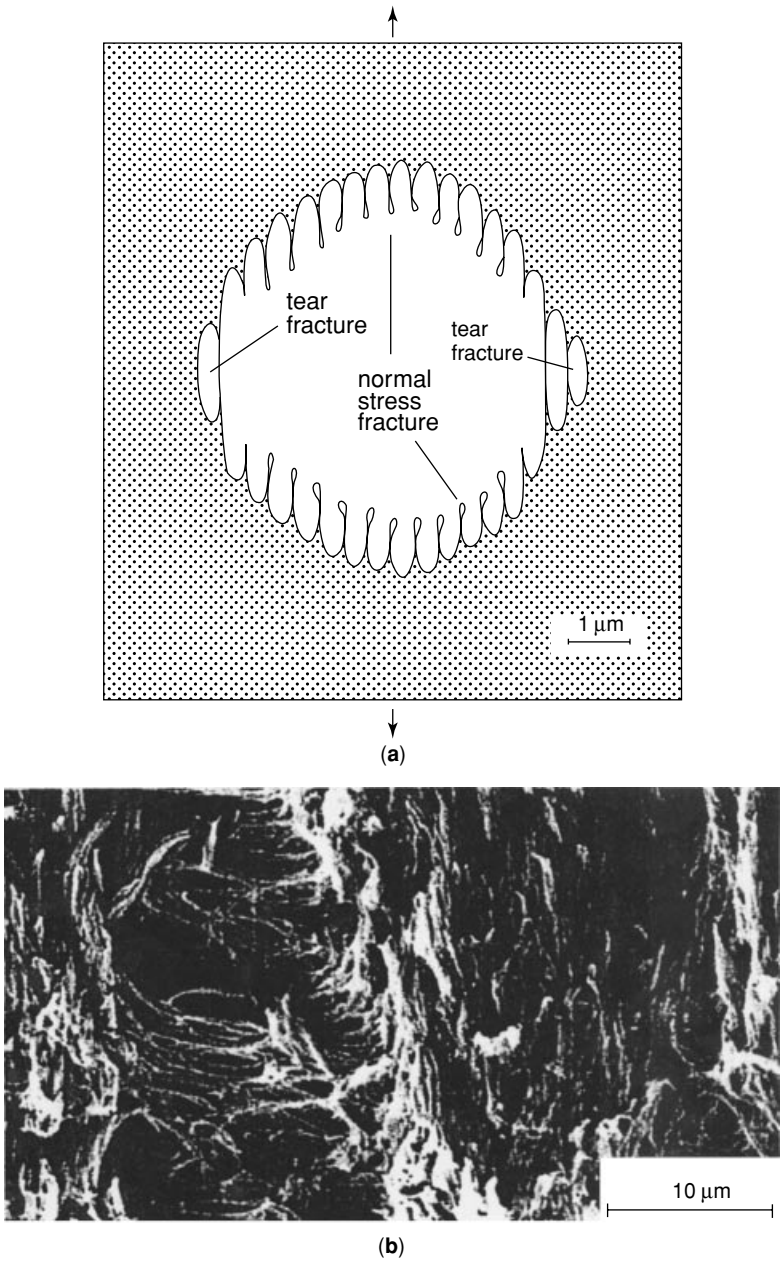

Fig. 3. Load fracture in different types of plastic. (**a**) Schematic (ductile thermoplastic); (**b**) normal stress fracture with peak formation, PA 66; (**c**) load fracture of UP with minor plastic deformation; and (**d**) load fracture of a cross-linked elastomer (rubber).

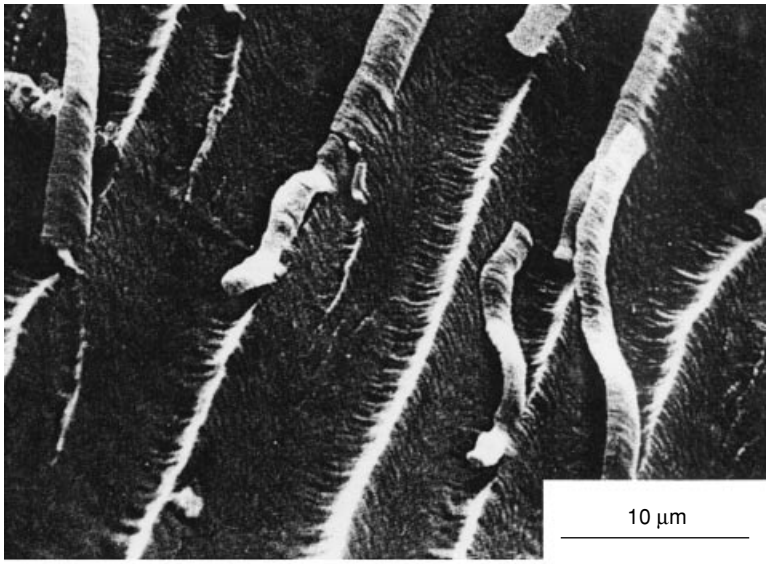
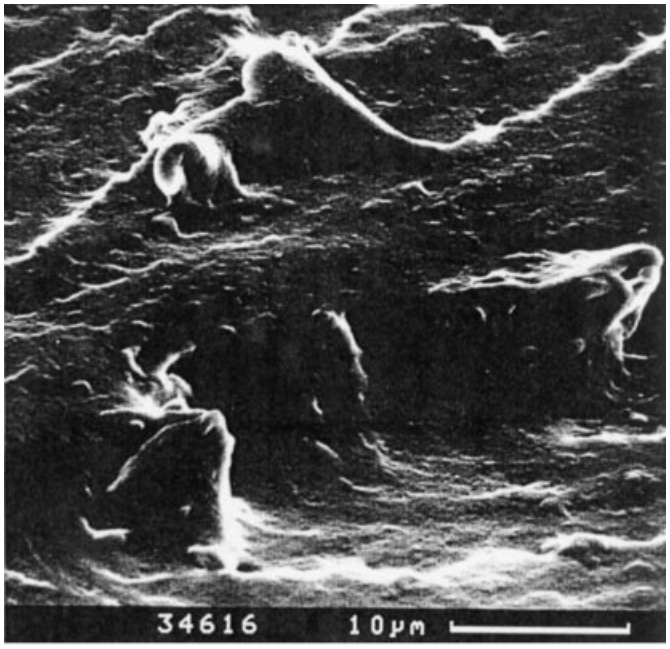
tearing. As a result, during peak-like stretching, nodular thickenings often occur at the end (Figs. 3a and 3b).

As this stretching process requires time, the deformation is dependent on the rate of loading up to fracture. Additionally, elevated temperatures facilitate



(**c**)



(**d**)

Fig. 3. (*Continued*)

rearrangements. When the acting stress is applied at low deformation rates and elevated temperatures, the molecules are more able to comply with it than if it occurs suddenly and at low temperatures.

With thermosets, the high degree of cross-linking of the molecules constitutes a fundamental barrier to deformation. Therefore, the elastic, completely reversible

deformation components are more predominant and the relaxing and viscous ones are less predominant than in thermoplastics. This is the reason why thermosets tend to undergo brittle fracture (Fig. 3c).

In the case of elastomers, the partially entangled macromolecules primarily undergo elastic deformation because of the low crosslinking density and the weakness of the secondary valence forces. Fracture takes the form of molecule chain fracture caused by high elongation. The permanent deformation is relatively minor, and is recognizable from the short peaks and threads. At temperatures below the glass-transition temperature of the elastomer, the secondary valence forces become stronger and the fracture comes more and more to resemble that undergone by thermosets (Fig. 3d).

Normal Stress Fracture. Stretching under external stress causes the material domains to be extended as peaks. After separation, the ends recoil quickly and form thickenings. Separation occurs perpendicularly to the tensile axis (Figs. 3a and 3b).

Tear Fracture. Normal stresses, such as flexure, that are distributed unevenly across the cross section may cause the material to tear from an external or an internal surface, eg, from a material defect. In such cases, the peaks stand at an angle in the fracture surfaces. If elongation is uniform, rims form at the crack front that remain visible in both fracture surfaces as beads with undulating crests after separation (Fig. 4). Further characteristics of tear fracture are V- and U-shaped ramps, whose tips point against the direction of fracture propagation.

Shear Fracture. Polymer failure is initiated when critical shear stresses are exceeded. Stretching at the separation faces ultimately leads to lips and peaks that on two mating fracture surfaces point toward each other. Fracture due to shear failure can only be distinguished from that due to tear fracture on two mating fracture surfaces. The separating mechanism involved is that of normal stress fracture and tear fracture, since gliding along defined crystal planes as in metals cannot occur (Fig. 5).

Crazing. *Crazing*, also called *stress cracking*, is the formation of roughly panel-like material areas that open frequently under the influence of wetting agents after an induction time has elapsed; opening is spontaneous and perpendicular to the maximum tensile stress. Unlike empty cracks, crazing involves bridging by 10- 50-nm-thick fibrils between the separation surfaces (Fig. 6). The formation of crazes is accompanied by an increase in volume (reduction in density) in contrast to the constant volume if shear yielding takes place. Crazing is not synonymous with complete failure of the molded part and may even relieve locally stressed material areas. Only as the crazing grows and then ruptures, particularly on impact stress, do cracks form.

Crazing can occur both on free surfaces and inside the work piece, and therefore is either semicircular or circular. In the case of transparent plastics, the expansion of the circle is visible to the unaided eye (stress whitening). In SEM, ruptured crazing is characterized as follows:

(1) Arc-like borders that are clearly different from residual force fracture
(2) Features of ductile fracture, ie peaks and threads

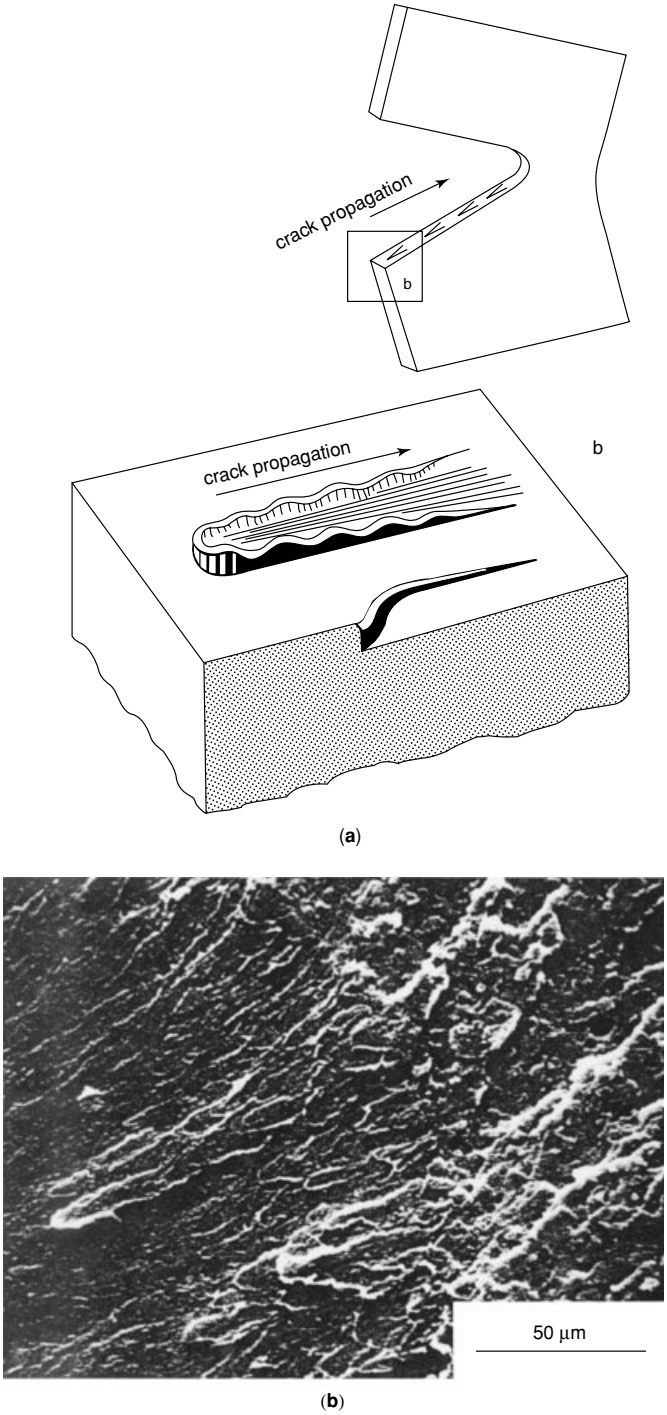


Fig. 4. Tear fractures. (**a**) U- and V-shaped ramps with rims; (**b**) V-shaped radial crack propagation in PS crazing; (**c**) tear fracture at a free film surface; and (**d**) ruptured crazing in PS with films exhibiting deformation in an otherwise low deformation fraction.

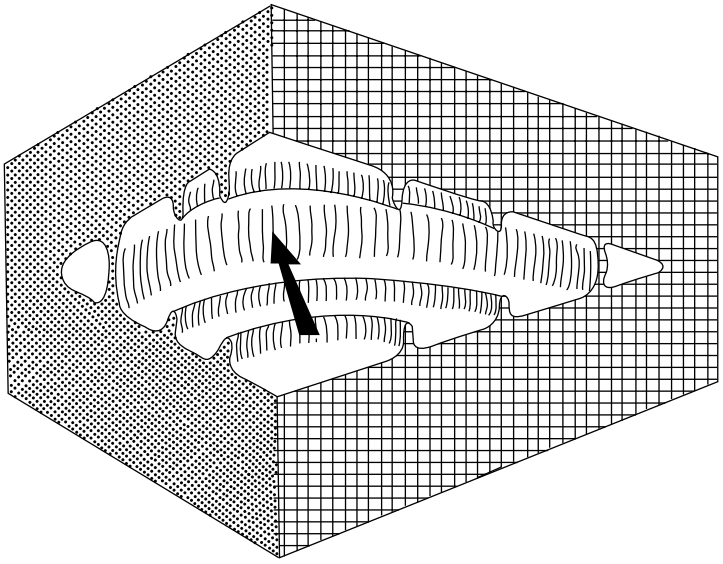
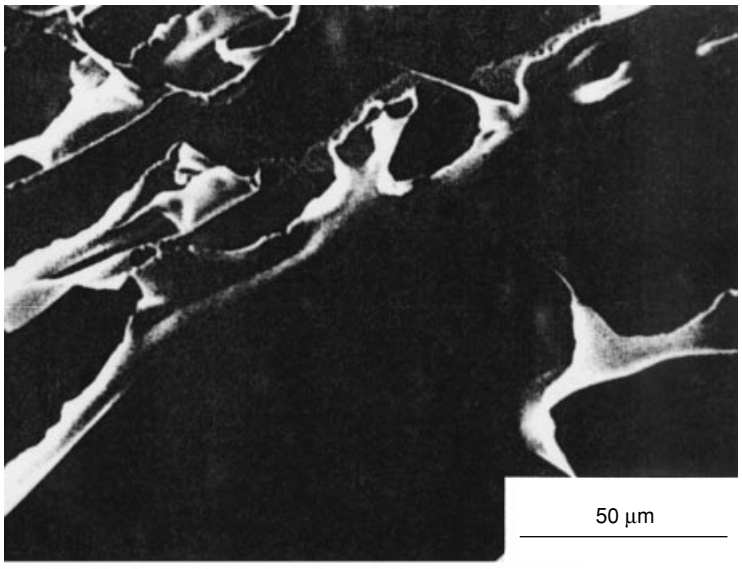


(**c**)

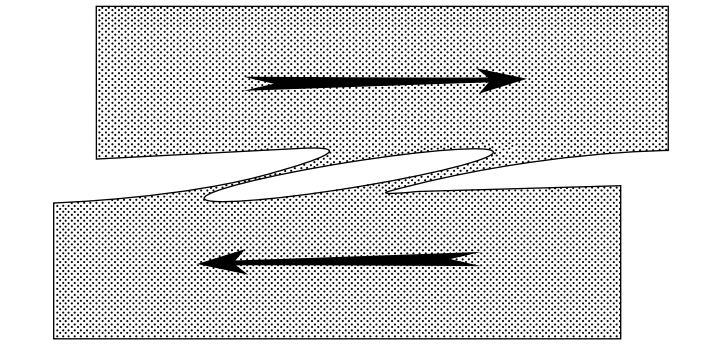


(**d**)

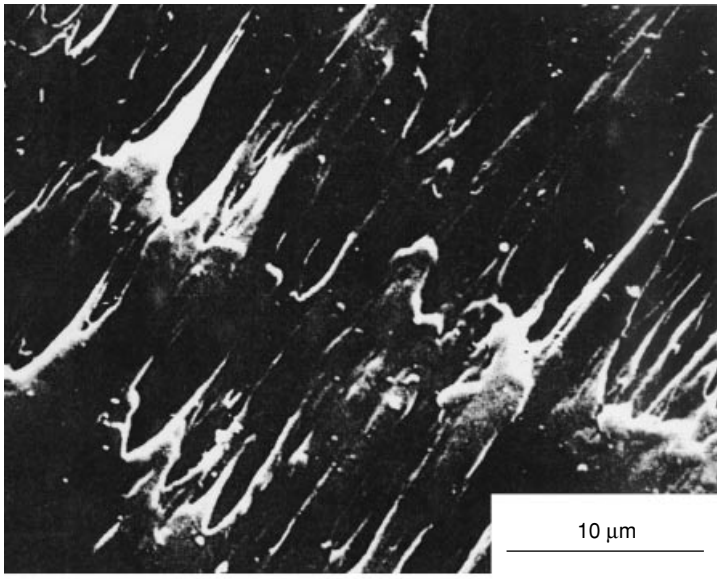
Fig. 4. (*Continued*)

Accordingly, crazing is the initial stage of ductile fracture. Crazing on surfaces occurs in homogeneous materials, generally as a result of continuous slow tensile stress, but not of impact stress. Consequently, it is comparable to creep failure in metals. Rubber-modified polymers also exhibit crazing following impact stress.

Ruptured crazing generally contains a central normal stress zone and a contiguous tear zone. The concentric propagation of crazing can be recognized from



(**a**)



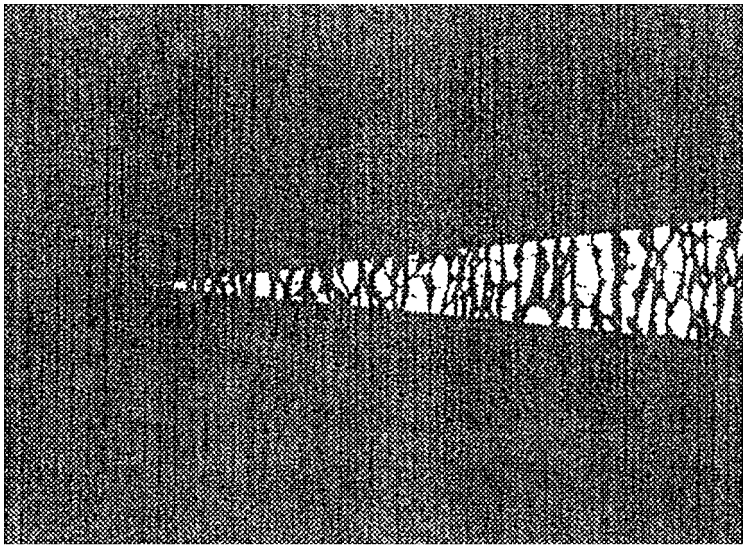
(**b**)

Fig. 5. Shear failure. (**a**) Shear failure in polymers and (**b**) shear-stretched peaks on PBT tooth flank after dry running.

V shaped markings. The chemicals which loosen secondary valence bonds, particularly solvents, reduce the tensile stress required for crazing. Crazing and environmental stress cracking are therefore frequently initiated on surfaces accessible to chemicals.

Ductile Fracture. There are two types of ductile fracture, and the deciding criterion is the length of the peak remaining in the fracture:

(1) Polymers that undergo high plastic deformation to fracture—permanent peak length $> 10\ \mu$m
(2) Polymers that undergo minor plastic deformation to fracture—permanent peak length $= 1$–$10\ \mu$m



(**a**)

(**b**)

Fig. 6. Crazing. (**a**) Schematic and (**b**) normal stress peaks in fracture surface of a PP part.

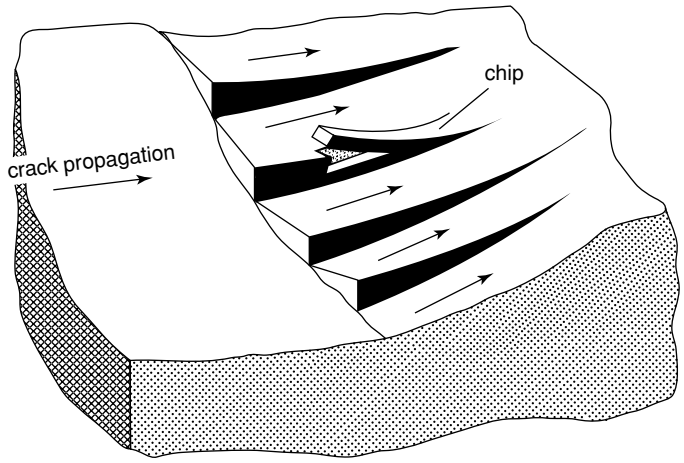
According to this classification, fractures with permanent peak lengths <1 μm are brittle. Materials generally considered to be prone to high plastic deformation are: PE, PP, PA, POM, PBTP, PETP, PTFE, PC, PVC, and ABS. Polymers categorized as having poor deformation (peak length after fracture 1–10 μm) are PS, SAN, EP, and UP. In conditions that hinder deformation (high stress rate, low temperature, multiaxial stress state and foreign additives), otherwise-ductile materials may fall into this category, such as PE, PA, POM, PBTP, PTFE, PC, PVC, and ABS.

Brittle Fracture. Polymers do not exhibit brittle fracture comparable to the cleavage fracture occurring in metals with a body-centered cubic lattice structure. Even in the case of low temperature fractures, high magnification reveals films and peaks resulting from ductile deformation. To be sure, the deformations are restricted to a planar layer less than 1 μm thick. As the deformed volume is very small, this is brittle fracture in macroscopic terms. Microscopic examination reveals that the stressed 1-μm layer is distributed on both fracture faces after separation. This gives rise to oval lids or torn-open blisters, steps, and striped patterns. The edges of the microstructures are lined with fine beads and sometimes with short threads. Since the brittle fracture spreads out across the material, it leaves behind structures that permit conclusions to be made about the direction of fracture propagation. These are called *cleavage stops* and they are formed wherever the material is inhomogeneous. They cause the fracture front to divide into several fracture paths that recombine again during the course of further propagation. This explains the occurrence of step-like patterns and chips which splinter off (Fig. 7).

Fatigue Fracture. Like other materials, polymers withstand static stress more than they can withstand dynamic stress, especially the tensile stress situations. As alternating stress decreases, the number of stress cycles that can be endured increases. This results in a flattening of the fatigue endurance curve.

Vibration-Induced Creep Fracture. Genuine fatigue strength would only be feasible if the alternating load were to be absorbed purely elastically in the long term. However, this would presuppose extensive elastic behavior at the microlevel as well. At the same time, irreversible stretching processes must be expected at inhomogeneities on the surface or inside the material. These give rise to heat simultaneously, which in turn promotes the mobility of the molecule chains. This explains why a type of dynamic fatigue fracture exists in polymers which is on a par with continuous creep failure and is known as *vibration-induced creep fracture*. Owing to poor thermal conductivity, vibration-induced creep fracture also varies with frequency. High frequencies and high loads harbor the risk of local softening and even melting in the middle of the cross section. In this case, characteristics of periodic crack propagation must not be expected in the fracture surface, i.e., there are no fatigue striations (Fig. 8).

When dependable fatigue fracture characteristics such as fracture paths, fatigue striations, secondary cracks, or spherical melt voids occur, fatigue fracture may be identified. However, it is also possible that vibrational load will only leave behind load fracture features. Fatigue fracture without fatigue striations may be expected particularly in very ductile polymers, at high operating temperatures and at high alternating load frequencies. Theoretically possible is a dynamic fatigue fracture with extreme fracture constriction with point or edge-like separation.



(**a**)

(**b**)

Fig. 7. Brittle fracture. (**a**) Cleavage stops, recombining fracture planes, and splintering chips and (**b**) cleavage stops in brittle fracture.

Normally, an extensively rounded crack emanating from the surface or from an internal defect will migrate through the material.

On the other hand, it is important to note that discontinuous crack growth under a static load may yield fracture surfaces, which may look quite similar to fatigue striations. To observe this phenomenon, the material has to be able to slowdown or even stop the crack propagation after the static load initiated the

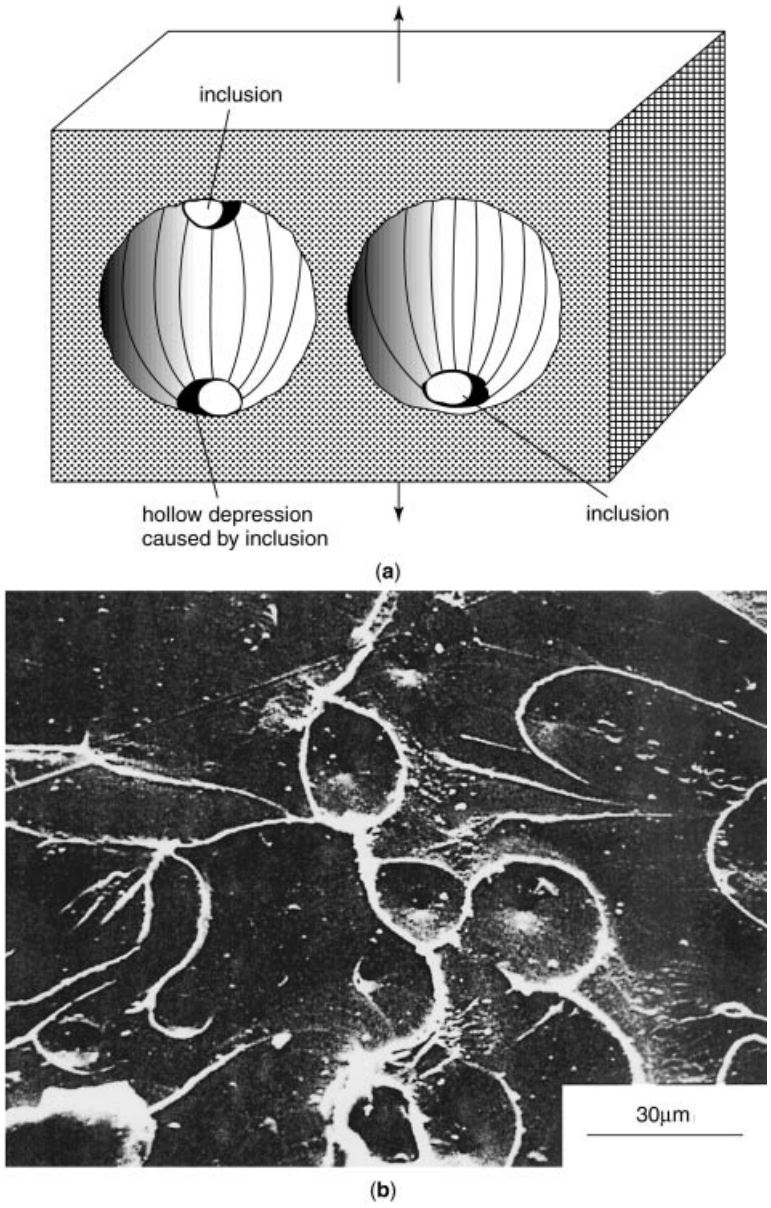


Fig. 8. Vibration-induced creep fracture. (**a**) Radially propagating dynamic fatigue fracture inside the material and (**b**) dynamic creep fracture in PS samples.

crack. Then the next tension build-up takes place until it is released in further crack growth. The varying growth rates result in varying surface roughness, which may eventually be confounded with fatigue striations.

Genuine Vibration Fracture. A genuine crack tip will form under alternating load in polymers with low deformation capability. Owing to the spatial rigidity

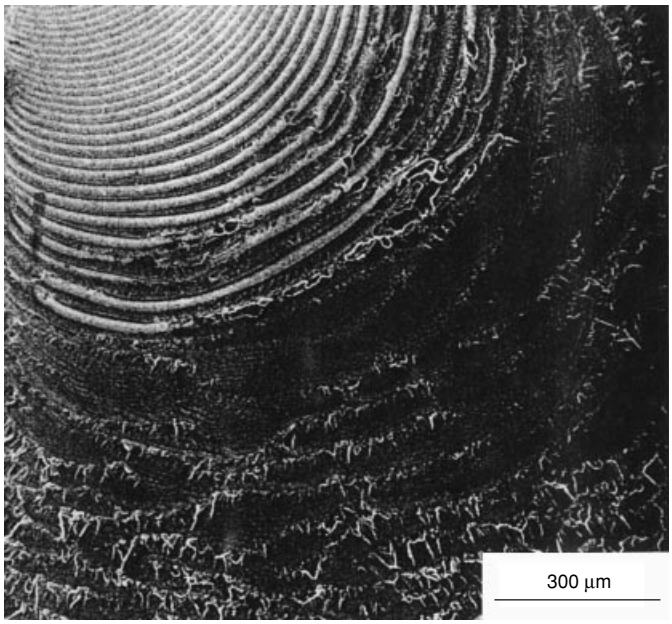

Fig. 9. Tensile fatigue striations in SAN with residual force fracture at elevated load.

of the molecule bonds, the molecule chains are severed by the crack tip after just minor stretching. A crack front with sharp notch base may form and migrate through the plastic under the alternating load. This gives rise to parallel fatigue striations. This phenomenon is dependent on the loading frequency and level as well as on the material. Genuine dynamic fatigue fracture has been observed in PC, SAN, PVC, PE, PA, and PP. Looking at the possible deformation or even separation in the crack base, it is possible to distinguish more or less ductile fatigue striations (Fig. 9).

Genuine Ductile Fatigue Fracture. Dynamic fatigue fracture may propagate on different fracture paths and expand at different times. Materials relatively easy to deform yield fold-like, rounded, cloth-like residual fractures between the fracture paths (Fig. 10). The fatigue striations too are more fold-like and rounded and the fracture plane contains exposed inclusions.

Genuine Brittle Fatigue Fracture. In polymers that are very difficult to deform, fatigue striations with very flat profiles and sharp-edged steps occur between the paths. Fatigue striations are frequently very faint and barely recognizable. When the dynamic fatigue fracture propagates in the form of a crack front, inclusions function as hindrances. Hard inclusions are surmounted by the fracture front, with the result that they become plainly visible or are masked in the fracture surface. Soft inclusions are sliced through by the sharp-edged crack root (Fig. 11). These features make brittle dynamic fatigue fracture the most similar to dynamic fatigue fracture in metals.

Influence of Chemicals—Environmental Stress Cracking. In metallurgy, *corrosive stress cracking* is the simultaneous interaction of a certain

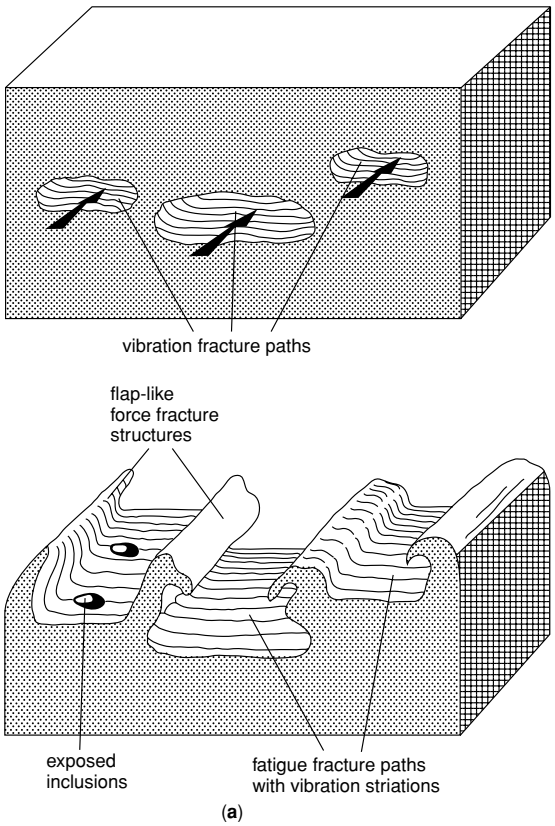

Fig. 10. Propagation of dynamic fatigue fracture in offset fracture paths with fatigue striations and cloth-like residual fractures. (**a**) Schematic and (**b**) example for nylon-6,6 (PA 66).

sensitive material in conjunction with a specific medium and tensile stresses. If one of these three components is absent, stress cracking does not occur. In plastics, the comparable phenomenon is usually called environmental stress cracking, especially if solvents weaken the physical intervalence forces. If a solvent will cause stress cracking in a certain polymer, it can be estimated by comparing the

solubility parameters of solvent and polymer. Equal parameters support the solubility of the solvent in the polymer. However, a prediction of the forming of environmental stress cracking only on the basis of the solubility parameters is not possible. Other factors such as viscosity of the solvent, geometric features, and processing conditions of the part, direction, and size of the load play a significant role in the formation of cracks. Also, there is the term *corrosive stress cracking*, which emphasizes the rarer chemical effect of an aggressive medium during the fracture process.

Aside from environmental stress cracking, occlusion of foreign materials into the molecule or the dissolution of certain components may bring about permanent changes in the mechanical properties. These lead to a change in deformability. An example is the initial dissolution of the crack base and thus acceleration of separation. If, under tensile stress, additional crazing occurs at the surface, it promotes ingress of the medium into the work piece (Fig. 12a). In one and the same combination of material/medium, the level of the tensile stress governs whether brittle or ductile fracture occurs.

Characteristics of genuine stress cracking are separation surfaces with feather-like propagation patterns, huge cracks at right angles to the main fracture surface, and micropeaks (0.1 μm in diameter and 0.3 μm in length).

Chemicals can weaken secondary valences and increase the deformability of the polymers. Through the inclusion of chemicals in vacancies, it is also possible, however, to hinder the mobility of the macromolecules and consequently for a loss of deformability to occur (Fig. 12b). The material becomes permanently changed and its properties differ greatly from those in the as-delivered state. This behavior must be distinguished from stress cracking in which only the simultaneous effect of tensile stress and medium causes fracture. Separation occurs after sufficient embrittlement through external stress or through internal stress, which is increased by the embrittlement.

Partial solution of the crack tip by chemicals always occurs when chemicals dissolve the material at the crack tip and thereby accelerate crack propagation.

Special Crack Causes. Apart from crack formation due primarily to loading and material, and which has just been discussed above, in fracture analysis there are always fracture characteristics that are attributable to design, processing deficiencies, or both. However, it is often not possible to definitively assign, for example, failing weld lines and voids to defects in design or processing.

Weld Lines. In unreinforced polymers, smooth fracture surfaces may be a sign of weld-line failure (Fig. 13a). This is a case of adhesive failure: the melt fronts were unable to join together in such a way that cohesive failure and the corresponding deformation in the fracture surface or different fracture planes, shown in Figure 13b, could occur.

In reinforced polymers, the orientation of the reinforcing materials often provides clues as long as the reinforcing materials are capable of aligning in the melt. This is the case with fibers. Figure 14 shows a molded part made of glass-fiber-reinforced polyamide where the fracture occurred in the knit-line area. Clearly evident are the glass fibers lying mostly parallel to the surface. If the fracture had occurred within the bulk material, glass fibers would be projecting mainly vertically from the fracture surface.

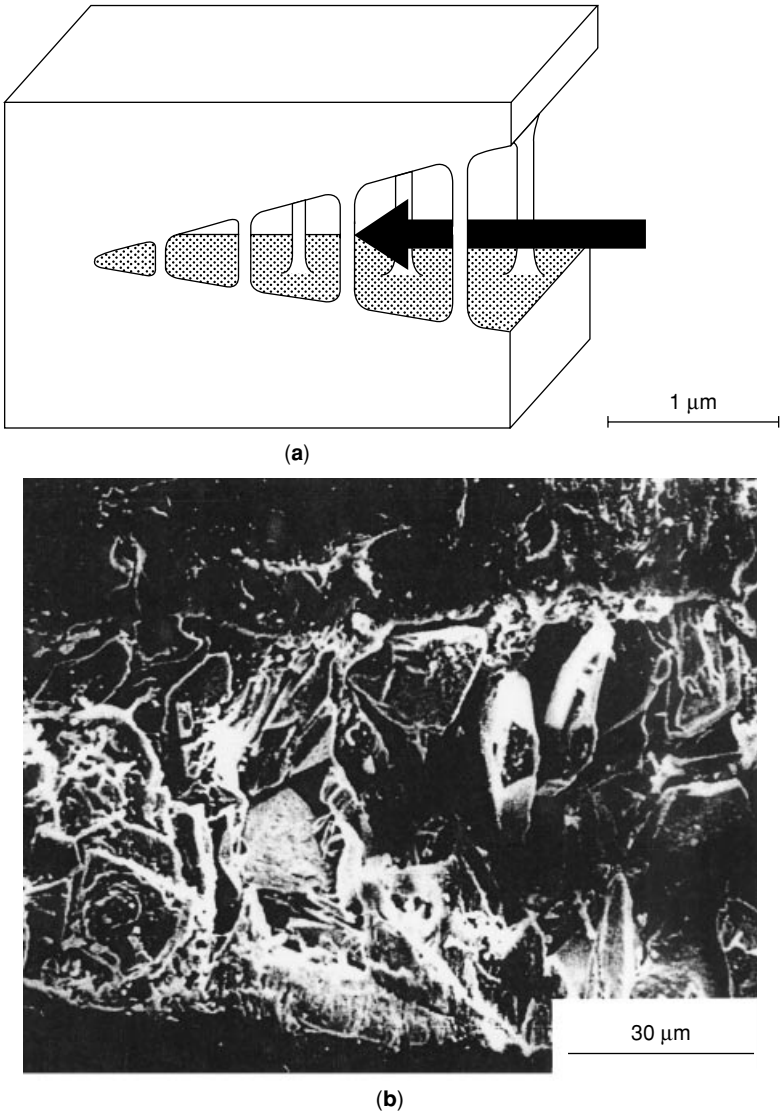

Fig. 12. Effect of chemicals. (**a**) Crazing promotes penetration of medium into inside and (**b**) ruptured crazing; NaOH has an embrittling effect on PP.

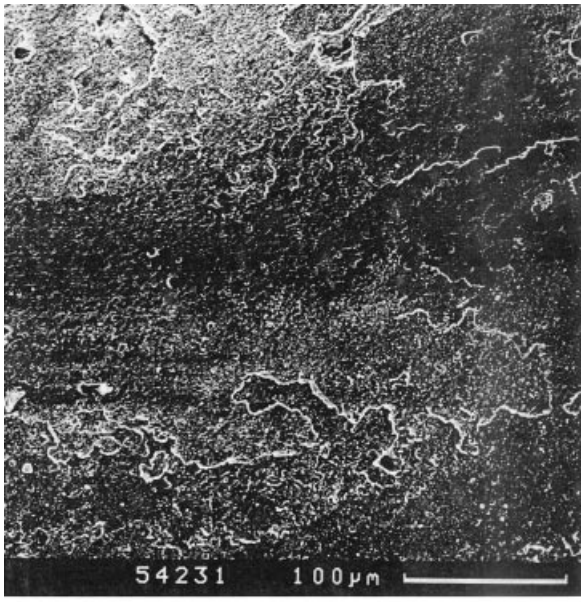
If blends are involved, the poor miscibility of most polymers with each other generally leads to a situation in which one component forms a matrix in which the other is dispersed. It is then possible that only the matrix component is found in the weld line. Proof of this can be established, where the blend composition is appropriate, by conducting comparative etching at the fractured weld-line surface and a reference fracture through the blend.

Voids and Gas Inclusions. Voids and gas inclusions are relatively easy to identify in unreinforced polymers. They constitute the only voids in the fracture



(**a**)

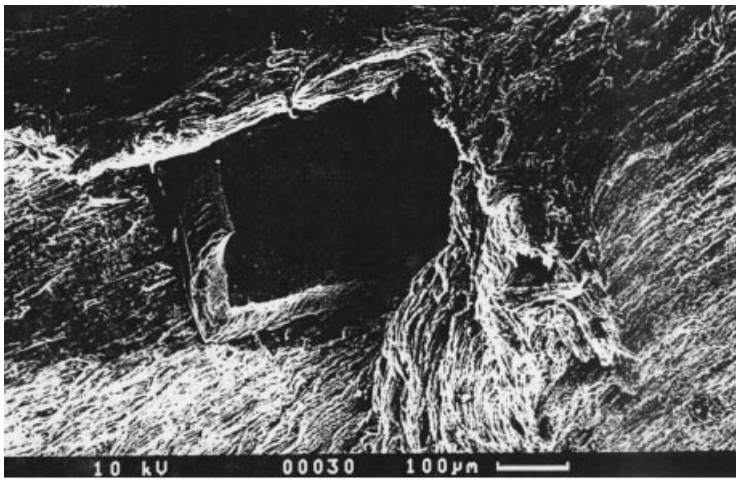
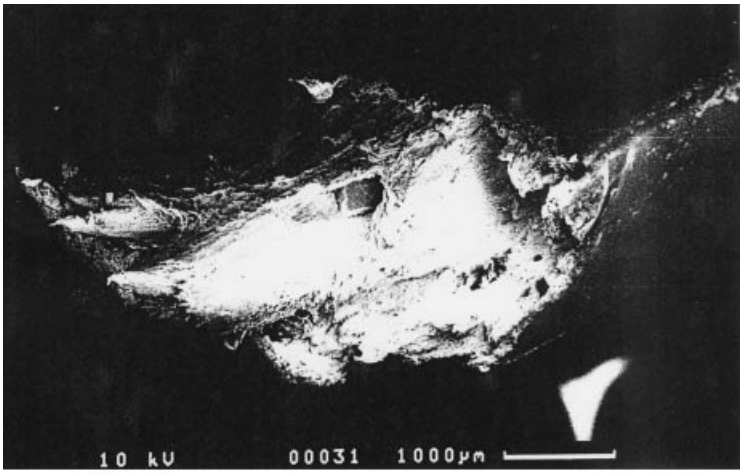
surface (Fig. 15). The situation is more difficult with filled materials as here the fillers erupt alternately from the respective opposite fracture surface, thereby leaving holes behind. As a result, confusion is possible. In such cases, however, it is often possible to classify the void by means of measurements.

Contaminants. While contaminants are an inhomogeneity in the material composition, it is not uncommon for them to originate from processing in the wider sense. In terms of fractography, inhomogeneities—especially contaminants



(**a**)



(**b**)

Fig. 16. Paint particles in the fracture surface of a molded polypropylene part.

such as paint particles—are found in the middle of fracture mirrors because they mark the cause of the crack and thus the origin of the crack (Fig. 16). On account of the different mechanical properties of the contaminant and the surrounding material, stress concentrations occur at their interface that may lead to cracking. Here, force transmission and thus adhesion between the contaminant and the matrix is of crucial importance to the stress-loading capability. With the help of energy dispersive x-ray scanning (EDX or EDS) an elemental analysis of inorganic inclusions would be possible (see SURFACE ANALYSIS).

Quantitative Evaluation of Fracture Surfaces

The objective of quantitative fractography is the quantitative description of the fracture surface in terms of parameters such as roughness, fiber orientation, phase content, and particle size distribution. Therefore different characteristics such as shape (area), size (eg length, diameter), anisotropy (orientation, direction), and distribution (spacing) of material components or topographical details are being evaluated.

The mathematical task of reconstructing the material's three-dimensional structure parameters from measured data obtained on a section of the material is called *stereology*. Different principles are used for areal, linear, and point analyses. The problem of scale is solved with a fractal approach, making the length of a curve a function of the size of the measuring device (22).

Important for the daily routine is the unchangable combination of an image with the corresponding scaling bar, so that an enlargement of the image simultaneously adopts the size of the bar. Otherwise the dimensions of topographical details cannot be evaluated correctly.

For measuring the topology of the fracture surface (i.e. roughness), direct contact profilometry, laser profilometry, or the atomic force microscopy are available (6). With the help of a coordinate system, contour maps of the fracture surface can be drawn based on roughness data or through-focus procedures for the light microscope.

An example for the use of fractography for evaluating the phase morphology of polymer blends is shown in Figure 17. The specimen, a PP with 30-wt% of a metallocene polymerized polyethylene (mPE), was fractured at −30°C. Afterwards the mPE-phase was dissolved in xylene, so that the resulting holes visualize the distribution of mPE in the PP matrix. The micrograph shows a

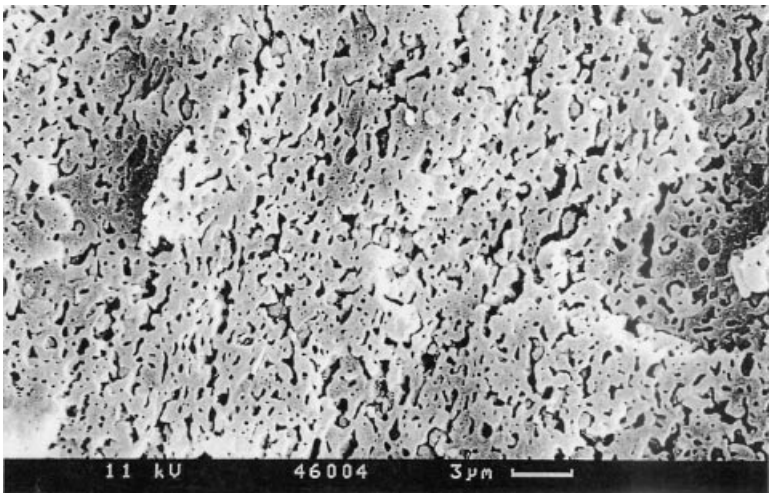


Fig. 17. Phase morphology of polypropylene with 30-wt% mPE (fractured at −30°C, mPE dissolved in xylene). From Ref. 23.

homogeneous dispersion of the minor phase. When carrying out an image analysis in order to quantify the content and phase distribution of the dispersed phase, the two-dimensional SEM picture of the three-dimensional fracture surface may not be representative enough for a good statistical value, based on stereological methods for sections. Preparing a thin section or a polished surface would be advisable.

Fractography is an indispensable tool for extending understanding of how and why a material fails. On account of its great depth of field, SEM is an essential item of equipment for fracture surface analysis. Scanning electron microscopic examination, together with the crack formation concepts (classification into fracture modes and description of their characteristics), provides an opportunity to reconstruct failure processes and to illustrate the limits to loading.

FRACTURE

Introduction

Fracture is defined as stress-biased material disintegration through the formation of new surfaces within a body. Fracture starts out as a localized event that eventually encompasses the whole object (Fig. 1). Fracture is synonymous with rupture and breakage but not with failure. The latter term is more general and also encompasses nonmechanical breakdown through heat (thermal failure) or environmental degradation (chemical attack, irradiation).

For fracture to occur, it is generally necessary that a specimen be subjected to mechanical loads and that the resulting, initially homogeneous (viscoelastic) material deformation—which eventually would lead to creep and ductile failure—becomes heterogeneous and initiates material separation. The most likely sites for material separation are structural irregularities, growing material *defects*, or preexisting cracks. In a polymeric material, such sites are for instance given by inclusions of particles or voids, craze-like features, or cracks. Crazes and subsequently cracks extend as the material between voids and adjacent to a crack tip deforms and/or disintegrates. Depending on the nature and the extent of such deformation, breakdown occurs in quite different modes of failure: as brittle fracture by rapid crack propagation (Fig. 1), crazing, or slow crack growth, or by ductile failure (Fig. 2).

The mode of failure (of a cracked specimen) is not an inherent property of a given material in a given environment. It also depends on the loading rate and especially on the local state of stress, which is strongly influenced by the configuration of the crack itself. For this reason a mechanical analysis of a cracked, stressed body is presented first, which is based on linear and nonlinear elastic fracture mechanics.

Linear Elastic Fracture Mechanics

Fracture mechanics concepts describe the behavior of cracks or other defects when a body is loaded. A crack constitutes a discontinuity within a body. At the boundary of the discontinuity, very high local stresses and strains are usually observed, and in the limit of a sharp crack in an elastic body, these may theoretically be infinite or singular. Linear elastic fracture mechanics (LEFM) describes the conditions under which a crack grows or propagates, creating new surface area. LEFM assumes a globally linear elastic deformation with energy absorption confined to a very local region at the crack tip. The theory has been extended to plastically deforming materials, which undergo rate-independent, irreversible deformation. Neither of these assumptions is strictly true for polymers, since all exhibit a more

or less viscoelastic and time-dependent behavior. However, much of the behavior observed in the fracture of polymers can be described in terms of LEFM. There are two approaches to describing the condition of fracture. In the first, the *balance of energy* is discussed; energy is released from the elastically deformed specimen if the length of a crack increases, and at the same time energy is absorbed by the creation of the new crack surface area. In the second approach, the local stress field around the crack tip is considered and its intensity at fracture is characterized by some parameter, the *fracture toughness*. Fracture mechanics is a macro theory, being concerned with the overall behavior of a body. The particular material behavior is considered only in connection with fracture criteria or with the nature of the deformation processes involved. Much of the theory is thus not material specific and applies equally to all materials. When dealing with ductile polymer fracture, plasticity modifications are of value. It is possible to modify the analysis to encompass time effects; this is particularly necessary for the two extreme phenomena such as slow crack growth and dynamic or impact fracture. References 2–4–5 cover these topics in much more detail and provide an extensive bibliography.

Resistance or *R* Curve. It is a useful approach to define the toughness of a material in terms of its resistance or R curve, as shown in Figure 3. Here R is the energy per unit area necessary to produce the new fracture surface S. For a crack of length a_0 and in a plate of uniform thickness B, the incremental increase in surface area ΔS may be expressed in terms of the crack growth Δa. Any virgin material will first resist to crack-growth initiation by crack tip deformation; the development of this *process zone* is associated with a certain resistance $R = R_c$. Subsequent growth in many polymers may be described, as shown in line A, with R increasing as the crack extends. (As will be shown below, this is usually ascribed to an increase of the local plastic flow in a zone of size r_y around the crack tip). If however the extent of this zone, which represents the energy absorption, remains the same, R remains constant as shown in line B. This is so for the more brittle fractures, where the energy absorption is very local and the zone is small and very much less than a_0. For tougher materials, an increasing r_y is more likely. The plastic zone size r_y is a very important parameter, since it provides a length factor which controls the various size effects.

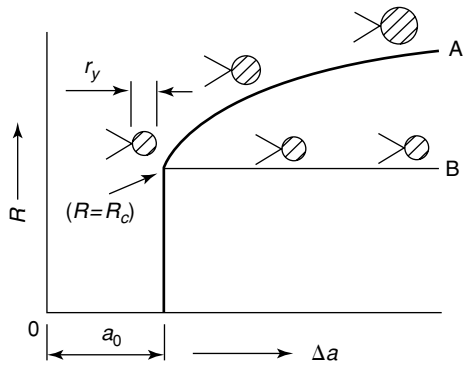

Fig. 3. The resistance or R curve. See text for significance of curves A and B.

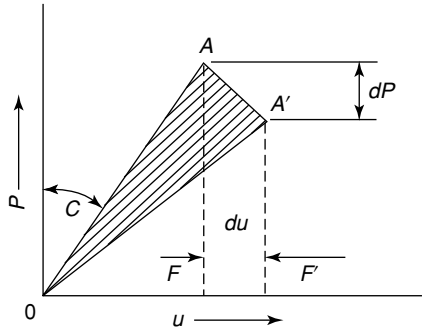

Fig. 4. Energy release during crack extension in an elastic plate shown by the shaded area.

Energy-Release Rate. As first formulated by Griffith (6), the driving force for fracture comes from the energy which is released by the growth of the crack. Such growth violates the continuity within the body and results in the final energy state being lower than the initial; the difference is released and available to overcome the crack resistance R. This is shown in Figure 4 for a linearly elastic body, in which crack growth initiates at A. The growing crack reduces the stiffness of the sample, which results in a reduction in load P and an increase in deformation (to the point A'). The initial stored energy corresponds to the area $0AF$ and that after crack growth to $0A'F'$. During crack extension, external work has been furnished, which is given by $AA'F'F$. The energy $\mathrm{d}U$ which is released by the system corresponds to the shaded area $0AA'$ and is given by

$$\mathrm{d}U = 1/2(P\mathrm{d}u - u\mathrm{d}P) \tag{1}$$

where u is the deformation in the direction of applied load.

The rate of energy release $\mathrm{d}U/B\mathrm{d}a$ is given the symbol G and expressed by

$$G = \frac{1}{B}\frac{\mathrm{d}U}{\mathrm{d}a} = \frac{1}{2}\left(P\frac{\mathrm{d}u}{\mathrm{d}a} - u\frac{\mathrm{d}P}{\mathrm{d}a}\right) \tag{2}$$

where a is the crack length. Introducing the compliance C of the body which is a function of crack length

$$C = \frac{u}{P} \tag{3}$$

we obtain

$$G = \frac{P^2}{2B}\frac{\mathrm{d}C}{\mathrm{d}a} = \frac{u^2}{2B}\frac{1}{C^2}\frac{\mathrm{d}C}{\mathrm{d}a} = \frac{U}{B}\frac{1}{C}\frac{\mathrm{d}C}{\mathrm{d}a} \tag{4}$$

Thus, G can be determined from the load and the deflection at crack extension, provided the compliance $C(a)$ is known. For any load, lines of G vs a can be plotted for a cracked body, as shown in Figure 5, together with an (arbitrary) R

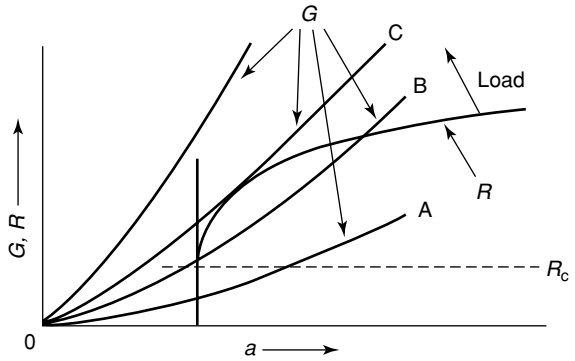

Fig. 5. Energy-release rate G and material resistance R for various loads levels.

curve. For the load of line A, there is no growth when G intersects R, but for line B there is. However, just after initiation $R > G$, which prevents immediate and unstable crack growth. The crack would grow, of course, if the load were increased. Cracks in a time-dependent material can also grow, in a stable manner, by plastic deformation at loads smaller than the breaking stress (see further below). Crack growth will be stable if

$$G = \frac{\mathrm{d}U}{B\mathrm{d}a} = R \text{ and } \frac{1}{B}\frac{\mathrm{d}G}{\mathrm{d}a} = \frac{1}{B^2}\frac{\mathrm{d}^2U}{\mathrm{d}a^2} < \frac{\mathrm{d}R}{B\mathrm{d}a} \tag{5}$$

For the tangency condition C there is a small region of stable growth (up to the tangency point), followed by instability. For a constant $R(a) = R_c$, there is no growth until $G = R_c$, and the initiation is immediately followed by unstable growth. G at initiation is usually written as G_c $(=R_c)$. An important example of fracture mechanics concerns the stability of a crack of length $2a$ in an infinitely wide sheet loaded with a constant stress σ, as shown in Figure 6.

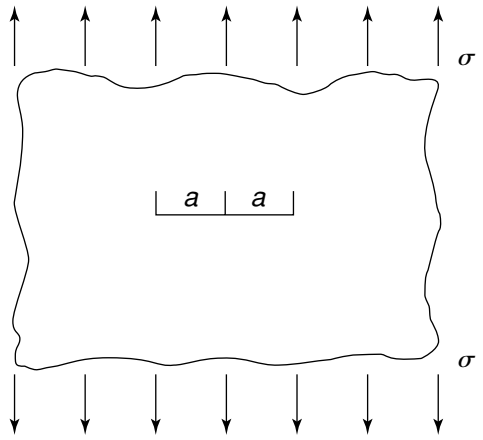

Fig. 6. The infinite sheet.

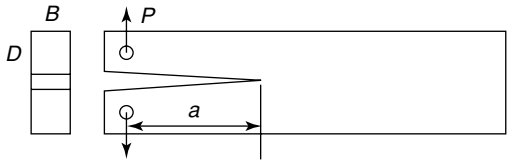

Fig. 7. The double-cantilever beam (DCB).

The energy-release rate G for the above geometry has been derived (6,7) as

$$G = \frac{\pi \sigma^2 a}{E} \tag{6}$$

where E is the Young's modulus. In a perfectly brittle material undergoing no plastic work, we have at fracture $G_c = 2\gamma = \pi\sigma^2 a/E$, where γ is the true surface work of the solid. Thus, the basic relationship of fracture mechanics is that $\sigma^2 a \approx$ constant at fracture. In this case $dR/da = 0$ and $dG/da > 0$, and the fracture is always unstable. However, this does not hold for a cracked specimen at fixed displacement.

Another important specimen geometry is the double-cantilever beam (DCB) shown in Figure 7. From beam theory,

$$C = \frac{8a^3}{EBD^3} \tag{7}$$

where B is specimen thickness and D specimen width. In practice, $C \propto an$, $n < 3$, because of rotation at the beam ends, and this empirical result is frequently used in practice. Using equations (4) and (7) we have

$$G = \frac{12P^2a^2}{EB^2D^3} = \frac{3}{16}\frac{ED^3u^2}{a^4} \tag{8}$$

Again, $G = G_c = 2\gamma$ at fracture giving load-crack length and displacement-crack length relationships at fracture, and also $dR/da = 0$. Fixed load gives $dG/da > 0$ as before, resulting in unstable growth, but for constant displacement, $dG/da < 0$ and stable growth occurs.

In principle, any body can be characterized by finding $C(a)$ by measurement or computation. Thus, by detecting crack-growth initiation, the G value at fracture, termed G_c, can be found. Subsequent stability can be described in terms of dG/da and dR/da. Some more general aspects to the analysis are also important and, in particular, the fact that G may be described for any elastic body, not necessarily linear, as

$$G = \int^s W dy \quad \text{displacement constant} \tag{9}$$

where W is the strain–energy–density function, y the coordinate normal to the crack direction, and s some closed contour taken around the crack tip. This form

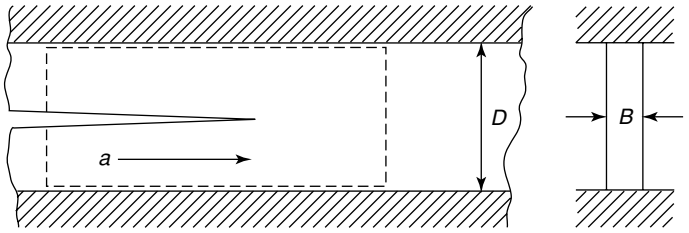

Fig. 8. The parallel strip.

is particularly useful for the analysis of nonlinear elastic systems as encountered in rubber elasticity (8). An example is a very wide parallel strip (Fig. 8) where a contour may be taken, as indicated by the broken line. The horizontal portions give no contribution since $dy = 0$, and if the vertical lines are remote from the crack tip, the part behind it has no stored energy, whereas that in front has the energy per unit volume of the uncracked strip, eg, W_0. Equation (9) then gives

$$G = W_0 D \tag{10}$$

The result is obvious, since a strip of width dx has an initial stored energy of $W_0 BD\ dx$. After fracture, this is reduced to zero by the creation of area $B\ dx$, giving the above results. Of course, W_0 may be found for any type of elastic behavior simply by loading the strip initially. This result is also true in this case even when the crack speed is high and there are no kinetic energy effects, since these must all eventually go to zero as in the static case, though it is debatable if kinetic energy is truly reversible in real systems.

Stress–Intensity Factor. The stresses around the crack tip, as shown in Figure 9, may be expressed in the form of a series:

$$\sigma = \frac{Kf(\theta)}{\sqrt{2\pi r}} + A(\theta) + B(\theta) r^{1/2} + \cdots \tag{11}$$

where f, A, B, etc, are functions of the angle θ, and r is the distance from the crack tip. As the crack tip is approached ($r \to 0$), all terms other than the first two tend to zero and the first term is dominant; $A(\theta)$ represents nonsingular stresses which can have effects, but, in general, the first singular term, which tends to ∞ as $r \to 0$ dominates. The form of the stress field is the same for all remote

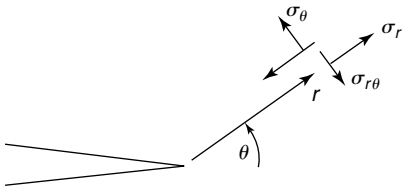

Fig. 9. Local stresses around a crack tip.

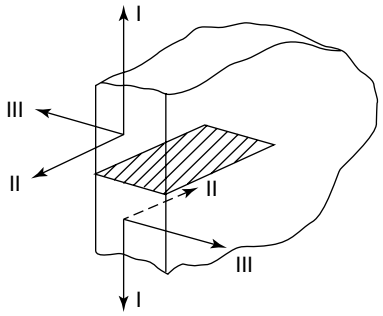

Fig. 10. Modes of loading.

loading states and is determined by $f(\theta)$. The *magnitude* of the local stresses is conveniently expressed by K, the stress–intensity factor, which is a function of the remote loading σ. K is defined as

$$K = \sigma\sqrt{2\pi r} \quad \text{as} \quad r \to 0 \quad \text{at} \quad \theta = 0 \tag{12}$$

If a characterizing parameter in the local region of the crack tip is sought, clearly σ (or strain) is not useful since it tends to infinity as $r \to 0$. However, the product $\sigma\sqrt{r}$ is finite in the local zone and for this reason K (and not σ) is taken as the local parameter characterizing the mechanical effort to which a cracked specimen is subjected. If stress intensity is the decisive parameter, fracture should occur once K attains a critical value K_c; K_c is termed fracture toughness.

It is convenient to express the loading on a crack in terms of three orthogonal components (Fig. 10), which may be super-imposed to give any loading state: Mode I, the opening mode; Mode II, the shear mode; and Mode III, the out-of-plane shear mode. An applied loading may give rise to a mixture of all three modes, which can be expressed in terms of K_I, K_{II}, and K_{III}. Mode I is the most severe and thus generally the most important; in the presence of a combination of loading modes this often results in local mode-I fracture.

For the most frequently observed modes I and II, the local stress fields may be written as (2)

$$\sigma_\theta = \frac{K_I}{\sqrt{2\pi r}}\frac{1}{2}\cos\frac{\theta}{2}(1+\cos\theta) - \frac{K_{II}}{\sqrt{2\pi r}}\frac{3}{2}\sin\frac{\theta}{2}(1+\cos\theta) \tag{13}$$

$$\sigma_r = \frac{K_I}{\sqrt{2\pi r}}\frac{1}{2}\cos\frac{\theta}{2}(3-\cos\theta) - \frac{K_{II}}{\sqrt{2\pi r}}\frac{1}{2}\sin\frac{\theta}{2}(1-3\cos\theta) \tag{14}$$

$$\sigma_{r\theta} = \frac{K_I}{\sqrt{2\pi r}}\frac{1}{2}\sin\frac{\theta}{2}(1+\cos\theta) - \frac{K_{II}}{\sqrt{2\pi r}}\frac{1}{2}\cos\frac{\theta}{2}(1-3\cos\theta) \tag{15}$$

$$K_{\mathrm{I}} = \sigma_\theta \sqrt{2\pi r} \quad \text{at} \theta = 0 \tag{16}$$

$$K_{\mathrm{II}} = \sigma_{\mathrm{r}\theta} \sqrt{2\pi r} \quad \text{at} \theta = 0 \tag{17}$$

In mode-I loading of a brittle material, fracture occurs when K_{I} attains a critical value K_{Ic}. In combined-loading modes, crack propagation is not colinear and some complications result. If in a state involving modes I and II fracture occurs by crack opening, then the crack will propagate under an angle θ_{c} (2). This angle is obtained from equation (13):

$$K_{\mathrm{Ic}} = K_{\mathrm{I}} \frac{1}{2} \cos\frac{\theta_{\mathrm{c}}}{2}(1 + \cos\theta_{\mathrm{c}}) - K_{\mathrm{II}} \frac{3}{2} \sin\frac{\theta_{\mathrm{c}}}{2}(1 + \cos\theta_{\mathrm{c}}) \tag{18}$$

and an additional condition that

$$\frac{\mathrm{d}\sigma_\theta}{\mathrm{d}\theta} = 0 \quad \text{which is equivalent to } \sigma_{\mathrm{r}\theta} = 0 \tag{19}$$

giving

$$0 = K_{\mathrm{I}} \frac{1}{2} \sin\frac{\theta_{\mathrm{c}}}{2}(1 + \cos\theta_{\mathrm{c}}) - K_{\mathrm{II}} \frac{1}{2} \cos\frac{\theta_{\mathrm{c}}}{2}(1 - 3\cos\theta_{\mathrm{c}}) \tag{20}$$

In pure mode I ($K_{\mathrm{II}} = 0$), θ_{c} is zero as expected, whereas in pure mode II ($K_{\mathrm{I}} = 0$), $\theta_{\mathrm{c}} = \cos^{-1} 1/3 = \pm 70.3^\circ$.

Relation between *G* and *K*. The local singular stress field is described by K_{I} and it is from this discontinuity that the energy is released by way of G. It is to be expected, therefore, that G and K_{I} would be related and this can be demonstrated by deriving G around a local contour (2):

$$K_{\mathrm{I}}^2 = EG \tag{21}$$

The π factor in equation (11) is introduced in the definition of K_{I} to remove any numerical constant in equation (21). There is no similar result for mode II alone or for mixed modes, since the propagation is not colinear ($\theta_{\mathrm{c}} \neq 0$) and the above result would not be valid.

Returning to the case of the infinite plate,

$$K_{\mathrm{I}}^2 = EG = \pi \sigma^2 a \tag{22}$$

If σ is measured at fracture for a given a, K_{Ic} is obtained and the fracture toughness is characterized without the need to know E, which is involved when G is used. This is of considerable benefit in the polymer field, where E is time-dependent and often uncertain. K_{Ic} may also be defined for specimens having a noninfinite geometry by means of a more general form of equation (21′):

$$K_{\mathrm{I}}^2 = Y^2(a/W)\sigma^2 a \tag{23}$$

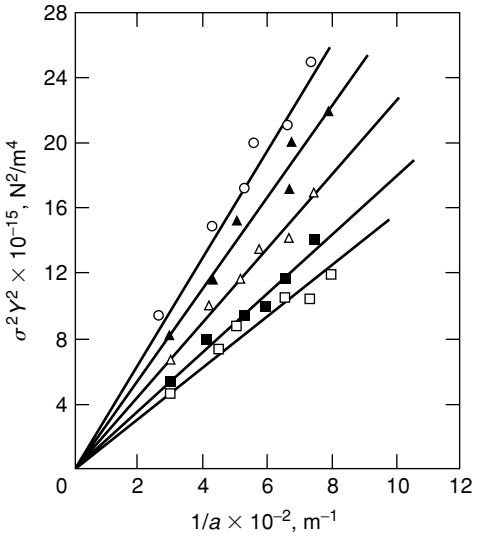

Fig. 11. Crack-initiation data. Single-edge notch bend data for polyacetal at temperatures of 20 to −60°C. The symbols represent the following temperatures: □, 20°C; ■, 0°C; △, −20°C; ▲, −40°C; ○, −60°C.

where $Y^2(a/W)$ is a calibration function [to account for the noninfinite sample geometry, it is available for most practical cases (9,10)]. For the infinite plate Y^2 is π, all other cases tend to this result for $a/W \to 0$. For a linearly elastic material it is assumed that relation 22 is valid up to fracture; a plot of σ^2Y^2 vs $1/a$ should result in a straight line passing through the origin, the slope of which is equal to ${K_{\mathrm{Ic}}}^2$. Figure 11 demonstrates that in the temperature range of $-60°\mathrm{C} < T < 20°\mathrm{C}$ polyacetal behaves in a linear elastic manner. Nonlinearity in the σ^2Y^2 vs a^{-1} graph occurs because of local plasticity and/or damage formation in the crack tip zone.

For the important compact tension geometry (Fig. 12c), K_{I} is generally expressed in terms of the applied load P:

$$K_{\mathrm{I}} = \frac{P}{B\sqrt{W}} Y(a/W) \tag{24}$$

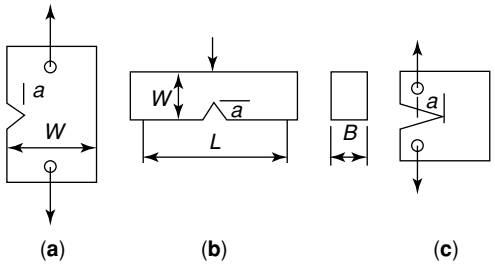

Fig. 12. Testing geometries: (**a**) single-edge notch tension (SENT), (**b**) single-edge notch three-point bending (SENB), and (**c**) compact tension (CT).

Of course, the correction function Y is another way of expressing the compliance calibrations given in equation (4); for a three-point bend test (Fig. 12b), for example, is

$$\frac{dC}{da} = \frac{9}{2}\frac{L^2}{BW^4E}Y^2a \tag{25}$$

where L is the length of the beam.

An important alternative form is the energy version of the general equation (4):

$$G = \frac{U}{BW\phi} \tag{26}$$

in which the calibration factor is expressed by

$$\phi = \frac{C}{dC/d(a/W)} = \frac{\int Y^2 x\,dx}{Y^2x} + \frac{L}{18W}\frac{1}{Y^2x} \tag{27}$$

where $x = a/W$.

Values of ϕ are available for bending (2), and G_c may be found by measuring the energy to crack initiation and via equation (25). In any test, the three parameters at fracture (a, G_c, K_c) can be measured and various combinations of E and G determined. Thus, from the load $P = u/C$ in a bending experiment, the displacement G/E is obtained by

$$\frac{G}{E} = \frac{u^2W^2}{9L^2a}\frac{1}{(\phi Y)^2} \tag{28}$$

$G/E = (\pi/4)\rho$, where ρ is the elastic tip radius of the crack under load. If all three of the above parameters are used, consistency can be checked, and in addition, E is found.

Fracture Mechanics Admitting Confined Plasticity and Viscoelasticity

Irwin Model of Plasticity and Size Effects. The elastic analysis predicts infinite stresses at the crack tip, but local yielding prevents this from happening. Irwin has modeled this situation by a small, local yielding zone surrounded by a larger, outer elastic zone (Fig. 13). For a state of plane stress ($\sigma_z = 0$) as in thin plates or at the surface of thick plates, the radius of the plastic zone r_y can be derived from equation (20) to be approximately

$$r_y \approx \frac{1}{2\pi}\left(\frac{K_{Ic}}{\sigma_y}\right)^2 \text{(planestress)} \tag{29}$$

The elastic stresses in the outer zone can be calculated from the Irwin model by assigning a fictitious length $a + r_y$ to the crack.

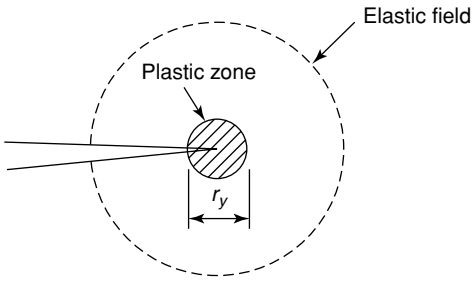

Fig. 13. Irwin model: Small plastic zone surrounded by an elastic field.

In the center of thick plates a state of plane strain is approached in which the contraction in the z direction is constrained ($e_z = 0$) and $\sigma_z = \nu(\sigma_r + \sigma_\theta)$. Because of these constraints the plastic zone radius is much smaller:

$$r_y' \approx \frac{1}{2\pi}\left(\frac{K_{Ic}}{\sigma_y}\right)^2 (1-2\nu)^2 (\text{planestrain}) \tag{30}$$

Within the plastic zone, $\nu \to 1/2$ and so the stress state tends to be equitriaxial tension $\sigma_r = \sigma_\theta = \sigma_z$, the most severe in fracture terms. In testing it is desirable to employ the most severe conditions to explore the worst case. To achieve this, the specimen dimensions (B, W) must be considerably greater than the plastic zone. This is defined by the ASTM size criterion (11) for bend testing which requires a minimum thickness:

$$\hat{B} > 2.5\left(\frac{K_{Ic}}{\sigma_y}\right)^2 \tag{31}$$

approximately equivalent to $\hat{B} > 16 r_y$. If $B < \hat{B}$ the stress state tends to be plane stress and the measured toughness values are unrealistically high.

Line Zone or Dugdale Model. In many polymers, crazes form at stress concentrations such as crack tips (12). A craze is a planar structure, which can be realistically modeled by a line zone, as shown in Figure 14. Here, microyielding at the craze boundaries is modeled by a line of elastic tractions as in the Dugdale model. There is mechanical equilibrium if the zone length is

$$r_y = \frac{\pi}{8}\left(\frac{K_{Ic}}{\sigma_y}\right)^2 \tag{32}$$

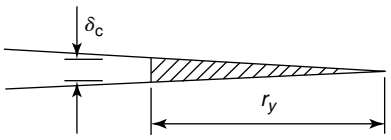

Fig. 14. The line zone model well represents single crazes.

Another useful parameter arises, since the displacement at the crack tip δ_c (in a state of plane stress) is predicted by this model as

$$\delta_c = \frac{K_{Ic}^2}{E\sigma_y} = \frac{G_c}{\sigma_y} \tag{33}$$

The critical crack tip opening displacement δ_c (CTOD) can be used as a fracture criterion. A constant δ_c is equivalent to constant K_{Ic} and G_c as used in LEFM. If δ_c remains constant outside the LEFM range, it can be used to make predictions for viscoelastic and large-scale plasticity behavior.

Viscoelastic Effects. In all the above analyses, fracture mechanics parameters were considered to be independent of time; consequently G_c (or K_{Ic}) would have to be independent of loading rate or crack speed. However, most polymers show some degree of viscoelasticity, which can have an important influence on fracture behavior. This is particularly pronounced in cross-linked elastomers. The time-dependent fracture of polymers has been reviewed repeatedly (13–15). Without going into details the pioneering work in the sixties and seventies of Williams, Barenblatt, Knauss and Müller, Retting, Williams and Marshall, and Schapery should be mentioned. These authors have extended Griffith's work to linearly viscoelastic materials. They pointed out that the work of fracture in polymers depends on the load history, that is on the rate of crack growth $\dot{a}$, and that viscoelastic creep crack growth can be described by replacing the elastic by viscoelastic moduli. In simplifying, it can be said that the time dependence of crack growth in polymers has three different origins: firstly, it is influenced by the viscoelastic behavior of the far field stresses (the energy necessary to drive the crack is released as a function of time rather than instantaneously). Secondly, there are viscous losses because of the (steady) extension of the process zone through plastic flow and/or the formation and growth of fibrils. Thirdly, cracks grow, occasionally in a discontinuous manner, because of the weakening and rupture of the material in the process zone through disentanglement, chain scission, and formation and coalescence of voids (see section on Fracture Phenomena for a discussion of these mechanisms).

It is generally a reasonable assumption that yield strain e_y and ultimate strain or crack opening displacement δ_c are relatively constant with loading rate (2,13–17), whereas the elastic modulus follows a power law in time:

$$\frac{\sigma_y}{E} = e_y \quad \text{and} \quad \frac{E}{E_0} = \left(\frac{t}{t_{0-}}\right)^{-n} \tag{34}$$

where e_y, E_0, t_0, and n are constants. If a constant δ_c criterion in the line zone model is assumed and if the time scale is related to the inverse of crack speed, a relation between $\dot{a}$ and K is obtained, which has been verified experimentally for many thermoplastic and thermosetting polymers (16–20):

$$\dot{a} = A(K_I)^{1/n} \tag{35}$$

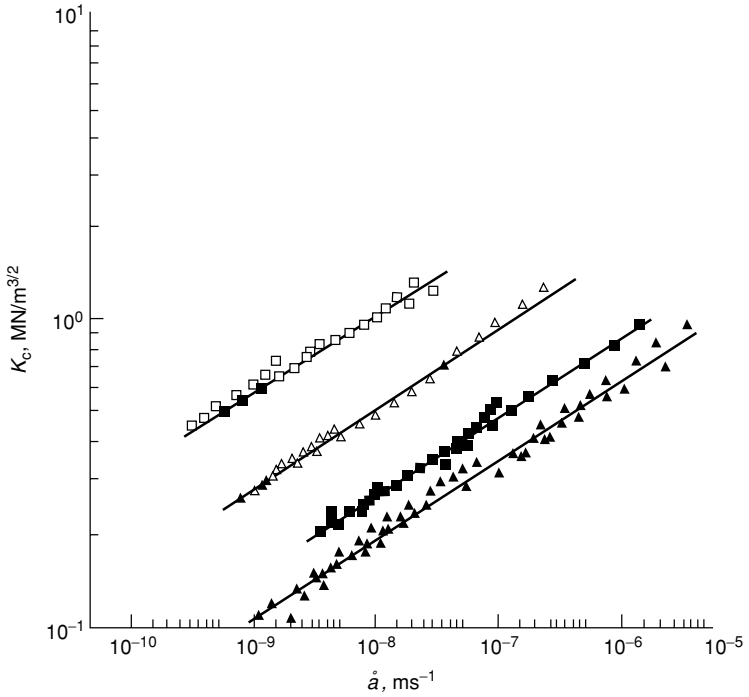

Fig. 15. K_c–$\dot{a}$ curves for polyethylene in distilled water at different temperatures. Slopes = 0.25. The symbols represent the following temperatures: □, 19°C; △, 40°C; ■, 60°C; ▲, 75°C.

This form represents a continuous relationship between K and $\dot{a}$; in a log–log plot straight lines are obtained as well illustrated by Figure 15 for polyethylene in distilled water at different temperatures.

Since it is usually convenient to measure the crack speed in a specimen in which K does not vary with a for a given load or loading rate, the double-torsion and tapered-cantilever beam tests are used (Fig. 16). In the first we have

$$K^2 = \frac{3(1+\nu)}{2}\frac{P^2 l^2}{B^2 D^3} \tag{36}$$

where l is the distance from the center of the specimen to the point of load support. For the tapered beam,

$$K^2 \approx \frac{45P^2}{B^2 D_0^3} \quad \text{for a tape angle } \alpha \approx 11^\circ \tag{37}$$

Under dead loads (constant P), K values are constant resulting in a fixed crack speed, which can be measured over a certain distance of crack growth; the K_c–$\dot{a}$ curve is then determined by changing the load. Environmental data are obtained by conducting the test with the specimen immersed in the environment.

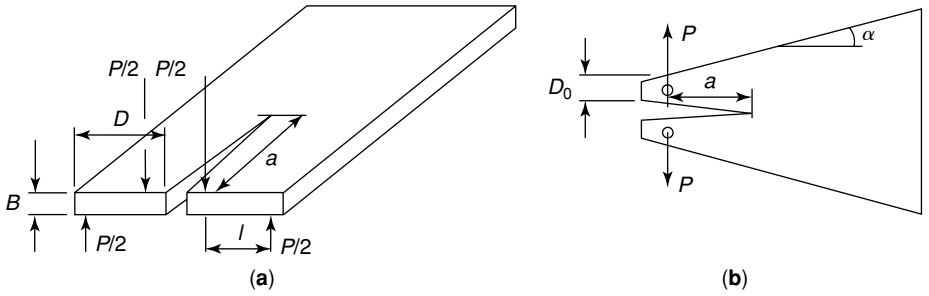

Fig. 16. Crack-growth testing geometries for constant K tests: (**a**) double tension, (**b**) tapered cantilever.

Side grooves are often used in these tests to guide the crack, with appropriate modifications made to the formula for K. Typical data for polyethylene in water are given in Figure 15.

Such data on $K_c(\dot{a})$ are of particular importance because they provide a method by which long-term failure may be predicted from much shorter-term results. The measured crack-growth rates may be integrated to predict failure times. For example, the time for a flaw of original length a_0 to grow to a length much more than a_0 is given by

$$t = t_i\left[1 + \frac{5n}{1-n}\left(\frac{a_0}{r_0}\right)\right], \quad n \ll 1 \tag{38}$$

where $r_0 = (\pi/8)\,(\delta_c/e_y)$ is the zone size, and t_i is the crack initiation time. For very small flaws, $t \sim t_i$ and very little of the life is spent in crack propagation. Such a result predicts $\sigma \propto t^{-n}$ for a constant stress test, ie, the log stress–log rupture time curve has the reverse slope of the log K–log $\dot{a}$ crack-growth line (Fig. 15). Such a behavior has been verified experimentally for a number of thermoplastic and thermosetting polymers (16–20).

Fracture Mechanics of Dissipative Materials

Plasticity Effects. In LEFM, it is assumed that the plastic-zone size r_y is very small, but because of specimen size limitations it is often difficult to take measurements under conditions where this is true. In any event, a first correction can be made by increasing the crack length a by r_y to compensate for the modification of the elastic stress field by the plastic zone. In this case, the computed toughness parameters are termed K_{eff} and G_{eff}. A schematic representation of the determination of the stress intensity factor from a compact tension test is given in Figure 17. In the case of brittle or semibrittle fracture, a straight line is obtained if P_{max} is plotted as a function of $BW^{1/2}Y[(a/W)^{1/2}]$. For a perfectly elastic material, the line passes through the origin and the slope gives K_{Ic} (eq. (23), Fig. 11). In the case of a plastically deforming material, the line will not pass through the origin. However, by introducing an appropriate effective crack length $a + r_y$ into

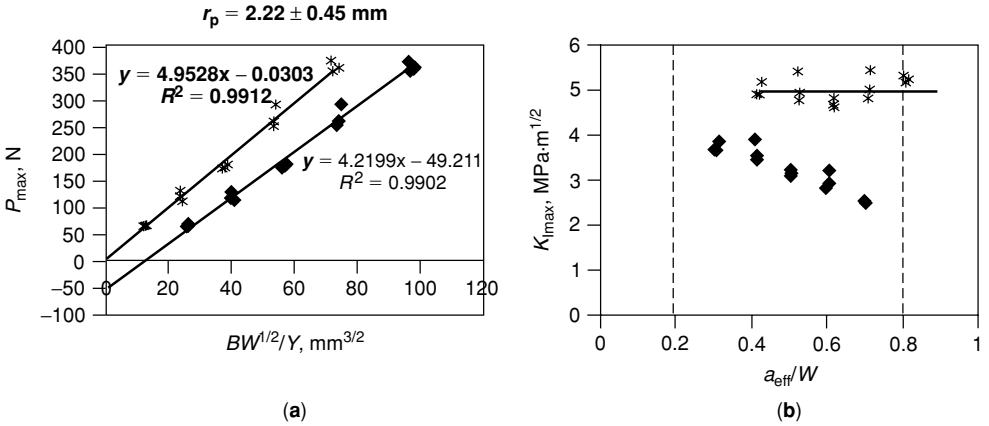

Fig. 17. (**a**) Determination of K_{Ic} for a perfectly elastic material, (**b**) Effect of introducing an appropriate effective crack length $a + r_y$ into the correction function $Y^n[((a + r_y)/W)^{1/2}]$. ◆ $r_p = 0$ mm; ✱ $r_p = 2.22$ mm. From Ref. 21.

the correction function $Y[((a + r_y)/W)^{1/2}]$, the line can be made to pass through the origin. The slope then gives the effective toughness K_{eff}. The appropriate plastic zone size r_y can be determined by iteration from equation (23) (21).

The ratio between the effective energy-release rate G_{eff} and the linear elastic value G_c is approximated by

$$\frac{J}{G} = \left[1 - \frac{1}{2}\left(\frac{\sigma}{\sigma_y}\right)^2\right]^{-1} \tag{39}$$

where $G = \pi\sigma^2 a/E$. This correction is useful for $\sigma/\sigma_y < 0.8$, and it can be seen that $G_{eff} \rightarrow G_c$ for small stresses. On the other hand, as the fully plastic condition is approached, such corrections are not satisfactory because they are very sensitive to the stress and the analysis is better couched in terms of displacement.

A simple case where this can be done is that of three-point bending, shown in Figure 18. If the ligament is fully plastic with a stress distribution as shown, the collapse load is given by

$$P = \sigma_y \frac{B}{L}(W - a)^2 \tag{40}$$

The plastic-zone work is $U_p = Pu_p$, where u_p is the displacement. The general definition of fracture toughness R, analogous to G for stable growth, may be used:

$$R = J = \frac{1}{B}\frac{dU_p}{da}, \; u_p = \text{constant} \tag{41}$$

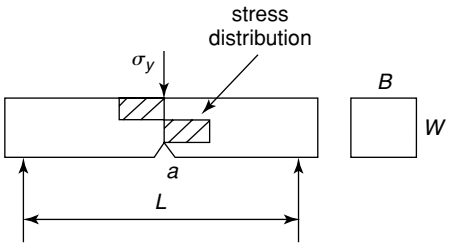

Fig. 18. Fully plastic three-point bending.

In the context of an important plastic deformation the computed toughness is termed J_c. Thus

$$J_c = \frac{2U_p}{B(W-a)} \tag{42}$$

This assumes a fully plastic ligament and ignores elastic effects but does allow J to be found in the fully plastic case. In fact, this form is true when elastic energy is included, provided that $L/W = 4$. This analysis has been widely employed for measuring the toughness of very tough materials since the stress state in the ligament is very close to plane strain for the three-point bend test. Thus, the J_c measured at crack initiation should be the same as G_c in an LEFM test. The specimens may be much smaller and the size criterion is

$$B \text{ and } (W-a) > 25\left(\frac{J_c}{\sigma_y}\right) \tag{43}$$

which is generally about a factor of 3 less than the LEFM value (11,22).

***J*-Integral.** Crack initiation in these fully plastic cases is usually followed by slow, stable growth, and it is often difficult to determine when growth has been initiated. It has been attempted to solve this problem by a procedure (22,23) in which several identical specimens with $a/W \sim 0.5$ are tested, but each is loaded to a different load-point displacement. The energy under each load-deflection curve is measured and J should be found from equation (41). Each specimen is broken open after cooling in liquid nitrogen to reveal the growth reached when the test was stopped. Growth is then plotted as a function of J and, by extrapolation to zero, J_c at initiation is obtained. However, the crack tip is often blunted considerably. This can be modeled by assuming a semicircular crack tip; the apparent blunting growth is then $\delta/2$ and this growth is given by

$$\Delta a_b = \frac{\delta}{2} = \frac{J}{2\sigma_y} \tag{44}$$

The extrapolation of the measured Δa values, which include Δa_b, should then be made to the blunting line of slope $2\sigma_y$. This is shown in Figure 19 in which A is the blunting line and B the initiation condition $J = J_c$.

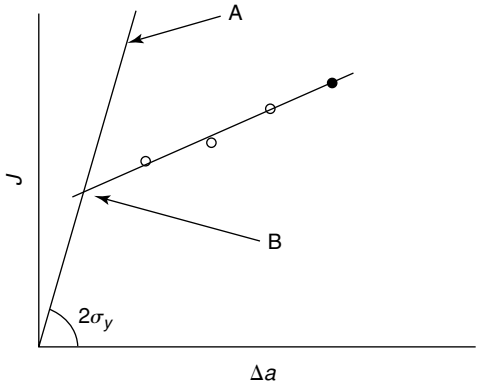

Fig. 19. Determination of J_c in a fully plastic three-point bend test, A: blunting line; B: initiation condition $J = J_c$.

Concept of Essential Work of Fracture (EWF). The EWF method was originally proposed for the evaluation of the fracture properties of thin metal sheets. In recent years, it has also been used for the characterization of the fracture behavior of tough polymers (24).

The EWF concept is based on the assumption that the total work of fracture W_f is the sum of two deformation energies W_e and W_p, dissipated in two distinct regions at the crack tip, the so-called process zone or inner fracture zone, and the outer plastic zone (Fig. 20a):

$$W_f = W_e + W_p \tag{45}$$

The energy dissipated in the process zone W_e, is related to the creation of new surfaces. It depends, therefore, on the size $A = lt$ of the surface of the zone to be fractured, where t is sample thickness and l the ligament length (see Fig. 20a). The energy W_p dissipated in the outer plastic zone depends on the volume V of that zone [proportional to the square of the ligament length and the sample thickness (24,25)]. W_e and W_p can therefore be expressed by

$$W_e = W_e A = w_e lt \tag{46}$$

$$W_p = w_p V = w_p \beta l^2 t \tag{47}$$

The quantity w_e is referred to as the specific essential work of fracture (in kJ/m^2) and the parameter w_p is called the specific nonessential or plastic work of fracture (in MJ/m^3). The factor β is dependent on the strain hardening capacity of the material, which determines the shape and extension of the plastic zone parallel to the loading direction. It is assumed that β does not vary with the ligament length (24). If this condition is met, then the force–displacement curves of specimens with different ligament lengths display the same shape. Using equations (45) and (46),

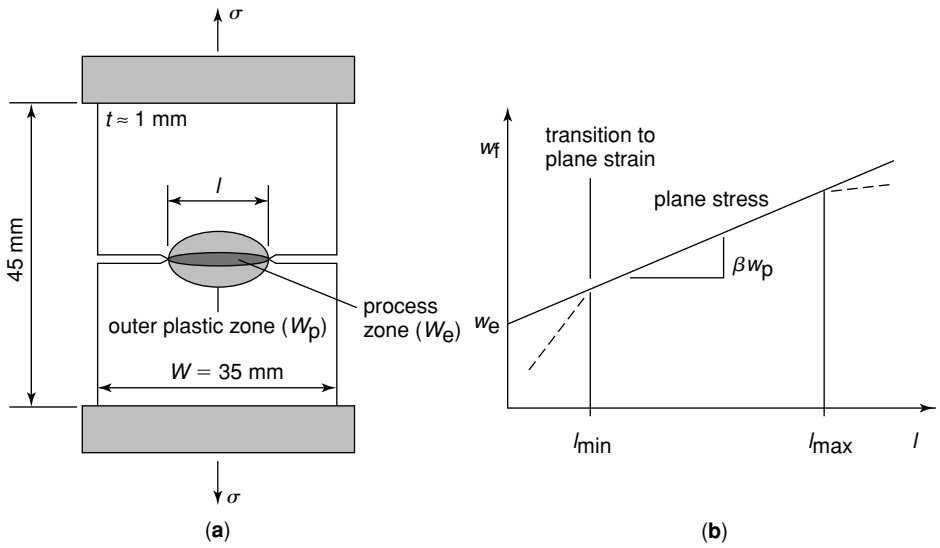

Fig. 20. (**a**) Double-edge notched tension (DENT) specimen and indication where the essential (W_e) and the nonessential work of fracture (W_p) is dissipated, (**b**) schematic EWF plot.

the total work of fracture can be expressed by

$$W_f = w_e l t + w_p \beta l^2 t \tag{48}$$

The specific work of fracture w_f is obtained by normalizing W_f:

$$w_f = \frac{W_f}{lt} = w_e + \beta w_p l \tag{49}$$

A plot of w_f versus the ligament length results in a straight line (EWF plot), as sketched in Figure 20b. The specific essential work of fracture w_e is given by the intercept of the EWF plot with the y-axis. The slope of the curve yields the plastic work term βw_p. This quantity is a geometry dependent measure of the ductility of the material since it depends on the size of the plastic zone and the specific plastic work. The essential work of fracture w_e is considered as a characteristic material parameter. For the evaluation of the EWF parameters w_e and βw_p, the European Structural Integrity Society (ESIS) protocol recommends the use of double-edge notched tension (DENT) samples. In principle, it is also possible to determine a w_e value for plane strain conditions (24). Evidently, w_e and βw_p are dependent on temperature and strain rate (21,25–27).

In order to ensure plane stress behavior, the DENT specimens must satisfy certain geometry requirements. Typically, there are two critical regimes in the EWF plot as sketched in Figure 20b. At low ligament lengths the stress state in the sample changes from plane stress to plane strain. As a result, w_f decreases more rapidly than for plane stress conditions. The ligament length corresponding to the transition from plane stress to plane strain behavior depends on the individual

polymer. The ESIS test protocol recommends for the lower limit of the ligament length a value of $l_{min} = 3t - 5t$ (24).

Samples with high ligament lengths often fail in a semibrittle manner prior to full ligament yielding owing to "edge-effects." The specific work of fracture therefore shows a negative deviation from the linear relationship. Full ligament yielding, however, is a prerequisite for the applicability of the EWF method. In order to exclude nonlinear behavior, the maximum ligament length should not exceed $l_{max} \approx W/3$ (24). This limit was proposed on the basis of previous investigations. The maximum ligament length can also be estimated from an analysis of the plastic zone size r_p at the crack tip. Nonlinear effects occur if $l > 2r_p$ (24). Usually, $W/3$ and $2r_p$ are close to each other. However, for some polymers the relationship between w_f and l remains linear beyond $l_{max} = W/3$ (22). In other words, l_{max} depends on the polymer in question.

As for the LEFM approach, the EWF data must be checked for validity. The maximum net section stress σ_{max} ($=F_{max}/lt$) in the ligament is supposed to depend very little on ligament length; it should satisfy the following relationship (24):

$$0.9\sigma_m < \sigma_{max}(l) < 1.1\sigma_m \tag{50}$$

where σ_m is the average value of the maximum net section stress σ_{max}. Data which do not satisfy equation (49) should be rejected from the determination of w_e and βw_p. Furthermore, the net section stress σ_{max} in the ligament should not exceed the theoretical stress in the ligament of DENT specimens at the onset of yielding. Under plane stress conditions the latter quantity is given by the following relation:

$$\sigma_{max} = 1.15\sigma_y \tag{51}$$

Note, it is probable that $w_e = G_c$ for the appropriate stress state.

Fracture Development

Initiation and Propagation. Most polymer objects are homogeneous on a macroscopic scale and their first response to a (gradually) applied critical load is a more or less homogeneous deformation, which eventually will turn into the different forms of ductile or brittle failure. For brittle fracture to occur the homogeneous deformation has to become localized, whereas ductile failure generally involves a more extended region (Fig. 2) and occasionally the whole specimen. Ductile deformation phenomena leading to polymer failure include yielding with and without neck formation, creep, and flow. The latter two phenomena certainly do not comply with the definition of fracture given in the introduction, since neither creep nor flow would give rise to the formation of new surfaces within the body. All these phenomena and the criteria of their initiation are discussed elsewhere in this Encyclopedia (see MECHANICAL PROPERTIES; VISCOELASTICITY). Reference will be made where appropriate since these phenomena frequently precede and/or modify subsequent brittle fracture.

The most likely sites for *crack nucleation* or *initiation* are irregularities of the polymer network or stress concentrators already present such as defects, inclusions, or surface scratches. Generally, a nucleus or a defect need to grow,

sometimes for a long time, before they reach a size sufficient to influence their own growth and to provoke eventually the instability of the loaded object. Thus, the following four stages of fracture development can be distinguished:

(1) **crack nucleation**

(or activation of an existing defect);

(2) **thermally activated extension**

in mode I the plane of crack growth is rather smooth (mirror), the rate $\dot{a}$ normally increases with crack length a and stress intensity factor K (eq. (34)), $\dot{a}$ decreases through crack tip blunting (or at constant external displacement due to the increase in compliance C, eq. (7)). Such a decrease can lead to crack arrest and also give rise to the so-called stick-slip behavior of crack propagation;

(3) **nucleation of secondary cracks**

ahead of the primary crack and thermally activated coalescence between primary and secondary crack planes leading to some roughness of the fracture surface. The rate of crack propagation can increase notably during this stage, thus its contribution to the total time under stress of a sample can mostly be neglected;

(4) **unstable crack propagation**

once K_{Ic} is reached [$G_c > R(a)$].

In Figure 21 the fracture surface of a specimen of PMMA is shown. Loaded in tension, the specimen deformed homogeneously up to 70 MPa when brittle fracture occurred. It is important to point out that even under the condition of apparently instantaneous fracture, a semicircular, mirror-like zone had grown in a stable manner to about one half of the specimen thickness (stages 2 and 3).

The specimen failed after K_{Ic} was reached. These different stages exist in most cases of tensile brittle fracture, but their duration, their relative importance, and additional structural features (Wallner lines in impact, parabolic markings due to the initiation of secondary cracks, striations in fatigue) depend on the stress–time history (19).

In order to understand and avoid (or at least, to predict correctly) a fracture event, one has to know the elementary molecular mechanisms involved in crack advance and the effect of the principal extrinsic and intrinsic variables. In the following we will discuss, therefore, the strength determining structural elements of the different polymer classes.

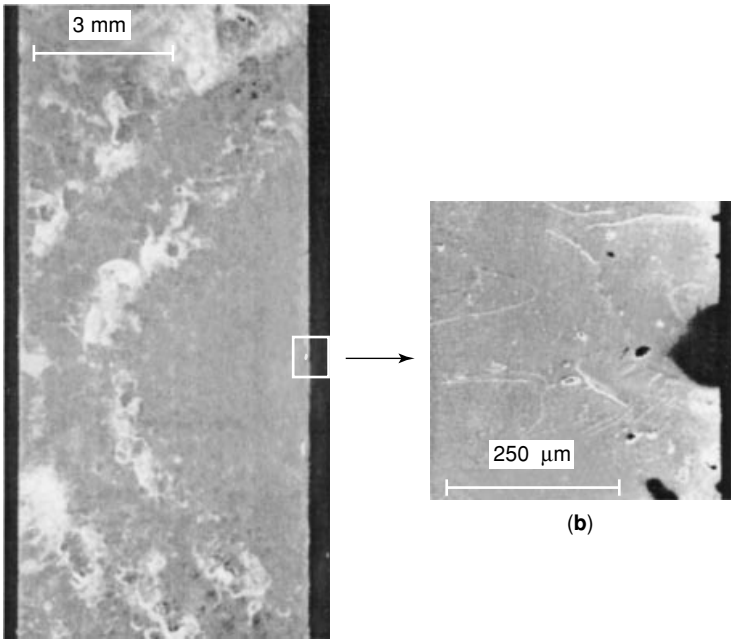

Fig. 21. Brittle fracture of a PMMA specimen loaded in tension at 23°C; (**a**) the surface shows the semicircular, thermally activated crack grown to about one half of the specimen thickness, (**b**) crack initiation at a surface defect.

Essential Elements of Polymer Structure. *Amorphous thermoplastics* are formed by randomly coiled, interpenetrated chain molecules, which cohere by weak van der Waals forces. To give tenacity to such a physical network it is indispensable that stresses are transferred by the chain backbones over long distances. This requires long, well entangled chains. The molecular weight M_w must be many times larger than the molecular weight between entanglements (M_e). And the entanglement density ν_e has been found to be a prime parameter controlling the tendency for crazing of glassy polymers (see CRAZING)) (12). Readily crazing polymers like polystyrene have a ν_e of the order of 3×10^{25} m^{-3}, whereas tough homopolymers generally have a $\nu_e > 20\times10^{25}$ m^{-3}. In fact, compiling data from literature (26,27) shows that K_{Ic} scales with $\nu_e^{1/2}$ (Fig. 22).

The same conditions concerning M_w and ν_e also apply to semicrystalline polymers (see Fig. 22). In addition, semicrystalline thermoplastics are characterized by their heterogeneous, lamellar, and frequently spherulitic structure (Fig. 23). Morphological features of particular importance for the deformation behavior include the size, morphology, and perfection of spherulites, the strength of the interspherulitic boundaries, and the physical structure of the crystalline phase. The smallest building-blocks considered here are aggregates of crystal lamellae connected by amorphous regions (Fig. 24). These latter consist of a network of nonextended entangled chains, dangling chain ends and/or loops, and more or less taut tie-molecules. Above T_g there is a pronounced difference between the

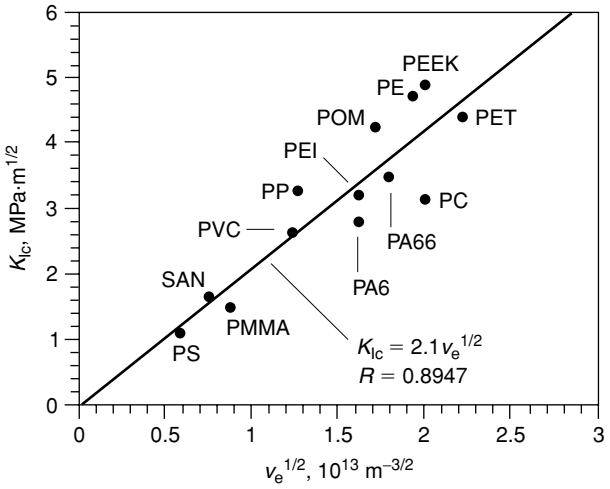

Fig. 22. Representative static plane-strain toughness values of different amorphous and semicrystalline thermoplastics as a function of the square root of the entanglement density. From Refs. 26 and 27.

Young's modulus of an amorphous region (typically very much less than 1 GPa) and that of a crystalline lamella in the chain axis direction (235 GPa for orthorhombic polyethylene and 40 GPa for helical isotactic polypropylene). Thus, the amorphous regions will account for most of the elastic and anelastic deformation. The regions oriented perpendicular to an applied (uniaxial) stress will initially mainly deform by interlamellar separation (Fig. 24c). In this case, strong hydrostatic tensions within the constrained amorphous network are created. At the same time, the tie chains become more extended and transfer locally concentrated elastic stresses to the lamellae (28). Stress relief can occur in three ways: by homogeneous deformation of the amorphous network (only possible in thin films), through void formation in the interlamellar regions involving chain scission, segmental slip and/or disentanglement (Fig. 24f) and/or through crystal plastic deformation (Figs. 24d and 24e).

Thermoplastic elastomers, blends, and filled polymers also show a superstructure consisting of different phases. These structures and their pronounced

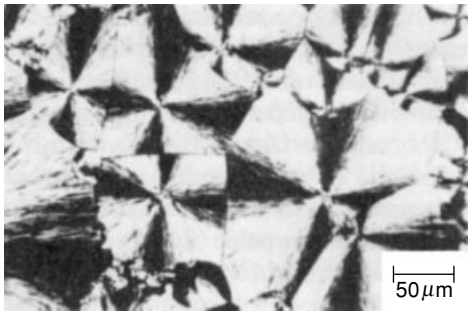

Fig. 23. Spherulitic structure of melt-crystallized polypropylene.

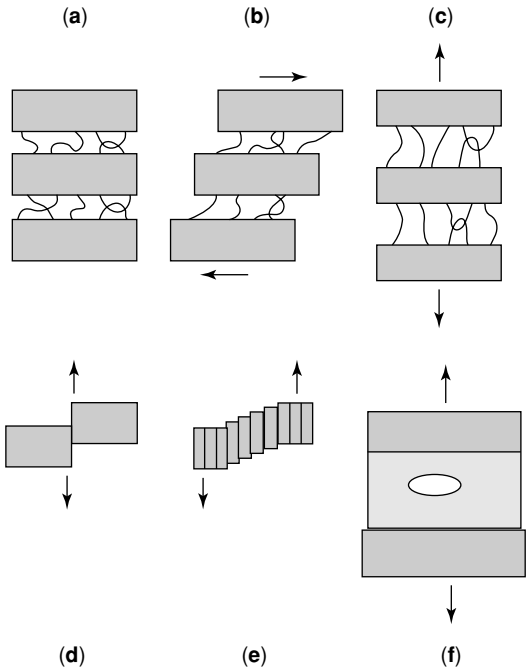

Fig. 24. Schematic representation of the possible deformation processes of a stack of crystal lamellae: (**a**) the initial state, (**b**) interlamellar shear, (**c**) interlamellar separation, (**d**) intralamellar block shear, (**e**) intralamellar fine shear (not shown: bending and rotation of lamellae), and (**f**) cavitation within the amorphous regions.

effect on the deformation mechanisms and ultimate properties will be discussed elsewhere (see ELASTOMERS, THERMOPLASTIC; POLYMER BLENDS).

Filled rubbers form a complex network of cross-linked chains connected to surface-active particles such as carbon black or amorphous silica (see CARBON BLACK). Here we will only indicate the structural features of importance in unfilled cross-linked elastomers. Two breakdown mechanisms are conceivable: the initiation and growth of a cavity in a moderately strained matrix and the accelerating, cooperative rupture of interconnected, highly loaded network chains. The second mechanism is more important under conditions, which permit the largest breaking elongation λ_{bmax} to be attained (29). In that case, the quantity λ_{bmax} is expected to be proportional to the inverse square root of the cross-link density ν_e; in fact, an increase of λ_{bmax} with $\nu_e{}^{-0.5}$ to $\nu_e{}^{-0.78}$ is found experimentally for a variety of networks. The maximum elongation λ_{bmax} is the *only* feature of large deformation behavior which depends only on network topology (29).

The structure of cross-linked resins is characterized by the average mass M_c of the segments between cross-links, their configuration and by the nature of the cross-linking agent (for instance amine-cured epoxy resin systems show distinct β-relaxations resulting in greater toughness and flexibility and in higher T_g values as compared to anhydride-cured polymers). Generally, Young's modulus in the glassy state, yield strength and the glass transition temperature increase with $1/M_c$, that is, with increasing cross-link density. On the other hand, the critical

crack opening displacement δ_c and the critical energy release rate G_{Ic} grow with M_c (30).

Deformation and Damage Mechanisms of Thermoplastic Polymers

Effect of Temperature. In the context of this article we will discuss the fracture behavior of thermoplastic polymers more extensively. When a spherulitic sample is strained, local strains within a lamellar stack will vary considerably, depending on the local Young's modulus, the relative orientation of the lamellar stack with respect to the principal stress direction, and on the intensity and relative importance of the elementary deformation and damage mechanisms. The activation energies of such mechanisms are widely different and their rates vary accordingly. The potential barrier U_{tt} for twisted translation of, eg, a CH_2-group with respect to its neighbor in a polyethylene-crystal is at room temperature 2.1 kJ/mol, whereas the energy U_s for chain scission amounts to 335 kJ/mol. The tensile deformation of HDPE at room temperature and modest rates of loading is below the yield point determined by lamellar separation, interlamellar shear, and some uncorrelated intralamellar slip [preferentially along the (100) plane]. Correlated intralamellar (coarse block) slip was observed at Hencky strains ε_H between 0.1 and 0.6, lamellar fragmentation and fibril formation at $\varepsilon_H > 0.6$, and truly plastic flow at $\varepsilon_H > 1$ (27,31–33). The considerable plastic deformation remains homogeneous under these conditions, and it leads to a highly oriented fibrillar structure which finally fractures in a fibrous manner and at very little additional deformation.

This behavior changes with decreasing temperature. The amorphous regions stiffen below T_g, conformational changes and intra-lamellar slip processes become more difficult, the overall yield is suppressed (Fig. 25F), the density of stored elastic energy increases, and the deformation becomes more and more localized. The mode of fracture is particularly influenced by the competition between *correlated intralamellar slip* and the *cavitation* within and *fibrillation* of the amorphous intercrystalline regions. The former mechanism dominates at higher temperature and modest rates of deformation and leads to extended plastic deformation, the latter giving rise to craze-like features and stress whitening. Depending on the stability of the formed craze micro fibrils the stress-whitened zones can be more or less extended. Fracture at liquid nitrogen temperature (Fig. 25A) is initiated by the scission of interlamellar tie-molecules (33).

As a second example the fracture behavior of an amorphous, unplasticized poly(vinyl chloride) (PVC) is presented (Fig. 26). At low temperatures there is no intersegmental slip, fracture stresses σ_b are high, and fracture is brittle showing a substantial variability in σ_b. This is explained by the presence of a large number of network irregularities and/or flaws of different size or severity, the most severe of which determines the fracture strength. With the onset of chain relaxation and small-scale plastic deformation, the elastic strain energy at the crack tip is reduced and possibly some local strain hardening occurs (34,35). This counterbalances the detrimental effect of a defect leading to much less scatter in the semibrittle and ductile regions (Fig. 26). Evidently, elimination of defects not only reduces the observed scatter but also increases the service life of a structure (19,36).

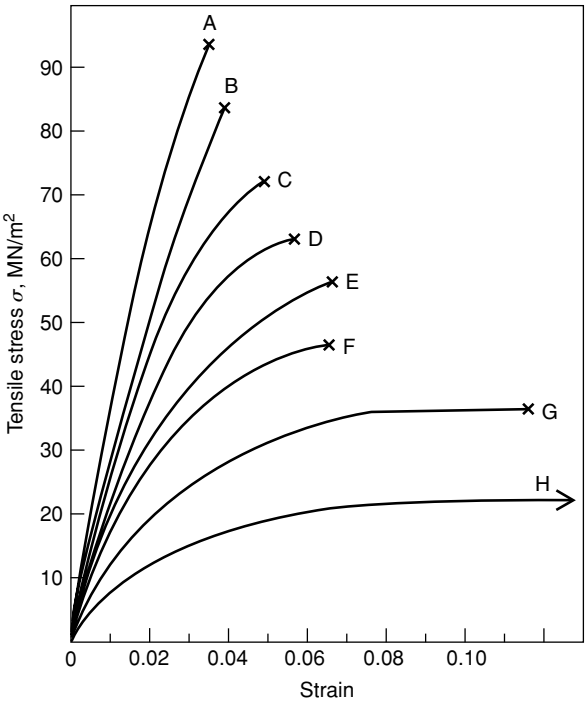

Fig. 25. Stress–strain curves of polyethylene at different temperatures: A, 93 K; B, 111 K; C, 149 K; D, 181 K; E, 216 K; F, 246 K; G, 273 K; H, 296 K. From Ref. 32.

Effect of Loading Rate. As to be expected for a viscoelastic material, increasing the rate of loading has the same effect as decreasing the temperature. As an example the behavior of a high molecular weight polypropylene (PP) is shown schematically in Figure 27. It exhibits the same deformation and fracture phenomena mentioned above, which range from extensive shear and stress whitening (at loading rates v from 0.1 to 1 mm/s) to small scale yielding and crazing (10 mm/s), multiple crazing (50 mm/s to 1 m/s), and the formation of a single craze turning into a crack (at $v = 2$–10 m/s) (26,27).

The evolution of the critical stress intensity factor of the PP homopolymer reflects perfectly well the observed stress–strain behavior. Toughness K_{Ic} decreases with the decreasing amount of plastic deformation at increasing rates of loading. This is different, though, for rubber toughened PP where the rate of cavitation of rubber particles increases with loading rate. The cavitation gives rise to local matrix plasticity and thus to an increase in K_{Ic} (Fig. 28, see also Figs. 32 and 33) (21,26,27).

Stress Transfer and Internal Main Chain Mobility. In concluding this section it can be stated that brittle fracture of a polymer occurs if two conditions are met: firstly, lateral stress transfer between segments must be efficient so as to build up a high strain energy density. And secondly, internal main chain mobility must be small since it would counteract large axial chain stresses. The competition between stress transfer and stress relaxation determines the level of stored energy (which can be reached), the damage (which is created or activated), and the

mode of fracture. This is convincingly shown by the brittle fracture of elastomers at liquid nitrogen temperature when the axial stresses imposed onto the chains by intersegmental shear become so important that chain scission occurs (19,37). The critical tensile stress for brittle fracture of a thermoplastic is well correlated with the level of interaction between (or packing density of) the chain backbones (19,38). On the other hand, reducing the degree of crystallinity (through quenching, introduction of chain branching, or addition of an atactic component) improves toughness at the expense of sample stiffness. This statement is corroborated by the decrease of the impact resistance rating of a homopolymer with increasing storage modulus (brittle if $E' > 4.49$ GPa, brittle if bluntly notched if $E' > 3$ GPa) (19,38). The role of chain mobility is demonstrated by the positive correlation between

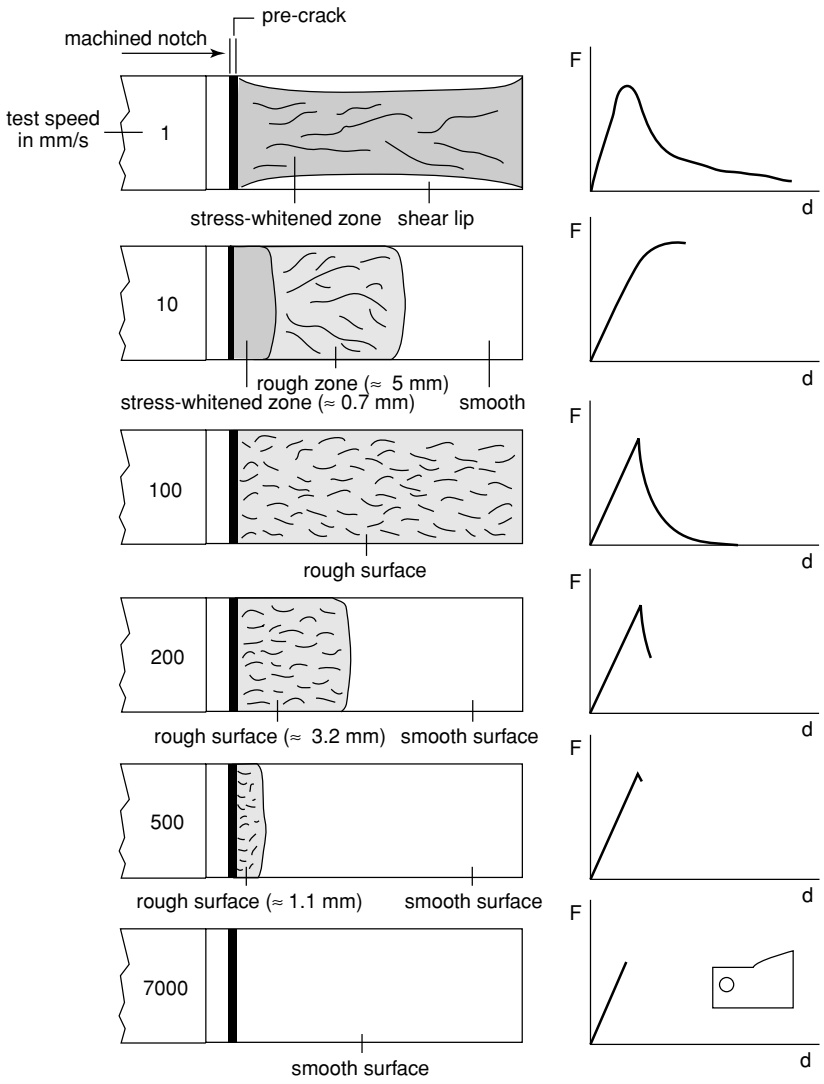

Fig. 27. The effect of loading rate on the mode of fracture of a high molecular weight PP. From Refs. 26 and 27.

polymer toughness and the β-peak intensity of tan δ (21) and by the frequent coincidence of the temperature of secondary relaxations with that of brittle–ductile transitions (19,39). The fine interplay between lateral stress transfer and chain mobility can be seen by the different craze extension modes displayed by a methyl methacrylate glutarimid copolymer strained at different temperatures (40,41). At $T < 0^\circ$C, craze tips are sharp and grow by chain scission and at $T < 50^\circ$C, stresses at the craze tip are distributed by chain slip over diffuse deformation zones, which become more confined at 80°C. Secondary crazes appear because of disentanglement, if straining is done at 130°C, and the sample deforms homogeneously above the glass transition at 145°C.

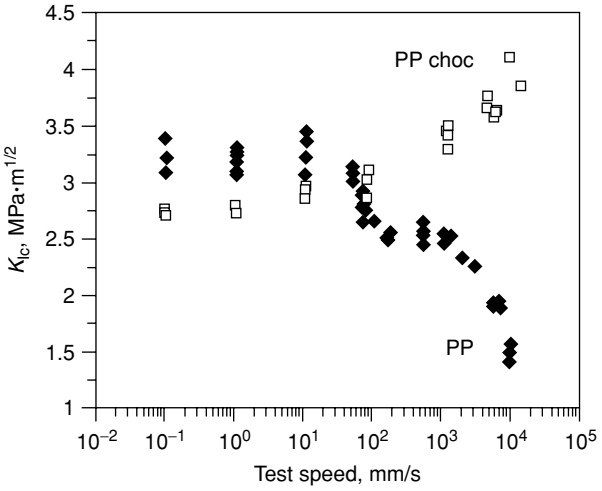

Fig. 28. The effect of loading rate on the toughness of a high molecular weight PP. From Refs. 26 and 27.

Two important modifications have to be mentioned, which permit to control stiffness and toughness of a polymer material separately: polymer orientation and reinforcement through a second phase such as core-shell particles, mineral fillers, or short fibers (see REINFORCEMENT).

Durability

All the above examples concern the more or less rapid loading of a sample up to fracture. The most frequent load histories, however, are application of a constant load at a level much below the fracture strength (see VISCOELASTICITY) or the repeated application of a (regularly or statistically) varying load (see FATIGUE). The long-term strength or durability of a polymer material depends foremost on its resistance to slow crack growth and to environmental attack.

Slow Crack Growth. Many thermoplastics exposed to constant and moderate stresses over extended periods of time, as for instance pipes under internal pressure, fail in either of two different modes, in a ductile or in an apparently brittle manner. The durability is often represented as a stress–lifetime (σ–t) diagram (Fig. 29). The simultaneous action of two failure mechanisms gives in this case rise to two different branches of the lifetime curves. At moderate stresses (above $\sim$50% of σ_y) the HDPE pipes fail in a ductile manner because of plastic instability of the creeping material (Fig. 2, which corresponds to Point 1 in Fig. 29). The ductile failures are strongly stress-activated (E_a = 307 kJ/mol) giving rise to the flat portions of the σ–t curves. Fracture at smaller stresses and after more extended time periods often occurs in an apparently brittle manner by thermally activated slow crack growth (SCG) (steep branches in Fig. 28, E_a = 181 kJ/mol). Such a crack usually initiates from a defect, mostly at a boundary (Fig. 30a); it grows by transformation of matrix material into fibrillar matter. Further growth of this craze-like feature occurs through the disentanglement and breakdown of the numerous microfibrils, which leave some traces on the (moderately plane) fracture

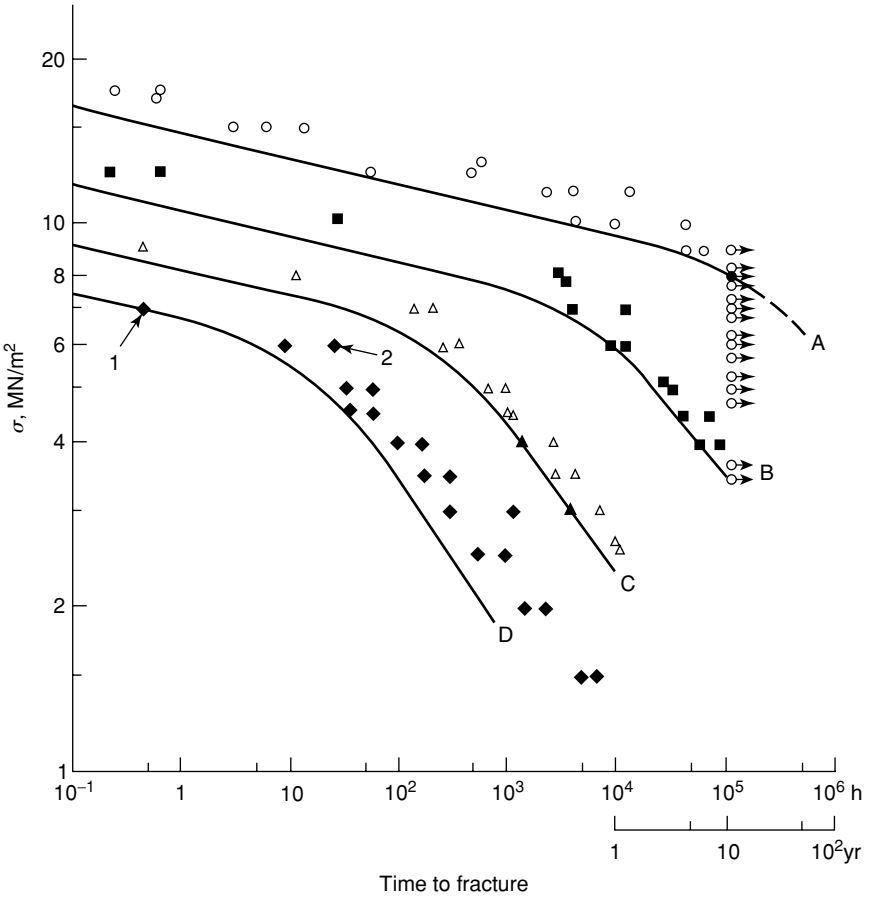

Fig. 29. Times to failure of HDPE water pipes under internal pressure p at different stresses and temperatures: A, 20°C; B, 40°C; C, 60°C; D, 80°C. 1 = ductile failure (see Fig. 2); 2 = creep crazing (see Fig. 28). Circumferential stress $\sigma = d_m/2s$, where d_m = average diameter and s = wall thickness. From Ref. 19.

zone (Fig. 30b). The temperature dependence of the two failure mechanisms—and of the transition points—follow an Arrhenius equation. The displacement with temperature of the two branches in the (σ–t) diagram is generally highly regular, so that reliable predictions may be made of the lifetime as a function of stress level by extrapolation of the steeper branch (42).

The rate $\dot{a}$ of SCG increases with the applied stress and the time-to-failure decreases. For HDPE, the rate $\dot{a}$ has been found to be proportional to K_c^4 (17; Fig. 15). The rate is reduced by all parameters, which increase the number of tie-molecules and/or make chain pull-out and disentanglement more difficult like high molecular weight and presence of short-chain branches (SCB). A dramatic increase of durability with branch density has been found (43,44). A density of 5 butyl-groups/1000°C increases the time-to-failure of linear HDPE by up to a factor of 10^4 with the resistance to SCG of an ethylene–hexene copolymer residing in those chains whose $M_w > 1.5 \times 10^5$ (44). There is an indication of a threshold

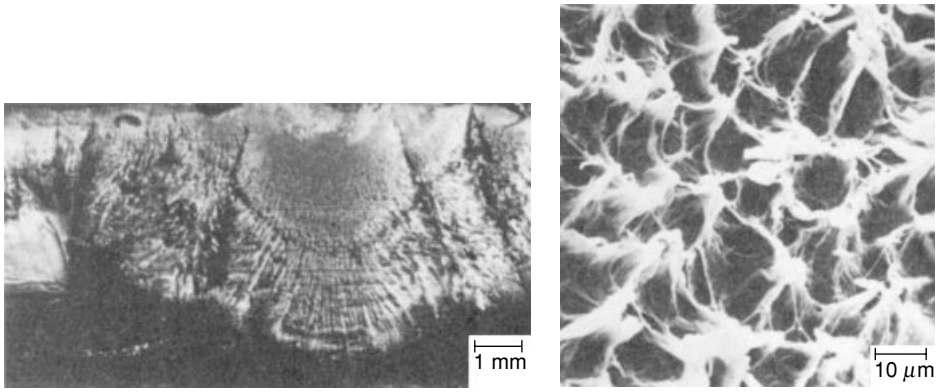

Fig. 30. (**a**) Surface of a creep craze formed in HDPE under conditions shown as point 2 in Figure 27: $\sigma_v = 6$ MN/m^2, $T = 80°$C; (**b**) Detail of the fracture surface close to the upper center of the zone which was apparently the point of creep craze initiation. From Ref. 19.

value for the hoop stress, below which defects do not develop into creep cracks (45). Under such conditions, a third and horizontal branch of the σ–t_b curve is observed (at about 3 MPa for HDPE at 80°C). SCG can be substantially reduced by cross-linking, as for instance observable in peroxy cross-linked HDPE (46).

While most studies of durability show a linear log (t_b)–log (σ) relationship, the slopes may vary depending on sample geometry, crack tip blunting, preorientation, or material degradation. Long-term studies with fully notched tensile specimens basically confirm the results of Figure 29 (47,48). This creep rupture test is a reliable and rapid method and much simpler to perform. A perfect proportionality was found (48) between the times to failure t_b in hydrostatic pipe rupture tests and the t_b in uniaxial, fully notched creep tests, the latter being 10 times faster, however. The use of a surfactant (ethylene glycol) accelerated the tests by another factor of 4 while maintaining the proportionality between the times to failure of the different (pipe) materials, thus permitting their grading. Such a possibility (to accelerate tests) is especially welcome in view of the continuous improvement of resins. In fully notched creep tests (according to ASTM F1473), an increase in lifetime (by a factor of 1.5–2) in the transition region was observed (47) when the stress was increased to such a level that ductile deformation just became the dominant mechanism. This effect, due to crack tip blunting, leads to a hook in the σ–t_b diagram (47). They also report an abnormal temperature-shifting behavior for some copolymers of ethylene with hexene or octene.

From the original concept of flow, ie, the thermally activated motion of molecules across an energy barrier, various fracture theories of solids have emerged, considering, eg, a reduction of primary and/or secondary bonds (19,49, 50). The importance of primary bonds for static strength had been deduced very early from the dependencies of sample strength on molecular weight and volume concentration of primary bonds. A more general approach, the rule of cumulative damage (51), does not explicitly specify the nature of the damage incurred during loading, but attempts to account for the influence of load history on sample

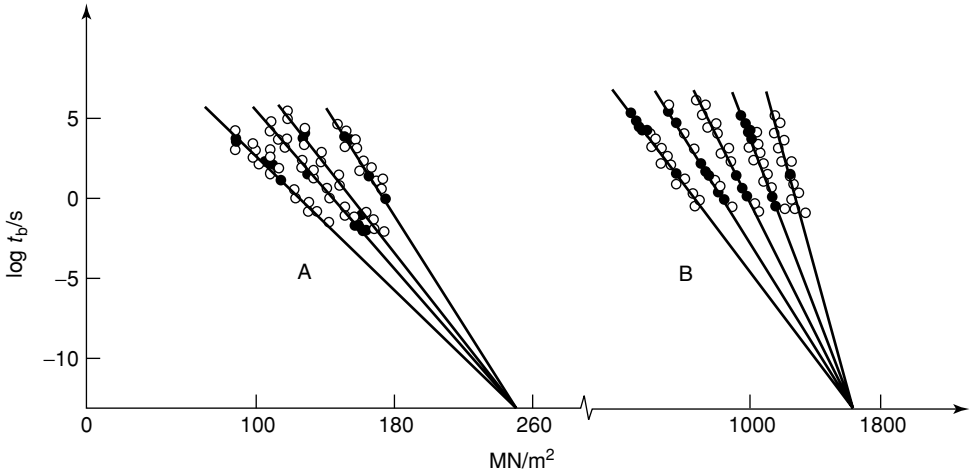

Fig. 31. Times to fracture under constant uniaxial load σ_0. A, Cellulose nitrate (CN) at temperatures of 70, 30, −10, and −50°C, reading from left to right. B, Nylon-6 at temperatures of 80, 30, 18, −60, and −110°C, reading from left to right. To convert MN/m^2 to psi, multiply by 145. From Refs. 19 and 50.

strength. The kinetic theory of fracture proposes that the "rate of local material disintegration" is proportional to $1/[t_b(\sigma_0)]$ and that fracture occurs after a critical concentration of damage has been attained:

$$t_b = t_0 \exp(U_0 - \gamma\sigma_0)/\mathrm{RT} \tag{52}$$

The three parameters involved have to be interpreted as energy of activation U_0 of breakage of some bonds (primary or secondary), as an inverse of a molecular oscillation frequency t_0, and a structure-sensitive parameter γ. Experimental data and theoretical curves according to equation (51) are given in Figure 31. At this point it should be stated again, that the durability of a polymer does not so much depend on the ultimate strength—and breakage—of the backbone chains, but on their capacity to effectively transmit stresses over long distances. This capacity suffers from low molecular weight and all chain parameters, which favor slip, pull-out, and disentanglement.

At relatively high temperatures, the lifetime is limited by a third mechanism, the oxidative degradation of the backbone chains. Such loss in mechanical strength can occur abruptly, giving rise to a vertical branch of the σ–t_b curve (26,45,46, 52). In order to retard oxidative damage, stabilizers are added to most polymers, especially to polyolefins and PVC (see DEGRADATION). The presence of a stabilizer not only has a positive effect on the time of final breakdown but it also appears to reduce the rate of SCG (45), probably by hindering the selective degradation of highly loaded tie-molecules (26,27). On the other hand, the lifetime is reduced if stabilizer is extracted from a pipe wall through contact with an active liquid. Active agents in this respect include even stagnant, deionized hot water (52). A still greater reduction in lifetime will occur in the presence of certain surface-active media or of a liquid under flow (see below).

Multiaxial Stress Criteria and Environmental Effects

Multiaxial States of Stress. Throughout this article we have indicated that failure depends on the level and on the multiaxiality of stress. The classical approach to predict safe operating conditions is based on the assumption that failure must be expected whenever the components of the stress tensor (usually the three principal stresses σ_1, σ_2, and σ_3) combine in such a way that a strategic quantity reaches a critical value C (19,53). The condition $f(\sigma_1, \sigma_2, \sigma_3) = C(T, \varepsilon)$ represents a two-dimensional failure surface in three-dimensional stress space. Such failure criteria, which are not based on fracture mechanics, describe most commonly the initiation of Crazing or Yielding. They have to be considered here for two reasons. In the first place they permit to judge whether crazing or general yielding are initiated *before* brittle fracture. Secondly, they help to predict the extent of local plastic deformation, which has a notable influence on toughness. In the following we will mention three criteria, which are applied to the shear yielding of homogeneous polymers, to craze initiation and to the formation of voids or cavities respectively.

Shear Yielding. The most widely used criterion of von Mises is based on the assumption that only the energy of distortion determines the criticality of a state of stress. It can be expressed as

$$(\tau_{\text{oct}})^2 = \frac{1}{9}[(\sigma_1 - \sigma_2)^2 + (\sigma_2 - \sigma_3)^2 + (\sigma_3 - \sigma_1)^2] < (\tau^*)^2 \tag{53}$$

where τ^* designates a critical value, which could be expressed in terms of eg, the octahedral shearing stress τ_{oct}, or the yield stress τ_{y} in pure shear. The above expression does not take into account the rigidifying effect of hydrostatic pressure. Thus, the critical octahedral shear stress should be corrected accordingly:

$$\tau_{\text{oct}} < \tau_0 - \mu p \tag{54}$$

where μ describes the sensibility of yield stress to pressure. If $p = (\sigma_1 + \sigma_2 + \sigma_3)/3$ (the hydrostatic component of the stress tensor) is positive, it designates a tension, which reduces τ_{oct}. On the other hand, application of compressive stresses or external hydrostatic pressure will increase the critical (octahedral) shear stress. This leads to a difference between the uniaxial compressive strength σ_{cb} and the uniaxial tensile strength σ_{tb}, the ratio $m = \sigma_{\text{cb}}/\sigma_{\text{tb}}$ varying between 1 and 1.45 (see YIELDING).

Craze Initiation. Although the effect of multiaxial states of stress on the brittle and ductile failure of isotropic polymers is sufficiently well represented by the above classical failure criteria, this is not the case for crazing or the failure of anisotropic polymers, ie, oriented sheets, fibers, single crystals, etc. For craze initiation we will cite the stress-bias criterion as proposed by Sternstein (54):

$$\sigma_{\text{craze}} = |\sigma_1 - \sigma_2| \geq A(T) + \frac{B(T)}{\sigma_1 + \sigma_2 + \sigma_3} \tag{55}$$

where A and B are functions of the temperature T. For uniaxial stress two elegant formulations exist, namely the relation of Kambour (55) that σ_{craze} is a linear function of the cohesive energy density (CED) times ΔT (where $\Delta T = T_g - T_{test}$), and that of Wu (56) that σ_{craze} is linearly related to the entanglement density ν_e.

Formation of Voids or Cavities. Voids or cavities are most likely formed in flexible polymers subjected to triaxial strains. It is a major mechanism to initiate heterogeneous deformation in elastomers, in the amorphous phase of semicrystalline polymers above its T_g and in elastomer-modified polymers (57). Based on these considerations, the volume strain ε_v has been used as a critical quantity (26,27,58):

$$\varepsilon_v = (1+\varepsilon_{xx})(1+\varepsilon_{yy})(1+\varepsilon_{zz}) - 1 \tag{56}$$

It is supposed that cavities (in elastomeric modifier particles) form wherever $\varepsilon_v > \varepsilon_{vc}$. The volume strain ε_v in the vicinity of a sharp crack (in the plane of the crack, for opening mode I and for small strains) can be expressed as

$$\begin{aligned} \varepsilon_v &= \frac{2K_I}{E\sqrt{2\pi r}}(1-\nu-2\nu^2)(\text{plane strain}) \\ \varepsilon_v &= \frac{2K_I}{E\sqrt{2\pi r}}(1-2\nu)(\text{plane stress}) \end{aligned} \tag{57}$$

If Poisson's ratio ν is taken to be 0.43 (as for a semicrystalline, rubber-modified polypropylene), the term in parentheses amounts to 0.20 in plane strain and to 0.14 in plane stress. This means that the critical distance where $\varepsilon_v > \varepsilon_{vc}$ is by a factor $1/\sqrt{(0.20/0.14)} = 2$ *larger* in plane strain than in plane stress. The same applies for the size of the plastic zone if matrix plastic deformation is triggered by particle cavitation. This is a remarkable result since it is exactly the opposite of what the von Mises criterion would predict.

For a rubber modified polypropylene Gensler has numerically determined the contours of the (plastic) zone where a critical volume strain of 0.4% was exceeded for deformation rates of 100 and 5800 mm/s, and for plane stress and plane strain conditions, respectively (Fig. 32) (26,27). The shape of the calculated cavitation zone corresponds reasonably well to the actual shape of the stress-whitened zone (see Fig. 33a). Under both plane stress and plane strain conditions, the size of the plastic zone increases slightly with increasing test speed. What seems to be more important, however, is the gradual change of the stress state from plane stress to plane strain, which is responsible for the significant increase of the extension h of the plastic zone with increasing testing speed (Fig. 33a). These studies confirm again the excellent correlation between the toughness K_{Ic} and the size of the plastic zone (Fig. 33b) (26,27).

Environmental Effects. Environmental parameters acting on a specimen from outside are generally classified as physical (electromagnetic radiation, particle irradiation), physicochemical (like wetting or swelling), or chemical (oxidation, other forms of chemical attack). The action of these latter parameters mostly influences the strength of a polymer through the intervening structural changes (see also DEGRADATION; RADIATION CHEMISTRY OF POLYMERS; WEATHERING). At this point a special effect, the formation of environmental stress cracks (ESC) has to

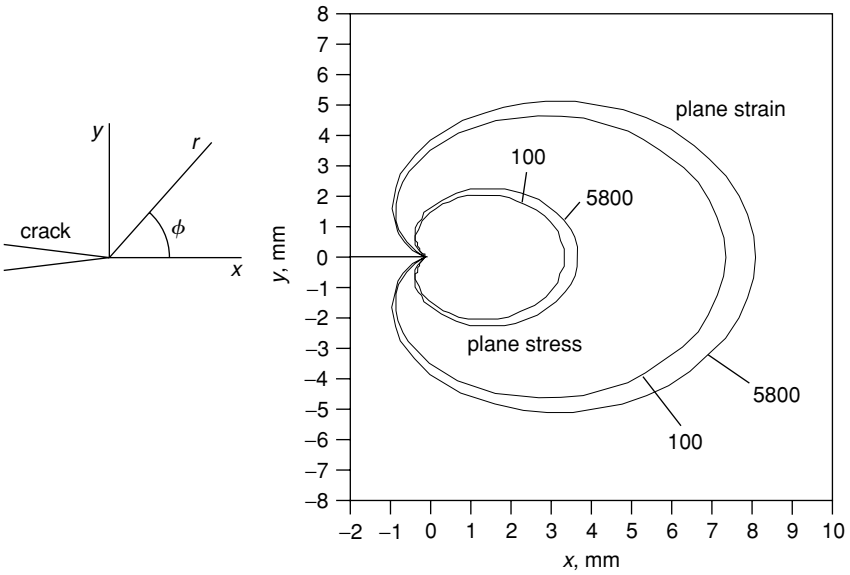

Fig. 32. Calculated shape of the plastic zone ahead of the crack tip in CT specimens of impact modified high molecular weight polypropylene as a function of test speed (100 and 5800 mm/s) and stress state. From Refs. 26 and 27.

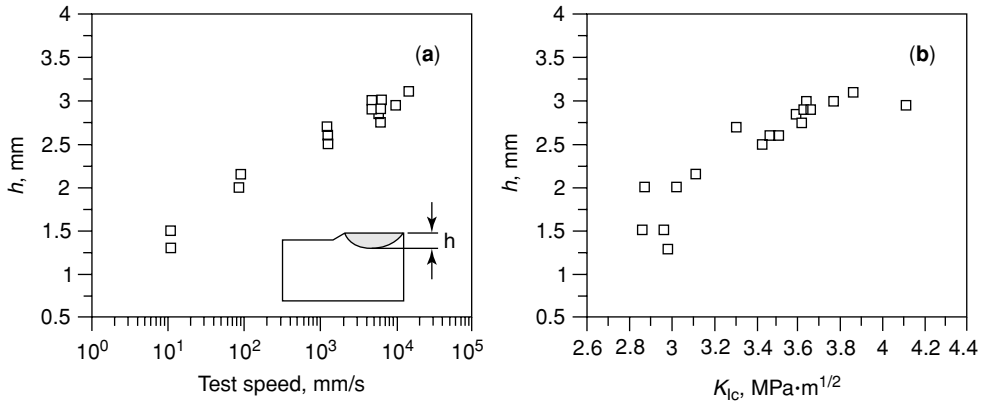

Fig. 33. Extension h of the stress-whitened zone parallel to the loading direction as a function of (**a**) the test speed and (**b**) the stress intensity factor K_{Ic}. From Refs. 26 and 27.

be discussed. Such a synergistic interaction between mechanically stressed polymers and the ambient medium is observed in many rubbers and thermoplastics in contact with sensible liquid or gaseous environments. The origin of ESC is a stress-enhanced sorption and/or diffusion of the environmental agent by the polymer, which leads to swelling and plasticization (or even degradation) of the contacted (surface) zone of the polymer. The increased local chain mobility greatly facilitates crazing and eventually cracking. The critical strain ε_c for craze initiation can be notably reduced as compared to that in air or in an inert medium

(dry crazing). For amorphous polymers, a strong correlation between ε_c and the difference $\{\delta_s - \delta_p\}$ of the solubility parameters of environment (s) and polymer (p) has been found (12,19,59). The smallest values of ε_c are usually observed for those polymer-solvent pairs where the equilibrium solubility S_v shows a maximum. The action of alcohols on PMMA, of Lewis acids and some metal salts on polyamides, and of hydrocarbons and detergents on polyolefins should be specifically mentioned (59).

Environmental agents also influence the later stages of stress cracking, ie, craze growth and breakdown, resulting in crack formation. The fracture-mechanics concept has proved to be useful to explain quantitatively the kinetics of crack growth in a liquid environment if the wetting, spreading, flow, and diffusion behavior of the liquid at the crack tip and within the capillaries opened up through the craze are taken into account. The three typical stages of environmental stress cracking are well represented by a semicrystalline polymer, LDPE in contact with a detergent (Fig. 34). Sorption starts with the application of stress, but for an incubation period (t_i) the stress-cracking agent has no, or little, apparent effect. In the following period there is a rather modest increase in durability with decreasing K_c, since at this stage SCG is strongly assisted by the action of the active liquid (Stage II, steep slope of the K_c–t_b curve). A durability threshold is only attained at a very low level of K_c (Fig. 34). On the other hand, in the absence of the stress-cracking agent the rate of SCG depends very strongly on the applied stress intensity factor K_c (eq. (34)). Thus one observes a very pronounced increase in durability if K_c is decreased from the value of the initial toughness of $K_{Ic} = 0.9\ \text{MPa} \cdot \text{m}^{1/2}$ (a rather flat K_c–t_b curve). An amorphous polymer [ABS with and without a nonionic surfactant (60)] would behave in a rather similar manner also exhibiting these three different stages.

The ESC fracture behavior of semicrystalline polymers can be understood on the basis of a stress-activated diffusion of stress-cracking agent into the interlamellar regions. Fracture at $t_b < t_i$ occurs by local drawing of the practically unplasticized sample. In the second stage ($t_b > t_i$) and at higher stresses, ESC leads to a mixed mode fracture involving large-scale plastic deformation, void

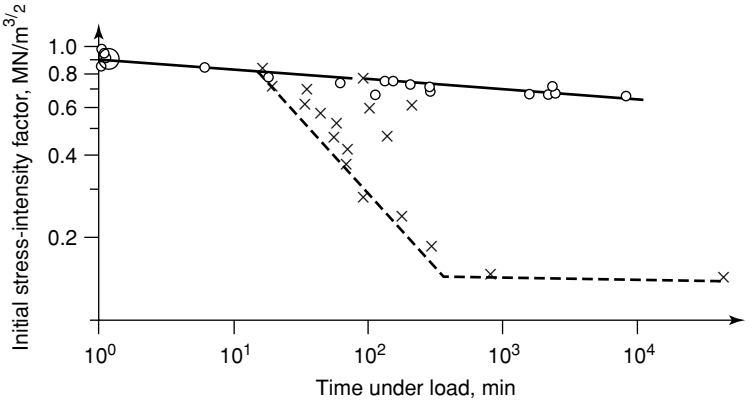

Fig. 34. Environmental crack growth: (——) in air, (———) in an active environment (detergent).

formation, and multiple cracking giving rise to a fairly rough fracture surface. In low stress ESC at $t_b \gg t_i$ fracture occurs by craze breakdown or interlamellar failure (through chain disentanglement or rupture), leaving rather smooth fracture surfaces. From this analysis it can be deduced that environmental effects are reduced through the same factors which improve the interlamellar connectivity. The excellent proportionality between the times to failure of different polymer grades in the presence and absence of a surfactant mentioned above (48) is further evidence.

Characterization and Test Methods

Fracture toughness characterization has been discussed throughout this article from different view points. It requires well-defined specimens and procedures, which have already been indicated. For convenience this information is here summarized again.

Fracture mechanics specimens:

(1) Compact tension (CT), Fig. 12
(2) Double cantilever beam (DCB), Fig. 7
(3) Double-edge notch for essential work of fracture (EWF), Fig. 20
(4) Double torsion (DT), Fig. 16
(5) Single-edge notch tension (SENT), Fig. 12
(6) Single-edge notch three point bending (SENB), Fig. 12
(7) Tapered cantilever, Fig. 16.

Fracture concepts treated in individual paragraphs:

(1) Linear elastic fracture mechanics (including the Irwin model of confined plasticity, the line-zone or Dugdale model and viscoelastic effects)
(2) Fracture mechanics of dissipative materials (including the J-integral and the Essential work of fracture concepts).
(3) Slow crack growth
(4) Multiaxial states of stress
(5) Environmental effects

For a more detailed discussion on testing methods the reader is referred to the International Standards (ASTM, ISO) and the cited comprehensive literature (2–5).

Special care has been taken to elucidate the molecular and physical background of fracture phenomena.

GLASS TRANSITION

Operational Definition

At a relatively simple-minded practical and operational (and thus theoretically nonrigorous) level of treatment, we can define (1) the *glass-transition temperature* (T_g) as the temperature at which the forces holding the distinct components of an amorphous solid together are overcome by thermally induced motions within the time scale of the experiment, so that these components are able to undergo large-scale molecular motions on this time scale, limited mainly by the inherent resistance of each component to such flow. The practical effects of the glass transition on the processing and performance characteristics of polymers are implicit in this definition.

In most polymeric as well as nonpolymeric amorphous materials, the ability to undergo large-scale molecular motions implies the freedom to flow, so that the material becomes a fluid above T_g. However, in the special class of polymers commonly described as "thermosets," covalent cross-links limit the ability to undergo large-scale deformation. Consequently, above T_g, thermosets become "elastomers" (also known as "cross-linked rubbers").

On the experimental time scale, above T_g, nonthermoset amorphous materials are viscous fluids. Their glass transitions can then be viewed as transitions, over the experimental time scale, from predominantly elastic "solid-like" to predominantly viscous "liquid-like" behavior. In fact, traditionally, the glass transition has often been identified in practical terms (not only for polymers, but also for amorphous inorganic materials) as taking place when the viscosity reaches a threshold value (most commonly taken to be 10^{13} P). The glass transition occurs in the reverse direction if the temperature is instead lowered from above to below T_g, with the material then undergoing "vitrification." Again with the

exception of thermosets, this reverse transition upon cooling can be described as going from viscous to elastic behavior. For every glass former, there is a temperature-dependent frequency f (T), and a time scale $t(T)=1/f$ (T), such that at frequencies higher than f the system is elastic and for lower frequencies it is viscous.

In thermosets large-scale molecular motions also become possible above T_g, but these motions are limited by the cross-links that serve as topological constraints for the chain segments between them. (The chain segments between cross-links are the "distinct components" for such materials). The general operational definition given above, therefore, remains valid. However, the specimen as a whole does not and cannot undergo large-scale viscous flow. In fact, it may instead exhibit strongly elastic behavior above T_g because of the presence of the network junctions. The glass transition, therefore, involves the onset of large-scale motions (in other words, "viscous" behavior) on the molecular scale in all amorphous materials. However, on a larger length scale, in thermosets, it cannot be described as occurring between predominantly elastic and predominantly viscous behavior. In the remainder of this article, whenever the glass transition is described in terms of its effect on the viscosity in large-scale flows, it should be understood that thermosets and elastomers are being excluded from the scope of the discussion.

Experimental Methods and Modeling

Several well-established experimental methods are available to measure T_g. The tabulated data are subject to many uncertainties. These uncertainties include the use of different experimental methods, ill-characterized differences between samples in terms of their precise composition and thermal history, and the nonequilibrium (kinetic) aspect of the glass transition which introduces an inherent rate dependence. It is, therefore, best to compare T_g values by using data obtained with the same experimental method for well-characterized samples, whenever possible.

Many theories based on thermodynamic and kinetic considerations, as well as many quantitative structure–property relationships with different amounts of empiricism, have been developed for T_g as a result of decades of research. Further work along these directions can be expected to result only in incremental improvements in fundamental understanding and predictive ability. The rapidly increasing power of computational hardware and software has encouraged attempts to study the glass transition by fully atomistic or coarse-grained numerical simulations, and significant progress may be expected along this exciting new research frontier in coming years.

Practical Importance and Common Methods for Measurement

The glass transition is by far the most important one among the many transitions and relaxations (2) observed in amorphous polymers. When an amorphous polymer undergoes the glass transition, almost all of its properties that relate to its processing and/or performance change dramatically. These changes are important both in determining the processing and performance characteristics of polymers,

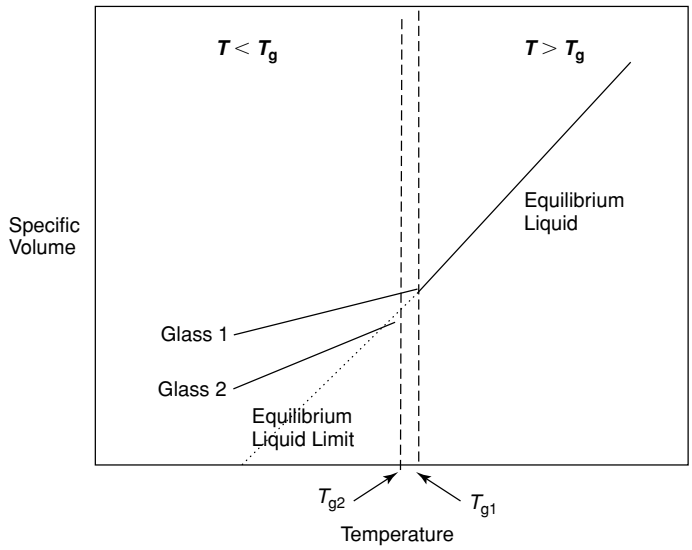

Fig. 1. Schematic illustration of temperature dependences of specific volumes of amorphous materials. This figure also illustrates the effects of the nonequilibrium nature of glass structure, which results from kinetic factors. Glass 1 and Glass 2 are specimens of the same polymer, but subjected to different thermal histories. For example, Glass 1 may have been quenched from the melt very rapidly, while Glass 2 may either have been cooled slowly or subjected to volumetric relaxation via annealing in the glassy state.

and in the selection of suitable methods for measuring the value of T_g itself. The following are some important examples of the effects of going through T_g, as well as of the common methods for measuring T_g based on these effects (1).

The temperature dependence of the specific volume (1/density) of an amorphous material is shown schematically in Figure 1. The coefficient of thermal expansion (rate of change of specific volume with temperature) increases from its value for the "glassy" polymer to its typically much larger value for the "rubbery" polymer when the temperature increases from below to above T_g. The rate of decrease of the density with increasing temperature then becomes much faster above T_g. However, unlike melting where there is a discontinuity in the specific volume itself, the specific volume is a continuous function of the temperature at T_g; only its slope changes in going through the glass transition. Figure 1 also illustrates the effects of the nonequilibrium nature of glass structure, which results from kinetic factors, as will be discussed further later in this article. The effect of T_g on the coefficient of thermal expansion enables its measurement by *dilatometry*.

The dependence of the specific heat capacity of an amorphous polymer on the temperature is shown schematically in Figure 2. The heat capacity of an amorphous polymer jumps from its value for the "solid" polymer to its significantly larger value for the "liquid" (molten or rubbery) polymer at T_g. However, unlike melting where there is a discontinuity in the enthalpy, the enthalpy is a continuous function of the temperature at T_g; only its slope changes in going through the glass transition. The effect of T_g on the heat capacity enables its measurement by *differential scanning calorimetry*, which is by far the most commonly used method to measure it.

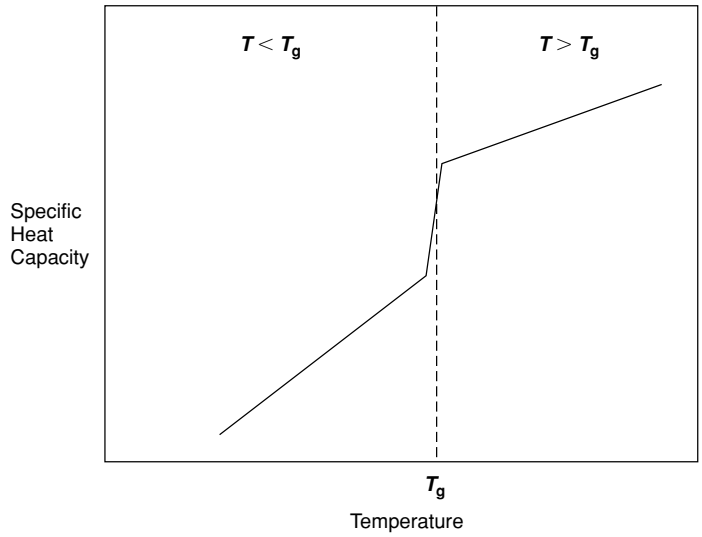

Fig. 2. Schematic illustration of temperature dependences of specific heat capacities of amorphous polymers. The heat capacity "jumps" to a much higher value over a narrow temperature range as the polymer goes through the glass transition. It increases more slowly with increasing temperature above T_g than it did below T_g.

An amorphous polymer typically "softens" drastically as its temperature is raised above T_g, so that its structural rigidity is lost. At the typical time scale of a practical observation, the key indicators of stiffness (the tensile and shear moduli), which decrease very slowly with increasing temperature below T_g, decrease rapidly over a narrow temperature range with further increase in temperature by several (sometimes up to three or even four) orders of magnitude upon traversing T_g. The typical behavior of the tensile (Young's) or shear modulus upon going through the glass transition is compared for a linear (physically entangled but not chemically cross-linked) amorphous polymer, a chemically cross-linked amorphous polymer, and a semicrystalline polymer, in the schematic drawings shown in Figure 3. [However, strictly speaking, this summary is an oversimplification. The elastic moduli for elastic frequencies are not sharp functions of T. The apparent changes are due to the change of f (T) when one works at the time scale of the experiment.] The yield stress also decreases rapidly upon traversing T_g, going to zero slightly above T_g. These changes in the mechanical properties, from "glassy" (below T_g), to "leathery" (in the immediate vicinity of T_g), to "rubbery" (above T_g), have strong implications in terms of practical applications of polymers. These changes also enable the use of mechanical testing methods to measure T_g. Among such methods, *dynamic mechanical spectroscopy*, which measures the viscoelastic characteristics of a polymer under mechanical deformation, is the most reliable and most widely utilized one.

It is worth noting that, in practice, the "heat distortion temperature" (3) is used more often than T_g in the product literature of commercial polymers as an indicator of the mechanical softening temperature. It is closely related to (usually slightly lower than) T_g for amorphous polymers.

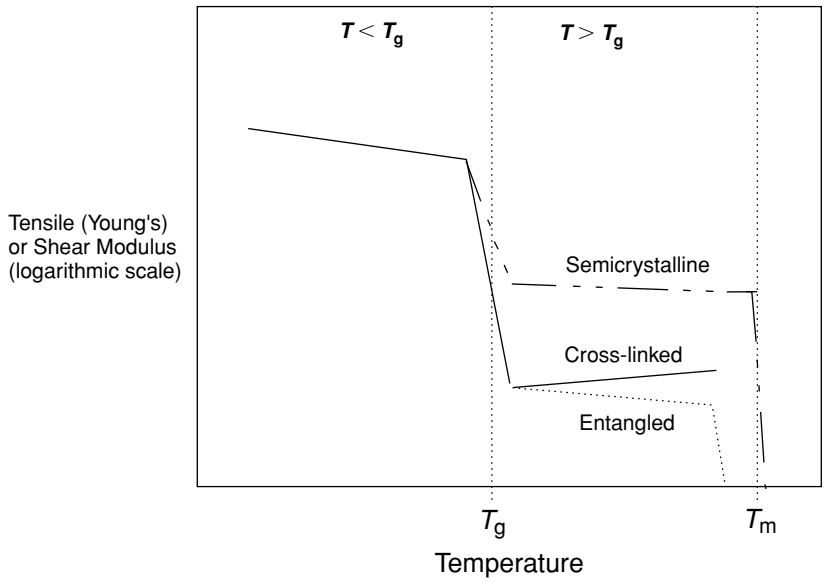

Fig. 3. Schematic illustration of typical behavior of tensile (Young's) and shear moduli upon going through the glass transition. Linear (physically entangled but not chemically cross-linked) amorphous polymers, chemically cross-linked amorphous polymers, and semicrystalline polymers are compared. These two moduli decrease slowly for $T < T_g$, and then drop rapidly over a narrow temperature range as the temperature increases above T_g. The drop may be up to 4 orders of magnitude for amorphous polymers, while it is smaller for semicrystalline polymers. The slight gradual increase in the modulus of the chemically cross-linked polymers above T_g is a result of entropic effects, as described by rubber elasticity theory, and persists until T is raised sufficiently for the polymer to undergo degradation. The gradual decrease in the modulus of a physically entangled polymer over the "rubbery plateau," followed by a precipitous drop into the "terminal zone" where the polymer becomes fluid-like, is due to increasing slippage of labile entanglement junctions. The crystallites in a semicrystalline polymer may provide a wide rubbery plateau regime if $T_m \gg T_g$, and the polymer then becomes fluid-like above T_m.

The rates of change (slopes of the curves) of many important properties (such as the refractive index, surface tension, and gas permeabilities) as a function of temperature, the value of the dielectric constant, and many other optical and electrical properties, often change considerably at T_g. These changes enable the measurement of T_g by using techniques such as *refractometry* and *dielectric relaxation spectroscopy*. Refractometry provides results which are similar to those obained from dilatometry because of the correlation between the rates of change of the specific volume and of the refractive index with temperature. Dielectric relaxation spectroscopy is based on general physical principles which are similar to those in dynamic mechanical spectroscopy, the main difference being in its use of an electrical rather than a mechanical stimulus.

In considering the methods summarized above for measuring T_g, it is important to note that, as discussed later in greater detail, the observed value of T_g can be affected significantly by kinetic factors. T_g is, therefore, dependent on the measurement rate. For example, the T_g measured by differential scanning calorimetry can be increased significantly by increasing the heating rate or by decreasing the

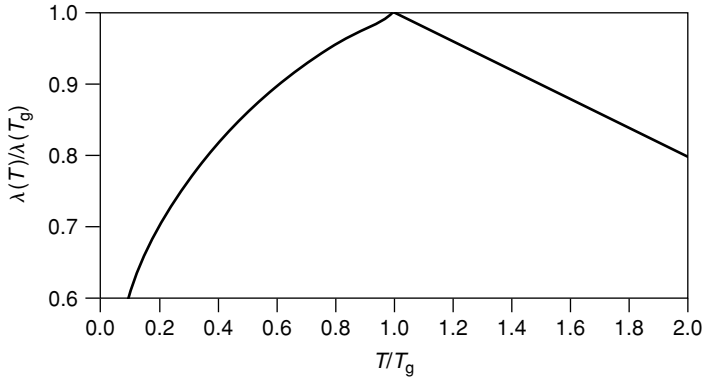

Fig. 4. Approximate form of the temperature dependence of the thermal conductivity $\lambda(T)$ of amorphous polymers, showing that it goes through its maximum value at T_g.

cooling rate during a calorimetric scan. Furthermore, the glass transition does not occur at a single sharply defined temperature but instead over a range of temperatures. There is often confusion in the literature about which point in that range (its onset, midpoint, or end) to use as the value of T_g. Similarly, the glass-transition range depends both on the rate (frequency) of measurement and on whether the specimen is being heated or cooled, in measuring T_g by dynamic mechanical spectroscopy or by dielectric relaxation spectroscopy. The typical temperature and/or frequency scanning rates used most often in different types of experiments also differ significantly. It is worth remembering, therefore, that not only are there many different methods for measuring T_g, but each method only gives a range of temperatures over which the glass transition occurs, and the T_g range measured by any one method can also vary because of the use of different testing conditions.

The thermal conductivity of a completely amorphous polymer goes through its maximum value at T_g, as illustrated in Figure 4.

The melt viscosity above T_g is typically lower than the viscosity in the glassy state below T_g by more than 10 orders of magnitude. Melt processing by techniques such as extrusion, injection molding, and compression molding requires temperatures significantly above T_g. If T_g is expressed in Kelvin, the optimum melt-processing temperature is normally at least $1.2T_g$. The general form of the dependence of the zero-shear melt viscosities η_0 of amorphous polymers as a function of the temperature is illustrated schematically in Figure 5. It is seen that η_0 has a non-Arrhenius "universal" shape for $T_g \leq T \leq 1.2T_g$, where the "reduced temperature" T/T_g roughly serves as the "corresponding states" variable. This universal behavior is lost above $1.2T_g$. The curves for different polymers separate from each other. For $T \gg 1.2T_g$, an Arrhenius-like (activated flow) regime is approached asymptotically. The activation energy in the extrapolation to the hypothetical limit of $T \to \infty$ depends on the chemical structure of the polymer.

One of the many practical uses of T_g is in characterizing polymer blends. When polymers with significantly different T_g values are blended, the effects on T_g often provide a useful indication of the extent of relative miscibility. For example, suppose that two polymers with T_g values of T_{g1} and T_{g2} (where $T_{g1} < T_{g2}$) are blended. If the blend manifests two distinct T_g values, near T_{g1} and T_{g2},

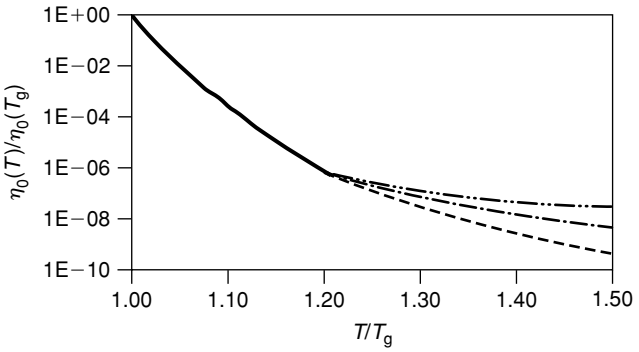

Fig. 5. Schematic illustration of general form of temperature dependence of zero-shear melt viscosities η_0 of amorphous polymers. It is seen that η_0 has a non-Arrhenius "universal" shape for $T_g \leq T \leq 1.2T_g$, where the "reduced temperature" T/T_g serves as the "corresponding states" variable. This universal behavior is lost above $1.2T_g$. The curves for different polymers separate from each other, as shown below for three polymers. For $T \gg 1.2T_g$, an Arrhenius-like (activated flow) regime is approached asymptotically. The activation energy in the extrapolation to the hypothetical limit of infinite temperature depends on the chemical structure of the polymer.

with relative intensities corresponding to the volume fractions of the components, this result usually implies that the polymers are immiscible and separated into macroscale phase domains. If the two glass transitions are broader than those observed for the individual polymers, and/or if the T_g values in the blend (T_g^{g1} and T_g^{g2}) fall between those of the polymers ($T_{g1} < T_g^{g1} < T_g^{g2} < T_{g2}$), this result usually indicates some intermixing of the polymers. If a single T_g value in the range of $T_{g1} < T_g < T_{g2}$ is observed and its position is correlated strongly with the volume fractions of the polymers, this result usually indicates that the polymers are miscible over the volume fraction range where such a single T_g value is observed. However, the use of T_g measurements to assess miscibility is subject to pitfalls, such as whether the T_g's differ sufficiently to allow resolution by a given measurement method, and whether the phase domains in a particular multiphase system are large enough for their effects on T_g to be detectable with that experimental technique (4).

Another practical use of T_g is in characterizing blends of polymers with small molecules. Over the industrially important blend composition ranges where the small molecules are dissolved in a polymeric matrix, such blends are usually referred to as *plasticized polymers*.

The glass transition also plays a major role in determining both the physical properties and the processing characteristics of semicrystalline polymers. Amorphous portions "melt" or "soften" at T_g. Crystalline portions remain "solid" up to the melting temperature T_m. (In practice, usually a semicrystalline polymer contains crystallites over a range of sizes and correspondingly a range of T_m values.) A semicrystalline polymer can be considered as a solid below T_g, as a composite consisting of solid and rubbery phases above T_g but below T_m, and as a fluid above T_m. The effect of the glass transition on the physical properties of semicrystalline polymers decreases with increasing crystallinity. Crystallization upon cooling from the

melt (from $T > T_m$) occurs over the range of $T_g < T < T_m$. Several industrially important fabrication processes (such as thermoforming, blow molding, and preparation of biaxially oriented films) take advantage of this crystallization temperature range, in manufacturing articles with the desired semicrystalline morphologies.

Thermoplastic elastomers (TPEs) (5) are multiphase polymers which behave like elastomers over a wide temperature range, but which can be melt-processed after raising the temperature sufficiently. They are used in many applications. Many TPEs are semicrystalline, with their practical use temperatures ranging from a lower limit of T_g (below which the amorphous phase solidifies so that the elastomeric behavior is lost) to an upper limit of T_m (above which the specimen becomes a viscous fluid so that its structural integrity is lost); see Figure 3. (The crystallites in such TPEs can thus be imagined to behave like meltable cross-links.) Many other TPEs are completely amorphous, with a use temperature range of T_{g1} (for lower-T_g phase) to T_{g2} (for higher T_g phase). On the other hand, certain families of thermoplastic elastomers have sharp glass transitions near room temperature and manifest reversible changes of up to 3 orders of magnitude in stiffness in going through T_g. These materials are known as *shape memory polymers* (6,7). These attributes make them ideally suited for some important specialized applications such as catheters which are rigid when handled by a surgeon outside the human body at room temperature (25°C), but flexible when inserted into the body (∼37°C).

Key Physical Aspects

Despite its apparent simplicity, the operational definition of T_g given earlier comprehends both of the key aspects of the physics of the glass transition. It states that, when a solid is heated up to T_g, it acquires enough thermal energy to be able to overcome two types of resistance to the large-scale motions of its components (1):

(1) The *cohesive forces* holding its different components together. The relevant components for the glass transition in amorphous polymers are chain segments. The cohesive forces can be quantified in terms of properties such as the cohesive energy density or the solubility parameter (square root of cohesive energy density).

(2) Attributes of the individual components (chain segments in polymers) which resist viscous flow. Resistance to the viscous flow of polymer chain segments is related to the topological and geometrical arrangement of their atoms, especially as expressed by the somewhat nebulous concept of *chain stiffness*. The glass transition occurs when there is enough freedom of motion for chain segments of up to several "statistical chain segments" (Kuhn segments) in length to be able to execute cooperative motions (8,9). As a general rule, the length of the Kuhn segment increases with increasing chain stiffness. See the two classic textbooks by Flory (10,11) for background information on statistical chain segments and on other configurational properties of polymer chains.

The effects of chain stiffness and cohesive forces on the value of T_g are different from each other. The "intrachain" effect of the stiffness of individual chain segments is generally (but not always) somewhat more important than the "interchain" effect of the cohesive (attractive) forces between different chains in determining the value of T_g.

Fundamental Theoretical Considerations

Based on the considerations summarized in previous section, it is not surprising to find that most theories of the glass transition (12–30) describe this phenomenon, either explicitly or implicitly, in terms of key physical ingredients whose values strongly depend on the chain stiffness and/or the cohesive forces. These theoretical treatments invariably treat the observed value of T_g as a kinetic (rate-dependent) manifestation of an underlying thermodynamic phenomenon. However, they differ significantly in their description of the nature of this phenomenon at a fundamental level.

Differences of opinion exist concerning the issue of whether or not the discontinuities observed at T_g in the second derivatives of the Gibbs free energy (ie, the coefficient of thermal expansion and the heat capacity) justify referring to the glass transition as a "second-order phase transition". It is important to note that the observed value of T_g is a function of the rate of measurement. For example, when the glass transition is approached from below, heating a specimen very quickly results in a higher apparent T_g than heating it very slowly. Conversely, when the glass transition is approached from above, cooling a specimen very quickly results in a lower apparent T_g than cooling it very slowly (see Fig. 1). There is, therefore, obviously, an important rate-dependent (kinetic) aspect of the glass transition. Nonetheless, it appears that the glass transition may also have an underlying fundamental thermodynamic basis. In other words, there is always a *thermodynamic equilibrium state*, defined as the state which has the lowest possible Gibbs free energy. Therefore, a thermodynamic driving force (preference for achieving as low a free energy as possible) must exist toward that equilibrium state. However, at the prevailing conditions of temperature and pressure, the approach toward that thermodynamic equilibrium state is so slow that the material seems to be "frozen" into a thermodynamically metastable glassy state. Consequently, *the consideration of the glass transition as a kinetic manifestation of an underlying thermodynamic phenomenon provides a reasonable fundamental physical framework for theories of the glass transition.*

The most essential aspects of this interplay of kinetics and thermodynamics are that (*1*) the glass transition involves freezing–defreezing phenomena, (*2*) one sees no sharp change in the parameters describing the static structure (such as the density and the structure factors) relative to the fluid after the vitrification event, and (*3*) what is a glassy material over a short time scale becomes a fluid over a sufficiently long time scale. (Sometimes, "sufficiently long" may mean millions of years, as in some geological phenomena.) The real mystery of the glass transition is in the acceleration of freezing (fragility) that makes the frequency $f(T)$ depend more strongly on the temperature than would be expected from a simple Arrhenius-type activated flow theory.

Quantitative Structure–Property Relationships

It is often important, especially in developing polymers for industrial applications, to be able to predict, rapidly, rough values for T_g as well as the probable trends between structural variants within and between polymer families. There is a long tradition of using quantitative structure–property relationships, developed by the statistical analysis of experimental data to express T_g as a function of (hopefully well-selected) compositional and structural descriptors, for such calculations. All such correlations either explicitly or implicitly attempt to account for the effects of chain stiffness and cohesive forces. One such correlation is the familiar relationship of van Krevelen (31) based on group contributions. Many other empirical correlations, which also usually express T_g as a function of quantities calculated via group contributions, have been used with limited success. A review article (32) provides detailed quantitative critical assessments, and extensive lists of the original references, for some of the best-known empirical correlations for T_g. Some of the many other interesting attempts to estimate T_g, which were not reviewed (32), include the method of Askadskii and Slonimskii (33,34), an alternative version of this method developed by Wiff and co-workers (35), and the combination of molecular modeling and group contributions in the method of Hopfinger and co-workers (36).

More recently, new quantitative structure–property relationships for T_g have been developed (1); they are based on the statistical analysis of experimental data for 320 linear (uncross-linked) polymers collected from many different sources, containing a vast variety of compositions and structural features. The T_g of the atactic form was used, whenever available, for polymers manifesting different tacticities. The T_g values of a subset of the polymers listed in this extensive tabulation are reproduced (with some minor revisions) in Table 1. (It is important to caution the reader here that these data were assembled from a wide variety of sources. Many different experimental techniques were used in obtaining these data.) The resulting relationship for T_g has the form of a weighted sum of "structural terms" mainly taking the effects of chain stiffness into account plus a term proportional to the solubility parameter δ which takes the effects of cohesive interchain interactions in an explicit manner, as shown in equation (1):

$$T_g \approx a + b\cdot\Delta + (\text{weighted sum of 13 structural terms}) \quad (1)$$

Literature data for the dependence of T_g on the number-average molecular weight (M_n) were also tabulated in Reference 1, and used to develop a quantitative structure–property relationship for the fitting parameter K_g in equation (2) (developed from considerations of free volume) where $T_{g\infty}$ is the limiting value of T_g for $M_n \rightarrow \infty$ (37). As shown for poly(ethylene terephthalate) in Figure 6 (38), T_g increases asymptotically toward $T_{g\infty}$ with increasing M_n. $T_{g\infty}$ is often larger than the commonly quoted T_g of a polymer, as measured at ordinary molecular weights. For example, $T_{g\infty} \approx 382$ K for polystyrene and $T_{g\infty} \approx 434$ K for bisphenol A polycarbonate, in comparison with the commonly quoted values of $T_g \approx 373$ K and $T_g \approx 423$ K, respectively. A subset of the data tabulated elsewhere (1) for the dependence of T_g on M_n, as fitted by using equation (2), is listed in Table 2. The final form of the resulting quantitative structure–property relationship is given by

$$T_g \approx T_{g\infty} - 0.002715\frac{T_{g\infty}^3}{M_n} \tag{3}$$

Many commercial polymers are cross-linked, ranging from lightly cross-linked elastomers to very densely cross-linked thermosets. The effects of crosslinking on the properties of polymers can be roughly classified as follows (40,41): (*1*) *Topological effect* caused by topological constraints introduced by cross-links on the properties. This effect is referred to simply as the *cross-linking effect* by many authors. (*2*) *Copolymerization effect* (also referred to as the *copolymer effect*) related to the change of the fractions of two or more types of repeat units with increasing cross-linking. Depending on the types of monomers involved, this effect may either strengthen or weaken the trends expected on the basis of the topological

[a]Data presented here are a part of literature data summarized in Ref. 1 (see Ref. 39 for a more extensive discussion) to develop a relationship for the parameter K_g in equation (2).

effect, and may even reverse them in some cases. The analysis of a large amount of experimental data collected from the literature [(1); for a more detailed discussion see (39)] led to the simple quantitative structure–property relationship given by equation (4) (illustrated in Fig. 8), where n (defined by eq. (5)) is the average number of "repeat units" between cross-links. M_c is the average molecular weight between cross-links. M is the molecular weight per repeat unit. $T_g(\infty)$ is T_g at the uncross-linked limit ($n\rightarrow\infty$). N_{rot} is a "number of rotational degrees of freedom per repeat unit" parameter.

$$T_g(n) \approx T_g(\infty)\left[1+\frac{5}{n\times N_{rot}}\right] \tag{4}$$

$$n=\frac{M_c}{M} \tag{5}$$

In many phase-separating block copolymers (especially segmented multiblock copolymers such as polyurethanes where the blocks are usually short), lowering the soft block M_n *increases* the soft phase T_g because of "cross-link-like" topological constraints imposed by hard phase domains.

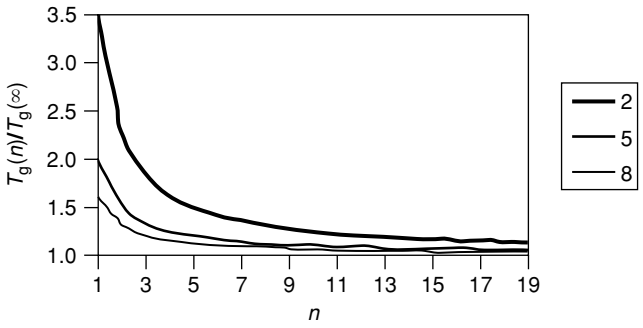

Fig. 8. Illustration of simple quantitative structure–property relationship given by equation (4) for the dependence of T_g on cross-linking. $T_g(\infty)$ is the T_g of the uncross-linked limit ($n \rightarrow \infty$, where n is the number of repeat units between cross-links). N_{rot} is a "number of rotational degrees of freedom per repeat unit" parameter. Each curve is labeled by the value of N_{rot}.

Other recently published correlative methods for predicting T_g include the "group interaction modeling" (GIM) approach of Porter (42), neural networks (43–45), genetic function algorithms (46), the CODESSA (acronym for "Comprehensive Descriptors for Structural and Statistical Analysis") method (47), the "energy, volume, mass" (EVM) approach (48,49), correlation to the results of semiempirical quantum mechanical calculations of the electronic structure of the monomer (50), and a method that combines a thermodynamic equation-of-state based on lattice fluid theory with group contributions (51).

Most theories and quantitative structure–property relationships for T_g only consider the case of a random distribution of repeat units along the polymer chains in treating copolymers. They give equations which predict a monotonic change of T_g between the T_g values of the homopolymers of the constituent repeat units, as a function of composition. However, the distribution of repeat units in a copolymer is often nonrandom. It may, for example, manifest various levels of "blockiness." Sometimes, T_g shows a nonmonotonic dependence on the composition variables, usually as a result of deviations of the repeat unit sequence from complete randomness. Some developed useful relationships correlating the T_g of a copolymer to the sequence of its repeat units have been developed (52). See also a review by Schneider (53), dealing with the deviations of T_g from simple additive relationships for copolymers and miscible polymer blends, and a review by Cowie and Arrighi (54), discussing the glass transition and sub-T_g relaxations in blends in greater depth. It should also be noted that sometimes nonmonotonic dependence of T_g on copolymer composition may arise as a result of preferential ("specific") types of nonbonded interactions (such as polar interactions and hydrogen bonding) between certain types of repeat units causing nonmonotonic composition dependence for the cohesive energy density. It has been shown that the differences between the solubility parameters (square root of the cohesive energy density) of the components of a random copolymer or a miscible blend can be correlated with the magnitude of such effects (53). In the context of experimental data for copolymers of vinylidene chloride, it has been shown how "the T_g-composition relationship is affected by four distinct structural features: the size, shape, and polarity of the comonomer unit, and the sequence distribution" (55).

It is important to note that quantitative structure–property relationships for T_g (as well as for other polymer properties) can be combined with nonlinear optimization techniques to perform "reverse engineering." These approaches involve working backwards, from a desired set of properties toward the repeat unit structures of the polymers that may give those targeted properties. See References 56–58 for some examples.

Detailed Simulations

In recent years, the rapidly increasing power of computational hardware and software has encouraged attempts to study the glass transition by fully atomistic or coarse-grained numerical simulations. Such simulations can be used to probe details of the physical processes taking place in a system at length scales, which cannot be probed by thermodynamic and kinetic theories which are based on a more "global" description of the system at larger length scales. Some of the details that can be probed by such simulations are also not accessible by any of the existing experimental techniques. Simulations have already begun producing valuable physical insights.

An objective of such work is to predict T_g by identifying the temperature at which discontinuities occur in the properties obtained directly from the results of the simulations. The results obtained thus far are insufficient to demonstrate conclusively the ability to accomplish this task routinely and reliably within computer time requirements that would be acceptable for the practical use of detailed simulations to predict T_g. The main challenge, at a fundamental level, is that the time scales involved in the glass transition are very long compared to what can currently be explored routinely in simulations on model systems large enough to represent a bulk polymer sample adequately and sufficiently fine-grained to account adequately for the effects of differences in chemical structure. Another significant challenge, at the implementation level, is the difficulty of developing potential functions (often referred to as "force fields") of sufficient quality to provide faithful representations of the properties and dynamics of the materials of interest. Significant progress is expected in coming years with further improvements in computer hardware and simulation software. It may, ultimately, become possible to use detailed simulations to predict reliably the effects of subtle variations in polymeric structure and conformation, which are very difficult to capture either with theoretical equations based on "global" thermodynamic and kinetic considerations or with empirically based relationships.

For further information, see the following four especially interesting articles:

(1) A review article (59) on the prediction of T_g by extending volume–temperature curves generated by molecular dynamics simulations to low temperatures.

(2) A study of the question of whether computer simulation can solve the challenge of understanding the glass transition and the amorphous state of matter (60).

(3) Molecular dynamics simulations of the thermal properties of ultrafine polyethylene powders (61). This study shows that, for particle diameters below 10 nm, both T_g and T_m are expected to decrease rapidly with decreasing particle diameter.

(4) Isobaric (constant pressure) and isochoric (constant volume) glass transitions in polymers were first observed for bisphenol A polycarbonate (62). A molecular dynamics study of such transitions in a model amorphous polymer has also been reported (63). This study shows that the glass transition is primarily associated with the freezing of the torsional degrees of freedom of polymer chains (related to chain stiffness), which are strongly coupled to the degree of freedom associated with the nonbonded Lennard–Jones potential (related to interchain cohesive forces).

Comprehensive List of Factors Determining T_g

Several of the most important factors determining the value of T_g have been discussed earlier:

(1) *Rate of measurement*
(2) *Structural and compositional factors*—the most fundamental of which are *chain stiffness* and interchain *cohesive forces*
(3) *Number-average molecular weight*
(4) *Cross-linking*

The following are the additional factors which affect the value of T_g:

(1) Morphological effects, and especially *crystallinity*.
   a. The presence of the rigid crystallites, and of the interphase regions ("tie molecules") between amorphous and crystalline regions, often increases T_g (1,38,64), as shown for poly(ethylene terephthalate) in Figure 6 (38). In addition, the decrease of the amorphous fraction of the polymer naturally leads to a decrease in the strength (intensity) of its amorphous relaxations, with the decrease in the strength of the glass transition at a given percent crystallinity normally being larger than the decrease in the strength of the secondary (sub-T_g) relaxations (65). The increase in T_g due to crystallinity bears some resemblance to the increase in T_g due to cross-linking, so that it can be viewed somewhat superficially to arise from the topological constraints introduced by the crystallites. This simple physical picture, however, is not entirely correct. Unlike a crosslink in an amorphous polymer, which can be viewed as a "point-like" network junction, a crystalline domain in a semicrystalline polymer can be very large, such domains can occupy a very large fraction of the total volume of the specimen, and they often transition into the amorphous phase gradually via "interphase" regions of significant thickness. It has, therefore, not yet proved to be possible to develop any simple and statistically significant general quantitative structure–property relationship for the

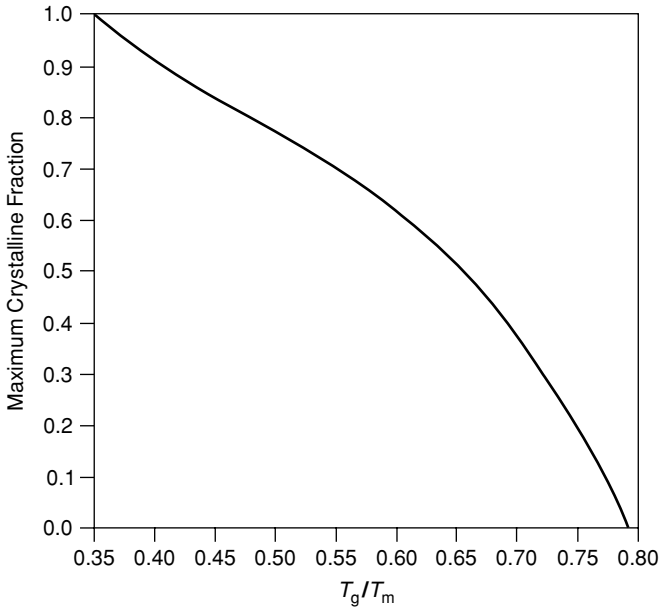

Fig. 9. Empirical relationship for maximum crystalline fraction under isothermal quiescent crystallization as a function of the ratio T_g/T_m, where the temperatures are in Kelvin.

effects of crystallinity on T_g, unlike equation (4) which works quite well in describing the effects of cross-linking.

b. While crystallinity influences T_g, T_g in turn influences the crystallization of a polymer when it is cooled down from the melt (38). The temperature at which the isothermal quiescent crystallization rate is at its maximum is roughly halfway between T_g and T_m. The maximum crystalline fraction increases with increasing T_m/T_g (with temperatures expressed in Kelvin) which can be viewed as an index for the driving force for crystallization, and thus decreases with increasing T_g/T_m as shown in Figure 9. A very important physical difference between T_g and T_m is worth noting in this context. They both depend strongly on chain stiffness and on cohesive energy density, *but* only T_m depends on how easily polymer chains can be packed into a periodic lattice. Otherwise, the T_m/T_g ratio and crystallizability would have been very similar for all polymers, instead of depending strongly on the smoothness and regularity of polymer chains.

(2) The effects of *orientation* via mechanical deformation on T_g have been reviewed (64). T_g increases in those amorphous regions of a semicrystalline polymer that are either attached to crystallites or so close to them that their chain segment mobilities are hindered because of the interference of the crystallites. On the other hand, orientation has little effect on T_g in amorphous regions far away from crystallites as well as in completely amorphous polymers.

Table 3. Glass-Transition Temperatures of Syndiotactic, Isotactic, and Atactic Polymers[a]

Polymer	T_g (syndiotactic), K	T_g (isotactic), K	T_g (atactic), K
Poly(methyl methacrylate)	433	316	378
Poly(ethyl methacrylate)	393	281	324
Poly(isopropyl methacrylate)	412	300	327
Poly(*n*-butyl methacrylate)	361	249	293
Poly(isobutyl methacrylate)	393	281	321
Poly(cyclohexyl methacrylate)	436	324	377
Poly(2-hydroxyethyl methacrylate)	377	308	359
Poly(methyl acrylate)	–	283	281
Poly(ethyl acrylate)	–	248	249
Poly(isopropyl acrylate)	270	262	267
Poly(*sec*-butyl acrylate)	–	250	251
Poly(cyclohexyl acrylate)	–	285	292
Poly(methyl α-chloroacrylate)	450	358	416
Poly(ethyl α-chloroacrylate)	393	310	366
Poly(isopropyl α-chloroacrylate)	409	341	363
Polystyrene	378	360	373
Poly(α-methyl styrene)	453	–	446
Polypropylene	269	255	267
Poly(*N*-vinyl carbazole)	549	399	423
Poly(vinyl chloride)	T_g increased with syndiotactic triad content (28–43%), and decreased with isotactic triad content (13–21%) showing lowest and highest values of 352 and 370 K, respectively, for a set of samples.		

[a]Data presented here are a part of literature data summarized in Ref. 1.

(3) *Conformational factors*. The most important conformational factor is the *tacticity* of vinyl-type polymers. A polymer such as poly(methyl methacrylate) can have quite different values of T_g, depending on whether it is isotactic, syndiotactic, or atactic. See Table 3 for a collection of literature data (1) on the effects of tacticity on T_g. A theoretical analysis of the effects of tacticity variations on T_g has been provided (52).

(4) The presence of *additives, fillers, unreacted residual monomers, and/or impurities*, whether deliberately included in the formulation of a resin, or left over as undesirable by-products of synthesis. For example, plasticizers of low molecular weight generally decrease T_g (1,19,31,66,67), as illustrated in Figure 10. On the other hand, under some conditions, T_g may increase when rigid nanoscale additives are incorporated into a polymer (64).

(5) *Thermal history*. The annealing (or "physical aging") of amorphous polymers at elevated temperatures below T_g usually increases T_g. This increase is larger for higher annealing temperatures, provided that the annealing temperature remains below T_g. It approaches an asymptotic limit as a function of time. For example, see Reference 68 for bisphenol A polycarbonate and Reference 64 for amorphous rigid poly(vinyl chloride).

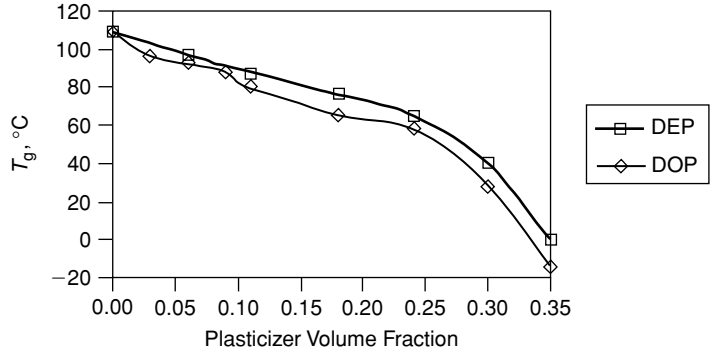

Fig. 10. Data illustrating typical effects of plasticization on T_g (67) for poly(methyl methacrylate) (obtained by polymerization of purified methyl methacrylate monomer), plasticized with diethyl phthalate (DEP) or dioctyl phthalate (DOP).

(6) *Thermal, thermooxidative, and/or photochemical degradation*. The onset of rapid degradation sometimes occurs in the temperature range of the glass transition, obscuring the distinction between the glass transition and degradation. For example, T_g values of 700 K or above, reported in the literature for some polymers with very stiff chains, are often not true T_g values, since degradation and softening take place simultaneously and inextricably.

(7) *Pressure* (P). T_g is usually measured under normal atmospheric pressure. The effect of P on T_g is rarely considered, although it may become important in processing polymers under high hydrostatic pressure. Increasing P increases T_g (19,63,64,69,70). The observed rate of change of T_g with increasing P (the derivative dT_g/dP) seems to be of the same order of magnitude for many polymers. The following examples from a tabulation of literature data (64) illustrate the typical magnitude of this effect: T_g went from (a) 100°C at atmospheric pressure (P_{atm}) to 182°C for polystyrene at P=200 MPa, (b) 103°C at P_{atm} to 121°C at P=100 MPa for poly(methyl methacrylate), (c) 75°C for poly(vinyl chloride) at P_{atm} to 89°C at P=100 MPa, and (d) 31.5°C at P_{atm} to 48.5°C at P=80 MPa for poly(vinyl acetate).

(8) *Specimen size effects*.

a. Sometimes, as in many electronics and lubrication applications, very thin polymeric films are used. The T_g values of such films can differ significantly from the bulk values for the same polymers (71–76). It was shown that T_g decreases with decreasing thickness for thin free-standing polystyrene films (71). T_g also decreases with decreasing thickness for polymers that have no specific interactions with the substrate on which they have been placed (72), as shown in Figure 11. By contrast, if strong attractive specific interactions between the polymer and the substrate restrict the mobility in the interfacial region, the behavior becomes very different and T_g may increase with decreasing thickness (73,74).

b. The surface of a polymeric specimen may behave differently from the bulk in its glass-transition behavior. For example (75), the surface T_g of a monodisperse polystyrene film was observed to be lower than the

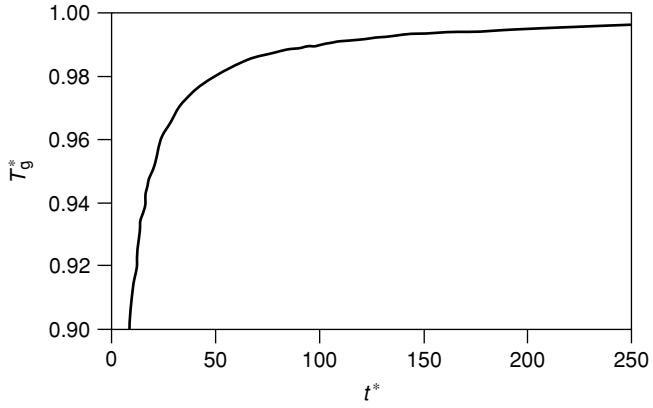

Fig. 11. "Master curve" for thickness (t) dependence of T_g of thin films of polymers that have no specific interactions with the substrate (72). The equation for the curve is $T_g* = t*/(1+t*)$; where $T_g* = T_g(t)/T_g(\text{bulk})$, T_g is in Kelvin, $t* = t/L$, and L is the statistical chain (Kuhn) segment length. By contrast, if strong specific interactions between the polymer and the substrate result in restricted interfacial region mobility, the behavior becomes very different from what is shown below and T_g may instead increase with decreasing thickness.

bulk T_g. This result was interpreted in terms of an increase in the free volume near the surface region, being induced by the preferential surface localization of chain end groups.

c. Finite specimen size, resulting from confinement within small spaces, can also affect T_g significantly. For example, it has been observed that the T_g of two glass-forming organic liquids decreased (but not as much as the decrease of T_m) when the confining controlled pore glass diameter decreased over the range of 73–4 nm (77,78).

(9) *Incorporation of ionic charges*. An ionic polymer (sometimes referred to as an "ionomer") contains both covalent and ionic bonds in its chain or network structure (79,80). Examples include metal salts of poly(acrylic acid), poly(styrene-*co*-methacrylic acid), and sulfonated polystyrene. The effect of ionic bonds on T_g somewhat resembles the effect of covalent cross-links for organic polymers, as T_g generally increases with ion concentration. However, ionic bonding is more complex than covalent cross-linking, because of the possible effects of (*1*) ionic valency, (*2*) chain stiffening induced by incorporating ionic charges along the chain backbone, (*3*) ionic aggregation, and (*4*) thermal lability of "ionic cross-links."

This long list of factors affecting T_g demonstrates that many factors not related either to the composition or to the structure of a polymer can significantly affect T_g. Some internal inconsistency, and the need to exercise judgment and to make choices, is therefore inherent in preparing any data set collected from different sources for use in developing or validating any correlative or predictive scheme for T_g. In the best of all possible worlds, one would synthesize all of the polymers which will be used in the dataset, characterize them very carefully, and

then measure their T_g's under identical test conditions. For practical reasons, however, the use of data from many different sources in examining the trends in T_g is often unavoidable.

A review article (81) provides further insights into the many factors determining T_g.

HARDNESS

Introduction

Hardness H defines the resistance to local deformation of a material when indented, drilled, sawed, or abraded. It involves a complex combination of properties (elastic modulus, yield strength, strain-hardening capacity). The prevailing deformation mechanism depends upon the material and the type of tester. Hardness is either measured by (*1*) static penetration of the specimen with a standard indenter at a known force, (*2*) dynamic rebound of a standard indenter of known mass dropped from a standard height, or (*3*) scratching with a standard pointed tool under a load. The hardness tester, indenter shape, and force employed strongly influence the hardness numbers (1).

Hardness is used in identification, classification, and quality control. Hardness tests provide a rapid evaluation of variations in mechanical properties affected by changes in chemical or processing conditions, heat treatment, microstructure, and aging. Since the hardness test usually produces an insignificant permanent change in the specimen, it is considered to be a nondestructive test.

The methods commonly used in determining the *hardness* of polymers are static indentation methods. Here, the indenter penetrates the test specimen at normal incidence under the application of a known force. Typical forces range from 10^{-2} to 1 kN, leading to indentation widths of a few millimeters. The hardness is determined from the optical imaging of the residual width of indentation. Pyramidal indenters are preferred because the contact pressure is independent of the load applied and the indentation is less affected by elastic release than other indenters (1).

The *microhardness* technique is used when the specimen size is small or when a spatial map of the mechanical properties of the material within the

Encyclopedia of Polymer Science and Technology. Copyright John Wiley & Sons, Inc. All rights reserved.

micron range is required. Forces of 0.05–2 N are usually applied, yielding indentation depths in the micron range. While microhardness determined from the residual indentation is associated with the permanent plastic deformation induced in the material (see section on Basic Aspects of Indentation), microindentation testing can also provide information about the elastic properties. Indeed, the hardness to Young's modulus ratio H/E has been shown to be directly proportional to the relative depth recovery of the impression in ceramics and metals (2). Moreover, a correlation between the impression dimensions of a rhombus-based pyramidal indentation and the H/E ratio has been found for a wide variety of isotropic polymeric materials (3). In oriented polymers, the extent of elastic recovery of the imprint along the fiber axis has been correlated to Young's modulus values (4).

More recently, *ultramicrohardness* and *nanohardness* testers have been developed with the purpose to mechanically characterize near surfaces and thin films (5). Continuous load–displacement monitoring, as the indenter is driven into and withdrawn from the film, substitutes the imaging method used in conventional static indentation methods. Smaller loads can be applied ($10^{-1} - 2 \times 10^3$ mN) so that a minimum residual depth of several tens of nanometers can be achieved at best. The advantage of continuous depth-sensing recording entails a high level of precision due to automatic registering of data, thus, avoiding the error in determining the indentation size. In addition, each test gives a complete loading/unloading data cycle, rather than just a simple reading. This approach enables hardness, elastic modulus, yield strength, and the energy used during loading and unloading to be determined. In addition, the H/E ratio derived from continuous depth-sensing recording can be shown to be directly proportional to the ratio between the elastic and plastic components of indentation at peak load (6).

During the last two decades, studies of the hardness properties of polymers have evolved from topics of applied significance to fundamental studies aiming at acquiring an understanding of the structure–property relationship of polymer materials including glassy and semicrystalline polymers and copolymers, as well as polymer blends and composites (4,7,8). Figure 1 illustrates the hardness of polymer materials as compared with typical values for metals and alloys.

Basic Aspects of Indentation

Figure 2 shows the contact geometry for a pyramid indenter at zero load, at maximum load, and after unloading. The material under the indenter consists of a zone of plastic deformation (a few times the penetration depth distance) surrounded by a larger outer zone of elastic deformation. Several effects can be distinguished during the indentation process:

(1) An instant elastic recovery of the indentation depth upon load release. The loss of contact with the indenter allows for a change in the shape of the indentation.
(2) A permanent plastic deformation. Hardness is related to the irreversible deformation, measured from the diagonal of the residual impression, d.
(3) A time-dependent contribution during loading. The plastic deformation in polymers is known to be influenced by the time at which the load is held

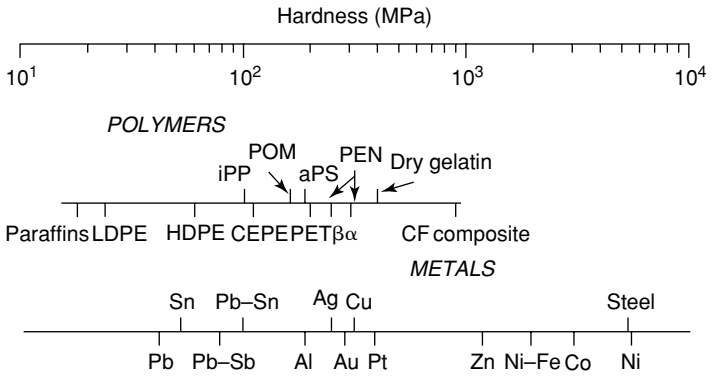

Fig. 1. Typical microhardness values of polymers compared with data for metals. LDPE, low density polyethylene; HDPE, high density polyethylene; iPP, isotactic polypropylene; CEPE, chain-extended polyethylene; POM, polyoxymethylene; aPS, atactic polystyrene; PET, poly(ethylene terephthalate); PEN, poly(ethylene naphthalene-2,6-dicarboxylate); CF composite, carbon-fiber composite. Hardness data of metals and alloys markedly depend on composition, degree of work-hardening, processing conditions, etc. For this reason, the values in Figure 1 should be considered as typical values rather than as absolute values. Most of the data for metals are taken from Ref. 1.

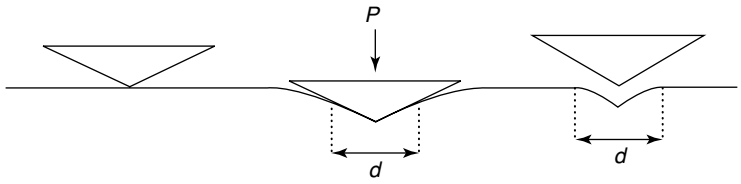

Fig. 2. Schematic illustration of the contact geometry of a pyramid indenter during a static indentation test at zero load, under load, and after load release.

(creep effect). To minimize the creep effect, indentation times of a few seconds are usually employed (4).

(4) A long delayed elastic recovery (*viscoelasticity*). The residual indentation should be measured immediately after load release in order to minimize the viscoelastic recovery of the material.

Microhardness of Polymer Glasses

The microhardness of glassy polymers decreases with increasing temperature because of thermal expansion (9). At the glass-transition temperature T_g, the onset of liquid-like motions takes place. The motions of long segments above T_g require more free volume and lead to a fast decrease of microhardness with temperature. The microhardness of several glassy polymers, measured at room temperature, has been shown to be directly proportional to its glass-transition temperature (10).

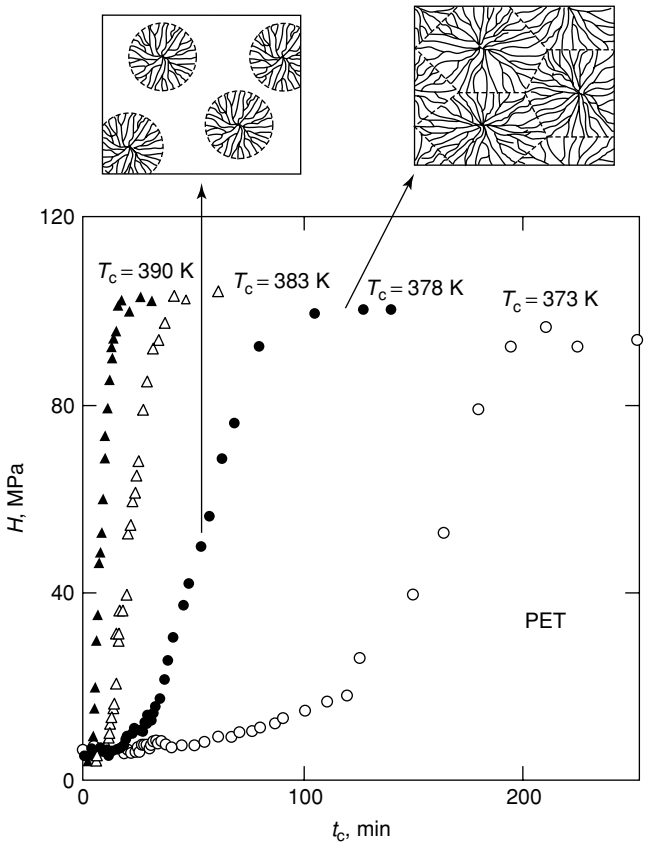

Fig. 3. Variation of microhardness for PET with crystallization time t_c for different crystallization temperatures T_c.

Structure Development: The Role of Crystallinity

Hardness has been shown to be a useful technique to detect the structural changes occurring during crystallization (11,12). Figure 3 shows the hardness variation in the course of isothermal crystallization of poly(ethylene terephthalate) (PET) at various crystallization temperatures T_c. A sigmoidal rapid hardness increase with increasing time t_c is followed by a slower hardness increase. The comparatively rapid H increase, during primary crystallization, is connected with the growth of polycrystalline aggregates (spherulites) until they impinge on each other, finally filling up the sample completely. The much slower hardening process is denoted as secondary crystallization and is related with crystal thickening and formation of new crystals. For samples crystallized from the glassy state where spherulitic growth is incomplete, H can be described as follows (12):

$$H = H_{\text{sph}}\Phi + H_a(1 - \Phi) \tag{1}$$

Here, H_{sph} is the hardness value of the spherulites, H_a is the hardness of the amorphous interspherulitic regions, and Φ is the volume fraction of

crystallized spherulites. During primary crystallization, H_{sph} remains constant and hardness is directly proportional to the volume occupied by the spherulites (12). The hardness variation in the course of isothermal crystallization of PET and poly(ethylene naphthalene-2,6-dicarboxylate) (PEN) has been shown to follow Avrami law (13,14).

For samples in which spherulitic growth is complete ($\Phi = 1$), $H = H_{sph}$ and the hardness of the material can be accounted for using (7)

$$H = H_c\alpha + H_a(1-\alpha) \tag{2}$$

Here, H_c is the hardness of the crystalline lamellae within the stacks, H_a is the hardness of the amorphous intraspherulitic material, and α is the fraction of crystalline material within the spherulites. Equation (2) is consistent with a parallel model of crystalline and amorphous regions, which has been proved to be successful in a wide variety of polymeric materials (7).

Microhardness Dependence on Nanostructure

Equation (2) suggests that the volume fraction of crystalline material controls the microhardness value of a polymer. However, it was soon recognized the large influence of the crystalline lamellar thickness l_c upon microhardness in case of chain-folded and chain-extended polyethylene (PE) (4). Based on a thermodynamic approach, the dependence of hardness on the average crystal thickness was derived (15):

$$H_c = \frac{H_c^{\infty}}{1} + (b/l_c) \tag{3}$$

Here, H_c^{∞} is the hardness of an infinitely thick crystal and b is a parameter related to the surface free energy of the crystal, σ_e, and to the energy required for plastic deformation of the crystal blocks, $\Delta h (b = 2\sigma_e/\Delta h)$.

Figure 4 shows the plot of H_c^{-1} (derived using eq. (2)) versus l_c data for poly(ethylene oxide) (PEO), crystallized at various temperatures (M_n=13,000), and chain-folded PE, annealed at 130°C for different annealing times (M_n=11,700). Using equation (3), the plot of H_c^{-1} versus l_c^{-1} yields an ordinate intercept $(H_c^{\infty})^{-1}$ and a slope b/H_c^{∞}. Values of $H_c^{\infty} = 150$ MPa and $H_c^{\infty} =$ 170 MPa are derived for PEO and PE respectively. The H_c^{∞} value for PET, PEN, poly(butylene terephthalate) (PBT), and isotactic poly(propylene) (iPP) crystals has also been reported (16–19).

It is to be noted that H_c^{∞} is intimately related to the packing of the chains in the crystals (4). Since the crystal hardness reflects the response of the intermolecular forces holding the chains within the lattice, it has been shown that the microhardness technique permits to distinguish between polymorphic modifications of the same polymer (20,21). Indeed, the study of the transition from the α to the β form in iPP confirmed that changes in H were directly related to the different crystal hardness values of each phase (20). More recently, the microhardness technique has been successfully applied to follow the reversible strain-induced polymorphic α–β transition occurring on PBT (21).

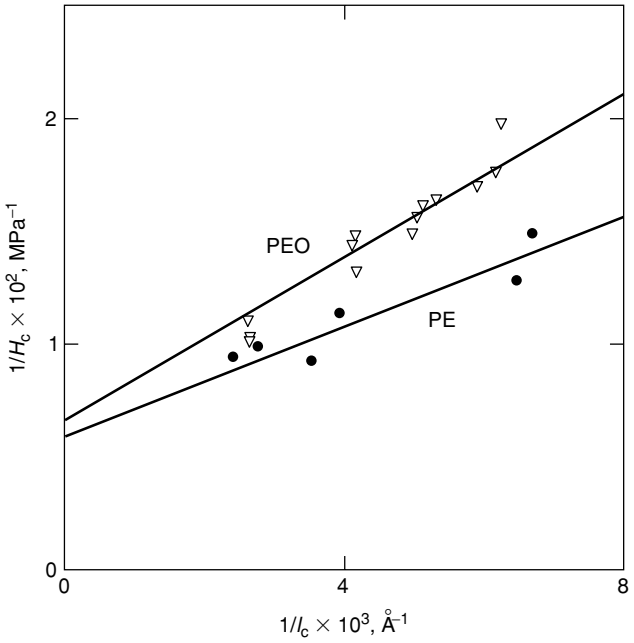

Fig. 4. Plot of reciprocal crystal hardness H_c^{-1} as a function of reciprocal crystal thickness l_c^{-1} for PEO (▽) and PE (●).

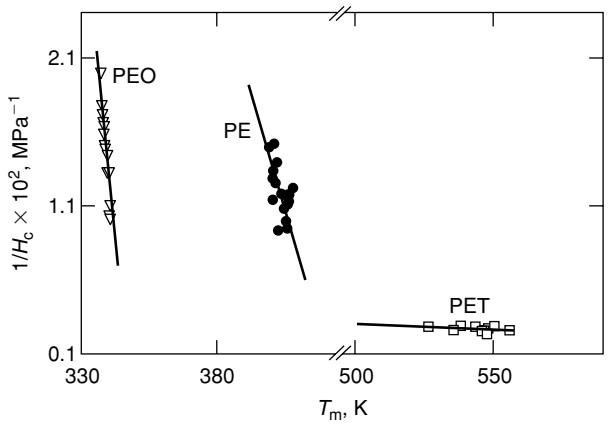

Fig. 5. Variation of H_c^{-1} with T_m for different polymeric materials: PEO (▽), PE (●), and PET (□).

Microhardness Correlation to Thermal Properties

While the hardness depression due to finite thickness lamellae is given by equation (3), Thomson–Gibbs equation accounts for the melting point depression of a crystal of thickness l_c with respect to the equilibrium melting point T_m^0 (22). It has been shown that by combination of Thomson–Gibbs equation and equation (3), the reciprocal value of the crystal hardness is directly proportional to the melting

temperature of the crystals, as seen in Figure 5, for PEO, PE, and PET. The three series of H_c^{-1} versus T_m data fit into a straight line. From these linear regressions, one can derive the T_m^0 values for each polymer, provided H_c^∞ is known or vice versa.

Creep Behavior

An important aspect concerning the indentation mechanism in polymers is the time-dependent part of the plastic deformation. Several studies on polymeric materials have shown that hardness decreases with indentation time, following a function of the form (4,23)

$$H = H_1 \Delta t^{-k} \tag{4}$$

Here, H_1 is the hardness at a given reference time $\Delta t = 1$ and k is the so-called creep constant. The creep constant is a measure of the rate at which the material flows under the indenter and can be derived from the slope of a log H versus log Δt plot. Data near $\Delta t = 0.1$ min are usually adopted as the hardness value for polymers (4). Recent research evidences the strong influence of temperature upon the k values (23). At room temperature, the k- parameter has been shown to primarily depend on l_c (23).

Correlation of Microhardness to Macroscopic Mechanical Properties

According to the classical theory of plasticity, indentation hardness for a Vickers indenter is approximately equal to three times the yield stress measured in frictionless compression, Y_c (1). However, recent data evidence that the theory fails when dealing with polymers (24). Indeed, hardness-to-compressive yield stress ratios of $H/Y_c \approx 2$ have been found for various chain-folded and chain-extended PE samples due to the nonnegligible elastic strains of the indented material (24). On the other hand, hardness-to-tensile yield stress ratios of $H/Y_t \approx 3$ have been obtained on a wide variety of PE samples, provided the strain rate of the tensile test is comparable to that employed in the hardness test (24,25).

As pointed out in the Introduction, the hardness to Young's modulus ratio may be derived from the extent of elastic recovery in the depth of a Vickers indent (2). H/E values of different polymers have also been found to be linearly related to the ratio of the lengths of the short and long diagonals of a Knoop imprint (3). The correlation between microhardness and Young's modulus has been explored on various PE samples of different morphology (24,26). It has been shown that an H-increase parallels a rise in the Young's modulus values derived from tensile testing (24,26). Furthermore, the H/E_c ratio (E_c is the Young's modulus value determined from compression testing) was shown to be the lowest for highly crystalline samples such as chain-extended PE, in agreement with an enhanced plastic behavior (24).

Microhardness of Blends

Hardness is a promising technique for the structural investigation of multicomponent blends. The hardness technique can provide information on the degree of

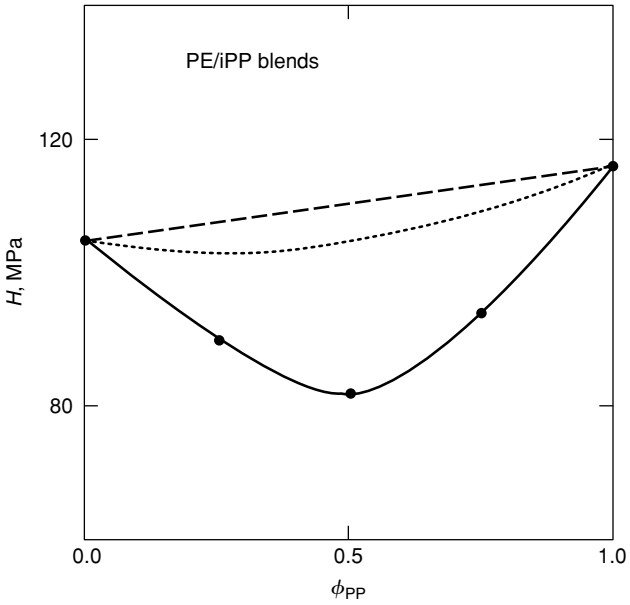

Fig. 6. Plot of microhardness of PE/iPP blended gel films as a function of the weight concentration of iPP. The dashed line follows equation (5), using the hardness values of the individual homopolymers. The dotted line is derived from the crystallinity values for each component within the blend.

interpenetration of the blend component. The case of blends of low density (LD) and high density (HD) PE is an example where the microhardness can be very well described in terms of an additive (parallel) system of two independent components, H_1 (LD) and H_2 (HD) (27):

$$H_{\text{blend}} = H_1\phi + H_2(1-\phi) \tag{5}$$

where ϕ is the fraction of LDPE component. Equation (5) emphasizes the existence of distinct H values for the two phases owing to a molecular segregation at a crystal level.

In other systems, such as in iPP/EPR, PE/iPP, and iPP/polyamide (PA) blends, a deviation from the additivity law given by equation (5) is detected (19,28,29). Figure 6 illustrates, as an example, the obtained deviation of H from the additivity law (dashed line) for PE/iPP blends, ϕ being in this case the weight fraction of polypropylene. If one takes into account the measured crystallinity values for the H_1 and H_2 components within the blends, and the H_c values of the homopolymers, then equation (5) leads to the dotted line in Figure 6. Still, the experimental data are clearly deviated from the predictions of equation (5). The low experimental H values found for the PE/iPP blends are due to a depression in the H_c^{PE} and H_c^{PP} values as a consequence of an increase in the surface free energy of the crystals (see eq. (3)) (28).

The use of the microhardness technique in blends of condensation polymers [PET/PEN and PET/polycarbonate (PC)] evidences the formation of copolymer sequences within the blends (30).

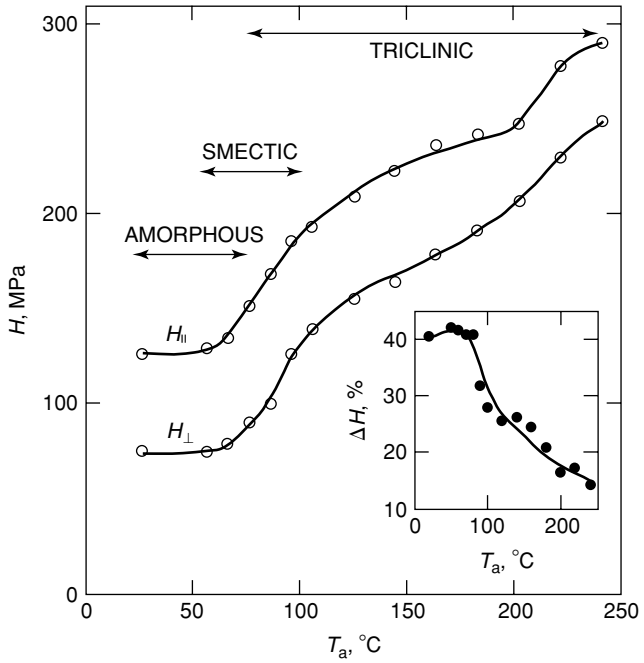

Fig. 7. Plots of $H_{\parallel}$ and $H_{\perp}$ as a function of annealing temperature for cold-drawn PET. The inlet illustrates the plot of indentation anisotropy ΔH vs T_a for the same material.

Indentation Anisotropy of Oriented Polymers

Uniaxial mechanical deformation produces a conspicuous anisotropic shape of the residual indentation (4). The anisotropy depends on the orientation of the diagonals of indentation relative to the axial direction. Two well-defined hardness values emerge. One value (maximum for a Vickers indenter) can be derived from the indentation diagonal parallel to the fiber axis, $d_{\parallel}$. The second one (minimum) is deduced from the diagonal perpendicular to it, $d_{\perp}$. The former value responds to an instant elastic recovery of the fibrous network in the draw direction. The latter value defines the plastic component of the oriented material. It is useful to define the indentation anisotropy as $\Delta H = 1 - (d_{\parallel}/d_{\perp})$.

A ΔH increase with increasing draw ratio λ has been found for solid-state extruded and highly drawn polymers, and a correlation between indentation anisotropy and Young's modulus has been found (4,31). Indentation anisotropy values of several carbon-fiber composites have been reported (32). Recently, the indentation anisotropy of cold-drawn PET, annealed at different temperatures, has also been examined (33).

Figure 7 illustrates the $H_{\parallel}$ and $H_{\perp}$ values as a function of annealing temperature T_a for cold-drawn PET. The $H_{\perp}$ increase with rising T_a reveals firstly, the gradual appearance of smectic domains (apparent at $T_a = 50^{\circ}C$) and secondly, the developing of a triclinic structure for $T_a \geq 80^{\circ}C$. The insert of Figure 7 shows the rapid decrease of ΔH with increasing T_a above 70°C. This result suggests that a molecular relaxation mechanism in the amorphous layers takes place above T_g

($T_g \approx 70^\circ$C), leading to a decrease in the elastic response of the fibrils to indentation along the chain direction.

Test Methods

Scratch Hardness Tests. The method is based on the ability of one solid to scratch another. A corner of a diamond cube is drawn across the sample surface under a force of 29.4 mN applied to the body diagonal of the cube; this creates a V-shaped groove of width λ, which is measured microscopically (34). The hardness is given by

$$\mathrm{HS} = \frac{10{,}000}{\lambda^2} \tag{6}$$

The constant 10,000 is arbitrary and λ is in μm.

Dynamic Rebound Test: Scleroscope. In this test, the rebound of a diamond-tipped weight dropped from a fixed height is measured (34). There are two models of the instrument: Model C (HSc) uses a hammer of small mass ($\approx$2.3 g) and a large height of fall ($\approx$251 mm); Model D (HSd) uses a hammer of about 36 g and a short fall ($\approx$18 mm).

Indentation Depth Reading: Rockwell Test. In this test, the depth of the indentation is read from a dial indicator; no microscope is required (34). In the Rockwell hardness tests, a load of 98 N is first applied to the surface and the depth of penetration is thereafter reckoned as the zero of measurement. A further load of 588, 980, or 1470 N is applied and removed leaving the additional depth of indentation recorded on a dial. The hardness is then expressed in terms of the dial reading on an arbitrarily numbered scale. The indenter used may be a steel spherical penetrator or a diamond cone with a hemispherical tip. The scales, indenter, and loads employed are chosen to adapt to the material properties. Results given by different testers are not readily interconverted.

Tests Based on the Optical Imaging of Indentation. Hardened steel, tungsten carbide, or diamond indenters are usually employed. Hardness values are determined from the load and the measurement of the residual indentation after load removal (1). The spacing between indents must be large enough (typically twice the width of the indentation) to be unaffected by deformation resulting from nearby indents. The sample thickness must be 10 or 1.5 times thicker than the width of the residual impression for spherical or pyramidal indenters, respectively. A microscope equipped with a micrometer eyepiece is used to measure the diameter of the impression up to 0.5 μm at most. The surface of the specimen must be flat, smooth, free of dirt, and unlubricated.

Brinell. In the Brinell test, a hardened steel ball is forced into the specimen. The standard test uses a 10-mm ball and a force of 29.42 kN (34). The Brinell hardness HB is equal to the applied force divided by the area of the indentation:

$$\mathrm{HB} = \frac{2P}{\pi D\left[1 - \sqrt{(1 - d/D)^2}\right]} \tag{7}$$

in which P is the force in N, D is the diameter of the ball in mm, and d is the diameter of the impression in mm. The minimum radius of a curved specimen surface is $2.5D$. Published tables simplify the conversion from the hardness values obtained with one standard load to the other (34).

Pyramid Indenters. The most common pyramid indenters are the *Vickers, Knoop*, and *Berkovich* indenters. The Vickers indenter consists of a square-based diamond pyramid with included angles (α) of 136° between nonadjacent faces. The Knoop test uses a rhombic-based diamond with included angles of 172° and 130° between opposite edges. The Berkovich indenter is a diamond trigonal pyramid whose facets form an angle of 65.3° with respect to the normal to the base.

Hardness value is calculated by dividing the load P by the facet or projected area of indentation, A:

$$H = \frac{P}{A} = C\frac{P}{d^2} \tag{8}$$

Here d is the average of both diagonal lengths, the length of the long diagonal or the height of the triangular impression for the Vickers, Knoop, and Berkovich indenters respectively. Hardness values in equation (8) are given in MPa if the force is in N and d in mm. C is a geometric constant whose value depends on the indenter shape and whether the projected area or the facet contact area of indentation is being used to calculate the hardness number. For a Vickers indenter, the facet area is most commonly used ($C = 1.854$). Knoop and Berkovich microhardness values are traditionally derived using the projected area of indentation ($C =$ 14.23 and 1.766 respectively).

The Vickers indenter penetrates the surface about twice as far as the Knoop indenter for a given load. The latter is very sensitive to material anisotropy because of the twofold symmetry of the indentation. The Berkovich indenter is preferred to the four-side pyramids when extremely small indentations are produced.

The indenter geometry is known to influence hardness values in polymers as well as in metals, ceramics, and glassy materials. For conical, spherical, and triangle-based pyramid indenters, hardness values are known to increase with decreasing included angle at the indenter tip (decreasing radius of the spheres) (1,35,36). This seems to be due to the detailed processes involved in the plastic flow around the indenter, together with a higher interface friction effect as the indenter included angle decreases (1,35). For the standard Brinell, Vickers, and Berkovich tests, a number of papers report on the correlation between the different hardness scales (1,37–39). Brinell and Vickers hardness values are almost identical up to a Brinell hardness of about 3 GPa (1). A few papers also show a good agreement between Vickers and Berkovich hardness numbers (37,38). Finally, a fairly good correspondence is also found for Knoop and Vickers hardness values (1,38,39) although significant deviations have also been reported (40).

Continuous Load–Depth Recording. In ultramicroindentation and nanoindentation devices the displacement and load are monitored continuously. It should be possible to vary the applied load, or imposed displacement, either in ramp mode or with a discontinuous increment (step mode) (41). Figure 8 illustrates a loading–hold–unloading cycle obtained for PET using an

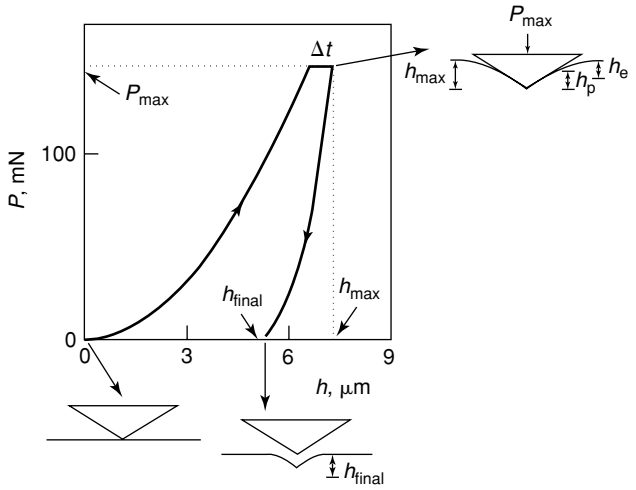

Fig. 8. Typical compliance curve for glassy PET obtained from continuous depth-sensing recording.

ultramicrohardness tester operating in ramp mode. The load is incremented at constant speed up to the maximum load P_{max} held thereafter for a period of time Δt and subsequently released at the same rate as in the loading cycle. Continuous depth-sensing recording does not give values of absolute hardness directly. This is because the area of indentation is not explicitly measured. However, the loading/unloading data can be processed on the basis of well-established assumptions to yield hardness and Young's modulus values (6,42). These approaches consider that the on-load maximum indentation depth h_{max} is the sum of the plastic and the elastic components of indentation, h_p and h_e respectively (see Fig. 8). It is further assumed that the area of contact between the indenter and specimen is determined by the plastic deformation only. The h_p value is then calculated from the analysis of the unloading curve (6,42). For a Vickers indenter, $A = 26.4h_p^2$, where A is the facet area of contact between the indenter and the specimen. Similar geometrical relationships between A and h_p can be derived for other indenters. Hardness is then calculated according to equation (8). The elastic modulus values may be derived from the analysis of the unloading curves.

Indentation studies on different polymeric materials suggest that the hardness values derived from continuous depth-sensing recording compare fairly well with the hardness numbers derived from the direct measurement of the size of indentation (35,43,44). This result suggests that hardness numbers determined from the contact area under load are comparable to post-indentation hardness values.

The actual trend in hardness testing is to use the nanoindentation instruments in conjunction with atomic force microscopes (45). Load–displacement measurements are used to derive hardness and elastic modulus data while the atomic force microscope yields additional topographic information of the indentation area. Measurements at depths of 1 nm can be performed.

HYDROGELS

Introduction

Hydrogels are hydrophilic polymers that absorb water and are insoluble in water at physiologic temperature, pH, and ionic strength because of the presence of a three-dimensional network. The cross-links can be formed by covalent bonds, or electrostatic, hydrophobic, or dipole–dipole interactions. The hydrophilicity is due to the presence of hydrophilic groups, such as hydroxyl, carboxyl, amide, and sulfonic groups along the polymer chain.

The area of hydrogel research has expanded dramatically in the last 10 years, primarily because hydrogels perform well for biomedical applications. This is true for both the synthetic and natural hydrogels. Hydrogels work well in the body because they mimic the natural structure of the body's cellular makeup. Recent advances in the use of hydrogels for tissue engineering, drug delivery, and contact lens application, to name but a few of the many biomedical applications of hydrogels, have led to (for the first time) the potential to design artificial organs in a controlled fashion, to deliver drugs to specific sites in the body, and to fabricate the first true extended wear contact lenses.

This article focuses on the biomedical applications of hydrogels. Several areas of nonbiomedical applications are also discussed. Hydrogels can be classified as synthetic, natural, "smart," and biodegradable hydrogels. There may be many more classes of hydrogels, but this class division is based on the current focus of hydrogel research. Hydrogels which are interpenetrating polymer networks (IPNs) and block copolymers, for example, are discussed throughout the article. The preparation of hydrogels focuses on the details of free-radical cross-linking polymerization, chemical cross-linking, irradiation cross-linking, and physical interaction cross-linking techniques.

Properties

A hydrogel is a cross-linked polymer that swells in water to an equilibrium value. The dry hydrogel is called a *xerogel* or dry gel. When the hydrogel is dried, water evaporates from the gel and causes collapse of the gel structure. If water is removed without disturbing the network, either by freeze-drying or by organic solvent extraction techniques, the resultant hydrogel is extremely porous. These materials are referred to as *aerogels* (1). The amount of water a material needs to absorb to be classified as a hydrogel remains undefined, but most researchers generally agree that if a material absorbs at least 10% water and is insoluble in water, it can be classified as a hydrogel. The swollen equilibrated state of a hydrogel results from a balance between the osmotic driving forces that cause the water to enter the hydrophilic polymer and the cohesive forces exerted by the polymer chains in resisting expansion (2,3). They attain an equilibrium swelling state that depends on the osmotic driving forces and the cross-link density. An equilibrated state is reached quickly following immersion of the dry (xero) gel in water. Most hydrogels, in fact, reach an equilibrium concentration of water within 15 min of hydration time. The degree of hydration (water content) can be expressed using the following equation:

$$\%\text{Water(weight)} = [(\text{hydrated weight} - \text{dry weight})\text{hydrated weight}] \times 100$$

The degree of water absorption related to the dry state of the polymer is called *percent hydration*. This is calculated using the following equation:

$$\%\text{Hydration} = [(\text{hydrated weight} - \text{dry weight})\text{dry weight}] \times 100$$

The more hydrophilic the polymer and/or monomers used to prepare the hydrogel, the higher the degree of hydration. This hydration can also, to some extent, be controlled through cross-link density. The higher the degree of cross-linking for a given polymer system will result in a corresponding decrease in water content. An expression for polymer swelling is found in the Flory–Huggins equation where the volume fraction of the polymer in the swollen gel is expressed as

$$V_2 = \left(m_\mathrm{p} d_\mathrm{p}^{-1}\right) / \left(m_\mathrm{p} d_\mathrm{p}^{-1} + m_\mathrm{w} d_\mathrm{w}^{-1}\right)$$

where m_p and m_w are the weights of dry polymer and solvent, respectively, and d_p and d_w are the densities of dry polymer and solvent at 25°C (4,5).

The hydrophilicity of the hydrogel system can also be expressed by means of an interaction parameter (χ). This parameter defines the interaction energy during the process of hydration. The parameter is determined experimentally from stress–strain curves and the swelling characteristics of the hydrogel using the Flory–Huggins equation,

$$\chi = -\left[\nu_\mathrm{e} v_1 \left(\langle\alpha\rangle_0^2 (v_2)^{1/3} - v_2/2\right) + \ln(1 - v_2) + v_2\right] v_2^{-2}$$

where ν_e is the concentration of elastically effective chains in a volume unit of

unswollen polymer, v_1 is the molar volume of solvent, and $\langle\alpha\rangle$ the isotropic dilation factor. One can approximate $\langle\alpha\rangle^2_0$ to equal $(v_0)^{2/3}$ if the polymerization is performed in a solvent (v_0 in this case is the volume fraction of the monomer in the original mixture or the volume fraction of the polymer at network formation), and ν_e can be approximated from stress–strain curve.

The water that is contained in hydrogels is believed to consist of a "bound" water and "free" water (6). When the dry hydrogel polymer is placed in water, the hydrophilic groups along the polymer chain are hydrated first. Water will form a hydration sphere around these hydrophilic groups. This type of water is called *bound water*. The bound water molecules are believed to be tightly held in the hydrogel matrix through a series of chemical interactions, such as hydrogen bonding. As the hydrogel continues to hydrate, additional water that is absorbed by the hydrogel is referred to as *unbound or free water*. This water fills the voids and pores of the hydrogel. The water in this hydration sphere has less structure and higher mobility than does bound water. Higher water content hydrogels contain more free water. It is the free water that is believed to be responsible for the "end of day" dehydration characteristics of high water content hydrogel contact lenses. These types of water are determined experimentally using dsc (differential scanning calorimetry) and nmr (nuclear magnetic resonance) techniques. It is important to note, however, that not all researchers believe that free and bound water exists. From heat-capacity measurements in the hydrogel poly(HEMA) [poly(2-hydroxyethyl methacrylate)] and a study of the thermodynamics from mixing water with poly(HEMA), researchers have indicated that strong interactions of water with the polar groups along the polymer chain does not occur. Evidence as determined by pulsed gradient nmr indicates that all of the water in poly(HEMA) hydrogels diffuses as a homogeneous water phase (7).

The amount and type of water that is contained in the hydrogels determines the diffusion and transport characteristics of the hydrogel. This is important for drug delivery and contact lens application. It has been shown that the low water transport characteristics of some contact lens hydrogel system is the major factor responsible for contact lens adhesion. The oxygen permeability and water transport characteristics of conventional hydrogels increase with increasing levels of hydration. Details of the diffusion and dynamic transport behavior or hydrogels can be found in excellent reviews (8). The design of a high water content hydrogels for biomedical application where mechanical integrity is required can be a serious problem because of the fact that high water content hydrogels typically possess very poor tear strengths.

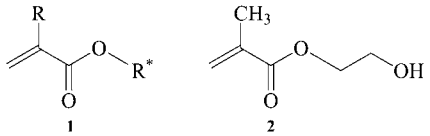
Classes of Hydrogels

Hydrogels can be classified as either synthetic or natural according to their origin, degradable or stable depending on their stability characteristics, and "intelligent" or conventional depending on their ability to exhibit significant dimensional changes with variations in pH, temperature, or electric field.

Conventional Synthetic Hydrogels. The class of conventional synthetic hydrogels is prepared by free-radical polymerization of vinyl-activated monomers. These monomers can be classified according to type and charge. The water content

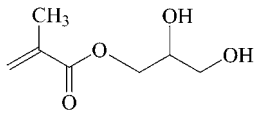
of the resultant hydrogel can vary widely, depending on the hydrophilicity of the monomer and degree of cross-linking. A difunctional monomer is added to cross-link the polymer chains.

One of the most important classes of monomers used to prepare synthetic hydrophilic polymers and hydrogels are the methacrylates and acrylates. The principal monomer is shown in (**1**) where R=H (acrylate) and R=CH_3 (methacrylate). A wide variety of commercially available hydrophilic acrylates and methacrylates exist. A huge advantage of this class of monomers is their relative ease of polymerization and low cost. The monomer 2-hydroxyethyl methacrylate (HEMA) (**2**) has been used extensively in the contact lens industry. Poly(HEMA) possesses a water content of 38% and has excellent mechanical strength. The monomer glyceryl methacrylate (**3**) when polymerized and cross-linked results in a hydrogel of approximately 70% water, depending on its purity and degree of cross-linking.



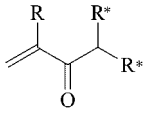
1

2

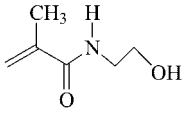


3

Another very important class of monomers used to prepare synthetic hydrogels is the acrylamide/methacrylamide (**4**) (R=CH_3 or H) based monomers. These include the monomers acrylamide (AA), *N*-methacrylamide (MAA), *N*,*N*-dimethylacrylamide (DMA), and diacetone acrylamide (DAA). The polymers prepared from AA, MAA, and DMA are all "super water absorbent" polymers, each capable of absorbing several times their weight in water. DMA is a particularly useful monomer for biomedical application in that it possesses excellent hydrolytic and thermal stability characteristics and moderately low levels of toxicity, unlike AA, which is extremely toxic. The polymerization of the monomer 2-hydroxyethylmethacrylamide (**5**) also results in a "super water absorbent" polymer. Despite its similar structure to the methacrylate analogue HEMA, this polymer is capable of water contents as high as 85%, simply because of substitution of the ester for an amide linkage.



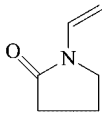
4



5

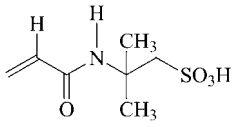
The class of hydrophilic monomers based on the cyclic lactams is also an important class of monomers. The most widely used lactam monomer is *N*-vinyl pyrrolidinone (NVP) (**6**). This is also a "super absorber." Hydrogels prepared from

this monomer absorb several times their weight in water, despite the hydrophobic aliphatic ring structure. Cross-linking agents for NVP and NVP-based copolymerizations include *N*,*N*-methylenebisacrylamide and allyl methacrylate. The monomer NVP is widely used for contact lens application, and in fact, most commercial contact lens materials contain NVP.



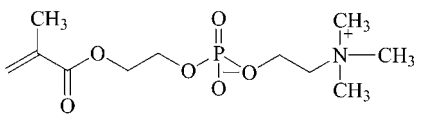
6

Monomers that contain ionic functionality are also widely used for the preparation of hydrogels. These include methacrylate, methacrylamide, and styrene-based monomers that contain acidic or basic functionality. In this class of monomers is included methacrylic acid, acrylamidomethylpropylsulfonic acid (**7**), and *p*-styrene sulfonate. These are typically used as comonomers at low concentration. The ionic functionality in a buffered saline environment dramatically increases the water content of the resultant hydrogel. For example, copolymerization of 2 wt% methacrylic acid with HEMA results in a hydrogel having a water content of 60% (compared with a 38% water content for HEMA alone). In a similar fashion, the cationic monomer methacryloyloxyethyltrimethylammonium chloride (MAC) is extremely hydrophilic. A hydrogel containing 60% NVP, 10% MAC, and 30% HEMA results in a material having an equilibrium water content of 87% (9).



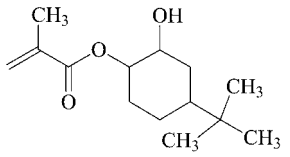
7

The copolymerization of MAC with methacrylic acid results in ampholytic hydrogels. These are hydrogels that contain both anionic and cationic characteristics (10). These materials exhibit interesting pH-dependent behavior. Zwitterionic hydrogels, based on 2-(methacryloyloxy)ethyl-2′-(trimethylammonium)ethyl phosphate inner salt (**8**), have also been designed for improved biocompatibility. These hydrogels mimic the zwitterionic structure of phospholipids such as phosphatidylcholine, which is a major component of the outer membrane of all living cells (11). Zwitterionic monomers contain both a cationic and anionic charge on the same molecule.



8

It is important to note that almost all high water content hydrogels possess poor mechanical properties. This is a huge disadvantage of hydrogels, especially when one needs to design a material for an application that requires some mechanical integrity. A homopolymer of poly(NVP), for example, resembles a hydrated gelatin. In order to overcome the poor strength of these materials, it is necessary to copolymerize these "super absorbent" monomers with monomers that are capable of improving the overall tear strength of the material. Several monomers have been successfully used. One such monomer is methyl methacrylate (MMA). Low concentrations of MMA in a copolymer formulation typically result in a reduction in water content, but a dramatic improvement in mechanical integrity is also observed. Monomers such as cyclohexyl methacrylate and *t*-butylcyclohexyl methacrylate also work well (12). These monomers improve the mechanical properties of hydrogel formulations by imparting rigidity to the polymer network. This approach, however, is seriously limited in that phase separation often occurs before acceptable properties are achieved. One approach to overcome this phase separation issue, while improving the overall hydrogel strength, is through the use of "hydrophilic-bulky" strengthening agents, such as 4-*t*-butyl-2-hydroxycyclohexyl methacrylate (TBE) (**9**) (13). Excellent mechanical characteristics and optical clarity have been achieved through the use of TBE. A 80/20 (w/w) copolymer of NVP and TBE results in an 85% water-containing hydrogel that possesses a tear strength equivalent to the 38% water-containing hydrogel poly(HEMA).

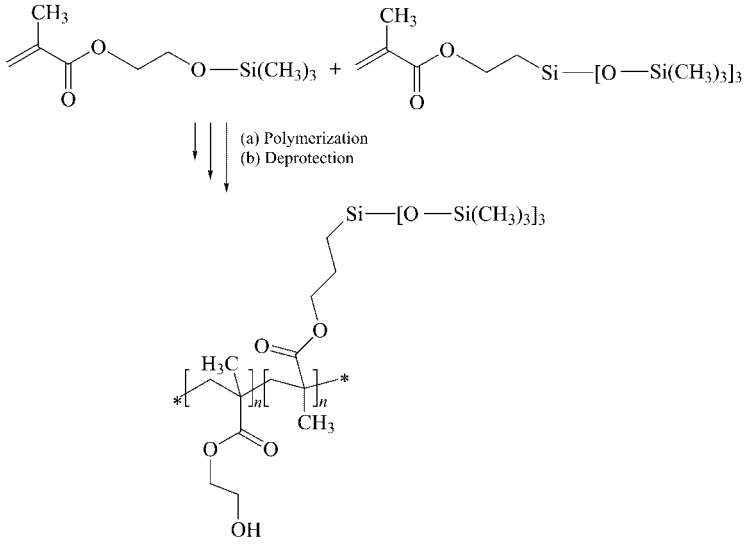


9

Silicone Hydrogels. A new class of hydrogels based on silicone has been developed (14). These materials were developed in an attempt to combine the high oxygen permeability of polydimethylsiloxane and the excellent water absorption characteristics of conventional non-silicone hydrogels. This new class of hydrogels was developed primarily for contact lens application. These silicone hydrogels are also prepared by free-radical polymerization techniques.

The biggest limitation in the design of silicone hydrogels is that silicone-based monomers are hydrophobic and insoluble in hydrophilic monomers. The copolymerization of methacrylate-functionalized silicones with hydrophilic monomers generally results in opaque, phase-separated materials. There have been essentially three approaches in the design of transparent silicone hydrogels, ie, in minimizing the phase separation that occurs during polymerization of methacrylate-functionalized silicones with hydrophilic monomers. One approach has involved a protection–deprotection procedure (**15**). This involves the protection of a hydrophilic monomer with a hydrophobic protecting group. Copolymerization of the protected monomer with a methacrylate-functionalized silicone, followed by removal of the protecting group, results in a transparent silicone hydrogel. For example, trimethylsilyl-protected 2-hydroxyethyl methacrylate is

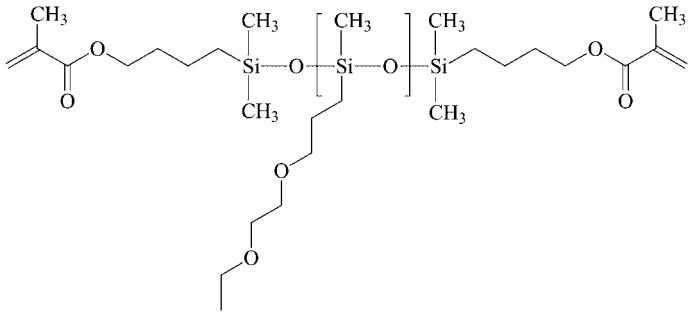
readily soluble in silicone-based monomers. Copolymerization of the protected HEMA with the monomer methacryloyloxyethyl tris(trimethylsilyloxy)silane forms a transparent, hydrophobic material that, following immersion in a mild basic or acidic deprotecting solution and extraction to remove hexamethyldisiloxane, gives a transparent silicone-based hydrogel (**10**). This is a good approach in principle; however, it is extremely expensive because of the large number of processing steps and length of time required for complete deprotection.



10

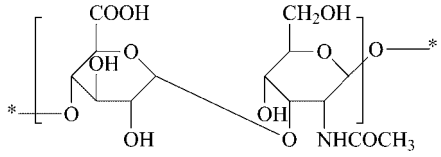
Another approach has been the use of a solubilizing co-solvent. For example, the addition of a co-solvent that is capable of solubilizing an incompatible mixture of silicone and a hydrophilic monomer, in many cases, results in transparent materials following cure. Examples of co-solvents include isopropyl alcohol, hexanol, and methyl dodecanoate. This approach has the additional advantage of controlling the glass-transition temperature of the material. The addition of higher concentrations of co-solvent results in a lower glass-transition temperature as a result of a higher polymer chain flexibility (higher free volume). It is imperative that the glass transition of the material is below the cure temperature in order to effect a complete cure.

The third and most successful approach has been the preparation of siloxanes containing hydrophilic groups to improve the solubility of silicone-based materials with hydrophilic monomers. In this approach several synthetic avenues have been pursued including the synthesis of hydrophilic-TRIS [tris(trimethylsiloxysilyl)propyl methacrylate] derivatives, siloxanes containing hydrophilic blocks, and siloxanes containing hydrophilic grafts, such as polyethyleneglycol-grafted silicones (**11**) (16–19).



11

Natural Hydrogels. Naturally occurring water-soluble polymers include polynucleotides, polypeptides, and polysaccharides. These polymers are derived from a variety of naturally occurring sources such as plants, animals, and humans, or are synthesized. The polymer collagen, for example, is obtained from cows, pigs, and humans, depending on the type of collagen required. Polypeptides can be synthesized by a protection/solid support scheme or through recombinant DNA techniques. Hydrogels of naturally occurring polymers are prepared by the chemical or physical cross-linking of these polymers. The chemical cross-linking reaction of polysaccharides (alginate, chitin, chitosan, cellulose, oligopeptides, and hyaluronic acid (**12**)) and proteins (albumin, gelatin) leads to a variety of well-defined hydrogels (20–22). Hydrogels prepared from these polymers exhibit excellent biocompatibility, primarily because they mimic the structural components of the body. In humans, glycoaminoglycans are hydrogels that exist in the connective tissue, such as skin, tendon, and bone (23,24). Additional information on the naturally occurring polymers can be found in excellent reviews (25,26).



12

"Smart" Hydrogels. A truly amazing class of hydrogels that has found potential use for a wide variety of applications is the class of "smart" or "intelligent" hydrogels. Smart hydrogels are, in most respects, very much similar to conventional hydrogels. They are synthesized using similar methods and absorb water. Smart hydrogels, however, deserve to be in their own class. The uniqueness of this class is due to the unusual volume changes that these polymers exhibit under the application of very specific stimuli. Smart hydrogels exhibit significant volume changes in response to stimuli such as changes in pH, temperature, electric field, and light (27–29). The major reason for the interest in these polymer systems

is that the smart polymers, in most respects, behave like biopolymers in nature; small changes of some specific stimuli dictate most of the biochemical response in the body. The desire to form hydrogel systems that can mimic biological systems drives a huge area of research. This volume change is abrupt and occurs with only a small change in stimuli. In solution these changes are referred to as the lower critical solution temperature (LCST), where at a specified temperature the polymer precipitates from solution. For a hydrogel system, these changes are marked by an order of magnitude change in the size, shape, and water content of the hydrogel. The hydrogel returns to its original state when the stimuli is removed. These shifts are triggered by changes in the physical state of the hydrogel as a result of changes in the hydrophilic/hydrophobic microstructure of the hydrogel. In designing such systems, the goal is to control the balance of the hydrophobic/hydrophilic nature of the hydrogel system. The driving force behind these transitions varies, with common stimuli including (*1*) the neutralization of charged groups by either pH shift, (*2*) the addition of an oppositely charged polymer, and (*3*) change in the efficiency of hydrogen bonding with an increase in temperature or ionic strength (30).

Biodegradable Hydrogels. Biodegradable hydrogels, much similar to that of the smart hydrogels category, has expanded at such a fast pace that it now deserves to be in its own class. The uses of biodegradable hydrogels now encompass a wide variety of applications, for both biomedical and nonbiomedical uses. In the design of biomedical products, the basic objective is to fabricate materials that resorb or degrade in a physiological environment so that the device ultimately disappears with no adverse reaction (31,32). Degradable polymers undergo chain scission to form low molecular weight oligomers or monomers. Ultimately, the oligomers and monomers are either fully degraded to biosubstances or are eliminated by the body. Degradation is characterized by loss of molecular weight, loss of mass and mechanical strength. The definition of biodegradation is broad and includes a variety of degradative mechanisms, depending on whether the degradation follows (33). Degradation hydrolytic, thermal, or enzymatic degradation pathways (see BIODEGRADABLE POLYMERS, MEDICAL APPLICATIONS).

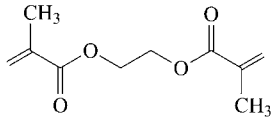
Methods of Preparation

Free-Radical Polymerization. Free-radical polymerization cross-linking is the preferred route used to prepare hydrogels from the class of acrylates, amides, and vinyl lactams. It can also be used to prepare hydrogels from the naturally occurring polymers if the polymer backbone or chain end of the natural polymer has been functionalized with a radically polymerizable group. It is also the preferred route to prepare interpenetrating network hydrogels (IPNs) using either synthetic monomers or natural polymers (again funtionalized with a radically polymerizable group). The IPNs hydrogels are networks that contain two polymer systems, each in its own cross-link network.

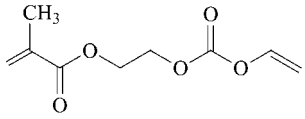
To form a hydrogel by free-radical polymerization, a difunctional cross-linking agent must be added to the polymerization. The classical gelation

theory can be applied to most of these polymerizations, especially for methacrylate–dimethacrylate monomer combinations that have similar reactivity (34). This theory allows for a fairly precise determination of the overall kinetics of the system, which includes estimates of the gelation and vitrification point. There are a variety of cross-linkers one can choose from. For methacrylate polymerizations, a common cross-linker is ethylene glycol dimethacrylate (**13**) that is added at a concentration of 0.1–1.0%. For acrylamide systems, methylene bisacrylamide is very common. For lactam-based systems, ethylene divinylurea works extremely well.

Problems arise when one attempts to copolymerize monomers of unlike reactivity, such as the copolymerization of HEMA with the vinyl lactam NVP. For this type of polymerization, a block-type copolymer possessing high levels of unreacted NVP results. This is due to the slow kinetics of NVP polymerization and unsuitable reactivity ratio of this comonomer system. The reactivity ratios (r_1 and r_2 values) result in a "blocky" backbone. This high level of unreacted NVP can be overcome by designing cross-linkers that are capable of polymerizing with both lactam and methacrylate functionality. For example, the cross-linker methacryloxyethyl vinyl carbonate (**14**) (MEVC) is an excellent example of a cross-linker that possesses reactivity for both a methacrylate and vinyl lactam functionality. The vinyl carbonate group has the same reactivity as the vinyl bond in NVP (35). The copolymerization of NVP and HEMA with MEVC results in a significant increase in water content (when compared with conventional methacrylate cross-linkers) because of the higher incorporation of NVP in the copolymer.



13



14

The chemistry of typical free-radical polymerizations involves an initiation, propagation, chain transfer, and termination step leading to the formation of a cross-linked polymer system (36). The initiation step (radical formation step) utilizes chemistries that when subjected to thermal or ultraviolet radiation form radicals that react with activated monomers, such as a methacrylate. A wide variety of thermal, ultraviolet, visible, and redox initiators are commercially available. Typical thermal initiators include the class of azo compounds, such as azobisisobutylonitrile (AIBN), and peroxide initiators, such as the peroxydicarbonates and the hindered peroctoates. Polymerization conditions vary

widely depending on the type of initiator and its half-life. For example, the respective 10-h half-life data of AIBN is 64°C, and for cumylperoxydecanoate the 10-h half-life is 38°C. This is extremely helpful in controlling polymerization exotherms, reactivity ratios, and monomer solubility. Typical commercially available ultraviolet and visible light initiators include the benzoin methyl ethers, acetophenones, and benzoyl phenyl phosphine oxides, to name but only a few.

The polymerizations can be performed either in solution or neat. There are advantages to both methods depending on the product end use. Solution polymerizations can be helpful when the preparation of large quantities of hydrogel are required. The solvent for most reactions is water; however, a wide variety of polar solvents can be used with the only requirement that they can be exchanged for water in the hydration step. The polymerization exotherm can be controlled by choice of solvent. For many copolymerizations, the addition of a suitable "solubilizing" solvent is necessary to solubilize monomers of widely varying hydrophilicity. Also, a solvent can aid in the molecular weight control. By use of a chain-transfer solvent such as an alkyl mercaptan, molecular weight and end-group functionality can be controlled (37).

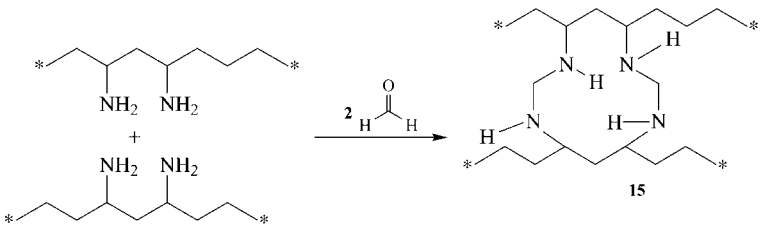
Neat polymerizations, also sometimes referred to as bulk polymerizations, are typically performed between metal or glass plates utilizing a flexible spacer to accommodate shrinkage. Clamps are used to assure a complete seal. The metal plates are many times treated with a fluoro polymer, and the glass plates are treated with a chloromethylsilane to facilitate plate separation and to eliminate adhesion of the polymer film. The filled plates are cured in an oven or under ultraviolet or visible lights, depending on the desired initiation mode. Following the cure, the films are removed and extracted with an appropriate solvent. Neat polymerizations are very fast, usually requiring only minutes for total monomer conversion. This, however, limits the reaction size in that exotherms are difficult to control. A big advantage of neat polymerizations is that there is no need for solvent removal. Solvent removal can be very time-consuming, requiring either extensive thermal devolatilization or solution extraction steps.

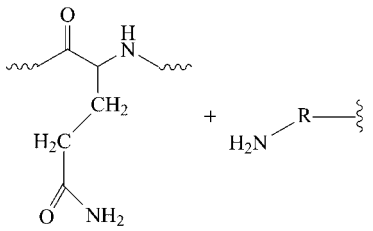
Emulsion and suspension polymerizations are also an important route to obtain hydrogels by free-radical polymerization (38). For some applications, this is the preferred route, particularly when droplets or spheres of the hydrogel are desired. This is an important route to prepare hydrogels for drug delivery application. For these polymerizations, the initiator, solvent, and monomer are added together with a suspending agent and/or emulsifier. The cross-linker can be added but is not necessary, depending on whether one desires a soluble polymer. A major disadvantage of this route is that the emulsifier and/or suspending agent is sometimes difficult to remove.

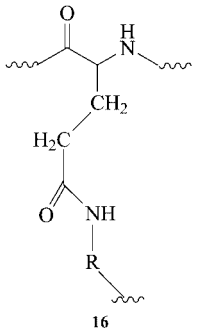
Chemical Cross-Linking of Polymers. Another important method used to prepare hydrogels is by the cross-linking of hydrophilic polymers (39). This route can be employed for both the synthetic and naturally occurring polymers. In this reaction, a bifunctional cross-linking agent is added to a dilute solution of the hydrophilic polymer. The hydrophilic polymer contains functionality that is capable of reacting with the cross-linking agent. The reaction is typically in solution,

but may also be performed through a suspension reaction where microparticles or spheres are desired.

Most of the naturally occurring polymers can be cross-linked in this fashion. For example, the polymers albumin and gelatin can be cross-linked with formaldehyde or a difunctional dialdehyde (40,41). The aldehyde reacts with the amino group along the albumin polymer backbone (**15**). Also, using a similar approach, chrondroitin sulfate can be cross-linked with diaminododecane catalyzed by dicyclohexycarbodiimide (42). In this example, increasing the concentration of diaminododecane increased the degree of cross-linking. Cystein-bearing polypeptides can be cross-linked through cystein bonds (43,44). Another example is the cross-linking of poly(vinyl alcohol) using a diisocyanate-terminated poly(ethylene oxide). Hydrogels have also been prepared from functionalized poly(ethylene glycol) (PEG) through enzymatic cross-linking. PEG functionalized with a glutaminamide and a lysine-containing polypeptide were cross-linked by the reaction of a natural tissue enzyme, transglutaminase (**16**). Transparent gels of water contents as high as 90% have been prepared by this route (45).







16

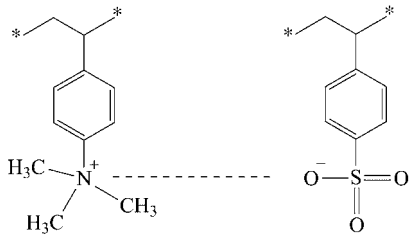
Irradiation Cross-Linking of Polymers. Hydrogels can also be obtained by ionizing-radiation techniques. This route can be employed for both the synthetic and naturally occurring polymers. *Ionizing radiation* is a radiation that possesses enough energy to ionize simple molecules either in air or water (46). The radiation can be in the form of an electron beam irradiation or γ–radiation. This cross-linking reaction can be accomplished by irradiation of a hydrophilic polymer in bulk or in solution. These reactions are usually performed in water. The preferred method, however, is irradiation of a polymer solution. The solution method is preferred because it requires less energy for formation of a macroradical, and radical efficiency is increased because of the reduced viscosity of the reaction mixture. When a polymer solution is irradiated, reactive sites along the polymer backbone are formed. The main reactive species (when water is used as the reactive solvent) are hydrated electrons, hydroxyl radicals, and hydrogen atoms. It is the hydroxy radicals, however, that lead to abstraction of hydrogen atoms along the polymer chain with formation of a "multisite" radical functionalized macromolecule. When these radicals combine, a cross-link is formed. This is not true for all polymer systems; some polymers, in fact, will degrade under ionizing radiation (47). Many polymers in solution will undergo simultaneous cross-linking and degradation reactions. Each polymer system is unique and the optimum irradiation conditions need to be determined experimentally to minimize chain degradation and maximize cross-linking reactions.

Gels through Physical Interactions. Hydrogels can also be formed through a series of physical interactions. It is this type of reaction that, in fact, provides most of the cellular network in the body. These physical interactions include polyelectrolyte complexation, hydrogen bonding, hydrophobic association, and crystalline entanglements. Typical methods to prepare films utilizing physical interactions involves solvent casting or precipitation techniques.

Polyelectrolyte Complexation. Hydrogels can be easily formed through the formation of polyelectrolyte complexes (48). The bonds formed through polyelectrolytic complexation occur between pairs of charged sites along the polymer backbone. The hydrogels formed through electrolytic complexation are insoluble in water, and the electrolytic bonds can be very stable depending on the pH of the system (7–10 kcal).

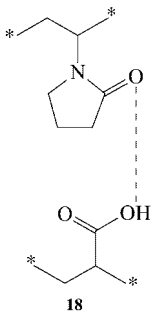
Polyelectrolyte complexes are divided into four subclasses depending on the basicity and acidity of the polyelectrolytes. These include strong acid–strong base, strong acid–weak base, weak acid–strong base, and weak acid–weak base subclasses. The composition of these complexes is dictated by the degree of dissociation of the electrolytic components.

The complexation of poly(sodium styrene sulfonate) and poly(4-vinylbenzyltrimethylammonium chloride) is easy to form (**17**) (49). By combining two water-based solutions of each polymer at equimolar concentration, the complex forms immediately as evident by the formation of white precipitate. Another example is the polyelectrolyte complexation of an amino group containing chitosan with the polymer sodium alginate (50). Sodium alginate also forms a strong complex through the association of calcium ions (51).



17

Hydrogen Bonding. Hydrogels can also be formed through the hydrogen bonding of macromolecular chains. A hydrogen bond is formed through the association of electron-deficient hydrogen and a functional group of high electron density. Similar to the polyelectrolytic complexes described above, hydrogen-bonded complexes occur in many biological systems. The hydrogen-bonded complex (**18**) of poly(acrylic acid) and poly(NVP) is one of the more common (52,53). This complex is affected by a variety of factors, such as the molar ratio of each polymer, the solution temperature, polymer concentration, type of solvent, and polymer structure (degree of association between complexing functionalities). This complex will not form a gel at neutral pH.



18

Hydrophobic Association. Hydrogels can also be formed through hydrophobic associations (54–58). Polymer systems such as block copolymers, graft copolymers, and polymer blends form microphase/microdomain separated structures. The hydrophobic domains in these structures behave as associated crosslink sites. These polymers combine hydrophobic segments that form unique hydrophobic phases dispersed (or surrounded) by hydrophilic water absorbing regions. These hydrophobic-associated polymer blends typically possess poor mechanical properties because of poor interfacial adhesion, and films are usually opaque because of macrophase polymer separation. Control of the size of the hydrophobic phase tends to improve the optical transparency and mechanical integrity. A precise balance needs to be established.

One of the major advantages of this approach is the resultant low cost economics of the system. Commercially available polymers can be used to generate a wide variety of high strength, low cost hydrogels. This is particularly true of polymer blends. The hydrophobic phases of blend hydrogels form multicross-link sites along the polymer backbone and, so loss of the water-soluble polymer is

minimized. This is extremely important for biomaterials where polymer leaching cannot be tolerated. Another advantage of this approach is that these polymer blends are soluble in organic solvents and flow at elevated temperatures. This allows for the processing of these hydrophobic blends by injection molding. Covalently cross-linked systems are insoluble in organic solvents and do not flow even at elevated temperatures. An excellent example of a hydrophobically associated hydrogel is the copolymer of poly(butyl methacrylate-*co*-methacrylamide-*co*-acrylic acid) with a blend of poly(*N*,*N*-dimethylacrylamide-*co*-*N*-vinylpyrrolidone) (59,60). Hydrophobic association is the predominant associated force holding this polymer blend together. It is reported that this polymer is stable in water at a pH range of 1–11.

Biomedical Applications of Hydrogels

One of the first areas of commercial application for hydrogels was contact lenses (61). In the 1950s and 1960s Otto Wichterle in Prague discovered the hydrogel poly(HEMA), and a very simple process to prepare contact lenses (62). The process consisted of spinning a monomer solution in a preformed optical quality mold. This ingenious work was completed on an old-fashioned "erector set" in the early morning hours of Christmas. Since that time the area of hydrogel research has expanded rapidly. Hydrogels have been used for a wide variety of nonbiomedical applications, but the primary area of hydrogel research has focused on biomedical applications. This is the result of the generally excellent biocompatibility exhibited by hydrogels. Hydrogels have been successfully used for a wide variety of biomedical applications including contact lenses, intraocular lenses, drug delivery devices, implants, and scaffolds for living cell encapsulations.

Contact Lenses.

Conventional Hydrogels. With the discovery of poly(HEMA), the contact lens industry began to flourish. This is because HEMA is a transparent, soft material that, when hydrated, absorbs 38% water, and as a result is very comfortable to wear. The HEMA lens also has excellent wetting characteristics and biocompatibility. Within a few years following this discovery, a number of companies began to market their own version of the HEMA lens. A multitude of new hydrogel contact lenses emerged (63–66). Most were based on copolymers of HEMA, NVP, and glyceryl methacrylate, together with cross-linkers and initiators. These materials were marketed as daily wear lenses, ie, wear the lens for one day, remove it at night for cleaning, and again wear the lens the next day.

With the huge success of the daily wear contact lens market, researchers began to look for ways to increase the contact lens wearing time. This started a huge research effort to design contact lens materials for extended wear application, with the primary goal to simplify the patients cleaning and wearing schedule. Such design was not a trivial task. The design of a new contact lens material for extended wear application requires a material to satisfy a number of very strict design requirements. The material must be optically transparent, possess chemical and thermal stability, biocompatibility, and be wettable to tears. It must also have suitable mechanical properties. This requires a material to have a low modulus for patient comfort and high tear strength for lens handling

durability. In addition, it is important that the material can be processed through free-radical polymerization techniques. Finally, the material must be permeable to oxygen. There is a lack of blood vessels in the corneal network, and so the cornea obtains almost all of its oxygen requirements from the atmosphere. Placing a contact lens over the eye that does not "breathe" may result in a number of physiological problems (microcysts, inflammation, infections, and corneal ulcers) (67).

There have been several approaches in the design of high oxygen permeable hydrogels for extended wear contact lens application. The first and simplest approach reduces the lens thickness to increase the oxygen transmissibility. The key intrinsic material properties that are a measure of oxygen diffusion are oxygen permeability (Dk), where D is the diffusion coefficient and k is a proportionality coefficient called the *Henry's law coefficient*, and oxygen transmissibility (DkL^{-1}), where the actual amount of oxygen reaching the cornea is inversely proportional to the lens thickness L. Several thin-lens designed contact lenses were introduced to the market with, however, limited success. These lenses were extremely difficult to handle, and most thin-lens designs did not provide enough oxygen permeability for extended lens wear application.

The second approach consists of designing hydrogels with a high water content. A direct correlation exists between water content and oxygen permeability, and so the higher the water content, the higher the hydrogel's oxygen permeability (Fig. 1, ■). There are two methods of designing high water hydrogels. The first involves the polymerization of highly hydrophilic monomers, such as NVP. The second utilizes the use of ionic monomers. The polymerization of HEMA with small concentrations of methacrylic acid, in a buffered saline environment results in a significant increase in water content. For example, with the addition of 2 wt% of methacrylic acid to HEMA, a 60% water content is realized (as compared with 38% for pure HEMA). Both methods require the use of cross-linkers and initiators and may need strengthening agents.

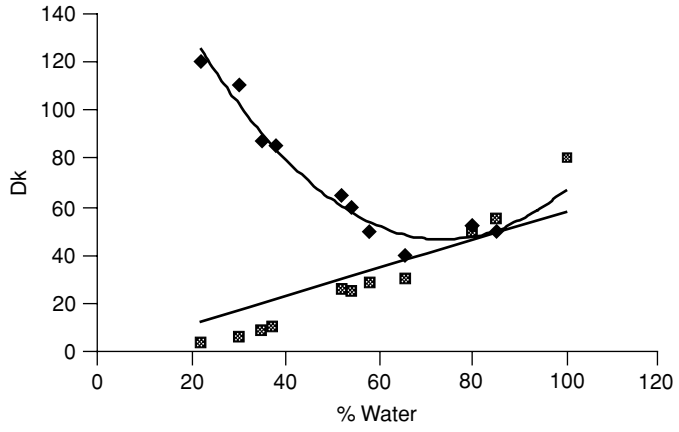


Fig. 1. Relationship between Dk and percent water for conventional hydrogels (■) and TPVC-based silicone hydrogels (◇) (Dk in units of Barrers).

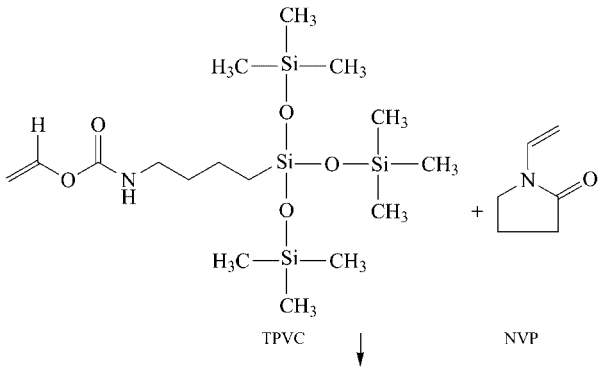
At the time of the discovery of high water content hydrogels, these materials were considered a huge breakthrough with the potential, many practitioners believed, to be the "ultimate contact lens material." This promise, however, was short-lived. There are several limitations of high water content hydrogels. The first is that high water content hydrogels typically possess poor tear strengths and often exhibit a high affinity for protein, particularly for hydrogels possessing an ionic functionality (68). Deposits can affect material wetting, patient comfort, visual acuity, and may even cause inflammatory responses. In addition, in dry environments, high water content hydrogels can induce a clinical response known as *epithelial dehydration* (a dehydration of the corneal epithelial cells) (69). This results in damage to the corneal epithelial cells. This phenomenon is a result of the high rate of water evaporation that occurs with the high water content hydrogels.

Silicone Hydrogels. Another approach in the design of an extended wear contact lens consisted of the development of materials based on polydimethylsiloxane elastomers (PDMS). PDMS appeared to be an ideal polymer for use in an extended wear lens because it possessed a low modulus of elasticity, excellent transparency, and high oxygen permeability (70). The major drawback is that PDMS is completely nonwettable to tears, thus requiring surface treatment to impart wettability. These surface treatments were typically ineffective, resulting in surfaces that possessed marginal wetting characteristics and a high affinity for lipids. Another significant drawback was that silicone lenses under normal wear conditions adhered to the cornea. This was attributed to the low water transport and high recovery characteristics of silicone (See SILICONES).

In an attempt to combine the high oxygen permeability of PDMS and the excellent comfort, wetting, and deposit resistance of conventional hydrogels, the design of silicone-based hydrogels for contact lens application has been studied. This approach was also an attempt to design materials that did not adhere to the cornea. But most of all, it would provide lenses possessing levels of oxygen permeability high enough for extended wear application with minimal physiological impact.

One simple, yet elegant approach in the design of a transparent silicone hydrogel has been reported (71,72). This material has been introduced commercially under the trade name Balafilcon. This new silicone hydrogel system is based on a vinyl carbamate substituted TRIS derivative: (Tris(trimethylsiloxy)silylpropylvinylcarbamate) (TPVC, (**19**)). The TPVC molecule contains the hydrophobic silicone portion, and attached to this silicone is a hydrophilic vinyl carbamate group. This "direct hydrophilic" attachment now gives the silicone significant hydrophilic character. The TPVC molecule is soluble in all proportions with hydrophilic monomers, such as HEMA and NVP. In addition, the vinyl carbamate group provides a "polymerization link" for copolymerization with hydrophilic monomers. The polymerization reaction of TPVC with NVP (and a suitable cross-linker) cast using uv initiation methods, results in transparent, high Dk, low modulus gels that are insoluble in water. Figure 1 (◇) shows the relationship between oxygen permeability (Dk) versus percent water for the TPVC-based silicone hydrogels. This is an important relationship in that it clearly shows the Dk advantage in designing hydrogels based on silicone. In contrast to conventional non-silicone-based hydrogels, the Dk decreases with increasing

water content because of the lower concentration of TPVC in the higher water content copolymers.



19

Intraocular Lenses. An intraocular lens (IOL) is an implant that is used to replace the diseased or damaged natural lens of the eye (73–77). The lens is supported in the eye through the use of haptics or loops that are attached directly to the IOL optics. There have been a wide variety of materials that have been successfully used as IOLs, ranging from the rigid poly(methyl methacrylate) to the soft elastomer silicone. The current trend in IOL research is to design materials that can be folded and inserted through a small corneal incision. The natural lens is removed using emulsification techniques, and the IOL lens is placed in the original capsule bag that held the lens. Once the IOL is inserted, the lens recovers to its original shape. The small incision is desirable to reduce the degree of induced astigmatism (loss of sphericity) in the operated eye and to minimize corneal trauma.

Hydrogels have also been successfully used for small incision IOLs. There are a number of commercially available hydrogel IOLs based predominately on HEMA, that range in water content from 17 to 28%. Aromatic-based methacrylates, such as phenylethyl methacrylate, are added to increase the refractive index of the lens. A higher refractive index will allow for a thinner IOL design (for power considerations) and result in an IOL that can be inserted through a smaller opening and recover its shape faster. A recent research effort has focused on an expandable IOL hydrogel where the lens is inserted in a dehydrated state and allowed to hydrate in the eye. This allows for the insertion of IOLs with reduced dimensions that make insertion through a small opening possible (78). Once the lens is implanted in the eye, it quickly hydrates, expands, and reaches its final dimensions within minutes.

Drug Delivery. The goal of drug delivery is to maintain the drug concentration in the body (plasma) within therapeutic limits for long periods of time. A constant drug release rate (zero-order) is desired. Conventional drug administration (oral delivery, injection) usually results in poor control of the plasma drug concentration. The controlled release of drugs from polymeric matrices has, however, been very successful. Many polymeric devices that deliver drugs at a

sustained release rate are now commercially available. Controlled release devices offer the desired therapeutic range of drug dose. Controlled drug delivery applications include sustained delivery (time) and target delivery systems (insertion at the diseased site). The delivery of drugs such as protein-based drugs, eg, insulin and growth factor, and also conventional drugs, eg, steroids and antibiotics, can be achieved.

Controlled release systems can generally be divided into three sections depending on their mode of release: diffusion controlled, chemical erosion, and solvent activated (79). In a diffusion-controlled device, the drug is surrounded by an inert barrier and diffuses from a reservoir, or the drug is dispersed throughout a polymer and diffuses from the polymer matrix. In a chemical erosion device, the drug is dispersed in a bioerodible polymer system or is covalently linked to a polymer backbone via a hydrolyzable linkage. As the polymer or hydrolyzable link degrades, the drug is released. In a solvent-activated device, the drug is dispersed within polymeric matrix and the device is swelled with a suitable solvent (usually water). As the device swells, the drug is released.

Conventional Hydrogels. Hydrogels have been used extensively in the field of controlled drug delivery (80–85). The advantages of using hydrogels in drug delivery systems are that they can be used at a local level, ie, insertion at the diseased site. This has become important because many of the new protein-based drugs require delivery in this fashion. The release of a growth factor, for example, to a specific site is highly desirable. This is because many biologically active polypeptides have very short half-lives and can not be administered orally (86). The hydrogel can be cross-linked at the diseased site by photopolymerization techniques, complexation, and enzymatic cross-linking. The hydrogel will also conform to the local anatomy (organs, vessels).

A wide variety of conventional cross-linked homo- and copolymeric hydrogels have been used for drug delivery application. In most hydrogels, the rate of diffusion through the bulk depends on two primary factors: the extent of cross-linking and water content. The extent of cross-linking determines the extent of swelling and the distance between chains within the hydrogel network. When entrapped drugs are diffusing within the network, the rate of diffusion can depend on the interchain separation and the size of the diffusing drug. The rate of diffusion is also controlled by water content. The general approach is to design hydrogels with very specific levels of hydrophilicity/hydrophobicity. This hydrophilic/hydrophobic balance controls water content and drug diffusion, where each drug will diffuse according to its dissolution profile (87). For water-soluble drugs dispersed in a high water content hydrogel, drug release will be rapid.

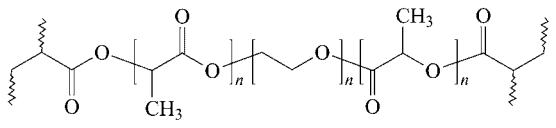
Hydrogel drug delivery systems can be used in the hydrated or dry states. The drug is incorporated during the polymerization process or through diffusion techniques using preformed films, tablets, etc (equilibrium absorption from concentrated drug solutions). A major limitation of incorporating the drug during the polymerizing process is that the drug will release during the extraction process (the process used to remove unreacted monomers) and, as a result, this technique is rarely used for biomedical applications. The diffusion method is a viable alternate to disperse and deliver drugs. In this method, the hydrogel is soaked in a drug solution until an equilibrium dispersion is reached. The hydrogel is then dried, packaged, and sterilized before use. Dried hydrogels release the drug as the

material hydrates (the drug will diffuse very slowly in an unhydrated hydrogel). The release of water-soluble drugs from a dry hydrogel involves the simultaneous absorption of water and desorption of drug through a swelling-controlled diffusion mechanism (88). As water penetrates a glassy hydrogel matrix that contains a dissolved or dispersed drug, the polymer swells and its glass-transition temperature is lowered. As the water enters the material, a water front forms that separates the glassy polymer from the swelled hydrated polymer. In regard to drug distribution and release, the solvent front separates the drug in the unhydrated core from the swollen water phase. As the water phase continues to grow and expand, the drug diffuses and is released. The drug release kinetics during this process can range from a square root of time dependence (Fickian) to a linear time (Case II transport) dependence. The Case II transport is governed by the rate of polymer relaxation. For most cases, the intermediate situation, which is termed non-Fickian (rate of Fickian diffusion and polymer relaxation are comparable), is observed (89). For example, thiamine HCl release from an initial dry poly(HEMA) hydrogel bead, as plotted versus the square root of time, shows an initial non-Fickian behavior with linearity established only after long periods of time.

Many conventional hydrogel designs that achieve zero-order drug-release are available. The manufacture of reservoir-based hydrogels (reservoir of drug encapsulated and surrounded by a polymer membrane) and matrix diffusion systems (drug is homogeneously dispersed in the hydrogel matrix) using common hydrogels, such as HEMA and glyceryl methacrylate, are relatively easy. The zero-order release rate can be achieved in many cases using either approach; however, the release rate of drugs from a matrix-type system typically declines continuously proportional to the square root of time. Soaking a poly(HEMA)/progesterone matrix, followed by uv irradiation in the presence of a cross-linker, can result in a rate-controlled membrane that exhibits a fairly steady release rate (90). Another use of a controlled release device makes use of a semicrystalline hydrogel (91). The hydrogels in these examples are based on poly(vinyl alcohol) and poly(ethylene oxide). In these systems, films are prepared through solution casting techniques. The films are subjected to an annealing process that creates varying degrees of crystallinity depending on the annealing time and temperature. The degree of crystallinity can be controlled and the degree of crystallinity is the controlling factor of drug release. The rate of crystal dissolution in water controls the rate of drug release. A commercial drug delivery application utilizing hydrogels has been introduced by Geltex pharmaceuticals (92). In this work a nonabsorbed hydrogel based on poly(allylamine) substituted with quaternary amine was designed for hypercholesterolemia (high cholesterol). The quaternary amine binds selectively with cholesterol. This polymer acts in the intestine as a bile acid scavenger to lower serum cholesterol levels in patients with increased risk of vascular disease. Bile acid sequestrants act by binding bile salts in the intestine and prevent them from passing through the intestinal wall and back into the blood stream. A U.S. NDA (new drug application) was filed in July 1999 with approval received in May 2000.

Degradable Hydrogels. Many research groups have studied the use of degradable hydrogels for drug delivery (93). The encapsulated drug will release at a controlled rate depending on such factors as pH, temperature, and cross-link density. Many examples of degradable drug delivery hydrogels can be found in the literature (39).

One of the first successful degradable release systems was based on the polyester hydrogels. These hydrogels are prepared by the copolymerization of malonate-type polyesters (polyesters that contain pendent backbone unsaturation) with monomers, such as NVP and acrylamide. Release of serum albumin occurs from these systems by a bulk erosion process. Other drugs can also be used. As the ester linkage of the polyester backbone hydrolyzes, the entrapped drug is gradually released to the surrounding environment. The release rate depends on the cross-link density. The degradation components of these erodible cross-linked polyesters result in nontoxic, water-soluble by-products. In a similar system, polyester macromers of a poly(ethylene glycol)-*co*-(lactic acid or glycolic acid) were prepared and evaluated for use as bioerodible hydrogels (94). These gels degrade upon hydrolysis of the oligo(α-hydroxy acid) regions and release the by-products poly(ethylene glycol), the hydroxy acid, and oligo(α-acrylic acid) (**20**). The degradation rate can be controlled by tailoring the concentration of α-hydroxy acid. If polymerized in contact with tissue, the gels adhere, and if polymerized prior to tissue placement, the gels are nonadhesive. The protein albumin was entrapped within these hydrogels and shown to release at a consistent rate. The release rate was dependent on the cross-link density and the molecular weight of the protein.



20

Drug-delivery devices combining cross-linked conventional hydrogels, where the drug is covalently linked via a degradable oligopeptide side chain, have been designed for targeted anticancer drugs. In this example, hydrogels of *N*-(2-hydroxypropyl)methacrylamide were prepared. The drug was attached synthetically by a degradable oligopeptide linkage. *In vitro* experiments have shown that these devices target ovarian carcinoma cells with promising results (95). Another interesting example of hydrogels for drug delivery utilizes the concept of degradable natural polymers (96). In this work, the natural oligosaccharide hyaluronic acid (HA) is chemically modified through the use of a pendent hydrazido functional group that is covalently linked to a wide variety of drugs, such as steroids. The covalent link is hydrolytically unstable and under mild conditions it releases the drug.

"Smart" Hydrogels. Research efforts on the design of smart hydrogels for drug delivery application has increased significantly over the past few years (30,31,97). Such systems show promise as drug-delivery devices because of the rapid release of conventional and protein-based drugs during the expansion/contraction of these hydrogel systems. Efforts have focused primarily on designing systems that make use of change in pH and temperature. The idea behind this approach is that smart hydrogels will both expand and contract, forming a hydrogel "switch" that releases drug or protein in a controlled fashion. When a drug is incorporated into a smart hydrogel, the diffusion of the polymer is dependent on the gel-state. Smart hydrogels can be designed to release drugs either above or below the lower critical solution temperature (LCST). Smart hydrogels

have been designed to release drugs at low pH (gastric release application) and at basic pH (intestinal release application).

Some brilliant work in this area has been described. Most of this has been based on the polymer poly(isopropyl acrylamide) (IPA) (97–99). IPA has a critical solution temperature close to that of body temperature (32°C). A large variety of IPA-based polymers (grafts, block) containing varying concentration of hydrophobic monomers have been synthesized. The concentration of hydrophobic monomer controls the critical solution temperature. Recent examples include the design of thermosensitive hydrogels as heparin-releasing polymers for the prevention of thrombosis. In this system, copolymers such as of *N*-isopropylacrylamide, butyl methacrylate, and acrylic acid were cross-linked together with heparin. At temperatures below the LCST, the polymer swelled significantly and solution loading of the drug was performed. Above the LCST, the gel de-swelled and released heparin. Another example makes use of a hydrogel based on an ether–urethane–isopropylacrylamide IPN for use as a heparin-release system. In this example, the "smart" polymer was applied as a coating on polyurethane catheters. This heparin-release coating system resulted in a significant reduction in thrombus formation on test surfaces in contact with venous blood (100).

The design of smart polymers as glucose-sensitive systems that release insulin has recently been described (101,102). The ultimate goal in this work is to design an artificial pancreas. This is accomplished by incorporating glucose oxidase into a pH- or temperature-sensitive smart polymer. An insulin-releasing drug-delivery system was produced by the incorporation of glucose oxidase, bovine serum albumin, and insulin into a gel of poly(*N*,*N*-dimethylamino)ethyl methacrylate-*co*-ethylacrylamide)(103,104). Exposure of this system to glucose in the desired physiological concentration range resulted in a reduction in the system pH and swelling of the polymer (as brought about by protonation of the polymer). This swelling causes a release of insulin. Another system based on a polymer complex of poly(*N*-vinyl-2-pyrrolidinone-*co*-phenylboronic acid acrylamide-*co*-dimethylaminopropylacrylamide) and poly(vinyl alcohol) also shows glucose sensitivity. In this system, a stable gel forms at pH 7.4 because of the "covalent" linkage of the boronate–hydroxy groups. The gel contains insulin. Through the addition of glucose, the complex dissociates and transforms the gel to a sol-state (the gel begins to solubilize) resulting in swelling and subsequent insulin release (105).

Tissue Engineering. The use of biomedical materials over the last 20 years has, in most respects, been extremely successful. A wide variety of materials have been developed that have been successfully used to replace hips, heart valves, and the natural lens of the eye, to name but a few successful applications. The major drawback in this area of research, however, is that these materials, for almost all cases, can only perform for short periods of time. No long-term replacements have to date been developed. The clinical needs are even greater in the case of organs, where replacement by organ transplantation is the only option. The area of tissue engineering, however, offers some intriguing possibilities.

The goal of tissue engineering is to create living, three-dimensional tissue/organs using cells obtained from readily available sources, such as cells obtained directly from the patient (31). The ultimate goal in this work is to grow cells specific to a particular organ and then to direct the cell growth to form the

actual organ. This theoretically can be accomplished through the attachment of specific cells to a scaffolding matrix that directs cell attachment, differentiation, and growth. In order to do this amazing feat, a physical scaffold is required to allow for the organization of cells to form the specific organ (to simulate cell growth, migration, and differentiation). These scaffolds need to interact with the cells through highly specific bioreactions that control cell adhesion and growth factor responses. The scaffolds are ideally biodegradable. Some fabulous work in this area has recently been reported.

The use of biodegradable hydrogels as a temporary-support template for cartilage has been reported (106). Cartilage is a biphasic material made up of collagen as the solid support suspended in a gel of proteoglycans. Within this gel are the chondrocytes that are responsible for maintaining the extracellular matrix of cartilage (glycosaminoglycans and type II collagen). For this work the hydrogel calcium alginate was used as the scaffold. The alginate polymer was prepared by dissolving in water and adding calcium ions to form a "complexed" cross-link polymer network. The immobilization of chondrocytes in alginate was accomplished simply by soaking the alginate in a solution of chondrocytes. Researchers have demonstrated that the chondrocytes maintained their structure, were capable of proliferating at rates significantly higher than that of monolayer cultures, maintained their production of glycosaminoglycans and collagen, and formed a mechanically functional matrix in a hydrogel network. This has all led to the first successful experiments that have shown that new cartilage can be created *in vivo* using hydrogel scaffolding.

In a similar concept, the design of biodegradable hydrogels for bone regeneration through growth factor release has been reported (107). In this research effort, gelatin was cross-linked with either glutaraldehyde or carbodiimide. The growth factor was added by solution adsorption into the preformed gelatin hydrogels. The cationic growth factor was held in the gelatin matrix through complexation with the anionic sites along the gelatin backbone. The gelatin enzymatically degrades in the body to release the growth factor. When implanted into a bone defect, the growth factor resulted in accelerated bone regeneration and closed the bone defect.

Wound Dressings. Hydrogels have also been used as wound dressings because most hydrogels are soft, flexible, conform to the wound, are biocompatible, and are permeable to water vapor and metabolites. As wound dressings, they absorb the exudate, do not stick to the wound, allow for access of oxygen to the wound site, and accelerate healing. This is actually a very large market with total sales of synthetic wound dressings, as reported in 1999, of $350 million (108). The dressing is usually applied as a thin preformed/prehydrated film. The hydrogel wound dressings are based on hydrocolloid/hydrogels and alginate dressings. Hydrophilic monomers and polymers used to prepare the hydrogel bandages are based on NVP, poly(ethylene oxide), and poly(vinyl alcohol).

Biosensors. A *biosensor* is a compact device or probe that detects, records, and transmits information regarding a physiological change or the presence of various chemical or biological materials in the environment. A biosensor is a probe that integrates a biological component, such as a biological product (enzyme or antibody), with an electronic component to yield a measurable response. Biosensors are used to monitor changes in the physiological environment (109). The usual

aim of a biosensor is to produce either discrete or continuous electronic signals that are proportional to a single analyte or a related group of analyte (110). The biosensors typically comprise a biological sensing element, a transducer, a signal conditioner, a data processor, a signal generator, and one or more organic or inorganic membranes. Hydrogels have been used as reactive matrix membranes in biosensors. Hydrogels possess several advantages over other materials in that they exhibit rapid and selective diffusion characteristics of the analyte, as well as provide support. For example, there has been a significant amount of success in the area of lipid bilayer based biosensor membranes. One of the early disadvantages of these bilayer probes was their poor ion diffusion characteristic. Hydrogels were successfully used to provide both the required ion diffusion and also the support for the thin lipid bilayer membrane (111). Among the various types of biosensors, those that measure glucose have received the most attention, due primarily to the fact that nearly 6% of the population suffers from diabetes (112). In these biosensors, the consumption of oxygen or the formation of hydrogen peroxide is monitored (enzyme glucose oxidase catalyzes the reaction of glucose and oxygen to form gluconic acid and hydrogen peroxide). Hydrogels are used as enzyme immobilization matrices in these type of biosensors. Enzyme entrapped in a hydrogel of poly(HEMA), polyacrylamide, and poly(vinyl alcohol) have been reported (113).

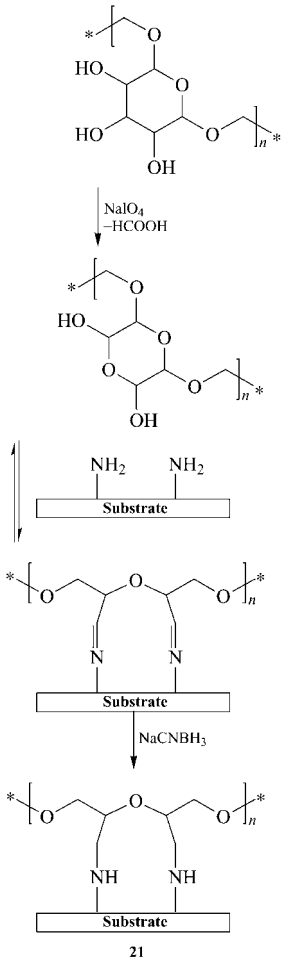
Surface Coatings Applications of Hydrogels. The surface treatment of polymeric materials is one of the most active research areas in the field of biomedical materials. It is generally agreed that the surface of any material is what dictates its cellular response in the body. Attempts to design biocompatible surfaces have been explored with significant success for many years. This approach, ie, minimization of chemical and physical interactions between the substrate polymer and blood, is the most promising avenue for short-term clinical success. It has been shown that materials functionalized with surfaces consisting of groups such as carboxylate, sulfate, or sulfonate groups act as antithrombogenic agents in that they repel plasma proteins and platelets. The grafting of poly(ethylene oxide) functionalized surfaces onto a variety of material substrate results in an increase in hydrophilicity and provides a reduction of complement activation and platelet adhesion (114). In a similar example, the grafting of poly(HEMA) onto a variety of surfaces has also provided an improvement in antithrombogenic properties. Novel techniques of surface modification, based on molecular imprinting, have led to hydrogel systems with the ability to recognize biological and pharmaceutical compounds. Gel surfaces can be molecularly designed for specific applications (115,116). For example, polyacrylamide gels modified with an adhesion receptor, asioaloglycoprotein, were prepared to study cell adhesion. This work, as well as other similar research efforts, has helped gain an understanding of the required surface functionality for improved receptor response (117,118). Also, in the area of contact lens research, the formation of a hydrogel surface on nonwetting substrates, such as silicone, provides an avenue for a wettable, biocompatible material possessing excellent comfort characteristics. These have all been made possible utilizing techniques such as plasma oxidation, the surface-initiated polymerization of hydrophilic monomers, and the graft functionalization of high molecular hydrophilic polymers through covalent coupling.

Plasma Surface Modification. One of the earliest approaches to design wettable, hydrogel-like surfaces was by glow discharge plasma and/or corona discharge techniques. Corona treatment of polymer surfaces consists of the reaction of oxygen with the polymer surface under an electric discharge to create polar functionality such as carboxyl, ether, carbonyl, or hydroxyl groups. The formation of polar groups raises the surface free energy and allows for surface wetting. Low pressure glow discharge oxygen plasma has also been used successfully on silicone-based materials. This results in a wettable surface that consists primarily of hydrated cross-linked silicate/silanol functionality. In fact, the Silsight™ silicone elastomer lens, commercialized primarily for pediatric aphakic (loss of natural crystalline lens) patients, is made wettable through oxygen plasma techniques.

Since these early efforts to generate wettable surfaces through oxidative treatments, a variety of novel plasma processes have been developed (119). These efforts have focused primarily on plasma polymerization (deposition). This effort is in an attempt to deposit a continuous thin hydrophilic polymer film layer. In this process, polymerizable gases (monomers) are introduced to the plasma reactor during or after the glow discharge treatment. The plasma conditions initiate polymerization that results in deposition of a thin polymer surface, where the surface chemistry can be manipulated by choice of monomer. This technique results in primarily a covalent polymer attachment.

Direct Covalent Coupling. Similar approaches to covalently attached polymers via glow discharge plasma have also been pursued. In these efforts, the polymers were solution-adsorbed and surface-grafted under inert gas plasma. A free-radical mechanism for the grafting has been proposed. This approach has been used to coat a variety of substrates with hydrogels. Upon plasma treatment radicals are formed on the surface that react with oxygen to form hydroperoxy compounds. The homolytic decomposition of the hydroperoxides form radicals that initiate the polymerization (thermal or ultraviolet) of hydrophilic monomers, such as HEMA (120). The adsorption can best be accomplished by using surface-active compounds that preferentially immobilize on the surface before introduction of the plasma.

In addition to the conventional plasma polymerization approaches, a significant number of research programs have focused on the design of wettable surfaces utilizing a combination of glow discharge plasma and polymer grafting through classical chemical reaction techniques (121). One approach demonstrates the successful covalent attachment of a polysaccharide (**21**). In this process, a silicone surface is aminated using glow discharge ammonia plasma. The aminated surface is then reacted with an oxidized dextran to form a covalently attached (via a Schiff-based linkage) dextran. Following reduction to a stable secondary amine linkage, a highly wettable surface is formed (122). Another approach makes use of covalent grafting utilizing solution techniques only. In this example, the vinyl acetate groups of a medical grade poly(ethylene-*co*-vinyl acetate-*co*-vinyl chloride) was saponified using a solution of methanol and sodium hydroxide and then reacted with hexamethylene diisocyanate to form a highly reactive isocyanate-modified surface. The resultant surface is then reacted, again via solution techniques, with an amine functionalized hydrophilic polymer (123).



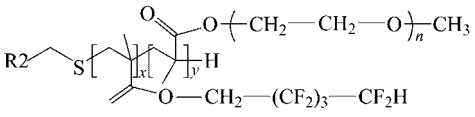
21

Hydrogel Surfaces through In Situ Polymerization Techniques. Several research groups have reported on efforts to design wettable silicone-based materials through *in situ* polymerization techniques. These are attempts to design wettable, biocompatible surfaces without the need for surface treatment. The primary driver for this research is cost. Without the need for a secondary surface treatment, a large reduction in lens cost would be achieved.

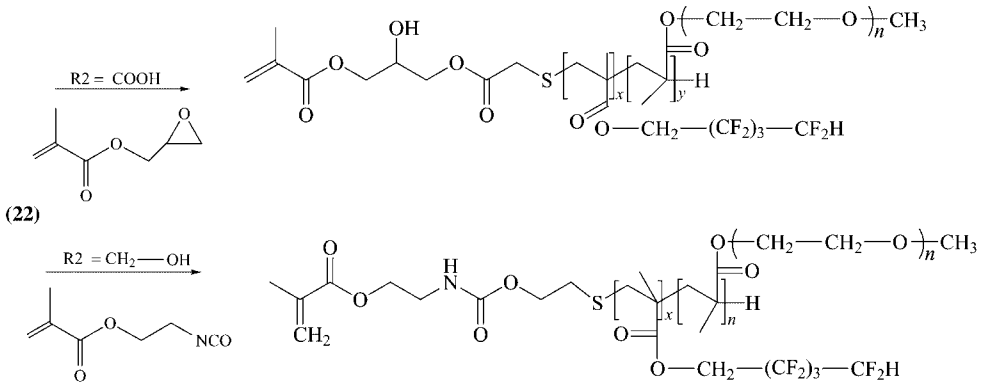
Significant progress in this area has been made. It has been shown recently that the polarity of the casting substrate may provide an avenue for surface wetting without surface treatment. The casting of silicone-based formulations from polar mold materials results in a surface rich character. For example, a copolymer based on a fluorinated silicone and the hydrophilic monomer, DMA was cast against the hydrophilic mold resin Barex (copolymer of acrylonitrile and styrene). X-ray photoelectron spectroscopy analysis of the surface showed a threefold increase in surface nitrogen concentration as compared with the same formulation cast from a hydrophobic polypropylene resin. The Barex cast material resulted in

a hydrogel-like surface as a result of the preferential polymerization–migration of DMA at the Barex surface.

The use of polymerizable surfactants (surface-active macromer, SAM) in silicone formulations has been explored to form hydrogel-like surfaces without a surface treatment (124). Several surface-active water-soluble macromers were evaluated. The SAMs were prepared using a two-step synthetic procedure. In this procedure, hydrophobic alkylmethacrylates or fluoromethacrylates monomers are polymerized with polyoxyethylene methacrylates using a functional mercaptan as a chain-transfer agent. The resultant hydroxyl or carboxylate capped macromer (**22**) is further functionalized with a polymerizable methacrylate.



(22)



(22)

The SAMs are surface-active, yet possess significant hydrophilic character. They are simply added to a silicone formulation, at concentrations of 0.1–0.5%, and polymerized. It has been shown that the polymerization of SAMs in silicone-based formulations results in a significant increase in surface polarity. This is due to migration of the SAM to the mold–lens interface before polymerization. Clinical performance has also been improved. The incorporation of SAMs has had a positive effect on surface wetting and deposition characteristics.

Nonbiomedical Applications

This article has detailed a variety of biomedical applications of hydrogels. It is important to note, however, that many applications of hydrogels for

nonbiomedical use have been successfully designed. These include the use of hydrogels for chemical valves, bioseparation devices, biomimetic actuators, thermoresponsive surfaces, affinity precipitation, anodes for bridge-building application, water retention for soil application, and disposable diapers the details of which can be found in other articles (10,31,125–128).
