HYPERBRANCHED POLYMERS

Introduction

Material engineers have been trying to improve polymer properties with a variety of technologies and ingenuity. Polymers have been modified in numerous different ways in order to alter their properties. The most utilized ways to alter properties have either been to simply develop a new monomer and synthesize a new polymer or to modify an existing polymer by some chemical route. Modification normally consists of changing a catalyst or using different comonomers.

In nature, condensation of polyfunctional monomers, having two different functional groups, occurs under the enzymatic control, resulting in tree-shaped, highly branched, but still soluble, macromolecules. In 1952, Paul Flory (1) theoretically described hyperbranched polymers obtained by condensation of AB_x-monomers in a statistical growth process. Flory pointed out that such a molecule would have one A-group, DP+1 B-groups, and poor mechanical properties because of high branching and absence of chain entanglements. The synthesis of hyperbranched polymers remained an unsolved challenge for synthetic chemists and it was not until the late 1980s that the concept was reawakened by Kim and Webster who also coined the term hyperbranched (2,3).

Since then, synthetic chemists have explored numerous ways to achieve statistically branched macromolecular structures. In theory, all polymer-forming reactions can be utilized for the synthesis of hyperbranched polymers. In practice, some reactions are far more suitable than others.

The synthesis of dendrimers has been carried out in parallel to the exploration of hyperbranched polymers. The number of papers describing dendrimers by far exceeds the number of papers concerning hyperbranched polymers.

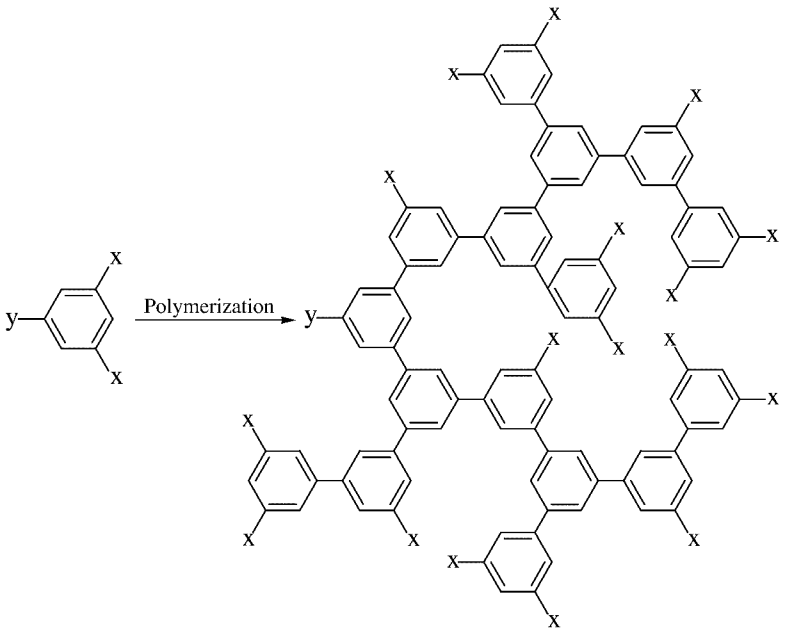

Fig. 1. Polyphenylenes were prepared via Pd(0) [such as $Pd(PPh_3)_4$] or Ni(II) catalyzed coupling reactions of various dihalophenyl derivatives such as dibromophenylboronic acid (3–5).

Monomers

Polyphenylenes. One of the first hyperbranched polymers described in the literature was the class of polyphenylenes (3–5). The polyphenylenes were prepared via Pd(0)- or Ni(II)- catalyzed coupling reactions of various dihalophenyl derivatives such as dibromophenylboronic acid. The polymers were highly branched polyphenylenes with terminal bromine groups which could be further transformed into a variety of structures, eg, methylol, litiate, or carboxylate (Fig. 1). The halofunctional hyperbranched polymers obtained have M_n between 2 and 32 kg/mol depending on the polymerization conditions.

Aliphatic Polyesters. Polyesters are an important class of condensation polymers, and the availability of a few commercial dihydroxy carboxylic acids has triggered several research groups to look into hyperbranched polyesters in great detail. Several old patents concerning highly branched and hyperbranched polyesters exist. One of the oldest patents, of 1972, concerns the polymers obtained by condensation of polyhydroxy monocarboxylic acids and their use in coatings (6). Essentially, one monomer, 2,2-bis(methylol)propionic acid (bis-MPA), has been used for the preparation of hyperbranched aliphatic polyesters. The cocondensation of bis-MPA and a four-functional polyol [di-(trimethylol)propane] resulting in hydroxy-functional hyperbranched polyesters has been described (7). The degree of branching has been found to be 0.45. The molecular weight and number of terminal hydroxyl groups can be varied by altering the stoichiometric ratio between the polyol core and bis-MPA.

Similar materials, hyperbranched polyesters based on bis-MPA and a polyol, are now commercially available from Perstorp AB (http://www.perstorp.com). under the trade name Boltorn (Fig. 2). The average number of hydroxyl groups per molecule can be tailored between 8 and 64 and the molecular weight can be varied between ca 2,000 and 11,000. The copolymerization of bis-MPA and a polyol core keeps the molecular weight distribution fairly low, typically below 2.

Aromatic Polyesters. Considerable attention has been paid to aromatic hyperbranched polyesters synthesized from monomers derived from 3,5-dihydroxy benzoic acid (DBA). The thermal stability of DBA is not good enough to allow direct esterification of DBA, and therefore chemical modifications are necessary. Some aromatic monomers used for the synthesis of hyperbranched polymers are presented in Figure 3.

In a systematic investigation of hyperbranched polyesters derived from 3,5-bis(trimethylsiloxy) benzoyl chloride (8–11), the monomers were condensed at 150–200°C and also by using low temperature esterification procedures. The polymers were found to have a degree of branching close to 0.55 and apparent molar masses (M_n) in the range of 16–60 kDa, as determined by gpc relative to linear polystyrene standards. Several functionalizations were made on the phenolic end groups in order to investigate how the nature of the end groups affected the glass-transition temperature (T_g).

Another investigation (12,13) describes hyperbranched polyesters derived from 3,5-bis(trimethylsiloxy) benzoyl chloride and from 3,5-diacetoxybenzoic acid, both of which yield phenolic polyesters after hydrolysis. Hyperbranched polyesters obtained from melt condensation of 5-acetoxyisophthalic acid and 5-(2-hydroxy)-ethoxyisophthalic acid respectively were also studied. The latter yields a soluble product while the former results in an insoluble polymer because of formation of anhydride bridges.

In a comparison (14) of the polyesterification of silylated 5-acetoxyisophthalic acid and of free 5-acetoxyisophthalic acid, the nonsilylated monomer yielded insoluble products, indicating that a cross-linked material was obtained. The degree of branching for these materials was found to be close to 0.6 and independent of reaction conditions. Star-shaped and hyperbranched polyesters have also been synthesized by polycondensation of trimethylsilyl 3,5-diacetoxybenzoate (15) and a number of hyperbranched polymers based on the trimethylsilylester of β-(4-hydroxyphenyl)propionic acid have been reported (16).

Aromatic hyperbranched polyesters have been synthesized from 5-(2-hydroxyethoxy)isophthalate copolymerized with 1,3,5-benzenetricarboxylate (core molecule) as a moderator of the molar mass (17). The degree of branching was found to be 0.60–0.67, as determined by ^{13}C nmr. Apparent molar masses (M_w) were found to be 5–36 kDa according to sec characterization using linear polystyrene standards.

Polyester-amides. DSM is marketing the poly(ester-amide) Hybrane™ which is the second commercially available hyperbranched polymer (Fig. 4) (http://www.hybrane.com). It is also a hydroxy-functional product, but instead of ester linkages it comprises amide and ester connectivities. The synthesis is accomplished in two steps: cyclic anhydrides are reacted with diisopropanolamine to give an amide-intermediate, carrying two hydroxyl groups and one carboxylic acid. The subsequent polymerization takes places via an oxazolinium-intermediate, which

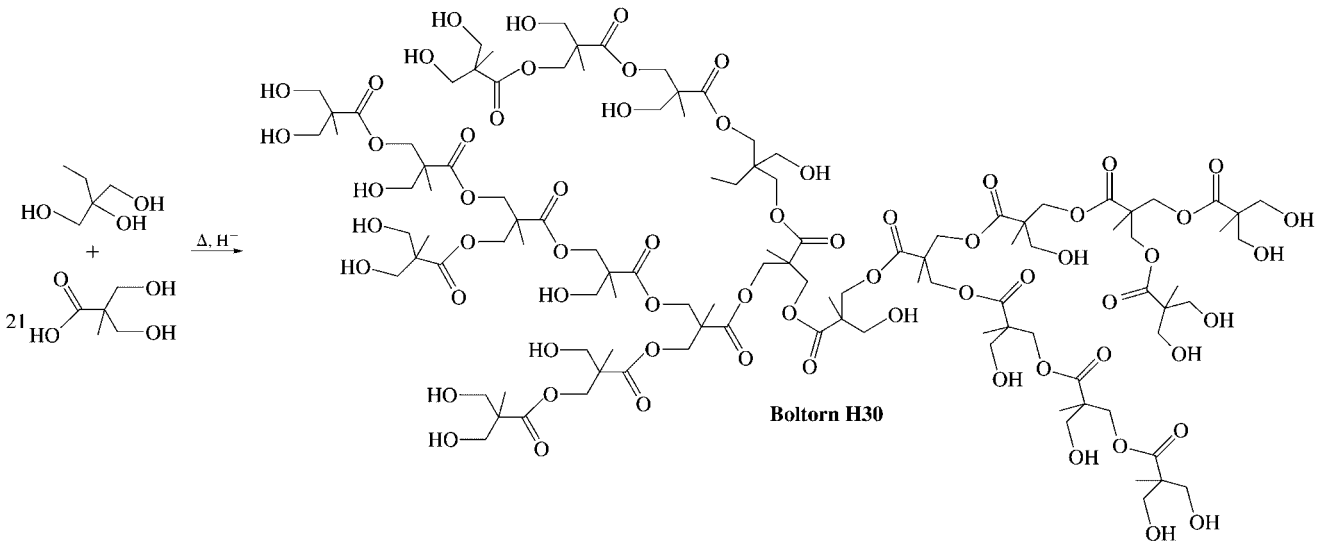

Fig. 2. Hyperbranched polyester based on bis-MPA and a polyol, commercially available from Perstorp AB (http://www.perstorp.com) under the trade name Boltorn.

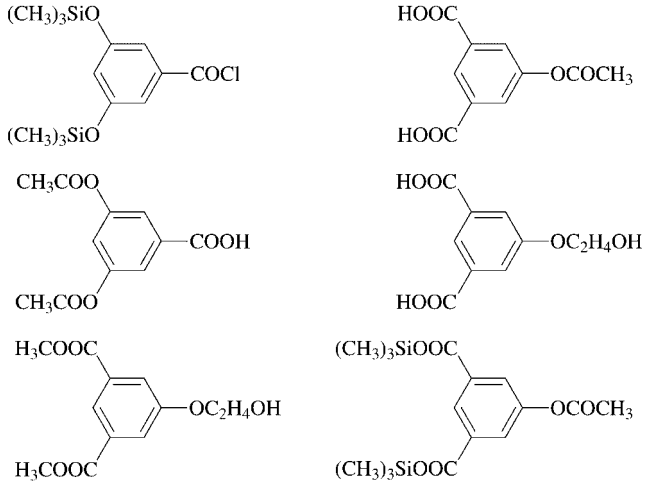

Fig. 3. Aromatic monomers used for the synthesis of hyperbranched polyesters (3–5).

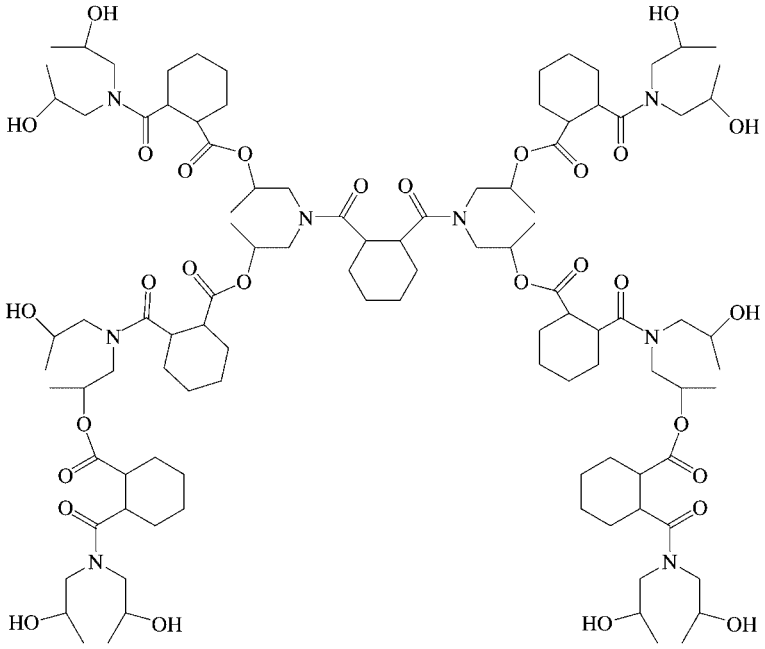

Fig. 4. Poly(ester-amide) Hybrane (http://www.hybrane.com).

results in the formation of a hydroxy-functional hyperbranched polymer. The properties of Hybrane can be altered by the choice of anhydride compounds.

Polyethers. A one-pot synthesis of hyperbranched benzylic polyethers based on self-condensation of 5-(bromomethyl)-1,3-dihydroxybenzene in solution has been developed (18). The effect of variation of reaction conditions such as monomer concentration, time, and type of solvent was explored and it was

concluded that an increased reaction time and polar solvents increased the molar mass while a change in monomer concentration had less effect. Polymers with molar masses up to 120 kg/mol, as determined with low angle laser light scattering, were obtained under optimum conditions. The desired O-alkylation was accompanied by approximately 30% C-alkylation. Therefore the degree of branching was difficult to determine. It was also shown that the phenolic end groups could easily be transformed into other moieties such as benzyl, silyl, or acetate end groups with a subsequent change in T_g and solubility of the polymers. However, one main problem which appeared was that the monomer showed to be extremely allergenic, which limits the use of this structure.

Aromatic Poly(ether-ketone)s. The synthesis of hyperbranched aromatic poly(ether-ketone)s based on monomers containing one phenolic group and two fluorides which were activated toward nucleophilic substitution by neighboring groups has been described (19,20). The molar mass and polydispersity of the formed poly(ether-ketone)s could be controlled by reaction conditions such as monomer concentration and temperature. The formed polymers had high solubility in common solvents such as THF.

Also, the synthesis of hyperbranched poly(ether-ketone)s based on AB_2-monomers having either one phenolic and two fluoride groups or two phenolic and one fluoride groups has been described (21).

Properties of Hyperbranched Polymers

One reason for the emerging interest in hyperbranched polymers and other macromolecular architectures is the possibility to obtain improved material properties compared to conventional, linear polymers. Already, Flory predicted that highly branched polymers would exhibit different properties compared to linear polymers (1). He stipulated that the amount of entanglements would be lower for polymers based on AB_x-monomers with subsequent reduction in mechanical strength, and this was one of the reasons why these polymers at that point were abandoned. Changes in properties related to architectural changes in hyperbranched polymers rather than chemical changes have to some extent been evaluated but a full understanding is still lacking. Two questions in this area of late have been focused on the extent to which these changes in properties occur and also why they occur.

Solution Properties. One of the first properties that was reported to differ for hyperbranched polymers as compared to linear analogues was the high solubility induced by the branched backbone. Hyperbranched polyphenylenes have very good solubility in various solvents as compared to linear polyphenylenes which have very poor solubility and the solubility depends to a large extent on the structure of the end groups, eg, highly polar end groups such as carboxylates would make the polyphenylenes even water-soluble (2).

Not only good solubility but also solution behavior differs for hyperbranched polymers compared with linear polymers. Hyperbranched polymers such as hyperbranched aromatic polyesters (12,13) exhibit a very low α-value in the Mark–Houwink–Sakurada equation and low intrinsic viscosities. This is consistent with highly branched and compact structures. A comparison has been made between linear polymers, hyperbranched polymers, and dendrimers with respect to

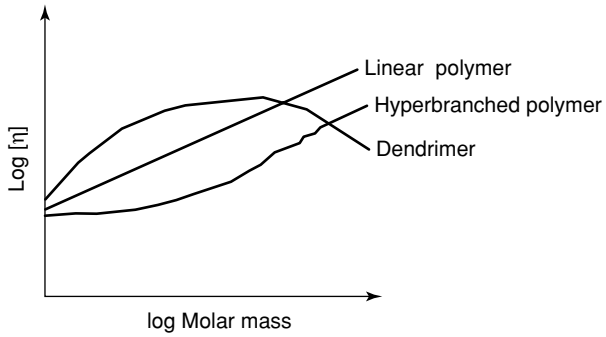

Fig. 5. Comparison between linear polymers, hyperbranched polymers, and dendrimers with respect to intrinsic viscosities as a function of molar mass (22).

intrinsic viscosities as a function of molar mass, which clearly shows the differences induced by variations in the backbone architecture (Fig. 5) (22).

Another special feature for dendritic polymers is the possibility to combine an interior structure with a certain polarity with a shell (end groups) having another polarity, eg, a hydrophobic inner structure and hydrophilic end groups. For example, hyperbranched polyphenylenes with carboxylate end groups have been described as unimolecular micelles where the carboxylate end groups make the polymer water-soluble and the hydrophobic interior can host a guest molecule (4). This has also been described by other authors (21), who solubilized hydrophobic molecules in water by using hyperbranched aromatic poly(ether-ketone)s having acid end groups. They did not see any critical micelle concentration (CMC) but observed a steady increase in solubility of the hydrophobic compound with polymer concentration. From these observations they concluded that a unimolecular micelle behavior applied. In a recent review (23), the guest-host possibility is described for various dendritic polymers with the aim toward medical applications such as drug delivery.

The size of dendritic polymers in solution has been shown to be greatly affected by solution parameters such as polarity and pH. For example, it has been shown that the size of dendrimers with carboxylic acid end groups in water can be increased by as much as 50% on changing the pH (24).

Thermal Properties. One of the first questions that arises when looking at a new group of polymers such as hyperbranched polymers is what determines the glass-transition temperature. The normal interpretation of T_g is related to relatively large segmental motions in the polymer chain segments, and the role of the end groups diminishes above a certain molecular weight. This is different in hyperbranched polymers since segmental motions are affected by the branching points and the presence of numerous end groups. The glass transition has instead been proposed (4,5) to be a translational movement of the entire molecule instead of segmental movement, hence increasing the importance of the end group structure. The backbone part of hyperbranched polymers was also suggested to affect the T_g but to a much lesser extent. The glass-transition temperature is one of the properties that has been reported for most of the hyperbranched polymers

described in the literature. The results have been either based on calorimetric or rheological measurements. Values of T_g for a series of hyperbranched aromatic polyesters with different end groups have been presented in a review paper (25). It was shown that the chemical structure of the end groups had a large impact on the T_g. The glass-transition temperature shifted as much as 100°C (from 255 to 150°C), going from carboxylic acid to acetate end groups. This and other reports (26) show the large impact of end group structure on the T_g, hence indicating the importance of this structural part. The backbone of course also affects the T_g, eg, an aliphatic polyester has a much lower T_g than an aromatic one (25). The T_g for polyether dendrimers has been found to follow a modified Flory equation where the amount and structure of end groups are accounted for indicating a similarity with T_g for linear polymers (27). However, no full model to predict the T_g for hyperbranched polymers exists since several other factors such as degree of branching, steric interactions due to crowding, backbone rigidity, and polarity in combination also play an important role for the glass-transition temperature. The glass-transition temperature of dendritic polymers is also discussed in another paper (28).

The thermal stability of hyperbranched polymers is related to the chemical structure in the same manner as that for linear polymers, eg, aromatic esters are more stable than aliphatic ones. The use of hyperbranched polymers have, however, in some cases been shown to improve the thermal stability when used as additives. An increased thermal stability of polystyrenes has been shown when a small amount of a hyperbranched polyphenylene was used as a rheology modifying additive to polystyrene.

A study of the PVT properties of hyperbranched aliphatic polyesters (29) showed that these polyesters were dense structures with smaller thermal expansion coefficients and lower compressibility compared to some linear polymers.

Mechanical and Rheological Properties. The rheological properties for hyperbranched polymers are characterized by a Newtonian behavior in the molten state, ie, no shear thinning or thickening is observed (29), indicating a lack of entanglements for these polymers. The nonentangled state imposes rather poor mechanical properties, resulting in brittle polymers. This has limited the use of these polymers as thermoplastics to applications where the mechanical strength is of minor importance. The large amount of branching also makes most of these polymers amorphous, although exceptions exist. Hence, these polymers are mainly suitable as additives or as thermosets when high mechanical strength is required for a certain application.

The melt behavior has been shown to be greatly affected by the structure of the end groups where an increase in polarity of the end groups can raise the viscosity several orders of magnitude (30) (Fig. 6). This is of great importance when looking at applications where a low viscosity is essential for the processing of the material (31).

Another difference is the relationship between molar mass and melt viscosity. The increase in melt viscosity with molar mass for linear polymers is linear with a transition when the molecular weight reaches the critical mass for entanglements M_c, where the slope increases. This is different for hyperbranched polymers. The viscosity increase is less pronounced and levels out at higher molar masses (29).

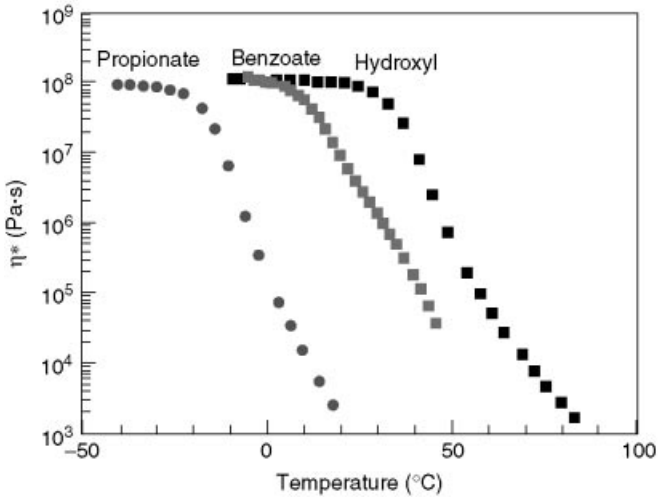

Fig. 6. Hyperbranched polyester based on bis-MPA and a polyol with end groups of different polarities (30).

Hyperbranched polymers are often referred to as Amorphous Polymers since the branching of the backbone reduces the ability to crystallize in the same manner as for linear polymers. Some exceptions have, however, been presented where the polymers have been modified to induce crystallization. Hyperbranched aliphatic polyesters were made semicrystalline by attaching alkyl chains with 14 carbons or longer as end groups (32). The crystallization was affected by several factors such as length of the end groups and the size of the hyperbranched polyester. Different combinations of these actors yielded different transition temperatures as well as different crystalline structures.

Polymerization

Polycondensation. The step-growth polymerization of AB_x-monomers is by far the most utilized synthetic pathway to hyperbranched polymers. A number of AB_2-monomers, suitable for step-growth polymerizations, are commercially available. This has, of course, sparked off the interest for hyperbranched condensation polymers, and a wide variety has been presented in the literature (11,25,33,34).

A typical condensation procedure involves the one-step reaction where the monomer and suitable catalyst/initiator are mixed and heated to the required reaction temperature. To accomplish a satisfactorily conversion, the low molar mass condensation product formed through the reaction has to be removed. This is most often pursued by a flow of inert gas and/or by reducing the pressure in the reaction vessel. The resulting polymer is usually used without any purification or, in some cases, after precipitation of the dissolved reaction mixture into a nonsolvent.

When polymerizing highly functional monomers one must always consider the occurrence of unwanted side reactions leading to the onset of gelation. In

the reacting AB_x-system the preferential reaction has to be A reacting with B. Unwanted side reactions have to be suppressed. Even a very low amount of A–A or B–B reactions would inevitably lead to gelation.

The one-pot polymerization of AB_2-monomers offers no control over molecular weight, and subsequently, gives rise to highly polydisperse polymers (1). The copolymerization of AB_2-monomers with B_y-molecules introduces a tool not only to control the molecular weight but also to reduce the molecular weight distribution.

In a classical step-growth polymerization of AB-monomers, backbiting occurs, resulting in formation of intramolecular cyclics. This of course puts the molecular growth to an end, since the functional groups are lost. When polymerizing AB_2-monomers, there is a possibility of losing the unique focal point because of intramolecular cyclics. This leads to the loss of the reactive A-group in the focal point but the cyclized molecule still holds a number of reactive B-groups, which can lead to further increase in molecular weight.

However, the maximum molecular weight and the rate of polycondensation are reduced by the occurrence of cyclization reactions. Although, one might speculate that a moderate degree of cycle formation is desired since this will reduce the molecular weight distribution.

One way to reduce the cycle formation is to add the AB_2-monomer successively throughout the reaction in a so called slow-addition. Several authors have shown that slow addition of monomer leads to a reduction in side reactions and an increase in molecular weight (35,36). Several authors have studied the occurrence of cyclization in hyperbranched systems (37,38).

Assuming that all B-groups have the same reactivity, the chemical reaction giving rise to a branched molecule is identical to the reaction resulting in a linear polymer. Statistically, this will eventually result in a hyperbranched polymer. However, dependent on the chemical structure of the monomer, steric effects might favor the growth of linear polymers. Computer simulations of condensation of AB_x-monomers and co-condensation of AB_x-monomers with B_y-functional cores have been published. Only a few papers deal with the experimentally studied structure buildup in hyperbranched polymers (39).

One discrepancy with condensation polymers is that they are sensitive toward hydrolysis, which might restrict the use of such polymers. Some hyperbranched polymers are synthesized by substitution reactions that provide more hydrolytically stable polymers.

Ring-Opening Procedures to Hyperbranched Polymers. The use of ring-opening polymerization for the synthesis of hyperbranched polymers has, so far, been rather limited. Conceptually, ring-opening polymerization holds an advantage over ordinary step-growth polymerizations in that no low molecular weight compound has to be removed. This facilitates the formation of high molecular weight compounds.

The Pd-catalyzed ring-opening polymerization of a cyclic carbamate in the presence of an initiator, which also acts as a core molecule, to afford a hyperbranched polyamine has been reported (40,41). The polymerization was denoted to be multibranching. Multibranching implies that the number of propagating chain ends increase with the progress of the polymerization.

Ring-opening polymerization of hydroxy-functional cyclic ethers could, in accordance with hydroxy-functional lactones, give rise to hyperbranched polyethers.

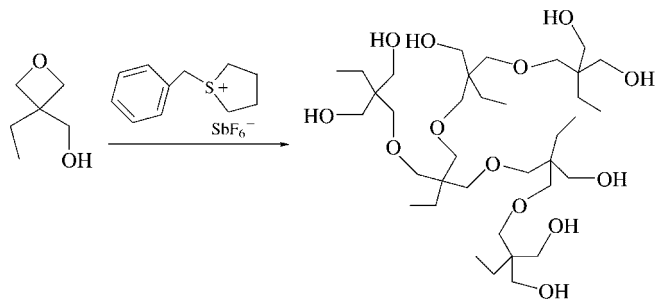

Fig. 7. Cationic ring-opening polymerization of 3-ethyl-3-(hydroxymethyl)oxetane to a hydroxy-functional hyperbranched polyether (45,46).

One example of such a compound is glycidol, an oxirane-ring substituted with a hydroxymethyl group. Already in the mid-1980s, both the anionic and cationic polymerizations of glycidol had been extensively investigated and it was concluded that branched polymers were formed (42,43). More recently, the anionic ring-opening polymerization of glycidol has been reported (44).

Anionic polymerization of 2-hydroxymethyloxetane is unsuccessful (34). The failure of such a reaction is most likely due to the fact that oxetanes are not known to ring-open under basic conditions. The successful cationic ring-opening polymerization of 3-ethyl-3-(hydroxymethyl)oxetane gave hydroxy-functional hyperbranched polyethers (45,46) (Fig. 7). The cationic polymerization can proceed according to two different mechanisms, activated chain end (ACE) or activated monomer mechanism (AMM) (45) (Fig. 8).

The ring-opening polymerization of an AB-monomer, 4-(2-hydroxyethyl)-ε-caprolactone, has been reported (47). ε-Caprolactone is easily polymerized using ring-opening polymerization under facile conditions, and the primary hydroxyl group can be used to initiate the polymerization. The polymers are reported to

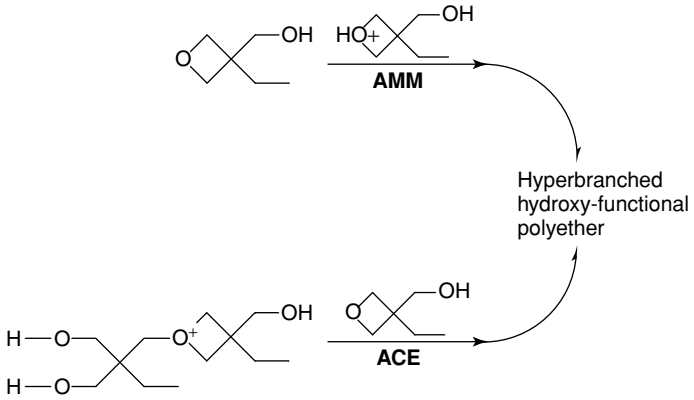

Fig. 8. Cationic ring-opening polymerization can proceed in accordance to two different mechanisms, activated chain end (ACE) or activated monomer mechanism (AMM).

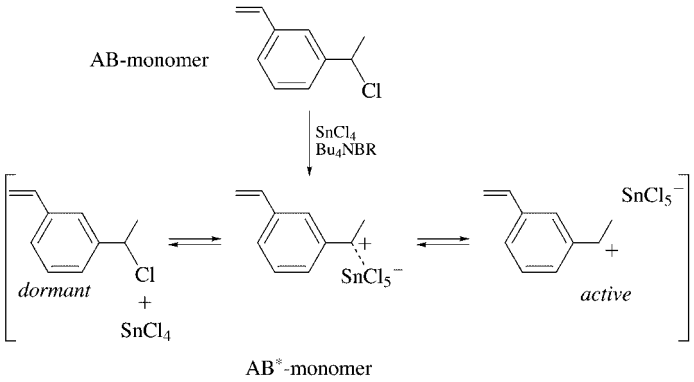

Fig. 9. Self-condensing vinyl polymerization (SCVP) (48).

have molecular weights in the range of 65,000–85,000 (PDI ca 3.2) as determined by sec.

Self-Condensing Vinyl Polymerization. The first hyperbranched vinyl polymer was presented in 1995 (48) and this marked the birth of the "second generation" of hyperbranched polymers. Hitherto, exclusively step-growth polymerization had been utilized to accomplish hyperbranched polymers. This had, of course, also limited the potential applications to areas where condensation-type polymers are acceptable.

3-(1-Chloroethyl)-ethenylbenzene was cationically polymerized in the presence of $SnCl_4$. The polymerization was termed "self-condensing" vinyl polymerization (SCVP) (Fig. 9) because the polymerization was found to proceed by repeated step-wise couplings of otherwise chain-growing species.

3-(1-Chloroethyl)-ethenylbenzene is an AB-monomer where the A-group is the readily polymerizable vinyl group and the B-group the latent initiator moiety, a benzyl halide. External activation of the labile B-group was afforded by the addition of $SnCl_4$ (Fig. 10).

The presentation of SCVP marked the onset of extensive research focussing on the use of vinyl monomers for the synthesis of hyperbranched polymers. Lately,

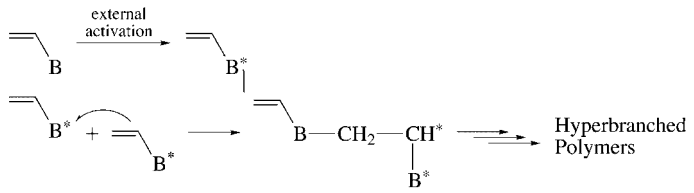

Fig. 10. AB∗ represents the activated monomer. The polymerization is initiated by the addition of B∗ to an A-group, which leaves a dimer carrying one double bond and two active sites, B∗. Given the chemical structure of the monomer, it can be assumed that the reactivities of A∗ and B∗ are similar and that is why both the initiating B∗-group and the newly created propagating cation can react with the vinyl group of another molecule (monomer or polymer) in the same way.

there has been a great interest in "living" free-radical procedures that possess accurate control over molecular weight, molecular weight distribution, and chain ends. The SCVP concept was further developed into TEMPO-initiated "living" free-radical polymerization synthesis of hyperbranched polystyrenes (49). The extensive development of metal-catalyzed "living" free-radical polymerization brought about new possibilities to use radical polymerization as a tool to obtain advanced macromolecular architectures. Atom-transfer radical polymerization (ATRP) techniques were developed to obtain hyperbranched polystyrenes (50), and the first use of group-transfer polymerization to obtain hyperbranched methacrylates was reported (51).

Since then, a number of different approaches, based on vinyl monomers and various initiating systems, have been explored to yield hyperbranched polymers such as poly(4-acetylstyrene) (52), poly(vinyl ether) (53), and polyacrylates (54).

The polymerization of AB$*$-functional vinyl monomers is fundamentally different from the step-growth polymerization of AB_2-monomers. Condensation of AB_2-monomers immediately results in hyperbranched polymers since the reactivity of the end groups are the same, regardless of what type of repeat unit (linear or dendritic) that is formed.

In the case of AB$*$-monomers it is not obvious how the chain growth takes place. Depending on the chemical structure of the monomer there will be a competition between conventional, linear, chain-growth polymerization, via the double bond, and the branching reaction, ie, where the group capable of initiation (B$*$), reacts with a vinyl group. If the reactivities of the two different propagating species are exactly the same, one envisions that a randomly branched system will be the result. However, all monomers attempted in SCVP so far possess unequal reactivity of the propagating sites. A systematic investigation on how the branching could be maximized by altering the reaction conditions when polymerizing 4-chloromethylstyrene using metal-catalyzed "living" free-radical polymerization was done (55).

Since free-radical polymerization is the most important industrial polymerization process, the development of polymerization procedures for vinyl monomers greatly opened up the application for hyperbranched polymers.

Proton-Transfer Polymerization. Proton-transfer polymerization (PTP) (Fig. 11) has been reported as a versatile route to hyperbranched polymers (56). Conceptually, PTP is an acid–base controlled reaction where the nucleophilicity and basicity of monomer and intermediates play important roles.

A base serves as an initiator and abstracts the labile proton from the monomer, forming a reactive nucleophilic species, $^{-}AB_2$, (**2**). This species rapidly adds to the B-group on a monomer, leaving an anionic site in the dimer, (**3**). This species is less nucleophilic than (**2**) and undergoes a rapid, thermodynamically driven, proton exchange with monomer, instead of nucleophilic addition. This produces a new nucleophile, (**2**), and an inactive dimer, (**4**). The multiplicity of reactive B-groups in each growing molecule that contains a single H–A group ensures the formation of a hyperbranched molecule.

The usefulness of the PTP concept was further demonstrated in a study (57) where hyperbranched aliphatic polyethers were synthesized from a diepoxide and a three-functional alcohol utilizing the concept of A_2–B_3 monomers.

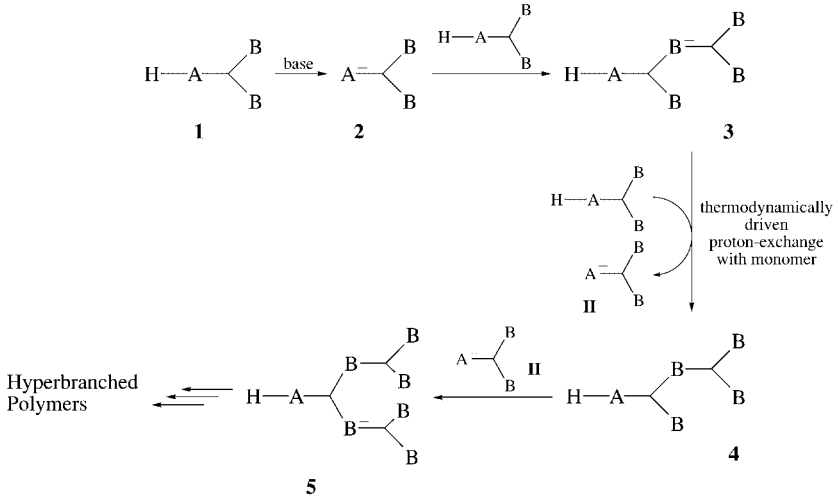

Fig. 11. Proton-transfer polymerization (PTP) (56).

Analytical and Test Methods

Degree of Branching. In a perfectly branched dendrimer only one type of repeat unit can be distinguished, apart from the terminal units carrying the chain ends. A more thorough investigation of a hyperbranched polymer (assuming high conversion of B-groups) reveals three different types of repeat units as illustrated in Figure 12. The constituents are *dendritic units* (*D*), fully incorporated A_xB-monomers; *terminal units* (*T*) having the two A-groups unreacted; and *linear units* (*L*) having one A-group unreacted. The linear segments are generally spoken of as defects. The term *degree of branching* (DB) was coined in 1991 (8) as (eq. (1))

$$\mathrm{DB} = (\Sigma D + \Sigma T)/(\Sigma D + \Sigma L + \Sigma T) \tag{1}$$

To date, two different techniques have been used to determine the degree of branching. The first technique (8) involves the synthesis of low molar mass

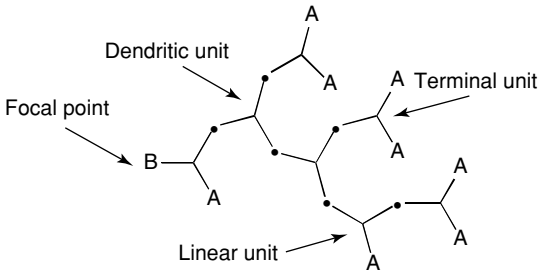

Fig. 12. The constituents in a hyperbranched polymer are *dendritic units* (*D*), fully incorporated A_xB-monomers; *terminal units* (*T*) having the two A-groups unreacted; and *linear units* (*L*) having one A-group unreacted.

model compounds resembling the repeat units to be found in the hyperbranched skeleton. The model compounds are characterized with ^{13}C nmr. From the spectra of the model compounds the different peaks in the spectra of the polymers can be assigned. The degree of branching is calculated from the integrals of the corresponding peaks in the spectrum of the polymer.

In a second method (38), based on the degradation of the hyperbranched backbone, the chain ends are chemically modified and the hyperbranched skeleton is fully degraded by hydrolysis. The degradation products are identified using capillary chromatography. Two chemical requirements have to be fulfilled to use this technique successfully. Firstly, degradation must not affect chain ends, and secondly, the conversion into elementary subunits must be complete.

The expression in equation (1) has been frequently used to characterize hyperbranched polymers. The definition leads to high DB values at low degrees of polymerization. Another expression for the degree of branching where also the degree of polymerization is taken into consideration has been introduced (58). The same group also published findings from computer simulations of ideal experiments where all the monomers are added to the core molecules, keeping the total number of molecules constant throughout the reaction (35). Increasing the functionality of the core resulted in decreased polydispersity for the final polymer. The degree of branching was found to have a limiting value of 0.66 with slow monomer addition at high degree of conversion.

It is of vital importance to understand how the degree of branching affects the properties of a hyperbranched polymer. One way to obtain polymers with higher degrees of branching is to use preformed dendron-monomers. Using this concept (21) it was found that the resulting polymers with the highest degree of branching also exhibited the highest solubility in organic solvents. This topic has also been studied by investigating the hyperbranched poly(siloxysilanes) obtained from AB_2-, AB_4-, and AB_6-monomers (59).

Uses

Numerous applications have been suggested for hyperbranched polymers but few have reached commercial exploitation. Only a few papers have been published where a certain application of a hyperbranched polymer has been addressed.

Thermosets. One area where hyperbranched polymers may find use is for thermoset applications. The low melt viscosity can improve the processing properties while extensive cross-linking can result in sufficient material strength.

Among the first studies presenting the use of hyperbranched polymers for thermoset applications was the synthesis of unsaturated polyester resins based on aliphatic hyperbranched polyesters (7). A number of resins with various amounts of maleate/allyl ether moieties were attached as end groups were synthesized. The resins could be cross-linked by a free-radical mechanism giving films with final film hardnesses depending on the amount of functional groups. Based on the same base polyester, several resins with different viscosities (before cure) and different curing rates could be obtained. The same group has also conducted studies of acrylated hyperbranched polyesters for electron beam curing (60).

Also, methacrylated polyesters and their use in photopolymerizations of films and fiber-reinforced polymer composites have been studied. The resins were found to have a low viscosity and a higher curing rate than those of corresponding linear unsaturated polyesters (61,62).

Coatings. The use of hyperbranched polymers as base for various coating resins has been described in the literature. Different resin types are obtained depending on the reactive end group structure which is attached to the hyperbranched polymer.

A number of different thermoset resin structures based on hyperbranched aliphatic polyesters have been described (63). The results can best be exemplified by their results on hyperbranched alkyd coating resins. A comparative study between an alkyd resin based on a hyperbranched aliphatic polyester and a conventional high solid alkyd, which is a less branched structure, yielded the following results. The hyperbranched resin had a substantially lower viscosity than the conventional resin with comparable molar mass, ie, less solvent is needed in order to obtain a suitable application viscosity. The hyperbranched resin also exhibited much shorter drying times than the conventional resin although the oil content was similar. These achievements would not be possible without a change in architecture of the backbone structure of the resins (Figs. 13 and 14).

Studies on acrylate resins (64,65) based on hyperbranched aliphatic polyesters have shown the possibility to vary both the polarity (wetting behavior) and T_g of the thermoset by changing either the polarity of the end groups or the cross-link density. This study shows that it is possible to vary the T_g within a large range (50–150°C) by changing the amount of reactive end groups (cross-linkable groups) utilizing the same hyperbranched polyester as a base structure. FT-Raman measurements of the residual unsaturation on these systems also showed that the acrylate functional end groups are all accessible to polymerization, ie, they are not trapped inside the hyperbranched polyester structure. The

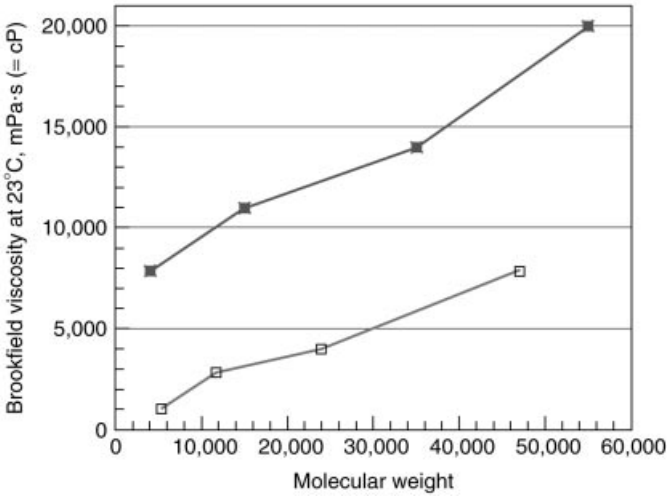

Fig. 13. Hyperbranched resins have a substantially lower viscosity than conventional resins with comparable molar mass (alkyd resin made from Boltorn). —■— Reference alkyds and —⊟— dendritic alkyds.

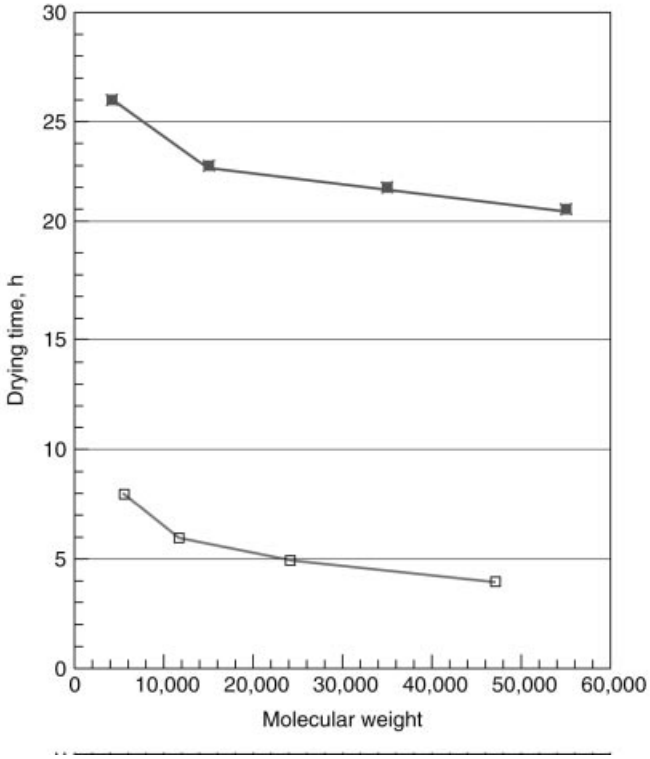

Fig. 14. Hyperbranched resins have much shorter drying times than conventional resins (alkyd resin made from Boltorn). ⊣■⊢ Reference alkyds and ⊣□⊢ dendritic alkyds.

uv polymerization of the resins also proceeded at a high rate compared to conventional acrylate resins. The structure of the nonreactive end groups affected the T_g to some extent although the cross-link density had a much larger impact on the T_g. The structure of the nonreactive end groups had a much larger effect on other properties such as the wetting behavior. Changing these groups from carboxylic acid groups to propionate groups increased the contact angle of water from 10° to 75°. Overall, it can be concluded that the thermoset properties can be greatly varied within a wide range by changes in functionality of the end groups while retaining the same backbone structure.

Solid thermoset resins have increasing importance in several fields; one of the dominating groups is powder coatings. Powder coatings are based on resins that are solid at ambient temperature and flow at elevated temperature to form a uniform coating layer. Most systems are based on amorphous reactive polymers that cross-link in the molten state forming a thermoset coating. It has been demonstrated that semicrystalline powder coatings based on hyperbranched polyesters can be synthesized (66).

ε-Caprolactone was grafted on hydroxy-functional hyperbranched aliphatic polyesters forming semicrystalline copolymers (Fig. 15). The crystallinity and rheological properties were found to be tailorable by means of the appropriate choice of hyperbranched polyester and the degree of polymerization of the crystalline

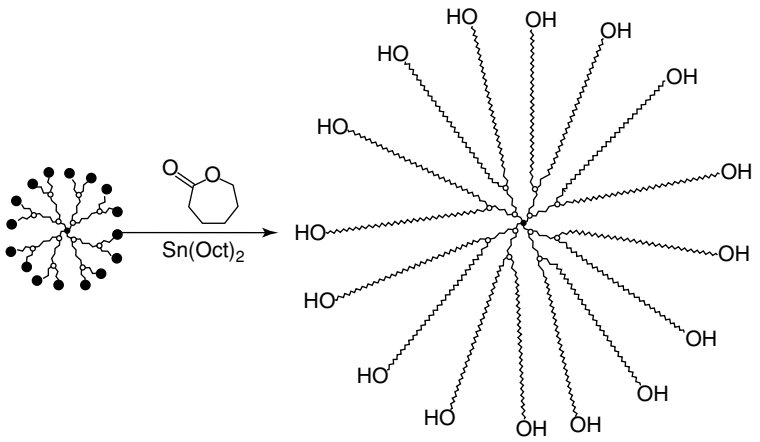

Fig. 15. Ring-opening polymerization of ε-caprolactone using Boltorn and stannous octanoate as a macroinitiator (66).

grafts (ε-PCL). Cross-linkable resins were obtained by methacrylation of the terminal hydroxyl groups. The resins were found to have suitable melt rheology for low temperature powder coatings. All resins were uv-cured in the molten state to yield flexible films with low levels of residual unsaturation. The properties of the final cross-linked films were shown to be dependent on the structure of the resins, ie, long side chains could crystallize in the network producing a semicrystalline network. Crystallization of short chains was hindered by the cross-linking.

Additives.

Toughening for Epoxy-Based Composites. One application that has been suggested for hyperbranched polymers is as additives where the hyperbranched polymers improve a property such as toughening (67). One reason for this is the possibility to adjust the polarity of the polymer to make it either compatible or incompatible with another polymer. Reaction-induced phase separation by adjusting the polarity of an hyperbranched aliphatic polyester relative to an epoxy/amine thermoset system has been demonstrated (67) (Fig. 6). An epoxy-modified hyperbranched polyester was used as toughener and the critical energy release rate G_{1c} of carbon fiber-reinforced epoxy was improved from 1.4/kJ/m^2 to 2.5/kJ/m^2 (1.19 ft·lbf/in^2). This result is obtained by a reaction driven phase separation. An advantage compared to the more conventional ones is that no filtering of toughener during fiber-impregnation can take place. The phase separation is accomplished by a careful design of reactivities of the different components as well as designing the surface polarity of the hyperbranched resin (67).

Processing Aids. The use of hyperbranched polyphenylenes as processing aid for polystyrenes has been reported (4). The melt viscosity of polystyrene was reduced while not affecting the final properties to any larger extent. The addition of the polyphenylenes also improved the thermal stability of the system.

The use of hyperbranched polymers as a processing aid for linear low density polyethylene (LLDPE) has been investigated (68). Various generations of Boltorn were used which had either 16 carbon atom alkanes or a mixture of 20/22 carbon atom alkanes on the end groups. Blends of up to 10% hyperbranched polymer

content were mixed via extrusion at 170°C to produce 1-mm diameter fibers. Processability, surface appearance, and the rheological properties of the blends were evaluated. It was found that the power requirement for extrusion was significantly decreased as a result of reduced blend viscosity, and also, the mass flow rate for a given extruder speed was greater than virgin LLDPE for all hyperbranched polymer blends. Melt fracture and sharkskin of the blends was successfully eliminated, and minimal preprocessing time was required for the effect to take place. Surface analysis using x-ray photoelectron spectroscopy and transmission electron microscope techniques were performed with both showing that the hyperbranched polymer had a preference to accumulate at the fiber surface. Rheological experiments were similarly affected, therefore, the blend viscosity is really a composite of a hyperbranched polymer rich phase and a neat LLDPE phase. It was suggested that the hyperbranched polymer rich phase acted as a lubricating layer at the polymer/die wall interface. The hyperbranched polymer with a greater degree of end group substitution acted better as a processing/rheological property aid. The results suggest that hyperbranched polymers, at trace levels of ~500 ppm, may offer a number of advantages when used as a processing aid for LLDPE.

Surface Modification. Corrosion of metal surfaces is a serious problem worldwide. It has been demonstrated that even rather thin organic layers can passivate and block electrochemical reactions on metal surfaces. Hydrophobic, fluorinated, hyperbranched poly(acrylic acid) films can block these unwanted electrochemical reactions (69–72). Hyperbranched films containing acrylic acid were synthesized on mercaptoundecanoic acid self-assembling monolayers on gold via sequential grafting reactions. This technique was shown to be useful to obtain thick and homogeneous films. The acid groups were accessible for modifications. Fluorination of these films gave surfaces that were analyzed with cyclic voltametry and ac-impedance measurements. These studies showed that the barrier toward redox reactions was greatly improved.

Conclusion

The area of hyperbranched polymers is a young and rapidly growing area within the field of macromolecules. A number of applications where the special properties of these polymers have already been described and some hyperbranched polymers are already in the marketplace. Numerous polymers with highly branched backbone structures have been synthesized and characterized. Dendritic polymers, comprising dendrimers and hyperbranched polymers, are polymers based on A_xB-monomers, ie, monomers having one B-functionality and two or more A-groups resulting in polymers with a potential branching point in each repeat unit. The difference between dendrimers and hyperbranched polymers is that the former are well-defined, layerwise constructed polymers with a branching point in each repeat unit, while the latter contain not fully reacted monomers in the polymer backbone. One main advantage of hyperbranched polymers over dendrimers is that the synthesis is less tedious, making more material available at a reasonable cost.

The synthesis of hyperbranched polymers can be made in several different ways. Classical condensation reactions are the most commonly used. The condensation reactions are either made in bulk or in solution where the A_xB-monomers

are condensated by themselves or in combination with a B_y-core monomer. The use of a B_y-core monomer improves the control over molecular weight and dispersity of the hyperbranched polymer. Another approach to the synthesis of hyperbranched polymers is the use of self-condensing vinyl polymerization, which is a way of using vinyl-functional monomers to obtain hyperbranched polymers. The introduction of this approach has greatly increased the number of possible monomers that can be used for this group of polymers.

A wide variety of hyperbranched polymers has been described in the literature. The properties of hyperbranched polymers have been shown to depend on several parameters, the most important ones are the backbone and the end-group structure in combination. The properties of hyperbranched polymers differ from linear polymers, for example, the solubility, which is much higher for hyperbranched polymers. Hyperbranched polymers normally exhibit an amorphous, nonentangled behavior, ie, a Newtonian behavior in the melt. Attachment of reactive end groups in various amounts leads to thermoset structures where the T_g and cross-link density can be greatly varied for the same hyperbranched polymer. A number of applications have already been suggested, related to the special properties of hyperbranched polymers.

INJECTION MOLDING

Introduction

Injection molding is an extensive global manufacturing process for making simple to intricate plastic, ceramic, and metal parts. Injection molding converts wax, thermoplastics, thermosets as well as powdered metals, and magnesium into thousands of products (1,2). Commercial processes and equipment have been developed for a wide variety of materials, though the bulk of what is injection molded are thermoplastics. Applications appear limitless, from compact discs to jet plane canopies, to medical implants. Nearly all consumer products have some injection-molded components. In the year 2000 injection molding consumed approximately 32 wt% of all plastics sold worldwide, roughly 4.95×10^7 metric tons (3). This is second to extrusion which consumed 36 wt% of all plastics sold worldwide. The United States consumes about 33% of the plastic sold worldwide. In the United States, the plastics industry ranks as the fourth largest after motor vehicles, petroleum refining, and automotive parts. Plastic processing and products continue to grow at a faster pace than the national average. This is in spite of the trend of the United States going toward an information and service industry and away from manufacturing. In the United States there are about 6000 molding shops, down from a high of about 8000 in the early 1990s. Consolidation continues as monitored by the trade journals, for which web sites are listed (4–8). There are an estimated 80,000 injection presses in operation within the United States.

The injection-molding process provides low cost fabrication of large and small parts to precision tolerances. Many of these parts are nearly impossible to make in production volumes by other techniques. Injection molding can form parts as small as a cubic millimeter (micromolding), and parts as large as garbage dumpsters and 1.2×2.4 m (4×8 ft) filter panels are in production. A wide range of

injection-molding processing capability characterizes the industry. Quality and tolerances can be high if scientific principles are followed. Tolerances near 0.025 mm (0.001 in.) are difficult to achieve but are possible if concurrent engineering is applied to certain parts. One of the strengths of injection molding over other plastic forming processes is that parts can have fine three-dimensional (3-D) details in their shape and surface finish. Typical nominal-wall thickness ranges from 0.5 to 6.4 mm (0.020–0.250 in.); however, thickness of 0.08–50 mm (0.003–2.0 in.) are also possible. Injection molding is the plastic processing method of choice for large quantities of identical parts. Quantities in the millions are possible with one or more molds that can form several parts at one time. The efficiency of this process has changed the quality of life for most Americans, especially low income households.

Properties of injection-molded parts can be unique. Given a metal or plastic's typical properties, injection molding imparts some of its own. Because of flow patterns, molecular orientation, and other factors, molded part properties are often different than those of the base material. An example of the benefits of orientation is the "living hinge", the flexible plastic hinge found on spice, shampoo, and dental floss containers. Properties of injection-molded parts can be flexible or stiff, soft or hard, tough or brittle, clear or opaque, specific chemically resistant and flame retardant. Parts can be tinted, colored, plated with various metals, and recycled.

Economic Aspects

Profit margins for the industry are generally low and have averaged around 6% as shown in Figure 1.

Another perspective to Figure 1 is to exclude resin cost and calculate the cost to run an injection-molding machine on an hourly basis. Usually this is expressed as a charge per hour for a given size machine. The range for hourly rates is US \$10–\$175/h, depending on machine size ranked in tons of clamp pressure. Machine clamp pressures range from 69 to 1.4×10^5 MPa (5–10,000 tons), most being below 1.4×10^4 MPa (1000 tons).

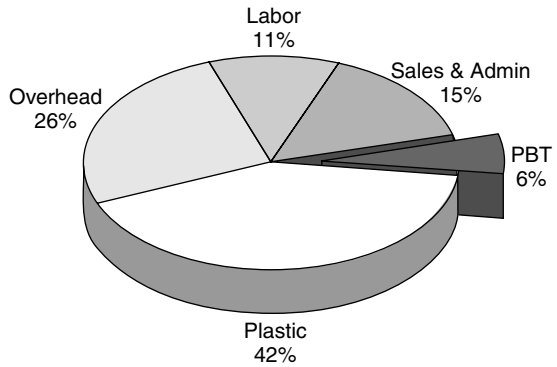

Fig. 1. Costs and profit margins for molders. *Source*: Facts & Figures of the US Plastics Industry, published yearly by The Society of the Plastics Industry, Inc. Includes custom and proprietary molders; PBT = profits before taxes.

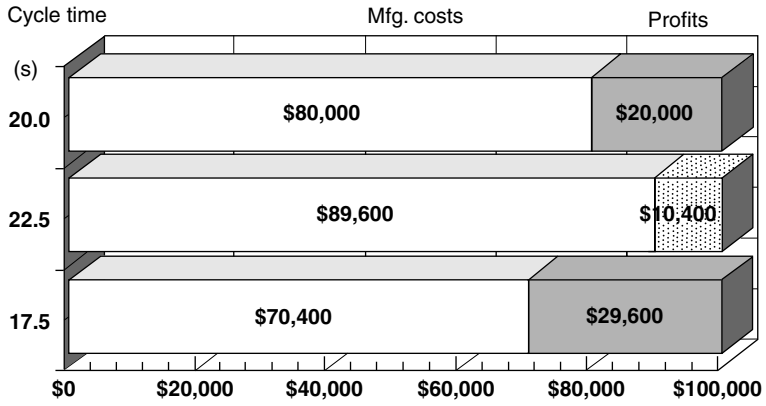

Fig. 2. Quoted profit per $100,000 of sales. Courtesy of D. Paulson.

Most businesses operating injection-molding shops (molders) will bid a job to make 20%, or greater, profit before taxes, yet they realize far less as Figure 1 shows. Resin cost is often included in part quotes, which means that if the price of the plastic increases the molder must absorb the cost, and profits decrease. Molders rarely have much of an influence on resin pricing. Quoting, therefore, should provide a mechanism that allows resin price fluctuations to be passed on to the customer, yet this is not common practice in the industry. Another reason for low profit margins is that when quoting, the exact cycle time (the time required to make a part) is not known or cannot easily calculated; that is, the quote is based on an estimated cycle time. Often after the mold is built and trialed, production cycles are longer than estimated or quoted and the molder cannot renegotiate the contract. This effect of cycle time on profit is known, yet poorly understood (9). The top bar of Figure 2 shows a typical bidding situation with a 20% return added to costs for a 20-s cycle.

The middle bar shows how a 10–15% cycle time increase, averaged to 22.5 s, can cut profits by nearly 50%. Using the same concept, a 10–15% decrease in cycle time improves profits by ~50%, for a 2.5-s decrease in cycle time. Few molders know their actual costs and most are not willing to spend money to shorten cycles.

This low profit margin is the cause for many consolidations and hurts a molder's ability to attract capital for machine replacement as new technology emerges. Figure 1 also points out that molders only sell time that is used to make acceptable parts. Any time not used to make acceptable parts such as mold changes, downtime, repairs, and time to make rejects is lost profit opportunity and must be kept to a minimum to be internationally competitive.

The Injection Molding Process and Machine

Injection molding is a forming process. Material (plastic, metal, ceramic, wax, etc) is fed into a hopper which delivers it to the feed section of the barrel and screw. The material is melted usually via a screw that melts or blends the material and then pushes liquefied material (eg, plastic) into the mold, which forms the part.

The injection-molding industry is relatively young when compared to other manufacturing processes, such as metals, wood, or cement. Although patented in 1870 by Smith and Locke and 1872 by Hyatt, the first commercial plunger machines were developed in the late 1920s and 1930s. Egan patented the reciprocating screw in 1956. Since then the elements of the machine have stayed the same but advances continue with the evolution of advanced computer controls, hydraulic circuits, and computer numerically controlled (CNC) all electric presses. There are several variations and extensions of injection molding within the industry that provide unique capabilities to the process and in turn special properties to parts. Virtually all share the common elements of the following:

(1) Material preparation: The plastic/metal/mixture may be cleaned, dried, colored, blended, heated, cooled, or in some way readied for use in the machine. This can be one resin, thermoplastic or thermoset, or combination of base resin and additives. Additives include colors, metal particles, foaming agents, antistatic agents, fillers, fibers, flow aids, stabilizers, antioxidants, mold-release agents, binders, flame retardants, etc.

(2) Material, usually dried plastic granules, is fed (usually by gravity) into a feed port or throat of a heating cylinder or barrel.

(3) Material melting and/or mixing, [usually thermoplastics via heat (heater bands) and mechanical shear (flights of a screw shearing the plastic at inside surface of a barrel wall)], preparing it to be pushed into the cavity: As the screw rotates, it pumps plastic forward to prepare enough material for injection. The injection unit, barrel, and screw are now something like a syringe ready to inject fluid.

(4) Filling the cavity by pushing the material under pressure [7 to ∼414 MPa (1000–60,000 psi)] into a mold cavity. The cavity sees less pressure, between 1.4 and 140 MPa (200–20,000 psi), because of large pressure losses as the plastic travels the path to the part. This path includes the nozzle of the injection-molding machine, the sprue (a tapered cone) that connects the nozzle to the runner, the runner (usually a round channel), and the gate or entryway to the part.

(5) The mold or tool that contains the cavity that forms the part and provides heat to cure thermoset parts or cooling to set up or freeze thermoplastic parts. Typically, the mold cools the molten plastic to a rigid or semirigid form so that it can withstand the force of ejection (part removal) and retain its shape. Not all of the energy to melt the plastic is removed by the mold. Cooling continues after ejection and the part continues to shrink. Parts made with certain plastics, ie, semicrystalline, may take 3 days to 6 weeks to stabilize. Post-molding conditioning can be critical to achieve desired performance, dimensional criteria, or flatness.

(6) The clamp which holds the mold halves together during filling and packing the part with plastic.

(7) Part removal or an ejection mechanism. This occurs after the clamp opens, separating the mold at the parting line into halves. The part is pushed (ejected) out of the mold and drops to a box, conveyor belt, or is taken out by a robot.

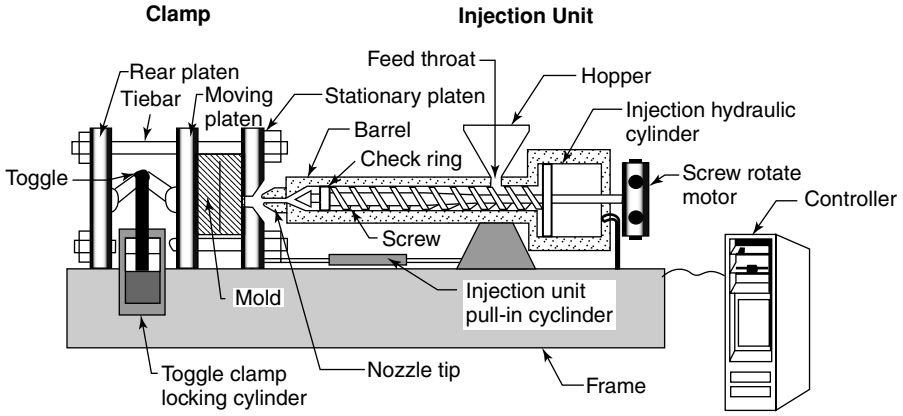

Fig. 3. Basic hydraulic (toggle clamp) injection-molding machine components. Illustration by John W. Bozzelli & Rick J. Bujanowski.

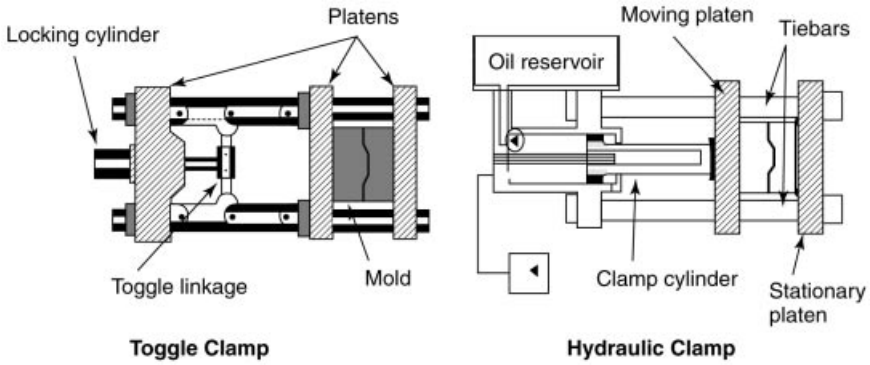

Fig. 4. Toggle and hydraulic clamps. Illustrations by Rick J. Bujanowski & John W. Bozzelli.

(8) A controller, usually a computer, that coordinates and controls the various steps of the process and components of the machine.

Figure 3 depicts many of these components in a typical hydraulic injection-molding machine with a toggle clamp.

There are a number of variations in machine construction and processing techniques (10). There are hydraulic (Fig. 4), hydromechanical, and toggle clamping machines (Fig. 4). There are also tiebar-less clamps as shown in Figure 5, and two-platen machines that were developed to save floor space over the normal three-platen machine.

Two-platen machines do away with the rear platen by locking the moving platen to the four tiebars. Here the moving platen closes on the mold as usual, then a tiebar locking mechanism locks onto the four tiebars, allowing a hydraulic pancake cylinder to build clamp pressure by pushing the moving platen toward the stationary platen. Clamps shown in Figures 3–5 are horizontal clamps; vertical

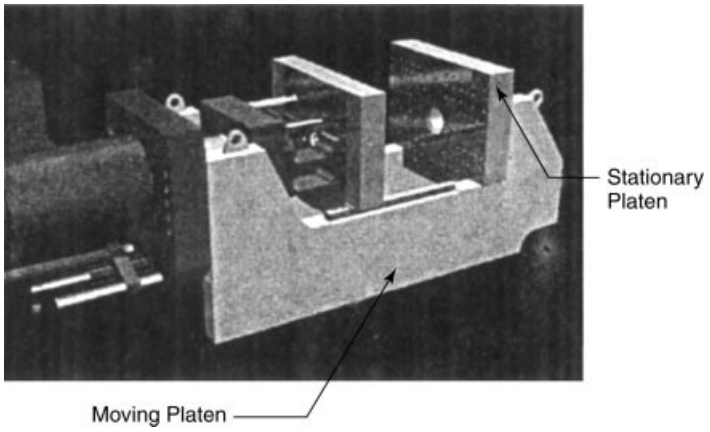

Fig. 5. Tiebar-less clamp. Courtesy of Engel Machinery Inc.

clamps are also available, where a platen moves up and down. Vertical clamps are useful in insert molding to use gravity to hold the insert in place as the mold closes. In all cases except in tiebar-less machines, the tiebars are stretched to build clamp pressure (tonnage) that holds the mold halves together during injection and packing of the plastic into the mold.

A significant shift in the industry, which started in the 1990s, is to use electric motor servo-drives rather than hydraulics to power machines. Greater accuracy, less noise, 20–60% less power requirements, and no hydraulic fluids are claimed advantages.

The process for making a part is called the molding cycle. This cycle is depicted in Figure 6 with the average time for that function stated as a percentage of the total cycle time.

A cycle or cycle time is the elapsed time required for the injection-molding machine to complete the process of forming a part. It can be timed starting at any point of the cycle to the same point on the next cycle. Cycle times range from below 4 s for compact discs to hours for jet canopies, both made from polycarbonate. Machines have been made that can cycle in less than one second.

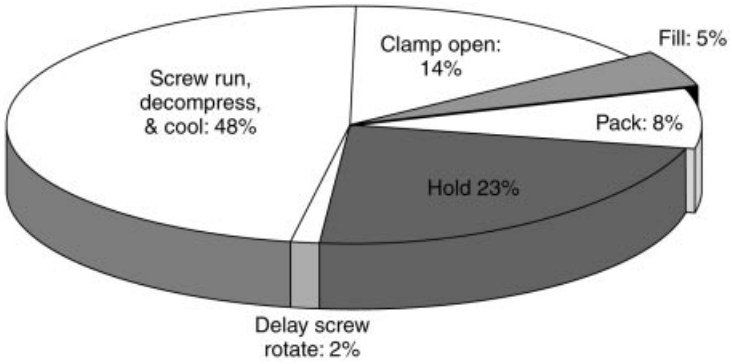

Fig. 6. The injection molding cycle.

Variations and Extension to the Injection-Molding Process

Injection Blow Molding. A preform (this looks like a test tube with bottle cap threads) is injection molded in one cavity, removed and then placed into another where it is pressurized with gas to stretch the hot preform into a thinner-walled seamless bottle or container such as a milk bottle or gas tank. This is depicted in Figure 7. This is an extension of injection molding more than a variation.

Injection Compression/Coining. With this technique the mold is only partially closed during injection. At the appropriate time and with the right amount of plastic in the mold, the clamp is then completely closed, forcing (compressing) the plastic to the shape of the mold cavity. A variation on this is coining. The clamp is closed but the mold has components that compress the plastic in the cavity as the plastic cools. Coining is where the cavity volume is changing during the solidification of the plastic. Plastic is injected into the cavity and then the movable platen closes completely, or a mold component moves to compress the plastic to compensate for shrinkage or densification.

Gas-Assist Injection Molding. Here, plastic is injected into the cavity until it is 50–85% full, then high pressure gas, usually nitrogen, is injected to finish filling the cavity by pushing the plastic flow front to the end of the cavity. This leaves a gas bubble or channel inside the part. This saves plastic, reduces cost, and often improves part strength especially in thick sections. Gas can be injected at the nozzle of the machine or directly into the mold as depicted in Figure 8. Gas-assist molding can be considered as a variation of co-injection molding where the outer layer or skin of the part is plastic and the core is a gas channel rather than another type of plastic.

Gas Pack or External Gas-Assist Injection Molding. This is a variation of coining but uses a gas, usually nitrogen, to pack out a certain section of a part to meet dimensional requirements. The gas is injected on the rear (ejector) side of the part to push the molten plastic against the cosmetic side of the mold surface.

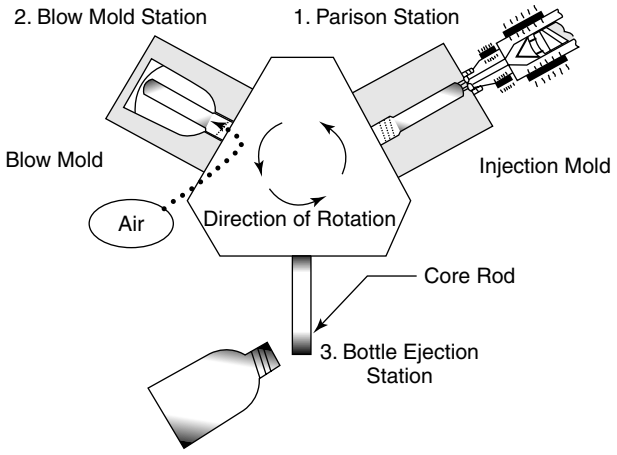

Fig. 7. Injection blow molding.

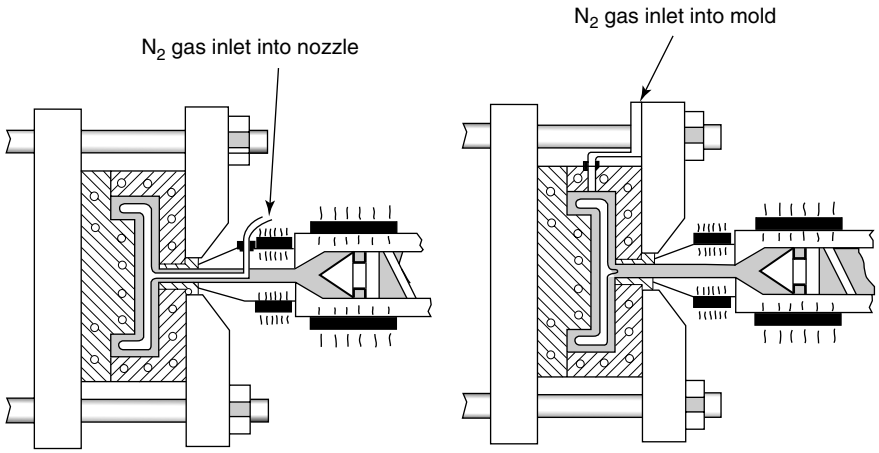

Fig. 8. Gas-assist injection molding (nozzle & mold gas entry with bubble in part). Illustration by Rick J. Bujanowski & John W. Bozzelli.

Gas-Counter Pressure Injection Molding. Normally, as plastic enters a mold it displaces the air within the cavity. The air is vented to the atmosphere via specially designed vents specific to the type of plastic being molded. In gas-counter pressure molding an O-ring is installed around the perimeter of the cavity and a gas pressurizes the cavity. During injection this counter pressure gas, usually between 345 and 2760 kPa (50–400 psi), prevents gases, water, nitrogen, etc from emerging to the surface. Gas-counter pressure molding will provide a smooth skin and nice appearance when processing plastic with a foaming agent. The counter pressure prevents the gas bubbles from developing at the surface.

Structural Foam Molding. Plastic pellets are blended with a chemical blowing (foaming) agent, usually in pellet form, and injected into the mold under normal molding conditions. The foaming agent can also be a gas or liquid. The cavity is filled only to 70–95% full and then the foaming agent releases a gas, usually nitrogen, to finish fill. The parts surface is usually splayed or rough. The resulting part has a significant density reduction, saving material costs. Density reduction ranges from 5 to 35% with an average in the 8–20% range, yet the parts are stiffer than solid wall parts. In combination with gas-counter pressure the rough surface caused by the gas bubbles coming to the surface can be eliminated. The counter pressure gas prevents the foam bubbles from developing at the surface; cosmetics are as good as regular injection molding. Injection and cavity pressures are lower than that with conventional injection molding and sometimes the term low pressure molding is applied. Machine and mold costs are lower due to the lower pressure requirements. Trexel Inc. has recently brought out a new variation to foam molding, the Mucel® Process. It injects high pressure gas (N_2 or CO_2) into the barrel achieving supercritical fluid conditions to dissolve the gas into the polymer. A special screw aids in dispersing the gas into the molten plastic before injection. Once in the cavity, small bubbles evolve as pressure is lowered as the part cools.

Thin-Wall Molding. This is identical in concept to normal injection molding but the parts produced have much thinner nominal walls; notebook computer

shells and cellular phone housings are examples. While an exact definition of "thin-wall" has not yet been defined, the range is often in the 0.08–0.80 mm (0.003–0.030 in.) range. Sometimes thin-wall is defined as a wall thickness to flow length ratio in the range of 150–300 to 1. Modified injection-molding machines that provide fast injection rates and higher injection pressures are usually required.

Insert Injection Molding. Plastic can be injected around another material or another plastic to form a part with plastic partially or completely encapsulating the other material or "insert." A metal grid, screw, or electronic circuit can be encapsulated by placing the item into a cavity, the mold closing around it forming the cavity and holding the insert in place and then injecting plastic. The plastic connectors on the end of a wire harness, automotive battery tops with terminals, and car windows with molded weather-stripping gasket are insert molded.

In-Mold Decorating. This is a variation of insert injection molding where the insert is a label, fabric, or some type of appliqué that is mounted flush to one side of a mold and held in place, sometimes by vacuum, and plastic is injected behind it. Wood-grain car dashboard pieces, labels on food containers, and fabric on seats are examples of in-mold decorating.

Multishot Injection Molding. This is similar to insert molding where the insert is usually another plastic component. A soft grip over a rigid plastic handle, many toothbrush handles with soft and hard sections, and an automotive tail-light with clear, red, and orange lenses are typical examples. State-of-the-art multishot molding uses an injection press fitted with two to six injection barrels. They can inject different colors or different materials simultaneously or through a timed sequence. Normally, the mold pivots or rotates between shots. The first part or inner section is made and then the second plastic is shot around or through the first.

Co-injection Molding. This type is similar to multishot molding. Using a timed or position sequenced injection, two or more plastics in different barrels can provide a skin or outside wall made of an expensive plastic with the core or inside filled with a foam, gas, or recycled or cheaper plastic. Fence rails or railroad ties can be made with a post-consumer or recycled plastic as the core on the inside and virgin prime material as the skin on the outside for acceptable appearance and performance.

Metal/Ceramic/Carbide Injection Molding or Powder Injection Molding (PIM). This is similar to plastic injection molding but the plastic resin is replaced with metal, a plastic–metal blend, or ceramic powder. For example, a plastic binder, often polypropylene or acetal, encapsulates or is used as a carrier for fine metal particles. Loading can be near 80% metal. This plastic–metal combination is forced under high pressure into the mold cavity. The "green" fragile part is ejected and then the plastic or binder is removed with acid, solvents, water, catalytic vapor, or heat. The resulting part is placed in a sintering oven and a precisely controlled heating regimen sinters the metal particles together yielding a metal part. Metal molding is an excellent technique to form complex metal shapes that would be difficult or impossible to machine. Ceramic molding is similar. Pure metal molding is also practiced. Magnesium in granular or powder form can be fed to a screw, melted, and injected into a mold.

Reaction Injection Molding. Two or more components are fed into the barrel feed throat, often preblended; the screw continues the mixing and then

injects the mixture into a mold. The mold can be heated or cooled. Once mixing is started a chemical reaction begins. Careful control of barrel and mold temperatures as well as residence time in the barrel are critical to prevent premature curing. It is possible to have the compound cure and seize the screw within the barrel.

Liquid Injection Molding. Molding machines with special barrels, screws, and feed systems mix and then inject liquids into a mold cavity. Similar to reaction injection molding the two liquids, often silicone or urethane based, react to form a thermoset part. Baby bottle nipples and keycap return springs are two current silicone type applications.

Micromolding. This is an extension of injection molding to extremely small part molding. Part weights in micromolding are already below 1.0 g. Technology is evolving to injection-mold parts in the milligram (or 10^{-3} g) range.

Components of a Successful Injection-Molding Product

A successful plastic product depends on the optimization of each of the following four principal components: part design, material selection and handling, tool design and construction, and processing/machine capabilities.

These interact with each other and they are equally important. One or more is often neglected by most in the molding industry, which causes delays in production and significant profit loss throughout the entire life cycle of the product. To employ all four from the beginning of a project is "concurrent" engineering and their implementation is scientific injection molding (SIM). SIM is a detailed strategy of optimizing each one of these components and not allowing errors to be compensated through processing. The synergy of working with all four from the beginning of a project has shown profit increases of 100% and faster development times to market and significantly fewer manufacturing problems.

Part Design. A successful plastic product must begin with a good part design. Because injection molding is a comparatively new and a rapidly expanding industry, it is often the case that an engineer with little plastics training is forced into plastic part design. This combination of no plastics experience and a tendency to apply rules for metals to complex shapes is ill-advised and often leads to project delays, failures, cost overruns, and production problems. Issues such as draft angles, weldlines, and polish in the direction of draw are singular to plastics. Plastics are unique, different than the materials most designers are familiar with and do not have a uniform set of precise design rules. A common mistake for the uninitiated designer is to increase nominal wall thickness to gain strength. With plastics, generally thicker means weaker due to more internal stresses. Thicker walls add weight and higher production cost because of longer cycle times. To gain stiffness or strength in a plastic wall, properly designed reinforcing ribs can be added.

Different plastics have different amount of shrink upon cooling, higher for semicrystalline resins (eg, polypropylene can shrink 0.030 in./in.) and lower for amorphous plastics (eg, polystyrene can shrink 0.006 in./in.). Further, shrinkage, especially for semicrystalline materials, varies due to thickness, cooling rate, and often color. Whatever stays hotter for a longer time will shrink more. Therefore, changes in nominal wall thickness cause differential cooling, which causes

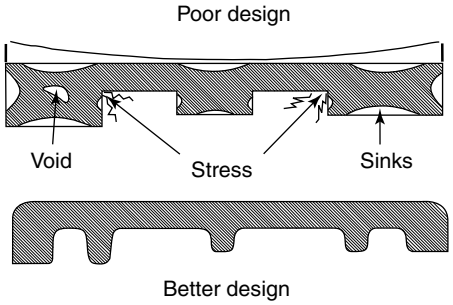

Fig. 9. Cooling and nominal wall thickness. Courtesy of Glenn Beall.

differential shrinkage that causes warp. Warp distorts the part out of dimensional tolerance. This distortion may be immediate after ejection from the mold, or after assembly in the application environment. For example, the fit and shape of an interior trim piece of a car's dashboard are fine in production and assembly, but once on the road and after a few thermal cycles (cool nights and hot days) the trim piece warps out of shape. With plastics, nominal wall-thickness changes and sharp corners should be avoided. If nominal wall-thickness changes are necessary the variation must be minimized. How fast the wall changes thickness will also influence properties and performance. Blending different thickness wall sections will minimize internal stresses. The first rule in plastic part design is uniform nominal wall thickness, yet few parts are designed on this basic premise. Figure 9 shows an application of uniform nominal wall thickness.

During part design one must take into consideration material, tool, and processing issues. When designing a part the mold is also being designed. For example, to have a dimensionally stable, high performance part it must be cooled as uniformly as possible. Is it possible to get water channels to all sections of the part so that it will cool evenly? Can the part be removed from the mold? Part design forces these and other tool construction details. Often the gate or entry point for the resin is determined by the cosmetic or performance requirements; however, it may not be possible because of mold building requirements. A good plastic part designer knows and comprehends the other three components and makes the difficult compromises to meet material, tooling, and processing requirements.

Schools and training programs have not kept up with demand for plastic part designers because of industry growth. Lack of proper training and drive for short product development times are two of the many causes for "engineering changes" as the mold is being built. That is, the design is changed after work has started on making the mold. Often a design change is made and there is no steel to accommodate the change. The mold builder cuts it to the previous design. Figures 10 and 11 depict the cost of engineering changes at different stages of a project and the impact design has on the profit margin of a project. Engineering changes must be completed in the design phase before production tooling is made. Unfortunately, the industry norm is to start cutting the tool (mold) before the design is finalized.

Industry trends will continue to challenge design. Trends to consolidate multiple functions into few parts for easier and faster assembly results in more

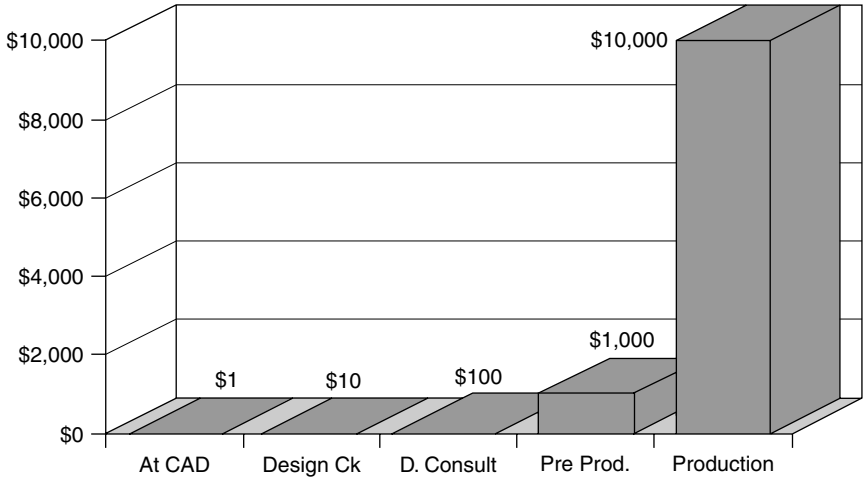

Fig. 10. Costs for design changes. Courtesy of Glenn Beall, data from Martin Marietta Co.

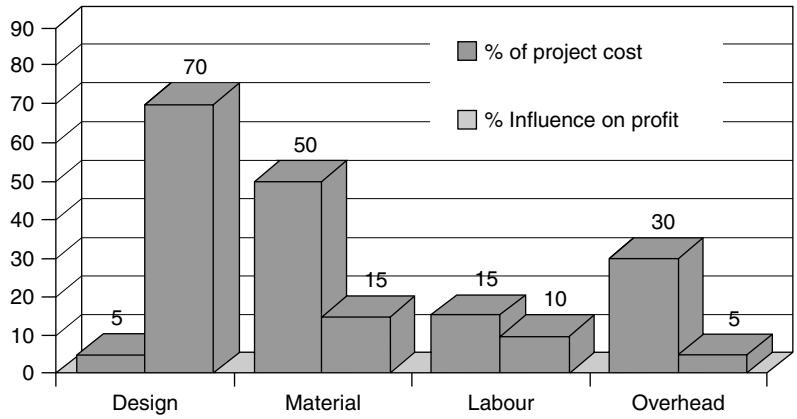

Fig. 11. Costs vs influence. Courtesy of Glenn Beall, data from Hewlett Packard/Ford Motor Co.

complex plastic part geometries. Thinner walls to save plastic and longer flow paths in larger parts are other trends that test design limits. It is imperative that part design heed fundamental design principles as outlined in References (11) and (12). Better performance is often tied to tighter tolerances. This forces more attention to the details in each of the four components for making a successful plastic part.

Material Selection and Handling. Material selection is usually done during early stages of part design. Involvement of processing and material specialists are valuable in optimizing this tough decision-making process. With data bases covering over 32,000 resins the task is daunting (13), especially when most of the data provided does a poor job of predicting the time and temperature behavior of plastic materials in end applications. Sepe's handbook provides practical time temperature data for 120 families of thermoplastic materials based on dynamic

mechanical analysis (14). Although most of the 32,000 resins are not used in large quantities many have specific properties and applications. During material selection the rush to production often takes precedence over the necessary thorough determination of the applications' physical requirements and exposure to environmental factors.

Thorough review of the performance criteria for the application is critical. Before a plastic is selected a list of criteria should be built on answers to questions such as transparency, use temperature, thermal cycle, dimensional tolerances, cosmetic aesthetics, agency approval UL, FDA, NSF etc, and wear and abrasion needs. Environmental conditions are crucial and must be evaluated under time, temperature, concentration of the chemical or radiation, and stress within and applied to the part. Strength, fatigue, rate of loading, elongation, cleaning aids or solvents, body oils or fluids, shipping and storage conditions, expected misuse, and liability concerns must also be considered. For all plastic product failures, 32% is due to environmental stress-crack resistance issues (15). Environmental concerns for waste disposal and recycling must also be evaluated.

The process of injection molding influences the material's properties. Parts made by injection molding retain stress developed during injection, packing, or cooling. Properties in the flow direction are often different than that in the cross flow direction for anisotropic behavior. Shrinkage can be greater in the cross flow direction, while tensile strength is stronger in the flow direction. Addition of additives often provides one benefit, such as color, mold release, radiation stabilization, or wear resistance, but compromise another property such as impact or elongation. Part performance is further complicated by use of temperature range, complex design features, nominal wall thickness, sharp internal corners, process variations, etc. The end result is that nearly all the typical property data sheets of a material supplier dictate that an injection-molded part must be tested in its end application to verify performance.

Material handling is part of the molding process. Plastic must be properly prepared before entry into the feed throat of an injection-molding machine. Plastic granules can get contaminated with foreign material during shipping, and handling especially in regrind operations. Fines, metal, dirt, moisture, or another plastic must be removed before processing. Typically, the only precaution taken is to pass the plastic over a magnet to trap ferrous metal fragments before use. For resins that are hygroscopic it is necessary to dry them to remove the moisture before processing. Polycarbonates, nylons, urethanes, and polyesters are examples of plastics that are sensitive to hydrolysis. Hydrolysis occurs as the polymer is melted in the barrel of the injection-molding machine in the presence of moisture and results in parts with poor physical properties. The parts may look acceptable but the molecular chains are shorter due to hydrolysis, and parts will not perform to expectations. Once dry, the resin must be conveyed and stored dry until processed. It is common for the industry to dry the plastic but convey and/or store it exposed to plant air. Normally, the plastic must be processed within 30 min before it readsorbs enough moisture to mandate redrying. Some resins especially sensitive to moisture adsorption and hydrolysis present a drying challenge because of poor dryer design, maintenance, and operation. Figure 12 shows a common layout of a two-bed desiccant dryer. Two-, three-, and four-bed desiccants are common in the industry.

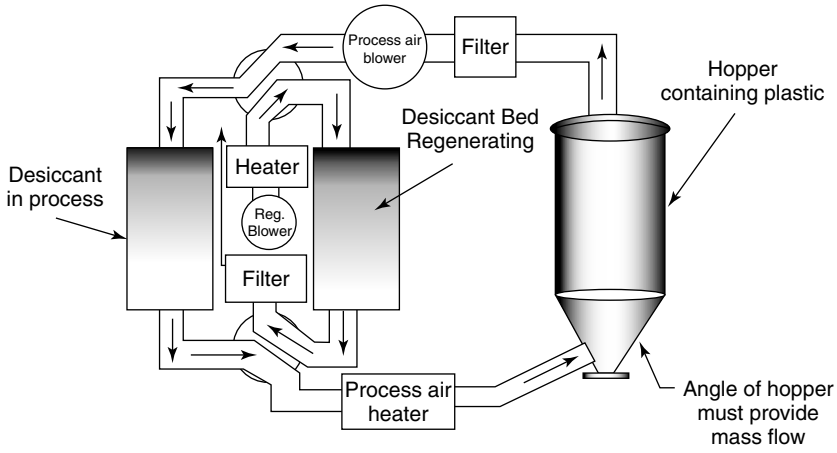

Fig. 12. Two-bed desiccant dryer.

Poor dryer maintenance leads to inactive desiccants, air leaks in hoses, clogged filters, defective heaters, and the inability to maintain a low dew point of the drying air. Parts made from improperly dried or wet resins should not be reground for reuse if the plastic is subject to hydrolysis. Degradation by hydrolysis destroys properties and is not reversible.

Blending in additives is another common resin preparation step before feeding plastic to the injection-molding machine. For most additives this is best done and usually performed at the plastic resin producer's facility after polymerization and before extrusion into pellets. However, at-the-press additives are popular. The additive can be granules, powders, or liquids, which can modify the base resins in appearance and performance. Coloring is an example of an additive used to change appearance. Typically, the natural resin is blended with a coloring agent. If the resin producer adds the color the resin is "precolored" as delivered to the molder. If the coloring is done at the molding shop it is called in-house coloring with natural resin and color concentrate or master batch coloring. The concentrated colorant, usually in granular form but can be powder or liquid, is blended with the natural resin (usually in a ratio of 20:1, ie, 20 kg of resin to 1 kg of colorant) and then fed into the feed throat of the molding machine. Colored plastic parts do not peel or show scratches like painted parts, the color is throughout the part. Colorants change not only the base resin's appearance but also its physical and processing properties. Different colors of the same resin will have different properties and may require different processing conditions. This is especially true for semicrystalline resins as colors often change the degree of crystallinity.

Tool Design and Construction. Mold design and construction is critical to all molding processes. Injection molding can not be accomplished without a mold or "tool." Building a mold is capital and time intensive (16). Tooling cost breaks down into 10% for engineering, 15% for material, and 75% labor. Current trends show that material and labor costs are increasing so much that low pressure forming processes that can function with less expensive tooling are gaining favor, such as rotomolding, blow molding, and thermoforming.

A mold performs many different functions. It can be highly complex leading to high initial cost and a maintenance burden. However, for the plastics industry simpler equates to elegance, lower cost, and higher production. The main functions of a mold are to form the shape and surface finish of the part from the molten plastic and then cool or heat the plastic to solidify or cure it so that the part can be removed from the mold. The demand for 3-D complex parts has evolved mold making into an art form second to none. Novel mold designs and construction techniques allow ever more complex shapes to be made to exacting tolerances. The mold must be ruggedly built to withstand repeated cycles, sometimes in the millions, and enormous pressures. The typical injection mold will be pressurized to 1.4–140 MPa (200–20,000 psi) to shape and pack a cavity full of plastic.

The simplest mold is the two-plate mold as depicted in Figure 13.

This two-plate mold forms one part with a cavity and core. The molten plastic enters the mold through the sprue bushing which mates perfectly with the nozzle of the molding machine. In Figure 13 the sprue bushing delivers molten plastic directly into the part. The part is "sprue gated." A "gate" is a restricted entry point for the plastic to fill the part. There are several gate designs, each with its unique advantages and disadvantages. In a multicavity tool the flow of plastic is channeled at right angles from the sprue bushing to the different cavities by means of a runner system as shown in Figure 14 (cold runner).

If multicavity molds must be built to meet product demand and the part must be center-gated (eg, round gears) there are two tooling options: a three-plate mold or a hot runner mold. A three-plate mold provides a runner path as shown in Figure 15, which allows for center-gating multiple parts.

Since this runner system comes out of the mold as the part is ejected, it is known as a cold runner. Ideally, the runner system provides the shortest path possible to each part with equal flow distance and equal pressure-drop to each

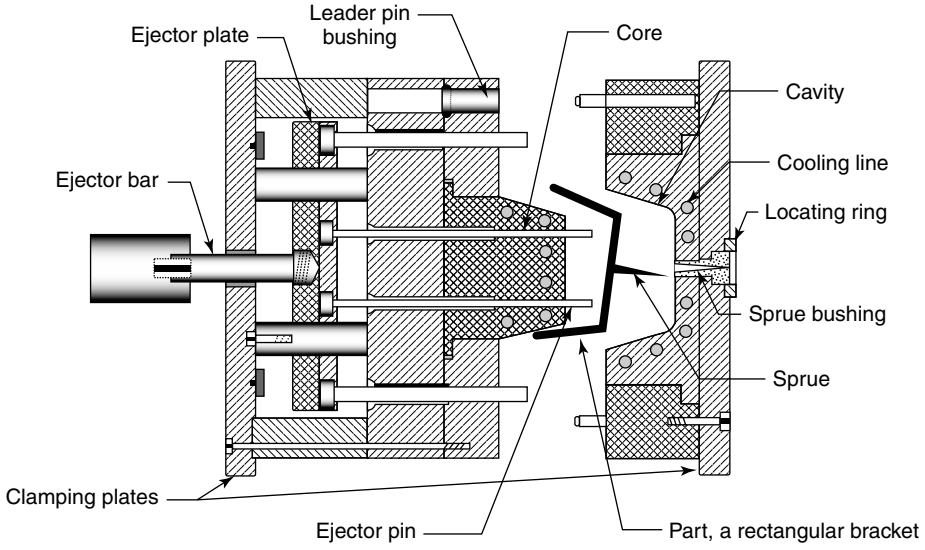

Fig. 13. Basic components of a two-plate mold. Illustration by John W. Bozzelli.

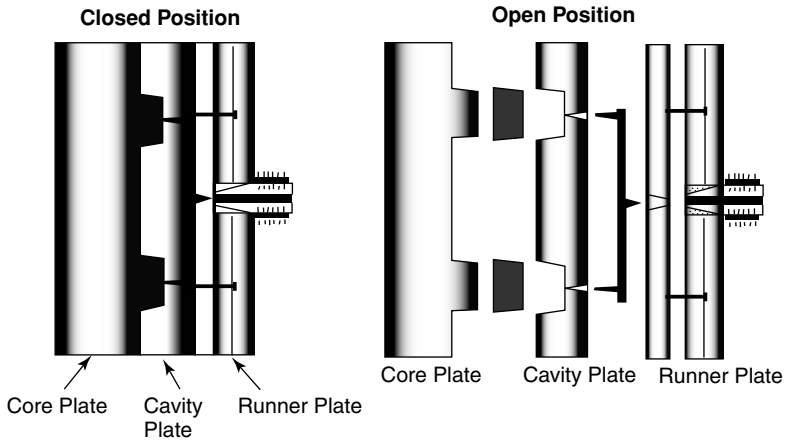

Fig. 15. Three-plate two-cavity mold.

part. Multicavity tools can make identical (Fig. 15) or nonidentical or dissimilar parts. Tools that make nonidentical parts are called family molds. Parts for a model airplane are made in one shot from a family tool and are usually packaged attached to the runner. Making quality parts in a family tool is more difficult than making parts in a multicavity tool with identical cavities because of flow imbalances. Usually, plastic will not fill a small part the same way as it will fill a large part within the same mold.

Multicavity tools can be built to make over 100 parts per cycle. These are complex molds that can cost hundreds of thousands of dollars. The cold runner systems in multicavity tools can be extensive, wasting plastic. The runner has to be separated from the part, handled, discarded, or reground for reuse if possible. An alternative to cold runners and a trend in the molding industry are hot runners or runnerless molds. Hot runners serve the same purpose as cold runners, ie,

to provide a flow channel to each cavity, but unlike cold runners, they are heated channels that keep the plastic molten during the entire cycle. The molten runner stays in the tool between shots, always ready to deliver plastic to the cavity. These hot runners are heated externally by surrounding the channel with an appropriate electric heating element or internally where the electric element is inside the channel. While this concept of hot runners may seem fairly easy to accomplish, a hot runner tool is more expensive, incurs higher maintenance costs, and often more difficult to start and run than cold runner counterparts. Runnerless mold design and construction adds several more degrees of complexity to an already intricate task. Mold making, especially hot runner tools, must be done by specialized mold makers in combination with mold filling simulation analysis. Figure 14 shows a balanced hot runner layout for two cavities. Figure 16 shows details of an internally vs externally heated hot tips used to deliver plastic to parts in hot runner tools.

With mold costs increasing due to complexity and required fast mold build times, the need to reliably predict plastic flow behavior has intensified. Mold filling simulation has evolved with the industry to become a significant factor in aiding the design and construction of molds (17). There are several software programs available. They range from those that make simple two-dimensional 2-D calculations quickly and inexpensively to the sophisticated 3-D software suites that can calculate pressure drops, shrinkage, warp, and cooling characteristics costing thousands of dollars. Highly trained, experienced engineers or technologists are needed to obtain reasonable predictions with this software.

Mold making is a complex and intricate undertaking. Skills required include the knowledge of machining various metals, computers, CNC programming, electronics, hydraulics, metallurgy, polymer flow, polymer shrinkage, etc. Mold makers have to make knowledgeable compromises on types of metal used to withstand corrosion, pressure, temperature, heat conduction, thermal expansion, etc. How the metal is cut, heat-treated, coated, or polished influences the quality and cost of the mold. The mere direction of polishing strokes can influence the ability for the plastic part to be ejected. Polish on a mold can be from a lens quality high polish

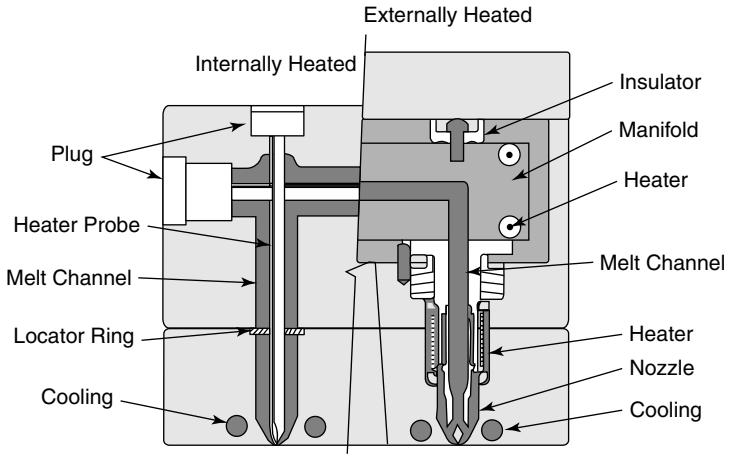

Fig. 16. Hot runner tips. Courtesy of Husky Injection Molding Systems Ltd.

or gloss to a texture that imitates wood or leather grain. Polishing can be 50% of the tooling cost.

The foremost challenge in tool building is fast response. How fast can the mold be made and at the least cost? With unrelenting demand for shorter lead times between concept to production, speed of part design and tool construction becomes strategic. Prototype tools are sometimes made before production tooling to test design or performance of both the part and the tool. An entire industry has developed to service "rapid prototype tooling," building some tools in days rather than weeks. The technologies that are currently in use include metal casting, laser sintering, metal spray-up, and Kirksite. As important as mold makers are to injection molding, the United States has yet to develop an organized apprentice program that can be compared to those of Europe and the Pacific rim. More mold makers are needed because of industry growth, demand for faster build times, and more complex tools, yet there is a decreasing supply of talented mold makers within the United States. With plastic a growth industry ranked fourth in the U.S. manufacturing community, this situation may inhibit growth and our ability to be internationally competitive.

Processing. For all plastic processings the goal is to optimize the process in order to provide volumes of parts with optimum performance in the least amount of time. This requires molding within the constraints of the plastic, tool, machine, and part. To accomplish this goal, molding must be scientific from the plastic's point of view and focus on four key processing variables: plastic flow rate or fill time, plastic pressure, plastic temperature, and plastic cooling rate and time.

These are plastic conditions, but the first consideration is that the injection molding machine does what is required and expected. Reliability and repeatability are one set of issues, while proper control of injection rate, molten plastic uniformity, and other variables are another. Because of the number of machine makers and variations in design and construction it is crucial to evaluate and monitor actual machine performance. Hydraulic vs toggle clamping, electric vs hydraulic drives, and different hydraulic architectures are some of the variations possible. Process or machine monitoring, while not commonly used in the industry, does provide scientific data to objectively evaluate machine performance (18,19). Hydraulic pressures, stroke position, temperatures, cavity, and nozzle plastic pressures are common variables monitored. Figure 17 shows a typical plot of hydraulic and cavity pressure curves vs time for a two-stage process. First stage fills the cavity to 99% full and the second stage finishes filling and packs the cavity to the required pressure and then holds the plastic in the cavity until the gate cools and freezes. After the second stage the screw rotates to plasticize or melt the plastic and charge the front of the screw with the next shot.

Plastic Flow Rate. Plastic viscosity changes with shear or injection rate. Thus, injection rate (or the time to fill a cavity 99% full) determines a resin's viscosity while filling the cavity. Normally viscosity vs shear rate data is gathered from a capillary rheometer and plotted on log scales to provide a straight line. Figure 18 is a viscosity vs shear rate curve for a typical plastic developed by using an injection-molding machine as a rheometer (20,21). This involves using the Hagan–Poiseuille equation to derive the relationship that viscosity is proportional to the pressure drop and time (fill time) as the plastic flows from the nozzle to the end of fill making a 95–99% full shot (short shot).

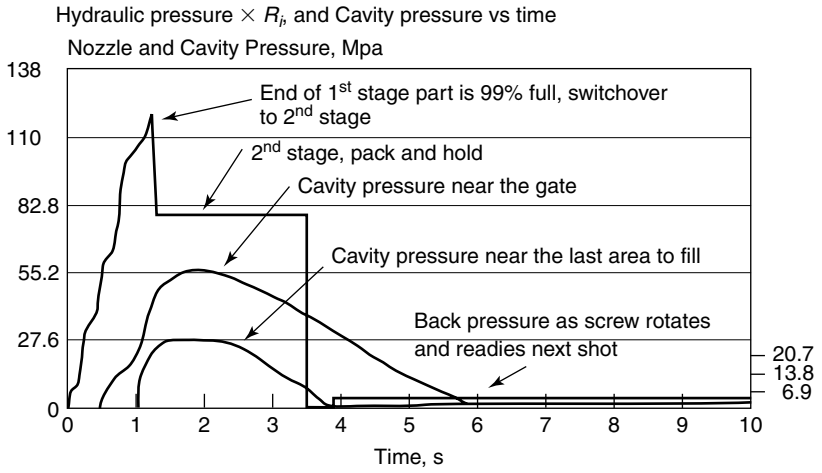

Fig. 17. Nozzle and cavity pressures vs time, good shot. Illustration by Rick J. Bujanowski & John W. Bozzelli. To convert MPa to psi, multiply by 145.

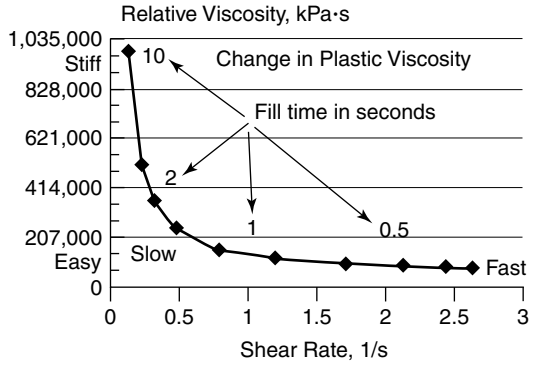

Fig. 18. Typical plastic flow. The change in plastic viscosity is at constant temperature. Shear rate correlates to flow rate or fill time. To convert kPa·s to psi·s, multiply by 0.145. To convert kPa·s to P, multiply by 10,000.

These data are then plotted on linear scales to dramatize (for the molder) the viscosity change in plastics relative to shear rate. For injection-molding processors (people who run the injection-molding machine) shear rate correlates to injection speed or fill time. The viscosity of plastics is high at slow injection rates and low at fast injection rates. The viscosity dependence on shear rate for plastics mandates that the molding machine accurately controls injection rate or "fill time" for process control. Injection speed or fill time must be controlled and constant to within ±0.04 s shot-to-shot and run-to-run. If fill time varies, viscosity will vary; if viscosity varies parts will vary. The flow-front shear rate is highly transient during filling, either accelerating or decelerating as it flows into a complex 3-D cavity during this fill time. Constant fill time is one way to keep these transient velocities consistent shot to shot. Machines must be set up and run to maintain a constant injection rate or fill time. Machines often have the ability to store

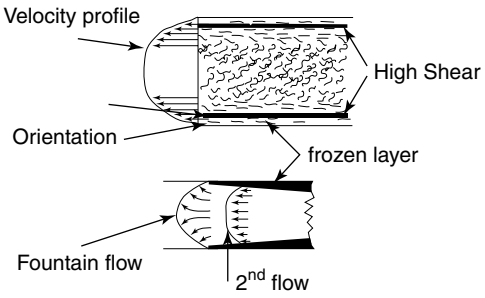

Fig. 19. Fountain flow.

process set points such as injection speed or velocity in millimeters per second. However, because of calibration errors and normal wear on a press, duplicating a millimeters per second (mm/s) set point called up from computer memory is no guarantee that fill time will be repeated. Unfortunately, the industry trend is to duplicate machine set points, not the actual velocities. It is best to monitor and control fill time.

Polymer flow through the nozzle, sprue, runner, gate, and part is best described with the concept of fountain flow. This describes the movement of the long-chain molecules. Figure 19 depicts this fountain flow concept where the long chains freeze at the side walls (there is zero velocity at the side walls of the flow path), orientate, and provide a velocity gradient and a high shear region just inside the frozen outer layer.

This explains why in-mold decorating can be done with delicate fabrics or paper labels without tearing the decoration while plastic flows over it to fill the cavity. Powdered-metal and metal molding do not exhibit this type of flow behavior.

Historically, most discussions on polymer flow focus only on viscosity. However, with many of the newer resins that are highly impact modified or have high elasticity, viscosity tells only part of the story for flow behavior. Two plastics can have identical viscosity characteristics and yet mold differently. Elastic response and the polymer's ability to transmit pressure become increasingly important as part designs increase in complexity. Both viscous and elastic response are required to properly characterize flow through complex cavities (22).

Controlling fill time is so important for plastic molding that a specific molding strategy has evolved. This strategy is based on separating fill (first stage or boost) from pack and hold (second stage). During fill, abundant hydraulic pressure (power) must be available to the hydraulic cylinder so that the flow-control valve on the injection-molding machine controls flow. First-stage hydraulic pressure set-point or limit must not control injection speed. There must be a pressure differential, ΔP, across the flow control valve so that the screw maintains injection velocity during fill. This concept of filling on first stage under velocity control is analogous to cruise-control on a car. If the plastic has to go through a gate or thin section, there has to be plenty of energy (hydraulic pressure) available to do it, just like a car going up a hill on cruise control. As with cruise control, if you run out of power (hydraulic pressure in the case of molding) you slow down. If you slow down, as the curve in Figure 18 shows, you move to the left and the plastic's viscosity gets stiffer. If the hydraulic injection cylinder does not have abundant hydraulic

pressure and the material gets stiffer due to a temperature change or different lot, you have a compounding effect. The injection speed slows, which in turn drives the viscosity stiffer and again the injection speed slows. This actually can end up as an unfilled part or short shot. Many molders run with little or no pressure differential across the flow-control device, preventing state-of-the-art closed loop machines from correctly controlling the first stage or filling the part. This is called "pressure-limited molding." Processing with an appropriate ΔP, not too high to flash the mold, allows the machine to attenuate viscosity changes on first stage. If the machine is set up correctly, it will adapt on any given shot to compensate for viscosity changes during filling the part. This removes the need for processors to tweak first-stage settings during production. Also, there is no lost production while waiting for someone to realize the machine is making unacceptable parts because of a change in viscosity such as a lot or temperature change.

Predicting the flow through the runner system (hot or cold), the gate and part is known as mold-filling simulation or mold-flow analysis as referenced in the tooling discussion. All deal with the viscosity vs shear rate relationship and continue to evolve. For example, why inside cavities on a multicavity (over four) mold fill differently than outside cavities has recently been explained ((23)). That is, some cavities fill first and others fill later during injection or the first stage. This happens even though the flow distance and pressure drop to each cavity is identical. This is known as unbalanced filling, which can make nonidentical parts even though the mold cavities are identical. It also sets up these cavities for nonuniform packing during the second stage. Once filling the mold is accomplished, the cavity must be packed with molten plastic to a pressure that provides appropriate dimensions and surface finish.

Plastic Pressure. The pressure gradient across a part establishes most of the part's attributes. The plastic pressure during pack and hold (second stage) influences dimensions, warp, gate area strength, gate vestige, and some visual characteristics such as sink marks and gloss. There is a pressure drop along the flow path from the plastic within the nozzle to the part's last area to fill. This pressure drop provides a measure of the difficulty of molding. The larger the pressure drop, the larger the amplification of the process variables. Determining this pressure drop is not straightforward, as different machines develop different plastic pressures at the same hydraulic pressures. By knowing a machine's intensification ratio (hydraulic ram area vs the area of the nonreturn valve acting like a piston pushing the plastic) we can calculate the plastic pressure in the nozzle. Often this plastic pressure is noted as injection pressure or specific pressure on a machine's specification sheet. Figure 20 depicts the hydraulic advantage or intensification ratio of hydraulic pressure intensified to plastic pressure in the nozzle.

During the early stages of the industry the machine producers made nearly all machines with a 10:1 intensification ratio with maximum injection pressures ~140 MPa (20,000 psi). If the maximum hydraulic pressure allowed to the hydraulic injection cylinder was 14 MPa (2000 psi), with an intensification ratio of 10:1, the maximum molten plastic pressure available in the nozzle was 140 MPa (20,000 psi). Today, machines are available with intensification ratios from 6:1 to 43:1 and corresponding plastic pressures up to ~415 MPa (60,000 psi). Figure 20 depicts a hydraulic cylinder and screw with a 16:1 intensification ratio.

This intensification ratio and resulting maximum available injection pressure were a factor in U.S. machine producers losing a significant portion of the

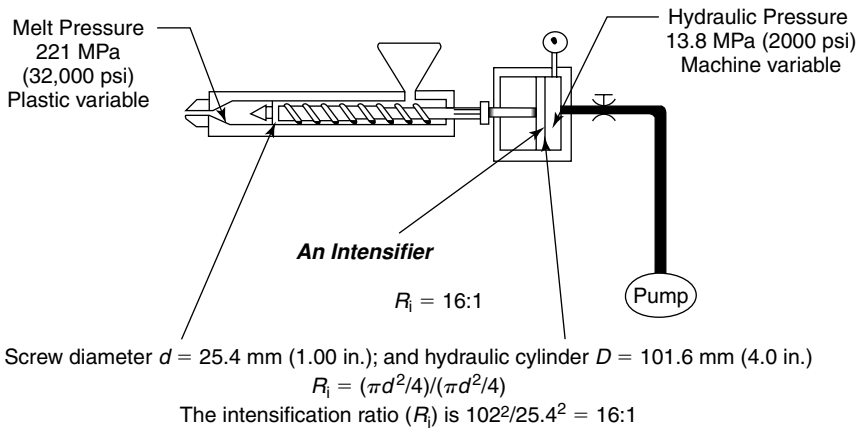

Fig. 20. Hydraulic vs plastic pressure. Illustration by John W. Bozzelli & Rick J. Bujanowski.

market to foreign competitors. The United States was slow to respond to the need for higher injection pressures required for long flow paths and complex thin-wall parts. It is suggested that machines purchased have at least 207 MPa (30,000 psi) of injection pressure, higher if the intention is for thin-wall molding. This will provide machines with greater flexibility in precision molding at no extra cost. They will also have better injection velocity control.

Over 90% of the hydraulic machine producers currently *do not* report plastic pressure on the controller or gauges. Hydraulic pressure is the standard. Production scheduling often forces a mold to be run in several different presses, each with a potentially different intensification ratio. Processors need to control this plastic pressure variable for consistent parts. Many molders reproduce hydraulic pressures (a machine variable) and not the critically important molten plastic pressures (the key plastic variable). With the advent of all electric machines this issue may resolve itself. Electric injection-molding machines use plastic pressure values for set points and reported pressures on their controllers. Injection pressure is sensed through a transducer mounted on the thrust bearing pushing on the screw, and it must read in plastic or injection pressure.

Knowing and controlling both injection and cavity pressures during filling (first stage) and packing (second stage) provides for excellent process control and part consistency. In the first stage (filling) the goal is to make a 99% full part before switching or transferring to the second stage (pack and hold). The part is slightly short or unfilled if the process was stopped at the end of the first stage. Since the part is short, the pressure near the last area to fill or the end of the flow front is zero. The pressure at the beginning of flow inside the nozzle can be calculated from the hydraulic pressure at the end of the first stage and using the intensification ratio. Thus, the plastic-pressure drop can be calculated for any short shot. By a series of short shots the pressure loss during the first stage (or filling the part) can be detailed without the use of cavity transducers. This data can be compared to mold-filling simulation calculations to check accuracy. A typical short shot study might show pressure losses as follows.

Nozzle	20.6 MPa	3,000 psi
Hot runner and gate	38.0 MPa	5,500 psi
Filling the part	82.7 MPa	12,000 psi
Total	*141.3* MPa	*20,500* psi

This information allows the processor to find high pressure-loss areas, which can be modified to provide easier flow and therefore a more robust molding process that makes acceptable parts. Lower pressure drop leads to better process control and consistency.

Switching from the first stage or velocity (V) control to the second stage or pressure (P) control is known as first to second stage transfer, or VP transfer. This switchover occurs as the screw moves forward and reaches a set point or position that provides the right amount of material to fill the mold 95–99.9% full. Other possible switchover conditions can be based on time, hydraulic pressure, or cavity pressure. Switchover by cavity pressure is more repeatable than by position, which is more repeatable than time. Switchover by hydraulic pressure is not recommended, as it limits the machine's ability to control velocity. To properly control the development of cavity pressure in the mold requires sharp machine response from the first to the second stage and accurate pressure control (see Figure 17, nozzle pressure curve).

The purpose of the second stage is to finish filling the mold and build cavity pressure to sufficient levels to replicate the shape and finish of the mold cavity. This is a different pressure loss than seen in filling or the first stage. Too much packing pressure will result in parts that are overpacked or flashed, causing wasted plastic and dimensional variances. Too little pressure or lack of control will produce nonfilled parts (shorts), dimensional variances, and unacceptable parts. Cavity pressure measurements (transducers are required) provide a methodology to verify part consistency. While cavity pressure measurement capability has been available for ~25 years, it is rarely used in the molding industry. Costs, incorrect placement, lack of large data gathering and storage capability, lack of training, delicate transducers (pressure sensors), and difficulty in interfacing with the molding machine have all been negative factors. Focus had only been on peak cavity pressures. More complete data can be found with cavity pressure curve integrals or area under the cavity pressure curves. For example, gate seal or plastic backflow out of the cavity is not seen if only peak pressures are monitored. Process monitoring instrumentation and appropriately located transducers can be used to inspect parts for 100% acceptance or rejection for dimensional tolerances. Cavity pressure measurements will not inspect for cosmetic or aesthetic criteria, which can be done via computer vision systems. Newer easier-to-use sensors that measure both cavity pressure and temperature are under development based on ultrasonics (24,25).

Before the amount of pressure to pack the part to the specified tolerances can be found, second stage (pack and hold) time must be determined. Second stage pressure is a timed event and must be on either (a) long enough to make sure the gate is frozen so plastic does not backflow out of the part or (b) for just long enough to pack the part out but not overpack the gate. Backflow of plastic out of the part into the runner can occur if second stage pressure timer ends before

the gate freezes. This allows the higher pressure that has been developed in the cavity to push plastic back out the gate so that the gate area of the part does not have molecules too closely packed or overpacked. Once the mold is filled, plastic cools and shrinkage requires more plastic to compensate. The amount of plastic that can be packed into the cavity during the second stage time depends on how long it takes for the gate to seal or freeze off. Gate freeze or gate seal time can be determined with a cavity pressure sensor near the gate or by plotting part weight vs increasing second stage (pack and hold) time. Cavity pressure curves from measurements near the gate will show changes in slope on the cooling portion (decreasing pressure vs time) of the curve between gate seal and gate unseal. However, cavity pressure data is rarely available. Part weight experiments are more common and require weighing parts, excluding the runners, as the processor changes the amount of second stage time. Part weight vs second stage time are recorded and graphed. The resulting graph shows stable part weights when the gate is sealed and a drop in weight at second stage times where the gate is not frozen. Part weight will vary as second stage time is changed until gate freeze occurs. Cycle time must be kept constant during this experiment to keep the energy load on the mold consistent.

Once gate seal time is established, the processor can optimize the amount of second stage pressure. It is this pack and hold pressure that establishes the parts dimensions and density. If running with second stage time long enough achieves gate seal, raising second stage pressure will increase part weight and size. Lower pressures produce lighter and smaller parts. A well-made mold that correctly accommodates for shrinkage (difficult to do) and the correct packing pressure will provide a part centered on the dimensional specifications. This provides an optimized process to meet dimensional criteria. The gate area will normally be packed to a higher pressure than the last area to fill. There is a pressure gradient from the gate area to the last area to fill. Within the part there is some pressure loss which can vary considerably on a shot-to-shot basis. The pressure gradient must be duplicated for consistent parts. This pressure gradient can be minimized if the processor runs with second stage times shorter than those needed for gate seal. Plastic can be allowed to backflow out of the cavity to reduce pressure near the gate after filling. These cavity pressures can be measured with cavity pressure transducers (see Fig. 17, the cavity pressure curves).

Correctly adjusting screw rotation speed, backpressure, clamp opening, ejection, and clamp closing will optimize the rest of the cycle. During screw rotation, there is pressure held against the hydraulic cylinder in the injection unit. This resistance pressure is called backpressure and must be overcome by the metering section of the screw acting like a pump pushing plastic in front of it, preparing for the next shot. Something like filling a syringe for a shot. With a properly designed screw, minimum screw rotation speeds to keep the cycle constant, and backpressures ~7.0 MPa (1000 psi) plastic pressure, uniform molten plastic consistency can be achieved. Clamp movement should be smooth and set appropriately to protect damaging the expensive mold. Ejection should not distort the part with too much speed or pressure.

The clamp keeps the mold halves together as cavity pressure develops during filling and second stage packing. Clamp force is generated by the stationary and rear platen stretching the four tiebars after the moving platen pushes the mold closed. It is important that the tool takes up most of platen area between the

tiebars and that the clamping force is uniform. Uniform clamp force around the parting line prevents excessive tool and clamp wear. Clamping a mold correctly requires a level machine, parallel platens, and uniform stretch of each of the four tiebars. Occasionally, high injection pressures will overcome the clamping force, separate the mold halves, then produce flashed parts. These must be trimmed or discarded. Clamping forces required are usually estimated and rarely scientifically calculated or measured. Industry guidelines vary from 20.7 to 68.9 MPa (1.5 to ~5 tons/in.^{2}) of the projected area of the part and runner. Thin-wall applications can require as much as 110 MPa (8 tons/in.^{2}).

Different types of molding machine clamps (toggles, hydraulic, and hydromechanical) have different advantages. Toggles are fast and energy efficient, yet it is difficult to set clamp tonnage accurately. Better toggle machines use strain gages to measure stretch of the tiebars which relates clamp tonnage. With toggles, clamp force changes as mold temperature changes due to the thermal expansion of the mold and machine components. Hydraulic clamps are easy to set, less energy efficient but are sometimes slower due to the large volume of oil necessary to fill the hydraulic cylinder. Hydraulic clamps automatically compensate for thermal mold expansion. Molding machines are ranked by clamp tonnage within the molding industry. Machines range from 69 to 1.4×10^5 MPa (5–10,000 ton/in.^{2}).

Plastic Temperature. Correct temperature and uniformity are crucial for a consistent process. Monitoring of plastic temperature is difficult and rarely utilized in the industry. Control of temperature is done via thermocouples partially embedded into the barrel wall, usually three to four along the length of the barrel. The actual molten plastic is not monitored for temperature and >90% of the temperature values provided as data are barrel wall temperatures that can be off by ±25°C (45°F). Temperature control is done via proportional-integral-derivative (PID) controllers or PID algorithms on computer controlled presses. Calibration of thermocouples is seldom done. PID temperature control of the nozzle tips is also important, yet ~40% of the industry uses variacs.

Heat necessary to melt the plastic granules comes from two sources. The heater bands start the melting process by getting the plastic to stick to the barrel wall. Between 10 and 40% of the heat necessary to melt the plastic comes from the heater bands. Most of the heat comes from the frictional or shear heat developed as the flights of the screw rotate within close proximity of the barrel wall. The flights shave plastic from the barrel wall into a spiral pool between the flights. Between 60 and 90% of the energy necessary to melt the plastic comes from screw rotation or shear at the barrel wall—flight interface. Temperature override can occur, and the open space between the heater bands is necessary for barrel cooling. Some machines have cooling fans placed between the heater bands to aid control.

Screw design and construction are important aspects to any plastic processing, yet design gets little attention in the injection-molding industry. Figure 21 shows a general–purpose screw which is what is specified or accepted for ~85% of machines delivered. The screw is divided into three zones: feed, normally 50% of the flights; transition, 25%; and metering, 25%.

The feed zone conveys plastic forward to the transition zone and has a constant root diameter. The root diameter tapers through the transition zone, which compresses the granules forcing air back toward and out of the feed throat and hopper. The main purpose of the transition zone is to compress the plastic and provide the shear heating to drive the melting process. Ideally, by the end of the

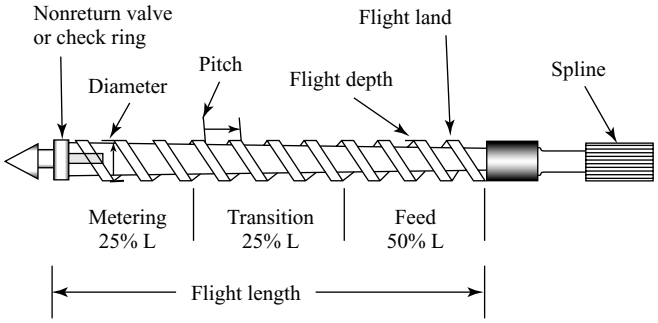

Fig. 21. Screw components. Illustration by Rick J. Bujanowski & John W. Bozzelli.

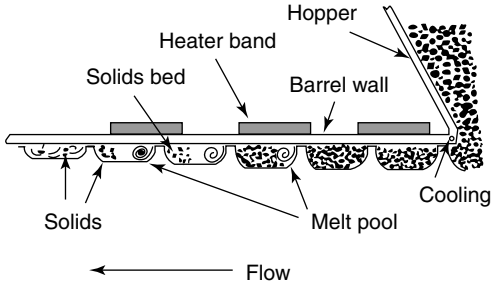

Fig. 22. Melt Model, solids pass. Illustration by John W. Bozzelli & Rick J. Bujanowski.

transition zone the plastic is melted, but usually the solid bed breaks up. Unmelted solids along with molten plastic get delivered to the metering section, which acts like a pump to push the plastic forward, charging plastic for the next shot (see Fig. 22).

As plastic is pushed forward (overcoming backpressure) the screw is forced to retract. There is now a cylinder of plastic in front of the screw tip and nonreturn valve. Upon injection, the screw moves forward seating the nonreturn valve or check ring, which acts like a plunger, piston, or ram to push the plastic out the nozzle tip into the sprue bushing of the mold.

Molten plastic uniformity is required for optimum processing performance; hence, screw specification is another strategic issue. The standard general-purpose screw is known to produce unmelted solids (26,27). These unmelted solids clog gates and produce inferior parts. Molten plastic uniformity can be achieved with state-of-art screws and metering sections as represented in Figure 23.

Screw and barrel specifications deal with type of material to be processed, shot volume, and plastic uniformity. Shot volume (the part, runner, and sprue)

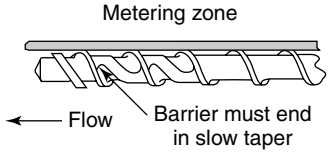

Fig. 23. Modified metering section. Illustration by Rick J. Bujanowski & John W. Bozzelli.

should be 25–65% of the barrel capacity. Barrel and screw hardness and corrosion resistance depend on the type of material to be processed. Glass fiber or other abrasive fillers require hard barrels to prevent excessive wear. Materials that may produce acid gases, HCl from PVC, or other volatiles that may chemically attack the barrel and screw call for more chemically resistant steels such as stainless or plating the screw with a chemically resistant metal such as nickel. Screw design specifications also involve compression ratio, how much is the plastic compressed within the flights of the screw from feed to metering zone, length-to-diameter ratio or L/D, and shape of the screw flights. The screw should be highly polished to allow plastic to slip on the screw and stick to the barrel, have sharp flights with a large trailing radius so as to prevent dead spots from causing degradation of the polymer.

Plastic Cooling Rate and Time. Cooling is over 90% of the molding cycle, so optimization is critical to provide the minimum cycle time and optimum profits. Analyzing the cycle in Figure 6 shows that cooling for the part actually occurs in each segment except for filling. Molding is a thermal process and so consistent steady-state conditions cycle to cycle are crucial. Within the cycle there are large swings in temperature, yet cycle-to-cycle consistency is paramount. This is the reason automatic cycles provide better quality and production over manual cycles. Automatic cycles allow the machine to cycle unattended. Manual cycle depend on an operator to take parts out of the mold, then re-cycling the process. Manual cycles do not run at a constant cycle time, allowing heat loads to vary on the mold and machine. Molds take several cycles to reach equilibrium because of the cooling process being a combination of radiation, air convection, and conduction cooling as coolant flows through the channels of the mold. Time to reach this steady-state mode can be minutes or hours depending on the part, tool size, and mold-cooling capacity. Often the machine's platens that hold the mold must come to temperature equilibrium with the environment before the cycles are in steady state. Thus, the machine's environment can and does influence the process. Air conditioning a molding plant is expensive but it aids in steady-state processing, leveling season heat and cooling loads on the mold.

Not all of the heat energy put into the resin must be removed by mold cooling. The part can be ejected warm as long as it is rigid enough to withstand the force of ejection and hold its shape during post-molding handling by humans, robots, conveyors, or as they accumulate in a box or bin. Part cooling will continue after ejection and must be kept consistent to maintain part uniformity and prevent warping. Whatever the cause, nonuniform cooling will add retained stress to a part. Nonuniform nominal wall thickness, improper packaging, even inconsistent part placement on a table after ejection can cause dimensional variations and warp. This is particularly important for semicrystalline, high shrink resins, which can take weeks to stabilize because of continued crystallization.

Mold cooling or temperature control is typically done with a thermolator that pumps water, water and ethylene glycol mixture, or oil through channels in the mold to heat or cool the plastic. Heat transfer (usually cooling) problems develop if corrosion or deposits accumulate in the channels (water lines) in the mold. Other issues are that water lines are not drilled uniformly around the part, coolant lines are not routed correctly, or coolant flow is not turbulent. Flow turbulence is defined by a Reynolds number of 3500 or greater and is difficult to achieve in some plants because of inadequate feed and return line size or restrictions in the tools cooling

channels. Molds often have different size cooling lines yet fed by the one multifrost manifold. Larger lines get more coolant flow at the expense of smaller lines, leading to nonuniform cooling. Chiller (refrigerated or chilled water) operation, cooling tower condition, water treatment, and filtration are important areas that demand constant monitoring to maintain optimum and consistent cooling. Certain cooling checks should be made on a routine basis. For instance, each cavity must receive the same coolant flow rate. Additionally, the pressure drop from inlet to outlet for each mold circuit should be ∼210 to 240 kPa (30–35 psi) pressure drop or greater. Temperature differential between inlet vs outlet should be below 2°C (4°F).

Handling of the parts after production must also be controlled for consistency. For high tolerance parts in semicrystalline resins (polyethylenes, nylons, acetal, and polypropylene), each part must be treated to the same post-mold conditions of handling, storage, etc. Cooling influences post-molding shrinkage. Parts in the center of a box do not cool like those on the sides, and the different cooling rate may be the cause of rejects. The concept is to treat every part the same. All parts must be ejected, cooled, and packaged identically, or differences in dimensions and warp develop even though parts were good out of the press.

INORGANIC POLYMERS

Introduction

Inorganic polymer science represents an area that has been held back by the synthetic problem of constructing macromolecular chains. However, advances in the last two decades or so of the twentieth century have led to the preparation of a variety of new polymers that contain main group elements, transition-metals, and even lanthanides. It is plausible that some of these new materials, with properties that are difficult or impossible to achieve with existing organic materials, may fulfill the requirements of specialized markets; such developments remain an interesting future challenge. Polysiloxanes (silicones) represent the most well-developed class of inorganic polymers and these materials are discussed in a separate article (see SILICONES). In addition, although surveyed briefly in this article, more detailed information on POLYPHOSPHAZENES and POLYSILANES and POLYCARBOSILANES can be found elsewhere in the Encyclopedia. Here we focus on other main classes of inorganic polymers.

Inorganic Polymers Based on Main Group Elements

Polyphosphazenes. Polyphosphazenes (**1**) have a polymeric backbone composed of alternating phosphorus and nitrogen atoms. The side groups, R, can be alkoxy, aryloxy, amino, alkyl, aryl, inorganic, or organometallic groups. This large range of accessible structural variations is accompanied by a wide range of polymer properties that are highly dependent upon the nature of the side groups (see Table 1).

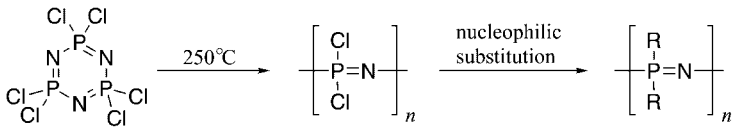
1

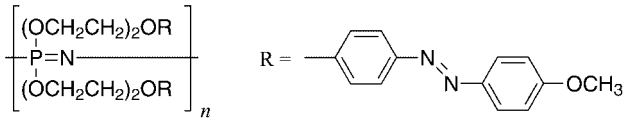
In addition, the phosphorus–nitrogen backbone inherently possesses a unique range of unusual properties. For example, it is extremely flexible which in turn can give rise to low glass-transition temperatures, particularly in the case of poly(alkoxyphosphazenes) such as the *n*-butoxy derivative ($T_g = -105^\circ$C) (1,4). Furthermore, the backbone is thermally and oxidatively stable, as well as optically transparent from 220 nm to the near infrared region, which makes it resistant to breakdown in many harsh environments, as evidenced by the flame-retardant properties of many polyphosphazenes.

Ring-Opening Polymerization (ROP). The first polyphosphazene synthesized, poly(dichlorophosphazene) (**2**), was prepared in cross-linked form by Stokes at the end of the nineteenth century by the thermal ROP of the cyclic trimer $[Cl_2PN]_3$ (**3**) (1). This material, referred to as "inorganic rubber," remained a chemical curiosity because of its intractability and hydrolytic instability until the mid-1960s when it was shown that if the ROP of pure $[Cl_2PN]_3$ is carried out carefully, uncross-linked poly(dichlorophosphazene) (**2**), which is soluble in organic solvents, is formed (5). Subsequent reaction of this highly reactive polymeric species with nucleophiles has been shown to yield a wide range of hydrolytically stable poly(organophosphazenes) (eq. 1) (1,6–8).

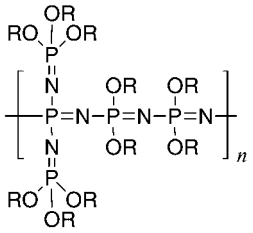


3 **2** **1** (1)

This macromolecular substitution route, used primarily with alkoxides, aryloxides, or primary amines, is largely responsible for the immense structural diversity of poly(organophosphazenes) and allows the tuning of certain properties and the introduction of others through the choice of nucleophile. Highlights concerning the use of the macromolecular substitution route with **2** and related materials involve the introduction of side groups, which lead to liquid crystallinity (see polymer **4**) (9), photochromism (10), photocross-linkability (11–13), and the preparation of novel polymers such as (**5**) with short-chain branching (14,15).



4

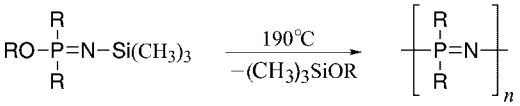


5

The thermal ROP route requires the synthesis and careful purification of the cyclic trimer $[Cl_2PN]_3$ and the use of elevated temperatures where control of molecular weight is very difficult and cross-linking can take place at high conversion, which can limit the yield.

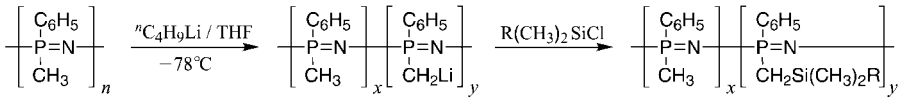
Condensation Polymerization. Although several polyphosphazenes have been commercialized, much work has focused on the development of cheaper and more convenient methods for making these materials. Also, the reaction of poly(dichlorophosphazene) with organometallic reagents such as Grignard or organolithium reagents generally leads to chain cleavage as well as substitution, and thus macromolecular substitution does not provide a satisfactory route to polymers with only alkyl and aryl side groups bound by direct P—C bonds. To these ends several promising condensation routes have been developed.

In the early 1980s, a condensation route to polyphosphazenes from phosphoranimines was discovered (eq. 2) (16).



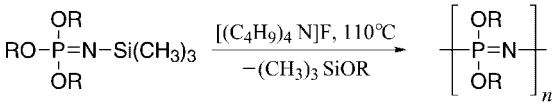
(2)

The polymerization is in fact a chain-growth reaction and allows access to high molecular weight polyphosphazenes such as poly(dimethylphosphazene) and poly(methylphenylphosphazene) (2). Methyl deprotonation/substitution of these polymers as well as electrophilic aromatic substitution of the phenyl substituents in poly(methylphenylphosphazene) have been developed as versatile strategies for the derivatization of both of these polymers (eq. 3) (3).

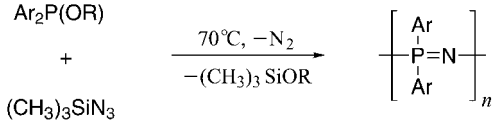


(3)

An alternative, direct route to fluoroalkoxy phosphazene polymers and aryl derivatives which also permits access to block copolymers has been developed (eqs. 4 and 5) (17,18).

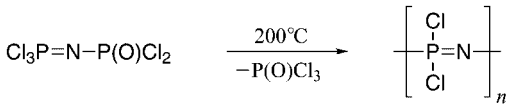


(4)



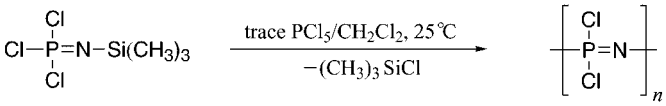
(5)

The development of condensation routes to poly(dichlorophosphazene) have also been reported. One promising route operates at 200°C (eq. 6) (19).



(6)

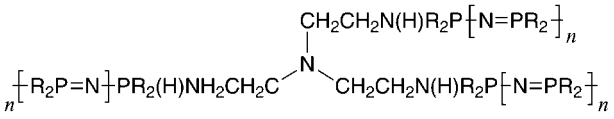
In 1995, details of a synthesis of poly(dichlorophosphazene) which operates at room temperature and allows for good molecular weight control were reported (eq. 7) (20). It involves the condensation of phosphoranimines in the presence of cationic initiators such as a PCl_5. The polymerization has been shown to proceed via a cationic chain-growth mechanism that shows "living" characteristics (21). Two equivalents of the initiator react with one equivalent of a chlorinated phosphoranimine to form a reactive ion pair (eg, $[Cl_3P{=}N{=}PCl_3]^+PCl_6^-$), which further reacts with monomer to propagate chain growth.



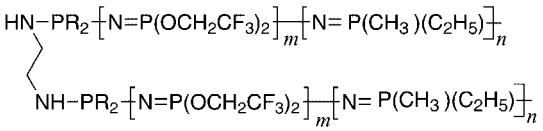
(7)

This synthetic method has been extended to the direct synthesis of poly(organophosphazenes) as well as the development of star and block copolymers. For example, triarmed star-branched polyphosphazenes (eg, **6**) can be synthesized through the initiation of trifunctional phosphoranimines (22). It has also been shown that the presence of "living" active sites at the termini of the polymer chains allows for addition of a second monomer and the formation of block copolymers (23), such as (**7**) which is formed through the initiation of a difunctional linear phosphoranimine and the subsequent introduction of two different monomers (24). These developments offer the prospect of improved routes

to phosphazene polymers, which may well facilitate more rapid and extensive commercialization.



6



7

Monomer Synthesis. Both the ROP and condensation routes to poly(dichlorophosphazene) require high purity monomers. For the traditional ROP process, ultrahigh purity $[NPCl_2]_3$ is required. The most common method for its preparation is through the reaction of PCl_5 with NH_4Cl in a high boiling halogenated solvent, such as chlorobenzene or tetrachloroethane, at 150°C. The yields can approach 70–80% under specialized conditions, but 50% is more typical (25).

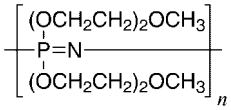
The phosphoranimine most commonly used in the aforementioned condensation route to poly(dichlorophosphazene) is $Cl_3P{=}NSi(CH_3)_3$. The synthesis of this compound has been described (21) and is based on a modification of an earlier procedure (26) involving the reaction of PCl_5 with $LiN(Si(CH_3)_3)_2$ at −78°C in hexane. However, the purification required by this method is a challenge and leads to an overall yield of <40%.

It has also been reported that the reaction of $N(Si(CH_3)_3)_3$ with PCl_5 can be manipulated to maximize yields of either the cyclic trimer (76%) or the pure phosphoranimine monomer (40%) through variations in reaction conditions (25). These reactions use milder conditions than previously reported methods, with higher yields. In addition, the major side product, $(CH_3)_3SiCl$, can be recycled to form one of the starting materials, $N(Si(CH_3)_3)_3$.

N-Silylphosphoranimines with alkyl and aryl substituents can be synthesized by reaction of commercial starting materials such as PCl_3, $((CH_3)_3Si)_2NH$, and Grignard reagents by way of a three-step process, with typical yields of 60–70%. These precursors are also accessible via a "one-pot" synthesis, which requires only isolation of the final product with yields of about 75% (3).

Uses. Some of the most useful polyphosphazene derivatives are fluoroalkoxy derivatives, and amorphous copolymers are very useful as flame-retardant, hydrocarbon-solvent, and oil-resistant elastomers and have found aerospace and automotive applications. Polymers such as the amorphous comb polymer poly[bis(methoxyethoxyethoxy)phosphazene] (**8**) are of considerable interest as components of polymeric electrolytes in battery technology (1).

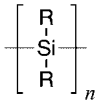
Polyphosphazenes are also of interest as biomedical materials and bioinert, bioactive, membrane-forming, and bioerodable materials (1).



8

Polysilanes

Properties. Since the first reports of soluble and processible polysilanes (**9**) in the late 1970s, these macromolecules have attracted widespread interest from both a fundamental and an applied perspective (1,27–29). The use of Wurtz coupling has allowed the preparation of a range of polymers with alkyl or aryl substituents at silicon that are high in molecular weight with $M_n > 10^5$. Since 1980, there has been a remarkable growth in interest concerning these polymers and they have been found to possess a variety of fascinating properties. The backbone of silicon atoms gives rise to unique electronic and optical properties.



9

One of the most remarkable features of the all-silicon backbone is that it leads to the delocalization of σ electrons, a phenomenon which is virtually unknown in carbon chemistry (30). This can be understood in terms of the nature of the molecular orbitals associated with the Si—Si σ bonds. These are more diffuse than those associated with C—C σ bonds as they are constructed from higher energy 3*s* and 3*p* atomic orbitals. This leads to significant interactions between the adjacent Si—Si σ bonds along a polysilane chain, a situation analogous to that for the π bonds in π-delocalized polymers such as polyacetylene. Thus, a band model is more appropriate than a localized model (1,28). As a consequence of the delocalization of σ electrons, the σ—$\sigma*$ transition, which occurs at 220 nm in $(CH_3)_3Si—Si(CH_3)_3$, moves to lower energy as the number of silicon atoms in the chain increases. In the high polymers, the σ—$\sigma*$ band-gap transitions occur in the near uv region at ca 300–400 nm (Table 2). The lowest absorption bands of polysilanes have also recently been assigned to excitonic rather than interband transitions (32). The electron delocalization also leads to appreciable electrical conductivity following doping. For example, conductivities of up to 0.5 S/cm have been reported for polysilastyrene (**10**), after doping with AsF_5 (1). In addition, many of the polymers are thermochromic as the conformations adopted by the polymer change with temperature, which alters the degree of σ-delocalization along the main chain. Because of their low energy σ—$\sigma*$ transitions, polysilanes

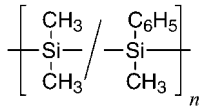
[a] In solution.
[b] Refs. 28 and 31.

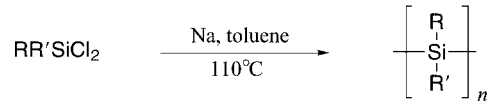
are photosensitive and have attracted considerable attention as photoresist materials in microlithography (1,27,28).



10

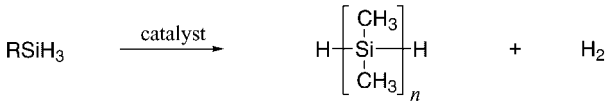
Synthesis. The first report of a soluble polysilane appeared in 1978 and the material was prepared by the treatment of a mixture of organodichlorosilanes with sodium metal (33). Instead of only the expected cyclic oligomers, a polymeric product, termed polysilastyrene (**10**), was formed. Poly(dimethylsilane) had been previously prepared as a highly crystalline insoluble material (1,27,28). The introduction of phenyl groups in the random copolymer reduces the crystallinity and allows the material to be soluble and processible.

The main method used to synthesize polysilanes involves the thermally-induced Wurtz coupling reaction of organodichlorosilanes with alkali metals (eq. 8). Although improvements in this process have been reported (eg, the use of ultrasound), the harsh conditions for this reaction tend to limit the side groups that can be successfully introduced to nonfunctionalized alkyl and aryl units and makes scale-up unattractive (1).



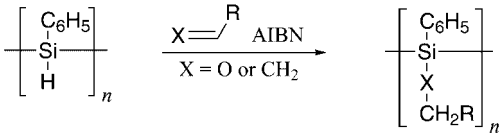
(8)

Because of these limitations, considerable effort has been focused on the development of new synthetic routes to polysilanes. Transition-metal-catalyzed dehydrogenative coupling, discovered in 1985 (eq. 9) (34), is potentially very attractive; however, the molecular weights of the polysilanes formed to date are generally quite low (M_n < 8,000). The catalysts used for these coupling reactions are usually titanocene or zirconocene derivatives (34,35).



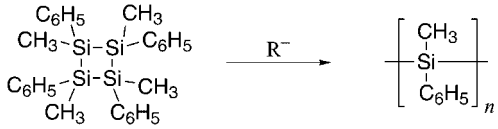
(9)

The catalytic dehydrogenation route yields novel polysilanes with Si—H functionalities, which are of interest as ceramic precursors (36). In addition, it has been shown that a variety of new side groups can be introduced using a derivatization approach (eq. 10) (37).



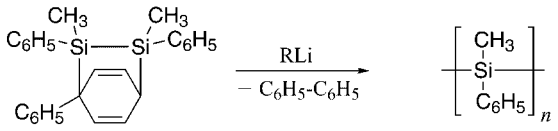
(10)

In 1991, a novel ROP route to polysilanes was reported (eq. (11)) (38). The key to this approach is to take readily accessible octaphenylcyclotetrasilane, which is too sterically crowded to undergo ROP, and to replace some of the phenyl groups by smaller methyl substituents (via a two-step process) to make the ring polymerizable.



(11)

Another route to polysilanes that involves the anionic polymerization of disilabicyclooctadienes, which function as sources of masked disilenes (eq. 12), has been described (39,40). Amphiphilic block copolymers formed by this anionic route, such as poly(1,1-dimethyl-2,2-dihexyldisilene)-*b*-(2-hydroxyethyl methacrylate), undergo self-assembly to form micelles (41).



(12)

Uses. The delocalization of σ electrons in polysilanes gives rise to unique electronic and optical properties. Also, several polysilanes have been found to function as useful thermal precursors to silicon carbide fibers and these materials have attracted attention with respect to microlithographic applications and as polymerization initiators (1,27,28). The use of these materials as hole transport layers in electroluminescent devices has also been explored (42). Indeed, the photoconductivity of poly(methylphenylsilane) doped with C_{60} has been studied and has been found to be comparable with the best materials available (43).

Polygermanes and Polystannanes

Properties. The remarkable properties of polysilanes has led to significant interest in the development of polymer chains based on the heavier Group 14 elements, germanium and tin.

Studies of polygermanes indicate that the σ delocalization is even more extensive than for polysilanes and that the σ—$\sigma*$ band-gap transition for the high polymers is significantly red-shifted by ca 20 nm in comparison to the silicon analogues (44,45) (Table 3). Other studies have shown that these materials possess semiconductive behavior upon oxidative doping (49) as well as significant nonlinear optical behavior (50) and thermochromicity (45).

High molecular weight polystannanes possess σ electrons that are extensively delocalized as illustrated by the band-gap transition, which occurs at 384–388 nm for poly(dialkylstannanes) (in THF) and at even higher wavelengths for some poly(diarylstannanes) (Table 3) (48,51). In addition, exposure of thin films of the polymers to the oxidant AsF_5 leads to significant electronic conductivities of ca 0.01–0.3 S/cm (52). Polystannanes are highly photosensitive and exhibit photobleaching behavior, and on uv-irradiation depolymerize to yield cyclic oligomers. The materials are thermally stable to 200–270°C in air and, at more elevated temperatures, function as interesting precursors to SnO_2 (52).

Synthesis. Polygermanes (**11**) were prepared in the mid-1980s by Wurtz coupling techniques similar to those used to prepare the silicon analogues (eq. 13) (1). A variety of alkyl and aryl derivatives can be prepared by this method but the harsh reaction conditions are not tolerant of many functional groups (53).

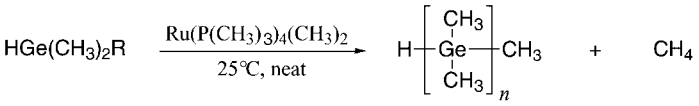
11 (13)

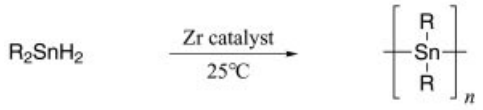
Dehydrocoupling has been investigated, but has proven relatively unsuccessful (54). Electrochemical reduction of halogermanes has proven somewhat successful and has provided a route to poly(germane–germane) and poly(germane–silane) copolymers (47,55). The ruthenium catalyst, $Ru(P(CH_3)_3)_4(CH_3)_2$, can be employed in the demethanative coupling of trimethylgermane, which gives relatively high molecular weight polygermanes under mild conditions (25°C) (eq. 14) (46,56).



R = CH_3, Ar (14)

Early attempts to generate polystannanes by Wurtz coupling of organodichlorostannanes have yielded only low molecular weight oligomers and reduction products. The first high molecular weight materials were made using

transition-metal-catalyzed dehydrogenative coupling of secondary stannanes R_2SnH_2 (eq. 15) (51). Yellow polystannanes (**12**) (R = *n*-butyl, *n*-hexyl, or *n*-octyl) of substantial molecular weight (up to M_w = ca 96,000, M_n = ca 22,000) were prepared using various zirconium catalysts. This method is applicable to the preparation of poly(diarylstannanes) possessing solubilizing substituents (48,57). Interestingly, a change in catalyst from zirconocene-based systems to $HRh(CO)(P(C_6H_5)_3)_3$ has been shown to lead to highly branched polystannane structures (58).

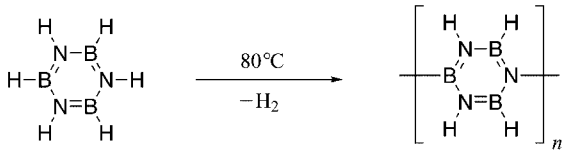


12 (15)

Uses. Both polygermanes and polystannanes may find applications because of their unique optical, electronic, and chemical properties. Some of these potential uses include photoresist layers (44,59,60), third-order nonlinear optical materials (50), charge transport polymers (61,62), photoconductors, microlithographic materials (63), and photoinitiators (59).

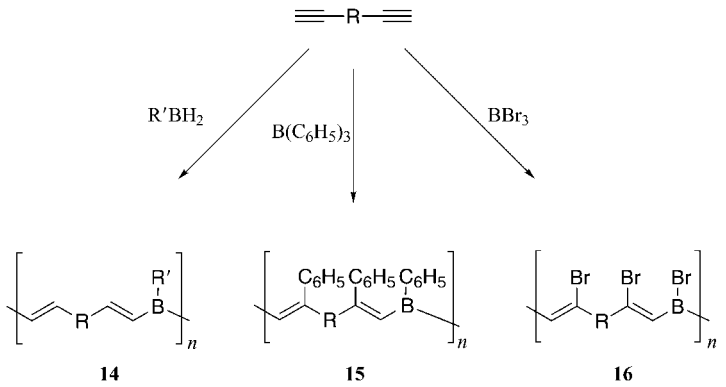
Boron-Containing Polymers

Boron-containing polymers are of considerable intrinsic interest, as possible reactive intermediates and as precursors to boron-based ceramics (64–69). The synthesis of polyborazines (**13**) (M_w up to ca 7600, M_n up to ca 3400) via thermally induced dehydropolymerization of borazines (eq. 16) has been reported (68). The polymers were isolated as white solids and characterization suggested the presence of a significantly branched structure. Pyrolysis at 1200°C yielded white turbostratic boron nitride in 85–93% yield.



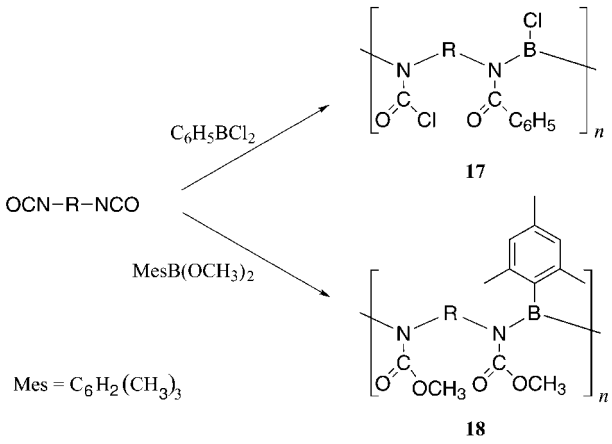
13 (16)

A wide range of novel polymers with boron in the backbone have been prepared by means of boration polymerizations (65,70–82). Diynes can be polymerized by hydroboration (70,71), phenylboration (65), and haloboration (72) to yield polymers (**14**),(**15**), and (**16**) (eq. 17). When an appropriate aromatic or heteroaromatic diyne is used, the resulting polymers have been shown to have extended π-conjugation through the vacant *p*-orbital of the boron atom (73,74). In fact, several have been shown to exhibit blue fluorescence emission.



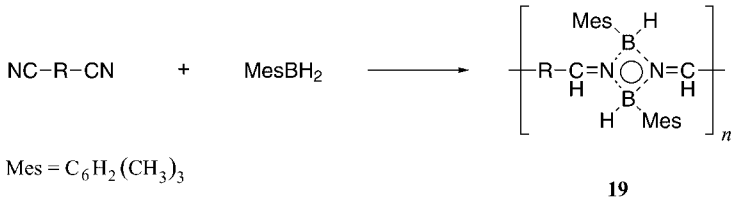
(17)

Diisocyanates have been shown to undergo haloboration–phenylboration polymerization to give halosubstituted polymers (**17**) (75). They also undergo alkoxyboration in the presence of mesityldimethoxyborane to produce poly(boronic carbamates) (**18**) (eq. 18) (76).



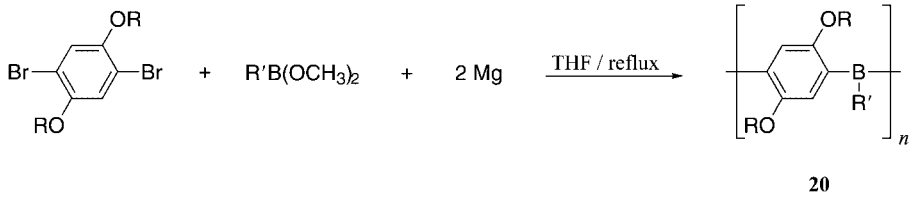
(18)

Dicyano compounds undergo hydroboration to produce poly(cyclodiborazanes) (**19**), which have proven relatively stable towards air and thermal oxidation (eq. 19) (77–79). Some examples have been prepared where the dicyano compound allows for incorporation of a charge transferred structure (80). These exhibit extended π-conjugation through the cycloborazane unit.



(19)

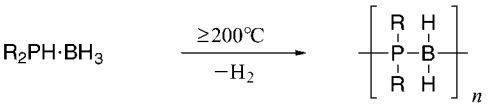
Finally, the polycondensation reaction between bifunctional Grignard reagents and aryldimethoxyboranes, carried out under a nitrogen atmosphere, in THF, gives rise to poly(phenylene-boranes) (**20**) (eq. 20) (83). The conjugated polymers may have potential applications in electronic devices such as LEDs.



20

(20)

Transition-metal-catalyzed dehydrocoupling of phosphine–borane adducts (**21**) has been shown to give rise to high molecular weight polyphosphinoboranes (**22**) (84). In the 1950s and 1960s, several claims of the synthesis of polyphosphinoboranes (**22**) were made (eq. 21). The main route studied was the thermal dehydrocoupling of $R_2PH{\cdot}BH_3$ adducts at 200°C and above; however, structural characterization of the polymers was minimal and reported yields and molecular weights were very low (85,86).

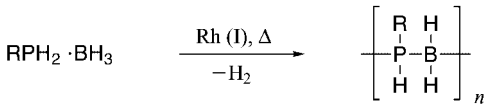


R = alkyl

21 **22**

(21)

The dehydrocoupling of various adducts (**21**) has now been studied in the presence of various catalysts, such as $RhCl_3$, $[Rh(\mu\text{—}Cl)(1,5\text{-cod})]_2$, and $[Rh(1,5\text{-cod})_2]^+$ (87). The bulky adduct (**21**) ($R_1 = R_2 = C_6H_5$) was shown to undergo dehydrogenative coupling to form only a linear dimer or a mixture of the cyclic trimer and tetramer, depending upon the temperature used. However, primary phosphine–borane adducts, such as $C_6H_5PH_2{\cdot}BH_3$ and $iC_4H_9PH_2{\cdot}BH_3$, were found to undergo catalytic dehydrogenative polymerization under similar conditions to yield soluble polyphosphinoboranes (**22**) (eq. 22). When the polymerization is carried out in solution, the resulting polymers are low in molecular weight (eg, $M_w \approx 5600$ for $R = C_6H_5$) whereas the neat polymerization affords high molecular weight phosphorus–boron polymers (eg, $M_w \approx 31{,}000$ for (**22**) $R = C_6H_5$). These polymers are air and moisture stable in the solid state, and detailed studies of the physical properties have yet to be conducted but the novel phosphorus–boron backbone allows for interesting possibilities such as low temperature flexibility, flame retardancy, and ceramic formation.

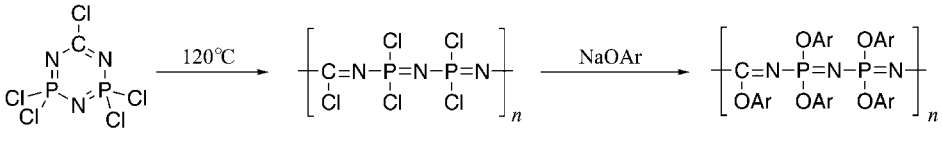


$R = C_6H_5, iC_4H_9$

22 (22)

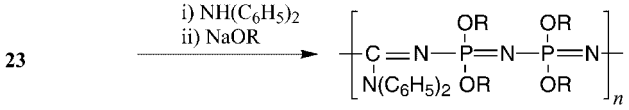
Polycarbophosphazenes

Polycarbophosphazenes possess a backbone of phosphorus, nitrogen, and carbon atoms and can be regarded as derivatives of "classical polyphosphazenes" (**1**) in which every third phosphorus atom is replaced by carbon. The first examples of these materials were discovered in 1989 (88). Thermal ROP of a cyclic carbophosphazene was used to prepare the chlorinated polymeric species (**23**), which undergoes halogen replacement reactions with nucleophiles such as aryloxides and aniline to yield hydrolytically stable poly(aryloxycarbophosphazenes) (**24**) (M_w = ca 10^5, $M_n = 10^4$) (eq. 23) (88–91). The polymer backbone in these materials was found to be less flexible than in classical polyphosphazenes. For example, the halogenated polymer (**23**) possesses a T_g of −21°C compared to a value of −66°C for poly(dichlorophosphazene) (**2**).



23 **24** (23)

The reaction of (**23**) with alkylamines has also been studied (91). The resulting poly(alkylaminocarbophosphazenes) are sensitive to hydrolysis. However, arylamino derivatives are moisture stable and, in addition, a novel, regioselectively substituted polymer (**25**) was successfully prepared via the sequential reaction with $NH(C_6H_5)_2$ and trifluoroethoxide anions (eq. 24).



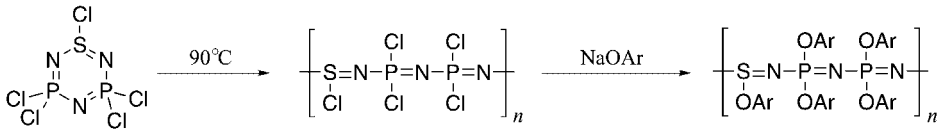
$OR = OCH_2CF_3$

25 (24)

Sulfur–Nitrogen–Phosphorus Polymers

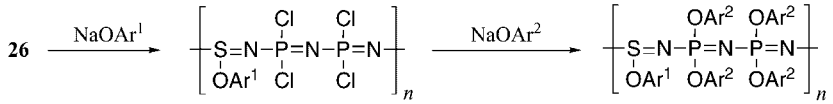
Sulfur–nitrogen–phosphorus polymers possess backbones that can be regarded as compositional hybrids of those present in sulfur–nitrogen polymers, such as the solid-state polymer poly(sulfur nitride) $[SN]_x$ or polyoxothiazenes $[RS(O)=N]_n$ and classical polyphosphazenes, $[R_2P=N]_n$ (**1**) (92). Poly(sulfur nitride), $[SN]_x$, possesses remarkable properties such as electrical conductivity at room temperature and superconductivity below 0.3 K (93). $[SN]_x$ is insoluble and has a polymeric structure in the solid state with interchain S···S interactions. As these interactions are crucial to the properties of the material, $[SN]_x$ is best regarded as a solid-state polymer rather than a polymeric material with discrete macromolecular chains of the type discussed in this article.

The first well-characterized examples of sulfur–nitrogen–phosphorus materials, polythiophosphazenes, were reported in 1990 (94). These polymers were prepared via the thermal ROP of a cyclothiophosphazene (eq. 25). This yielded the hydrolytically sensitive polythiophosphazene (**26**) with a backbone of three-coordinate sulfur(IV), nitrogen, and phosphorus atoms. Although reaction of (**26**) with nucleophiles such as aryloxides yielded materials (**27**) with improved hydrolytic stability, degradation was still rapid except where very bulky substituents such as *o*-phenylphenoxy were present.



26 **27** (25)

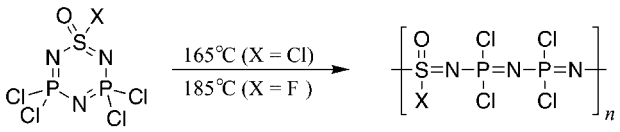
Although the backbone of polythiophosphazenes appears to be quite fragile, a particularly interesting feature of the substitution reactions of (**26**) is that the S—Cl bond is much more reactive than the P—Cl bonds. Regioselective substitution at the sulfur center is possible and yields macromolecules (**29**) with different aryloxy substituents at sulfur and phosphorus (eq. 26) (94,95).



28 **29** (26)

In 1991, another class of sulfur–nitrogen–phosphorus polymers, polythionylphosphazenes, were reported (96,97). These materials, which possess four-coordinate sulfur(VI) atoms in the backbone, possess improved stability and were prepared by a thermal ROP of cyclic thionylphosphazenes (**30**), with either chlorine or fluorine at the sulfur(VI) center, at 165–180°C (eq. 27) (98). An

ambient temperature synthesis involving initiation by Lewis Acids such as $GaCl_3$ has been subsequently developed (99).



30 X = Cl or F **31** (27)

The halogenated polythionylphosphazenes (**31**) that are formed in these ROP reactions (together with small quantities of macrocyclic byproducts) are quite sensitive to hydrolysis but a variety of moisture-stable derivatives have been prepared by reaction of this species with aryloxides or amines (100–102). Mixed substituent aryloxy–alkoxy polymers have also been prepared (92). Interestingly, with aryloxides, regioselective substitution at phosphorus is observed and in the resulting polymers (**32**) the sulfur(VI)-halogen bond remains intact. Remarkably, this regioselectivity is the exact reverse of that detected for the polythiophosphazenes described earlier where the sulfur(IV)-halogen bond is more reactive. In contrast to the reactions with aryloxides, reaction with primary or secondary amine nucleophiles leads to substitution at both the phosphorus and the sulfur(VI) centers to give poly(aminothionylphosphazenes) (**33**) (102,103).

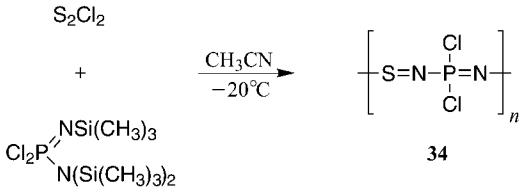
X = Cl or F R = alkyl or aryl

32 **33**

Ab initio calculations on isotactic polythionylphosphazene (**31**) (X = Cl or F) indicate a localized electronic structure for the polymer backbone and predict that a *cis–trans* helical conformation is the most energetically favorable for isolated macromolecules (104). This is in contrast to the analogous "classical" polyphosphazene (**1**) where a *trans*-planar conformation is preferred. Studies of the properties of the polythionylphosphazenes also reveal significant differences in thermal transition behavior and polymer morphology compared to classical polyphosphazenes. For example, the polymer $[NSOF\{NP(OC_6H_5)_2\}_2]_n$ is an amorphous elastomer ($T_g = -15^\circ C$), whereas the analogous classical polyphosphazene $[NP(OC_6H_5)_2]_n$ is a microcrystalline thermoplastic ($T_m = 390^\circ C$, $T_g = -6^\circ C$). The T_gs of the fluorinated polythionylphosphazenes are lower than those of the analogues with chlorine at sulfur. For example, for (**31**) (X = F) $T_g = -56^\circ C$ whereas for (**31**) (X = Cl) $T_g = -46^\circ C$ (101). Poly(aminothionylphosphazenes) possess high gas permeability and have found utility as matrices for phosphorescent dyes for oxygen sensing applications (105).

Also noteworthy is an interesting condensation route reported which leads to polymers with backbones of alternating S(O)—N and P—N units (106).

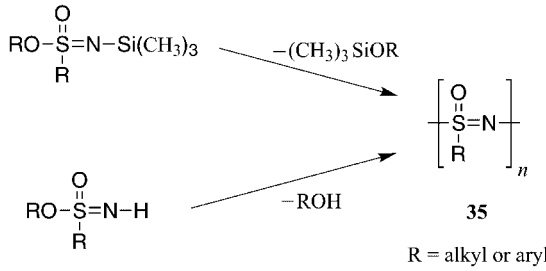
Preliminary reports of the first polythiazylphosphazenes (**34**), which possess three-coordinate sulfur(III) atoms, have appeared (eq. 28) (107). These materials would represent true hybrids of poly(sulfur nitride) and polyphosphazenes and further developments in this area should prove to be particularly interesting.



(28)

Polyoxothiazenes

Partially characterized polyoxothiazenes were briefly reported in the early 1960s (108). However, in 1992 the first well-characterized examples (**35**) with alkyl or aryl substituents at sulfur were described (109). These polymers, which possessed estimated molecular weights of M_w = ca 10^5 and M_n = ca 10^4, were synthesized via the condensation polymerization of *N*-silylsulfonimidates at 120–170°C over 2–8 days (eq. 29). These reactions are catalyzed by added Lewis acids (eg, $BF_3{\cdot}O(C_2H_5)_2$) and bases (eg, fluoride). By using a mixture of different sulfonimidates, random copolymers such as $[CH_3S(O){=}N]_m[C_6H_5S(O){=}N]_n$ were also successfully prepared. Free sulfonimidates were also found to thermally condense to yield poly(organooxothiazenes) at lower temperatures than their *N*-silyl analogues (eq. 29) (109,110).



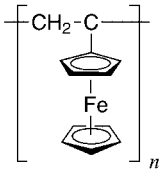
(29)

Polyoxothiazenes appear to be highly polar. For example, $[CH_3S(O){=}N]_n$ is soluble in DMF, DMSO, hot water, and concentrated H_2SO_4. Studies of the thermal transition behavior of these materials have indicated that they are amorphous, which is consistent with an atactic structure. Interestingly, the T_g of $[CH_3S(O){=}N]_n$ is ca. 60°C, which is dramatically higher than for $[(CH_3)_2P{=}N]_n$ (T_g = −46°C). This suggests a much less flexible backbone for polyoxothiazenes compared to polyphosphazenes, as might be expected from

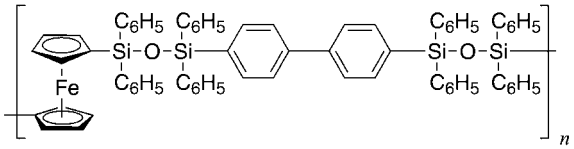
studies on polythionylphosphazenes (vide supra). Thermogravimetric analysis (TGA) showed that the polymers are stable to weight loss up to ca 270°C (at a heating rate of 10°C/min). Theoretical studies on $[CH_3\ S(O){=}N]_n$ have indicated that a *cis–trans* helical conformation is the most stable for this polymer (110).

Inorganic Polymers Based on Transition Elements

Ferrocene-Based Polymers. The excellent thermal stability and interesting physical (eg, redox) properties associated with the ferrocene moiety have led to extensive efforts aimed at the incorporation of this unit into polymer structures. The inclusion of this moiety in the side-group structure of polymers has been very successful and requires only minor modifications of previously established synthetic methodologies. For example, poly(vinylferrocene) (**36**) can be prepared via the free radical addition polymerization of vinylferrocene (111). The incorporation of ferrocene moieties into the main chains of polymers where the metal atoms are separated by a considerable distance has also been achieved. The extensive organic chemistry of the metallocene nucleus has allowed for the preparation of well-defined difunctional ferrocenes that have been used in controlled polycondensation reactions to yield well-defined products of appreciable molecular weight. Examples of products derived from such reactions involve the poly(arylene–siloxane–ferrocenes) (eg, **37**) (112), ferrocene-containing polyesters (113), and novel "accordian" type polymers (114,115).

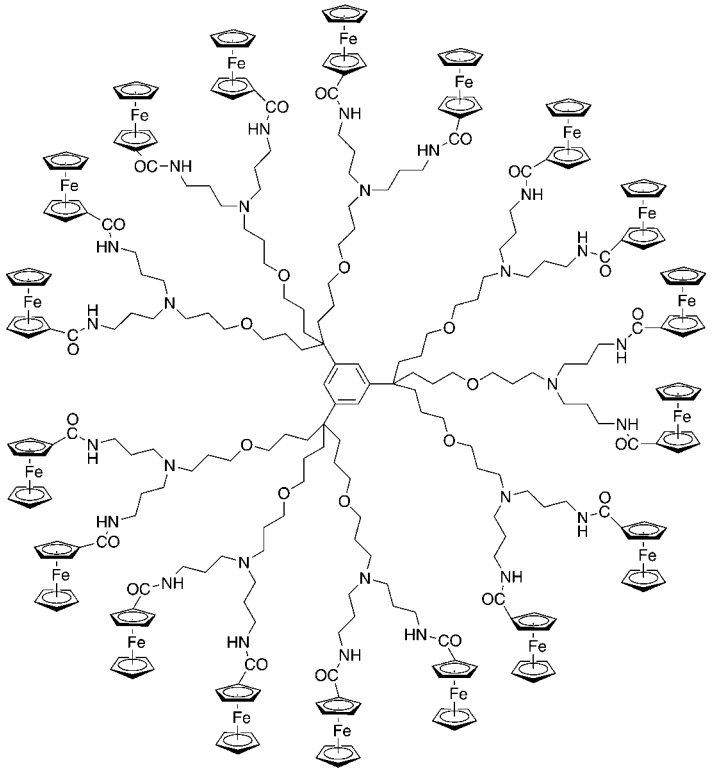


36

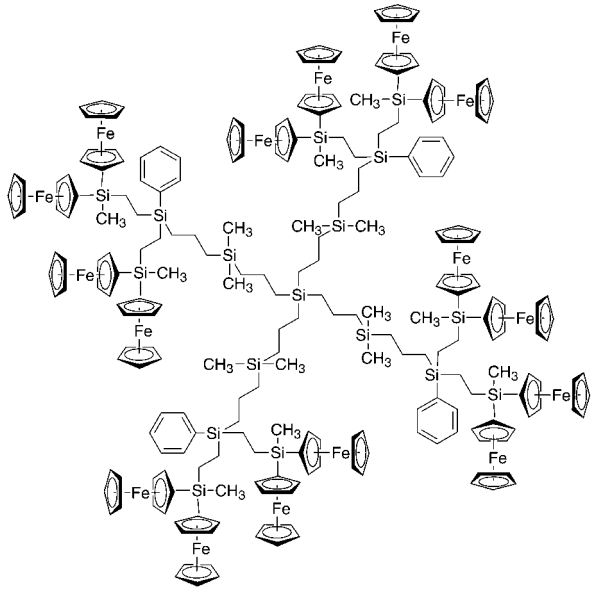


37

The versatile chemistry of the ferrocenyl moiety has also allowed for the preparation of a large number of dendrimeric structures with this group at the periphery (116–118). A series of dendrimers based upon polypropylenimine cores have been reported (119,120) and star-shaped macromolecules with ferrocene units at the periphery have been produced (121), as well as amido-ferrocene dendrimers (eg, **38**) (122). A convergent approach has allowed for the synthesis of dendrimers (**39**) for which the ferrocene units at the periphery display electronic interaction (123).



38

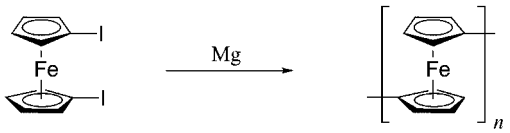


39

In contrast, very few examples of polymers with ferrocene units in close proximity, which could take advantage of interactions between the metal atoms, have been prepared. The development of materials with interesting physical (eg, electronic and/or magnetic) properties might be anticipated based on the properties of molecular species in which two ferrocene units are linked close together. Thus, in such systems the iron atoms can interact and in some cases yield delocalized, mixed valent species upon one-electron oxidation, even when the metal atoms are up to 0.7 nm apart (124,125). Work in this field has largely yielded low molecular weight ($M_n \ll 10{,}000$) and often poorly defined materials (126). For the synthesis of well-characterized polymers ($M_n <$ ca 11,000) with main chains of ferrocene groups and vinylene, divinylene, or oligovinylene units see Reference 127.

Polyferrocenylenes

A typical early route to polyferrocenylenes (**40**) with $M_n < 5000$ involved polycondensation processes such as the recombination of ferrocene radicals generated via the thermolysis of ferrocene in the presence of peroxides. However, these materials have been found to possess other fragments such as CH_2 and O in the main chain (128,129). More structurally well-defined polyferrocenylenes (**40**) ($M_n < 4000$) have been prepared (130) via the condensation reaction of 1,1-dilithioferrocene·TMEDA (tetramethylethylenediamine) with 1,1-diiodoferrocene and, significantly, the reaction of 1,1′-dihaloferrocenes with magnesium (eq. 30) has been shown to afford low molecular weight ($M_n = 4600$ for soluble fractions) materials with appreciable crystallinity (131). In the latter case, oxidation with 7,7,8,8-tetracyanoquinodimethane (TCNQ) afforded doped polymers that were delocalized on the Mössbauer time scale (ca 10^{-7} s) at room temperature and which possessed electrical conductivities of up to 10^{-2} S/cm.

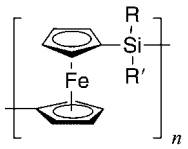


40 (30)

Polyferrocenylsilanes

Properties. Polyferrocenylsilanes possess a backbone of alternating ferrocene and organosilane units. Since the early 1990s when the first high molecular weight, well-characterized examples were prepared by a ROP approach, considerable effort has been directed towards understanding the properties of polyferrocenylsilane materials, the vast majority of which are soluble in common organic solvents (132,133). It was noted early on that electrochemistry of the high polymers such as (**41**) ($R = R' = CH_3$) possess two reversible oxidation waves in a 1:1 ratio (132,134). This provided clear evidence for the existence of interactions between the iron atoms, and led to the proposal that initial oxidation

occurred at alternating iron sites along the main chain. Work on model oligomers with between two and nine ferrocene units has provided clear evidence in support of this postulate (135). Similar electrochemical behavior has subsequently been detected for a range of other polyferrocenylsilanes (134). Oxidative doping of poly(ferrocenyldimethylsilane) with I_2 has been shown to yield semiconducting materials (σ = ca 10^{-4} S/cm) whereas the pristine materials are insulating (σ = ca 10^{-14} S/cm) (133). A report indicates that several tetracyanoethylene (TCNE)-oxidized low molecular weight polyferrocenylsilanes (M_w = ca 1500) show electron delocalization on the Mössbauer time scale (ca 10^{-7} s) and also ferromagnetic ordering at low temperatures (136). Studies of high molecular weight $M_w > 10^5$ analogues have not reproduced this behavior (137). Thin films of the homopolymers and block copolymers with organic or inorganic co-blocks are attracting attention for numerous applications, such as chemomechanical sensors, electrochromic materials, electrode mediators, variable refractive index materials, hole transport layers, charge dissipation coatings for dielectrics, lithographic resists, and photonic band-gap materials (133,138–144).



41

The polymers also exhibit interesting morphology and several of the symmetrically substituted derivatives will crystallize. For example, the dimethyl derivative (**41**) (R = R′ = CH_3) is an amber, film-forming thermoplastic and possesses a T_m at 120–145°C depending on crystallite size and a T_g at 33°C whereas, in contrast, the *n*-hexyl analogue (**41**) (R = R′ = *n*-hexyl) is an amber, gummy amorphous material with a T_g of −26°C (133). The packing in the crystalline regions of polymer (**41**) (R = R′ = CH_3) has been shown to be analogous to that of a linear pentamer (135,141,142). In addition, as the iron atom in ferrocene acts as a "molecular ball-bearing," this gives these polymers a large degree of conformational flexibility and consequently T_gs are lower than might be expected for polymers with such a bulky unit in the main chain (133) (Table 4).

Several polyferrocenylsilanes can be fabricated in the melt (eg, R = R′ = CH_3 above 150°C) (Fig. 1). Polyferrocenylsilanes have been found to exhibit excellent thermal stability to weight loss (up to 350–400°C) and have been shown to yield interesting composites containing Fe nanoparticles at 500–1000°C (145–147). Controlled cross-linking of the polyferrocenylsilanes can be used to make magnetic ceramic films and monoliths with the same shape as the polymer precursor as well as solvent-swellable, redox-active gels (148,149). The solution properties of polyferrocenylsilanes such as the dimethyl derivative (**41**) (R = R′ = CH_3) have been well-characterized by light-scattering experiments and viscometry and Mark–Houwink parameters have been established (150).

Table 4. Thermal Transition and gpc Molecular Weight Data for Selected Polyferrocenylsilanes[a]

Water-soluble polyferrocenylsilanes have also been prepared and these possess, for example, oligoethoxy or ionic side chains (151,152). These materials can be used in layer-by-layer assembly processes to form superlattices with a range of potential applications (153). Novel random copolymers (**42**) with oligosilane spacers have also been prepared by using a thermal copolymerization process (154,155). These polymers possess interesting photophysical and charge transport properties. Indeed, the skeletons of the polysilane segments can be selectively cleaved using uv light because of the photosensitive nature of the Si-Si bond. Block copolymers containing polyferrocenylsilane blocks (*vide infra*) have demonstrated interesting self-assembly behavior and are of interest for nanostructure applications (156). For example, cylindrical worm-like micelles with a polyferrocenylsilane core

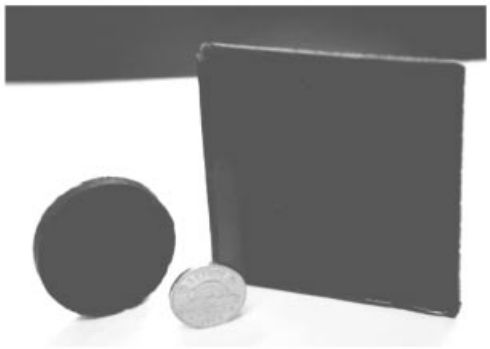

Fig. 1. Samples of melt processed polyferrocenylsilanes.

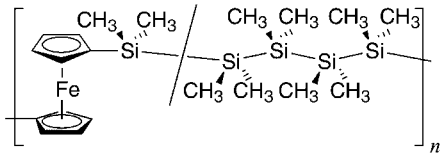
and a polysiloxane corona can be fabricated and are of potential use as semiconducting nanowires and as etching resists in nanolithography (157).

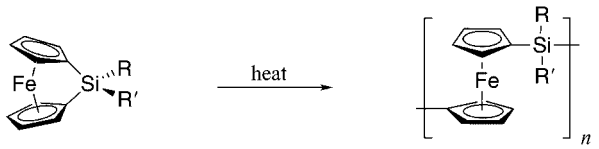


42

Synthesis.

Ring-Opening Polymerization. Early attempts to prepare macromolecules in which the ferrocene units are separated via an organosilane spacer group focused on the use of polycondensation reactions. Partially characterized, impure polyferrocenylsilanes were prepared via the reaction of dilithioferrocene with organodichlorosilanes. The molecular weights of 1400–7000 reported for these materials are characteristic of polycondensation processes where exact reaction stoichiometries are virtually impossible to achieve because one reactant, in this case dilithioferrocene, cannot be readily prepared in pure form (116).

In 1992, the first synthesis of high molecular weight polyferrocenylsilanes (**41**) ($M_w = 10^5$–10^6, $M_n > 10^5$) via a thermal ROP route was reported (132,158). This process involved heating silicon-bridged [1]ferrocenophanes (**43**) in the melt at 130–220°C (eq. 31). The presence of a single-atom bridging the ferrocene unit in the monomer leads to a strained structure in which the planes of the cyclopentadienyl rings are tilted with respect to one another by an angle of ca 21°. In contrast, in ferrocene the cyclopentadienyl rings are parallel. The presence of strain in the ferrocenophane, which has been measured to be ca 80 kJ/mol for (**43**) ($R = R' = CH_3$), is believed to provide the driving force for the ROP process (132,158).

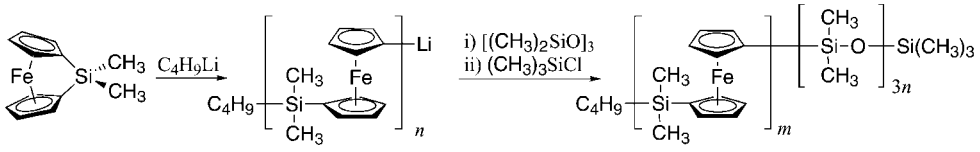


43 **41**

R = alkyl, aryl, ferrocenyl etc (31)

Since this initial discovery, a wide range of silicon-bridged [1]ferrocenophanes with either symmetrically or unsymmetrically substituted silicon atoms have been prepared and similarly polymerized (Table 4). Polymerization of a mixture of different silicon-bridged [1]ferrocenophanes has also been shown to yield random copolymers (159).

Silicon-bridged [1]ferrocenophanes undergo living anionic ROP using initiators such as n-C_4H_9Li in THF (160,161). This has permitted the synthesis of polyferrocenylsilanes with controlled molecular weights and narrow polydispersities and has also allowed the preparation of the first block copolymers containing skeletal transition-metal atoms (160,161). Block copolymers such as (**44**) have been prepared with other monomers that undergo anionic polymerization such as cyclic siloxanes (see eq. 32) or organic monomers such as polystyrene and isoprene (161,162). The resulting block copolymers undergo phase separation in the solid state and, in solution, micellar aggregates are formed (156,163).

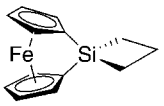


43 **41** **44**

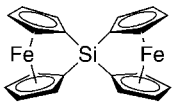
(32)

Also, the transition-metal-catalyzed ROP of silicon-bridged [1]ferrocenophanes in the presence of various transition-metal complexes (eg, Pt^{II}, Pt^0, Rh^I, Pd^{II}) has been developed (164). This route, which takes place in solution at room temperature, is much milder than, and doesn't have the same stringent monomer purity requirements as, anionic ROP. Furthermore, molecular weight control is possible through the use of Si—H containing capping agents such as $(C_2H_5)_3SiH$, and access to block and graft copolymers and star polymers is possible (164,165).

Monomer Synthesis. Sila[1]ferrocenophane monomers such as (**43**) are readily available on a substantial laboratory scale (>100 g) from the reaction of dilithioferrocene tetramethylethylenediamine ($fcLi_2$·TMEDA) with the appropriate dichloroorganosilane (166). Spirocyclic sila[1]ferrocenophanes such as (**45**) and (**46**) are also easily synthesized (167). Sila[1]ferrocenophane monomers with alkoxy, aryloxy, and amino substituents at silicon are readily accessible through reaction of dichlorosila[1]ferrocenophane with the appropriate alcohol, phenol or amine in the presence of base (168).



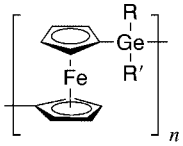
45



46

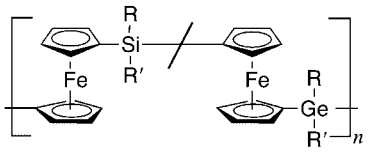
Other Polyferrocenes

The ROP route has been extended to the synthesis of other polymers from [1]ferrocenophane precursors. Polyferrocenylgermanes (**47**) were first reported in 1993 and have been well-characterized and possess quite similar thermal transition behavior, morphology, and electrochemical behavior to the analogous polyferrocenylsilanes (169). Poly(ferrocenylsilane-ferrocenylgermane) random copolymers (**48**) have also been prepared via the thermal polymerization of mixtures of the respective monomers (169).



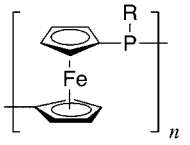
R = alkyl, aryl, etc

47



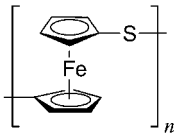
48

Polyferrocenylphosphines (**49**) (and the corresponding phosphine sulfides) are also accessible via the thermal ROP of phosphorus-bridged [1]ferrocenophanes (170). Polymers of this type have been previously prepared by condensation routes and the catalytic potential of some of their transition-metal derivatives has already been noted. In addition, the first sulfur-bridged [1]ferrocenophanes have been prepared and polymerized to give polyferrocenylsulfides, (eg, **50**) (171).



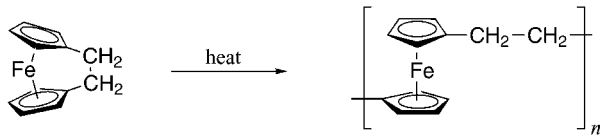
R = alkyl, aryl, etc

49



50

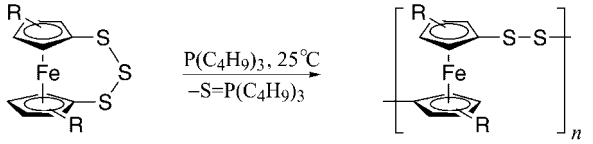
Hydrocarbon-bridged [2]-ferrocenophanes (**51**) possess strained ring-tilted structures (tilt-angles = ca 21°) and these species have been found to yield polyferrocenylethylenes (**52**) via ROP at 250–300°C (eq. 33) (172). As a consequence of the presence of a more insulating bridge, these polymers show much smaller interactions between the iron atoms compared to polyferrocenylsilanes.



51 52 (33)

Analogous hydrocarbon-bridged [2]ruthenocenophanes (tilt angles = ca 29–30°) undergo thermal ROP to yield poly(ruthenocenylethylenes) (172). These materials exhibit significantly different electrochemistry from their iron analogues.

In early 1992, it was reported that [3]trithiaferrocenophanes, which are essentially unstrained, function as precursors to poly(ferrocenylene persulfides) via a novel atom abstraction polymerization route (eq. 34) (173). Thus, reaction of [3]-trithiaferrocenophanes (**53**) with $P(C_4H_9)_3$ led to the formation of the phosphine sulfide $S{=}P(C_4H_9)_3$ and the polymers (**54**).



53 54 (34)

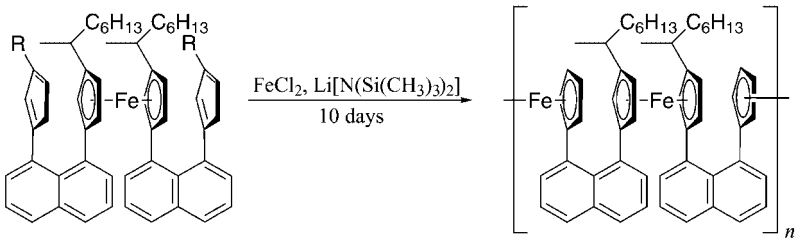
The presence of a butyl substituent on the cyclopentadienyl ring is necessary for the polymer to be soluble. The molecular weight (M_w) of (**54**) (R = n-C_4H_9) was determined to be 40,000 by gel permeation chromatography (gpc). The [3]ferrocenophanes (**53**) (R = H) and (**53**) (R = n-C_4H_9) can be copolymerized to give soluble copolymers with $M_w = 25{,}000$.

Poly(ferrocenylene persulfides) possess a range of novel properties (173–175). They are photosensitive and the S–S bonds can be reversibly reductively cleaved with $Li[B(C_2H_5)_3H]$ and then regenerated upon oxidation with I_2. Their electrochemical behavior is similar to that detected for polyferrocenylsilanes except that the interaction between the iron sites appears to be even greater. The atom abstraction route using $P(^tC_4H_9)_3$ as a desulfurization agent has also been extended to the preparation of other poly(ferrocenylene persulfides) with t-butyl substituents and also high molecular weight (M_w = 50,000–1,000,000) network polymers by the use of [3]ferrocenophanes with two trisulfido bridges as monomers (174).

Face-to-Face Metallocene Polymers

The development of rigid-rod metallocene polymers with a multistacked structure using condensation routes has been reported (176–180). This involved treatment of the ferrocene monomers (**55**) with $FeCl_2$ and $Na[N(Si(CH_3)_3)_2)]$ and this yielded purple polymers (**56**) with molecular weights up to $M_n = 18{,}000$, although higher

molecular components were also present (eq. 35). Mixed metal copolymers containing Ni and Fe whose soluble fractions were of low molecular weight ($M_n < 3000$) were also reported by using $Ni(acac)_2$ instead of $FeCl_2$ (176). The electrical and magnetic properties of these novel polymers and copolymers are clearly worthy of investigation. Interestingly, structural work on well-defined oligomers suggests that the stacked metallocene units in the polymer form a helical structure (180).

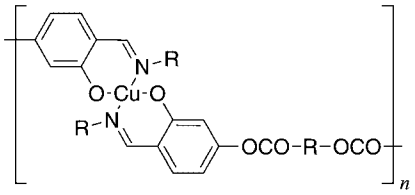


R = H or 2-octyl

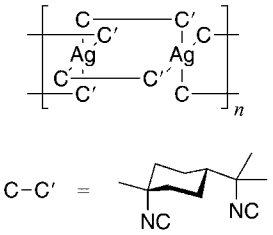
55 **56** (35)

Coordination Polymers

In the past, attempts to prepare coordination polymers have been hindered by the insolubility and consequent intractability of the products. These problems arise from the inherent skeletal rigidity of these materials, and the introduction of solubilizing or flexibilizing groups either in the polymer backbone or side-group structure is necessary for useful products to be obtained. Such modification has yielded a range of interesting and well-characterized materials with intriguing properties. For example, novel liquid crystalline polymers (**57**) containing paramagnetic Cu^{II} centers have been prepared (181) and soluble, luminescent silver-containing polymers (**58**) have been reported (182).



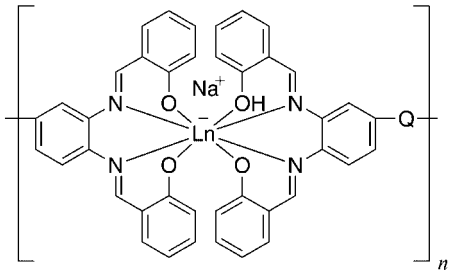
57



58

In addition, well-characterized lanthanide containing polymers (**59**), which possess polyelectrolyte behavior and exhibit interesting photophysical properties, have been reported (183). The tetradentate Schiff-Base ligands greatly stabilize the lanthanide ions in solution and allow for efficient energy transfer to the

lanthanide centers. Several of the polymers are soluble in polar organic solvents such as DMSO, and molecular weights (M_n) up to 1.8×10^4 have been established. The polymer (**59**) (Ln = Eu or Eu/Y) is an interesting candidate for luminescent and lasing applications (184). Similar polymers containing cerium and zirconium in the main chain have also been prepared and these possess M_n values up to 3×10^4 (185). Films of these polymers have conductivities of $\sim 10^{-7}$ S/cm which increase to $\sim 10^{-3}$ S/cm upon I_2 doping (186).

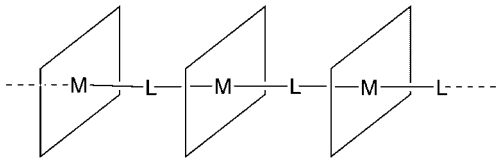


Ln = Eu, La, Gd, Y, Yb

Q = _, CH_2, SO_2

59

Phthalocyanine-based polymers, such as the "shish-kebab" polymers (**60**), are also of considerable interest and significant electrical conductivities of up to ca 0.1 S/cm have been detected for chemically or electrochemically doped materials (187,188). If flexible organic substituents are present on the periphery of the phthalocyanine ring, these materials can also be soluble (at least low molecular weight fractions).

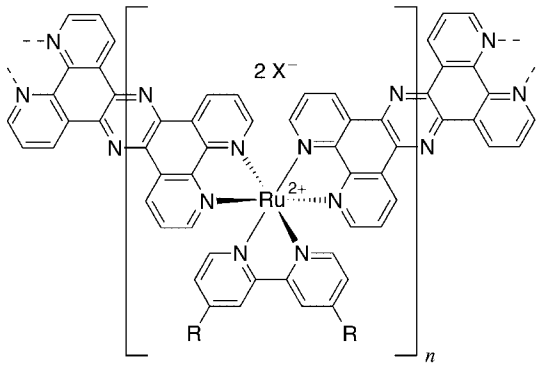


= phthalocyanine L = bipy, CN^-

M = Fe, Ru, Os, Co, Rh, Mn, Cr

60

Well-defined and readily soluble ruthenium coordination polymers (**61**) have been synthesized through the reaction of a bisbidentate ligand and a metal center that already possesses one bidentate ligand (189–191). In these complexes, the random stereospecificity at the ruthenium centers results in a ribbon-like conformation of the polymers with the extension of the chain dependent upon the substituent R. The Ru^{II} centers appear to behave independently and the polymers appear to be stable against heat and uv irradiation. They have molecular weights on the order of $M_w = 40{,}000$–$50{,}000$.

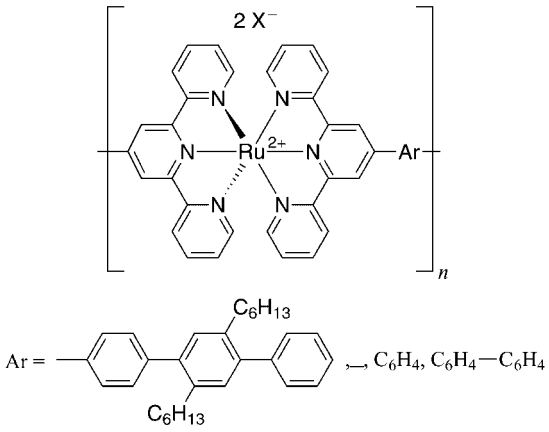


R = H, C_6H_5, CH_3, $CH_2—C_{10}H_{15}$

X^- = Cl^-, BF_4^-, PF_6^-, ...

61

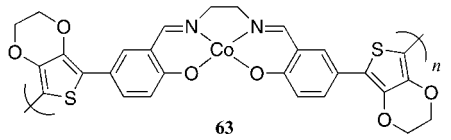
A similar strategy applied to the reaction of a bistridentate monomer with an appropriate ruthenium compound gives rise to the rod-like polymers (**62**), which are soluble due to the *n*-hexyl substituents (192,193). These polymers display a pronounced polyelectrolytic effect in salt-free dimethylacetamide.



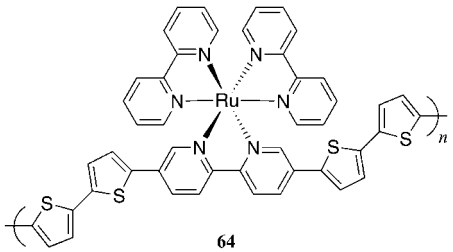
X^- = Cl^-, BF_4^-

62

Polythiophene-metal complex hybrid polymers such as (**63**) and (**64**) have been explored (194,195). The polythiophene-cobalt salen hybrid (**63**) participates in the electrocatalytic reduction of oxygen and is highly conducting in nature. Polymers such as (**64**) have also been shown to be conducting. A variety of related structures have been prepared and similar strategies have also resulted in the preparation of polymeric metallorotaxanes (196).

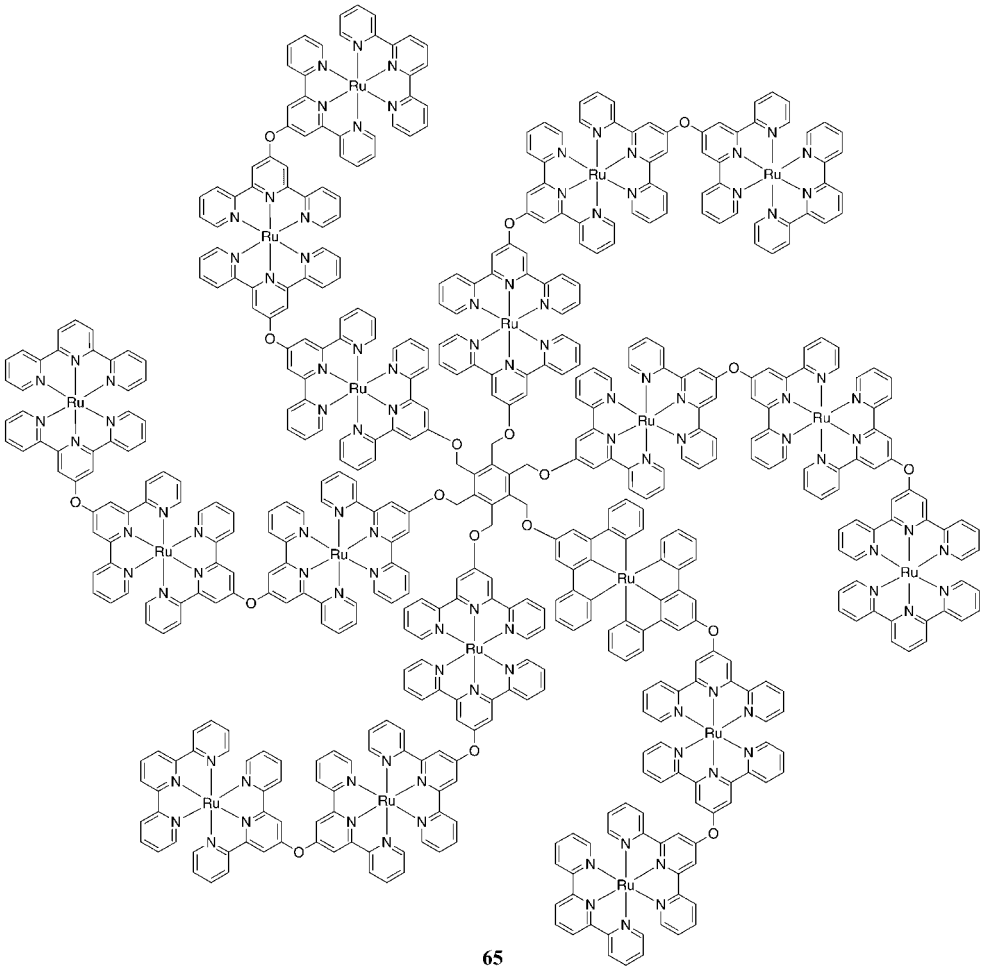


63



64

The generation of dendrimeric coordination polymers has also been an area of significant activity. Imaginative routes to novel Ru- or Pt-polypyridyl systems (eg, **65**) (197) have been reported and many other ligand systems have been exploited (117,118,198–201). These materials are of interest with respect to their photophysical and electrochemical properties and possibly their catalytic behavior.

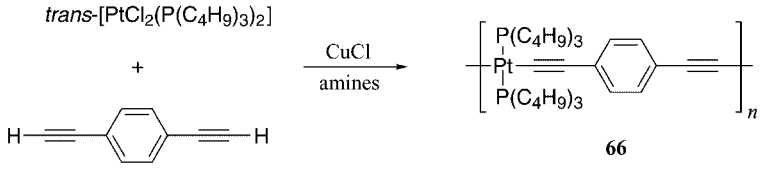


65

Rigid-Rod Organometallic Polymers

Macromolecules with backbones that possess conjugated C≡C units and transition-metal atoms, termed polymetallaynes, represent some of the best-characterized examples of transition-metal-based polymers prepared to date (202).

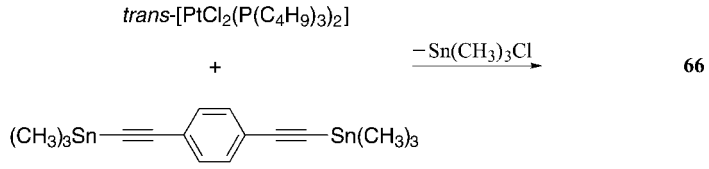
The first polymetallaynes contained nickel, palladium, or platinum atoms in the main chain and were isolated in 1977 as yellow, film forming materials (203–205). These were prepared by efficient copper halide-catalyzed coupling processes (eg, eq. 36) and possessed estimated molecular weights (M_w) from 13,000 to 120,000.



66

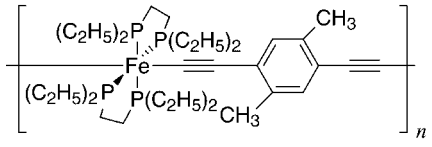
(36)

There has been an important expansion in this area which has yielded a range of new rigid-rod materials via the creative use of a variety of new and well-defined polycondensation strategies. For example, a new route to the polyplatinynes (**66**) that involved the reaction of *trans*-$PtCl_2(PR_3)_2$ complexes with bis(trimethylstannyl)diynes (eq. 37) has been reported (206). These rigid-rod polymers possessed estimated weight-average molecular weights up to ca 100,000 according to gpc measurements.

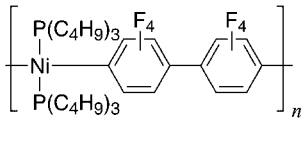


(37)

This synthetic procedure can be extended to allow the incorporation of other transition elements into the polymer main chain such as iron (to give **67**) by using $FeCl_2[(C_2H_5)_2\ PCH_2CH_2P(C_2H_5)_2]_2$ as the transition-metal-containing reactant (207). In addition, condensation routes to organonickel polymers (**68**), have been devised (208,209) and interesting organocobalt (210) and organozirconium (211) polymers containing metallacyclopentadiene moieties in the main chain have been reported.

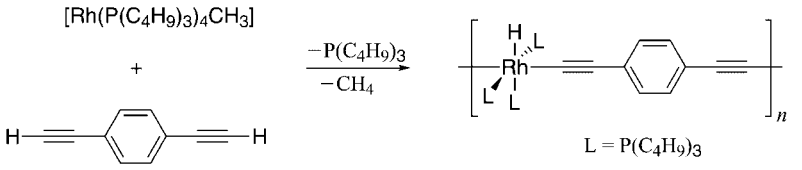


67



68

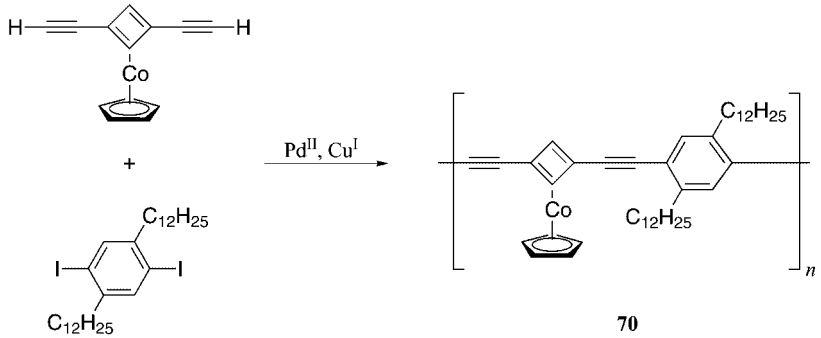
In another interesting synthetic development, it was shown that a range of rhodium-containing polymetallynes (**69**) are accessible via the reaction of the unsubstituted diynes with $Rh(PR_3)_4CH_3$ in a reaction that involves reductive elimination of methane and the loss of a phosphine ligand (eq. 38) (212). In the case where trimethylphosphine ligands are attached to rhodium, the polymers are insoluble but the tri(*n*-butyl)phosphine analogues are soluble and yield free-standing solvent-cast films from THF.



69 (38)

Over the past 15 years the physical properties of polymetallaynes have received continued attention because of their novel rigid-rod structures and their conjugated backbones (213–222). Thus, polyplatinynes form ordered, liquid crystalline mesophases in solvents in which they are soluble such as trichloroethylene (213), and these materials also possess novel, third-order nonlinear optical properties (214) that are of interest for electrooptic device applications. Optical absorption and photoluminescence spectroscopic studies and extended Hückel calculations have shown that polymetallaynes possess a delocalized polymer backbone whose electronic structure is modified by the nature of the transition metal, coligands, and the unsaturated hydrocarbon spacer (215–217). For example, optical band gaps for a series of polyplatinynes with platinum centers joined by σ-conjugated acetylide-arene linkages of varying length have been measured to be in the range of 2.5–3.1 eV, which is lower than for model complexes and is consistent with conjugation through the metal centers (216).

Other developments in the area of rigid-rod transition-metal-based polymers include the synthesis of a range of thermotropic liquid crystalline organocobalt polymers (eg, **70**) in which the metal is bound to skeletal cyclobutadiene units (eq. 39) (223).



70 (39)

In addition, the preparation and characterization of novel lyotropic liquid crystalline aramides (**71**) with complexed chromium(tricarbonyl) units have been

reported (224). These materials are soluble in organic solvents, which leads to potential processing advantages for the uncomplexed organic polymer as the $Cr(CO)_3$ groups can be easily added and removed and poly(*p*-phenyleneterephthalamide) is only soluble in concentrated sulfuric acid (224,225). Work on the coordination of transition-metal fragments to π-hydrocarbon units can be found in Reference 226.

LASER LIGHT SCATTERING

Introduction

In a broad definition, laser light scattering (LLS) could be grouped as inelastic (eg, Raman, fluorescence, and phosphorescence) and elastic (no absorption) light scattering. However, in polymer and colloid science, LLS is normally referred to in terms of static (elastic) or dynamic (quasi-elastic) measurements, or both (1). Static LLS as a classic and absolute analytical method measures the time-average intensity, and it has been long and widely used to characterize both synthetic and natural macromolecules (2). On the other hand, dynamic LLS measures the intensity fluctuation. This is where the word *dynamic* comes from. The visibility of the scattering objects (macromolecules or colloidal particles) in LLS depends on the refractive index difference (dn) between the scattering object and dispersion medium.

In the last two decades, thanks to the advance of stable laser, ultrafast electronics, and personal computer, LLS (especially dynamic LLS) has evolved from a very special instrument for physicists and physical chemists to a routine analytical tool in polymer laboratories or even to a daily quality-control device in production lines. Commercially available research-grade LLS instruments (eg, ALV, Germany, and Brookhaven, U.S.A.) are capable of making static and dynamic measurements simultaneously for studies of colloidal particles in suspensions or macromolecules in solutions as well as in gels and viscous media.

The interaction of laser light (an electromagnetic radiation) with matter can be described in terms of two fundamental quantities: the momentum transfer ($\boldsymbol{K}$) and the energy transfer ($\Delta\omega$), obeying the conservation equations:

Encyclopedia of Polymer Science and Technology. Copyright John Wiley & Sons, Inc. All rights reserved.

$$\hbar K = \hbar(k_I - k_S)$$
$$\text{and} \tag{1}$$
$$\hbar\Delta\omega = \hbar(\omega_I - \omega_S)$$

where $\hbar = h/2\pi$ with h being Planck's constant; $\boldsymbol{k}_{\mathrm{I}}$, $\boldsymbol{k}_{\mathrm{S}}$, and ω_{I}, ω_{S} are, respectively, the incident and scattered wave vectors with magnitudes $2\pi/\lambda_{\mathrm{I}}$, $2\pi/\lambda_{\mathrm{S}}$ and angular frequencies $2\pi\nu_{\mathrm{I}}$, $2\pi\nu_{\mathrm{S}}$. For structural and dynamic information, $\mathrm{R} \sim \boldsymbol{K}^{-1}$ can be used as a spatial resolution ruler in static LLS to probe the sizes of colloidal particles and macromolecules, and $\tau \sim 1/\Delta\nu = 1/(\nu_{\mathrm{I}} - \nu_{\mathrm{S}})$ can be used as a characteristic time range in dynamic LLS to measure the relaxation of colloids in suspension, or macromolecules in solution.

The amplitude of scattering vector $\boldsymbol{K}$, written as q [$=4\pi \sin(\theta/2)/\lambda$], is a pertinent parameter. In principle, one can change either the scattering angle θ or the wavelength λ of the beam in the scattering medium to alter q. However, in LLS, it is not practical to vary $\boldsymbol{K}$ by λ. Therefore, q is typically varied by θ in the range 15°–160°, implying that in static LLS we can only measure the size (R) down to about tens of nanometers, much larger than that in small-angle x-ray scattering (3). In dynamic LLS, translational motions of macromolecules or particles within the size range 1–1000 nm can be measured. The characteristic time of relaxation in dynamic LLS, which includes translational, rotational, and internal motions, could vary from seconds to tens of nanoseconds (4). There are different ways to measure the characteristic time (5), but we shall discuss only the commonly used self-beating intensity–intensity time correlation spectroscopy.

Many reviews, books, proceedings, and chapters have been published on the topic. Serious LLS users should consult References (1) and (2) and other books, rather than proceedings or articles, as reference materials. In particular, the first monograph on the theoretical aspects of dynamic LLS (6) is highly recommended because it remains as the best source reference. In this article there is concentration on experimental detail. Often, static and dynamic LLS are used separately; generally, polymer chemists are more familiar with static LLS and only use dynamic LLS to size particles, whereas polymer physicists are not custom to precise static LLS measurements and sample preparation. This seriously limits their application. This article specially deals with this problem by using several typical examples to show how static and dynamic LLS can be combined to extract more information, such as the characterization of molar mass distribution, estimation of composition distribution of a copolymer, the adsorption/grafting of polymer chains on colloidal particle surfaces, and the self-assembled nanostructure of block copolymers.

Static Laser Light Scattering

For the convenience of discussion, both macromolecules and colloidal particles are referred to as *particles* hereafter. When a light beam I_{INC} hits a solution, the excess Rayleigh ratio $R_{\mathrm{vv}}(q)$ of the solute particles for the vertically polarized incident and scattering lights has the form

$$\frac{HC}{R_{\mathrm{vv}}(q)} \approx \frac{1}{M_w P(q)} \tag{2}$$

where $H[=4\pi^2 n^{2T,P}_{0(\partial n/\partial C)}2/(N_A\lambda_0^4)]$ is an optical constant for a given polymer solution and a laser light source, $M_w(=\int_0^\infty f_w(M)\,M\mathrm{d}M\int_0^\infty f_w(M)\,\mathrm{d}M)$ is the weight-average molar mass and $f_w(M)$ is the weight distribution of molar mass. The scattering factor $P(q)$ for particles with different shapes have been previously derived (7, 8) and graphically displayed (9). It is related to q and the root-mean square z-average radius of gyration $\langle R_g{}^2\rangle_z{}^{1/2}$, or written as $\langle R_g\rangle$, where $\langle R_g{}^2\rangle_z$ is defined as $\int_0^\infty f_w(M)MR_g^2\mathrm{d}M/\int_0^\infty f_w(M)M\mathrm{d}M$. When $\langle R_g\rangle$ is smaller than $1/q$, ie, $q\langle R_g\rangle \ll 1$, we have

$$P(q)\approx 1-1/3q^2R_g^2+\cdots \tag{3}$$

It can be shown that equation (3) is not only valid for the Gaussian chain but also for particles with an arbitrary shape as long as $q\langle R_g\rangle \ll 1$. Considering the interparticle interference between the scattered lights, Debye (10) showed in 1947 that the concentration dependence can be virial expanded as a power series in the concentration, the combination of which with equations (2) and (3) leads to

$$\frac{HC}{R_{vv}(q)}\approx\frac{1}{M_w}\left(1+\frac{1}{3}\langle R_g^2\rangle_z q^2+\cdots\right)+2A_2C+\cdots \tag{4}$$

Where A_2 is the second virial coefficient. This is the most basic equation in static LLS. With $R_{vv}(q)$ measured over a series of C and q, one can obtain $<R_g>$ and A_2, respectively, from the slopes of $[HC/R_{vv}(q)]_{c\to 0}$ vs q^2 and $[HC/R_{vv}(q)]_{q\to 0}$ vs C; and M_w from $[HC/R_{vv}(q)]_{c\to 0,q\to 0}$. The Zimm plot, $HC/R_{vv}(q)$ vs (q^2+kC) with k an adjustable constant, allows the extrapolations of $q\to 0$ and $C\to 0$ to be made on a single grid (11). Figure 1 shows a typical Zimm plot for thermally sensitive and biocompatible poly(N-vinyl caprolactam) in water at 25°C (12).

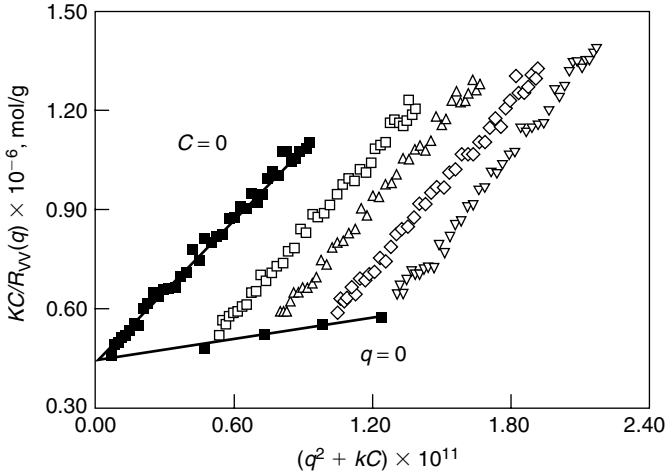

Fig. 1. Typical Zimm plot for thermally sensitive and biocompatible poly(N-vinyl caprolactam) ($M_w = 2.34\times 10^6$ g/mol, $<R_g> = 79$ nm, and $A_2 = 1.59\times 10^{-4}$ (mol·mL)/g^2) in water at 25°C.

It should be noted that equation (4) is valid under the restriction that the solution exhibits no absorption, no fluorescence, and no depolarized scattering. As for anisotropic rigid or rigid-like rods with a depolarized scattering, readers should refer to the excellent review article in Reference (13), and the references therein. As for the correction of absorption and fluorescence, readers are advised to refer to the characterization of Kevel in concentrated sulphuric acid (14–16). In practice, the Rayleigh ratio is determined by a relative method; namely, by measuring the scattering intensity of a standard, eg, benzene or toluene, we can calculate the Rayleigh ratio of a solution by

$$R_{vv}(q) = R^{o}_{vv}(q)\frac{\langle I\rangle_{\text{solution}} - \langle I\rangle_{\text{solvent}}}{\langle I^{o}\rangle}\left(\frac{n}{n^{o}}\right)^{\gamma} \tag{5}$$

where the superscript "o" denotes the standard and $<I>$ is the time-averaged scattering intensity. The term (n/n^{o}) is a refraction correction for the scattering volume and $1 \leq \gamma \leq 2$, depending on the detection optics. If a slit is used, we only need to correct the refraction in one direction ($\gamma = 1$). On the other hand, if a pinhole with a size much smaller than the beam diameter is used at the center of the scattering cell, we have to correct the refraction in two directions ($\gamma = 2$). When the pinhole size is comparable to the beam diameter, $1 < \gamma < 2$, which should be avoided. In practice, a slit ($\sim$200 μm) is preferred. Note that static LLS theory is not complicated, but the alignment of LLS spectrometer is much more difficult.

Dynamic Laser Light Scattering

When the incident light is scattered by a moving particle, the detected frequency of the scattered light will be slightly higher or lower owing to the Doppler effect, depending on whether the particle moves towards or away from the detector. The frequency distribution of the scattered light is slightly broader than that of the incident light. This is why dynamic LLS is also called quasi-elastic light scattering (QELS). In comparison with the incident light frequency ($\sim 10^{15}$ Hz), the frequency broadening Δf $\sim 10^{5}$–10^{7} Hz is so small, that it is difficult, if not impossible, to detect Δf in frequency domain. But, it can be recorded in the time domain via a time correlation function so that dynamic LLS is sometimes known as photon correlation spectroscopy (PCS).

Without a local oscillator (ie, a constant fraction of the incident light reaching the detector *intentionally* or *unintentionally* by various sources, such as surface scratching or reflection), the self-beating of the scattered electric field leads to the intensity–intensity time correlation function $G^{(2)}(q, t)$, which is related to the normalized scattered electric field–electric field time correlation function $|g^{(1)}(q, t)|$ $(=<\boldsymbol{E}(q, 0)\boldsymbol{E}*(q, t)>/<\boldsymbol{E}(q, 0)\boldsymbol{E}*(q, 0)>)$ by the Siegert relation:

$$G^{(2)}(q,t) = \langle I(q,0)I(q,t)\rangle = A(1 + \beta|g^{(1)}(q,t)|^{2}) \tag{6}$$

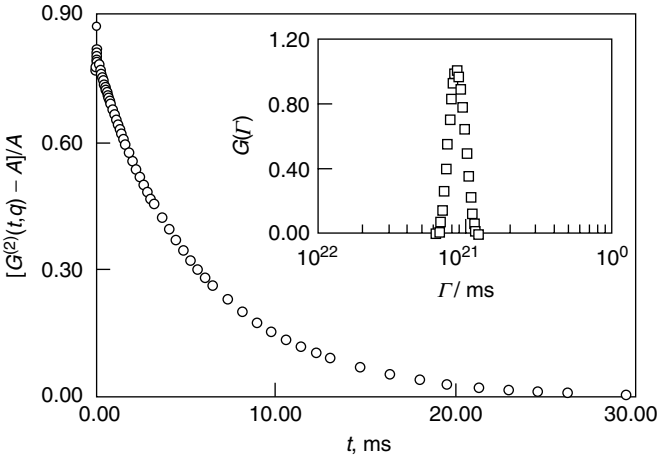

Fig. 2. Typical normalized intensity–intensity time correlation function for thermally sensitive and biocompatible poly(*N*-vinyl caprolactam) ($M_w = 2.34 \times 10^6$ g/mol, $<R_g> =$ 79 nm, and $A_2 = 1.59 \times 10^{-4}$ mol·mL/g^2) in water at 25°C.

where A ($\equiv <I(q, 0)I(q, 0)>$) is the baseline, t is the delay time, β is a parameter depending on the coherence of the detection optics, and $I(q, t)$ is the detected scattering intensity or photon counts at time t, including contributions from both solvent and solute. Therefore, $I_{\text{solution}}(q, t) = I_{\text{solvent}}(q, t) + I_{\text{solute}}(q, t)$. Figure 2 shows a typical normalized intensity–intensity time correlation function for thermally sensitive and biocompatible poly(*N*-vinyl caprolactam) in water at 25°C.

In a real experiment, β_{app} [$=\beta(I_{\text{solute}}/I_{\text{solution}})^2$] instead of β is measured by the extrapolation of $[G^{(2)}(q, t)]_{t\to 0}$ in equation (6) (17). The reader should be aware of this fact, especially for weakly scattered dilute low molar mass polymer solution. For example, if $I_{\text{solute}} = I_{\text{solvent}}$, $\beta_{\text{app}} = \beta/4$. Note that β is a constant for each given detection geometry so that it can be determined by using a strongly scattered object, such as narrowly distributed latex particles (~100 nm). Knowing β, one can calculate I_{solute} from β_{app}. A beginner in LLS should note that such a measurement is not a routine method and only reserved for some particular experiments in which a direct and accurate measurement of $I_{\text{solution}} - I_{\text{solvent}}$ is difficult. Generally, the relaxation of $|g^{(1)}(q, t)|$ includes both diffusion (translation and rotation) and internal motions. Let us first consider the translational diffusion relaxation. For a polydisperse sample with a continuous distribution of molar mass M or size R, we have

$$|g^{(1)}(q,t)| = \int_0^\infty G(\Gamma)e^{-\Gamma t}\mathrm{d}\Gamma \tag{7}$$

where $G(\Gamma)$ is the line width distribution. Note that by the definition of $|g^{(1)}(q, t)|$, $G(\Gamma)$ is an intensity distribution of Γ. For a dilute solution, the measured line width Γ is related to q, C, and the translational diffusion coefficient D by (18,19)

$$\Gamma = q^2 D(1 + k_d C)\left(1 + f\left\langle R_g^2\right\rangle_z q^2\right) \tag{8}$$

where k_d is the diffusion second virial coefficient and f is a dimensionless parameter depending on the structure, internal motions, and solvent. When $C \Rightarrow 0$ and $q \Rightarrow 0$, $\Gamma/q^2 \Rightarrow D$.

Equation (7) indicates that once $|g^{(1)}(q, t)|$ is determined from $G^{(2)}(q, t)$ through equation (6), $G(\Gamma)$ can be computed from the Laplace inversion of $|g^{(1)}(q, t)|$ (20–26). In the last three decades, many computation programs were developed. At the earlier stage, the caculation speed was a very important factor in the development. This constraint has gradually been removed in the last 10 years. Among many programs, the CONTIN program (27) is still the most used and accepted one. However, it should be noted that equation (7) is one of the first kind Fredholm integral equations. Its inversion is an ill-conditioned problem because of the bandwidth limitation of photon correlation instruments, unavoidable measurement noises, and a limited number of data points; namely, the inversion does not lead to a unique $G(\Gamma)$. Therefore, it is more important to *reduce the noises in the measured intensity time correlation function than to choose a program for data analysis* (26,27). It is crucial to thoroughly clean (ie, dust-free) the solution. A practical checkup is to measure the scattered intensity at 15° for 5–10 min. If there is no sharp intensity pulse, the sample is "clean." Unfortunately, many of the LLS users did not realize this problem or did not want to face it. It is dangerous to use a "dirty" solution and explain whatever comes from it.

It is worth noting that there is a temptation among LLS users to extract too much information from $G^{(2)}(q, t)$, actually from experimental noises. In the literature, three or four peaks in $G(\Gamma)$ were often reported. It has to be warned that even a bimodal distribution of $G(\Gamma)$ has to be justified by other physical evidences or preexperimental knowledge. This does not mean that many of the Laplace inversion programs developed in the past are useless. On the contrary, they have been quite successful in retrieving some desired information. Therefore, the Laplace inversion should be used with a clear understanding of its ill-conditioned nature and its limitation.

The contribution of the rotational relaxation to Γ has been discussed (6,13). At a very small scattering angle, the internal and rotational a relaxations are relatively so fast that its contribution to Γ can be neglected. The internal motions of a long flexible polymer chain, also known as the normal modes or "breathing modes," can only be observed at higher scattering angles. The spectral distribution of the light scattered from a flexible polymer chain has been derived (6,28). Figure 3 shows typical plots of $G(\Gamma/q^2)$ vs Γ/q^2 for a narrowly distributed high molar mass polystyrene standard in toluene at different x values (29). The change of $G(\Gamma/q^2)$ is due to the fact that the line width (Γ) associated to the translational diffusion increases with x, but those related to the internal motions are independent of the scattering angle.

The uninitiated reader may wish to consult books on polydispersity analysis (30,31). In practice, one can use a fast but limited cumulants analysis to obtain the average line width $<\Gamma>$ and relative width $\mu_2/<\Gamma>^2$ of $G(\Gamma)$ (20), wherein $[G^{(2)}(q, t) - A]/A$ is expanded as

$$\ln\left[\frac{G^{(2)}(q,t)-A}{A}\right] = \ln\beta - \langle\Gamma\rangle t + \frac{\mu_2 t^2}{2!} + \frac{\mu_3 t^3}{3!} + \cdots \tag{9}$$

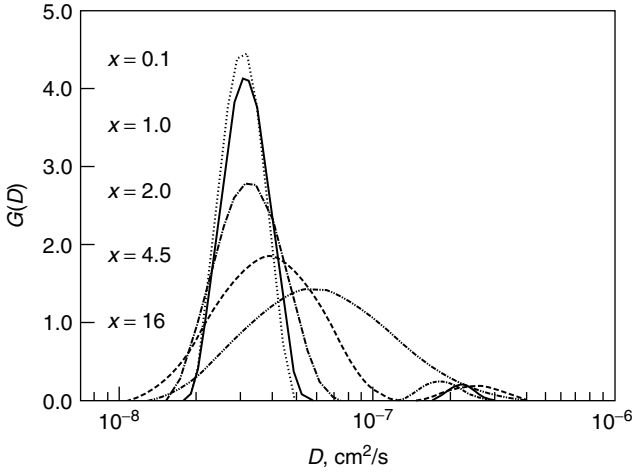

Fig. 3. x-dependence of $G(\Gamma/K^2)$ for a high molar mass polystyrene standard ($M_w = 1.02 \times 10^7$ g/mol and $M_w/M_n = 1.17$) in toluene at $T = 20^\circ$C, where $x = (R_gK)^2$ and $G(\Gamma/K^2)$ was calculated by using the CONTIN Laplace inversion program.

where $<\Gamma> = \int_0^\infty \Gamma G(\Gamma)\, d\Gamma$ and $\mu_m = \int_0^\infty (\Gamma - <\Gamma>)^m\, G(\Gamma)\, d\Gamma$. For $\mu_2/<\Gamma>^2 < 0.2$, the second-order cumulants fit is sufficient, while when $\mu_2/<\Gamma>^2 \sim 0.2$–$0.3$, the third-order cumulants fit is required. For an even higher value of $\mu_2/<\Gamma>^2$, we cannot simply use a higher order expansion to solve the problem because we do not know how many terms are sufficient to avoid an overfitting of experimental noises. For a broadly distributed sample, the Laplace inversion could yield more reliable $<\Gamma>$ and $\mu_2/<\Gamma>^2$ as long as the measured time correlation function is obtained within a proper bandwidth range and has a sufficient photon count, eg, the baseline has a total count over 10^6. The Laplace inversion method is particularly useful if $G(\Gamma)$ is a bimodal distribution where the two peaks are well separated by a factor of 2 or more.

Methods of Combining Static and Dynamic LLS

Dynamic LLS is famous for its application in particle sizing. $G(\Gamma)$ obtained from a dilute dispersion is converted to the hydrodynamic size distribution $f(R_h)$ by means of $D = \Gamma/q^2$ and the Stokes–Einstein relation $D = k_BT/6\pi\eta R_h$ with k_B, T, and η being the Boltzmann constant, the absolute temperature, and solvent viscosity, respectively. All the parameters in the conversion are either well-known constants or precisely measurable by other methods. Therefore, using dynamic LLS to size the particle size distribution is an absolute method without any calibration. Many commercial instruments have been successfully developed on this principle; details have been compiled in a book (32). However, a combination of static and dynamic LLS can provide much more than the characterization of the weight-average molar mass and the particle size distribution.

Characterization of Molar Mass Distribution. Among other methods, using a combination of static and dynamic LLS to characterize the molar mass

distribution of a polymer has yet to become popular because it requires a well-aligned spectrometer that is capable of doing both static and dynamic LLS, a better understanding of LLS theory, and a calibration between D and M. It is worth noting that LLS as a nonintrusive and nondestructive method has its own advantages, eg, it can use a strong corrosive solvent, such as concentrated sulphuric acid, and it can be operated at temperatures as high as 340°C. Though not involving fractionation as in gpc, $G(\Gamma)$ obtained in dynamic LLS could lead to the molar mass distribution if we have

$$D = k_D M^{-\alpha_D} \tag{10}$$

where k_D and α_D are two scaling constants (33). It has been confirmed that for a flexible polymer, $0.5 < \alpha_D < 0.6$ in a good solvent and $\alpha_D = 0.5$ in a Flory Θ-solvent; for a rigid rod-like chain, $\alpha_D = 1$; and for a semirigid worm-like chain, $0.6 < \alpha_D < 1$. Equations (2), (6) and (7) indicate that both $Mf_w(M)$ and $G(D)$ are proportional to the excess scattered intensity. Using equation (10), we have (19)

$$f_w(M) \propto D^{1+2/\alpha_D} G(D) \tag{11}$$

Therefore, one can transfer D to M and $f_w(M)$ to $G(D)$ if knowing k_D and α_D, very similar to gpc or the particle sizing where we know that $k_D = k_B T/6\pi\eta$ and $\alpha_D = -1$. Figure 4 shows such obtained differential weight distributions $f_w(M)$ of molar mass for four different poly(N-vinyl caprolactam) fractions in water at 25°C.

The most straightforward method for calibrating D vs M is to measure both D and M for a set of narrowly distributed samples with different molar masses (34,35). However, only a very few kinds of polymers, eg, polystyrene and

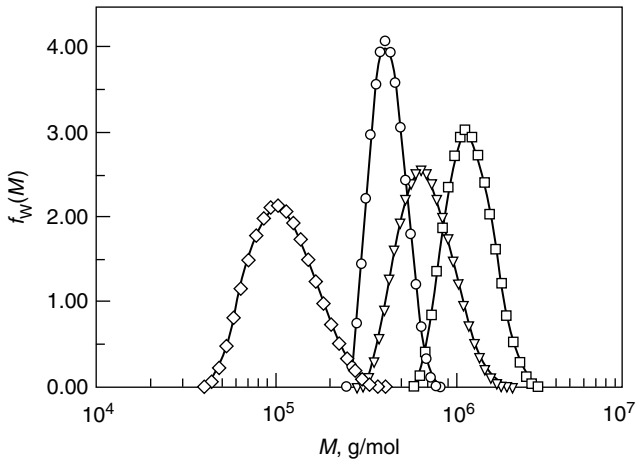

Fig. 4. Typical differential weight distributions $f_w(M)$ of molar mass for four different poly(N-vinyl caprolactam) fractions in water at 25°C, which were calculated by a combination of static and dynamic LLS results, ie, from the line-width distribution $G(\Gamma)$ and the weight-average molar mass (M_w).

poly(methyl methacrylate), can be prepared in such a manner. A traditional time-consuming fractionation method has to be used. Hence, we often have to satisfy ourselves with one or more broadly distributed samples. For two or more samples, one can determine both α_D and k_D from the measure values of M_w and $G(D)$ by a method described in Reference (19). In the case of only one sample, one can estimate α_D from the Mark-Houwink constant from the calibration between intrinsic viscosity and molar mass, ie, $[\eta] = k_\eta M_w{}^\alpha \eta$. It has been shown that $\alpha_D \approx (\alpha_\eta + 1)/3$ for a coil chain (33,36). With α_D estimated from α_η, M_w from static LLS, and $G(D)$ from dynamic LLS, one can determine k_D in the characterization of linear polyethylene in 1,2,4-trichlorobenzene at 135°C (37,38), where α_D was estimated from $\alpha_\eta = 0.72$ (39). Also, LLS can be combined with gpc to find α_D and k_D (40,41). Use of a combination of static and dynamic LLS to estimate the molar mass distribution of some special polymers has been reviewed (42).

Estimation of Copolymer Composition Distribution. A copolymer is normally polydisperse not only in molar mass but also in chain composition. A combination of static and dynamic LLS can be used to estimate its composition distribution. Consider a copolymer sample consisting of monomers A and B and suppose that the copolymer species "i" is characterized by the molar mass M_i and the weight fraction ($w_A(M_i)$). Assume that for a given M, there is no further composition heterogeneity. For a given copolymer in solvents 1 and 2, eq (12) applies (43,44)

$$\frac{f^{(1)}_{w,\mathrm{app}}(M)}{f^{(2)}_{w,\mathrm{app}}(M)} = \left\{ \frac{v^{(2)}}{v^{(1)}} \frac{w_A(M) v_A^{(1)} + \left[1 - w_A(M)\right] v_B^{(1)}}{w_A(M) v_A^{(2)} + \left[1 - w_A(M)\right] v_B^{(2)}} \right\}^2 \tag{12}$$

where $f_{w,\mathrm{app}}(M)$ is the apparent weight distribution, v is specific refractive index increment, and the superscripts denote two solvents. The values of v, v_A, and v_B in two solvents can be predetermined using differential refractometer. The ratio on the left-hand side can be determined as a function of M since $f_{w,\mathrm{app}}(M)$ and M_w is obtainable using Equations (10) and (11). Therefore, Equation (12) allows the determination of $w_A(M)$. Once $w_A(M)$ is known, $v(M)$ and $f_w(M)$ can be computed (43,44). Figure 5 shows such obtained weight composition for two PET–PCL samples with different weight-average molar masses but the same overall composition. It clearly shows that the PET content increases as the molar mass for $M < \sim 4 \times 10^4$ and approaches a constant value (~14%) in the high molar mass range.

Investigation of Interchain Aggregation. Using dynamic LLS to size polymer aggregates is only a simple application. A combination of static and dynamic LLS can lead to the weight fraction and molar mass of the aggregates. If a solution contains individual polymer chains and clusters (or aggregates), static LLS can lead to an apparent weight-average molar mass $M_{w,\mathrm{app}} = M_{w,L} w_L + M_{w,H} w_H$, where the subscripts "L" and "H" denote low molar mass polymer chains and high molar mass clusters, respectively, and w_L and w_H are their weight fractions with $w_L + w_H = 1$. If clusters are much larger than individual chains,

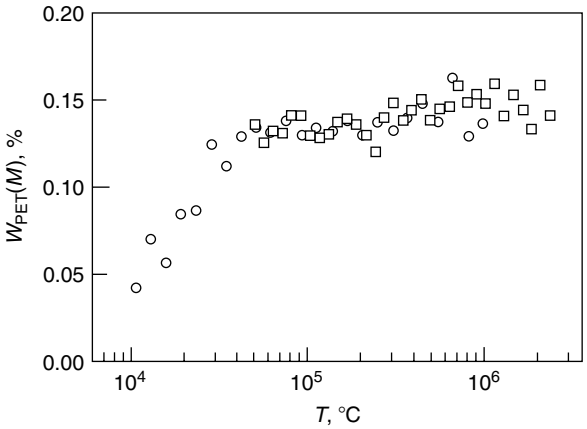

Fig. 5. Estimate of the chain composition distributions for low mass (○) and high mass □ 13% PET–PCL samples by a combination of static and dynamic LLS.

dynamic LLS can detect two distinct peaks $G_{\mathrm{L}}(D)$ and $G_{\mathrm{H}}(D)$, as shown in Figure 6 (45). The area ratio A_{r} of these two peaks equals the intensity ratio, ie,

$$A_r = \frac{A_L}{A_H} = \frac{\int_{\mathrm{o}}^{D_M} G_L(D)\mathrm{d}D}{\int_{\mathrm{D}_M}^{\infty} G_H(D)\mathrm{d}D} = \frac{M_{w,L}x_L}{M_{w,H}x_H} \tag{13}$$

with D_{M} being the cutoff translational diffusion coefficient between $G_{\mathrm{L}}(D)$ and $G_{\mathrm{H}}(D)$. Using Equations (12) and (13), one can calculate $M_{\mathrm{w,L}}x_{\mathrm{L}}$ and $M_{\mathrm{w,H}}x_{\mathrm{H}}$ from

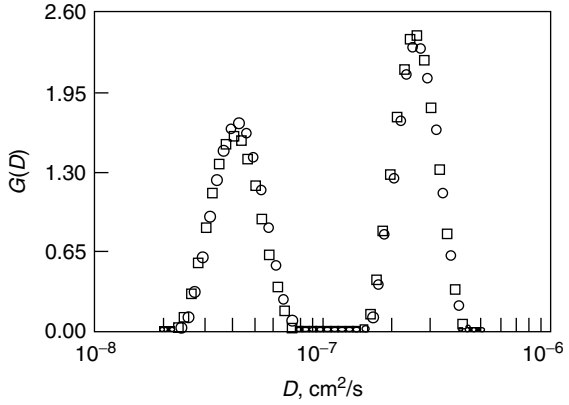

Fig. 6. Translational diffusion coefficient distributions $G(D)$ of a simulated polymer mixture at two scattering angles ("○", 14° and □, 17°). The mixture contains two polystyrene standards of distinctly different weight-average molar masses (3.0×10^5 and 5.9×10^6 g/mol) and a high mass polystyrene.

$M_{w,app}$ and A_r. Knowing any one of $M_{w,L}$, $M_{w,H}$, x_L, and x_H permits finding the rest of the three. This method has been thoroughly tested (45) and used to characterize thermoplastic polymers with phenolphthalein in their backbone chains (46).

Elucidation of Colloidal Particles. Besides sizing colloidal particles, one can use a combination of static and dynamic LLS to elucidate the structure and density of particles, the adsorbed surfactant or polymer layer, and the particle formation (47–52). The following is just one example of how to determine the particle density (ρ) by combining static and dynamic LLS. For a colloidal particle with a uniform density, its molar mass $M = (4/3)\pi R^3 \rho N_A$, where R is its radius and N_A is the Avogadro constant. D can be converted to R_h. In general, $R_h \geq R$, so that one can assume that $R_h = R + b$ with b being the thickness of the solvated layer. Thus,

$$D = \frac{1}{1 + b(4\pi\rho N_A/M)^{1/3}} \left(\frac{k_B T}{6\pi\eta}\right) (4\pi\rho N_A)^{1/3} M^{1/3} \tag{14}$$

Comparing equation (14) with equation (10) and considering $b \ll R$, one finds approximately $\alpha = 1/3$ and $k_D = (k_B T/6\phi\eta)(4\pi\rho N_A)^{1/3}/[1 + b(4\pi\rho N_A/M)^{1/3}]$. Replacing M in equation (14) with M_w given

$$M_w = \frac{1}{\left[1 + b\left(4\pi\rho N_A/M_w\right)^{1/3}\right]^3} \left(\frac{4\pi\rho N_A}{3}\right) \left(\frac{k_B T}{6\pi\eta}\right)^3 \Big/ \int_0^\infty G(D) D^3 \mathrm{d}D \tag{15}$$

Equation (15) contains two unknown parameters b and ρ. Knowing one of them, one can calculate the other from M_w and $G(D)$. In this way, it was found that the polystyrene nanoparticles made of only a few uncross-linked chains have a slightly lower density than bulk polystyrene or conventional polystyrene latex (53).

Study of Self-assembly of Diblock Copolymers. Diblock copolymer can self-assemble into a core–shell nanostructure in a selective solvent in which the core and shell are, respectively, made of the collapsed insoluble blocks and the swollen soluble blocks. For the first approximation, the core–shell nanostructure can be described by two concentric spheres with different, but uniform, densities (ρ_c and ρ_s). Instead of neutron scattering, a combination of static and dynamic LLS can also lead to the core radius (R_c) and shell thickness (ΔR) from $<R_g>/<R_h>$ by the following principle.

For a sphere with a uniform density, we can write the core and the shell masses (M_c and M_s) as $M_c = 4\pi\rho_c R_c^3/3$ and $M_s = 4\pi\rho_s(R^3 - R_c^3)/3$, where R_c is the core radius and R is the particle radius. According to the definition of R_g for a sphere, we have

$$R_g^2 = \frac{\int_v \rho(r) r^2 \mathrm{d}v}{\int_v \rho(r) \mathrm{d}v} = \frac{\int_0^{R_c} 4\pi\rho_c r^4 \mathrm{d}r + \int_{R_c}^{R} 4\pi\rho_s r^4 \mathrm{d}r}{M_c + M_s} = \frac{3\left[M_c R_c^2 R^3 - (M_c + M_s) R_c^5 + M_s R^5\right]}{5(M_c + M_s)(R^3 - R_c^3)} \tag{16}$$

Setting the mass ratio M_c/M_s as A and the radius ratio R_c/R as x, we can rewrite equation (16) as

$$\frac{R_g}{R_h} = \left\{ \frac{3\left[Ax^2 - (1+A)x^5 + 1\right]}{5(1+A)(1-x^3)} \right\}^{1/2} \tag{17}$$

where R has been replaced with R_h. Note that M_c/M_s equals to the molar mass ratio of the insoluble block to the soluble block, a constant for a given diblock copolymer. Therefore, for each measured $<R_g>/<R_h>$, we can find a corresponding x according to equation (17) and calculate R_c and ΔR since $R_c = <R_h>x$ and $\Delta R = <R_h> - R_c = <R_h>(1-x)$.

Figure 7 shows a typical average association chain number (n_{chain}) dependence of R_c and ΔR of self-assembled core–shell nanostructures of a rod-coil diblock copolymer, poly(styrene-*block*-(2,5-bis[4-methoxyphenyl]oxycarbonyl)styrene) (PS-b-PMPCS). The fact that R_c is nearly a constant and close to the contour length of the PMPCS block (~31 nm), but ΔR increases with n_{chain}, clearly reveals that when more copolymer chains are self-assembled into the core–shell nanostructure, the insoluble rod-like PMPCS blocks are simply inserted into the core, whereas the soluble coil-like polystyrene

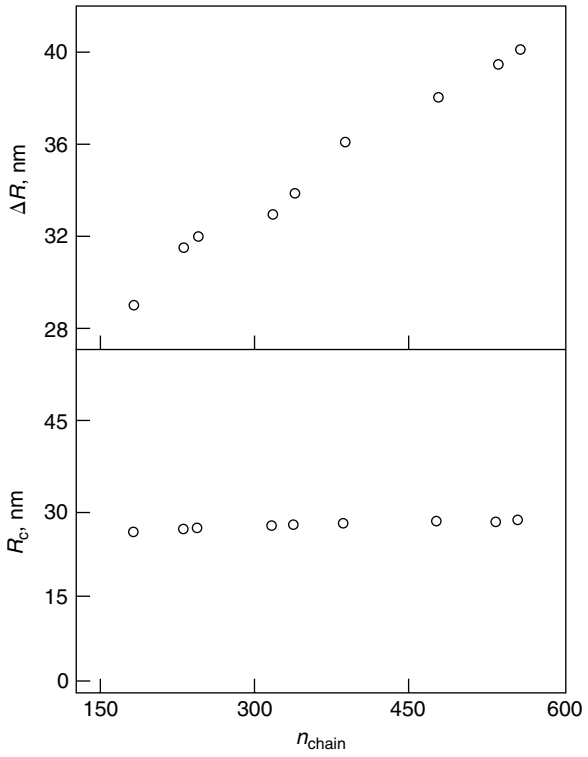

Fig. 7. Average association chain number dependence of the core radius (R_c) and shell thickness (ΔR_h) of self-assembled core–shell nanostructures of a rod-coil diblock copolymer, poly(styrene-*block*-(2,5-bis[4-methoxyphenyl]oxycarbonyl)styrene) PS-b-PMPCS in *p*-xylene at 25°C.

blocks are forced to stretch in the shell as a result of the repulsion in a good solvent.

Practice of Laser Light Scattering

A laser light scattering spectrometer contains a limited number of components; namely, the light source, the optics, the cell holder, and the detector. Nowadays, an LLS instrument should have a digital output (single-photon counting) from a fast photomultiplier, ie, the output current pulse should be treated by preamplifier/amplifier/discriminator before it is connected to a digital time correlator, a single plug-in board to a personal computer.

Light Source. Traditionally, the light source is a helium–neon (He–Ne) laser with a wavelength of 632.8 nm and an output power of 5–50 mW or an argon-ion (Ar^+) laser with a wavelength of 488 or 514.5 nm and an output power of 50–400 mW. Krypton lasers have also been used because their wavelength can be longer than 632.8 nm. The additional cost and somewhat short plasma tube life are drawbacks. The laser used in dynamic light scattering should have a TEM_{00} mode with a Gaussian intensity profile. The reader should choose a laser with a beam amplitude rms noise less than 0.5%. Noted that in dynamic LLS, long-term stability is not very important since the maximum delay time is usually no more than a few minutes, typically less than 1 s, but both the beam point and intensity stabilities are important from static LLS. More recently, there is a tendency to replace these gas lasers with solid-state CW lasers.

The frequency-doubled Nd-YAG laser (532 nm) is a much better choice nowadays if two wavelengths are not required. In comparison with gas lasers, the solid laser has the following advantages: (*1*) its beam diameter is smaller so that small scattering angles are easier to access; (*2*) it is ∼1000 times more coherent; (*3*) it is ∼10 times more stable; (*4*) it has a smaller overall size; (*5*) it is air-cooled and requires only plug-in electric power; and (*6*) its running cost is lower by a factor of ∼5 or more. It is expected that solid-state lasers will gradually replace gas lasers in most applications. The manufacturers have started to provide a new kind of solid-state CW diode lasers in visible (∼670 nm) and near visible (780–830 nm) range, which are particularly useful in the study of conjugated polymers.

Optics and Cell Design. It is well known that laser light follows Gaussian optics. If a laser beam is focused through an aperture by a lens, the diameter (d_s) of the focus spot will be $\sim 1.22 l\lambda\, f/r_0$ with f and r_0 being the focal length and beam radius, respectively. If $r_0 \sim 0.8$ mm, $\lambda \sim 532$ nm, and $f \sim 300$ mm, typically $d_s \sim 0.25$ mm so that the incident beam divergence (d_s/f) is less than 1 Mrad, which is sufficiently small. A polarizer may be placed in the light path before the incident beam strikes the sample cell to define the polarization (normally vertical) of the incident beam. Nowadays, the polarization ratio of lasers is better than 100:1 so that the polarizer is not necessary for a normal LLS measurement.

The conventional sample cell holder in LLS consists of a hollow cylindrical brass block with an outside diameter of 50–80 mm and an inside diameter of 10–20 mm, which matches the outside diameter of the scattering cell. The brass block is normally placed inside a cylindrical optical glass cup filled with a fluid

(eg, xylene, toluene, and silican oil), the refractive index of which matches that of glass ($\sim$1.5) to reduce the surface scattering and cell curvature. A proper alignment of the optical path requires the variation of the scattered intensity of a standard, benzene or toluene, after the scattering volume correction by sin θ is less than 1% (if the scattering volume is chosen by a slit) or 2% (if a small pinhole is used) over an angular range of $\sim 15^\circ$–150°. In principle, the scattering cell with an optical quality should be used. However, it is found in practice that a selected normal cylindrical sample vial is also satisfactory, which reduces the cost and makes it disposable.

On the other hand, if one is only interested in dynamic LLS, a rectangular cell can also be used or even preferred. It is noted that the scattering volume ($\sim 200 \times 300 \times 300\ \mu m^3$ or 0.02 μL) is so small that one can use a small scattering cell, eg, a melting-point capillary with a μL-solution volume for dynamic LLS (54), even though it is difficult to use it in static LLS. The scattering cell can also be a flow type (55) so that it can be used as an *in situ* LLS detector for gpc and electrophoresis. Another challenge in polymer analysis is to characterize polymers soluble only at high temperatures. An important advancement in this direction is the design of a novel light scattering cell holder that is capable of operating at temperatures as high as 340°C (56–61). It was first developed at State University of New York at Stony Brook and is now available in DuPont (Experimental Station), BASF (Ludwigshafen, Germany), and our laboratory.

It has to be stated that the optics together with the cell design in LLS are going through a drastic change because of the development of optical fiber technology (62–65). Figure 8 shows a fiber-optic detector probe comprising a single-mode optical fiber and a graded index microlens, which can form an integral part of the scattering cell. In this cell-detector probe design, the probes can eliminate the need for a goniometer, which is often one of the bulkier components of the spectrometer. Moreover, the probe can be in contact with the solution or dispersion so that the requirement of a transparent window in the sample chamber can be relaxed.

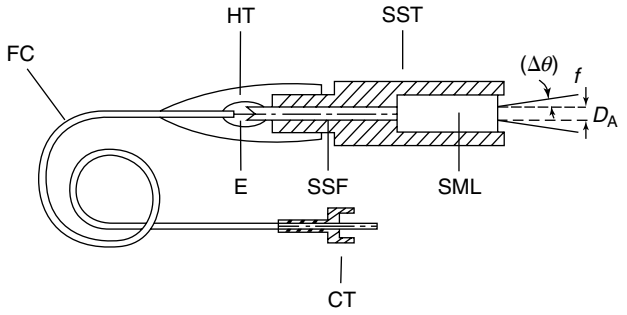

Fig. 8. Schematic of a typical fiber-optic probe. SST: a matching piece of cylindrical stainless steel; SML: SELFOC microlens; SSF: a stainless steel or ceramic ferrule used for mounting the bare optical fibre; E: epoxy used for holding fibre in ferrule; HT: heat shrink tubing; FC: fibre cable; CT: SMA type II male connector. D_A and $(\Delta\theta)$ are the effective detector aperture and divergence angle, respectively.

Detectors and Detection. Commercially available standard photomultiplier tubes (PMTs) with a low dark count (<30 Hz) and a short after-pulsing are normally used to count photons. When a He–Ne laser light source is used, an S-20 photocathode is preferable because of its higher sensitivity in the red range. PMTs, such as EMI 9863 and new Hamamatsu miniature PMTs, are more suitable. To reduce dark count, the PMT with a relatively smaller photocathode (typically 2.54 mm in diameter) should be used. If the laser light is in the blue and green range, PMTs with a bialkali photocathode is more adequate because it has a lower dark count at room temperature. The selected EMI 9893 PMT with a low dark count and a short after-pulsing has been popular for this purpose. The RCA C31034 PMT with a broad spectral response (300–800 nm) is good for the entire visible range, but it is more delicate and expensive. The silicon avalanche photodiode (SAP) is another new development and holds promise in making miniature light-scattering apparatuses. With a broad spectral response, SAPs are matched to diode lasers to simplify the LLS instrumentation, especially if it is combined with a fibre-optic probe, as recently demonstrated by ALV (Germany).

Figure 9 shows two commonly used configurations of the detection optics. In static LLS, the first pinhole (P1) can be replaced by a slit so that the alignment will be easier, but it has to be switched back to a pinhole for dynamic LLS, which makes simultaneous static and dynamic measurements impossible. In **A**-configuration, the scattering volume is mainly determined by the diameter (d_{P1}) of P1 (or the slit width). The first pinhole should be as close as possible to the cell, so that the scattering volume will be better defined. However, because of the existence of the cell holder and index matching cup, the first pinhole is normally 10–15 cm away from the scattering center. The second pinhole is located exactly on the focal plane of the lens and the opening angle of d_{P2}/f determines the uncertainty of the scattering angle ($\Delta\theta$). The coherent factor (β) in equation (6) is mainly determined by the opening angle of d_{P2}/L_0 but also influenced by d_{P1}. In this design, the alignment will be easier and the distance between the cell and the

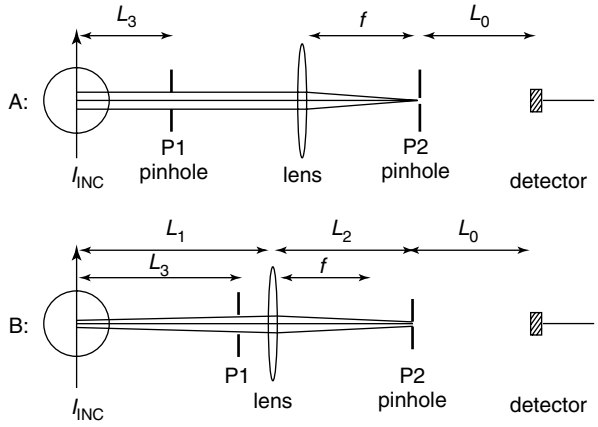

Fig. 9. Two commonly used configurations of the detection optics for both static and dynamic laser light scattering, where I_{INC} is the incident light and f the focal length.

detector could be smaller. In practice, $f \sim 10$ cm, $L_0 \sim 10$ cm, $d_{P1} \sim 200$–400 μm, and $d_{P2} \sim 100$–200 μm.

In **B**-configuration, L_1, L_2, and f are related by $1/L_1 + 1/L_2 = 1/f$, ie, the scattering center and the second pinhole are located exactly on the imagining planes of the lens. The scattering volume is precisely determined by d_{P2}. $\Delta\theta$ is determined by the opening angle of d_{P1}/L_3. Therefore, the first pinhole should be placed as close as possible to the lens, which has no difficulty in practice. If $L_1 = L_2 = 2f$, ie, the so-called $2f$–$2f$ configuration, the second pinhole is optically moved to the scattering center. β is still determined by the opening angle of d_{P2}/L_0. In this configuration, $f \sim 5$–10 cm, smaller than the previous one. For a given d_{P2}, the scattering volume can be enlarged by a factor of L_1/L_2 (normally, $L_1/L_2 \leq 3$) so that one can simultaneously have a stronger scattering intensity, a higher β, and a smaller $\Delta\theta$ for a given distance between the scattering center and the detector. However, the alignment is more difficult but manageable.

Sample Preparation. If a polymer can be dissolved in more than one solvent, the choice of solvent for LLS should be made generally according to the following guidelines: (*1*) colorless to avoid absorption; (*2*) a higher contrast, ie, a higher dn/dC; and (*3*) less polar and less viscous to make dust-free preparation easier. In practice, there may be no choice. For example, poly(1,4-phenyleneterephthalamide) (PPTA or Kevlar) is only soluble in very strong and viscous acids. In such a case, ultracentrifugation instead of filtration has to be used (16,66). As for a copolymer, the selection of proper solvents is even more difficult because at least two solvents that satisfy the three guidelines are needed. For this reason, only a few works related to copolymer characterization have been reported so far (67–70). As for polymers only soluble at high temperatures, the preparation of a polymer solution for LLS is a challenge. Finding a solvent with a high boiling point is often not easy, and dissolution and clarification at high temperatures are even more difficult. Two novel high temperature dissolution-and-filtration apparatuses have been developed (56,59).

Differential Refractometer. One of the most important parameters in static LLS is the specific refractive index increment (dn/dC), which is defined as $\lim_{C \Rightarrow 0}(dn/dC)_{T,P,\lambda}$. Equation (2) shows that an error of $E\%$ in dn/dC will lead to an error of $2E\%$ in M_w. The refractive index increment Δn of a polymer solution is usually measured using either a differential refractometer or an interferometer. In a differential refractometer, the light beam is refracted at the boundary between solution and solvent. Commonly, the beam displacement is directly measured and then converted to Δn after multiplying a calibration constant. The refractometer is normally calibrated by using a solution with an accurately known refractive index difference Δn (71,72). This is not an absolute method since the constant has to be calibrated at the same conditions as those used in LLS. In an interferometer, two light beams with identical geometrical paths passed two different optical paths. One passes through solution and the other passes through solvent. This method relies on the interference of the two beams. Its details can be found elsewhere (73,74). In a high temperature LLS measurement, the conventional divided differential refractometer cuvette has to be replaced by a deformed cylindrical light-scattering cell in which the laser beam is refracted by the solution/air interface (57).

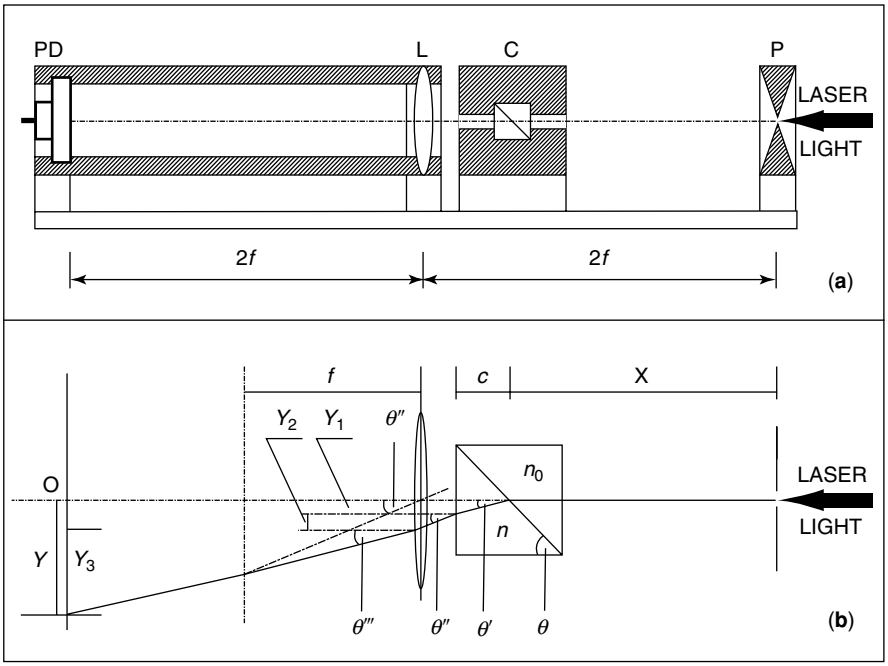

Fig. 10. **(a)** Schematic view of a novel differential refractometer (commercialized by ALV GmbH, Langen, Germany), which consists of a pinhole (P), a differential refractometer cuvette (C), a lens (L, $f = 10$ cm), and a position-sensitive detector (PD). All components are rigidly mounted on a 40-cm long optical rail. (**b**) Light path in which one compartment of the cuvette contains a solvent with refractive index n, and the other contains a solution with slightly different refractive index $n = n_0 + \Delta n$. The cuvette and angles θ', θ'' and θ''', (actually very small, $\sim$0.01 rad) are enlarged to make the light path distinct.

Figure 10 schematically shows a novel differential refractometer which was first designed by one of the authors (75) and later commercialized by ALV GmbH (Langen, Germany). A small pinhole (P) with a diameter of 200–400 μm is illuminated with a laser light. The illuminated pinhole is imaged to a position-sensitive detector (PD) (Hamamatsu S 3932) by a lens (L) located at an equal distance from the pinhole and the detector. The focal length (f) of the lens is 100 mm. This refractometer adopted a ($2f$–$2f$) design. Note that in a conventional ($1f$) design, a parallel incident light beam is used and the distance between the detector and the lens is only one focal length. The conventional design cannot solve the beam drift problem associated with a laser. A temperature-controlled refractometer cuvette (C) (Hellma 590.049-QS) is placed just in front of the lens. It is a flow cell divided into two compartments with a volume of $\sim$20 μL. All the components are rigidly mounted on a small optical rail. The refractometer has dimensions of only 40 cm in length, 15 cm in width and 10 cm in height. The length can be easily reduced to 20 cm with another lens if necessary. The output voltage (-10 to 10 V) from the position-sensitive detector is proportional to the displacement of the light spot from the center of the detector and can be measured by a digital voltmeter or an analogue-to-digital data acquisition system and a personal computer. Figure 10b

shows the basic principle and the light path of the refractometer, where θ', θ'', θ''', and the cuvette are drawn enlarged to make the details clear. It can be shown that $Y = K\Delta n$, where $K = [X + c''(1 - 1/n_0)] \tan(90^\circ - \theta)$. For a given optical setup and solvent, X, c, θ, n_0, and hence K are constants. Therefore, the signal is proportional to Δn. This ($2f$–$2f$) design is optically equivalent to placing the detector directly behind the pinhole, so that the beam drift problem is solved. The refractometer with its present dimensions can be easily installed into any existing laser light-scattering spectrometer (75).

LIGHT-EMITTING DIODES

Introduction

The role of polymers in light-emitting diodes (LEDs) traditionally has been associated with the use as a structural material. Epoxy resins are routinely applied as the transparent "packaging material" in conventional LEDs in which light is generated at the junction of two *inorganic* semiconductors. The polymer provides the structural integrity of the device and serves as the optical medium that enables the extraction of light (1). During the last decade, however, LEDs have been developed in which the semiconducting, electroluminescent (EL) material itself is a polymer. These devices are usually referred to as polymer LEDs or PLEDs and have attracted significant attention in both academic and industrial environment. The principal interest in the use of EL polymers is based on their promise to combine the ease of processability and mechanical flexibility of macromolecular materials with the exceptional, readily-tailored properties of organic semiconductors. PLEDs offer the prospective of low production costs, light weight, large area, fast switching times, low power consumption, high brightness, large viewing angle, and crisp colors. Thus, the new technology may feature distinct advantages over existing flat-panel display devices such as conventional emissive displays, inorganic LEDs, and liquid crystal displays (LCDs). As a result, the list of potential applications of PLEDs ranges from small, low information-content displays for simple electronic devices such as pagers and portable phones to high resolution video-rate displays for use in desktop monitors and ultrathin television sets. In addition, PLEDs may be employed as flat lighting devices, for example in automotive rear lights or as backlights in LCDs.

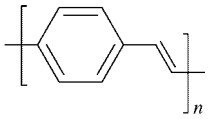
Since the first demonstration of a PLED in 1990 (2), the field has progressed with an almost unbelievable pace, and the technology has matured to the edge

Encyclopedia of Polymer Science and Technology. Copyright John Wiley & Sons, Inc. All rights reserved.

of commercial exploitation (3). In view of the over 5000 publications on PLEDs published to date, it is clearly outside the scope of this article to review this exciting progess in detail. Rather, a comprehensive overview focusing on the general concepts, as well as the current state-of-the-art, is given. For a more detailed description regarding the chemical, physical, and engineering aspects of PLEDs, the reader is referred to a selection of excellent reviews which have appeared in the recent past (4–11). It should be noted that the discussion of LEDs based on low molecular weight organic emitters has been omitted here for apparent reasons. However, the latter share many of the features of PLEDs (12,13), and despite the more demanding device manufacturing processes of low molecular weight organic LEDs, their technological application is slightly more advanced than that of PLEDs (3–5,9).

Device Physics and Device Design Considerations

An LED is an electrooptical device that exploits the EL effect of a fluorescent, semiconducting material and emits electromagnetic radiation in the ultraviolet, visible, or infrared regime of the electromagnetic spectrum when an electric current is applied (1) (see LEDs (Light Emitting Diodes)). Conventional LEDs, commercially introduced in the 1960s, are based on inorganic semiconductors such as GaAs, GaP, AlGaAs, GaAsP, and InGaP. Electroluminescence in organic materials was originally discovered in the early 1960s (14), but useful devices were demonstrated only some 20 years later (12,13). Electric-field-induced light emission from a fluorescent, semiconducting polymer was first observed in 1990, when an electrical field was applied to a thin film of poly(*p*-phenylene vinylene) (PPV) (2).



PPV

The LED reported then materialized the most simple device configuration of a PLED which, in accordance with the number of organic layers used, is usually referred to as a single-layer device (Fig. 1). The semiconducting polymer film (typical thickness 50–500 nm) is sandwiched between two electrodes, of which at least one has to be (semi)transparent in order to allow the generated light to escape from the device. Adopting a standard Schottky-configuration, a high work function anode such as semitransparent indium tin oxide (ITO) and a low work function cathode such as Al, Mg or Ca are employed, leading to nonlinear rectification and, thus, rendering the device into a diode. If an external voltage, or bias, is applied, oppositely charged carriers—holes and electrons—are injected above a threshold voltage from the electrodes into the conduction band (CB) and the valence band (VB), respectively, of the semiconducting polymer (Fig. 2). These electronic levels correspond to the electron affinity (EA) and ionization potential (IP) of the polymer. Because of the applied electric field (typically of the order

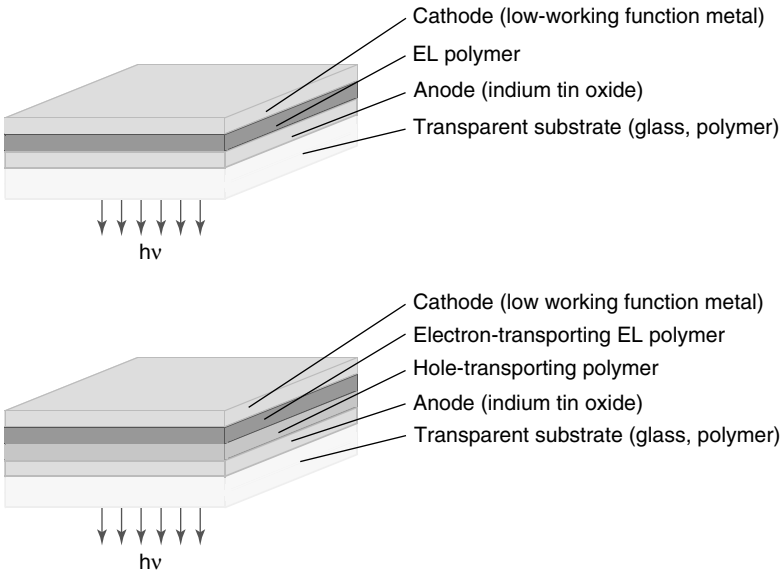


Fig. 1. Schematic drawings of the configurations of a single-layer PLED (top) and a two-layer PLED (bottom).

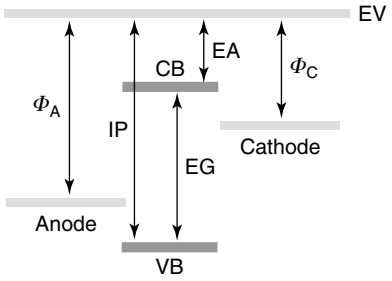

Fig. 2. Simplified schematic representation of the electronic energy levels in a single-layer PLED. CB and VB are the conduction band and valence band, respectively, of the semiconducting polymer, which equal to the ionization potential (IP) and electron affinity (EA) relative to vacuum level (EV). The work functions (or Fermi levels) for anode (Φ_A) and cathode (Φ_C) and the band gap (EG) are also indicated.

of 10^6 V/cm, corresponding to an operating voltage of a few volts), these carriers travel through the polymer toward the oppositely charged electrode. On their way, the charge carriers will either recombine within the emitting polymer layer with an opposite charge and form singlet and triplet excited states (excitons), or they reach the opposite electrode and discharge without having contributed to the EL effect. The singlet excited states created through charge-recombination are identical with those generated through photoexcitation, and, as in the case of fluorescence, they relax to the electronic ground state under the emission of light. The color of the latter is governed by the energy difference between the singlet excited state and the electronic ground state, also referred to as the band

gap (EG) of the EL polymer. The triplet excited states, by contrast, decay through nonradiative processes.

The theoretical internal quantum efficiency of a PLED, η_{int}, is defined as the number of photons generated per injected electron:

$$\eta_{\text{int}} = \eta_{\text{PL}} \eta_r \chi \tag{1}$$

η_{int} is primarily governed by the (solid-state) fluorescence quantum efficiency of the polymer, η_{PL}, which can exceed 65% (15), the fraction of injected charge carriers that form excited states, η_{r}, and the fraction of singlet excited states created (as opposed to triplets), χ. Unfortunately, spin statistics dictate a χ of only 1/4, although recent work suggests that this limitation can, in principle, be overcome (16). To make things worse, internal reflection effects, which are governed by the device's geometry and the refractive index of the light-emitting polymer (n), allow only a fraction of the generated light to be extracted from the device. Thus, in a typical device configuration, the external quantum efficiency of a PLED, η_{ext}, is lower than η_{int} by a factor of $2n^2$ (17):

$$\eta_{\text{ext}} = \eta_{\text{int}} / 2n^2 \tag{2}$$

Approximating the refractive index of the EL polymer with a value of 1.4 allows to put up an upper limit of about 5% for η_{ext}, which still compares favorably with the typical performance of conventional inorganic LEDs (0.2–8%) (1). It should be noted that special geometries may be used to improve the light extraction from the device (18). For engineering purposes, it is often desirable to express the performance of an LED through its power efficiency η_{pow}:

$$\eta_{\text{pow}} = \eta_{\text{ext}} E / U \tag{3}$$

η_{pow} is the optical power output divided by the electrical power input, and is calculated from η_{ext} using the applied voltage U and the average energy E of the emitted photons. Since the human eye is usually the detector for visible LEDs, the key performance parameter of an LED is the luminous efficiency η_{lum} (units: lm/W) which is a product of η_{ext} and the relative eye sensitivity curve S which has been defined by the Commission Internationale de L'Eclairage, CIE):

$$\eta_{\text{lum}} = \eta_{\text{ext}} S \tag{4}$$

Reference values that are frequently used to evaluate the performance of PLEDs are the luminous efficiencies of conventional inorganic LEDs (0.15–20 lm/W) or unfiltered incandescent lamps (17 lm/W) (1). Finally, the absolute brightness of an LED, or luminance (usually quoted in cd/m^2), and luminance per current density (cd/A) are also frequently used parameters to describe the performance of LEDs. Here, the brightness of a laptop computer (200 cd/m^2) or of a TV cathode ray tube (500 cd/m^2) are often employed as benchmarks (19).

As can be deduced from equation (1), the optimizations of charge-injection and charge-transport (both of which directly influence the fraction of injected charge carriers that form excited states, η_{r}) are important aspects for the design

of efficient PLEDs. In order to allow for efficient charge-injection and, concomitantly, low operating voltages, the work functions of cathode and anode should match the EA and IP (or in semiconductor terminology, conduction band and valence band) of the semiconducting emitter, respectively, as closely as possible. Unequal barrier heights at the two electrode–polymer junctions are undesirable because one carrier will be injected preferentially, leading to an increased driving voltage and a reduced luminous efficiency. At the other hand, most organic semiconductors are *p*-type conductors, allowing holes to be transported more efficiently than electrons. Consequently, substantial research efforts have been made regarding the identification of optimal electrode–polymer combinations. A general possibility, of course, is the chemical modification of the emitting polymer, with the intent to tailor—besides the color-determining band gap—its EA, IP, and/or charge-transport characteristics. Another strategy is the design of two-layer (or even three-layer) devices in which, for example, a hole-transporting polymer and an electron-transporting, light-emitting polymer are combined (7). The resulting heterojunction between the two semiconducting polymers allows to control the charge-injection rates and helps to confine the charge recombination to the emitting layer (Fig. 1). In addition, this architecture effectively reduces problems associated with the migration of oxygen and metal ions from the electrodes into the organic layer and the related creation of quenching sites in the emission zone. Consequently, the two-layer architecture has become the preferred PLED embodiment.

Materials

The design of PLEDs relies on a variety of different materials, including a transparent substrate, the (semi)transparent anode, a hole-transporting layer in case of the usual two-layer structure, the EL polymer itself, an additional electron-conducting/hole-blocking layer in case of a three-layer device, the cathode, and finally some additional packaging material(s).

Polymeric materials such as polyester-based films have initially been heralded as desirable substrates because of the unique potential to create mechanically flexible displays (20). However, moisture and oxygen have to be rigorously excluded from the device so as to prevent rapid degradation of the EL polymer and the cathode. Thus, in view of the notoriously poor barrier characteristics of polymeric substrates, glass is the current substrate and packaging material of choice because of its unmatched barrier characteristics. Nevertheless, recent studies have shown that the barrier characteristics of polymeric substrates can greatly be improved by applying a coating of silicon nitride or silicon oxynitride through a vapor deposition process (21).

Essentially all PLED devices described in the literature rely on ITO as the high work function anode material, although a number of alternative transparent conducting oxides have become available (22). ITO offers good electrical conductivity and a transmittance of $>85\%$ at a film thickness of <150 nm, and allows the generated light to escape from the device. ITO-coated glass is routinely used as the electrode material in LCDs and a variety of other applications and is readily available at comparably low cost. Most importantly, ITO offers a work function

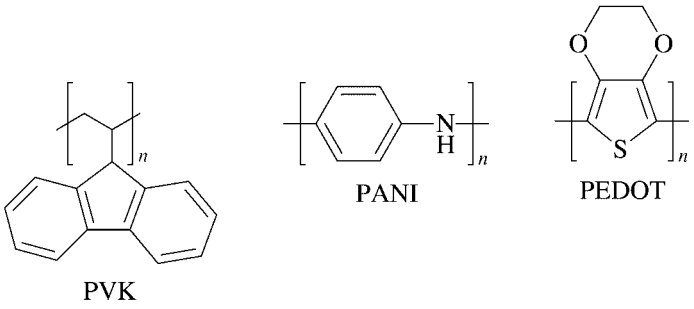

Fig. 3. Chemical structures of poly(vinylcarbazole) (PVK), poly(aniline) (PANI), and poly(3,4-ethylene dioxy thiophene) (PEDOT) which are frequently used as the hole-transport layer in two-layer devices.

of between 4.5 and 5.0 eV (relative to vacuum level), which matches the IP of frequently used conjugated organic polymers and allows for reasonably efficient hole-injection. Unfortunately, the electronic characteristics of ITO depend quite strongly on the manufacturing conditions and cleaning treatments. In addition, its surface structure can vary substantially, making the use of ITO often rather cumbersome.

As mentioned before, the two-layer architecture has become the preferred PLED embodiment (Fig. 1), thus requiring a first polymer layer with efficient hole-transport characteristics (6). Poly(vinylcarbazole) (PVK) is an extensively investigated, commercially available hole-conductor, which has been frequently used in this context (Fig. 3). Alternatively, polymeric triphenyldiamines have been employed (23). More recently, poly(aniline) (PANI) and poly(3,4-ethylene dioxy thiophene) (PEDOT) which are commercially available from Ormecon and Panipol Ltd. and Bayer AG, respectively, have found widespread application instead (4,10). Used in their electrically conducting form, these polymers not only allow efficient hole-injection and hole-transport, but also offer an effective electron transport. As a result, the electric field across this layer is dramatically reduced, limiting the undesired migration of charged species from the anode through the device (see LEDs (Light Emitting Diodes)).

Light generation is achieved in the actual light-emitting layer which, in a typical two-layer configuration, usually also acts as an electron-transport material; the design considerations for EL polymers are discussed in detail below, together with an overview of typical material systems.

Finally, a low work function cathode is required for electron-injection. A variety of different cathode materials have been employed, including Ca, Li, Mg, Al, Cr, or alloys of these metals, sometimes also combined with Ag. Since electron-injection is often a limiting factor for the device efficiency, the metal with the lowest work function of the above series (Ca, 2.9 eV) is a preferred option. However, while Ca-based devices may work well in the laboratory, the practical application of this metal is stifled by its sensitivity toward oxidation. Changing the cathode material to Mg (work function 3.7 eV) or Al (4.3 eV) leads to improved device stability, however, usually at the expense of an increase in driving voltage and a reduced device efficiency.

Development of EL Polymer Systems. The characteristics of the emissive layer are, of course, of predominant importance for optimum device performance. Thus, the design of light-emitting polymers has received particular attention during the last decade. In view of the abundance of EL polymers that have been synthesized and investigated to date (4–11), it is far beyond the scope of this review to provide a comprehensive overview. Consequently, a number of selected examples are presented which illustrate the various design concepts, are based on the most commonly employed building blocks, and are relevant from an application point of view. Important design considerations address the need for

(1) high intrinsic photoluminescence efficiency
(2) high purity (elimination of traps which provide nonemissive decay paths for excitons)
(3) adequate charge-transport characteristics (low barrier for charge-injection, reversible formation of charge carriers, balanced charge transport)
(4) appropriate color of emitted light
(5) high optical transparency (no re-absorption or scattering of the emitted light)
(6) good processability
(7) high film quality (homogeneous thickness of typically 50–500 nm, no pinholes or cracks, smooth surface, compatibility to adjacent layers)
(8) high thermomechanical stability (no softening under operating conditions)
(9) long lifetime (high thermal, light, oxidative, and environmental stability)
(10) low price

This list of fundamental requirements has indeed been a veritable challenge for materials design in terms of synthesis, understanding of structure–property relationships, and processing. The majority of the vast number of polymeric EL materials investigated to date origins from the family of conjugated polymers, ie, macromolecules featuring an extended π-conjugated backbone (Figs. 4a and b). Important examples of classes of conjugated polymers used as emitting layer in PLEDs (Fig. 5) include poly(arylene)s, poly(arylene vinylene)s, and, to some extent, also poly(arylene ethynylene)s (24). Unfortunately, the very same conjugation which renders these macromolecules semiconducting is also the origin of the difficulties that were initially encountered in attempts to process the early, more simple forms of these polymers into useful shapes, ie, high quality films. These difficulties are directly related to the fact that conjugated polymers are relatively rigid macromolecules which exhibit high melting enthalpies and low melting entropies, resulting in melting temperatures that are typically far beyond thermal decomposition. In addition, the nonpolar chemical nature of many conjugated polymers permits only modest enthalpic interactions with potential solvents, which prevents simple solution-processing. These problems have been overcome by a number of different design strategies which, naturally, follow those already successfully applied for nonconjugated rigid-rod polymers (25). The latter include (*1*) the use of so-called precursor routes; (*2*) the derivatization of π-conjugated polymers with flexible (or alternatively bulky) side chains which increase the entropy

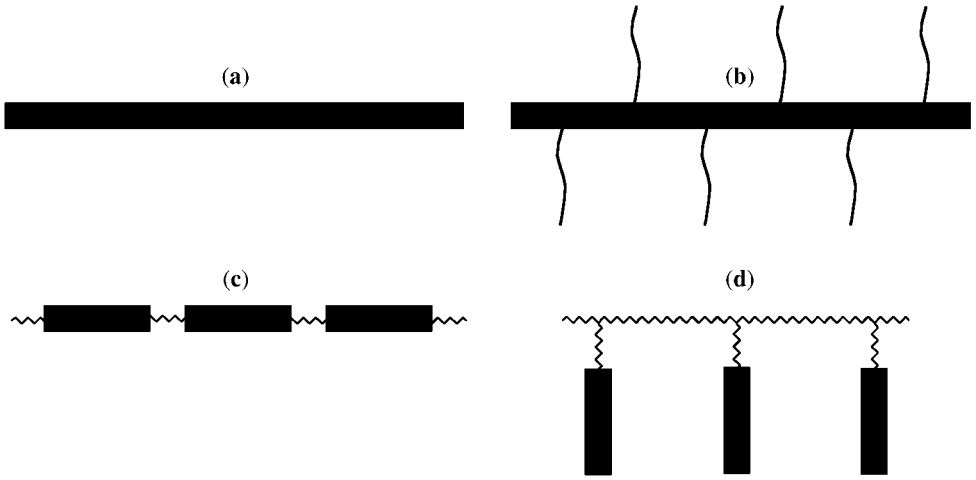

Fig. 4. Schematic representation of typical EL polymer architectures. (**a**) "Plain," conjugated main chain, (**b**) hairy-rod structure, (**c**) semiflexible, "segmented" structure, and (**d**) nonconjugated polymer with conjugated side chains. ▬, π-conjugated moiety; ∿∿, flexible segment; and —, solubilizing side chain.

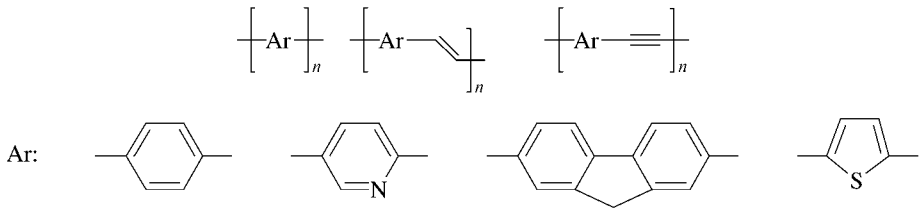

Fig. 5. Chemical structures (generalized) of different classes of conjugated polymers used as EL materials.

gain upon dissolution (and also reduce interchain interactions) and, thus, render the polymer soluble (Fig. 4b); (*3*) the introduction of flexible "spacer" units between the conjugated moieties which reduce the overall rigidity of the polymer backbone, again leading to improved solubility (Fig. 4c); and (*4*) the use of nonconjugated, processable polymers which feature the conjugated moieties in the form of side chains (Fig. 4d) *or* (*5*) as guest molecules which are not covalently connected to the matrix polymer but are rather dissolved or dispersed in the latter.

The so-called precursor route represents a particularly attractive way to synthesize and process underivatized π-conjugated polymers which were initially employed in many of the early studies on PLEDs, including PPVs and poly(*p*-phenylene)s (PPPs) (26,27). The concept relies on the three steps of synthesizing tractable, nonconjugated "precursor" macromolecules comprising appropriately selected leaving groups, processing of these precursor polymers according to standard (mostly solution-based) techniques, and converting the precursor

polymer into the final (intractable) conjugated species by (usually heat-induced) abstraction of the leaving group. A classical example is the synthesis of yellow-green-light-emitting PPV (see structure above) (28), which has been used and optimized by a variety of research groups (26,29). A special version of the precursor route that has received considerable attention in connection with the preparation of PPV-based LEDs makes use of a chemical vapor deposition (CVD) process (8,26). Here, the starting material is vaporized under high vacuum conditions and pyrolized to result in suitable monomers, which subsequently undergo CVD and polymerization on a substrate. This solvent-free process usually results in high quality films of a precursor-PPV, which can be subsequently converted to the conjugated form. However, all precursor methods suffer from major difficulties in that (*1*) the conversion from precursor to π-conjugated polymer is often not quantitative (leading to defects which may interrupt the conjugation in the polymer backbone), (*2*) the removal of low molecular weight conversion products (which may adversely affect some of the polymer's properties) is not trivial, (*3*) the precursor polymers often exhibit a limited oxidative stability, and (*4*) generally undesirable side reactions may occur. On the other hand, the process also allows to tune the material properties to a certain extent. For example, partial conversion of precursor/π-conjugated polymer results in segmented polymers (Fig. 4c) with improved performance and modified color of the emitted light, as described below.

A different approach is the design of inherently soluble, "hairy-rod" EL polymers according to the design strategy outlined in Fig. 4b. The latter allows film processing by standard solvent-based methods, eg, spin- and dip-coating, screen- and ink-jet printing, as well as Langmuir Blodgett (LB) techniques. The electronic properties of these macromolecules are primarily governed by the chemical structure of the conjugated polymer backbone itself, but a number of additional tools can be employed to further manipulate band gap (emission color), charge-injection/charge-transport characteristics, thermomechanical stability, thermal/oxidative stability, and other relevant properties (4,6,8,11). The incorporation of electron-deficient aromatic rings and the integration of electron-withdrawing or electron-donating substituents into the conjugated system are illustrative examples of how the electronic characteristics can be varied over a wide range. Another important general tool for property tailoring is the control of the effective conjugation length through the introduction of side chains which exhibit steric interactions and force the backbone to twist, or by using copolymers that comprise well-defined conjugated segments that are separated by aliphatic "spacer" moieties (Fig. 4c). Such segmented conjugated polymers (Fig. 4c), nonconjugated polymers with conjugated side chains (Fig. 4d), and also blends of nonconjugated matrix polymers and low molecular weight EL compounds (in which the crystallization-induced segregation of the EL guest molecules and the polymeric matrix poses a serious problem) were reviewed extensively in the literature (4,6,8,11,26). The nonconjugated spacer moieties disrupt the electronic conjugation, concomitant with a shift of the band gap toward higher energies, ie, into the blue regime of the visible spectrum, which with extended conjugated structures has proven to be difficult to access. Moreover, confinement of excitons is achieved by stifling the migration of the latter to quenching sites, which usually leads to

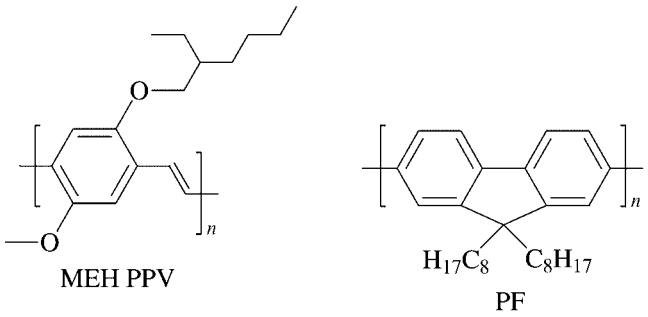

Fig. 6. Chemical structures of poly[2-methoxy-5-(2′-ethylhexyloxy)-*p*-phenylene vinylene] (MEH PPV) and poly(9,9-dioctyloxy fluorene).

an appreciable enhancement of luminescence efficiency. However, as mentioned heretofore, the nonconjugated moieties disrupt the electronic conjugation, suggesting intrinsic limitations with respect to charge transport (it should be noted in this context that also polymers with a fully conjugated backbone structure feature only a finite effective conjugation length which in case of PPV, for example, extends over less than 10 repeat units, cf Ref. 8).

From the multitude of organo-soluble conjugated EL materials investigated to date, two classes of materials seem to have shown the most promising overall matrix of properties, at least from an industrial point of view, namely derivatized PPVs and poly(fluorene)s. The most widely studied soluble PPV derivative is the orange-light-emitting poly[2-methoxy-5-(2′-ethylhexyloxy)-*p*-phenylene vinylene] (MEH PPV) which was introduced in 1991 (30). It was the first soluble light-emitting material to be used in a PLED (Fig. 6) (31). The alkyloxyy substituents not only render the polymer soluble but also shift the EL emission to higher wavelengths when compared to the parent PPV. A wide variety of poly(2,5-dialkoxy-*p*-phenylene vinylene)s and other 2,5-derivatized PPVs have since been investigated (4,6), and a few PPV derivatives, including a phenyl-substituted-PPV, have been developed for commercial exploitation for example by Covion and are used in the pilot production of Philips Electronics and Uniax Corp. (32). Besides the PPVs, poly(9,9-dialkyl fluorene)s (Fig. 6) have recently emerged as an extremely promising class of polymeric light-emitting materials (10), and a series of poly(fluorene) homo- and copolymers have been developed by the Dow Chemical Co. (32).

Towards Technological Exploitation

Only a decade after the first demonstration of electroluminescence in polymeric materials, the performance of PLEDs now appears to meet many of the requirements for applications at the low performance end of the display market, and the field has matured to the point of commercial exploitation; the most current overview of the state-of-the-art can be found in an outstanding review (4). A number of electronics and polymer companies, including Cambridge Display Technology Ltd., Covion, Dow Chemical Co., Philips Electronics, and Uniax Corp., have

disclosed prototypes or pilot products that offer a luminous efficiency η_{lum} between 10 and 22 lm/W at an (average) brightness between 100 and 1000 cd/m^2 (4,10,32). Thus, these devices clearly meet the brightness requirements for many display applications and also match the efficiency of conventional inorganic LEDs incandescent lamps. However, it should be noted that bright and efficient devices are primarily available in the green range of the emission spectrum, while presently available blue- and red-light-emitting materials result in devices which are substantially less bright and efficient (4,7). Thus, substantial progress regarding the availability of different colors is required before full-color devices based on red, green, and blue pixels can be made available.

Probably, one of the most critical aspects from an application point of view is that of device lifetime. Although the requirements for the latter strongly depend of the particular application, operating lifetimes of >10,000 h are usually targeted (4,5), often at elevated temperatures. Detailed studies conducted at a variety of laboratories (4,10) have indeed demonstrated that this requirement can, in principle, be met when adequately packaging the device. However, most of the "successful" lifetime studies were conducted under constant current conditions, and a gradual rise of the driving voltage was reported to maintain the initial current and brightness. This situation not only suggests an irreversible degradation of the device but also presents a challenge for the electronic device drivers.

The most basic device architecture of PLEDs has been described above; most technical applications rely on much more sophisticated designs. For example, almost every display application will demand arrays of many individually addressable pixels, similar to conventional LCDs (Fig. 7). Pixilated PLEDs rely on the creation of a "grid" of intersecting anode and cathode rows, which is usually generated by photolithographic patterning of the ITO anode into columns and vapor deposition of the cathode rows through a corresponding mask. As it is well known for LCDs (33), the devices can be operated in either passive- or active-matrix mode. Passive-matrix addressing relies on the consecutive addressing of the rows (typically within a period of 1/30 s or less) and on applying a simultaneous bias to the columns holding active pixels. Where an active row and column intersect, the electric field directly causes EL emission. This format, which is usually used for low resolution applications, requires high scanning rates in order to avoid flickering of the image. Moreover, because each pixel is active only for a short fraction of the cycle, it will require to generate very high intensity (ie, >10,000 cd/m^2) under a high current density during its "on" state in order to produce an acceptable average luminance. The active matrix architecture moderates the need to cycle at high rates by giving every pixel a "memory" in the form of a capacitor and a transistor. While this architecture seems mandatory for high resolution and large-area displays, it adds, of course, another layer of complexity to the device.

Another step toward high end application is, of course, the creation of multicolor devices, featuring red, green, and blue pixels. A variety of approaches have been suggested to achieve the latter, including (*1*) the use of uv or blue LEDs and external color conversion through green and red-light-emitting fluorescent dyes applied to the appropriate pixels, (*2*) the use of white LEDs in combination with conventional absorbing color filters, (*3*) the stacking of individual, independent device segments in vertical fashion, and (*4*) the use of advanced deposition

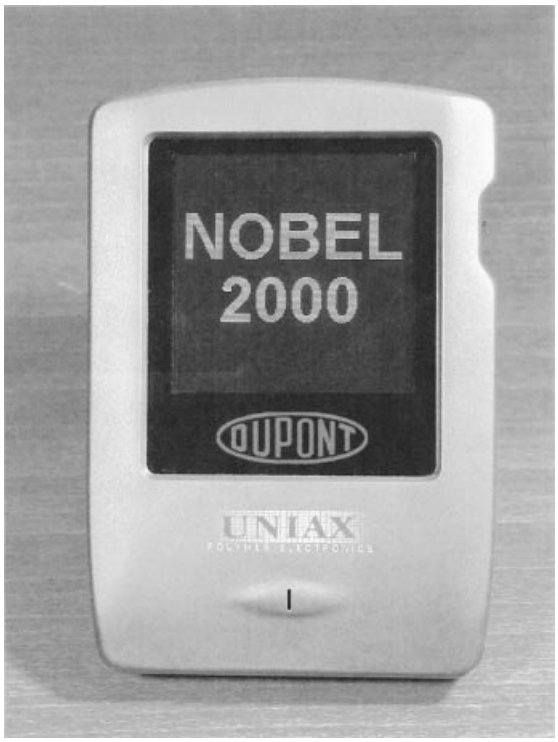

Fig. 7. Polymer LED passive matrix display; 160 × 160 pixels with pitch of 300 μm. Picture provided by Nobel Laureate Dr. Alan J. Heeger, courtesy of Uniax Corp., Santa Barbara, Calif.

processes that allow the deposition of different EL polymers in patterned fashion, for example, by ink-jet printing (4).

Another exciting development has been the design of PLEDs which emit linearly polarized light and, among other applications, might find use as backlights of conventional LCDs (8,34). The central feature in these devices is a high degree of uniaxial supramolecular orientation of the light-emitting polymer layer, which is most easily achieved by using thermotropic liquid-crystalline PLED materials such as poly(9,9-dialkyl fluorene)s or segmented poly(arylene vinylene)s. Monodomain alignment in thin films of these materials is usually accomplished by using an alignment layer such as a rubbed poly(imide) film, leading to highly polarized photo- and electroluminescence, with dichroic ratios (ratio of the intensity of emitted light polarized parallel and perpendicular to the orientation direction, respectively) that can exceed 20.

After only a decade of development, PLEDs indeed seem to have matured to the edge of commercial exploitation. The technology is expected to initially address the market for small- and medium-sized alphanumeric displays, as used in calculators, handheld telephones, pagers, car radios, personal digital assistants information readouts on household appliances, and in automobiles, which has a current annual volume of about US$2.5 billion, with high growth rates expected.

The display technologies traditionally employed in these applications are LCDs, vacuum fluorescence displays, and inorganic LEDs. Industrial sources estimate that by 2004–2005, organic LEDs (including PLEDs as well as LEDs based on small organic molecules) may capture between US$350 to US$700 million of that market (3,35). In the long run, PLEDs also have the potential to replace current high resolution video-rate displays in, eg, desktop monitors, ultrathin television sets, and the like.

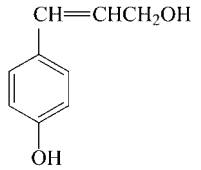
LIGNIN

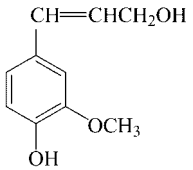
Introduction

The word lignin is derived from the Latin word *lignum* meaning wood. It is a main component of vascular plants. Indeed, lignin is second only to polysaccharides in natural abundance, contributing 24–33% and 19–28%, respectively, to dry wood weights of normal softwoods and temperate-zone hardwoods.

According to a widely accepted concept, *lignin* [8068-00-6] may be defined as an amorphous, polyphenolic material arising from enzymatic dehydrogenative polymerization of three phenylpropanoid monomers, namely, coniferyl alcohol [485-35-5] (**2**), sinapyl alcohol [537-35-7] (**3**), and *p*-coumaryl alcohol (**1**).



(**1**)



(**2**)

(**3**)

The traditionally held biosynthesis process, which consists essentially of random radical coupling reactions, sometimes followed by the addition of water, of primary, secondary, and phenolic hydroxyl groups to quinonemethide intermediates, leads to the formation of a three-dimensional polymer that lacks the regular and ordered repeating units found in other natural polymers such as cellulose and proteins. Traditionally no other enzymes or proteins are thought to be required (1).

The random biosynthesis process is under review. Dirigent proteins, acting as templates, are proposed to assist the orientation of lignin precursors to afford stereoselective phenoxy radical coupling (2,3).

Normal softwood lignins are usually referred to as guaiacyl lignins because the structural elements are derived principally from coniferyl alcohol (more than 90%), with the remainder consisting mainly of *p*-coumaryl alcohol-type units. Normal hardwood lignins, termed guaiacyl–syringyl lignins, are composed of coniferyl alcohol and sinapyl alcohol-type units in varying ratios. In hardwood lignins, the methoxyl content per phenylpropanoid unit is typically in the range of 1.2–1.5 (4). Grass lignins are also classified as guaiacyl–syringyl lignins. However, unlike hardwood lignins, grass lignins additionally contain small but significant amounts of structural elements derived from *p*-coumaryl alcohol. Grass lignins also contain *p*-coumaric, hydroxycinnamic, and ferulic acid residues attached to the lignin through ester and ether linkages (5).

The distribution of lignin in individual cells of lignified wood has been well examined. The lignin concentration is rather uniform across the secondary wall, but there is a significant increase in lignin concentration at the boundary of the middle lamella and primary wall region (6). This pattern of lignin distribution, with the highest concentration in the interfiber region and a lower, uniform concentration in the bulk of the cell walls, is typical for most wood cells. Thus lignin serves the dual purpose of binding and stiffening wood fibers through its distribution between and in the cell walls.

Lignin performs multiple functions that are essential to the life of the plant. By decreasing the permeation of water across the cell wall in the conducting xylem tissues, lignin plays an important role in the internal transport of water, nutrients, and metabolites. It imparts rigidity to the cell walls and acts as a binder between wood cells, creating a composite material that is outstandingly resistant to compression, impact, and bending. It also imparts resistance to biological degradation.

In commercial chemical pulping of wood, the reverse process in nature is performed to isolate fibers for papermaking. In the process, wood is delignified by chemically degrading and/or sulfonating the lignin to water-soluble fragments. The industrial lignins thus obtained are used in many applications.

Structure and Reactions

The structural building blocks of lignin are linked by carbon–carbon and ether bonds (7,8). Units that are trifunctionally linked to adjacent units represent branching sites which give rise to the network structure characteristic of lignin (see Figs. 1 and 2). Thus lignin consists of complex and diverse structures, including in softwood lignin an eight-member ring configuration (dibenzodioxocin) (11).

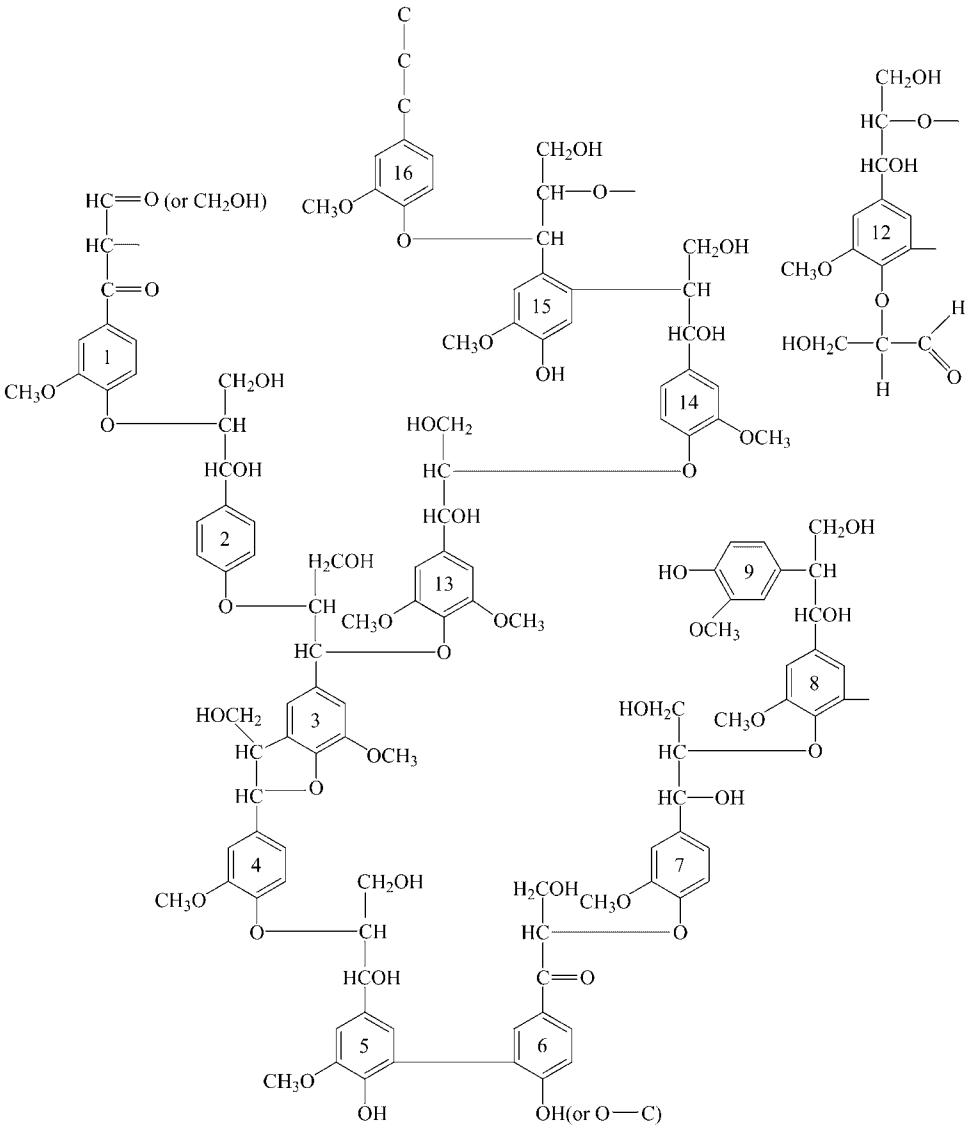

Fig. 1. Structural model of spruce lignin (9).

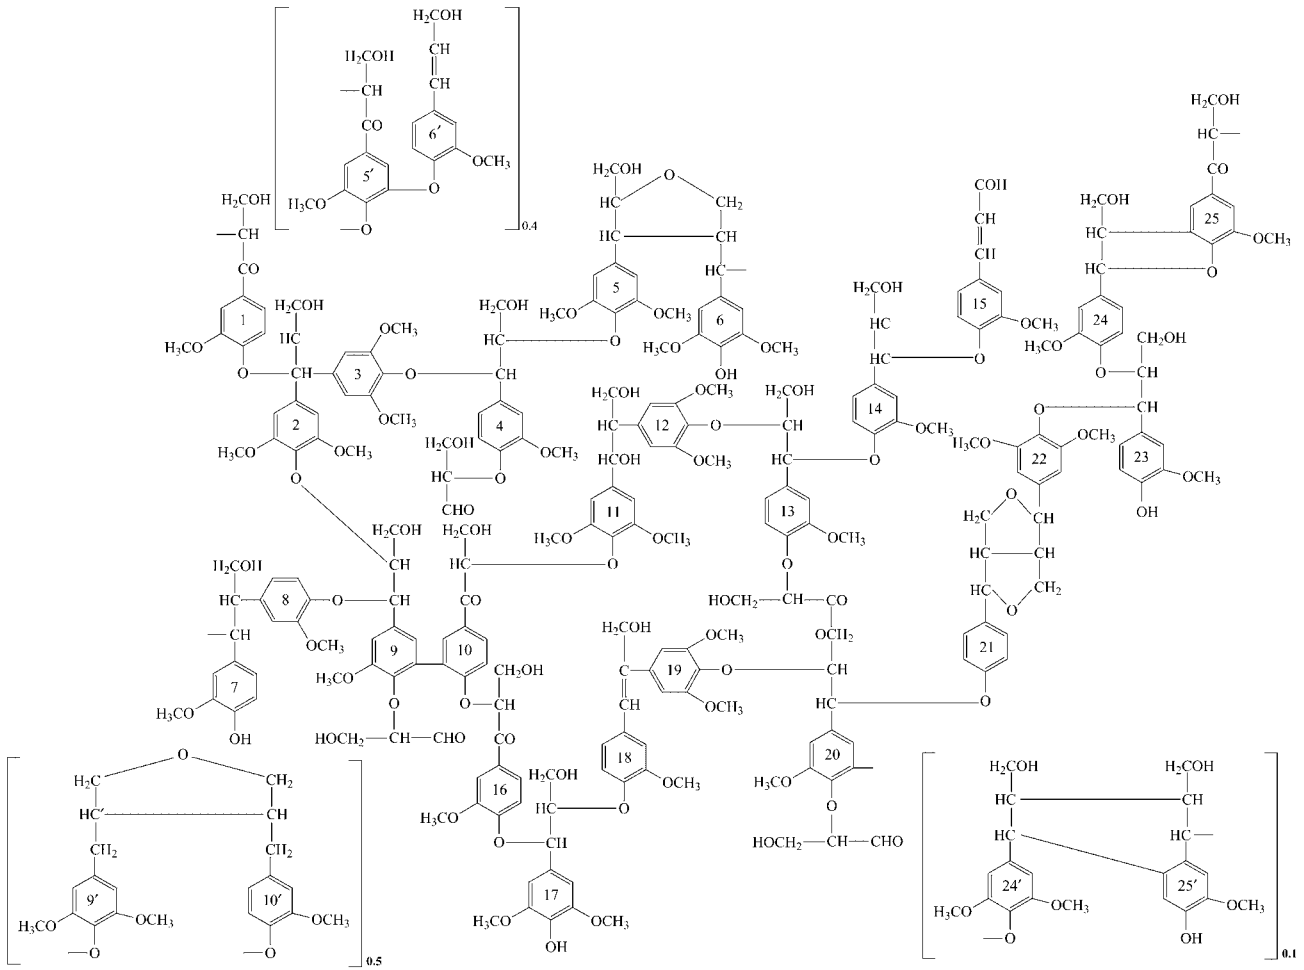

Fig. 2. Structural model of beech lignin (10).

Table 1. Types and Frequencies of Interunitary Linkages in Softwood and Hardwood Lignins (Number of Linkages per 100 C_9 Units)

Linkage	Softwood lignin[a]	Hardwood lignin[b]
β–*O*–4	49–51	65
α–*O*–4	6–8	
β–5	9–15	6
β–1	2	15
5–5	9.5	2.3
4–*O*–5	3.5	1.5
β–β	2	5.5

[a]Ref. 12.
[b]Ref. 7.

The types and frequencies of several prominent interunitary lignin linkages are summarized in Table 1.

Because the interunit carbon–carbon linkages are difficult to rupture without extensively fragmenting the carbon skeleton of the lignin, solvolysis of the ether linkages is often utilized as the best approach for degrading lignin. Of the functional groups attached to the basic phenylpropanoid skeleton, those having the greatest impact on reactivity of the lignin include phenolic hydroxyl, benzylic hydroxyl, and carbonyl groups. The frequency of these groups may vary according to the morphological location of lignin, wood species, and method of isolation.

Electrophilic Substitution. The processes by which the aromatic ring in lignin is modified by electrophilic substitution reactions are chlorination, nitration, and ozonation. Chlorination, widely used in multistage bleaching sequences for delignifying chemical pulps, proceeds by a rapid reaction of elemental chlorine with lignin in consequence of which the aromatic ring is nonuniformly substituted with chlorine. In nitration, nitro groups are introduced into the aromatic moiety of lignin with nitrogen dioxide (13). As one of several competing processes, electrophilic attack of ozone on lignin ultimately leads to ring hydroxylation (14).

Conversion of Aromatic Rings to Nonaromatic Cyclic Structures. On treatment with oxidants such as chlorine, hypochlorite anion, chlorine dioxide, oxygen, hydrogen peroxide, and peroxy acids, the aromatic nuclei in lignin typically are converted to *o*- and *p*-quinoid structures and oxirane derivatives of quinols. Because of their relatively high reactivity, these structures often appear as transient intermediates rather than as end products. Further reactions of the intermediates lead to the formation of catechol, hydroquinone, and mono- and dicarboxylic acids.

Aromatic rings in lignin may be converted to cyclohexanol derivatives by catalytic hydrogenation at high temperatures (250°C) and pressures [20–35 MPa (200–350 atm)] using copper–chromium oxide as the catalyst (15). Similar reduction of aromatic to saturated rings has been achieved using sodium in liquid ammonia as reductants (16).

Conversion of Cyclic to Acyclic Structures. Upon oxidation, the aromatic rings of lignin may be converted directly to acyclic structures, eg, muconic acid derivatives, or indirectly by oxidative splitting of *o*-quinoid rings. Further oxidation creates carboxylic acid fragments attached to the lignin network.

Ring Coupling and Condensation Reactions. Many oxidants, eg, ClO_2, O_2, generate free radicals in lignin. Coupling of such reactive radicals ultimately leads to diphenyl structures. In alkaline media, phenolic units may react with formaldehyde forming methylol derivatives that condense with themselves or with other phenols. This formaldehyde condensation reaction is the basis for using technical lignins in the preparation of adhesives.

Cleavage of Ether Bonds. Ether linkages at the α- and β-positions are the most abundant functional groups on the propanoid side chain of lignin. Under acidic conditions these linkages undergo solvolytic cleavage, initially forming secondary alcohols which are converted to carbonyl, ethylene, and carboxyl structures through a combination of dehydrations and allylic rearrangements, leading eventually to fragmentation of the side chain (17).

The alkali-promoted cleavage of α- and β-ether linkages, an important step in alkaline pulping processes, is mainly responsible for the fragmentation and dissolution of lignin in the pulping liquor. Addition of bisulfide ion to the aqueous alkaline media, as in the case of kraft pulping, enhances the rate and extent of β-aryl ether cleavage in phenolic units (18).

Cleavage of Carbon–Carbon Bonds. Under appropriate conditions, the propanoid side chain in lignin may be ruptured to form three-, two-, or one-carbon fragments. This carbon–carbon fragmentation occurs in a variety of laboratory treatments and technical processes such as in bleaching of chemical pulps with Cl_2, ClO_2, and O_2, in microbial degradation (19), and in photo-oxidation (20).

Substitution Reactions on Side Chains. Because the benzyl carbon is the most reactive site on the propanoid side chain, many substitution reactions occur at this position. Typically, substitution reactions occur by attack of a nucleophilic reagent on a benzyl carbon present in the form of a carbonium ion or a methine group in a quinonemethide structure. In a reversal of the ether cleavage reactions described, benzyl alcohols and ethers may be transformed to alkyl or aryl ethers by acid-catalyzed etherifications or transetherifications with alcohol or phenol. The conversion of a benzyl alcohol or ether to a sulfonic acid group is among the most important side-chain modification reactions because it is essential for the solubilization of lignin in the sulfite pulping process (21).

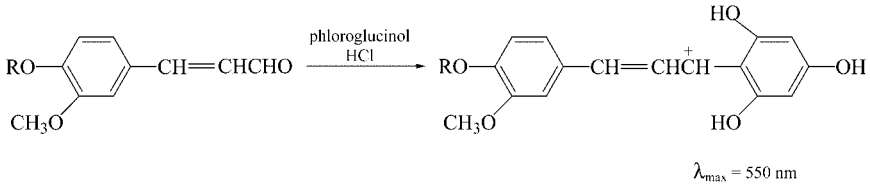
Formation and Elimination of Multiple Bond Functionalities. Reactions that involve the formation and elimination of multiple bond functional groups may significantly affect the color of residual lignin in bleached and unbleached pulps. The ethylenic and carbonyl groups conjugated with phenolic or quinoid structures are possible components of chromophore or leucochromophore systems that contribute to the color of lignin.

Reduction of ring-conjugated carbonyl groups to the corresponding primary and secondary alcohols is generally achieved by reaction with sodium borohydride. Ring-conjugated olefinic groups may be converted to their saturated components by hydrogenation.

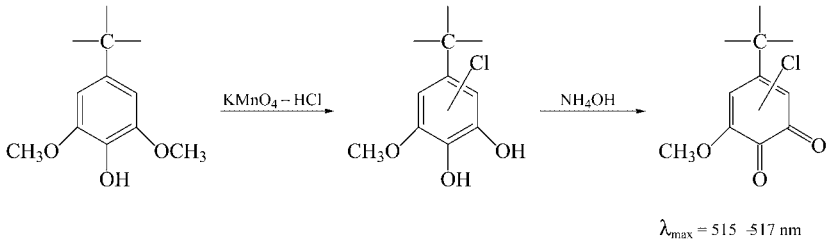
Analytical Methods

Detection of Lignin. The characteristic color-forming response of lignified tissue and some lignin preparations on treatment with certain organic and inorganic reagents was recognized in the early nineteenth century. More than 150 color reactions have now been proposed for the detection of lignin (22). Reagents used in these reactions may be classified into aliphatic, phenolic, and heterocyclic compounds, aromatic amines, and inorganic chemicals. Among the important reactions are the Wiesner and Mäule color reactions.

The Wiesner Reaction. The reaction of lignified tissue and phloroglucinol–hydrochloric acid gives a visible absorption spectrum with a maximum at 550 nm. This has been attributed to coniferaldehyde units in lignin as the groups responsible for the color formation.



The Mäule Color Reaction. The procedure for this test consists basically of three sequential treatments of lignified material with 1% potassium permanganate, 3% hydrochloric acid, and concentrated ammonium hydroxide. A red-purple color develops for hardwoods and a brown color for softwoods. The steps comprising the Mäule reaction may be represented as follows (23,24):



Determination of Lignin Content. Lignin content in plants (wood) is determined by direct or indirect methods (25). The direct method includes measurement of acid-insoluble (ie, Klason) lignin after digesting wood with 72% sulfuric acid to solubilize carbohydrates (26). The Klason lignin contents of representative lignified materials are shown in Table 2.

In contrast to the direct determination of lignin content, indirect methods do not involve the isolation of a lignin residue. These include spectrophotometric methods and procedures that are based on oxidant consumption. A uv microspectrophotometric method has been used to determine the distribution of lignin in the various cell wall regions of softwoods (27). Supplementing the uv-microscopic technique is a method in which lignin is brominated and the bromine uptake,

Table 2. Klason Lignin Contents of Lignified Materials[a]

Material	Klason lignin content, %
Softwoods	26–28.8

[a]Ref. 25.

which is proportional to the lignin content, is determined by a combination of scanning or transmission electron microscopy (sem or tem) and energy dispersive x-ray analysis (edxa) (28). A number of spectral methods for determining lignin content are based on totally dissolving the sample in a suitable solvent and measuring the uv absorbance of the solution. Among the solvents used to dissolve lignocellulosic material are sulfuric acid, phosphoric acid, nitric acid, cadoxene, and acetyl bromide in acetic acid. The acetyl bromide method appears to have gained the most widespread acceptance (29).

The methods of oxidant consumption are used exclusively in the analysis of residual lignin in unbleached pulps. These procedures are all based on the common principle that lignin consumes the applied oxidants at a much faster rate than the carbohydrates, and oxidant consumption under carefully specified conditions can be regarded as a measure of lignin concentration in the pulp.

Two oxidants commonly used are chlorine and potassium permanganate. The *Roe chlorine number*, the uptake of gaseous chlorine by a known weight of unbleached pulp [ie, Technical Association of the Pulp and Paper Industry (TAPPI) Standard Method T202 ts-66] has been superseded by the simpler hypo number (ie, TAPPI Official Test Method T253 om-86), eg, chlorine consumption in treatment of the pulp with acidified sodium or calcium hypochlorite.

By far the most commonly used oxidation method is the corrected permanganate number test (30) in which the number of mL of 0.1 *N* $KMnO_4$ consumed by 1 g of oven-dried pulp under specified conditions (kappa number) is determined (TAPPI Historical Method T236 hm-85). Typical kappa numbers for representative pulps are shown in Table 3.

Characterization of Lignin. Lignin is characterized in the solid state by Fourier transform infrared (ftir) spectroscopy, uv microscopy, interference microscopy, cross polarization/magic angle spinning nuclear magnetic resonance (cp/mas nmr) spectroscopy, photoacoustic spectroscopy, Raman spectroscopy,

Table 3. Kappa Numbers for Typical Pulps[a]

Pulp	Kappa number range
Kraft (bleached grade)	
Softwood	25–35
Hardwood	14–18
Neutral sulfite semichemical (softwood)	80–100
Bisulfite (softwood)	30–50
Acid sulfite	
Softwood	16–22
Hardwood	14–20
Kraft (chlorinated and alkali extracted)	
Softwood	5–8
Hardwood	3–6

pyrolysis-gas chromatography–mass spectroscopy, and thermal analysis. In solution, lignins are characterized by spectral methods such as uv spectroscopy, ftir spectroscopy, ^{1}H nmr spectroscopy, ^{13}C nmr spectroscopy, electron spin resonance spectroscopy (esr), and by several chemical degradation methods such as acidolysis, nitrobenzene and cupric oxidations, permanganate oxidation, thioacidolysis, hydrogenolysis, nuclear exchange reaction, ozonation and dfrc (derivitization followed by reductive cleavage). The details of these characterization methods have been discussed (31,32).

FTIR spectroscopy is a versatile, rapid, and reliable technique for lignin characterization. Using this technique, the *p*-hydroxyphenyl, guaiacyl, and syringyl units, methoxyl groups, carbonyl groups, and the ratio of phenolic hydroxyl to aliphatic hydroxyl groups can be determined. The uv microscopy method is best suited for investigating the topochemistry of lignin in wood, namely, for determining the concentration and chemical structure of lignin in different layers of the cell wall. CP/MAS NMR spectroscopy provides for another spectral technique whereby lignin can be characterized in the solid state. Results obtained by cp/mas nmr are in good agreement with Klason lignin contents for softwoods.

In solution, lignin is most conveniently analyzed qualitatively and quantitatively by uv spectroscopy. Typical absorptivity values D at 280 nm for milled wood lignins MWL(s) and other types of lignins are listed in Table 4. These values are used for quantitative determination of the lignins in suitable solvents.

^{1}H and ^{13}C nmr spectroscopies provide detailed information on all types of hydrogen and carbon atoms, thus enabling identification of functional groups and types of linkages in the lignin structure. Detailed assignments of signals in ^{1}H and ^{13}C nmr spectra have been published (34,35). A review of the use of ^{31}P nmr as an analytical tool for lignin is available (36). Through phosphitylation of the various hydroxyl groups present in lignin, unique quantitative and qualitative information has been obtained.

Electron spin resonance (esr) and electron paramagnetic resonance (epr) spectroscopy are essential tools for the study of structure and dynamics of molecular systems containing one or more unpaired electrons. These methods have found application as a highly sensitive tool for the detection and identification of

Table 4. Absorptivity Values *D* of Lignin at 280 nm[a]

Lignin	*D*, L/(g·cm)	Solvent

[a]Ref. 33.

free-radical species in lignin and lignin model compounds (37,38). Milled wood lignin generally exhibits a singlet esr signal with a *g*-value of 2.0023 and a line width of 1.6 mT (16 G), typical of a phenoxy radical.

Among the chemical degradation methods, acidolysis, nitrobenzene and cupric oxide oxidations, permanganate oxidation, thioacidolysis, and hydrogenolysis are all based on a common principle of chemically degrading lignin polymers to identifiable low molecular weight products through side-chain cleavages and maintaining the aromatic nature of the lignin units. By these methods, the make-up of monomeric units in the lignin (eg, guaiacyl–syringyl–*p* -hydroxyphenyl ratio) is determined. In addition, the identification of dimeric and trimeric degradation products reveals the types of linkages existing in the lignin. A new degradation method termed dfrc (derivatization followed by reductive cleavage) has been found to be simpler and is gaining acceptance (39). Combination of dfrc with ^{31}P nmr has revealed information about the structural nature of hydroxyl-bearing moieties of lignin (40).

A technique based on ozonation, in contrast, provides information on the structure of the lignin side chain by degrading the aromatic rings (41). Thus the side chain of the dominant structure in all native lignins, the arylglycerol–β-aryl ether moiety, can be obtained in the form of erythronic and threonic acids. Ozonation proves to be an elegant method for determination of the stereospecificity in lignin.

The quantities of noncondensed and condensed phenyl nuclei in various lignins and in the morphological regions of cell walls are determined by a nucleus exchange method (42). The data obtained from this method indicate that lignin in the middle lamella is more condensed than lignin in the secondary wall and that hardwood lignin is less condensed than softwood lignin. By combining nucleus exchange with nitrobenzene oxidation, the methylol groups formed in the condensation of lignin with formaldehyde can be directly measured without isolation of the lignin.

Functional Group Analysis. The move toward instrumental analysis and away from wet methods is illustrated in the methods of analysis of the various fuctional groups present in lignin. NMR has become a particularly useful tool.

Each section below contains information about both the classical wet method as well as references to the most current instrumental techniques.

The total hydroxyl content of lignin is determined by acetylation with an acetic anhydride–pyridine reagent, followed by saponification of the acetate, and followed by titration of the resulting acetic acid with a standard 0.05 *N* NaOH solution. Either the Kuhn–Roth (43) or the modified Bethge–Lindstrom (44) procedure may be used to determine the total hydroxyl content. The aliphatic hydroxyl content is determined by the difference between the total and phenolic hydroxyl contents. Total hydroxyl content has been determined, after derivitization, by ^{31}P, ^{13}C, ^{1}H, and ^{19}F nmr techniques. This was recently reviewed (45).

The phenolic hydroxyl group is one of the most important functionalities affecting the chemical and physical properties of lignin. It facilitates the base-catalyzed cleavage of interunitary ether linkages and oxidative degradation, and has a pronounced influence on the reactivity of lignin polymers in various modification reactions such as sulfomethylation with formaldehyde and bisulfite. Regarding classical analysis, the periodate method is based on the oxidation of a phenolic guaiacyl group with sodium periodate to orthoquinone structures, wherein nearly 1 mole of methanol per mole of phenolic hydroxyl group is released (46). Measurement of the methanol formed is approximately equivalent to the phenolic hydroxyl content. Another classic method is aminolysis (44) consisting of acetylation of lignin and aminolysis with pyrrolidine to remove acetyl groups such as 1-acetylpyrrolidine. The amount of removed acetyl is a measure of the phenolic hydroxyl content of lignin. These and other procedures for determining phenolic hydroxyl groups have been compared (47). The advantages and disadvantages of each of these methods compared with nmr spectroscopy has also been discussed (45). A simple and reliable ^{1}H nmr method that does not require derivitization has been reported. This method relies on D_2O exchange of the phenolic proton. An instrument capable of 500 MHz or greater is required (48). Table 5 lists the total phenolic and aliphatic hydroxyl contents of some representative milled wood, bamboo, and technical lignins.

As early as 1922, the presence of carbonyl groups in spruce lignin was postulated (50). Coniferaldehyde [458-36-6] has definitely been identified as a building block in lignin, and the α-carbonyl content has been found to increase in the milling of wood and during pulping processes. The total carbonyl content of lignin is determined by a borohydride or hydroxylamine hydrochloride method (51),

Table 5. Phenolic and Aliphatic Hydroxyl Contents of Milled Wood and Technical Lignins[a]

	Hydroxyl content, mol/C_9 unit		
Lignin	Total	Phenolic	Aliphatic
Spruce MWL	1.46	0.28	1.18
Bamboo MWL	1.49	0.36	1.13

[a]Ref. 54.

and the α-carbonyl content from analysis of uv alkaline difference spectra. An ^{19}F nmr method employing quantitative trifluoromethylation of lignin was recently reported, which is claimed to be not only more precise than the previous methods, but can differentiate between the various types of carbonyl groups (52).

The method of choice for determining carboxyl groups in lignin is based on potentiometric titration in the presence of an internal standard, *p*-hydroxybenzoic acid, using tetra-*n*-butylammonium hydroxide as a titrant (53). The carboxyl contents of different lignins are shown in Table 6. In general, the carboxyl content of lignin increases upon oxidation.

Methoxyl groups are determined by the Viebock and Schwappach procedure (55). In treatment of lignin with hydroiodic acid, the methoxyl group is cleaved, forming methyl iodide which is quantitatively stripped from the reaction mixture and collected in a solution of sodium acetate and glacial acetic acid containing bromine. The bromine reacts with methyl iodide to form alkyl bromide and iodine bromide. The iodine thus produced is titrated with a dilute standard sodium thiosulfate solution by using 1% starch solution as an indicator. The methoxyl content can be quantitatively determined with high accuracy based on the quantity of iodine recovered. A technique that offers a simpler procedure using gas chromatography (gc) has been reported (56). This method relies on quantiative analysis of methyl iodide by gc after reaction with hydroiodic acid. This bypasses the complex apparatus, as well as the distillation, trapping, and titration steps.

Finally, the sulfonate content of lignin is determined by two main methods: one typified by conductometric titration in which sulfonate groups are measured directly, and the other which measures the sulfur content and assumes that all of the sulfur is present as sulfonate groups. The method of choice for determining the sulfonate content of lignin samples that contain inorganic or nonsulfonate sulfur, however, is conductometric titration (57).

Properties

Molecular Weight and Polydispersity. Because it is not possible to isolate lignin from wood without degradation, the true molecular weight of lignin

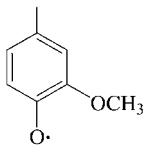
in wood is not known. Different methods for measuring the molecular weight of isolated lignins give various results, and aggregation of lignin molecules may prevent determination of real molecular weight. Light scattering and vapor-phase pressure osmometry are the traditional methods of analysis. Using these methods, the weight-average molecular weight M_w of softwood milled wood lignin is estimated to be 20,000; lower values have been reported for hardwoods (58).

Various methods based on sec (size exclusion chromatography) have been reported. An initial stumbling block for this method was an affinity between Lignin and early sec columns, and the use of linear polystyrene sulfonate standards (59). Since that time, various standardization techniques such as universal calibration, mals (multiple angle light scattering) and maldi-tof (matrix assisted laser desorption ionization-time of flight) mass spectrometry have been coupled with sec (60,61). With the maldi-tof method the M_w of softwood kraft lignin was found to be close to 3000. Purified softwood lignosulfonates have been estimated to have a M_w of 30,000 by mals (62). Kraft lignins invariably have lower molecular weights than lignosulfonates, indicative of a more extensive degradation of the lignin during the kraft pulping process. Hopefully, a method that gives the actual molecular weight of isolated lignins will be verified by one of the above listed techniques.

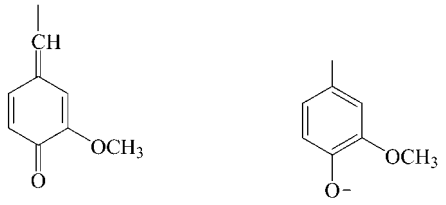
Solution Properties. Lignin in wood behaves as an insoluble, three-dimensional network. Isolated lignins (milled wood, kraft, or organosolv lignins) exhibit maximum solubility in solvents having a Hildebrand's solubility parameter, σ, of 20.5–22.5 $(J/cm^3)^{\frac{1}{2}}$ [10–11$(cal/cm^3)^{\frac{1}{2}}$], and $\Delta\mu$ in excess of 0.14 μm, where $\Delta\mu$ is the infrared shift in the O—D bond when the solvents are mixed with CH_3OD. Solvents meeting these requirements include dioxane, acetone, methyl cellosolve, pyridine, and dimethyl sulfoxide.

Thermal Properties. As an amorphous polymer, lignin behaves as a thermoplastic material undergoing a glass transition at temperatures that vary widely depending on the method of isolation, sorbed water, and heat treatment (62). Lignin stores more energy than cellulose in wood. For example, the glass-transition temperature T_g and heat capacity at 350 K for dioxane lignin are 440 K and 1.342 J/(g·K), respectively (63). Thermal softening of lignin at elevated temperatures accelerates the rate of delignification in chemical pulping and enhances the bond strength of fibers in paper- and boardmaking processes. In commercial thermomechanical pulping, a pretreatment of wood chips with sulfite lowers the T_g of lignin to 70–90°C (63), thus decreasing the power consumption in defibration. Other physical properties of lignin have been comprehensively reviewed (51).

Chemical Properties. Lignin is subject to oxidation, reduction, discoloration, hydrolysis, and other chemical and enzymatic reactions. Many are briefly described elsewhere (64). Key to these reactions is the ability of the phenolic hydroxyl groups of lignin to participate in the formation of reactive intermediates, eg, phenoxy radical (**4**), quinonemethide (**5**), and phenoxy anion (**6**):



(**4**)



(**5**) (**6**)

The free-radical intermediate initiates light-induced discoloration (yellowing) and enzymatic degradation of lignin (38,65). Nucleophilic addition occurs at the quinonemethide center, of which the most important reactions are the addition of sulfonate groups to the α-carbon during sulfite pulping and the sulfide assisted depolymerization in kraft pulping (Fig. 3).

The significance of phenoxy anions is well-recognized in the isolation of kraft and other water-insoluble technical lignins by acid precipitation. The ionization of phenolic hydroxyl groups coupled with the reduction of molecular size renders native lignin soluble in the aqueous pulping solution, thus enabling its separation from the polysaccharide components of wood.

The aromatic ring of a phenoxy anion is the site of electrophilic addition, eg, in methylolation with formaldehyde. The phenoxy anion is highly reactive to

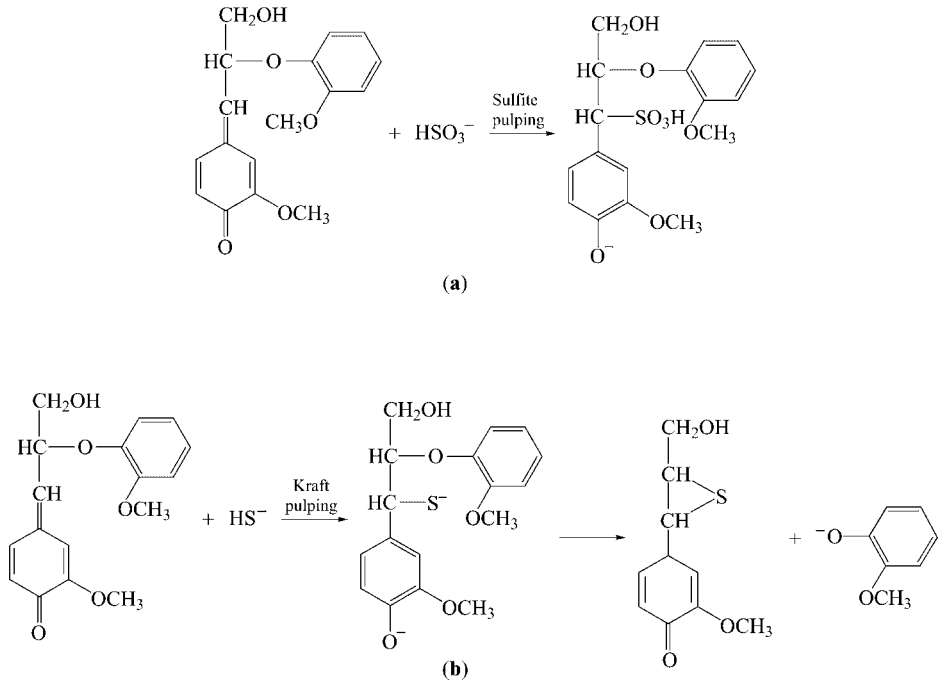


Fig. 3. Reactions at the quinonemethide center during pulping: (**a**) sulfite pulping and (**b**) kraft pulping.

many oxidants such as oxygen, hydrogen peroxide, ozone, and peroxyacetic acid. Many of the chemical modification reactions of lignin utilizing its aromatic and phenolic nature have been reviewed elsewhere (66).

During the last decade there has been increased interest in the use of lignolytic enzymes that degrade lignin, for the pulping of wood, bleaching of fiber, or for modification of lignin-based chemical feedstocks. The pretreatment of pulpwood with enzymes has seen limited commercial use. With a number of research groups dedicated to this technology, it should continue to gain commercial acceptance (67).

Industrial Lignins

Industrial lignins are by-products of the pulp and paper industry. Lignosulfonate [8062-15-5], derived from sulfite pulping of wood, and kraft lignin [8068-05-1], derived from kraft pulping, are the principal commercially available lignin types. Organosolv lignins [8068-03-9] derived from the alcohol pulping of wood are also reported to be available commercially, in the past, but is no longer available in any quantity (68).

The production capacity of lignin in the Western world is estimated to be ca 8×10^5 t/year (Table 7). Although the production of lignosulfonates has been declining, kraft lignin production has increased. Of the companies listed in Table 7, LignoTech Sweden and Westvaco produce kraft lignins. The rest produce lignosulfonates.

Advances in technology have increased the importance of lignin products in various industrial applications. They are derived from an abundant, renewable resource, and they are nontoxic and versatile in performance.

Lignosulfonates. Lignosulfonates, also called lignin sulfonates and sulfite lignins, are derived from the sulfite pulping of wood. In the sulfite pulping process, lignin within the wood is rendered soluble by sulfonation, primarily at benzyl alcohol, benzyl aryl ether, and benzyl alkyl ether linkages on the side chain of phenyl propane units (69). Some demethylation also occurs during neutral and alkaline sulfite pulping, and this leads to the formation of catechols and methane sulfonic acid (see Fig. 3).

Table 7. European and American Lignin Manufacturers

Producer	Country	Annual capacity, t/year
Borregaard LignoTech	Europe	400,000

Depending on the type of pulping process, lignosulfonates of various bases, including calcium [8061-52-7], sodium [8061-51-6], magnesium [8061-54-9], and ammonium lignosulfonates [8061-53-8], can be obtained. Typical compositions for hardwood and softwood spent sulfite liquors are given in Table 8. In addition to whole liquor products, commercial forms of lignosulfonates include chemically modified whole liquors, purified lignosulfonates, and chemically modified forms thereof.

Isolation of Lignosulfonates. Various methods have been developed for isolating and purifying lignosulfonates from spent pulping liquors. One of the earliest and most widely used industrial processes is the Howard process, where calcium lignosulfonates are precipitated from spent pulping liquor by addition of excess lime. Lignin recoveries of 90–95% are obtainable through this process. Other methods used industrially include ultrafiltration and ion exclusion (69), which uses ion-exchange resins to separate lignin from sugars.

Laboratory methods for isolating lignosulfonates include dialysis (71,72), electrodialysis (73), ion exclusion (73,74), precipitation in alcohol (75,76), and extraction with amines (77–79). They can also be isolated by precipitation with long-chain substituted quarternary ammonium salts (80–82).

Physical and Chemical Properties of Lignosulfonates. Even unmodified lignosulfonates have complex chemical and physical properties. Their molecular polydispersities and structures are heterogeneous. They are soluble in water at any pH but insoluble in most common organic solvents.

Typical C_9 formulas reported for isolated softwood and hardwood lignosulfonates are $C_9H_{8.5}O_{2.5}(OCH_3)_{0.85}\ (SO_3H)_{0.64}$ and $C_9H_{7.5}\ O_{2.5}(OCH_3)_{1.39}(SO_3H)_{0.68}$, respectively. These correspond to monomer unit molecular weights of 235 for softwood lignosulfonates and 254 for hardwoods. Polymer molecular weights are polydisperse and difficult to determine precisely. However, a range of 1000–140,000 has been reported for softwood lignosulfonates (83), with lower values reported for hardwoods (84).

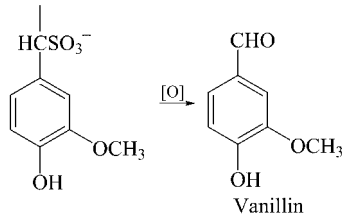
A number of different functional groups are present in lignosulfonates. ^{13}C nmr analysis of a purified sulfonated lignin from Western hemlock revealed 2.0% phenolic hydroxyl, 17.5% sulfonate, 12.5% methoxyl, and 0.6% carboxyl groups per unit weight of lignosulfonates (85). Additional studies indicate that

lignosulfonates also contain limited numbers of olefinic, carbonyl, and catechol groups (86).

Lignosulfonates exhibit surface activity but have only a slight tendency to reduce interfacial tension between liquids. When compared with true surface-active agents, they are not effective in reducing the surface tension of water or for forming micelles (87). Their surface activity can be improved, however, by introducing long-chain alkyl amines into the lignin structure (88), by ethoxylation of lignin phenolic structures (89), or by conversion to oil-soluble lignin phenols (90).

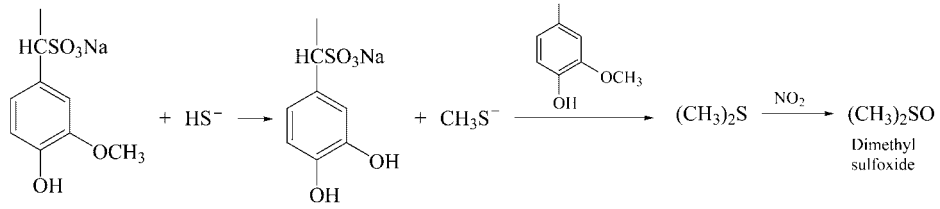
Lignosulfonate Uses. Worldwide, the single largest use of lignosulfonates is as water reducers for concrete. Both hardwood and softwood lignosulfonates are widely used as lower end water reducers. Recently, higher molecular weight products produced by fractionation of softwood lignosulfonates have been used as midrange water reducers, and efforts are underway to modify lignosulfonates for use as superplasticizers.

From a historical perspective, two other large-volume uses include production of vanillin and dimethyl sulfoxide (DMSO) (91). Commercially, softwood spent sulfite liquors or lignosulfonates can be oxidized in alkaline media by oxygen or air to produce vanillin [121-33-5].



Vanillin

Through reaction with sulfide or elemental sulfur at 215°C, lignosulfonates can also be used in the commercial production of dimethyl sulfide and methyl mercaptan (92). Dimethyl sulfide produced in the reaction is further oxidized to DMSO, a useful industrial solvent.



Dimethyl sulfoxide

Additional large-volume uses of lignosulfonates include animal feed pellet binders, dispersants for gypsum board manufacture, thinners/fluid loss control agents for drilling muds, dispersants/grinding aids for cement manufacture, and in dust control applications, particularly road dust abatement.

Lignin technology has advanced significantly, and increased research and development efforts have resulted in specialty uses in several key market areas.

Dye Dispersants. One such area is dye manufacture, where lignosulfonates act as primary dispersants, extenders, protective colloids, and grinding aids. Products produced by the reaction of lignosulfonates with benzyl alcohols have low azo dye reduction properties, low fiber-staining properties, high dispersion efficiency, good grinding aid qualities, and increased heat stability (66). Lignosulfonates prepared by sulfonation of kraft lignin are also widely used in this application. Such products are particularly useful in applications requiring superior heat stability.

Pesticide Dispersants. Modified lignosulfates and lignosulfonates derived from kraft lignins are used in the formulation of pesticides. In wettable powders, suspension concentrates, and water-dispersible granules, they act as dispersants and prevent sedimentation. They also act as binders in the production of granular pesticides. Typical usage levels in these types of products range from 2 to 10%.

Carbon Black Dispersant. Specially modified lignosulfonates are used in a wide range of pigment applications to inhibit settling and decrease solution viscosity. Applications include dispersants for dark pigment systems used to color textile fibers, coatings, inks , and carbon black. Lignosulfonates are also used as grinding aids and binders in the pelletizing of carbon black.

Water Treatment/Industrial Cleaning Applications. Boiler and cooling tower waters are treated with lignosulfonates to prevent scale deposition (93). In such systems, lignosulfonates sequester hard water salts and thus prevent their deposition on metal surfaces. They can also prevent the precipitation of certain insoluble heat-coagulable particles (94). Typical use-levels for such applications range from 1 to 1000 ppm.

In industrial cleaning formulations, lignosulfonates function as dirt dispersants and suspending agents (95). Rinsing properties are improved, corrosivity is reduced, and the amount of wetting agent needed is lowered when lignosulfonates are added to acid and alkaline industrial cleaning formulations. Typical use-levels in such formulations range from 0.05 to 2.0%.

Complexing Agent for Micronutrients. Complexes of lignosulfonates and iron, copper, zinc, manganese, magnesium, boron, or combinations of such are used to provide essential micronutrients to plants growing in metal-deficient soils. In most instances application of such complexes is by foliar spray. When applied in this manner the micronutrients can be readily absorbed by the plant without undesired leaf burn (96). Lignosulfonate complexes can also be used in soil treatment where they maintain availability of metals longer than if metals are applied alone (97).

Lignosulfonate–metal complexes are weaker complexes than those formed from amine-based complexing agents such as ethylenediaminetetracetic acid (EDTA). They are compatible with most pesticides/herbicides, but their use in phosphate fertilizers is not recommended

Oil-Well Cement Retarders. Sodium and calcium lignosulfonates are the most commonly used retarders for oil-well cements (98). They are effective with all Portland cements and are generally added in concentrations from 0.1 to 2%. Depending on their structure and purity and on the nature of the cement, they

are effective to about 250°F bottom hole circulating temperature. This range can be extended to 400°F by addition of sugar acids or sodium borate.

Expanders for Lead-Acid Batteries. Oxylignin, a sodium lignosulfonate derived from the vanillin process, is the premier expander for lead-acid batteries (99). When added to the negative plate at dosages of 0.1–0.5%, battery lifetimes are expanded from days to years.

Other Uses. Other uses of specially modified lignosulfonates include leather tanning (100), as flotation and wetting aids in ore processing, as sacrificial agents in enhanced oil recovery (101), as precipitating agents in protein recovery (102, 103), in deicing formulations (104), and as wood preservatives (105). Medicinally, lignosulfonates have been purported to have value as antithrombotic (106) and antiviral (107,108) agents.

Interest in acrylic-graft copolymers of lignosulfonates is also growing. Commercially such products have found use as dispersants/fluid loss control agents for oil-well drilling muds and cements (109,110), as scale control agents in water treatment (111), as water reducing agents in the manufacture of bricks and ceramic materials (112), and as low inclusion animal feed binders (113).

Kraft Lignins. Kraft lignins, also called sulfate or alkali lignins, are obtained from black liquor by precipitation with acid. Generally, acidification is conducted in two steps. In the first step, carbon dioxide from the waste gases of boiler fires or from lime kilns is used to reduce the pH of the liquor from 12 to 9–10. About three quarters of the lignin is precipitated in this step as a sodium salt. After isolation, the material thus obtained can be used as is or further refined by washing. By suspending the salt in water and lowering the pH to 3 or less with sulfuric acid, refined lignin is obtained.

Typical compositions for softwood and hardwood kraft black liquors are shown in Table 9. Most commercial kraft lignins are sulfonated kraft lignins or lignin amines. A few nonsulfonated products are, however, available.

Physical and Chemical Properties of Kraft Lignins. Kraft lignins are soluble in alkali (pH > 10.5), dioxane, acetone, dimethyl formamide, and methyl cellosolve. They are insoluble in water at neutral and acidic pH, have number-average molecular weights in the 2000–3000 range, and are less polydisperse

Table 9. Compositions of Kraft Black Liquors[a]

than lignosulfonates. A C_9 formula of $C_9H_{8.5}O_{2.1}S_{0.1}(OCH_3)_{0.8}(CO_2H)_{0.2}$ has been reported for softwood kraft lignin corresponding to a monomer molecular weight of about 180 (114). Because of the high degree of degradation during pulping, they also have a large number of free phenolic hydroxyl groups (4.0%).

The aromatic rings of kraft lignins can be sulfonated to varying degrees with sodium sulfite at high temperatures (150–200°C) or sulfomethylated with formaldehyde and sulfite at low temperatures (<100°C). Oxidative sulfonation with oxygen and sulfite is also possible.

Many of the chemical reactions used to modify lignosulfonates are also used to modify kraft lignins. These include ozonation, alkaline–air oxidation, condensation with formaldehyde and carboxylation with chloroacetic acid (115), and epoxysuccinate (116). In addition, cationic kraft lignins can be prepared by reaction with glycidylamine (117).

The physical and chemical properties of kraft lignin differ greatly from those of lignosulfonates. A summary of these differences is presented in Table 10.

Applications of Kraft Lignins. Because of the high fuel value of black liquor, kraft lignin products are generally used in high value applications. In many applications, the base lignin must be modified (ie, through sulfonation or oxidation) prior to use. Once modified, kraft lignins can be used in most of the same applications in which lignosulfonates are used. These include usage as emulsifying agents/emulsion stabilizers (118), as sequestering agents (119), as pesticide dispersants (120), as dye dispersants (66,121,122), as additives in alkaline cleaning formulations (123), as complexing agents in micronutrient formulations, as flocculants (124), and as extenders for phenolic adhesives (125). In addition, kraft lignins can also be used as an extender/modifier and as a reinforcement pigment in rubber compounding (126,127).

Sulfonated kraft lignins derivatized via ethoxylation have recently been used as dispersants in numerous applications including pesticides and dyestuffs (128). Propoxylated lignosulfonates have found use commercially as nonretarding dispersants for oil-well cements (129).

Table 10. Properties of Kraft Lignins and Lignosulfonates[a]

Property	Kraft lignins	Lignosulfonates
Molecular weight	2,000–3,000	20,000–50,000
Polydispersity	2–3	6–8
Sulfonate groups, meq/g	0	1.25–2.5
Organic sulfur, %	1–1.5	4–8
Solubility	Soluble in alkali (pH < 10.5), acetone, dimethylformamide, methyl cellosolve	Soluble in water at all pHs; insoluble in organic solvents
Color	Dark brown	Light brown
Functional Groups	Many phenolic hydroxyl, carboxyl, and catechol groups; some side-chain saturation	Fewer phenolic hydroxyl, carboxyl, and catechol groups; little side-chain saturation

[a]Ref. 70.

Toxicology of Lignosulfonates and Sulfonated Kraft Lignins. Rather extensive testing has shown that lignosulfonates are nontoxic. In most cases, LD_{50} values are greater than 5 g/kg. The safe use of lignosulfonates in the manufacturing and processing of a wide variety of food and food packaging applications is covered under the following U.S. Food and Drug Administration regulations: (*1*) as adjuvants in pesticide formulations exempt from the requirements of tolerance when applied pre- or postharvest (21 CFR 182.99, 40 CFR 180.1001); (*2*) as dispersant or stabilizers in pesticides applied pre- or postharvest to bananas (21 CFR 172.715); (*3*) as a boiler water additive used in the preparation of steam that will contact food (21 CFR 173.310); (*4*) as components of paperboard or paper in direct contact with moist, fatty, or dry food (21 CFR 176.170, 178.3120, 176.120, 176.180); (*5*) as component in food packaging adhesives (21 CFR 175.105); (*6*) as component of defoamers used in manufacturing food-packaging grade paper or paperboard (21 CFR 176.210); and (*7*) in animal feed as pelleting or binder aid (limit of 4%), surfactant in molasses (limit of 11%), and source of metabolizable energy (limit 4%) (21 CFR 573.600).

Organosolv Pulping Lignins. In organosolv pulping processes, hardwood chips are batch cooked for set times at appropriate temperatures and pH in an aqueous ethanol or methanol liquor. In the process, lignin, hemicelluloses, and other miscellaneous components of the wood are extracted into the alcoholic pulping liquor forming a black liquor. Organosolv lignin is recovered from the black liquor by precipitation, settled, centrifuged or filtered, and dried (127,130). The resulting lignin is a fine, brown, free-flowing powder.

Physical and Chemical Properties. Organosolv lignins are soluble in some organic solvents and in dilute alkali. They are insoluble in water at neutral or acidic pH. They have number-average molecular weights lower than 1000 and polydispersities between 2.4 and 6.3 (68). A C_9 formula of $C_9H_{8.53}O_{2.45}(OCH_3)_{1.04}$ has been reported for one organosolv lignin (68). This corresponds to a monomer molecular weight of 188.

Applications. These materials are still in developmental infancy, and are not currently available commercially. The lignins produced in these processes have potential application in wood adhesives, as flame retardants , as slow-release agents for agricultural and pharmaceutical products, as surfactants , as antioxidants, as asphalt extenders, and as a raw material source for lignin-derived chemicals.

Other Lignins. In addition to main commercial lignins, there are a number of other lignins of no or limited commercial value. One of these is produced almost exclusively in the Commonwealth of Independent States (CIS) where wood is used to produce glucose by acid hydrolysis. The lignin isolated as a by-product of this process is called acid hydrolysis lignin. It is claimed that in modified form such lignins can be used as rubber filling agents, as binders in wood adhesives, as additives in fabric treating compounds where they impart decay resistance, and as flotation aids in ore processing.

Numerous lignins have also been isolated in the laboratory including milled wood lignins, dioxane lignins, and enzymatically liberated lignins. These laboratory prepared lignins have different chemical and physical properties depending on the chemical modifications undergone during their isolation, and the quantities obtained are after limited.

LIQUID CRYSTALLINE POLYMERS, MAIN-CHAIN

Introduction

The liquid crystallinity of low molecular weight liquid crystals (LMWLCs) was found more than 100 years ago, when Reinitzer synthesized several esters of cholesterol. In the liquid crystalline (LC) state, the substance shows characteristics of a liquid in terms of its mobility, while it exhibits characteristics of a crystalline material in terms of its optical properties because of the anisotropy in the structure (1,2).

After more than two decades of research work on LMWLCs, Vorländer, in 1923, realized that liquid crystalline polymers (LCPs) must exist too (3,4). The first reference to a polymeric mesophase was in 1937 when Bawden and Pirie found that a solution of tobacco mosaic virus formed two phases, one of which was birefringent in certain concentrations (4). The first liquid crystalline phase for a synthetic polymer was a solution of poly(γ-benzyl-l-glutamate), reported by Elliot and Ambrose in 1950 (5). A few years later, Flory, based on the lattice model, proposed his well-known theory in treatment of liquid crystallinity in lyotropic systems (6). Flory proposed to divide the molecule into several submolecules, usually called segments, which consists of rigid rod-like moieties. Using this model, he concluded that molecular structure and geometry were the most important factors to induce liquid crystallinity. According to the Flory theory, a state with partial order can be formed above a critical concentration whereas the orientations of molecules are totally random below the critical concentration. The transition from a random to a partial order state is discontinuous. During the phase transition, isotropic phase and anisotropic phase coexist (7). The predicted critical axial ratio for the phase transition is 6.4 in a nonsolvent system (7). Flory later incorporated

the temperature effect into the lattice model. For LMWLCs, the aspect ratio is defined as L/d, in which L is the length and d is the diameter of the molecule. For LCPs, the aspect ratio is replaced by the persistence ratio by substituting the molecule length L by the persistence length q.

The revelation of the theory to form the LC phase and the discovery of LC properties from rigid-chain polymers occurred coincidently, which led to an extensive search for new kinds of rigid-chain LCPs from academia and industry. DuPont scientists led the invention and successfully synthesized and identified lyotropic LCPs made of rigid wholly aromatic polyamides in the 1960s and later commercialized the high performance fiber under the name Kevlar (8,9). This became an important milestone in the development of LCPs. Since then, many LCPs with excellent mechanical properties have been synthesized and their applications in various areas have been explored. Workers at Carborundum in the early 1970s patented an aromatic copolyester based on a biphenol monomer and later used the trade name as Ekkcel I-2000 to test market (10,11). This material was diagnosed to possess LC characteristics several years after the invention. Eastman Kodak reported the first well-characterized thermotropic aromatic–aliphatic copolyesters by the reaction of *p*-acetoxybenzoic acid (ABA) and poly(ethylene terephthalate) (PET), later tested market under the trademark X7G (12–14). Both Ekkcel and X7G failed in commercialization because the former had to be processed at extremely high temperatures, whereas the later had too much PET which lowered the performance. Celanese developed various tractable wholly aromatic thermotropic polyesters and poly(ester-amide)s with the trademark Vectra in early 1980s, based on composition reported in patents and elsewhere (15,16). Early development of Vectra LCP aimed at fiber applications, and the unique applications in electrical and electronic interconnection devices were serendipitously discovered and developed in the 1980s. Today, Kelvar fibers have replaced steel, fiber glass, asbestos, and graphite for varieties of applications, including radial tires, brake linings, and composites. Vectra LCP series of resins have been molded for electronic, telecommunication, medical, and other applications. Extruded and blown films are used for strength members and print circuit board, respectively (5,17).

Thermotropic main-chain LCPs have unique combination of properties from both LC and conventional thermoplastic states; these include melt processibility, high mechanical properties, low moisture take-up, and excellent thermal and chemical resistance. With the successful development of these LCPs and recognition of their unique properties, comprehensive research and development have been carried out by both academia and industry (3,5,9,11,14,16–26). Among various R&D directions, the synthesis of new LCPs (3,14,16,17,19–22,24,26), their rheology behavior (27–31), morphology, compatibility and processing of LCPs and blends (32–34) have received most attention.

Synthesis of Main-Chain LCPs

Polyesters and poly(ester-amide)s are two important series of main-chain LCPs. In general, poly(ester-amide)s show increased thermal stability compared to polyesters (5,9,16). They both are synthesized by polycondensation reactions. In

order to increase the reactivity, monomers usually have to be acetylated *in situ* or before conducting the polycondensation reaction (5,9,16). Using the synthesis of LC polyester as an example, the synthesis procedure is described as follows. The transesterification reactions start with phenyl esters of diacids with acetylated aryl diols at relatively high temperatures. Normally, the reaction temperature is higher than the highest melting point of monomers. In order to reduce oxidation, the polymerization is commonly conducted in a nitrogen atmosphere. When low melt viscosity oligomers are obtained, the melt becomes turbid since the fluctuations of orientation of the mesogenic domains are in the range of the wavelength of visible light. A vacuum is then applied to the reaction system to further remove the by-products from the melt and to increase molecular weights. In order to facilitate the diffusion process, a stainless high-torque steel stirrer is desirable to improve the mixing and to accelerate the evolution of by-products, such as acetic acid. A multistep change in the temperature profile is the key to facilitate the molecular weight enhancement. The polymerization reaction can be carried out with or without a catalyst. Catalysts may affect the color and the thermal stability of the final product (18,35). In the reported kinetics study of bulk LCP polycondensation (36–38), for example, the ABA/2,6-acetoxynaphthoic acid (ANA) reaction system, the kinetics was investigated by titrimetry of evolved acetic acid trapped in a sodium hydroxide solution or monitoring the volume of acetic acid. It was found the polycondensation obeyed second-order kinetics irrespective of whether the reaction was catalyzed or uncatalyzed. A Similar conclusion was found for thin-film polymerizations (35).

Most monomers for LCP syntheses are highly crystalline, but do not have characteristics of liquid crystallinity (16,20–22,24–26). During the polymerization, an LC phase forms, and the LC texture evolves with the progress of polymerization and further annealing. To study the in situ morphological evolution of LCPs and annihilation of liquid crystal textures (or defects) during polymerization reactions, a powerful and convenient technique has been developed using the heat-stage polarizing microscope (39,40). This novel approach modernizes the previous film polymerization technique (41–44) and has been extended to investigate the reaction kinetics, effects of catalysts, and monomer structures on the formation of various main-chain LC polyesters and poly(ester-amide)s (35,45,46) as well as to study the evolution of surface energy of LCPs during the polymerization reactions (47). Figure 1 shows a typical evolution of polymerization for 73/27 ABA/ANA with a thickness of 10 μm at 230°C. After the monomer crystals melt and the reaction system reaches the proposed temperature, the reaction system becomes a homogenous phase as shown in Figure 1 (500 s). In the early stage of polycondensation reaction, oligomers form in the molten monomer phase. Their molecular weights and chain lengths increase with reaction time. When the chain lengths of oligomers reach a certain value, they form the LC phase and separate from the isotropic melt. Figure 1 (515 s) shows the reaction-induced phase-separation process during polymerization. The dark area in the micrographs is the isotropic phase; the bright area represents the LC phase. The first sign of forming the LC phase is that many bright LC domains instantaneously appear in the view range. Because of the polydispersity of the chain length, oligomers are partitioned within the isotropic and LC phases according to their chain lengths. A fraction with relatively longer chain lengths forms LC domains, while others remain in the isotropic

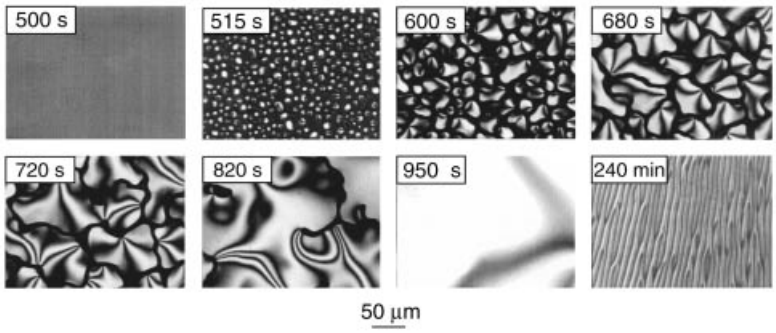

Fig. 1. Micrographs showing morphologies of 73/27 ABA/ANA polymerization reaction system at different reaction times. All the micrographs were obtained from the same area of the same sample. Reaction temperature: 230°C.

phase (39). After the appearance of LC phase, the sizes of LC domains quickly increase, and correspondingly the number of domains decreases because of domain growth and coalescence of adjacent LC domains. As a result, the total view area becomes an anisotropic LC phase (950 s).

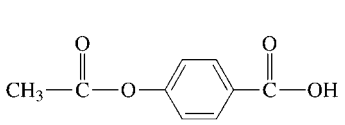
LCPs exhibit a variety of textures of different length scales, originated from flow and deformation. A frequently observed texture called *banded texture or stripe texture* often emerges in the samples in which relaxation or shrinkage of molecular chains occurs. The conditions inducing this texture include the following: subjecting to shear and/or elongation flow (48), evaporating the solvent from a lyotropic LC (49,50), and quenching a thermotropic LC from a high temperature (51). As a consequence of stress relaxation after shear or volume deficiency induced by solvent evaporating or quenching, banded texture appears but the local order does not decrease significantly. In the 73/27 ABA/ANA reaction system, with the increase in molecular weight, the volume deficiency causes the appearance of banded texture since adhesion to the substrate prevents uniform shrinkage in three dimensions. Figure 1 (240 min) shows banded texture in the late reaction stage. However, the banded texture may not appear in some other compositions and reaction temperatures. For example, in some cases, the crystallization occurs and interrupts the formation of banded texture (39).

Modification of Main-Chain LCPs. Modifications of main-chain LCPs suitable for conventional processing equipment, without compromising the uniqueness of LC characteristics and the superior mechanical properties, have received most attention. Low cost LCPs are also in high demand. Most frequently used methods include synthesizing by random copolymerization, introducing kinks into the polymer chains by using meta or ortho linkages, introducing flexible linkages, and incorporating bulky side groups into the polymer chains (5,9,16–18,20–22).

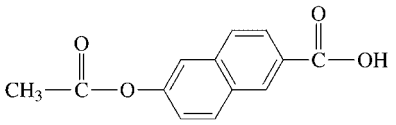
Random Copolymerization. Random copolymerization is an effective way to disturb the regular structure of the polymer chain. The lack of periodicity along the chain inhibits crystallization, and thus reduces the crystallinity and depresses T_m (the transition temperature to form an LC phase), without necessarily leading to an additional loss of mesogenicity and T_i (the transition temperature

from an LC phase to an isotropic phase). This approach has been adapted when designing random copolymers such as Vectra A by Celanese (Ticona) with commercial success. Vectra A is a copolyester based on ABA and ANA with a mole ratio of 73/27. The melting point of this LCP is around 280°C, which is much lower than the melting points of either ABA or ANA homopolymers (5,16,18).

The morphologies of both ABA and ANA homopolymers and 73/27 ABA/ANA copolymer prepared by thin-film polymerization show that crystallization occurs in the homopolymerization systems and the liquid crystal state remains stable in the copolymerization system (39–44), clearly indicating that the random copolymerization is an effective way to retard the crystallization. Transmission electron microscopy revealed that the microstructures of homopolymers of ABA and ANA had more obvious lamellar texture (41–44).

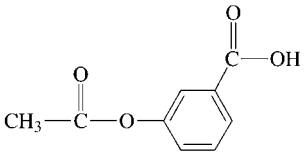


p-Acetoxybenzoic acid (ABA)



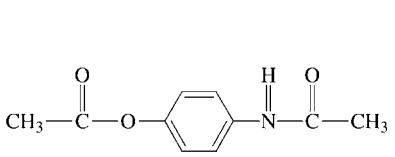
2,6-Acetoxynaphthoic acid (ANA)

Introduction of Kinks. Introduction of kinks into the polymer backbone effectively reduces the regularity of the molecules, and thus lowers the melting temperature. However, the incorporation of kinking units has an unfavorable influence on the liquid crystallinity since the kinks disrupt the straightness of the molecules. Also, the inducing of kinks into molecular chains is unfavorable for the thermal stability of the LCPs (16–26). The exact role of kinks has attracted remarkable attention because the formation of liquid crystallinity is not directly related to the kink content and many interesting phenomena have been found. For example, *m*-acetoxybenzoic acid (mABA) has a kink created by the meta linkage. However, the thin-film polymerization results of mABA/ANA indicate that the LC phase may still be observed even when the mABA content is as high as 66 mol% at 183°C (44).

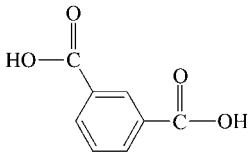


m-Acetoxybenzoic acid (mABA)

Isophthalic acid (IA) is a monomer extensively employed to modify LCPs because its cost is low and the meta linkage can induce a kink into the molecular chain. The resultant polymer has a lower T_m. However, the meta linkage also has a detrimental effect on the stability of the LC phase because it will disturb the LC character if its percentage is too high. In the thin-film polymerization of ABA/acetoxy acetanilide (AAA)/IA system, the critical meta-linked IA content is 26 mol% at 280°C, which means the liquid crystal phase can only be formed when IA content is lower than 26% and crystallization occurs once the IA content is higher than this critical point (45).

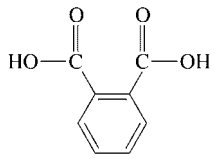


Acetoxy acetanilide (AAA)



Isophthalic acid (IA)

Phthalic acid (PA) has an ortho linkage which can also introduce a kink into the molecular chain. However, it is seldom utilized to modify the LCPs because the liquid crystal phases are not stable for the systems containing PA units (46). Recently, it was found that, in the early stage of thin-film polymerization, both ANA/AAA/PA and ANA/AAA/IA systems form liquid crystal phase when the PA or IA content is 20%. However, with the further reaction going on, the ANA/AAA/PA system crystallizes, whereas the ANA/AAA/IA system remains in the LC state (46).



Phthalic acid (PA)

Since kinks shorten the persistence length of the polymer chain, the LC characteristics may be destabilized if the kink content is high. Figure 2 shows the critical ANA content for the two reaction systems, ANA/AAA/IA and ANA/AAA/PA, to form liquid crystallinity at different reaction temperatures. For the ANA/AAA/PA system, the window of reaction temperature is wide because of the low melting point (205°C) of PA, and the critical ANA content range is very

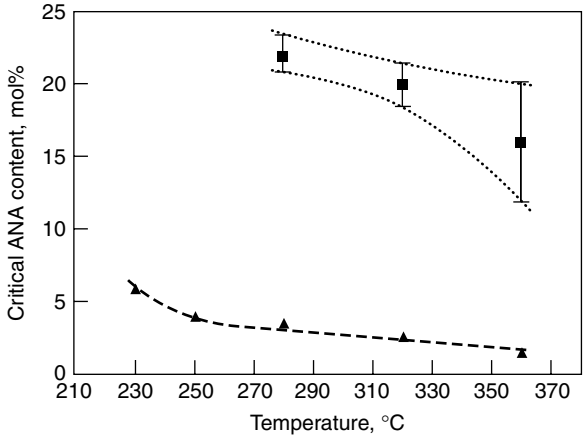


Fig. 2. The dependence of the critical ANA content for ANA/AAA/PA and ANA/AAA/IA systems on reaction temperature. ■ ANA/AAA/IA system; ▲ ANA/AAA/PA system.

narrow for all the temperatures we investigated. For the ANA/AAA/IA system, the reaction temperature window is restricted by the high melting point (342°C) of IA. When conducting the polymerizations at low temperatures, such as 250°C, the reactions are incomplete and IA crystals remain after reaction. So the reaction temperatures used have to be relatively high, from 280 to 360°C. The most striking and interesting phenomenon in Figure 2 is that PA has a much higher tendency to form liquid crystallinity than IA. One of the causes may be due to the *cis* conformation of the bridging groups, especially for the amide group, which can compensate for the 60° angular conformation induced by an ortho linkage. As a result, the reaction system containing PA may have more opportunities to form a relatively straight conformation than the system containing IA. The other possibility is that the resultant polymer in the ANA/AAA/PA system may form a spiral chain conformation because of the rotation of the bridging groups, thus inducing liquid crystallinity (46).

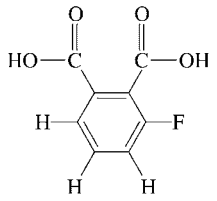
The final morphology of LCPs depends on kinks content because the elastic constants of LC during the reaction are strongly affected by the kink structure. During polymerization, the defects in the LC phase involve very high distortion energy in the case of rigid or semirigid polymers. Disclinations with opposite signs tend to attract each other in order to release the energy and lead to the annihilation and the decrease in the number of defects (52–55). Because the elastic constant values decrease with increasing kink content, the defect density increases with increasing kink content since LCPs with kinks cannot annihilate fast and completely in the reaction system (45,46).

Modification with Flexible Segments. Modification with flexible segments is another important way to improve the melt processibility. By inserting flexible segments to separate the mesogenic units along the polymer chain, the chemical periodicity of the molecule is preserved. These polymer systems are referred to as semirigid polymers. The influence of flexible linkages on the melting temperature can be considered in several ways. In addition to facilitate the motion of the polymer chain, the random distribution of monomeric units also decreases the melting temperature further if the flexible segments are introduced by a copolymerization. The disadvantages of introducing a flexible spacer to a polymer chain are that it disturbs the liquid crystallinity and affects the thermal stability of the resultant polymer.

The most typical spacer segments used consist of flexible polymethylene $-(CH_2)_n-$ of varying length n. T_i decreases in a zigzag fashion in homologous series in which the spacer length regularly increases. This zigzag characteristic is referred to the odd–even effect. T_i tends to be higher when there is an even number n of methylene groups in the spacer, but this oscillation is attenuated on ascending the series. This effect is best understood by assuming the conformation of the methylene spacer to be all trans, which has the lowest energy. An even-numbered polymethylene spacer possesses a set of low energy *trans* conformers that force the rigid units to adopt a collinear disposition. In contrast, an odd-numbered spacer places the two mesogenic groups in the angled orientation disfavoring the ordering of a nematic phase (19).

Introduction of Lateral Groups. Lateral groups have been introduced to lower the melting points of LCPs. Grafting bulky side groups onto the polymer main chain influences the melting temperature in several ways. It effectively

increases the interchain distance and reduces the interchain forces so that the efficiency of the chain packing is reduced. Moreover, this effect is much enhanced by the copolymerization because the randomness of the polymer chain further decreases the crystallinity and melting point (19,23). Unfortunately, the lateral group has a strongly unfavorable effect on the formation of liquid crystallinity, especially for the bulky lateral groups, which will immediately cause the loss of liquid crystallinity if they are randomly distributed in the molecular chain. Two reaction systems ANA/AAA/3-fluorophthalic acid (FPA) and ABA/AAA/PA were compared to identify the effect of lateral group on liquid crystallinity. Because of the kink structure of the PA unit and the different sizes of hydrogen and fluorine atoms affect the formation of crystallinity, the critical ABA content to form the LC phase for the ABA/AAA/FPA and ABA/AAA/PA systems at 280°C are 9 and 5%, respectively, indicating that fluorine atoms modify chain distance and conformation and lower the stability of the LC phase (56).



3-Fluorophthalic acid (FPA)

Rigid-chain polymers containing different concentration of laterally attached side rods have been demonstrated in bulk reactions using a Vectra LCP as the base material, as illustrated in Figure 3 (57). These polymers exhibit liquid crystallinity even up to a maximum side-rod concentration of 20 mol%. The crystallinity of the

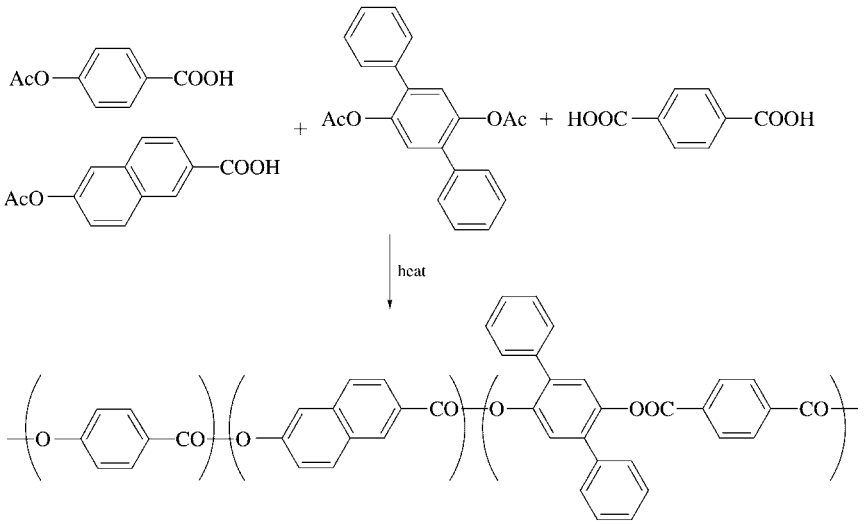


Fig. 3. Incorporation of laterally attached side rods.

polymers, however, decreases with the increase in the side-rod concentration. The advantage of these polymers is their lower dielectric constants compared with their parent polymers, ie, similar polymers but without laterally attached side rods. A dielectric constant of 2.6 can be achieved by incorporating 10 mol% of laterally attached side rods, which is 0.5 lower than that of its parent polymer. The reduction in dielectric constant may be attributed to low crystallinity and less dense packing structure of the polymers induced by incorporating of laterally attached side rods. This series of polymers also has good thermal stability (see also LIQUID CRYSTALLINE POLYMERS, SIDE-CHAIN).

Thermal Stability and Degradation

Thermal stability, degradation behavior, and kinetics of commercially available main-chain LC polyesters such as Ticona's Vectra, BP-Amoco's Xydar, DuPont's Zenite, Eastman's X7G, and Mitsui's LC polyimide have been reported (58–62). There are two degradation processes for most of these LCPs in air, but only one in N_2. By observing the ftir bands, it can be concluded that CO_2 is the dominant product in both N_2 and air, and it exists all through the degradation process. In air, the by-products may consist of H_2O, CO, CO_2, phenols, aryl esters, ketones, and others through dehydration, decarboxylation, and decarbonylation. The stability at the beginning of the decomposition process follows the order Xydar SRT-900 > Vectra A950 > Vectra B950 (60). The activation energy E_a of thermal degradation for Vectra A950 and Vectra B950 are about 232 and 197 kJ/mol in N_2, and 222 and 159 kJ/mol in air, respectively (60).

Crystallization

Crystallization of main-chain LCPs is considerably different from that of conventional polymers, such as polyethylene or PET. LCPs have reduced flexibility compared to the latter, which implies that large translations of their molecules are required for recrystallization. Thus the crystallization process in an LC phase may present its own peculiarities. The orientational order associated with mesophase may act as a precursor for further crystal growth, especially in monotropic LCPs where the metastability of mesophase generally leads to the formation of a more stable crystal phase.

The overall crystallization process includes two steps, primary nucleation followed by crystal growth. The process can be well described by the Avrami equation (63,64) as shown:

$$1 - \theta = \exp(-Kt^n)$$

where θ is the relative crystallinity at time t, n is the dimensionality of crystal growth, and K is a temperature-dependent constant that depends on the growth geometry, the number of nuclei present, and the linear growth rate of polymer crystals. For most LCPs, n is found to be less than 1 for the growth of liquid crystallinity.

The crystallization process for most commercially available LCPs can be found elsewhere (65–72). For most LCPs, there are two transition processes: one is a fast transition process, ascribed to the aggregation of rigid chains, and the other is a slow transition process developing gradually during the later heat-treatment stage. These two processes also manifest in different crystal structures. For LCPs synthesized from ABA/ANA compositions, the fast process leads to hexagonal packing with cylindrical symmetry along the chain direction, while the slow process gives rise to orthorhombic packing (66). The Avrami parameter n values for Vectra A are in the low range 0.2–0.5, which is due to the fact that each crystal does not grow with a constant radial growth rate (70). The crystallization and phase transition behavior in LC polyimides have been investigated (73–78). Smectic-layered structures have been found for some polyimides.

Surface Energy

The surface energies of Vectra A, Vectra B, and Xydar have been reported using contact angle techniques at room temperature (79,80). Experimental data suggest that surface energy values match between the two-liquid geometric method (81,82) and the three-liquid acid–base (83,84) method if a correct combination of testing liquids is used. However, three-liquid Lifshitz–van der Waals acid–base method is more suitable for the surface energy calculation of these three LCPs, and provides much more information, eg, acidity and basicity of LCP surfaces. The average surface energies of Vectra A-950, Vectra B-950, and Xydar are 41.0, 41.9, and 42.3 mJ/cm^2, respectively. In addition, all these three LCPs should be classed as monopolar Lewis bases because their Lewis acid components, γ^+, are negligible. The incorporation of a small amount of $-C(CF_3)_2-$ in the main chain can lower LCP's surface energy and the fluorocarbons are preferentially enriched at the air–polymer interface (85).

Morphology and Microstructure

In the LC phase and within a volume element, the molecules are aligned along one common direction in average, labeled by a unit vector $\boldsymbol{n}$. A region within the sample volume where the directon does not change very much is defined as a *domain*. The distribution of domain orientations within the sample forms texture (86,87). The various rheological behaviors, which strongly affect the processing conditions and final properties of these materials, are the results due to the interaction between the texture and the flow field. To sum up, the final properties are determined to a large extent by the microstructure, which, in turn, is due to a combination of the inherent properties of the LCPs and the flow conditions during processing.

It has been reported that three kinds of distinct fibrils could be observed in oriented LCP fibers, extrudates, and mold parts; they are 50-nm microfibrils, 500-nm fibrils and 5 μm macrofibrils (88). For highly oriented fine fibers, the LC domains are elongated along the fiber direction with a size of about 500 nm

in the transverse direction. A periodic and inherent defect layer of about 50 nm has also been noticed in the fiber structure. For large diameter extruded rods, the degree of orientation decreases from the outer skin to the core because the shear rate is higher at the outer skin than at the core (89). Increasing the draw ratio cannot eliminate the skin–core structure. However, by changing the temperature profile within the extrusion die, one may be able to induce a higher shear rate at the core and thus enhance the overall degree of orientation and fiber modulus (90). The mechanical properties of extruded LCP films in various directions follow typical macromolecular composites theory and can be predicted using the Tsai–Hill equation (91). Because of the complexity of flow patterns during the injection molding, a layered structure can be found in the cross-section of molded parts (5,16,88). Each layer corresponds to each flow pattern. However, the degree of orientation decreases as one proceeds from the skin to the core (88). Later studies revealed much detailed morphology of the nature of the microfibrillar hierarchy and the shape of the microfibrils was found to be tape-like (92,93).

LCP Rheology and Blends

Since the main characteristic of thermotropic LCP melts is the persistence of order in the material even when the stresses causing deformation are removed, the rheological behavior of LCP is different from normal polymers. The viscosity vs shear rate behavior for LCPs can be represented by three distinct regions: (*1*) a shear thinning region at low shear rates, (*2*) a Newtonian region in an intermediate shear rate region, (*3*) a power-law shear thinning region at high shear rates (27). Although very few sets of data show all the three regions in a single polymer, analysis of the published data of a number of authors for LCPs identified the three flow regions (28). An important characteristic of LCPs is that they have longer relaxation times compared with flexible coil polymers. Two relaxation times for LCP melts one for the stresses and the other for orientation have been reported (29). Although these phenomena were related through the stress-optical law for conventional flexible coil polymers, they were independent for LCPs. The relaxation time of orientation was longer than the relaxation time of stress; thus, the orientation LCPs achieved during processing was retained in the solid state more easily than for flexible chain polymers.

Using the unique and superior properties of LCPs to enhance the thermal and mechanical performance of various engineering resins, studies have been conducted since late 1980s (94–104). The LCP phase is preferentially oriented in the direction of flow. LCPs can also be viewed as a processing aid (lubricant), which effectively reduces the viscosity of the blends if the LCP content is low (32,94,96–99). It is found that the LCP domains do not always deform into fibrils as reinforced elements for some LCP/thermoplastic blends. One must provide adequate shear stress and torque history to deform LCPs into elongated fibrils. The rule of thumb is to have process conditions which yield the viscosity ratio of the dispersed LCP phase to the thermoplastic matrix to be lower than 1 (99,103). LCPs blends also suffer from poor adhesion strength between the LCP phase and the thermoplastic matrix. Forming cross-linkable LCP blends is one of the ways to overcome it

(105–107). LCP/LCP blends have also been developed (33,108) to yield LCPs with a better performance.

Applications of Main-Chain LCPs

Thermotropic LCPs have a great potential as structural materials. They have high strength and stiffness in the direction of the molecular alignment and their low melt viscosity and low shrinkage facilitate processing. Most applications of main-chain LCPs are based on the excellent mechanical properties of these materials (3,5,9,16,17,26,30). As we know, high modulus and high tensile strength occur when polymer molecules are aligned and extended. In ordinary isotropic polymers, the molecules tend to align and to uncoil in tensile and shear fields, but recoil and partially lose their orientation when removing the stress. To obtain high modulus, there are the following requisites: the individual molecule should be stiff, the alignment of the molecules has to be nearly prefect, and ratio of the aromatic to aliphatic linkages must be high. These conditions are satisfied by wholly aromatic LCPs because of their high tendency to align and to remain in that orientation. The chemical structures of wholly aromatic LCPs provide a good answer for these attainments.

Because thermotropic wholly aromatic LCPs have characteristics such as high strength, low melt viscosity, low shrinkage, ease of processibility, excellent thermal resistance, low water, and gas absorption, they have wide applications in following areas: fibers, rods, sheets, composites used in mechanical and chemical industries; chip carriers, connectors, switches used in electronics; connectors, couplers, buffers used in fiber optics; interior components, brackets in aerospace; and so on (3,5,9,16,17,26,30).

LCP fibers have high strength and stiffness and are lightweight. Fabrics of LCP fibers (such as Vectran fibers) have been used as ballistic garments, helmets, and military flak jackets. Excellent cut/tear resistance and thermal insulation also make LCP fibers desirable for protective gloves and clothing. Sheet products made from mineral-filled LCP variants or multilayer copper and LCP laminates have been used for thermoforming and electroplating for printed circuit board. Large-diameter melt-extruded LCP rods have been used to replace steel wire and even used as strength members in optical cable applications. This is because LCP rods have the following characteristics: lightweight and flexible, excellent tensile properties, which prevent optical fibers from breaking during the lay down process, very small negative coefficient of thermal expansion, which minimize the external stress, good chemical resistance, and almost zero water regain. LCP rivets offer an attractive alternative to metal for fasteners without the high cost and heavy weight of titanium or the corrosion problem associated with aluminum. Because Kevlar and Vectran fibers are strong, nonabrasive, dimensionally and thermally stable, they also have been used to reinforce brake linings. For injection-molding resins, the addition of fillers or fiber-reinforced elements into neat LCP resins may be the best approach to obtain high quality. Most commercial LCP products contain 30–70% fillers or fiber-reinforced elements in order to lower the LCP cost and have balanced mechanical and electrical properties. LCPs offer at least a few advantages over other engineering resins in electric applications, for example, low

mold shrinkage, fast cycling time, capability of molding thin parts, low moisture regain, and better chemical and mechanical properties. In addition, LCPs are little affected by radiation.

LCPs have been in commercial use for over 20 years, and new applications are still emerging. It is expected that commercial LCPs are still in the growth phase and that significant increases in usage will occur in the twenty-first century.

LIQUID CRYSTALLINE THERMOSETS

Introduction

Liquid crystalline thermosets (LCTs) may generally be defined as low molar mass, multifunctional monomers, which can be cured thermally, chemically, or photochemically in the melt state, leading to a highly cross-linked, high glass-transition temperature material which exhibits liquid crystalline order. These materials are expected to exhibit properties that combine the useful benefits of both cross-linked thermosets and liquid crystals, such as low viscosity for ease of processing, good dimensional stability, high glass-transition temperatures, good thermal stability, high mechanical properties, the ability to be oriented, and good barrier properties. Among the applications envisioned for these materials are high performance resins for composites, optical thin films, and packaging material for microelectronics. The eventual use of LCTs for these types of applications will depend on the continued investigation and development of their properties.

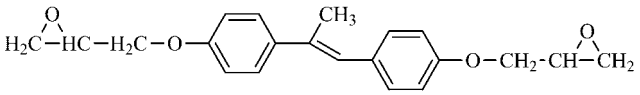
The first mention of LCTs is in a paper by de Gennes in 1969 (1). The first experimental investigations occurred in the 1970s (2,3). However, significant numbers of publications did not appear in the literature until the 1990s. Early efforts focussed primarily on the liquid crystalline structure of the monomers or the cured networks, whereas more recently there have been efforts to examine the evolution of structure during cure, the nature of the cure process, and a variety of properties.

Molecular Structure of Monomers

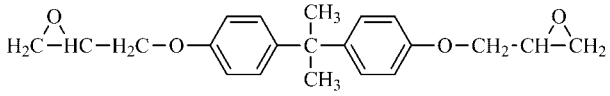
Quite a large number of different monomer structures have been synthesized (4). Reactive end groups utilized include epoxy (5–10), acrylate and methacrylate

Encyclopedia of Polymer Science and Technology. Copyright John Wiley & Sons, Inc. All rights reserved.

(11–14), maleimide and nadimide (15–21), vinyl (22,23), isocyanate and cyanate ester (24–27), and ethynyl (28–30). In one case, a dual-curing monomer containing both acrylate and ethynyl groups has been made (31). The mesogen is generally aromatic, and may include ester (6–8,10,16,19–21,25–30,32–34), amide (15,18), or azomethine (35,36) linkages. There may also be a flexible spacer, typically between the mesogen and the reactive group (10,13,37). Two fairly unusual structures involve twin mesogen LCTs, in which there are two mesogenic units separated by a flexible spacer (34,36,38,39), and LCTs in which the reactive group is placed between the flexible unit and the mesogen (40). It is also possible to create branched monomers that exhibit a liquid crystalline phase (41). While most monomers exhibit either achiral nematic or smectic phases, by appropriate choice of the monomer structure it is possible to create chiral smectic (42) and discotic phases (43). Tables 1 and 2 provide a representative list of monomers that have been synthesized. Two epoxies that have been extensively compared are shown below.



1



2

Diglycidyloxy-α-methylstilbene (**1**) is a liquid crystalline epoxy, while the diglycidyl ether of bisphenol A (**2**) is a typical non-liquid-crystalline epoxy.

LCT monomers follow the general rules for liquid crystalline behavior that have been found for nonreactive low molar mass liquid crystals (44–48). Thus, bulky substituents tend to destabilize the liquid crystalline phase (16,27–30,33,35), longer flexible units favor the formation of smectic phases (40,49), and odd–even effects are seen in the transition temperatures as a function of flexible spacer length (36,40,49). Rigid mesogens that form liquid crystalline order upon cure may not be liquid crystalline themselves. For example, **1** is itself a monotropic nematic, with a melting temperature of 128°C and an isotropic to nematic transition upon cooling of 95°C (50). Extension of **1** with a flexible unit such as glutaric acid creates an oligomer which is enantiotropic (8). In this case the structure may be likened to that of a main chain liquid crystalline polymer containing rigid and flexible segments. The phase diagram for binary mixtures of LCT monomers may be calculated using the same techniques as are employed for low molar mass liquid crystals, although slight discrepancies are found between theoretical and experimental phase diagrams (51). These discrepancies may be accounted for by the reactive nature of LCTs, whereby a complex mixture of partially reacted species is formed during the experiment that is not accounted for in the theory. It has also been found that the type of linkage can have an effect on the phases shown. For example, Lee and co-workers have examined the effect of an ester group versus an ether group between the mesogen and the flexible spacer of an epoxy LCT

(52). They found that the ester group leads to a monomer with a smaller nematic temperature range. As in low molar mass liquid crystals, this can be attributed to reduced intermolecular interactions due to the electron-withdrawing character of the ester group, and lower geometrical anisotropy due to the larger size of the ester group.

Cure Behavior

Reaction Kinetics. The presence of a liquid crystalline phase can have a dramatic effect on polymerization rates. The activation energy can be lower in the liquid crystalline phase, implying a higher rate constant (53). For those monomers which are initially isotropic, isothermal differential scanning calorimetry measurements show an initial exotherm due to the polymerization in the isotropic phase, followed by a second exotherm due to a rate acceleration when the reacting system undergoes a phase transition to a liquid crystalline phase. This phenomenon appears to be general, as it appears in both chain-growth (54–56) and step-growth (57–59) systems. Mormann and Bröcher found a similar second exotherm for an epoxy system that was undergoing a smectic to nematic transition during cure (60). This may be due to the lower viscosity of the nematic phase.

Several studies have compared the kinetic parameters that result from polymerization in different phases for chain-growth systems. Douglas and co-workers used Raman spectroscopy to compare liquid crystalline and non-liquid crystalline bisacetylene monomers (28). They found that the initial polymerization rate was higher in the liquid crystalline phase. Other studies have examined the photopolymerization of methacrylates and acrylates using differential scanning calorimetry. Hoyle and co-workers found there was no change in the initial polymerization rate as a function of phase, but the maximum rate was reached at lower conversions as the order of the phase increased (56). Guymon and Bowman performed a detailed kinetic study for liquid crystalline and non-liquid-crystalline diacrylates polymerized in a liquid crystalline solvent (61). Remarkably, they found that the polymerization rate is higher at lower temperatures, again due to the greater order present in the lower temperature liquid crystalline phases. A detailed analysis showed that this rate increase is caused by a decrease in the termination rate constant rather than by an increase in the propagation rate constant.

Kinetic studies have also been conducted on epoxy systems. For amine cure, it is generally assumed that the primary amine has a greater reactivity than the secondary amine. However, two studies found that for liquid crystalline epoxies the secondary amine is more reactive than the primary amine (62,63). There is no

complete explanation for this behavior, but it has been suggested that it is caused by the lower viscosity of the nematic phase. More detailed kinetic analysis has been done to model the kinetics during the complete reaction. Non-liquid crystalline epoxies are typically found to follow an autocatalytic model, in which one considers the reaction between an epoxide and an amine or anhydride hardener, with the reaction catalyzed by a species formed during the reaction (eg hydroxyl group). This model fits the isothermal differential scanning calorimetry data for both isotropic epoxies, and for liquid crystalline epoxies that show only a single exothermic peak during cure (57,64). For systems that do show a second peak due to a phase change during cure, modifications to the autocatalytic model are needed. The basic concepts inherent in these modifications are that the reaction proceeds at a different rate in the liquid crystalline phase than in the isotropic phase, and the isotropic and liquid crystalline phases contribute to the rate according to the relative proportion of each phase present. Liu and co-workers developed a model by modifying the autocatalytic model with a rate-enhancement term (57,59) and also introduced an error function so that the contribution of the rate-enhancement term increases as the conversion increases. Micco and co-workers also developed a model by assuming that the reaction rate is autocatalytic in the isotropic phase but linear with conversion to the liquid crystalline phase (58). They also assumed a form for the rate of growth of the liquid crystalline phase, and that the isotropic and liquid crystalline phases contributed to the overall rate in proportion to their volume fractions. Given the similarities of the two models, it is not surprising that both are able to model the double exotherm. Unfortunately, these models do not give much insight into the mechanism behind the rate enhancement, although Liu and co-workers do propose that their rate-enhancement term is associated with an increased concentration of reactive groups at the layer boundaries in the smectic phase.

Network Formation. Only very little work has been conducted on examining the effect that the liquid crystalline phase may have on the network formation. The two studies conducted indicate that in fact the liquid crystalline phase has no effect on gelation. Jahromi and co-workers examined the viscoelastic behavior of a liquid crystalline epoxy during cure at a single temperature (65). They found that the critical gelation exponent was equal to 0.5, which is also found for isotropic epoxies. Cho and Douglas performed measurements on a different epoxy at multiple temperatures, and found that the conversion at gelation was independent of cure temperature, as would be expected for a purely statistical step-growth process (66). Both studies found that the conversion at gelation was in good agreement with that calculated from standard theories of gelation via step growth. Thus it appears that, at least in epoxy systems, gelation is independent of the phase in which the cure reaction occurs.

Phase Evolution during Cure. Although the liquid crystalline properties of LCT monomers are easily understood on the basis of low molar mass liquid crystals, the structures of the resulting networks are much more complicated, resulting from an interplay among the monomer structure, the effect of cross-linking, and the cross-linking agent, if one is present. In some cases, there is no change in the liquid crystalline texture during cure, and the network exhibits the same liquid crystallinity as does the monomer (28,30,67). Even in such cases, however, there may be a slight loss of order at the molecular level due to the cross-linking reaction. Such an effect has been predicted theoretically (68),

and there is at least some experimental evidence that this may actually occur (69).

In many cases, however, the liquid crystalline order of the network is not the same as that of the monomer. Most common is the case in which the order of the network is actually greater than that of the monomer, in seeming contradiction with the theoretical calculations mentioned above. The most common example is **1**, which is a monotropic nematic liquid crystal as a monomer, and can be cured from the isotropic phase to give a liquid crystalline network (50,67,70). There are also other examples of this behavior (38,39,71–74), including systems which are initially nematic and then cure to give a smectic network (3,67,71). In general this behavior is explained on the basis of a minimum aspect ratio for the molecule that is required for liquid crystallinity to occur (28,39). It is assumed that the cure reaction increases the aspect ratio such that the molecules organize into a liquid crystalline phase. However, this explanation does not account for transitions from a monomer that is nematic to a network that is smectic, nor why some monomers that are initially isotropic form a network that is smectic. Therefore, it has also been suggested that specific molecular interactions between either the mesogens or the cross-linking molecules may be operative in the formation of smectic phases (38,69).

There are also several cases in which the molecular order decreases during cure, with the formation of a nematic network from a smectic monomer (75,76) or isotropic networks from both nematic and smectic monomers (28,40,76). This phenomenon is explained as being due to the disruption of the order due to the formation of cross-links. For example, Gavrin and Douglas synthesized a series of bisethynyl LCTs in which the cross-linking group is attached directly to the mesogen (40). In this particular case the cross-linking group is not decoupled from the mesogen through a flexible spacer, and thus if the distance between the molecules in the liquid crystalline phase is inconsistent with the bonding distance, the liquid crystallinity will be disrupted. This behavior is therefore similar to the general requirements for a flexible spacer to decouple the mesogen from the backbone in side-chain liquid crystalline polymers. However, other bisethynyl LCTs do not lose liquid crystallinity during cure (28), and thus there are clearly some details of this behavior that are not yet understood.

Another important factor affecting the network structure, at least in epoxies, is the cross-linking agent that is used. A study on this factor was conducted by Mihara and co-workers (77). They examined several combinations of mesogenic and nonmesogenic epoxies and amines. The most significant result from their study was that it is possible to create a liquid crystalline network if a mesogenic amine is used, even if the epoxy used is nonmesogenic. This clearly indicates the strong role that the hardener may play in determining the liquid crystalline structure of the network. Another example of this phenomenon occurs with **1** (50,70). When cured with a difunctional amine the resulting network forms a nematic structure. However, when cured with the unsymmetric tetrafunctional amine sulfanilamide, the resulting network forms a smectic structure. The authors propose that this difference is caused by the unequal reactivities of the two amine groups in sulfanilamide. The aromatic amine tends to react more easily, causing chain extension with little cross-linking, which is assumed to favor formation of the smectic phase. Only at the later stages of cure does the sulfonamide group react, resulting in cross-linking. However, Barclay and co-workers have found

that **1** and its oligomers cross-linked with the symmetric tetrafunctional amine methylenedianiline can form either a nematic or smectic phase, depending on the molecular weight distribution; oligomers with a narrower distribution tend to form the smectic phase (67). This result suggests that the most important factor may be the presence of molecular interactions that drive the formation of the smectic phase, and that a broader molecular weight distribution disrupts the regularity of that structure, leading to a nematic phase. Similarly, use of an aliphatic acid to cure 2,6-diglycidyloxynaphthalene results in a nematic network, despite the low aspect ratio of the epoxy monomer (72). In this case, hydrogen bonding may play an important role in the formation of the liquid crystalline structure.

It is apparent, then, that the formation of liquid crystalline structure in cured LCT networks is a complicated process and is currently difficult to predict. Nevertheless, for practical applications it is desirable to at least have knowledge of the liquid crystallinity that may form as a function of the cure conditions. To achieve this, a number of workers have created transformation diagrams that show the liquid crystalline phases that form as a function of cure temperature and cure time (28,30,36,38–40,70,71,73,78). Figure 1 is one example of these types of diagrams. One of the interesting questions that arises from these types of diagrams is the conversion dependence of the phase transformation. Several studies have addressed this issue by performing independent measurements of conversion versus time at various cure temperatures, and then converting the time axis to conversion (63, 66,78). They find that the conversion at which the transformation occurs increases with increasing cure temperature. This is because at higher cure temperatures the critical molecular length for liquid crystallinity to occur is higher, and thus a greater conversion is needed. This explanation is supported by experimental results on other systems, for which an increase in isotropization temperature as a function of cure time at a single cure temperature has been reported (50).

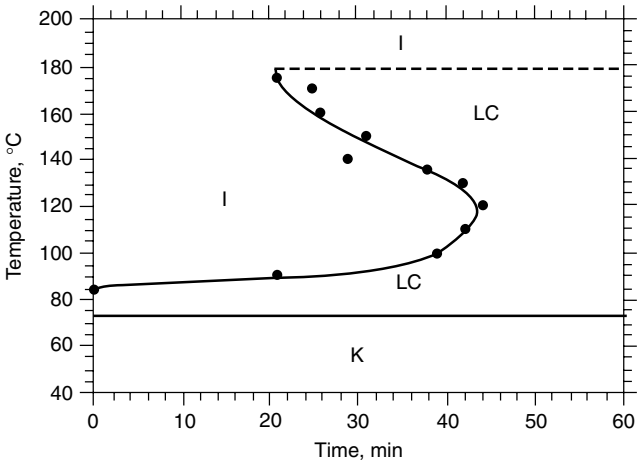

Fig. 1. Transformation diagram for **1** cured with sulfanilamide showing changes in morphology as a function of the cure time. This particular diagram shows the time at which phase transformations occur when the sample is cured isothermally at a given temperature. I, isotropic; LC, liquid crystalline; K, crystalline. Properties

Mechanical Properties. Liquid crystalline polymers are known to have outstanding mechanical properties due to their microdomain morphology and their ability to be oriented. It is expected, therefore, that LCTs may have the same advantages. The effects of orientation are considered in a later section; here we consider only macroscopically unoriented systems.

As part of their study on orientation effects, Benicewicz and co-workers measured the tensile modulus of **1**(69). They obtained a value of 3 GPa, which is typical for non-liquid-crystalline epoxies. Earls and co-workers also found flexural modulus values of approximately 3–4 GPa for both **1** and **2**(9). Tan and co-workers found even lower values of modulus for different liquid crystalline epoxies, although they did not make a direct comparison to isotropic systems (79). Ortiz and co-workers also found no enhancement in modulus for **1**, with the storage modulus in the glassy state actually lower than for an isotropic epoxy and the compressive modulus the same (80). From this limited data it appears that the liquid crystalline phase has no advantage for tensile modulus. This may not be surprising since modulus in the glassy state is governed by bond deformations and rotations, which will be relatively unaffected by the liquid crystalline state. Ortiz and co-workers did find, however, an increase in the dynamic modulus in the rubbery state above what is predicted from rubber elasticity theory (80). This increase is greater for the smectic phase than for the nematic phase. They explain this behavior by proposing that deformation due to motion of the cross-links in an ordered phase will disrupt that ordered phase, resulting in an additional free energy penalty due to the deformation. They also examined additional compressive properties, and found that the liquid crystalline phase results in a lower yield stress, no strain-softening region, and a lower strain at failure. They propose that this behavior occurs because the rigid and extended nature of the network segments prevents plastic deformation. Similarly, Earls and co-workers found a slightly lower flexural strength for **1** compared to that for **2**(9).

Enhancements in fracture toughness for LCTs are greater than for other properties. Several studies have examined the fracture behavior of LCT epoxies. Both Sue and co-workers and Ortiz and co-workers found that **1** cured in the liquid crystalline phase had a higher fracture toughness than **1** cured in the isotropic phase (80,81). Robinson and co-workers conducted a detailed investigation, comparing **1** and **2** cured with the same curing agent with the same cure cycle (82). By varying the epoxy-to-hardener ratio, they found that the morphology of **1** changed, with the domain size decreasing with increasing deviation from balanced stoiochiometry. As a result, the fracture toughness for **1** was higher than that for the isotropic epoxy only at and near the stoichiometric formulation. Carfagna and co-workers found that this increased fracture toughness extends to fiber-reinforced composites, although the increase in impact resistance for LCTs was not as great in the composites as for the neat resin (83). The mechanism for this enhanced fracture toughness has been investigated by TEM. Sue and co-workers found that the crack appears to grow preferentially at the boundaries of the liquid crystalline domain, resulting in crack deflection and segmenting, with this mechanism becoming less effective as the domain size decreases (81). Ortiz and co-workers found that failure occurs by formation of individual microcracks, which grow and

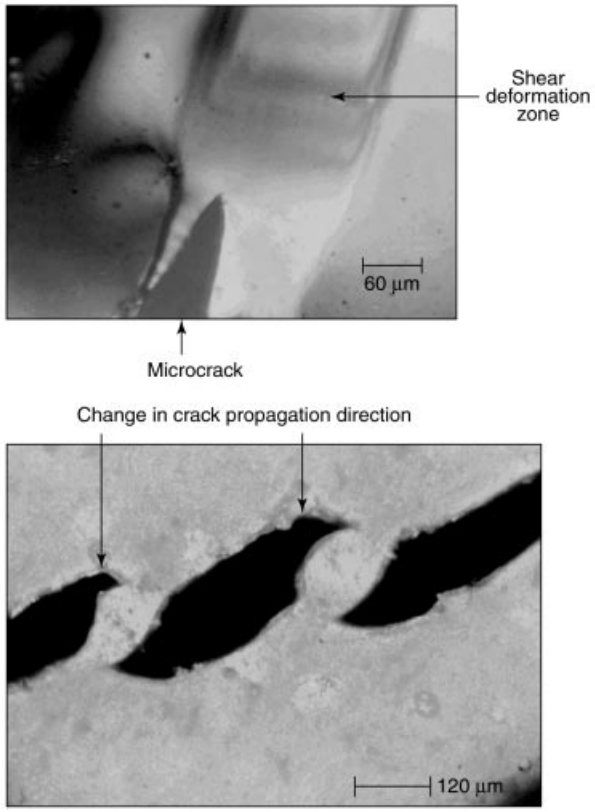

Fig. 2. Thin films of (**a**) **2** and (**b**) **1**, both cured with methylene dianiline, strained in tension, and observed between crossed polars in an optical microscope. In (**a**) can be seen the typical behavior of an isotropic epoxy: a single crack with birefringence caused by a shear deformation zone ahead of the crack tip. In (**b**) there are multiple cracks; these cracks undergo slow, stable propagation due to failure of individual liquid crystalline domains in front of and at the crack tip. Reprinted with permission from Ref. 84, Copyright (2000), Kluwer Academic Publishers.

coalesce, eventually resulting in failure (84). This is in contrast to the isotropic epoxy, which fails by formation and growth of a single crack. Figure 2 shows a comparison between the two systems. Ortiz and co-workers proposed that the individual microcracks undergo stable propagation due to failure of individual liquid crystalline domains (84). These mechanisms are consistent with the results of Robinson and co-workers (82), in that it would be expected for these toughening mechanisms to become less effective as the domain size decreases.

Several studies have examined the adhesive properties of LCTs. Ochi and Takashima, and Carfagna and co-workers both found an increase in the lap shear strength for an LCT epoxy compared to an isotropic LCT (85,86). However, Frich and Economy (87) found that the lap shear strength with a titanium substrate for an LCT that cures by transesterification was lower than that for an isotropic resin. Given the limited data available, it is not clear whether these differences are due to the substrates, surface pretreatment, the type of cure reaction, the liquid crystalline phase, or some other factor. However, most of these studies did find

that the failure mode for the LCT was cohesive or mixed cohesive and adhesive, as opposed to only adhesive for the isotropic thermosets. Thus, it appears that regardless of the lap shear strength, the LCT has a greater bonding strength to the substrates. In one case both materials failed in a cohesive manner, and thus the increased lap shear strength appears to be related to the higher fracture toughness of the liquid crystalline material (86).

Thermal Stability. Only a few studies have examined the thermal stability of LCTs. When the monomers are specifically designed to contain no aliphatic carbons, the thermal stabilities can be very high. For example, Melissaris and co-workers synthesized rigid rod monomers with ethynyl end groups (88,89), while Gavrin and co-workers synthesized monomers with phenylethynyl end groups (90). In both cases degradation temperatures were reported to be at least 400°C in both air and nitrogen atmospheres. Thermal stability has also been examined for epoxy LCTs. The thermal stability is affected by the type and concentration of hardener used; as the aliphatic content of the resin mixture increases, the thermal stability decreases (91,92). One study showed that an anhydride hardener resulted in lower thermal stability than an amine hardener, perhaps due to the difference in cross-link structure (93). In one study liquid crystalline epoxies were compared directly to **2**(94). When the epoxies were cured with an anhydride hardener the liquid crystalline epoxies showed a higher onset temperature for degradation, but when an amine hardener was used **2** had a higher onset temperature. In general, the results suggest that the high thermal stability is a consequence of the types of bonds present and is not significantly affected by the liquid crystalline phase.

Permeability. Liquid crystalline polymers are known to exhibit very low permeability to various permeants due to the packing of molecules in the liquid crystalline and crystalline states. The low permeability of LCPs can be understood on the basis of a two-phase model, in which it is assumed that the permeant does not penetrate into the domains, but can only diffuse through the domain boundaries (95–97). On the basis of these results, it might be expected that LCTs would also show low permeability. Carfagana and co-workers measured the sorption isotherm for **1** and found no difference in water sorption between the nematic and isotropic states (98). In contrast, Earls and co-workers found that **1** cured in the smectic state absorbed considerably less methylene chloride, methylethyl ketone, dimethyl formamide, and bleach after 30 days compared to that adsorbed by **2**; weight gains for **1** were all less than 1%, while weight gains for **2** ranged from 1.0% (bleach) to 26.6% (methylene chloride)(9). Feng also found considerable differences between **1** and **2** in the smectic phase (99). Using a permeation technique to measure the transport of water vapor through thin films, he found that the permeability, diffusion coefficient, and sorption coefficient were all substantially lower for **1**. From the limited data available, it appears that the liquid crystalline state present in the cured resin has an important effect on the diffusion properties, with the smectic phase being considerably less permeable than the nematic or isotropic phases.

Optical Properties. All of the optical applications of LCTs have considered the cholesteric phase. The cholesteric phase is interesting because thin films of a cholesteric liquid crystal oriented such that the helical axis is perpendicular to the plane of the film will selectively reflect circularly polarized light with a wavelength determined by the pitch of the helix. For low molar mass liquid crystals,

films are typically created by mixing a nematic liquid crystal with small amounts of a chiral molecule. The pitch of the helix is determined by both the concentration and the temperature, and thus they are utilized as simple temperature sensors. The goal of creating a cholesteric LCT is driven by the desire to permanently fix the helical pitch, and thus the reflected wavelength, for use in optical devices.

There are several approaches that have been used to create cholesteric LCTs. These include polymerizing nematic LCTs in the presence of a nonpolymerizable chiral molecule (100–104), polymerizing a non-liquid-crystalline monomer in the presence of a nonpolymerizable chiral molecule (105), and copolymerizing nematic and chiral LCTs (100,106). As with low molar mass liquid crystals, in general the pure cholesteric compounds do not reflect light in the visible range, although there is at least one example of a diacrylate which reflects red light when it is not polymerized (106).

Several studies have examined the properties of the cross-linked cholesteric LCTs and proposed some interesting applications. Hikmet and Zwerver showed that removal of the nonpolymerizable molecule leads to an irreversible change in the helical pitch, and thus the wavelength of reflected light (101). This change could be induced locally by writing with a laser beam, suggesting that these materials could be used for optical storage. Ishihara and co-workers used cholesteric LCTs as optical notch filters that filter light of specific wavelengths for displays, allowing better color purity for those displays (105). Heynderickx and Broer also considered cholesteric LCTs for display applications (104). In their case they used a cholesteric LCT film as a compensation foil to eliminate the wavelength dependence of transmission for a supertwisted nematic display.

Orientation of LCTs in External Fields

The liquid crystalline order of LCTs allows them to be oriented by external fields. Orientation may be induced at a surface, or by electric or magnetic fields. Curing the material subsequent to, or during, orientation leads to a cured thermoset which has some degree of macroscopic order. Unlike liquid crystalline polymers, shear fields and mechanical deformation in the uncured state are not considered to be as effective, because of the rapid relaxation of the monomers and the difficulty in maintaining such fields during the cure process. Nevertheless, mechanical deformation has been shown to be effective at orienting lightly cross-linked materials by heating above their T_g and subsequently cooling to lock in the orientation, although the ability to orient decreases dramatically with increasing cross-link density and the orientation is lost upon heating above T_g (107,108). The orientation process tends to enhance certain properties of the cured LCT, although the potential benefits have not yet been fully explored.

Surface Induced Orientation. Liquid crystals are well known to orient at surfaces (109). This effect is utilized in liquid crystal displays, in which orientation of the liquid crystal at a surface is transmitted throughout a thin film. Often this orientation can be achieved simply by rubbing a polymer such as polyimide repeatedly along a given direction. This rubbing process results in orientation of the liquid crystal along the rubbing direction. Given that this technique works well for low molar mass liquid crystals, it is not surprising that it has been utilized

to align thin films of LCTs (12,22,23,56,110). The technique appears to be very general, and has been applied to epoxies, vinyl ethers, and methacrylates, using both thermal and photoinitiated polymerization. The orientation in these systems can be measured using either infrared spectroscopy or X-ray scattering. The resulting orientation is expressed in terms of the second moment of the orientation function, or the orientation parameter, which is given by

$$\langle P_2 \rangle = \frac{1}{2}(3\langle \cos^2 \alpha \rangle - 1) \quad (1)$$

where α is the angle a molecule makes with respect to the alignment direction and the angular brackets denote an average over all molecules. The limiting values for $<P_2>$ are -0.5 for perfect orientation perpendicular to the alignment direction, 0 for no orientation, and 1.0 for perfect orientation parallel to the alignment direction. Values for $<P_2>$ resulting from surface-induced orientation typically range from 0.6 to 0.94, indicating a high degree of alignment.

An interesting application of surface-induced alignment of LCTs is orientation at the surface of fibers in fiber-reinforced composites. Adams and Mallon have shown that a low molar mass liquid crystal is oriented at the surface of a carbon fiber parallel to the fiber direction (111), while Sue and co-workers found that **1** can be oriented along the fiber direction, depending on the cure schedule and the epoxy/hardener formulation (112). These findings raise the possibility of creating fiber-reinforced composites with controlled matrix orientation and/or tailored interfaces, which may improve the fiber/matrix interface and result in improved properties (see REINFORCEMENT).

Electric-Field-Induced Orientation. Despite the fact that electric field orientation of liquid crystals is an important technology used, for example, in liquid crystal displays, there has been almost no work on the electric field alignment of LCTs. This may be because electric fields are effective only for thin films; the high field strengths required, on the order of 10^4 V/cm or greater, can lead to dielectric breakdown in thick samples. Nevertheless, although bulk orientation cannot be obtained via electric fields, use of electric fields does provide a complement to the surface-induced techniques described above.

The only description of electric field orientation comes out of work by Ober and co-workers (37,113). They used ac electric fields, which allowed them to control orientation either parallel or perpendicular to the field direction. This is caused by an electrohydrodynamic effect, by which there exists a critical field frequency, below which the molecule orients parallel to the electric field and above which the molecule orients perpendicular to the electric field. Ober and co-workers were able to show control over the direction of orientation in a cyanate ester LCT by changing the frequency of the applied field during the cure (113). In contrast, an epoxy LCT flipped from a parallel to a perpendicular orientation during isothermal cure at a given applied frequency (37). This was attributed to a change in the critical frequency due to the increase in viscosity during cure.

Magnetic-Field-Induced Orientation. Liquid crystals may be oriented in magnetic fields, even though they are diamagnetic, due to the anisotropy in their diamagnetic susceptibility. The advantage of magnetic fields over surface-induced orientation or electric fields is that samples are not confined to thin films.

In fact, orientation in magnetic fields is more efficient in thicker samples, due to anchoring effects at walls. The result is that magnetic fields are the only way to obtain samples of highly cross-linked materials on which bulk properties can be measured.

de Gennes has described the fundamental physics behind the orientation of liquid crystals in magnetic fields (109). Essentially, we can consider an isolated rod placed in a magnetic field. This rod experiences a torque due to the presence of the field, given by (109,114)

$$L_{\mathrm{M}} = -\frac{1}{2}\Delta\chi B^2 \sin 2\theta \tag{2}$$

where $\Delta\chi$ is the anisotropy in the diamagnetic susceptibility parallel and perpendicular to the molecular axis (χ_{par} - χ_{perp}), B is the magnetic field strength, and θ is the angle of the molecular axis with respect to the magnetic field direction. Most liquid crystals have a positive $\Delta\chi$, meaning that the molecular axis aligns parallel to the applied field. Opposing this magnetic torque is a viscous torque, given by

$$L_{\mathrm{V}} = -\gamma_1 \frac{\mathrm{d}\theta}{\mathrm{d}t} \tag{3}$$

where γ_1 is the rotational viscosity coefficient. Essentially, this viscous torque is caused by the drag exerted on the molecule by the surrounding medium. The time dependence of the orientation process can be obtained by assuming that steady state has been reached, i.e. the sum of these torques is zero. Solving the resulting differential equation leads to

$$\tan\theta = \tan\theta_0 \exp\left(\frac{-t}{\tau}\right) \tag{4}$$

where θ_0 is the initial angle of the molecule when the field is first applied, and τ is a relaxation time given by

$$\tau = \frac{\gamma_1}{\Delta\chi B^2} \tag{5}$$

There are two important assumptions in this approach. The first is that the viscosity is a constant. Clearly for LCTs this cannot be true, as the viscosity increases during cure. It is straightforward to include a time-dependent viscosity in the model, although it makes the solution of the differential equation more complicated. The implications of this time-dependent viscosity will be discussed below. The other assumption is that this is a monodomain sample, with all molecules at the same angle with respect to the magnetic field. To account for polydomain samples, it is possible to integrate equation 4 over all possible domain orientations. When this is done, the distribution function for domain orientations is given by (114)

$$\rho(\theta,t) = \frac{\sin\theta_0}{\sin\theta}\frac{\mathrm{d}\theta_0}{\mathrm{d}\theta} \tag{6}$$

where the relationship between θ_0 and θ is defined by equation 4. Finally, the model prediction for average orientation angle of the domains, $< \cos^2\theta >$, is

$$\langle \cos^2\theta \rangle = \frac{\int_0^{\pi/2} \rho(\theta,t) \sin\theta \cos^2\theta \, d\theta}{\int_0^{\pi/2} \rho(\theta,t) \sin\theta \, d\theta} \quad (7)$$

which can then be used to calculate $<P_2>$ using equation 1.

Experimentally, it has proven quite feasible to orient LCTs in magnetic fields. Two classes of materials have been studied: epoxies, which are thermally polymerized in the presence of a magnetic field (69,79,107,115–118). and acrylates or methacrylates, which are oriented in a magnetic field and then photopolymerized (12,56,119,120). Most of the work understanding the factors affecting the degree of orientation have been conducted on epoxies. From the model described above, we see that the factors that could improve orientation are higher field strength; lower initial viscosity and slower viscosity increase; longer time in the magnetic field; and a more anisotropic diamagnetic susceptibility. However, very few studies have examined these factors in detail. Benicewicz and co-workers have shown that orientation increases for **1** cured with sulfanilamide system up to a field strength of approximately 10 T (69). Lincoln and Douglas examined the combined effects of field strength, time in the field, and B-staging (prereaction) (118). They found that orientation increases with higher field strength, longer time in the field, and less B-staging (due to the lower viscosity).

The liquid crystalline phase present during the orientation process is also an important factor. Theoretically, the decrease in energy upon orientation of a single molecule in the gas phase is orders of magnitude less than the thermal energy, and thus a single molecule is randomized by thermal fluctuations. In a liquid crystalline phase, however, motions of the molecules are coupled, and thus the total energy decrease of the system is much greater than the thermal energy. In addition, it has been shown theoretically that packing constraints in a smectic liquid crystal cause orientation to be considerably more difficult than in a nematic (121). Thus, we would expect that under identical conditions nematic LCTs would show the greatest degree of orientation, smectic LCTs would show a lower degree of orientation, and isotropic thermosets would show no orientation. These expectations are confirmed by experimental results. Hoyle and co-workers photopolymerized a methacrylate LCT at various temperatures in a 0.53-T field (56). Substantial orientation was observed when polymerization was conducted at low temperatures in the nematic phase. However, no orientation was observed at high temperatures, when the monomer existed in the isotropic phase. Barclay and co-workers examined **1** and oligoethers of **1**, cured with methylene dianiline (67,107). Compound **1** showed much lower orientation compared to the oligoethers, because **1** itself is initially isotropic, while the oligoethers are initially nematic. Thus, the oligoethers have more time for orientation to occur, and presumably also have lower viscosity since orientation can occur before any chain branching or cross-linking can occur due to the cure reaction. Jahromi used deuterium NMR to show that the rate of orientation is lower in the smectic phase than in the nematic phase (115).

Very little work has been done to understand the kinetics of the orientation process. The model described above has been used to examine the factors affecting the degree of orientation (122). The rate of orientation is determined

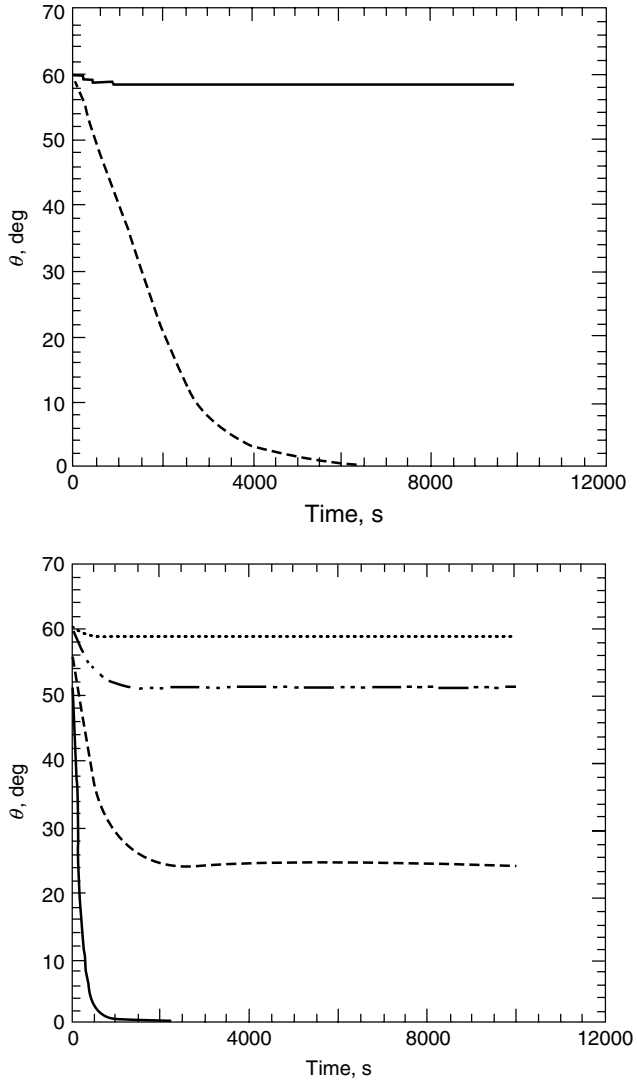

Fig. 3. Model calculations of the magnetic field orientation of liquid crystals. Calculations were conducted using equations 2 and 3. In (**a**) comparison is made between a nonreactive liquid crystal with a constant viscosity and a reactive liquid crystal with an exponentially increasing viscosity due to the cure reaction —— reactive; - - - - unreactive. In (**b**) is seen the effects of magnetic field strength for the reactive liquid crystal . . . . . 0.01 T; —— . . . 0.025 T; – – - 0.05 T; - - - - 0.1 T. From Ref. 122. To convert T to gauss, multiply by 10^4.

by a competition between the magnetic field and the viscosity. Figure 3a show the effect of the time-dependent viscosity as predicted by the above model. For a liquid crystal with a constant viscosity, the viscosity only serves to retard the orientation process; thus at long times the monodomain sample becomes completely oriented in the direction of the magnetic field. However, when the viscosity increases exponentially with time, there comes a point where the magnetic field strength is not sufficient to overcome the viscosity, and orientation ceases. In real systems, this point may correspond to the gel point. Figure 3b shows that if

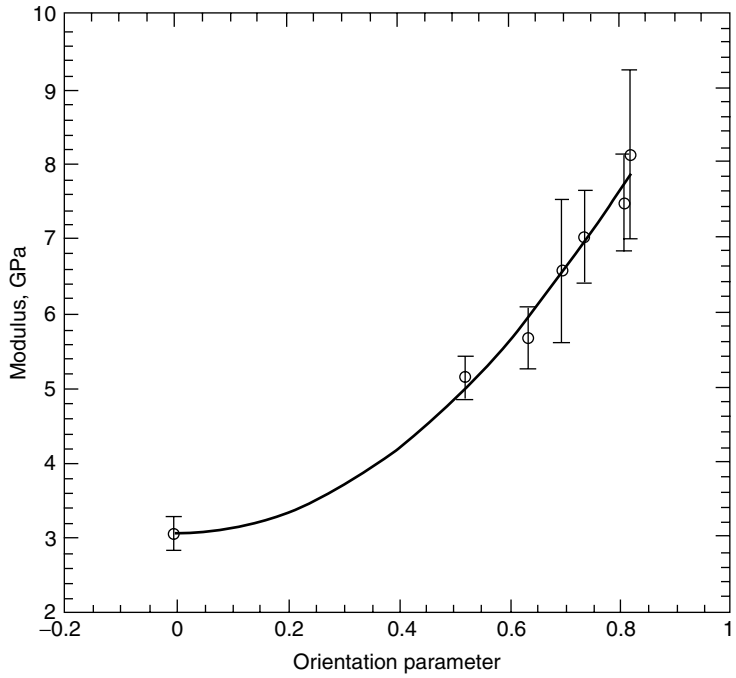

Fig. 4. Effect of magnetic field strength on the tensile modulus of compound **1** cured with sulfanilamide. The line is a quadratic fit to the data, which indicates that the modulus is determined by the average orientation of the molecules. the field strength is high enough complete orientation can be achieved before the viscosity increase overcomes the magnetic field. Unfortunately, there have been no detailed comparisons to date between this model and experimental results, and so the quantitative accuracy of this model cannot be evaluated. However, predicted trends do correspond to the experimental results described above.

A few studies have examined the effect of orientation on bulk properties. Figure 4 shows the change in tensile modulus with orientation for **1** cured with sulfanilamide. Overall, the tensile modulus can be increased three times by orientation. The authors interpret the quadratic dependence of the modulus on orientation parameter as indicating that the modulus depends on the average orientation of the smectic layers (69). Tan and co-workers also found an increase in tensile modulus upon orientation (79). It has also been shown that orientation leads to an anisotropic coefficient of thermal expansion (low thermal expansion in the direction of orientation) (69,107), as well as a higher tensile strength and elongation at break (79). In contrast, experiments using a non-liquid-crystalline epoxy show no enhancements in properties after curing in a magnetic field (123), further confirming that the liquid crystalline phase is needed for orientation to occur.

Future Directions for Research

The synthesis of LCT monomers and understanding of their cure behavior appears to be fairly well established. Although further effort may be needed to

identify LCT monomers appropriate for specific situations, the general principles of how molecular structure affects the phases present, and the development of different phase structures during cure, is well understood. Future work is likely to be focussed on properties and applications of LCTs. For example, only relatively little work has been conducted on bulk mechanical properties or permeability of solvents or gases in LCTs. Important fundamental questions remain regarding the mechanism of enhancement in these properties over conventional isotropic thermosets, as well as the origin of differences in properties between different liquid crystalline phases (eg nematic vs smectic). Considerable work is also needed to fully understand and control the orientation of LCTs using external fields. Finally, applications for LCTs are not yet developed. A few optical devices have been constructed using LCTs, but general application of LCTs to optical applications has not been demonstrated. Similarly, the use of LCTs in composite structures remains limited in scope. Substantial effort is needed to show whether LCTs can exhibit performance benefits that will justify their use in future applications.

MASS SPECTROMETRY

Introduction

For many years, mass spectroscopists have searched for ways to place charged polymeric molecules in the gas phase without degrading the polymer molecule. With charged polymer molecules in the gas phase, the many methods of mass spectrometry (ms) used for small molecules can be applied to large molecules. In the same way, placing unfragmented polymer molecules into the gas phase offers polymer science one of the most powerful absolute techniques that can be applied to single-chain characterization. The ms techniques offer the possibility to obtain polymer single-chain structural information as a function of its molecular mass, eg, repeat units, end groups, copolymer composition distributions, and polymer architecture, as well as the overall molecular mass distribution (MMD). One can also envision studying gas-phase chemical reactions involving polymer chains to further study chain structure, ie, copolymer sequencing, or chain branching. This hope has been realized in the last 10 years with the advent of soft ionization methods in mass spectrometry, matrix-assisted laser desorption/ionization (MALDI), and electrospray ionization (esi) methods. These methods place unfragmented high molecular weight polymer molecules in the gas phase. Using MALDI methods, one can examine polymers with molecular mass from about 500 to about 1,500,000 (1). Using esi methods, polymers with molecular masses up to 5,000,000 have been measured in the gas phase (2).

In this article, focus is on the soft ionization technique MALDI, which is mainly in use for synthetic polymers. ESI is briefly discussed, although the electrospray method has been generally confined to polar polymers, which are water-soluble. Other ionization methods that have been used on synthetic polymers, mainly laser desorption (LD) and field desorption (FD), are confined to low

Encyclopedia of Polymer Science and Technology. Copyright John Wiley & Sons, Inc. All rights reserved.

molecular mass polymers. LD and FD methods are discussed in some detail in other references on ms (3,4).

Readers should note: A search of the current literature will reveal that esi and MALDI methods are most commonly used on biopolymers. Any simple search using the names of these methods will give many more articles on biopolymer uses of these methods than articles on synthetic polymers.

In the last edition of this encyclopedia, a detailed discussion of traditional small molecule ms was given in connection with studies on the degradation of polymers and studies on additives in polymers. These topics will not be considered in this article. The reader is referred to the 1987 Encyclopedia article or other more current reviews (5,6).

This review begins with an abbreviated history of the work done to successfully place a high molecular mass polymer into the gas phase. Then there is a description of the two most common methods used to place charged high mass molecules into the gas phase, esi, and MALDI. Because of its dominant use with synthetic polymers, the MALDI method is described in detail, including sample preparation, data analysis, and the problems this method poses. The time-of-flight mass spectrometry (tof-ms) system is also described in detail since it is the most common in use today for synthetic polymers. References to other ms and detection systems are also provided for the interested reader. Additionally, issues of quantification will be reviewed because to determine MMD or molecular composition distribution (MCD) for copolymers one must be able to quantify the ms data. A variety of applications of MALDI to synthetic polymers are described.

History of MALDI and Electrospray

Electrospray ionization of polymers was introduced in 1968 (7) in an effort to study polystyrene by ms. In 1984, the technique was further developed for biopolymers (8). Spectra of poly(ethylene glycols) (PEG) up to molecular masses of 17,500 were also obtained using esi (9). In 1992, esi techniques were used to obtain ms on a poly(ethylene oxide) (PEO) of about 5,000,000 (2). Since esi techniques multiply charge macromolecules, both these studies were able to get spectra on a quadrupole ms with an m/z of less than 2000, where z is the number of charges. However, with many different n-mers in a normal narrow MMD of a synthetic polymer, the effect of z often as high as 40 means that one needs to obtain resolution in m/z of a small fraction of a mass unit to see the entire MMD.

In 1988, a laser-based desorption method was developed (10) which produced ions of both high molecular mass synthetic polymers and biopolymers. In that same year, the laser desorption technique using an organic molecule matrix now commonly called MALDI was developed (11). The technique was originally described for biopolymers. In 1992, it was shown that the MALDI technique could be applied to synthetic polymers (12–15).

The Analysis Process

Mass spectrometry may be viewed as comprised of three distinct processes: (1) The production of charged gas-phase species from the original analyte. This step

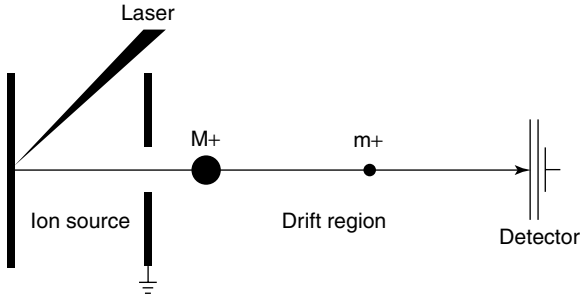

Fig. 1. Schematic of linear tof-MALDI instrument.

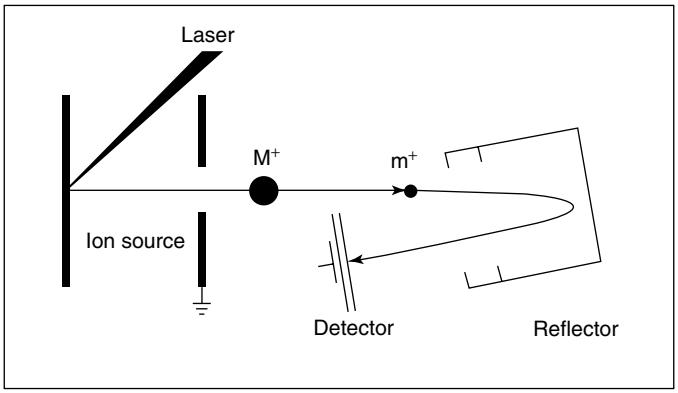

Fig. 2. Schematic of reflectron tof-MALDI instrument.

involves a way to get the analyte into the gas phase and a way to ionize it. For both MALDI and esi, these events occur in the same process; for other ms techniques used on lower mass molecules, this is not necessarily the same process; (2) The separation of the analytes by mass or, more correctly, by m/z; and (3) The detection of the ions.

Herein will be considered the MALDI-tof-ms with a microchannel plate (MCP) detector (see Fig. 1 for the schematic of a linear MALDI-tof-ms and Fig. 2 for the schematic of a reflectron MALDI-tof-ms). This is currently the instrument most commonly used to analyze synthetic polymers.

Introduction of the Polymer Molecule into the Gas Phase and Ion Formation. Since the advent of lasers, it has been hoped that with very short laser pulses of an appropriately chosen wavelength, energy could be transferred into the translational modes of the polymer molecule in such a rapid way that the molecule would go into the gas phase before it broke apart (fragmented). Although there had been numerous tries (7), only small polymers with masses less than 2000 or so could be gotten into the gas phase without significant fragmentation (16,17). These methods of laser desorption or field desorption are described in more detail in the previous encyclopedia article and recent books (3,4,18). Since these methods are limited to low molecular mass polymers they will not be considered here.

The MALDI Process. The MALDI process is the ablation of the analyte cocrystallized with an organic small molecule matrix, most commonly an organic acid. The process (11) initially used and also in common use today is as follows: A polymer (biological or synthetic) is cocrystallized or co-mixed with the matrix molecule in the solid phase. A short uv or ir laser pulse is used to ablate the matrix and the analyte mixture creating a plume of matrix and analyte species. The ablation process involves the uv or ir absorption by the matrix molecule. The laser energy excites the matrix molecule, causing it to vaporize and decompose into what is now considered a supersonic phase transformation (19). This process excites many modes of the matrix and transfers the energy from electronic or vibrational modes into translational modes in the matrix. For MALDI-tof-ms, the most commonly used laser is the 337-nm wavelength uv nitrogen laser. This laser has a pulse width of about 3 ns and generally performs well in the ablation of the matrices commonly used.

The laser energy per unit area is a variable that one can adjust with a variable absorbing neutral density filter. The ablation energy per unit area is usually adjusted to the lowest level that will produce polymer ions. This keeps the initial energy of the plume lower. Lower initial plume energy results in lower initial velocity distributions of the molecular ions, minimizing broadening and reducing the fragmentation of the polymer.

The matrix is selected to absorb most of the energy; few (if any) electronic states of the analyte (the polymer) are excited directly. However, since the analyte is intimately mixed with the matrix, the analyte is carried into the gas phase as a consequence of the phase transformation in the matrix. The analyte, the matrix molecules, clusters of matrix molecules, cations and cation clusters, as well as various combinations of each of these species have been detected in the plume from this laser ablation process (21–23).

For biopolymers, it is thought that the biopolymer is protonated by the many protons released in the plume and thus charged as a positive ion (4). For synthetic polymers, only those which have labile protons are easily charged in the same way (like polyacrylic acid and polystyrene sulfonate). Most synthetic polymers are charged by the addition of a metal ion. In some cases, adventitious metal ions are present in the matrix at concentrations sufficient to allow for their addition to the polymer in the gas phase. (Careful analysis of polymers of known end groups allows unambiguous identification of the attached metal cation.) In other cases, the ions have to be added to the matrix–polymer mixture to give enough of the proper ion to attach to the polymer. Generally, polar polymers are charged by alkali metal ions. These are either added to the solutions used to create the solid matrix analyte mix or often exist as impurities, either from the glassware or solvent used in the sample preparation or in the matrix material. For nonpolar polymers containing double bonds, transition-metal salts with Ag or Cu cations are added to the solution containing the matrix analyte mixture, and these ions charge the polymer in the gas phase. For reasons not completely understood at this time, regardless of the normal stable charged state of the metal ion ie, $+1$,$+2$, or $+3$, the MALDI process generally favors only singly charged n-mers in the gas phase (24). This generalization does not hold for very large molecular mass where multiply charged synthetic polymers can often be seen (1). Once charged, the metal polymer species is then accelerated into the separation region of the ms.

Other Soft Ionization Processes for Large Molecules. Electrospray ionization creates ions by a potential difference between a metal capillary tube and the inlet to the mass spectrometer. The electric field generates charged droplets in the form of a fine mist (see Ref. 25). Application of a drying gas or heat evaporates the solvent, reducing the droplet size and eventually resulting in the formation of molecular ions.

Truly monodispersed polymers like large biomolecules may be examined by esi-ms. These samples typically show a distribution of multiply charged molecules and no evidence of fragmentation. The multiple charging process has the effect of lowering the m/z values to a range easily measured by quadrupole ms, molecular mass typically in the range 500–2500. The molecular mass of biopolymers can be calculated since more than one charged state is observed. However, the multiple charging of esi is a drawback for synthetic polymers. Here, there are many n-mers even with a synthetic polymer having a narrow MMD. Each n-mer in the MMD forms many multiply charged species. These multiply charged species for each n-mer together with the distribution of n-mers results in an m/z spectrum that requires a resolution often not available in many mass spectrometers to separate all the species present. Because esi-ms uses solutions of the polymer as the sample, esi-ms is easily connected to liquid chromatography systems, such as hplc or sec. The coupling of esi with chromatographic process is often used to deconvolute the complex spectra described above (26).

The Separation Process. Once the analyte is in the gas phase as an ion, analytes must be separated on the basis of mass to charge (m/z). A variety of separation techniques are available. The most common form of ms separation is the quadrupole mass filter (3,4). Because this method is limited to m/z less than 3000 or so, it is not generally used with MALDI. However, a quadrupole is commonly used with esi where multiply charged analytes allow one to examine high masses for m/z less than 3000.

Fourier transform mass spectrometry (ftms) is an ion cyclotron resonance method (3,4). This method is currently limited to masses less than 20,000. Thus, it works well for lower molecular mass polymers. Often it is used with MALDI. However, the MALDI process is so energetic that the initial velocity of the analytes can cause some intensity difficulties that make the method difficult to quantify. Because of the expense of the magnet required to obtain quality data with this method, only a few laboratories use this method.

For MALDI, the most common mass separation technique is tof-ms. In its simplest form, the ions in the MALDI plume are accelerated by a high voltage (often as high as 25 kV) for a distance of a few millimeters during which the ions obtain a velocity v. The accelerated ions drift in an evacuated tube, typically about a meter long, at this velocity. (Some instruments have flight tubes as long as 6 m). The equation describing this simple process is

$$zeV = 1/2mv^2 \tag{1}$$

where V is the electric potential applied to accelerate an ion of charge ze. Once in the drift tube the translational energy of the ion is given by the r.h.s. of the equation. There is a correction for the initial velocity of the particle in equation (1) but if the field is large enough, this is a small correction (18,27). If the drift

tube is long compared to the acceleration region, then $v = L/(t - t_0)$ where L is the length of the drift tube and $t - t_0$ is the time from some arbitrary zero time t_0 set by the arrival of the ablating laser pulse. Thus, we have

$$m/z = 2eV(t - t_0)^2/L^2 \tag{2}$$

or

$$m/z = a(t - t_0)^2 \tag{3}$$

Equation (3) is the equation relating mass and charge to time, which is used as the general calibration for a tof-ms instrument. Often some small corrections are added to equation (3) (18,28) for the final tof calibration equation.

In current instruments, two modifications from a simple tof instrument are included. One is the reflectron, a set of ion mirrors which slow the ions down, reverses their direction, and by increasing the actual length of the flight path, increases the resolution. See Figure 2 for a schematic of an instrument with a reflectron. By appropriate choice of reflectron voltages and shape of the voltage fields, one can improve resolution even more. This is described in detail in other references (18). The overall effect of the reflectron is to make little change in equation (2) for use as a calibration equation.

Although the reflectron improves the resolution of the instrument, there can be loss of signal because of ion optics as well as late fragmentation. Fragmentation that occurs while the molecule is in the linear flight tube is considered late fragmentation. (Early fragmentation is fragmentation in the initial plume.) Molecules that fragment in the late fragmentation process will have the proper kinetic energy and arrive at the correct time at the detector in the linear region. Once in the reflectron, these ions are reacclerated with the mass of the charged fragment. Thus, they arrive at the reflectron detector at the "wrong" time.

The second modification is called delayed extraction. In earlier instruments, a single high voltage accelerating electric field was continuously applied while the plume was formed by laser ablation. Instruments with delayed extraction have a second field plate located a few millimeters away from the original field plate. The second field plate is energized for a brief time, keeping the plume trapped for a short time (hundreds of nanoseconds), between the two field plates. The second field is then suddenly dropped to zero potential, accelerating the ions from the contained plume. This brief containment of the analyte plume allows it to come to some modest equilibration, decreasing the range of initial translational velocities and thus improving the resolution of the final spectra (27,28).

Detectors. Several detectors are available for tof-ms instruments. An optimum detector should show no ion velocity dependence. The detector should not saturate or should have a sufficiently rapid recovery rate on the time scale of the smallest collection time interval. No current detector satisfies these requirements. Many of the most common detectors have been discussed (3).

The MCP detector is the most commonly used on instruments employed for the analysis of synthetic polymers. The MCP detector is made up of an assembly of lead glass capillaries coated on the inside with electron-emissive materials and fused together. The capillaries are biased by a high voltage. Ions strike the inside

wall, creating secondary electrons which amplify each ion impact signal with a gain of 10^3 or 10^4. Higher gains are obtained with two MCP detectors in series.

In a study (29) of differences in signals from two detectors, using the same tof instrument, equimass blends of narrow PMMA standards were used to simulate a wide polydispersity polymer and it was shown that different detection systems produced different MMD for the polymer blend using the same sample preparation method and the same analyzer conditions. The differences arose from detection mechanisms, saturation effects in the detector, and signal to noise problems.

Matrices for the MALDI Process. The matrix is crucial to the MALDI process. It is generally believed that how the polymer is situated in the matrix has a significant influence on the success of the MALDI process. Liquid matrices have been used in a number of applications for biopolymers but only a few applications for synthetic polymers. Solid matrices are most common for both biopolymers and synthetic polymer work. The earliest experiments (11) that described the MALDI technique employed solid matrices.

Liquid Matrices. Liquid matrices have the advantage that they present a homogeneous material for the polymer to reside in (in contrast to the crystal of a solid matrix which is discussed in a later section) and thus show less variation in signal as the laser probe is moved across the sample compared to use of a solid matrix with hand spotting (30). Furthermore, with a liquid matrix it is more likely that one can detect precipitation of the polymer sample in the sample preparation. Such an observation cannot be made during the solvent evaporation step of the solid matrix polymer preparation.

The major disadvantage of the liquid matrix is high vapor pressure of the liquid, often too high for the vacuum systems of many current tof instruments. The use of atmospheric pressure ms in MALDI analyses (31) may lead to the increased use of liquid matrices. Furthermore, the liquid matrices seem to have poorer mass resolution than the same polymer in solid matrices. Finally, many instruments are designed with vertical sample holders, which are not impossible to work with but certainly this sample alignment does not favor the use of these matrices. Little work has been done on this promising method of sample introduction.

m-Nitrobenzyl alcohol (*m*-NBA) and 2-nitrophenyl octyl ether (*o*-NPOE) are commonly used MALDI liquid matrices. These substances were originally used as fast ion bombardment (FAB) ms (3,4) liquid matrices. Liquid systems with liquid mediators and uv absorbers, some of which were normal solid matrices, have been developed (30). These gave excellent sodium cationized PEO spectra. A glycerol mediator with sodium and potassium ferrocyanide as the matrix absorber has been used (32,33).

Solid Matrices. Most work on synthetic polymers use the solid matrices developed for the biopolymer analysis. To use these matrices, solutions of polymer, matrix, and cationizing salt are mixed. The solvent is then allowed to evaporate from these solutions deposited onto a sample surface. The mass proportion ratios of the matrix:polymer:salt in the final solid mixture cover the range of 5:1:2 to 2000:1:1. These proportions are often dependent on molecular mass of the polymer (1). The choice of matrix compounds for synthetic polymers with respect to the polarity of the polymer have been discussed (34). As a general rule, matrix polarity should be matched with the polarity of the polymer so that both are soluble in a common solvent. Since the MALDI sample preparation requires intimate

mixing of matrix, analyte, and salt, this choice will assure the best co-mixing of the final solid mixture of the analyte and the matrix. The following table for the appropriate choice of matrix and polymer in terms of solvent strength may be helpful. The arrangement in the table is more hydrophilic at the top proceeding to more hydrophilic.

Matrix	Polymer
Thiourea	Poly(ethylene glycol)
Dihydrobenzoic acid	Poly(propylene oxide)
Cyanohydrobenzoic acid	Poly(vinyl acetate)
Ferulic acid	Poly(tetramethylene glycol)
Indol acrylic acid	Poly(methyl methacrylate)
Dithranol	Polystyrene
Retinoic acid	Polybutadiene
Diphenyl butadiene	Polydimethylsiloxane

Although this table provides a good first rule for the choice of various matrices for each polymers, its usefulness is often overridden by the sample preparation methods described later in this review.

A recent review (20) of MALDI of synthetic polymers offers an extensive reference list of polymers and the appropriate matrix to use with them.

Sample Preparation Methods for Solid Matrices. Sample preparation is critical to MALDI using solid matrices. The presumption is that the polymer and the salt must be well dispersed in the final matrix mixture to achieve a one-to-one representation of the polymer MMD in the solution to the polymer MMD in the gas phase. Yet, the matrix is commonly crystalline and the polymer may be either semicrystalline, like PEO, or glassy, like atactic polystyrene. Kinetic processes occurring during the loss of solvent from the solution of the mixture of matrix, salt, and polymer must occur either to co-crystallize the polymer with the matrix and salt or to embed the polymer in the defect structure of the organic matrix. To obtain the correct representation of the MMD in the ms, each n-mer in the MMD must occur in the ms in proportion to its appearance in the original MMD.

The intimate dispersion of the salt in the matrix is also important (35,36); if the salt is not well dispersed, there may be a loss of signal. The matrix is often an organic acid. By making the salt of the matrix acid and mixing this with the parent matrix acid, increased polymer signal is obtained. Too much salt, however, leads to no polymer signal since matrix salt alone is often not a good matrix for the polymer.

Generally, there are two common approaches to sample deposition onto the target surface, hand-spotting and electrospraying. In one approach, the solutions described above are hand-spotted from a microliter pipette onto a target plate; 0.5–2 μL of solution are used to deposit micrograms of polymer, matrix, and salt mixtures onto the plate. The solvent is allowed to evaporate rapidly (often with help from a fan or heating or by drawing the pipette tip across the plate, spreading the solvent out). One usually obtains crystals of the matrix. This is called "hand-spotting" or the "air-dried droplet technique." The advantage to this method is that it requires little additional equipment. However, the samples have large

signal variations across the target plate; one finds areas of large polymer signal, "a sweet spot," and other regions where no polymer signal is found. This inconsistency across the sample is reduced somewhat by a variety of modifications of the hand-spotting method. In a procedure used by various workers (37,38), the matrix crystals are crushed with a spatula. This leads to additional sample homogeneity. Others have examined the different modifications of the hand-spotting technique (39).

However, in general, hand-spotting leads to a relative standard deviation of 40% in the total signal intensity variation across the target surface. The electrospraying method of sample preparation, described below, can produce targets that exhibit less than 5% relative standard deviation of total signal intensity across the target surface (40).

The same solutions that are used for hand-spotting are used in the electrospray technique. These solutions, after mixing, are then drawn into a microliter syringe that is placed into a syringe pump. The needle of the syringe is held at a potential between 3 kV and 7 kV against the sample target as ground. When the solution is delivered at 2–20 μL/min, a fine spray of charged droplets is delivered out of the needle. The sprayed solvent evaporates from the droplets, and the polymer:salt:matrix mixture is deposited on the sample plate nearly dry (40,41). This procedure keeps the crystals of the matrix small (ca 2–5 μm diameter) (35,40) and the polymer matrix and salt in an intimate mixture.

The signal from electrospray sample deposition shows little shot-to-shot variability as long as the sample depth is thicker than the amount of sample that can be ablated by a few laser shots at the same location of the target (42). This methodology also shows good shot-to-shot repeatability for biopolymers (41).

Choice of Salts. Synthetic polymers generally obtain a charge by a different mechanism than biopolymers. Most biopolymers obtain a charge by addition or loss of a proton from the parent molecule. This is because biopolymers have acid groups available to them. For synthetic polymers like polystyrene sulfonic acid, this mode is also available. However, most synthetic polymers do not contain labile protons. Those synthetic polymers that are polar or contain double bonds can be cationized, however. The polar polymer molecules require a metal ion, often an alkali like Na^+ or K^+, to attach to the polymer *n*-mers to obtain a charge. The Na and K metal ions are usually found in the matrix itself or introduced through the glassware used in sample preparation. For example, with PEO or PMMA, the common matrices used for these polymers have enough Na and K so that one commonly sees ions with both Na and K attachment without the addition of any Na or K salt. One can also add salts to the sample preparation solutions causing these salts to attach to the polymer *n*-mers. For polymers with double bonds, polybutadiene or polystyrene for example, one normally has to add Ag or Cu salts. These metal salts are found to work best, although other salts also give spectra (43). In fact, some matrices give spectra for these polymers with Na or K salts but the quality of the spectra is poor compared to spectra obtained with transition-metal salts. Polymers without polarity or double bond, for example polyethylene or polypropylene, have difficulty being cationized. Only a few papers report MALDI spectra on these saturated hydrocarbon polymers (44,45).

Commonly, salts that are soluble in the same solvent as the polymer and the matrix are added to the polymer matrix solvent mix. Nitrate, chlorides, etc

are commonly tried, but these do not easily dissolve in the organic solvents commonly used (tetrahydrofuran, acetone, chloroform). One often uses trifluoroacetic acid (TFA) salts; for example, Ag TFA or CuTFA are commonly used to cationize polystyrene. Only one paper has reported any effect of the anion on the cationization process (46).

Other materials have been used to cationize the polymers. Metallocenes (ferrocene, nickelocene, and cobaltocene) have been used as cationizing agents for polystyrene and PEO (47). These cations have the advantage that they are soluble in many organic solvents and also do not have the isotopic splitting seen with Ag, which often complicates the interpretation of the MALDI spectra.

Quantification of MALDI for MMD and Moments of MMD

Mass Axis Quantification. Mass axis quantification is most easily done. Calibration of most tof instruments is usually done with biopolymers of known molecular masses. These biolpolymer are selected because they typically provide a single major peak whose mass is known accurately; thus, mass axis quantification is quite straightforward. Calibration usually can be done using three of these biopolymers. Collecting data with 2-ns time intervals, one can get better than single-unit resolution on an instrument with a 1.5-m flight tube in reflectron mode at about 7000. Good mass resolution and calibration is required for end group determination, copolymer composition determination, and for polymer architecture studies.

Signal Axis Quantification. For synthetic polymers, signal axis quantification is of utmost importance to obtain a good representation of the MMD or MCD or to compute the moments of the MMD to compare with classical polymer characterization methods like light scattering or membrane osmometry.

The signal axis may be in error due to a variety of reasons. Many of these issues have been discussed (48). Most of the issues related to uncertainties arising from sample preparation have been discussed in some detail in the earlier sections on matrices and sample preparation.

Uncertainties Arising from Ablation, Ionization, and Drift Regions. Little is known about the desorption/ionization process in MALDI. Work on the same type of polymer of different molecular masses suggests that higher ablation energies are required for polymers of higher molecular masses. Thus, since the normal procedure is to adjust the laser ablation energy to just above the threshold needed to obtain the polymer spectra in MALDI, the desorption process of MALDI could also cause the moments determined by mass spectrometry to be lower than the true moment. It is not known whether low mass molecules desorb better than higher mass molecules, but, if preferential desorption of low mass molecules occurs, it could account for the low MALDI values often reported when the moments from MALDI are compared to those obtained by classical methods (49–53).

For homopolymers, the dominant polymer repeat units commonly show high signal intensity. Also, less intense intermediate peaks may be seen adjacent to the major high intensity repeat units. These intermediate peaks more often than not have the same repeat unit as the major peaks. These intermediate peaks may arise from a variety of sources. It is most obvious that end groups or cations may

differ. One can have two different sets of end groups on linear chains or many different types of end groups on branched chains. This gives rise to a main group series of peaks arising from the major pair of end groups and a second series of peaks from the second set of end groups.

One may see additional peaks from different metal cations attaching to the polymer. As noted before for polar polymers like PEO and PMMA, one does not need to add salts to the matrix. Impurities in the matrix in the form of Na or K seem to be in sufficient concentration to cause the addition of Na or K to the polymers. For example, with PMMA it is not uncommon to see peaks separated by 16 u, the difference between the molecular mass of Na and K. This peak intensity will change by the addition of one or the other metal ion. All the above peaks will appear in both the linear and reflectron mode.

Some intermediate peaks will often appear differently in linear and reflectron modes for reasons other than sensitivity differences between the two modes. If the reflectron spectra is different from the linear spectra, this may be due to fragmentation during the flight down the linear flight tube. Of course, fragmentation occurring in the ablation region (the source region) cannot be detected this way. Ablation region fragmentation may be detected by the appearance of more n-mers in the low mass regions of the MMD as the laser energy is increased.

Finally, the intermediate peaks may arise from matrix adducts to the polymer. Matrix adducts of polystyrene polymers of molecular mass 3900 and 7000 of the form MatrixAgPolymer and MatrixAgAgPolymer have been found (21). Figure 3 shows the entire spectrum, and Figure 4 shows these adduct peaks in a polystyrene of molecular mass of about 7000 used in the NIST Interlaboratory Comparison (49,54).

Uncertainties Arising from the Detector. The detector is another influence on the MMD that may impact the moments calculated by MALDI-tof-ms. The

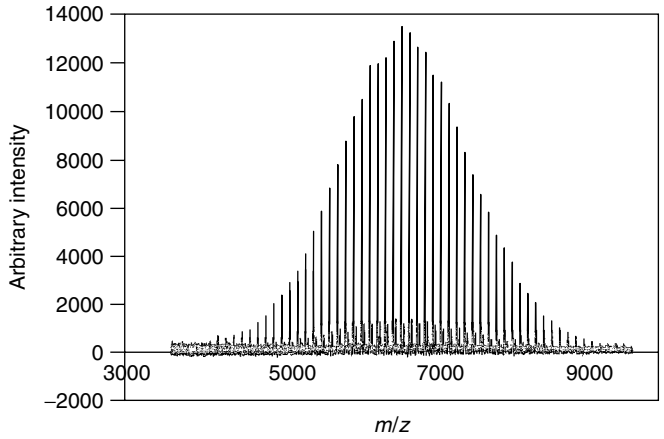

Fig. 3. MALDI-tof-ms of polystyrene around 7000 molecular mass. This MALDI spectrum was generated using dithranol as the matrix and AgTFA as the salt. The polystyrene, dithranol, and salt were dissolved in tetrahydrofuran. The solution was then electrosprayed onto the sample plate. The polymer analyzed in reflectron mode with an extraction voltage of about 25 keV.

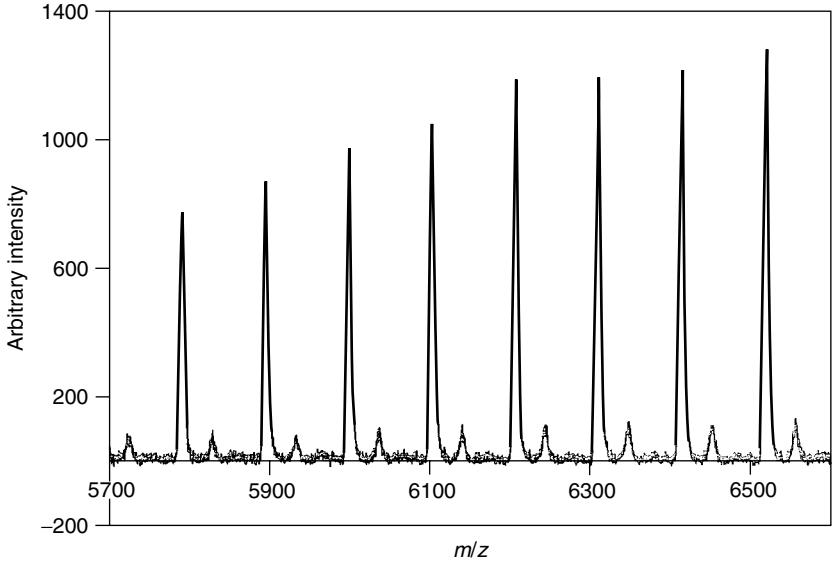

Fig. 4. Detail of MALDI-tof-ms of polystyrene polymer shown in Figure 3. The smaller peaks between the main peaks have been shown (21) to be the result of matrix adducts. This is an example where these intermediate peaks are not from polymer molecules terminated with other end groups or from *n*-mers charged with different salts.

detector in most of the instruments is an MCP detector. The smaller molecular mass molecules hit the detector first, and the larger molecules follow later. If there is saturation occurring in the detector, then there would be a discrimination against the high mass molecules. The issue of detector saturation has been discussed by many authors (51,55,56). Since the matrix molecules or low molecular mass polystyrene molecules could saturate the detector before the higher molecular mass molecules arrive at the detector, this would cause the computation of a lower M_n and M_w than the true values.

The detector may also be less sensitive to larger mass polymer molecules because of the way the ions are detected. MCP detectors count the number of ions by an ion-to-electron conversion when the ionized polymer collides with the detector plate. A bias occurs against the high mass species when the ion-to-electron conversion is diminished due to a decrease in the impact velocity of the larger ionic species (51,57). If a discrimination against the high mass polymer molecules exists, this would cause the estimated moments of the distribution to be less than the true value of the moment.

Uncertainties from Data Analysis. Baselines drawn in MALDI-tof-ms are similar to that of a spectroscopic or chromatographic system where a many-point baseline must be drawn. Baseline corrections may be a cause of the disagreement between the moments determined by classical methods and those determined by MALDI. There is much more noise in the low mass end of the spectra obtained by MALDI-ms. Some of this noise may arise from fragments of the polymer, clusters of matrix and salt, or metal clusters. If the baseline correction does not account for this difference in baseline noise, then these data may overweight the lower part

of the MMD and thus the calculated M_n and M_w would be expected to be lower than the true moments.

Assuming a correct baseline is drawn, the question arises as to how to compare the MMD estimated from a tof mass spectrometer to that obtained from size exclusion chromatography (sec) using a UV or differential refractive index (DRI) detector. A sec is the instrument most commonly used to obtain the MMD for synthetic polymers. The most obvious difference between the two techniques is that the tof detector counts numbers of ions of n-mers while the DRI or UV detectors on sec instruments measures mass concentration of the polymer. The mass concentration of the polymer is proportional to the product of the molecular mass of the n-mer and the number of molecules of that n-mer per unit volume. Thus, in the ms we obtain the number MMD while in the sec we normally obtain the mass MMD. Furthermore, the raw signal of each must be corrected for the transformation from time to mass, which is different for each instrument. This transformation has been discussed in detail (58).

Finally, there is a problem of the detection for higher n-mer masses in MALDI. Since the detector is an ion detector, a counter of the number of n-mers, peaks disappear into the noise before peaks would disappear into the noise on a normal sec detector, which detects the total mass associated with each n-mer. The consequences of this signal-to-noise problem on the polydispersity (M_w/M_n) studied by MALDI-tof-ms has been discussed (59).

The above discussion assumes that the polymer is a linear homopolymer. For branched polymer there is not a simple direct relationship of elution volume in sec to molecular mass. For a copolymer, the signal differs in both the DRI or the uv detector for different groups in the copolymer. Further, it is usually assumed that there is no effect of molecular mass on the DRI or uv response. Although this is the case for high molecular mass species, as we go to very short chains the DRI and uv are affected by the presence of end groups. This is discussed in more detail in the section on narrow MMD.

The effect of instrumental broadening on the sec data has not been discussed. For a polymer with little polydispersity the chromatographic broadening is important in sec and may lead to prediction of larger polydispersities than those found by MALDI. Some measurement condition differences which cause effects greater than those between the mass and number MMDs have been studied (60).

Applications of MALDI-tof-ms

Narrow MMD Homopolymers. Generally, most laboratories obtained reasonable agreement for narrow MMD polymers between moments of MMD obtained from MALDI and those obtained by classical methods, eg light scattering to obtain M_w and end group analysis or osmometry to obtain M_n or sec. Good agreement between classical methods and MALDI for polymers with $M_w/M_n < 1.2$ has been observed (61,62). A study (63) of PMMAs by sec and MALDI support this view. A careful study of polystyrene of molecular mass 5050, 7000, and 11,600 and blends of the three has been done (48). Using the polystyrene 5050 and 11,700 and studying changes in the MMD of the polymer of 7000 by blends, showed no systematic uncertainties within 0.5% in the MMD or the moments of the MMD.

A MALDI-tof-ms interlaboratory comparison was conducted by NIST among 23 laboratories using MALDI-tof-ms on a well-characterized polystyrene to assess the robustness of the method to determine the MMD (49). An example of a MALDI-tof-ms spectrum from this polymer is given in Figure 3. The polystyrene was synthesized to have a tertiary butyl end group at one end and a proton at the other. An nmr characterization of M_n was found to give 7050 ± 400. The M_w was found to be 7300 ± 600 by light scattering. The expanded uncertainty values following the "±" represent both type A uncertainties (statistical uncertainty) and type B uncertainties (systematic uncertainties) (64). An ftir spectroscopy confirmed the presence of a single pair of end groups and no other end groups in measurable amounts.

Each participating laboratory was asked to perform MALDI-ms using two distinct protocols. Each laboratory was asked to do three repeats of each protocol to check for intralaboratory variability.

By compiling all the returned data using all protocols into one preliminary analysis, it was found that MALDI-ms returned an M_n of 6600 ± 100 and an M_w of 6700 ± 90. The uncertainty values following the "±" represent only type A standard uncertainties (statistical uncertainty). These M_w and M_n obtained from MALDI were below the M_w and M_n of the classical methods but still within the overlapping uncertainty ranges. The statistical uncertainty in the ms measurements was very small, indicating that from laboratory to laboratory, reproducibility was extremely good.

In a few reported cases, the agreement for narrow distribution polymers has not been good (52). This can generally be attributed to the failure of the classical method at low molecular mass. For example, calibration of sec at low molecular mass is at best difficult. Furthermore, the effect of end groups on the detector response is often not taken into account nor is the effect of broadening on the computed moments properly taken into account at the lower molecular masses. For example, the DRI detector requires the dn/dc be constant, independent of molecular mass for the calculation performed by most current software programs. But dn/dc is known to be affected by end groups (65).

$$\mathrm{d}n/\mathrm{d}c = a + b/M \tag{4}$$

For most polymers, the second term on the r.h.s. has a contribution below 100 repeat units or molecular mass less than 10,000 for polystyrene.

Generally, the effect of not correcting for broadening is to increase the apparent values of sec values of M_n and M_w. This effect may be seen by comparing the moments calculated from sec and from MALDI in the data (63) on narrow MMD polymers.

Broad MMD Homopolymers. Early in the studies on MALDI of synthetic polymers, it was hoped that MALDI could be used successfully for both narrow and broad MMD. Soon it was discovered that for a variety of reasons the correct MMD of broad MMD polymers could not be obtained in one step by MALDI-tof-ms. Good agreement between MALDI and gpc for MMD moments for polymers with polydispersities less than $M_w/M_n = 1.1–1.2$ was found (50). Polymers with higher polydispersities regularly showed incorrect moments of the MMD (50,66).

A number of authors used the procedure of simulating a broad MMD by preparing a multicomponent blend of a number of narrow fractions to mimic a

broad MMD. This way of controlling the amount of each part of the MMD allowed them to show that they do not get the correct representation of the expected MMD from the mixed systems. This procedure also provides a method to examine the various causes of this problem, including instrumental effects (55), sample preparation (67), desorption/ionization issues (51), and laser power (68).

None of these studies have lead to significant improvements in doing the MALDI-ms of polymers with high polydispersities. Generally, this problem has been overcome by coupling MALDI-tof-ms to various chromatographic methods to separate polymers.

MALDI as a Chromatography Detector. The sec is the most commonly used chromatography technique for analysis of polymers. Two common approaches have been used to obtain a MMD from the combination of MALDI and sec. In one case, one fractionates the polymer using sec, collecting each fraction and obtaining the MALDI on each fraction. One then must combine the data from each MALDI spectra to create the MMD on the polymer. This is done by summing each MALDI chromatogram used in obtaining the moments to obtain M_n and M_w and the polydispersity (69). This technique is thought to suffer some of the discrimination issues brought out in the discussion in the broad MMD section (20).

In another method, fractions are taken from the sec at well-defined elution volumes. A MALDI analysis of these fractions is made and the peak of the mass MMD M_p is computed from the MALDI data on the fraction. The M_p so obtained is then used to calibrate the sec. The calibrated sec is then run to get the exact MMD of the polymer (70). A number of authors have used this technique. Two limitations of this technique should be mentioned. The first problem arises because one must have relatively narrow mass fractions in each sec fraction used for this to work. Thus, linear or lightly branched homopolymers or random or alternating copolymers meet this criterion. Branched polymers or polymers with rings or closed loops may show broad MMD fractions for narrow sec fractions. This is because branched polymers or polymers with rings and loops can have the same hydrodyamic volumes for molecules with widely varying masses (71–74). Block copolymers in a solvent such that one block is extended and the other is collapsed (with very different hydrodynamic volumes) may result in mass broadening too. This effect will make it difficult to assign a mass to the broadened fraction by MALDI and thus to get a good calibration for the sec columns. The second problem comes from the assignment of the total mass of the material in each sec fraction. For a copolymer, for example, a single detector may not be enough to assign the total mass of different groups at a given molecular mass. Two detectors at least may be required for copolymers.

In one case (71) a different phenomenon is observed: Poly(bisphenol A carbonate) terminated with hydroxyl groups undergoes self-association by hydrogen bonding in solution and these molecular aggregates remain in the sec column. In the application of the sec MALDI method, self-aggregation is suppressed in the sample preparation for the MALDI analysis and thus a very broad molecular mass for each MALDI appears. This is an extreme case where sec alone cannot provide a narrow MMD for MALDI.

A number of papers discuss placing a MALDI-ms instrument in line with a continuous chromatographic process (75,76). For example, a method called Aerosol MALDI has been developed. In this method, elutant from an sec is mixed with

matrix prior to pneumatic nebulization, which sprays directly into a mass spectrometer. MALDI is performed on aerosol particles using a 355-nm laser. The solvent is evaporated from the aerosol particles by passing the aerosol through a heated tube. This technique has been used successfully with PEG of mass 1000 u and polypropylene glycol also of mass 1000 u. Mass resolution with this method is less than with normal MALDI. In addition, the problem with data analysis is overwhelming. Baseline determinations, identification of peaks, and quantification are all problems.

The sec method separates polymers on the basis of the polymer size alone. In sec, only the interaction of a polymer which excludes it from the wall is operative. An attractive interaction between the polymer in solution and the solid portion of the porous separation medium can substantially affect molecular separation. The attractive interaction counterbalances the exclusion effect until a compensation point, "the adsorption theta point," is obtained (77,78). Selective molecular separation is lost at this compensation point. For an even greater attractive polymer porous media interaction, the polymer becomes adsorbed onto the surface of the porous media so that the higher molecular weight polymers exhibit an inhibited flow through the porous media. The change from an excluding interaction to an attractive interaction with the porous media can be affected by changing the solvent strength by use of mixed solvents.

For block copolymers, one can choose a solvent system that will have one block at the polymer compensation point and another block in the exclusion regime.

This chromatographic method has been used to examine the polyethylene oxide-*co*-polymethylene (PM) block system (79). The solvent is chosen so that the PEO is at its critical condition, ie, there is no separation with respect to the molecular mass of the PEO, but there is separation with respect to PM. MALDI-tof-ms was used as a detector on this system. Each separate PM peak was continuously transferred onto a MALDI target. The fractionation was made into separate PM peaks. Within each PM peak there is a MMD of PEO. This allowed the authors to estimate both the MMD and MCD for the whole polymer.

End Groups. Polymer end groups play an important role in determining polymer properties. This is increasingly important as the molecular mass of the polymer decreases. Low molecular mass polymers with well-defined end group functionality are used as prepolymers for many important final polymer products, ie, polyurethanes, epoxies, uv cure adhesives, and various other thermosets (qv). For example, polyurethanes are commonly made by a three-step processing in which the activity of the end groups is important in determining the final product (see POLYURETHANES).

Bulk functionality of prepolymers can be determined by nmr, uv–vis spectroscopy, or titration methods. The sec data from multiple detectors can sometimes be used to obtain estimates of functionality, but this is often not available due to the lack of difference of detector signal between the end group compared to the central groups. Even if this is possible, sec does not allow one to separate monofrom multifunctional end groups. Further, the calibration of sec at low molecular masses is, at best, difficult. MALDI-tof-ms offers a unique probe of the end group functionality as a function of the molecular mass of the polymer itself. For polymers of molecular masses below 10,000 or so, current commercially available MALDI-tof-ms instruments can differentiate end groups differing by a few mass

units. With the sensitivity of ftms, one can achieve single mass unit end group identification up to 20,000 (3).

PMMA with a variety of end groups was analyzed and it was shown that the various end groups can be identified (80). A variety of PMMAs of industrial relevance have also been examined and it was possible to distinguish many end groups using "time-lag-focusing" (delayed extraction) for polymers with molecular masses of 16,000 (81,82).

MALDI has been applied to the analysis of poly(alkylthiophenes) (PAT), a rigid rod-type polymer (83), and it was possible to determine the end-group compositions of the PAT samples; H/H, H/Br, and Br/Br end groups were found. The samples showed large variations in the presence of each end-group pair as a function of preparation conditions. Such end-group monitoring is necessary for the development of new materials from these polymers. Further, for the polymers with Br end groups, some end-group loss as a function of laser power was found, with more fragmentation at higher laser powers.

Finally, the end groups in poly(bisphenol A carbonate) have been examined (84). It was possible to distinguish among a variety of end groups for polymers with masses up to 16,000. This work was done with the MALDI acting as an sec detector.

Copolymers. MALDI-tof-ms of copolymers offers the opportunity to obtain an MMD and MCD. However, to obtain an MCD the ms can only be done on low mass copolymers. This is generally difficult because the number of *n*-mers separated by only a few mass units quickly becomes very high for copolymer composition near 50-50. If the mole faction of one of the copolymers is small, it is possible to obtain single or nearly single n-mer resolution for the MCD of the copolymer.

As simple example, MALDI-tof-ms has been used to study the number of α-methyl styrene (α-MeSty) repeat units in SRM 1487, a narrow MMD PMMA NIST standard reference material of about 6300 g/mol (62). Here, the major copolymer component is MMA and α-MeSty is the minor component. The α-MeSty is, in fact, part of the initiator for this polymer and the material is either a "MMA styrene MMA" triblock copolymer or a "styrene MMA" diblock copolymer, with the α-MeSty block length containing 0–6 α-MeSty.

In a more comprehensive study, the copolymer systems polystyrene-*block*-poly(α-MeSty) and poly(α-MeSty)-*block*-poly(4-vinyl pyridine) were examined (85–87). These copolymers have a much more complex MCD as a function of molecular mass than the one just discussed (62), and the resulting MALDI-tof-ms spectra reflect this complexity. In the work (87) on poly(α-MeSty)-*block*-poly(4-vinyl pyridine), polymers with different mole ratios of α-MeSty and 4-vinyl pyridine were studied. The composition of the maximum peak was used to start the analysis. The compositional assignment of this maximum peak was made from nmr data and/or the initial chemical composition of the polymer reaction mixture. The rest of the peaks were assigned by a procedure that references the composition of the main peak. From this analysis the two dimensional distribution of the di-block copolymer was obtained as shown in Figure 5. Such use of collateral data shows that ms alone may not be enough to obtain such a complex copolymer distribution. However, with the copolymer composition distribution, a richer understanding of the copolymer chemistry can be obtained.

In a study (85) on the copolymer system polystyrene-*block*-poly(α-MeSty), it was possible to confirm that the copolymer composition agrees with the predicted

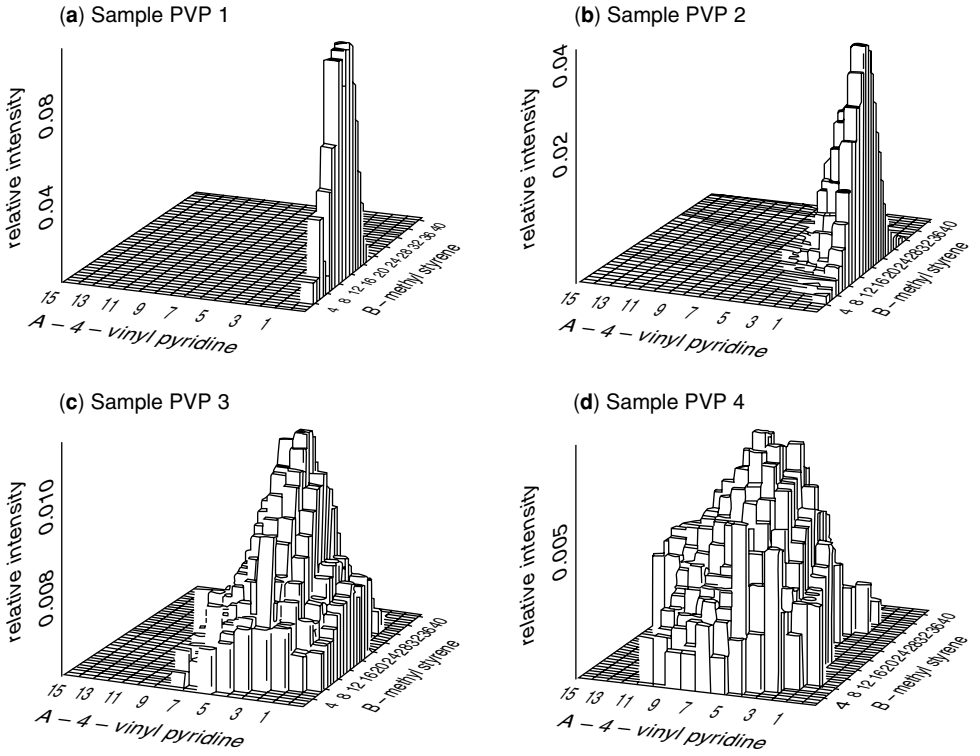

Fig. 5. MMD for one homopolymer and three copolymers of block copolymer of poly(α-MeSty)-*block*-poly(4-vinyl pyridine) as a function of mole fraction of poly(α-MeSty). (**a**) PVP1 is the MMD for poly(α-MeSty) homopolymer; (**b**) PVP2 is the MMD and MCD of the diblock copolymer poly(α-MeSty)-*block*-poly(4-vinyl pyridine) with 0.9 ± 0.1 mole fraction poly(α-MeSty); (**c**) PVP3 is the MMD and MCD of the diblock copolymer poly(α-MeSty)-*block*-poly(4-vinyl pyridine) with 0.63 ± 0.1 mole fraction poly(α-MeSty); (**d**) PVP2 is the MMD and MCD of the diblock copolymer poly(α-MeSty)-*block*-poly(4-vinyl pyridine) with 0.45 ± 1 mole fraction poly(α-MeSty). Reproduced from Ref. 87.

Zimm–Schulz distribution (88,89). Using an analysis method similar to that used previously on the poly(α-MeSty)-*block*-poly(4-vinyl pyridine) system, the MMD of both parts of the copolymer were determined. The data analysis method was claimed to verify the random coupling hypotheses. The hypothesis (90) that the polydispersity of individual blocks is higher than the polydispersity of the whole polymer was confirmed (85). That is, block copolymers with narrow MMD have broad complex chemical composition distribution.

The composition and sequence distribution of poly(butyleneadipate-*co*-butyleneterephthalate) have been studied (91). The intensity of the ms peaks was compared with theoretical intensities obtained using a Bernoulli distribution of the sequences. This result is in excellent agreement with nmr analysis of the bulk polymer.

Many other authors have shown MALDI-tof-ms of copolymers, but have not offered analysis to obtain a composition distribution as have the previous

authors. For example, the alternating copolymers of polycarbonate and two random copolyethers used as nonlinear optical materials were examined (92). Poly(*p*-phenylene ethynylene)-*block*-poly(ethylene oxide) has been studied (93). Also, styrene-*block*-isoprene copolymers have been examined (94). Much of the current work on copolymers has been reviewed (95).

MALDI to Elucidate Polymer Chemistry. Perhaps one of the most profitable future uses of MALDI will be for elucidation of polymer chemistry. Examining a reaction not yet complete or looking for polymer side products differing only by an end group will yield important reaction kinetics information. Unlike nmr, uv, or ftir, where one can perhaps find the presence of differing end groups or internal species for the overall MMD, MALDI can identify these species and how they can appear as a function of molecular mass. A caveat to all this work is the matrix attachment studies (21). Without careful studies of the linear and reflectron modes for each reaction examined and the effect of matrix and attached ion on the resultant spectra, one has to consider many of the conclusions from these studies tentative.

Some of the early examples of this use of MALDI to elucidate polymer chemistry are presented here. One can often elucidate polymer chemistry by examining the polymer products during or at the end of a reaction. Much of what has been discussed in the copolymer section relates to this. The work in References 85–87 describes the distribution from which the chemistry can be elucidated.

In the work on SRM 1487, a low molecular mass PMMA, the authors related their findings to the polymer chemistry of the initiator (62). Based on the synthesis information, SRM 1487 would have the following structure:

$$\text{H-PMMA-}\{\alpha\text{-MeSty}\}_m\text{-PMMA-H} \tag{5}$$

where m is the number of α-MeSty repeat units. The course of the anionic reaction of PMMA initiated by α-MeSty with a Na gegen-ion had been extensively studied (96,97) and the conclusion was that dimer and tetramer α-MeSty difunctional anion initiators are the dominant species in the initiation reaction ($m = 2$ or 4). MALDI studies suggested that all values of m from $m = 0$ to $m = 7$ were possible. However, no chains with $m = 6$ were found.

MALDI-tof-ms was used to examine the products from some anionic polymerizations with styrene initiated by *sec*-butyl-Li or t-$C_4H_9O(CH_2)_3$ Li and extended by isoprene (98). Several electrophilic reagents affected termination. The results showed unusual end group rearrangements to yield some end groups not normally expected. From this observation it was possible to suggest new mechanisms for the termination reaction of the polymer.

MALDI-tof-ms has been used to study the preparation of linear polysiloxanes with hydride end-capped and cyclic polysiloxanes from the ring-opening anionic polymerization reaction with hexamethylcyclotrisiloxane and octamethylcyclotrisiloxane (99). The PDMS reaction was followed by MALDI and the incorporation of the hydride end cap and the creation of the cyclics was studied as a function of time. Further studies (100) employed MALDI and sims; it was found that MALDI provides more reproducible relative intensities of the n-mers than does SIMS.

Polymer Architecture Elucidated by MALDI. Although ms is a mass determining device, ms studies in combination with an understanding of polymer chemistry allows one to make deduction on the architecture of polymer molecules. In this section, a study of trifunctional polymerizations similar to those studied by Flory in the early 1940s (see, for example, Ref. 101 is described). Here, however, instead of a carbon-based backbone a silicon-based backbone was studied.

The prepolymers of the polysilsesquioxanes were studied by MALDI-tof-ms (102,103). Polysilsesquioxanes are three-dimensional polymers with a repeat unit of the form $[RSiO_{3/2}]$ where each silicon is coordinated with three oxygen atoms. After a low temperature sol–gel synthesis and processing, silsesquioxanes are then fully cross-linked to from a fourfold coordinate structure. One important unknown in the processing of silsesquioxanes is the "degree-of-condensation" of the prepolymer silsesquioxanes before it is converted into the final product. That is, how many of the silicon atoms are threefold coordinated with bridging oxygen atoms and how many have terminal silanol (SiOH) groups?

In the polymerization process to create the prepolymer, a condensation reaction of two silanol groups to create one Si—O—Si bridge with the elimination of water occurs. In the prepolymer, these terminal silanol groups control the reactivity of the polymer in subsequent processing steps that result in a cross-linked product. Before the use of MALDI-ms only the average number of terminal silanol groups in the whole sample could be measured by ir spectroscopy. Condensation of SiOH groups out of the growing prepolymer silsesquioxane molecule can lead to the formation of intramolecular Si—O—Si bridges with the loss of water. This elimination reaction is easily identified via high resolution tof-ms. Figure 6 shows the overall spectrum while Figure 7 shows the detail of a single low mass oligomer

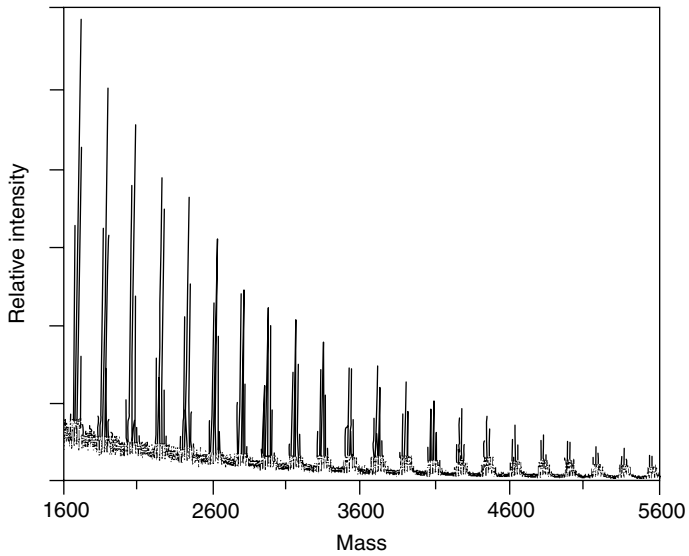

Fig. 6. The central portion of the full mass spectrum of a polysilsesquioxane prepolymer showing the characteristic shape of a condensation polymer. The major repeats show the changing number of $RSiO_{3/2}$ with a repeat of 188, 12 u.

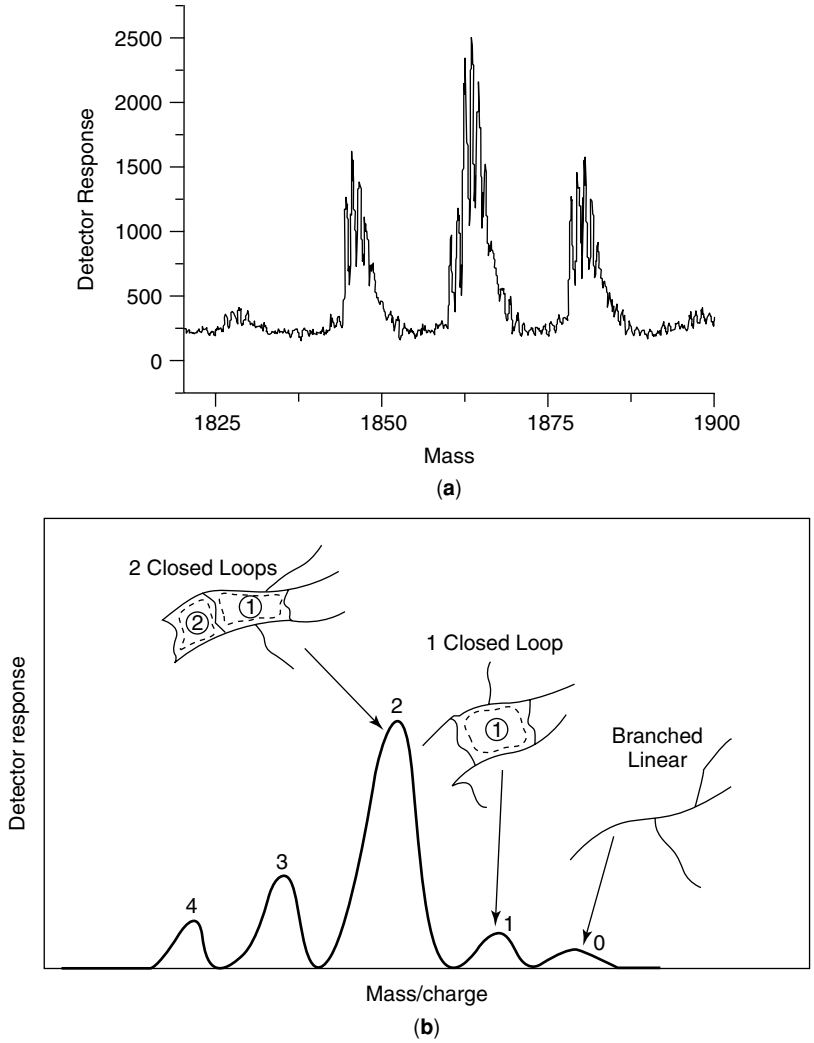

Fig. 7. (**a**) A single-repeat unit detail of the full mass spectrum shown in Figure 6. The distance between peaks in a single major cluster is 18 u, indicative of the intermolecular loss of water; (**b**) The schematic of the polymer ms shows the relation of each peak of the ms to the degree of intermolecular polymer condensation, the important polymer architecture change in this system.

from the overall spectrum. The maximum possible mass of an oligomer with n repeat units occurs when every silicon atom has one silanol group in addition to one R-group and two bridging oxygen atoms. However, the highest intensity peak generally does not occur at the maximum possible mass. Instead, lower mass peaks are more intense. These peaks correspond to the loss of water as a pair of —SiOH groups react. This indicates that intramolecular reactions are occurring.

Each loss of 18 u closes a loop in the molecule moving it away from a highly branched linear structure toward a closed polyhedron. In the limit of the loss of

all silanol groups, a fully condensed polyhedral structure results. For example, for n=8 the fully condensed structure is a cube with Si atoms at each corner and Si—O—Si linkages for the cube edges. Thus, the structure and chemical architecture of each n-mer can be deduced from MALDI-tof-ms.

In another determination of architecture by MALDI (84), the appearance of cyclics and linears in the poly(bisphenol A carbonate) has been investigated. It was possible to distinguish between the linear and cyclic species. From MALDI studies, a separate sec calibration line was obtained for the cyclic and the linear species. This work was done with the MALDI acting as an sec detector.

MEMBRANE TECHNOLOGY

Membranes have gained an important place in chemical technology and are being used increasingly in a broad range of applications. The key property that is exploited is the ability of a membrane to control the permeation of a chemical species in contact with it. In packaging applications, the goal is usually to prevent permeation completely. In controlled drug delivery applications, the goal is to moderate the permeation rate of a drug from a reservoir to the body. In separation applications, the goal is to allow one component of a mixture to permeate the membrane freely, while hindering permeation of other components. Since the 1960s, membrane science has grown from a laboratory curiosity to a widely practiced technology in industry and medicine. This growth is likely to continue for some time, particularly in the membrane gas separation and pervaporation separation areas. Membranes will play a critical role in the next generation of biomedical devices, such as the artificial pancreas and liver. The total membrane market grew from $10 million to $2–3 billion in the 40 years prior to 2000. Spectacular growth of this magnitude is unlikely to continue, but a doubling in the size of the total industry to $5 billion during the decade following is likely.

Historical Development

Systematic studies of membrane phenomena can be traced to the eighteenth century philosopher scientists. For example, Abbé Nolet coined the word *osmosis* to describe permeation of water through a diaphragm in 1748. Through the nineteenth and early twentieth centuries, membranes had no industrial or commercial uses but were used as laboratory tools to develop physical/chemical theories.

For example, the measurements of solution's osmotic pressure made with membranes by Traube and Pfeffer were used by van't Hoff in 1887 to develop his

Encyclopedia of Polymer Science and Technology. Copyright John Wiley & Sons, Inc. All rights reserved.

limit law, which explains the behavior of ideal dilute solutions. This work directly led to the van't Hoff equation. At about the same time, the concept of a perfectly selective semipermeable membrane was used by Maxwell and others in developing the kinetic theory of gases.

Early investigators experimented with any type of diaphragm available to them, such as bladders of pigs, cattle, or fish and sausage casings made of animal gut. Later, collodion (nitrocellulose) membranes were preferred, because they could be made reproducibly. In 1907, Bechhold devised a technique to prepare nitrocellulose membranes of graded pore size, which he determined by a bubble test (1). Other workers (2–4) improved on this technique, and by the early 1930s microporous collodion membranes were commercially available. During the next 20 years, this early microfiltration membrane technology was expanded to other polymers, notably cellulose acetate. Membranes found their first significant application in the filtration of drinking water samples at the end of World War II. Drinking water supplies serving large communities in Germany and elsewhere in Europe had broken down, and filters to test for water safety were needed urgently. The research effort to develop these filters, sponsored by the U.S. Army, was later exploited by the Millipore Corp., the first and still the largest microfiltration membrane producer.

By 1960, the elements of modern membrane science had been developed, but membranes were used in only a few laboratory and small, specialized industrial applications. No significant membrane industry existed, and total annual sales of membranes for all applications probably did not exceed $10 million in 2000 dollars. Membranes suffered from four problems that prohibited their widespread use as a separation process: they were too unreliable, too slow, too unselective, and too expensive. Partial solutions to each of these problems have been developed since the 1960s, and now membrane-based separation processes are commonplace.

The seminal discovery that transformed membrane separation from a laboratory to an industrial process was the development, in the early 1960s, of the Loeb–Sourirajan process for making defect-free, high-flux, asymmetric reverse osmosis membranes (5). These membranes consist of an ultrathin, selective surface film on a microporous support, which provides the mechanical strength. The flux of the first Loeb–Sourirajan reverse osmosis membrane was 10 times higher than that of any membrane then available and made reverse osmosis practical. The work of Loeb and Sourirajan, and the timely infusion of large sums of research dollars from the U.S. Department of Interior, Office of Saline Water (OSW), resulted in the commercialization of reverse osmosis and was a principal factor in the development of ultrafiltration and microfiltration. The development of electrodialysis was also aided by OSW funding.

The 20-year period from 1960 to 1980 produced a significant change in the status of membrane technology. Building on the original Loeb–Sourirajan membrane technology, other processes, including interfacial polymerization and multilayer composite casting and coating, were developed for making high performance membranes. Using these processes, membranes with selective layers as thin as 0.1 μm or less can be made. Methods of packaging membranes into spiral-wound, hollow-fine-fiber, capillary and plate-and-frame modules were also developed, and advances were made in improving membrane stability. By 1980, microfiltration,

ultrafiltration, reverse osmosis, and electrodialysis were all established processes with large plants installed around the world.

The principal development in the 1980s was the emergence of industrial membrane gas separation processes. The first significant development was the Monsanto Prism® membrane for hydrogen separation, in the late 1970s (6). Within a few years, Dow was producing systems to separate nitrogen from air, and Cynara and Separex were producing systems to separate carbon dioxide from methane. These applications of membrane gas separation are now well established, and several thousand membrane plants have been installed. Gas separation technology is evolving and expanding rapidly, and further substantial growth will be seen, particularly in the separation of vapor/gas mixtures such as propylene from nitrogen and propane and butane from methane. The final development of the 1980s was the introduction of the first commercial pervaporation systems for dehydration of alcohol by GFT, a small German engineering company. By 1990, GFT had sold more than 100 plants. Many of these plants are small, but the technology has been demonstrated and a number of other important pervaporation applications are now at the pilot-plant stage.

Types of Membrane

Although this article is limited to synthetic membranes, excluding all biological structures, the topic is still large enough to include a wide variety of membranes that differ in chemical and physical composition and in the way they operate. In essence, a membrane is nothing more than a discrete, thin interface that moderates the permeation of chemical species in contact with it. This interface may be molecularly homogeneous, that is, completely uniform in composition and structure, or it may be chemically or physically heterogeneous, for example, containing holes or pores of finite dimensions. A normal filter meets this definition of a membrane, but, by convention, the term *membrane* is usually limited to structures that permeate dissolved or colloidal species, whereas the term *filter* is used to designate structures that separate particulate suspensions. The principal types of membrane are shown schematically in Figure 1 and are described briefly in the following subsections.

Isotropic Microporous Membranes. A *microporous membrane* is very similar in its structure and function to a conventional filter. It has a rigid, highly voided structure with randomly distributed, interconnected pores. However, these pores differ from those in a conventional filter by being extremely small, of the order of 0.01–10 μm in diameter. All particles larger than the largest pores are completely rejected by the membrane. Particles smaller than the largest pores, but larger than the smallest pores are partially rejected, according to the pore size distribution of the membrane. Particles much smaller than the smallest pores will pass through the membrane. Thus, separation of solutes by microporous membranes is mainly a function of molecular size and pore size distribution. In general, only molecules that differ considerably in size can be separated effectively by microporous membranes, for example, in ultrafiltration and microfiltration.

Nonporous, Dense Membranes. *Nonporous, dense membranes* consist of a dense film through which permeants are transported by diffusion under the

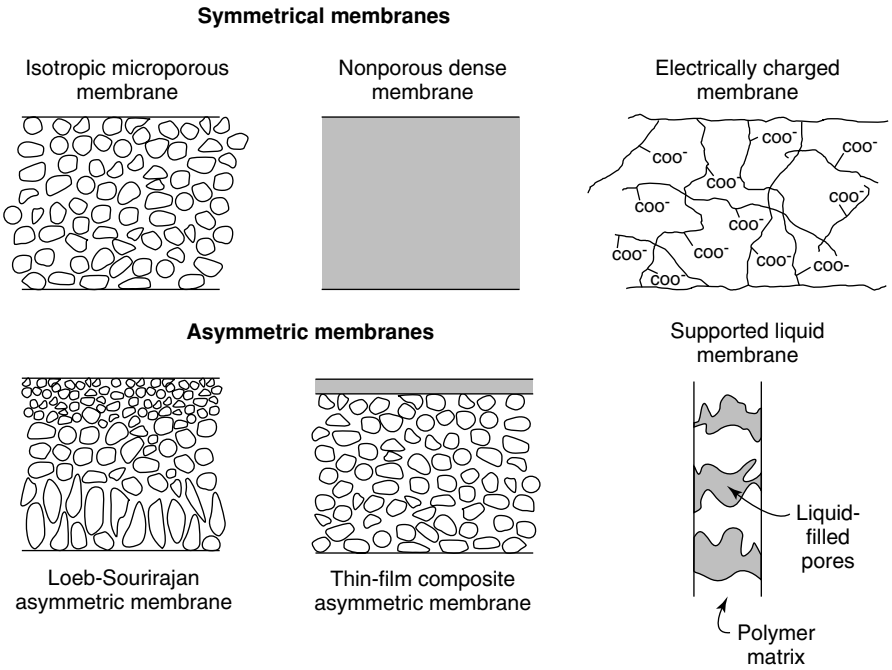

Fig. 1. Schematic diagrams of the principal types of membrane.

driving force of a pressure, concentration, or electrical potential gradient. The separation of various components of a solution is related directly to their relative transport rate within the membrane, which is determined by their diffusivity and solubility in the membrane material. An important property of nonporous, dense membranes is that even permeants of similar size may be separated when their concentration in the membrane material (ie, their solubility) differs significantly. Most gas separation, pervaporation, and reverse osmosis membranes use dense membranes to perform the separation. However, these membranes usually have an asymmetric structure to improve the flux.

Electrically Charged Membranes. *Electrically charged membranes* can be dense or microporous, but are most commonly microporous, with the pore walls carrying fixed positively or negatively charged ions. A membrane with positively charged ions is referred to as an *anion-exchange membrane* because it binds anions in the surrounding fluid. Similarly, a membrane containing negatively charged ions is called a *cation-exchange membrane*. Separation with charged membranes is achieved mainly by exclusion of ions of the same charge as the fixed ions of the membrane structure, and to a much lesser extent by the pore size. The separation is affected by the charge and concentration of the ions in solution. For example, monovalent ions are excluded less effectively than divalent ions and, in solutions of high ionic strength, selectivity decreases. Electrically charged membranes are used for processing electrolyte solutions in electrodialysis.

Asymmetric Membranes. The transport rate of a species through a membrane is inversely proportional to the membrane thickness. High transport rates

are desirable in membrane separation processes for economic reasons; therefore, the membrane should be as thin as possible. Conventional film fabrication technology limits manufacture of mechanically strong, defect-free films to about 20-μm thickness. The development of novel membrane fabrication techniques to produce asymmetric membrane structures was one of the major breakthroughs of membrane technology. *Asymmetric membranes* consist of an extremely thin surface layer supported on a much thicker porous, dense substructure. The surface layer and its substructure may be formed in a single operation or formed separately. The separation properties and permeation rates of the membrane are determined exclusively by the surface layer; the substructure functions as a mechanical support. The advantages of the higher fluxes provided by asymmetric membranes are so great that almost all commercial processes use such membranes.

Ceramic, Metal, and Liquid Membranes. The discussion so far implies that membrane materials are organic polymers and, in fact, the vast majority of membranes used commercially are polymer-based. However, in recent years, interest in membranes formed from less conventional materials has increased. Ceramic membranes, a special class of microporous membranes, are being used in ultrafiltration and microfiltration applications, for which solvent resistance and thermal stability are required. Dense metal membranes, particularly palladium membranes, are being considered for the separation of hydrogen from gas mixtures, and supported or emulsified liquid films are being developed for coupled and facilitated transport processes.

Preparation of Membranes and Membrane Modules

Because membranes applicable to diverse separation problems are often made by the same general techniques, classification by end-use application or preparation method is difficult. The first part of this section is, therefore, organized by membrane structure; preparation methods are described for symmetrical membranes, asymmetric membranes, ceramic and metal membranes, and liquid membranes. The final two subsections cover the production of hollow-fine-fiber membranes and membrane modules.

Symmetrical Membranes. Symmetrical membranes have a uniform structure throughout; such membranes can be either dense films or microporous.

Dense Symmetrical Membranes. These membranes are used on a large scale in packaging applications, and they are also used widely in the laboratory to characterize membrane separation properties. However, it is difficult to make mechanically strong and defect-free symmetrical membranes thinner than 20 μm, so the flux is low, and these membranes are rarely used in separation processes. For laboratory work, the membranes are prepared by solution casting or by melt pressing.

In solution casting, a casting knife or draw-down bar is used to spread an even film of an appropriate polymer solution across a glass plate. The casting knife consists of a steel blade, resting on two runners, arranged to form a precise gap between the blade and the plate on which the film is cast. A typical hand-casting knife is shown in Figure 2. After the casting has been made, it is left to stand, and the solvent evaporates to leave a uniform polymer film.

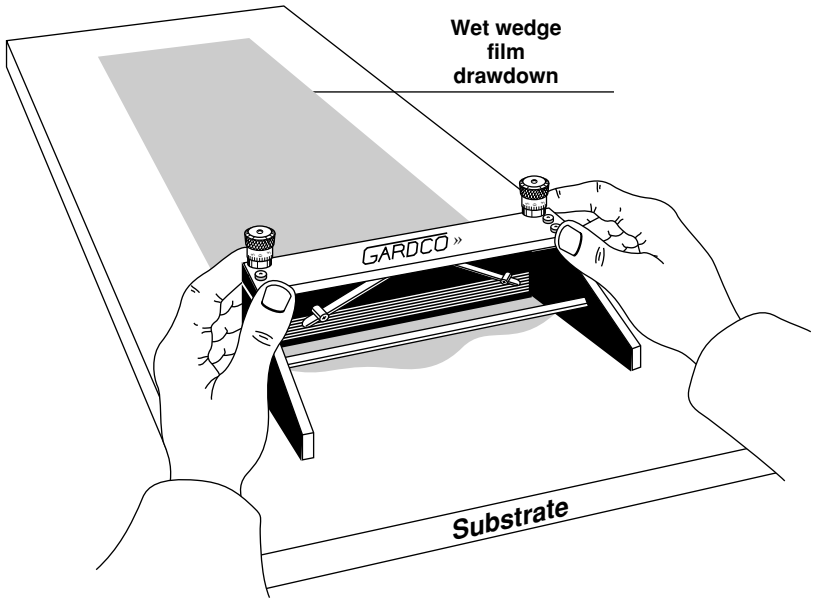

Fig. 2. A typical hand-casting knife. Courtesy of Paul N. Gardner Co., Inc.

Many polymers, including polyethylene, polypropylene, and nylons, do not dissolve in suitable casting solvents. In the laboratory, membranes can be made from such polymers by melt pressing, in which the polymer is sandwiched at high pressure between two heated plates. A pressure of 8–15 MPa (1000–2000 psi) is applied for 0.5–5 min, at a plate temperature just above the melting point of the polymer. Melt forming is commonly used to make dense films for packaging applications, either by extrusion as a sheet from a die or as blown film.

Microporous Symmetrical Membranes. These membranes, used widely in microfiltration, typically contain pores in the range of 0.1- to 10-μm diameter. As shown in Figure 3, microporous membranes are generally characterized by the average pore diameter d, the *membrane porosity* ε (the fraction of the total membrane volume that is porous), and the *tortuosity of the membrane*, τ, (a term reflecting the length of the average pore through the membrane compared to the membrane thickness). The most important types of microporous membrane are those formed by one of the solution-precipitation techniques discussed in the next section under Asymmetric Membranes; about half of microporous membranes are made in this way. The remainder is made by various proprietary techniques, the more important of which are outlined in the following subsections.

Irradiation. Nucleation track membranes were first developed by the Nuclepore Corp. (now a division of Whatman, Inc.) (7). The two-step preparation process is illustrated in Figure 4. A polymer film is first irradiated with charged particles from a nuclear reactor or other radiation source; particles passing through the film break polymer chains and leave behind sensitized/damaged tracks. The film is then passed through an etch solution, which etches the polymer preferentially along the sensitized nucleation tracks, thereby forming pores. The length of time the film is exposed to radiation in the reactor determines the number

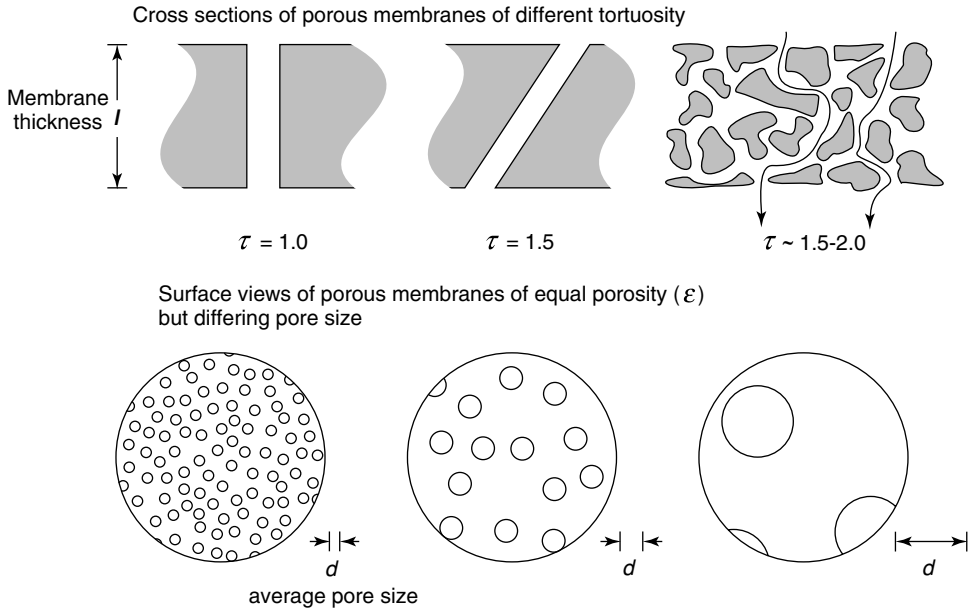

Fig. 3. Microporous membranes are characterized by tortuosity τ, porosity ϵ, and their average pore diameter d. (**a**) Cross sections of porous membranes containing cylindrical pores. (b) Surface views of porous membranes of equal ϵ, but differing pore size.

of pores in the film; the etch time determines the pore diameter. Because of the unique preparation techniques used to make nucleation track membranes, the pores are uniform cylinders traversing the membrane almost at right angles. The membrane tortuosity is, therefore, close to 1.0. The membrane porosity is usually relatively low, about 5%, so fluxes are low. However, because these membranes are very close to a perfect screen filter, they are used in analytical techniques that require filtration of all particles above a certain size from a fluid so that the particles can be visualized under a microscope.

Expanded Film. Expanded-film membranes are made from crystalline polymers by an orientation and stretching process. In the first step of the process, a highly oriented film is produced by extruding the polymer at close to its melting point coupled with a very rapid drawdown (8,9). After cooling, the film is stretched a second time, up to 300%, at right angles to the original orientation of the polymer crystallites. This second elongation deforms the crystalline structure of the film and produces slit-like voids 20–250 nm wide between crystallites. The process is illustrated in Figure 5. This type of membrane was first developed by the Celanese Corp. and is sold under the trade name Celgard; a number of companies now make similar products. The membranes made by W. L. Gore, sold under the trade name Gore-Tex, are made by this type of process (10).

The original expanded-film membranes were sold in rolls as flat sheets. These membranes had relatively poor tear strength along the original direction of orientation and were not widely used as microfiltration membranes. They did, however, find a principal use as porous, inert separating barriers in batteries and some medical devices. More recently, the technology has been developed to produce

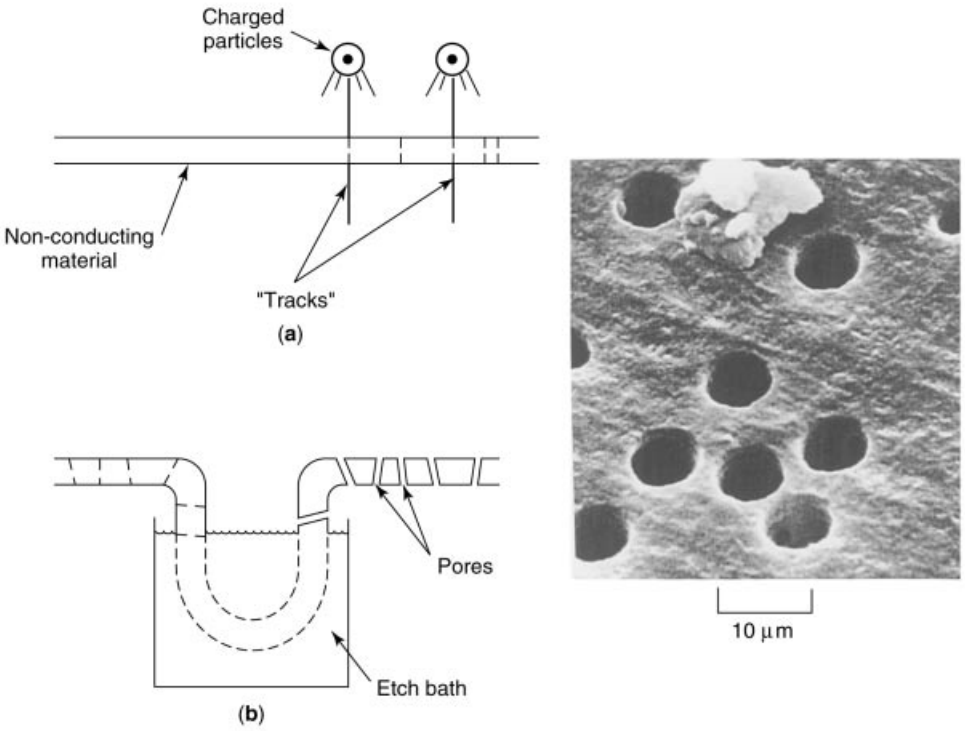

Fig. 4. Diagram and photograph of the two-step process to manufacture nucleation track membranes. (**a**) Polycarbonate film is exposed to charged particles in a nuclear reactor. (**b**) Tracks left by particles are preferentially etched into uniform cylindrical pores.

these membranes as hollow fibers, which are being used as membrane contactors (11,12).

Template Leaching. Template leaching offers an alternative manufacturing technique for insoluble polymers. A homogeneous film is prepared from a mixture of the membrane matrix material and a leachable component. After the film has been formed, the leachable component is removed with a suitable solvent and a microporous membrane is formed (13,14). The leachable component could be a soluble, low molecular weight solid or liquid, or even a polymeric material such as poly(vinyl alcohol) [PVA] or poly(ethylene glycol). The same general method is used to prepare microporous glass (15). In this case, a two-component glass melt is formed into sheets or small tubes, after which one of the components is leached out by extraction with an alkaline solution.

Asymmetric Membranes. In industrial applications other than microfiltration, symmetrical membranes have been displaced almost completely by asymmetric membranes, which have much higher fluxes. Asymmetric membranes have a thin, selective layer supported on a more open porous substrate. Hindsight makes it clear that many of the membranes produced in the 1930s and 1940s were asymmetric, although this was not realized at the time. The importance of the asymmetric structure was not recognized until Loeb and Sourirajan prepared the first high-flux, asymmetric, reverse osmosis membranes by what is

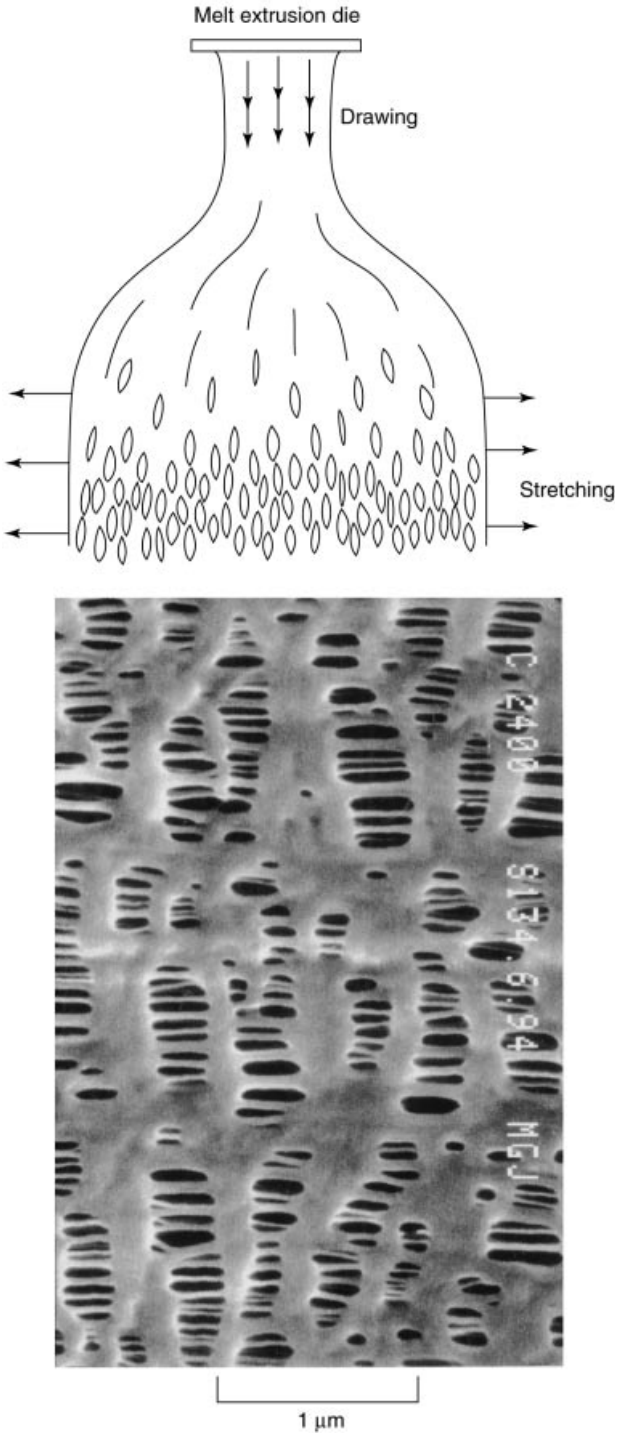

Fig. 5. Preparation method and scanning electron micrograph of a typical expanded polypropylene film membrane, in this case Celgard.

now known as the Loeb–Sourirajan technique (5). Loeb and Sourirajan's discovery was a critical breakthrough in membrane technology. The reverse osmosis membranes they produced were an order of magnitude more permeable than any symmetrical membrane produced previously. More importantly, demonstration of the benefits of the asymmetric structure paved the way for the development of other types of asymmetric membranes.

Phase Inversion (Solution Precipitation). *Phase inversion*, also known as *solution precipitation* or *polymer precipitation*, is the most important asymmetric membrane preparation method. In this process, a clear polymer solution is precipitated into two phases: a solid, polymer-rich phase that forms the matrix of the membrane, and a liquid, polymer-poor phase that forms the membrane pores. If precipitation is rapid, the pore-forming liquid droplets tend to be small and the membranes formed are markedly asymmetric. If precipitation is slow, the pore-forming liquid droplets tend to agglomerate while the casting solution is still fluid, so that the final pores are relatively large and the membrane structure is more symmetrical. Polymer precipitation from a solution can be achieved in several ways, such as cooling, solvent evaporation, precipitation by immersion in water, or imbibition of water from the vapor phase. Each technique was developed independently; only since the 1980s has it become clear that these processes can all be described by the same general approach based on polymer/solvent/nonsolvent phase diagrams. Thus, the Loeb–Sourirajan process, in which precipitation is produced by immersion in water, is a subcategory of the general class of phase-inversion membranes. The theory behind the preparation of membranes by all of these techniques has been discussed in a number of monographs and review articles (16–19).

Polymer Precipitation by Cooling. The simplest solution-precipitation technique is thermal gelation, in which a film is cast from a hot, one-phase polymer solution. When the cast film cools, the polymer precipitates, and the solution separates into a polymer matrix phase containing dispersed pores filled with solvent. The precipitation process that forms the membrane can be represented by the phase diagram shown in Figure 6. The pore volume in the final membrane is determined mainly by the initial composition of the cast film, because this determines the ratio of the polymer to liquid phase in the cooled film. However, the spatial distribution and size of the pores is determined largely by the rate of cooling and, hence, precipitation of the film. In general, rapid cooling produces membranes with small pores (20,21).

Polymer precipitation by cooling to produce microporous membranes was first commercialized on a large scale by Akzo (22). Akzo markets microporous polypropylene and poly(vinylidine fluoride) membranes produced by this technique under the trade name Accurel. Polypropylene membranes are prepared from a solution of polypropylene in *N*,*N*-bis(2-hydroxyethyl)tallowamine. The amine and polypropylene form a clear solution at temperatures above 100–150°C. Upon cooling, the solvent and polymer phases separate to form a microporous structure. If the solution is cooled slowly, an open cell structure results. The interconnecting passageways between cells are generally in the micron range. If the solution is cooled and precipitated rapidly, a much finer structure is formed. The rate of cooling is, therefore, a key parameter determining the final structure of the membrane (20).

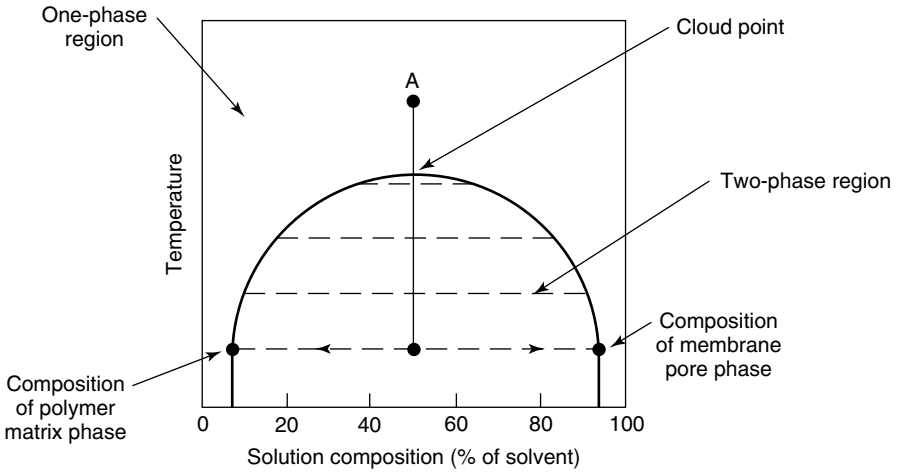

Fig. 6. Phase diagram showing the composition pathway traveled by the casting solution during precipitation by cooling. Point A represents the initial temperature and composition of the casting solution. The cloud point is the point of fast precipitation. In the two-phase region tie lines linking the precipitated polymer phase and the suspended liquid phase are shown.

A schematic diagram of the polymer precipitation process is shown in Figure 7. The hot polymer solution is cast onto a water-cooled chill roll, which cools the solution, causing the polymer to precipitate. The precipitated film is passed through an extraction tank containing methanol, ethanol, or isopropanol to remove the solvent. Finally, the membrane is dried, sent to a laser inspection station, trimmed and rolled up. The process shown in Figure 7 is used to make flat-sheet membranes. The preparation of hollow-fiber membranes by the same general technique has also been described.

Polymer Precipitation by Solvent Evaporation. This technique was one of the earliest methods of making microporous membranes (1–4). In the simplest form of the method, a polymer is dissolved in a two-component solvent mixture consisting of a volatile solvent, such as acetone, in which the polymer is readily soluble, and a less volatile nonsolvent, typically water or an alcohol. The polymer solution is cast onto a glass plate. As the volatile solvent evaporates, the casting solution is enriched in the nonvolatile nonsolvent. The polymer precipitates, forming the membrane structure. The process can be continued until the membrane has completely formed, or it can be stopped, and the membrane structure fixed, by immersing the cast film into a precipitation bath of water or other nonsolvent. Scanning electron micrographs of some membranes made by this process are shown in Figure 8 (23).

Many factors determine the porosity and pore size of membranes formed by the solvent evaporation method. The average size of the nonsolvent droplets held in the polymer casting solution increases during the evaporation process. As Figure 8 shows, if the membrane is immersed in a nonsolvent after a short

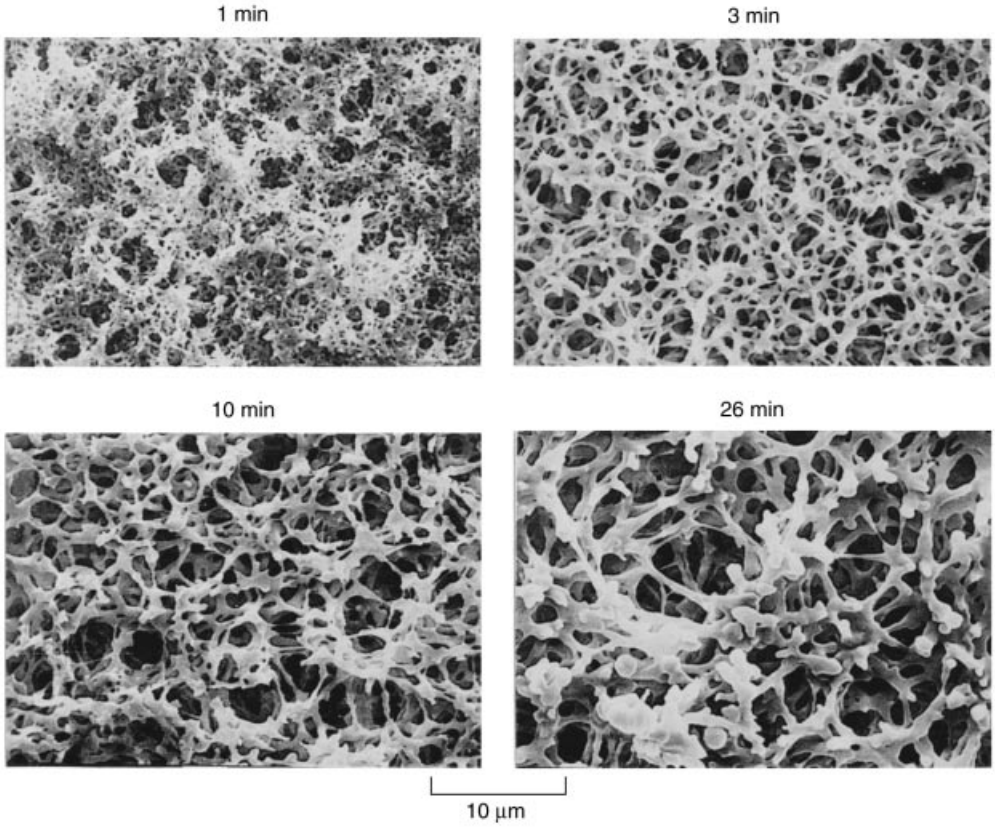

Fig. 8. Scanning electron micrographs of the bottom surface of cellulose acetate membranes cast from a solution of acetone (volatile solvent) and 2-methyl-2,4-pentanediol (nonvolatile solvent). The evaporation time before the structure is fixed by immersion in water is shown. Reprinted from Ref. 23, Copyright 1974, with permission from Elsevier Science.

evaporation time, the resulting membrane will be finely microporous. If the evaporation step is prolonged before fixing the structure by immersion in water, the average nonsolvent droplet diameter will be larger and consequently the average pore size will be larger. In general, increasing the nonsolvent content of the casting solution, or decreasing the polymer concentration, increases porosity. It is important that the nonsolvent be completely incompatible with the polymer. If partly compatible nonsolvents are used, the precipitating polymer phase contains sufficient residual solvent to allow it to flow and collapse as the solvent evaporates. The result is a dense rather than microporous film.

Polymer Precipitation by Imbibition of Water Vapor. Preparation of microporous membranes by simple solvent evaporation alone is not practiced widely. However, combinations of solvent evaporation with precipitation by imbibition of water vapor from a humid atmosphere are the basis of many commercial phase-inversion processes. The processes often involve proprietary casting formulations that are not normally disclosed by membrane developers. However, during the development of composite membranes at Gulf General Atomic, this type of membrane was prepared and the technology described in some detail in a series of Office of Saline Water Reports (24). These reports remain the best published description of the technique. The type of equipment used is shown in Figure 9. The casting solution typically consists of a blend of cellulose acetate and cellulose nitrate dissolved in a mixture of volatile solvents, such as acetone, and nonvolatile nonsolvents, such as water, ethanol, or ethylene glycol. The polymer solution is cast onto a continuous stainless steel belt. The cast film then passes through a series of environmental chambers; hot, humid air is usually circulated through the first chamber. The film loses the volatile solvent by evaporation and simultaneously absorbs water from the atmosphere. The total precipitation process is slow, taking about 10 min to complete. The resulting membrane structure is fairly symmetrical. After precipitation, the membrane passes to a second oven, through which hot, dry air is circulated to evaporate the remaining solvent and dry the film. The formed membrane is then wound on a take-up roll. Typical casting speeds are of the order of 0.3–0.6 m/min. This type of membrane is widely used in microfiltration applications (25).

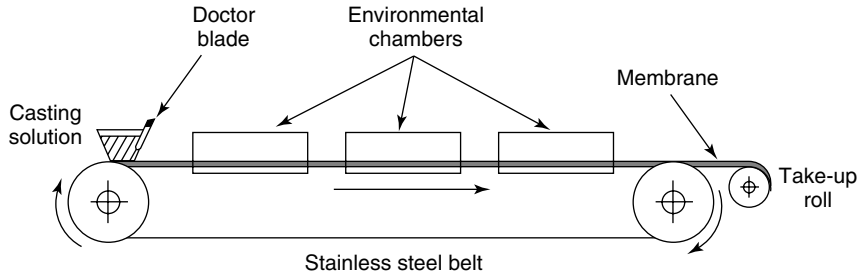

Fig. 9. Schematic of casting machine used to make microporous membranes by water-vapor imbibition. A casting solution is deposited as a thin film on a moving stainless steel belt. The film passes through a series of humid and dry chambers, where the solvent evaporates from the solution, and water vapor is absorbed from the air. This precipitates the polymer, forming a microporous membrane that is taken up on a collection roll.

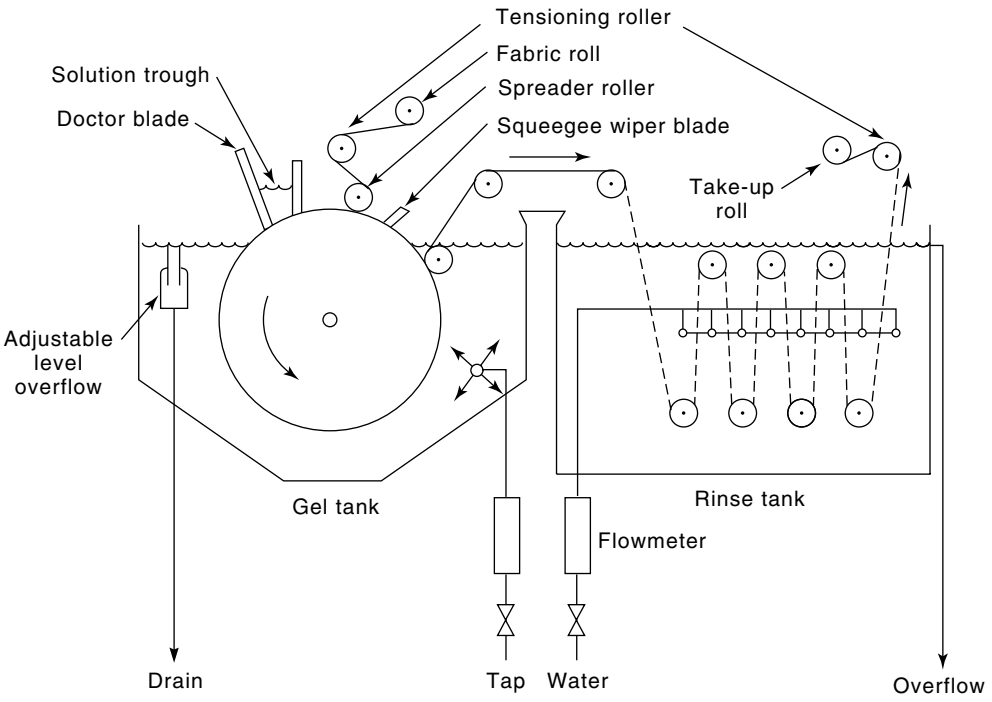

Fig. 10. Schematic of Loeb–Sourirajan membrane casting machine used to prepare reverse osmosis or ultrafiltration membranes. A knife and trough is used to coat the casting solution onto a moving fabric or polyester web which enters the water-filled gel tank. After the membrane has formed, it is washed thoroughly to remove residual solvent before being wound up.

Polymer Precipitation by Immersion in a NonSolvent Bath. This is the Loeb–Sourirajan process, the single most important membrane-preparation technique; almost all reverse osmosis, ultrafiltration, and many gas separation membranes are produced by this procedure or a derivative of it. A schematic of a casting machine used in the process is shown in Figure 10. A typical membrane casting solution contains approximately 20 wt% of dissolved polymer. This solution is cast onto a moving drum or paper web, and the cast film is precipitated by immersion in a water bath. The water precipitates the top surface of the cast film rapidly, forming an extremely dense, selective skin. This skin slows down the entry of water into the underlying polymer solution, which precipitates much more slowly, forming a more porous substructure. Depending on the polymer, the casting solution, and other parameters, the dense skin varies from 0.1 to 1.0 μm in thickness. Loeb and Sourirajan, the original developers of this process, were working in the field of reverse osmosis (5). Later, others adapted the technique to make membranes for other applications, including ultrafiltration and gas separation (6,19,26).

A great deal of work has been devoted to rationalizing the factors affecting the properties of asymmetric membrane made by this technique and, in particular, understanding those factors that determine the thickness of the membrane skin that performs the separation. The goal is to make this skin as thin as possible, but still defect free. The skin layer can be dense, as in reverse osmosis or gas

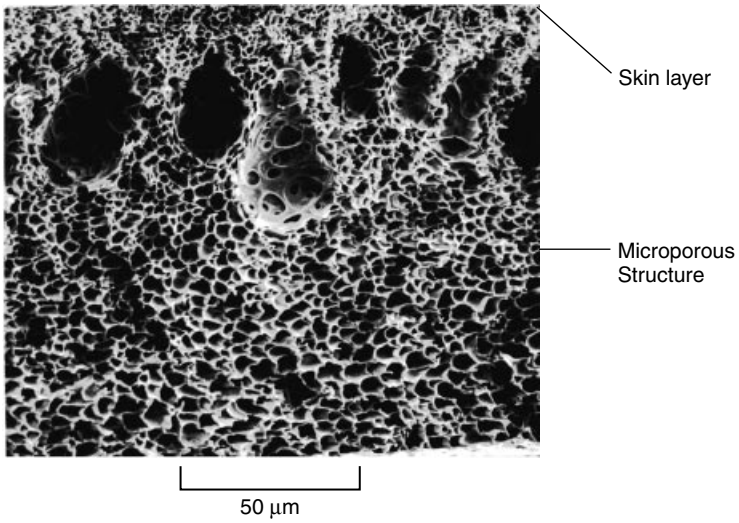

Fig. 11. Cross-sectional scanning electron micrograph of an asymmetric Loeb–Sourirajan ultrafiltration membrane. The large macrovoids under the membrane skin (top surface) are common in this type of ultrafiltration membrane.

separation, or finely microporous with pores in the 10- to 50-nm-diameter range, as in ultrafiltration. In good quality membranes made by this technique, a skin thickness as low as 50–100 μm can be achieved. A scanning electron micrograph of a Loeb–Sourirajan membrane is shown in Figure 11.

The phase-diagram approach has been widely used to rationalize the preparation of these membrane (16–19,26). The ternary phase diagram of the three-component system used in preparing Loeb–Sourirajan membranes is shown in Figure 12. The corners of the triangle represent the three components, polymer, solvent, and precipitant, while any point within the triangle represents a mixture of three components. The system consists of two regions: a one-phase region, where all components are miscible, and a two-phase region, where the system separates into a solid (polymer-rich) phase and a liquid (polymer-poor) phase. Although the one-phase region in the phase diagram is thermodynamically continuous, for practical purposes it can conveniently be divided into a liquid and solid gel region. Thus, at low polymer concentrations, the system is a low viscosity liquid, but, as the concentration of polymer is increased, the viscosity of the system also increases rapidly, reaching such high values that the system can be regarded as a solid. The transition between liquid and solid regions is, therefore, arbitrary, but can be placed at a polymer concentration of 30–40 wt%. In the two-phase region of the diagram, tie lines link the polymer-rich and polymer-poor phases. Unlike low molecular weight components, polymer systems in the two-phase region are often slow to separate into different phases and metastable states are common, especially when a polymer solution is rapidly precipitated.

The phase diagram in Figure 12 shows the precipitation pathway of the casting solution during membrane formation. During membrane formation, the system changes from a composition A, which represents the initial casting solution

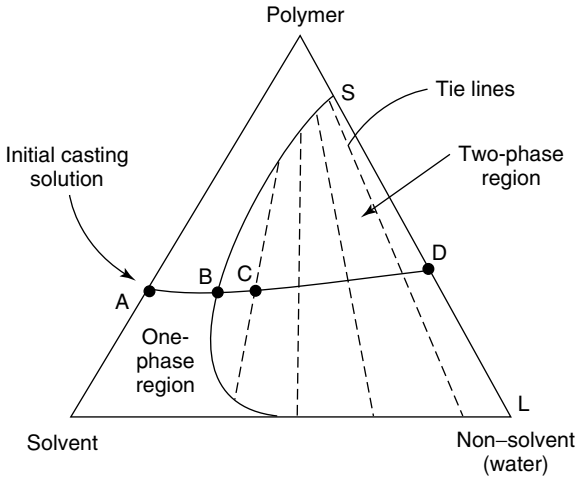

Fig. 12. Phase diagram showing the composition pathway traveled by a casting solution during the preparation of porous membranes by solvent evaporation: A, initial casting solution; B, point of precipitation; and C, point of solidification.

composition, to a composition D, which represents the final membrane composition. At composition D, the two phases are in equilibrium: a solid (polymer-rich) phase, which forms the final membrane structure, represented by point S, and a liquid (polymer-poor) phase, which constitutes the membrane pores filled with precipitant, represented by point L. The position D on the line S–L determines the overall porosity of the membrane. The entire precipitation process is represented by the path A–D, during which the solvent is exchanged by the precipitant. The point B along the path is the concentration at which the first polymer precipitates. As precipitation proceeds, more solvent is lost and precipitant is imbibed by the polymer-rich phase, so the viscosity rises. At some point, the viscosity is high enough for the precipitated polymer to be regarded as a solid. This composition is at C in Figure 12. Once the precipitated polymer solidifies, further bulk movement of the polymer is hindered. The rate and the pathway A–D taken by the polymer solution vary from the surface of the polymer film to the sublayer, affecting the pore size and porosity of the final membrane at that point. The nature of the casting solution and the precipitation conditions are very important in determining the kinetics of this precipitation process, and detailed theoretical treatments based on the ternary-phase-diagram approach have been worked out.

In the Loeb–Sourirajan process formation of minute membrane defects may occur. These defects, caused by gas bubbles, dust particles, and support fabric imperfections, are often very difficult to eliminate. These defects may not significantly affect the performance of asymmetric membranes used in liquid separation operations, such as ultrafiltration and reverse osmosis, but can be disastrous in gas separation applications. Henis and Tripodi (6), following earlier work (27) at General Electric, showed that this problem can be overcome by coating the membrane with a thin layer of relatively permeable material. If the coating is sufficiently thin, it does not change the properties of the underlying selective layer, but it does plug membrane defects, preventing simple convective gas flow through

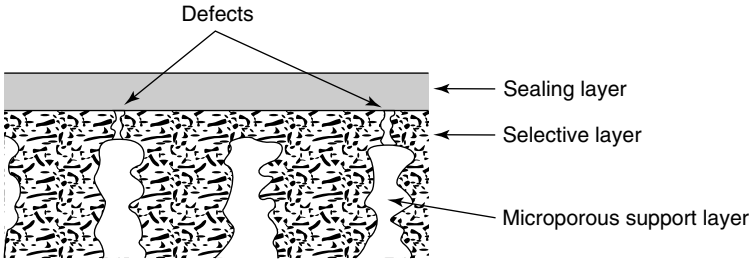

Fig. 13. Schematic of coated gas separation membrane.

defects. They applied this concept to sealing defects in polysulfone Loeb–Sourirajan membranes with silicone rubber (6). The form of these membranes is shown in Figure 13. The silicone rubber layer does not function as a selective barrier but rather plugs up defects, thereby reducing nondiffusive gas flow. The flow of gas through the portion of the silicone rubber layer over the pore is very high compared to the flow through the defect-free portion of the membrane. However, because the total area of the membrane subject to defects is very small, the total gas flow through these plugged defects is negligible. When this coating technique is used, the polysulfone skin layer of the Loeb–Sourirajan membrane no longer has to be completely free of defects; the Henis–Tripodi membrane can be made with a thinner skin than is possible with an uncoated Loeb–Sourirajan membrane. The increase in flux brought about by decreasing the thickness of the selective skin layer more than compensates for the slight reduction in flux caused by the silicone rubber sealing layer.

Cellulose acetate Loeb–Sourirajan reverse osmosis membranes were introduced commercially in the 1960s. Since then, many other polymers have been made into asymmetric membranes in attempts to improve membrane properties. In the reverse osmosis area, these attempts have had limited success, the only significant example being DuPont's polyamide membrane. For gas separation and ultrafiltration, a number of membranes with useful properties have been made. However, the early work on asymmetric membranes has spawned numerous other techniques in which a microporous membrane is used as a support to carry another thin, dense separating layer.

Interfacial Composite Membranes. A method of making asymmetric membranes, involving interfacial polymerization, was developed in the late 1960s. This technique was used to produce reverse osmosis membranes with dramatically improved salt rejections and water fluxes compared to those prepared by the Loeb–Sourirajan process (28). In the interfacial polymerization method, an aqueous solution of a reactive prepolymer, such as polyamine, is first deposited in the pores of a microporous support membrane, typically a polysulfone ultrafiltration membrane. The amine-loaded support is then immersed in a water-immiscible solvent solution containing a reactant, for example, a diacid chloride in hexane. The amine and acid chloride then react at the interface of the two solutions to form a densely cross-linked, extremely thin membrane layer. This preparation method is shown schematically in Figure 14. The first membrane was based on polyethyleneimine cross-linked with toluene-2,4-diisocyanate, to form the structure shown in

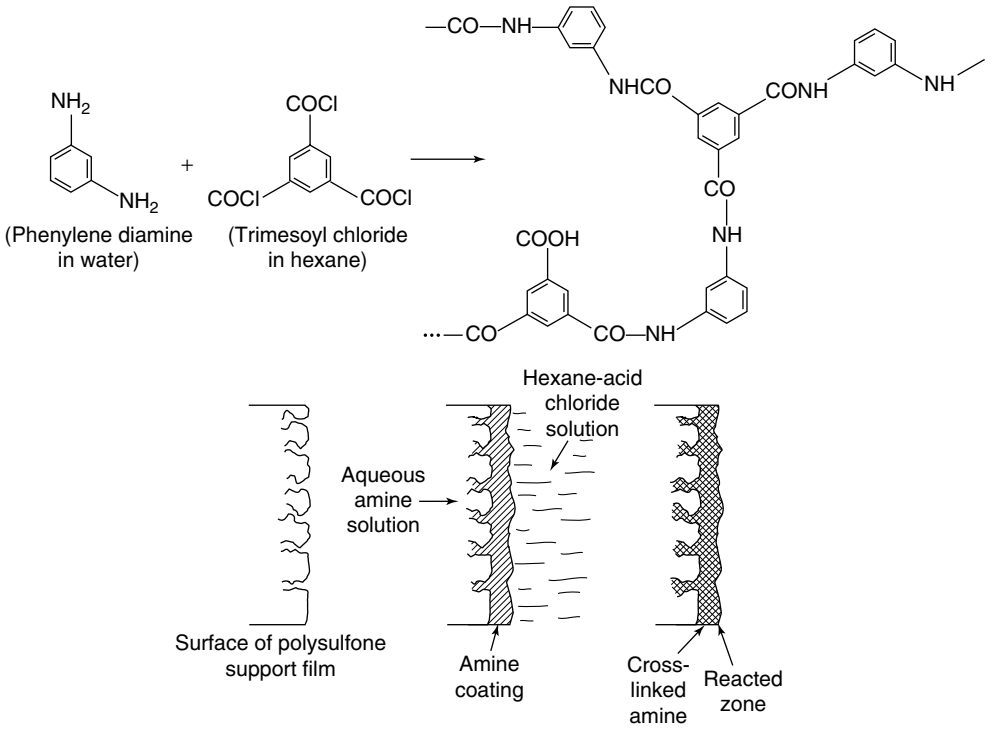

Fig. 14. Schematic of the interfacial polymerization process. The microporous film is first impregnated with an aqueous amine solution. The film is then treated with a multivalent cross-linking agent dissolved in a water-immiscible organic fluid, such as hexane or Freon-113. An extremely thin polymer film forms at the interface of the two solutions. The chemistry illustrated in this example is for the FT-30 membrane using the interfacial reaction of phenylene diamine with trimesoyl chloride. This membrane is widely used for desalination.

Figure 14. The process was later refined at FilmTec (28,29) and UOP (30) in the United States, and at Nitto (31) in Japan. The chemistry of these membranes has been reviewed (32).

Membranes made by interfacial polymerization have a dense, highly cross-linked interfacial polymer layer formed on the surface of the support membrane at the interface of the two solutions. A less cross-linked, more permeable hydrogel layer forms under this surface layer and fills the pores of the support membrane. Because the dense, cross-linked polymer layer can only form at the interface, it is extremely thin, of the order of 0.1 μm or less, and the permeation flux is high. Because the polymer is highly cross-linked, its selectivity is also high. The first reverse osmosis membranes made this way were 5–10 times less salt-permeable than the best membranes with comparable water fluxes made by other techniques.

Interfacial polymerization membranes are less applicable to gas separation because of the water-swollen hydrogel that fills the pores of the support membrane. In reverse osmosis, this layer is highly water swollen and offers little resistance to water flow, but when the membrane is dried and used in gas separations the gel becomes a rigid glass with very low gas permeability. This glassy polymer fills

the membrane pores and, as a result, defect-free interfacial composite membranes usually have low gas fluxes, although their selectivities can be good.

Solution-Cast Composite Membranes. Another very important type of composite membrane is formed by solution-casting a thin (0.5–2.0 μm) film on a suitable microporous film. Most solution-cast composite membranes are prepared by a technique pioneered at UOP (33). In this technique, a polymer solution is cast directly onto the microporous support film. The support film must be clean, defect-free, and very finely microporous, to prevent penetration of the coating solution into the pores. If these conditions are met, the support can be coated with a liquid layer 50–100 μm thick, which after evaporation leaves a thin selective film, 0.5–2 μm thick. This technique was used to form the Monsanto Prism® gas separation membranes (6) and at Membrane Technology and Research to form pervaporation and organic vapor/air separation membranes (34,35). A schematic drawing and scanning electron micrograph of this type of membrane are shown in Figure 15.

Composite membranes may consist of three or more layers. A highly permeable gutter layer is coated onto the support to provide a smooth, continuous

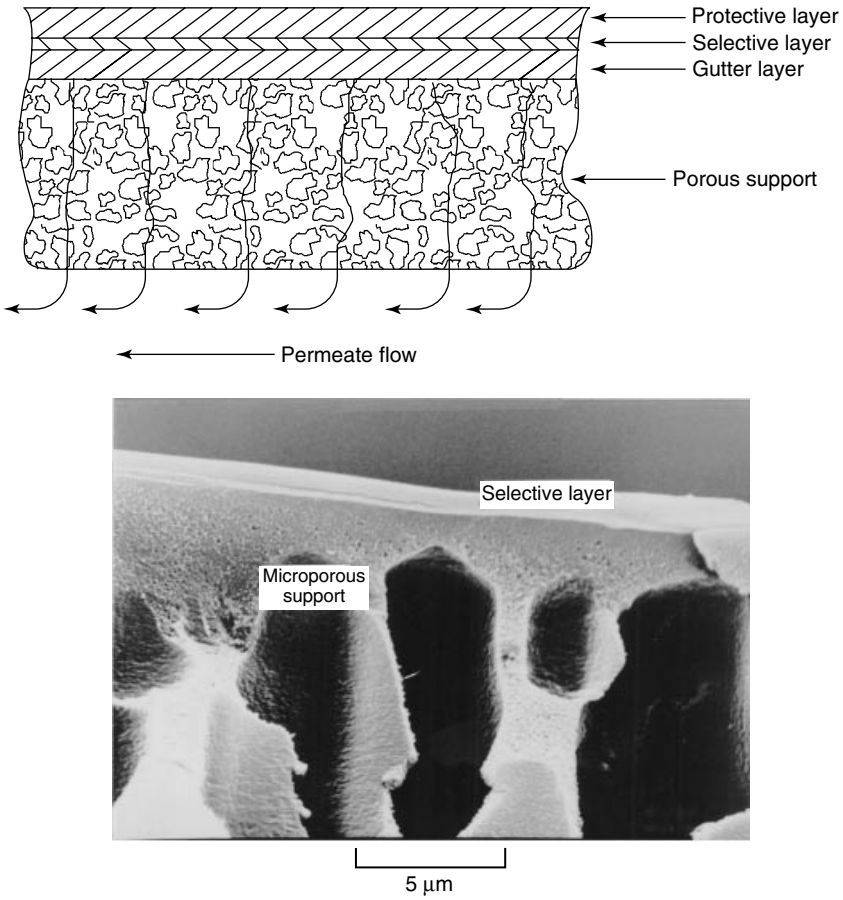

Fig. 15. Schematic drawing and scanning electron micrograph of a multilayer composite membrane.

Table 1. Summary of Less Widely Used Membrane Preparation Techniques

Preparation technique	Membrane characteristics	References
Plasma polymerization	Monomer is plasma polymerized onto the surface of a support film. Resulting chemistry is complex	36–39
Reactive surface treatment	An existing membrane is treated with a reactive gas of monomer to form an ultrathin surface layer	40–42
Dynamically formed membranes	A colloidal material is added to the feed solution of an ultrafiltration membrane. A gel forms on the membrane surface and enhances the membrane selectivity	43,44
Molecular sieve membranes	An ultrafine microporous membrane is formed from a dense, hollow-fiber polymeric membrane by carbonizing or from a glass hollow fiber by chemical leaching. Pores in the range 0.5–2 nm are claimed	45–48
Microporous metal membranes by electrochemical etching	Aluminum metal, for example, is electrochemically etched to form a porous aluminum oxide film. Membranes are brittle but uniform, with small pore size 0.02–2.0 μm	49,50

surface and to conduct the permeate to the pores of the microporous support. The thin, selective layer is coated onto the gutter layer, and finally a highly permeable top layer may be added to protect the membrane from damage during module preparation.

Other Asymmetric Membrane Preparation Techniques. A number of other methods of preparing membranes have been reported in the literature and are used on a small scale. Table 1 provides a brief summary of these techniques.

Metal Membranes. Palladium and palladium alloy membranes can be used to separate hydrogen from other gases. Palladium membranes were studied extensively during the 1950s and 1960s, and a commercial plant to separate hydrogen from refinery off-gas was installed by Union Carbide (51). The plant used palladium/silver alloy membranes in the form of 25-μm-thick films. The plant was operated for some time, but a number of problems, including long-term membrane stability under the high-temperature operating conditions, were encountered; later the plant was replaced by pressure-swing adsorption systems. Small-scale palladium membrane systems are still used to produce ultrapure hydrogen for specialized applications (52,53). These systems use palladium/silver alloy membranes, based on those developed in 1960 (54). Membranes with much thinner effective palladium layers than those that were used in the Union Carbide installation can now be made. One technique is to form a composite membrane

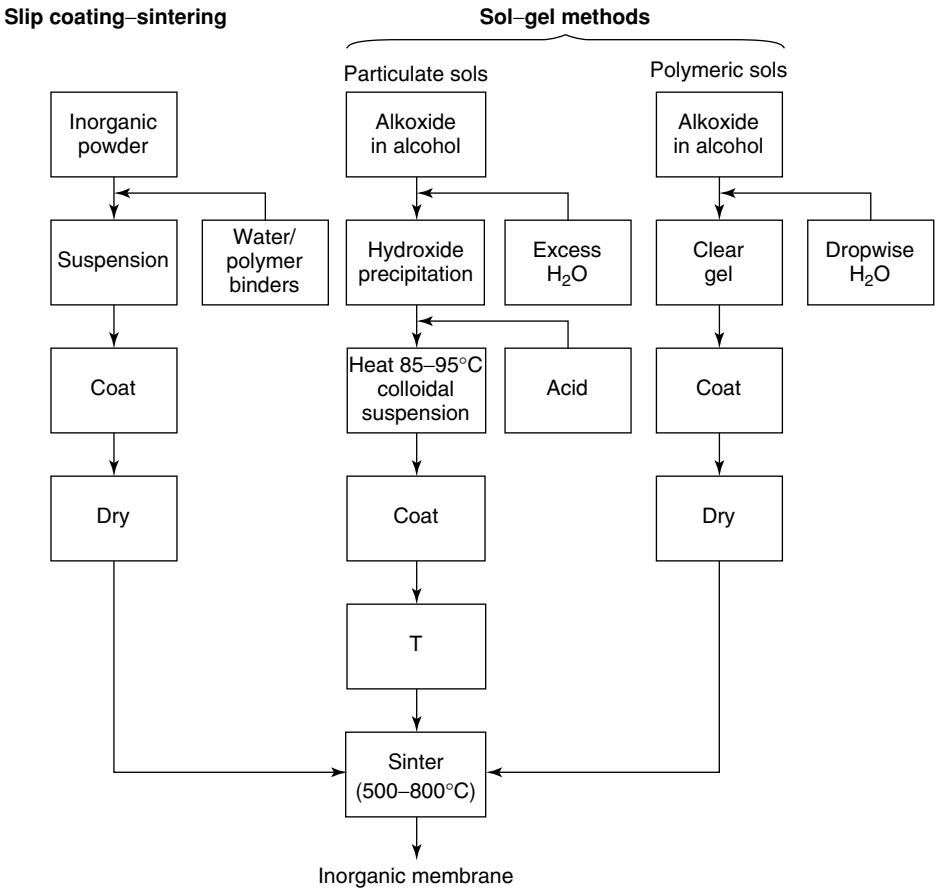

Fig. 16. Sol–gel and simple slip-coating–sintering process used to make ceramic membranes.

comprising a polymer substrate onto which is coated a thin layer of palladium or palladium alloy (55). The palladium layer can be applied by vacuum methods, such as evaporation or sputtering. Coating thicknesses of the order of 100 nm or less can be achieved.

Ceramic Membranes. A number of companies have developed ceramic membranes for ultrafiltration and microfiltration applications. Ceramic membranes have the advantages of being extremely chemically inert and stable at high temperatures, conditions under which polymer films fail. Most ceramic membranes are made by the slip-coating–sintering or sol–gel techniques outlined in Figure 16 (56–58).

The slip-coating–sintering process is the most widely used. In this process, a porous ceramic support tube is made by pouring a dispersion of a fine-grain ceramic material and a binder into a mold and sintering at high temperature. The pores between the particles that make up this support tube are large. One surface of the tube is then coated with a suspension of finer particles in a solution of a cellulosic polymer or PVA which acts as a binder and viscosity enhancer to hold

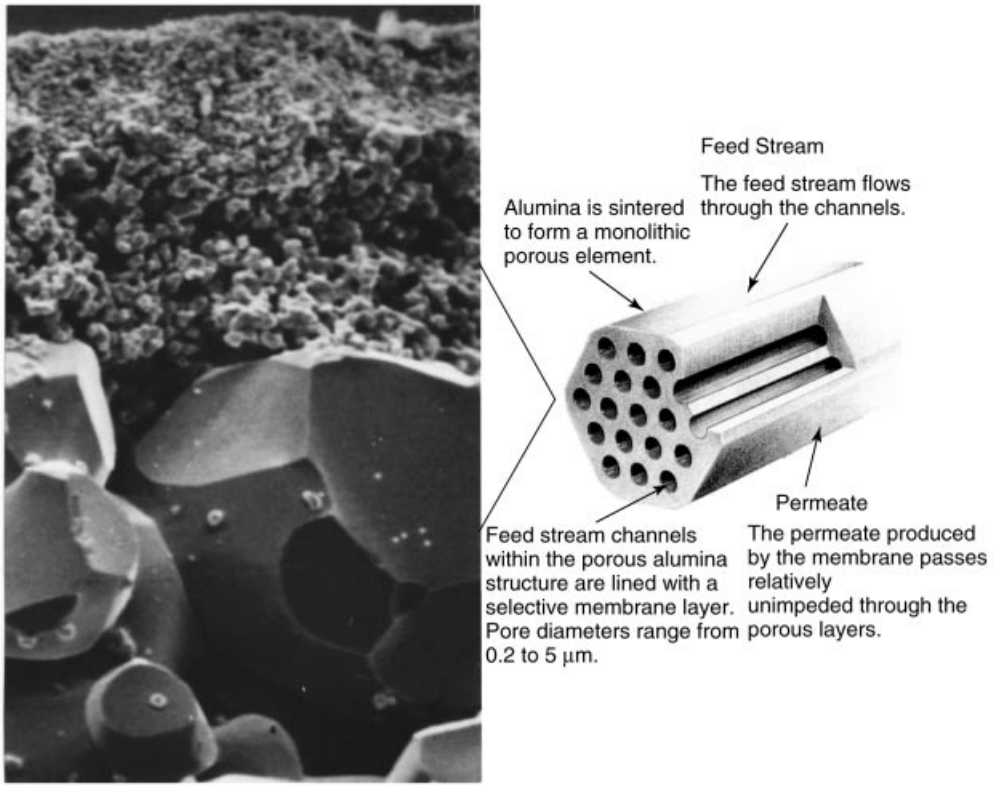

Fig. 17. Cross-sectional scanning electron micrograph of a three-layered alumina membrane/support (pore sizes 0.2, 0.8, and 12 μm, respectively).

the particles in suspension. This mixture is called a slip suspension; when dried and sintered at high temperatures, a finely microporous surface layer remains. Usually several slip-coated layers are applied in series, each layer being formed from a suspension of progressively finer particles and resulting in an anisotropic structure. Most commercial ceramic ultrafiltration membranes are made this way, generally in the form of tubes or perforated blocks. A scanning electron micrograph of the surface of this type of multilayer membrane is shown in Figure 17.

The slip-coating–sintering method can produce membranes with pore diameters down to about 10–20 nm. More finely porous membranes are made by sol–gel techniques. In the sol–gel process slip-coating is taken to the colloidal level. Generally the substrate to be coated with the sol–gel is a microporous ceramic tube formed by the slip-coating–sintering technique. The solution coated onto this support is a colloidal or polymeric gel of an inorganic hydroxide. These solutions are prepared by controlled hydrolysis of metal salts or metal alkoxides to hydroxides.

Sol–gel methods fall into two categories, depending on how the colloidal coating solution is formed. In the particulate–sol method a metal alkoxide is hydrolyzed by addition of excess water or acid. The resulting precipitate is maintained as a hot solution for some time before it is cooled and coated onto the microporous support membrane. After careful drying and sintering at 500–800°C,

a very finely microporous layer is formed. In the polymeric sol–gel process, partial hydrolysis of the metal alkoxide in alcohol is accomplished by adding the minimum of water to the solution. The alkoxide groups then react to form an inorganic polymer molecule that can be coated onto the microporous support. On drying and sintering, the inorganic polymer converts to a metal oxide ceramic film.

Liquid Membranes. A number of reviews summarize the considerable research effort in the 1970s and 1980s on liquid membranes containing carriers to facilitate selective transport of gases or ions (59,60). Although still being studied in a number of laboratories, the more recent development of much more selective conventional polymer membranes has diminished interest in processes using liquid membranes.

Hollow-Fiber Membranes. Most of the techniques described previously were developed originally to produce flat-sheet membranes, but the majority can be adapted to produce membranes in the form of thin tubes or fibers. Formation of membranes into hollow fibers has a number of advantages, one of the most important of which is the ability to form compact modules with very high surface areas. This advantage is offset, however, by the generally lower fluxes of hollow-fiber membranes compared to flat-sheet membranes made from the same materials. Nonetheless, the development of hollow-fiber membranes in the 1960s (61) and their later commercialization by Dow, Monsanto, DuPont, and others represents one of the most significant events in membrane technology.

Hollow fibers are usually of the order of 25 μm to 2 mm in diameter. They can be made with a homogeneous dense structure, or preferably with a microporous structure having a dense selective layer on the outside or inside surface. The dense surface layer can be integral, or separately coated onto a support fiber. The fibers are packed into bundles and potted into tubes to form a membrane module. More than a kilometer of fibers may be required to form a membrane module with a surface area of 1 m^2. A module can have no breaks or defects, requiring very high reproducibility and stringent quality control standards. Fibers with diameters 25–200 μm are usually called hollow-fine fibers. The fibers are too fine to allow the feed fluid to be pumped down the fiber bore so the feed fluid is generally applied to the outside of the fibers and the smaller volume of permeate removed down the bore. Fibers with diameters in the 200 μm to 2 mm range are called capillary fibers. The feed fluid is commonly applied to the inside bore of the fiber, and the permeate is removed from the outer shell.

Hollow-fiber fabrication methods can be divided into two classes (62,63). The most common is *solution spinning*, in which a 20–30% polymer solution is extruded and precipitated into a bath of a nonsolvent, generally water. Solution spinning allows fibers with the asymmetric Loeb–Sourirajan structure to be made. An alternative technique is *melt spinning*, in which a hot polymer melt is extruded from an appropriate die and is then cooled and solidified in air or a quench tank. Melt-spun fibers are usually relatively dense and have lower fluxes than solution-spun fibers, but, because the fiber can be stretched after it leaves the die, very fine fibers can be made. Melt spinning can also be used with polymers such as poly(trimethylpentene), which are not soluble in convenient solvents and are difficult to form by wet spinning.

Solution (Wet) Spinning. The most widely used solution spinneret system was first devised by Mahon (61). The spinneret consists of two concentric capillaries: the outer capillary having a diameter of approximately 400 μm and

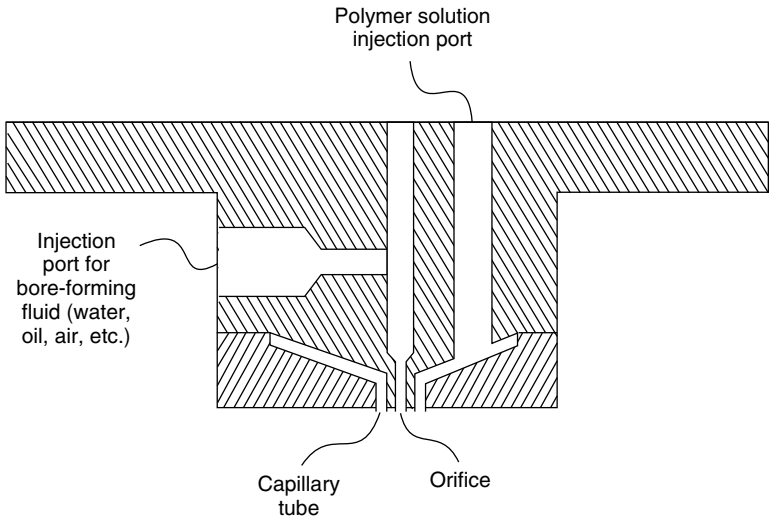

Fig. 18. Twin-orifice spinneret design used in solution-spinning of hollow-fiber membranes. Polymer solution is forced through the outer orifice, while bore-forming fluid is forced through the inner capillary.

the central capillary having an outer diameter of approximately 200 μm and an inner diameter of 100 μm. Polymer solution is forced through the outer capillary while air or liquid is forced through the inner one. The rate at which the core fluid is injected into the fibers relative to the flow of polymer solution governs the ultimate wall thickness of the fiber. Figure 18 shows a cross section of this type of spinneret.

A complete hollow-fiber spinning system is shown in Figure 19. Fibers are formed almost instantaneously as the polymer solution leaves the spinneret. The amount of evaporation time between the solution exiting the spinneret and entering the coagulation bath is a critical variable. If water is forced through the

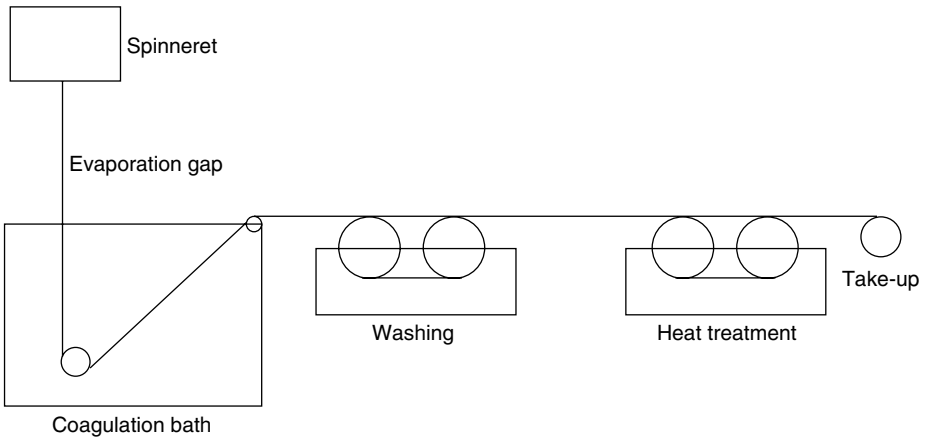

Fig. 19. A hollow-fiber solution-spinning system. The fiber is spun into a coagulation bath, where the polymer spinning solution precipitates to form the fiber. The fiber is then washed, dried, and taken up on a roll.

inner capillary, an asymmetric hollow fiber is formed with the skin on the inside. If air under a few pounds of pressure, or an inert liquid, is forced through the inner capillary to maintain the hollow core, the skin is formed on the outside of the fiber by immersion in a suitable coagulation bath (64).

Wet spinning of this type of hollow fiber is a well-developed technology, especially in the preparation of dialysis membranes for use in artificial kidneys. Systems that spin more than 100 fibers simultaneously on an around-the-clock basis are in operation. Wet-spun fibers are also used widely in ultrafiltration applications, in which the feed solution is forced down the bore of the fiber. Nitto, Asahi, Microgon, and Abcor all produce this type of fiber, generally with diameters of 1–3 mm.

Melt Spinning. In melt spinning, the polymer is extruded through the outer capillary of the spinneret as a hot melt, the spinneret assembly being maintained at a temperature between 100 and 300°C. The polymer can be extruded either as a pure melt or as a blended dope containing small amounts of plasticizers and other additives. Melt-spun fibers are usually stretched as they leave the spinneret, to form very thin fibers. Formation of such small-diameter fibers is a main advantage of melt spinning over solution spinning. The dense nature of melt-spun fibers leads to lower fluxes than can be obtained with solution-spun fibers, but, because of the enormous membrane surface area of these fine hollow fibers, this may not be a problem.

Membrane Modules. A useful membrane process requires the development of a membrane module containing large surface areas of membrane. The development of the technology to produce low cost membrane modules was one of the breakthroughs that led to the commercialization of membrane processes in the 1960s and 1970s. The earliest designs were based on simple filtration technology and consisted of flat sheets of membrane held in a type of filter press: these are called plate-and-frame modules. Systems containing a number of membrane tubes were developed at about the same time. Both of these systems are still used, but because of their relatively high cost they have been largely displaced by two other designs—the spiral-wound module and the hollow-fiber module.

Spiral-Wound Modules. Spiral-wound modules were used originally for artificial kidneys, but were fully developed for reverse osmosis systems. This work, carried out by UOP under sponsorship of the Office of Saline Water (later the Office of Water Research and Technology), resulted in a number of spiral-wound designs (65–67). The design shown in Figure 20 is the simplest and most common, and consists of a membrane envelope wound around a perforated central collection tube. The wound module is placed inside a tubular pressure vessel, and feed gas is circulated axially down the module across the membrane envelope. A portion of the feed permeates into the membrane envelope, where it spirals toward the center and exits through the collection tube.

Small laboratory spiral-wound modules consist of a single membrane envelope wrapped around the collection tube. The membrane area of these modules is typically 0.6–1.0 m^2. Commercial spiral-wound modules are typically 100–150 cm long and have diameters of 10, 15, 20, and 30 cm. These modules consist of a number of membrane envelopes, each with an area of approximately 2 m^2, wrapped around the central collection pipe. This type of multileaf design is illustrated in Figure 21 (66). Such designs are used to minimize the pressure drop encountered

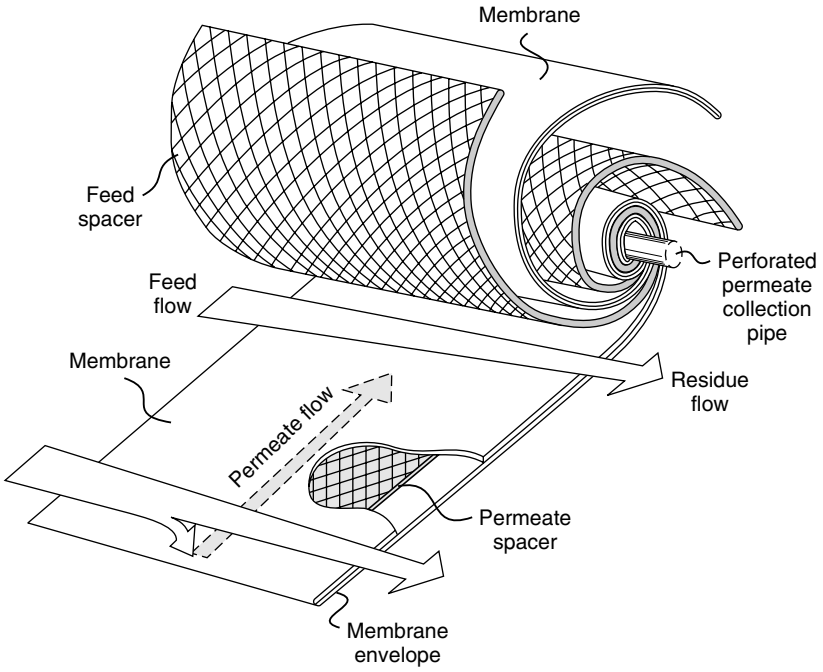

Fig. 20. Schematic of a spiral-wound membrane module.

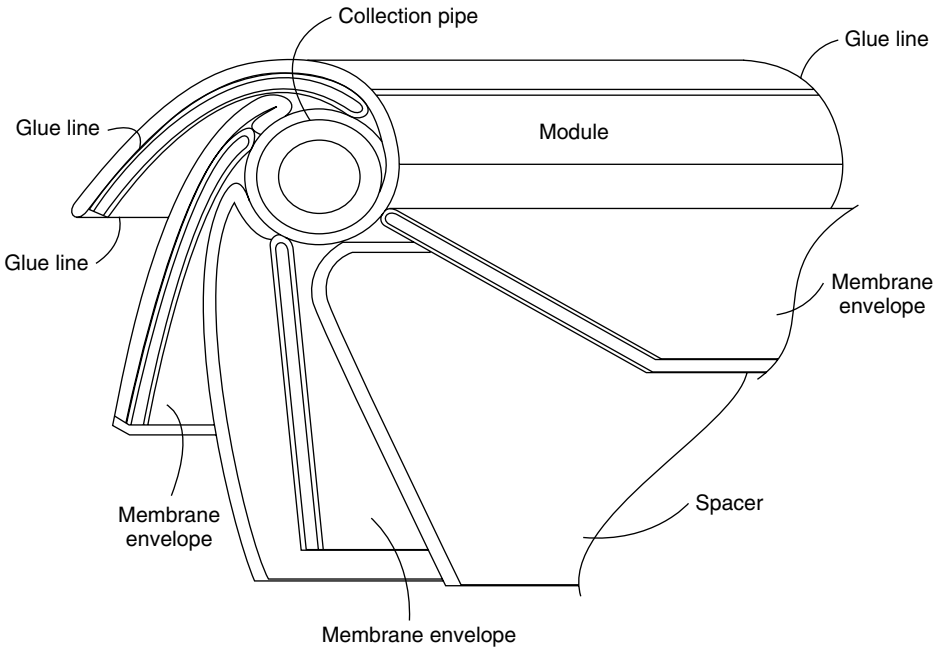

Fig. 21. Multileaf spiral-wound module, used to avoid excessive pressure drops on the permeate side of the membrane. Large, 30-cm-diameter modules may have as many as 30 membrane envelopes, each with a membrane area of about 2 m^2.

by the permeate fluid traveling toward the central pipe. If a single membrane envelope were used in these large diameter modules, the path taken by the permeate to the central collection pipe would be 5–25 m, depending on the module diameter. This long permeate path would produce a very large pressure drop, especially with high flux membranes. If multiple, smaller envelopes are used in a single module, the pressure drop in any one envelope is reduced to a manageable level.

Hollow-Fiber Modules. Hollow-fiber membrane modules are formed in two basic geometries. The first is the shell-side feed design illustrated in Figure 22a and used, for example, by Monsanto in their hydrogen separation systems or by DuPont in their reverse osmosis fiber systems. In such a module, a loop or a closed bundle of fiber is contained in a pressure vessel. The system is pressurized from the shell side; permeate passes through the fiber wall and exits through the open fiber ends. This design is easy to make and allows very large membrane areas to be contained in an economical system. Because the fiber wall must support a considerable hydrostatic pressure, these fibers are usually made by melt spinning and usually have a small diameter, of the order of 100-μm ID and 150- to 200-μm OD.

The second type of hollow-fiber module is the bore-side feed design illustrated in Figure 22b. The fibers in this type of unit are open at both ends, and the feed fluid is usually circulated through the bore of the fibers. To minimize pressure drops inside the fibers, the fibers often have larger diameters than the very fine fibers used in the shell-side feed system and are generally made by solution spinning. These so-called capillary fibers are used in ultrafiltration, in pervaporation, and in some low to medium pressure gas applications. Feed pressures are usually limited to less than 1 MPa (150 psig) in this type of module. A number of variants on the basic design have been developed and reviewed (68).

Plate-and-Frame Modules. Plate-and-frame modules were among the earliest types of membrane system; the design originates from the conventional filter-press. Membrane, feed spacers, and product spacers are layered together between two end plates, as illustrated in Figure 23 (69). A number of plate-and-frame units have been developed for small-scale applications, but these units are expensive compared to the alternatives, and leaks caused by the many gasket seals are a serious problem. Plate-and-frame modules are now generally limited to electrodialysis and pervaporation systems and a limited number of highly fouling reverse osmosis and ultrafiltration applications.

Tubular Modules. Tubular modules are now generally limited to ultrafiltration applications, for which the benefit of resistance to membrane fouling because of good fluid hydrodynamics overcomes the problem of their high capital cost. Typically, the tubes consist of a porous paper or fiberglass support with the membrane formed on the inside of the tubes, as shown in Figure 24. The first tubular membranes were between 2 and 3 cm in diameter, but more recently, as many as five to seven smaller tubes, each 0.5–1.0 cm in diameter, are nested inside a single, larger tube.

Module Selection. The choice of the appropriate membrane module for a particular membrane separation balances a number of factors. The principal factors that enter into this decision are listed in Table 2.

Cost, although always important, is difficult to quantify because the actual selling price of membrane modules varies widely, depending on the application.

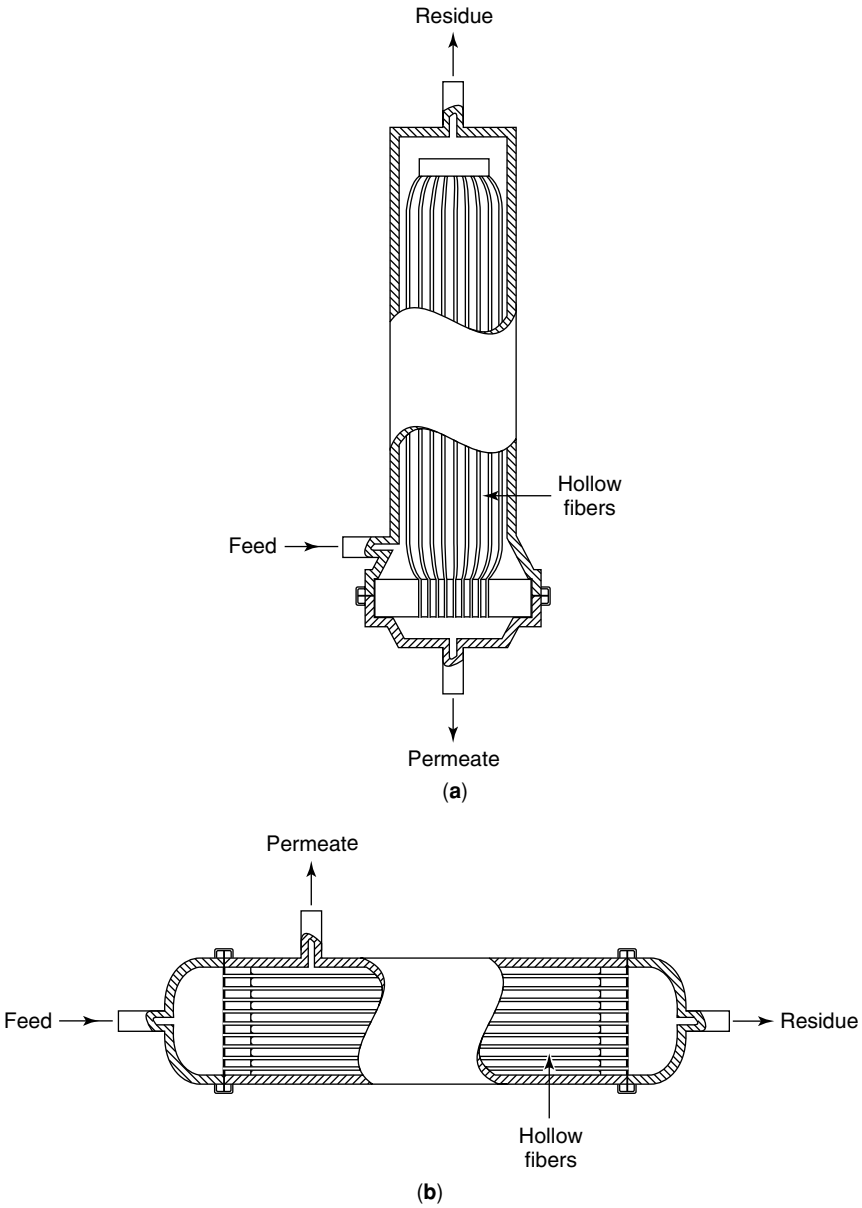

Fig. 22. Two types of hollow-fiber modules used for gas separation, reverse osmosis, and ultrafiltration applications. (**a**) Shell-side feed modules are generally used for high pressure applications up to ˜7 MPa (1000 psig). Fouling on the feed side of the membrane can be a problem with this design, and pretreatment of the feed stream to remove particulates is required. (**b**) Bore-side feed modules are generally used for medium pressure feed streams up to ˜1 MPa (150 psig), where good flow control to minimize fouling and concentration polarization on the feed side of the membrane is desired.

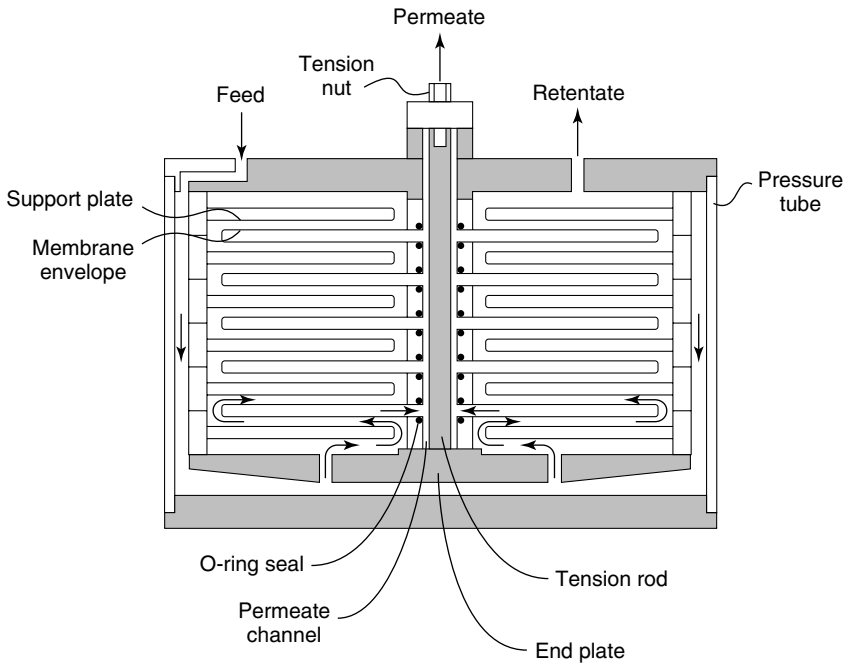

Fig. 23. Schematic of plate-and-frame module system. This design has good flow control, but the large number of spacer plates and seals leads to high costs.

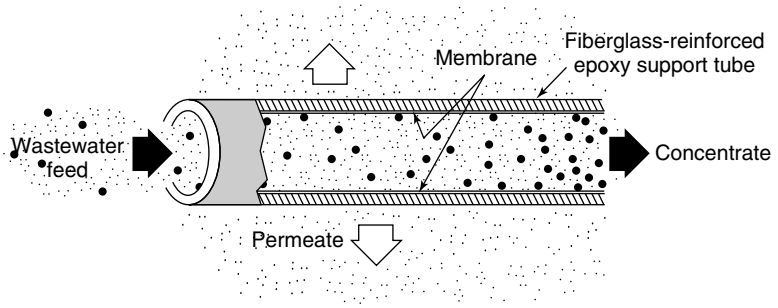
Generally, high-pressure modules are more expensive than low-pressure or vacuum systems. The selling price also depends on the volume of the application and the pricing structure adopted by the industry. For example, spiral-wound modules for reverse osmosis of brackish water are produced by many manufacturers, resulting in severe competition and low prices, whereas similar modules for use in gas separation are much more expensive. Estimates of module manufacturing costs are given in Table 2; the selling price is typically two to five times higher.

A second factor determining module selection is resistance to fouling. Membrane fouling is a particularly important problem in liquid separations such as

Table 2. Characteristics of the Principal Module Designs

	Hollow-fine fibers	Capillary fibers	Spiral-wound	Plate-and-frame	Tubular
Manufacturing cost, $/m^2	2–10	5–50	5–50	50–200	50–200
Resistance to fouling	Very poor	Good	Moderate	Good	Very good
Parasitic pressure drop	High	Moderate	Moderate	Low	Low
Suitability for high pressure operation	Yes	No	Yes	Difficult	Difficult
Limitation to specific types of membrane	Yes	Yes	No	No	No



(**a**)

(**b**)

Fig. 24. (**a**) Typical tubular ultrafiltration module design. In the past, modules in the form of 2- to 3-cm-diameter tubes were common; more recently, 0.5- to 1.0-cm-diameter tubes, nested inside a simple pipe (**b**), have been introduced.

reverse osmosis and ultrafiltration. In gas separation applications, fouling is more easily controlled. Hollow-fine fibers are notoriously prone to fouling and can only be used in reverse osmosis applications if extensive, costly feed-solution pretreatment is used to remove all particulates. These fibers cannot be used in ultrafiltration applications at all.

A third factor is the ease with which various membrane materials can be fabricated into a particular module design. Almost all membranes can be formed into plate-and-frame, spiral, and tubular modules, but many membrane materials cannot be fabricated into hollow-fine fibers or capillary fibers. Finally, the suitability of the module design for high pressure operation and the relative magnitude of pressure drops on the feed and permeate sides of the membrane can sometimes be important considerations.

In reverse osmosis, most modules are of the hollow-fine-fiber or spiral-wound design; plate-and-frame and tubular modules are limited to a few applications in

which membrane fouling is particularly severe, for example, food applications or processing of heavily contaminated industrial wastewater. Currently, hollow-fiber designs are being displaced by spiral-wound modules, which are inherently more fouling resistant, and require less feed pretreatment. Also, thin-film interfacial composite membranes, the best reverse osmosis membranes now available, have not been fabricated in the form of hollow-fine fibers.

For ultrafiltration applications, hollow-fine fibers have never been seriously considered because of their susceptibility to fouling. If the feed solution is extremely fouling, tubular or plate-and-frame systems are still used. Recently, however, spiral-wound modules with improved resistance to fouling have been developed, and these modules are increasingly displacing the more expensive plate-and-frame and tubular systems. Capillary systems are also used in some ultrafiltration applications.

For high-pressure gas separation applications, hollow-fine fibers appear to have a major segment of the market. Hollow-fiber modules are clearly the lowest cost design per unit membrane area, and their poor resistance to fouling is not a problem in many gas separation applications. Also, gas separation membrane materials are often rigid glassy polymers such as polysulfones, polycarbonates, and polyimides, which can be easily formed into hollow-fine fibers. Of the principal companies servicing this area only Separex and GMS use spiral-wound modules. Both companies use these modules to process natural gas streams, which are relatively dirty, often containing oil mist and condensable components that would foul hollow-fine-fiber modules rapidly.

Spiral-wound modules are much more commonly used in low-pressure or vacuum gas separation applications, such as the production of oxygen-enriched air, or the separation of organic vapors from air. In these applications, the feed gas is at close to ambient pressure, and a vacuum is drawn on the permeate side of the membrane. Parasitic pressure drops on the permeate side of the membrane and the difficulty in making high-performance hollow-fine-fiber membranes from the rubbery polymers used to make these membranes both work against hollow-fine-fiber modules for this application.

Pervaporation operates under constraints similar to low-pressure gas separation. Pressure drops on the permeate side of the membrane must be small, and many pervaporation membrane materials are rubbery. For this reason, spiral-wound modules and plate-and-frame systems are both in use. Plate-and-frame systems are competitive in this application despite their high cost, primarily because they can be operated at high temperatures with relatively aggressive feed solutions, conditions under which spiral-wound modules might fail.

Membrane Applications

The principal use of membranes in the chemical processing industry is in various separation processes. Seven major membrane separation processes are discussed in this section. These can be classified into technologies that are developed, developing, or to-be-developed, as shown in Table 3. Membranes, or rather films, are also used widely as packaging materials. The use of membranes in various biomedical applications, for example, in controlled release technology and in

Table 3. Various Membrane Separation Technologies

	Process	Status
Developed technologies	Microfiltration	Well-established unit processes. No major breakthroughs seem imminent
Ultrafiltration		
Reverse osmosis		
Electrodialysis		
Developing technologies	Gas separation	A number of plants have been installed. Market size and number of applications served are expanding rapidly
Pervaporation		
To-be-developed technologies	Facilitated transport	Major problems remain to be solved before industrial systems will be installed

artificial organs such as the artificial kidney, lung, and pancreas are only covered briefly here.

The four developed processes are microfiltration, ultrafiltration, reverse osmosis, and electrodialysis. All are well established, and the market is served by a number of experienced companies. The first three processes are related to filtration techniques, in which a solution containing dissolved or suspended solids is forced through a membrane filter. The solvent passes through the membrane; the solutes are retained. The three processes differ principally in the size of the particles separated by the membrane. Microfiltration is considered to refer to membranes with pore diameters from 0.1 μm (100 nm) to 10 μm. Microfiltration membranes are used to filter suspended particulates, bacteria, or large colloids from solutions. Ultrafiltration refers to membranes having pore diameters in the range 2–100 nm. Ultrafiltration membranes can be used to filter dissolved macromolecules, such as proteins, from solution. Typical applications of ultrafiltration membranes are concentrating proteins from milk whey, or recovering colloidal paint particles from electrocoating paint rinse waters.

In reverse osmosis membranes, the pores are so small, in the range 0.5–2 nm in diameter, that they are within the range of the thermal motion of the polymer chains. The most widely accepted theory of reverse osmosis transport considers the membrane to have no permanent pores at all. Reverse osmosis membranes are used to separate dissolved microsolutes, such as salt, from water. The principal application of reverse osmosis is the production of drinking water from brackish groundwater or seawater. Figure 25 shows the range of applicability of reverse osmosis, ultrafiltration, microfiltration, and conventional filtration. In some recent work, membranes that fall into the overlapping area between very retentive ultrafiltration membranes and very open ultrafiltration membranes are sometimes called nanofiltration membranes. The membranes have apparent pore diameters between 0.5 and 5 nm.

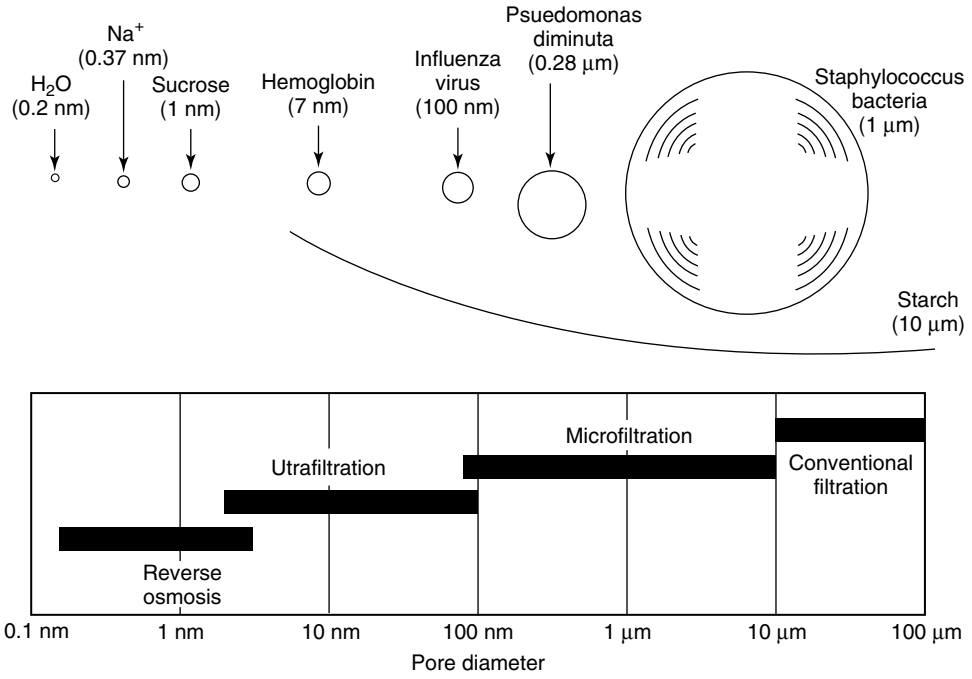


Fig. 25. Reverse osmosis, ultrafiltration, microfiltration, and conventional filtration are related processes differing principally in the average pore diameter of the membrane filter. Reverse osmosis membranes are so dense that discrete pores do not exist; transport occurs via statistically distributed free volume areas. The relative size of different solutes removed by each class of membrane is illustrated in this schematic.

The fourth fully developed membrane process is electrodialysis, in which charged membranes are used to separate ions from aqueous solutions under the driving force of an electrical potential difference. The process utilizes an electrodialysis stack, built on the plate-and-frame principle, containing several hundred individual cells formed by a pair of anion- and cation-exchange membranes. The principal current application of electrodialysis is the desalting of brackish groundwater. However, industrial use of the process in the food industry, for example to deionize cheese whey, is growing, as is its use in pollution-control applications.

Of the two developing membrane processes listed in Table 3, gas separation and pervaporation, gas separation is the more developed. At least 20 companies worldwide offer industrial membrane-based gas separation systems for a variety of applications. In gas separation, a mixed gas feed at an elevated pressure is passed across the surface of a membrane that is selectively permeable to one component of the feed. The membrane separation process produces a permeate enriched in the more permeable species and a residue enriched in the less permeable species. Important, well-developed applications are the separation of hydrogen from nitrogen, argon, and methane in ammonia plants; the production of nitrogen from air; the separation of carbon dioxide from methane in natural gas operations; and the separation and recovery of organic vapors from air streams. Gas separation is an area of considerable current research interest; the number of applications is expected to increase rapidly over the next few years.

Pervaporation is a relatively new process with elements in common with reverse osmosis and gas separation. In pervaporation, a liquid mixture contacts one side of a membrane and the permeate is removed as a vapor from the other. Currently, the only industrial application of pervaporation is the dehydration of organic solvents, in particular, the dehydration of 90–95% ethanol solutions, a difficult separation problem because an ethanol–water azeotrope forms at 95% ethanol. However, pervaporation processes are also being developed for the removal of dissolved organics from water and for the separation of organic solvent mixtures. These applications are likely to become commercial in the next decade.

The final membrane process listed in Table 3 is *facilitated transport*. No commercial plants are installed or are likely to be installed in the near future. Facilitated transport usually employs liquid membranes containing a complexing or carrier agent. The carrier agent reacts with one permeating component on the feed side of the membrane and then diffuses across the membrane to release the permeant on the product side of the membrane. The carrier agent is then reformed and diffuses back to the feed side of the membrane. The carrier agent thus acts as a shuttle to selectively transport one component from the feed to the product side of the membrane.

Facilitated transport membranes can be used to separate gases; membrane transport is then driven by a difference in the gas partial pressure across the membrane. Metal ions can also be selectively transported across a membrane driven by a flow of hydrogen or hydroxyl ions in the other direction. This process is sometimes called *coupled transport*.

Because the facilitated transport process employs a specific, reactive carrier species, very high membrane selectivities can be achieved. These selectivities are often far higher than those achieved by other membrane processes. This one fact has maintained interest in facilitated transport since the 1970s, but the problems of the physical instability of the liquid membrane and the chemical instability of the carrier agent are yet to be overcome.

Microfiltration. *Microfiltration* is generally defined as the separation of particulates between 0.1 and 10 μm by a membrane. Two principal types of membrane filter are used: depth filters and screen filters. Figure 26 compares typical pore sizes of depth and screen filters. Screen filters have small pores in the top surface that collect particles larger than the pore diameter on the surface of the membrane. Depth filters have relatively large pores on the top surface and so particles pass to the interior of the membrane. The particles are then captured at constrictions in the membrane pores or by adsorption onto the pore walls. Screen filter membranes rapidly become plugged by the accumulation of retained particles at the top surface. Depth filters, which have a much larger surface area available to collect the particles, provide a greater holding capacity before fouling.

Depth filters are usually preferred for the most common type of microfiltration system, illustrated schematically in Figure 27a. In this process design, called *dead-end or in-line filtration*, the entire fluid flow is forced through the membrane under pressure. As particulates accumulate on the membrane surface or in its interior, the pressure required to maintain the required flow increases until, at some point, the membrane must be replaced. The useful life of the membrane is proportional to the particulate loading of the feed solution. In-line microfiltration of solutions as a final polishing step prior to use is a typical application.

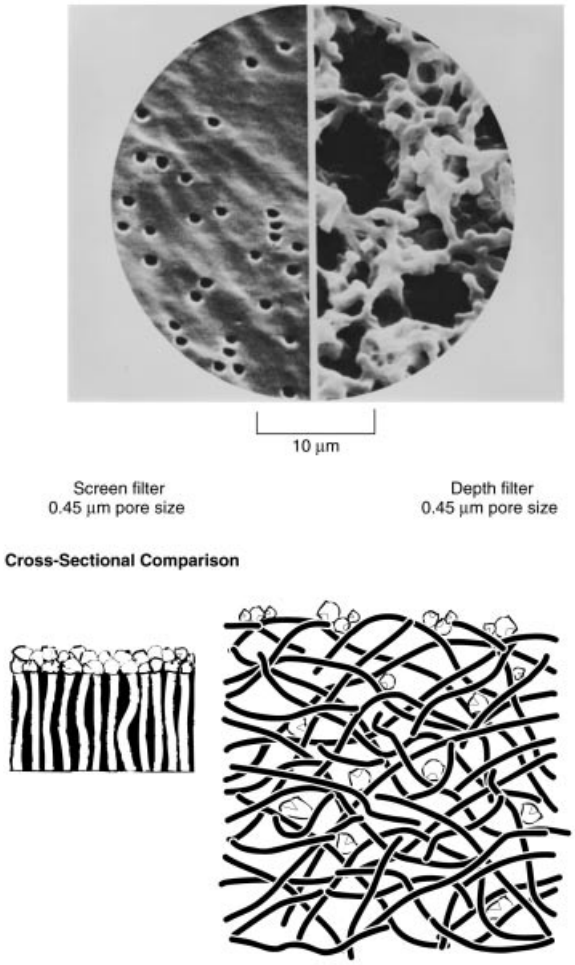

Fig. 26. Surface scanning electron micrograph and schematic comparison of nominal 0.45-mm screen and depth filters. The screen filter pores are uniform and small and capture the retained particles on the membrane surface. The depth filter pores are almost 5–10 times larger than the screen filter equivalent. A few large particles are captured on the surface of the membrane, but most are captured by adsorption in the membrane interior.

Increasingly, screen membranes are preferred for the type of cross-flow microfiltration system shown in Figure 27b. Cross-flow systems are more complex than the in-line (dead-end) filter systems because they require a recirculation pump, valves, controls, etc. However, a screen membrane has a much longer lifetime than a depth membrane and, in principle, can be regenerated by back flushing. Cross-flow filtration is being adopted increasingly for microfiltration of high-volume industrial streams containing significant particulate levels (70).

Ultrafiltration. The term ultrafiltration was coined in the 1920s to describe the collodion membranes available at that time. The process was first widely used in the 1960s when Michaels and others at Amicon Corp. adopted the then recently discovered Loeb–Sourirajan asymmetric membrane preparation

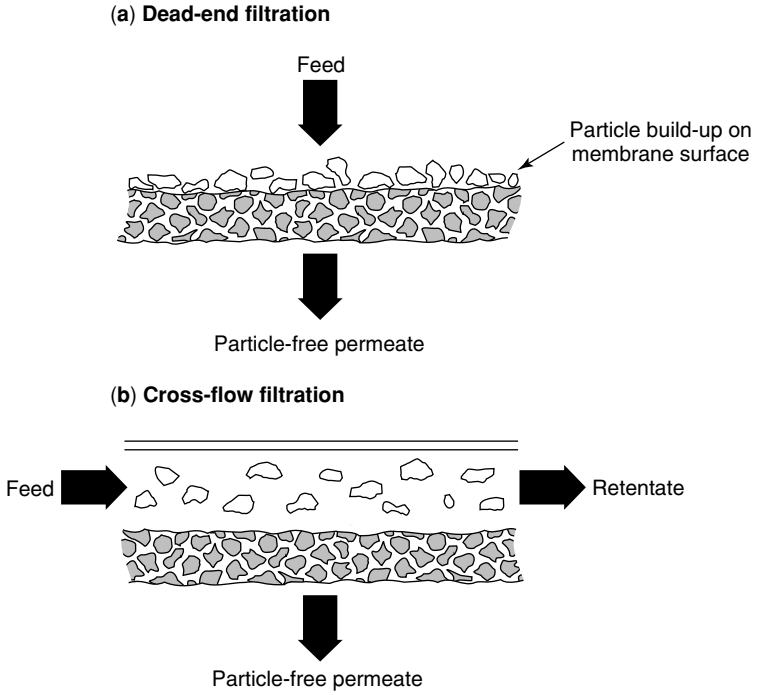

Fig. 27. Schematic representation of dead-end and cross-flow filtration with microfiltration membranes. The equipment used in dead-end filtration is simple, but retained particles plug the membranes rapidly. The equipment required for cross-flow filtration is more complex, but the membrane lifetime is longer.

technique to the production of ultrafiltration membranes (26). These membranes had pore sizes in the range 2–20 nm and found an immediate application in concentrating and desalting protein solutions in the laboratory. Later, Romicon, Abcor, and other companies developed the technology for a wide range of industrial applications. Early and still important applications were the recovery of electrocoat paint from industrial coating operations and the clarification of emulsified oily wastewaters in the metalworking industry. More recent applications are in the food industry for concentration of proteins in cheese production and for juice clarification (71). The current ultrafiltration market is in the range $150–250 million/year.

An example is the application of ultrafiltration to an automobile electrocoat paint operation shown schematically in Figure 28. Electrocoat paint is an emulsion of charged paint particles. The metal piece to be coated is made into an electrode of opposite charge to the paint particles and is immersed in a large tank of the paint. When a voltage is applied between the metal part and the paint tank, the charged paint particles migrate under the influence of the voltage and are deposited on the metal surface to form a coating over the entire wetted surface of the metal part. After electrodeposition, the piece is removed from the tank and rinsed to remove excess paint, after which the paint is cured in an oven.

The rinse water from the washing step rapidly becomes contaminated with excess paint, while the stability of the paint emulsion is gradually degraded

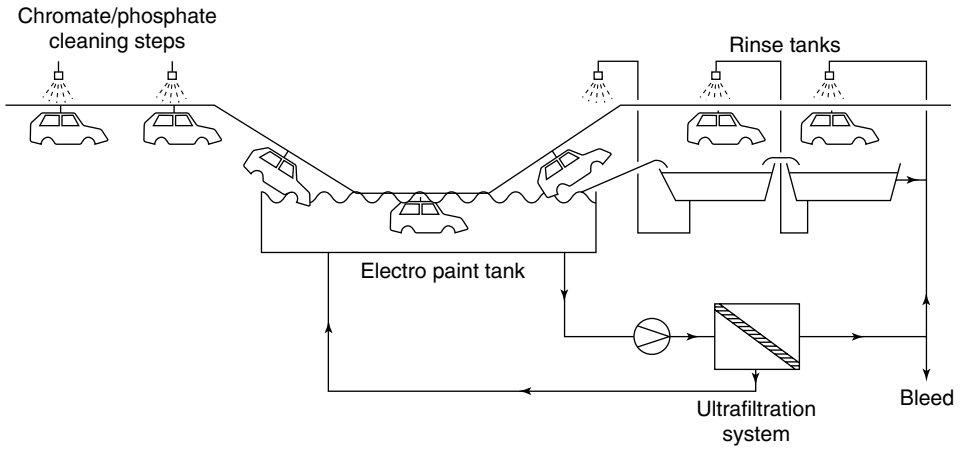

Fig. 28. Flow schematic of an electrocoat paint ultrafiltration system. The ultrafiltration system removes ionic impurities from the paint tank carried over from the chromate/phosphate cleaning steps and provides clean rinse water for the countercurrent rinsing operation.

by ionic impurities carried over from the cleaning operation before the paint tank. Both of these problems are solved by the ultrafiltration system shown in Figure 28. The ultrafiltration plant takes paint solution containing 15–20% solids and produces a clean permeate, containing the ionic impurities but no paint particles, which is sent to the countercurrent rinsing operation, and a slightly concentrated paint to be returned to the paint tank. A portion of the ultrafiltration permeate is bled from the tank and replaced with water to maintain the ionic balance of the process. A good review of other ultrafiltration applications is given in Reference (71).

Ultrafiltration membranes are usually asymmetric membranes made by the Loeb–Sourirajan process. They have a finely porous surface or skin supported on a microporous substrate. The membranes are characterized by their *molecular weight cutoff*, a loosely defined term generally taken to mean the molecular weight of the globular protein molecule that is 95% rejected by the membrane. A series of typical molecular weight cutoff curves are shown in Figure 29. Globular proteins are usually specified for this test because the rejection of linear polymer molecules of equivalent molecular weight is usually much less. Apparently, linear, flexible molecules are able to snake through the membrane pores, whereas rigid globular molecules are retained.

A key factor determining the performance of ultrafiltration membranes is concentration polarization, which causes membrane fouling due to deposition of retained colloidal and macromolecular material on the membrane surface. The pure water flux of ultrafiltration membranes is often very high—more than 1 $cm^3/(cm^2 \cdot min)$ [350 $gal/(ft^2 \cdot day)$]. However, when membranes are used to separate macromolecular or colloidal solutions, the flux falls within seconds, typically to the 0.1 $cm^3/(cm^2 \cdot min)$ level. This immediate drop in flux is caused by the formation of a gel layer of retained solutes on the membrane surface because of the concentration polarization. The gel layer forms a secondary barrier

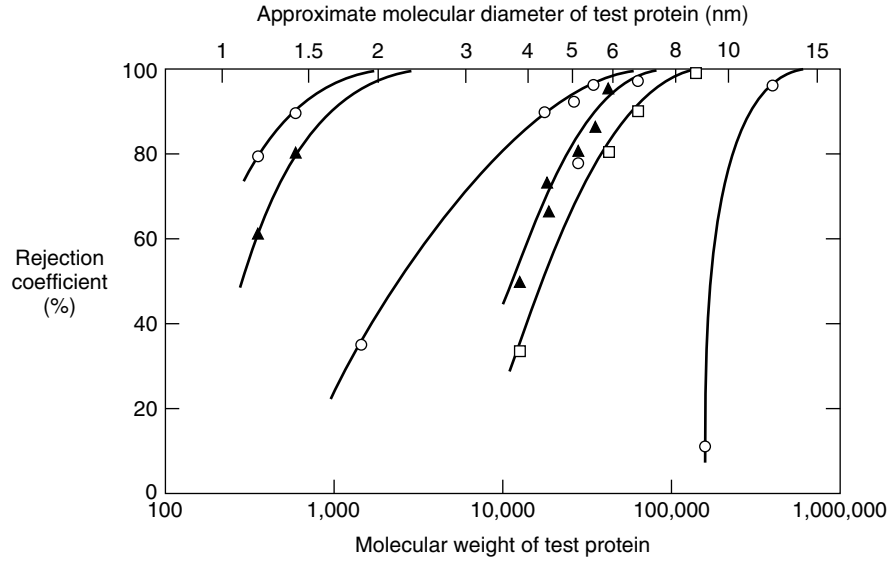

Fig. 29. Rejection of test proteins as a function of molecular weight, in a series of ultrafiltration membranes with different molecular weight cutoffs. As these data show, membranes with complete sharp molecular weight are not found outside of manufacturers' catalogs.

to flow through the membrane, as illustrated in Figure 30. This first decline in flux is determined by the composition of the feed solution and its fluid hydrodynamics. Sometimes the resulting flux is constant for a prolonged period, and when the membrane is retested with pure water, its flux returns to the original value. More commonly, however, a further slow decline in flux occurs over a period of hours to weeks, depending on the feed solution. Most of this second decrease in flux is caused by slow consolidation of the secondary layer formed by concentration polarization on the membrane surface. Formation of this consolidated gel layer, called *membrane fouling*, is difficult to control. Control techniques include regular membrane cleaning, back flushing, or using membranes with surface characteristics that minimize adhesion. Operation of the membrane at the lowest practical operating pressure also delays consolidation of the gel layer.

A typical plot illustrating the slow decrease in flux that can result from consolidation of the secondary layer is shown in Figure 31. The pure water flux of these membranes is approximately 200 L/min, but on contact with an electrocoat paint solution containing 10–20% latex, the flux immediately falls to about 40–50 L/min. This first drop in flux is due to the formation of the gel layer of latex particles on the membrane surface, as shown in Figure 30. Thereafter, the flux declines steadily over a 2-week period. This second drop in flux is caused by slow densification of the gel layer under the pressure of the system. In this particular example the densified gel layer could be removed by periodic cleaning of the membrane. When the cleaned membrane is exposed to the latex solution again, the flux is restored to that of a fresh membrane.

If the regular cleaning cycle shown in Figure 31 is repeated many times, the membrane flux eventually does not return to the original value on cleaning. Part of this slow, permanent loss of flux is believed to be due to precipitates on the

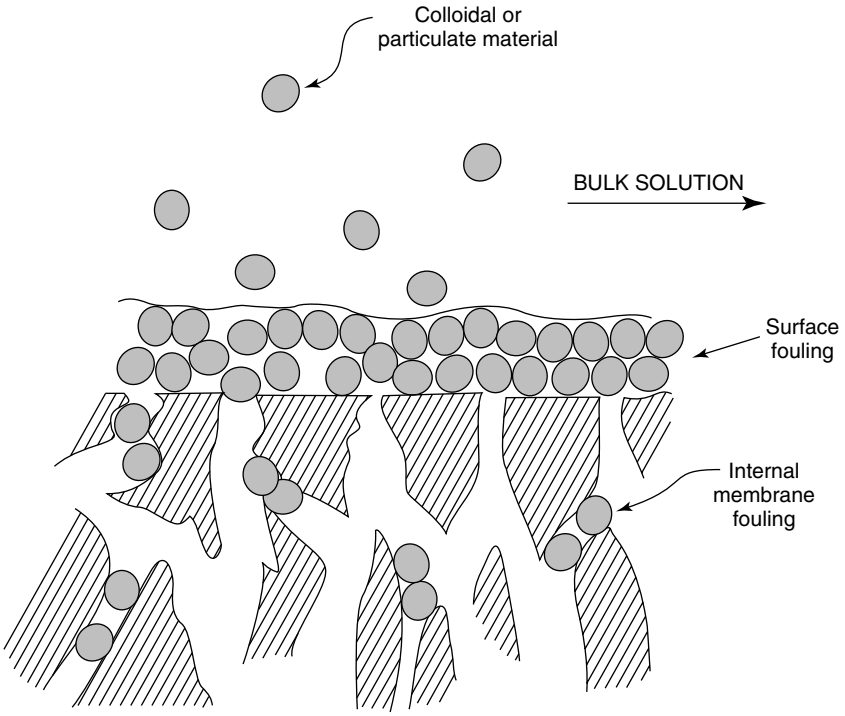

Fig. 30. Schematic representation of fouling on an ultrafiltration membrane. *Surface fouling* is the deposition of solid material on the membrane that consolidates over time. This fouling layer can be controlled by high turbulence, regular cleaning, and using hydrophilic or charged membranes to minimize adhesion to the membrane surface. Surface fouling is generally reversible. *Internal fouling* is caused by penetration of solid material into the membrane, which results in plugging of the pores. Internal membrane fouling is generally irreversible.

membrane surface that are not removed by the cleaning procedure. A further cause of the permanent flux loss is believed to be internal fouling of the membrane by material that penetrates the membrane pores and becomes lodged in the interior of the membrane, as illustrated in Figure 30.

As described previously, the initial cause of membrane fouling is concentration polarization, which results in deposition of a layer of material on the membrane surface. In ultrafiltration, solvent and macromolecular or colloidal solutes are carried toward the membrane surface by the solution permeating the membrane. Solvent molecules permeate the membrane, but the larger solutes accumulate at the membrane surface. Because of their size, the rate at which the rejected solute molecules can diffuse from the membrane surface back to the bulk solution is relatively low. Thus their concentration at the membrane surface increases far above the feed solution concentration. In ultrafiltration the concentration of retained macromolecular or colloidal solutes at the membrane surface is typically 20–50 times higher than the feed solution concentration. These solutes become so concentrated at the membrane surface that a gel layer is formed and becomes a secondary barrier to flow through the membrane. The formation of the gel layer

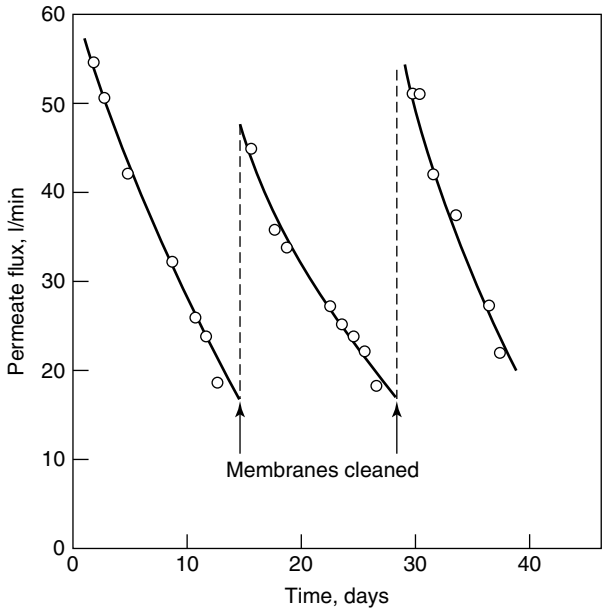

Fig. 31. Ultrafiltration flux as a function of time of an electrocoat paint latex solution. Because of fouling, the flux declines over a period of days. Periodic cleaning is required to maintain high fluxes.

is easily modeled mathematically and is reviewed in detail elsewhere (71–74). One consequence of the formation of the gel layer on the membrane surface is that ultrafiltration membrane fluxes reach a limiting plateau value that cannot be exceeded at any particular operating condition.

The effect of the gel layer on the flux through an ultrafiltration membrane at different feed pressures is illustrated by the experimental data in Figure 31. At a very low pressure p_1, the flux J_v is low, so the effect of concentration polarization is small, and a gel layer does not form on the membrane surface. The flux is close to the pure water flux of the membrane at the same pressure. As the applied pressure is increased to pressure p_2, the higher flux causes increased concentration polarization, and the concentration of retained material at the membrane surface increases. If the pressure is increased further to p_3, concentration polarization becomes enough for the retained solutes at the membrane surface to reach the gel concentration c_{gel}, and form the secondary barrier layer. This is the limiting flux for the membrane. Further increases in pressure only increase the thickness of the gel layer, not the flux.

Experience has shown that the best long-term performance of an ultrafiltration membrane is obtained when the applied pressure is maintained at or just below the plateau pressure p_3 shown in Figure 32. Operating at higher pressures does not increase the membrane flux but does increase the thickness and density of retained material at the membrane surface layer. Over time, material on the membrane surface can become compacted or precipitate, forming a layer of deposited material that has a lower permeability; the flux then falls from the initial value.

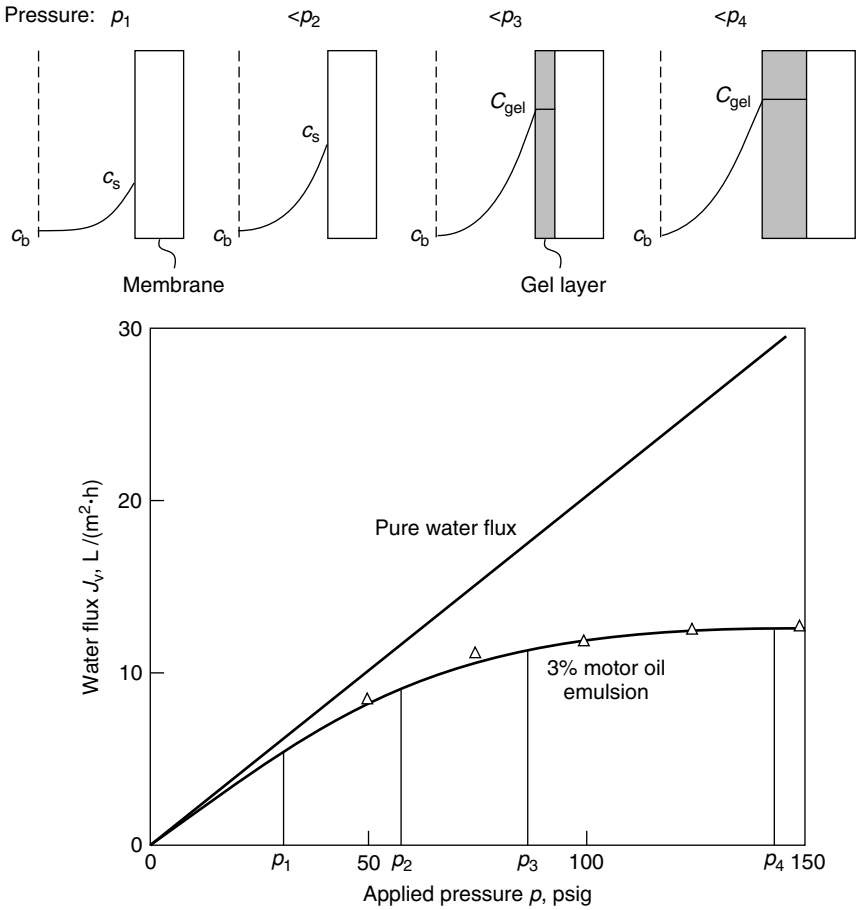

Fig. 32. The effect of pressure on ultrafiltration membrane flux and the formation of a secondary gel layer. Ultrafiltration membranes are best operated at pressures between p_2 and p_3 at which the gel layer is thin. Operation at high pressures such as p_4 leads to formation of thick gel layers, which can consolidate over time, resulting in permanent fouling of the membrane.

Reverse Osmosis. This was the first membrane-based separation process to be commercialized on a significant scale. As described previously, the breakthrough discovery that made reverse osmosis possible was the development of the Loeb–Sourirajan asymmetric cellulose acetate membrane. This membrane made desalination by reverse osmosis practical; within a few years commercial plants were installed. Currently, the total worldwide market for reverse osmosis membrane modules is about $300 million/year, split approximately between 15% hollow-fiber and 85% spiral-wound modules. The general trend of the industry is toward spiral-wound modules for this application, and the market share of the hollow-fiber products is falling (75).

The first reverse osmosis modules made from cellulose diacetate had a salt rejection of approximately 97–98%. This was enough to produce potable water (ie water containing less than 500-ppm salt) from brackish water sources, but was

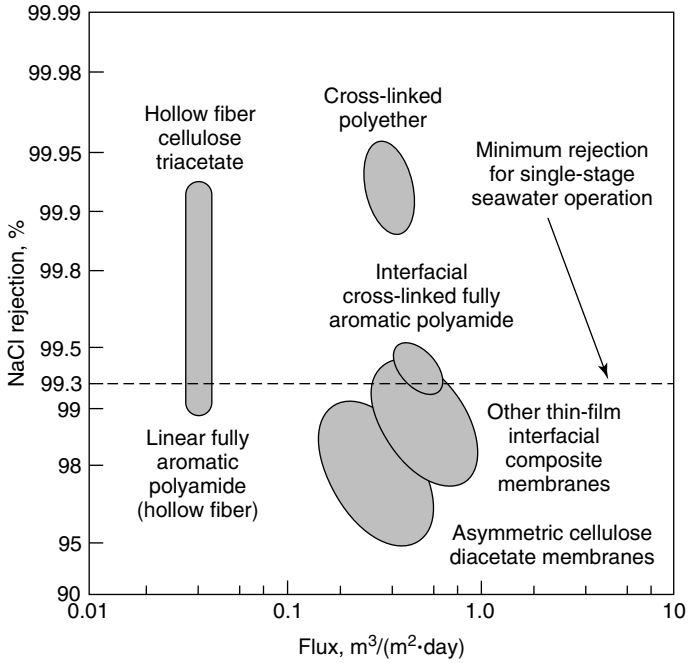

Fig. 33. Performance characteristics of membranes operating on seawater at 5.5 MPa (56 kg/cm^2) and 25°C (75).

not enough to desalinate sea water efficiently. In the 1970s, interfacial composite membranes with salt rejections greater than 99.5% were developed, making seawater desalination possible (28,29); a number of large plants are operating worldwide.

The performance characteristics of the membranes available in 1990 are shown in Figure 33. Hollow-fine-fiber membranes made by Toyobo and DuPont have relatively low fluxes, but because large membrane areas can be made so economically in hollow-fiber form, these membranes can still compete. The highest flux, highest performance membrane is the cross-linked polyether membrane formerly made by Toray. However, this membrane is unstable to oxidation, and all free oxygen and chlorine must be removed from the feed water to the membrane, a process that is expensive and subject to failure. As a result, most of the reverse osmosis membrane market is divided between various types of thin-film interfacial composite membranes and cellulose diacetate Loeb–Sourirajan membranes. Cellulose diacetate membranes still retain a fraction of the market because of their greater chemical and mechanical stability compared to interfacial composites. This advantage is gradually disappearing as improved interfacial composite membranes are developed (76).

The performance of reverse osmosis membranes is generally described by the water and salt fluxes (77,78). The water flux J_w is linked to the pressure and concentration gradients across the membrane by the term

$$J_w = A(\Delta p - \Delta \pi) \quad (1)$$

where A is a constant, Δp is the pressure difference across the membrane, and $\Delta\pi$ is the osmotic pressure differential across the membrane. As this equation shows, at low applied pressure when $\Delta p < \Delta\pi$, water flows from the dilute to the concentrated salt-solution side of the membrane by normal osmosis. When $p = \Delta\pi$, there is no flow. When the applied pressure is higher than the osmotic pressure ie, $\Delta p > \Delta\pi$, water flows from the concentrated to the dilute salt-solution side of the membrane.

The salt flux J_s across a reverse osmosis membrane can be described by the equation

$$J_s = B(c_1 - c_2) \tag{2}$$

where B is a constant and c_1 and c_2 are the salt concentration differences across the membrane.

It follows from these two equations that the water flux is proportional to the applied pressure, but the salt flux is independent of pressure. This means the membrane becomes more selective as the pressure increases. Selectivity can be measured in a number of ways, but conventionally, it is measured as the salt rejection coefficient R defined as

$$R = \left(1 - \frac{c_2}{c_1}\right) \times 100\% \tag{3}$$

Some data illustrating the effect of pressure on the water and salt fluxes and the salt rejection of a good quality reverse osmosis membrane are shown in Figure 34.

Although the principal application of reverse osmosis membranes is still desalination of brackish water or seawater to provide drinking water, a recent, significant market is production of ultrapure water by filtration of municipal drinking water. Such water is used in the electronics industry, where huge amounts of extremely pure water with a total salt concentration significantly below 1 ppb are required to wash silicon wafers.

A simplified flow scheme for a brackish water reverse osmosis plant is shown in Figure 35. In this example, it is assumed that the brackish water is heavily contaminated with suspended solids, so flocculation followed by a sand filter and a cartridge filter are used to remove particulates. The pH of the feed solution might be adjusted, followed by chlorination to sterilize the water to prevent bacterial growth on the membranes and addition of an antiscalant to inhibit precipitation of multivalent salts on the membrane. Finally, if chlorine-sensitive interfacial composite membranes are used, sodium sulfite is added to remove excess chlorine before the water contacts the membrane. Generally, more pretreatment is required in plants using hollow-fiber modules than in plants using spiral-wound modules. This is one reason why hollow-fiber modules have been displaced by spiral-wound systems in most brackish water installations.

A feature of the system design shown in Figure 35 is the staggered arrangement of the module pressure vessels. As the volume of the feed water is reduced as water is removed in the permeate, the number of modules arranged in parallel is also reduced. In the example shown, the feed water passes initially through four modules in parallel, then through two, and finally through a single module

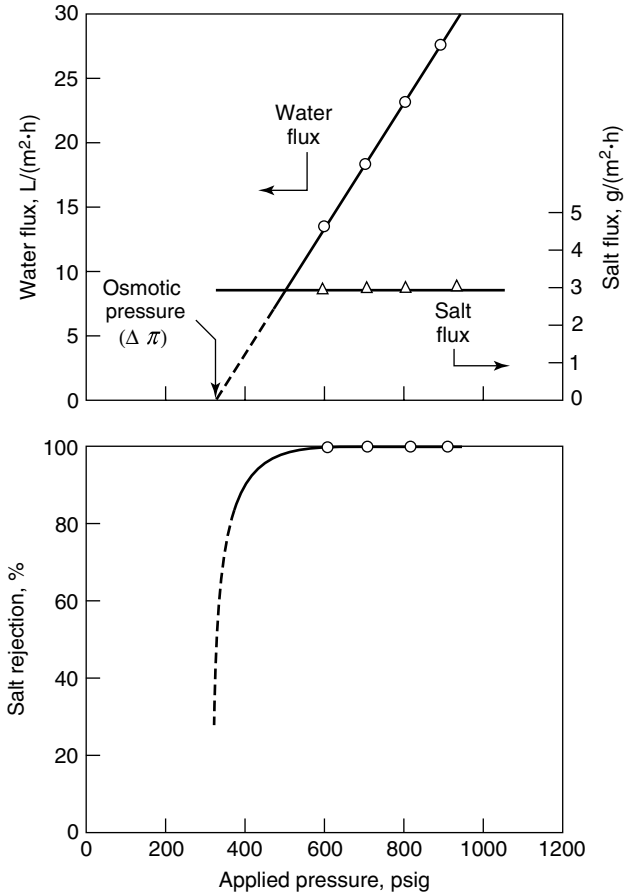

Fig. 34. Water and salt fluxes through a high performance reverse osmosis membrane, when tested with a 3.5% NaCl feed solution. The water flux increases, whereas the salt flux is essentially independent of applied pressure. To convert MPa to psig, multiply by 145 (78).

in series. This is called a *Christmas tree or tapered module design* and provides a high average feed solution velocity through the modules.

The operating pressure of reverse osmosis systems has gradually fallen over the past 20 years as the permeability and rejections of membranes have steadily improved. The first plants operated at pressures up to 60 atm, but typical brackish water plants now operate at pressures in the 10- to 20-atm range. Capital costs of brackish water plants have stayed remarkably constant for almost 20 years; the rule of thumb of $1.00/(gal·day) capacity is still true. Accounting for inflation, this, of course, reflects a very large reduction in real costs resulting from the better performance of today's membranes.

Electrodialysis. *Electrodialysis* is an electrochemical separation process in which a gradient in electrical potential is used to separate ions with charged, ionically selective membranes. A schematic of the simplest type of electrodialysis system is shown in Figure 36 (79–81). The process uses an electrodialysis stack,

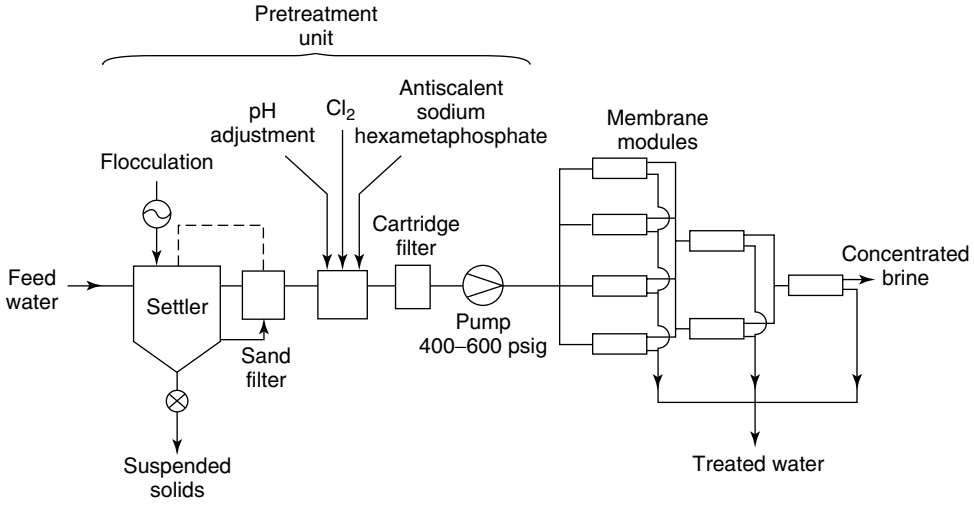

Fig. 35. Flow schematic of a typical brackish water reverse osmosis plant. The plant contains seven pressure vessels, each containing six membrane modules. The pressure vessels are in a "Christmas tree" array to maintain a high feed velocity through the modules.

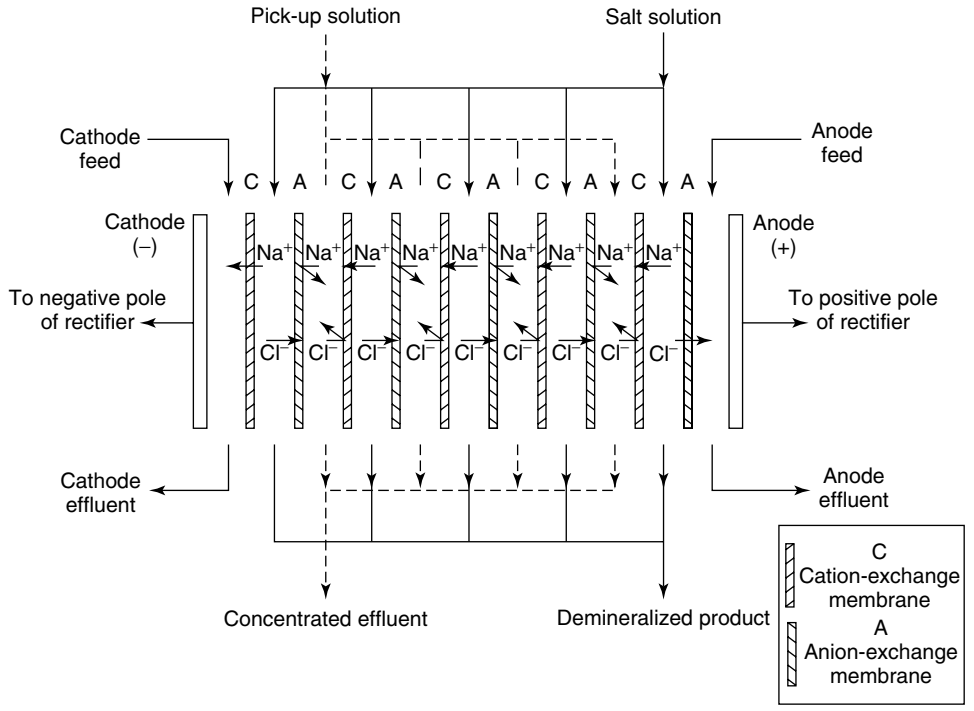

Fig. 36. Schematic diagram of a plate-and-frame electrodialysis stack. Alternating cation and anion permeable membranes are arranged in a stack of up to 100 cell pairs: C, cation-exchange membrane; A, anion-exchange membrane.

built on the plate-and-frame principle and containing several hundred cells each formed by a pair of anion- and cation-exchange membranes. Anion-exchange membranes contain fixed, positively charged entities, such as quaternary ammonium groups, fixed to the polymer backbone. These membranes are permeable to negatively charged ions, but positive ions are excluded from permeation by the fixed charges. Similarly, cation-exchange membranes contain fixed, negatively charged groups, such as sulfonic acid groups. Cationic membranes are permeable to positively charged ions, but not to negatively charged ions. The arrangement of the membranes in an electrodialysis stack is such that every second cell becomes depleted of salt, while the adjacent cells become concentrated in salt. The degree of concentration is determined by the rate of flow of solution through the stack.

Electrodialysis is used widely to desalinate brackish water, but this is by no means its only significant application. In Japan, which has no readily available natural salt brines, electrodialysis is used to concentrate salt from seawater. The process is also used in the food industry to deionize cheese whey, and in a number of pollution-control applications.

In the past, the principal problem inhibiting the use of electrodialysis was slow deterioration of the membranes by chemical degradation and scaling. In the 1970s the introduction of a process called *polarity reversal* reduced the scaling problem significantly. In this process, the flow of current through the electrodialysis stack is reversed periodically by reversing the polarity of the electrodes. When the polarity of the electrodes is reversed, the concentrated stream becomes the demineralized product stream and the demineralized stream becomes the concentrated stream; automatic valves are used to switch the streams. When the current is reversed, scale deposited on the membranes in the previous cycle is dissolved. Typically, the current of an electrodialysis stack is reversed every 15–20 min. One or two minutes production of the system is lost after each reversal, but the reduced scaling and fouling of the membranes more than compensates for this loss in productivity.

One of the most attractive features of electrodialysis is its energy efficiency. The electric current A needed to desalinate a solution is directly proportional to the quantity of ions transported through the membranes and is given by the equation

$$A = zFQ\Delta c/\xi \tag{4}$$

Here z is the electrochemical valence, F is the Faraday constant, Q is the feed solution flow rate, Δc is the difference in concentration between the feed and product solution, and ξ is the current utilization factor. The current utilization factor is always less than 100% because of losses in the stack. Because the membranes are not perfectly semipermeable, some co-ions diffuse across the membrane. Some water is also transferred across the membrane by osmotic flow. Finally, some current flows through the stack manifold and is dissipated as electrical heating. Nonetheless, electrodialysis uses significantly less energy than competitive processes such as evaporation or reverse osmosis, especially for low concentration feed solutions.

Gas Separation. During the 1980s, gas separation using membranes became a commercially important process; the size of this application is still increasing rapidly. In gas separation, one of the components of the feed permeates a selective membrane at a much higher rate than the others. The driving force is

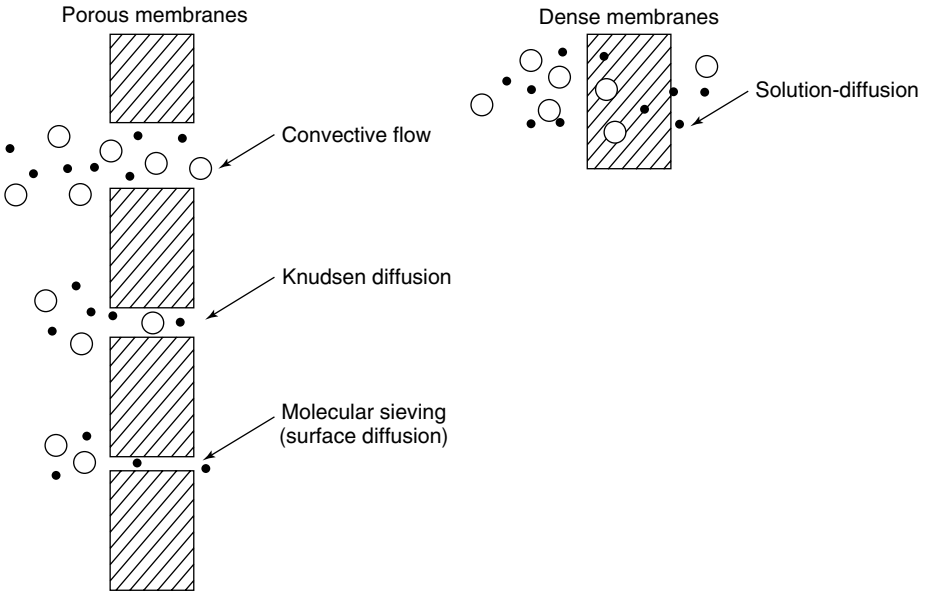

Fig. 37. Mechanisms for permeation of gases through porous and dense gas separation membranes.

the pressure difference between the pressurized feed gas and the lower pressure permeate.

Both porous and dense membranes can be used as selective barriers; Figure 37 illustrates the mechanism of gas permeation through both classes. Three types of porous membranes, differing in pore size, are shown. If the pores are relatively large, in the range 0.1–10 μm, gases permeate the membrane by convective flow, and no separation occurs. If the pores are smaller than 0.1 μm, then the pore diameter is the same size or smaller than the mean free path of the gas molecules. Diffusion through such pores is governed by Knudsen diffusion, and the transport rate of different gases is inversely proportional to the square root of the molecular weight. The latter relationship, sometimes called *Graham's law of diffusion*, was exploited on a massive scale in the separation of $U^{235}F_6$ and $U^{238}F_6$ during the Manhattan Project. Finally, if the membrane pores are very small indeed, of the order 0.5–2 nm, then molecules are separated by molecular sieving. Actual transport mechanisms through this type of membrane are complex and include both diffusion in the gas phase and diffusion of adsorbed species on the surface of the pores (surface diffusion). Nonetheless, ceramic and ultramicroporous carbon membranes have been prepared with extraordinarily high separations for very similar molecules (45–47).

Although microporous membranes are a topic of research interest, all current commercial gas separations are based on the fourth type of mechanism shown in Figure 37, namely diffusion through dense polymer films. Gas transport through dense polymer membranes is governed by the equation

$$J_i = \frac{P_i[p_{i(o)} - p_{i(l)}]}{l} \tag{5}$$

where J_i is the flux of component i, $p_{i(o)}$ and $p_{i(l)}$ are the partial pressure of the component i on either side of the membrane, l is the membrane thickness, and P_i is a constant called the membrane permeability, which is a measure of the membrane's ability to permeate gas (78). The ability of a membrane to separate two gases, i and j, is the ratio of their permeabilities, $\alpha_{i,j}$, called the membrane selectivity:

$$\alpha_{ij} = \frac{P_i}{P_j} \tag{6}$$

In this equation the permeabilities of gases are measured with the gas mixture. The selectivity calculated from the ratio of pure gas permeabilities is sometimes called the ideal gas selectivity and is often higher than the actual selectivity value. Permeability P_i can be expressed as the product of two terms. One, the diffusion coefficient D_i, reflects the mobility of the individual molecules in the membrane material; the other, the Henry's law sorption coefficient k_i, reflects the number of molecules dissolved in the membrane material. Thus, equation (6) can also be written as

$$\alpha_{ij} = \left(\frac{D_i}{D_j}\right)\left(\frac{k_i}{k_j}\right) \tag{7}$$

The ratio D_i/D_j is the ratio of the diffusion coefficients of the two gases and can be viewed as the mobility selectivity, reflecting the different sizes of the two molecules. The ratio k_i/k_j is the ratio of the Henry's law sorption coefficients of the two gases and can be viewed as the sorption or solubility selectivity, reflecting the relative condensabilities of the two gases. If molecule i is larger than j, then the mobility selectivity will always be less than 1. The sorption selectivity, however, is normally greater than 1, reflecting the higher condensability of large molecules compared to small ones. The balance between the sorption selectivity and the mobility selectivity determines whether a membrane material is selective for large or small molecules in a gas mixture.

In all polymer materials, the diffusion coefficient decreases with increasing molecular size, because large molecules interact with more segments of the polymer chain than small molecules do. Hence, the mobility selectivity always favors the passage of small molecules over large ones. However, the magnitude of the mobility selectivity term is different for glassy and rubbery materials (82), as the data in Figure 38 show. With increasing permeant size, diffusion coefficients in glassy materials decrease much more rapidly than diffusion coefficients in rubbers, in which the polymer chains can rotate freely. For example, the mobility selectivity of natural rubber for nitrogen over pentane is approximately 10. The mobility selectivity of polyvinyl chloride, a rigid, glassy polymer, for nitrogen over pentane is more than 100,000 (83).

The second factor affecting the overall membrane selectivity is the sorption or solubility selectivity. The sorption coefficient of gases and vapors, which is a measure of the energy required for the permeant to be sorbed by the polymer, increases with increasing condensability of the permeant. This dependence on condensability means that the sorption coefficient also increases with molecular

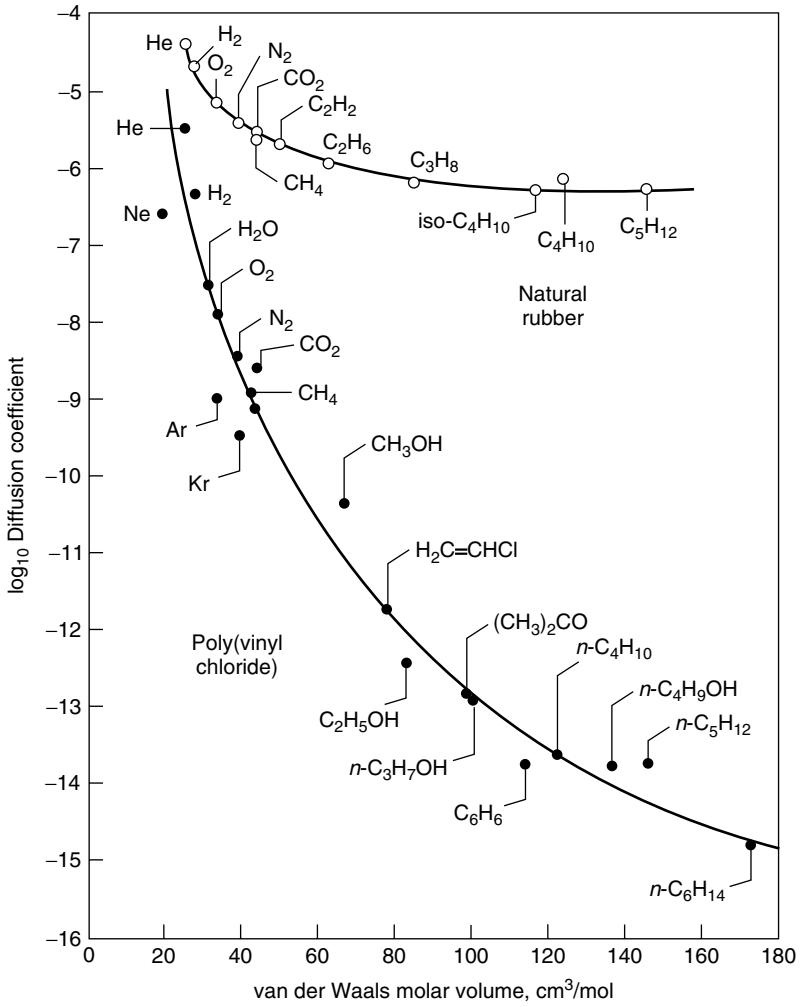

Fig. 38. Diffusion coefficient as a function of molar volume for a variety of permeants in natural rubber and in poly(vinyl chloride). Reprinted from Ref. 83, Copyright 1982, with permission from Elsevier Science.

diameter, because large molecules are normally more condensable than small ones. The Henry's law sorption coefficient can, therefore, be plotted against boiling point or molar volume as shown in Figure 39 (84). As the figure shows, sorption selectivity favors the larger, more condensable molecules, such as hydrocarbon vapors, over the permanent gases, such as oxygen and nitrogen. The difference between the sorption coefficients of permeants in rubbery and glassy polymers is far less marked than the differences in the diffusion coefficients.

It follows from the preceding discussion that the balance between the mobility selectivity term and the sorption selectivity term in equation (7) is different for glassy and rubbery polymers. This difference is illustrated by the data in Figure 40 (85). In glassy polymers such as polyetherimide, the mobility term is usually

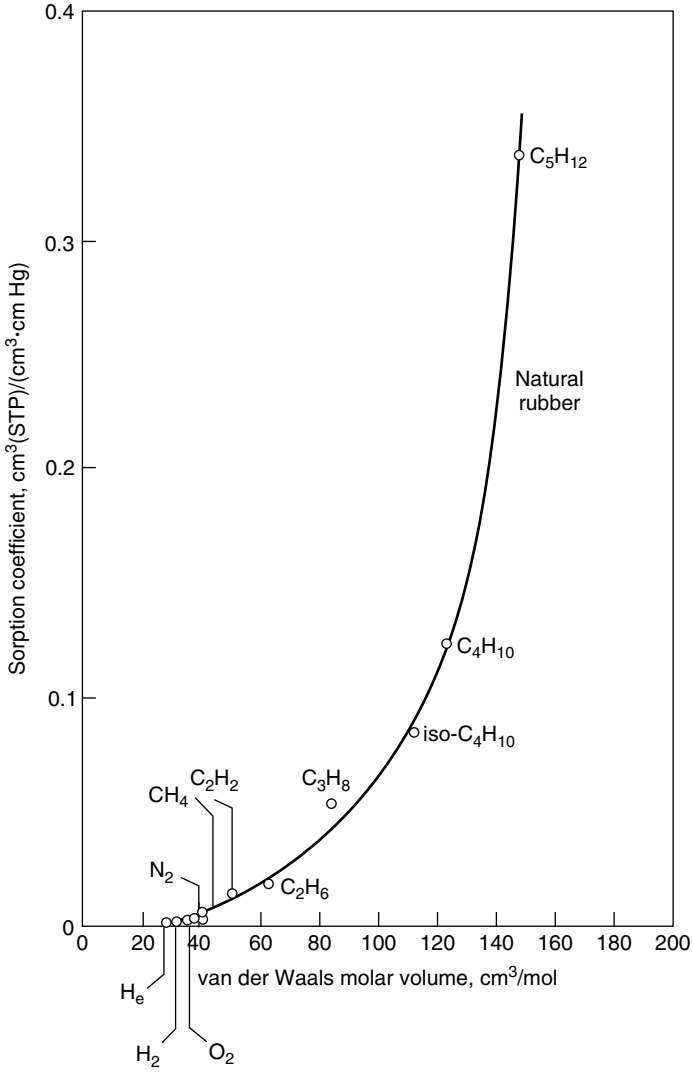

Fig. 39. Gas sorption coefficient as a function of molar volume for natural rubber membranes. Larger permeants are more condensable and have higher sorption coefficients.

dominant, permeability decreases with increasing permeant size, and small molecules permeate preferentially. When used to separate organic vapors from air, therefore, glassy membranes are air selective. In rubbery polymers, the sorption selectivity term is usually dominant, permeability increases with increasing permeant size, and large molecules permeate preferentially. The separation properties of polymer membranes for a number of the most important gas separation applications have been summarized in Reference 86.

Both hollow-fiber and spiral-wound modules are used in gas separation applications. Spiral-wound modules are favored if the gas stream contains oil mist or condensable vapors as in the separation of hydrocarbon vapors from

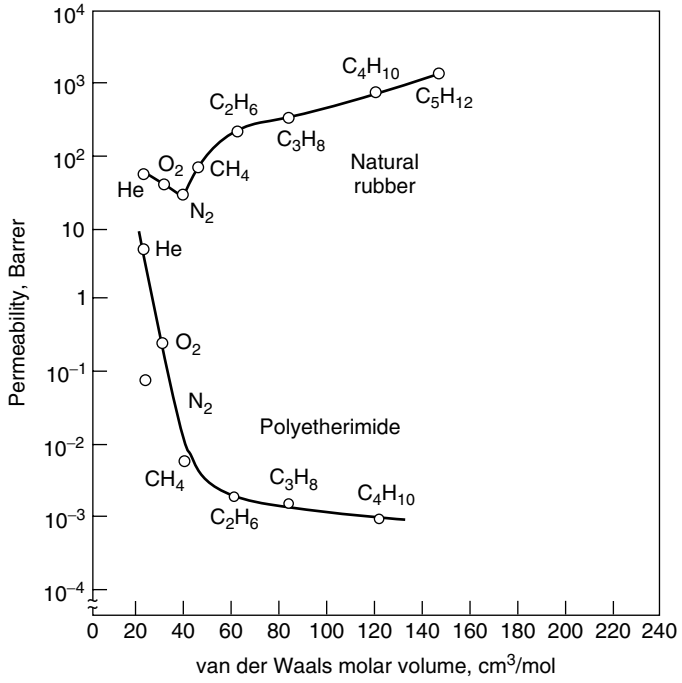

Fig. 40. Permeability as a function of molar volume for a rubbery and glassy polymer, illustrating the different balance between sorption and diffusion in these polymer types. The rubbery membrane is highly permeable; the permeability increases rapidly with increasing permeant size because sorption dominates. The glassy membrane is much less permeable; the permeability decreases with increasing permeant size because diffusion dominates (85).

$$1\ \text{Barrer} = \frac{0.335 \times 10^{-15}\text{m} \cdot \text{mol}}{\text{m}^2 \cdot \text{s} \cdot \text{Pa}} \left(\frac{10^{-18}\text{cm}^3(\text{STP}) \cdot \text{cm}}{\text{cm}^2 \cdot \text{s} \cdot \text{cm Hg}} \right)$$

nitrogen or hydrogen or in natural gas separations. Table 4 summarizes the current commercial gas separation applications (87,88). The first large-scale commercial application of gas separation was the separation of hydrogen from nitrogen in ammonia purge gas streams, launched in 1980 by Permea (now a division of Air Products). This process was followed by a number of similar applications, such as hydrogen/methane separation in refinery off-gases and hydrogen/carbon monoxide adjustment in oxo-chemical synthetic plants. Several hundred of these plants have now been installed.

Following Permea's success, several companies produced membrane systems to treat natural gas streams, particularly to separate carbon dioxide from methane. The goal is to produce a stream containing less than 2% carbon dioxide to be sent to the national pipeline and a permeate enriched in carbon dioxide to be flared or reinjected into the ground. Cellulose acetate is the most widely used membrane material for this separation, but because its carbon dioxide/methane selectivity is only about 15, two-stage systems are often required to achieve a sufficient separation. The membrane process is generally best suited to relatively small streams, but the economics have slowly improved over the years and more

Table 4. Gas Separation Application Areas for Membranes

Gas separation	Applications
O_2/N_2	Nitrogen from air, oxygen enrichment of air
H_2/hydrocarbons	Refinery hydrogen recovery
H_2/CO	Syngas ratio adjustment
H_2/N_2, Ar, CH_4	Ammonia purge gas
CO_2/CH_4	Acid gas treatment of natural gas
Hydrocarbons/air	Hydrocarbon recovery, pollution control
H_2O/air	Air dehumidification
H_2O/CH_4	Natural gas dehydration
H_2S/CH_4	Sour gas treatment of natural gas
He/CH_4	Helium separation from natural gas
He/N_2	Helium recovery

than 100 natural gas treatment plants have now been installed—some quite large. Figure 41 shows flow schematics for one-stage and two-stage carbon dioxide membrane separation plants.

By far the largest gas separation process in current use is the production of nitrogen from air. The first membranes used for this process were based on

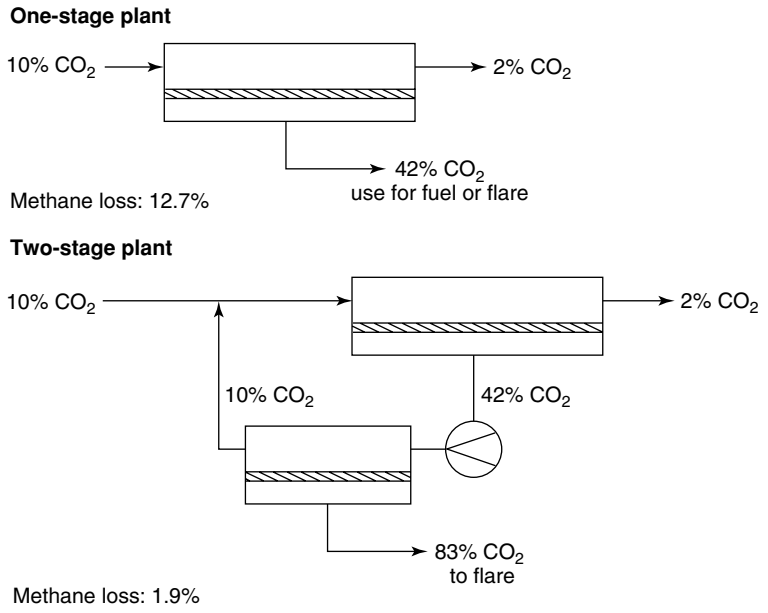

Fig. 41. Flow scheme of one-stage and two-stage membrane separation plants to remove carbon dioxide from natural gas (α_{CO2}/CH_4 of 15 is typical for cellulose acetate membranes). Because the one-stage design has no moving parts, it is very competitive with other technologies especially if there is a use for the low pressure permeate gas. Two-stage processes are more expensive because a large compressor is required to compress the permeate gas. However, the loss of methane with the fuel gas is much reduced.

polysulfone, poly(methyl pentane), and ethyl cellulose. These materials had oxygen/nitrogen selectivities of 4–5, and the economics of the process were marginal. The second-generation materials now used have selectivities in the range 7–8 and significantly higher fluxes. With these membranes, the economics of nitrogen production from air are very favorable, especially for small plants producing 0.14–14 standard m^3/min (5–500 scfm) of nitrogen. In this range, membranes are the low–cost process, and most new nitrogen plants use membrane systems. More than 5000 such systems have been installed.

A growing application of membrane systems is the removal of condensable organic vapors from air and other streams. Unlike the processes described earlier, organic vapor separation uses rubbery membranes, which are more permeable to the organic vapor. More than 100 organic vapor recovery plants have been installed. In Europe, most of the plants recover gasoline vapors from air vented during transfer operations; in the United States, most plants recover olefins and light hydrocarbons from chemical processing streams.

Pervaporation. In this separation process, illustrated schematically in Figure 42, a multicomponent liquid stream is passed across a membrane that preferentially permeates one or more of the components. As the feed liquid flows across

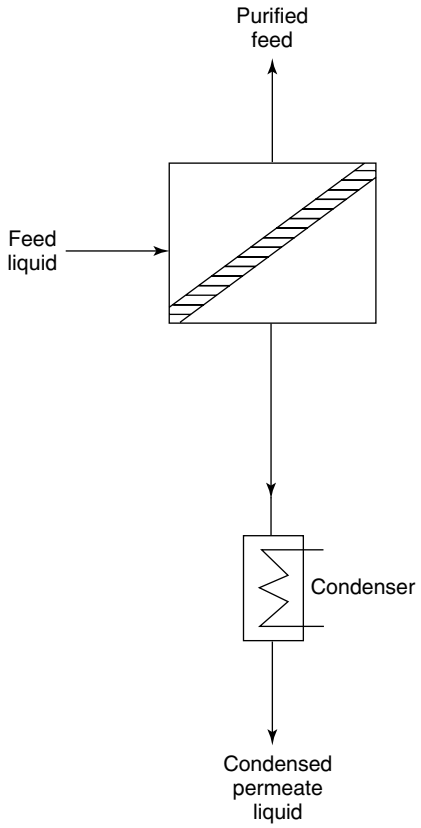

Fig. 42. Schematic of the basic pervaporation process.

the membrane surface, the preferentially permeated component passes through the membrane as a vapor. Transport through the membrane is induced by maintaining a vapor pressure on the permeate side of the membrane that is lower than the vapor pressure of the feed liquid. The pressure difference is achieved by cooling the permeate vapor to below the temperature of the feed stream, causing it to condense. This spontaneously generates a partial vacuum on the permeate side of the membrane. The condensate is then removed as a concentrated permeate fraction; the residue, depleted of the permeating component, exits on the feed side of the membrane. The process can be applied to the removal of dissolved water from organic solvents, to the extraction of organic solvents from water, and to the separation of mixed organic solvents.

The separation β_{pervap} achieved by a pervaporation process can be defined in the conventional way as

$$\beta_{\text{pervap}} = \frac{c_i''/c_j''}{c_i'/c_j'} \tag{8}$$

where c_i' and c_j' are the concentrations of components i and j on the feed liquid side and c_i'' and c_j'' are the concentrations of components i and j on the permeate side of the membrane. Because the permeate is a vapor, c_i'' and c_j'' can be replaced by p_i'' and p_j'', the vapor pressures of components i and j on the permeate side of the membrane. The separation achieved by the membrane can then be expressed by the equation

$$\beta_{\text{pervap}} = \frac{p_i''/p_j''}{c_i'/c_j'} \tag{9}$$

The most convenient mathematical method of describing pervaporation is to divide the overall separation processes into two steps, as shown in Figure 43 (89). The first is evaporation of the feed liquid to form a (hypothetical) saturated vapor phase on the feed side of the membrane. The second is permeation of this vapor through the membrane to the low pressure permeate side of the membrane. Although no evaporation actually takes place on the feed side of the membrane during pervaporation, this approach is mathematically simple and is thermodynamically completely equivalent to the physical process. The evaporation step from the feed liquid to the saturated vapor phase produces a separation β_{evap}, which can be defined as the ratio of the concentrations of the components in the feed vapor to their concentrations in the feed liquid,

$$\beta_{\text{evap}} = \frac{p_i'/p_j'}{c_i'/c_j'} \tag{10}$$

where p_i' and p_j' are the partial vapor pressures of the components i and j in equilibrium with the feed solution.

The second step, permeation of components i and j through the membrane, is related directly to conventional gas permeation. The separation achieved in this

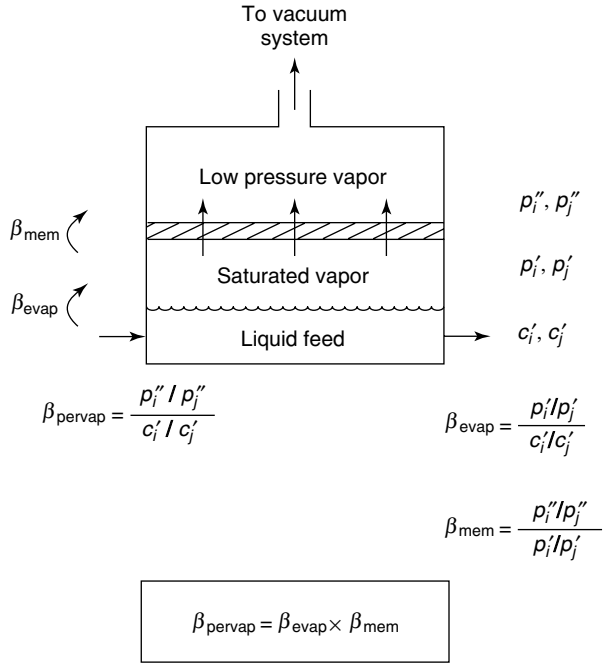

Fig. 43. The separation performed by a pervaporation membrane, β_{pervap}, is the product of the independent processes of evaporative separation β_{evap} and membrane permeation separation β_{mem}.

step, β_{mem}, can be defined as the ratio of components in the permeate vapor to the ratio of components in the feed vapor:

$$\beta_{mem} = \frac{p_i'' / p_j''}{p_i' / p_j'} \tag{11}$$

From the definitions given in equations (8–11), we can write the equality

$$\beta_{pervap} = \beta_{evap} \times \beta_{mem} \tag{12}$$

This equation shows that the separation achieved in pervaporation is proportional to the product of the separation achieved by evaporation of the liquid and the separation achieved by permeation of the components through a membrane. To achieve good separations both terms should be large. It follows that, in general, pervaporation is most suited to the removal of volatile components from relatively involatile components, because β_{evap} will then be large. However, if the membrane is sufficiently selective and β_{mem} is large, nonvolatile components can be made to permeate the membrane preferentially (89).

The selectivity of pervaporation membranes varies considerably and has a critical effect on the overall separation obtained. The range of results that can

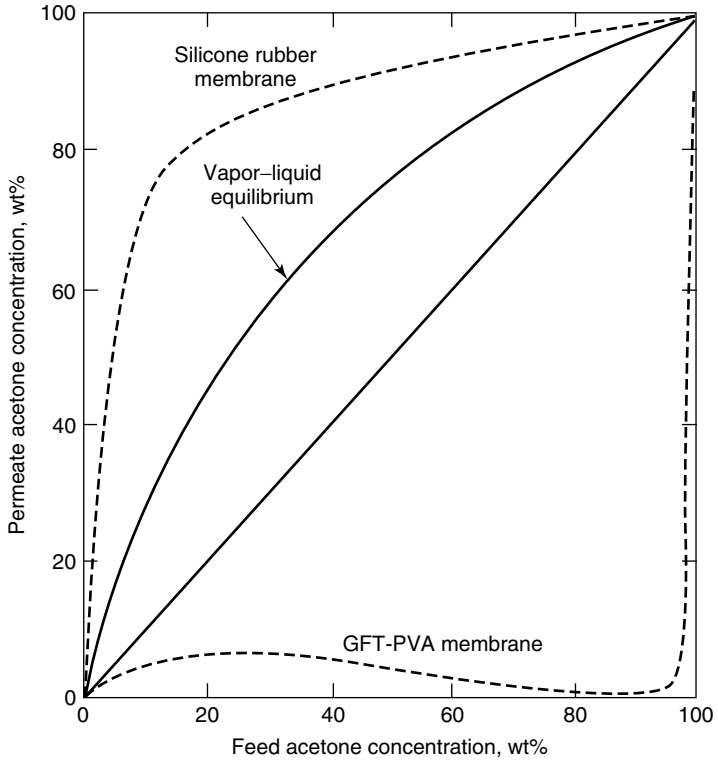

Fig. 44. The pervaporation separation of acetone–water mixtures achieved with a water-selective PVA membrane and with an acetone-selective silicone rubber membrane. The PVA membrane is best suited to removing small amounts of water from a concentrated acetone solution, whereas the silicone rubber membrane is best suited to removing small amounts of acetone from a dilute acetone stream. Reprinted from Ref. 91 by courtesy of Marcel Dekker, Inc.

be obtained for the same solutions and different membranes is illustrated in Figure 44 for the separation of acetone from water using two types of membrane (90,91). The figure shows the concentration of acetone in the permeate as a function of the concentration in the feed. The two membranes shown have dramatically different properties. The silicone rubber membrane removes acetone selectively, whereas the cross-linked PVA membrane removes water selectively. This difference occurs because silicone rubber is hydrophobic and rubbery, thus permeates the acetone preferentially. On the other hand, PVA is hydrophilic and glassy, thus permeates the small hydrophilic water molecules preferentially.

The acetone-selective, silicone rubber membrane is best used to treat dilute acetone feed streams and concentrate most of the acetone in a small volume of permeate. The water-selective PVA membrane is best used to treat concentrated acetone feed streams containing only a few percent water. Most of the water is then removed and concentrated in the permeate. Both membranes are more selective than distillation, which relies on the vapor–liquid equilibrium to achieve a separation.

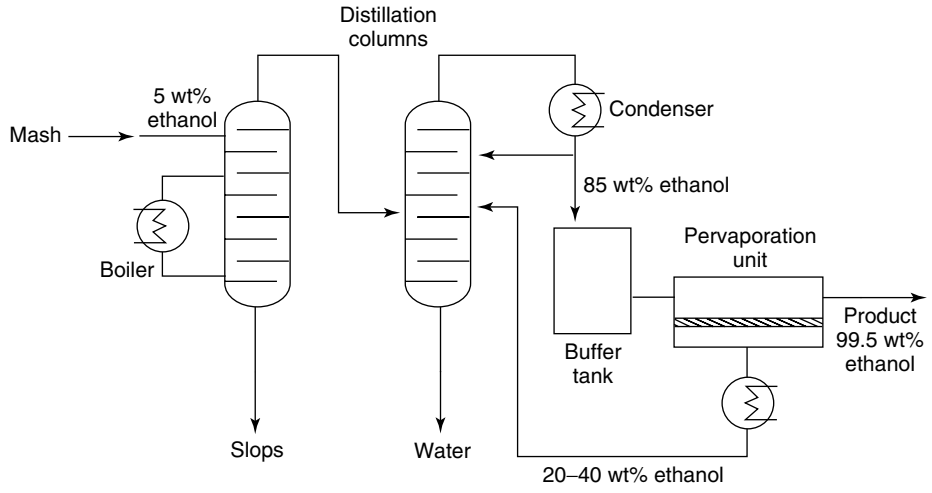

Fig. 45. Integrated distillation/pervaporation plant for ethanol recovery from fermentors. The distillation columns concentrate the ethanol/water mixture from 5 to 80%. The pervaporation membrane produces a 99.5% ethanol product stream and a 40–50% ethanol stream that is sent back to the distillation column.

Pervaporation now has two commercial applications. The first and most developed is the separation of water from concentrated alcohol solutions. The leader in this field, GFT of Neunkirchen, Germany, installed their first major plant in 1982. Currently, more than 100 plants have been installed by GFT for this application (92). The second application is the separation of small amounts of organic solvents from contaminated water (93). In both applications, organics are separated from water. This separation is relatively easy because organic compounds and water exhibit distinct membrane permeation properties as a result of their difference in polarity. The separation is also amenable to membrane pervaporation, because the feed solutions are relatively nonaggressive and do not chemically degrade the membrane.

A flow scheme for an integrated distillation–pervaporation plant operating on a 5 wt% ethanol feed from a fermentation mash is shown in Figure 45. The distillation column produces an ethanol stream containing 85–90 wt% ethanol, which is fed to the pervaporation system. To maximize the vapor pressure difference across the membrane, the pervaporation module usually operates at a temperature of 80°C with a corresponding feed stream vapor pressure of 400–600 kPa (4–6 atm). Despite these harsh conditions, the membrane lifetime is good and qualified guarantees for up to 4 years are given.

Figure 45 shows a single-stage pervaporation unit. In practice, at least three pervaporation stages are used in series, with additional heat being supplied to the ethanol feed between each stage. This compensates for pervaporative cooling of the feed and maintains the feed at 80°C. The heat required is obtained by thermally integrating the pervaporation system with the condenser of the final distillation column. Most of the energy used in the process is, therefore, low grade heat. Generally, about 0.5 kg of steam is required for each kilogram of ethanol

produced. The energy consumption of the pervaporation process is, therefore, about 559 kJ/L (2000 Btu/gal) of product, less than 20% of the energy used in azeotropic distillation, which is typically in the range 3–3.4 MJ/L (11,000–12,000 Btu/gal). Moreover, pervaporation uses very low grade steam, which is available in most industrial plants at very low cost.

Although most of the installed solvent dehydration systems have been for ethanol dehydration, dehydration of other solvents, including isopropanol, glycol, acetone, and methylene chloride, has been considered.

No commercial systems have yet been developed for the separation of the more industrially significant organic–organic mixtures. However, current technology now makes development of pervaporation for these applications possible, and a number of laboratories are actively developing the process. It can only be a matter of time before commercially significant organic–organic separations are attempted using pervaporation. The first pilot-plant results for an organic–organic application, the separation of methanol from methyl *tert*-butyl ether–isobutene mixtures, was reported by Air Products (94). This is a particularly favorable application, and currently available cellulose acetate membranes give good separation. Exxon and Texaco have worked on organic–organic separation by pervaporation, particularly the separation of aromatics from aliphatic hydrocarbons in refinery process streams.

Other Membrane Separation Techniques. The six membrane separation processes described earlier represent the bulk of the industrial membrane separation industry. A seventh process, dialysis, is used on a large scale to remove toxic metabolites from blood in patients suffering from kidney failure (95). The first successful artificial kidney was based on cellophane (regenerated cellulose) membranes and was developed by W.J. Kolf in 1945. Over the past 50 years, many changes have been made. Currently, most artificial kidneys are based on hollow-fiber modules having a membrane area of about 1 m^2. Cellulose fibers are still widely used, but are gradually being displaced by fibers made from polycarbonate, polysulfone, and other polymers, which have higher fluxes or are less damaging to the blood. As shown in Figure 46, blood is circulated through the center of the fiber, while isotonic saline, the dialysate, is pumped countercurrently around the outside of the fibers. Urea, creatinine, and other low molecular weight metabolites in the blood diffuse across the fiber wall and are removed with the saline solution. The process is quite slow, usually requiring several hours to remove the required amount of the metabolite from the patient, and must be repeated one to two times per week. Nonetheless, 100,000 patients use these devices on a regular basis.

In terms of membrane area used and dollar value of the membrane produced, artificial kidneys are the single largest application of membranes. Similar hollow-fiber devices are being explored for other medical uses, including an artificial pancreas, in which islets of Langerhans supply insulin to diabetic patients, or an artificial liver, in which adsorbent materials remove bilirubin and other toxins.

One other membrane separation technique, yet to be used on a commercial scale, is carrier facilitated transport. In this process, the membrane used to perform the separation contains a carrier which preferentially reacts with one of the components to be transported across the membrane. Most of the work on

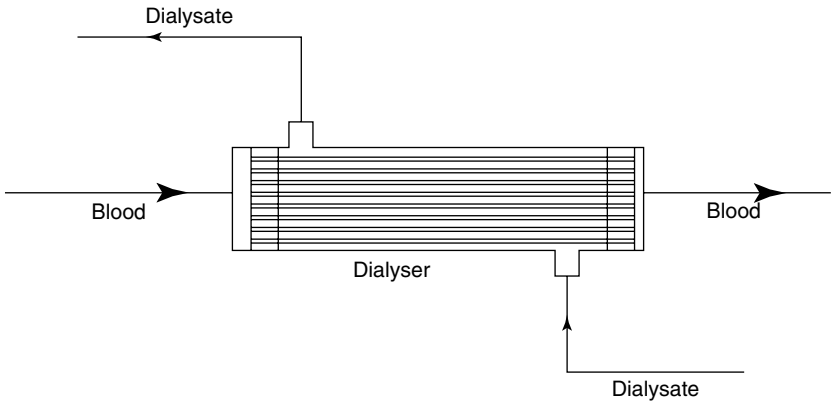

Fig. 46. Schematic of a hollow fiber artificial kidney dialyser used to remove urea and other toxic metabolites from blood. Several million of these devices are used every year.

carrier facilitated transport has employed liquids containing a dissolved complexing agent (59,60). Membranes are formed by holding the liquids by capillary action in the pores of a microporous film. The carrier agent reacts with one permeating component on the feed side of the membrane and then diffuses across the membrane to release the permeant on the product side of the membrane. The carrier agent is then reformed and diffuses back to the feed side of the membrane. Thus, the carrier agent acts as a selective shuttle to transport one component from the feed to the product side of the membrane. Facilitated transport membranes can be used to separate gases; membrane transport is then driven by a difference in the gas partial pressure across the membrane. Metal ions can also be transported selectively across a membrane, driven by a flow of hydrogen or hydroxyl ions in the opposite direction; this process is sometimes called coupled transport. Examples of facilitated transport processes for gas and metal ion transport are shown in Figure 47.

Because the facilitated transport process employs a reactive carrier species, very high membrane selectivities can be achieved. These selectivities are often far larger than those achieved by other membrane processes, a factor that has maintained interest in facilitated transport. However, no significant commercial applications exist or are likely to exist in the next decade. The principal problems are the physical instability of the membrane and the chemical instability of the carrier agent.

Membrane Contactors. In the membrane processes described earlier, the membrane acts as a selective barrier, allowing relatively free passage of one component while retaining another. In membrane contactors the membrane functions as an interface between two phases but does not control the passage of permeants across the membrane (12,13). Delivery or removal of gases from liquids is the largest application of contactors.

One example is the blood oxygenator used during surgery when the patient's lungs cannot function normally. A flow schematic of one of these hollow-fiber devices is shown in Figure 48. More than 1 million procedures per year use blood

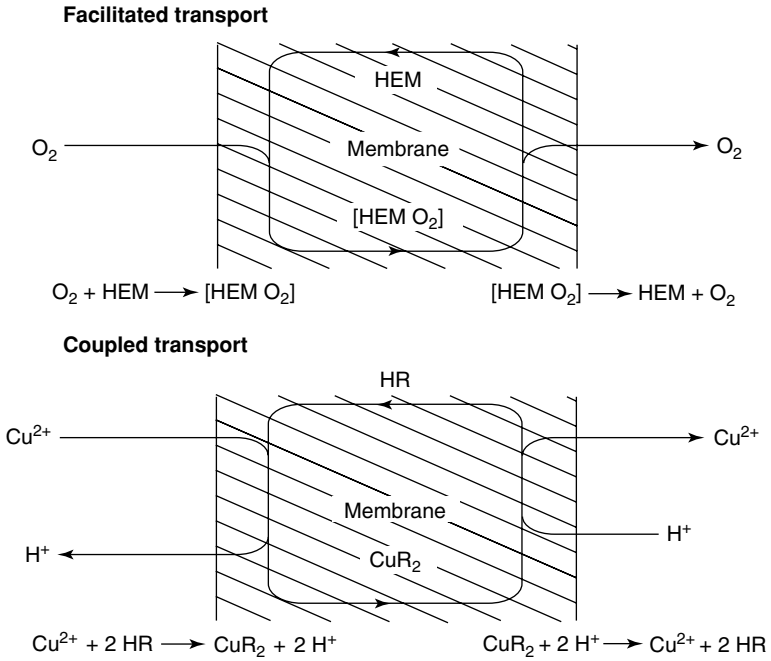

Fig. 47. Schematic examples of facilitated transport of gases and metal ions. The gas-transport example shows the transport of oxygen across a membrane using hemoglobin (HEM) as the carrier agent. The ion-transport example shows the transport of copper ions across the membrane using a liquid ion-exchange reagent as the carrier agent.

oxygenators. Each device costs about $500–600, so the total annual market is about $500 million.

Membrane contactors have also found some industrial applications, most commonly to deoxygenate ultrapure water for the electronics industry (96) or for boiler feed water and to adjust carbonation levels in beverages (97). Microporous hollow-fiber membrane modules are most commonly used. The aqueous phase is circulated on the shell side of the fiber and a gas sweep or vacuum flows down the inside of the fibers.

Controlled Drug Delivery. A significant application of membranes is to moderate the release of biologically active agents, such as insecticides, fertilizers, and most importantly, drugs. Although the concept of controlled drug release using a rate-controlling membrane to moderate drug delivery can be traced to the 1950s, the founding of the Alza Corp. in the late 1960s gave the entire technology a decisive thrust. The products developed by Alza during the subsequent 25 years stimulated the entire pharmaceutical industry (98,99).

Controlled release can be achieved by a wide range of techniques; a simple example, a transdermal patch, is illustrated in Figure 49. In this device, a drug is held in a reservoir surrounded by a membrane. With such a system, the release rate of drug is constant as long as a constant concentration of drug is maintained within the device. Such a constant concentration is maintained if the reservoir contains a saturated solution and sufficient excess of solid drug. Systems that

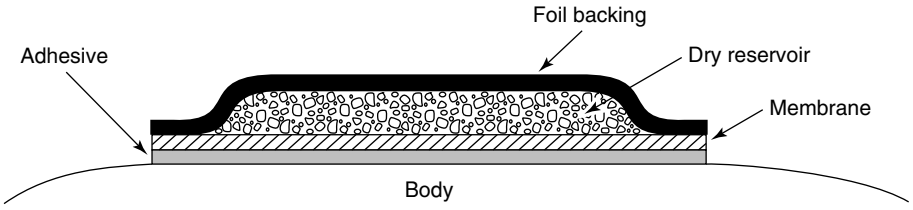

Fig. 49. Schematic of transdermal patch in which the rate of delivery of drug to the body is controlled by a polymer membrane. Such patches are used to deliver many drugs including nitroglycerine, estradiol, nicotine, and scopalamines.

operate by this principle are commonly used in transdermal patches to moderate delivery of drugs such as nitroglycerine (for angina), nicotine (for smoking cessation), and estradiol (for hormone replacement therapy) through the skin. Other devices using osmosis or biodegredation as the rate-controlling mechanism are also produced as implants and tablets.

The Future

Since the 1960s, membrane science has grown from a laboratory curiosity to a widely practiced technology in industry and medicine. This growth is expected

to continue for some time, particularly in the membrane gas separation and pervaporation separation areas. It is also clear that membranes will pay a critical role in the next generation of biomedical devices, such as the artificial pancreas and liver. The total membrane market has grown from $10 million to $2 billion in the 40 years prior to 2000. Spectacular growth of this magnitude is unlikely to continue, but a doubling in the size of the total industry to $5 billion during the decade following is likely.

METHACRYLIC ESTER POLYMERS

Introduction

Historically speaking, methacrylic ester polymers and acrylic ester polymers developed concomitantly. In 1933, acrylates were copolymerized with ethyl methacrylate; this work led to the commercialization of ethyl methacrylate monomer. The homopolymerization of methyl methacrylate [80-62-6] to form poly(methyl methacrylate) [9011-14-7] (PMMA) found a special market in safety glass which consisted of two glass plates separated by a thin layer of poly(methyl methacrylate). Cast sheets of PMMA were brought to market in the 1930s by the Rohm and Haas Co. and E. I. du Pont de Nemours & Co., Inc., in the United States as well as by Rohm and Haas AG and Imperial Chemicals Industries, Ltd., in Europe. These cast sheets were used as structural materials; the shatter resistance, light weight, high transparency, and moldability recommended the use of PMMA for windows and military aircraft canopies. Methacrylates entered the injection and compression molding arenas in 1938. Finally, during the 1930s, methyl methacrylate found a great deal of use as a comonomer in the production of acrylic polymers by emulsion and solution polymerization (1,2). These copolymers have primarily been employed as high quality paints and coatings.

Properties

Methacrylic ester monomers are a versatile group of monomers whose chemical properties are primarily determined by the nature of the R side-chain group in the structure

$$CH_2{=}C(CH_3)OOR$$

Encyclopedia of Polymer Science and Technology. Copyright John Wiley & Sons, Inc. All rights reserved.

Polymer physical and chemical properties also depend upon the R group, the molecular weight, and the tacticity of the polymer.

Methacrylic monomers differ from acrylics (see ACRYLIC ESTER POLYMERS) in that they have a methyl group in the α position of the vinyl group; this methyl group lends stability, hardness, and stiffness to the polymers formed from methacrylic ester monomers. Methacrylics will readily polymerize with other methacrylic and acrylic monomers. This ability to form copolymers among these two already diverse groups allows the industrial chemist to create polymers with an incredible breadth of properties ranging from tacky adhesives to hard powders and rigid sheets. Although more costly than many other commonly employed industrial monomers, methacrylics have found a great deal of industrial usage because of their unique balance of performance properties as well as their ease of use. Methacrylic ester monomers can be copolymerized readily with either methacrylic or acrylic ester monomers to form an even greater variety of acrylic copolymers. These polymers find applications that range from extremely tacky adhesives to hard powders and sheets.

Glass-Transition Temperature (T_g). Although often cited as a single value, the glass transition often takes place over a broad range of temperatures. The glass transition is manifested in a polymeric material as an embrittlement when moving across the range from high to low temperatures. Other properties, such as chemical reactivity, mechanical and dielectric relaxation, viscous flow, load-bearing capacity, hardness, tack, heat capacity, refractive index, thermal expansivity, creep and diffusion, register large changes after traversing the glass-transition range.

Methacrylic ester polymers display the same change from hard, brittle, glass-like materials below the T_g value to relatively soft, flexible, rubbery materials above the T_g. Movement to even higher temperatures can result in a change to a flowable, tacky material. Table 1 contains basic physical data (density, solubility parameters, and refractive index values) for the most common methacrylic ester polymers.

The glass transition can be measured by a variety of techniques. The most commonly accepted methods currently are differential scanning calorimetry (dsc) (3,13) and dynamic mechanical analysis (dma) (5,6). Other methods employed in the past have included the approximation methods of Vicat softening temperature and brittle point measurement. More accurate numbers were also determined by methods which rely on the changes manifested in the physical properties of the polymer, such as dilatometry (volume) and refractive index measurements. The T_g values for a large variety of polymers are found in References 6, 7, 14, and 15.

The tacticity of the polymer backbone can significantly influence the glass-transition temperature of a given type of polymer. In general, T_g values decrease in the order syndiotactic > atactic > isotactic (16). Free-radical polymerization (which constitutes the vast majority of industrial acrylic polymer production) generates mainly atactic polymers because of the symmetric nature of the radical species. Table 2 contains the T_g values for a variety of methacrylic ester polymers with different tacticity types.

A wide range of glass-transition temperatures can be accessed by copolymerizing methacrylic and acrylic ester monomers (Fig. 1). Values for the

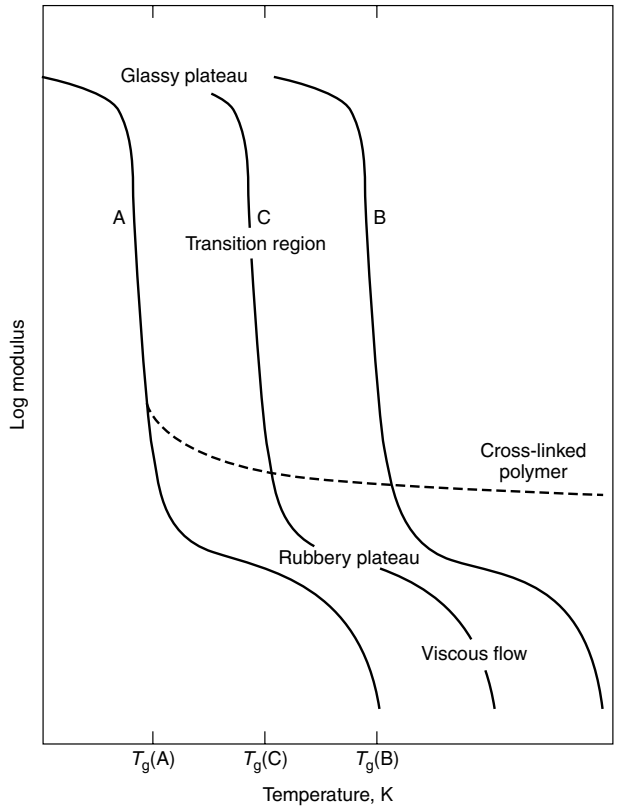

Fig. 1. Modulus–temperature curve of amorphous and cross-linked methacrylic polymers: A, a softer polymer; B, a harder polymer; and C, a 1:1 copolymer of A and B.

glass-transition temperature can be calculated from the overall composition of the polymer as well as the individual T_g values for the homopolymers of the constituent monomers (17). Soft (low T_g) components can be used as internal plasticizers or softeners which are permanently bound to the polymer backbone.

Modulus–temperature curves of the type shown in Figure 1 are useful for analyzing the degree of rigidity within a polymer. Not only can one observe the differences in hardness of a polymer, but cross-linking can also be measured through the proper use of the modulus–temperature curves (18). Cross-linking is generally used to increase the physical toughness and decrease the solubility of a polymer.

Molecular Weight. The properties of methacrylic ester polymers (and most other types of polymers for that matter) improve as molecular weight increases. Beyond a certain level (100,000–200,000 for methacrylic ester polymers) this improvement in polymer properties reaches a plateau. One example of a property that follows this trend is the glass-transition temperature which can be described by the equation

$$T_g = T_{gi} - k/M_n$$

where T_{gi} is the glass-transition temperature for a polymer of infinite molecular weight and M_n is the number-average molecular weight. Typical values of k fall in the range of 2×10^5 (10) for methacrylic polymers. Reference 19 summarizes the effect of molecular weight on polymer properties.

Mechanical Properties Related to Polymer Structure. Although the contributions of the side chains influence polymer properties in similar fashion for both methacrylic and acrylic compositions, methacrylates exhibit higher T_g values than their acrylic counterparts (same side chain) because the α hydrogen on the polymer backbone restricts the rotational motion of the backbone. This stiffening of the backbone is manifested as higher tensile strength and lower elongation for the methacrylic analogues to the acrylic polymers given the same side chain (see Table 3).

The smallest side-chain monomer in the alkyl methacrylate series, methyl methacrylate, polymerizes to form a hard material ($T_g = 105°C$) which can be cut into shapes. If the material is heated above its glass-transition temperature, the PMMA can be bent or molded to fit any form desired. Upon cooling, the material retains the molded shape upon cooling; in this manner, fighter plane canopies, among other objects, were made out of PMMA during World War II. This highly useful "flexible plastic glass" was sold by the Rohm and Haas Co. under the trade name Plexiglas for several decades.

As the side-chain length is increased for the methacrylate monomers, the T_g decreases rapidly for the series of C1–C12. *n*-Butyl methacrylate [97-88-1]

[a] Refs. 20 and 21.
[b] To convert MPa to psi, multiply by 145.

homopolymer, for example, has a T_g value of 20°C and is far softer than PMMA; lauryl methacrylate [142-90-5] continues the progression to softer, more rubbery materials ($T_g = -65$°C). After a certain length of chain is passed, the van der Waals attractive forces among the chains reach a level high enough that crystallization of the side chains takes place and the T_g moves to higher values. Octadecyl methacrylate [32360-05-7] polymerizes to form a hard polymer with a T_g of 36°C.

Another factor in the determination of how rigid a polymer backbone will be is the steric bulk of the side chain. Branching within the side chain will restrict the freedom of movement for the backbone in similar fashion as the α hydrogen of the methacrylate monomers. As cited above, *n*-butyl methacrylate homopolymer has a T_g value of 20°C; poly(*tert*-butyl methacrylate), on the other hand, has a T_g of 107°C. The effect is proportional to the overall size of the side chain as well; the longer and more branched the chain, the more movement will be restricted and T_g will be elevated.

Optical Properties. Poly(methyl methacrylate) is essentially transparent in the 400- to 700-nm visible light range (22); this clarity along with the ease of machining described above contributes to this material's popularity as a substitute for glass. The polymer gradually becomes less transparent as the wavelength range is increased until the material is opaque beyond 2800 nm. Additives are commonly incorporated in PMMA cast sheets to block the transmission of uv rays in the wavelength range 290–350 nm. Poly(methyl methacrylate) allows radio and television broadcast waves to transfer through the material while blocking α and β radiations (23).

Poly(methyl methacrylate) is capable of serving as a waveguide for visible light. When light is shone through the edge of PMMA, the light emerges through the opposite edge of the material, with virtually no loss of intensity; the primary reason for this property is that when visible light reaches the air/polymer interface at an angle of 42.2° or greater, it reflects back into the polymer intact. This useful optical property in combination with the mechanical properties described above has resulted in the PMMA's use in fiberoptics, automotive tailights, camera lenses, remote lighting, reducers, magnifiers, and prisms (24).

Electrical Properties. Poly(methyl methacrylate) has an extremely high surface resistivity which, combined with the weather resistance of the material, leads to the use of PMMA in high voltage applications. Some of these basic electrical properties (23) are listed in Table 4.

Chemical Properties. The chemical-resistance properties of methacrylic ester polymers are even higher than those of the acrylic esters. Methacrylic esters undergo a lower degree of hydrolysis in either acidic or alkaline media than acrylics. Both acrylics and methacrylics easily outperform vinyl acetate-containing polymers which are well known to be susceptible to hydrolysis of the side-chain ester. There are marked differences in the chemical-resistance properties of different forms of PMMA. The syndiotactic (alternating) form of PMMA is the most chemically inert. The rate of hydrolysis for syndiotactic PMMA is lower than that for isotactic (26); radical polymerizations generate large portions of syndiotactic PMMA and benefit in terms of stability.

In terms of solubility resistance (25), PMMA is generally not harmed by inorganic solutions, mineral oils, animal oils, low concentrations of alcohols, paraffins,

olefins, amines, alkyl monohalides, and aliphatic hydrocarbons and higher esters (>10 carbon atoms). Chemical species which will degrade PMMA include lower esters (ethyl acetate, isopropyl acetate), aromatic hydrocarbons (benzene, toluene, xylene, phenols), cresol, carbolic acid, aryl halides (chlorobenzene, bromobenzene), aliphatic acids (butyric acid, acetic acid), alkyl polyhalides (ethylene dichloride, methylene chloride), high concentrations of alcohols (methanol, ethanol, 2-propanol), and high concentrations of alkalies and oxidizing agents. In Table 5, the chemical- and photochemical-resistance properties of PMMA are compared to those of two other transparent plastic materials: polycarbonate and cellulos acetate butyrate (27). In terms of thermal stability, methacrylates will depolymerize (28) at a greater than 95% level when exposed to temperatures above 300°C.

Methacrylate Monomers

Properties. Table 1 of methacrylic acid and derivatives (qv) lists many of the basic properties of methacrylic acid monomers. Tables 6 and 7 contain many of the additional physical and thermodynamic properties for commercially important monomers (29–32).

Manufacture of Monomers. The commercial processes for manufacturing these monomers are contained in Methacrylic acid and derivatives (33).

Handling, Health and Safety Factors. Mild steel is the material of choice for transporting and storing methacrylic ester monomers which are shipped by way of rail cars or tanker trucks. Stainless steel (Types 304 and 316) are used for transport and storage of acidic monomers.

Methacrylic monomers are relatively nontoxic, based upon oral, dermal, and inhalation exposure test data for rats and rabbits (30,34,35). However, these monomers can be skin sensitizers and are mildly to severely irritating after eye or skin contact. Liver and kidney damage can result from repeated near-lethal exposures. Overall toxicity is generally inversely proportional to the length of the side-chain ester group (see ACRYLIC AND METHACRYLIC ACID POLYMERS).

Radical Polymerization

The majority of commercial methacrylic ester polymers are produced by free-radical initiators. Peroxides and azo compounds function as typical initiators for this type of polymerization. Other possible routes for producing methacrylic polymers with radicals include photoinitiation and radiation-induced polymerization. Both γ ray and electron-beam radiation have been employed in the production of methacrylic ester polymers (36–38). At constant temperature, there is a first-order dependence of the polymerization rate on monomer concentration and a one-half-order dependence on initiator concentration. Rate data for the polymerization of various methacrylic monomers using the azo compound 2,2′-azobisisobutyronitrile [78-67-1] (AIBN) are shown in Table 8.

The polymerization of methacrylic monomers is highly exothermic and involves an increase in the density of the forming polymeric material. Both effects must be accounted for in industrial processes. The degree of shrinkage upon conversion from monomer to polymer decreases as the side-chain length increases, but on a molar basis, the shrinkage level is relatively constant (40).

The propagation mechanism for the free-radical polymerization of methacrylic monomers involves the head-to-tail chain addition of monomer units to grow the polymer chain. Chain termination can occur by either radical combination or disproportionation (41).

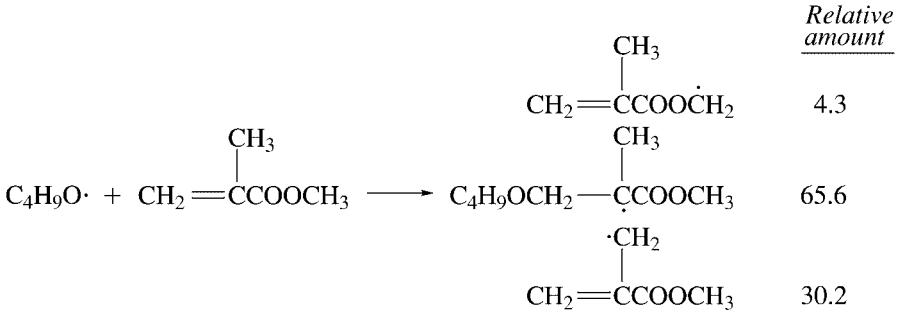
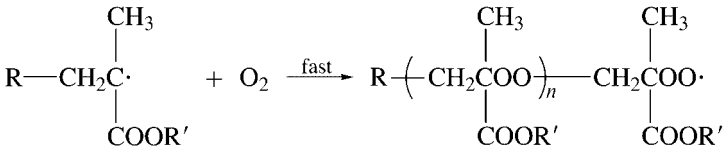
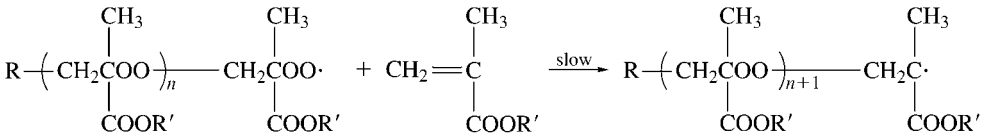
In the case of free-radical polymerizations initiated by oxygen-based radicals (eg *t*-butoxy radical), hydrogen abstraction from both the polymer backbone and the α-methyl side chain also occurs (42–45).



As in many free-radical processes, oxygen will form an adduct with the active radical end of a polymer and slow the rate of polymerization. An alternating polymer consisting of methyl methacrylate and dioxygen units can be formed through this inhibition mechanism. For this reason, a positive flow of nitrogen is typically used in industrial processes. Extra care must be taken to exclude oxygen when running polymerizations at lower temperatures where oxygen solubility in water is higher.



The addition of the O_2 unit is very rapid, but because of this relative stability of this adduct, the overall rate of polymerization slows down markedly. Termination levels increase as more O_2 adducts are formed.



In addition to the decrease in overall polymerization rate, there are decreases in kinetic chain length and molecular weight distribution observed when these polymerizations are run in the presence of oxygen (46).

Copolymerization affords a great deal of leverage in tuning the final properties of methacrylic polymers. Methacrylic ester monomers copolymerize smoothly with acrylic monomers; this ease of copolymerization allows one to create copolymer materials with widely varying properties by using the soft, flexible acrylics with hard, brittle methacrylics. One can control properties further by controlling molecular architecture such that alternating polymer chains with methacrylate-rich and acrylate-rich segments are formed. Finally, specialty monomers can be used in small amounts to specifically target certain properties (eg film adhesion to certain substrates) or to allow for further reactions such as cross-linking. Some of the more common specialty functional monomers are displayed in Table 9.

Bulk Polymerization

Bulk polymerization is used primarily for the production of cast sheets of PMMA. During the course of these polymerizations, an autoacceleration known as the *Trommsdorf or gel effect* is observed at approximately 20–50% conversion. This phenomenon is attributable to an increase in viscosity as monomer is converted to polymer within the reactor. Once the viscosity reaches the critical point, termination begins to slow down below the rate of propagation. Therefore, the overall rate of polymerization increases and an increase in the rate of heat generated from the reactor is observed. Because termination is slowing, the molecular weight of material generated after the gel-effect point has been reached is higher than material generated earlier in the process; molecular weight in this case is limited only by the diffusion of monomer to the growing radical chain end (47).

Three main types of bulk polymerization are practiced commercially: batch cell casting, continuous casting, and continuous bulk. Batch cell casting is used to produce roughly half of the PMMA generated globally with the continuous casting and continuous bulk methods splitting the remainder of production equally. Sheets

Table 9. Common Functional Monomers for Copolymerization with Acrylic and Methacrylic Esters

Functionality	Monomer	Structure
Carboxyl	Methacrylic acid		Acrylic acid		Itaconic acid	Amino	2′-text-Butylaminoethyl methacrylate		2-Dimethylaminoethyl methacrylate	Hydroxyl	2′-Hydroxyethyl methacrylate		2-Hydroxyethyl acrylate	N-Hydroxymethyl	N-Hydroxymethyl acrylamide		N-Hydroxymethyl methacrylamide	Oxirane	Glycidyl methacrylate	Multifunctional	1,4-Butylene dimethacrylate	
are produced with widths of approximately 1 m and lengths of several meters; thicknesses range from 0.16 to 15 cm.

Sheet Production. Poly(methyl methacrylate) sheets are produced with all three methods of bulk polymerization. Because of its inherent ease of operation, batch cell dominates this area (48–52). In this method, each sheet is formed in a mold composed of two plate glass sheets separated by a flexible spacer; a flexible spacer with springs attached is needed so that the plates can be brought closer together during the course of the polymerization to account for the increase in density as monomer is being converted to polymer. The mold is filled from one open corner with monomer (or monomer/polymer syrup), initiator, and other additives; the mold is then closed to begin the curing process. Curing itself is accomplished through the use of a carefully controlled temperature ramp to ensure complete cure and to minimize any possibility of losing control of the polymerization exotherm. The curing process takes anywhere from 10 h for thin sheets to several days for the thickest materials. Once formed, the polymer sheets are cooled separated from their reusable glass holders. The finished sheet is then annealed at 140–150°C over the course of several hours to reduce stress within the sheets and guarantee completeness of cure.

Monomer–polymer syrups are used to (*1*) aid in the shrinkage issues encountered in the formation of PMMA sheets, (*2*) shorten the polymerization induction period, and (*3*) lower the temperature necessary for initiation. These syrups contain roughly 20% polymeric material along with the monomer and can be made either by dissolving 20% finished PMMA in monomer or partially polymerizing

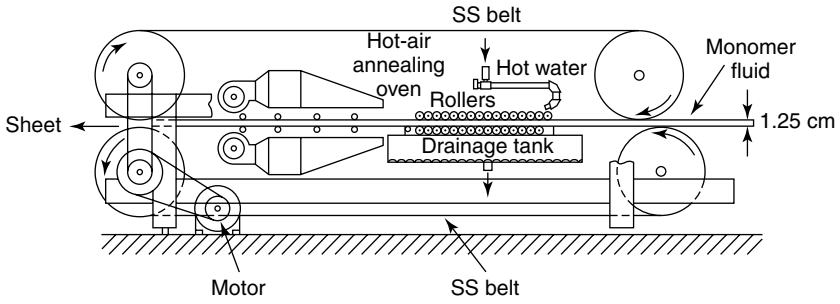

Fig. 2. Continuous process for manufacturing PMMA plastic sheet.

a batch of PMMA to the 20% level. Batch cell casting can also be used for the production of PMMA rods and tubes.

Continuous production of PMMA is accomplished using a method developed in 1968 (53). This method (Fig. 2) utilizes a polymer–monomer syrup which is delivered to a curing and annealing apparatus between two parallel stainless steel belts that are held at an angle to maintain the desired spacing between the belts. A gasket seals the reacting zone of the setup while it moves down the line at approximately 1 m/min. The reaction conditions for this type of reactor are ∼70°C for ∼45 and ∼10 min annealing time at ∼110°C. Masking tape is used to protect the sheets when they have cooled.

Poly(methyl methacrylate) is thermoplastic and can be formed into practically any shape when heated (54,55). Continuous production is employed when thin sheets are desired or highly filled materials (eg synthetic marble) are being formed.

Molding Powder. Poly(methyl methacrylate) is used extensively in injection and extrusion molding of plastics (56). The PMMA can take many forms from 0.3-cm pellets to fine beads and granulated powders. The molding powders are formed by extrusion of either bulk polymerized methyl methacrylate or from a polymer–monomer syrup which is heat-treated to remove the unreacted methyl methacrylate monomer. The PMMA emerges as a narrow rod which is chopped into the appropriately sized powder.

Synthetic Marble. Highly filled monomer or monomer–polymer syrup mixtures are used to form synthetic marble materials. A single belt approach can be employed in the formation of synthetic marble with only one smooth side (57,58). Aluminum oxide, calcium carbonate, titanium dioxide, etc, are used at loading levels of ∼60%; the specific materials of choice are determined according to the translucence, chemical-resistance, and water-resistance properties desired (59,60).

Solution Polymerization

Solution polymerization is a commercially significant means of manufacturing methacrylic polymers for the coatings, adhesives, and laminates markets. Soluble

[b]Ref. 60.

peroxides, peroxypivalates, and azo initiators are used to initiate the polymerization in an organic solvent. Polymers with molecular weights in the range of 2000–200,000 are made by this process. Higher molecular weights generate viscosities which are very difficult to process and are typically made by other processes (61,62).

The solubility properties of solution polymers depend upon the length of the ester side chain. Polymers with less than four carbons are soluble in aromatic hydrocarbons and only sparingly soluble in aliphatic hydrocarbons. Those polymers which are made from higher alcohols are soluble in aliphatic hydrocarbons. Solvent plays a role not only in solubilizing the polymer but also as a chain transfer agent which helps control the viscosity of the solution polymer by keeping the molecular weight low. Chain transfer constants (C_s) for methyl methacrylate in common solvents are given in Table 10.

Initiator choice is another important consideration for solution polymerizations; the rate of thermolysis, cost, and initiator solubility in the diluent solvent are considerations in the choice of reaction solvent. Use levels range from a few hundredths of a percent to several percent by weight on the monomer used in the synthesis. The molecular weight of the polymer produced is inversely proportional to the level of initiator employed in the synthesis. Another consideration in the choice of initiator is the tendency of hydroperoxides to abstract hydrogens from the polymer backbone and side chains. *tert*-Amylhydroperoxide and di-*tert*-amylperoxide generate *tert*-amyloxy radicals which undergo β scission to generate ethyl radicals and one equivalent of acetone. The carbon-based ethyl radicals have lower energy than their oxygen-based sources (63). In addition to solvent and initiator selection, molecular weight can be controlled through the use of chain transfer agents and manipulation of the monomer concentration and reaction temperature (64).

Stainless steel is the material of choice for reactors used in solution polymerization. Nickel and glass can also be employed, provided that the reactor is constructed to withstand pressures of 446 kPa (65 psi). Because of the wide range of viscosities encountered in solution polymerization, a variety of stirring impellers are employed. For lower viscosities (<1000 cP) an anchor-type agitator is used; higher viscosities necessitate the use of a ribbon-type impeller, which sweeps virtually the entire volume of the reactor and, therefore, prevents polymer from remaining near the edges of the reactor.

Temperature control is of utmost importance in solution polymerizations because of the large quantity of heat liberated during the course of the polymerization. All industrial-scale reactors include cooling jackets and rupture disks in order to control the temperature and conditions within the reactor. In order to maintain efficient cooling of a solution polymer batch, it is imperative to maintain control over the viscosity of the batch. Another method for controlling reactor temperature is through the gradual addition of monomers to the batch; total cycle times for these batches generally fall in the range of 8–24 h (65). As a final precaution a chemical inhibitor is stored in the reactor area in order to quickly shut down the polymerization in the event that temperature control is compromised.

A typical reactor charge sheet for the solution polymerization of a terpolymer containing 27.5% 2-ethylhexyl acrylate, 41.3% methyl methacrylate, and 31.2% hydroxyethyl methacrylate is shown below:

Ingredient	Parts, wt%
Reactor charge	
Xylene	28.4
Ethoxyethanol	14.1
Monomer charge	
2-Ethylhexyl methacrylate	15.5
Methyl methacrylate	23.3
Hydroxyethyl methacrylate	17.6
Initiator charge	
tert-Butyl perbenzoate	1.1

For this polymerization, a reactor temperature of ~140°C is maintained for roughly 3 h while the monomer mixture is fed into the reactor. Following the completion of the monomer addition, the batch is held at 140°C to finish the batch. The final product consists of a 58% solids clear, viscous polymer which is cooled and packaged for delivery to the customer (66).

Stainless steel is used for the shipping and ground transport of methacrylic resins. Depending on the size of a particular order, these resins can be delivered in drums, tank trucks, or rail cars; water is rigorously excluded to prevent rusting and discoloration of the solution polymer. Because of the temperature dependence of the viscosity of these polymers, all transport containers are maintained at a specific temperature in order to permit effective transfer of the material once it has been delivered (67). Again, steel is the material of choice for the construction of transfer valves and pipes.

Emulsion Polymerization

Methacrylic ester latex polymers and copolymers are employed in the architectural coatings, paper, textile, floor polish, and leather industries. Methacrylic esters are most typically copolymerized with acrylates such as ethyl acrylate and butyl acrylate. These products are opaque, milky-white dispersions which can be formed at 30–60 wt% solids levels. One of the principal advantages to the use of emulsion polymerization versus solution polymerization is that the viscosity of the material is independent of molecular weight (68,69). Extremely high molecular weights (>1,000,000) can be obtained without any viscosity penalty being incurred. Particle sizes for these polymer latexes typically fall in the range of 0.1–1 μm. The polymerizations themselves take place very rapidly, with the latex water continuous phase providing a tremendous amount of heat capacity to the batch so that temperature control becomes more facile than in solution polymerization. The use of water also allows the polymer producer to eliminate the expensive and hazardous solvents often employed in solution polymerization.

Surfactants are employed to stabilize the emulsion polymer particles; anionic, cationic, and steric stabilizers are all used for the production of latexes, depending on whether one wants a negative, positive, or neutral potential surface on the formed polymer particle. The specific anionic options available for use are alkyl sulfates, alkyl sulfosuccinates, and alkylarene sulfonates and phosphates. Standard nonionic surfactants include alkyl or aryl polyoxyethylenes. In recent years, alkyl phenol ethoxylates have fallen into disfavor because of their reported problems with bioaccumulation in aquatic life. This still somewhat controversial, environmentally-driven issue has necessitated the use of alternative surfactants which have a lower impact on the environment. Typically, the aryl ring is eliminated to solve this problem.

Initiation for emulsion polymerizations occurs in the aqueous continuum; therefore, water soluble initiators such as ammonium or sodium persulfate are used. This oxidizing initiator can be cleaved either thermally or via redox reaction to generate sulfate radicals which function as the initiating species for these polymerizations. One of the advantages in using the redox approach for initiation is the temperature-independence of the rate for this reaction. Emulsion polymerizations can be run in the 25–60°C range versus 75–90°C for thermally initiated runs. In order to run a redox-initiated polymerization, a reductant is needed to directly or indirectly (through the use of a multivalent metal promoter) reduce the oxidant. Although there are many choices, common reductants include isoascorbic acid [89-65-6], sodium sulfoxylate formaldehyde [6035-47-8], and sodium hydrogensulfite [7631-90-5].

Reactors for the emulsion polymerization of methacrylic esters are made of stainless steel and are jacketed for temperature control; these reactors are built to withstand pressures of 446 kPa (65 psi) and contain emergency stacks with rupture disks in case of excess pressure buildup within the reactor. Agitation is a critical issue for emulsion polymerization. Variable-speed drive shafts are used along with stainless steel agitators to mix the batch. Baffles on the reactor walls are also common features of industrial emulsion polymerization reactors. Temperature control is maintained through the use of steam and cold water circulation with the jacket of the reactor. Feed lines for the monomer emulsion, initiators, and

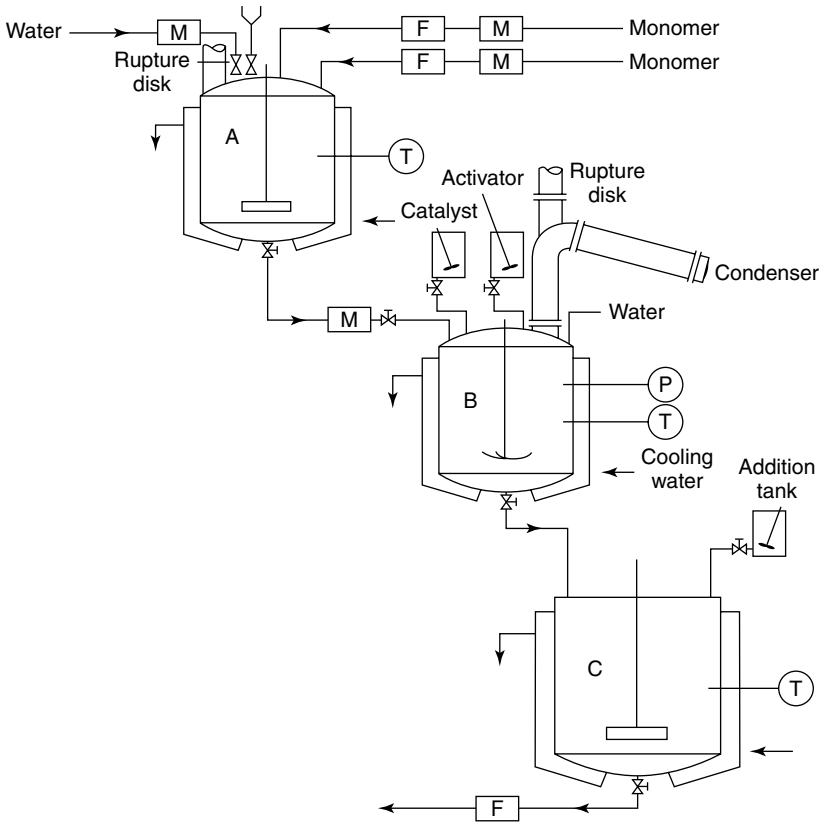

Fig. 3. Emulsion polymerization plant: A, emulsion feed tank; B, polymerization reactor; C, drumming tank; F, filter; M, meter; P, pressure gage; and T, temperature indication.

reductants are placed at the top of the kettle. Figure 3 contains a schematic for a typical industrial emulsion polymerization reactor.

Monomer emulsion preparation takes place in stainless steel tanks which are equipped with their own pressure gages, temperature indicators, and rupture disks. Because of the high (>70%) monomer content in a typical emulsion, close attention must be paid to the emulsion to ensure that it does not autoinitiate and produce an uncontrolled exotherm. Once safely formed, monomer emulsions can be added to the main reactor chamber either all at once or via gradual addition. Gradual addition is more commonly employed so that a high degree of temperature control is maintained.

Following the polymerization, the polymer latex is transferred to a drumming tank which serves as a temporary storage vessel from which the polymer is packaged for delivery to the customer. Drumming tanks are additionally used to adjust the pH, solids content, and other final properties of the latex. For this purpose, drumming tanks are equipped with their own agitation systems. Following filtration, the latex is transferred from the drumming tank into a storage vessel either for immediate delivery or for temporary storage on-site.

A typical recipe for an emulsion polymerization process is contained in the table below (70,71):

Ingredient	Parts
Monomer emulsion charge	
Deionized water	13.65
Sodium lauryl sulfate	0.11
Methyl methacrylate	22.50
Butyl acrylate	22.05
Methacrylic acid	0.45

This process generates a 50% methyl methacrylate, 49% butyl acrylate, and 1% methacrylic acid terpolymer at 45% solids. The monomer emulsion is first formed by adding the ingredients in the order listed while agitating the monomer emulsion container. The reactor charge (30.90 parts deionized water and 0.11 parts sodium lauryl sulfate) are added and heated to 85°C. The initiator (0.23 parts ammonium persulfate) is then charged prior to the beginning of the monomer emulsion feed. The emulsion is fed over 2.5 h, and a reactor temperature of 85°C is maintained during the monomer emulsion feed and subsequent polymerization. Upon completion of the emulsion feed, the reactor temperature is raised to 95°C for 0.5 h to complete the polymerization in terms of both monomer conversion and persulfate decomposition. The polymer latex is then cooled to room temperature, filtered, and packaged.

Latex polymers and copolymers of methacrylic esters are shipped in drums, tank trucks, and rail cars constructed of stainless steel or resin-coated steel and are insulated to prevent freezing of the latex. Storage tanks are, likewise, insulated and in some cases heated to prevent freezing of the latex material. Sedimentation, skinning (surface film), gritting (solids formation within latex), gumming (deposition on walls), and sponging (aerogel formation) are all concerns in the stabilization of methacrylic polymer dispersions. Other issues in the storage and handling of latexes include pH drift, evaporation, temperature fluctuation, shear and turbulence, and foaming (see FOAMS). Bactericides are commonly used to preserve polymer latexes from microbial attack (65).

Suspension Polymerization

In order to form polymer dispersions with particle sizes > 1 mm, suspension polymerization is used. The beads generated via this method of polymerization find their main usage in ion-exchange resins and molding powders. Molding powder compositions range from 100% methyl methacrylate to 20% acrylate copolymer for increased flexibility and improved processing properties. Amino or acid functional monomers are additional options in copolymer suspension polymerizations for ion-exchange; di- or tri-functional monomers are included in order to controllably cross-link the polymer beads.

The initial step in a suspension polymerization involves the suspension of 0.1- to 5-mm monomer droplets in water. The droplets are stabilized against

ripening by the inclusion of a protective colloid or suspension agent. Unlike emulsion polymerization, an oil-soluble initiator is used for suspension polymerizations. The initiator enters the monomer droplet and is thermally dissociated to produce radicals and initiate polymer chain growth. Water again served as a dispersion medium and a heat sink within these polymerizations. Particle sizes generated using this method are in the 0.1- to 5-mm range and are controlled through the suspension agent as well as the agitation rate. The polymer beads are isolated and washed via filtration or centrifugation.

Suspension agents commonly used include cellulose derivatives, polyacrylate salts, starch, poly(vinyl alcohol), gelatin, talc, clay, and clay derivatives (65,72). The primary role of these agents is to preserve a specific monomer droplet size and prevent the ripening (enlargement through coalescence) of the monomer droplets. Glycerols, glycols, polyglycols, and inorganic salts are also used to enhance suspension polymer properties (65). Finally, lubricants such as lauryl or cetyl alcohol and stearic acid and cross-linkers such as di- and trivinylbenzene, diallylesters of dibasic acids, and glycol dimethacrylates are common components of suspension processes.

Polymerization takes place within the monomer droplets and, therefore, follows a course consistent with the behavior of a bulk polymerization (65,73). Ideally, there are no transfer processes taking place between the aqueous continuum and the monomer droplets during these polymerizations. Initiators such as azo and peroxy compounds are chosen such that they are highly soluble in the monomer phase and highly insoluble in the aqueous phase; molecular weight distributions are determined in large part by the amount of initiator charged to a particular polymerization (65).

Reactor equipment is very similar to that used in emulsion polymerizations as depicted in Figure 3. The agitation and safety hardware are virtually identical as are the materials of construction. In a typical polymerization, water, suspension agents, monomer mixture, initiator, and other additives are charged to the reactor kettle in this order. The reaction mixture is then heated under careful agitation to the desired initiation temperature. Large rises in temperature and/or pressure are often encountered in suspension polymerizations; reaction times are quite rapid for this type of polymerization. Once finished, the slurry is cooled and filtered or centrifuged to isolate the polymer beads. The beads are then washed with copious amounts of water and dried either on aluminum trays in an oven maintained at 80–120°C or in a stainless steel rotary vacuum drier (65) (see DRYING).

A standard suspension polymerization process for the production of PMMA beads begins with the charging of 24.64 parts of methyl methacrylate and 0.25 parts of benzoyl peroxide to a 30°C solution containing 0.42 parts disodium phosphate, 0.02 parts monosodium phosphate, and 0.74 parts of Cyanomer A-370 (polyacrylamide resin) in 79.93 parts of deionized water. The reaction mixture is brought to 75°C and held there for 3 h. After cooling, the beads are isolated by filtration, washed with water, and dried (74).

Nonaqueous Dispersion Polymerization. A nonaqueous dispersion (NAD) polymer can be formed by first dissolving a methacrylic monomer in organic solvent and polymerizing to form an insoluble polymer in the presence of an amphipathic graft or block copolymer. The block or graft copolymer serves as a stabilizing agent and allows the insoluble methacrylic polymer to form a stable

Table 11. Examples of Methacrylic Nonaqueous Dispersion Polymers

Polymer	Diluent	Dispersant	Reference
Poly(methyl methacrylate)	Aliphatic hydrocarbon	Hydroxystearic acid–acrylic graft copolymer	70
Poly(methyl methacrylate)	Aliphatic hydrocarbon	Drying oil-modified polyester	72
Poly(methyl methacrylate)	Hexane	Isobutylene-*co*-isoprene graft copolymer	73
Poly(methyl methacrylate)	Methanol	Ethylene glycol–methyl methacrylate graft copolymer	74
Poly(ocytyl methacrylate)	methanol	Ethylene glycol–octyl methacrylate graft copolymer	70
Poly(methacrylic acid)	Chloroform–ethanol	Methacrylate functional polyester	70

colloidal particle. Particle sizes for these samples range from 0.1 to 1.0 μm with outliers in the range of 15 μm possible (75–77). These polymers are often used in the coatings industry as substitutes for aqueous emulsion polymers. The advantages of NAD polymers over emulsion polymers include low heat of evaporation and drying which is independent of the prevailing humidity level; disadvantages include toxicity of organic solvents, odor, cost, and flammability. Table 11 displays some examples of commercially significant NAD polymers.

Graft Polymerization

The construction of graft polymers involves the attachment of side branches of one composition to a main chain of a separate composition. One method of preparation depends upon the creation of radical sites along the main chain so that branches of the second composition can be grown out from monomer to create the grafted portions (78–80). Graft polymers may take the form of solution polymers, bulk polymers, or dispersions. methacrylate butadiene styrene (MBS) and methacrylate acrylonitrile butadiene styrene (MABS) are the most commercially significant graft polymers. Grafting methods used have included chemical (81,82), photochemical (83), radiation (83,84), and mastication (85). Methyl methacrylate has been grafted onto such diverse polymer backbones as cellulose (86), poly(vinyl alcohol) (87), polyester (88), polyethylene (89), poly(styrene) (90), poly(vinyl chloride) (91), and other alkyl methacrylates (92).

The preparation of MABS first involves the dissolution or dispersion of polybutadiene in a methyl methacrylate/acrylonitrile mixture which can either serve as the continuous phase in bulk polymerization or take the form of monomer droplets in suspension polymerization. The refractive indices of the two phases formed are matched such that the final material is tough, transparent, highly impact-resistant, and able to be melted and formed into diverse shapes.

MBS polymers are prepared via an emulsion polymerization process which consists of the formation of methyl methacrylate and styrene grafts on an already-formed styrene–butadiene backbone. The final product is used as an impact modifier in poly(vinyl chloride) materials.

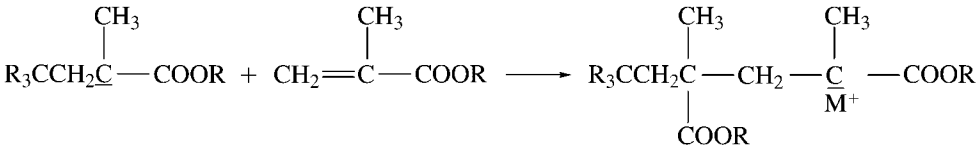
Ionic Polymerization

Cationic polymerization is not an option in the formation of methacrylic ester polymers. Methacrylic monomers can, in fact, be used as solvents or colsolvents in the formation of polymer by a cationic mechanism (93,94).

Anionic polymerization, on the other hand, is frequently used to form methacrylic ester polymers. Initiation is accomplished in organic solvents via organometallic initiating species. Polymers of exceptionally narrow molecular weight distributions are possible by using anionic polymerization; molecular architecture can be finely (95) controlled as well. Polymers with high degrees of crystallinity are also obtainable through the careful control of reaction conditions. The method has not yet achieved large-scale commercial success because of the high costs involved in the formation of these polymers. Stereoregular poly(methyl methacrylate) (96,97) and poly(*n*-butyl methacrylate) have been prepared through the use of anionic polymerization. Polar solvents are used to form syndiotactic polymers and nonpolar solvents are employed in the formation of isotactic anionic polymers; solvent choice can, therefore, be used to form polymers with entirely different physical properties. The anionic polymerization of methacrylic esters has been covered extensively in the literature (98–101).

Michael additions are thought to be responsible for initiation in anionic polymerization:

Chain growth occurs through the head-to-tail addition of monomer units:



Although it is possible to polymerize both methacrylic and acrylic esters by anionic polymerization (102), copolymers of these two classes are not observed.

Group transfer polymerization, first reported by DuPont in 1983 (103), allows the production of methacrylic esters with controlled architectures. This technique uses a silyl ketene acetal initiator to produce block polymers, comb-graft polymers, star polymers, and functional polymers (103,104).

Living Polymerization

One of the most exciting areas currently in the radical polymerization of methacrylic ester monomers is the field of living polymerization. *Living polymers* are defined in Reference 105 as polymers that retain their ability to propagate for a long time and grow to a desired maximum size while their degree of termination or chain transfer is still negligible. Because of these properties, exceptional control can be exercised over the topology (ie linear, comb), composition (ie block, graft), and functional form (ie telechelic, macromonomer) of these polymers (106).

Atom transfer radical polymerization (ATRP) and nitroxide-mediated (107–109) polymerization both show promise in terms of the ability to fine-tune polymer architecture using living radical methods. ATRP has been successfully used in the polymerization of methyl methylacrylate using copper (110), ruthenium/aluminum alkoxide (111), iron (112), and nickel (113) catalyst systems.

Analytical Test Methods and Specifications

Plastic Sheet. Clear and colored transparent, clear and colored translucent, and colored semiopaque PMMA sheets are manufactured commercially. Properties such as uv resistance, mar resistance, crazing resistance, impact resistance, and flame resistance can be improved through the use of additives. Some of the physical properties of PMMAs are displayed in Table 12.

Solution Polymers. The main properties of interest for solution polymers are their composition, solids content, solvent type, viscosity, molecular weight, and glass-transition temperature. Composition information can be obtained through refractive index measurements, spectroscopic techniques, and pyrolytic gas–liquid chromatography. Solids content is measured by volatilizing the diluent solvent and measuring the percentage decrease in sample mass. Solution viscosities can be measured via Brookfield viscometer; intrinsic viscosity can be used to obtain estimates of solution polymer molecular weights (115).

Emulsion Polymers. Methacrylic ester latex properties for characterization include composition, solids content, particle-size distribution, viscosity, pH, glass-transition temperature, and minimum film-forming temperature. Composition information is obtained through nmr spectroscopy, pyrolytic gas chromatography, and refractive index measurement. Gravimetric methods are used to measure solids content; particle size distribution information is obtained through light scattering methods, microscopy, or capillary hydrodynamic flow techniques. Photon correlation spectroscopy is also used to measure particle size distributions (116). Viscosity measurements are made using Brookfield or similar

Table 12. Typical Properties of Commercial Poly(methyl methacrylate) Sheet[a]

Property	Value	ASTM test method
Specific gravity	1.19	D792-66

[f] To convert kJ to kcal, divide by 4.184.

viscometers. Finally, glass-transition measurements can be made either by dma or dsc.

Emulsion polymers typically have a series of stability tests run on them before they are approved for sale commercially (117). These tests include freeze–thaw, mechanical shear, and thermal stability. The settling tendencies of a latex are assessed as is the formulation stability with regard to other dispersions, salts, surfactants, and pigments.

Suspension Polymers. Suspension polymers of methacrylic esters are characterized by their composition and particle size distribution. Because of their large particle sizes, these materials are typically passed through sizing screens which separate the various fractions according to polymer bead diameter. Materials destined for the molding powders market are subjected to melt-flow studies under the conditions of use that they will encounter for their specific application. Ion-exchange beads are, likewise, studied with regard to their ion-exchange capacity, density (wet and apparent), solvent swelling, moisture holding capacity, porosity, and salt-splitting characteristics (118).

Health and Safety Factors

Provided that there are no toxic additives or high levels of residual monomers, methacrylic ester polymers are classified as nontoxic. These materials find use in dental fillings, dentures, contact lenses, medicine dispensers, and food packaging. However, some acrylic and methacrylic dispersions can be skin or eye irritants due to the surfactants used in stabilization.

Because of the toxicity of the monomers involved in forming methacrylic ester polymers, extra precautions are taken to avoid any release of monomer into the surrounding area. Most industrial polymerization reactors are run with closed kettles to prevent monomer vapor from escaping into the surrounding air.

One of the hazards uniquely associated with the production of methacrylic powders and sheets is explosion of polymer dust. These materials are flammable and must be treated with care to avoid static discharges which can serve as ignition sources. Poly(methyl methacrylate) is widely used in buildings under codes which limit the fire hazards associated with this material. Solution polymers of methacrylic esters are considered flammable while latex emulsion polymers are nonflammable because of the aqueous continuous phase.

Uses

The primary market for methacrylate resins in the United States is in the glazing and skylights area. These resins also find significant usage in consumer products, transportation signs, lighting fixtures, plumbing (spas, tubs, showers, sinks, etc), panels, and siding (119,120).

Glazing. Methacrylic ester polymers are well-suited for use as glazing, lighting, or decorative materials because of their unique balance of light transmittance, light weight, dimensional stability, and formability as well as their

weather, impact, and bullet resistance. Some of the specific applications for these materials include windows for aircraft fuselages (121), banks, police cars, hockey rinks, storm doors, bath and shower doors, and showcases. The ability to manufacture either colored or clear versions of methacrylate sheets recommends their use in decorative window mosaics, side glazing, color coordinated structures, and sunscreens (122,123). Both sheets and molding pellets have been used for lighting, solar control, and in signs (124–128).

Medicine. For years, dentures, dental fillings, and denture bases have been made using methacrylic ester polymers (129,130) (see DENTAL MATERIALS). These polymers can also be used to prevent tooth decay in natural teeth by serving as a barrier which can be coated over the surface of the tooth. The dimensional behavior of these bone-cement composites has been reported (131) as has the structure of the cold-cured acrylic resin (132). Both hard and soft contact lenses have been made using polymethacrylates (133,134). hHYDROGELS (qv) comprising poly(2-hydroxyethyl methacrylate) are used in soft contact lenses (135,136).

Optics. Polymethacrylates are naturally good choices for the fiberoptics market because of their optical clarity and low thermal resistance (137). Fresnel and eyeglass lenses have been made using polymethacrylates (138–140).

Oil Additives. Long-chain polymethacrylates increase the viscosity of oil as temperature increases and are therefore used as additives to improve the performance of lubricating oils and hydraulic fluids in internal combustion engines (141). Through the careful control of polymer molecular weight and composition, oils of constant performance over broad temperature ranges are made possible (142). Polymethacrylates can be used to improve the viscosity index, sludge dispersancy, and antioxidant properties of an oil (143) (see ANTIOXIDANTS). Through the grafting of polyethylene and polypropylene onto long-chain polymethacrylates, multipurpose lubricants having viscosity index, pour point depression properties, and detergent dispersing capabilities are possible (144).

Other. Synthetic marble fixtures and bathtubs are made using methacrylic ester polymers (145,146). Opaque and clear methacrylate sheets have been used as structural components in the manufacture of recreational vehicles (147). These materials are additionally used for electrical insulation. Thermoplastic methacrylate resins are used in lacquer coatings for plastics, in printing inks, as heat seal lacquers for packaging, as screen printing media for decorative porcelain, in traffic paints, and for the protection of buildings from acid rain and weathering (148). Other copolymer used are discussed in the article ESTER POLYMERS.

MICROMECHANICAL PROPERTIES

Introduction

Mechanical properties of polymeric materials are important for nearly all applications in industry, technology, and the household. Particularly, stiffness, strength, and toughness are decisive properties in many uses. Mechanical properties depend strongly on chemical as well as on supermolecular structure of the polymeric material. While the chemical, molecular structure defines some basic properties such as rigidity, thermal softening, and melting behavior, the ultimate mechanical properties are fixed by the supermolecular structures or morphology. The same molecular structure can yield to many varied morphologies dependent on factors such as orientation due to fabrication, different cooling rates, changes in thermal history, and secondary crystallization.

However, not all of the manifold structural or morphological details influence the ultimate mechanical properties to the same degree. There are details which determine properties more than other ones, ie, there are so called "property determining structures." Besides, it is not sufficient to study the average structure and morphology of a material, but the variation of morphological details or extreme sizes of the details have to be known. Smaller structural details have become increasingly important for a defined improvement of mechanical properties with a shift from details on the micrometer scale to details on the nanometer scale, eg, in block copolymer or nanocomposites, Polymer-Clay.

The influence of all of the different structural details on the mechanical properties is determined by micromechanical processes, which appear under the applied loading conditions. Depending on the very different structural details and loading conditions, there is a very large variety of micromechanical processes of deformation and fracture. These processes define the *micromechanical properties* of a polymeric material or the *micromechanics*. Therefore, micromechanical properties form the bridge between structure or morphology and ultimate mechanical properties. Improved knowledge of the micromechanical properties allows a deeper insight into the influence of morphology on the mechanical properties, ie, it allows a better understanding of structure–property correlations (see Fig. 1).

A detailed knowledge of structure–property correlations is not only of academic interest but also important for the polymer industry. It enables a defined modification of the morphology for realizing special desired properties for practical applications. This way was called "microstructural construction of polymers" (1). In addition, study of micromechanics in polymeric model materials may reveal new micromechanical processes, yielding improved, new and up-to-now impossible combinations of different mechanical properties, eg, combinations of contradictory properties, such as stiffness, strength, and toughness. Transforming such new micromechanical mechanisms from model samples to technically usable materials by defined scaling-up may yield new classes of polymers, eg, in the field of nanostructured materials.

The term "*micromechanics*" covers all processes on mesoscopic, microscopic, and nanometer scales that occur inside a material in response to an external loading (2). These processes include reactions of macromolecules, such as stretching or

scission of molecular segments, reptation (snake-like) movement, microyielding, microcavitation, forming of crazes, shear bands or deformation zones up to crack initiation, propagation, and fracture.

Recently, several different techniques to study micromechanical properties have been applied. Besides spectroscopic and scattering techniques, the microscopic techniques of electron microscopy and atomic force microscopy are particularly useful for direct determination of micromechanical properties in polymers (2–7). A brief overview about successfully applicable techniques is given in this article. Using these techniques, micromechanical properties of different polymers that have been studied are also reviewed.

Every study of micromechanical processes must be coupled with a detailed investigation of the morphology and, in particular, of those structural parameters of most importance for the property of interest (see "representative volume" - below). Often, structural defects exist that are responsible for premature failure of materials. In the following, direct imaging techniques of electron microscopy and atomic force microscopy are discussed in more detail, since they allow a very direct determination of the micromechanical processes in dependence on the local morphology, and yield often a very clear picture of the micromechanical behavior of the material. Additional information about special micromechanical properties can be revealed by using several other techniques. However, unlike the direct microscopic methods, these techniques yield mainly integral results from a larger sample volume, but complete the picture.

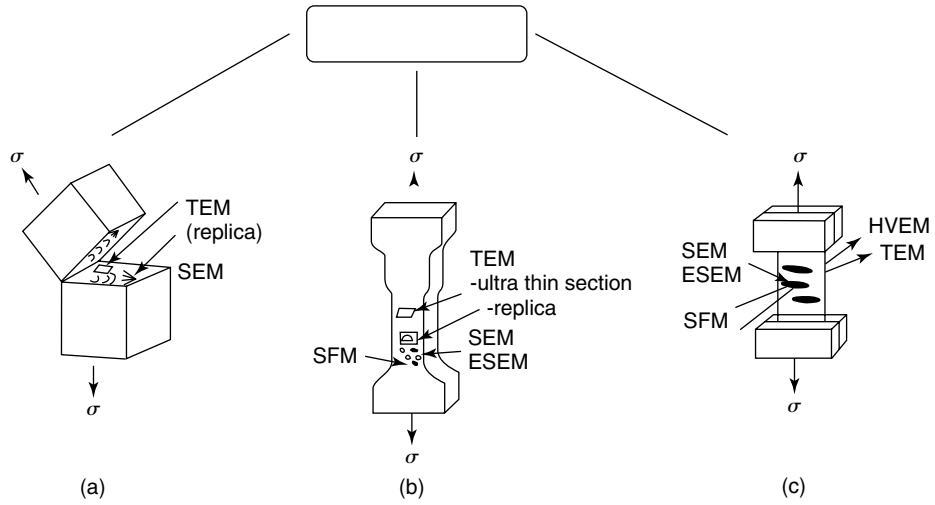

Fig. 2. Survey of (electron and scanning force) microscopic methods for investigating micromechanical processes in polymers. σ indicates the applied tension stress and the arrows indicate area and direction of investigation in the microscope (see text for full details). (**a**) fracture surfaces—tension test, impact test, broken pieces; (**b**) surfaces of deformed (loaded) bulk samples; (**c**) *in situ* deformation of thin samples.

Microscopic Techniques

A survey of successful methods is given in Figure 2, demonstrating three main techniques (2–4):

(1) Fracture surfaces can be directly investigated in the scanning electron microscope (sem, microfractography, Fig. 2a), demonstrating most significantly the final processes of deformation, crack initiation, and crack propagation up to fracture. In particular, structural heterogeneities (defects), which initiate fracture and influence crack path, can be detected (see FRACTOGRAPHY). Using sem, the surface topography of bulk specimen can be very easily inspected with the only precondition of coating with a thin conducting layer. Using thin replicas from the fracture surface, transmission electron microscopy (tem) can also be applied (however, preparation of thin replicas from a polymer surface is a relatively difficult procedure) (see MICROSCOPY).

(2) Deformation of bulk material is followed by investigation of the changes at the surfaces by sem, environmental scanning electron microscopy (esem, with the advantage of avoiding any conducting layer), and atomic or scanning force microscopy (sfm) or, after replication, by tem. Changes inside the bulk material are studied by preparation of ultrathin sections from deformed regions using a cryo-ultramicrotome (occasionally after selective chemical staining to improve the contrast) and by tem investigations (Fig. 2b). In semicrystalline polymers, changes of the crystalline orientation can be studied by electron diffraction.

(3) Samples of different thicknesses (usually semithin or ultrathin sections prepared by ultramicrotomy) can be deformed in tensile devices and the deformed samples investigated directly by sem, esem, sfm, tem, or high voltage electron microscopy (hvem) (Fig. 2c).

The advantage of techniques 1 and 2 is the possibility of studying bulk material, deformed under defined stress conditions and loading temperatures. Disadvantages of technique 1 lie in the difficulty of detecting the initial stages of deformation and in the impossibility of carrying out experiments *in situ*. In technique 2, problems may arise from a possible modification of the deformation structures at the sample surfaces in sem or sfm studies and from the danger of damaging the deformation structures by the preparation of ultrathin films (usually by ultramicrotomy) in tem studies.

Tests *in situ* can be performed by technique 2 only using an esem (because of avoiding a conducting surface layer) and by technique 3 using different microscopes in combination with tensile devices. Additional advantages of technique 3 lie in the investigation of processes by using special tensile devices to perform deformation tests at lower or higher temperatures (usually from -150°C to 200°C). Using these tensile stages, samples of different thicknesses can be studied: thicker samples (thick sections) can be investigated in an sem, esem, and sfm, revealing deformation processes near the surface. A method particularly advantageous is the investigation of semithin sections, up to several micrometers thick, in a 1000-kV hvem. Such samples, on one hand, show a relatively high mechanical stability and often they represent the micromechanical behavior typical for these polymers and, on the other hand, the investigation in an hvem enables high magnifications and resolutions. Ultrathin sections or films are necessary for using conventional 100- to 200- kV tem. These ultrathin samples are often mounted for supporting on a Cu grid (8) or on a film with a hole.

Using sfm, a direct study of surface structures is possible in air without the need for coating with a conducting layer and without any radiation damage, but with a resolution in the nanometer range. Therefore, this method is of particular interest for micromechanical investigations and real *in situ* tests.

Choice of the appropriate size and thickness of the sample depends on several factors, including the morphology of the polymeric material, sample shape or geometry, and stress state (eg, plane strain or plane stress state). Therefore, the various techniques mentioned above allow the study of very different polymers.

An often-discussed problem is the "transformation" of results from microscopic investigations on thin samples to the bulk material. The typical dimensions or features of the morphology (the "property determining structures") must be smaller than the sample thickness, that is, the samples have to contain a representative part of the morphology (a "representative volume"). If the thin sections contain a representative part of the morphology, the character of the deformation (the deformation mode) is often unchanged; however, the absolute values of deformation (degree of elongation) are usually higher in thin samples than in the bulk (2–4). Therefore, across the scale of structures, certain scales can correspond to specific properties. For example, modulus as measured by standard ISO tensile test with specimen cross-section 4 mm by 10 mm scales to volume fraction crystallinity in semicrystalline polymers, but yield stress, deformation, and crack

initiation and propagation may well relate to processes in amorphous, interlamellar regions or near molecular scale events five to six orders of magnitude in scale lower than that of the specimen geometry.

A general problem of all electron microscopic tests of polymers *in situ* is radiation damage. Polymers, as organic materials, are particularly sensitive to electron-beam irradiation with several primary effects (eg, ionization, rupture of chemical bonds) and secondary effects (eg, mass loss, cross-linking, reduction in crystallinity, charging up). The sensitivity to irradiation decreases with increasing carbon content in the polymeric material, for example in the sequence polytetrafluoroethylene (PTFE), poly (vinyl chloride) (PVC), poly(methyl methacrylate) (PMMA), polycarbonate (PC), polyethylene (PE), and polystyrene (PS) (9). Irradiation damage occurs very quickly during irradiation in the electron microscope. Such damaged specimens are frequently well suited for investigating morphology (10) (except by means of electron diffraction), but are not appropriate for tests *in situ*. The damage of the specimen can be somewhat reduced by taking precautions in the instrumentation and manner of operation (eg, use of "low dose" technique, highly sensitive photographic material, or of electronic image intensifiers with coupled image recording, application of higher acceleration voltage in an hvem) (2,11).

An additional problem associated with the direct investigation of polymeric materials by electron microscopy is in the usually low contrast between structural details. In connection with deformation, the effect of "straining-induced contrast enhancement" is of particular importance. Structural elements, such as particles, which possess a smaller Young's modulus than the surrounding material, show a preferred extensibility or deformation during stretching of the sample. In the direction of the electron beam, the thickness of the sample decreases at these places, thus causing a difference in the intensity of the transmitted electron beam and an enhanced contrast (2,10).

Scattering (Diffraction) Techniques

Different methods of measuring the scatter function of corpuscular as well as wave radiations are used for indirect measurements of microscopic heterogeneities or changes in morphology, which develop under the action of load, especially development, distribution and size of crazes and craze fibrils in amorphous and rubber-toughened polymers, and change of lamellae in semicrystalline polymers (see SCATTERING).

As it is well known from the principles of light and x-ray optical instruments, irradiation of a material having periodic structures results in interference phenomena when wavelength of the incident radiation and structural periodicity are in the same order of magnitude. X-ray diffraction was the first direct evidence for the presence of periodicity in inorganic crystalline solids. Correlation between wavelength of the incident ray, structural periodicity in the material under examination, and diffraction angle is expressed by Bragg's Law (1913). Although Bragg's Law was primarily used to explore the atomic structure of these solids, different diffraction techniques have been developed to study the structure of all states of matter with different beams, such as ions, electrons, neutrons, and

protons, whose wavelength is an integral multiple of the distance between two- or three-dimensional periodic structures.

Different types of radiation interact elastically with different structural units of the material to be investigated. So x-rays are scattered on electronic cloud, while electrons are deflected in the electric field of atomic nuclei. An exception includes neutron scattering where wavelength of incident radiation is larger than the diameter of atomic nuclei, so that scattering is independent on diffraction angle but depends on differences of scattering cross sections of atomic nuclei.

Wide-angle x-ray scattering (waxs) enables us to study changes in crystallinity and orientation (texture analysis) and, for instance, processes of lamellae twisting in semicrystalline polymers (12).

Small-angle x-ray scattering (saxs) is used to study fibrillar and lamellar structures and detects appearance of microcavities (13), eg, microvoids between craze fibrils and interfibrillar spacing (14). Using intense x-ray radiation from a synchrotron source, real-time measurements can be performed in a low speed and frequency range (15–19). Thus, some insight into stretching and buckling of craze fibrils during fatigue (17) and in development of crazes in PC during loading is gained (18).

Small-angle light scattering (sals) can be used if polymers are able to scatter light because of density or birefringence fluctuations in the order of wavelength of the light, eg, in the case of spherulites.

Small-angle scattering of electrons (saes) (15) can be performed in a tem using ultrathin specimens, yielding long periods of regular deformation structures (eg, craze fibrils). However, electron diffraction is seldom used for research of polymeric materials, since it needs a very long camera length and, therefore, a high apparative expenditure. A recent, and very convenient alternative method is the Fourier transform analysis of electron micrographs (2).

Small-angle neutron scattering (sans) enlightens the fluctuation of density, concentration, and magnetic properties in the material and, therefore, it enables investigation of changes of conformation of macromolecules and makes it possible, in combination with the other scattering techniques, to compare structures of crazes grown in samples of different thicknesses (19).

Interference Optics

In transparent materials, the classical methods of light-optical interference are widely used in the determination of small dimensions that are of the order of the wavelength of light. Successful applications are investigations of the micromechanics of crazes at crack tips in transparent glassy thermoplastics (20). Usually, fracture-mechanics specimen are used with an artificial crack and a craze ahead of the crack tip. The specimen, with a polished surface adjacent to the optical arrangement, is illuminated in reflection with monochromatic light under normal incidence and normal to the crack plane. Typical fringe systems appear because of the interference between reflections from the two crack faces and at the two boundaries between crazed and uncrazed material. From the accurately determined positions of the individual fringes and with the knowledge of the refractive index of the craze, the crack openings and craze thicknesses can be calculated.

The interference-optical method can easily be applied to static or very slow-moving cracks. Special experimental arrangements are necessary to investigate short-time problems of fast-moving cracks or high frequency fatigue.

Other optical methods include the shadow-optical method of caustics based on the deflection of light by the elastic-stress field around the crack tip. It gives direct information on the stress-intensity factor or the strain–energy release rate (21).

Spectroscopic Techniques (Rheooptical Methods)

A rheooptical method includes a mechanical test under static conditions (tensile test, stress relaxation, cyclic test) carried out simultaneously with an optical measurement. Among other optical methods such as x-ray scattering, nmr spectroscopy, polarized fluorescence or birefringence, the Fourier transform infrared (ftir) spectroscopy has become one of the most frequently applied tools in rheooptics (22). Advantage of infrared spectroscopy is its sensitivity, rapidity, and the ability to investigate changes of molecular orientations not only in separate structural units but also in various phases of multiphase systems. From the ratio of intensities of beams polarized parallel and perpendicular to the deformation direction, orientation functions can be calculated.

The ftir measurements can be performed both in transmission and in reflection mode. The transmission mode requires thin samples with thicknesses up to 500 μm depending on the nature of the material and the intensity of the interesting bands. No limit is in the reflection mode, but an extremely flat sample is required. The difficulty of rheooptical ftir spectroscopy is to find suitable bands for quantitative orientation measurements.

Microindentation Hardness

The indentation test is one of the simplest ways to measure mechanical properties of a material. The micromechanical behavior of polymers and the correlation with microstructure and morphology have been widely investigated over the past two decades (23). Conventional microindentation instruments are based on the optical measurement of the residual impression produced by a sharp indenter penetrating the specimen surface under a given load at a known rate. Microhardness is obtained by dividing the peak load by the contact area of impression. From a macroscopic point of view, hardness is directly correlated to the yield stress of the material, ie, the minimum stress at which permanent strain is produced when the stress is subsequently removed.

Although hardness derived from residual impression measurements is an indicator of the reversible plastic deformation processes, information about elastic release of the indentation depth is mostly lost. Continuous load-displacement monitoring (as the indenter is driven into and withdrawn from the film) substitutes the imaging method used in conventional microindenters. The need to characterize the surface of very thin films and near surfaces has led to the development of ultra- and nanoindentation testers with indentation depths within the submicrometer scale

Other Techniques

Additional details of micromechanical properties can be studied using several other techniques. These additional techniques include the following:

(1) **Dynamic mechanical relaxation tests:**

measurement of molecular mobility in different polymer phases as a function of temperature (24).

(2) **Nuclear magnetic resonance (nmr):**

determination of molecular mobility (25).

(3) **Electron spin resonance (esr):**

measurement of chain scission and radical formation (13).

(4) **Acoustic emission (AE):**

study of fracture processes, eg, rupture of fibers in fiber-reinforced thermoplastics (26).

(5) **Acoustic microscopy (ultrasound acoustic microscopy):**

determination of cracks near a surface (27).

Classification of Micromechanical Properties

The mechanical behavior of materials under stress can be graphically illustrated by macroscopically determined stress–elongation curves and characterized by typical values of moduli, strength, yield stress, strain, toughness, and others. Different types of stress–strain curves are schematically shown in Figure 3, which are connected with different groups of micromechanical processes.

Type a: Linear increase of load with very high modulus and strength with a low elongation at break; behavior is typical of high strength fibers (eg, highly oriented fibers of PE with ultrahigh molecular weight) and is mainly determined by the structure of microfibrils, appearance of molecular defects, and entanglements.

Types b and c: Nearly linear increase of load with high modulus up to a relatively high strength with quasibrittle fracture (type b) or semiductile behavior (type c) with a relatively small elongation at break. Examples are the amorphous

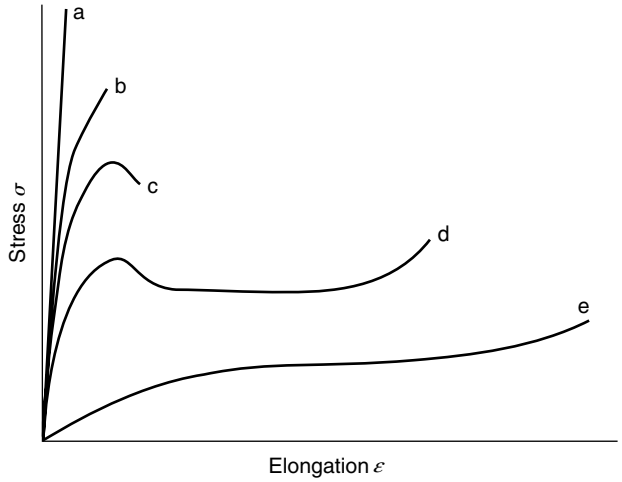

Fig. 3. Characteristic types of stress–elongation curves of polymers. See text for a description of types a–e indicated in the figure.

glassy polymers PS, SAN (styrene–acrylonitrile), and PMMA and the amorphous ductile polymers PVC and PC. Micromechanical properties are connected with local yield processes (see "Plastic Deformation Processes" below).

Type d: After a more or less pronounced yield point at a medium stress, a large elongation appears at nearly the same load (cold drawing). The ductile fracture can be preceded by an additional increase of load (strain hardening). Typical examples are the rubber-toughened or high impact polymers (HIPS, ABS, ACS) and the semicrystalline polymers PE or PP. Micromechanical mechanisms are discussed below in "Toughening Mechanisms," "Yielding in Semicrystalline Polymers," and "Yielding in Block Copolymers."

Type e: Slow and continuous increase of load, homogeneous deformation, and fracture at large elongations. This behavior is typical to rubber and rubber-like materials.

The curves in Figure 3 illustrate the deformation behavior of different polymers at room temperature. However, nearly all polymers can be made to show tensile engineering stress-engineering strain curves a–e dependent on temperature, strain rate, geometry, and stress state.

Plastic Deformation Processes in Amorphous Homopolymers

Local plastic deformation processes in amorphous glassy or semiductile polymers (corresponding to curves b and c in Fig. 3) may appear at different scales, and are sketched in Figure 4. Also in macroscopic brittle materials, macromolecular segments are deformed (eg, by stretching or disentanglement) until chain scission and microvoid formation occur at highly localized places of stress concentration on a microscopic scale (nanometer scale). A relatively sharp crack propagates without large energy absorption and produces a brittle fracture (on the top in

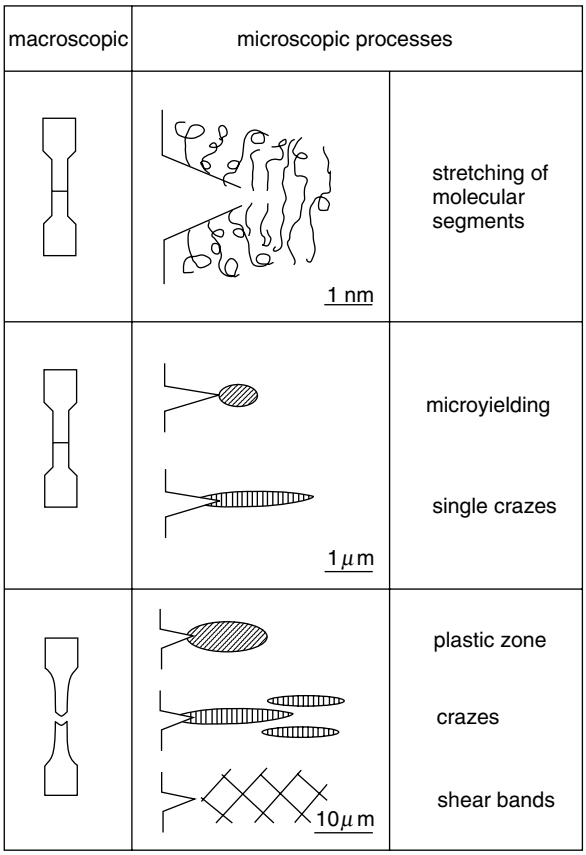

Fig. 4. Schematic representation of basic mechanisms of local, plastic deformation on different scales in amorphous polymers (group I mechanisms). The left shows what is visible on the macroscopic scale, while the center illustrates the microscopic processes, as described on the right (hatched areas are plastically deformed).

Fig. 4). Semibrittle materials show a small volume of plastically stretched polymeric material ahead of a crack tip on a micrometer scale, eg, in the form of crazes or shear bands. Macroscopic fracture is quasibrittle or semiductile, occasionally with necking. Larger plastic deformation involves large volumes on a mesoscopic scale (10-μm scale), including formation of larger or multiple crazes or shear bands. In this sequence (from top to bottom in Fig. 4), the plastic deformation involves larger volumes, yielding an increase in the amount of energy absorption (an increase of toughness).

Crazing in Amorphous, Glassy Polymers. Deformation structures typical of amorphous, glassy polymers are the so-called crazes. Crazes are long, narrow plastic deformation zones, sharply delimited from the surroundings (28). Polymeric material is to a high degree plastically deformed in crazes (in PS usually up to about 150–250%). Figure 5a shows a craze in PS having well-ordered thin fibrils of 5–20 nm in diameter, running in the direction of tension, whereas the longitudinal directions of the crazes are perpendicular to the tension. An

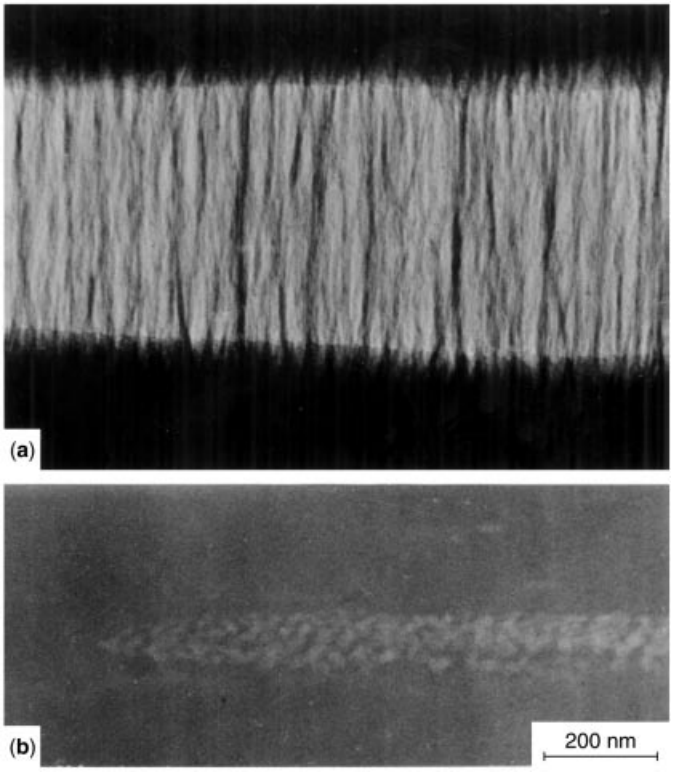

Fig. 5. Structure of a craze in PS (deformed semithin section in HVEM). (a) Fully developed craze with a clearly pronounced fibrillation; (b) domain-like structure of a pre-craze ahead of the true craze.

advantageous method of determining the center-to-center distance of fibrils is optical diffraction of electron micrographs, proving center-to center distances of 10–50 nm (2). The structure first visible ahead of the craze tip, ie, in the transformation or processing zone of the craze, is shown in the micrograph of Figure 5b, revealing bright "domain"-like spots of 20–50 nm in diameter. There is a critical minimum diameter $d_{\min}$ of less than 20 nm of the domains. These domains appear brighter than the surrounding material as they are slightly plastically deformed. All domains are arranged in a narrow band with a thickness of a few tens of nanometers and a length of usually some micrometers. These zones ahead of the fully developed crazes are called "pre-crazes" (2,29). They considerably contributed to better understanding of the formation mechanism of crazes.

The initiation and formation of crazes can be discussed in connection with the entanglement model (30,31). In amorphous polymers, the macromolecules are assumed to form topological links, ie, the so-called entanglements, responsible for strength and deformability of the polymeric material. Entanglements are formed only if the length or molecular mass of macromolecules are high enough (existence of a critical entanglement molecular mass, about 17,500 for PS). Adjacent entanglements can be considered to form a network. The average diameter of the

meshes of this network in PS is about 15 nm (with an entanglement distance of ~10 nm). The material between the entanglements (ie, in the meshes of the network) is assumed to be mechanically weaker. During stretching, the meshes are preferentially deformed, yielding the domain-like structure of the pre-crazes (Fig. 5b). After stronger deformation the domains rupture, forming microvoids. The entangled material between these microvoids is plastically stretched and transformed into the fibrils of a developed craze (Fig. 5a). During this process the microvoids coalesce partially and are transformed from a closed cell structure into an open cell structure. This crazing mechanism based on such an "entanglement network model" or "domain model" (31) probably describes details of formation of fibrillated crazes better than other models.

The fibrillar structure of the crazes is typical of PS. Another glassy polymer is styrene–acrylonitrile (SAN) copolymer with a PS content of usually about 74%. In this material the dominant deformation structures are homogeneously deformed zones, but in many cases they coexist with the fibrillated crazes (2,29). Depending on the loading conditions (stress state, loading velocity, temperature), the deformation character can be shifted from one to another. Another typical glassy polymer is PMMA with a typical appearance of homogeneously deformed crazes at room temperature (29).

Measurement of microindentation experiments on crazes in the micron range revealed additional information about micromechanical properties of the craze fibrils (32). The craze zones' microhardness was determined and the elastic moduli of the crazed material were calculated from the elastic recovery curves of indentations. The crazes were created in miniaturized tensile samples of some amorphous polymers (PS, SAN, PMMA, PVC) during slow crack propagation under fatigue loading at room temperature. The calculated elastic moduli of the stretched material inside the crazes are higher than those of the bulk material. This is consistent with the concept of the oriented entanglement network and the highly oriented polymer chains within the craze.

The transition from the undeformed glassy polymer to the highly plastically deformed crazes at temperatures below the glass-transition temperature can also be discussed in connection with the universal appearance of multiple glass-transition of macromolecules (33). The basic idea is that a localized stress concentration increases the local free volume and reduces locally the glass-transition temperature to the level of test temperature. Therefore, the increase in external stress results in a step-by-step transition from the glassy behavior of the undeformed polymer material to more flexible modes and a mobile state of macromolecules. The rapid changes of macromolecular mobility in dependence on stress state were demonstrated by electron microscopy of the pre-craze structures and the corresponding real crazes (34).

Although crazes are typical of amorphous glassy polymers, crazes or craze-like features have also been observed in many other amorphous polymers (see below), semicrystalline polymers (eg, in PE, PP, PA), and in rubber-modified high impact polymers (eg, HIPS, ABS). In the literature they were often designated as microcracks, deformation zones, or yield zones (28).

Yielding in Amorphous Ductile Polymers. Typical amorphous ductile polymers are PVC and PC. Deformation at room temperature results in the

formation of shear bands or homogeneous deformation bands (2,29). It is generally accepted that crazes with a fibrillated internal structure appear if the entanglement density is low, ie, if the distance between entanglements is large (as in PS) (28,30). With decreasing entanglement distance (or molecular weight), there is a transition to a finely fibrillated form of crazes and to homogeneous deformation bands.

The influence of entanglement density on internal structure of crazes and deformation bands can be demonstrated by a special effect in PC (as an example of a high-temperature-resistant polymer). Usual bisphenol A polycarbonate (BPA-PC) shows a glass-transition temperature T_g of 148°C and chemically modified versions on the base of trimethylcyclohexane (TMC-PC from Bayer AG) reach a T_g of 238°C because of a reduced chain mobility. Because of the good compatibility with usual PC, blends with T_gs between 148°C and 238°C are available (35). Here, blends with T_g of 180°C and 200°C are used (called PC-2 and PC-3, respectively). The usual PC as well as the types with higher glass-transition temperatures show a characteristic transition in the deformation behavior. At room temperature and somewhat higher temperatures, typical shear bands and homogeneous deformation zones appear. At temperatures between 60 and 80°C below the particular glass-transition temperature, there is a transition into the formation of fibrillated crazes. With increasing deformation temperature, the fibrillation of the crazes becomes coarser (increase of the long period of fibrillation). This effect is summarized in Figures 6 and 7.

These transitions in the deformation character can be understood by processes on the macromolecular level. With increasing temperature, the stress necessary for thermally induced disentanglement drops more rapidly than the stress necessary for molecular mobility (yield stress). There are three regions depending on temperature of deformation:

(1) $T \approx$ RT (well below T_g): High entanglement density and high macromolecular mobility (yield stress lower than disentanglement stress) result in homogeneous yielding (shear bands and deformation zones).
(2) $T \approx T_g - \Delta T$ (ΔT = 60–80°C): Thermally induced disentanglement (reduced disentanglement stress up to the range of yield stress or reduction of entanglement density) results in the transition from homogeneous yielding to crazing.
(3) $T < T_g$ ($T \approx T_g$): Intense thermally induced disentanglement (lower disentanglement stress than yield stress) results in coarsening of craze structure with increasing fibril thickness and fibril spacing.

The effect of coarsening of the fibrillar structure of crazes with increasing temperature below the glass-transition temperature has been also found in SAN and PC by electron microscopy and saxs (34).

Fibrillated crazes are usually thinner than the homogeneous deformation bands. Therefore, the whole content of polymeric material, which is plastically deformed, is smaller in the crazes and larger in the shear bands or deformation zones. The result is shown macroscopically in the unusual effect of a decrease of toughness and an embrittlement with increasing temperature.

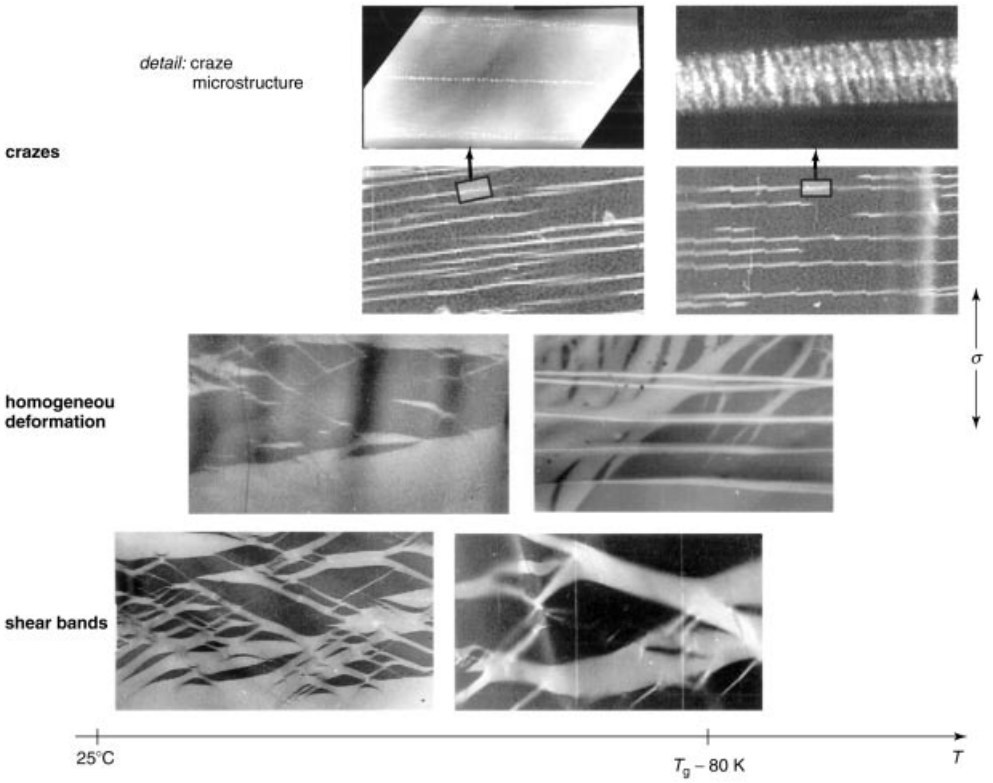

Fig. 6. Influence of the deformation temperature T on type and internal structure of deformation zones in PC (RT = room temperature, T_g = glass-transition temperature; deformed thin specimens, 200-kV tem).

Fig. 7. Mechanisms of Enhancing the Toughness in Heterogeneous Polymers

The toughness of a material can be enhanced by increasing the ability of the material to deform plastically. This is achieved in toughening mechanisms (see IMPACT RESISTANCE). The idea common to all of these mechanisms is the initiation of a very large number of very small local yield events. Mechanisms that have been discussed and that have been carried out in practice are sketched in Figure 8. Type A involves the initiation of a large number of microcracks by (usually) inorganic particles, short fibers, or something similar; because the increased energy absorption occurs only through the creation of new internal surfaces, a noticeable effect is to be expected only in very brittle material or at low temperatures. In type B, ductile particles, distributed in a brittle matrix, are plastically stretched in the area of the crack tip, bridging the two crack surfaces. This "bridging mechanism"

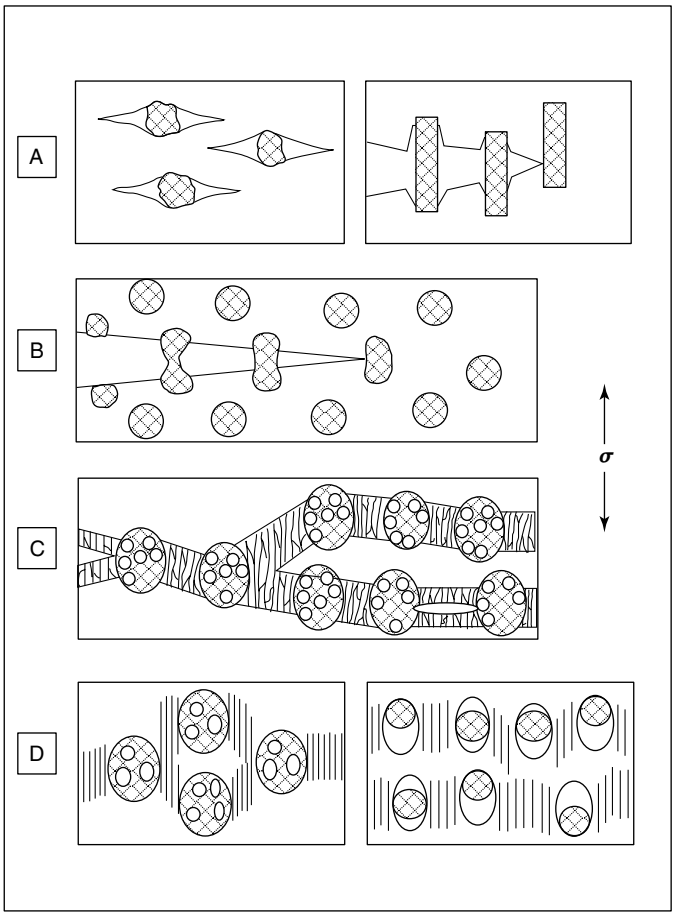

Fig. 8. General mechanisms of enhancing the toughness of structurally modified polymers-group II mechanisms (in the boxes the crosshatched areas are inorganic particles, fibers or weak (rubber-like) particles distributed in a bulk matrix polymer; σ indicates the applied tension stress).

is also effective only in brittle materials, such as in epoxies (of course, it appears also in rubber-toughened polymers, but not as a main energy-absorbing factor). Types C and D behavior involves the initiation of a large number of small plastic zones (crazes or shear bands), induced by stress concentration at soft structural heterogeneities, eg, rubber particles. While in type C stress concentration at the soft rubber particles is sufficient for craze initiation [this mechanism is the typical mechanism of high impact polystyrene (HIPS)], in type D cavitation inside or at the particles is necessary for intense plastic yielding between the particles (typical of toughened semicrystalline polymers such as toughened PP or PA).

A precondition of toughness enhancement is prevention of premature crack propagation; there are some "crack stop mechanisms" including effects of crack tip blunting, reduction of critical stress concentrations, or reduction of crack length and crack propagation velocity (2).

Toughening of a brittle matrix polymer by rubber particles with a volume content of about 5–25% is of major importance to the plastic industry. It has proved so effective that the technology has been extended to almost all of the commercial glassy thermoplastics (including PS, SAN, PMMA, PVC), many semicrystalline polymers (such as PP and PA), and several thermosetting resins. Rubber toughening of polymers involves three important steps of deformation, which can be summarized in a so-called "three-stage mechanism of toughening" (2,36) (see Fig. 9).

(1) The first step at individual rubber particles is stress concentration σ_K and often cavitation inside the rubber particles.
(2) If the particle volume content is in average above 10%, a remarkable superposition of the individual particle stress fields appears. The result is a higher stress concentration σ_K' and the more intense initiation of local matrix yielding in the form of fibrillated crazes, homogeneous crazes, or shear yielding.
(3) The third step is stabilizing the deformation structure by preventing a premature crack propagation (by crack stop mechanisms such as limitation of crack length or crack tip blunting at or in the rubber particles) and by stabilizing the rubber particle cavities due to the plastically deformed adjacent rubber and matrix strands.

The dominant matrix deformation mechanism depends mainly on the type of matrix material, but strongly also on test temperature, strain rate of testing, and on type, shape, and size of rubber particles (2,36–38). Fibrillated crazes are typical of toughened PS (HIPS), a coexistence or a transition from fibrillated crazes to homogeneous ones is typical of toughened SAN (ABS), homogeneous deformation appears in many grades of ABS, toughened PVC, and toughened PMMA. Shear yielding is the dominant mechanism of the toughened semicrystalline polymers PA and PP.

Rubber toughening is often assumed to be identical to the modification by rubber particles. However, there is an alternative and also very effective possibility of rubber toughening of amorphous polymers—the *rubber network toughening* (2). Here, small thermoplastic particles, eg, PVC particles (about 1 μm in diameter),

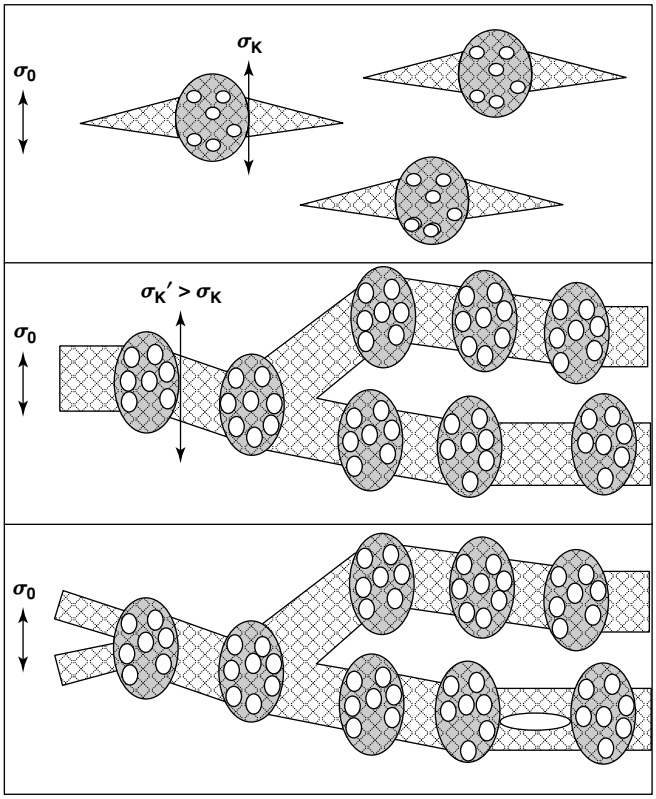

Fig. 9. Schematic presentation of the three-stage mechanism of toughening with multiple initiation of local yield events (eg, crazes as in case C in Fig. 8).

are embedded by a network or honeycomb structure of rubber (for instance EVAc). Since there are very tiny network layers in the range of a few tens of nanometers, the rubber content is usually below 10%, ie, the PVC content reaches more than 90%. During loading, the rubber network is stretched, which initiate the PVC particles to yield and to absorb deformation energy. A deformation mechanism similar to the network toughening is the so called *inclusion yielding*, where stiffer thermoplastic particles are distributed in a somewhat softer matrix (eg, SAN particles distributed in a PC matrix) (39). Under load, the particles are forced to deform plastically. Both mechanisms demonstrate the possibility to transform stresses via a softer matrix, which are high enough to reach the yield stress of the stiffer particles.

Most of these micromechanical processes are highly localized and depend strongly on the local morphology. Therefore, direct imaging by electron microscopy techniques with a high local resolution are of particular importance, and most of our knowledge of rubber toughening arises from the application of such techniques (2,36–38).

Toughened Polymers with Amorphous Matrix. The fundamental deformation step is the formation of crazes in the stress field around the rubber

particles (ie, in the zones of highest stress concentration, the equatorial zones around the particles). It can clearly be shown that crazes start in the matrix directly at the interface to the rubber particles. If the distance between rubber particles is small enough, crazes are intensively formed between the particles (cf Fig. 9).

HIPS deforms generally by formation of fibrillated crazes, whereas many ABS grades show the formation of fibrillated crazes and homogeneous crazes (homogeneous deformation bands, shear deformation). A transition between these deformation modes appear in dependence on loading velocity and particularly on test temperature. Such transitions can be advantageously studied by electron microscopy and using a special tensile holder with cooling and heating facilities (40).

Very fine and well-dispersed morphologies can be obtained by blending the glassy polymer with core-shell particles. Successful materials possess three-stage core-shell particles (40). In the example used here, the particles consist of a single core of PMMA, surrounded by a 20-nm thick inner shell of grafted and lightly cross-linked poly(butyl acrylate-*co*-styrene) (PBA) and an outer grafted shell of PMMA. This PMMA layer is about 10 nm thick, and is sufficiently miscible with SAN or PMMA as matrix materials to provide good adhesion between the modifier particles and the matrix.

The typical micromechanical behavior of this material at room temperature is shown in Figure 10. The lower magnification in Figure 10a shows a dense pattern of cavitated and elongated rubber particles and plastically deformed matrix material between the particles. The matrix deformation occurs mainly in the form of homogeneous shear deformation zones and a small number of short and relatively thin fibrillated crazes (40).

The cavitation mechanism within the modifier particles begins with microvoid formation and fibrillation in the butyl acrylate shell, as shown in higher magnification in Figure 10b. The fibrillated shells with the internal PMMA cores resemble spiders. The fibrils are connected by the PMMA cores, and the cavities in

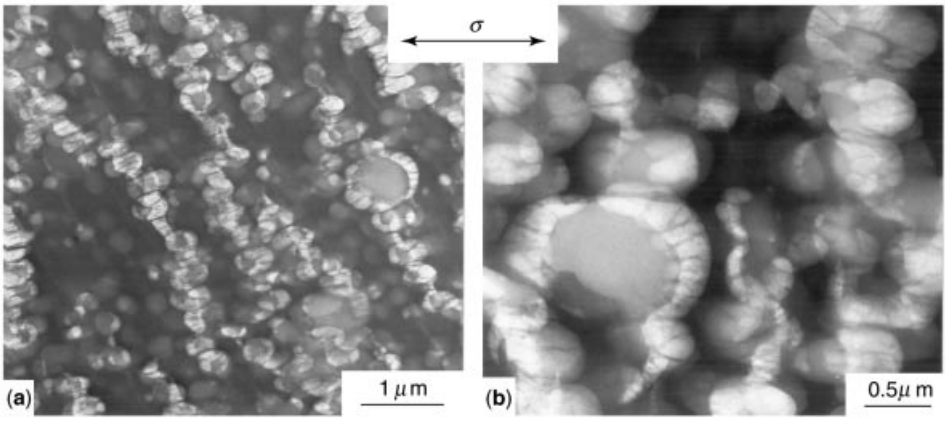

Fig. 10. Deformation structures of an SAN/PBA blend. (**a**) lower magnification; (**b**) higher magnification (tem micrographs, deformation direction, see arrow).

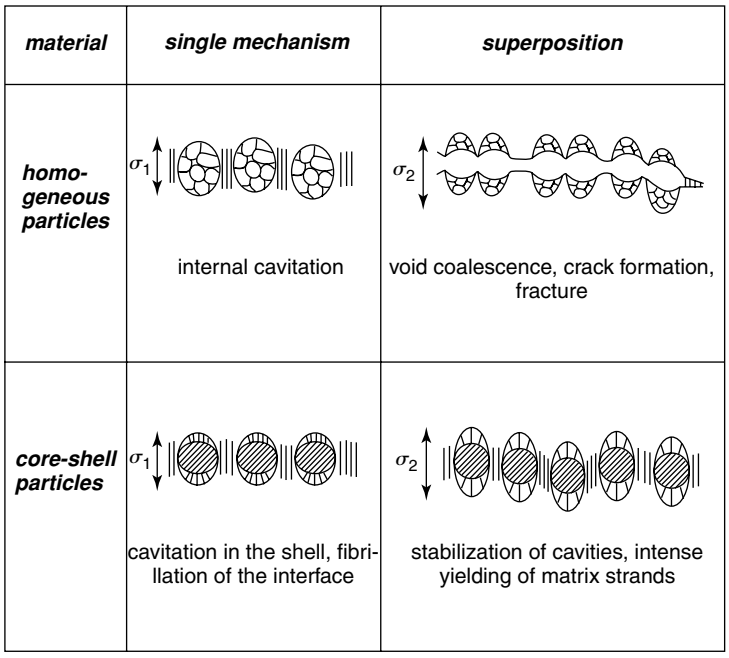

Fig. 11. Comparison of the action of homogeneous and core-shell particles in toughened polymers concerning the single mechanism at particles and the superposition effect between particles.

the PBA shells are limited in their size by the fibrils between the core and the outer shell. This stabilization of cavities by the core-shell structure is an advantage of this type of particles over homogeneous rubber particles. This remarkable difference between homogeneous rubber particles and core-shell particles is sketched in Figure 11. In both cases, the starting mechanisms of cavitation inside the particles, stress concentration at the surface of the particles, and initiation of plastic yielding of adjacent matrix parts are very similar. However, if we consider later stages of deformation, superposition of stresses between the particles occur and differences become visible. In the often possible case of closely connected homogeneous rubber particles, the voids inside the particles can coalesce, leading to larger voids, crack initiation and, consequently, a premature fracture. Using core-shell particles, the individual microvoids are stabilized in their size, and void coalescence is prevented, with the result of an intense plastic yielding of the matrix.

Usually, the hard polymer cores of the modifier particles are not deformed, as is visible in the micrographs of Figure 10. This is usually accepted since it hardly seems possible to deform a glassy polymer core inside a rubbery shell. However, there are results that show that a plastic yielding of the hard cores should be possible: fibrils are drawn out from the PMMA cores, leading to a flattening of the cores. The stretching of the cores into fibrils is very similar to the mechanism of fibril drawing in craze formation. This mechanism of yielding of glassy cores inside modifier particles is a new toughening mechanism, contributing to energy absorption during deformation (1,40). A precondition to this effect is that the rubbery shell of the modifier particles forms fibrils showing a remarkable strain

hardening effect, leading to stresses in the fibrillated shell, which are high enough to draw fibrils from the hard core.

The advantage of core-shell particles to toughen PMMA has been demonstrated by investigation of deformed samples by HVEM (41). Besides core-shell and homogeneous rubber particles, many other types of rubber particles have been studied (eg, cells, drops, coils). A qualitative and quantitative estimation of the size and structure of differently shaped rubber particles on the toughness of modified PS on the basis of detailed electron microscopic studies can be found in Reference 42.

Usually, ABS polymers show a good toughness by an intense formation of stress-induced crazes or homogeneous deformation zones at and between rubber particles. Recently, a surprising effect has been found in some ABS grades: When creep tests were performed with loads well below the yield stress and if the specimens were tested afterwards in the tensile mode, samples broke atypically brittle at a low strain level (43). Such a drastic embrittlement was observed after preloading with stresses between 25 and 55% of the short-term yield stress. Lower and higher preloading stresses yield only a smaller reduction of toughness.

The microscopic investigation revealed the reason of this effect. The materials showing the embrittlement possess a pronounced bimodal distribution of the rubber particles with smaller particles of 50–250 nm and a smaller fraction of bigger ones between 350 nm and 1 μm. During preloading of this material, a few extremely long crazes with lengths up to a few millimeters are formed (Fig. 12). They start at the biggest rubber particles often near the sample surfaces and propagate in a straight line across the material without being influenced by the other smaller particles. It seems that, for the long crazes, the material behaves like a homogeneous material. During subsequent tensile test, cracks can propagate very quickly in these long crazes and initiate the brittle fracture.

This special type of craze, for which ABS had not been known up to now, is called "macrocraze." The formation of macrocrazes correspond to the large distance between the very big rubber particles and can be understood in connection with changes of Young's modulus both of the matrix and the rubber particles during loading. It is known that the moduli of thermoplastics and rubber decrease with decreasing load velocity $\dot{\varepsilon}$ (in tensile test or with decreasing frequency in torsion pendulum test). This is schematically drawn in Figure 12c for SAN matrix and small and big rubber particles, as used in the ABS of Figures 12a and b. The big rubber particles show another constitution than the smaller ones and possess a higher deformability or lower modulus. This is detectable from *in situ* deformation tests of the material in the HVEM (using a technique described in more detail in Ref. 2. Starting with deformation tests with a very high speed (impact test or test at low temperatures below glass-transition temperatures of rubber particles), the modulus of rubber particles is very high, comparable with the modulus of the glassy SAN matrix (the modulus ratio G_R/G_M is nearly 1). Therefore, there is nearly no stress concentration at the rubber particles ($\sigma_c \approx \sigma_0$), and no crazes are initiated. With decreasing test speed (with a load rate in the usual application range or with increasing temperature to room temperature) the modulus of the glassy matrix is unchanged, but the modulus of rubber particles decreases drastically. In this range, the ratios of moduli G_R/G_M are much lower than 1, and the

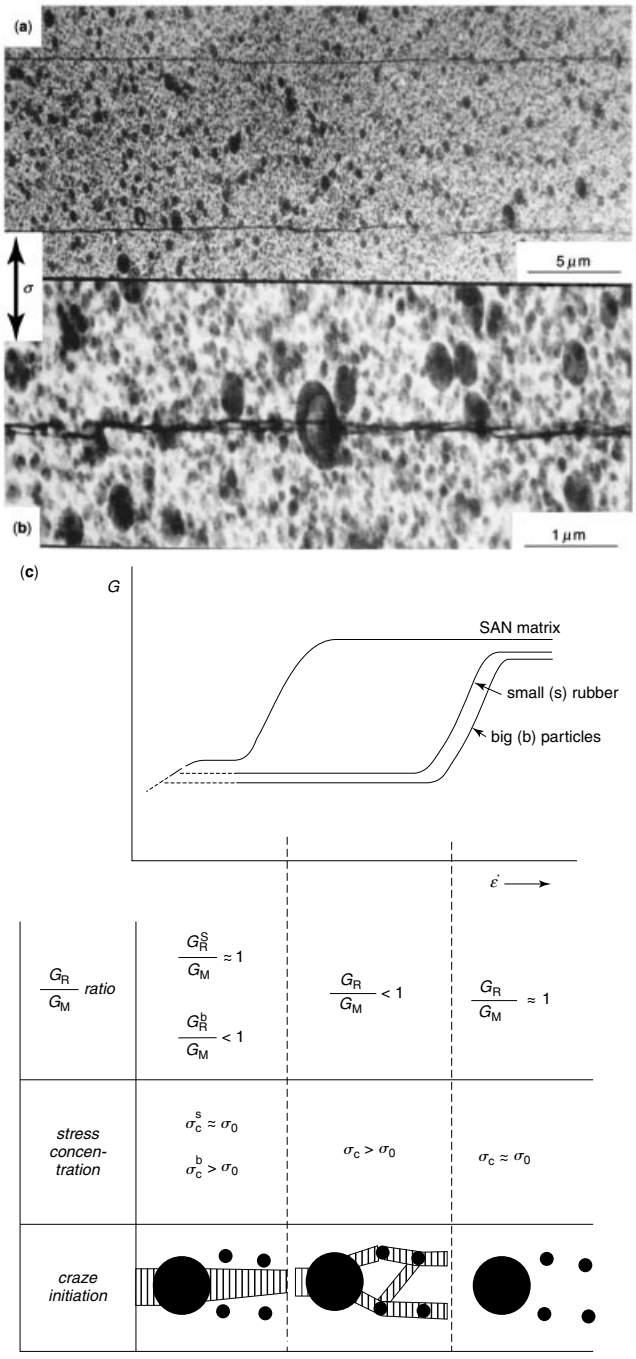

Fig. 12. (**a**, **b**) Formation of very long, tiny crazes (so-called macrocrazes) after preloading in an ABS with only a few large rubber particles (sample preloaded for 166 h with 40% of yield stress, stained with OsO_4, 1-μm thick ultramicrotome section, HVEM). (**a**) general view of two macrocrazes; (**b**) higher magnification of part of a macrocraze; (**c**) schematic of the decrease of the shear modulus G of thermoplastic SAN matrix material and cross-linked rubber with decreasing load rate $\dot{\varepsilon}$ (corresponding to an increased temperature). Below: ratio of moduli G_R and G_M of rubber and matrix, corresponding stress concentration and initiation and propagation of crazes. From Reference 16.

stress concentration at rubber particles reaches a maximum ($\sigma_c/\sigma_0 > 1$). This results in an intense initiation of crazes at larger as well as smaller rubber particles (range of intense plastic energy absorption, range of toughness).

A further decrease of test speed $\dot{\varepsilon}$ down to very low values corresponds to the situation during creep and static preloading. Here, the modulus of the glassy SAN matrix decreases to the level of the rubber. Under the action of a tensile stress this situation can be considered similar to the glass-transition range of matrix material, discussed in detail in References 33 and 34. While the smaller (harder) rubber particles show a modulus similar to the matrix modulus (moduli ratio $G_R^s/G_M \approx 1$) the bigger (weaker) rubber particles are somewhat weaker than the matrix (moduli ratio $G_R^b/G_M < 1$).

Therefore, only the largest rubber particles are able to stress concentrate and to initiate crazes. ABS regions with the smaller rubber particles do not show any differentiation in modulus (they behave like a homogeneous material). Here, the crazes that are initiated at the largest rubber particles propagate without modification and can grow to macrocrazes.

Toughened Polymers with Semicrystalline Matrix. It is well known that toughness of semicrystalline polymers such as PA (polyamide) and PP can be increased similar to the amorphous polymers by the addition of relatively small amounts of rubber particles such as EPR or EPDM. As in HIPS and ABS, the modifier particles act as stress concentrators, initiating a plastic deformation of matrix strands between the particles as the main energy absorption step. In impact-modified PA and PP at room temperature, plastic deformation takes place through shear deformation (mechanism of multiple shear deformation).

In contrast to crazing, shear deformation does not involve dilatation of material, but relief of local plastic constraint by formation of voids and subsequent strain field interactions between voids often enhance localized shear yielding and is an important precondition of effective toughening. Figure 13 shows scanning force micrographs of highly deformed parts of PP toughened by an addition of 20% EPDM rubber particles. The particles are cavitated and fibrillated and, together with the adjacent matrix strands, they are strongly plastically deformed, elongating up to 900%. Details of the influence of particle type, internal structure, and size of particles, as well as of interparticle distance, are discussed in References 36, 44, and 45.

Toughened PP shows a decrease of toughness with decreasing temperature. In stress–strain tests, Young's modulus and strength increase but elongation at break and the area below stress–strain curve (corresponding to toughness) decrease. This change is connected with changes in micromechanical processes. Transmission electron micrographs of PP/EPDM deformed at RT and -40°C are shown in Figure 14. Figure 14b reveals a coexistence of shear yielding and crazing, and Figure 14c shows only formation of fibrillated crazes at and between elongated particles.

The use of core-shell particles has an advantage over homogeneous rubber particles that is very similar to that discussed above (cf Fig. 11). An additional advantage is that they enable a low temperature toughness. Deformation tests of PP with core-shell EPR (ethylene–propylene–rubber) particles at very low temperatures of up to -100°C revealed that the EP shell is cavitated and elongated

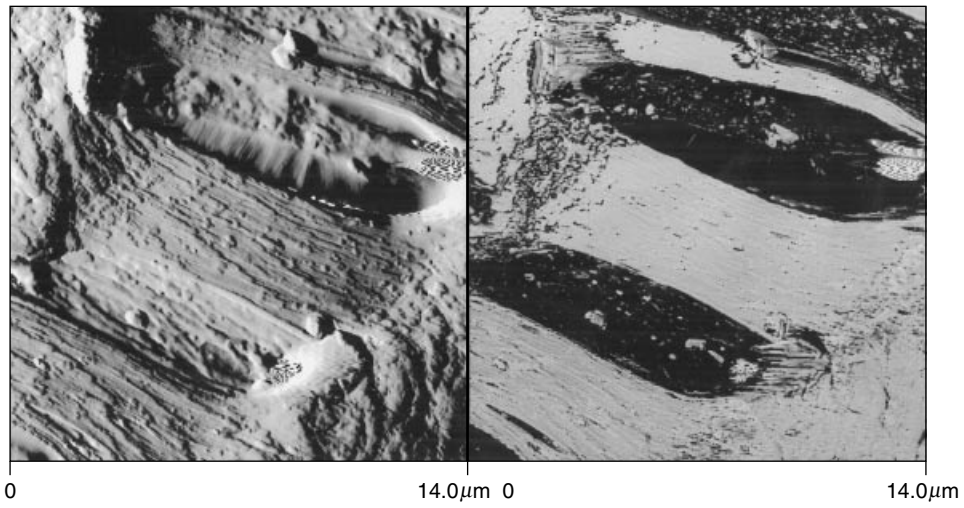

Fig. 13. Scanning force micrographs of a deformed PP/EPDM blend revealing the elongated particles with the highly plastically stretched matrix strands in between (deformation direction from top left to bottom right; sfm tapping mode: left, amplitude signal; right, phase signal).

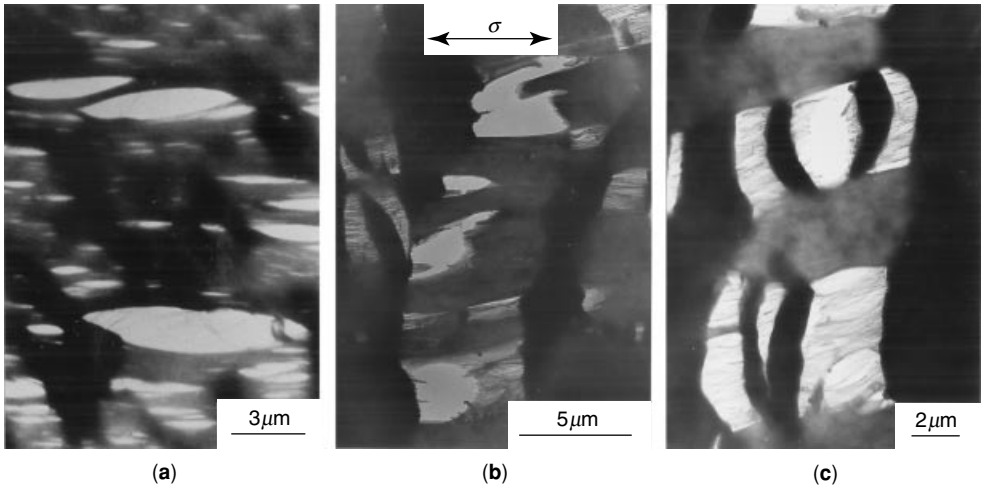

Fig. 14. Deformation structures of PP impact-modified with EPDM at different test temperatures: (**a**) RT – cavitated particles as well as adjacent matrix strands are strongly plastically deformed by shear yielding; (**b**) −40°C—coexistence of shear yielding and crazing; (**c**) −40°C – fibrillated crazes between elongated particles (thin sections, deformed and investigated by hvem (**a**) and tem (**b** and **c**)). From Reference 1.

with fibrillation inside, and the adjacent matrix parts show fibrillated crazes (1). It is an effect far below the glass-transition temperature of the rubber phase, and it demonstrates that toughening processes are not limited by the glass-transition temperature of modifier particles. The important step is local stress concentration at the voided particles, which initiate the formation of crazes. These micromechanical results reveal that it should be possible to increase low temperature toughness

of PP and other semicrystalline polymers. Essential structural preconditions are the use of modifier particles that are able to cavitate and to stabilize cavities so as to avoid growth of voids into cracks.

Polymer Blends. The aim of producing polymer blends is to improve different properties and to reduce costs. There are many publications and books, which review preparation and structure of multiphase polymer blends (38). A central problem is to realize an optimum morphology, eg, an optimum size of particles of the polymer, which is in the minority in a matrix of a polymer in majority. One attractive route to multiphase polymeric materials, which promotes high interfacial adhesion and excellent morphology control, together with related mechanical properties, is *in situ* formation of compatibilizing during reactive blending. Using compatibilizers, the size of dispersed particles in a matrix can be decreased. As shown in Reference 46, the size of PA 6 particles in a PP matrix can be drastically reduced using increasing amounts of an SEBS-*g*-MA compatibilizer, however, not the smallest, but an optimum size and constitution of particles yielding the best properties.

Often, blending a polymer with particles of a second polymer is connected with an increase of toughness. As an example, blends of a metallocene-based high density ethene/1-hexene copolymer (HDPE, density 0.93 g/cm^3) with 20 vol% of an elastomeric ethene/1-hexene copolymer (VLDPE, hexene content 17.2 mol%, density 0.867 g/cm^3) were used as model blends to study the morphology development and the micromechanical behavior (47,48). Use of the sfm tapping mode and a special force modulation technique enabled local deformations of the sample and changes in the morphological structures in a defined specimen area to be recorded directly while the external elongation was successively increased. In order to carry out *in situ* deformation experiments, the sfm was equipped with a deformation unit and a periodic pattern was evaporated on the back side of the sample. Figure 15 illustrates the positioning of the sample. The optical micrographs show an overview (Fig. 15a) of the sample with the evaporated pattern and two artificial notches (diffuse black areas) on the left and on the right, and in Figure 15b the marked area in the sample center. The sfm phase signal image in Figure 15c shows the blend morphology with elastomeric particles (appearing bright) in the HDPE matrix with crystalline lamellae (occurring dark owing to their higher stiffness in comparison to the adjacent interlamellar amorphous areas).

The micrographs of Figure 16 illustrate typical results of the sfm *in situ* tensile test. The images show a sample area of 2 μm $\times$ 2 μm marked in Figure 15c before deformation (at the top) and after a deformation of about 35% (at the bottom). On the left, the height signal images show the surface topography, and on the right-hand side, the sample is visible in phase signal images. A comparison of the micrographs shows that the area between the dotted lines is nearly homogeneously strained. However, deformations on the submicron range are strongly inhomogeneous. Especially, the strong deformation of the elastomeric particles is accompanied by a very heterogeneous deformation of the surrounding semicrystalline matrix. Adjacent segments between particles (perpendicular to the load direction) reveal a considerably increased elongation, whereas segments between particles in the direction of loading are nearly not deformed. This correlates with the distribution of stress concentration around soft particles. Additionally, the behavior of crystalline lamellae under stress can

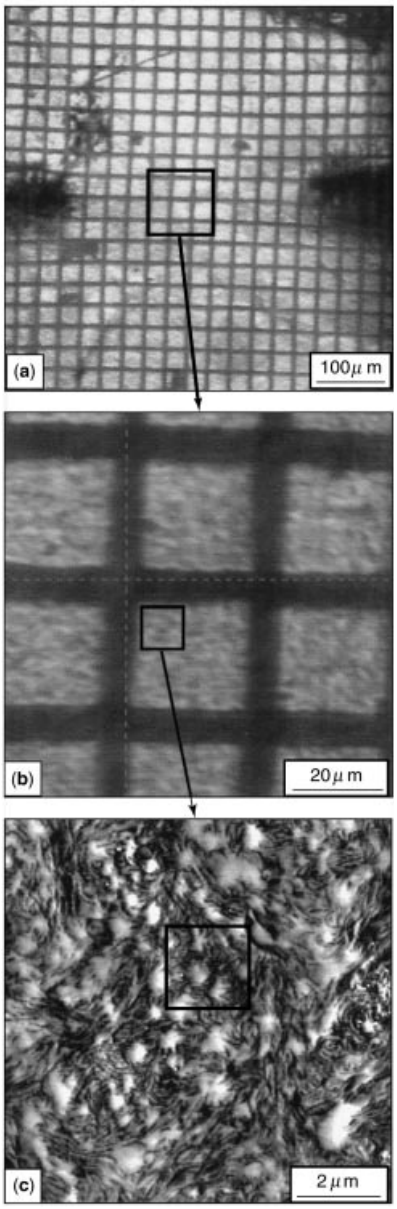

Fig. 15. Specimen from an HDPE/VLDPE blend for *in situ* sfm deformation test with an evaporated pattern to observe an area of interest; (**a**, **b**) optical micrographs; (**c**) sfm phase signal image in tapping mode. From Reference 48.

be directly observed. The appearance of the crystalline lamellae is improved in Figure 17 after an imaging processing by a high pass filter (48). These micrographs very clearly reveal that the lamellae are composed of single crystal blocks (in an appearance as beaded strings). Some types of deformation behavior of lamellae are visible:

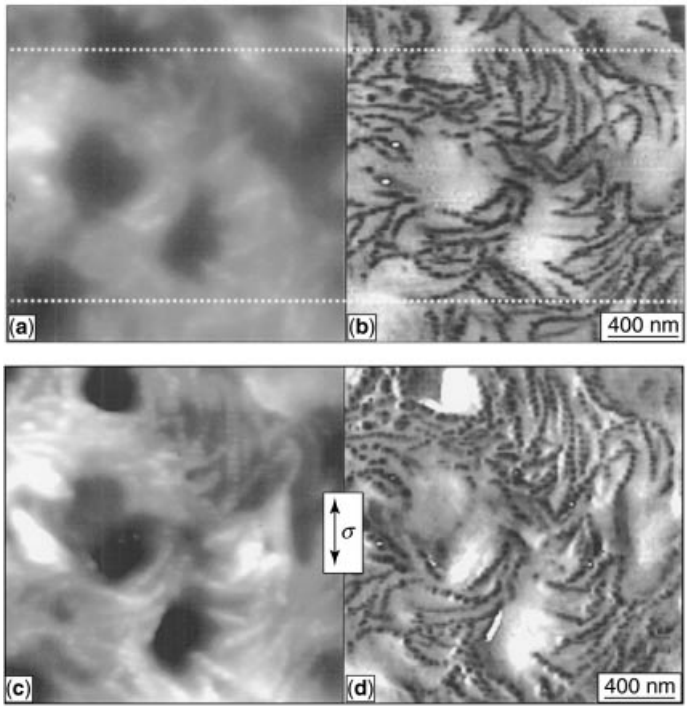

Fig. 16. Marked specimen area from Figure 15 before deformation (**a**, **b**) and after deformation (**c**, **d**) in sfm tapping mode height images (**a**, **c**) and phase signal images (**b**, **d**). From Reference 48.

(1) Lamellar segments perpendicular to the loading direction (segment between the points A and B in Fig. 17) rotate in stress direction without changing the segment length.
(2) Lamellae aligned in loading direction (segment between points C and D) are stretched with an increasing separation of the crystalline blocks.
(3) Lamellae in other orientations show a combination of both effects; for example, segment between the points E and F reveals a rotation and an elongation.

Yielding in Semicrystalline Polymers. In the literature, it is often assumed that the large plastic deformation of the semicrystalline polymers such as PE or PP is a continuous orientation of the chain segments in the deformation direction (ie, a continuous change in the *c*-texture). This assumption is mainly based on x-ray scattering measurements. The result of steadily increasing *c*-axis orientation is based on averages from a relatively large volume of a sample. Direct electron microscopic investigations revealed that the improvement of the *c*-axis orientation results from a superposition of several local deformation processes. In detail, the orientation of PE has been divided into three stages (2,4,49). In the first stage, mainly the amorphous, interlamellar parts contribute to the deformation.

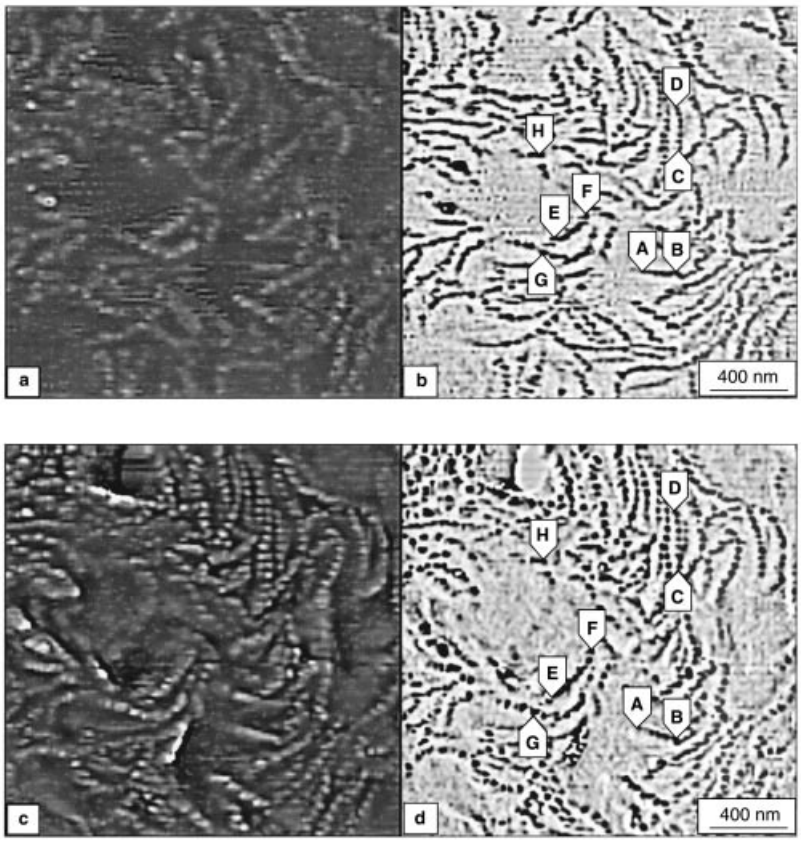

Fig. 17. Micrographs of Figure 16 after additional image processing; the capitals mark lamellar segments under different degree of deformation (eg, twisting, stretching, block separation). From Reference 48.

Larger lamellae can break into shorter pieces, and the lamellae tend to twist with their length direction toward the deformation direction. The processes of twisting and orientation of the lamellae do not appear homogeneously in the whole sample. There are smaller regions with a pronounced or stronger orientation and others with a weaker one. This makes clear that the deformation at the beginning strongly depends on the yield properties of the amorphous material between the lamellae. In the second stage a transition from the lamellar appearance into a microfibrillar arrangement occurs, with the improvement of the *c*-axis orientation in the third stage.

Some aspects of the first stage of deformation are visible in the *in situ* deformation test of a PE blend by sfm in Figures 16 and 17 and are also revealed by tem studies of crack-tip crazes in PE (48).

Yielding in Block Copolymers. While polymer blends show macrophase-separated morphologies, which often lead to a deterioration of mechanical properties because of the immiscibility of the components, in block copolymers microphase-separated structures at the typical size scale 10–100 nm

are observed. A wide spectra of mechanical properties and micromechanical deformation mechanisms are observed in such block copolymers attributable to the existence of a large variety of highly ordered microphase separated morphologies with a periodicity in the range of radius of gyration of the copolymer molecules (50,51). While a great deal of work has been carried out on morphology and phase behavior of these fascinating materials, only a little has been done regarding the correlation between morphology, mechanical properties, and underlying micromechanical processes of deformation and fracture.

Pioneering works on the micromechanical deformation mechanisms in block copolymers date back to the mid-eighties when cavitation mechanism in styrene–butadiene (SB) diblock copolymers containing PB cylinders in a PS matrix was proposed (52,53). Based mainly on tem investigations, a two-step craze growth mechanism was proposed:

(1) In the first stage the PB cylinders are strongly deformed till the cavitation stress of PB is reached. As a consequence, the PB cylinders cavitate resulting in the formation of voids.
(2) In the second step PS is plastically deformed by local stress concentration resulting in a cellular deformation structure.

Mechanical behavior of block copolymers are governed by the molecular architecture (AB diblock, ABA or ABC triblock, $(AB)_n$ star block, etc), symmetry of the blocks, and microphase-separated morphology (50). Most extensively studied and more interesting from the technical point of view are SBS triblock copolymers based on polystyrene and polydienes (PB or PI), where the outer glassy styrene blocks physically cross-link the elastomeric B phase at both the ends. In SBS triblock copolymers of sufficient molecular weight, the mechanical properties can be tailored simply by adjusting its composition. Thermoplastic elastomers having dispersed glassy phase (spheres or hexagonally arranged cylinders) in a rubbery matrix like Kraton (Shell Chemical Co.) or Styroflex (BASF AG) have elongations at break that are severalfold and tensile strengths above 30 MPa. These high values are contributed with stretching the elastomeric network and rotation and orientation of the dispersed phase. The tem, ftir spectroscopy, and saxs studies of SBS triblock copolymers with styrene cylinders revealed that the initial stage of tensile deformation is governed by preferential orientation of elastomeric chains and later stages by a breakdown of the glassy domains (54).

Another class of copolymers having interesting mechanical properties are weakly segregated block copolymers. One of the most striking effect observed in these block copolymers is a synergism in tensile properties (51,55,56). In a certain composition range, the tensile strength was found to exceed that of pure PS, as illustrated in Figure 18. Irrespective of the block copolymer architecture (diblock, triblock, or star block), this effect was observed and shows that it is attributed to the widened interface resulting from enhanced phase mixing. Therefore, in triblock copolymers this synergistic effect occurs over a broader composition range than in diblock copolymers because of enhanced miscibility of triblock copolymers. The deformation structures observed in these block copolymers depend in detail on type and orientation of the microphase-separated morphology. Particularly interesting are the mechanisms of “craze termination,” “craze tip blunting,” and

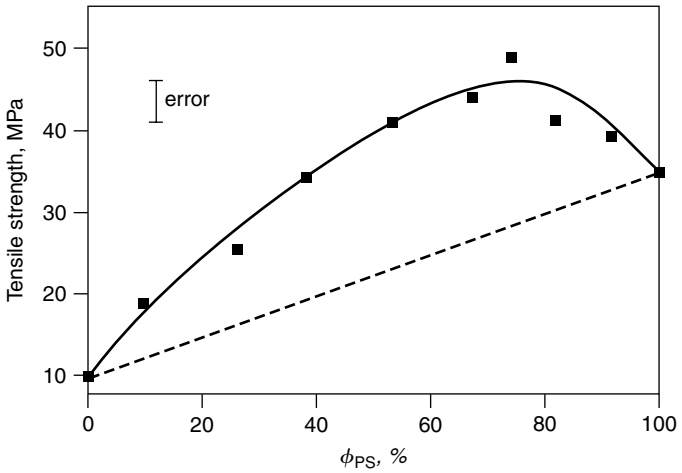

Fig. 18. Dependence of tensile strength on volume fraction of PS for PBMA-*b*-PS-*b*-PBMA triblock copolymers and pure PS and PBMA (strain rate 1.6×10^{-4} s^{-1}). From Reference 51.

"craze deviation" during propagation of crazes through an arrangement of stacks of lamellae (51,55).

A craze in a block copolymer with lamellar morphology is shown in Figure 19a with an internal structure of highly extended craze fibrils of PS and PBMA. The PBMA lamellae are cavitated and, therefore, appear brighter than the dark, thicker PS lamellae. Because of the microvoids in the PBMA lamellae, a stress concentration is built up in the adjacent PS lamellae that initiate a large plastic deformation of these PS lamellae. This is similar to the mechanism as described by Argon for PS-*b*-PB diblock copolymers (53). The diameter of the PS fibrils is 15–25 nm with long periods of about 100–130 nm. In the undeformed material the PS lamellae are about 80–90 nm thick. This is much larger than

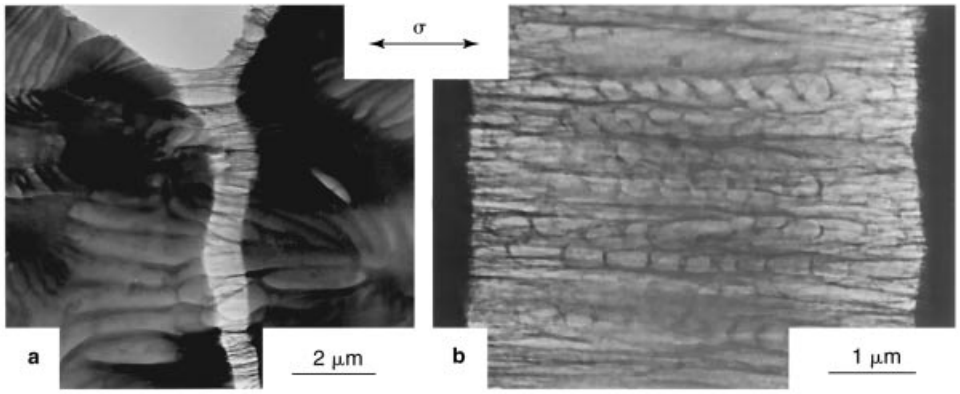

Fig. 19. hvem micrographs of crazes in PS-*b*-PBMA diblock copolymers with different morphology. (**a**) Lamellar morphology, PS volume content 67%; (**b**) Hexagonally packed PBMA cylinders, PS volume content 76%.

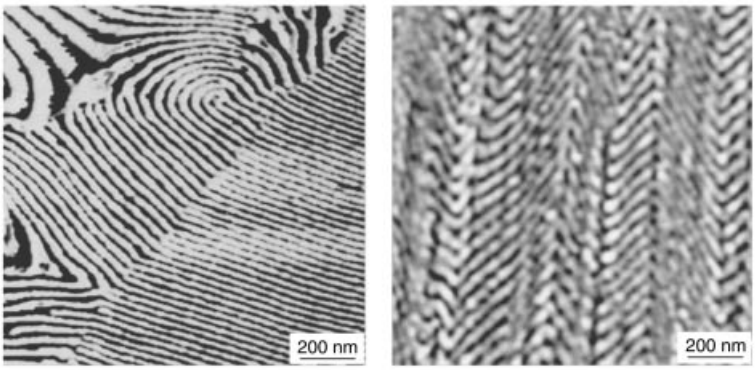

Fig. 20. Tapping mode sfm images of a lamellar SBS triblock copolymer before (left) and after deformation (right); deformation direction vertical, PS phase appears light.

the thicknesses of the deformed PS lamellae, clearly indicating their large plastic deformation.

A craze in a block copolymer with PBMA cylinders is shown in Figure 19b with an internal cellular structure of the craze. The PBMA cylinders are cavitated in the craze and, therefore, appear bright. This is followed by a large plastic deformation of the PS parts (appearing dark) up to fibrils.

In block copolymers with lamellar morphology, mechanical properties and deformation structures vary with the orientation of the lamellae with respect to the direction of applied load. When the material is loaded in a perpendicular direction to the lamellar orientation, lamellae are folded in a fish-bone-like arrangement (57). Such a lamellar folding in a solution cast film of an SBS triblock copolymer is shown in Figure 20 (58).

Nowadays, star-block copolymers are earning growing interest because of their improved mechanical and rheological properties. Introducing a "tapered chain" and giving the stars a highly asymmetric block structure lead to the evolution of a nonclassical lamellae-like morphology in spite of a very high styrene content (about 75%) and correspondingly high ductility (59). Investigating such asymmetric SB star-block copolymers with alternating PS and PB lamellae confirmed the result of a high plastic deformation of the PS lamellae (60) which is also shown in the crazes of Figure 19. tem micrographs of stained samples of a star-block copolymer with a PS content of 74% show alternating PS and PB lamellae (see Fig. 21a). Thicknesses and long periods of the PS lamellae range between 10–25 nm and 30–50 nm, respectively. Tension of the sample in a parallel direction to the length direction of the lamellae shows a stretching of the whole morphology (Fig. 21b). The PS as well as the PB lamellae are highly plastically deformed in parallel direction to the applied stress. This is clearly indicated by a reduced thickness and long period of PS lamellae up to 7–15 nm and 20–35 nm, respectively (see Figs. 21c and 21d). Here, the lamellae are deformed without any cavitation or microvoid formation and without the formation of local craze-like deformation bands. The deformation of the lamellae reaches elongations up to 300%; this corresponds to the typical elongations of the fibrils inside the crazes in PS.

From Ref. 60.

This homogeneous yielding of PS lamellae together with adjacent PB ones can be considered as a new deformation and toughening mechanism, called *thin layer yielding mechanism*. This effect appears only in thin PS layers with a thickness smaller than a critical thickness (see Fig. 22). This critical thickness D_{crit} is comparable with the maximum thicknesses of the craze fibrils in PS, ie, in the range of 20 nm. The difference between fibril stretching in PS crazes and thin layer yielding of PS lamellae is to be seen in the fact that craze fibrils are stretched between microvoids, whereas the PS lamellae are deformed together with the adjacent PB lamellae.

These results show that the tensile properties of block copolymers, such as stiffness, tensile strength, elongation at break, and toughness, can be improved as compared to those of pure homopolymers, polymer blends, and rubber-toughened polymers. Moreover, this demonstrates the possibility of creating a new class of polymers with improved properties based on materials with structures at the nanometer scale.

MODELING OF POLYMER PROCESSING AND PROPERTIES

Introduction

The properties of polymeric systems are strongly dependent on their structure which is itself fully controlled by the processing conditions. Thus, it is now well accepted that the mechanical strength of polymer fibers steadily increases with an improvement of the orientation of the macromolecular chains (1). This is the reason why fiber spinning is typically followed by a drawing step with the purpose of aligning and extending the chains along the fiber axis. In some applications, the polymer must be processed from solution, and fiber formation itself requires a coagulation step in order to consolidate the polymer into a solid filament suitable for drawing. In that case, the solvent-coagulant exchange at the polymer interface strongly controls the internal structure of the fiber (2), and hence its ultimate tensile strength and elongation at break. In other techniques, fiber formation from solution occurs upon rapid quenching to a lower external pressure and/or temperature (3). In this case, the size and the porosity of the fiber is strongly dependent on the polymer concentration and quenching conditions.

A theoretical description of all the factors controlling the effect of processing conditions on polymer structure and properties is extremely complex because of the need to consider a wide variety of different factors such as polymer concentration, molecular weight, as well as external variables (time, temperature, pressure). In view of this complexity, this work has focused on the development of kinetic Monte-Carlo lattice models. These models are mesoscopic in the sense that the unit lattice length is of the order of the statistical segment length for the polymer chain and atomic level details are omitted. The objective of this review is to describe these models in some detail and show their value in getting a better

understanding of the interplay between processing conditions, polymer structure, and product properties.

Polymer Drawing

This section focusses on polymer deformation in the *solid state*. Models for flow-induced structure and orientation in the *molten state* have been presented in References 4 and 5. Most previous approaches (1,6,7) for describing the deformation of solid polymer systems are essentially phenomenological and static representations which are incapable of providing a unified description of the various morphological changes that may occur depending on the dynamics and on the structure at the molecular level. All these models are incapable of simultaneously providing quantitative information on (*1*) stress–strain behavior, molecular extension, and fracture; (*2*) morphological changes that occur during deformation; and (*3*) the effect of testing variables, such as temperature and strain rate.

One model for the deformation of polymer solids has been described at length in References 8 and 9. It is briefly reviewed here. Figure 1 gives this model representation of the entangled solid polymer network prior to deformation. The entanglements, ie, knots formed between chains, are denoted by the heavy black circles. For polyethylene in the melt, the molecular weight between entanglements, $M_e^{melt} = 1900$, which corresponds to $n = 14$ statistical segments. For solution cast polyethylene samples, M_e is easily obtained from

$$M_e = M_e^{melt}/\phi \tag{1}$$

in which ϕ denotes the polymer concentration. The dotted lines in Figure 1 represent the attractive (van der Waals or hydrogen) intermolecular bonds connecting sections either of the same chain or of different chains. Tensile drawing is assumed to occur along the y-axis.

The network is deformed at a constant temperature T and a rate of elongation ε. During deformation, the bonds between chains are allowed to break according to the Eyring kinetic theory of fracture (7), ie, at a rate

$$v = \tau \exp[-(U - \beta\sigma)/kT] \tag{2}$$

Here, τ is the thermal vibration frequency, U and β are the activation energy and volume, and

$$\sigma = M_\varepsilon \tag{3}$$

is the local stress. In equation (3), ε is the local strain and K is the elastic constant for the bond. The breaking of these attractive bonds leads to a release of the chain strands, which are now available to support the external load. Once broken, these bonds are assumed not to reform.

As the stress of the "freed" chain strands increases, slippage through entanglements sets in at a rate that has the same functional form as that for the attractive bonds (eq. (2)) but with different values for the activation energy U and

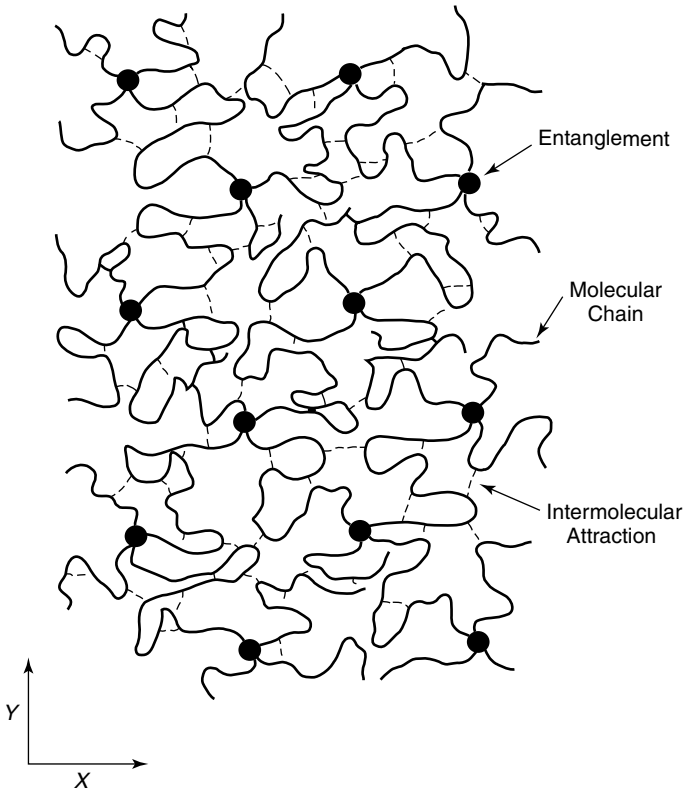

Fig. 1. Schematic representation of a model for an unoriented polymer network. The heavy black circles represent the entanglement loci and the dotted lines denote the attractive bonds between chains. Reprinted with permission from Ref. 8. Copyright (1987) American Chemical Society.

volume β. In eq. (2), σ now represents the difference in stress in two consecutive chain strands that are separated by an entanglement. This stress difference is calculated using the rubber elasticity theory (10). Thus, the stress on a stretched chain strand having a vector length $\boldsymbol{r}$ is given by

$$\sigma = \alpha kTL^{-1}(r/nl) \tag{4}$$

In equation (4), n denotes the number of statistical chain segments of length l in the strand whereas L^{-1} is the inverse Langevin function and α is a proportionality constant.

Equations (2) and (3) for the attractive bond breaking process are executed on the computer with the help of a Monte-Carlo lottery in which bond i breaks according to a probability

$$p_i = v_i/v_{\max} \tag{5}$$

Here, v_i is obtained from equation (2), whereas $v_{\max}$ is the rate of breakage of the most strained bond in the array. After each visit of a bond, the time t is

incremented by $1/[v_{max}n(t)]$ where $n(t)$ is the total number of intact bonds at time t. The simulation of chain slippage through entanglements is executed using a similar technique in which $n(t)$ now denotes the total number of entanglements left at time t. The present model also allows for chain breaking when the local draw ratio on a particular chain strand exceeds its maximum value given by the square root of its number of statistical segments.

After a very small time interval δt has elapsed, the attractive bond breaking, chain slippage, and fracture processes are halted and the network is elongated along the tensile y-axis by a small constant amount determined by the rate of elongation ε. The network is then relaxed to its minimum energy configuration, using a series of fast computer algorithms, described in Reference 11, which steadily reduce the net residual force acting on each entanglement point. Upon completion of network relaxation, the Monte-Carlo process of bond breakings and chain slippage is restarted for another time interval δt, and so on and so forth, until the network fails.

Morphologies of Deformation. Figure 2 shows a series of calculated stress–strain curves for melt-crystallized polyethylene at three different molecular weight values ($M = 1900$, 9500, and 250,000). The lowest molecular weight sample exhibits a low elongation at break and brittle failure. As the molecular weight is increased ($M = 9500$), the stress–strain curve exhibits a so-called yield

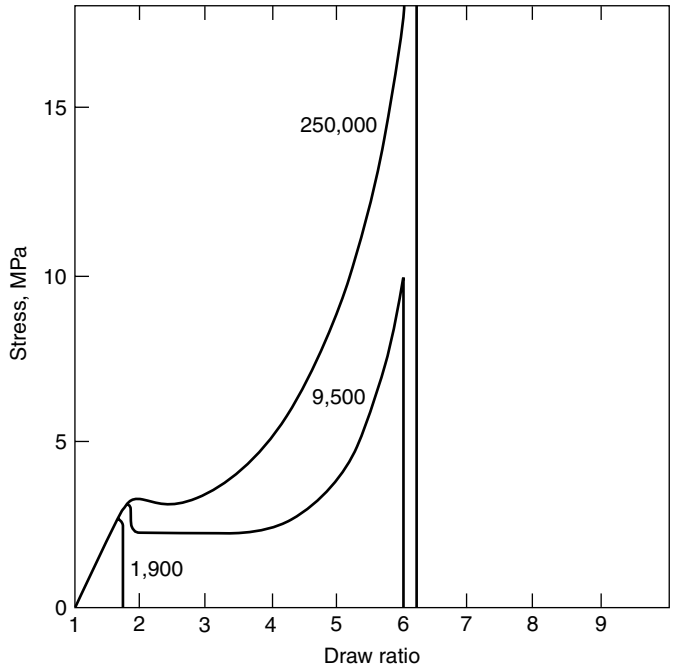

Fig. 2. Calculated stress–strain curves for three poylethylene samples of different molecular weights. To convert MPa to psi, multiply by 145. Reprinted with permission from Ref. 8. Copyright (1987) American Chemical Society.

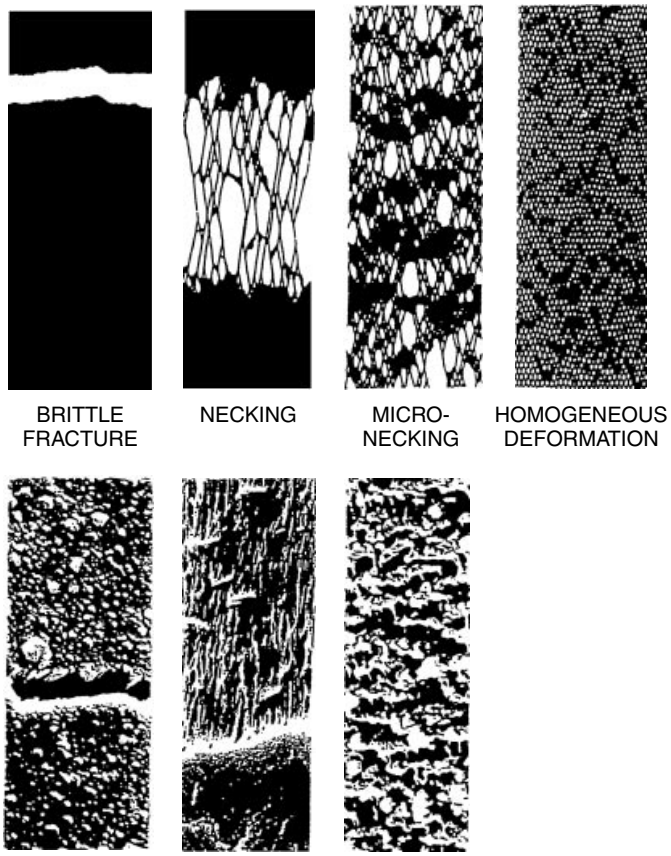

Fig. 3. Dependence of morphology on molecular weight. *Top*: Deformation morphologies obtained from the model for melt-crystallized polyethylene at increasing values of the molecular weight. From left to right: $M = 1900$, $M = 8500$, $M = 20{,}000$, and $M = 250{,}000$. *Bottom*: Experimental morphologies obtained at comparable molecular weights. Reprinted with permission from Ref. 8. Copyright (1987) American Chemical Society.

point (the first maximum in the stress–strain curve), followed by a flat region characteristic of neck formation. At draw ratio values $\lambda < 4$, strain hardening is observed. For the highest $M = 250{,}000$, strain hardening occurs almost immediately past the yield point.

A set of computer-generated morphologies is presented in Figure 3 (top) for different melt-crystallized polyethylene samples with increasing values (from left to right) of the molecular weight. As was clearly exemplified in the stress–strain curve (Fig. 2), the low molecular weight sample exhibits brittle failure with a sharp breaking surface. As the molecular weight is increased, a necking mode of deformation is observed, ie, a region of highly deformed molecular chains bridging two sections in which the macromolecules are still in a random coil configuration. This necking region propagates along the sample by continuously drawing more and more chains from the undeformed sections into the deformed region. At $M = 20{,}000$ a micro-necking morphology is observed in which numerous necks are obtained. For still higher $M = 250{,}000$, the number of micro-necks becomes

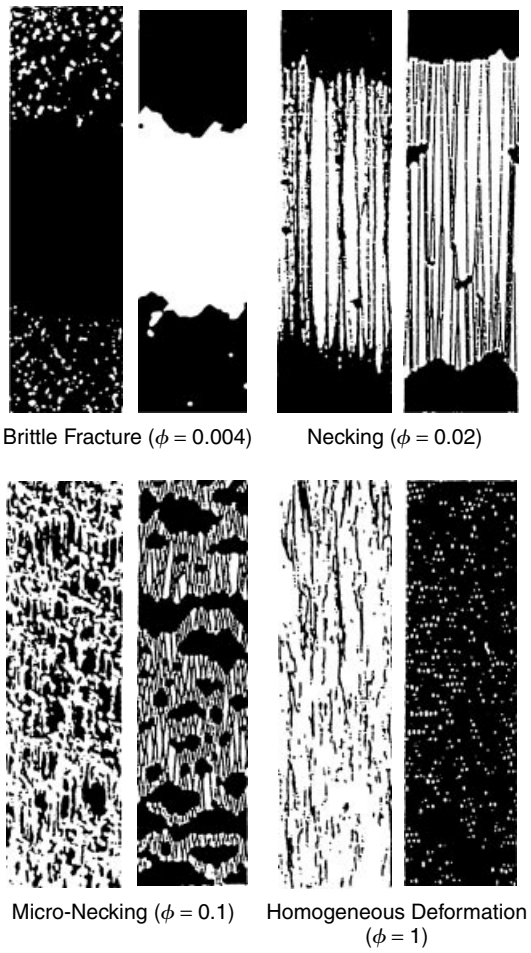

Fig. 4. Dependence of morphology on degree of dilution ϕ ($M = 500{,}000$). Deformation morphologies obtained from experiment (left) and from the model (right) for solution cast polyethylene at increasing values of the entanglement spacing factor ϕ. From left to right: $\phi = 0.004$, $\phi = 0.02$, $\phi = 0.1$, and $\phi = 1$. In all cases, $M = 475{,}000$. Reprinted with permission from Ref. 9. Copyright (1988) American Chemical Society.

so large that the deformation becomes essentially homogeneous. The bottom of the figure shows experimental morphologies obtained at comparable molecular weight values. An excellent agreement between theory and experiment is found.

A similar set of transitions can be obtained by keeping the molecular weight constant and varying the entanglement spacing, as is obtained in solution cast samples (see eq. (1)). Figure 4 shows a sequence of experimental (left) and calculated (right) morphologies for $M = 475{,}000$ at increasing values of ϕ (9). As with the results of Figure 3, model morphologies are in good qualitative agreement with experimental observation. This illustrates that the present approach is capable of handling the very complex issue of connecting events on the molecular level to macroscopic properties and features.

Importance of Drawing Conditions. As noted in the introduction, the mechanical properties of polymeric fibers are strongly dependent on the length of the macromolecular chains and also on their orientation with respect to the fiber axis. Since orientation increases with draw ratio (1), it is of uttermost importance to identify the factors controlling polymer drawability. A detailed study of the importance of temperature and elongation rate on the maximum draw ratio of melt-crystallized polyethylene, using the model described above, has been presented in Reference 12. This work was motivated by early experimental investigations which seemed to indicate that, for each molecular weight, there may exist an optimum draw temperature and/or rate of deformation (13,14). Figure 5a shows the

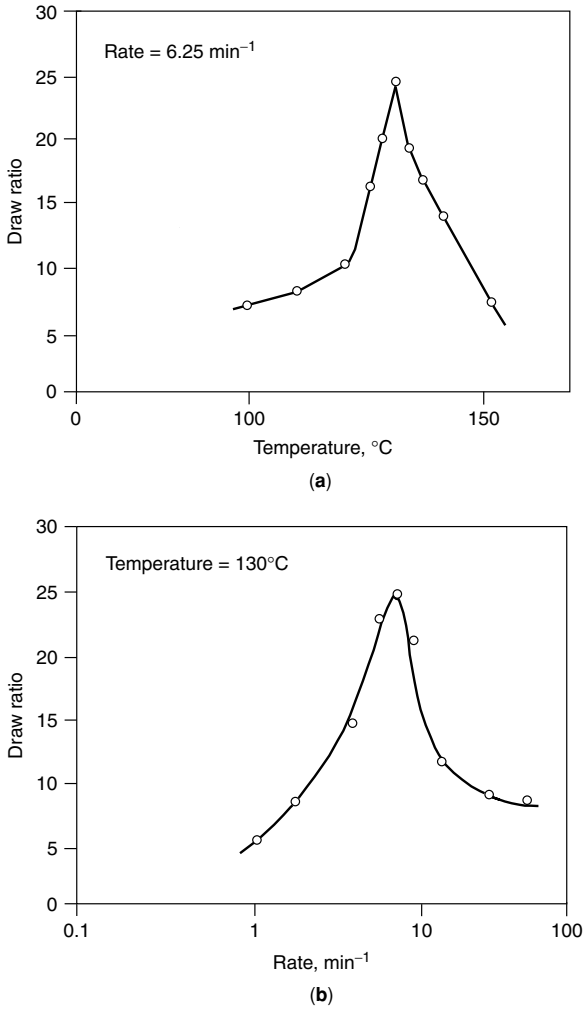

Fig. 5. Calculated dependence of the maximum draw ratio on testing conditions for melt-crystallized polyethylene with $M = 143{,}000$. (a) Dependence on temperature at constant elongation rate (6.25 min^{-1}); (b) Dependence on elongation rate at constant temperature (130°C). Reprinted with permission from Ref. 12. Copyright (1988) American Chemical Society.

calculated dependence of the draw ratio on temperature for *monodisperse* melt-crystallized polyethylene with $M = 143{,}000$. The figure reveals a sharp maximum in the draw ratio at $T = 130^{\circ}$C. A careful examination of the present model results gives the following insight. At low temperature $T < 100^{\circ}$C, all the samples break at their "natural" draw ratio $\lambda = 5$, as determined from the number of statistical segments between entanglements in the melt. As the temperature is increased, the model results reveal an onset of slippage of chains through entanglements, which leads to a steady increase in drawability. There is, however, an upper limit to that increase. Thus, at $T = 130^{\circ}$C, the rate of chain slippage becomes comparable to the rate of straining the overall sample and any further increase in temperature leads to a progressive decrease in drawability. Results (not reproduced) for other *monodisperse* molecular weights show a similar behavior with different values for the optimum drawing temperature. These observations are of importance since they predict that the sharp optimum of Figure 5a cannot be observed for a polydisperse sample as every single molecular weight in the distribution has an optimum temperature window which will be different from the others. Also, since our model is based on a thermally activated rate theory, we expect that results similar to those of Figure 5a will be obtained when keeping the temperature constant and varying the elongation rate. A confirmation of that model prediction is given in Figure 5b.

A further test of our model results is presented in Figure 6, which displays actual experimental samples drawn to their breaking point at different values of the deformation temperature and at a constant elongation rate of 23 min^{-1}. The samples are for NBS SRM 1484 linear polyethylene which has a close-to monodisperse molecular weight distribution with $M_{\text{n}} = 111{,}000$ and $M_{\text{w}} = 125{,}000$. It is evident that, for this particular rate, the optimum drawing temperature is around 75°C. Note that the location of the optimum temperature window is different from that predicted from our model simulations (see Fig. 5a). A better fit could have been obtained by adjusting the activation energy for chain slippage, which has not been attempted in the present calculations.

The results discussed above for monodisperse polyethylenes clearly demonstrate that each molecular weight exhibits a different temperature or elongation window within which optimum drawing occurs. The model reveals that, within those windows, the rate of slippage of chains through entanglements reaches its optimum value. These observations strongly point to the need for very accurate control of the temperature and rate of deformation for optimum drawing, particularly for high molecular weight polymers.

Polymer Coagulation

Polymer coagulation defines the process by which a solution of a polymer in a good solvent is quenched in a nonsolvent, leading to solvent–nonsolvent exchange and polymer precipitation. This process is at the basis of a wide range of industrial processes including wet spinning (3), fibridation (15), and membrane formation (16). A major drawback of the solution/coagulation process is that the coagulant moves into the polymer gel by forming large tear-dropped macrovoids (fingers), which are usually very difficult to eliminate. Several theories have been

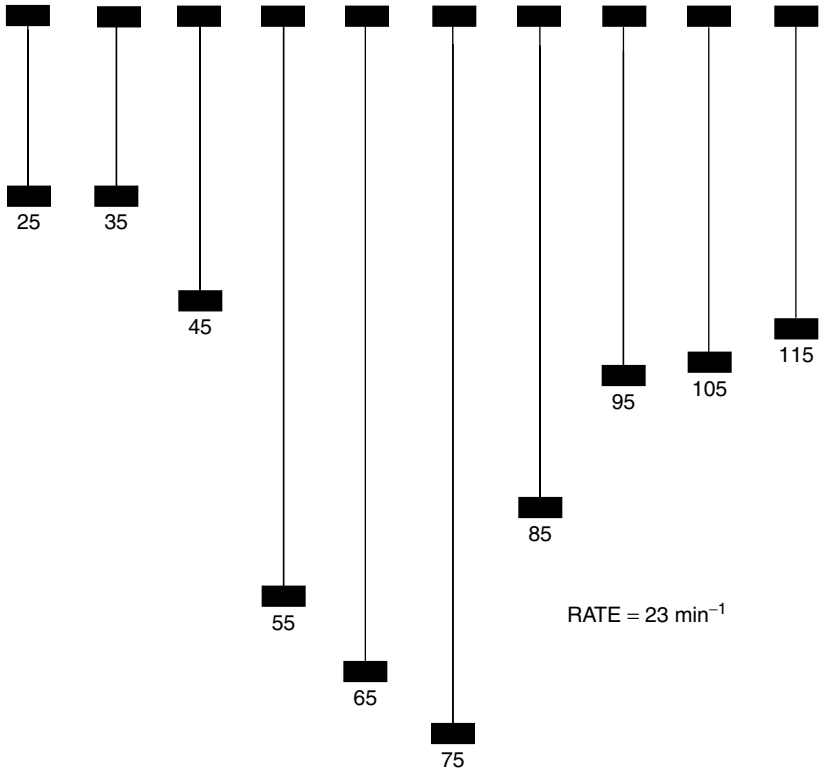

Fig. 6. Dependence of maximum draw ratio on temperature (°C) (Polyethylene $M = 10^5$). Actual melt-crystallized NBS SRM 1484 polyethylene samples drawn to break at different temperatures. The elongation rate was 23 min^{-1}. Reprinted with permission from Ref. 12. Copyright (1988) American Chemical Society.

proposed for describing finger formation. These include linear stability analyses of the solvent–nonsolvent exchange at the polymer interface (17,18) and studies of the mass transfer paths before the onset of phase separation (19–21). All these studies are based on the derivation of analytical equations for diffusion of the polymer, solvent, and coagulant. In view of the great complexity of the problem, all previous models had to resort to several simplifying assumptions: (*1*) the diffusion process is purely one-dimensional, (*2*) thermodynamic equilibrium is always preserved at the bath–polymer interface, (*3*) phase separation is not considered and is assumed to occur through nucleation and growth. In fact, it is now well accepted that polymer coagulation is a *nonequilibrium* process, entirely controlled by the rate of solvent–coagulant exchange through the interface.

In view of the great difficulties associated with analytical studies of the development of polymer structure during coagulation, a computer simulation of the ternary diffusion process is employed. One approach has been described at length in Reference 22. In brief, the coagulation process is simulated on a lattice, whose sites represent either a nonsolvent, a solvent, or a polymer aggregate. For simplicity, all three components are assumed to have equal molar volume and the

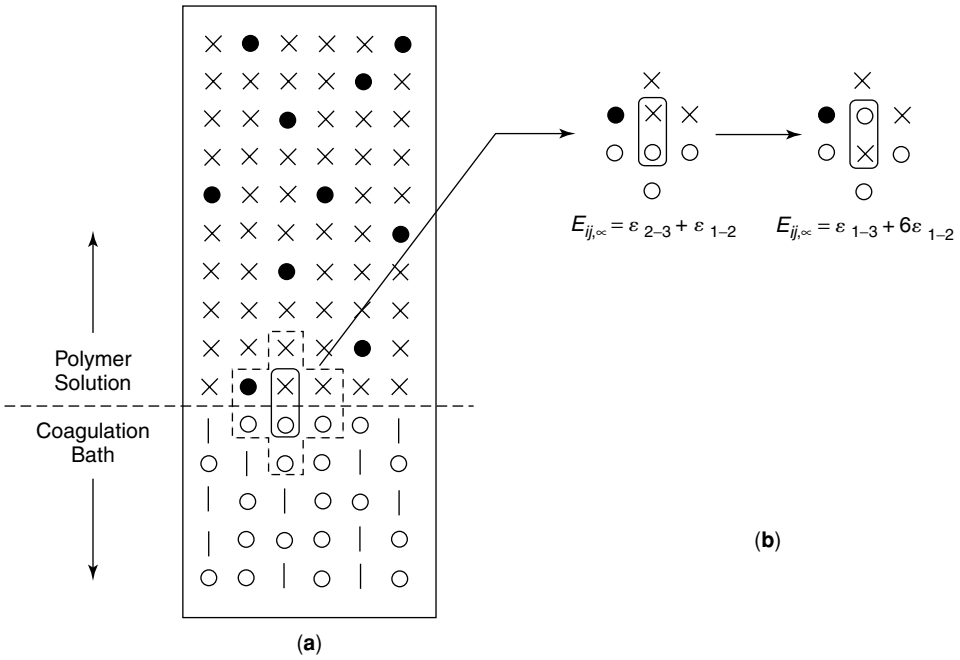

Fig. 7. Schematic representation of a lattice model for diffusion of a coagulant into a polymer solution. The polymer, the solvent, and the coagulant particles, are denoted by symbols ●, ×, and ○, respectively. The diffusion process is simulated through a series of two-particle exchanges on nearest-neighbor lattice sites. The rates of exchange are obtained from equation (6) in which $E_{ij,\alpha}$ and $E_{ji,\alpha}$ are the interaction energies of the pair with nearest-neighbor particles, before and after the exchange (see Fig. 7b). As diffusion proceeds, the coagulant–polymer interface (dashed line) moves upwards and, since the coagulation bath is assumed to be infinite, the lattice sites below that interface are being continuously replenished with coagulant particles (see text). Courtesy of *Journal of Polymer Science*.

simulation is limited to a two-dimensional geometry similar to that encountered in typical experimental studies. In these setups, a drop of polymer solution is placed between two microscope slides whereas the coagulant is introduced near the edge (2,23). A schematic representation of the two-dimensional model of polymer coagulation is given in Figure 7a. The polymer solution is represented by a lattice of sites which are filled-in, according to the polymer weight fraction, by either a solvent or a polymer particle. A detailed study of the importance of the polymer particle "size" can be found in Reference 24. The bottom five rows of the lattice represent the infinite bath filled-in with coagulant particles. Coagulant, solvent, and polymer sites are referred to by indexes 1, 2, and 3 respectively. The ternary polymer–solvent–coagulant diffusion process is simulated as follows. A pair of nearest-neighbor—i and j—lattice sites are picked at random. Denoting by α the local environment for that pair, the rate for an exchange $ij \rightarrow ji$ within α is calculated from (25)

$$v_{ij\rightarrow ji,\alpha} = \tau_{i,j} - 1\exp[\beta(E_{ij,\alpha} - E_{ji,\alpha})/2] \tag{6}$$

In equation (6), $\tau_{i,j}^{-1}$ is related to the mutual diffusion coefficient $D_{i,j}^{\infty}$ of i and j particles *at infinite dilution* through (26)

$$D_{i,j}^{\infty} = \tau_{i,j}^{-1(\delta x)} 2 \tag{7}$$

where δx denotes the unit lattice length. Note that, in equation (6), all the effects of particle interactions are relegated to the Boltzmann exponent of (half) the energy difference between initial and final states for the exchanging pair. That functional form is guided by a requirement of commutativity of the individual two-particle exchanges (25). Using equation (6), a probability for exchange is then calculated through

$$p_{ij \to ji,\alpha} = v_{ij \to ji,\alpha} / v_{\max} \tag{8}$$

in which $v_{\max}$ denotes the highest rate of exchange among all the pairs on the lattice (see also eq. (5)). Having determined the probability p for an exchange $ij \to ji$ (eqs. 6–8), a random number between 0 and 1 is generated and the move is allowed if that number falls below p. After each visit of a pair and whether the pair is allowed to exchange or not, the overall "time" t is incremented by $1/[v_{\max} n]$ in which n denotes the total number of pairs of sites on the lattice (note the similarity with our Monte-Carlo process for polymer drawing, as described earlier). In addition to two-particle exchanges, the model also allows for small clusters to move through a series of one-lattice-step displacements of entire rows or columns of polymer particles. Also, since the coagulant bath is assumed to be infinitely large, solvent particles diffusing into the bath to a depth of more than 5 lattice units with respect to the polymer–bath interface are systematically removed from the lattice and replaced by coagulant particles.

Skin and Finger Formation. First attention is turned to the application of the model to the coagulation of a solution of 20% Nomex®, an aromatic polyamide commercialized by DuPont, dissolved in *N*-methylpyrrolidinone (NMP). An estimation of the range of values of the model parameters can be found in Reference 22. Figure 8 shows the calculated morphology obtained after precipitation in water for a time $t = 0.02$ s. Only the polymer particles have been represented. The figure clearly reveals that the coagulant diffuses inside the polymer gel through a series of finger-like structures. The latter have a strikingly similar shape and originate through regularly spaced pores in a thin skin, in perfect agreement with experimental observation (2). Note the important shrinkage of the polymer gel whose initial position was located at the bottom of the figure. A careful analysis of our model results leads to the following insight into the origin of the skin/finger formation. Immediately upon immersion of the polymer gel in the coagulation bath, the fast solvent-coagulant exchange across the interface combined with the large repulsive forces between polymer and coagulant cause an immediate precipitation at the interface. This process is too fast for any segregation of the Nomex particles into polymer-rich and polymer-poor domains and, as a result, a thin skin starts to form. Since the polymer concentration is low, the skin, in its early stages, is not homogeneous and it presents defects along its contour. The latter form the initiation pores for fingers, which then quickly grow inside the polymer solution as it is faster for a solvent particle to exit through a pore

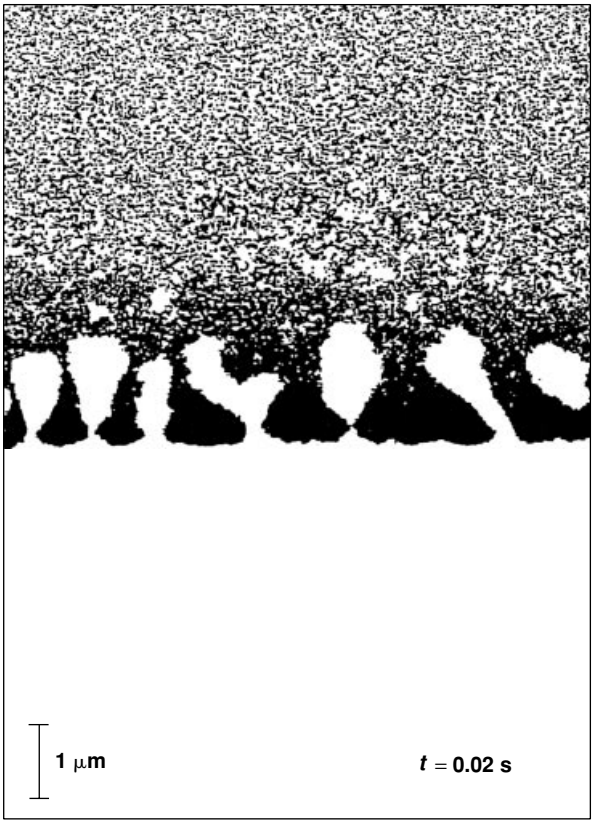

Fig. 8. Calculated coagulant–polymer interface for a 20% solution of Nomex in NMP precipitated in water at $t = 0.02$ s. The figure is for a square lattice of 450 × 600 sites; only polymer particles (symbol •) have been represented. The figure is for $\varepsilon_{1-2} = 0.77$, $\varepsilon_{2-3} = 0$, and $\varepsilon_{1-3} = 2.8$. Courtesy of *Journal of Polymer Science*.

than through a defect-free skin. In support of the proposed mechanism for finger formation, experiments clearly reveal that fingers do not develop when a skin is absent or when the polymer volume fraction is too high, ie, when skin defects are less probable.

Importance of the Solvent–Coagulant Miscibility. To recall, the miscibility between solvent and coagulant is, in this model, controlled by the interaction energy parameter ε_{1-2}. A study of the effect of that parameter on the morphology of the precipitated polymer is presented in Figures 9a–d, for approximately the same coagulation time $t = 0.02$–0.03 s. For perfect mixing ($\varepsilon_{1-2} = 0$, Fig. 9a), the polymer is seen to coagulate into large agglomerates of ca 0.3 mm in diameter (dust-like structure). As the miscibility of solvent and coagulant decreases ($\varepsilon_{1-2} = 0.5$ and $\varepsilon_{1-2} = 0.77$, Figs. 9b and 9c), the present model results clearly reveal the development of finger-like structures which also become more regular as ε_{1-2} increases. Finally, for very immiscible solvent and coagulant ($\varepsilon_{1-2} = 1.5$, Fig. 9d), the formation of a sponge-like structure with spherical pores filled-in with

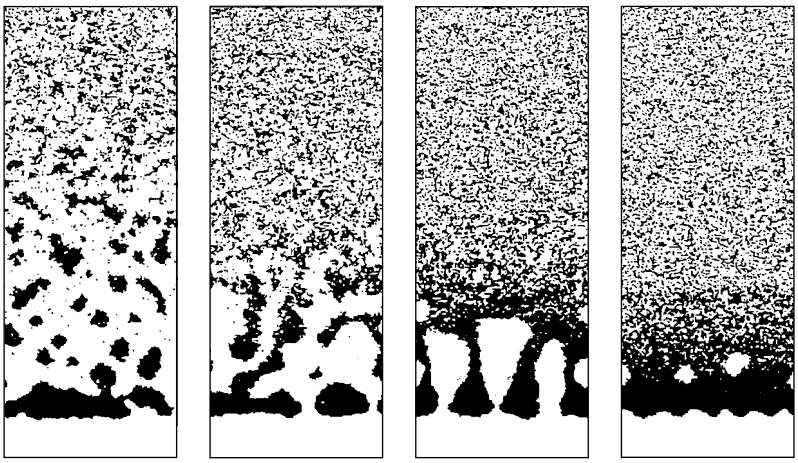

Fig. 9. Effect of the solvent–coagulant miscibility on polymer structure. (a) $\varepsilon_{1-2} = 0$, (b) $\varepsilon_{1-2} = 0.5$, (c) $\varepsilon_{1-2} = 0.77$, and (d) $\varepsilon_{1-2} = 1.5$. The structures are for a coagulation time $t = 0.02$ s, except (d) which is for $t = 0.03$ s. All the other parameters are the same as in Figure 8. The extent of shrinking of the polymer–coagulant interfaces with respect to their initial positions have not been represented. Courtesy of *Journal of Polymer Science*.

coagulant is observed. It is interesting to note that the sequence of precipitated morphologies obtained in Figure. 9 through a decrease in solvent–coagulant miscibility is also very similar to that observed experimentally (27) when increasing the initial polymer concentration. Based on our understanding from the model, this is not surprising since a decrease in solvent–coagulant miscibility effectively makes solvent and polymer particles more alike as far as the coagulant is concerned. A further investigation of the model results also reveals that the transition from sponge to finger to dust-like structures is also accompanied by a dramatic increase of the rate of coagulation, in perfect agreement with experimental observation. Thus, for the dust-like structure studied in Figure 9a, it is found that the diffusion coefficient for the penetration depth of the coagulation front is around 10^{-5} cm^2/s. For the sponge-like structure of Figure. 9d, a diffusion coefficient of ca 2×10^{-7} cm^2/s is found.

Effect of Additives in the Coagulant. In industrial applications, the coagulant power and coagulant–solvent miscibility are often varied through the incorporation of additives into the coagulant. These additives may consist of pure polymer solvent or of large amounts of inorganic salts. The presence of an additive in the coagulant can be easily accounted for in the lattice model (28). Figures 10a–c show the effect of adding $CaCl_2$ to water during coagulation of a 20% solution of Nomex in NMP. The figures clearly reveal a transition from a finger-like to a dense polymer structure at ~50% $CaCl_2$ concentration. Further investigation of the model results reveals that the transition is not associated with any decrease in the rate of coagulation, which stays at high values around 10^{-5} cm^2/s. The approach, therefore, clearly confirms the advantages of using high salt concentrations in the coagulant. Further study of the model results also reveals that

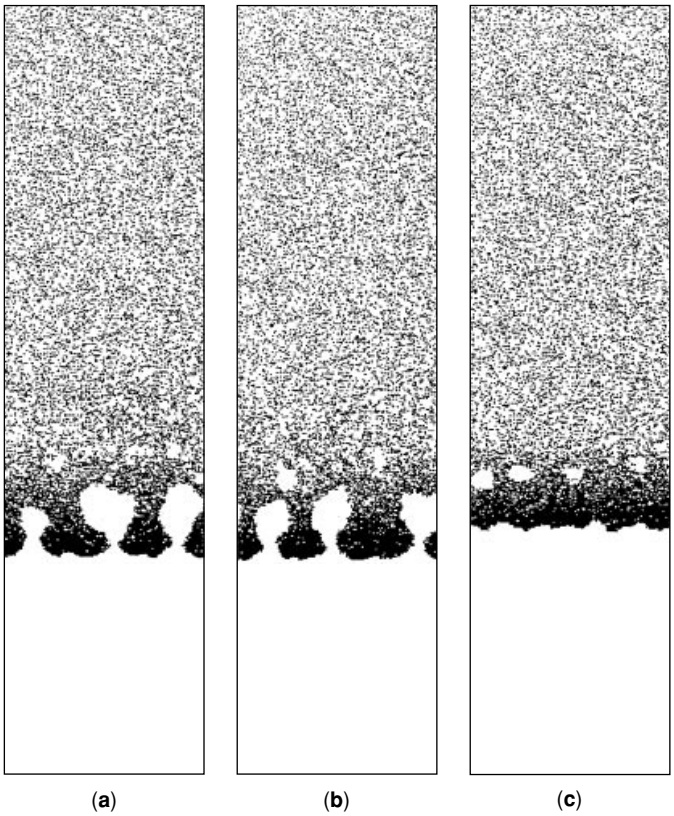

Fig. 10. Effect of adding increasing amounts of $CaCl_2$ to the aqueous coagulant. The amounts of $CaCl_2$ are as follows: (a) 35%, (b) 40%, and (c) 50%. All three figures are for a coagulation time $t = 0.015$ s. Reprinted from Ref. 28. Copyright (1995), with permission from Excerpta Medica Inc.

the success of that technique rests upon the use of a salt that is poorly miscible with the polymer solvent. This observation is in line with the previous finding (see Fig. 9) that a decrease in solvent–coagulant miscibility leads to more dense polymer structures. The effect of adding high concentrations of the solvent to the aqueous bath has also been studied. At 35–49% solvent, the model results clearly reveal a transition from a finger-like morphology into a more uniform structure, as observed experimentally (29,30). However, in contrast to the case of a salt addition, that transition is also associated with a dramatic decrease in the rate of coagulation. Thus, with 49% solvent in the coagulant, no polymer has yet precipitated after $t = 0.02$ s and coagulation becomes an extremely slow process entirely controlled by particle nucleation and growth.

Admittedly, these results are for short coagulation times ($t < 0.03$ s) which has allowed the study of structures no larger than a few microns in depth. Therefore, it could be argued that, being for small coagulation times $t < 0.03$ s, the results of the present paper are not representative of the fully coagulated structures that sometimes require up to a few minutes to obtain. In support of these results, it

should be noted, however, that actual micrographs of coagulated morphologies obtained at different times, ranging from a few seconds to several minutes, do not reveal any evidence for a change in polymer structure with time. Thus, a change in these calculated morphologies at later times remains improbable and the gross morphology of the final polymer structure should be adequately described by the present model results.

Polymer Quenching

The previous section presented a model study of the coagulation of a polymer solution brought upon by *diffusion* of a nonsolvent. The present section focuses on the faster process of phase separation inside a binary polymer–solvent system induced by an abrupt change in external temperature and/or pressure. This problem is of obvious importance in polymer processing techniques based on thermally induced phase separation (31) or on rapid expansion of supercritical solutions (32). A typical example of the latter is the flash spinning process. Here, a polymer solution is first heated under high pressure and then rapidly released through a spinnerette, leading to the formation of a fibrillar polymeric network.

Equilibrium properties of polymers in dilute solutions are reasonably well understood (33) and polymer–solvent phase equilibria can be easily obtained through the use of the classical Flory-Huggins mean-field lattice model (34) or, alternatively, from more recent computer simulations of Gibbs ensembles (35,36). On the other hand, the development of polymer morphology inside the coexistence curve is only poorly understood and previous work has been restricted essentially to kinetic studies of the collapse of a *single* polymer chain (37–39). For that reason, attention is turned to multichain systems and focus is on the very early stages ($t \ll 1$ s) of spinodal decomposition, during which equilibrium concentrations and morphologies are being established. The purpose of developing such a multichain model is to get a better understanding of the dependence of polymer structure on molecular weight, polymer concentration, and quenching conditions.

In this model (40), first an array of polymer chains at infinite temperature is constructed for a given value of the chain volume fraction V_f and chain length N (henceforth in statistical segment units). This is obtained by randomizing an ordered array of chains by a series of Monte-Carlo moves of two kinds. The first is a *nonlocal* reptation which randomly moves a bond from one end of a chain to the other (36). The second incorporates *local* random moves such as end-flip, 2-bond kink jump, and 3-bond crankshaft motion (41). Upon completion of that process, an interaction energy $\varepsilon < 0$ is imposed between pairs of nonbonded nearest-neighbor chain segments and the system is quenched to a finite temperature T. The new state of the polymer chains is then obtained, as a function of time, by using the *local* Monte-Carlo moves described above (ie, nonlocal reptation is excluded) which are made to occur at a rate (see also eq. (6))

$$v = \tau^{-1} \exp[-\beta(U_f - U_i)/2] \tag{9}$$

in which U_f and U_i denote the local energy in the final and initial states, respectively, whereas τ corresponds to the reorientation time of a statistical segment,

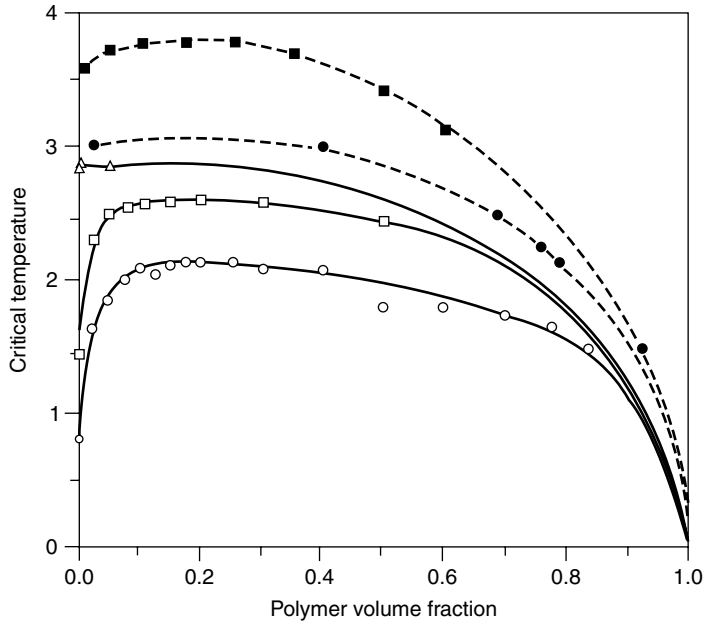

Fig. 11. Dependence of the critical temperature $-k_B T_c/\varepsilon$ on polymer volume fraction. Results obtained by the present approach are denoted by open symbols ○, $N = 20$; □,: $N = 60$; and △: $N = 1000$. Both local and nonlocal (ie, reptation) moves have been used in our Monte-Carlo simulations. Filled-in symbols are reproduced from Reference 35 (●, $N = 100$) and Reference 36 (⬒, $N = 64$). The curves are drawn to guide the eye. Reprinted with permission from Ref. 40. Copyright (1997) American Chemical Society.

which is of the order of 10^{-8} s. As in all previous models, after each attempted move, the overall "time" t is incremented by $1/[v_{max}n]$ in which v_{max} represents the highest rate among all n possible moves on the lattice.

The polymer–solvent phase equilibria are obtained from a study of the behavior of the specific heat

$$C = [\langle \nu^2 \rangle - \langle \nu \rangle^2]\varepsilon^2/[(N+1)k_B T^2] \tag{10}$$

in which ν denotes the number of nearest neighbor nonbonded polymer segments. The critical temperature $-k_B T_c/\varepsilon$ for phase separation is obtained from the location of the maximum in a plot of C vs T. Model results for the dependence of that critical value on the polymer volume fraction V_f are presented in Figure 11 for chains of length $N = 20$ (symbol ◯), 60 (□), and 1000 (△). The figure reveals a pronounced asymmetry of the curves and a shift of their maxima toward higher T_c and lower V_f with an increase in N, in perfect agreement with experimental observation. Also represented are theoretical predictions obtained from two previous approaches: (*1*) the slab geometry model (Ref. 35; symbol ●) and (*2*) the Gibbs ensemble simulations (Ref. 36; symbol ⬒). Both sets of results are in good qualitative agreement with model predictions.

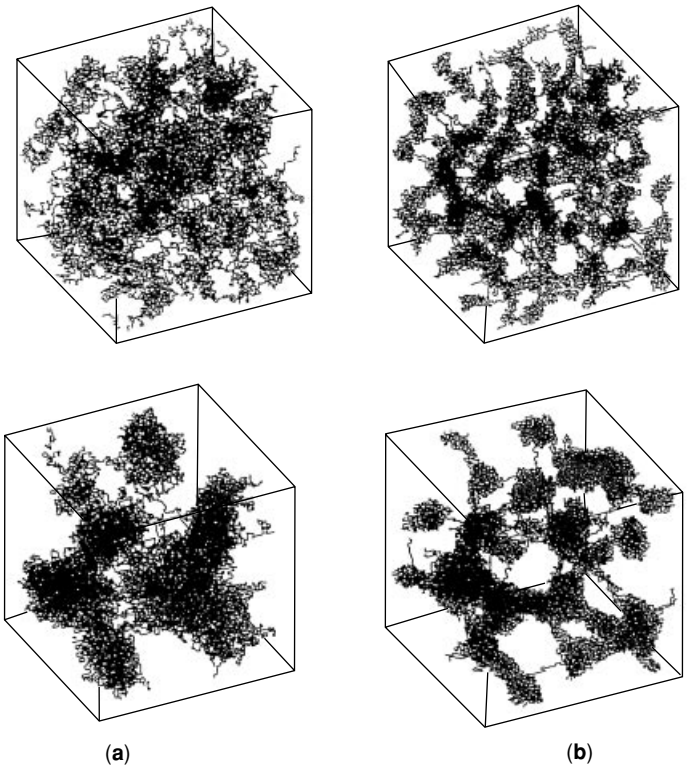

Fig. 12. Polymer morphologies obtained at $-k_B T/\varepsilon = 2.5$ and 1.0 for two different simulation times: $t = 5 \times 10^3 \tau$ (top) and $t = 15 \times 10^4 t$ (bottom). The representations are for cubic lattices of 70 unit lengths (~70 nm) in each direction. Reprinted with permission from Ref. 40. Copyright (1997) American Chemical Society.

Effect of Quench Depth. Now attention is turned to an analysis of the structure development upon quenching inside the binodal curves of Figure 11. The results are presented in Figure 12 for two (reduced) temperatures $-k_B T/\varepsilon = 2.5$ (Fig. 12a) and $-k_B T/\varepsilon = 1.0$ (Fig. 12b). The top set of morphologies is for a short time $t = 5 \times 10^3 \tau$. A bicontinuous sponge-like morphology is observed, in agreement with experimental observation (31,42) and with a recent viscoelastic model study (43). High temperatures (left) are seen to lead to a coarser morphology, whereas lower ones (right) form a lacy structure with fine and dense fibrils. Further study of the model results indicates that, within that early stage, spinodal decomposition occurs to quickly establish equilibrium concentrations and the polymer forms a continuous percolated structure whose fine features are exacerbated at very deep quenches. For large simulation times $t = 10^5 \tau$ (bottom set of morphologies in Fig. 12), the figures reveal a substantial coarsening of the structures and a progressive breaking up of the continuous polymer gel into isolated spherical aggregates. This is the so-called percolation-to-cluster transition. Within that regime, it was also found that the rate of coarsening increases with a decrease in quenching temperature.

The Case of Mixed Solvent Systems. There has been a recent interest in the use of mixed solvent systems for polymer processing and isolation. It is now common in industrial processes for polymer coagulation to employ solvent mixtures which are designed to bring the polymer solution close to its solubility limit. The formulation of these systems is often empirical and the behavior of polymer chains in mixed solvents is still poorly understood. The present study focuses on a 70/30 blend of chains of two different lengths $N_1 = 4000$ and $N_2 = 50$ (in statistical segment units). The blend is dissolved at 3.3% concentration in two different solvents: (*1*) a mixture of 80% good solvent (repulsive interaction energy with the polymer $\varepsilon = 1$) and 20% bad solvent ($\varepsilon = 41$) and (*2*) a single solvent system with average solvent power. The study proceeds as follows (44). First the two polymer solutions are equilibrated at high temperatures. These solutions are then quenched inside the two-phase region at the same temperature T until thermodynamic equilibrium is achieved. The polymer structures obtained in the two solvents for a quenching temperature $T = 40$ are depicted in Figures 13a and 13b. In the average solvent case (Fig. 13a), the polymer blend is seen to precipitate in a dense spherical globule. For the solvent mix (Fig. 13b), on the other hand, the precipitated structure is more diffuse and a fraction of the chains remains soluble in the solvent phase. Further investigation of the model results reveals that those chains, which represent about 5% of the total polymer mass, are made exclusively of the short length component. The presence of that soluble fraction is due to preferential adsorption of the good solvent by the low molecular weight chains (44–46). These results are of great importance as they indicate that quenching a polydisperse system below the cloud point may induce molecular weight segregation between the two phases: the longer chains, which precipitate out first, tend to populate the polymer-rich phase whereas the shorter

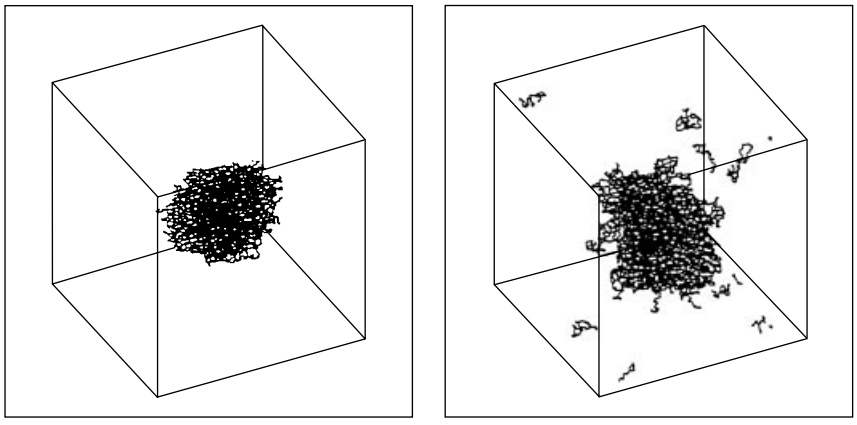

Fig. 13. Effect of solvent characteristics on precipitated polymer morphologies. The figure is for a blend precipitated in (a) the average solvent and (b) a mixture of 80% good solvent ($\varepsilon = 1$) with 20% bad solvent ($\varepsilon = 41$). Total polymer concentration is 3.3% and quenching temperature is set at $T = 40$ (in k_B units). The representation is for a simple cubic lattice of $70 \times 70 \times 70$ sites. Fig. 14. Effect of quench depth, T, on precipitated polymer morphologies. (a) $T = 20$, (b) $T = 10$, and (c) $T = 2$ (in k_B units). The figure is for a 32/68 blend of chains of lengths $N_1 = 4000$ and $N_2 = 10$, dissolved in a mixture of 80% good solvent ($\varepsilon_{2-3} = -0.25$) with 20% bad solvent ($\varepsilon_{1-3} = 45$). Total polymer concentration is 3.3%. Courtesy of *Journal of Polymer Science*.

chains, having greater solubility, remain in the solvent phase. The effect of quench depth on the soluble polymer fraction has also been studied. The model results are shown in Figure 14 for a 32/68 blend of chains of lengths $N_1 = 4000$ and $N_2 = 10$, precipitated at increasing quench depths: (*1*) $T = 20$; (*2*) $T = 10$, and (*3*) $T = 2$ (in k_B units). The model reveals that the soluble fraction first decreases and then increases with quench depth. This increase is due to a higher preferential adsorption at low temperatures. It should be noted also that this effect seems to be indicative of a solvent mixture in which the good solvent has a tendency to form a complex with the polymer ($\varepsilon_{2-3} = -0.25$).

Thermally Bonded Nonwovens

Mechanical Properties. The processing of fibers into planar fibrous materials such as papers, nonwovens, and wood fiber boards has received a lot of attention over the years because of their great versatility and their ease of manufacturing into complex shapes for a wide range of applications. In spite of its importance, little attention has been paid to the fracture behavior of fibrous sheets. Previous theories are based on random lattice models with various types of disorder (47,48). The fibrous nature of the networks has been included in more recent approaches (49,50). These models, however, are confined to two-dimensional representations and, as such, they are incapable of describing actual sheet structures in which bonding between layers plays a major role. They are also based on simplified fracture criteria and provide only static calculations of stress–strain curves. Again, analytical approaches that attempt to tackle all the aspects of paper deformation are clearly impossible and, for that reason, one needs to turn to computer modeling. Here the focus is on nonwoven sheets, such as Tyvek®, which are formed by pressing spunbonded fibrous webs (layers) between two smooth heated rolls. These webs are created through flash spinning of a solution of high density polyethylene through a spinneret containing a single hole.

In the model (51), a spunbonded web (henceforth referred to as "layer") is represented by an array of fiber strands connected on a two–dimensional x-y lattice.

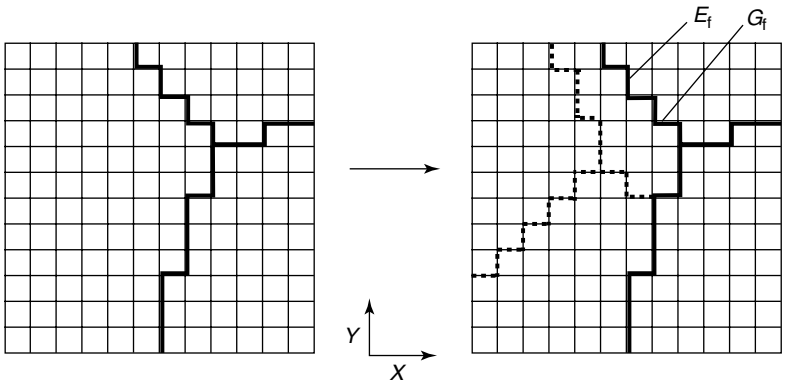

Fig. 15. Model construction of a fibrous layer. E_f and G_f denote the elastic tensile and shear modulus for the fiber. Reprinted from Ref. 51. Copyright (1997), with permission from Excerpta Medica Inc.

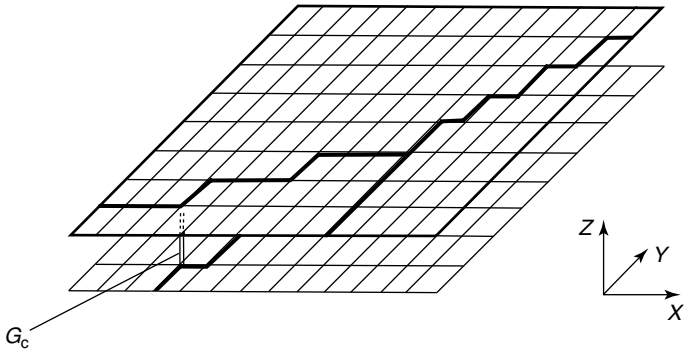

Fig. 16. Consolidation into a sheet structure. G_c denotes the shear modulus of the bonds introduced during consolidation. Reprinted from Ref. 51. Copyright (1997), with permission from Excerpta Medica Inc.

This array is built in a sequence of steps. At each step, a lattice site is chosen at random and three fiber strands are constructed from that site until they reach either the edge of the lattice or a previously constructed strand (see Fig. 15). Each of the strands within a layer is modeled as a ribbon, made itself of a series of lattice bonds. The sheet structure is then obtained by piling up a series of layers on top of each other along the z-axis and consolidation is realized through bonding nearest-neighbor fiber sites between layers (see Fig. 16). Upon tensile deformation, the individual fiber bonds are stretched and their local stresses combined with thermal activation rate theory (see eq. (2)) define probabilities for bond rupture. As in previous models, at regular time intervals, the individual lattice sites are relaxed toward mechanical equilibrium with their neighbors by a systematic sequence of operations which steadily reduce the net residual force acting on each site.

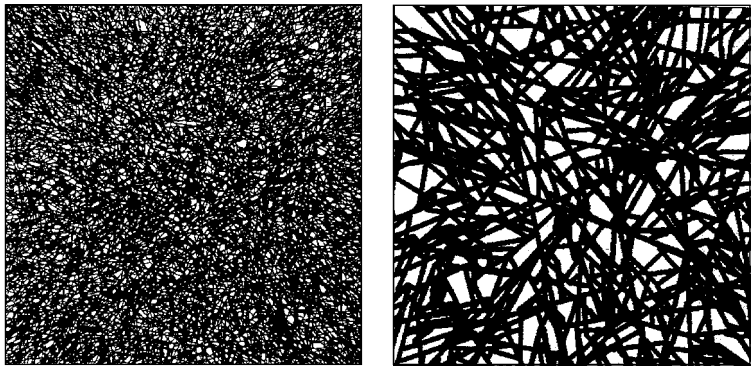

Fig. 17. Actual computer representations of two 3-layer sheets having different fiber cross sections. The top structure is for a square cross section (aspect ratio $\alpha = 1$), whereas the bottom is for ribbon-like fibers (cross-section aspect ratio $\alpha = 7$). Both structures are for a 37% fiber volume fraction. Reprinted from Ref. 57. Copyright (1998), with permission from Excerpta Medica Inc.

The results, to be presented below, will be for application to Tyvek sheets. Figure 17 shows actual computer representations of two 3-layer sheets having different fiber cross sections. The *lhs* structure is for a square cross section (aspect ratio $\alpha = 1$), whereas the *rhs* is for ribbon-like fibers with cross-section aspect ratio $\alpha = 7$. Both structures are for a 37% fiber volume fraction. Note that the sheet of Figure 17b has a fewer number of pores but, more larger voids. Figure 18 shows calculated stress–strain curves for polyethylene sheets for two different values of the shear modulus G_f of the fiber. The two curves show the presence of two distinct regions characterized by different moduli. Within the first region, which extends to ~9% elongation, computer results reveal an extensive deformation of the consolidating bonds. These bonds start to break at 2–4% elongation, which results in a continuous bending down of the stress–strain curve. At higher elongations, one enters the second region which is characterized by a gradual increase in the load supported by the fibers. As a result, the slope of the curve within that region is seen to be strongly dependent on the fiber shear modulus G_f. The latter observation is in line with the previous model finding (52) in that the *tensile* deformation of structures reinforced with randomly oriented fibers is fully controlled by the *shear* modulus of the fibers.

Permeability. Nonwoven fibrous media are also being extensively used in filtration and barrier applications. Several analytical approaches have been proposed for describing the dependence of their permeability on the shape and volume fraction of fibers (53–56). For simplicity, all these studies assumed that the fibrous media is made of a regular array of equidimensional cells, each consisting of a fiber segment surrounded by air. This is certainly not the case experimentally as fibrous media are made from a deposition process in which fibers are laid into a dense and compact mat. In one approach (57), the permeability of the sheet to diffusional flow is studied by a Monte-Carlo process. Here, the sheet is put in contact with a large external bath of small particles which diffuse through the

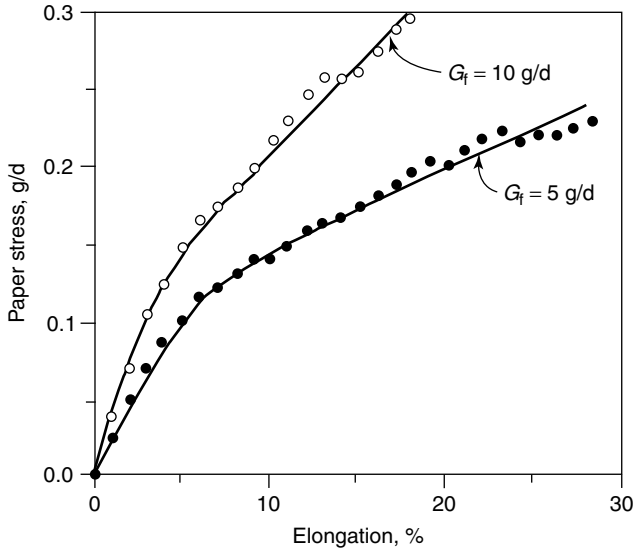

Fig. 18. Calculated stress–strain curves for two polyethylene sheets with $G_f = 10$ g/d and $G_f = 5$g/d (10 g/$d \cong$1 GPa). In reference to the units commonly used in the paper industry, a stress of 0.1 g/d is equivalent to a load of 10 lbs/in. on a 7 mil sheet. The curve is drawn to guide the eye. Reprinted from Ref. 51. Copyright (1997), with permission from Excerpta Medica Inc.

structure by hopping between nearest-neighbor lattice sites. This model allows one to study in detail the importance of the sheet density, fiber shape, and the role of interstitial voids between layers.

Model results for the dependence of diffusivity D (see Ref. 57) on fiber volume fraction V_f are presented in Figure 19. For simplicity, the data have been normalized by the diffusivity D_0 at $V_f = 0$. First, square fibers are examined ($\alpha = 1$, Fig. 9a). Calculated data have been represented by symbols ○ and ● for sheets of 5 and 10 layers, respectively. For both sheets, the diffusivity shows a monotonic decrease with fiber volume fraction up to $V_f = 0.4$. Also represented in the figure (symbol +) are calculated data from Reference 53 The predictions are higher than the present study because, as stated earlier, previous approaches assume each fiber to be surrounded by air so that the pores always belong to the continuous phase, except at $V_f = 1$. Ribbon-like fibers with $\alpha = 7$, are shown in Figure 19b. Comparison with the previous figure shows a strong decrease in diffusivity with an increase in cross-section aspect ratio α. These observations may seem surprising in view of the large pore areas previously observed in Figure 17b at large $\alpha = 7$. At constant V_f, diffusivity is, however, mainly controlled by the *tortuosity* of the diffusion path across the sheet. The length of that path obviously increases with α, as wide fibers act as large obstacles which force a diffusing particle to wander within a plane perpendicular to flow. Also represented in Figure 19b are predictions from previous theories (54,56) for $\alpha = 6$. As in Figure 19a, these approaches lead to an overestimation of the diffusivity at high V_f because they neglect contacts between fiber elements.

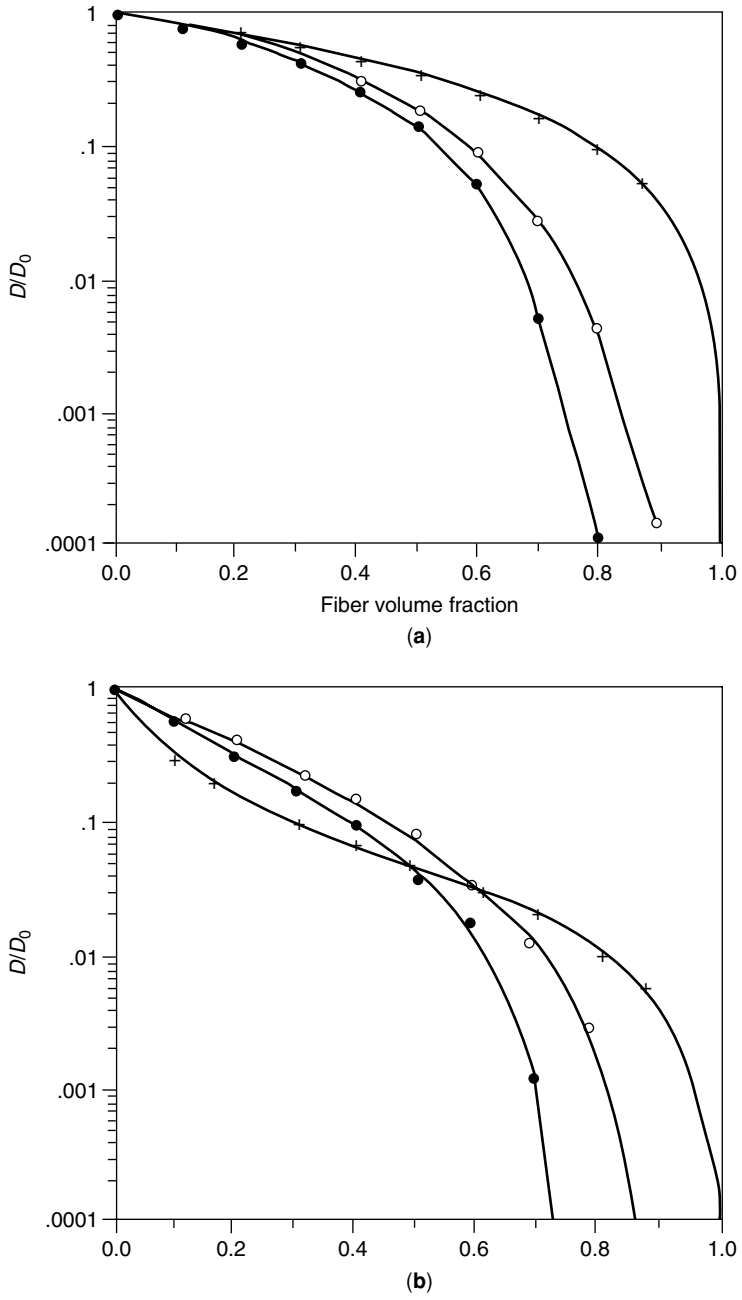

Fig. 19. (a) Normalized diffusivity D/D_0 for sheets of fibers with $\alpha = 1$. Symbols are as follows: ◯ and •, data calculated with our model for 5- and 10-layer sheets; +, model data taken from Reference 53. (b) Same as Figure 19a but, for sheets of fibers with $\alpha = 7$. Model data taken from Reference 56 for $\alpha = 6$ are denoted by the symbol +. Other model data obtained in Reference 54 fall along the same line. Reprinted from Ref. 57. Copyright (1998), with permission from Excerpta Medica Inc.

Conclusions

In summary, a series of kinetic Monte-Carlo models for the study of the effect of processing conditions on polymer structure and properties have been presented. These models are mesoscopic in the sense that the unit lattice length is of the order of the statistical segment length for the polymer chains and atomic level details are omitted. There studies have clearly revealed the importance of molecular weight, molecular weight distribution, and density of entanglements in controlling the drawability of flexible polymers in the solid state. The approach has also allowed description in detail of the processes of coagulation and quenching of a polymer solution and reproduction the wide variety of different polymer structures that can be obtained. Finally, turning to the processing of fibers into planar fibrous materials such as papers and nonwovens, it has been shown that kinetic Monte-Carlo models can be equally successful at predicting their mechanical and permeability properties.

NANOCOMPOSITES, POLYMER–CLAY

Introduction

Polymer matrix nanocomposites are a fairly new class of engineered materials which offer for a broad range of properties, an interesting and even radical alternative to more conventional filled polymers, yet at much lower filler loadings. They can be defined as polymer matrix systems in which the dispersed inorganic reinforcing phase has at least one of its dimensions in the nanometer range, which is quite close to the scale of elementary phenomena at the molecular level. The resulting unique combination of large interfacial area and small interparticle distance strongly influences nanocomposite behavior.

Current status of research and industrial development of polymer nanocomposites clearly outlines the prominent position of clay nanocomposites and the present review is mainly devoted to the latter materials.

From a general point of view, filler aspect ratio is a pertinent parameter to distinguish between various types of nanocomposites. Table 1 summarizes typical dimensions of particles under concern. Spherical silica particles are an example of isotropic nanoparticles which either provide increased composite stiffness while retaining matrix transparency, or exhibit novel optical properties by forming colloidal crystals. Although it is obviously critical to the optical behavior, it is generally observed that optimum mechanical properties are not achieved in conjunction with the best state of dispersion (1). When only two dimensions are in the nanometer range, fiber-like structures, such as whiskers or carbon nanotubes, with aspect ratios ranging between 50 and 1000 are dealt with. For instance, cellulose whiskers extracted from tunicate shells have been shown to dramatically improve composite stiffness in the case of poly(vinyl chloride) or

Table 1. Typical Nanofiller Dimensions

Material	Shape	Typical dimensions
Silica particles	Spheres	Diameter: 30–150 nm
Cellulose whiskers	Rigid rods	Diameter: 15 nm; length: 1 μm
Carbon nanotubes	Flexible tubes (multiwall)	Diameter: 30 nm; length: 10–50 μm
Layered silicates	Flexible discs	Diameter: 50–500 nm; thickness: 1 nm

poly(styrene-*co*-butyl acrylate) matrix in the rubbery state. In the latter material a 3 order of magnitude modulus improvement is achieved at only 6 mass% whisker content. Percolation of a rigid whisker network is evoked to account for such a property increase (2). Reaching a conductivity percolation threshold at very low loadings, owing to the nanoscale dispersion of carbon nanotubes with large aspect ratio, has also been of prime importance for designing conductive polymer blends with electrostatic paintability, while limiting resin embrittlement (3). Preliminary experiments with carbon nanotube–polymer composites also underline the potential of this nanofiller for entering the field of composite materials for structural applications as well (4). Opportunities for functional and/or structural applications of carbon nanotubes will mainly depend on the capacity to reach large-scale production at moderate cost and to monitor composite elaboration while retaining nanotube integrity.

Among the variety of composites that display unique structure and behavior at the nanometer level, as compared to classical micrometer scale particulate filled materials, the use of layered silicates as a reinforcing phase is by far the most successful way of designing polymer nanocomposites with a broad range of markedly modified properties. A report from Toyota Central Research Laboratories of the development of a polyamide-6 (PA6)-based clay nanocomposite with remarkable thermomechanical behavior, at low clay loadings relative to conventional filler additives (below 5 mass% instead of 20–30 mass%), triggered extensive research efforts worldwide (5). In fact the benefits were shown not only for strength and stiffness, but also for thermal stability and barrier properties (6). Accordingly, the following presentation focuses on these materials, starting with a brief description of the layered silicates commonly used, followed by nanocomposite structural characterization and elaboration routes. Various properties of interest are reviewed together with the currently emerging structure–property relationship schemes.

Polymer-Layered Silicate Nanocomposites

Layered silicates, the more widely used in polymer nanocomposites, belong to the same structural group, the 2:1 phyllosilicates, and more specifically to the smectite group. They comprise natural clay minerals such as montmorillonite, hectorite, and saponite and also synthetic layered minerals, fluorohectorite, laponite, or magadiite. An idealized structure for montmorillonite is presented in Figure 1. Elementary clay platelets consist of a 1-nm-thick layer made of two tetrahedral sheets of silica fused to an edge-shared octahedral sheet of alumina or magnesia. Isomorphic cation substitution results in an excess of negative charges within

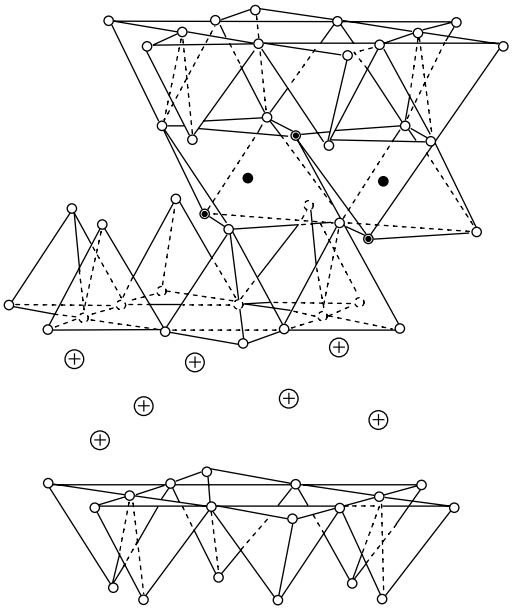

Fig. 1. Structure of montmorillonite. ● Al or Mg; ◉ OH; ◯ O; ⊕ exchangeable cations.

the layer. Stacking of the layers leads to a regular van der Waals gap called *gallery* or *interlayer*. Cations located in the galleries (eg Ca^{2+}, Na^{+}) counterbalance the excess layer charges. They are usually hydrated. This negative surface charge is quantified as the cation-exchange capacity (CEC), usually in the range from 80 to 150 meq/100 g for smectites. The interlayer space can be penetrated by organic cations or polar organic liquids as well. Exchange reactions with organic cations (aminoacids, alkylammonium ions, etc) enable to render the silicate surface organophilic. A key parameter of the stacking is the basal spacing or *d*-spacing, which ranges from 0.96 nm (ie, the layer thickness) in the fully collapsed state to about 2 nm, depending on the nature of the interlayer cation and the amount of adsorbed water (7). Individual lamellae have a high aspect ratio, with a diameter typically in the range 50–500 nm. Primary crystals (also called *tactoids*) consist of 8–10 lamellae, with usually disordered stacking. Their aggregation leads to a turbostratic structure. This organization is reflected in the x-ray diffraction (xrd) pattern where diffuse *hk* bands rather than sharp *hkl* reflections are observed. The basal reflection (001) is of more interest since it is used to derive the *d*-spacing. It will be dependent on the amount and nature of intercalated molecules in the galleries.

Characterization of Nanocomposite Microstructure. Mixing clay with a polymer does not necessarily lead to a nanocomposite. Elaboration strategies are aimed at monitoring dispersion of the inorganic compound at the nanometer level, that is down to the elementary clay platelet. Figure 2 provides a schematic illustration of the various microstructures readily achievable, namely a conventional filled polymer with clay particles in the micrometer range, an

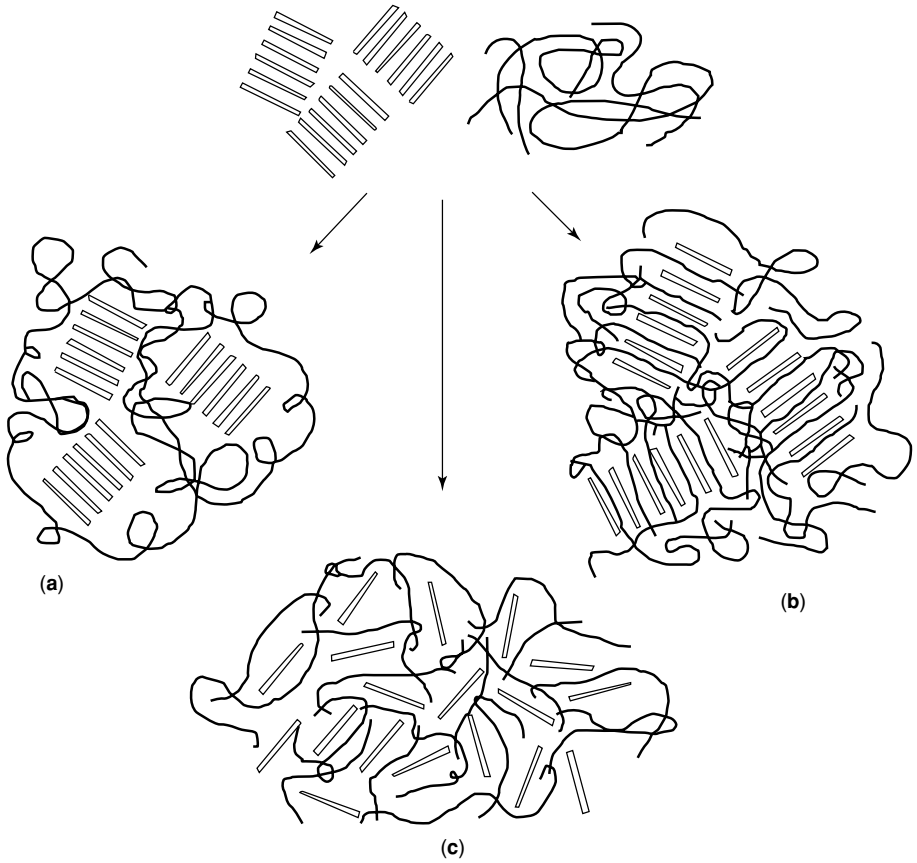

Fig. 2. Schematic representation of clay platelet dispersion as (**a**) primary crystals, (**b**) intercalated, or (**c**) exfoliated structures.

intercalated nanocomposite in which extended polymer chains are intercalated in the gap between silicate layers while the stacking order is retained (note that in this case the host gallery height is much smaller than the radius of gyration of the polymer chain), and a delaminated (or exfoliated) nanocomposite where clay layers are individually dispersed in the host polymer matrix.

The two basic tools used to elucidate nanocomposite morphology are x-ray diffraction (xrd) and transmission electron microscopy (tem). They provide complementary information on clay dispersion in the host matrix.

The basal plane reflection (00l) diffraction peak yields a direct evaluation of the d-spacing between the clay lamellae, as long as layer registry is preserved to some extent. It allows therefore to follow the structural evolution from the pristine clay stacking to any intercalated state. With changes in d values in the range 1–4 nm, such data are accessible at low diffraction angle, ie, for $1 < 2 < 9^{\circ}$. Follow up of the increase in peak width at half maximum also reflects the increase in the degree of disorder in layer stacking during the intercalation process [see eg, (8)].

Figure 3 illustrates the change in d-spacing of a stearylammonium-modified montmorillonite (C_{18}Mt) blended with a maleic anhydride-modified polypropylene

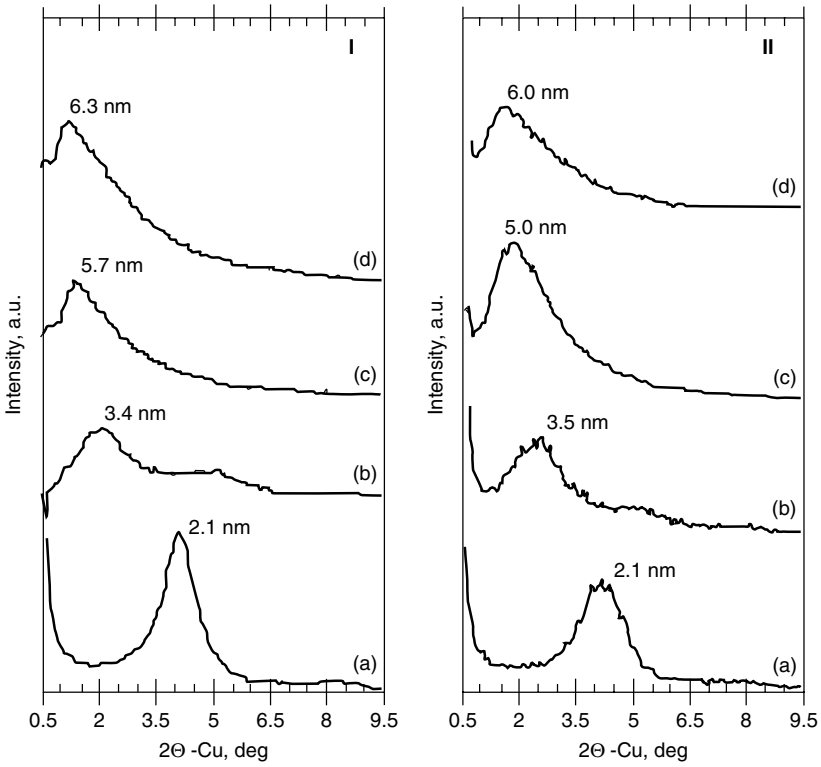

Fig. 3. Evolution of the *d*-spacing showing montmorillonite intercalation in PP-MA oligomer (**I**), and no subsequent change upon further blending with PP (**II**). Reproduced from Ref. 9.

oligomer (PP-MA). As the amount of the latter component is increased, the interlayer distance increases drastically (spectra Ia–d), indicating the efficiency of the intercalation process. Spectrum IIa reveals the lack of intercalation of C_{18}Mt by pure PP. Spectra IIb–d do not show any change in the state of intercalation assessed in Spectra I when the PP-MA intercalated organoclay is further dipersed in a PP matrix. It is concluded that PP penetration in the galleries is not favored in this particular case (9).

Whenever the xrd pattern becomes silent, meaning that the interlayer spacing is no longer accessible by conventional wide-angle x-ray diffraction, the need still remains to have access to a mesoscale description of the spatial distribution of the clay platelets. Small-angle x-ray scattering may provide some answers regarding average interparticle distance, and also about platelet orientation with respect to process geometry (10).

Transmission electron microscopy has the great advantage to give a direct view of the microstructure. Typical micrographs reveal alternating dark and bright bands refering to the silicate layers and polymer matrix respectively. The illustrations of Figure 4 show exfoliated and intercalated-exfoliated structures in the case of 1 and 5 mass% dimethylditallow ammonium-modified montmorillonite

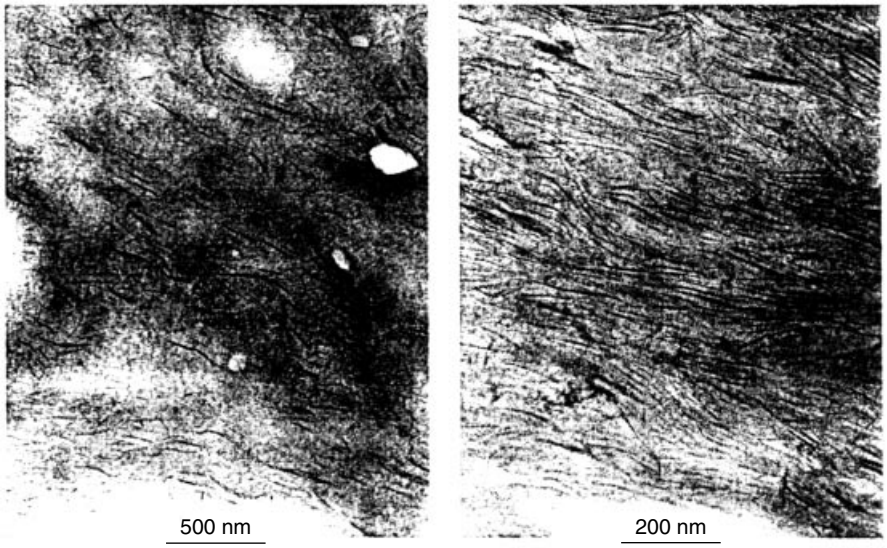

Fig. 4. Transmission electron microscopy of water-aided melt-dispersed organoclay in PA6. Courtesy of Dr M. van Es, DSM Reseach, Geleen.

dispersed by melt extrusion in a PA6 matrix. Additionally tem enables imaging of any mesoscale long-range ordering of the clay. It also reveals platelet flexibility promoted by the high aspect ratio and nanometer thickness as illustrated in Figure 5 for an intercalated organoclay tactoid in a PP matrix. An accurate description of polymer clay nanocomposites is therefore available from a combination of electron microscopy and xrd techniques.

Elaboration of Polymer–Organoclay Nanocomposites

Various methods have been developed in order to prepare polymer-layered silicate nanocomposites. These include *in situ* polymerization, polymer intercalation in

solution, emulsion polymerization in the presence of layered silicates, and melt intercalation. A few examples are given below to illustrate the different strategies. Review articles are available for more detailed information [see eg (11–13), and references therein].

***In situ* Polymerization.** Early works in the 1960s (14) demonstrated the feasability of intercalation polymerization of methyl methacrylate (MMA) after insertion–adsorption of the polar monomer between the lamellae of a sodium montmorillonite. Polymerization was initiated by free-radical catalysts or with γ irradiation. Renewed interest for the method in the last decade came from the work on PA6–clay hybrids at Toyota Central Research Laboratories (5), following a scheme adopted earlier by Unitika Co. (15). Sodium montmorillonite was first cation exchanged with ω-amino acids [$H_3N^+(CH_2)_{n-1}COOH$]. X-ray diffraction data show that the basal spacing is highly sensitive to the length of the alkyl chain. For $n > 11$, the ω-amino acid chain lies slanted to the layer and provides optimum swelling behavior by ε-caprolactam. 12-Amino-l-lauric acid ($n = 12$) modified montmorillonite (12-Mt) was used for performing the *in situ* ring-opening polymerization of ε-caprolactam. The carbonyl end groups of 12-Mt initiate polymerization and an increasing amount of polyamide-6 is bonded to the clay as the 12-Mt clay content is increased as clearly established by nmr studies (16). The resulting hybrid is either exfoliated at low 12-Mt content or increasingly intercalated beyond 10 wt% clay. In an alternative approach, the same team successfully developed a so-called one-pot synthesis of PA6–clay hybrid without preliminary cation exchange of the montmorillonite. Ring-opening polymerization of ε-caprolactam with 6-amino-l-caproic acid as an accelerator was performed in a water dispersion of montmorillonite in the presence of an acid. Phosphoric acid seems to be the best candidate to achieve true exfoliation in this particular process (17). 12-Amino-l-lauric acid was also successfully used both as a fluorinated silicate modifier and as a monomer in order to prepare a polyamide-12-based nanocomposite with exfoliated–intercalated structure (18). Some attempts to produce polystyrene (PS)-based nanocomposites through the *in situ* polymerization route have been reported (19). Intercalated structures are obtained. Intercalative polymerization of ε-caprolactone has also been achieved in the presence of α-protonated amino acid-exchanged montmorillonite. Upon heating, the organic acid groups initiate ring-opening polymerization of the monomer and the resulting polymer is ionically bound to the silicate platelets with a good level of delamination as revealed by xrd (20). *In situ* polymerization has also been extended to polyolefins, polyesters, or polycarbonate in recent years.

The production of thermoset-based nanocomposites by the same method has been investigated by many authors (21–23). In the case of epoxy–clay nanocomposites, the organophilic clay is first swollen in the mixture of epoxy prepolymer and curing agent. The gel state and final structure are strongly dependent on the nature of the onium ion, cross-linking amine, and curing conditions. In particular, larger chain length of the alkylammonium and ion-exchange with protonated primary amines should be preferred. Polyurethane networks are equally good candidates for clay nanolayer reinforcement (22). The approach consists in solvating polyol precursors in montmorillonite exchanged with long-chain onium ions and further adding the diisocyanate curing agent. Intercalated tactoids are obtained in the final cured nanocomposite.

Intercalation in Solution. In the case of water-soluble polymers, it is possible to prepare solvent-cast nanocomposites by using water as a cosolvent. Pristine montmorillonite can be easily dispersed in water, owing to its hydrophilic character, and blending for instance with polymers such as poly(ethylene oxide) (PEO) or poly(vinyl alcohol) (PVOH) is thus achievable (see eg (24–26)). Intercalated–exfoliated structures are observed for PVOH-based nanocomposites. On the contrary, in the presence of PEO, intercalated silicate layers are organized as large clay tactoids; this indicates that reaggregation of the initial silicate water suspension occurred during the film casting process. A similar elaboration strategy has also been developed, starting from an organoclay. In the examples of poly(ε-caprolactone) and poly(*l*-lactide), chloroform was used as a cosolvent. In both situations no evidence of intercalation could be found but the clay tactoids displayed a remarkable geometric arrangement, with their surfaces lying parallel to the cast film surface (27). These few illustrations are indicative of the high sensitivity of the final materials structure to the nature of the host matrix and to the interplay of polymer–polymer and polymer–clay interactions.

The above technique can be advantageously adapted to a situation where the polymer of interest is not soluble in any solvent, as is the case for polyimides. The polyimide precursor, ie, a poly(amic acid) solution in dimethylacetamide, is prepared and blended to a dispersion of an organomodified montmorillonite in the same solvent. Dimethylacetamide is then gradually removed, and upon heating the poly(amic acid) film at 300°C under nitrogen atmosphere the polyimide–clay hybrid is obtained. When an ammonium salt of dodecylamine is used in the ion-exchange process, true exfoliation is achieved and furthermore the clay platelets align parallel to the film surface (28).

Emulsion Polymerization. Considering the high hydrophilic character of sodium montmorillonite, it was anticipated that polymerization in an aqueous medium might provide an alternative route for polymer–clay nanocomposite preparation. The first report dealing with such an approach concerned the emulsion polymerization of MMA dispersed in a water phase in the presence of Na^+-montmorillonite. The structural analysis confirms intercalation of the PMMA in the clay galleries. A PS–clay nanocomposite has been elaborated according to the same procedure, with the same resulting intercalated morphology. Intercalation by the emulsion technique was also achieved for an epoxy system, again without requiring any ion-exchange treatment (29).

Melt Intercalation. Although emulsion polymerization or *in situ* polymerization may be considered as viable routes for industrial-scale production, as exemplified for PA6 with the latter process, melt compounding remains the most obvious route for cost-effective development of nanoreinforced polymers. The first industrial applications refer to the PA6–clay hybrid *in situ* polymerization process patented by Toyota (30), but growing interest in achieving clay nanodispersion by melt compounding is observed worldwide (31). Patent literature is clearly indicative of the current trend with many references to polyamides and other polar polymers such as polyesters or polyimides [see eg (32)]. Emphasis is put on the nature of the surfactant and processing conditions. Nonpolar polymers such as polyolefins are also highly attractive candidates with research efforts primarily driven by the automotive market. Polypropylene–clay hybrids have been prepared by melt mixing an organoclay, maleic anhydride-modified PP oligomers (PP-MA),

and PP. The polar PP-MA intercalates in the clay galleries and the quality of clay dispersion in the hybrids are clearly affected by the degree of miscibility of the polar oligomers in PP (9,33).

Direct melt intercalation of PEO in pristine montmorillonite by static annealing of cold-pressed powder mixture slightly above the melting temperature of PEO has been reported (34). The resulting *d*-spacing of the order of 1.8 nm indicates that the PEO chains are constrained in a 0.8-nm interlayer space. Differential scanning calorimetry studies reveal that the polymer is deprived of any thermodynamic transition. Neither the heat capacity jump characteristic of the glass transition nor the melting endotherm is observed. Chain dynamics appear quite peculiar in these systems. Thermally stimulated current results point at the essentially noncooperative nature of the motions of the confined chains. Intercalation kinetics have also been followed by xrd monitoring of the basal spacing reflection in model systems consisting of monodisperse PS and organically modified fluorohectorite. The most striking result is that the mobility of the polymer chains in this confined environment seems larger than that in the bulk melt (34,35). Spin-echo nmr experiments using deuterated PS suggest the coexistence of multiple environments, from solid-like to liquid-like, for intercalated chains. Molecular dynamics simulations relate this complex dynamic behavior to strong density inhomogeneity normal to the surface [(36), and Refs. 45 to 49 therein].

An extensive investigation of nanocomposite preparation with the aid of a swelling agent that is known to intercalate the clay provides some additional interesting experimental ground on the phase behavior. The results underline the influence of the polymer/swelling agent miscibility (as assessed by a solubility parameter approach) on nanocomposite formation. The example of an epoxy monomer as the swelling agent shows that either complete miscibility or strong immiscibility are preferable (37).

Structure Development in Polymer–Clay Nanocomposites

Whatever the elaboration route is, understanding phase behavior of the resulting nanocomposites is of prime importance to achieve reliable material development.

A lattice-based mean field model has been developed in order to address the problem of nanocomposite formation (38). By deriving the evolution of the free energy of the system with interlayer spacing, the model provides some basic predictions regarding the equilibrium states (ie, exfoliated, intercalated, or immiscible), in relation to the enthalpic and entropic factors of the interacting constituents, namely the silicate, the tethered surfactant chains, and the polymer. Polymer confinement results in entropy loss but the latter may be compensated in part by the entropy gain induced through the increase in conformational freedom of the tethered surfactant chain upon layer separation. As a consequence, melt intercalation is predicted to depend primarily on energetic (enthalpic) factors. Polar polymers or polymers containing groups interacting with the silicate surface will favor polymer–clay hybrid formation (35,38).

A theoretical investigation of the phase behavior of model analogues of polymer–clay nanocomposites has been conducted (39). Combining a self-consistent field model with density functional theory, the investigation underlines

some trends regarding phase morphology and stability for these systems. In particular, the calculations point at the key influence of the surfactant chain length. Polymer-like values lead to enhanced miscibility of the clay platelets and polymer matrix (exfoliated structure), even at moderate level of interactions between the grafted chains and polymer melt (39). The equilibrium behavior of a mixture of functionalized and nonfunctionalized chains (taken chemically identical) in the presence of two infinite planar surfaces has alternatively been considered using scaling theory. Functionalized chains have a telechelic architecture; ie, the active groups are located at each end of the chain. Qualitative phase diagrams are derived with prime consideration of the respective influences of interaction energy between the surface and the end group, and volume fraction ϕ of functionalized chains. Provided the interaction energy ε is high enough, exfoliation occurs more easily as ϕ is increased, whereas low ε values result in an immiscible mixture (40).

Nanocomposites Behavior

Thermal Stability. Thermal stability improvement was already recognized in the pioneering work by Blumstein on PMMA intercalated in montmorillonite. Intercalated PMMA degraded at a temperature 50°C higher than that of conventional unfilled PMMA. In recent years, thermogravimetric analysis of various polymer–clay systems have confirmed this observation even for low nanofiller loadings [see eg (13,41), and references therein]. A particularly striking example is that of cross-linked poly(dimethylsiloxane) incorporating 10 mass% exfoliated organomontmorillonite (42) for which thermal stability under nitrogen flow is enhanced by 140°C. Overall, restricted thermal motion in silicate interlayers and hindering of the diffusion of decomposition products are certainly key factors, but polymer structure and nature of the degradation mechanisms and degradation conditions are equally important to account for the disparities observed in literature.

Owing to what has been said previously on the role of the organic modifier of the layered silicate in elaboration and phase behavior of the polymer–clay nanocomposites, understanding of the key structural factors that influence its thermal degradation is of prime importance. Major concern is of course toward processing conditions and fire-retardant behavior as well. Recent work (43) on alkyl quaternary ammonium montmorillonite by a combination of thermogravimetric analysis, Fourier transform infrared spectroscopy, and mass spectrometry points at the complex degradation behavior of the organic surfactant. The initial degradation temperature is insensitive to chain architecture and length, or exchange ratio. Compared to the parent alkyl ammonium, the thermal stability of a fraction of the surfactant is substantially lowered because of catalytic sites on the layered silicates. Polymer processing generally implying temperatures higher than 180°C, chemical degradation of the surfactant is expected to occur. Many questions remain regarding the role of the decomposition products on the melt intercalation mechanism and subsequent nanocomposite phase stability. In this respect the potential of nmr techniques to follow the fate of the organic modifier seems quite promising (44).

Crystal Organization. Semicrystalline polymer nanocomposites present a unique interplay between nanoscale morphology of crystal lamellae on one hand and clay platelet organization on the other. Considering the importance of interfacial interactions and the confined chain environment, one may expect drastic changes in crystal organization. The case of PA6–clay hybrids is rather well documented. The preferred orientation of the silicate layers under melt-flow conditions, together with polymer confinement, will affect crystallization behavior. For instance, in injection-molded bars, close to the surface both the silicate layers and polymer chain axes (and hence lamella thickness) are parallel to the surface, whereas the chain axes rotate by 90° inside the bar and remain perpendicular to the silicate layers (45). Clay also favors nucleation of the γ phase (16,44), contrary to bulk PA6 which predominantly crystallizes in the more stable α form. The elevated temperature (205°C) crystal morphology of PA6–clay hybrids has been examined by performing simultaneous small- and wide-angle x-ray scattering (46). These results clearly establish that the nanoscale correlations of the silicate layer organization (40–60 nm) affect polymer crystallization, resulting in a less-ordered crystal γ phase. Evidence is also provided of the impact of polymer-layer interactions (tethered vs nontethered chains), the more defective lamellae pertaining to the *in situ* polymerized (tethered) nanocomposites. Spherulitic structure is unable to develop as in bulk polymers, which ought to influence the nonelastic mechanical response. Similar crystallization behavior is also observed in other semicrystalline polymers such as poly(ε-caprolactone) or poly(ethylene terephtalate) nanocomposites (27,47). The observation of high melting temperature phases, though defective, might come from a reduced entropy of fusion ΔS_f due to the confined crystallization environment.

Fire-Retardant Behavior. Controlling polymer flammability remains a key issue in numerous applications of engineering plastics and commodity polymers as well. The fire-retardant additive approach provides cost-effective solutions, but generally at the expenses of some physical and mechanical properties. There is also growing pressure for environmentally safe products and processes, including recyclability and use of halogen-free compounds. For these reasons, recognition of improved flammability properties in the case of polymer–clay nanocomposites has triggered the development of extensive research programs on a large variety of materials (41,48,49).

Cone calorimetry is used to evaluate the flammability under fire-like conditions. Relevant parameters such as the rate of heat release (HRR) and its peak value, heat of combustion (Hc), smoke yield (specific extension area, SEA), and carbon monoxide yield are obtained. Table 2 shows some typical data for layered silicate nanocomposites based on organically treated montmorillonite, with polyamide 6, poly(propylene-*graft*-maleic anhydride), and polystyrene as the host matrix. Nanocomposites under investigation have either delaminated (PA6) or intercalated–delaminated structures. In all cases there is a substantial reduction in peak HRR value (50–75%), whereas Hc and CO formation show little variation.

Table 2 also compares the PS–clay nanocomposite with a PS–clay mix for which intercalation does not occur. The kinetics of heat release are displayed in Figure 6. In the case of the mix, particle dispersion is only achieved at the primary particle micrometer level. The peak HRR value remains identical to

Table 2. Cone Calorimeter Data[a]

	Residue yield, %	Peak HRR, kW/m^2	Mean HRR, kW/m^2	Mean Hc, MJ/kg	Total heat released, MJ/m^2	Mean SEA, m^2/kg	Mean CO yield, kg/kg
Nylon-6	1.0	1011	603	27	413	197	0.01
Nylon-6–clay 2% delaminated	3.0	686	390	27	406	271	0.01
Nylon-6–clay 5% delaminated	5.7	378	304	27	397	296	0.02
PS	0	1118	703	29	102	1464	0.09
PS–clay mix 3% immiscible	3.2	1080	715	29	96	1836	0.09
PS–clay 3% intercalated	3.7	567	444	27	89	1727	0.08
PP-*g*-MA	0	2028	861	38	219	756	0.04
PP-*g*-MA–clay 5% intercalated	8.0	922	651	37	179	994	0.05

that of pure PS while the intercalated PS–clay nanocomposite shows a 50% reduction.

The observed reduced flammability in the nanocomposites may not be attributed to an additional retention of carbon alone since the residue yields are not markedly increased. Some key insights are provided by radiative gasification experiments which enable to follow pyrolysis either in a nitrogen or in a nitrogen–oxygen atmosphere. The example of PA6 nanocomposites is revealing

enough of enhanced char formation and reduced mass loss rate in comparison to pure PA6. The current interpretation of these results is that the nanocomposite flame-retardant mechanism occurs through the build up of a reinforced char layer, which acts as an insulator, and a mass transport barrier so as to slow down the escape of the decomposition products. Developments according to this concept include the use of a PA6–clay nanocomposite in intumescent formulations as in the case of ethylene–vinyl acetate copolymers with ammonium polyphosphate (50). Enhanced flame-retardant performance is related to the formation of a thermally stable phosphocarbonaceous structure in the char, and the blend even shows a slight improvement in mechanical behavior.

Processing conditions also strongly influence the flame-retardant behavior. For example, in the case of PS-based nanocomposites, extrusion above 180°C under partially oxidative conditions yields an intercalated nanocomposite but with no flammability improvement, whereas the melt-extruded system at 170°C under nitrogen or vacuum exhibits flame-retardant efficiency (41). The way thermal degradation of the organic modifier alters the flammability reduction mechanism has yet to be understood.

Barrier Properties. Early work in the Toyota Research group acknowledged the great potential of polymer–clay nanocomposites to reduce moisture absorption and decrease water and gas permeability, even at low clay loadings (6). A further advantage for packaging applications lies in the fact that lowering of permeability is achieved while preserving transparency, owing to the suitable dispersion of platelets smaller than the wavelength of visible light.

The example of polyimide clay films illustrates the dramatic decrease of permeability coefficients. Only 2 mass% montmorillonite loading reduces the permeability by more than 50% of the pure polymer value for water vapor, oxygen, or helium. Notwithstanding possible changes in diffusion and/or solubility, it has been postulated that the major role of the clay platelets consists in substantially increasing the path length of the permeant, that is by creating a highly tortuous path, due to the high aspect ratio of the clay. A simple theory derived by Nielsen expresses the relative permeability as follows:

$$P_c/P_o = 1/[1+(L/2W)V_f]$$

in which V_f is the volume fraction of plates, L is the plate length, and W is the thickness. P_c and P_o stand for the nanocomposite and polymer permeability respectively.

Using equivalent loadings of clay but varying the aspect ratio yields results in fairly good agreement with the theoretical prediction (28). In the same way, a significant reduction in water vapor permeability was observed in the case of a poly(ε-caprolactone)–organomontmorillonite nanocomposite, showing a fivefold reduction at only 4.8 vol% clay whereas it is only halved at best with a 20 vol% conventionally filled silicate composite (20). The tortuosity model shows discrepancies between actual aspect ratios measured by tem and values deduced from curve fitting. Among the reasons for that are the deviations from the ideal dispersion of platelets parallel to the film surface, and possible aggregation of individual platelets.

Although tortuosity plays a role in barrier enhancement, some other factors ought to be taken into account (see BARRIER POLYMERS). Recent work on MXD6

Table 3. Comparison of PA6 and PA6–Clay Hybrids Mechanical Properties[a]

Property	PA6 clay hybrid	PA6
Tensile strength, MPa[b]		
At 23°C	97	69
At 120°C	32	27
Tensile modulus, GPa[c]		
At 23°C	1.9	1.1
At 120°C	0.6	0.2
Flexural strength, MPa[b]		
At 23°C	143	89
At 120°C	33	12
Flexural modulus, GPa[c]		
At 23°C	4.3	2.0
At 120°C	1.2	0.3
Izod impact, J/m[d]	18	21
Charpy impact, KJ/m^2[e]	6.1	6.2
HDT (1.82 MPa), °C	152	65

[a]After Ref. 5.

[e]To convert kJ/m^2 to ft·lbf/in.^{2}, divide by 2.4.

nanocomposites is indicative of an oxygen permeation reduction in humid environment far beyond what is expected from the increase in path length alone (51). In the light of the findings regarding chain packing and dynamics in such confined environments (36), models for the prediction of barrier properties ought to take into account the changes induced in terms of solubility and diffusion. A conceptual model has been proposed (52). So far no general predictive approach is available.

Mechanical Behavior. Being able to improve strength and stiffness with limited alteration of toughness is a goal readily achievable with polymer–clay nanocomposites (see MECHANICAL PROPERTIES; REINFORCEMENT).

Table 3 gathers some key data of the original work by the Toyota group (5), which show the dramatic influence of organomontmorillonite on mechanical properties of PA6–clay hybrids at low mineral loading (4.7 mass%). The improvement in strength is claimed to have little or no influence on impact properties as evaluated from Izod or Charpy tests. Increase in modulus is paralleled by a substantial rise in heat distortion temperature. A concept of constrained polymer region related to the ion-bonding strength of clay and PA6 is introduced to account for the observed behavior.

Linear Elastic and Rubber Elastic Behavior. Although stiffening is quite noticeable in the glassy regime of the amorphous phase, the most spectacular effect is seen in the rubber elastic regime phase, as already evoked in the case of reinforcement by cellulose whiskers (2). The PA6–clay hybrids example presented in Table 3 is quite representative of the situation encountered with semicrystalline thermoplastics, but elastomeric networks benefit as well of clay layer dispersion with a two- to threefold increase in modulus for polyurethane or epoxy networks

(22). In the meantime, improved elongation at break is observed, contrary to what is seen in classical filled systems, presumably due in part to dangling chain formation in the network (see ELASTICITY, RUBBER-LIKE). The dynamic mechanical loss peak related to the glass-transition mechanism is equally informative on the extent of polymer–clay interaction. This shows mainly in the reduction of the loss peak area and/or in the evolution of the peak temperature with clay content and elaboration conditions (5,53). Predictive modeling of both storage and loss modulus faces a complex challenge in order to account for the mechanical coupling between the phases, the potential existence of an interphase, and/or a certain degree of connectivity between the fillers. In the latter situation, a percolation approach should be useful (2,54). Otherwise models derived from Halpin–Tsai equations seem quite promising for modulus prediction in relation to clay platelet arrangement (55,56).

Plasticity and Rupture. The main drawback identified regarding the solid-state drawing behavior is certainly the limited elongation at break encountered for most thermoplastic–clay nanocomposites (9,33) in the vicinity or below the glass-transition temperature. Nanovoiding and subsequent extensive fibrillation of the polymer matrix is clearly evidenced from volume strain measurements during drawing (53) and from *in situ* tem observations (57). Such enhancement of nanoscale plasticity offers an opportunity for optimizing the stiffness/toughness balance. However critical microvoids may develop from areas where load transfer is no more achievable because of splitting of clay platelet aggregates. This points at the most critical issue in nanocomposite development, ie, monitoring of elaboration and processing conditions.

Key Role of Processing. Scarce work has been devoted to the influence of processing on microstructure and properties of polymer–clay nanocomposites (58, 59). It is shown that twin-screw extrusion enables achieving a significant degree of dispersion of the clay platelets, provided residence time and degree of shearing are optimized in conjunction with the nature of the organoclay. Thermal stability of the organic modifier is again at the heart of the problem.

In the same way as demonstration was made in the last decade of the importance of processing to design polymer blends, taking the full benefits of the interesting combination of properties displayed by polymer nanocomposites will mainly rely on key developments in the field of processing. Automotive and packaging markets are undoubtedly the driving force for it.

PACKAGING, FLEXIBLE

Introduction

Flexible packaging is used to deliver a product from the manufacturer or distributor to the retailer or ultimate consumer and protect that product during shipping, display, and storage. The total North American market for flexible packaging was estimated to be worth approximately $17 billion in the year 2000 (1). Flexible packaging provides a lightweight, cost-effective means for the transportation, storage, and display of many products. Flexible packaging offers many advantages over competitive rigid packaging including reduced weight and volume of packaging material used, and subsequently discarded, as well as increased consumer convenience. Whatever the application or use, polymer materials are selected, and the entire packaging structure is designed, to meet the performance requirements specific to that particular application.

Performance requirements may include the requirements of all users in the value chain. For consumers this may mean the packaging protects the product, identifies the product, and is easy to open. For retailers the packaging may provide eye-catching graphics that help sell the product and is of the proper physical form for display purposes. For the packager, flexible packaging may need to provide high packaging speeds and low scrap rates, as well as meeting the functional requirements for protecting the product inside the package. Specific performance requirements will vary greatly from one type of package to another. But in every case meeting the performance requirements will help assure proper protection of the goods being packaged.

Encyclopedia of Polymer Science and Technology. Copyright John Wiley & Sons, Inc. All rights reserved.

Forms of Flexible Packaging

Flexible packaging films may be in the forms of wraps, bags, and pouches of many shapes and sizes. Packages may be as small as a single-serving sugar pouch or as large as a palletized load of mulch bags. Packaging may be supplied to the packaging end-user in the form of premade bags or pouches, or rolls of film. The film may be applied directly to the packaged goods, as in the case of stretch film, or may be formed into a package in-line with the filling machinery, as in the case of a bag formed on a vertical form/fill/seal machine used to package candy. Some packages are formed in a step that occurs well before the product is packaged. Then the product is placed inside the package and the package is secured.

Key Performance Requirements. Some of the key performance requirements for high performance flexible packaging include the following. Barrier properties: to keep oxygen, water, light, or grease from entering the package or from leaving the package. Barrier properties may be characterized by measuring the permeation of oxygen and water vapor through the packaging material. Selective permeability: to allow oxygen and carbon dioxide to permeate through the package at a calculated rate, in order to extend the life of fresh-cut produce, for example. Oxygen, carbon dioxide, and water vapor permeability are frequently measured and specified (see BARRIER POLYMERS). Abuse resistance: to prevent damage to the packaging material and its contents during shipping and storage. Abuse resistance may include puncture resistance, tear strength, impact strength, and modulus. Some packages require good toughness at refrigerated or freezer temperatures. Sealability: to allow packages to be made at high packaging speeds and keep the product secure by preventing the package seams from failing. Sealability may be characterized by heat seal and hot tack strength, heat seal and hot tack initiation temperatures, seal-through-contamination performance, caulkability, and seal integrity. *Hot tack* refers to the strength of the seal while still in the molten state. It is critically important for packages where the product drops into the package while the seal is still partly molten. *Caulkability* refers to the ability of the sealant material to flow, filling in gaps around folds, wrinkles, or product contaminants. Machineability: to allow the packaging films to be easily run on high speed automatic packaging equipment. Machineability is governed largely by film modulus, film thickness, seal properties, and coefficient of friction. Consumer appeal: package appearance is an important factor driving product preference by consumers. Appeal is largely related to print quality and package gloss. Film thickness and modulus may also impact consumer appeal.

Polymer Materials Frequently Used in Flexible Packaging. Polymer materials commonly used in flexible packaging include linear low density polyethylene (LLDPE) (ETHYLENE POLYMERS, LLDPE, PROPYLENE POLYMERS (PP)), low density polyethylene (LDPE) (ETHYLENE POLYMERS, LDPE), high density polyethylene (HDPE) (ETHYLENE POLYMERS, HDPE), high molecular weight high density polyethylene (HMW-HDPE), and polypropylene (PP). Higher value, more specialty polymers used include polyolefin plastomers (POP), ultralow density polyethylene (ULDPE) (Ethylene Polymers, VLDPE), metallocene-catalyzed linear low density polyethylene (mLLDPE), enhanced polyethylene (EPE), ethylene vinyl acetate (EVA) copolymers, acid copolymers, (IONOMERS), nylon or polyamide

(PA), poly(ethylene terephthalate) (PET), ethylene vinyl alcohol (EVOH), and poly(vinylidene chloride) (PVDC). See POLYAMIDES, PLASTICS; POLYESTERS, THERMOPLASTIC; VINYL ACETATE POLYMERS; VINYL ALCOHOL POLYMERS; VINYLIDENE CHLORIDE POLYMERS (PVDC). See also FILMS AND SHEETING.

These polymers are selected for the specific performance that they provide, and are combined in the final package design to meet all the requirements for the specific application in which they are being used. Often there are many different combinations of materials or film constructions that will meet the minimum performance requirements of an application. In these cases selection of the final packaging structure may be based on considerations such as availability from multiple suppliers and ability to provide differentiation over competitive packaging. For example a combination of a box and an inner liner may be used or a stand-up pouch may be used, each combination providing the minimum requirements for product protection and safety. One manufacturer may select to use a box and inner liner and other manufacturers may elect to package their product in a stand-up pouch for the same product. Or one manufacturer may choose to use a stand-up pouch and another manufacturer may choose to use a pillow pouch for the same product.

Polymers may also be combined with other materials, such as foil or paper, to create a flexible package with performance attributes not achievable by the polymers alone. This is done through the lamination or extrusion coating process, described below.

Manufacturing Techniques

Polymer films may be manufactured by blown film or cast film extrusion or by extrusion coating of a polymer onto another substrate such as paper or aluminum foil (see FILMS, MANUFACTURE; EXTRUSION). Blown films are made by melting and pumping polymer through an annular die. Cast films are made by melting and pumping polymer through a flat die. The extrusion coating process is similar to the cast film process except that the molten polymer is coated directly onto another material. The selection of manufacturing process is governed by factors such as the size of the job to be run, the type of packaging material to be made, performance requirements for the end-user packaging, and availability of equipment. Cast film extrusion equipment typically operates at much higher output rates than blown film equipment, so it may be advantaged for production of large volumes of film of a single type, such as in the manufacture of stretch film. Blown film extrusion typically runs at a lower rate and may result in film with improved physical properties. Blown film also allows for adjustment of the bubble size and resulting width of the film produced, a key advantage when films of many different widths must be produced on the same machine.

The coextrusion process is used to combine multiple materials into a single film (see COEXTRUSION). Both blown films and cast films may be coextruded in three, five, seven, or more layers. The combination of multiple materials in a single film allows a cost-effective means of combining the performance properties of several polymers in a single film. One example would be the coextrusion of a

barrier polymer such as EVOH or PVDC with a sealant resin such as LLDPE, EVA, or a POP. Coextrusion is widely used in producing high performance packaging films such as those used to package foods. It is also widely used to produce industrial films such as stretch film, and is increasingly used in producing other types of industrial films.

Polymer films may be stretched, or oriented, to impart improved properties useful for a variety of packaging applications. Oriented film is produced by a double bubble or tenter frame process. A thick film or sheet is manufactured at a thick gauge, typically 0.254–0.508 mm (10–20 mil) and is subsequently oriented (stretched) in a semisolid state to many times its original dimensions (see FILMS, ORIENTATION). The multiple-step production is normally done in a continuous operation. The stretching of the sheet to make the final film may occur simultaneously in the machine and transverse directions, or the stretching may occur sequentially. After orienting, the films are typically 12.7–25.4 μm (0.5–1.0 mil) thick. The film is typically supplied in roll form. Biaxially oriented polypropylene (BOPP) is most often manufactured using a tenter frame process. Oriented polyethylene films are usually manufactured using a double bubble process. PVC films may also be oriented. Some oriented films are crosslinked to further enhance their performance. Compared to other films, oriented films typically provide improved optical properties, higher stiffness, and increased film shrinkage during packaging, which leads to improved package appearance.

Lamination is used to combine two or more films into a single packaging structure. It allows for the combination of materials that cannot be coextruded. An example would be a lamination of aluminum foil and a polyethylene sealant film. More complicated laminations may include multiple types of polymer film, paper, and foil. Laminations can be categorized into main types: adhesive laminations and extrusion laminations. In adhesive laminations, the substrates are combined using an adhesive material. In extrusion laminations the substrates are adhered together using a molten polymer, often LDPE, as the adhesive layer. Lamination offers an additional benefit of allowing for the protection of the printing ink between layers of polymer, thus providing superior graphics to packages which are surface printed. Many packages with superior graphics, such as glossy stand-up pouches, have a reverse printed outer layer laminated to structural and sealant materials. Laminations are also used to provide a barrier to oxygen, moisture, or light. The barrier functionality may be provided by foil or a barrier polymer such as EVOH or PVDC. Most high value processed meat and cheese packages are laminations. This allows for both the combinations of various materials into the packaging structure and for the superior graphic properties possible by reverse printing the surface layer of the package and protecting the printing inks within the package itself. Since laminations are more costly than coextruded or monolayer films, laminations are generally reserved for use in higher value applications.

Metallization is used to apply a thin coating of metal, typically a form of aluminum, to a polymer film. This provides improved oxygen and water barrier properties as well as barrier to light. The best known use of metallized film is probably potato chip bags. Metallized films may also be used for nuts and salty snacks. Metallized films may be coated to provide sealability or may be laminated to

another polymer film to provide improved properties such as seal integrity. Other types of coatings, whether to provide barrier properties of other functionality, may also be applied to polymer films used in flexible packaging.

Methods of Producing Packages. Packages may be formed in-line by a variety of techniques or may be supplied to the packer as preformed pouches or bags. Packaging may be created by wrapping or shrinking a basic film around a bundle of goods. Examples of in-line packaging forming include vertical form/fill/seal (VFFS), horizontal form/fill/seal (HFFS), and thermoform/fill/seal. In VFFS operations, film from a roll is passed through a series of rollers and is shaped by a forming collar into a tube. The film moves in a vertical direction (down) over a filling tube. A vertical seal is made, forming the film into a continuous tube. As the film continues through the machine, a horizontal seal is made, perpendicular to the machine direction of the film, forming the bottom-end seal of the bag. The product is dropped into the partially formed bag and the top-end seal is made. The process may operate in a step-wise or continuous manner. One example of a product normally packaged on VFFS equipment is fresh-cut produce. In HFFS operations, the film moves in a horizontal direction during the packaging step, eliminating the need for high hot tack strength. One application that typically uses HFFS equipment is chunk cheese. In thermoform/fill/seal operations, a bottom web is formed, product is added, and the top web, which is normally flat, is sealed to the bottom web. Thermoform/fill/seal packaging is frequently used for bacon and processed meats. Stand-up pouches and other types of packaging may be formed in-line with the filling equipment, or may be fully or partially prefabricated prior to the filling step.

Uses and Types of Flexible Packaging

Flexible packaging is used for the packaging of all types of items including food products, medical devices, industrial goods, and consumer goods. The packaging types can be described in terms of the products being packaged, such as bakery goods, or by the type of packaging being used, such as shrink film. Major uses for flexible packaging are described below.

Food Packaging. One key use of high performance flexible packaging films is the packaging of food for distribution and retail sale. Food products are increasingly being packaged at the manufacturer end for sale to the ultimate consumer in the original package. This is a change from the traditional distribution system where the product was wrapped for the consumer at the butcher shop.

Fresh Red Meat. Fresh red meat is often transported in large pieces from the slaughtering house to local butcher shops in large barrier bags. These bags are designed to provide a barrier to oxygen. As well as oxygen barrier, package toughness and seal integrity are key requirements for these bags. These bags may contain PVDC or EVOH as a barrier material, along with layer of various PE resins for toughness and sealability.

Processed Meat. Processed and cook-in meat such as luncheon meat, ham, bologna, and salami are packaged in barrier films that are designed to

keep oxygen from entering the package. This extends the shelf-life of the meat product and allows the retailer to display the product for sale for an extended period of time. It also allows the consumer to keep the product in their refrigerator, unopened, for some period of time after purchase. These packages are often printed with eye-catching graphics to increase the likelihood of retail sale. These films may contain a barrier polymer, printing surface such as PET or nylon, toughness layers of LLDPE or ULDPE, and a sealant layer that could be LLDPE, a POP, or an ionomer. In addition to low permeability to oxygen, abuse resistance and seal integrity are critical to maintaining the proper atmosphere inside the package. Optical properties such as high gloss and high clarity are important to create consumer appeal. Barrier requirements for processed meats range from 0.2 to 1.0 $cm^3/(100\ in.^2 \cdot day \cdot atm)$ for oxygen transmission rate (OTR) and 0.2–0.5 $g/(100\ in.^2 \cdot day)$ for water vapor transmission rate (WVTR).

Case-Ready Meat. An emerging use for plastic packaging is in the packaging of case-ready meats. In this application, a smaller package of fresh meat is packaged immediately after the slaughtering operation and distributed through retail stores directly to consumers. This saves the step of having the local butcher cut and prepare the individual cuts of meat for retail sale. It allows for reduced labor at the retail level and better usage of various cuts of meat. It also provides an improved level of food safety because handling of the raw food is reduced. Pork products such as pork loins and ribs are commonly sold in case-ready flexible packaging. Beef and other meat products are increasingly being sold in case-ready packaging. Different types of case-ready systems operate using different systems for product protection and extension of shelf-life. Some products are packaged in barrier packages, totally excluding oxygen from the package. Some case-ready systems package the food in a high oxygen environment, and these systems also use barrier films. Other systems package the meat in a bag or tray/lid combination that allows oxygen to permeate the package at the proper time to allow reddening of the meat that is expected by consumers.

Retortable Pouches. A growing use of flexible packaging is in the replacement of metal cans with retortable pouches. These pouches are typically laminations containing biaxially oriented nylon for toughness, foil for oxygen barrier, and a PP sealant film. These pouches may contain items like tuna, pet food, and soup. The food items are held at elevated temperature after packaging, so the packages must remain intact at elevated temperatures. A minimum requirement might be the ability to withstand a temperature of 130°F for 20 min. In addition to temperature resistance, toughness, seal strength, and barrier properties are critically important.

Bakery Products. Bakery products such as bread, bagels, and tortillas are usually sold in plastic bags. These bags are typically surface printed LDPE or LLDPE and their main functional requirement is to protect the product from drying out or being damaged during distribution. Good machineability is required for high packaging speeds. These films are typically surface printed monolayer structures. A haze of 5% or less is typically required of these high clarity films. Films generally require COF of below 0.2 for fast packaging speeds.

Candy and Confectionery Packaging. Candy and other sweets are packaged in flexible packaging. At the smallest level, individual bite-size portions of a candy product may be packaged in a small pouch or a twist–wrap type package. Candy bars are typically wrapped with oriented PP film that has been surface printed. These items may then be packaged in a secondary bag, which may be a laminated structure containing polyethylene and sometimes reverse printed BOPP films. The outer bags must have sufficient toughness to protect the food inside. The films are generally very glossy for maximum consumer appeal. To provide fast packaging speeds the films need to have high hot tack strength combined with low hot tack and heat seal initiation temperatures.

Cheese. Most cheese sold in the United States is prepackaged in some type of flexible packaging. Types of cheese packaging include individually wrapped slices of processed cheese, chunk cheese, and shredded cheese. Both chunk cheese and shredded cheese require substantial barrier to oxygen to prevent mold growth and spoilage. Either EVOH or PVDC may provide the oxygen barrier. While EVOH is generally coextruded into the film structure, PVDC may be coated onto the surface of a film via a coating process. They also require excellent seal integrity and abuse resistance to prevent the controlled atmosphere inside the package from being lost. Cheese packages are often laminations made with reverse printed outer webs containing PET or nylon for superior graphical presentation. They may also be extrusion coated structures where the sealant layer has been extrusion coated onto the outer layer. Sealant layers may consist of EVA, an ionomer, or a POP. Low heat seal initiation temperature (90°C or below) and good seal through contamination performance are required of the sealant material used. Processed cheese typically require films with OTR of 0.6–1.0 $cm^3/(100\ in.^2 \cdot day \cdot atm)$ and WVTR of 1.0 $g/(100\ in.^2 \cdot day)$.

Fresh-Cut Produce. Key performance requirements for fresh-cut produce packaging include proper oxygen and carbon dioxide permeability, seal integrity, machineability, and consumer appeal. Consumer appeal includes both feel and appearance. Feel is generally determined by film thickness and modulus while appearance is governed by print quality and film optical properties such as clarity, haze, and gloss. In order to extend the shelf-life of the produce being packaged, films must provide a level of oxygen permeability that is properly matched to the respiration rate of the produce inside the package. Cut produce respires after harvesting consuming oxygen and giving off carbon dioxide. By controlling the permeation of gases through the package the environment inside the package is controlled, respiration is slowed, and shelf-life is extended. The bags must have complete seal integrity in order to prevent the unplanned transfer of gases between the bags and the environment. Bags may contain PP, LLDPE, ULDPE, EVA, or POP. Oxygen transmission rate requirements vary widely depending on the type of produce being packaged, but common items range from about 100 $cm^3/(100\ in.^2 \cdot day \cdot atm)$ for caesar salad mixes, 150–200 $cm^3/(100\ in.^2 \cdot day \cdot atm)$ for iceberg salad mixes, ad 200–350 $cm^3/(100\ in.^2 \cdot day \cdot atm)$ for specialty salad mixes such as baby greens and exotic lettuces.

Frozen Foods (Fruits, Vegetables, IQF Poultry). Frozen foods are packaged in a variety of packaging types. Examples of frozen foods packaged in flexible packaging include frozen fruits, vegetables, french fries, and individually quick frozen chicken breasts. Many frozen foods are packaged in surface printed

polyethylene films. Some higher value added items are packaged in laminations, which may be shaped into stand-up pouches. Most frozen food bags are made on standard VFFS machinery. Low temperature toughness, modulus, high hot tack strength, and high seal strength are key requirements for frozen food packaging. Some packages are clear and require good clarity, while others are pigmented and require good gloss. LLDPE, ULDPE, EVA, and POP resins are all commonly used in creating frozen food packaging. Stiffness must be adequate for high speed packaging, and packaging films must have tear and puncture strength high enough to prevent package damage during transportation and storage.

Crackers, Cookies, and Cake Mixes. Inner Liners are used for packaging products such as cereal, crackers, and cookies inside a box. The key performance requirement for packaging these products is most often moisture barrier. The packaging film selected must be capable of keeping the product dry and in excellent condition upon delivery to the consumer. The packaging must offer seal integrity and machineability as well. Certain products have additional requirements such as puncture resistance—to keep the product from poking through the packaging film—and flavor and aroma barrier for highly flavored cereals. Most inner liners contain HDPE for its moisture barrier properties and a sealant layer which may be EVA or POP. Heat seal initiation temperatures of 90°C and below are commonly required. MVTR of 0.2 g/(100 in.^{2}·day·atm) or below is often required.

Salty Snacks. Salty snacks are frequently high in fat content and may require a package that provides an oxygen barrier in order to prevent the fat in the food from going rancid. They may also require grease resistance to keep the package from leaving an oily spot. Salty snacks may be packaged in barrier films containing foil, a metallized polymer film, or a barrier polymer such as EVOH or PVDC.

Potato Chips. Potato chips are often packaged in metallized films. Metallization of a polymer film provides a combination of oxygen barrier, moisture barrier, and light barrier. The use of a clear polymer film would not provide equivalent light barrier. Seal strength must be optimized to provide a secure package that can be easily opened by the consumer. Seal integrity and consumer appeal are also critical for this type of snack food packaging.

Ice. Ice bags are a specific type of carry-out bag used to transport manufactured ice. These bags are typically surface printed monolayer films. EVA copolymer is frequently used for these bags for its combination of sealability, low temperature toughness, and ease of manufacture into a film. Ice bags require good low temperature toughness, especially puncture strength, and adequate seal strength to prevent the bags from bursting. The bags must not, however, be so strong that the consumers cannot easily get to the ice inside the package.

Medical Device Packaging. Flexible films are used to package many types of medical devices. These packages must protect the device from contamination. Some medical devices are sterilized after packaging, and for these devices the packaging must be compatible with the sterilization procedure and must then maintain the sterile environment until the package is opened. Seal integrity and abuse resistance are key requirements for medical packaging (see MEDICAL APPLICATIONS).

Industrial Packaging.

Heavy Duty Shipping Sacks. Heavy duty shipping sacks are used for the transportation of items such as resin, salt, pet food, fertilizer, chemicals, topsoil, bark mulch, and compressed bales of fiber glass insulation. They typically contain 40 pounds or more of product. Heavy duty shipping sacks may be supplied as preformed bags or as rollstock, which is formed into bags in a continuous VFFS operation. Special machinery is required to form heavy duty shipping sacks on VFFS machinery in a high-speed continuous operation. These bags need moderate COF because they must easily pass through the packaging equipment, but stacked bags must slide off each other. Bags filled with hot products, such as salt, must also be able to withstand the filling temperatures without excessive stretching or dimpling of the film. Film toughness and creep resistance are also of key importance in many heavy duty shipping sack applications.

Shrink Film. Shrink film is used to collate bundles of goods. Industrial shrink film is typically manufactured by the blown film process from a blend of LDPE and LLDPE. Specialty polymers may be used to impart specific properties required for specialty applications of industrial shrink film. The use of LDPE, with its long chain branching and high level of molecular entanglement results in a film with a significant amount of molecular orientation locked into the film after fabrication. When the film is subsequently heated the oriented molecules tend to relax and return to an unoriented state. This allows the film to be shrunk around the packaged goods by the application of heat. This is most typically done in a shrink tunnel or sometimes with a hot air gun. Common uses of shrink film include cases of bottled water and soft drinks. Industrial shrink films are typically several mils thick. Shrink films require good shrinkage properties and holding force as well as enough abuse resistance to protect the product being packaged.

High Clarity Shrink Film (Oriented). Oriented, high clarity shrink film is used for the protection and display of high value consumer goods. It is distinguished from regular shrink film by its superior clarity and appearance, as well as increased shrinkage properties and higher stiffness. Goods are packaged by wrapping the film loosely around the goods, sealing the film to make a completely enclosed bag, and then shrinking the film by passing the package through a shrink tunnel or oven. Small holes may be poked in the film before wrapping to allow air to escape from the surface of the package while the film is shrinking. As in industrial shrink film, heat causes the molecules in the film to relax, causing the film return to its original unoriented size, and it shrinks tightly around the packaged goods. Since the polymer molecules in oriented shrink film are much more highly oriented, a greater level of shrinkage may be obtained. Boxed software and stationery products are often wrapped with high clarity shrink film. Ice cream cartons and other food products are also wrapped in high clarity shrink film. Optical properties, seal properties, shrinkage, and holding force are key requirements for oriented shrink film (see FILMS, ORIENTATION).

Liners. Liners, called trash bags by most consumers, are used for waste disposal in homes and businesses. Liners range in size from small bags used to line a bathroom wastebasket to large lawn and leaf bags sized to hold 40 gallons or more of waste. Liners may be supplied on a continuous roll, which

has been perforated for easy separation of the individual bags, or as separate bags contained in a box or bag. Liners are made from blown film, and the bags may be aligned in either the machine or cross direction. Bags supplied on rolls are aligned with the machine direction of fabrication, and the width of the bag is equal to the layflat obtained during blown film extrusion. Some bags, such as drawstring bags, may be aligned in the cross direction, or transverse to the direction of fabrication. These bags have seals on their sides that run perpendicular to the direction of fabrication. Liners are made primarily from LLDPE. Key properties include tear strength, impact strength, and tensile strength and modulus.

Storage Bags. Storage bags are small polyethylene bags, normally containing a plastic zipper or other closure, used by consumers and businesses for storing small quantities of food or other products. They are typically made from LDPE or LLDPE or blends of these two materials. Bag thickness may range from less than 1 mil to more than 3 mils depending on total bag size and intended use. Most bags are unprinted, though some contain a special labeling area on the outside of the bag for use by the consumer in marking the bags with a brief description of the items placed inside the bags. Most bags are clear to allow consumers to see the product inside the bag. Since many bags have zipper closures, the bags must be made from materials that are compatible with the simultaneous extrusion or attachment of the zippers.

Carry-Out Bags. Carry-out bags are used by consumers to carry purchased merchandise to their homes or businesses. These bags are typically polyethylene structures. Many are surface printed monolayer films. Some are coextruded films for enhanced performance. Examples include the merchandise bags used by department stores and discount stores and grocery sacks used at supermarkets. Depending on the specific use the bags may be fabricated from high molecular weight HDPE, LDPE, or LLDPE. Tensile strength and toughness are key requirements, although some carry-out bags are highly oriented HMW-HDPE, and consequently have low MD tear strength.

Stretch Film. Stretch film, or stretch/cling film, is used in the unitization of goods for transportation. A thin film is stretched, either by machine or by hand, and wrapped around multiple smaller packages to hold the goods together. The film clings to itself and to the pallet, securing the load. In its most common form, stretch/cling film is applied to a pallet of goods using a power prestretch pallet wrapper in an automated operation. In this operation the film is stretched, typically between 100 and 300% of its original length, by a set of rollers turning at different speeds and is then applied to a pallet of goods, which sit atop a moving turntable. Machine wrap film is typically supplied on rolls that are 20 or 30 in. wide. Hand wrap film is supplied on smaller rolls. Stretch/cling films may be manufactured by either a cast film or blown film process. Most stretch/cling films are coextruded structures, and LLDPE is the primary component of most stretch films. For specialized applications, coextrusions containing minor layers of PP, EVA, POP, or ULDPE may be employed. For most stretch film structures, a resin with good inherent cling is used as one or both surface layers, or a tackifier such as polyisobutylene is added to the structure to provide the proper level of cling force. Stretch film is used to hold entire or partial pallets of goods, such as resin bags, fertilizer bags, cartons of consumer goods or food products, together

during shipment. Most stretch film is removed by the retailer prior to the display of the packaged items for sale. Consumers can frequently view pallets of lawn and garden products, such as bark mulch and topsoil, still wrapped with stretch film on display at home improvement warehouses. Stretch films must have good stretchability, load retention, and puncture resistance.

Stretch Hooder. Stretch hooder film is used to form a large bag capable of containing an entire pallet of goods. Film is supplied on rolls and formed into a gusseted bag during the packaging operation. The bag is then stretched to increase its circumference and, while under tension, placed over a pallet of goods. The tension on the film is released as the film covers the goods, and the film contracts and secures the load. The main advantage of stretch hooder packaging over regular stretch wrap is that the load is completely covered on the top and sides. The chief disadvantage is that considerably more polymer is required to make a stretch hooder bag than to make enough stretch/cling film to contain the same load. Stretch hooder film is made on blown film extrusion equipment. Stretch hooder films must have good elastic memory and good abuse resistance.

PERFLUORINATED POLYMERS, PERFLUORINATED ETHYLENE–PROPYLENE COPOLYMERS

Introduction

Perfluorinated ethylene–propylene (FEP) resin is a copolymer of tetrafluoroethylene (TFE) and hexafluoropropylene (HFP) [116-15-4]; thus, its branched structure contains units of $-CF_2-CF_2-$ and of $-CF_2-CF(CF_3)-$. It retains most of the desirable characteristics of polytetrafluoroethylene (PTFE) but with a melt viscosity (MV) low enough for conventional melt processing. The introduction of HFP lowers the melting point of PTFE from 325°C to about 260°C.

The desire for a resin with PTFE properties yet capable of being fabricated by conventional melt processing led to the discovery of this product (1). It allows melt extrusion of wire insulations of longer continuous lengths than the batchwise paste extrusion of PTFE as well as the injection molding of intricately shaped parts. The FEP polymer is melt-fabricable without severe sacrifice in mechanical properties because the perfluoromethyl side groups on the main polymer chain reduce crystallinity, which varies between 30 and 45%. This change in the crystallinity causes FEP and other copolymer particles to behave differently from PTFE particles; they do not fibrillate like PTFE particles and therefore do not agglomerate easily.

As a true thermoplastic, FEP copolymer can be melt-processed by extrusion and compression, injection, and blow molding. Films can be heat-bonded and sealed, vacuum-formed, and laminated to various substrates. Chemical inertness and corrosion resistance make FEP highly suitable for chemical services; its dielectric and insulating properties favor it for electrical and electronic services; and its low frictional properties, mechanical toughness, thermal stability, and nonstick quality make it highly suitable for bearings and seals, high temperature components, and nonstick surfaces.

Mechanical properties are retained up to 200°C, even in continuous service, which is better than with most plastics. At high temperatures, these copolymers react with fluorine, fluorinating agents, and molten alkali metals. They are commercially available under the DuPont trademark Teflon FEP fluorocarbon resin. A similar product is manufactured by Daikin Kogyo and Dyneon and sold under the trademarks Neoflon and Hostaflon, respectively. The People's Republic of China

also manufactures some FEP products. Additional information on specific manufacturers' products can often be obtained by consulting their internet web sites (for example, www.dupont.com/teflon).

Monomers

Preparation. The preparation, properties, and uses of TFE have been described. Hexafluoropropylene was initially prepared by pyrolysis of PTFE (2,3) and by fluorination of 1,2,3-trichloropropane followed by dehalogenation (4). A number of other routes are described in the patent literature (5–10). Hexafluoropropylene can be prepared in high yield by thermally cracking TFE at reduced pressure at 700–800°C (11,12). Pyrolysis of PTFE at 860°C under vacuum gives a 58% yield of HFP (13). Fluorination of 3-chloropentafluoro-1-propene [79-47-0] at 200°C over activated carbon catalyst yields HFP (14). Decomposition of fluoroform [75-46-7] at 800–1000°C in a platinum-lined nickel tube is another route (15). The thermal decomposition of sodium heptafluorobutyrate [2218-84-4], $CF_3CF_2CF_2CO_2Na$ (16), and copyrolyses of fluoroform and chlorotrifluoroethylene [79-38-9] (17), and chlorodifluoromethane [75-45-6] and 1-chloro-1,2,2,2-tetrafluoroethane [2837-89-0] (18) give good yields of HFP.

Properties and Reactions. The properties of HFP are shown in Table 1. It does not homopolymerize easily and hence can be stored as a liquid. It undergoes many addition reactions typical of an olefin. Reactions include preparation of linear dimers and trimers and cyclic dimers (21,22); decomposition at 600°C with subsequent formation of octafluoro-2-butene and octafluoroisobutylene (23); oxidation with formation of an epoxide (24), an intermediate for a number of perfluoroalkyl perfluorovinyl ethers (25,26); and homopolymerization to low molecular weight liquids (27,28) and high molecular weight solids (29,30). Hexafluoropropylene reacts with hydrogen (31), alcohols (32), ammonia (33), and the halogens and their acids, except I_2 and HI (31,34–36). It is used as a comonomer to produce elastomers and other copolymers (37–41). The toxicological properties are discussed in Reference 42.

Copolymers

Hexafluoropropylene and tetrafluoroethylene are copolymerized, with trichloracetyl peroxide as the catalyst, at low temperature (43). Newer catalytic methods, including irradiation, achieve copolymerization at different temperatures (44,45). Aqueous and nonaqueous dispersion polymerizations appear to be the most convenient routes to commercial production (1,46–50). The polymerization conditions are similar to those of TFE homopolymer dispersion polymerization. The copolymer of HFP–TFE is a *random copolymer*; that is, HFP units add to the growing chains at random intervals. The optimal composition of the copolymer requires that the mechanical properties are retained in the usable range and that the MV is low enough for easy melt processing.

Table 1. Properties of Hexafluoropropylene[a]

Properties	Value
Molecular weight	150.021
Boiling point at 101 kPa[a], °C	−29.4
Freezing point, °C	−156.2
Critical temperature, °C	85
Critical pressure, kPa[b]	3254

Hexafluoropropylene–tetrafluoroethylene copolymers are available in low MV, extrusion grade, intermediate viscosity, high MV, and as dispersions. The low MV resin can be injection molded by conventional thermoplastic molding techniques. It is more suitable for injection molding than other FEP resins (51).

The extrusion grade is suitable for tubing, wire coating, and cable jacketing. It is less suitable for injection molding than the low MV resin because of its relatively high MV. The intermediate MV (Teflon FEP-140) resin is used for insulation of wires larger than AWG 12 (American wire gauge) and applications involving smaller wire sizes, where high current loads or excessive thermal cycling may occur. It is also ideal for jacketing wire braid construction, such as coaxial cables, and for heater cable jackets.

The high MV resin is used as liners for process equipment. Its MV is significantly higher than that of other resins, and therefore it is unsuitable for conventional injection molding. Stress-crack resistance and mechanical properties are superior to those of the other three products (52) (Table 2).

Modified HFP–TFE polymers offer a combination of high stress-crack resistance and high extrusion rates. Use of perfluorovinyl ethers as modifiers make it possible to achieve the superior performance without losing excellent chemical inertness and thermal stability (53–55).

Both high and low color concentrates are available for pigmenting extruded coatings of FEP resins. The concentrates are prepared for melt dispersion in

Table 2. Properties of Teflon FEP Fluorocarbon Resin[a]

Mechanical property	ASTM method	Teflon 110	Teflon 100	Teflon 140	Teflon 160
Melt flow number, g/10 min	D2116		7.0	3.0	1.5

extrusion applications. The pigments (thermally stable) are purified and carefully selected to meet electrical, mechanical, and thermal end use specifications. Color concentrate pellets are easily dispersed among clear pellets by conventional tumbling. The ratio of concentrate to natural resin varies, depending on the wire size, insulation thickness, and color intensity desired.

An FEP copolymer dispersion is available as a 55-wt% aqueous dispersion containing 6% nonionic surfactant (on a solids basis) and a small amount of anionic dispersing agent. Its average particle size is ca 0.2 μm.

Properties. The crystallinity of FEP polymer is significantly lower than that of PTFE (70 vs 98%). The structure resembles that of PTFE, except for a random replacement of a fluorine atom by a perfluoromethyl group (CF_3). The crystallinity after processing depends on the rate of cooling the molten polymer. The presence of HFP in the polymer chain tends to distort the highly crystallized structure of the PTFE chain and results in a higher amorphous fraction.

In the free-radical polymerization of FEP copolymers, chain termination occurs by binary coupling of chain ends, thus contributing to high molecular weights. Linear viscoelastic properties of these polymers in the amorphous melts were measured by dynamic rheometry. The FEP samples had high molecular weights and were found to verify the relation of zero shear viscosity vs $(\text{mol wt})^3$ predicted by the reptation theory. At lower molecular weights, the empirical relation of viscosity vs $(\text{mol wt})^{3.4}$ holds (56).

Transitions and Relaxations. Only one first-order transition is observed, the melting point. Increasing the pressure raises the melting point. At low pressures, the rate of increase in the melting point is ca 1.74°C/MPa (0.012°C/psi); at high pressures this rate decreases to ca 0.725°C/MPa (0.005°C/psi). Melting increases the volume by 8%. In the presence of the HFP comonomer, crystal distortion occurs with an increase in intramolecular distance that, in turn, reduces the melting point (57).

The relaxation temperature appears to increase with increasing HFP content. Relaxation involves 5–13 of the chain carbon atoms. Besides α and γ relaxations, one other dielectric relaxation was observed below −150°C, which did not vary in temperature or in magnitude with comonomer content or copolymer density (58). The α relaxation (also called Glass I) is a high temperature transition (157°C), and γ relaxation (Glass II) (internal friction maxima) occurs between −5 and 29°C. The chain conformation and crystal structure of a series of HFP–TFE copolymers containing up to 50 mol% of HFP were studied (59). Increasing HFP content leads to significant departures from the highly ordered crystalline structure of PTFE. The helical conformation of the chain relaxes and untwists to accommodate the $-CF_3$ pendant group in the HFP unit.

Thermal Stability. The polymer is thermally stable and can be processed at ca 270°C. Thermal degradation is a function of temperature and time, and the stability is therefore limited. The melt-flow rate (thermal degradation) increases significantly for short periods above 280°C, and degradation occurs at lower temperatures with longer hold times. The hourly weight loss is 0.0004% at 230°C, 0.001% at 260°C, 0.01% at 290°C, 0.02% at 320°C, 0.08% at 340°C, and 0.3% at 370°C. Degradation is not significant if the change in melt-flow rate during molding is <10%. Physical strength decreases after prolonged exposure above 205°C, which accounts for the lower temperature rating of FEP resins (60).

Radiation Effects. The primary effect of radiation is the degradation of large molecules to small molecules. Molecular weight reduction can be minimized by excluding oxygen. If FEP is lightly irradiated at elevated temperatures in the absence of oxygen, cross-linking offsets molecular breakdown (58,61).

The degree to which radiation exposure affects FEP resins is determined by the energy absorbed, regardless of the type of radiation. Changes in mechanical properties depend on total dosage, but are independent of dose rate. The radiation tolerance of FEP in the presence or absence of oxygen is higher than that of PTFE by a factor of 10:1. Vacuum uv irradiation seems to provide a high potential for surface modification as compared to plasma treatment (62).

Mechanical Properties. Extensive lists of the physical properties of FEP copolymers are given in References 63–67–68. Mechanical properties are shown in Table 3. Most of the important properties of FEP are similar to those of PTFE; the main difference is the lower continuous service temperature of 204°C of FEP compared to that of 260°C of PTFE. The flexibility at low temperatures and the low coefficients of friction and stability at high temperatures are relatively independent of fabrication conditions. Unlike PTFE, FEP resins do not exhibit a marked change in volume at room temperature because they do not have a first-order transition at 19°C. They are useful above −267°C and are highly flexible above −79°C (69).

Static friction decreases with an increase in load, and the static coefficient of friction is lower than the dynamic coefficient. The tendency to creep must be considered carefully in FEP products designed for service under continuous stress. Creep can be minimized by suitable fillers. Fillers are also used to improve wear resistance and stiffness. Compositions such as 30% bronze-filled FEP, 20% graphite-filled FEP, and 10% glass-fiber-filled FEP offer high PV values [∼400(kPa·cm)/s] and are suitable for bearings.

Articles fabricated from FEP resins can be made bondable by surface treatment with a solution of sodium in liquid ammonia, or naphthalenyl sodium in tetrahydrofuran (69) to facilitate subsequent wetting. Exposing the surface to corona discharge (70) or amines at elevated temperatures in an oxidizing atmosphere (71) also makes the resins bondable. Some of the more recent work is described in References 72,73–74.

Vibration-dampening properties at sonic and ultrasonic frequencies are excellent. However, the thickness of the resin must be sufficient to absorb the energy produced; this is usually determined experimentally.

Electrical Properties. Because of excellent electrical properties, FEP is a valuable and versatile electrical insulator. Within the recommended service temperature range, PTFE and FEP have identical properties as electrical insulators. Volume resistivity, which is $>10^{17}$ Ω·cm, remains unchanged even after prolonged soaking in water; surface resistivity is $>10^{15}$ Ω/sq.

At low frequencies, the dielectric constant of FEP remains the same (∼2). However, at >100 MHz the constant drops slightly with increasing frequency. As a true thermoplastic, FEP has a void content of zero and most of the fabricated material has a density of 2.14–2.17 g/cm^3. The National Bureau of Standards has selected Teflon FEP resins for dielectric reference specimens because of the stability of their dielectric constant. The dissipation factor has several peaks as

a function of temperature and frequency (3×10^{-4} at 100 kHz; 7×10^{-4} at 1 MHz). The magnitude of the dissipation factor peak is greater for FEP than for PTFE because the molecular structure of the former is less symmetrical. The dissipation factor is hardly affected by irradiation annealing (75) and unaffected by humidity. The dielectric strength is high (80 GV/mm for 0.25-mm film at 23°C) and unaffected by thermal aging at 200°C. At high frequencies, the dielectric properties deteriorate in the presence of corona. If the voltage stress is not high enough to cause corona ignition, an infinitely long dielectric life is expected at any frequency. Corona discharges on the surface or in a void initiate dielectric breakdown (76). The FEP resins are recommended for continuous service up to 205°C. Although they begin to melt flow at 270°C, they retain some structural integrity up to 250°C (75).

Chemical Properties. The FEP resin is inert to most chemicals and solvents, even at elevated temperatures and pressures. However, it reacts with fluorine, molten alkali metal, and molten sodium hydroxide. Acids or bases are not absorbed at 200°C and exposures of 1 year. The absorption of organic solvents is less than 1% at elevated temperatures and long exposure times. Absorption of chemicals or solvents has no effect on the chemical integrity of the FEP molecule and is a reversible physical process.

Gases and vapors permeate FEP resin at a rate that is considerably lower than that of most plastics. Because FEP resins are melt processed, they are void-free and permeation occurs only by molecular diffusion. Variation in crystallinity and density is limited, except in unusual melt-processing conditions.

Because of its low permeability, FEP polymer is used extensively in the chemical industry. Its permeation characteristics are similar to those of PTFE (Table 4). An inverse relationship between permeability and film thickness applies to FEP.

Table 4. Permeability of FEP Fluorocarbon Resins to Liquid Vapors and Gases

[a] Ref. 65 Test method ASTM E96-35T (at vapor pressure; for 25.4-μm film thickness). Values are averages only and not for specification purposes.
[b] Original data converted to SI units using vapor pressure data from Ref. 77.

Weathering. Articles fabricated from FEP are unaffected by weather, and their resistance to extreme heat, cold, and uv irradiation suits them for applications in radar and other electronic components. For example, after 15 years of solar exposure in Florida, the tensile strength and light transmission (96%) of a 25-μm-thick film was unchanged and the film remained crystal clear (78). Elongation increased slightly for the first 5–7 years of outdoor exposure, probably as a result of stress relaxation. Beyond 10 years, a small decrease was observed.

Optical Properties. Teflon FEP fluorocarbon film transmits more ultraviolet, visible light, and infrared radiation than ordinary window glass. The refractive index of FEP film is 1.341–1.347 (79).

Fabrication

Standard thermoplastic processing techniques can be used to fabricate FEP. Thermal degradation must be avoided, and a homogeneous structure and good surface quality must be maintained.

Injection Molding. Compared to most thermoplastic products, even the low MV resin has a significantly higher MV and therefore requires higher processing temperatures, slower injection rates, special mold design, and corrosion-resistant material of construction. When the flow velocity in melt processing exceeds a critical value, melt fracture occurs. The critical shear rate of FEP is much lower than that of other thermoplastics. Recommendations for materials of construction and the screw design, valves, smear heads, nozzle, operating conditions, and mold design are given in References 52,80, and 81.

Pigments (thermally stable at processing temperature) are dry blended with the resin before molding. At loadings of 0.1–1%, pigments have no appreciable effect on the dielectric strength, dielectric constant, or mechanical properties. The

dissipation factor of pigmented resin varies with the pigment and its amount (82).

Extrusion. Conventional melt-extrusion equipment is used in processing FEP resins. Commercial pigments are mixed with the resin before extrusion into wire coating, tubing, rods, molding, beading channels, etc. Coating thicknesses of 0.076–2.54 mm have been extruded over such materials as silicone rubber, poly(vinyl chloride), glass braid, metal-shielded cables, twisted conductors, and parallel multiconductor cables.

For primary insulation or cable jackets, high production rates are achieved by extruding a tube of resin with a larger internal diameter than the base wire and a thicker wall than the final insulation. The tube is then drawn down to the desired size. An operating temperature of 315–400°C is preferred, depending on holdup time. The surface roughness caused by melt fracture determines the upper limit of production rates under specific extrusion conditions (83,84). Corrosion-resistant metals should be used for all parts of the extrusion equipment that come in contact with the molten polymer (85).

Tubing is made in a wide range of sizes and is used as slip-on electrical insulation, instrument tubing, and for hoses. Small tubing, called spaghetti tubing, can be produced by a free-extrusion technique, whereas hose-size tubing is produced by conventional forming-box techniques; FEP also is extruded into films.

Dispersion Processing. The commercial aqueous dispersion of FEP contains 55 wt% of hydrophobic, negatively charged FEP particles and ca 6 wt% (based on FEP) of a mixture of nonionic and anionic surface-active agents. The average particle size is ca 0.2 μm. The dispersion is processed by the same technique used for PTFE dispersion. For example, the fabric is coated with FEP dispersion, the water is evaporated from the coating, the wetting agent is removed, and the FEP layer is fused with the fabric.

Dispersion is used as a coating for glass fabric, chemical barriers, and wire-insulating tapes; as adhesive coatings for bonding seals and bearings of PTFE to metallic and nonmetallic components; and as antifriction or antistick coatings for metals. The fusion of FEP to provide a continuous film depends on a time–temperature relationship; 1 min at 400°C or 40 min at 290°C is sufficient to achieve good fusion (86).

Other Techniques. The FEP resin is bonded to metal surfaces by the application of heat and pressure; it can be heat sealed or hot-gas welded. Heating FEP at 260°C and allowing it to cool slowly results in stress relieving, or annealing. The FEP film is used to weld PTFE-coated surfaces.

Effects of Fabrication on Product Properties. Extrusion conditions have a significant effect on the quality of the product (85). Contamination can be the result of corrosion, traces of another resin, or improper handling. Corrosion-resistant Hastelloy C parts should be used in the extruder. Surface roughness is the result of melt fracture or mechanical deformation. Melt fracture can be eliminated by increasing the die opening, die temperature, and the melt temperature and by reducing the extrusion rate. Bubbles and discoloration are caused by resin degradation, air entrapment, or condensed moisture. Excessive drawdown, resin degradation, or contamination can result in pinholes, tears, and cone breaks. The blisters are caused by degassing of primary coatings, and loose coatings are caused by rapid cooling and long cones.

Testing and Standards. Requirements for extrusion and molding grades are cited in ASTM specifications (87) and in Federal specification LP-389A of May 1964 (88). For fabricated shapes, FEP film and sheet are covered by Aeronautical Material Specifications (AMS) 3647 and LP-523 (89). Besides the specifications covered by the Fluorocarbons Division of the Society of the Plastics Industry, Inc. (90), other specifications are listed in Reference 91.

Economic Aspects

Because of the high cost of HFP, FEP is more expensive than PTFE. In the United States, in 2000, FEP sold at prices up to $35.2/kg, depending on the type and quantity. Most grades are marketed in a colorless, translucent, extruded pellet form. The dispersion containing about 55% solids is priced at ca $44/kg. FEP sales have increased rapidly because of usage in plenum cable.

Health and Safety

The safety precautions required in handling HFP–TFE copolymers are the same as those applied to handling PTFE (92). Large quantities have been processed safely by many different fabricators in a variety of operations. With proper ventilation, the polymer can be processed and used at elevated temperatures without hazard. The fumes from heated FEP or its thermal decomposition products are toxic in high concentrations, like the fumes or decomposition products of other polymers. Ventilation should be provided in areas where the resin is at processing temperature (270–400°C). At ambient temperatures, FEP resin is essentially inert. Inhalation of fumes given off by heated FEP resin may result in influenza-like symptoms. They may occur several hours after exposure and disappear within 35–48 h, even in the absence of treatment; the effects are not cumulative (52). Such attacks usually follow exposure to vapors evolved from the polymer without adequate ventilation or from smoking tobacco or cigarettes contaminated with the polymer. Toxicology study of the particulates and fumes is reported in Reference 93.

Applications. The principal electrical applications include hookup wire, interconnecting wire, coaxial cable, computer wire, thermocouple wire, plenum cable, and molded electrical parts. Principal chemical applications are lined pipes and fittings, over-braided hose, heat exchangers, and laboratory ware. Mechanical uses include antistick applications, such as conveyor belts and roll covers. A recent development of FEP film for solar collector windows takes advantage of light weight, excellent weatherability, and high solar transmission. Solar collectors made of FEP film are efficient, and installation is easy and inexpensive.

PERFLUORINATED POLYMERS, POLYTETRAFLUOROETHYLENE

Introduction

Polytetrafluoroethylene (PTFE) [9002-84-0], more commonly known as Teflon (E.I. du Pont de Nemours & Co., Inc.), a perfluorinated straight-chain high polymer, has a most unique position in the plastics industry because of its chemical inertness, heat resistance, excellent electrical insulation properties, and low coefficient of friction over a wide temperature range. Polymerization of tetrafluoroethylene monomer gives this perfluorinated straight-chain high polymer with the formula $-(CF_2-CF_2)_n-$. The white to translucent solid polymer has an extremely high molecular weight, in the $10^6 - 10^7$ range, and consequently has a viscosity in the range of 1–10 GPa·s ($10^{10} - 10^{11}$ P) at 380°C. It is a highly crystalline polymer and has a crystalline melting point. Its high thermal stability results from the strong carbon–fluorine bond and characterizes PTFE as a useful high temperature polymer.

The discovery of PTFE (1) in 1938 opened the commercial field of perfluoropolymers. Initial production of PTFE was directed toward the World War II effort, and commercial production was delayed by DuPont until 1947. Commercial PTFE is manufactured by two different polymerization techniques that result in two different types of chemically identical polymer. Suspension polymerization produces a granular resin, and emulsion polymerization produces the coagulated dispersion that is often referred to as a fine powder or *PTFE dispersion*.

Because of its chemical inertness and high molecular weight, PTFE melt does not flow and cannot be fabricated by conventional techniques. The suspension-polymerized PTFE polymer (referred to as *granular PTFE*) is usually fabricated by modified powder metallurgy techniques. Emulsion-polymerized PTFE behaves

Encyclopedia of Polymer Science and Technology. Copyright John Wiley & Sons, Inc. All rights reserved.

entirely differently from granular PTFE. Coagulated dispersions are processed by a cold-extrusion process (like processing lead). Stabilized PTFE dispersions, made by emulsion polymerization, are usually processed according to latex processing techniques.

Manufacturers of PTFE include Daikin Kogyo (Polyflon), DuPont (Teflon), Dyneon, Asahi Glass, Ausimont (Algoflon and Halon), and the CIS (Fluoroplast). India and The People's Republic of China also manufacture some PTFE products. Additional information on specific manufacturers' products can often be obtained by consulting their internet web sites (for example, www.dupont.com/teflon).

Monomer

Preparation. The manufacture of tetrafluoroethylene (TFE) [116-14-3] involves the following steps (2–9). The pyrolysis is often conducted at a PTFE manufacturing site because of the difficulty of handling TFE. New discoveries have made it somewhat easier to use it at remote places (10).

$$CaF_2 + H_2SO_4 \longrightarrow CaSO_4 + 2\,HF$$

$$CH_4 + 3\,Cl_2 \longrightarrow CHCl_3 + 3\,HCl$$

$$CHCl_3 + 2\,HF \xrightarrow{SbF_3} CHClF_2 + 2\,HCl$$

$$2\,CHClF_2 \xrightarrow{\Delta} CF_2{=}CF_2 + 2\,HCl$$

Pyrolysis of chlorodifluoromethane is a noncatalytic gas-phase reaction carried out in a flow reactor at atmospheric of subatmospheric pressure; yields can be as high as 95% at 590–900°C. The economics of monomer production is highly dependent on the yields of this process. A significant amount of hydrogen chloride waste product is generated during the formation of the carbon–fluorine bonds.

A large number of by-products are formed in this process, mostly in trace amounts; more significant quantities are obtained of hexafluoropropylene, perfluorocyclobutane, 1-chloro-1,1,2,2-tetrafluoroethane, and 2-chloro-1,1,1,2,3,3-hexafluoropropane. Small amounts of highly toxic perfluoroisobutylene, $CF_2{=}C(CF_3)_2$, are formed by the pyrolysis of chlorodifluoromethane.

In this pyrolysis, subatmospheric partial pressures are achieved by employing a diluent such as steam. Because of the corrosive nature of the acids (HF and HCl) formed, the reactor design should include a platinum-lined tubular reactor made of nickel to allow atmospheric pressure reactions to be run in the presence of a diluent. Because the pyrolysate contains numerous by-products that adversely affect polymerization, the TFE must be purified. Refinement of TFE is an extremely complex process, which contributes to the high cost of the monomer. Inhibitors are added to the purified monomer to avoid polymerization during storage; terpenes such as *d*-limonene and terpene B are effective (11).

Tetrafluoroethylene was first synthesized in 1933 from tetrafluoromethane, CF_4, in an electric arc furnace (12). Since then, a number of routes have been

Table 1. Physical Properties of Tetrafluoroethylene[a]

developed (13–19). Depolymerization of PTFE by heating at ca 600°C is probably the preferred method for obtaining small amounts of 97% pure monomer on a laboratory scale (20,21). Depolymerization products contain highly toxic perfluoroisobutylene and should be handled with care.

Properties. Tetrafluoroethylene (mol wt 100.02) is a colorless, tasteless, odorless, nontoxic gas (Table 1). It is stored as a liquid; vapor pressure at −20°C is 1 MPa (9.9 atm). It is usually polymerized above its critical temperature and below its critical pressure. The polymerization reaction is highly exothermic.

Tetrafluoroethylene undergoes addition reactions typical of an olefin. It burns in air to form carbon tetrafluoride, carbonyl fluoride, and carbon dioxide (25). Under controlled conditions, oxygenation produces an epoxide (26) or an explosive polymeric peroxide (25). Trifluorovinyl ethers, RO—CF=CF_2, are obtained by reaction with sodium salts of alcohols (27). An ozone–TFE reaction is accompanied by chemiluminescence (28). Dimerization at 600°C gives perfluorocyclobutane, C_4F_8; further heating gives hexafluoropropylene, CF_2=$CFCF_3$, and eventually perfluoroisobutylene, CF_2=$C(CF_3)_2$ (29). Purity is determined by both gas–liquid and gas–solid chromatography; the ir spectrum is complex and therefore of no value.

Uses. Besides polymerizing TFE to various types of high PTFE homopolymer, TFE is copolymerized with hexafluoropropylene (30), ethylene (31), perfluorinated ether (32,33), isobutylene (34), propylene (35), and in some cases it is used as a termonomer (36). It is used to prepare low molecular weight polyfluorocarbons (37) and carbonyl fluoride (38), as well as to form PTFE *in situ* on metal surfaces (39). Hexafluoropropylene [116-15-4] (40,41), perfluorinated ethers, and other oligomers are prepared from TFE.

In the absence of air, TFE disproportionates violently to give carbon and carbon tetrafluoride; the same amount of energy is generated as in black powder explosions. This type of decomposition is initiated thermally and equipment hot spots must be avoided. The flammability limits of TFE are 14–43%; it burns when mixed with air and forms explosive mixtures with air and oxygen. It can be stored in steel cylinders under controlled conditions inhibited with a suitable stabilizer. The oxygen content of the vapor phase should not exceed 10 ppm. Although TFE is nontoxic, it may be contaminated by highly toxic fluorocarbon compounds.

Manufacture of PTFE

Engineering problems involved in the production of TFE seem simple as compared with those associated with polymerization and processing of PTFE resins. The monomer must be polymerized to an extremely high molecular weight in order to achieve the desired properties. The low molecular weight polymer does not have the strength needed in end use applications.

Polytetrafluoroethylene is manufactured and sold in three forms: granular, fine powder, and aqueous dispersion; each requires a different fabrication technique. Granular resins are manufactured in a wide variety of grades to obtain a different balance between powder flows and end use properties (Fig. 1). Fine powders that are made by coagulating aqueous dispersions are also available in various grades. Differences in fine powder grades correspond to their usefulness in specific applications and to the ease of fabrication. Aqueous dispersions are sold in latex form and are available in different grades. A variety of formulation techniques are used to tailor these dispersions for specific applications.

Polymerization. In aqueous medium, TFE is polymerized by two different procedures. When little or no dispersing agent is used and vigorous agitation is maintained, a precipitated resin is produced, commonly referred to as granular resin. In another procedure, called *aqueous dispersion polymerization*, a sufficient dispersing agent is employed and mild agitation produces small colloidal particles dispersed in the aqueous reaction medium; precipitation of the resin particles is avoided. The two products are distinctly different, even though both are high molecular weight PTFE polymers. The granular product can be molded in various forms, whereas the resin produced by the aqueous dispersion cannot be molded, but is fabricated by dispersion coating or conversion to powder for paste extrusion with a lubricant medium. Granular resin cannot be paste extruded or dispersion coated.

Granular Resins. Granular PTFE is made by polymerizing TFE alone or in the presence of trace amounts of comonomers (42–44). An initiator, a small amount of dispersing agent, and other additives (45) may be present; an alkaline

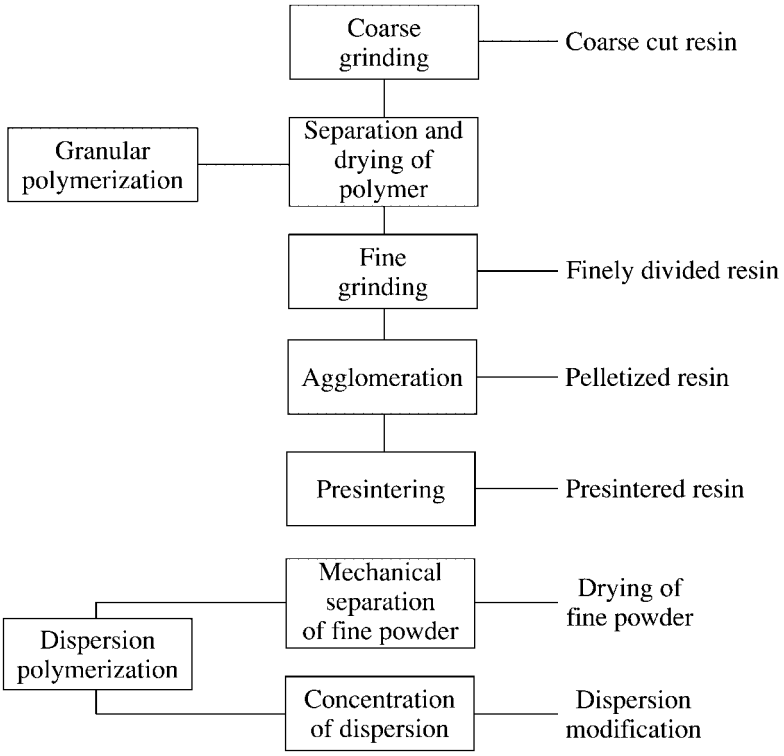

Fig. 1. Granular, fine powder, and dispersion PTFE products.

buffer is occasionally used (46). In the early stages of polymerization, an unstable dispersion is formed, but lack of dispersing agent and vigorous agitation cause the polymer to partially coagulate; the remainder of the process is fairly complex. The polymerized product is stringy, irregular, and variable in shape. The dried granular polymer is ground to different average particle sizes, depending on the product requirements, eg, the flow and other properties. Coarser fabrication of particles leaves a higher void in the sintered article. A better balance between handleability and moldability (ability to mold and sinter in the absence of voids) is achieved by agglomerating the finely divided resin to ca 400–800 μm (47–49). For ram extrusion of granular resin into long tubes and rods, a partially presintered resin is preferred. Granular PTFE resin is nonflammable.

Fine Powder Resins. Fine powder resins are made by polymerizing TFE in an aqueous medium with an initiator and emulsifying agents (50). The polymerization mechanism is not a typical emulsion type, but is subject to some of the principles of emulsion polymerization. The process and ingredients have a significant effect on the product. It is extremely important that the dispersion remains sufficiently stable throughout polymerization, avoiding premature coagulation (51), but unstable enough to allow subsequent coagulation into a fine powder. Gentle stirring ensures dispersion stability. The amount of emulsifying agent in the polymerization process is usually less than its critical micelle concentration.

The rate of polymerization and the particle shape are influenced by the amount of the emulsifying agent (52–55). The particle structure can be influenced by the polymerization process. Most of the particles are formed in the early stages of the polymerization process and the particles grow as the batch progresses; hence, the radial variation in molecular weight and polymer composition within the dispersion particle can be achieved by controlling the polymerization variables, including ingredients and operating conditions (56–62).

The thin dispersion rapidly thickens into a gelled matrix and coagulates into a water-repellent agglomeration that floats on the aqueous medium as the mechanical agitation is continued. The agglomeration is dried gently; shearing must be avoided.

Aqueous Dispersions. The dispersion is made by the polymerization process used to produce fine powders of different average particle sizes (63). The most common dispersion has an average particle size of about 0.2 μm, probably the optimum particle size for most applications. The raw dispersion is stabilized with a nonionic or anionic surfactant and concentrated to 60–65 wt% solids by electrodecantation, evaporation, or thermal concentration (64). The concentrated dispersion can be modified further with chemical additives. The fabrication characteristics of these dispersions depend on polymerization conditions and additives.

Filled Resins. Fillers such as glass fibers, graphite, asbestos, or powered metals are compounded into all three types of PTFE. Compounding is achieved by intimate mixing. Coagulation of the polymer with a filler produces a filled fine powder.

Properties

The properties described herein are related to the basic structure of PTFE and are exhibited by both granular and fine powder products. The carbon–carbon bonds, which form the backbone of the PTFE chain, and the carbon–fluorine bonds are extremely strong and are the key contributors in imparting an outstanding combination of properties. The fluorine atoms form a protective sheath over the chain of carbon atoms. If the atoms attached to the carbon-chain backbone were smaller or larger than fluorine, the sheath would not form a regular uniform cover. This sheath shields the carbon chain from attack and confers chemical inertness and stability. It also reduces the surface energy resulting in low coefficient of friction and nonstick properties.

Polytetrafluoroethylene does not dissolve in any common solvent; therefore, its molecular weight cannot be measured by the usual methods. A number-average molecular weight has been estimated by determining the concentration of end groups derived from the initiator. Earlier estimates, based on an iron bisulfite system containing radioactive sulfur, ^{35}S, ranged from 142×10^3 to 534×10^3 for low molecular weight polymer. The same technique applied to polymers of industrial interest gave molecular weights of $389\times10^3 - 8900\times10^3$ (65,66). In the absence of a normal molecular weight determination method, an estimated relative molecular weight is used for all practical purposes. It is obtained by measuring the specific gravity, following a standardized fabricating and sintering procedure (ASTM D1457-83). Because the rate of crystallization decreases with increasing

molecular weight, samples prepared from the high molecular weight polymer and cooled from the melt at a constant slow rate have lower standard specific gravities than those prepared from low molecular weight polymer cooled at the same rate (67). The correlation between number-average molecular weight (M_n) based on end group estimations, and standard specific gravity (SSG) is given by

$$SSG = 2.612 - 0.058 \log_{10} M_n$$

The SSG procedure assumes absence of voids (or constant void content). Voids depress the values of the measured specific gravity. The inaccuracies that result from voids can be corrected by applying ir techniques (68).

Melting and recrystallization behavior of virgin PTFE has been studied by dsc (69). A quantitative relationship was found between M_n and the heat of crystallization (ΔH_c) in the molecular weight range of $5.2\times10^5 - 4.5\times10^7$, where ΔH_c is heat of crystallization in J/g, which is independent of cooling rates of 4–32°C/min.

$$M_n = 2.1\times10^{10}\,\Delta H_c^{-5.16}$$

At ca 342°C, virgin PTFE changes from white crystalline material to almost transparent amorphous gel. Differential thermal analysis indicates that the first melting of virgin polymer is irreversible and that subsequent remeltings occur at 327°C, which is generally reported as the melting point. Most of the studies reported in the literature are based on previously sintered (ie, melted and recrystallized) polymer; very little work is reported on the virgin polymer. Melting is accompanied by a volume increase of ca 30%. Because the viscosity of the polymer at 380°C is 10 GPa·s (10^{11} P), the shape of the melt is stable. The melting point increases with increasing applied pressure at the rate of 1.52°C/MPa (0.154°C/atm) (70).

Virgin PTFE has a crystallinity in the range of 92–98%, which indicates an unbranched chain structure. The fluorine atoms are too large to allow a planar zigzag structure, which would permit chain flexibility; therefore the chains are rigid (71). Electron micrographs and diffraction patterns (72) of PTFE dispersion particles indicate that the rod-like particles present in virgin PTFE dispersions are fully extended chain crystals containing few defects. The spherical particles appear to be composed of similar rod-like entities that are wrapped around themselves in a more or less random fashion.

Between 50 and 300°C, PTFE obeys the relationship between stress τ and the apparent shear rate γ: $\tau = K\gamma^{1/4}$. Melting of PTFE begins near 300°C. Above this temperature, the shear stress at constant shear rate increases and the rheological exponent rises from 0.25 to 0.5 at the final melting point (73).

Transitions. Transitions observed by various investigators (74–80), their interpretation, and the modes of identification are shown in Table 2. Besides the transition at the melting point, the transition at 19°C is of great consequence because it occurs at ambient temperature and significantly affects the product behavior. Above 19°C, the triclinic pattern changes to a hexagonal unit cell. Around 19°C, a slight untwisting of the molecule from a 180° twist per 13 CF_2 groups to a 180° twist per 15 CF_2 groups occurs. At the first-order transition at 30°C, the

Table 2. Transitions in Polytetrafluoroethylene

Temperature, °C	Region affected	Technique	Reference
1st order			
19	Crystalline, angular, displacement causing, disorder	Thermal methods, x ray, nmr	75
30	Crystalline, crystal disordering	Thermal methods, x ray, nmr	75
90 (80 to 110)	Crystalline	Stress relaxation, Young's modulus, dynamic methods	78
2nd order			
−90 (−110 to −73)	Amorphous, onset of rotational motion around C—C bond	Thermal methods, dynamic methods	79
−30 (−40 to −15)	Amorphous	Stress relaxation, thermal expansion, dynamic methods	78
130 (120 to 140)	Amorphous	Stress relaxtion, Young's modulus, dynamic methods	78

hexagonal unit cell disappears and the rod-like hexagonal packing of the chains in the lateral direction is retained. Below 19°C there is almost perfect three-dimensional order; between 19 and 30°C, the chain segments are disordered; and above 30°C, the preferred crystallographic direction is lost and the molecular segments oscillate above their long axes with a random angular orientation in the lattice.

The dynamic mechanical properties of PTFE have been measured at frequencies from 0.033 to 90 Hz. Abrupt changes in the distribution of relaxation times are associated with the crystalline transitions at 19 and 30°C (81). The activation energies are 102.5 kJ/mol (24.5 kcal/mol) below 19°C, 510.4 kJ/mol (122 kcal/mol) between the transitions, and 31.4 kJ/mol (7.5 kcal/mol) above 30°C.

Polytetrafluorothylene transitions occur at specific combinations of temperature and mechanical or electrical vibrations. Transitions, sometimes called *dielectric relaxations*, can cause wide fluctuations in the dissipation factor.

Mechanical Properties. Mechanical properties of PTFE depend on processing variables, eg, preforming pressure, sintering temperature and time, cooling rate, void content, and crystallinity. Properties, such as the coefficient of friction, flexibility at low temperatures, and stability at high temperatures, are relatively independent of fabrication. Molding and sintering conditions affect flex life, permeability, stiffness, resiliency, and impact strength. The physical properties of PTFE have been reviewed and compiled (82–84) (Table 3).

A marked change in volume of 1.0–1.8% is observed for PTFE in the transition zone from 18 to 25°C. An article that has been machined on either side of this zone changes dimensions when passing through the transition zone; hence, the final operating temperature of a precision part must be accurately determined.

Table 3. Typical Mechanical Properties of Molded and Sintered PTFE Resins[a]

Property	Granular resin	Fine powder	ASTM method

Articles fabricated of PTFE resins exhibit high strength, toughness, and self-lubrication at low temperatures. They are useful from 5 K and are highly flexible from 194 K. They tend to return to their original dimensions after a deformation. At sintering temperature, they rapidly recover their original shapes. For most applications no special precautions are necessary because decomposition rates below the recommended maximum service temperature of 260°C are very low. Impact strength is excellent over a wide range of temperatures. Static friction decreases with an increase in load. Static coefficient of friction is lower than the dynamic coefficient and therefore reduces stick–slip problems.

The surface of PTFE articles is slippery and smooth. Liquids with surface tensions below 18 mN/m (=dyn/cm) are spread completely on the PTFE surface; hence, solutions of various perfluorocarbon acids in water wet the polymer (85). Treatment with alkali metals promotes the adhesion between PTFE and other substances (86) but increases the coefficient of friction (87).

Filled Resins. Filled compositions meet the requirements of an increased variety of mechanical, electrical, and chemical applications. Physical properties of filled granular compounds are shown in Table 4 (88,89).

Chemical Properties. Vacuum thermal degradation of PTFE results in monomer formation. The degradation is a first-order reaction (90). Mass spectroscopic analysis shows that degradation begins at ca 440°C, peaks at 540°C, and continues until 590°C (91).

Radiation Effects. Polytetrafluoroethylene is attacked by radiation. In the absence of oxygen, stable secondary radicals are produced. An increase in stiffness in material irradicated in vacuum indicates cross-linking (92). Degradation is due to random scission of the chain; the relative stability of the radicals in vacuum protects the materials from rapid deterioration. Reactions take place in air of oxygen and accelerated scission and rapid degradation occur.

Crystallinity has been studied by x-ray irradiation (93). An initial increase caused by chain scission in the amorphous phase was followed (above 3 kGy or 3×10^5 rad) by a gradual decrease associated with a disordering of the crystallites. The amorphous component showed a maximum of radiation-induced broadening in the nmr at 7 kGy (7×10^5 rad).

In air, PTFE has a damage threshold of 200–700 Gy (2×10^4–7×10^4 rad) and retains 50% of initial tensile strength after a dose of 10^4 Gy (1 Mrad), 40% of initial tensile strength after a dose of 10^5 Gy (10^7 rad), and ultimate elongation of 100% or more for doses up to 2–5 KGy ($2\times10^5 - 5\times10^5$ rad). During irradiation, resistivity decreases, whereas the dielectric constant and the dissipation factor increase. After irradiation, these properties tend to return to their preexposure values. Dielectric properties at high frequency are less sensitive to radiation than are properties at low frequency. Radiation has very little effect on dielectric strength (94).

Absorption, Permeation, and Interactions. Polytetrafluoroethylene is chemically inert to industrial chemicals and solvents even at elevated temperatures and pressures (95). This compatibility is due to the strong interatomic bonds, the almost perfect shielding of the carbon backbone by fluorine atoms, and the high molecular weight of the polymer. Under some severe conditions PTFE is not compatible with certain materials. It reacts with molten alkali metals, fluorine, strong fluorinating agents, and sodium hydroxide above 300°C. Shapes of small cross section burn vertically upward after ignition in 100% oxygen. Because gases may be evolved, the weight loss during sintering of a blend of PTFE and white asbestos is many times greater than loss from pure PTFE. Finely divided aluminum and magnesium thoroughly mixed with finely divided PTFE react vigorously after ignition or at high temperatures.

Absorption of a liquid is usually a matter of the liquid dissolving in the polymer; however, in the case of PTFE, no interaction occurs between the polymer and other substances. Submicroscopic voids between the polymer molecules provide space for the material absorbed, which is indicated by a slight weight increase and sometimes by discoloration. Common acids or bases are not absorbed up to 200°C. Aqueous solutions are scarcely absorbed at atmospheric pressure. Even the absorption of organic solvents is slight, partially resulting from the low wettability of PTFE. Since absorption of chemicals or solvents has no substantial effect on the chemical bond within the fluorocarbon molecule, absorption should not be confused with degradation; it is a reversible physical process. The polymer does not suffer loss of mechanical or bulk electrical properties unless subjected to severely fluctuating conditions.

Dynamic mechanical measurements were made on PTFE samples saturated with various halocarbons (96). The peaks in loss modulus associated with the amorphous relaxation near −90°C and the crystalline relaxation near room temperature were not affected by these additives. An additional loss peak appeared near −30°C, and the modulus was reduced at all higher temperatures. The amorphous relaxation that appears as a peak in the loss compliance at 134°C is shifted to 45–70°C in the swollen samples.

The sorption behavior of perfluorocarbon polymers is typical of nonpolar partially crystalline polymers (97). The weight gain strongly depends on the solubility parameter. Little sorption of substances such as hydrocarbons and polar compounds occurs.

As an excellent barrier resin, PTFE is widely used in the chemical industry. However, it is a poor barrier for fluorocarbon oils because similarity in the chemical composition of a barrier and a permeant increases permeation. Most liquids and gases (other than fluorocarbons) do not permeate highly crystalline PTFE. Permeabilities at 30°C [in 10^{15} × mol/(m·s ·Pa)] are as follows: CO_2, 0.93; N_2, 0.18; He, 2.47; anhydrous HCl, <0.01.

Gases and vapors diffuse through PTFE more slowly than through most other polymers (Table 5). The higher the crystallinity, and the less space between polymer molecules, the slower the permeation. Voids greater than molecular size cause an increase in permeability. However, the permeability of the finished article can be controlled by molding the resin to low porosity and high density. The optimum specific gravity for low permeability and good flexural properties is 2.16–2.195. Permeability increases with temperature as a result of the increase in activity of the solvent molecules and because of the increase in vapor pressure of the liquids. Swelling of PTFE resins and film is very low.

Electrical Properties. Polytetrafluoroethylene is an excellent electrical insulator because of its mechanical strength and chemical and thermal stability, as well as excellent electrical properties (Table 6).

Table 5. Permeability of PTFE Resin to Vapors

	Permeability constant[a,b], × 10^{15} mol/(m·s·Pa)	
Permeant	23°C	30°C
Benzene	1.81	2.93
Carbon tetrachloride	0.13

Dissipation factor, at 60 to 2×10^9 Hz	0.0003		D150-59T

[a]Ref. 83.

It does not absorb water and volume resistivity remains unchanged even after prolonged soaking. The dielectric constant remains constant at 2.1 for a temperature range of −40 to 250°C and a frequency range of 5–10 GHz.

Articles fabricated according to standard practice should have dielectric constants in the range of 2.05±0.5 when tested at room temperature (RT). The dielectric constant varies with density and factors that affect density. Machined components can be fabricated to a predetermined dielectric constant by controlling the rod density during processing by adjusting the preforming pressure on the resin and cooling after sintering. The dielectric constant and the density have a linear relationship. Predictable variations in the dielectric constant result from density changes that accompany thermal expansion occuring with increasing temperature. The dielectric constant did not change over two to three years of measurements.

The dissipation factor (the ratio of the energy dissipated to the energy stored per cycle) is affected by the frequency, temperature, crystallinity, and void content of the fabricated structure. At certain temperatures and frequencies, the crystalline and amorphous regions become resonant. Because of the molecular vibrations, applied electrical energy is lost by internal friction within the polymer, which results in an increase in the dissipation factor. The dissipation factor peaks for these resins correspond to well-defined transitions, but the magnitude of the variation is minor as compared to other polymers. The low temperature transition at −97°C causes the only meaningful dissipation factor peak. The dissipation factor has a maximum of 10^8–10^9 Hz at RT; at high crystallinity (93%) the peak at 10^8–10^9 Hz is absent.

As crystallinity increases, the internal molecular friction and the dissipation factor decrease. Voids reduce the dissipation factor in proportion to the percentage of microvoids present. Certain extruded shapes utilize air to reduce the effective dielectric constant and dissipation factor of a coaxial cable. The dielectric strength of these resins is high and is unaffected by thermal aging at 200°C. Frequency has a marked effect on the dielectric strength because corona discharge becomes more continuous as frequency increases. If the voltage stress is not high enough to cause corona ignition, a very long dielectric life is anticipated at any frequency. Corona discharges on the surface or in a void initiate dielectric breakdown (99). Surface arc resistance of these resins is high and not affected by heat aging. The resins do not track or form a carbonized conducting path when subjected to a surface arc in air. Polytetrafluoroethylene resins are capable of continuous service up to 260°C

and can withstand much higher temperatures for limited periods of time. They do not melt or flow and retain some strength even in the gel state which begins at 327°C.

Fabrication

Granular Resins. These resins are sold in different forms; an optimum balance between handleability and product properties is desired. A free-flowing resin is used in small and automatic moldings. A finely divided resin is more difficult to handle but it distributes evenly in large moldings and has superior properties in sintered articles; it is used for large billet- and sheet-molding operations. A presintered resin with low crystallinity and superior handleability is highly suitable for ram extrusion.

Virgin PTFE melts at about 342°C; viscosity, even at 380°C, is 10 GPa·s (10^{11} P). This eliminates processing by normal thermoplastic techniques, and other fabrication techniques had to be developed: the dry powder is compressed into handleable form by heating above the melting point. This coalesces the particles into a strong homogeneous structure; cooling at a controlled rate achieves the desired degree of crystallinity.

Molding. Many PTFE manufacturers give detailed descriptions of molding equipment, and procedures are presented in Reference 100. Round piston molds for the production of solid or hollow cylinders are the most widely used. Because preforming usually takes place below 100°C, carbon steel is a suitable material of construction. The compression ratio (ie, the bulk volume of the powder to the specific volume of the unsintered molding) for granular resins is 3:1 to 6:1. The powder should be evenly distributed and leveled in the mold, and to ensure adequate compression uniformly throughout the preform, maximum pressure should be maintained for a sufficient length of time, and then be released slowly.

Automatic molding permits high speed mass production and can be effective. Automatic presses can be operated mechanically, pneumatically, or hydraulically. The mold is filled by means of a special metering system from a storage hopper containing a free-flowing resin. Loading buckets that shuttle back and forth over the single-cavity mold are also used. Because automatic molding requires short cycles, the powder is usually compressed at high speed with a high preform pressure. Small articles such as rings, bushings, washers, gaskets, and ball-valve seats can be molded by this technique.

Isostatic molding allows uniform compression from all directions. A flexible mold is filled with a free-flowing granular powder and evacuated, tightly sealed, and placed in an autoclave containing a liquid that can be raised to the pressure required for performing. The moldings require subsequent finishing because close tolerance cannot be achieved.

Sintering. Electrical ovens with air circulation and service temperatures up to 400°C are satisfactory for sintering. In free sintering—the cheapest and most widely used process—a preformed mold is placed in an oven with a temperature variation of ±2°C. In pressure sintering, the preform is not removed from the mold; instead the mold containing the preform is heated in an oven until the sintering temperature is reached. During sintering and cooling, the mold

is again placed under pressure but lower than the preform pressure. Pressure-sintered products have internal stresses that can be relieved by subsequent annealing. In the pressure-cooling process, pressure is applied on the molded article after it has reached sintering temperature and is maintained throughout the cooling period. The final product has a lower void content than the free-sintered mold.

To improve homogenity, the preformed article is heated to 370–390°C. The time required for heating and sintering depends on the mold dimensions; cooling, which affects the crystallinity and product properties, should be slow.

Free-sintered articles do not have the same dimensions as the mold cavity because they shrink at right angles to the direction of the preform pressure and grow in the direction of the applied pressure.

For processing after sintering, in the least expensive method for sintered PTFE tape or sheet, a large billet is skived on a lathe after it has been sintered and cooled. High precision articles are machined from ram-extruded rods.

Articles that are too complicated to be made by machining are made by coining. A sintered molding is heated to its melting point, transferred to a mold, and quickly deformed at low pressure, where it is held until it has cooled sufficiently to retain the improved shape. However, the coined molding, if reheated to a high temperature, returns to its original shape, and hence there is a limit on the maximum temperature to which coined moldings can be heated.

Ram Extrusion. Compression molding is not suitable for the manufacture of continuous long moldings such as pipes or rods. In ram extrusion, a small charge of PTFE powder is preformed by a reciprocating ram and sintered. Subsequent charges are fused into the first charge, and this process continues to form homogeneous long rods (101). The die tube, which is made of a corrosion-resistant material, is heated by resistance heating. Good temperature control is essential, and the melted and compacted powder must not pass any constrictions in its path. Thermal expansion and friction produce great resistance to movement, and as a result, a considerable force is required to push the polymer through the tube. A high quality surface finish on the inside of the tube reduces the pressure. If adequate bond strength between successive charges is not developed, the extrudate may break at the interface (poker chipping). Free-flowing powders and presintered resins are preferred for ram extrusion. Ram-extruded rods are used for automatic screw machining. Tubing is used as pipe liners or stock from which seals, gaskets, and bellows are machined.

Fine Powder Resins. Fine powder PTFE resins are extremely sensitive to shear. They must be handled gently to avoid shear, which prevents processing. However, fine powder is suitable for the manufacture of tubing and wire insulation for which compression molding is not suitable. A paste-extrusion process may be applied to the fabrication of tubes with diameters from fractions of a millimeter to about a meter, walls from thicknesses of 100–400 μm, thin rods with up to 50-mm diameters, and cable sheathing. Calendering unsintered extruded solid rods produces thread-sealant tape and gaskets.

The paste-extrusion process includes the incorporation of ca 16–25 wt% of the lubricant (usually a petroleum fraction); the mixture is rolled to obtain uniform lubricant distribution. This wetted powder is shaped into a preform at low pressure (2.0–7.8 MPa or 19–77 atm), which is pushed through a die mounted

in the extruder at ambient temperature. The shear stress exerted on the powder during extrusion confers longitudinal strength to the polymer by fibrillation. The lubricant is evaporated and the extrudate is sintered at ca 380°C.

The exact amount of lubricant required for extrusion depends on the design of the extruder, the reduction ratio (ie, ratio of the cross-sectional preform area to the cross-sectional area in the die), and the quality of the lubricant. A low lubricant content results in a high extrusion pressure, whereas a high lubricant content causes a poor coalescence and generates defects in the extrudate.

Fine powder resins can be colored with pigments that can withstand the sintering temperature. The pigment should be thoroughly mixed with the powder by rolling the mixture before adding the lubricant. Detailed design parameters of the paste extruder are given in References 100, 102 and 103.

The extrudate is dried and sintered by passing it through a multistage oven located immediately after the extruder. Pipes and rods may be heated up to 380°C. The throughput rate depends on the length of the sintering oven. Residence time varies from a few seconds for thin-walled insulations on a wire to a few minutes for large diameter tubing. For short residence times temperatures may be as high as ca 480°C. The extrusion pressure depends on the reduction ratio, the, extrusion rate, the lubricant content, and the characteristics of the extruder.

To produce unsintered tape by paste extrusion, the fine powder is lubricated and preformed according to the procedure described earlier. The preform is extruded in the form of rods, which are calendered on hot rolls to the desired width and thickness. (104).

Different resins have been developed for use in different reduction–ratio application ranges (105,106). The powders suitable for high reduction–ratio applications, such as wire coatings, are not necessarily suitable for the medium reduction–ratio applications, such as tubings, or the low reduction–ratio applications, such as thread-sealant tapes or pipe liners. Applications and processing techniques are being used, which utilize the unique combination of properties offered by PTFE in fine powder form (107–109).

Dispersion Resins. Polytetrafluoroethylene dispersions in aqueous medium contain 30–60 wt% polymer particles and some surfactant. The type of surfactant and the particle characteristics depend on the application. These dispersions are applied to various substrates by spraying, flow coating, dipping, coagulating, or electrodepositing (110).

Aqueous dispersion is sprayed on metal substrates to provide chemical resistance, nonstick, and low friction properties. The coated surface is dried and sintered. Impregnation of fibrous or porous materials with these dispersions combines the properties of the materials with those of PTFE. Some materials require only a single dipping, eg, asbestos. The material is usually dried after dipping. For high pressure sealing applications, sintering at 380–400°C increases strength and dimensional stability. For film castings, the dispersion is poured on a smooth surface; the formed film is dried and sintered and peeled from the supporting surface.

Aqueous dispersions are used for spinning PTFE fibers. The dispersion is mixed with a matrix-forming medium (111,112) and forced through a spinneret

into a coagulating bath. The matrix material is removed by heating and the fibers are sintered and drawn molten to develop their full strength.

Effects of Fabrication on Physical Properties of Molded Parts. The physical properties are affected by molecular weight, void content, and crystallinity. Molecular weight can be reduced by degradation but not increased during processing. These factors can be controlled during molding by the choice of resin and fabricating conditions. Void distribution (or size and orientation) also affects properties; however, it is not easily measured.

Preforming primarily affects void content, sintering controls molecular weight, and cooling determines crystallinity. Voids caused by insufficient consolidation of particles during preforming may appear in the finished articles. Densities below 2.10 g/cm^3 indicate a high void content. Electrical and chemical applications require a minimum density of 2.12–2.14 g/cm^3. Particle size, shape, and porosity are also important in determining void content. Although void content is determined largely by particle characteristics and preforming conditions, sintering conditions can also have an effect. Temperatures too high or too low increase void content. Excessively high sintering temperature can decrease the molecular weight. The final crystallinity of a molding depends on the initial molecular weight of the polymer, the rate of cooling of the molding, and to a lesser extent on sintering conditions. The degree of crystallinity of moldings is affected by the cooling or annealing conditions.

Flexural modulus increases by a factor of 5 as crystallinity increases from 50 to 90% with a void content of 0.2%; however, recovery decreases with increasing crystallinity. Therefore, the balance between stiffness and recovery depends on the application requirements. Crystallinity is reduced by rapid cooling but increased by slow cooling. The stress-crack resistance of various PTFE insulations is correlated with the crystallinity and change in density due to thermal mechanical stress (113).

Applications

Consumption of PTFE increases continuously as new applications are being developed. Electrical applications consume half of the PTFE produced; mechanical and chemical applications share equally the other half. Various grades of PTFE and their applications are shown in Table 7.

Electrical Applications. The largest application of PTFE is for hookup and hookup-type wire used in electronic equipment in the military and aerospace industries. Coaxial cables, the second largest application, use tapes made from fine powder resins and some from granular resin. Interconnecting wire applications include airframes. Other electrical applications include computer wire, electrical tape, electrical components, and spaghetti tubing.

Mechanical Applications. Seals and piston rings, basic shapes, and antistick uses constitute two-thirds of the resin consumed in mechanical applications. Bearings, mechanical tapes, and coated glass fabrics also consume a large amount of PTFE resins. Seals and piston rings, bearings, and basic shapes are manufactured from granular resins, whereas the dispersion is used for glass–fabric coating

Table 7. Applications of Polytetrafluoroethylene Resins

Resin grade	Processing	Description	Main uses
Granular			
Agglomerates	Molding, preforming, sintering, ram extrusion	Free-flowing powder	Gaskets, packing, seals, electronic componenets, bearings, sheet, rod, heavy-wall tubing; tape and molded shapes for nonadhesive applications
Coarse	Molding, preforming, sintering	Granulated powder	Tape, molded shapes, nonadhesive applications
Finely divided	Molding, preforming, sintering	Powder for highest quality, void-free moldings	Molded sheets, tape wire wrapping, tubing, gaskets
Presintered	Ram extrusion	Granular, free-flowing powder	Rods and tubes
Fine powder			
High reduction ratio	Paste extrusion	Agglomerated powder	Wire coating, thin-walled tubing
Medium reduction ratio	Paste extrusion	Agglomerated powder	Tubing, pipe, overbraided hose, spaghetti tubing
Low reduction ratio	Paste extrusion	Agglomerated powder	Thread-sealant tape, pipe liners, tubing, porous structures
Dispersion			
General purpose	Dip coating	Aqueous dispersion	Impregnation, coating, packing
Coating	Dip coating	Aqueous dispersion	Film, coating
Stabilized	Coagulation	Aqueous dispersion	Bearings

and antistick applications. Most pressure-sensitive mechanical tapes are made from granular resins.

Chemical Applications. The chemical processing industry uses large amounts of granular and fine powder PTFE. Soft packing applications are manufactured from dispersions, and hard packings are molded or machined from stocks and shapes made from granular resin.

Overbraided hose liners are made from fine powder resins by paste extrusion, and thread-sealant tapes are produced from fine powder by calendering. Fabricated gaskets are made from granular resins and pipe liners are produced from fine powder resins. Fibers and filament forms are also available.

Highly porous fabric structures, eg, Gore-Tex, that can be used as membranes have been developed by exploiting the unique fibrillation capability of dispersion-polymerized PTFE (107).

Micropowders

The PTFE micropowders, also called waxes, are TFE homopolymers with molecular weights significantly lower than that of normal PTFE (114). The molecular weight for micropowders varies from 2.5×10^4 to 25×10^4, whereas that of normal PTFE is of the order of 10×10^6. Micropowders are generally white in color and are friable. The average agglomerate particle size is between 5 and 10 μm and is composed of smaller, "as polymerized" primary particles which are approximately 0.2 μm in diameter. The dsc curves of lower molecular weight micropowder show a higher heat of crystallization and melting (second heating) than normal PTFE. This is due to the higher crystallinity of the micropowder.

The production of micropowders involves the scission of the high molecular weight PTFE chain by gamma or electron beam irradiation at a variety of dosage levels. An increase in dosage reduces the molecular weight. The irradiated low molecular weight material is ground to a particle size ranging from 1 to 25 μm in the final product.

Economic Aspects

Polytetrafluoroethylene homopolymers are more expensive than most other thermoplastics because of high monomer refining costs. For extremely high molecular weights, ingredients and manufacturing process must be free of impurities, which increases costs. In the United States, the 2000 list prices from primary producers were between $15.2/kg and $20.4/kg, depending on the resin type. For example, granular PTFE resins cost $15.2–20.4/kg supplied in 45.45-kg containers. The coagulated fine powders cost $23.2–30.3/kg packaged in 45.45-kg containers. Formulated dispersions are $21.9–35.4/kg in 19- or 113-L containers. Although fine powder sales have increased in recent years, the sales of granular PTFE are the highest on a worldwide basis. Most of the resin is consumed in the United States (ca 9000 t in 1991), followed by Europe and Japan.

Testing and Standards

A description of PTFE resins and their classification are given in ASTM D1457-83. A comprehensive listing of industrial and military specifications covering mechanical, electrical, and chemical applications of PTFE can be found in Reference 115.

Health and Safety

Exposure to PTFE can arise from ingestion, skin contact, or inhalation. The polymer has no irritating effect to the skin, and test animals fed with the sintered polymer have not shown adverse reactions. Dust generated by grinding the resin also has no effect on test animals. Formation of toxic products is unlikely. Only the heated polymer is a source of a possible health hazard (116,117).

Because PTFE resins decompose slowly, they may be heated to a high temperature. The toxicity of the pyrolysis products warrants care where exposure of personnel is likely to occur. Above 230°C decomposition rates become measurable (0.0001% per hour). Small amounts of toxic perfluoroisobutylene have been isolated at 400°C and above; free fluorine has never been found. Above 690°C the decomposition products burn but do not support combustion if the heat is removed. Combustion products consist primarily of carbon dioxide, carbon tetrafluoride, and small quantities of toxic and corrosive hydrogen fluoride. The PTFE resins are nonflammable and do not propagate flame.

Prolonged exposure to thermal decomposition products causes so-called polymer fume fever, a temporary influenza-like condition. It may be contracted by smoking tobacco that has been contaminated with the polymer. It occurs several hours after exposure and passes within 36–48 h; the temporary effects are not cumulative.

Large quantities of PTFE resins have been manufactured and processed above 370°C. In various applications they are heated above the recommended use temperatures. No cases of serious injury, prolonged illness, or death have been reported resulting from the handling of these resins. However, when high molecular weight PTFE is converted to micropowder by thermal degradation, highly toxic products result.

Micropowders are added to a wide variety of material used in industry, where they provide nonstick and sliding properties (111). They are incorporated into the product by blending and grinding. To disperse well, the powder must have good flow properties. Conditions that make the powder sticky should be avoided.

The PTFE micropowders are commonly used in plastics, inks, lubricants, and finishes such as lacquer. Lubricants containing micropowders are used for bearings, valve components, and other moving parts where sliding friction must be minimized or eliminated. Nonstick finished that require good release properties, for example, in the food and packaging industry, commonly use PTFE micropowders.

In some applications the high heat stability of the micropowder can be utilized over a reasonably wide temperature range. A maximum service

temperature is normally 260°C, provided the crystalline melting point is between 320 and 335°C. Exposure above 300°C leads to degradation and possible evolution of toxic decomposition products.

The particulate morphology of PTFE micropowder in printing inks provides desirable gloss to the printed product. Its inherent lubricity results in good wear and slip properties and surface smoothness. The chemical resistance of the micropowder is as high as that of high molecular weight PTFE. It is therefore used in applications requiring service in strong or corrosive chemical environments such as concentrated mineral acids and alkalies.

PERFLUORINATED POLYMERS, TETRAFLUOROETHYLENE–ETHYLENE COPOLYMERS

Introduction

Copolymers of ethylene [74-85-1] and tetrafluoroethylene [116-14-3] (ETFE) have been a laboratory curiosity for more than half a century. These polymers were studied in connection with a search for a melt-fabricable polytetrafluroethylene (PTFE) resin (1–5); interest in them fell with the discovery of TFE–HFP (FEP) copolymers (6). In the 1960s, however, it became evident that a melt-fabricable fluorocarbon resin was needed with higher strength and stiffness than those of PTFE resins. Earlier studies indicated that ETFE [11939-51-6] might have the right combination of properties. Subsequent research efforts (7) led to the introduction of modified ETFE polymer [25038-71-5] (Tefzel) by E. I. du Pont de Nemours & Co., Inc., in 1970.

Modified ETFE are the products of real commercial value because they have good tensile strength, moderate stiffness, high flex life, and outstanding impact strength, abrasion resistance, and cut-through resistance. Electrical properties include low dielectric constant, high dielectric strength, excellent resistivity, and low dissipation factor. Thermal and cryogenic performance and chemical resistance are good. These properties, combined with elasticity, make this material an ideal candidate for heat-shrinkable film and tubing. This family of copolymers can be processed by conventional methods such as melt extrusion, injection molding, transfer molding, and rotational molding. The properties of the copolymers vary with composition; polymers containing 40–90% TFE (by weight) soften between 200 and 300°C, depending on composition (1). The TFE segments of the molecules account for >75% of the weight of an approximately 1:1 mole

ratio copolymer. The two monomers combine readily into a nearly 1:1 alternating structure. Such polymers exhibit a unique combination of mechanical, chemical, and electrical properties as well as excellent weatherability. However, thermal stress-crack resistance is poor. The copolymer can be modified with a termonomer that undergoes free-radical polymerization and does not cause undesirable chain transfer or termination during polymerization. The modified copolymer exhibits almost the identical physical, chemical, and electrical properties characteristic of the 1:1 alternating copolymer, but retains high ultimate elongation up to 200°C.

Ethylene and TFE are copolymerized in aqueous, nonaqueous, or mixed medium with free-radical initiators. The polymer is isolated and converted into extruded cubes, powders, and beads, or a dispersion. This family of products is manufactured by DuPont, Dyneon, Daikin, Asahi Glass, and Ausimont and sold under the trade names of Tefzel, Hostaflon ET, Neoflon EP, Aflon COP, and Halon ET, respectively. Additional information on specific manufacturers' products can often be obtained by consulting their internet web sites (for example, www.dupont.com/teflon).

Monomers

Tetrafluoroethylene of purity suitable for granular or dispersion polymerizations is acceptable for copolymerization with ethylene. Polymerization-grade ethylene is suitable for copolymerization with TFE. Modifying termonomers, eg, perfluorobutylethylene and perfluoropropylene, are incorporated by free-radical polymerization.

Manufacture

Tetrafluoroethylene–ethylene copolymers have tensile strengths two to three times as high as the tensile strength of PTFE or of the ethylene homopolymer (1). Because these copolymers are highly crystalline and fragile at high temperature, they are modified with a third monomer, usually a vinyl monomer free of telegenic activity. The termonomer provides the copolymer with side chains of at least two carbon atoms, such as perfluoroalkylvinyl or vinylidene compounds, perfluoroalkyl ethylenes, and perfluoroalkoxy vinyl compounds. For high tensile properties and cut-through resistance, a molar ratio of ethylene and TFE between 60:40 and 40:60 is required (8,9).

Copolymerization is effected by suspension or emulsion techniques under such conditions that TFE, but not ethylene, may homopolymerize. Bulk polymerization is not commercially feasible because of heat-transfer limitations and explosion hazard of the comonomer mixture. Polymerizations typically take place below 100°C and 5 MPa (50 atm). Initiators include peroxides, redox systems (10), free-radical sources (11), and ionizing radiation (12). Mixtures of inert solvent and water can be used, where the polymerization occurs in the solvent medium, while the water serves to lower the viscosity of the mixture and to remove the heat of polymerization (13,14).

Purely aqueous polymerization systems give copolymers that are not wetted by the reaction medium. The products agglomerate and plug valves, nozzles, and tubing, and adhere to stirrer blades, thermocouples, or reactor walls. These problems do not occur in organic media or mixtures of these with water.

Aqueous emulsion polymerization is carried out using a fluorinated emulsifier, a chain-transfer agent to control molecular weight, and dispersion stabilizers such as manganic acid salts and ammonium oxalate (15,16).

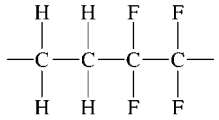
To obtain a 50:50 molar ratio of monomers in the polymer, a mixture of about 75:25 TFE to ethylene must be initially charged to the reactor, depending on reactor pressure and temperature. Reactivity ratios for this system have been studied (17,18). The effects of temperature, addition of termonomer, and ethylene/TFE ratio on degree of alternation and on molecular structure have been studied (19). Melting point of ETFE are higher than would be predicted based upon a linear relationship between polyethylene and PTFE melting points. ETFE is unique in this respect. All other common copolymers of TFE exhibit either linear or depressed melting points when compared to a line between the respective homopolymer melting point and that of PTFE. This positive melting point deviation occurs from about 35:65 to 65:35 mole ratios and is at a maximum at the 50:50 alternating copolymer, which melts at about 285°C, compared to about 235°C for the 65:35 TFE/ethylene composition. Melting points are lowered by the incorporation of modifier, but the overall shape of a curve of the positive melting point deviation is unaltered. The ability of adjacent chains to interpenetrate is thought to be responsible for this behavior. For the same reason, stiffness follows a similar positive deviation, also reaching a maximum at the 50:50 composition. Reactivity ratios of ethylene and TFE are as follows:

Temperature, °C	$r(C_2F_4)$	$r(C_2H_4)$
−35	0.014 ± 0.008	0.010 ± 0.02
65	0.045 ± 0.010	0.14 ± 0.03

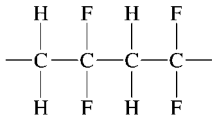
These values indicate strong alternation tendencies that decrease with increasing temperature. Computations show that 1:1 ETFE obtained at −30 and 65°C should have about 97 and 93%, respectively, of alternating sequences (20).

Properties

The equimolar copolymer of ethylene and TFE is isomeric with poly(vinylidene fluoride) but has a higher melting point (21,22) and a lower dielectric loss (23,24). A copolymer with the degree of alternation of about 0.88 was used to study the structure (25). The unit cell was determined by x-ray diffraction (26,27). Despite irregularities in the chain structure and low crystallinity, a unit cell and structure was derived that gave a calculated crystalline density of 1.9 g/cm^3. The unit cell is believed to be orthorhombic or monoclinic ($a = 0.96$ nm, $b = 0.925$ nm, $c = 0.50$ nm; $\gamma = 96°$).



Ethylene–tetrafluoroethylene unit



Poly(vinylidene fluoride) segment

The molecular conformation is that of extended zigzag. Molecular packing appears to be orthorhombic, each molecule having four nearest neighbors with the CH_2 groups of one chain adjacent to the CF_2 groups of the next. The x-ray spectrum of a 1:1 copolymer has two main peaks at $Z_0 = 19.63^\circ$ and $Z_0 = 21.00^\circ$, corresponding to Bragg distances of 0.45 and 0.42 nm, respectively. Compression-molded samples are 50–60% crystalline; however, crystallinity is greatly affected by composition, quench rate, and temperature.

Alternation is usually above 90%. Nearly perfect alternation of isomeric units in a ca 1:1 monomer ratio has been confirmed by infrared spectroscopy. Bands at 733 and 721 cm^{-1} have an intensity proportional to the concentration of $(CH_2)_n$ groups ($n = 4$ and <6, respectively) present in a copolymer containing 46 mol% TFE; intensity decreases with increasing concentration of fluorinated monomer.

The molecular weight and its distribution have been determined by laser light scattering, employing a new apparatus for ETFE dissolution and solution clarification at high temperature; diisobutyl adipate is the solvent at 240°C. The molecular weight of molten ETFE is determined by high temperature rheometry (28).

This polymer can be dissolved in certain high boiling esters at temperatures above 230°C (29–31), permitting a weight-average molecular weight determination by light scattering. Solution viscosity data suggest that the polymer exists as a slightly expanded coil under similar conditions (32).

Transitions. Samples containing 50 mol% TFE with ca 92% alternation were quenched in ice water or cooled slowly from the melt to minimize or maximize crystallinity, respectively (24). Internal motions were studied by dynamic mechanical and dielectric measurements, and by nuclear magnetic resonance. The dynamic mechanical behavior showed that the α relaxation occurs at 110°C in the quenched sample; in the slowly cooled sample it is shifted to 135°C. The β relaxation appears near −25°C. The γ relaxation at −120°C in the quenched sample is reduced in peak height in the slowly cooled sample and shifted to a slightly higher temperature. The α and γ relaxations reflect motions in the amorphous regions, whereas the β relaxation occurs in the crystalline regions. The γ relaxation at −120°C in dynamic mechanical measurements at 1 Hz appears at −35°C in dielectric measurements at 10^5 Hz. The temperature of the α relaxation varies from 145°C at 100 Hz to 170°C at 10^5 Hz. In the mechanical measurement it is 110°C. There is no evidence for relaxation in the dielectric data.

The activation energy is 318.1 kJ/mol (76 kcal/mol) for the α relaxation and 44.3 kJ/mol (10.6 kcal/mol) for the γ relaxation. These relaxations are attributed to the motion of long and short segments in the amorphous regions, respectively. As ETFE is isomeric with poly(vinylidene fluoride) (23), the γ relaxations occur at about the same temperature. Activation energies are similar and are attributed to the motion of short amorphous segments. The β relaxation in PVF_2 is considered to be the main-chain amorphous relaxation and is analogous to the α relaxation in the ETFE. However, the arrangement of dipoles in the all-trans conformation is more symmetrical.

Physical and Mechanical Properties. Modified ETFE has a good combination of mechanical properties, including excellent cut-through and abrasion resistance, high flex life, and exceptional impact strength. As wire insulation, it withstands physical abuse during and after installation. Lightweight wire constructions are designed with a minimum diameter and are useful as single, general-purpose insulation and for multiple or composite constructions.

Modified ETFE is less dense, tougher, and stiffer and exhibits a higher tensile strength and creep resistance than PTFE, PFA, or FEP resins. It is ductile, and displays in various compositions the characteristic of a nonlinear stress–strain relationship. Typical physical properties of Tefzel products are shown in Table 1 (33,34). Properties such as elongation and flex life depend on crystallinity, which is affected by the rate of crystallization; values depend on fabrication conditions and melt cooling rates.

Light transmittance of 25-μm films in the visible-to-ir range varies from 91 to 95% for Tefzel 200 and from 89 to 93% for Tefzel 280. In the uv range, transmittance increases from 50% at 200 nm to 90% at 400 nm.

Thermal Properties. Modified ETFE has a broad operating temperature range up to 150°C for continuous exposure (33). Cross-linking by radiation improves the high temperature capability further. However, prolonged exposure to higher temperatures gradually impairs the mechanical properties and results in discoloration. Thermal and oxidative degradation studies (35,36) suggest that main carbon chain sequences of two or more ethylene links are thought to be subject to thermal and oxidative degradation. To enhance the thermal stability of ETFE resins stabilizers may be added for high temperature applications (37). The copolymer will not support combustion in air. Limiting oxygen index (LOI) is about 30–31, depending on monomer ratio. LOI increases gradually as fluorocarbon content is increased up to the alternating composition. It then increases rapidly to the index of PTFE (38).

The thermodynamic properties of Tefzel 200 and 280 are shown in Table 2; the annual rate of loss of weight with thermal aging for Tefzel 200 ranges from 0.0006 g/g at 135°C to 0.006 g/g at 180°C after an initial loss of absorbed gases of 0.0013 g/g at elevated temperature. The excellent thermal stability of ETFE is demonstrated by aging at 180°C; at this temperature, the annual weight loss of six parts per 1000, or a 1% weight loss, takes almost 2 years.

Friction and Bearing Wear of the Glass-Reinforced Copolymer. Glass reinforcement improves the frictional and wear properties of modified ETFE resins (HT-2004). For example, the dynamic coefficient of friction [689.5 kPa (100 psi) at >3 m/min] for Tefzel 200 is 0.4, which drops to 0.3 for the 25% glass-reinforced product at these conditions (33). The wear factor also improves from

12×10^{-14} to 32×10^{-17} 1/Pa [6000×10^{-10}–16×10^{-10} (in.^{3}·min)/(ft·lbf·h)]. These frictional and wear characteristics, combined with outstanding creep resistance, indicate suitability for bearing applications. Glass-reinforced ETFE is less abrasive on mating surfaces than most glass-reinforced polymers. Its static

coefficient of friction depends on bearing pressure; for Tefzel HT-2004 the coefficient of friction changes from 0.51 at 68 Pa to 0.34 at 3.43 kPa (0.5 psi).

Dynamic friction depends on pressure and rubbing velocity (PV). The generation of frictional heat depends on the coefficient of friction and the PV factor. For the glass-reinforced product, temperature buildup begins at about PV 10,000 and thermal runaway occurs just below PV 20,000. High wear rates begin above PV 15,000. The wear rate depends on the type of metal rubbing surface and finish, lubrication, and clearances. Lubrication, hard shaft surfaces, and high finishes improve wear rates. Table 3 gives wear factors for steel and aluminum. Because the wear rate of both ETFE and the metal is much higher for aluminum than for steel, an anodized surface is preferred with aluminum.

Electrical Properties. Modified ETFE is an excellent dielectric (Table 4). Its low dielectric constant confers a high corona-ignition voltage. The dielectric constant does not vary with frequency or temperature. Both dielectric strength (ASTM D149) and resistivity are high. The loss characteristics are minimum; the dissipation factor, although low, increases at higher frequencies. Glass reinforcement increases losses and the dielectric constant rises from 2.6 to 3.4 (from 10^2

Table 4. Electrical Properties of ETFE Resins

Arc resistance, s	D495	75	110

to 10^{10} Hz); the dissipation factor is increased by 10-fold. Exposure to radiation also increases losses. Dielectric strength is not reduced by thermal aging, unless a physical break occurs in the material. The short-time test of ASTM D149 gives values of 16–20 kV/mm with 3-mm-thick specimens to 160–200 kV/mm with films 25–75 μm thick. Tracking resistance is about 70 s by ASTM D495. This is comparable to materials considered to be nontracking; under unusual conditions tracking occurs. When these resins are foamed they provide insulation with even lower dielectric constant (39).

Chemical Resistance and Hydrolytic Stability. Modified ETFE are resistant to chemicals and solvents (Table 5) that often cause rapid degradation in other plastic materials. Performance is similar to that of perfluorinated polymers (40), which are not attacked by strong mineral acids, inorganic bases, halogens, and metal salt solutions. Organic compounds and solvents have little effect. Strong oxidizing acids, organic bases, and sulfonic acids at high concentrations and near their boiling points affect ETFE to varying degrees.

Physical properties remain stable after long exposure to boiling water. Tensile strength and elongation of Tefzel 200 are unaffected after 3000 h in boiling water. The higher molecular weight ETFE behaves similarly, whereas the glass-reinforced product shows a reduction of 25–35% in tensile strength with loss of reinforcement.

Water absorption of Tefzel is low (0.029 wt%), which contributes to its outstanding dimensional stability as well as to the stability of mechanical and electrical properties regardless of humidity.

High temperature resistance of ETFE and other fluoropolymers in automotive fuels and their permeation resistance have been discussed (41,42).

The ETFE can be cross-linked by radiation (43), despite the high content of TFE units. The recommended upper continuous use temperature for commercial ETFE is 150°C. Physical strength can be maintained at higher temperatures when cross-linking agents are incorporated and cured by peroxide or ionizing radiation (44). The cut-through resistance of thin-wall wire insulation to a physical abuse during installation or use is increased at temperature up to 200°C. Short-term excursions to 240°C are possible for highly cross-linked resins. Cross-linking

[a] Changes in properties <15% are considered insignificant; test performed on 250–1250 μm microtensile bars; tensile strength, elongation, and weight gain determined within 24 h after termination of exposure.

reduces plasticity but enhances high temperature properties and nondrip performance. The irradiated resin withstands a 400°C solder iron for 10 min without noticeable effect.

Modified ETFE has excellent weather resistance; tensile strength and elongation are not affected. On the other hand, tensile and elongation properties of the glass-reinforced compound show a significant reduction.

Modified ETFE films are used as windows in greenhouses and conservatories because of their high transparency to both uv and visible light and excellent resistance to weathering (45). Pigmented films are applied on white boards and in outdoor advertising laminates. Biaxially oriented films have tensile properties and toughness similar to polyester films (46).

Vacuum Outgassing and Permeability. Under vacuum, modified ETFE give off little gas at elevated temperatures. The loss rate is about one-tenth of the acceptable maximum rates for spacecraft uses. Exposing 750-μm specimens for 24 h at 149°C to a high vacuum results in a maximum weight loss of 0.12%; volatile condensible material is less than 0.02%.

The following permeability values were determined on Tefzel film (100μm, ASTM D1434) at 25°C [1 nmol (m· s·GPa) = 0.5 (cm^3·mil)/(100 $in.^2$dia·atm)]:

	nmol/(m·s·GPa)
Carbon dioxide	500
Nitrogen	60
Oxygen	200
Helium	1800
Water vapor (ASTM E96)	3.3

Fabrication

Modified ETFE are commercially available in a variety of physical forms (Table 6) and can be fabricated by conventional thermoplastic techniques. Commercial ETFE resins are marketed in melt-extruded cubes, that are sold in 20-kg bags or 150-kg drums. In the United States, the 1992 price was $27.9–44.2/kg, depending on volume and grade; color concentrates are also available.

Like other thermoplastics, they exhibit melt fracture (47) above certain critical shear rates. In extrusion, many variables control product quality and performance (48).

Melt Processing

Articles are made by injection molding, compression molding, blow molding, transfer molding, rotational molding, extrusion, and coating. Films can be thermoformed and heat sealed (33). Because of high melt viscosity, ETFE resins are usually processed at high temperatures (300–340°C).

Injection-molded articles shrink about 1.5–2.0% in the direction of resin flow and about 3.5–4.5% in the transverse direction under normal molding conditions. A 25% glass-reinforced composition shrinks only about 0.2–0.3% in the flow direction and about 3.0% in the transverse direction. Although shrinkage depends on shape and processing conditions, uniformity is excellent.

Table 6. Forms of Modified ETFE Resins

Tefzel grade	Form	Melt flow,[a] g/10 min	Application
210	Extruded cubes	45	Injection molding, thin coating
200	Extruded cubes	8	General purpose, insulation, tubing, fasteners
280	Extruded cubes	3	Chemical resistance, jacketing, havy-wall, logging cables
HT-2000	Compacted powder	8	Compounded products
HT-2010	Compacted powder	3	Compounded products, coating lining
HT-2010	Compacted powder	45	Coating

[a] At 297°C and 45 N (5 kgf) load.

Molten ETFE polymers corrode most metals, and special corrosion-resistant alloys are recommended for long-term processing equipment; short-term prototype runs are possible in standard equipment.

Forming and Machining. Articles can be formed below the melting point with conventional metal-forming techniques. Tetrafluoroethylene–ethylene copolymers are readily machined with the same tools and feed rates as are used for nylon and acetal. For best dimensional stability, the article should be annealed at the expected use temperature before the final machine cut.

Coloring and Decorating. Commercial pigments that are thermally stable at the resin processing temperature may be used. Pigments may be dry-blended with the resin, or ETFE pellets may be blended with color concentrates, which are available in pellet form.

Nontreated surfaces can be hot-printed with special foils in a manner similar to a typewriter ribbon. The type is heated to about 321°C, and a printing pressure of 172–206 kPa (25–30 psi) is applied for about 0.25 s; no further treatment is required.

Stripes may be applied to wire coated with ETFE fluoropolymer over DuLite 817-5002 fluoropolymer clear enamel or other bases. Thermally stable pigments are required. Stripes may be applied by gravure-wheel-type applicators and oven-cured in-line.

Assembly. The success of many applications depends on the ability of ETFE fluoropolymer to be economically assembled.

Screw Assembly. Self-tapping screws are used for joining ETFE parts. For maximum holding power, the boss diameter should be about double the screw diameter, and the engagement length about 2.5 times the screw diameter; lubricants should be avoided. Threaded inserts can be molded in place, pressed in, or driven in ultrasonically.

Snap-Fit and Press-Fit Joints. Snap-fit joints offer the advantage that the strength of the joint does not diminish with time because of creep. Press-fit joints are simple and inexpensive, but lose holding power. Creep and stress relaxation reduce the effective interference, as do temperature variations, particularly with materials with different thermal expansions.

Cold or Hot Heading. Rivets or studs can be used in forming permanent mechanical joints. The heading is made with special tools and preferably with the rivet at elevated temperatures. Formed heads tend to recover part of their original shape if exposed to elevated temperatures, resulting in loose joints. Forming at elevated temperature reduces recovery.

Spin Welding. Spin welding is an efficient technique for joining circular surfaces of similar materials. The matching surfaces are rotated at high speed relative to each other and then brought into contact. Frictional heat melts the interface and, when motion is stopped, the weld is allowed to solidify under pressure.

Ultrasonic Welding. Ultrasonic welding has been applied to Tefzel with weld strength up to 80% of the strength of the base resin. Typical conditions include a contact pressure of 172 kPa (25 psi) and 1–2 s cycle time. The two basic designs, the shear and butt joints, employ a small initial contact area to concentrate and direct the high frequency vibrational energy.

Potting. Potting of wire insulated with Tefzel has been accomplished with the aid of a coating of a colloidal silica dispersion. The pots produced with a polysulfide potting compound meeting MIL-S-8516C Class 2 standards exhibit pullout strengths of 111–155 N (25–35 lbf).

Bonding. Surface treatment, such as chemical etch, corona, or flame treatments, is required for adhesive bonding of Tefzel. Polyster and epoxy compounds are suitable adhesives.

ETFE respond well to melt bonding to untreated aluminum, steel, and copper with peel strengths above 3.5 kN/m (20 lbf/in.). For melt bonding to itself, hot-plate welding is used. The material is heated to 271–276°C, and the parts are pressed together during cooling.

The plasma surface treatment of ETFE to improve adhesion has been studied (49).

Testing and Standards

A description of modified ETFE and their classification is given by the American Society for Testing and Materials under the designation D3159-83 (50). A comprehensive listing of industrial and military specifications is available (51).

Applications. Tefzel 200 is a general-purpose, high temperature resin for insulating and jacketing low voltage power wiring for mass transport systems, wiring for chemical plants, and control and instrumentation wiring for utilities. In injection-molded form, it is used for sockets, connectors, and switch components (52). Because of excellent mechanical properties it provides good service in seal glands, pipe plugs, corrugated tubing, fasteners, and pump vanes. In chemical service, it is used for valve components, laboratory ware, packing, pump impellers, and battery and instrument components.

Tefzel 210, the high melt-flow resin, provides a high speed processing product for use in coating of fine wire and injection molding of thin-walled or intricate shapes. It is also used for other fine-wire applications requiring high line speeds and mechanical strength, but where harsh environmental conditions are not anticipated.

For high temperature wiring with mechanical strength and stress-crack and chemical resistance, Tefzel 280 is preferred. Rated by UL at 150°C, it is widely used for insulating and jacketing heater cables and automotive wiring and for other heavy-wall application where temperatures up to 200°C are experienced for short peirod of time or where repeated mechanical stress at 150°C is encountered. It is also suitable for oil-well logging cables and is used in transfer moldings and extrusions for lined chemical equipment. It is injection molded into articles with metal inserts, thick sections, and stock shapes.

Health and Safety

Large quantities of Tefzel have been processed and used in many demanding service applications. No cases of permanent injury have been attributed to these resins, and only limited instances of temporary irritation to the upper respiratory tract have been reported (53).

As with other melt-processible fluoropolymers, trace quantities of harmful gases, including hydrogen fluoride, diffuse from the resin even at room temperature. Therefore, the resins should be used in well-ventilated areas. Even though the resin is physiologically inert and nonirritating to the skin, it is recommended that spills on the skin be washed with soap and water. These resins are stable at 150°C and are recommended for continuous use at this temperature. Degradation, as measured by weight loss, is insignificant up to the melting point of 270°C. At processing temperatures sufficient quantities of irritating and toxic gases are generated to require removal of the gases by exhaust hoods over the die and at the hopper heater. For extrusion into water, a quench tank or partially filled container for purging is recommended. In extrusion operations proper procedures must be maintained to control temperature and pressure. The weight loss with increasing temperature is as follows:

Temperature, °C	Hourly weight loss, %
300	0.05
330	0.26
350	0.86
370	1.60

To remove all decomposition products, a "total-capture" exhaust hood is recommended.

Under normal processing conditions at 300–350°C, Tefzel resins are not subject to autocatalytic degradation. However, extended overheating can result in "blow-backs" through extruder feed hopper or barrel front.

Prolonged soldering in confined spaces with restricted air circulation requires ventilation. A small duct fan is recommended for hot-wire stripping. Tefzel articles should not be exposed to welding conditions.

The limiting oxygen index of Tefzel as measured by the candle test (ASTM D2863) is 30%. Tefzel is rated 94 V-0 by Underwriters, Laboratories, Inc., in their burning test classification for polymeric materials. As a fuel, it has a comparatively low rating. Its heat of combustion is 13.7 MJ/kg (32,500 kcal/kg) compared to 14.9 MJ/kg (35,000 kcal/kg) for poly(vinylidene fluoride) and 46.5 MJ/kg (110,000 kcal/kg) for polyethylene.

Bulk quantities of Tefzel fluoropolymer resins should be stored away from flammable materials. In the event of fire, personnel entering the area should have full protection, including acid-resistant clothing and self-contained breathing apparatus with a full facepiece operated in the pressure-demand or other positive-pressure mode. All types of chemical extinguishers may be used to fight fire involving Tefzel resins. Large quantities of water may be used to cool and extinguish the fire.

The DuPont Haskell Laboratory for Toxicology and Industrial Medicine has conducted a study to determine the acute inhalation toxicity of fumes evolved from Tefzel fluoropolymers when heated at elevated temperatures. Rats were exposed to decomposition products of Tefzel for 4 h at various temperatures. The approximate lethal temperature (ALT) for Tefzel resins was determined to be 335–350°C. All

rats survived exposure to pyrolysis products from Tefzel heated to 300°C for this time period. At the ALT level, death was from pulmonary edema; carbon monoxide poisoning was probably a contributing factor. Hydrolyzable fluoride was present in the pyrolysis products, with concentration dependent on temperature.

PERFLUORINATED POLYMERS, TETRAFLUOROETHYLENE–PERFLUORODIOXOLE COPOLYMERS

Copolymers of tetrafluoroethylene and 2,2-bistrifluoromethyl-4,5-difluoro-1,3-dioxole (PDD) are perfluorinated amorphous polymers and possess unusual combination of properties. They retain the outstanding chemical, thermal, and surface properties of perfluorinated polymers in addition to having excellent electrical and optical properties; and have solubility at ambient temperature in a normal fluorosolvent. This family of copolymers is manufactured by DuPont and sold under the trade name of Teflon AF, amorphous fluoropolymers.

All tetrafluoroethylene-based homo- and copolymers, described in earlier papers, are semicrystalline with distinct melting points. On the other hand, tetrafluoroethylene–PDD copolymers are totally amorphous and can be tailored for specific glass-transition temperatures by altering the polymer composition (1). So these perfluorinated amorphous polymers exhibit properties derived from their amorphous structure and perfluorinated chains.

Monomer

Preparation. 2,2-Bistrifluoromethyl difluoro-1,3-dioxole (PDD) monomer is synthesized in four steps (2). In the first step, hexafluoroacetone and ethylene oxide are reacted to form 2,2-bistrifluoromethyl-4,5-dichloro-4,5-difluoro-1,3-dioxolane. This product is then fully chlorinated and subsequently partially fluorinated to difluoro-1,3-dioxolane. In the last step, the fluorinated product is dechlorinated to obtain the final product, PDD.

PDD Monomer

Properties. PDD is a colorless liquid with the boiling point of 33°C (3). It is very reactive and can homopolymerize, and therefore, needs to be stored at low temperature with a small amount of free-radical inhibitor. PDD can copolymerize with tetrafluoroethylene or other fluorinated monomers, such as vinylidene fluoride, vinyl fluoride, or chlorotrifluoroethylene.

Copolymerization. Copolymers of tetrafluoroethylene and PDD can be synthesized by free-radical initiators in either aqueous or nonaqueous medium (1). The homopolymer of PDD results in an amorphous polymer with the glass-transition temperature T_g of 335°C. This polymer is difficult to melt process because of the narrow processing window below its decomposition temperature. Copolymers can be prepared with any proportion of tetrafluoroethylene and PDD. Polymers containing less than 20 mol% PDD tend to be partially crystalline. At 20 mol% PDD, the T_g of the copolymer is about 80°C. The glass-transition temperature increases with an increase in PDD. The commercial Teflon AF products are copolymers of tetrafluoroethylene and PDD, and have glass-transition temperatures of 160 and 240°C for Teflon AF-1600 and Teflon AF-2400, respectively (4). During aqueous polymerization small amounts of acid fluoride or carboxylic acid end groups may be produced by ring-opening. For many applications these unstable ends are removed and converted to perfluorinated end groups by first treating the polymer with ammonia, followed by fluorination (5).

Properties. Teflon AF copolymers have many characteristics similar to those of other copolymers of tetrafluoroethylene, such as high-temperature stability, excellent chemical resistance, low surface energy, low water absorption, and high limiting oxygen index (LOI). On the other hand, many properties are different because of their amorphous structure. These polymers are soluble at ambient temperature in fluorinated solvents. They are transparent and have low refractive index. They are significantly stiffer and have high gas permeability. The glass-transition temperature of tetrafluoroethylene–PDD copolymers is sensitive to the structure of the dioxide monomer. It is likely that steric interactions involving the two trifluoromethyl groups lead to a highly congested chain structure with limited mobility (6). The structural study of these polymers indicate that there are microvoids in their structure and probably cause lower than expected polymer density, low dielectric constant, low refractive index, high gas permeability, and low thermal conductivity. Most likely the origin of these microvoids is loose chain packing caused by the high energy for rotation and reorientation of the dioxole ring containing polymer chain (7).

Table 1 summarizes mechanical, electrical, optical, and thermal properties of Teflon AF-1600 and AF-2400 (10). The dielectric constant for Teflon AF is lower than that for PTFE and is unaffected by humidity.

To convert MPa to psi, multiply by 145.
To convert Pa·s to P, multiply by 10.

The low temperature dielectric properties invetigation (11) revealed that the γ relaxation found at −186°C for PTFE is only one-third the intensity for AF-1600 and AF-2400. This relaxation is attributed to the cooperative motion of the four carbon atoms of a TFE dimer unit. The low concentration of such units in AF explains the difference in the intensity of γ relaxation.

The refractive index of Teflon AF is the lowest known for any solid organic polymer (12). One of the key properties of AF is its solubility in fluorinated solvents, such as "Fluorinert" FC-72, -75, and -40, perfluorobenzene, perfluoromethylcyclohexane, perfluorodimethylcyclohexane, perfluoroctane, or perfluorodecalin.

The thermal stability of Teflon AF approaches that of other perfluorinated polymers. At 260°C after 4 h of exposure no weight loss was observed. The weight losses after the exposure at 360, 380, 400, and 420°C were 0.3, 0.5, 1.9, and 8.8%, respectively.

Copolymers of PDD with other fluoromonomers are discussed in Reference 3.

Fabrication. Teflon AF is processed by a wide variety of techniques. AF solutions can be used for spin coating, dip coating, spraying, or casting. Melt-processing techniques such as extrusion and injection molding are used. Compression molding has also been used effectively. Spin coating is used to produce very thin and uniform coatings on flat substrates. The film thickness is influenced by the nature of the substrate, the spin speed, and the concentration of the solution. Dip coating is suitable for nonplanar surfaces (13). Compression molding is done about 100°C above T_g and may require longer heat-up time than other polymers because of its lower thermal conductivity. Laser ablation and vacuum pyrolysis techniques are also used (14,15).

Health and Safety. Safe practices employed for handling PTFE and PFA resins are adequate for Teflon AF (20). Adequate ventilation is required for processing above 330°C.

Applications and Economic Aspects. Teflon AF is used to provide antireflective coatings (16), low dielectric coatings, pellicles used in electronic chips (17), cladding in plastic optical fiber (18), as a low dielectric insulator, to coat gas separation membranes (19).

The PDD monomer used for AF is very expensive, which results in making AF products very costly. These polymers in solid form are sold in 25 and 500 g packages at prices $500 and $5000, respectively. The solutions are available in 100 mL and 1 L packages. They contain 1–18% solids, depending on the grade. The prices for solutions range from $70 for 1% solids of AF-2400 in 100 mL to $7810 for 18% solids of AF-16015-18 in 1 L package.

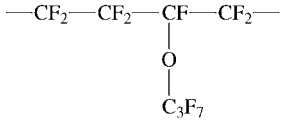
PERFLUORINATED POLYMERS, TETRAFLUOROETHYLENE–PERFLUOROVINYL ETHER COPOLYMERS

Introduction

Perfluoroalkoxy (PFA) fluorocarbon resins are designed to meet industry's needs in chemical, electrical, and mechanical applications. These melt-processible copolymers contain a fluorocarbon backbone in the main chain and randomly distributed perfluorinated ether side chains:



A combination of excellent chemical and mechanical properties at elevated temperatures results in reliable, high performance service to the chemical processing and related industries. Chemical inertness, heat resistance, toughness and flexibility, stress-crack resistance, excellent flex life, antistick characteristics, little moisture absorption, nonflammability, and exceptional dielectric properties are among the characteristics of these resins.

The introduction of a perfluoromethyl side chain (Teflon FEP) greatly reduces the crystallinity of polytetrafluoroethylene (PTFE). Crystallinity is reduced

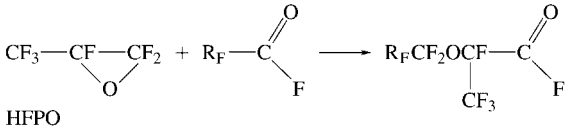
Encyclopedia of Polymer Science and Technology. Copyright John Wiley & Sons, Inc. All rights reserved.

even further by replacing the short side chain with a long side chain, such as perfluoropropyl ether. In contrast to Teflon FEP, only a small amount of vinyl ether is required to reduce crystallinity and develop adequate toughness.

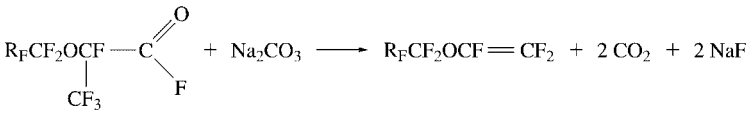
Tetrafluoroethylene (TFE) [116-14-3] and perfluorovinyl ether are copolymerized in aqueous (1,2) or nonaqueous (3) media. The polymer is separated and converted into various forms, such as extruded cubes, powders, beads, or dispersions. This family of products is manufactured by DuPont, Daikin, Dyneon, and Asahi Glass and sold under the trade names of Teflon PFA, Neoflon AP, Hostaflon TFA, and Aflon PFA, respectively. Additional information on specific manufacturers' products can often be obtained by consulting their internet web sites (for example, www.dupont.com/teflon).

Monomers

Preparation. The preparation of TFE has been described previously. Perfluorovinyl ethers (4–7) are prepared by the following steps. Hexafluoropropylene (HFP) [116-15-4] is oxidized to an epoxide HFPO [428-59-1] (5) which, on reaction with perfluorinated acyl fluorides, gives an alkoxyacyl fluoride.



The alkoxyacyl fluoride is converted to vinyl ethers by treatment with base at ca 300°C (8).



where $R_F = F(CF_2)_n$.

Alkoxyacyl fluorides are also produced by an electrochemical process (9).

The preparation of perfluoromethyl and perfluoroethyl vinyl ethers is described in References 10 and 11.

Properties. Properties of perfluoropropyl vinyl ether (PPVE) [1623-05-8], a colorless, odorless liquid (mol. wt. 266), are shown in Table 1. Perfluoropropyl vinyl ether is an extremely flammable liquid and burns with a colorless flame. It is significantly less toxic than HFP; the average lethal concentration (ALC) is 50,000 ppm (12).

Table 1. Properties of Perfluoropropyl Vinyl Ether, $F_3C—CF_2—CF_2—O—CF=CF_2$

Property	Value
Critical temperature, K	423.58
Critical pressure, MPa[a]	1.9
Critical volume, $cm^3/(g·mol)$	435
Surface tension, mN/m(=dyn/cm)	9.9
Boiling point, °C	36
Specific gravity at 23°C,	1.53
Vapour density at 75°C, g/cm^3	0.2

Flammable limits in air,[c] vol.%	1

[a]To convert MPa to atm, divide by 0.1013.
[b]To convert kPa to psi (psia), multiply by 0.145.
[c]Extremely flammable.

Copolymerization

Tetrafluoroethylene–perfluoropropyl vinyl ether copolymers [26655-00-5] are made in aqueous (1,2) or nonaqueous media (3). In aqueous copolymerizations water-soluble initiators and a perfluorinated emulsifying agent are used. Molecular weight and molecular weight distribution are controlled by a chain-transfer agent. Sometimes a second phase is added to the reaction medium to improve the distribution of the vinyl ether in the polymer (13); a buffer is also added. In nonaqueous copolymerization, fluorinated acyl peroxides are used as initiators that are soluble in the medium (14); a chain-transfer agent may be added for molecular weight control.

Temperatures range from 15 to 95°C, and the pressures from 0.45 to 3.55 MPa (65–515 psi). The temperatures used for the aqueous process are higher than those for the nonaqueous process.

Alkyl vinyl ethers tend to rearrange when exposed to free radicals (15). Temperatures must be kept low enough to prevent termination by free-radical coupling. In the aqueous process, temperatures below 80°C minimize the number of acid end groups derived from vinyl ether transfer. In the nonaqueous process, temperature must also be limited to avoid excessive vinyl ether transfer as well as reaction with the solvent. End groups are stabilized by treating the polymer (16) with methanol, ammonia, or amines (17–19). Treatment of PFA with elemental fluorine generates CF_3 end groups and a very low level of contamination (20), which is important for the semiconductor industry (21).

The polymer is separated from the medium and converted to useful forms such as melt-extruded cubes for melt-processible applications. Teflon PFA is also available as a dispersion, a fine powder, or in unmelted bead form.

Description and classification of PFA resins are given in Reference 22. Various specifications are given in Reference 23.

A family of copolymers containing TFE and perfluoromethyl vinyl ether modified with PPVE referred to as MFA is produced by Ausimont (24). The relatively small pendant group —O—CF3 seems to have a similar effect on the crystallinity reduction as is exhibited by —CF3 in FEP (perfluoropropylene–tetrafluoroethylene copolymer); however, the higher reactivity of perfluoromethyl vinyl ether than that of HFP makes the polymerization process more efficient. The performance characteristics are described in References 11 and 25.

A new family of copolymers called Teflon HP Plus has been introduced by DuPont using perfluoroethyl vinyl ether analogous to PPVE used to produce the standard PFA (26). A significantly higher reactivity of perfluoroethyl vinyl ether has made it possible to produce copolymers with widely different comonomer concentrations on a commercial scale while reducing the tendency to rearrange and form acid end groups from vinyl ether transfer. Even though perfluoroethyl group provides a somewhat shorter pendant group, its effect on the reduction of crystallinity is very similar to that of perfluoropropyl group. This makes the perfluoroethyl vinyl ether an optimum commonomer to produce a versatile family of products.

Properties

The melting point of commercial Teflon PFA is 305°C, ie, between those of PTFE and FEP. Second-order transitions are at −100, −30, and 90°C, as determined by a torsion pendulum (27). The crystallinity of the virgin resin is 65–75%. Specific gravity and crystallinity increase as the cooling rate is reduced. An ice-quenched sample with 48% crystallinity has a specific gravity of 2.123, whereas the press-cooled sample has a crystallinity of 58% and a specific gravity of 2.157.

Mechanical Properties. Table 2 shows the physical properties of Teflon PFA (28,29). At 20–25°C the mechanical properties of PFA, FEP, and PTFE are similar; differences between PFA and FEP become significant as the temperature is increased. The latter should not be used above 200°C, whereas PFA can be used up to 260°C. Tests at liquid nitrogen temperature indicate that PFA performs well in cryogenic applications (Table 3).

Unfilled Teflon PFA has been tested in mechanical applications, using Teflon FEP 100 as a control (30). Tests were run on molded thrust bearings at 689.5 kPa (100 psi) against AISI 1080, Rc 20, 16AA steel, and at ambient conditions in air without lubrication. A limiting PV value of 5000 was found. Wear factors and dynamic coefficients of friction are shown in Table 4.

Hardness is determined according to ASTM D2240 on 7.6 × 12.7 × 0.48 cm injection-molded panels (31). Results on the D scale are 63–65 for Teflon PFA and 63–66 for Teflon FEP.

Chemical Properties. A combination of excellent chemical and mechanical properties at elevated temperatures results in high performance service in the chemical processing industry. Teflon PFA resins have been exposed to a variety of organic and inorganic compounds commonly encountered in chemical service (32). They are not attacked by inorganic acids, bases, halogens, metal salt solutions,

organic acids, and anhydrides. Aromatic and aliphatic hydrocarbons, alcohols, aldehydes, ketones, ethers, amines, esters, chlorinated compounds, and other polymer solvents have little effect. However, like other perfluorinated polymers, they react with alkali metals and elemental fluorine.

Thermal Stability. Teflon PFA resins are very stable and can be processed up to 425°C. Thermal degradation is a function of temperature and time. A significant increase in melt flow rate indicates degradation after a short time above 425°C; at lower temperatures degradation takes longer. Degradation is not significant if the change in melt flow rate of the resin during molding is below 20%. Degradation is also indicated by the formation of small bubbles or discoloration; however, high stock temperatures may cause slight discoloration without adversely affecting properties.

Heat aging at 285°C, a temperature slightly below but near the melting point, increases the strength of Teflon PFA. Samples aged in a circulating air oven for 7500 h at 285°C show a decrease in melt flow number as defined by ASTM D2116. A decline in melt flow number indicates an increase in average molecular weight, which is also indicated by a 25% increase in tensile strength and enhanced ultimate elongation. Toughness is also measured by MIT flex life, which improves severalfold on heat aging at 285°C.

When exposed to fire, Teflon PFA contributes little in fuel value and is self-extinguishing when the flame is removed. The fuel value is approximately 5.4 MJ/kg (2324 Btu/lb). It passes the UL-83 vertical-flame test and is classified as 94VE-O according to UL-94. The limiting oxygen index (LOI) by ASTM D2863 is above 95%.

Electrical Properties. The electrical properties of Teflon PFA are given in Table 5. The dielectric constant of PFA resins is about 2.06 over a wide range of frequencies (10^2–2.4×10^{10} Hz), temperatures, and densities (ASTM D150). The values for PFA density vary only slightly, 2.13–2.17, and the dielectric

[a] Short term, 250-μm-thick sample.

constant varies only about 0.03 units over this range, among the lowest of all solid materials. Humidity has no measurable effect on the dielectric constant of PFA. The dielectric strength (short-term) of PFA resins is 80 kV/mm (0.25-mm films, ASTM D149); FEP films give similar results, whereas PTFE films are typically measured at 47 kV/mm. Like other fluoropolymer resins, PFA loses dielectric strength in the presence of corona discharge. The dissipation factor at low frequency (10^2–10^4 Hz) decreases with increasing frequency and decreasing temperature. Temperature and frequency have little influence on the dissipation factor over the frequency range 10^4–10^7 Hz. As frequencies increase to 10^{10} Hz, there is a steady increase in dissipation factor. Above 10^7 Hz, increases measured at room temperature are highest; a maximum at about 3×10^9 Hz is indicated. The higher dissipation factor with increasing frequency should be considered in electrical insulation applications at high frequencies. The volume and surface resistivities of fluorocarbon resins are high and are not affected by time or temperature. When tested with stainless steel electrodes (ASTM D495), no tracking was observed for the duration of the test (180 s), indicating that PFA resin does not form a carbonized conducting path (33,34).

Optical Properties and Radiation Effects. Within the range of wavelengths measured (uv, visible, and nir radiation), Teflon PFA fluorocarbon film transmits slightly less energy than FEP film (35) (Table 6). In thin sections, the resin is colorless and transparent; in thicker sections, it becomes translucent. It is highly transparent to ir radiation; uv aborption is low in thin sections. Weather-O-Meter tests indicate unlimited outdoor life.

Like other perfluoropolymers, Teflon PFA is not highly resistant to radiation (36). Radiation resistance is improved in vacuum, and strength and elongation are increased more after low dosages (up to 30 kGy or 3 Mrad) than with FEP or PTFE. Teflon PFA approaches the performance of PTFE between 30 and 100 kGy (3–10 Mrad) and embrittles above 100 kGy (10 Mrad). At 500 kGy (50 Mrad) PTFE, FEP, and PFA are degraded. The effect of radiation on tensile strength and elongation is shown in Table 7.

Fabrication

Teflon PFA resins are fabricated by the conventional melt-processing techniques used for thermoplastics (37). Processing equipment is constructed of corrosion-resistant materials and can be operated at 315–425°C. A general-purpose grade, PFA 340, is designed for a variety of molding and extrusion applications, including tubing, shapes, and molded components, in addition to insulation for electrical wire and cables. Because of the excellent thermal stability of PFA 350, a wide range of melt temperatures can be used for fabrication. Extrusion temperatures are 20–26°C above the melting point.

Teflon PFA 440 HP is a chemically modified form of PFA 340 that provides additional benefits such as enhanced purity and improved thermal stability. This product is suitable for producing tubing, pipe linings for production of ultrapure chemicals, semiconductor components, and fluid handling systems for high performance filters (38).

Extrusion. Like other thermoplastics, Teflon PFA resin exhibits melt fracture above certain critical shear rates. For example, samples at 372°C and 5-kg load show the following behavior:

Teflon PFA	Melt flow, g/10 min	Critical shear rate, s^{-1}
340	14	50
310	6	16
350	2	6

Because Teflon PFA melt is corrosive to most metals, special corrosion-resistant alloys must be used for the extrusion equipment, such as Hastelloy C, Monel 400, and Xaloy 306. Barrels, liners, screws, adapters, breaker plates, and dies are made of corrosion-resistant metals (39). Corrosion is promoted by resin degradation and high processing temperatures, long residence times, or dead spots. Extruders used with Teflon FEP are also suitable for PFA resins. Heaters and controllers capable of accurate operation in the range of 330–425°C are required. Extruder barrels should have three or four independently controlled heating zones, each equipped with its own thermocouple and temperature-indicating control.

The screw consists of a feed section, a rapid transition section, and a metering section; a rounded forward end prevents stagnation. The breaker plate that converts the rotary motion of the melt into smooth, straight flow should have as many holes as possible; both ends of each hole should be countersunk for streamlined flow.

The temperature of the melt downstream from the breaker plate may exceed the front barrel temperature because of the mechanical work transmitted to the resin by the screw; it varies with screw speed and flow rate. The melt temperature is measured by a thermocouple inserted into the melt downstream from the breaker plate. A hooded exhaust placed over the extruder die and feed hopper removes decomposition products when the extrudate is heated.

High melt strength of Teflon PFA 350 permits large reductions in the cross section of the extrudate by drawing the melt in air after it leaves the die orifice (40). At a given temperature, the allowable flow rates are limited at the low end by resin degradation and at the high end by the onset of melt fracture. A broader range of specific gravities (2.13–2.17) may be obtained in articles fabricated from PFA 350 than from FEP 160. Unlike with PTFE, higher crystallinity in PFA seems to have little effect on flex life.

Injection Molding. Any standard design plunger or reciprocating screw injection machine can be used for PFA 340, although a reciprocating screw machine is preferred (41). Slow injection into mold cavities avoids surface or internal melt fracture, and control of ram speed is important at low speed. Corrosion-resistant metals are used for parts in continuous contact with molten resin; Hastelloy C and Xaloy 306 or 800 are recommended.

Because the mold is usually maintained at temperatures below the melting point of the resin, corrosion on the mold surface is less than in the molding machine. Nonreturn ball check valves and ring check valves are used; the latter is preferred for PFA. A streamlined flow must pass through the valve, preventing areas of stagnant flow or holdup and localized degradation.

A smear head causes less stagnation and overpacking than a nonreturn valve. A conventional-type reverse-tapered nozzle with the bore as large as possible without sudden changes in diameter is preferred. Independently controlled, zone-type heaters for heating the nozzle and at least two zones on the cylinder are used.

At a holdup time longer than 10–15 min at a high temperature, resin degradation is avoided by keeping the rear of the cylinder at a lower temperature than the front. At short holdup times (4–5 min), cylinder temperatures are the same in rear and front. If melt fracture occurs, the injection rate is reduced; pressures are in the range of 20.6–55.1 MPa (3000–8000 psi). Low back pressure and screw rotation rates should be used.

The cycle can usually be estimated on the basis of about 30 s/3 mm of thickness; most of it is devoted to ram-in-motion time (except for very thin sections). The mold temperature used with PFA 340 is often the highest temperature that allows the part to be ejected undamaged from the mold and retain its shape while cooling.

The resin must be of highest purity for optimum processing characteristics and properties. Degradation results in discoloration, bubbling, and change in melt flow rate.

Transfer Molding. Valve and fitting liners are made by a transfer-molding process (42), with the valve or fitting serving as the mold. Melted resin is forced into the fitting at a temperature above the melting point of the resin. The melt may be produced by an extruder or an injection molding machine or melted cubes contained in a melt pot and transferred by applying pressure to a piston in the pot. After the resin transfer is completed, the fitting is cooled under pressure. Stock temperatures of 350–380°C and fitting temperatures of 350–370°C are used to process PFA 350. A slight adjustment in the cooling cycles may be required for transfer molding PFA 350 because it has higher melting and freezing points than FEP.

Rotocasting Teflon PFA Beads. The resin has sufficient thermal stability for a commercial rotocasting operation; that is, TE-9738 has a melting point of about 303°C. In rotocasting trials, incoming flue gas temperatures of 355–365°C (43,44) and heat cycles of 90–180 min have been used. Conventional rotations for major and minor axes can be applied without modifications; Freecote 33 performs adequately as a mold release agent. Mold release instructions can be followed without modification. Heating cylces, including a preheat and a fusion stage, give consistent rotocasting. Preheating at 15–30°C below the fusion temperature takes 10–25 min. Heat-cycled Teflon PFA rotocastings are translucent white, often with bluish tinge. Rotocastings that have been heated too long may darken to a translucent brown. Uniform cooling is essential for undistorted, stress-free products; combinations of air and water are employed. The rotocasting is cooled below the resin melting temperature with air at ambient temperature and then with a water spray, and finally with a stream of air.

Dispersion Processing. A commercial aqueous dispersion of Teflon PFA 335 contains more than 50 wt% PFA particles, about 5 wt% surfactants and fillers. This dispersion is processed by the same technique as for PTFE dispersion. It is used for coating various surfaces, including metal, glass, and glass fabrics. A

thin layer of Teflon PFA coating can also serve as an adhesive layer for PTFE topcoat.

Powder Coating. Teflon PFA is also available in a finely divided powder form. It can be used to produce thin layers on various surfaces by heating these surfaces above the melting point of PFA and then bringing the powder in contact with them. This allows a thin layer of the powder to melt on the surface of the substrate.

For some applications the powder is suspended in an aqueous medium or a solvent with the help of emulsifying agents and then sprayed onto the substrate. The powder is also used as a filler to prepare sprayable compositions of PTFE dispersions, which then can be used to coat various substrates (45).

Pigmentation. Commercial color concentrates of Teflon PFA containing approximately 2% pigment can be easily dispersed in clear extruded cubes. The resin can also be dry-blended with stable inorganic pigments. At 0.1–1% of concentration, the pigment has no appreciable effect on the dielectric strength and constant or mechanical properties. The dissipation factor of pigmented resin varies with the type and concentration of the pigment.

Pigment used for dry blending is dried overnight at 150°C in a vacuum oven to remove absorbed gases and moisture. It is screened through a 149-μm (100-mesh) screen directly onto the cubes, which are rolled or tumbled for at least 15 min. The pigmented resin is stored in an airtight container to prevent absorption of moisture.

Applications and Economic Aspects

The perfluorovinyl ether comonomer used for PFA is expensive, as is PFA. Most PFA grades are sold as extruded, translucent cubes in various colors at $50.00–65.00/kg. Some PFA types are also marketed in nonextruded forms.

Teflon PFA can be fabricated into high temperature electrical insulation and components and materials for mechanical parts requiring long flex life. Teflon PFA 350 is used as liner for chemical process equipment, specialty tubing, and molded articles for a variety of applications. Teflon PFA 340 is a general-purpose resin for tubing, shapes, primary insulation, wire and cable jacketing, injection- and blow-molded components, and compression-molded articles. Teflon PFA 440 HP is a chemically modified form of PFA 340 with enhanced purity and improved thermal stability while processing. This resin is suitable in semiconductor manufacturing, fluid handling systems for industry or life sciences, and instrumentation for precise measurements of fluid systems.

Health and Safety

Safe practices employed for handling PTFE and FEP resins are adequate for Teflon PFA (46); adequate ventilation is required for processing above 330–355°C. In rotoprocessing, a vacuum (250–750 Pa or 1.8–5.6 mm Hg) in the oven ensures exhaust to the outside (45). Removal of end caps or opening of sealed parts in a

well-ventilated area ensures ventilation of decomposition fumes. During rotoprocessing, molds should be vented.

PHOSGENE

Introduction

Phosgene [75-44-5] (carbonyl chloride, carbon oxychloride, chloroformyl chloride), Cl_2CO, is a colorless liquid with a low boiling point. The compound was first prepared in 1812 by J. Davy from the photochemical reaction of carbon monoxide and chlorine. Phosgene may be formed at elevated temperatures by oxidation of chlorinated solvents (1–5). Phosgene has been used in the preparation of a great variety of chemical intermediates. In addition, it is now widely used in the preparation of isocyanates, which are then used in the preparation of Polyurethanes (PUR), in the manufacture of Polycarbonates, and in the synthesis of chloroformates and carbonates, which are used as intermediates in the synthesis of pharmaceuticals and pesticides. Because of phosgene's toxicity, a high level of safety technology has been developed to ensure its safe handling.

Properties

Some physical properties of phosgene are listed in Table 1. At room temperature and pressure, phosgene is a colorless gas. Impurities may discolor phosgene, tranforming it from clear to pale yellow to green. Phosgene has a characteristic odor. At the time of intital exposure, the odor of phosgene gas can be detected only briefly. At ca 0.5 ppm in air, the odor has been described as pleasant and similar to that of newly mowed hay or cut green corn. However, at high concentrations, the odor may be strong, stifling, and unpleasant.

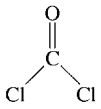
Table 1. Some Physical Properties of Phosgene[a]

Properties and characteristics	Value
Molecular weight	98.92
Melting point, °C	−127.84
Boiling point, °C[b]	7.48
Density at 20°C, g/cm^3	1.387
Vapor pressure at 20°C, kPa[c]	161.68
Vapor density (air = 1.0)	3.4
Critical temperature, °C	182
Density at critical point, g/cm^3	0.52
Critical pressure, MPa[d]	5.68
Latent heat of vaporization, at 7.5°C, J/g[e]	243
Molar heat capacity of liquid, at 7.5°C, J/K[e]	100.8
Molar heat of formation, kJ[e]	
From elements	218
From CO and Cl_2	108
Molar entropy, J/K[e]	
At 7°C	280
At 25°C	284
Surface tension, mN/m (=dyn/cm)	
At 0.0°C	34.6
At 16.7°C	20.1
At 34.5°C	17.6
At 46.1°C	15.9

[a] Ref. 6.
[b] At 101.3 kPa[c] = 1 atm.
[c] To convert kPa to psi, multiply by 0.145.
[d] To convert MPa to psi, multiply by 145.
[e] To convert J to cal, divide by 4.184.

In general, phosgene is soluble in aromatic and aliphatic hydrocarbons, chlorinated hydrocarbons, and organic acids and esters. It is removed easily from solvents by heating or sparging with air or nitrogen, but because of its toxicity, great care must be taken to control its presence in the atmosphere.

Phosgene is a planar molecule. The interatomic distances are 0.128 nm for C—O and 0.168 nm for C—Cl (1). The Cl—C—Cl angle is 117°. Infrared, ultraviolet, and Raman spectral properties are described in References 7,8–9.



Reactions. Phosgene interacts with many classes of inorganic and organic reagents. The reactions are described extensively in the literature, eg, see References 10,11–12. Reaction with sodium takes place at room temperature, but reaction with zinc requires warming.

Oxides and sulfides of metals react with phosgene at elevated temperatures, usually yielding very pure chlorides. The reaction of phosgene with cadmium

sulfide is a good method for preparing carbonyl sulfide (carbon oxysulfide), COS. The reactions of phosgene with calcium, magnesium, tin, and zinc oxide have been described (13–18). The reactions of titanium oxide with phosgene, tungsten trioxide with phosgene, and the chlorination of oxides of interest in the nuclear field, especially uranium oxide, plutonium oxide, and thorium oxide, have also been characterized (19–24).

Phosphates and silicates of metals often react with phosgene at elevated temperatures and yield the metal chloride and phosphorus oxychloride or silicon dioxide. The reaction with ferric phosphate at 300–350°C has been proposed as a synthetic method for phosphorus oxychloride, $POCl_3$.

Anhydrous aluminum chloride forms a variety of complexes with phosgene, eg, $Al_2Cl_6 \cdot 5COCl_2$ at low temperatures, $Al_2Cl_6 \cdot 3COCl_2$ at 30°C, and $Al_2Cl_6 \cdot COCl_2$ at above 55°C. Reaction with aluminum bromide yields carbonyl bromide, $COBr_2$, and aluminum chlorobromide, $AlCl_2Br$. Reaction of antimony trifluoride with phosgene and chlorine yields carbonyl fluoride (25). Phosgene reacts with sodium fluoride and HCN, yielding phosgene fluorocyanide and carbonyl fluoride (26).

$$AlBr_3 + COCl_2 \longrightarrow COBr_2 + AlCl_2Br$$

$$SbF_3 + COCl_2 + Cl_2 \longrightarrow COF_2$$

$$NaF + HCN + COCl_2 \longrightarrow COFCN + COF_2$$

Phosgene reacts slowly with cold water to produce CO_2 and HCl, and more quickly at higher temperatures (27). In the reaction of gaseous phosgene with water, it is difficult to get the necessary intimate mixing of the gas and the water.

$$COCl_2 + H_2O \longrightarrow 2\,HCl + CO_2$$

Ammonia reacts vigorously with phosgene. The products are urea, biuret, ammelide (which is a polymer of urea), cyanuric acid, and sometimes cyamelide (which is a polymer of cyanic acid). The secondary products probably arise through the very reactive intermediate carbamyl chloride, NH_2COCl.

Phosgene reacts with a multitude of nitrogen, oxygen, sulfur, and carbon centers. Reaction with primary alkyl and aryl amines yields carbamoyl chlorides which are readily dehydrohalogenated to isocyanates:

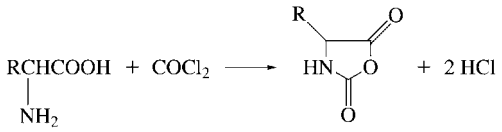
$$RNH_2 + COCl_2 \longrightarrow RNHCOCl + HCl$$

$$RNHCOCl \longrightarrow RN{=}C{=}O + HCl$$

Secondary amines form carbamoyl chlorides:

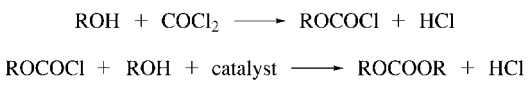
$$R_2NH + COCl_2 \longrightarrow R_2NCOCl + HCl$$

α-Amino acids react readily with phosgene to form oxazolidine-2,5-diones:



Hydrazine reacts with phosgene, yielding carbohydrazide:

The reaction of phosgene with alcohols yields chloroformates, and with a basic catalyst present, carbonates are formed.



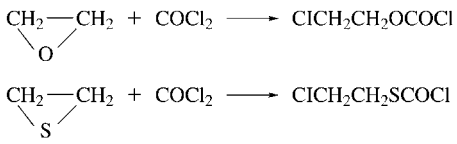
This reaction is commercially important since it serves as a basis for the manufacture of Polycarbonates.

Carboxylic acids react with phosgene to produce give acid chlorides (28).

Ketones also react with phosgene:

Amides react with phosgene to yield nitriles (qv).

Phosgene can also initiate ring opening.



Although $POCl_3$ is the traditional reagent in the Vilsmeier aldehyde synthesis, phosgene may be employed and its role, as well as that of the intermediates, has been studied extensively (29–31).

Manufacture

Phosgene is manufactured by the reaction of carbon monoxide with chlorine over activated carbon. However, depending on the quantity of phosgene needed and the availability of the raw materials, numerous variations of this basic synthetic process are being practiced. Continuous processing and a high degree of automation are required for phosgene purification, condensation, and storage. Because of its toxicity, careful and extensive safety procedures and safety equipment are incorporated in plant design and operation. The entire phosgene manufacturing process consists of preparing and purifying carbon monoxide, preparing and purifying chlorine, metering and mixing of the reactants, reacting the mixed gases over activated carbon, purifying and condensing the resulting phosgene, and recovering trace phosgene to assure worker and environmental safety.

Carbon monoxide may be manufactured according to standard processes from coke, ie, from coal, or by controlled oxidation of hydrocarbon fuels. A carbon monoxide process that yields a gas of the highest possible purity must be chosen. Noncondensable impurities are particularly objectionable since their presence makes the recovery of all the phosgene difficult. Water must be removed from the starting gas to preclude hydrochloric acid formation in the converter. The hydrocarbon and hydrogen content should be minimized because reaction of chlorine with methane or hydrogen could ignite a reaction between chlorine and steel, thereby destroying the equipment. Other impurities might poison the catalyst. Sulfides must be excluded since they produce sulfur chlorides which usually are very undesirable impurities. The chlorine must be as dry and pure as the carbon monoxide so as to avoid corrosion of the equipment and decomposition of phosgene by water and other impurities.

Activated carbon of high adsorptive capacity is suitable for use as a catalyst; it need not be treated with metallic salts or other substances. If starting materials of high purity are employed, excellent and economic catalyst efficiency is obtained. A special carbon catalyst has been shown to give lifetimes that are 5–10 times longer than that of conventional activated carbon and also significantly lower levels of the by-product, carbon tetrachloride (32).

The phosgene generators employed are relatively simple tubular heat exchangers that are filled with granulated activated carbon. Because the reaction is rapid and exothermic, efficient heat removal is important since decomposition of phosgene into its starting materials begins to take place at 200°C. The temperature of the carbon bed in the initial reaction zone of the tubes can reach 400°C, but it rapidly falls to product temperatures of 40–150°C. The reaction is normally run at normal pressure or at a slight excess pressure. A phosgene generation system which monitors the phosgene requirements of a plant and responds by producing only the needed amounts has been developed (33,34).

A flow diagram of the production of phosgene appears in Figure 1. Carbon monoxide and chlorine gas are mixed in equimolecular proportions. A small amount of excess carbon monoxide is used to ensure complete reaction of the chlorine. The product gases can be condensed to liquid phosgene and uncondensed gases, which are then scrubbed for removal of remaining phosgene. Uncondensed gaseous phosgene can be employed for in-line operations. The solvent used for absorption is typically the solvent used in a later process step. The remaining

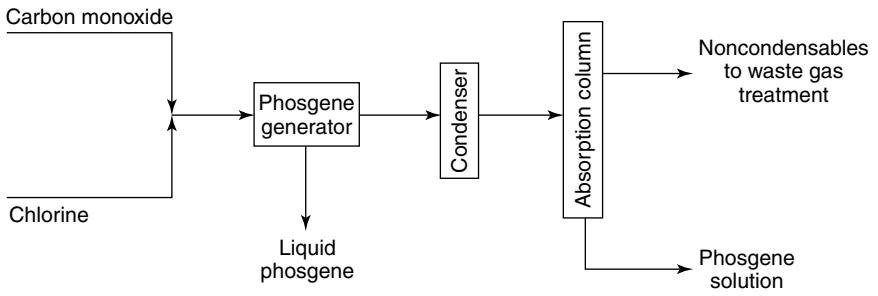


Fig. 1. Manufacture of phosgene from carbon monoxide and chlorine.

nonabsorbable gas stream is fed to the waste gas treatment system to be freed from phosgene.

Several methods of decomposing phosgene in waste gas streams are used. These are as follows:

Decomposition by caustic scrubbing. The waste gas stream is led through packed towers where a sodium hydroxide solution is introduced at the top of the towers. Venturi scrubbers could also be used. Make-up sodium hydroxide is added under pH control. The efficiency of scrubbing concentrated phosgene gas with caustic decreases significantly at caustic concentration below 4 wt% NaOH (35).

Decomposition with moist activated carbon. The waste gas stream is passed through packed activated carbon towers where water is fed at the top of the towers. The water is normally recycled. If the hydrochloric acid concentration in the recycled water exceeds 10%, the decomposition efficiency is greatly reduced. Thus a sufficient supply of fresh water must be assured (36).

Combustion. The waste gas stream is burned to convert phosgene to carbon dioxide and hydrochloric acid. An advantage of this method is that all components of the waste gas, such as carbon monoxide and solvent, are burned (37).

The outlet gas from the phosgene decomposition equipment is continuously monitored for residual phosgene content to ensure complete decomposition.

Analytical and Test Methods

Phosgene in air and in mixture with other gases can be detected by a variety of methods (38). Trace quantities to a lower limit of 0.05 μg/L air can be detected by uv spectroscopy (39). Both ir and gas chromatographies have been used extensively to measure phosgene in air at 1 ppb–1 ppm (7,40,41). Special and multiple-column gas-chromatographic methods have been used for more complex mixtures of gases containing phosgene (42–44). High performance liquid chromatography methods can also be used and offer detection limits of 5- to 10-ppb phosgene (45,46). Absolute determination of phosgene at levels below 100 ppb has been reported using pulsed flow coulometry (47). Laser photoacoustic spectroscopy has been used to detect phosgene at ppb levels (48).

Methods and instruments that are used to monitor phosgene content in air are well developed and have been reviewed (49–51). One detection instrument is

a porous tape that measures the concentration of phosgene in air in quantities as small as 6 ppb (52). Fourier transform infrared spectrometry techniques have been used to permit line and area monitoring in the area around phosgene plants (53).

Phosgene dose-indicator badges for personnel exposure monitoring are commercially available and validated (54,55). This is a simple, visually readable, passive sampler based on phosgene indicator paper which is impregnated with a solution of 4-*p*-nitrobenzylpyridine and *N*-benzylaniline. These indicator badges are used at a number of plant sites using phosgene.

Liquid phosgene is assayed by an iodometric method which involves the following reaction (56):

$$COCl_2 + 2\,NaI \longrightarrow CO + I_2 + 2\,NaCl$$

The released iodine is titrated with sodium thiosulfate.

The following specifications and standards have been reported (6):

Assay	Percent
$COCl_2$, min	99.0
Cl_2 (free), max	0.1
HCl, max	0.2

Storage and Handling

All phosgene containers require a Class A, poison-gas label as well as a corrosive label. Phosgene is transported in steel cylinders which conform to rigid safety-design specifications. The cylinders undergo special hydrostatic testing at 5.5 MPa (800 psi), and extension rings are incorporated in the cylinders to protect the valves. Phosgene is shipped in cylinders ranging in size from 43 to 909 kg. Careful testing for leaks is required after filling, and a vapor space must be accommodated in the storage vessel; excessive filling with liquid phosgene must be avoided.

Transportation requirements and classifications for phosgene are as follows:

DOT shipping name	Phosgene
DOT hazard class	2.3
RQ	Yes – 10 pounds
DOT labels	Poison, Corrosive
DOT placards	Poison
Bill of lading description	Phosgene, 2.3, UN1076, RQ (phosgene), inhalation hazard, poison gas and corrosive labels affixed
UN/NA number	UN1076
Additional DOT requirements	Return of empty containers: residue last contained: phosgene, 2.3, UN1076, RQ (phosgene), inhalation hazard, poison gas and corrosive labels affixed

Because phosgene reacts with water, great care must be taken to prevent contamination with traces of water since this could lead to a build up of pressure through the formation of hydrogen chloride and carbon dioxide. Wet phosgene is very corrosive; therefore, phosgene should never be stored with any quantity of water (4).

Health and Safety Factors

The odor threshold for phosgene is ca 0.5–1 ppm, but varies with individuals. Olfactory fatigue occurs after prolonged exposure (57). Phosgene may irritate the eyes, nose, and throat. The permissible exposure TLV by volume in air is 0.1 ppm (58). The TLV refers to the average airborne concentration at which it is believed nearly all workers may be repeatedly exposed on a daily basis without adverse effect. It is a time-weighted average for an 8-h day or a 40-h week and should be used as a guide for control only. The NIOSH REL (ceiling value) is 0.2 ppm for a 15-min excursion (59). Long-term exposure to phosgene has been reviewed, and potential hazards may exist at <0.2 ppm (60). Medical problems associated with phosgene exposure have been reviewed (61–63), and therapy for phosgene poisoning has also been reviewed (64–67).

When phosgene is inhaled, it reacts very little with the aqueous film on the mucous membranes of the upper respiratory tract. Most of it reaches the pulmonary alveoli, where gas exchange occurs. Here phosgene reacts with NH_2, OH, and SH groups of the blood–air barrier. This causes the blood–air barrier to lose its function as a membrane between the blood vessels and the pulmonary alveoli. As a result, blood plasma is able to pass from the blood vessels into the pulmonary alveoli, thereby increasingly disturbing the gas exchange.

Breathing phosgene causes pulmonary edema, which may be characterized by a delayed onset. The onset of pulmonary edema is a function of both concentration and length of exposure. Typically exposure above 50 ppm-minutes can lead to pulmonary edema (67). Exposed persons must be removed immediately from the contaminated area and decontaminated. Rescue workers should wear self-contained breathing apparatus. Injured persons should not be allowed any physical activity, and a physician should be consulted immediately. It is advisable to keep an exposed individual under the observation of a physician for 6–24 h, depending on the circumstances of exposure. In some instances this can be accomplished at the plant medical facility, or the exposed individual may require hospitalization.

In handling phosgene, extensive safety precautions and procedures are required to prevent exposure to phosgene. The first point is to design the phosgene system to prevent phosgene emissions from the closed equipment. Chemically resistant, high quality materials are used for plant equipment and lines which are inspected regularly. Pumps that are hermetically sealed to the outside or utilize multiple mechanical seals with buffer fluids are used for phosgene-containing streams. Stringent requirements are set for the quality and design of phosgene process control equipment, and critical areas have redundant control systems. The second point is to quickly detect leaks and contain or decompose escaped phosgene. This includes such measures as continuous alarm systems to monitor the working

atmosphere, systems for decomposing escaped phosgene (eg steam-ammonia curtains for gaseous emissions), jacketed pipes, and complete containments for phosgene plants (68,69). Vacuum systems are also used to mitigate phosgene releases. These systems consist of a series of vacuum hoses that can be put near a small leak to draw in escaping phosgene, which is then sent to a decomposition unit. More detailed information on current industrial practices for safely manufacturing or handling phosgene are available through the Chemical Manufacturers Association Phosgene Panel, Washington, D.C.

In case of extensive leaks or spills, immediate evacuation upwind of the phosgene source is necessary. Phosgene is 3.4 times as heavy as air and may collect in low-lying areas (6). Water should not be used on the source of a phosgene leak as the resulting corrosion enlarges the leak. Suitable personal protective equipment includes eye protection and respiratory equipment. In case of fire, it is essential to cool all phosgene-containing vessels. Leaks of liquid phosgene or phosgene solutions can be effectively combated by covering the phosgene-containing liquid with an absorbent and decomposition agents.

Waste Disposal. Because of its low boiling point and high toxicity, measures must be taken to prevent the entrance of phosgene into drains or sewers. If recycle of phosgene is not feasible, phosgene waste can be handled by one of the decomposition methods mentioned in the Manufacture section, ie, caustic scrubbing, moist activated carbon towers, or combustion.

Uses

Phosgene is an important and widely used intermediate. Practically all phosgene manufacture is captive, ie, it is used in the manufacture of other chemicals within the plant boundary. Only VandeMark (owned by Groupe SNPE) sells phosgene on the merchant market. Phosgene manufacturers with captive consumption in the United States are Aventis, BASF, Bayer, Dow, DuPont, GE Plastics, Huntsman/ICI, Lyondell, PPG, Twin Lake Chemicals, VandeMark, and Zeneca. The U.S. production of phosgene for 1999 was 1.55×10^6 t, and for 2000, it was approximately 1.61×10^6 t (70). The primary use of phosgene is the manufacture of isocyanates for the polyurethane industry, in which ca 80% of the phosgene output in the United States is consumed. The manufacture of toluene diisocyanate [1321-38-6] accounts for ca 40% of the phosgene consumption, while methylene diphenyl diisocyanate (MDI) [101-68-8] and polymeric MDI [9016-87-9] account for ca 40%. The polycarbonate industry accounts for ca 13% of the phosgene consumption, and the remaining 7% is used to produce aliphatic diisocyanates, monoisocyanates, chloroformates, agrochemicals, and intermediates for pharmaceuticals and dyestuffs. Although several commercial phosgene-free processes for producing polyisocyanates and polycarbonates have been announced, they are not expected to make large inroads into phosgene demand in the near future (71–75).

Phosgene can be employed in a variety of metal-recovery operations, eg, in the recovery of platinum, uranium, plutonium, and niobium (76–80). Phosgene has been proposed for the manufacture of aluminum chloride, beryllium chloride, and boron trichloride (81–83). Phosgene has been patented as a stabilizer, either by itself or in combination with thionyl chloride, for liquid SO_2 (84).

Phosgene is also used in the production of chloroformates, ie, chlorocarbonates, which are intermediates in the production of ore-flotation agents, perfumes, herbicides, and insecticides, and especially in the preparation of pharmaceuticals (85). Chloroalkyl chlorocarbonates have been manufactured as intermediates for pharmaceuticals and pesticides (86,87). Phosgene is also employed in the manufacture of carbonic esters. Phosgene has been suggested as a starting material for the manufacture of carbon tetrachloride and other chlorinated hydrocarbons (88–92). A number of pesticides have been patented based on the reaction of a thiol or dithiol with phosgene to form thiol chloroformates (93,94). The preparation of aromatic acids using phosgene and detailed process for the manufacture of terephthalic acid from toluene and phosgene have been described (95,96).

An important direct use of phosgene is in the preparation of polymers. Polycarbonates are the most significant and commercially valuable group. However, the use of phosgene has been described for other polymer systems, eg, fiber-forming polymeric polyketones and polyureas (97,98).

PHOSPHORUS-CONTAINING POLYMERS AND OLIGOMERS

Introduction

The only valid generalization about phosphorus polymers is that they tend to be flame retardant (1,2). The flame-retardant effect depends heavily on the phosphorus content. Red (polymeric) phosphorus, despite its combustibility, is a commercial flame-retardant additive. Other features of many phosphorus polymers are adhesion to metals, metal ion-binding characteristics, and increased polarity (2). The flexible P—O—C linkages tend to impart lower glass-transition temperatures. Phosphorus polymers with acid groups are used industrially for ion exchange, adhesion, and scale inhibition. Some form water-soluble coatings used as primers in metal protection and for photolithographic plates. The binding properties have led to dental applications. Cellulose phosphates have found some drug and ion-exchange uses. Academic interest has been stimulated by the relationship of certain phosphate polymers to natural products, such as the nucleic acids (see POLYNUCLEOTIDES).

This review gives most attention to those phosphorus polymers which have attained commercial use or which have been (or currently are) the subject of serious development efforts. Other reviews encompass phosphorus polymers of mainly academic interest (3,4). The commercial examples tend to be specialty polymers and none have attained large volume usage. One reason is cost. In addition, those polymers having P—O links are usually more hydrolyzable than corresponding C—O bonded polymers, and moreover the phosphorus acids which are liberated tend to catalyze further hydrolysis. Hydrolytically stable phosphine oxide

Encyclopedia of Polymer Science and Technology. Copyright John Wiley & Sons, Inc. All rights reserved.

types are known but are costly. Another hydrolytically stable class, the polyphosphazenes, is discussed in a separate article.

Phosphorus-containing oligomers (low polymers) have been included in this article because they have become more important commercially than high polymers, since they can be used as additives or coreactants to introduce sufficient phosphorus for flame retardancy or some other desired property provided by phosphorus, such as metal binding (5,6).

The modification of conventional polymers with small amounts of phosphorus, reactives, or comonomers to impart flame retardancy (1,4,6) or improve other properties has become commercially significant, and is discussed separately below in connection with the polymer class being modified.

Polymeric Form of Elemental Phosphorus

Phosphorus occurs in several allotropic forms. The principal commercial form is white (or yellow) phosphorus; the molecule consists of four phosphorus atoms arranged in a tetrahedron. Heating white phosphorus at 270–400°C, preferably with a catalyst, produces red phosphorus, a stable, nontoxic, high melting, insoluble polymeric solid. Red phosphorus (often stabilized by additives) has been used for many decades as the igniting agent for the striking surface of safety matches. It is insoluble, thermally quite stable, and nontoxic; while it can be ignited, it is surprisingly effective as a flame retardant for plastics, and it is now finding commercial use, especially in Europe to flame-retard nylon. Other applications and its mode of action have been reviewed (7).

To prevent decomposition of red phosphorus to the toxic and highly flammable white form, it is stabilized with additives (8) and/or encapsulated with a thermoset resin.

The structure of red phosphorus is not fully established. It is believed (9) to be a cross-linked polymer with chains having the structure shown in Figure 1.

Inorganic Phosphorus Polymers

Inorganic polyphosphates are covalently linked polymers (10,11). Chains of repeating phosphate units are formed by eliminating the elements of water from adjacent orthophosphate units. Such polycondensations take place, for instance, when orthophosphoric acid is heated, producing a broad distribution of linear molecules of various chain lengths corresponding to the general formula $HO[P(O)(OH)O]_nH$. A table of compositions for various weight percentages of P_2O_5 is given in Reference 10.

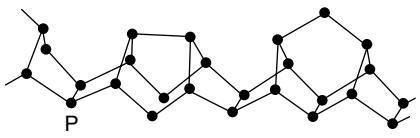

Fig. 1. Probable structure of red phosphorus.

Polyphosphoric acid itself has found utility mainly as a supported catalyst in the petroleum industry for alkylation, olefin hydration, polymerization, and isomerization, and for syntheses of fine chemicals and dyes. It is used to phosphorylate alcohol groups, for example in the production of anionic phosphate surfactants.

Heating alkali metal or alkaline earth metal dihydrogen phosphates produces polymeric salts (cyclic metaphosphates and linear polyphosphates) and cross-linked polyphosphates (ultraphosphates), depending on temperature and the presence of other ingredients (11,12). This complex group of polymers includes materials with crystalline, glass-like, fibrous, or ceramic properties as well as some with thermoplastic and thermoset characteristics; some are useful as binders for metals, ceramics, and dental restorations. Reviews are available on glasses (12,13), crystalline compounds (14), and polyphosphate fibers (15).

The water-soluble poly- and metaphosphates exhibit chelating properties. Glassy sodium metaphosphate (DP ca 15–20) is used in water treatment for scale inhibition (16). Long-chain sodium polyphosphates (metaphosphates) are used as preservatives in red meat, poultry, and fish (16). Long-chain sodium and potassium phosphates are added to sausage meat to improve color and texture (16).

Polyphosphates are produced naturally in some yeasts, comprising up to 30% of their total phosphate and up to a 600 degree of polymerization (17). These probably provide energy storage for the yeasts.

Some of the inorganic phosphate polymers possess properties resembling those of glassy organic plastics. Corning has attempted to commercialize low-melting phosphate-containing glasses as reinforcing fibers with excellent dimensional stability (18,19). The fibers can be made *in situ* by stirring in a high temperature thermoplastic melt. Phosphate glasses can also be molded at 360–400°C to make high refractive index lenses (20).

Heating of ammonium phosphates under an atmosphere of ammonia or in the presence of urea produces ammonium polyphosphate (21,22). At a high degree of polymerization, the product is a water-insoluble solid. This form of ammonium polyphosphate is used commercially as a flame-retardant additive for plastics and as the latent acid component in intumescent paints, mastics, and caulks (23,24). The water resistance can be further enhanced by encapsulation with a resin.

Polymeric Phosphorus Oxynitrides and Phosphorus Iminoimides

Condensed phosphoramides with linear, cyclic, or cross-linked structures are produced by the reaction of $POCl_3$ with ammonia. The higher molecular weight products are insoluble in water and on further heating are converted to a cross-linked insoluble polymer, phosphorus oxynitride $(PON)_x$ (25). Phosphorus oxynitride can be made by prolonged heating of melamine phosphates (26), urea phosphate (26), or ammonium phosphate under conditions where ammonia is retained (27). Phosphorus oxynitride is an effective flame retardant in those polymers, such as nylon 6, which can be flame retarded by exclusively char-forming condensed-phase means. However, phosphorus oxynitride is ineffective (at least by itself) in those

polymers, such as polybutylene terephthalate, which pyrolyze easily to volatile fuel (28–30).

An imido analog of phosphorus oxynitride, phospham, $(PN_2H)_x$, is made as the exhaustive self-condensation product of aminophosphazenes, but also may be made directly from elemental phosphorus and ammonia or from phosphorus pentasulfide and ammonia. Phospham is probably a thermoset phosphazene imide. It can be amorphous or crystalline. It is also an effective and thermally stable flame retardant, especially for high-temperature-processed polyamides (31). It was available for a short time as a development product from Japan.

Amorphous polymeric dielectric films of phosphorus nitrides and oxynitrides ("Phoslon") can be prepared on electronic substrates by chemical vapor deposition (32).

Organic Phosphorus Polymers

Phosphines. Polymeric phosphines exhibit strong metal-binding properties. Nonpolymeric phosphines, in particular triphenylphosphine, are employed as ligands for cobalt and rhodium in hydroformylation catalysts used in plasticizer manufacture. Extensive efforts have been made to attach phosphine–metal complexes to polymers in order to facilitate catalyst recovery and enhance selectivity (33). Problems of cost, catalyst life and activity, heat transfer, and mass transfer seem to have prevented commercialization.

Polymers from diarylphosphinylstyrenes have been prepared as ligands (34). Styryldiphenylphosphine monomer, commercially available in laboratory quantities, is easily polymerized or copolymerized (34,35). Copolymers of styryldiphenylphosphine with styrene cross-linked with divinylbenzene are commercially available in laboratory quantities.

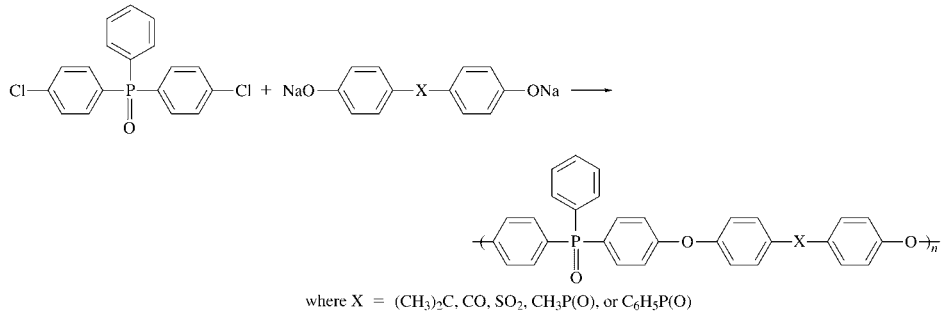
Some polymeric phosphonium salts have been reported to have advantages in reaction rate or ease of separation relative to monomeric phosphonium salts as catalysts for nucleophilic reactions where the large cation favors nucleophilic reactivity of the anion (36).

Phosphine Oxides. The outstanding property of polymeric phosphine oxides is their stability. Since the electron pair of the phosphine structure has been donated to an oxygen atom, the phosphine oxide group is unreactive, although it is very polar and subject to strong hydrogen bonding.

Polymeric phosphine oxides are made by a variety of condensation- and addition-polymerization methods. Radical-initiated copolymerization of compounds with $RPCl_2$ structures with olefins produces polydichlorophosphanes, which on hydrolysis yield polyphosphine oxides (37). Where *p*-xylylene (produced by pyrolysis) is the olefin, this copolymerization affords quite tenacious high-temperature thermoplastic phosphine oxides (38).

Polystyrenes with attached phospholene oxide rings are recoverable catalysts for converting isocyanates to carbodiimides (39).

A series of polyesters and polyethers made from aromatic phosphine oxides exhibit stability as well as flame resistance (40,41). Aromatic polyethers containing phosphine oxide structures are made according to the following reaction (41–43):



where X = $(CH_3)_2C$, CO, SO_2, $CH_3P(O)$, or $C_6H_5P(O)$

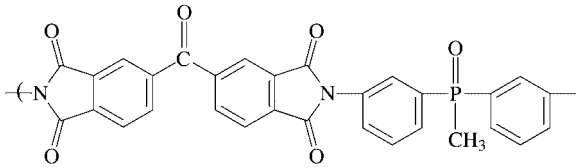
These polymers show good flame resistance and low smoke, and some have been introduced on a development scale for potential use in graphite composites and as electrical insulation for aircraft. Some polyphosphine oxides have been shown to be suitable for optical applications (44).

Aliphatic polyamides with a phosphine oxide unit in the dicarboxylic acid portion or the diamine portion of the polymer chain have been described (45–47). These were intended to have flame resistance while retaining adequate thermal and hydrolytic stability. The effect of the phosphine oxide on softening and heat distortion temperatures of these structures has been studied (48); some show elevated glass-transition temperatures (T_g) and softening temperatures compared to the phosphorus-free analogs, others show depressed melting behavior and loss of crystallinity. Increasing the content of phosphine oxide depresses the melting point and in most cases the crystallinity. In some cases incorporation of phenylphosphine oxide structures improves thermal properties.

One comparative study showed that the flame retardancy of an aromatic phosphine oxide copolymer was no better than that achieved by a similar amount of phosphine oxide structure as an additive (49).

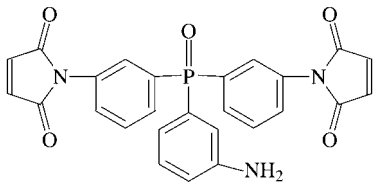
Aromatic polycarbonates containing diphenylphosphine oxide units attached laterally to the chain (using the diol made by adding diphenylphosphine oxide to benzoquinone) have been shown in a General Electric patent to achieve flame retardancy without loss of T_g or impact strength (50). The required intermediate, diphenylphosphinous chloride, is commercially available, but this application has not been commercialized.

Polyimides containing phosphine oxide structures have been explored in the quest for highly stable thermoplastics. In the search for flame-retardant, heat-stable composites for aerospace applications, structures such as the following were prepared:



This polymer is stable to 400°C and shows excellent adhesion to glass-fiber reinforcement (51–53).

Phosphine oxide-containing polyimides were produced at NASA by polymerization of phosphine oxide-containing maleimides illustrated by the following structure (54):



Ammonia-cross-linked textile finishes from tetrakis(hydroxymethyl) phosphonium salts have a primarily phosphine oxide structure and are discussed under the topic of cellulosic textile finishes.

Phosphinites and Phosphonites. In common with phosphines these classes of phosphorus structures have unshared electron pairs on the phosphorus. They tend to be unstable to oxidation and are good metal binders. Consequently, they have been prepared as antioxidant scavengers, catalyst ligands, and ion-extraction reagents, but no commercial applications of polymeric phosphinites or phosphonites are known.

Phosphites. Phosphites, mostly nonpolymeric, are employed as the peroxide-decomposing components of antioxidant systems for polyolefins and diene rubbers.

Polyphosphites, actually poly(hydrogen phosphonate)s, have been described as being made by transesterification of dialkyl phosphites with diols, but some examples have been shown to proceed concurrently with dealkylation and formation of acid end groups (55). If the acid end groups are realkylated such as by diazomethane, high molecular weight poly(hydrogen phosphonates) can be made (56). The use of diphenyl hydrogen phosphonate instead of dialkyl hydrogen phosphonate also permits achieving high molecular weight. These phosphite polymers can be oxidized to synthetic analogs of the nucleic acid backbone.

An oligomeric phenyl dipropylene glycol phosphite, averaging eight phosphite groups per mole, is a commercial color stabilizer (Doverphos 12, Dover Chemical Corp.) for rigid and plasticized PVC.

$$(C_6H_5O)[P(OC_6H_5)OC_3H_6OC_3H_6O]_7P(OC_6H_5)_2$$

Typical use levels are 0.25–1% in vinyls and polyurethanes.

A lower oligomeric dipropylene glycol phosphite, averaging three phosphite groups and five hydroxyl groups (GE's Weston PTP Phosphite) is used in foamed polyurethanes to control color development and prevent bun scorching.

Phosphinates. Phosphinate structures confer flame retardancy to polyester fibers (discussed separately below).

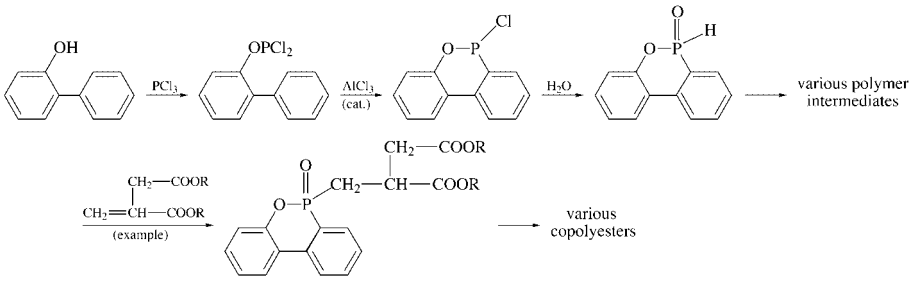
Esters of P-phenyl-P-vinylphosphinic acid can be polymerized to high molecular weight by free-radical initiators. The monomers are prepared from phenylphosphonous dichloride (57).

Oligomeric phosphinic/carboxylic acid copolymers are made by radical-catalyzed polymerization of acrylic and/or maleic acid in the presence of

hypophosphorous acid or sodium hypophosphite. The phosphinic unit is incorporated by a chain-transfer reaction (58,59). Products of this type are effective scale inhibitors for water treatment, and are commercially used.

(Hydroxymethyl)phenylphosphinic acid (an adduct of formaldehyde and phenylphosphinic acid) can be thermally dehydrated to form oligomers which are useful in flame retarding polyethylene terephthalate (60). These may have reached commercial usage in Europe.

A large and varied family of polymers have been made from a cyclic phosphinate made commercially from *o*-phenylphenol by the following reaction sequence:



The key intermediate, a cyclic hydrogenphosphinate, 9,10-dihydro-9-oxa-10-phosphaphenanthrene-10-oxide, has been converted, originally by Japanese manufacturers, to a variety of difunctional polymer intermediates. Addition to itaconic ester produces a dicarboxylic ester commercially used to make thermoplastic polyesters. This technology is discussed below in connection with modified polyester fibers and epoxy resins. Addition of the hydrogen phosphonate to itaconic acid and copolyesterification can be done in a single operation (61).

The cyclic hydrogen phosphinate can also be added to benzoquinone to make a substituted hydroquinone and a diglycidyl ether therefrom, discussed below in connection with epoxy resins.

Phosphinates made from acrylic acid and methyl- or phenylphosphonous dichloride are used commercially to provide inherent flame retardancy to polyester fibers.

Phosphonates. The principal synthetic routes include addition and condensation methods. Although a large number of vinyl and diene phosphonate monomers have been described in the literature (2,5,7,62), only bis(2-chloroethyl) vinylphosphonate (Akzo-Nobel's Fyrol Bis-Beta monomer), vinylphosphonic acid (Clariant), and dimethyl vinylphosphonate (Clariant) have been offered commercially. The diethyl vinylphosphonate is available in laboratory quantities.

Vinylphosphonates are slow to homopolymerize. They copolymerize with most common monomers but particularly well with vinyl acetate (63), vinyl chloride, and acrylonitrile (64). The copolymerization Q and e values for bis(2-chloroethyl) vinylphosphonate are 0.23 and 1.73, respectively (65), reflecting an electron-poor double bond and low resonance stabilization of the free radical. They are also prone to chain transfer. Representative copolymers have been studied and evaluated for their expected flame-retardant action (66) but cost considerations have generally not encouraged commercial use of vinylphosphonate esters for this purpose.

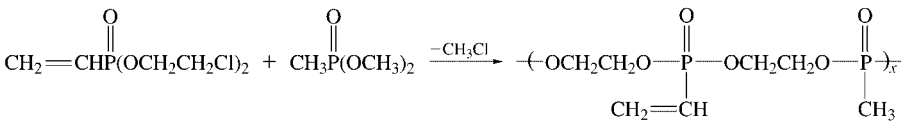
Plasticized vinyl polymers are made by terpolymerization of bis(2-chloroethyl) vinylphosphonate with vinyl chloride and alkyl acrylates (67–69). These terpolymers can be calendered to films and were for a time in commercial development by Stauffer Chemical Co., for use as truck and container decals with permanent plasticity.

Vinylphosphonic acid is produced in Germany and used, initially by Hoechst, later by others to manufacture a hydrophilic poly(vinylphosphonic acid) prepared by free-radical polymerization in a solvent (70,71). Poly(vinylphosphonic acid) is mainly used for the treatment of aluminum photolithography plates before application of the photosensitive layer (72,73). The coating improves the developing and printing characteristics of the plate. Dental cement applications of cross-linked poly(vinylphosphonic acid) have also been studied (74). Vinylphosphonic acid copolymers with vinylsulfonic acid have been patented as scale inhibitors for water treatment (75).

Isopropenylphosphonic acid polymers are water-soluble and are believed to have found commercial utility as scale inhibitors (76). A flame-retardant copolymer of α-phenylvinylphosphonic acid with styrene has been patented (77).

The tetraethyl ester of 1,1-vinylidenediphosphonic acid has been used to make cross-linked copolymers which are ion-exchange resins with selective chelation properties for toxic metal cations (78). An alternative method for introducing the diphosphonic acid structure is by reaction of a methylenediphosphonic ester with chloromethylated styrene copolymer beads (79). At least one such resin class, Diphonix, also containing sulfonic acid and other functional groups, has shown promise for treatment of radioactive waste and for iron control in copper electrowinning (80,81).

An oligomeric vinylphosphonate was commercialized in the 1970s as a flame-retardant finish on cotton, principally for children's sleepwear (82).



Upon free-radical-initiated curing, usually with a comonomer such as *N*-methylolacrylamide or with an amino resin, this monomer produces a cross-linked finish for cotton, resistant to laundering (83–85). This product was discontinued in the United States for marketing and cost reasons, but was later used in Japan for some nonapparel applications.

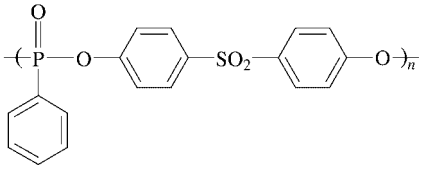
Vinylbenzylphosphonate diethyl ester was prepared by the Arbuzov reaction of vinylbenzyl chloride with triethyl phosphite, and this monomer was used as a precursor for experimental resins with metal-binding properties (86).

Copolymers of diethyl (methacryloyloxymethyl)phosphonate have recently been reinvestigated for possible flame-retardant use (87). Various acrylate and methacrylate monomers with phosphonic acid groups, which aid bonding to dentine, have shown promise for dental restoration purposes (88). Various allyl phosphonates (89) have been proposed for these uses but none appear to have found application.

Condensation Polymerization Routes to Polymeric Phosphonates. Reaction of a phosphonyl dichloride with an aliphatic diol produces polyphosphonates which are low melting and hydrophilic. Industrial interest has been concentrated on the polyphosphonates made from aromatic diols or aromatic phosphonyl dichlorides.

Because of the commercial availability of phenylphosphonyl dichloride (benzene phosphorus oxydichloride, BPOD), much work has been done on this intermediate to make polymeric phosphonates as flame-retardant thermoplastics or as additives for thermoplastics. In an early study, Toy (90) carried out the polycondensation of BPOD and dihydric phenols in a melt. Coover and McConnell added the use of an alkaline earth halide catalyst (91). For enhancement of the flame-retardant effectiveness as fiber additives, tetrabromobisphenols were used to make polyphosphonates (92). Various cocondensed polyesters with both phosphonate ester units and dicarboxylic ester units have been described and patented.

Toyobo in Japan introduced commercially the polymer or oligomer from phenylphosphonic dichloride and 4,4′-sulfonylbisphenol as an additive for polyester fibers, initially to meet the Japanese flame-retardant regulations for home furnishings (93,94).



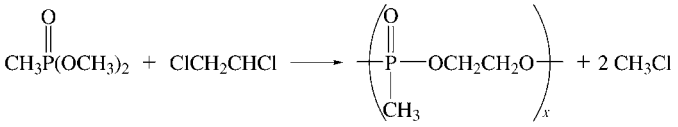
This oligomer, which seems to have a higher flame-retardant effect than the sulfur-free analogs, has been further studied and piloted in the United States (95–97). Its manufacture and use has also been developed in China and it is made there on a commercial scale (98).

Interfacial polycondensations for the synthesis of polyphosphonates by reaction of phosphonyl dichlorides with diols can be very rapid and, under favorable conditions, give high molecular weights (99,100).

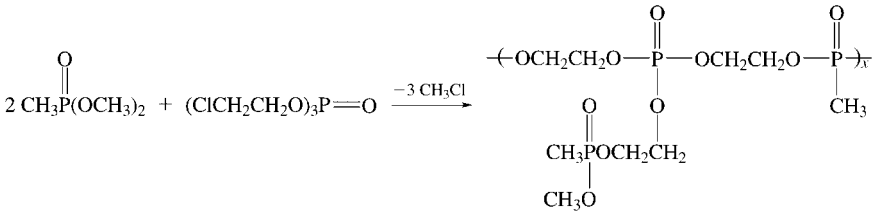
Transesterification of a Phosphonate with a Diol. This method proceeds well in the case of *O,O*-dialkyl hydrogen phosphonates (101) but less selectively with *O,O*-dialkyl alkyl- or arylphosphonates. With *O,O*-diaryl alkylphosphonates, ester exchange is an effective route to polymeric phosphonates (102–104):

Higher molecular weights can be attained by adding tri- or tetrahydric phenols or triaryl phosphates to the reaction mixture (105). A transparent flame-retardant poly(methylphosphonate) thermoplastic made by this technology was for a time in development by Bayer (103). Mechanical properties were excellent, although resistance to hot water was somewhat deficient.

Transalkylation of a Phosphonate with a Dihalide. This route is especially useful with *O,O*-dimethyl phosphonates and bis-primary dihalides, eg, in the production of a poly(ethylene methylphosphonate) (106):

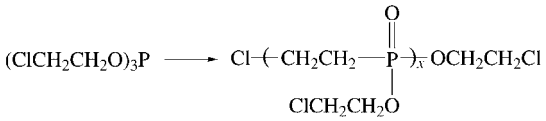


The reaction proceeds most readily in the presence of a basic catalyst (7,106). This chemistry was used for the commercial manufacture of a flame-retardant hydroxyl-terminated oligomer (7,107) suitable for flame-retarding thermoset resins and resin-impregnated paper.



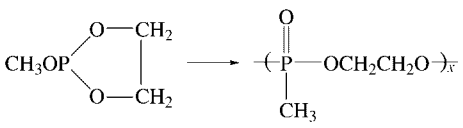
This route was superseded by an alternative halogen-free process using phosphorus pentoxide, as described below.

Arbuzov Polycondensation. To date industrial applications have been limited to production of oligomeric flame retardants, such as the conversion of tris(2-chloroethyl) phosphite to a mixture of its intramolecular Arbuzov rearrangement product, bis(2-chloroethyl) 2-chloroethylphosphonate and its oligomeric intermolecular Arbuzov products (108,109), where $x = 2$–6:

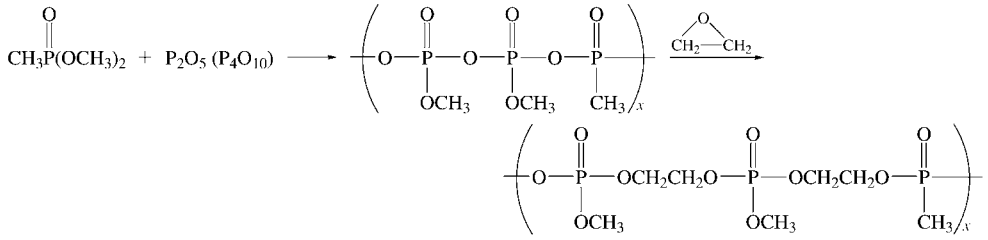


The detailed structure of the oligomers is open to some question; isomers and branched structures are likely. A product of this reaction, a mixture of monomeric and lower oligomeric compounds, is sold as Antiblaze 78 (A&W, now Rhodia) for flame retardance in urethane foam.

Arbuzov Cyclopolycondensation. This versatile reaction and related cyclopolymerizations have been extensively studied (101,110,111). A typical example is the cyclopolycondensation of methyl ethylene phosphite (112):



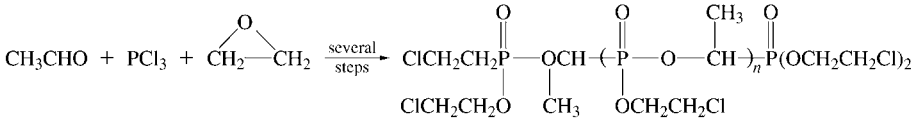
Insertion of an Alkylene Oxide into a Phosphonic Anhydride. A useful route to oligomeric flame retardants is based on the following two-step synthesis (113):



By inclusion of a limited amount of water or alcohol in the synthesis, oligomers of this type can be made with controlled hydroxyl content. Such products are exemplified by Akzo Nobel's Fyrol 51 or Fyrol 58 flame retardants which are useful as reactive oligomers in thermosets. In resin-treated automotive air filters this type of product is chemically linked into the resin and resists leaching by water when the filters are cleaned. Fyrol 51 has also found utility in making flame-retarded polyurethanes and textile finishes.

Insertion of a Diepoxide into a Phosphonate Ester. The insertion reaction of bisphenol A diglycidyl ether with diaryl aryl- or alkylphosphonates was shown to give polyphosphonates of moderate molecular weight (114).

Condensation of Phosphites with Aldehydes or Ketones. A phosphonate oligomer, Phosgard C22R (formerly made by Monsanto) flame retardant, has been used commercially as an additive in acrylics and thermoset plastics (115).



A related product was developed at Rohm and Haas Co., from acetone, ethylene glycol, and PCl_3, and probably has been used in flame-retarded acrylic sheets. (116,117).

Friedel-Crafts Reaction of PCl_3 on Styrenic Polymers, Followed by Oxidation. Ion-exchange resins with selective affinity for lanthanides and other "hard" cations have been made by the aluminum chloride-catalyzed reaction of PCl_3 with macroporous cross-linked styrenic resin beads. The initially formed phosphonous dichloride was hydrolyzed and oxidized to a resin with phosphonic acid groups (118).

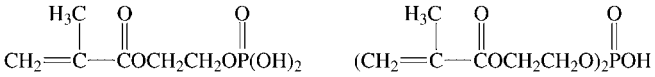
Phosphonylation of a Carboxylic Acid Polymer. The reaction of a water-soluble polycarboxylic acid with phosphorous acid is said to yield a polymer with hydroxybis(phosphonic acid) structures. These are effective scale-inhibiting agents for aqueous systems (119) but not known to have been commercialized. A similar reaction in a Chinese study is said to result in the replacement of carboxyl groups by phosphonic acid groups (120) to produce polymers with similar utility.

Phosphates. Polymeric phosphates are used for the preparation of flame-retardant polymers, ion-exchange resins, and models for natural biopolymers such as nucleic acids, teichoic acids (components of bacterial cell walls) (121), and polynucleotides, which are discussed in a separate article. Synthetic poly(1,3-alkylene phosphates) as mimics of the natural teichoic acids have been studied, particularly in respect to Mg^{2+} binding and ion transport (122).

Addition polymerization of unsaturated phosphate monomers has been extensively investigated, but to date only a few industrial applications have been found. Dental anticaries applications of phosphoenol pyruvate polymers and copolymers with acrylic acid have been demonstrated *in vitro* (123).

Monoallyl phosphates undergo chain transfer at the allylic methylene group and polymerize poorly (89). Triallyl phosphate polymerizes with free-radical initiation to a hard, clear cross-linked polymer. This monomer was briefly piloted by the former Marbon Co. but not successfully commercialized.

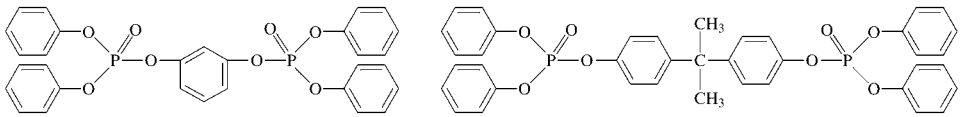
Acid phosphate monomers made from hydroxyethyl acrylate or methacrylate and P_2O_5 are useful acrylic or epoxy coating components and dental adhesives (124), and promote adhesion to metal substrates (125–128). The mono(methacryloxyethyl) phosphate and di(methacryloxyethyl) phosphate are available as Kayamer PM-1 and PM-2 from Nippon Kayaku, or the mixture as Ebecryl 170 from UCB Radcure:



Polycondensation of Phosphoryl Dihalides with Diols. Poly(arylene aryl phosphate)s can be made stepwise by first preparing a phenyl phosphorodichloridate which reacts with a dihydric phenol, or in one step by the reaction of phosphorus oxychloride with a mixture of monohydric and dihydric phenols. Depending on the reactant ratio, the products can be oligomers or high molecular weight thermoplastic or thermoset polymers (129).

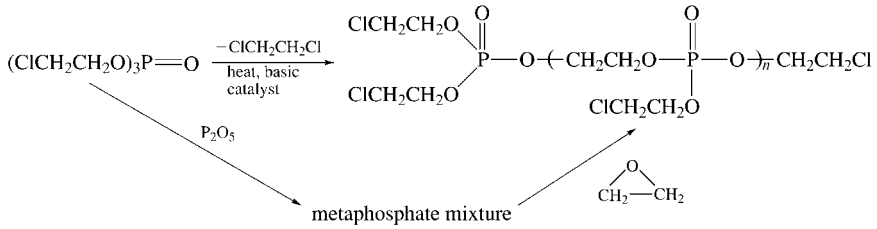
Aromatic phosphate polymers were found to have good transparency, hardness, and adhesion, but too brittle and hydrolytically unstable.

Oligomeric aromatic phosphates have been patented and commercially used as flame-retardant additives mainly for impact-resistant polystyrene blends with polyphenylene oxide and polycarbonate blends with acrylonitrile–butadiene–styrene (ABS) copolymers (130,131). They have also been shown useful in thermoplastic polyesters (92). The principal commercial examples are based on phenol and resorcinol (Akzo-Nobel's Fyrolflex RDP) or phenol and bisphenol A (Akzo-Nobel's Fyrolflex BDP or Albemarle's Ncendx P-30). Although these have the diphosphate as their principal ingredient, they also contain higher oligomers.



Some patents and publications suggest flame retardancy advantages for the higher oligomers (132,133). A systematic study of the oligomers and polymers made from alkyl and aryl dichlorophosphates and dihydric phenols showed that their flame retardancy (as expressed by oxygen index) is a function of phosphorus content and of thermal stability (134).

Insertion of Phosphorus Pentoxide into a Phosphate, Followed by Epoxide Insertion. The insertion of phosphorus pentoxide into a trialkyl phosphate or a tris(haloalkyl) phosphate produces oligomeric metaphosphoric anhydrides, which upon further insertion of an epoxide into the P—O—P linkages affords oligomeric phosphates. An older route for the chloroethyl phosphate oligomers used a transalkylation reaction for polycondensation, producing dichloroethane as by-product.



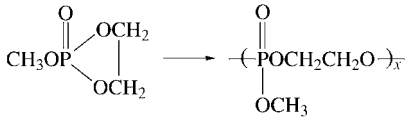
By inclusion of a proton source, such as H_3PO_4, water, or an alcohol, these oligomers can be made with hydroxyl functionality. Thus, a hydroxyl-terminated ethyl ethylene phosphate, Exolit OP 550, is made from triethyl phosphate, P_2O_5, phosphoric acid, water, and ethylene oxide. It has been introduced by Clariant as a reactive flame retardant for polyurethane foams (135).

The reaction of a trialkyl phosphate, P_2O_5, and ethylene oxide, omitting the addition of a proton source unlike the preceding synthesis, can produce a substantially nonfunctional oligomer (136). A product of this type, Akzo Nobel's Fyrol PNX, has been introduced as a high efficiency flame retardant for flexible or rigid polyurethane and polyisocyanurate foams. Because of its oligomeric character, it has low vapor emission (thus freedom from window fogging) in applications such as automobile seating (137).

Diepoxide Reaction with Phosphoric Acid. The reaction of phosphoric acid with diepoxides can produce linear polymers or gels which can be hydrolyzed to water-soluble poly(alkylene phosphates) (138,139).

Polycondensation of Compounds Containing a Phosphate Linkage. Polycondensation of tris(2-chloroethyl) phosphate, preferably in the presence of a nucleophilic catalyst, affords an oligomeric phosphate which was for a time produced by this process as a flame retardant for polyurethane foams, thermoset resins, and air-filter products (140–142). A preferred method, avoiding a chlorinated coproduct, is based on addition of phosphorus pentoxide and ethylene oxide to the tris(2-chloroethyl) phosphate, as discussed above.

Cyclopolymerization of Five- or Six-Membered Ring Phosphates. Poly(ethylene methyl phosphate) is formed from cyclic methyl ethylene phosphate (110).



The reaction is thermally reversible and, consequently, polymers and oligomers with P(=O)OCCOP(=O)O linkages cannot be used in high temperature applications.

Production of poly(alkylene hydrogen phosphates) can be accomplished by ring-opening polymerization of cyclic hydrogen phosphonates, followed by oxidation (for example by chlorination and hydrolysis). The intermediate chloride can also be converted to esters or amides (111).

Phosphorus–Nitrogen Polymers. The most extensively investigated class of such polymers is the polyphosphazenes, which have been reviewed in regard to flame retardancy (143) and which are discussed in a separate article in this Encyclopedia. Research on polymeric phosphonamides, phosphoramides, and phosphorimides has not as yet led to commercial results.

Condensation Polymerization of Phosphonyl Dihalides or Phosphoryl Dihalides with Diamines. Polyphosphonamides have been prepared by interfacial reaction of phenylphosphonic dichloride with diamines (99,144); these products have apparently not been commercialized. Polyphosphonic amides have been shown to have useful flame-retardant efficacy in polyolefin formulations with other phosphorus additives (145).

Film-forming polyphosphoramides (146) form reverse-osmosis membranes impervious to urea and appear to have promise for artificial kidney applications.

Condensation Polymerization of Phosphonate Esters or Diamides with Diamines and Related Reactions. Treatment of diphenyl methylphosphonate with diamines produces thermoplastic materials with elemental compositions corresponding to polymeric phosphonamides or imides (102,147,148).

Phosphorus-Modified Plastics, Resins, and Textiles

In many cases, only small quantities of phosphorus are introduced by various means into a polymer to achieve desired properties such as flame retardancy or improved adhesion.

Polyolefins. Polyethylene can be phosphorylated with phosphorus trichloride and oxygen by a free-radical chain reaction (118,149–151). Side reactions include separate oxidation of the phosphorus trichloride and of the polymer. Hydrolysis gives phosphonic acid structures, which can impart flame retardancy and improved adhesion to surfaces. These materials have been explored for dental and bone therapy applications but no commercial use is known.

Styrene Resins. The introduction of phosphorus acid groups into polystyrene gives ion-exchange resins with different selectivities than the usual sulfonated types. In one method $-PCl_2$ groups are attached to the aromatic ring by reaction of polystyrene (or cross-linked styrene–divinylbenzene copolymer) with phosphorus trichloride with an aluminum chloride catalyst (152). After hydrolysis and oxidation, the aromatic rings contain $P(O)(OH)_2$ groups. Hydrolysis alone gives polystyrenes with phosphinic acid groups (153). Polystyrenes with phosphonic or phosphinic acid groups show selective ion-exchange properties toward metals (154) (see ION-EXCHANGE RESINS; STYRENE POLYMERS).

A macroporous polystyrene–divinylbenzene with sodium phosphonomethylaminomethyl groups has been marketed as Duolite ES-467 ion-exchange resin

(Rohm and Haas Co.) which is highly effective in chelating divalent metal cations. It removes traces of calcium from saturated sodium chloride brine, such as the feed streams to chlorine-caustic electrolytic cells (155). This resin also has high affinity for lead and zinc, and has been used for treating industrial-waste streams and cooling-tower waters.

Vinyl and Acrylic Polymers. Vinyl and acrylic polymers containing phosphorus are prepared from a phosphorylated monomer or by treating the polymer with a phosphorus compound.

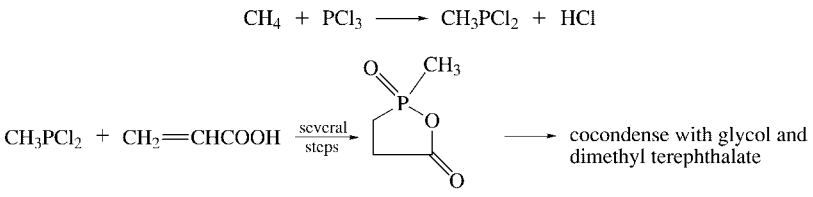
Phosphonate groups are introduced into PVC via the Arbuzov reaction with a trialkyl phosphite (149); this reaction is slow and is accompanied by dehydrochlorination of the PVC and by intramolecular Arbuzov rearrangement of the phosphite (156,157). However, this reaction of phosphites may play a role in stabilizing PVC.

Acrylic dental adhesives have been modified with a phosphate ester linkage by reaction of a glycidyl methacrylate or hydroxyethyl methacrylate with phosphorus oxychloride (158). One such product, a 3M Scotchbond, adheres to dentine as well as to tooth enamel. Adhesion to enamel can be improved in dental bonding cements by including an acryloxyalkyl- or acryloxyaryl acid phosphate component (159). Japanese products utilize an unsaturated phosphinic acid monomer to improve adhesion (160).

Phosphorus acid groups can be introduced into acrylic acid polymers by use of chain transfer during polymerization in the presence of phosphorous acid (which provides a phosphonic acid end group) or hypophosphorous acid (which can provide a phosphinic acid middle or end group) (61,161). Certain water-soluble polymers of the Belclene 700 series (originally Ciba Geigy, later FMC) contain phosphinic or phosphonic acid groups, believed to have been made in this manner. These polymers are effective scale inhibitors and can be used in industrial and institutional washing formulations to aid soil removal and dispersion with control of water-hardness deposits.

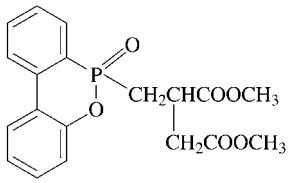
Thermoplastic Polyesters. Cocondensation with a phosphorus acid, diol, or diester introduces a small amount of phosphorus into polyesters for flame retardancy, color stability, electrical properties, or antistatic properties. Hoechst and Toyo Spinning (Toyobo) have increased the flame retardancy of poly(ethylene terephthalate) fibers by incorporating small amounts of phosphinates.

The Hoechst technology is shown by the following sequence (162,163):



The flame-retardant polyester fiber was marketed originally by Hoechst, later by Ticona as Trevira CS, and now by Kosa in the United States as Avora FR, and is used for decorative fabrics and curtains, upholstery fabrics, hospital bedding, and sleeping bags. These fibers also exhibit low smoke evolution, good appearance, and light stability.

Technology originally developed at Toyobo for polyester fiber places the phosphinate group on a side chain in a modified poly(ethylene terephthalate) by cocondensation with a phosphinate of the following structure (164–166):



This is an addition product of a hydrogen phosphinate with dimethyl itaconate. A diol with the same ring system can also be used to make other phosphorus-containing thermoplastic polyesters (167).

Numerous patents disclose alternatives for flame-retardant polyester fibers by introducing small amounts, such as less than 1%, of phosphorus. The cocondensation of less than 1% of phenylphosphonic acid into the polyester has been claimed sufficient to flame retard it to a Japanese standard (168). Perhaps of commercial utility is a polyester fiber made by transesterifying the oligomer of phenyl(hydroxymethyl)phosphinic acid into molten poly(ethylene terephthalate) (169).

Polyester Resins (Thermoset). Many patents describe polyesters containing an alkylene oxide reaction product with a phosphonic or phosphoric acid to promote flame retardance; some patents describe transesterifying a neutral or acid phosphate directly into the reaction mixture (170).

Small amounts of phosphorus sufficient to induce flame retardancy are incorporated by transesterification of dimethyl methylphosphonate or other phosphonates with unsaturated polyester resins (171,172).

The phosphorus can also be introduced in the form of a vinylphosphonate for copolymerization with styrene in the curing step. Polyesters of this type, with bis(2-chloroethyl) vinylphosphonate as part of the cross-linking system, were marketed for a time (173). The only use of phosphorus compounds in any significant volume in polyester resins has been that of triethyl phosphate or dimethyl methylphosphonate for viscosity reduction and flame retardancy in filled-polyester, sheet-molding compositions.

Polyamides. Bis(carboxyethyl)alkylphosphine oxide units can be introduced into the backbone of nylon-6,6 to impart flame retardancy with minimal sacrifice of physical properties. (174). Despite much effort on this approach, these products failed to reach commercialization probably for cost reasons. Small amounts of bis(carboxyethyl)phosphinic acid salts can be introduced into the chain of polyamide-6,6 to impart inherent flame retardancy and stain resistance to carpet fiber (175).

Epoxy Resins. In the combustion of epoxy resins, phosphorus inhibits the evolution of fuel gases and increases char (176). Much attention has been given to phosphorus additives or reactives in epoxy resins used as coatings for the purpose of increased adhesion to surfaces (177,178) and for fire resistance. More recently, a great deal of attention has been given to phosphorus-containing, flame-retarded electrical/electronic laminates and encapsulated electronic parts.

Some of this effort has been directed to replacement of tetrabromobisphenol A, a major reactive component of circuit boards (wiring boards). Extensive development of flame-retarded halogen-free circuit boards has taken place especially in Europe and the Far East to find alternatives to tetrabromobisphenol A-based epoxy circuit boards. The use of phosphate ester additives usually depresses the thermomechanical properties excessively, and so the use of reactive phosphorus compounds has been the preferred approach.

Phosphorus can be introduced into epoxy resins in diverse ways using reactive means. Diglycidyl phenylphosphonate (179) has been found useful for electronic epoxy products but cost has retarded its commercial development.

Phosphorus can be introduced into epoxy resins by introducing phosphorus halides pre-cure or as part of curing step (in either case, a β-chloroalkoxy phosphorus ester structure is produced), but these reagents are generally too corrosive and labile, and this approach has not been commercialized. Incorporation of phosphoric acid (180) or polyphosphoric acid (181) has shown somewhat more promise. Epoxy resins modified by reaction with alkyl acid phosphates, such as butoxyethyl acid phosphate, had development efforts by Dow Chemical Co. (182). Extensive study was done at Ford Co. on epoxy coatings, with alkyl acid phosphates reacted into the epoxy structure (126) for purposes of improved adhesion and corrosion protection. Reaction of dialkyl or diphenyl phosphates with epoxy resins and subsequent curing gave products with intumescent flame-retardant properties but diminished thermal stability. The use of diphenyl phosphate raised the glass-transition temperature (183) in some epoxy resins. The reaction of epoxy groups with phosphorus acids generates β-hydroxyalkyl phosphate or phosphonate linkages, along with hydroxy(polyoxyalkylene) phosphates or phosphonates, and also some self-condensation of the epoxy groups. In some cases, gelation occurs.

Oligomeric phosphoric/phosphonic anhydrides can be incorporated into epoxy resins to make prepolymers or used as curing agents (184–186).

The chain extension of epoxy resins can be conducted with dihydric phenolic resins containing phosphate linkages. Bis(3-hydroxyphenyl) phenyl phosphate can be used as a chain extender for epoxy resins, and can afford a UL-94 V-0 level of flame retardancy with phosphorus content as low as 1.5% after cure (187); however, the glass-transition temperature (T_g) is lowered by the flexible phosphate group.

The problem of achieving a high T_g in a circuit-board laminate (to avoid distortion during soldering) is alleviated by the use of a pendant rigid phosphorus-containing ring structure, namely the 9,10-dihydro-9-oxa-10-phosphaphenanthrene group, the synthesis of which was shown above.

This ring system has been used in epoxy resins as well as in thermoplastic polyesters. It has been the subject of many patents and publications, and is commercially produced in Europe and the Far East. Its original use was in Toyobo's flame-retardant polyester fiber, in the form of the itaconic ester adduct.

The hydrogen phosphinate itself can be reacted directly into epoxy resins to produce presumably a β-hydroxyphosphinate structure (188); however, this consumes epoxy functionality and creates chain ends which tend to reduce the T_g.

A more selective means for incorporation of this ring system is to react the hydrogen phosphinate with benzoquinone by reductive addition to produce the phosphinyl-substituted hydroquinone (189,190). This can be used as a chain

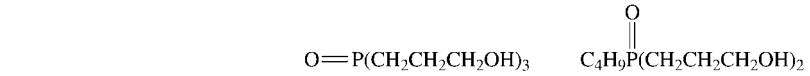
extension reagent with an epoxy resin to obtain flame retardancy with an improvement of T_g. A still further elaboration of this cyclic structure is the reaction of the hydroquinone with epichlorohydrin and base to make a diglycidyl ether (191) which can be used as part of the epoxy resin.

The same ring system can also be introduced into a novolac hardener by phosphinylation of one or more of the hydroxyl groups of the novolac, leaving the remaining groups to serve for the cross-linking (192).

A cyclic neopentyl hydrogen phosphonate can be added to the epoxy group to impart flame retardancy although the creation of an end group does tend to lower T_g (193).

Phosphonated aromatic diamines (195) can serve as flame-retardant curing agents for epoxy resins. Phosphoramides and bis(aminophenyl)methylphosphine oxide have been evaluated in the quest for stable, fire-resistant epoxy composites for aerospace applications (196–198). Economical means for producing the phosphine oxide structure have been lacking.

Phosphine oxide diols and triols were shown at FMC to be excellent reactive flame retardants or synergists with good thermal and hydrolytic stability in epoxy resins (199).



Their cost has retarded commercialization.

Polyurethanes and Isocyanurate-Modified Polyurethanes. Phosphorus flame retardants, both additive and reactive, are used in large quantities in Polyurethanes. Rigid urethane foams employed in thermal insulation must adhere to stringent fire regulations. Flexible foams used in automotive seating must pass the MVSS-302 fire standard; in furniture foam, they must pass the California state standard and other local fire codes.

Additive flame retardants continue to dominate the flexible foam market despite extensive work on reactive phosphorus compounds (200,201). A phosphonate–phosphate diol (6) has been used as a component of a blended flame retardant for flexible polyurethanes. A reactive phosphate diol (135) has recently been introduced by Clariant for use in flexible polyurethanes.

Reactive flame retardants have long been used in rigid foams. A successful early example, the diol Vircol 82 (Rhodia), is a diol made by reaction of dibutyl acid pyrophosphate with propylene oxide (202).

A phosphonate diol (Akzo-Nobel's Fyrol 6) is used in rigid foams, especially spray, froth, pour-in-place, and quasi-prepolymer foam formulations. It is a condensation product of diethanolamine with formaldehyde and diethyl phosphonate (203):

The diol structure permits permanent incorporation of the phosphonate group into the urethane foam. The phosphonate linkage is on a side chain rather

than in the backbone of the polyurethane, which increases the hydrolytic stability, and the amino group aids catalysis of the foaming.

A diol containing a phosphine oxide structure was shown to be useful in urethane coatings, adhesives, and rigid foams (204). Advantages included shelf stability of the amine catalyst–polyol mixture, low smoke, and good resistance to humidity (205).

A phosphorus-containing isocyanate can also be employed, although P(=O)N=C=O types, in general, are expensive to synthesize and, moreover, give hydrolytically unstable urethanes. The only phosphorus-containing isocyanate currently on the market is Bayer's Desmodur RFE, a solution in ethyl acetate of tris(*p*-isocyanatophenyl) thionophosphate (206).

This compound is not employed in urethanes. It is a cross-linking agent for adhesives and is used to increase bonding to rubber and plastic substrates and resistance to heat and solvents.

Phenolic and Amino Resins. Numerous patents describe incorporation of phosphorus to increase flame retardancy. Paper impregnated with phenolic resins or amino resins, such as that used in automotive air filters, is treated with oligomeric phosphates or phosphonates (6). Being low in volatility, they are retained during use. Large air filters must retain the flame retardant during washing and reuse; reactive (hydroxyl-terminated) phosphonate–phosphate oligomers are used for this application (207). Such structures presumably become chemically bound to the resin by formation of ether linkages.

Electronic circuit boards based on phenolic resin can be flame retarded by aryl phosphates including oligomeric types made by transesterification of aryl phosphates with novolacs (208). These partially phosphorylated novolacs are then incorporated into the thermoset structure.

Cellulosic Resins. In general, phosphorylation of cellulose or treatment of cellulose with phosphorus-containing resins produces a flame-retardant effect by increasing char yield although lowering the decomposition temperature somewhat. The mechanism has been extensively studied (209–211).

The direct phosphorylation of cellulose has been studied extensively, particularly to prepare flame-retardant cotton fabric or paper and ion-exchange materials (212). Heating cellulose with phosphoric acid results in little phosphorylation and much degradation. However, in the presence of urea or dicyandiamide, a sufficient degree of phosphorylation is achieved to impart self-extinguishing properties while allowing retention of useful strength. Such processes have been employed for semidurable, flame-retardant finishing of draperies. Resistance to a few washes is improved by using an amino resin such as methylolurea or methylolated dicyandiamide. Wood has been commercially treated for flame retardancy by aminoplast–phosphoric acid compositions (213).

Cellulose can also be phosphorylated by heating it with polyphosphoric salts, such as sodium hexametaphosphate (214). A water-insoluble sodium cellulose phosphate, Selectacel phosphate cation exchanger (Polysciences), is used in chromatography. A more highly substituted version, Selectacel SCP or Calcibind exchanger, is approved by the FDA for binding calcium in the gastrointestinal tract as a treatment for absorptive hypercalciurea (a disease causing recurrent calcium kidney stones) (215) (see CELLULOSE ESTERS, INORGANIC). Starches are phosphorylated by treatment with sodium orthophosphate, pyrophosphate,

metaphosphate, or tripolyphosphate (216). By varying the reagents and conditions, a wide range of properties can be achieved. A phosphate-treated starch swellable in cold water is used in instant puddings. Water-resistant phosphorylated starch is useful in paper sizing. A hydroxypropyl starch phosphate (Midwest Grain Products' Cosmogel 46) is heat and pH tolerant, and hydrates to a thick smooth paste useful in skin and hair care products.

Flame-Retardant Finishes on Cellulosic Substrates. The flame retarding of cotton and viscose-rayon fabrics has been the object of a large worldwide effort on phosphorus-containing finishes (217–219). The commercial cotton finishes are based on tetrakis(hydroxymethyl)phosphonium salts, usually the chloride or sulfate (220). These salts are prepared by reaction of formaldehyde with phosphine in the presence of an acid.

$$PH_3 + 4\,HCHO + HCl \rightarrow (HOCH_2)_4P^+Cl^-$$

The tetrakis(hydroxymethyl)phosphonium salts are applied to cellulosic fabric, most commonly as a urea precondensate (Albright & Wilson's, now Rhodia's Proban), and cured with ammonia vapor (221–223). The finish, after oxidation by air or hydrogen peroxide, has phosphine oxide structures in a cross-linked amino resin network, probably also lightly linked to the cellulose. This finish is durable to multiple launderings and is used for industrial cotton garments (224).

Other commercial finishes for cotton are less resistant to harsh laundering conditions, but can be applied by conventional pad-dry-cure methods. For example, the Ciba Pyrovatex CP flame retardant is based on the methylolated reaction product of dimethyl phosphite with acrylamide, which is condensed on the cotton fabric with an amino resin (225,226) to make a cross-linked amino resin containing a dimethyl phosphonate structure. Pyrovatex CP is principally $(CH_3O)_2P(O)CH_2CH_2C(O)NHCH_2OH$ with related side-reaction products (227,228). The chemistry of the Pyrovatex finish involves linkages both to cellulose directly and to aminoplast resins which then link to cellulose.

Phosphorylated Proteins. Naturally occurring phosphorus-containing proteins include such important examples as casein, discussed elsewhere in this Encyclopedia. In living organisms, proteins are often phosphorylated enzymatically on the serine or tyrosine hydroxyl group as an activation or regulation step, and over-phosphorylation may play a role in disease; this biochemistry is outside the scope of the present article.

Efforts to manufacture phosphorylated proteins by modification of nonphosphorus proteins have been reviewed (229). Phosphorylation of proteins with phosphorus oxychloride causes cross-linking and insolubilization, but improves gel-forming and water-binding properties. Phosphorylation with sodium trimetaphosphate improves functional properties of soybean protein, including water solubility. Nutritional and toxicological investigations are needed before such modified natural proteins can be used in foods (230).

PIEZOELECTRIC POLYMERS

Introduction

Piezoelectric polymers have been known for more than 40 years, but in recent years they have gained repute as a valuable class of "smart materials." There is no standard definition for smart materials, and terms such as intelligent materials, smart materials, adaptive materials, active devices, and smart systems are often used interchangeably. The term "*smart material*" generally designates a material that changes one or more of its properties in response to an external stimulus.

The most popular smart materials are piezoelectric materials, magnetostrictive materials, shape-memory alloys, electrorheological fluids, electrostrictive materials, and optical fibers. Magnetostrictives, electrostrictives, shape-memory alloys, and electrorheological fluids are used as actuators; optical fibers are used primarily as sensors (see SHAPE MEMORY POLYMERS)

Among these active materials, piezoelectric materials are most widely used because of their wide bandwidth, fast electromechanical response, relatively low power requirements, and high generative forces. A classical definition of piezoelectricity, a Greek term for "pressure electricity," is the generation of electrical polarization in a material in response to mechanical stress. This phenomenon is known as the direct effect. Piezoelectric materials also display the converse effect: mechanical deformation upon application of an electrical charge or signal. Piezoelectricity is a property of many noncentrosymmetric ceramics, polymers, and biological systems. Pyroelectricity is a subset of piezoelectricity, whereby the polarization is a function of temperature. Some pyroelectric materials are ferroelectric, although not all ferroelectrics are pyroelectric. Ferroelectricity is a property of certain dielectrics that exhibit spontaneous electric polarization (separation of the center of positive and negative electric charge that

makes one side of the crystal positive and the opposite side negative) that can be reversed in direction by applying an appropriate electric field. Ferroelectricity is named by analogy with ferromagnetism, which occurs in materials such as iron. Traditionally, ferroelectricity is defined for crystalline materials, or at least in the crystalline region of semicrystalline materials. More recently, however, a number of researchers have explored the possibility of ferroelectricity in amorphous polymers, that is, ferroelectricity without a crystal lattice structure (1).

Characteristics of Piezoelectric Polymers. The properties of polymers are very different from those of inorganics (Table 1), and they are uniquely qualified to fill niche areas where single crystals and ceramics cannot perform as effectively. As noted in Table 1, the piezoelectric strain constant (d_{31}) for the polymer is lower than that of the ceramic. However, piezoelectric polymers have much higher piezoelectric stress constants (g_{31}) which indicates that they are much better sensors than ceramics. Piezoelectric polymeric sensors and actuators offer the advantage of processing flexibility because they are lightweight, tough, readily manufactured in large areas, and can be cut and formed into complex shapes. Polymers also exhibit high strength and high impact resistance (2). Other notable features of polymers are low dielectric constant, low elastic stiffness, and low density, which result in high voltage sensitivity (excellent sensor characteristic) and low acoustic and mechanical impedance (crucial for medical and underwater applications). Polymers also typically possess high dielectric breakdown and high operating field strength, which means that they can withstand much higher driving fields than ceramics. Polymers offer the ability to pattern electrodes on the film surface and pole only selected regions. Based on these features, piezoelectric polymers possess their own established area for technical applications and useful device configurations.

Structural Requirements for Piezoelectric Polymers. The piezoelectric mechanisms for semicrystalline and amorphous polymers differ. Although the differences are distinct, particularly with respect to polarization stability, in the simplest terms, four critical elements exist for all piezoelectric polymers, regardless of morphology. These essential elements are (*1*) the presence of permanent molecular dipoles, (*2*) the ability to orient or align the molecular dipoles, (*3*) the ability to sustain this dipole alignment once it is achieved, and (*4*) the ability of the material to undergo large strains when mechanically stressed (3).

Semicrystalline Polymers

Mechanism of Piezoelectricity in Semicrystalline Polymers. Semicrystalline Polymers must have a polar crystalline phase to render them piezoelectric. The Morphology of such polymers consists of crystallites dispersed within amorphous regions, as shown in Figure 1a. The amorphous region has a glass-transition temperature that dictates the mechanical properties of the polymer, and the melting temperature of the crystallites dictates the upper limit of the use temperature. The degree of crystallinity in such polymers depends

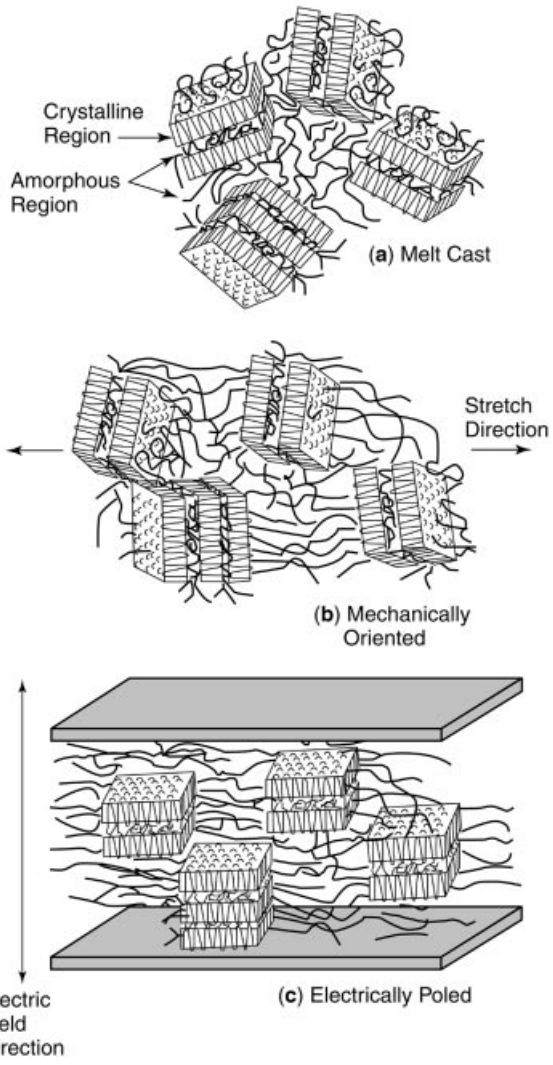

Fig. 1. Schematic illustration of random stacks of amorphous and crystal lamellae in the PVDF polymer: (**a**) the morphology after the film is melt cast; (**b**) after orientation of the film by mechanically stretching several times its original length; and (**c**) after depositing metal electrodes and poling through the film thickness.

on the method of preparation and thermal history. Most semicrystalline polymers have several polymorphic phases, some of which may be polar. Mechanical orientation, thermal annealing, and high voltage treatment are all, it has been shown, effective in inducing crystalline phase transformations. Stretching the polymer aligns the amorphous strands in the film plane, as shown in Figure 1b, and facilitates uniform rotation of the crystallites by an electric field. Depending on whether stretching is uniaxial or biaxial, the electrical and mechanical properties (and therefore the transduction response) are either highly anisotropic or isotropic in the plane of the polymer sheet. Electrical poling is accomplished by applying an electric field across the thickness of the polymer, as depicted in Figure 1c. An electric field of the order of 50 MV/m is typically sufficient to effect crystalline orientation. Polymers can be poled by using a direct contact method or corona discharge. The latter is advantageous because contacting electrodes is not required and samples of large area can be poled continuously. This method is used to manufacture commercial poly(vinylidene fluoride) (PVDF) film (see VINYLIDENE FLUORIDE POLYMERS(PVDF)). Some researchers have also successfully poled large areas of polymer films by sandwiching them between polished metal plates under a vacuum. This method eliminates electrical arcing of samples and the need for depositing metal electrodes on the film surface. The amorphous phase of semicrystalline polymers supports the crystal line orientation, and polarization is stable up to the Curie temperature. This polarization can remain constant for many years if it is not degraded by moisture uptake or elevated temperatures.

Piezoelectric Constitutive Relationships. The constitutive relationships that describe piezoelectric behavior in materials can be derived from thermodynamic principles (4). A tensor notation is adopted to identify the coupling between the various entities through mechanical and electrical coefficients. The common practice is to label directions as depicted in Figure 2. The stretch direction

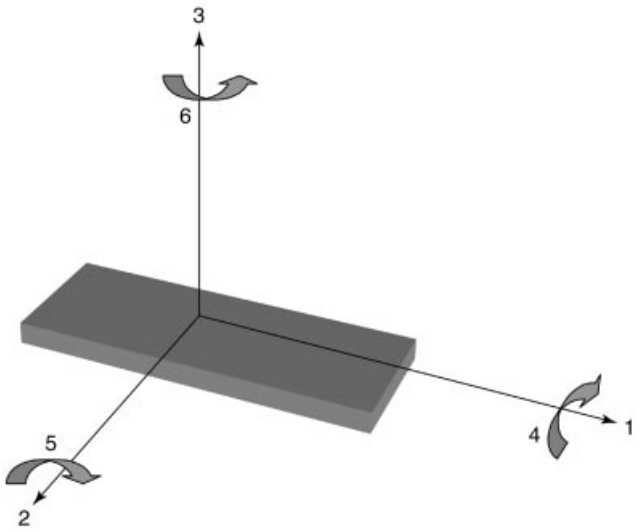

Fig. 2. Tensor directions for defining the constitutive relationships.

is denoted as "1." The "2" axis is orthogonal to the stretch direction in the plane of the film. The polarization axis (perpendicular to the surface of the film) is denoted "3." The shear planes, indicated by the subscripts "4," "5," and "6," are perpendicular to the directions "1," "2," and "3," respectively. By reducing the tensor elements and using standard notations (5), the resulting equations can be displayed in matrix form as follows:

$$\begin{vmatrix} S_1 \\ S_2 \\ S_3 \\ S_4 \\ S_5 \\ S_6 \end{vmatrix} = \begin{vmatrix} d_{11} & d_{12} & d_{13} \\ d_{21} & d_{22} & d_{23} \\ d_{31} & d_{32} & d_{33} \\ d_{41} & d_{42} & d_{43} \\ d_{51} & d_{52} & d_{53} \\ d_{61} & d_{62} & d_{63} \end{vmatrix} \begin{vmatrix} E_1 \\ E_2 \\ E_3 \end{vmatrix} + \begin{vmatrix} s_{11}^E & s_{12}^E & s_{13}^E & s_{14}^E & s_{15}^E & s_{16}^E \\ s_{21}^E & s_{22}^E & s_{23}^E & s_{24}^E & s_{25}^E & s_{26}^E \\ s_{31}^E & s_{32}^E & s_{33}^E & s_{34}^E & s_{35}^E & s_{36}^E \\ s_{41}^E & s_{42}^E & s_{43}^E & s_{44}^E & s_{45}^E & s_{46}^E \\ s_{51}^E & s_{52}^E & s_{53}^E & s_{54}^E & s_{55}^E & s_{56}^E \\ s_{61}^E & s_{62}^E & s_{63}^E & s_{64}^E & s_{65}^E & s_{66}^E \end{vmatrix} \begin{vmatrix} X_1 \\ X_2 \\ X_3 \\ X_4 \\ X_5 \\ X_6 \end{vmatrix} \tag{1}$$

$$\begin{vmatrix} D_1 \\ D_2 \\ D_3 \end{vmatrix} = \begin{vmatrix} \varepsilon_{11}^T & \varepsilon_{12}^T & \varepsilon_{13}^T \\ \varepsilon_{21}^T & \varepsilon_{22}^T & \varepsilon_{23}^T \\ \varepsilon_{31}^T & \varepsilon_{32}^T & \varepsilon_{33}^T \end{vmatrix} \begin{vmatrix} E_1 \\ E_2 \\ E_3 \end{vmatrix} + \begin{vmatrix} d_{11} & d_{12} & d_{13} & d_{14} & d_{15} & d_{16} \\ d_{21} & d_{22} & d_{23} & d_{24} & d_{25} & d_{26} \\ d_{31} & d_{32} & d_{33} & d_{34} & d_{35} & d_{36} \end{vmatrix} \begin{vmatrix} X_1 \\ X_2 \\ X_3 \\ X_4 \\ X_5 \\ X_6 \end{vmatrix} \tag{2}$$

Piezoelectricity is a cross coupling among the elastic variables, stress X and strain S, and the dielectric variables, electric charge density D and electric field E. Note that D is named in analogy to the B field in ferromagnetism, although some authors also refer to it as dielectric or electric displacement. There does not seem to be a standard nomenclature; however, it is the opinion of the authors of this article that electric charge density is a better description of this property. The combinations of these variables define the piezoelectric strain constant d, the material compliance s, and the permittivity ε. Other piezoelectric properties are the piezoelectric voltage constant g, stress constant e, and strain constant h given by the equations in Table 2. For a given constant, the first definition in the table refers to the direct effect, and the second refers to the converse effect. The piezoelectric constants are interrelated through the electrical and mechanical properties of the material. Electric field strength and displacement charge density are related through the dielectric constant, $\varepsilon\varepsilon_0$ (where ε_0 is the permittivity of free space), and stress and strain are related through the compliance according to

Table 2. Definitions of Piezoelectric Constants

Equations	Units
$d = (\mathrm{d}D/\mathrm{d}X)_\mathrm{E} = (\mathrm{d}S/\mathrm{d}E)_\mathrm{X}$	C/N or m/V
$e = (\mathrm{d}D/\mathrm{d}S)_\mathrm{E} = -(\mathrm{d}X/\mathrm{d}E)_\mathrm{S}$	C/m or N/Vm
$g = (\mathrm{d}E/\mathrm{d}X)_\mathrm{D} = (\mathrm{d}S/\mathrm{d}D)_\mathrm{X}$	Vm/N or m^2/C
$h = (\mathrm{d}E/\mathrm{d}S)_\mathrm{D} = -(\mathrm{d}X/\mathrm{d}D)_\mathrm{S}$	V/m or N/C

$$d_{ij} = \varepsilon_0 \varepsilon_i g_{ij} \tag{3}$$

$$e_{ij} = s_{ij} d_{ij} \tag{4}$$

The polarization P is a measure of the degree of piezoelectricity in a given material. In a piezoelectric material, a change in polarization ΔP results from an applied stress X or strain S under conditions of constant temperature and zero electric field. A linear relationship exists between ΔP and the piezoelectric constants. Because of material anisotropy, $\boldsymbol{P}$ is a vector that has three orthogonal components in the 1, 2, and 3 directions. Alternatively, the piezoelectric constants can be defined as

$$\Delta P_i = d_{ij} X_j \tag{5}$$

$$\Delta P_i = g_{ij} S_j \tag{6}$$

The electrical response of a piezoelectric material is a function of the electrode configuration relative to the direction of the applied mechanical stress. For a coefficient d_{ij}, the first subscript is the direction of the electric field or charge displacement, and the second subscript gives the direction of the mechanical deformation or stress. The C_{2v} crystallographic symmetry typical of synthetic oriented, poled polymer film leads to cancellation of all but five of the d_{ij} components (d_{31}, d_{32}, d_{33}, d_{15}, and d_{24}). If the film is poled and biaxially oriented or unoriented, $d_{31} = d_{32}$ and $d_{15} = d_{24}$. Most natural biopolymers possess D_∞ symmetry which yields a matrix that possesses only the shear piezoelectricity components d_{13} and d_{25}. Because the d_{33} constant is difficult to measure without constraining the lateral dimension of the sample, it is typically determined from equation 7 which relates the constants to the hydrostatic piezoelectric constant, d_{3h}.

$$d_{3h} = d_{31} + d_{32} + d_{33}. \tag{7}$$

The electromechanical coupling coefficient k_{ij} represents the conversion of electrical energy into mechanical energy and vice versa. The electromechanical coupling can be considered a measure of transduction efficiency and is always less than unity as shown here:

$$k^2 = \frac{\text{Electrical energy converted to mechanicalenergy}}{\text{Input electricalenergy}} \tag{8}$$

$$k^2 = \frac{\text{Mechanical energy converted to electricalenergy}}{\text{Input mechanicalenergy}} \tag{9}$$

Some k coefficients can be obtained from a measured d constant as follows:

$$k_{31} = \frac{d_{31}}{\sqrt{s_{11}^E \varepsilon_3^T}} \tag{10}$$

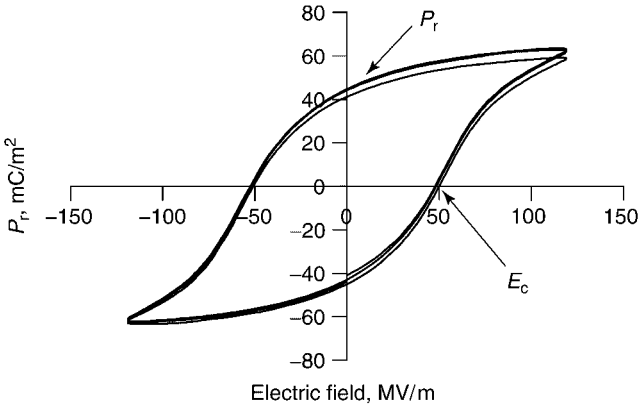

Fig. 3. Typical ferroelectric hysteretic behavior for PVDF.

Ferroelectricity in Semicrystalline Polymers. At high electric fields, the polarization in semicrystalline polymers such as PVDF is nonlinear with the applied electric field. This nonlinearity in polarization is defined as hysteresis. The existence of spontaneous polarization together with polarization reversal (as illustrated by a hysteresis loop) is generally accepted as proof of ferroelectricity. Figure 3 is an example of the typical hysteretic behavior of PVDF. Two other key properties typically reported for ferroelectric materials are the coercive field and the remanent polarization. The coercive field E_c, which marks the point where the hysteresis intersects the horizontal axis, is about 50 MV/m at room temperature for many ferroelectric polymers. The remanent polarization P_r corresponds to the point where the loop intersects the vertical axis. The values of E_c and P_r depend on temperature and frequency. The Curie temperature T_c is generally lower than but close to the melting temperature of the polymer. Below T_c, the polymer is ferroelectric and above T_c, the polymer loses its noncentrosymmetric nature.

Although ferroelectric phenomenon has been well documented in ceramic crystals, the question of whether polymer crystallites could exhibit dipole switching was debated for about a decade after the discovery of piezoelectricity in PVDF. Inhomogeneous polarization through the film thickness that yielded higher polarization on the positive electrode side of the polymer led to speculations that PVDF was simply a trapped charge electret. These speculations were dispelled when x-ray studies (6) demonstrated that polarization anisotropy vanishes because of high poling field strengths and that true ferroelectric dipole reorientation occurs in PVDF. One researcher used infrared to attribute the polarization reversal in PVDF to 180° dipole rotation (7). Others documented the same via x-ray pole analysis and infrared techniques for odd-numbered nylons (8).

State of the Art. Pioneering work in the area of piezoelectric polymers (9) led to the development of strong piezoelectric activity in poly(vinylidene fluoride) (PVDF) and its copolymers with trifluoroethylene (TrFE) and tetrafluoroethylene (TFE). These semicrystalline fluoropolymers represent the state of the art in piezoelectric polymers and are currently the only commercial piezoelectric polymers.

Table 3. Comparison of Piezoelectric Properties of Some Semicrystalline Polymeric Materials

Polymer	Structure	T_g, °C	T_m, °C	Max. use temp., °C	d_{31}, pC/N	Reference
PVDF		−35	175	80	20–28	2
PTrFE		32	150	90–100	12	2
Nylon-11		68	195	185	3 at 25°C, 14 at 107°.C	22
Polyurea-9		50	180	—	—	28

Odd-numbered nylons, the next most widely investigated semicrystalline piezoelectric polymers, have excellent piezoelectric properties at elevated temperatures but have not yet been embraced in practical application. Other semicrystalline polymers including polyureas, liquid crystalline polymers, biopolymers, and an array of blends have been studied for their piezoelectric potential and are summarized in the following section. The chemical repeat unit and piezoelectric constants of several semicrystalline polymers are listed in Table 3.

Poly(vinylidene fluoride) (PVDF). Interest in the electrical properties of PVDF began in 1969 when it was shown (9) that poled thin films exhibit a very large piezoelectric coefficient, 6–7 pC/N, a value about 10 times larger than had been observed in any other polymer. As seen in Table 3, PVDF is inherently polar. The spatially symmetrical disposition of the hydrogen and fluorine atoms along the polymer chain gives rise to unique polar effects that influence the electromechanical response, solubility, dielectric properties, and crystal morphology and yield an unusually high dielectric constant. The dielectric constant of PVDF is about 12, which is four times greater than that of most polymers, and makes PVDF attractive for integration into devices because the signal-to-noise ratio is smaller for higher dielectric materials (see DIELECTRIC RELAXATION). The amorphous phase in PVDF has a Glass Transition that is well below room temperature (−35°C); hence, the material is quite flexible and readily strained at room temperature. PVDF is typically 50–60% crystalline, depending on thermal and processing history, and has at least four crystal phases (α, β, γ, and δ); at least three are polar. The most stable, nonpolar α phase results upon casting PVDF from a melt and can be transformed into the polar β phase by mechanical stretching at elevated temperatures

or into the polar δ phase by rotating the molecular chain axis in a high electric field ($\sim$130 MV/m) (10). The β phase is most important for piezoelectricity and has a dipole moment perpendicular to the chain axis of 7×10^{-30} C·m (2.1 D). After poling PVDF, the room temperature polarization stability is excellent; however, polarization and piezoelectricity degrade as temperature increases and are erased at its Curie temperature. Previously, it was believed that polarization stability was defined only by the melting temperature of the PVDF crystals. Recently, however, some researchers suggest that the polarization stability of PVDF and its copolymers is associated with coulombic interactions between injected, trapped charges and oriented dipoles in the crystals (11). It has been hypothesized that the thermal decay of the polarization is caused by the thermally activated removal of the trapped charges from the traps at the surface of the crystals. The role of trapped charges in stabilizing orientation in both semicrystalline and amorphous polymers is still a subject that needs further study. The electromechanical properties of PVDF have been widely investigated. For more details, the reader is referred to the wealth of literature that exists on the subjects of piezoelectric, pyroelectric, and ferroelectric properties (2,6,12,13), and the morphology (14–16) of this polymer (see VINYLIDENE FLUORIDE POLYMERS).

Poly(vinylidene fluoride–trifluoroethylene and tetra fluoro ethylene) Copolymers. Copolymers of vinylidene fluoride with trifluoroethylene (TrFE) and tetrafluoroethylene (TFE) also exhibit strong piezoelectric, pyroelectric, and ferroelectric effects. These polymers are discussed together here because they behave similarly when copolymerized with PVDF. An attractive morphological feature of the comonomers is that they force the polymer into an all-trans conformation that has a polar crystalline phase, which eliminates the need for mechanical stretching to yield a polar phase. P(VDF–TrFE) crystallizes to a much greater extent than PVDF (up to 90% crystalline) and yields a higher remanent polarization, a lower coercive field, and much sharper hysteretic loops. TrFE also extends the use temperature by about 20°C to close to 100°C. Conversely, copolymers with TFE exhibit a lower degree of crystallinity and a suppressed melting temperature, compared to the PVDF homopolymer. Although the piezoelectric constants for the copolymers are not as large as those of the homopolymer, the advantages of P(VDF–TrFE) in processibility, enhanced crystallinity, and higher use temperature make it favorable for applications.

Researchers have recently reported that highly ordered, lamellar crystals of P(VDF–TrFE) can be made by annealing the material at temperatures between the Curie temperature and the melting point. This material is referred to as a "single crystalline film." A relatively large single crystal of P(VDF–TrFE) 75/25 mol% copolymer was grown that exhibits a room temperature $d_{33} = -38$ pm/V and a coupling factor $k_{33} = 0.33$ (17).

The result of introducing defects into the crystalline structure of P(VDF–TrFE) copolymer on electroactive actuation has been studied using high electron irradiation (18). Extensive structural investigations indicate that electron irradiation disrupts the coherence of polarization domains (all-trans chains) and forms localized polar regions (nanometer-sized, all-trans chains interrupted by trans and gauche bonds). After irradiation, the material exhibits behavior analogous to that of relaxor ferroelectric systems in inorganic materials. The resulting material is no longer piezoelectric, but rather exhibits a large electric field-induced strain

(5% strain) because of electrostriction. The basis for such large electrostriction is the large change in the lattice strain as the polymer traverses the ferroelectric to paraelectric phase transition and the expansion and contraction of the polar regions. Piezoelectricity can be measured in these and other electrostrictives when a dc bias field is applied. Irradiation is typically accomplished in a nitrogen atmosphere at elevated temperatures using irradiation dosages up to 1,200 kGy (120 Mrad).

Polyamides. A low level of piezoelectricity was first reported in polyamides (also known as nylons) in 1970 (19). A systematic study of odd-numbered nylons, however, initiated in 1980 (20) and served as the impetus for more than 20 years of subsequent investigations of piezoelectric and ferroelectric activity in these polymers. The monomer unit of odd nylons consists of even numbers of methylene groups and one amide group whose dipole moment is 12.3×10^{-30} C·m (3.7 D). Polyamides crystallize in all-trans conformations and are packed to maximize hydrogen bonding between adjacent amine and carbonyl groups, as seen in Figure 4 for an even-numbered and an odd-numbered polyamide. The amide dipoles align synergistically in the odd-numbered monomer, resulting in a net dipole moment. The amide dipole cancels in an even-numbered nylon, although remanent polarizations have been measured for some even-numbered nylons, as discussed later in this article. The unit dipole density depends on the number of methylene groups present, and polarization increases from 58 mC/m^2 for nylon-11 to 125 mC/m^2 for nylon-5 as the number of methylene groups decreases (8).

Polyamides are hydrophilic. Because water absorption is associated with hydrogen bonding to the polar amide groups, the hydrophilicity increases as the

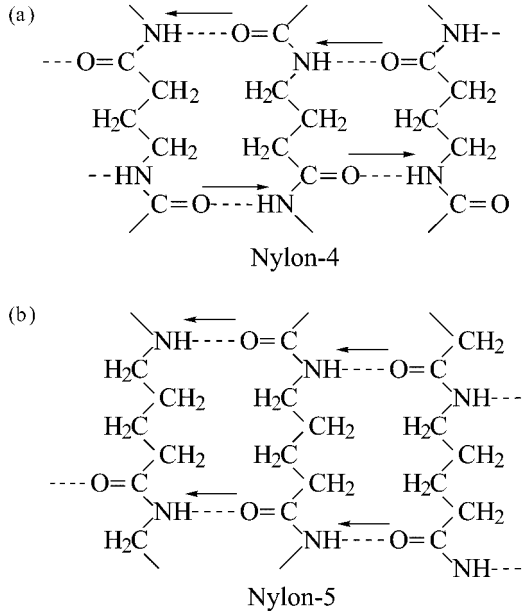

Fig. 4. Schematic depiction of hydrogen-bonded sheets showing dipole directions in the crystal lattices of (**a**) even (nylon-4) and (**b**) odd polyamides (nylon-5).

density of amide groups increases. Water absorption in nylon-11 and nylon-7 has been shown to be as high as 4.5% (by weight) and more than 12% for nylon-5 (21), whereas it is less than 0.02% for PVDF and its copolymers. Studies have shown that water absorption can have a dramatic effect on the dielectric and piezoelectric properties of nylons; however, water does not affect the crystallinity or orientation in thermally annealed films (21). Thus, films can be dried to restore their original properties.

At room temperature, odd-numbered nylons have lower piezoelectric constants than PVDF; however, when examined above their glass-transition temperatures, they exhibit comparable ferroelectric and piezoelectric properties and much higher thermal stability. The piezoelectric d and e constants increase rapidly as temperature increases. Maximum stable d_{31} values of 17 pC/N and 14 pC/N are reported for nylon-7 and nylon-11, respectively. Corresponding values of the electromechanical coupling constant k_{31} are 0.054 and 0.049. Studies have also shown that annealing nylon films enhances their polarization stability because it promotes denser packing of the hydrogen-bonded sheet structure in the crystalline regions and hinders dipole switching because of lowered free volume for rotation (22).

Though widely studied, piezoelectric polyamides have not been widely used in applications partly because of their low room temperature piezoelectric response and the problem of moisture uptake.

Liquid Crystalline Polymers. Liquid crystals consist of highly ordered rodlike or disk-like molecules. At their melting points they partially lose crystalline order and generate a fluid but ordered state. They can form layered structures called smectic phases or nematic phases that have an approximately parallel orientation of the molecular long axis. It was first predicted in 1975 that spontaneous polarization could be achieved in liquid crystals based on symmetry arguments (23). Subsequently, it has been shown that liquid crystalline molecules whose chiral carbon atoms link a mesogenic group and end alkyl chains may exhibit ferroelectric behavior in the smectic C phase (SmC$*$) (24). In this phase, the molecular axis tilts from the normal to the layer plane, and the molecular dipoles align in the same direction, yielding a net polarization. If such liquid crystalline molecules are introduced into the backbone or as a side group on a polymer, a ferroelectric liquid crystalline polymer can be obtained. There are three requirements for spontaneous polarization in a liquid crystal: a center of chirality, a dipole moment positioned at the chiral center that acts transverse to the molecular long axis, and a tilted smectic phase (25).

Polyureas. Polyureas are thermosets, long used as insulators in a number of applications. Until a few years ago, ureas were available mostly as insoluble powders or highly cross-linked resins. In 1987, a vapor deposition polymerization method was successfully developed that was later applied to synthesizing polyureas (26,27). Typically, a vapor deposition technique is used by evaporating OCN–R_1–NH_2 and H_2N–R_2–NH_2 monomers simultaneously on a substrate (where R_1 and R_2 are various aliphatic or aromatic groups). This prevents cross-linking and allows processing thicknesses in the hundreds of nanometers to tens of micrometers.

An exploration (27) of the dielectric and pyroelectric properties of polyurea films led to the discovery of their piezoelectricity. From the early 1990s to the

present, various aromatic and aliphatic polyureas were synthesized, and it was shown that they are piezoelectric (28,29). Aromatic polyureas were the first polyurea structures identified as piezoelectric. They exhibit a piezoelectric e constant of 15 mC/m^2 and have high temperature stability, which remains independent of temperature up to 200°C. Their pyroelectric coefficient is high because of their low dielectric loss compared to other polymers. The d constant is about 5 pC/N at room temperature and increases as temperature increases (28).

Owing to their structures, aliphatic polyureas possess higher flexibility in their molecular chains. Similarly to polyamides, hydrogen bonds play a large role in stabilizing the orientation polarization that is imparted. Polyureas that have an odd number of methyl groups exhibit overall nonzero polarization. Polyurea-9 was synthesized and processed first, and an e constant of 5 mC/m^2 was reported (29). Then, polyureas that have a smaller number of carbons were attempted because it was surmised that they should lead to a higher density of urea bond dipoles. Toward that end, polyurea-5 was synthesized, and it was found that the e and d constants are twice those of polyurea-9. Aliphatic polyureas exhibit ferroelectric hysteresis and in addition, are piezoelectric when they have odd numbers of methyl groups. Their thermal stability and piezoelectric coefficients depend highly on the poling temperature (typically 70–150°C) but are lower than those of aromatic polyureas.

Biopolymers. Piezoelectricity of biopolymers was first reported in keratin in 1941 (30). When a bundle of hair was immersed in liquid air, an electric voltage of a few volts was generated between the tip and the root. When pressure was applied on the cross section of the bundle, an electric voltage was generated. Subsequently, piezoelectricity has been observed in a wide range of other biopolymers including collagen (31,32), polypeptides like poly(γ-methylglutamate) and poly(γ-benzyl-L-glutamate) (33,34), oriented films of DNA (35), poly(lactic acid) (36), and chitin (37). Most natural biopolymers possess D_∞ symmetry and so they exhibit shear piezoelectricity. A shear stress in the plane of polarization produces an electric displacement perpendicular to the plane of the applied stress and results in a $-d_{14} = d_{25}$ piezoelectric constant. The piezoelectric constants of biopolymers are small relative to synthetic polymers; they range in value from 0.01 pC/N for DNA to 2.5 pC/N for collagen. The electromechanical effect in such polymers is attributed to the internal rotation of polar atomic groups linked to asymmetrical carbon atoms. Keratin and some polypeptide molecules assume an α-helical or a β-sheet crystalline structure in which the CONH dipoles align synergistically in the axial direction.

Currently, the physiological significance of piezoelectricity in many biopolymers is not well understood, but it is believed that such electromechanical phenomena may have a distinct role in biochemical processes. For example, it is known that electric polarization in bone influences bone growth (38). In one study, a piezoelectric PVDF film was wrapped around the femur of a monkey. Within weeks, a remarkable formation of new bone was observed. The motion of the animal caused deformation of the film, which produced a neutralizing ionic current in the surrounding tissue. This minute fluctuating current appears to stimulate the metabolic activity of bone cells and leads to the proliferation of bone.

Amorphous Polymers

The purpose of this section is to explain the mechanism and key components required for developing piezoelectricity in amorphous polymers and to present a summary of the polarization and electromechanical properties of the amorphous polymers currently under investigation.

Dielectric Theory. The piezoelectricity in amorphous polymers differs from that in semicrystalline polymers and inorganic crystals in that the polarization is not in a state of thermal equilibrium, but rather a quasi-stable state because of the freezing-in of molecular dipoles. The result is a piezoelectric-like effect. A theoretical model for polymers that have frozen-in dipolar orientation was presented to explain piezoelectricity and pyroelectricity in amorphous polymers such as poly(vinyl chloride) (39).

One of the most important properties of an amorphous piezoelectric polymer is its Glass Transition temperature because it dictates use temperature and defines the poling process conditions. T_g is (the temperature below which the material exhibits glass-like characteristics, and above which it has rubber-like properties). Orientation polarization of molecular dipoles is responsible for piezoelectricity in amorphous polymers. It is induced, as shown in Figure 5, by applying an electric field E_p at an elevated temperature ($T_p \geq T_g$) where the molecular chains are sufficiently mobile and allow dipole alignment with the electric field. Partial retention of this orientation is achieved by lowering the temperature below T_g in the presence of E_p, resulting in a piezoelectric-like

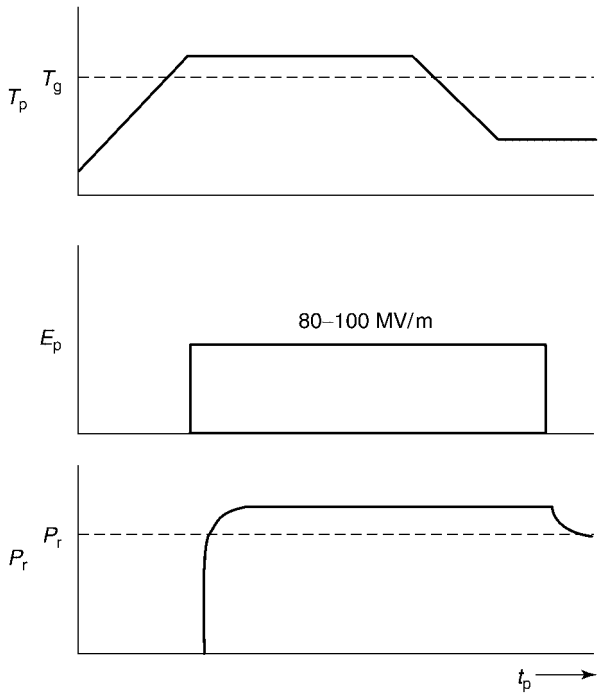

Fig. 5. Poling profile of an amorphous polymer.

effect. The remanent polarization P_r is directly proportional to E_p and the piezoelectric response. The procedure used to prepare a piezoelectric amorphous polymer clearly results in both oriented dipoles and space or real charge injection. The real charges are usually concentrated near the surface of the polymer, and they are introduced because of the presence of the electrodes. Interestingly, some researchers (40,41) have shown that the presence of space charges does not significantly affect piezoelectric behavior. The reason is twofold. The magnitude of space charges is usually not significant with respect to polarization charges. Secondly, space charges are essentially symmetrical with respect to the thickness of the polymer; therefore, when the material is strained uniformly, the contribution to the piezoelectric effect is negligible.

In what follows, the origins of the dielectric contribution to the piezoelectric response of amorphous polymers are addressed. The potential energy U of a dipole μ at an angle θ with the applied electric field is $U = \mu\ \mathbf{E} \cos\theta$. Using statistical mechanics and assuming Boltzman's distribution of dipole energies, the mean projection of the dipole moment $\langle\mu\rangle_E$ in the direction of the applied electric field is obtained:

$$\frac{\langle\mu_E\rangle}{\mu} = \coth\frac{\mu E_p}{kT} - \frac{kT}{\mu E} \tag{11}$$

This is the Langevin equation that describes the degree of polarization in a sample when an electric field E is applied at temperature T. Experimentally, a poling temperature in the vicinity of T_g is used to maximize dipole motion. The maximum electric field that may be applied, typically 100 MV/m, is determined by the dielectric breakdown strength of the polymer. For amorphous polymers, $\mu E/kT$ is much less than 1; this places these systems well within the linear region of the Langevin function. The remanent polarization P_r is simply the polarization during poling minus the electronic and atomic polarizations that relax at room temperature, once the field E_p is removed. The following linear equation for remanent polarization results when the Clausius–Mossotti equation is used to relate the dielectric constant to the dipole moment (42):

$$P_r = \Delta\varepsilon\ \varepsilon_0 E_p \tag{12}$$

It can be concluded that remanent polarization and hence the piezoelectric response of a material are determined by $\Delta\varepsilon$; this makes it a practical criterion to use when designing piezoelectric amorphous polymers. The Dielectric relaxation strength $\Delta\varepsilon$ may be the result of either free or cooperative dipole motion. Dielectric theory yields a mathematical approach for examining the dielectric relaxation $\Delta\varepsilon$ due to free rotation of the dipoles. The equation incorporates Debye's work based on statistical mechanics, the Clausius–Mossotti equation, and the Onsager local field and neglects short-range interactions (43):

$$\Delta\varepsilon_{\text{calculated}} = \frac{N\mu^2}{3kT\varepsilon_0}\left(\frac{n^2+2}{3}\right)^2\left[\frac{3\varepsilon(0)}{2\varepsilon(0)+n^2}\right]^2 \tag{13}$$

where N is the number of dipoles per unit volume, k is the Boltzmann constant, $\varepsilon(0)$ is the static dielectric constant, and n is the refractive index. One way to measure P_r in amorphous polymers is the thermally stimulated current (TSC) method (refer to section on characterization). P_r can be calculated from the liberated charge during TSC, and by reconciling that with the Onsager relationship, the dipole density can be calculated:

$$P_r = \frac{N\mu^2 E_p}{3kT_p}\left(\frac{\varepsilon_\infty + 2}{3}\right)^2\left[\frac{3\varepsilon(0)}{2\varepsilon(0)+\varepsilon_\infty}\right] \tag{14}$$

The piezoelectric constants are related to the polarization. From basic thermodynamics,

$$d_{3i} = \left(\frac{\partial P}{\partial \sigma_i}\right)_{\gamma,T} \tag{15}$$

A molecular theory of the direct piezoelectric effect in poled amorphous piezoelectric polymers has been developed. An expression for the hydrostatic coefficient appears in the original paper (41). Later, this theory was extended, and an equation for d_{31} was obtained (44,45). By differentiating equation 14 and modifying it to account for dimensional effects such as stretching (44,46),

$$d_{31} = P_r(1-\gamma)S_{11} + \frac{P_r(1-\gamma)}{3}(\varepsilon_\infty - 1)S_{11} \tag{16}$$

where γ is Poisson's ratio, ε_∞ is the permittivity at high frequencies, and S_{11} is the compliance of the polymer. The first term accounts for dimensional effects, and the second term gives the contribution of the local field effect.

Polarizability and Poling Conditions. Designing an amorphous polymer that has a large dielectric relaxation strength and hence piezoelectric response requires the ability to incorporate highly polar groups at high concentrations and cooperative dipole motion. A study of the relationship between relaxation times, poling temperatures, and poling fields is crucial to achieving optimal dipole alignment. Theoretically, the higher the electric field, the better the dipole alignment. The value of the electric field is limited, however, by the dielectric breakdown of the polymer. In practice, 100 MV/m is the maximum field that can be applied to these materials. Poling times need to be of the order of the relaxation time of the polymer at the poling temperature.

During poling, the temperature is lowered to room temperature, while the field is still on, to freeze-in the dipole alignment. In a semicrystalline material, however, locking-in the polarization is supported by the crystalline structure of the polymer, and it is therefore stable above the glass-transition temperature of the polymer. Because the remanent polarization in amorphous polymers is lost in the vicinity of T_g, their use is limited to temperatures well below T_g. This means that the polymers are used in their glassy state, where they are quite stiff and thus limit the ability of the polymer to strain as stress is applied. A piezoelectric amorphous polymer may be used at temperatures near its T_g to optimize its mechanical properties, but not too close so as to maintain the remanent polarization.

Although there are few data that address the stability of piezoelectric activity in amorphous polymers, it is clear that time, pressure, and temperature can contribute to dipole relaxation in these polymers. For a given application and use temperature, the effect of these parameters on the stability of the frozen-in dipole alignment should be determined.

Examples of Amorphous Piezoelectric Polymers. The literature on amorphous piezoelectric polymers is much more limited than that for semicrystalline systems. This is in part because no amorphous piezoelectric polymers have responses high enough to attract commercial interest. Much of the previous work on amorphous piezoelectric polymers was in nitrile-substituted polymers, including polyacrylonitrile (PAN) (47–49), poly(vinylidene cyanide–vinyl acetate) (PVDCN/VAc) (50–54), poly(phenyl ether nitrile) (PPEN) (55,56), and poly(1-bicyclobutanecarbonitrile) (57). Weak piezoelectric activity in poly(vinyl chloride) (PVC) and poly(vinyl acetate) (PVAc) has also been found (11,41,58,59). The most promising of these materials are vinylidene cyanide copolymers that exhibit large dielectric relaxation strengths and strong piezoelectricity. Table 4 shows the molecular structures of the most commonly encountered amorphous piezoelectric polymers.

Poly(vinylidene chloride). The carbon–chlorine dipole in poly(vinylidene chloride) (PVDC) has been oriented to produce a low level of piezoelectricity. The piezoelectric and pyroelectric activities generated in PVDC are stable and reproducible. PVDC has been used as a basis for understanding and studying piezoelectricity in amorphous polymers (39). The piezoelectric coefficients d_{31} of PVDC are reportedly in the range of 0.5–1.3 pC/N. This response was improved by simultaneous stretching and corona poling of film (44). The enhanced piezoelectric coefficient d_{31} ranged from 1.5–5.0 pC/N (see VINYLIDENE CHLORIDE POLYMERS (PVDC)).

PVDCN Copolymers. In 1980, exceptionally strong piezoelectric activity was found (50) in the amorphous copolymer of VDCN and VAc. The copolymer was poled at 150°C (20°C below its T_g) and cooled to room temperature in the electric field. A $P_r = 55$ mC/m^2 was obtained in a poling field of 50 MV/m. That is comparable to the P_r of PVDF. When local ordering, or paracrystallinity, is inherent in the polymer or is induced by mechanical stretching, an increase in the value of the remanent polarization is observed. For example, some researchers (51) assert that the large discrepancy between the measured and calculated $\Delta\varepsilon$ for PVDCN/VAc may be attributed to locally ordered regions in the polymer. $\Delta\varepsilon_{\text{calculated}} = 30$ for the copolymer PVDCN/VAc, and $\Delta\varepsilon_{\text{measured}} = 125$ (51). This large discrepancy in the values of $\Delta\varepsilon$ is indicative of cooperative motion of several nitrile dipoles within the locally ordered regions of the polymers. Cooperativity means that multiple nitrile dipoles respond to the applied electric field in a unified manner, instead of each dipole acting independently. Although the existence of cooperative dipole motion clearly increases the piezoelectric response of amorphous polymers, the mechanisms by which cooperativity can be systematically incorporated into the polymer structure remain unclear at this time (59).

The large relaxation strength exhibited by PVDCN/VAc gives it the largest value of P_r and hence d_{31} of all of the amorphous polymers. A number of authors have suggested that PVDCN/VAc also exhibits ferroelectric-like behavior (51–53) because of switching of the nitrile dipoles in an a.c. field. The switching time is long compared to that of a normal ferroelectric polymer.

Table 4. Structure, Polarization, and T_g of Piezoelectric Amorphous Polymers

Polymer	Structure	T_g, °C	d_{31}, pC/N	P_r, mCm^2	Reference
PVC		80	5	16	44
PAN		90	2	25	49
PVAc		30	—	5	59
P(VDCN/VAc)		170	10	50	51
PPEN		145	—	12	55
(β-CN) APB/ODPA		220	5 at 150°C	20	59

Other VDCN Polymers. The homopolymer of vinylidene cyanide is thermally unstable (60) and highly sensitive to moisture, but VDCN can be polymerized with a variety of monomers in addition to VAc, such as vinyl benzoate (VBz), methyl methacrylate (MMA), and others that form highly alternating chains. All of these copolymers show some degree of piezoelectricity although lower than PVDCN/VAc, which is explained by different activation energies for dipole orientation in the glassy state and different chain mobility that depends on the side group.

Polyacrylonitrile. Polyacrylonitrile (PAN) is one of the most widely used polymers (see ACRYLONITRILE POLYMERS). Shortly after it was shown that the PVDCN/VAc system is piezoelectric, researchers turned their attention to PAN because of its similarity to the aforementioned polymers. The presence of the large nitrile dipole in PAN indicated that it can be oriented by an applied electric field. PAN presented some challenges not encountered in other nitrile-substituted polymers, however. Although theoretical calculations predicted strong piezoelectric behavior, it was difficult to pole. Several investigators (47–49) proposed that the difficulty of poling PAN in the unstretched state is related to the strong dipole–dipole interaction of nitrile groups of the same molecule that repel each other, and thus prevent normal polarization. Upon stretching, the intermolecular dipole interactions facilitate packing of the individual chains and give rise to ordered zones. The remanent polarization of both unstretched and stretched PAN has been measured using the TSC method, and a twofold increase in remanent polarization (TSC peak at 90°C) was observed for PAN that was stretched to four times its original length (47). Another approach is the copolymerization of PAN with another monomer. Researchers have reported reduction of the hindering effect of the dipole–dipole interactions and enhancement of the internal mobility of the polymer segments when PAN is copolymerized with PA(polystyrene) or MMA. Ferroelectric behavior has been observed in P(AN–MMA), where, for given temperature and field conditions, a characteristic hysteretic loop is obtained (49). It was concluded that it may be one rare example where both ferroelectric and frozen-in dipole orientations are superimposed.

Nitrile-Substituted Polyimide. Amorphous Polymers that contain polar functional groups were synthesized (61–63) and investigated for use as high temperature piezoelectric sensors. (β-CN) APB/ODPA polyimide is one such system. The (β-CN) APB/ODPA polyimide possesses the three dipole functionalities shown in Table 5. Typically, the functional groups in amorphous polymers are pendent to the main chain. The dipoles, however, may also reside within the main chain of the polymer, such as the anhydride units in the (β-CN) APB/ODPA polyimide. The nitrile dipole is pendent to a phenyl ring ($\mu = 4.2$ D), and the two anhydride dipoles ($\mu = 2.34$ D) are within the chain, resulting in a total dipole moment of 29.4×10^{-30} C·m (8.8 D) per repeat unit.

The remanent polarization P_r of the (β-CN) APB/ODPA polymer found by the TSC method was approximately 20 mC/m^2 when poled at 80 MV/m above the T_g for 1 h (64). Excellent thermal stability was observed up to 100°C, and no loss of the piezoelectric response was seen after aging at 50°C and 100°C for as long as 500 h.

Partially cured films of the (β-CN) APB/ODPA system were simultaneously corona-poled and cured to enhance dipolar orientation and minimize localized

Table 5. Values of Dipole Moments Within Nitrile-Substituted Polyimide

Dipoles	Dipole identity	Dipole moment, C·m[a]
	Pendent nitrile group	1.39×10^{-29}
	Main-chain dianhydride group	7.8×10^{-30}
	Main-chain diphenyl ether group	4.33×10^{-30}

[a]To convert C·m to Debye, multiply by 2.997×10^{29}.

arcing during poling. The aligned polar groups should be immobilized by additional imidization and subsequent cooling in an electric field. Both the T_g and the degree of imidization increase almost linearly as the final cure temperature is increased (64). The value of P_r was higher for films cured at lower temperatures. The mobility of the molecules in a partially imidized state should be higher than that in the fully cured state and therefore produce a higher degree of dipole orientation.

The importance of dipole concentration in ultimate polarization is evident from a comparison of PAN and the (β-CN) APB/ODPA polyimide. PAN has a single nitrile dipole per repeat unit ($\mu = 3.5$ D) resulting in a dipole concentration of $1.34 \times 10^{28}/m^3$. This translates into an ultimate polarization of 152 mC/m^2 (20). The (β-CN) APB/ODPA polyimide, on the other hand, has a total dipole moment of 8.8 D per monomer. The dipole concentration of (β-CN) APB/ODPA, however, is only $0.136 \times 10^{28}/m^3$, resulting in an ultimate polarization of 40 mC/m^2, which is less than a fourth of that of PAN. As a result, similar polyimides that have increased nitrile concentrations were synthesized and characterized. Studies of these polymers show that polarization is significantly increased by increasing dipole concentration. Structure–property investigations designed to assess the effects of these dipoles on T_g, thermal stability, and overall polarization behavior are currently being pursued.

Even-Numbered Nylons. Nylon 6I and 6I/6T exhibit a *D–E* hysteretic loop across a temperature range of 30–65°C at a fixed maximum field of 168 MV/m (65). The remanent polarization increases as the temperature increases. Note that nylon 6I and 6I/6T are completely amorphous. The P_r is about 30 mC/m^2 (see POLYAMIDES, AROMATIC).

Aliphatic Polyurethane. Some researchers (1) have suggested that aliphatic polyurethane systems exhibit ferroelectricity that stems from the amorphous part at temperatures above the glass-transition temperature. This "liquid state"

ferroelectricity is very peculiar, seems to exist, and is supported by the hydrogen bonds present.

Characterization and Modeling

Most piezoelectric characterization methods were developed for crystalline ceramics and had to be adapted for piezoelectric polymers. Methods based on resonance analysis and equivalent circuits that can be used to characterize semicrystalline PVDF and its copolymers are outlined in IEEE standards (66). Details for applying resonance analysis to piezoelectric polymers have recently been explored (67). Because of the lossy nature of some polymers, the IEEE standards are not adequate, and other techniques are needed to describe piezoelectric properties more accurately.

Quasi-static direct methods are both versatile and well suited to investigating fully the piezoelectric response of polymers. Direct methods of this type are especially appropriate for amorphous polymers. TSC measurements (68) are used to measure the remanent polarization imparted to a polymer, and direct strain or charge measurements are used to investigate the piezoelectric coefficients with respect to the electric field, frequency, and stress.

TSC is a valuable tool for characterizing piezoelectric polymers. After poling a polymer, a measure of the current dissipation and the remanent polarization as a function temperature can be obtained by TSC. As the sample is heated through its glass-transition temperature (or Curie temperature for a semicrystalline polymer) at a slow rate (typically 1–4°C/min), the depolarization current is measured by an electrometer. The remanent polarization is equal to the charge per unit area and is obtained from the data by integrating the current with respect to time and plotting it as a function of temperature:

$$P_{\mathrm{r}} = \frac{Q}{A} = \frac{1}{A}\int I(t) - \mathrm{d}t. \tag{17}$$

Figure 6 illustrates a typical TSC result. Because permanent dipoles are immobile at temperatures well below T_{g}, the current discharge remains low in this temperature range. As temperature increases to and beyond the T_{g}, however, the onset of dipole mobility contributes to a significant increase in the current peak. The peak in the current and the subsequent polarization maximum usually occurs in the vicinity of the T_{g}.

Direct methods for measuring the strain that results from applying a field or vice versa, applying a strain, and measuring the accumulated charge are abundant. Interferometers, dilatometers, fiber-optic sensors, optical levers, linear variable displacement transducers, and optical methods are employed to evaluate the piezoelectric strain (converse effect) (69–72). The "out-of-plane" or thickness piezoelectric coefficient d_{33} can be ascertained as a function of the driving field and frequency. The coefficient is measured based on the equation

$$S_{33} = d_{33}E_3, \tag{18}$$

where S_{33} is the strain and E_3 is the applied electric field.

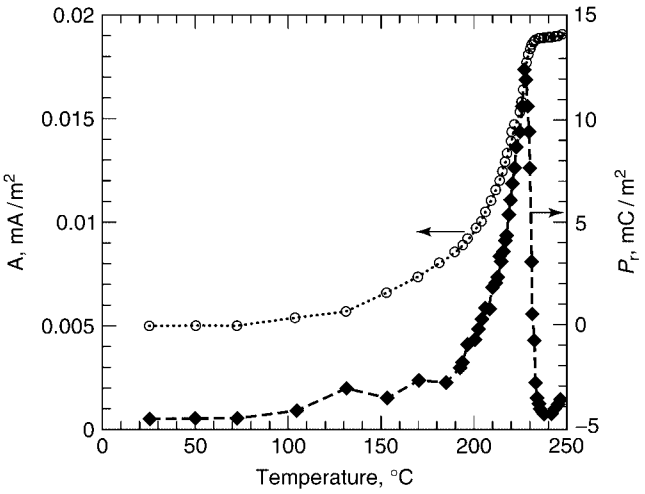

Fig. 6. Plot of thermally stimulated current for a typical amorphous poled polymer.

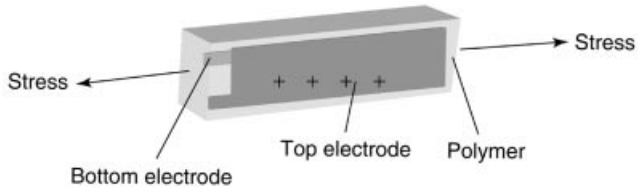

Fig. 7. Direct effect in polymers.

A modified Rheovibron, or similar techniques, have been used to measure the direct piezoelectric effect, where charges accumulated on the surfaces of the polymer are measured (59). The piezoelectric coefficient d_{31} can be obtained by straining the polymer in the direction of applied stress using a force F as depicted in Fig. 7. A charge Q is generated on the surface of the electrodes. A geometric factor is used to produce a geometrically independent parameter, surface charge density per unit applied stress:

$$d_{31} = \frac{Q/(WL)}{F/(Wt)}, \tag{19}$$

which has units of pC/N. W, L, and t are the width, length, and thickness of the sample, respectively.

Modeling. The methodology for modeling piezoelectric behavior in polymers varies, depending on the targeted properties. Approaches cover the range from macroscale to micro and atomistic scales. A detailed review of computational methods applied to electroactive polymers has been published (73).

In some cases, modeling can predict behavior where experiments cannot. Using molecular dynamics, the orientation polarization of the (β-CN) APB/ODPA polymer was assessed by monitoring the angle θ that the dipoles make with an

applied electric field (74). The bulk P_r was calculated, and the results agreed extremely well with experimental results (61). Computational modeling, however, gave insight into the contributions of the various dipoles present in a way experimental results could not. The model predicted that 40% of the orientation polarization was due to the dianhydride within the backbone of the ODPA monomer and demonstrated the importance of the flexible ether linkage (oxygen atom) in facilitating dipole alignment. Modeling insight of this kind is invaluable in guiding the synthesis of new materials.

Modeling of PVDCN/VAc can also play a role in understanding the cooperative motion responsible for the high dielectric relaxation strength of this class of polymers, not possible experimentally (75). Mesoscale simulation has been used to describe polarization reversal in PVDF films (76).

Applications and Future Considerations. The potential for applying piezoelectric and other electroactive polymers is immense. To date, ferroelectric polymers have been incorporated into numerous sensing and actuating devices for a wide array of applications. Typical applications include devices in medical instrumentation, robotics, optics, computers, and ultrasonic, underwater, and electroacoustic transducers. One important emerging application area for electroactive polymers is the biomedical field where polymers are being explored as artificial muscle actuators, as invasive medical robots for diagnostics and microsurgery, as actuator implants to stimulate tissue and bone growth, and as sensors to monitor vascular grafts and to prevent blockages (77,78). Such applications are ideal for polymers because they can be made biocompatible, and they have excellent conformability and impedance that match body fluids and human tissue. The intent of this article is not to detail specific applications; the interested reader may consult excellent sources on applications of piezoelectric and ferroelectric polymers (79–81).

In the future, we believe that fertile research areas for piezoelectric polymers will include work to enhance their properties, to improve their processibility for incorporation in devices, and to develop materials that have a broader use temperature range. Fundamental structure–property understanding has enabled the development of numerous semicrystalline and amorphous polymers. Based on this knowledge, future research that focuses on property enhancement via new chemistries that have higher dipole concentrations and incorporate dipole cooperativity may yield improved materials. Property enhancements may also be gained from processing studies to alter polymer morphology such as those used to make "single crystalline" fluoropolymers. Development of materials that can operate in extreme environments (high temperature and subambient temperature) is also important for expanding the use of piezoelectric polymers. Piezoelectric and pyroelectric constants of polymers are considerably lower than those of ferroelectric inorganic ceramics. Improvements in properties by incorporating polymers in composites with inorganics to obtain higher electromechanical properties and better mechanical properties are also valuable. To date, piezoelectric polymer–ceramic composites have been made wherein the polymer serves only as an inactive matrix for the active ceramic phase. This is due to the mismatch in permittivity between the polymer and ceramic which makes it difficult to pole both phases. Research that results in active polymer and ceramic phases could yield interesting electromechanical properties.

PLASTICIZERS

Introduction

A plasticizer is a liquid that is added to a material (usually a resin or elastomer) making that material softer, more flexible (by decreasing the glass-transition temperature T_g of the polymer), and easier to process. This broad definition encompasses the use of water to plasticize clay for the production of pottery, and oils to plasticize pitch for caulking boats. The most widely plasticized polymer is poly(vinyl chloride) (PVC) because of its excellent plasticizer compatibility characteristics. The development of plasticizers closely follows the development of this commodity polymer; however, plasticizers are also used with other polymer types.

The amount of plasticizer added to a polymer varies depending on the effect required. A small addition of plasticizer may be made to improve the workability of the polymer melt. This contrasts with large additions made with the specific intention of completely transforming the properties of the product. PVC without a plasticizer, ie, unplasticized PVC (PVC-U), is used in applications such as pipes, siding, and window profiles. With plasticizer added, articles such as automotive interior trim, jacketing, cable insulations, and PVC floorings are formed.

There are presently ~300 plasticizers manufactured. Of these ~100 are of commercial importance. A list of some common commodity and specialty plasticizers can be found in Table 1.

Types of Plasticizers

Two principal methods exist for softening a polymer to bring about the dramatic effects of plasticization. A rigid polymer may be internally plasticized by chemically

Diisodecyl adipate (DIDA)	10	426	77	0.916	25
Triheptylnonyl trimellitate (TnHNTM)	l7, l9	530	16	0.984	105
Tri(2-ethylhexyl) trimellitate (TOTM)	8	530	21	0.987	220
Triisononyl trimellitate (TINTM)	9	589	13	0.975	315
Di(2-ethylhexyl) sebacate (DOS)	8	426	131	0.911	25
Di(2-ethylhexyl) azelate (DOZ)	8	412	147	0.914	15

[a]To convert Pa to mm Hg, divided by 133.3.
[b]l is linear.

modifying the polymer or monomer so that the flexibility of the polymer is increased. Alternatively, a rigid polymer can be externally plasticized by the addition of a suitable plasticizing agent. The external plasticizing route is more common because of lower overall costs, and the use of external plasticizers allows the processor a certain degree of freedom in developing formulations for a range of products.

Internal Plasticizers. There has been much dedicated work on the possibility of internally plasticized PVC (FPVC). However, in achieving this by copolymerization significant problems exist: (*1*) the affinity of the growing polymer chain for vinyl chloride rather than a comonomer implies that the incorporation of a comonomer into the chain requires significant pressure; (*2*) since the use of recovered monomer in PVC production is standard practice, contamination of vinyl chloride with comonomer creates additional problems, and (*3*) the complexity of the reaction can lead to longer reaction times and increased costs.

External Plasticizers. There are two groups of external plasticizers, primary and secondary. A primary plasticizer, when added to a polymer, causes elongation and softness to be increased. These changes are brought about by mechanisms described in the following section. A secondary plasticizer, when added to the polymer alone, does not bring about these changes and may have limited compatibility with the polymer. However, when added to the polymer in combination with a primary plasticizer, secondary plasticizers enhance the plasticizing performance of the primary plasticizer. Secondary plasticizers are also known as extenders.

Theory and Mechanism of Plasticizer Action

Four general theories have been proposed to explain external plasticizer action. Some theories involve detailed analysis of polarity, solubility, and interaction parameters and the thermodynamics of polymer behavior, whereas others treat plasticization as a simple lubrication of chains of polymer from each other. An understanding of the plasticization process can be gained by combining ideas from each theory, and an overall theory of plasticization must include all these aspects.

The steps involved in the incorporation of a plasticizer into a PVC product can be divided into five distinct stages:

(1) Plasticizer is mixed with PVC resin—adsorption step.
(2) Plasticizer penetrates and swells the resin particles—adhesion step.
(3) Polar groups in the PVC resin are freed from each other—absorption step.
(4) Plasticizer polar groups interact with the polar groups on the resin—intermolecular plasticizing step.
(5) The structure of the resin is re-established, with full retention of plasticizer—intramolecular plasticizing step.

Steps 1 and 2 can be described as physical plasticization, and the precise details of how this is carried out depends on the applications technology involved, ie, suspension or dispersion PVC. The rate at which step 2 occurs depends on the

plasticizer viscosity, degree of branching, resin pore size and free volume, and particle size.

Steps 3 and 4, however, can be described as chemical plasticization since the rate at which these processes occur depends on the chemical properties of molecular polarity, molecular volume, and molecular weight. An overall mechanism of plasticizer action must give adequate explanations for this as well as the physical plasticization steps.

The importance of step 5 cannot be stressed too strongly, since no matter how rapidly and easily steps 1–4 occur, if plasticizer is not retained in the final product the product will be rendered useless.

The Lubrication Theory. The lubrication theory is based on the assumption that the rigidity of the resin arises from intermolecular friction binding the chains together in a rigid network. On heating, these frictional forces are weakened to allow the plasticizer molecules to lubricate the chains. Once incorporated into the polymer, the plasticizer molecules shield the chains from each other, thus preventing the reformation of the rigid network (1).

The Gel Theory. This theory extends the lubrication theory by having the plasticizer break the resin–resin attachments of a three-dimensional honeycomb or gel structure and by masking these centers of attachment from each other, preventing their reformation. This gel is formed by loose attachments occurring at intervals along the polymer chain. This facilitates the movement of plasticizer molecules, thus imparting flexibility.

The Free Volume Theory. The Free Volume Theory is a further extension of the lubricity and gel theories and can be used to explain both external and internal plasticization. Free volume is a measure of the internal space available in a polymer for the movement of the polymer chain, which imparts flexibility to the resin. Plasticizers increase the free volume of the resin and ensure that free volume is maintained as the resin–plasticizer mixture is cooled from the melt, preventing interactions between neighboring polymer chains. For the plasticized resins, free volume can arise from motion of the chain ends, side chains, or the main chain. The fact that free volume increases with molecular motion is useful in explaining internal plasticization achieved by side-chain addition, where each side chain acts as a small molecule and free volume of the system is increased.

The introduction of a plasticizer, which is a molecule of lower molecular weight than that of the resin, has the ability to impart a greater free volume per volume of material because there is an increase in the proportion of end groups and the plasticizer has a glass-transition temperature (T_g) lower than that of the resin itself.

Thermodynamic or Mechanistic Theory. From the observation of migration of plasticized polymers it is clear that plasticizer molecules are not bound permanently to the polymer, but rather a dynamic equilibrium exists between solvation and desolvation of the polymer chains by plasticizer. Different families of plasticizers are attracted to the polymer by forces of different magnitude but the attraction is not permanent. There is a continuous exchange where a plasticizer molecule becomes attached to an active group on the polymer chain only to be dislodged and replaced by another plasticizer molecule.

Antiplasticization. Many resins tend to become more ordered and compact as existing crystallites grow or new crystallites form at the expense of the fluid

parts of the amorphous material. For small additions of plasticizer, the plasticizer molecules may be totally immobilized by attachment to the resin by various forces. These tend to restrict the freedom of small portions of the polymer molecule necessary for the absorption of mechanical energy. This results in a more rigid resin with a higher tensile strength and base modulus than the base polymer itself. This phenomenon is termed antiplasticization. Above these low concentrations the polymer becomes plasticized.

Interaction Parameters.

The Hildebrand Solubility Parameter. This parameter, defined by δ (eq. 1), can be estimated based on data for a set of additive constants F, for the more common groups in organic molecules to account for the observed magnitude of the solubility parameter:

$$\delta = \sum F/V \tag{1}$$

where V represents molar volume. Solubility parameters can be used to classify plasticizers of a given family in terms of their compatibility with PVC (2).

Polarity Parameter. This parameter, defined by ϕ (eq. 2), shows a good correlation with plasticizer activity for nonpolymeric plasticizers. The parameter is defined as

$$\phi = [M(A_p/P_0)]/1000 \tag{2}$$

where M is the molar mass of plasticizer, A_p the number of carbon atoms in the plasticizer excluding aromatic and carboxylic acid carbon atoms, and P_0 the number of polar (eg, carbonyl) groups present. The 1000 factor is used to produce values of convenient magnitude. Polarity parameters provide useful predictions of the activity of monomeric plasticizers but not activity of plasticizers from different families.

The Solid-Gel Transition Temperature. This temperature or clear point, T_m, is a measure of plasticizer activity and is the temperature at which a single grain of PVC dissolves in excess plasticizer. The more efficient plasticizers show lower values of T_m as a result of their higher solvating power. This can be correlated with the ease of processing of a given plasticizer, with a control PVC resin.

The Flory–Huggins Interaction Parameter. These ideas, based on a study of polymer miscibility, have been applied to plasticizers according to the following equation (eq. 3) in which V_1 is the molar volume of the plasticizer, obtained from molar mass figures and density values at T_m, and χ represents the interaction parameter.

$$1/T_m = 0.002226 + 0.1351(1 - \chi)/V_1 \tag{3}$$

Specific Interactions. Some mechanism of attraction and interaction between PVC and plasticizer must exist for the plasticizer to be retained in the polymer after processing.

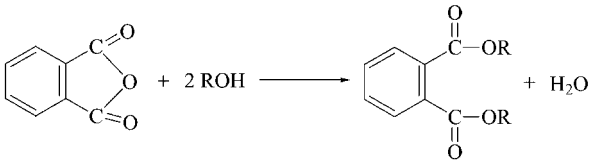
The role of specific interactions in the plasticization of PVC between the carbonyl functionality of the plasticizer were proposed on the basis of results from Fourier transform infrared spectroscopy. Reported shifts in the absorption frequency of the carbonyl group of the plasticizer ester to lower wave number are indicative of a reduction in polarity. These ideas have been extended using newer analytical techniques, in particular molecular modeling and solid-state nuclear magnetic resonance spectroscopy (nmr).

Molecular Modeling. A range of plasticizer molecule models and a model for PVC have been generated and energy minimized to observe their most stable conformations. Such models highlight the free volume increase caused by the mobility of the plasticizer alkyl chains. More detailed models have also been produced to concentrate on the polar region of the plasticizer and its possible mode of interaction with the polymer (3).

Solid-State Nuclear Magnetic Resonance Spectroscopy. Advances in technology have made the study of solids by NMR techniques of considerably greater ease. For the accumulation of solid-state ^{13}C nmr spectra, cross-polarization magic angle spinning (cpmas) can be utilized to significantly reduce signal-broadening effects present in solid state but not in the liquid state. The technique has been used to study the molecular effects of plasticization by comparing spectral shifts of PVC and plasticizer under various degrees of processing.

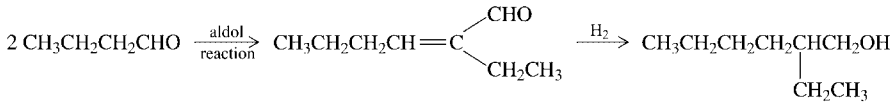
Phthalate Esters

The family of phthalate esters are the most abundantly produced worldwide. The plasticizer esters are produced from orthophthalic and terephthalic acid reacted with an appropriate alcohol (eq. 4). Phthalate esters are manufactured from methanol (C_1) up to C_{17} (4) alcohols although phthalate use as PVC plasticizers is generally in the range C_6 to C_{13}. Low molecular weight phthalates find use in nitrocellulose; higher phthalates as synthetic lubricants for the automotive industries.



(4)

Di-2-ethylhexyl phthalate(DEHP) [117-81-7], also known as dioctyl phthalate (DOP), is generally considered as the industry standard. The reason for this is that it is in the mid-range of plasticizer properties. DEHP (or DOP) is the phthalate ester of 2-ethylhexanol, which is normally manufactured by the dimerization of butyraldehyde (eq. 5), the butyraldehyde itself being synthesized from propylene.

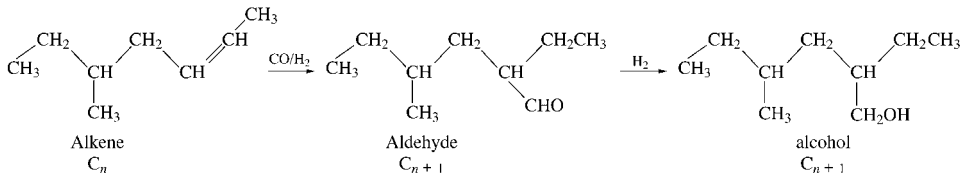


(5)

The widespread use of this plasticizer is a reflection of its all-around general-purpose plasticizing performance and its properties, suitable for a great many standard products. It possesses good plasticizing efficiency, fusion rate, and viscosity which, coupled with a competitive price, make it attractive to the PVC compounder and processor.

Diisononyl phthalate and diisodecyl phthalate are produced by esterification of oxo-alcohols of carbon chain length 9 and 10. The oxo-alcohols are produced through the carbonylation of alkenes (olefins). The hydroformylation or carbonylation process (eq. 6) adds a carbon unit to an alkene chain by reaction with carbon monoxide and hydrogen with heat, pressure, and catalyst. In this way a C_8 alkene is carbonylated to yield a C_9 alcohol. Because of the distribution of the C=C double bond in the alkene and the varying effectiveness of certain catalysts, the position of the added carbon atom can vary and an isomer distribution is generally created in such a reaction. The nature of this distribution depends on the reaction conditions. Consequently, these alcohols are termed *iso-alcohols* and the subsequent phthalates *iso-phthalates*.

Another method of producing a nonyl alcohol, which has gained predominance in the past few years, is by the dimerization process. In this process *n*-butylenes react to form an octene. Then through hydroformylation the 8-carbon olefin is converted to a nonyl alcohol (eq. 6). This alcohol has specific branching and some linearity that provides the corresponding ester with improved properties over esters made from isononyl alcohol.



(6)

The C_9 and C_{10} phthalates (DINP, DNP, and DIDP) generally compete with DEHP as commodity general-purpose plasticizers. Other phthalates are available at opposite ends of the carbon number range [eg, diisohexyl phthalate (DHP, C_6) and diisotridecyl phthalate (DTDP, C_{13})], but these serve more specialty markets. The C_8 phthalate, diisooctyl phthalate (DIOP), is also a commodity plasticizer where it is used as an alternate to DEHP for environmental reasons.

The fourth process used to produce phthalate alcohols is the Ziegler process and the Ziegler displacement process. In the Ziegler process straight chain even-numbered carbon alcohols are produced from ethylene. Triethylaluminum is produced from aluminum, hydrogen, and ethylene. With the addition of more

ethylene the chain is lengthened in two-carbon increments. Oxidation and hydrolysis yield the primary even-numbered alcohols.

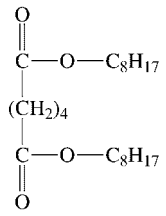
With the Ziegler displacement process the higher alkyl group is displaced from the chain growth product by ethylene. This yields a mixture of even-numbered linear alpha olefins with the trialkyl aluminum being recycled. The odd-numbered linear alcohols are produced through hydroformylation of the olefin and hydrogenation of the odd-numbered aldehydes.

The linear phthalates produced from these alcohols provide many advantages over their branched counterparts. Among these are processability, efficiency, volatility, viscosity, thermal stability, light stability, low temperature, and long-term permanence.

Citrate esters have gained some importance as an alternate to DEHP in medical, toy, and food applications. The citrate esters are more volatile, less compatible, more water sensitive, more difficult to fuse, and more costly than DEHP.

Adipate Esters

Alcohols of similar chain length to those used in phthalate manufacture can be esterified with adipic acid rather than phthalic anhydride to produce the family of adipate plasticizers. For example, esterification of 2-ethylhexanol with adipic acid yields di-2-ethylhexyl adipate (DEHA), also known as dioctyl adipate (DOA).

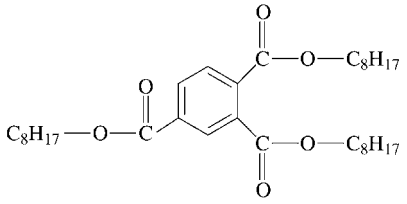


Di-2-ethylhexyl adipate

The family of adipic acid esters in PVC applications has improved low temperature performance relative to phthalates and lower plastisol viscosities, because of the lower inherent viscosities of the plasticizer. Adipates used are typically in the C_7–C_{10} range. Incompatibility problems can be encountered at higher carbon numbers, especially at high addition levels. Adipates are more volatile and have higher migration rates than phthalates. Because they are a specialty for the PVC industry, they are higher priced. As a result, it is not uncommon to encounter adipates used in blends with phthalates to produce a compromise of properties. Because of these limitations, linear phthalates are often used in place of adipates wherever possible.

Trimellitate Esters

These materials are produced by the esterification of a range of alcohols with trimellitic anhydride (TMA), which is similar in structure to phthalic anhydride with the exception of the third functionality (COOH) on the aromatic ring.



Tris-2-ethylhexyl trimellitate

Esters are produced in the ratio of 3 mol of alcohol to 1 mol of anhydride. Common esters in this family are tris-2-ethylhexyl trimellitate (trioctyl trimellitate, TOTM); L79TM, an ester of mixed linear C_7 and C_9 alcohols; L810TM, an ester of mixed linear C_8 and C_{10} alcohols; and trüsononyl trimellitate (TNTM), an ester based on isononyl alcohol.

In a flexible PVC compound the trimellitates are less volatile and have improved thermal stability over the phthalate and polymeric plasticizers. Their plasticizing effectiveness and compatibility are similar to phthalates. They offer better moisture and water resistance than the phthalates or polymeric plasticizers. Large volumes of trimellitate esters are used in 90°C and 105°C UL rated insulation compounds. Because of their extraction and migration resistance, thermal stability, and low volatility, the trimellitates are used in conjunction with 911P and DUP in automotive interior trim applications where windshield fogging is an issue.

Phosphate Esters

The principal advantage of phosphate esters is improved fire retardancy. The fire performance of PVC itself, relative to other polymeric materials, is very good because of its high halogen content, but the addition of plasticizers reduces this. Consequently, there is a need, in certain demanding applications, to improve the fire-retardant behavior of flexible PVC by reducing the limiting oxygen index (LOI) and smoke. Phosphate esters are combined with brominated phthalates for use in FPVC UL rated plenum cable applications. Tris-2-ethylhexyl phosphate shows good compatibility with PVC and also imparts good low temperature performance in addition to good fire retardancy.

2-Ethyhexyl diphenyl phosphate has widespread use in flexible PVC applications because of its combination of properties of plasticizing efficiency, low temperature performance, migration resistance, and fire retardancy.

Sebacate and Azelate Esters

Esters produced from 2-ethylhexanol and higher alcohols with linear aliphatic acids are used in some demanding flexible PVC applications where superior low temperature performance is required. Di-2-ethylhexyl sebacate (DOS) and di-2-ethylhexyl azelate (DOZ) are the commonly used members of this group. They offer superior low temperature performance but poorer compatibility, and command a significant premium. Their usage is generally limited to extremely demanding low temperature flexibility specifications, eg, underground jacketing cable in arctic environments.

Polymeric Plasticizers

Polymeric or polyester plasticizers are a class offering very good characteristics of low volatility, solvent, oil, stain, fat, and migration resistance to plasticized PVC. Polymerics usually are high molecular weight, linear, saturated, terminated polyesters of adipic, azelaic, or glutaric acids and propylene or butylene glycols. In most cases, termination is done by monohydric alcohols or monocarboxylic fatty acids. Polymerics have one of the following structures:

$$\underset{\mathbf{1}}{T_1\text{-}[G\text{-}A]_n\text{-}G\text{-}T_1} \qquad \underset{\mathbf{2}}{T_2\text{-}[A\text{-}G]_n\text{-}T_2}$$

where A is a dibasic acid, G a glycol, T_1, a fatty acid, T_2 a monohydric alcohol, and n the number of repeating units.

When polycondensation is carried out with a stoichiometric excess of acid (**1**), the carboxylic end groups are esterified with monoalcohols whereas with excess diol (**2**), the terminal hydroxy groups react with acetic acid or longer chain monocarboxylic acid. The polycondensation reaction yields a broad molecular weight distribution.

Choice of acid, glycol, and terminators is very important since the total architecture of the molecule is critical to achieve good compatibility with PVC because of the high molecular weight of the polyester. Because of their high molecular weight, polymeric plasticizers need to be heated up prior to dry blending and require a higher process temperature.

Because of lower efficiency than a monomeric plasticizer and higher costs, polymerics are used frequently in combination with phthalates to improve migration resistance and oil extraction characteristics over the phthalate system. Upholstery and aircraft seating subject to extraction by body or hair oil are examples of useful applications. Refrigerator gasketing, electrical tape, decals, and oil-resistant electrical wire use high levels of polymerics frequently as the sole plasticizer (5).

Polyester plasticizers range in viscosity from 900 to 300,000 m Pa·s (cP), as shown in Table 2. They can be classified as low, medium, and high viscosity products. As the viscosity increases the extraction resistance improves and the plasticizing efficiency decreases.

The chemical nature of the polymeric plasticizer can be used to classify them in relation to end-product performance. Table 2 shows that the acid component, diol component, and end groups as well as the molecular weight determine the performance properties.

Secondary Plasticizers

Also known as extenders, secondary plasticizers continue to play a significant role in flexible PVC formulations. They do not impart flexibility to the PVC resin alone, but when combined with a primary plasticizer act in such a way as to add flexibility and other properties to the final product (6). The majority of secondary plasticizers

Table 2. Polyester (Polymeric) Plasticizers: Composition, Properties, and Applications

Dicarboxylic acid	Diol	Viscosity	Properties and applications
Adipic acid	1,2-Propane diol, 1,3-propane diol, 1,3-butane diol, 1,4-butane diol, 1,6-hexane diol, neopentyl glycol	High, >10,000 mPa·s (cP); medium, 4000–8000 mPa·s (cP)	High resistance to gasoline, oils, fats, and bitumen; migration-resistant; tubing, films, cable insulation, and jacketing
		Low, <4000 mPa·s (cP)	Oil and fat resistance markedly less satisfactory; for spread coating alone or in combination with high viscosity esters; other uses as above
Azelaic acid	1,2-Propane diol, 1,3-propane diol, 1,3-butane diol, 1,4-butane diol, 1,5-pentane diol, 1,6-hexane diol	High, >10,000 mPa·s (cP)	High oil, gasoline, and fat resistance; adhesive tapes; other uses as for polysebacates
		Medium, 4000 to 8000 mPa·s (cP)	Easily processible; good compatibility; generally applicable polyester plasticizers
o-Phthalic acid	Ethylene glycol, 1,2-Propane diol, 1,3-Propane diol, 1,3-Butane diol, 1,4-Butane diol	Low, <4000 mPa·s (cP)	Easily processible; poor resistance to oils, fats, gasoline; reduced flexibility at low temperature
		<2000 mPa·s (cP)	Easy processing; for special applications
Sebacic acid	Ethylene glycol, 1,3-Propane diol, 1,3-Butane diol, 1,4-Butane diol, Neopentyl glycol	High, >10,000 mPa·s (cP)	Good resistance to gasoline, oil, fat, uv light; highly migration-resistant; good electrical properties; for high quality articles
		Medium, 4000–8000 mPa·s (cP)	Good compatibility with PVC, easily processible; for spread coating; protective clothing

in use are chlorinated paraffins, which are hydrocarbons chlorinated to a level of 30–70%. For a given hydrocarbon chain, viscosity increases with chlorine content, as does the fire retardancy imparted to the formulation. These materials aid fire retardancy because of their chlorine content. Chlorinated paraffins of the same chlorine content may have different volatilities and viscosities if they are based on different hydrocarbon chains.

Phthalate-chlorinated paraffin compatibility decreases as the molecular mass of the phthalate and the plasticizer content of the PVC formulation increase. Usually the chlorinated paraffin portion of the total plasticizer should not exceed 15%. Many compatibility graphs are available in the literature (7).

Other materials that are often referred to as secondary plasticizers include materials such as epoxidized soybean oil (ESO), epoxidized linseed oil (ELO), and epoxidized tallate oil (ETO). These act as secondary stabilizers because of their epoxy content by removing the HCI from the degrading polymer. The ETO provides the best low temperature properties of the epoxidized oils.

Plasticized Polymers: The Dominance of PVC

Over 90% of the plasticizer volume is used by the PVC industry. The reason for such high usage with PVC is that the benefits imparted by the plasticization of PVC are far greater than those imparted to other polymers. PVC is the only polymer able to accept and retain large concentrations of plasticizer. This is due in part to a morphological form comprising highly amorphous, semicrystalline, and highly crystalline regions. Without the wide range of additives available, eg, plasticizers, stabilizers, fillers, lubricants, and pigments, PVC would be of little use. The development of PVC as a commodity polymer is fundamentally linked to the development of its additives.

Different types of PVC exist on the market. The two principal types are suspension and paste PVC; the latter includes the majority of emulsions and dispersion PVC polymers. The plasticizer applications technologies associated with these two forms are distinctly different and are discussed separately. Details of the polymerization techniques giving rise to these two distinct polymer types can be found in many review articles (8) (see VINYL CHLORIDE POLYMERS).

Applications Technology

Suspension PVC. These polymers are produced by suspending vinyl chloride in water and polymerizing this monomer using a monomer-soluble initiator. PVC polymers produced via a suspension polymerization route have a relatively large particle size (typically 100–150 μm). Suspension polymers produced for the flexible sector have particles that are highly porous and are therefore able to absorb large amounts of liquid plasticizer during the mixing cycle. A typical flexible PVC formulation can be found in Table 3.

Using a ribbon blender, the resin, stabilizer, lubricant, and filler are heated to 70°C. The plasticizer is then distributed through piping running the length of the blender, and the heat remains on the jacketed blender until the dry point is

Table 3. Typical Flexible PVC Formulations

Ingredient	Parts by weight	Parts per hundred resin (phr)	wt%
PVC	75	100	50
Plasticizer	45	60	30
Filler	26.25	35	17.5
Stabilizer	3	4	2
Lubricant	0.75	1	0.5
Total	150	200	100

reached. If the plasticizer is preheated the dry point will be reached in less time. Polymeric plasticizers must be preheated to 70–80°C.

With a high speed mixer, set the jacket temperature at 90°C. Charge the resin and dry stabilizer, mix at high speed to 60°C. Add the plasticizer and other liquids and mix to the dry point at 70–85°C. Add the other solids and drop at 90–105°C with monomeric plasticizers. For polymerics, drop at 100–115°C. This dry blend can be either stored or processed immediately. Processing of suspension resin formulation is performed by a variety of techniques such as extrusion, injection molding, and calendering to fuse the PVC and produce the end product.

The dry blend can also be extruded and the extrudate pelletized to produce pellets of PVC compound, which can then be reprocessed to produce the final article. This has the benefit of ease of processing and storage of raw materials since all the formulation ingredients are contained in the gelled compound.

Plastisols. Plastisol-forming polymers are produced by microsuspension polymerization or dispersion polymerization (9). Microsuspension produces very fine particles of monomer to ensure that small particle sizes of polymer are produced. In emulsion or dispersion polymerization the vinyl chloride is dispersed in a water-soluble initiator; the vinyl chloride particles are small and stabilized using surfactants. There are also several variations of these two basic techniques.

Much lower particle size resins are produced when compared to suspension resins (1 μm vs 150 μm) with some residual surfactant from the polymerization process retained on the polymer. The small particle size imparts a lack of porosity to the resin and the demands on plasticizer behavior in a plastisol tend to be more complex. Choice of plasticizer is made with consideration given to the required viscosity of the plastisol and the required rheology of the plastisol. It is common to encounter formulations with two or three different plasticizers.

Plastisols differ from their suspension analogues in that after mixing with plasticizer they produce a paste or plastisol, similar in appearance to paint, rather than a dry blend. For plastisols charge 80% of the liquids into the mixer. Start the agitator and add the solids in the following sequence: filler, blending resin, dispersion resin. At no time should the mix temperature reach 35°C. This can be controlled through jacketing and the addition of some of the 20% of liquids originally held back. Take the mix through a high shear stage to break down the agglomerates. This will minimize viscosity buildup on aging due to plasticizer solvation. When there are no more lumps in the plastisol, add the remainder of the liquids and mix for homogeniety. The plastisol must be de-aerated before use, unless it is a foam plastisol. The plastisol can then be spread, coated, rotationally cast, or sprayed for processing.

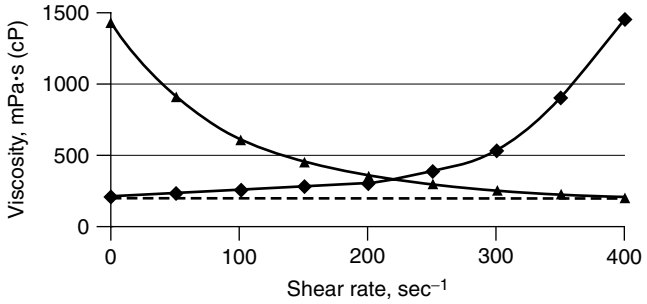


Fig. 1. Rheological behavior. - - - Newtonian; —•— dilatent; —▲— pseudoplastic.

Because the formulation ingredients in a plastisol are in liquid form, viscosity of the plastisol is of great importance and the intrinsic viscosity of the plasticizer contributes significantly to the plastisol viscosity, as does the precise polymerization conditions of the resin. The desired plastisol viscosity can be obtained by careful selection of polymer, plasticizer, and other formulation ingredients, but the shear rate applied to the plastisol also affects the viscosity. PVC plastisols are either (*1*) pseudoplastic, ie, viscosity decreases with shear; (*2*) near-Newtonian, ie, viscosity remains nearly constant with shear; or (*3*) dilatant, ie, viscosity increases with shear (see Fig. 1).

Effect of Plasticizer Choice on the Properties of Flexible PVC

A change in plasticizer affects the properties of a flexible PVC article. Certain properties are more important for some applications than others and some plasticizers find more extensive use in some application areas than others. The PVC technologist must ascertain the most important properties for an application and then make the correct choice of plasticizer. The two structural parameters that affect plasticizer performance are chain length or molecular weight and linearity.

In general, as the ester chain length increases, the following performance changes occur: solvation power decreases, efficiency decreases, volatility decreases, low temperature flex improves, low temperature brittleness improves, and compatibility decreases.

A comparison of linear vs branched chains show the following:

(1) Linear chains have a faster dry blend time.
(2) Branched chains have a faster fusion time.
(3) Branched chains are more compatible.
(4) Linear chains have better low temperature brittleness and flexibility.
(5) Linear chains are more efficient.
(6) Linear chains are less volatile.
(7) Branched chains have better electrical properties.
(8) Linear chains exhibit better uv stability and long-term permanence.
(9) Linear chains provide higher thermal stability.

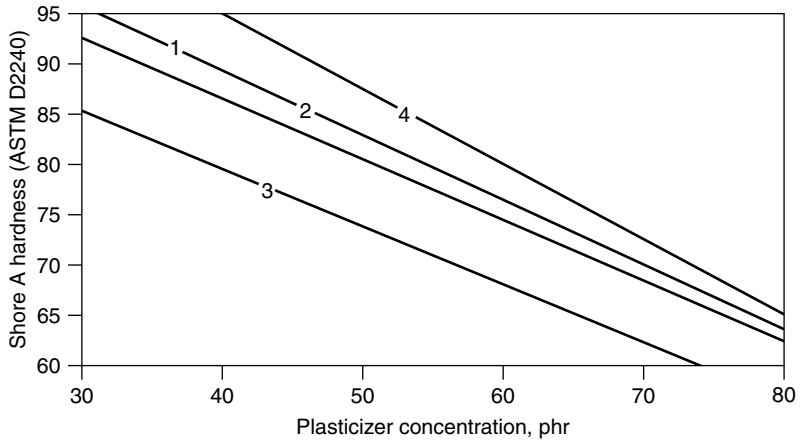

Fig. 2. Relative efficiency of plasticizers where (1) represents DEHP; (2) Palatinol® 9P; (3) DEHA; and (4) TOTM. (Palatinol is a registered trademark of BASF and 9P is a linear C_9 phthalate.)

Plasticizer Efficiency. This is a measure of the concentration of plasticizer required to impart a specified softness to PVC or shore hardness (Fig. 2). For a given acid constituent of plasticizer ester, ie, phthalate, adipate, etc, plasticizer efficiency decreases as the carbon number of the alcohol chain increases, eg, for phthalate esters efficiency decreases in the order BBP > DIHP > DOP > DINP > DIDP > DTDP (10). In addition to size of the carbon number of the alcohol chain, the amount of branching is also significant; the linear plasticizers are more efficient. Choice of the acid constituent can also be significant. For equivalent alcohol constituents, phthalate and adipate esters are both considerably more efficient than their trimellitate equivalent.

High Temperature Performance. High temperature performance in flexible PVC is related to plasticizer volatilization and plasticizer degradation (Fig. 3). Plasticizer volatilization, both from the finished article during use at elevated temperatures (eg, in electrical cable insulation) and also during processing [ie, release of plasticizer volatile organic compounds (VOCs)], is directly related to the vapor pressure and volatility of the plasticizer. The higher molecular weight phthalates give superior performance in this area. Higher molecular weight esters such as trimellitates are even less volatile and trimellitate esters find extensive use in the demanding wire and cable and automotive specifications, which have strict mass loss requirements. Branched esters have higher volatilities than their linear equivalents.

With regards to VOCs in the workplace, the same structure relationships apply. Not only does excessive plasticizer volatilization have environmental consequences, but since not all the plasticizer in use is entering the PVC resin this results in a harder material than anticipated. As a result of environmental protection legislation, more end users are looking at means of reducing or recovering and reusing plasticizer fumes and breakdown products.

Plasticizer molecules can undergo thermal degradation at high temperatures. Esters based on the branched alcohol isomers are more susceptible to such

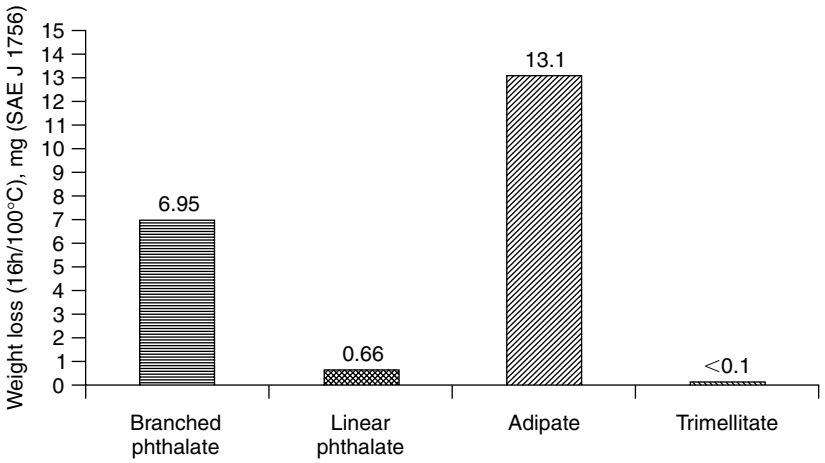

Fig. 3. Volatile loss of plasticizers from flexible PVC (Shore A80).

degradation because they have more tertiary carbon sites. With the addition of an antioxidant (topanol CA) to the plasticizer, its thermal properties can be improved.

Low Temperature Performance. The ability of plasticized PVC to remain flexible at low temperatures is of great importance in certain applications, eg, roofing, swimming pool liners, and tarpaulins. There is a significant contribution to low temperature performance from the alcohol portion of the ester, the greater the linearity of the plasticizer the greater the low temperature flexibility. The choice of the acid constituent of the plasticizer ester is also important. The linear aliphatic adipic, sebacic, and azeleic acids give excellent low temperature flexibility compared to the corresponding phthalates and trimellitates (Fig. 4).

Processing Properties. The dry blend and fusion characteristics of an FPVC are related to the molecular weight and degree of branching of the

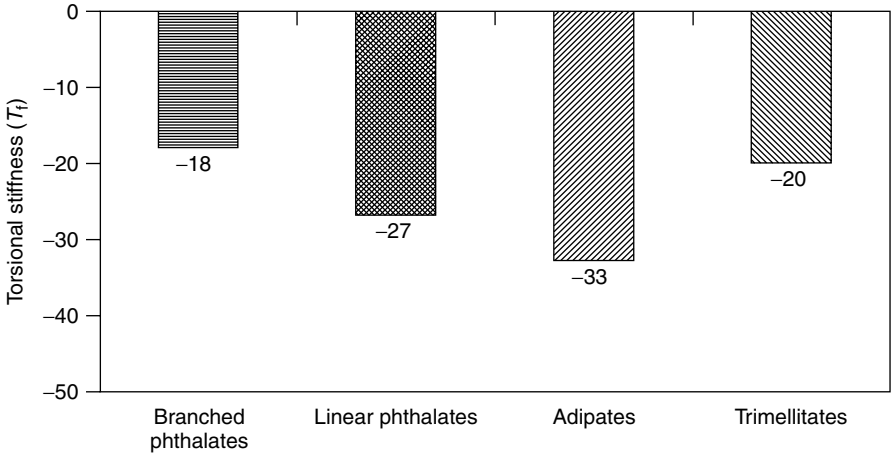

Fig. 4. Low temperature flexibility of plasticized PVC.

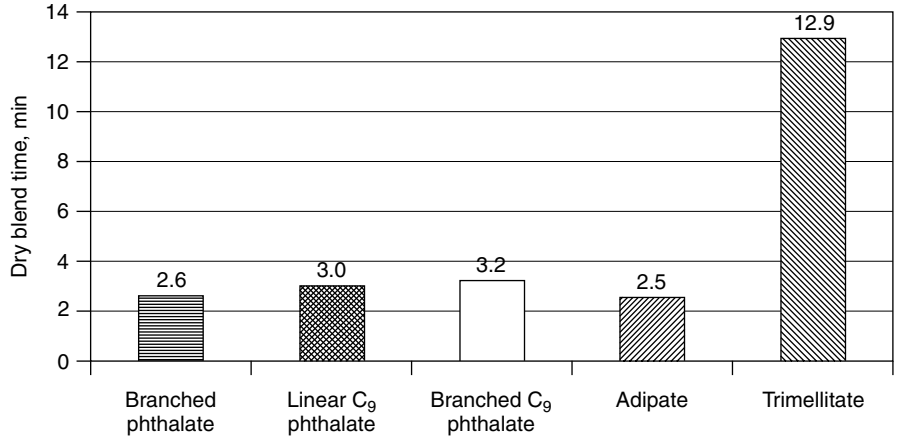

Fig. 5. Dry blend time of plasticized PVC.

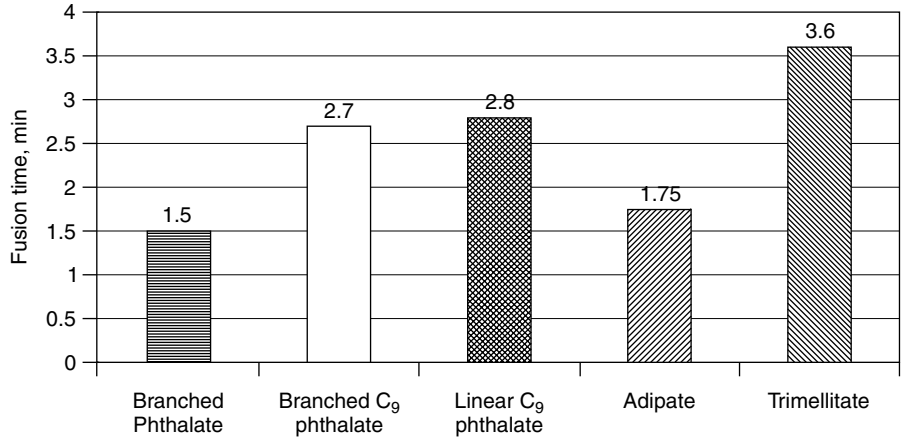

Fig. 6. Fusion time of plasticized PVC. Jacket temperature 96°C; rotor speed 63 rpm.

plasticizer (Fig. 5). In general, the shorter the chain length and the more linear the plasticizer, the shorter the dry blend time.

The fusion characteristics are a measure of the ability of a plasticizer to fuse with the polymer and develop maximum mechanical properties (Fig. 6). Fusion properties are often measured either as a processing temperature or time so as to obtain these properties. Ease of fusion is related to plasticizer branching and molecule size. The greater the branching of a plasticizer molecule, the greater attraction it has for the PVC polymer chain and the less additional energy, in the form of heat, is required. The smaller the plasticizer molecule the easier it is for it to enter the PVC matrix; larger molecules require more thermal energy to establish the desired interaction with the polymer. Thus, for the phthalate esters ease of fusion rate decreases in the order BBP > DIHP > DOP > DINP > DIDP.

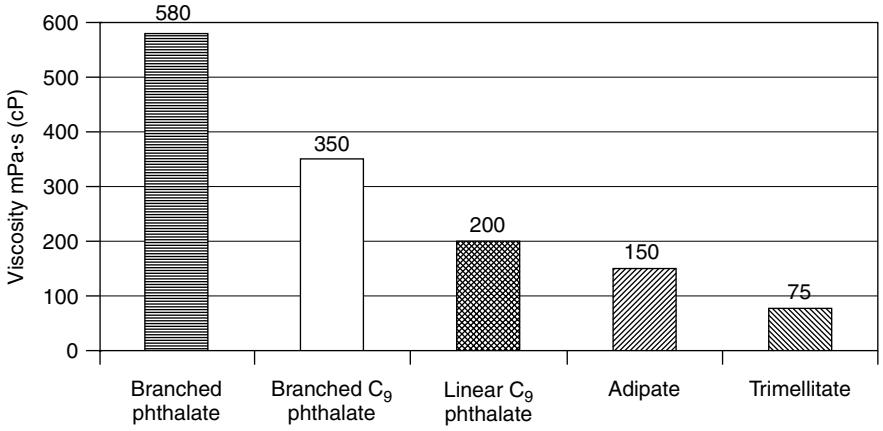

Fig. 7. Storage stability of plastisols (change in viscosity after 30 days).

Plastisol Viscosity and Viscosity Stability. After the primary contribution of the resin type in terms of its particle size and particle size distribution, plastisol viscosity has a secondary dependence on plasticizer viscosity (Fig. 7). The lower molecular weight and more linear esters have the lowest viscosity and hence show the lowest plastisol viscosity. Esters based on aliphatic acids, being of lower viscosity than the corresponding aromatic acids, show lower plastisol viscosities. Adipate esters have found widespread use in plastisol applications in blends with other esters. Plastisols are often mixed and then stored rather than processed immediately. It is of great importance in this case for the plasticizer to show viscosity stability at the storage temperature. It is not advisable to use a plasticizer of too great an activity, since grain swelling, leading to plastisol viscosity increase, can occur at room temperature for some active plasticizer systems.

Migration and Extraction. When plasticized PVC comes into contact with other materials, plasticizer may migrate from the plasticized PVC into the other material (Fig. 8). The rate of migration depends not only on the plasticizer but also on the nature of the contact material.

Plasticizer can also be extracted from PVC by a range of solvents, including water. The aggressiveness of a particular solvent depends on its molecular size and its compatibility with both the plasticizer and PVC. Water extracts plasticizer very slowly, oils are slightly more aggressive, and low molecular weight solvents are the most aggressive.

The key characteristic for migration and extraction resistance is molecular size. In general, the larger the plasticizer molecule the less it tends to migrate or be extracted.

Automotive Fogging. The term automotive fogging relates to the condensation of volatile material on a car windshield causing a decrease in visibility where light hits it. Although this volatile material may arise from a variety of sources, materials from inside the car may contribute to windshield fogging because of the high temperatures that can be encountered inside a car in a dry hot climate. In the case of flexible PVC such a contribution may arise from emulsifiers in the polymer, lubricants, stabilizers, plasticizers, and coating on the modifier.

Fig. 8. Plasticizer absorption by contact material in relation to chain length of the alcohol in the plasticizer. Solid lines indicate linear alcohol and dashed lines indicate branched alochol. —◇— Vinoflex® 507 rigid PVC; —■— Polystyrol® 475 K impact polystyrene; —▲— Terluran® 877 T (ABS); —●— Luran® 368 R (SAN); —⊠— Lupolen® 6011 L (HDPE); - -◇- - Vinoflex® 507 rigid PVC; - -■- - Polystyrol® 475 K impact polystyrene; - -▲- - Terluran® 877 T (ABS); - -●- - Luran® 368 R (SAN); ⊠ Lupolen® 6011 L (HDPE);

In each case manufacturers have studied their products in detail and recommend low fogging polymers, lubricants, stabilizers, and plasticizers. Tests have been designed (SAE J 1756) to assess the fogging performance of both the PVC sheet and the raw materials used in its production (Fig. 9). These tests involve heating of the sheet or raw material for a specified period at a set temperature in an enclosed apparatus with a cooled glass plate above the sheet or raw material. The reflectance of the glass plate is then compared before and after the test to ascertain the degree of fogging. In such a test, the fogging performance of a plasticizer is related to its volatility, vapor pressure, mass, and surface tension. The higher molecular weight and more linear plasticizers give superior performance. Trimellitate esters and 911 phthalates, with their high degree of linearity and low viscosity for plastisol applications, are used as low fogging plasticizers for these applications.

Long-term Permanence. Outdoor weatherability is dependent on branching and a properly stabilized formulation. Typically, to determine the permanence of FPVC accelerated uv weathering and thermal stability, studies are performed in the laboratory and outdoor weathering studies are carried out in Arizona, Florida, and northern industrial climate such as in New Jersey or Ohio. The percent elongation retained and discoloration are the measurable criteria.

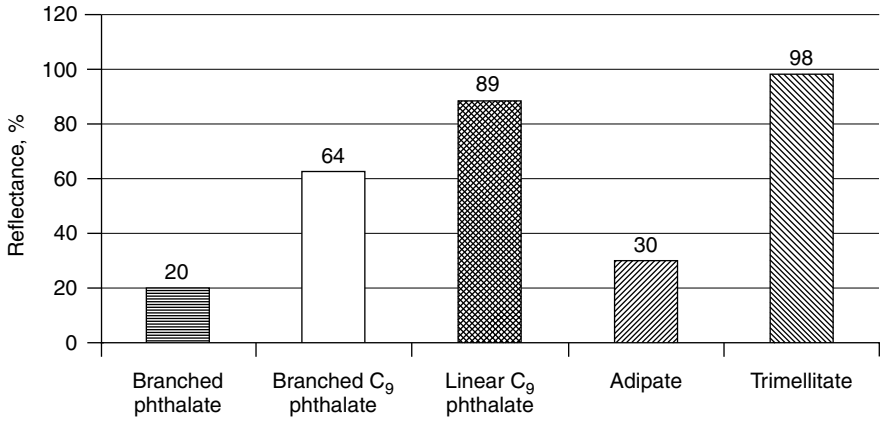

Fig. 9. Fogging of plasticized PVC for 3 h at 100°C (SAE J1756).

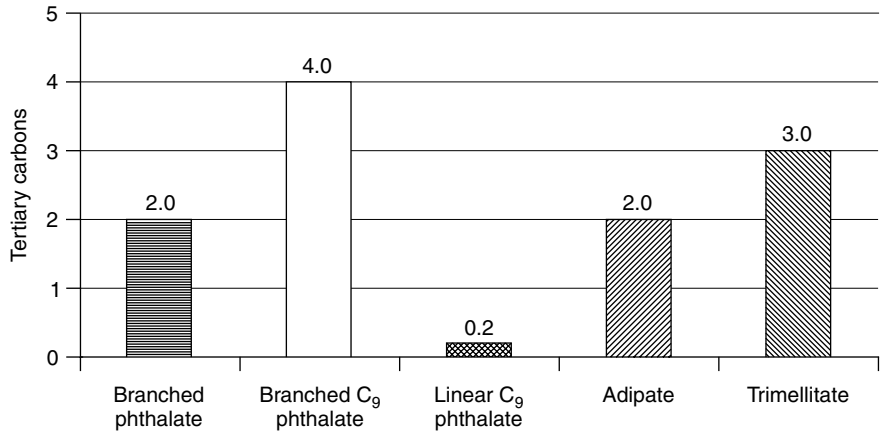

Fig. 10. Effect of branching on tertiary carbons.

Tertiary carbon sites on the plasticizer are weak spots where heat or light can initiate radical formation, which leads to degradation of the FPVC (Fig. 10). The higher the number of tertiary carbons the greater the probability for degradation and limited outdoor life.

Overall Assessment of Properties. Table 4 shows the effect for each criterion of increasing plasticizer concentration, increasing the size of the plasticizer molecule, increasing the linearity of the plasticizer molecule, and changing the acid constituent of the ester. There is no perfect plasticizer for every application. Choice depends on the performance requirements for the end use application and economics.

The Plasticization of Polymers Other Than PVC

The plasticization of PVC accounts for the majority of plasticizer use. However, a significant amount of plasticizers are used in non-PVC polymers. Although PVC

stands alone in its ability to accept and retain large quantities of commercial plasticizer, effective plasticization of other resins may be possible if certain conditions specific to the polymer of interest are met.

The first factor to be considered when looking at the plasticization of a polymer is the need. Even though some polymers may be compatible with large concentrations of plasticizer, the resultant softening benefits may be of little use. Other factors are short- and long-term compatibility.

For a plasticizer to enter a polymer structure the polymer should be highly amorphous. Once it has penetrated the polymer the plasticizer fills free volume and provides polymer chain lubrication, increasing rotation and movement.

The plasticizer content of a polymer may be increased by the suppression of crystallization in the polymer, but if crystallization subsequently occurs, the plasticizer exudes. For highly crystalline resins such as nylon, the small amounts of plasticizer allowable can change the nature of the small amorphous regions with a consequent overall change in properties.

Acrylic Polymers. Although considerable information on the plasticization of acrylic resins is scattered throughout journal and patent literature, the subject is complicated by the fact that the acrylic resins constitute a large family of polymers rather than a single polymeric species. A variation in physical properties may be obtained through copolymerization of two or more acrylic monomers selected from the available esters of acrylic and methacrylic acid (see ACRYLIC ESTER POLYMERS; METHACRYLIC ESTER POLYMERS).

Plasticizers are used with acrylics to produce tough flexible coatings. Compatabilities with common plasticizers are up to 10 wt% although with low molecular weight plasticizers, it can be higher. Plasticizers for acrylics include most of the common esters. There has been interest in the development of acrylic plastisols similar to PVC plastisols. Clearly, the same aspects of both plastisol viscosity and viscosity stability are important. Patents appear in the literature indicating that the number of available plasticizers that show both good compatibility with acrylic resins and satisfactory long-term plastisol stability may be fewer than those showing equivalent properties with dispersion PVC resins.

Patents have appeared which show the formulations containing PMMA emulsion polymer and PMMA suspension polymer combined with butyl benzyl phthalate and octyl benzyl phthalate. When replacing PVC applications the use of phosphate plasticizers may be required to give equivalent fire retardance.

Nylon. The high degree of crystallinity in nylon means that plasticization can occur only at very low levels. Plasticizers are used in nylon but are usually sulfonamide-based since these are generally more compatible than phthalates. These plasticizers help improve the processing of the nylon.

Poly(ethylene terephthalate). Poly(ethylene terephthalate) (PET) is a crystalline material and hence difficult to plasticize. Since PET is used as high strength film and textile fiber, plasticization is not usually required. Plasticizers may be used in small amounts as processing aids and external lubricants.

The main area of interest for plasticizers in PET is in the area of dyeing. Because of its lack of hydrogen bonds, PET is relatively difficult to dye. Plasticizers used in this process can increase the speed and intensity of the dyeing process. The compounds used, however, tend to be of low molecular weight since high volatility is required to enable rapid removal of plasticizer from the product (see POLYESTERS, THERMOPLASTIC).

Polyolefins. Interest has been shown in the plasticization of polyolefins but plasticizer use generally results in a reduction of physical properties, and compatibility can be achieved only up to 2 wt%. Most polyolefins give adequate physical properties without plasticization.

Polystyrene. Polystyrene shows compatibility with common plasticizers but is usually internally flexibilized with butadiene rubber. Small amounts of plasticizer are used to increase the flexibility further.

Fluoroplastics. Conventional plasticizers are used as processing aids for fluoroplastics up to a level of 25%. However, certain grades of Kel-F (chlorotrifluoroethylene) contain up to 25 wt% to improve elongation and increase softness. The plasticizers used are usually low molecular weight oily chloroethylene polymers.

Rubbers. Heavy petroleum oils, coal tars, and other predominantly hydrocarbon products have been used in rubber processing and formulations for many years. Esters such as DOA, DOP, and DOS, can be used with latex rubber, nitrile rubber, and chloroprene to reduce the T_g. The level of plasticizer is usually around 10–15 phr.

Economic Aspects

Worldwide consumption of plasticizers is estimated at 4.9×10^6 t (Fig. 11; Table 5) (11).

The distribution of plasticizers into various applications is shown in Figure 12.

Health and Safety Aspects

Numerous toxicological studies have been conducted on a variety of plasticizers. Because DEHP is the most widely used plasticizer and is a well-defined single

substance, it is the plasticizer that has been most thoroughly investigated in terms of its toxicology. There are more than 1000 scientific publications on the toxicology and environmental effects of DEHP (12).

Acute Toxicity. This studies the effect of the plasticizer on the species, usually a rodent, using a high dose where only a single or a few doses are given. Plasticizers posses a low acute toxicity with an LD_{50} greater than 2000 mg/kg body weight for oral route of exposure. Animal tests have indicated that plasticizers do not irritate the skin or eyes and are nonsensitizing.

Chronic Toxicity. Various animal species have undergone repeated oral exposure to phthalates for periods up to two years. Tumors were found in rodents at a dose level higher than what humans are exposed to. In mechanistic studies these tumors were found to be specific to rodents and therefore the effect is not relevant for humans. At lower dose levels, still many times higher than what humans are exposed to, no tumors are present. In these mechanistic studies phthalates were not genotoxic. Both *in vivo* and *in vitro* studies did not indicate

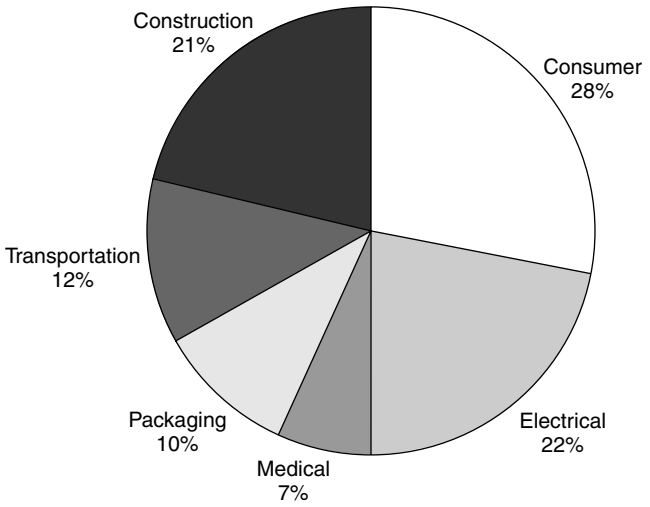

Fig. 12. Plasticizer market breakdown in North America.

any mutagenic potential. The DNA binding studies were also negative. These studies also showed that phthalates are weak peroxisome proliferators; however, peroxisome proliferation is species specific to rodents. Peroxisome proliferation was not evident in monkey and marmoset studies. Hypolipidemic drugs administered to rodents and humans cause peroxisome proliferation in the rodent but not in the human. The International Agency for Research on Cancer (IARC), a World Health Organization agency, has downgraded DEHP to category 3. DEHP is not classifiable as to its carcinogenicity to humans. The Canadian government has classified DEHP in Group IV—unlikely to be a carcinogen to humans.

Endocrine Modulation. Some scientists claim that chemicals in the environment may adversely affect the body's endocrine system and hormones. In studying phthalates, researchers looked at their ability to mimic the female hormone estrogen. The majority of the *in vitro* (test tube) and all the *in vivo* studies indicate that phthalates do not cause estrogenic effects. Although the mechanism is unknown, recent studies show that phthalates do not bind to the androgen receptor. Additional studies are under way to investigate whether phthalates produce other hormonal changes.

Developmental and Reprotoxicity. Some of the phthalates have shown reproductive effects in rodents at high dose levels. The relevance to humans is in question as primates appear resistant to the reproductive effects seen in rodents when tested with DEHP or DINP for 13 weeks at 2500 mg/kg/day (13).

Comparing estimates of the average human daily lifetime exposure to DEHP (0.3–6 μg/kg/day) to the level at which no effects are observed in rats indicates a margin of safety of 10,000 mg/kg/day for humans.

The Effect of Plasticizers on the Environment. Approximately 5 million tons of plasticizer is used annually in the world (14). Over 90% of the worldwide consumption is used to make FPVC, and 95% of these PVC plasticizers are

phthalate esters. Relatively few plasticizers are used in sufficient quantity to pose an environmental impact. For plasticizer grade esters phthalates are photodegradable, biodegradable, and are not bioaccumulative. They do not pose a hazard within their solubility parameter.

Phthalates can be emitted to the environment during their production, transportation, compounding and processing, life cycle, and disposal.

Because of the effect of uv degradation and microbial attack, a significant proportion of the emissions from the flexible PVC consists of plasticizer degradation products. In these instances, therefore, the level of plasticizers appearing in the environment will be significantly less than indicated by the plasticizer loss data.

Phthalate plasticizers are produced by esterification of phthalic anhydride in closed systems and so losses to the atmosphere are minimal. Inquiries of all the principal plasticizer producers indicate a maximum total emission of 0.02–0.1%, ninety percent of which is to the water compartment. This level is expected to decrease because of improvements in plant water treatment facilities.

The road, rail, and marine transport of phthalates is carried out by international companies with sophisticated tank cleaning facilities. Wash waters from these modern facilities are passed through a series of separators to remove any residual plasticizer, which is then incinerated. It is estimated that, as a result of cleaning and spillages, the maximum emission to the environment is 0.01%.

Process operations often do not involve direct use or contact with process water. Based on the manufacturing technology applied, aqueous emissions are expected to be minimal. During the production of FPVC products, plasticizers may be exposed for up to several minutes at temperatures of ~180°C. The loss of plasticizer by evaporation and degradation can be significant.

Air extracted from spread coating ovens contains typically 500 mg/m^3 plasticizer, which is present mostly as a condensate since the saturation concentration of common plasticizers in air is low. In those installations with filtration equipment, the average phthalate concentration in the air is reduced from 500 mg/m^3 to below 20 mg/m^3. The use of incineration equipment to clean the exhaust air reduces the residual phthalate concentration to practically zero. The use of filters and incinerators on calendering and spread coating plants is steadily increasing due primarily to the need to reduce emissions of solvents and other volatile organic compounds to the atmosphere.

Knowledge of the quantity of plasticizer used in each application together with the level of exhaust air treatment allows estimation of the level of plasticizer lost to atmosphere during these processes to be between 0.007 and 0.68%, with an average of 0.11%.

Emissions During Interior End Use. The majority of flexible PVC is used indoors in applications such as flooring, wall covering, upholstery, and wire and cable. Environ Corp. developed a model that attempts to quantify the plasticizer losses that occur in a typical room. Using theoretical and semiexperimental approaches they have arrived at an emission rate at 25°C of 2.3×10^{-4} $mg/s/m^2$. Using this emission rate with data on the annual production of PVC flooring, wall covering, etc, and estimates of their lifetimes, the plasticizer losses from all indoor flexible PVC articles can be calculated.

Emissions During Exterior End Use. When flexible PVC is used in exterior applications, plasticizer loss may occur due to a number of processes which include evaporation, microbial attack, hydrolysis, degradation, exudation, and extraction. The data from FPVC roofing has been used to estimate the plasticizer losses from all outdoor applications at 0.7–1%. This estimate may be too high. Much of this extracted plasticizer does not end up in the environment because considerable degradation takes place during the extraction process.

Emissions During Disposal and Incineration. The increasing use of modern incinerators to dispose of domestic waste results in complete combustion of plasticizers to carbon dioxide and water. The main route by which organic components are removed from a landfill is by ingress of water, extraction, and subsequent loss of water from the site to the environment. There are approximately 2000 active landfill sites with an annual combined water ingress of $40 \times 106\ m^3$. The solubility of the most common plasticizer, DEHP, in water is difficult to measure. The true solubility is considered to be around 50 μg/L, but various values are given in the literature. Assuming a worst case solubility of 1 ppm, then the maximum quantity of plasticizer extracted in the United Kingdom is 0.005%. A maximum of 0.02% plasticizer could be emitted to the environment from landfills in Western Europe. To obtain a more precise estimate of the situation, 25 effluent water samples from a variety of types of landfills have been analyzed. The highest concentration of DEHP detected was 30 parts per billion. If the highest figure is used instead of the assumed 1 ppm then the quantity from the whole of Europe becomes 0.0006%. In conclusion, the DEHP estimated emission factors for industrial point sources are as follows: air, 0.05–0.5 wt%; surface water, 0.001–0.01 wt%; soil, 0.001–0.01 wt%. Lower molecular weight phthalates would be greater and higher molecular weight phthalates would be less.

Storage and Handling

PVC plasticizers are viscous liquids with high boiling points and a very low vapor pressure. Their flash points are all well over 100°C so they are not classified as a flammable liquid. They are thermally stable and are practically insoluble in water. They have an indefinite shelf life in a sealed container. They can be stored safely in carbon steel storage tanks or drums for extended periods of time.

Tanks may be installed in a vertical or horizontal position. The vertical position is preferred to minimize air contact with the plasticizer and for drainage. The bottom of the tank should be inclined at 2–5% in the direction of the outlet valve. Underground storage tanks are not recommended. Besides carbon steel, storage tanks are made of stainless steel, aluminum alloy ($AlMg_3$), fiberglass reinforced plastic, and high density polyethylene.

The containment basin and walls should be constructed of concrete and be large enough to contain the tank's entire contents. If a basin serves more than one tank, its capacity must be sufficient to contain 110% of the largest tank plus the maximum rainfall in a 24-h period. Most plasticizers do not require heated

storage facilities although a heated plasticizer will flow more easily and have a faster dry blend time. Diundecyl phthalate and some polymeric plasticizers should be stored indoors or in a heated storage tank because of their higher pour point and crystallization.

All plasticizers should be filtered prior to compounding to prevent contamination of the FPVC and damage to the process equipment. For handling plasticizers personnel should wear neoprene gloves, chemical goggles, chemical splash suits, and boots. Spills should be contained, solidified, and placed in a suitable container for disposal as per federal, state, and local regulations. Waste disposal is by incineration or burial in a licensed facility. Plasticizers should not be discharged into waterways or sewer systems without proper authority as per federal, state, and local regulations.

POLY(3-HYDROXYALKANOATES)

Introduction

Poly(3-hydroxyalkanoates) (PHAs) are a family of polyesters accumulated as inclusion bodies (Fig. 1) by a wide variety of bacteria. They are water-insoluble, relatively resistant to aqueous hydrolysis but are readily biodegraded in any natural environment where microbial diversity exists. They can be produced from renewable resources and waste materials and, although temperature-sensitive, are potentially recyclable. Many PHAs have mechanical properties similar to those of common synthetic plastics.

Most PHAs contain exclusively 3-hydroxycarboxylate units (Fig. 2a) but many microorganisms can also accumulate a polymer containing 4-hydroxycarboxylate monomers [eg 4-hydroxybutyrate (4HB), where $p = 2$ and R = H] when fed the appropriate substrate. The most common PHA is poly(3-hydroxybutyrate) homopolymer (PHB, where R = CH_3). This was discovered and studied by Lemoigne during the 1920s (1). It was first suspected that these granules were lipid bodies as they were stained with hydrophobic dyes. Lemoigne proved that they were high molecular weight polyesters, years before the pioneering work of Carothers (2) on synthetic polyesters.

Although copolymers of 3-hydroxyalkanoates were identified as early as the 1960s (3), little importance was attributed to them. The term PHA only came into use during the 1980s to refer to PHB and the other 3-hydroxyalkanoate polymers. This definition had not been in use very long when copolymers containing 4-HB (4) or 5-hydroxyvalerate (5-HV) (5) were discovered. Their production involved the same enzymes as those for the synthesis of PHB but they contained units that had the hydroxyl group on the fourth or fifth carbon rather than the third. For this reason, the term PHA is now most commonly defined as polyhydroxyalkanoate. This also includes polymers containing units with double bonds and other reactive groups in their side chain. The term PHA is generally applied to the biologically synthesized polymers.

Two major classes of PHAs are known to exist. PHAs whose polymeric units are predominantly five carbons or less are classified as short-chain-length PHAs (SCL PHAs) while all others are referred to as medium-chain-length PHAs (MCL PHAs). The term MCL was coined because the number of carbons in the monomers roughly corresponds to those of medium-chain-length carboxylic acids. PHA nomenclature may still be in a state of flux as new structures continue to be discovered.

Properties

PHB exists in an amorphous state inside the bacterial cell. This seems to be necessary for its biosynthesis and there are several theories explaining how this state is maintained (6,7). Melting or solvent casting usually results in highly crystalline PHB because of its stereoregular nature. Crystallization may be avoided if the granules are isolated from the bacterial cells by a gentle enzymatic method,

which results in a stable latex suspension (6), but most PHB products are highly crystalline in nature. The rate of crystallization after melt processing can be increased by adding nucleating agents such as boron nitride, and by allowing the product to stabilize at the optimal crystallization temperature (about 60°C). The main drawbacks against the use of PHB are its brittle nature and its tendency to degrade near its melt temperature. Inclusion of a plasticizer (often a biodegradable one, such as triacetin) and annealing after initial crystallization aid in increasing flexibility. It has been demonstrated that impurities significantly increase the degradation rate (8). Thus a short processing time in the melt and a highly pure grade of polymer is recommended for PHB processing.

Effect of Side-Chain Length on PHA. The use of copolymers is another way to avoid degradation while increasing flexibility during melt processing of SCL PHA. Increasing the HV content of poly(3-hydroxybutyrate-*co*-3-hydroxyvalerate) [P(HB-*co*-HV)] from 0 to about 30% (expressed as mol% in this article) results in a concommitant decrease in melting point and Young's modulus (Table 1) but crystallinity remains high as a result of a phenomenon known as *cocrystallization* or *isodimorphism* (17). Above 30% HV the melting point begins to rise again. Increasing 4HB or 3-hydroxypropionate (3HP) monomers also lowers the melting point and gives a more flexible polymer. However, crystallinity decreases with increasing 4HB and 3HP since isodimorphism does not occur in these copolymers (18,19). Both 4HB and 3HP have much lower melting and glass-transition temperatures.

Conventional equipment used to process polyethylene can be used for pellets of PHA plasticized with a nucleating agent to form blow-molded, injection-molded, and film products. A key requirement is temperature control. It is recommended to operate at the lowest possible temperature and to keep the residence time at a minimum since the melting point of PHB is about 178°C and thermal degradation begins at about 180°C (depending on the purity). P(HB-*co*-HV) with a high HV content can have a melting point as low as 136°C. For most applications, it is suggested to process at a maximum temperature of 170°C, a maximum residence time of 3 min, and that molds and blow pin temperatures be kept at about 60°C (20). Mechanical properties deteriorate rapidly if the weight-average molecular weight falls below 400,000 g/mol.

Homopolymers of MCL PHA have not been biosynthesized to date. Although polymers designated as poly(3-hydroxyoctanoate) (PHO) have predominantly 3-hydroxyoctanoate repeating units (Fig. 2a where $P = 1$ and R = C_5H_{11}), they contain significant quantities (10% or greater) of other monomers, usually 3-hydroxydecanoate and 3-hydroxyhexanoate, depending on the bacterium and the carbon source. Melting temperature, Young's modulus, and tensile strength decrease as the length of the MCL PHA side chain increases (Table 1). MCL PHA can be toughened by annealing, which results in the formation of "crystalline cross-links."

Polymer Blends Incorporating PHA. The mechanical properties, morphology, biodegradability, and thermal and crystallization behavior of PHAs melt-blended or solvent-cast with nonbiodegradable polymers [such as poly(vinyl acetate)] and with biodegradable materials [such as wood cellulose fibers (21) and starch] have been reviewed (22). PHB blends with poly(ethylene oxide), poly(vinyl alcohol), poly (L-lactide), poly(D,L-lactide), poly(ε-caprolactone), poly(3-butyrolactone), P(HB-*co*-HV), and cellulose and starch derivatives have been

shown to be completely biodegradable (23). In a reactive blending process, the components have been mixed with a peroxide. This decomposes to form free radicals which cross-link the polymers (24).

Applications

The first commercial user of the P(HB-*co*-HV) resin was Wella AG, Darmstadt, Germany. They packaged hair and skin care products in injection blow-molded bottles. These products were introduced to the American and Japanese markets in 1991 and 1992 respectively.

Since PHAs are isotactic, they can serve as a feedstock for enantiomeric compounds, which can be used in the synthesis of chiral chemicals such as antibiotics, vitamins, fragrances, and pheromones. Optically pure monomers may be obtained from PHAs by chemical hydrolysis at 80–160°C using a titanate catalyst (25) or by enzymatic hydrolysis using extracellular bacterial depolymerases. It is possible to synthesize the optically active monomers by using bacteria, which can make the polymer but lack the 3-hydroxyalkanaote polymerase (Fig. 3a) or possess a high activity of intracellular PHA depolymerase. Monomers such as 4HB have therapeutic applications as an intravenous anaesthetic, for the treatment of narcolepsy, alcohol, heroin, and nicotine addiction (26).

PHB and P(3HB-*co*-4HB) have been evaluated for the controlled release of drugs (26,27). The drug may be microencapsulated in PHB and injected subcutaneously, or may be pressed into a pill and administered orally. Degradation is slow in the human body as it does not contain PHA depolymerases. Aqueous hydrolysis is probably responsible for *in vivo* degradation. PHB tablets of 60 mg (6.0 mm in diameter and 2.0 mm in thickness) degraded at a rate of 0.2 mg/week in the tissue of mice. In its present form, it might be considered for long-term applications in the body. PHB has been evaluated for use in surgical devices such as sutures, prosthetics, pins, dressings, and a three-dimensional heart valve scaffold (28). The monomers of PHB are natural metabolites found in the human body and are not toxic to humans. PHB and P(3HB-*co*-4HB) have been shown to be compatible with human tissue and mouse fibroblast cells. These materials elicit only a very mild immunological response in mice or rats (27).

Films of PHB and P(HB-*co*-HV) have piezoelectric properties. A charge is generated if a PHB crystal is deformed by hydrostatic force, thermal expansion, or other forces. Some synthetic piezoelectric polymers such as poly(vinylidene fluoride) are known to stimulate bone growth. It has been suggested that films of PHB and P(HB-*co*-HV) wrapped around bone fractures may accelerate the healing process (27).

PHAs are moisture-resistant and have gas barrier properties similar to the best coated films. They have potential use as plastic moisture barriers. Possible markets include mulch films, food and agricultural packaging, drink cartons, feminine hygiene products, disposable diapers, and disposable kitchen items, such as plastic films which are difficult to separate for recycling. Coatings may be applied with PHA as an amorphous latex which can be either reconstituted from the crystalline form of the polymer or obtained directly from a bacterial suspension by enzymatically dissolving the other cellular components. In the latter case, it

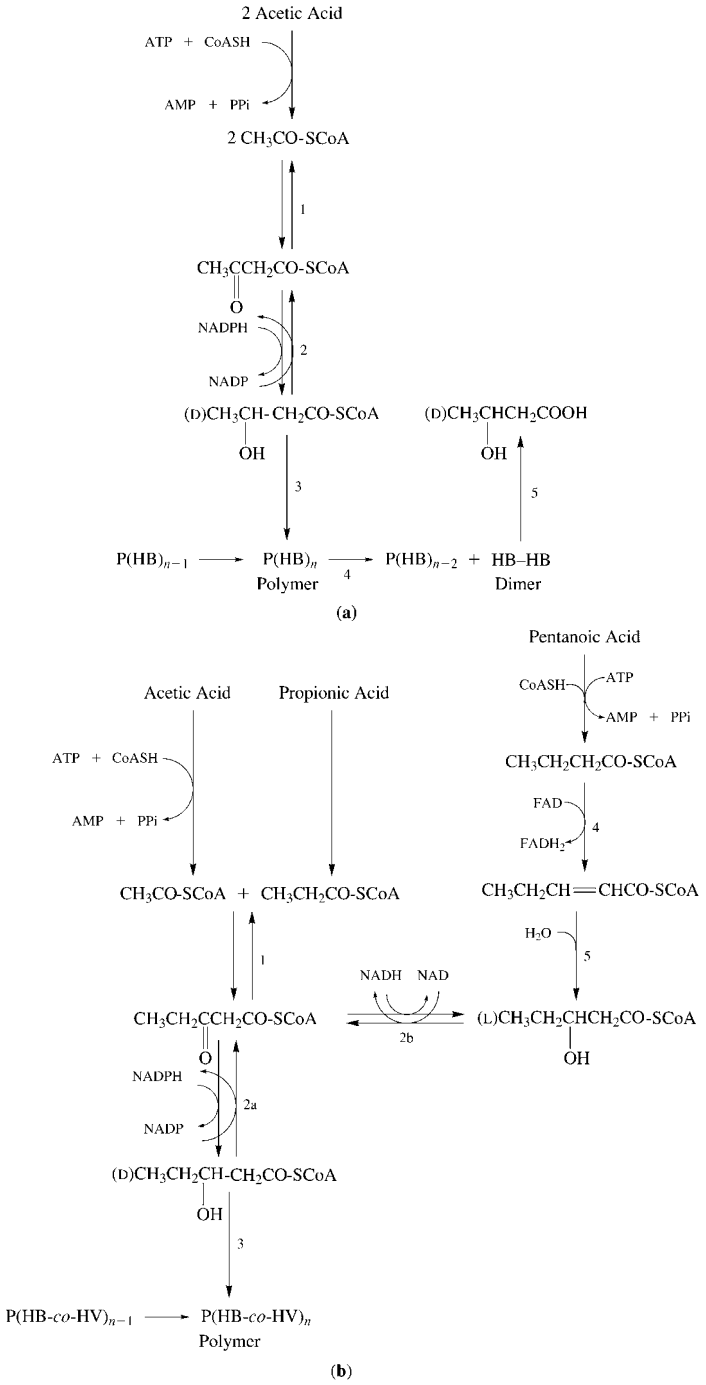

Fig. 3. (**a**) Biosynthesis of SCL PHA; 1, 3-ketothiolase; 2, NADPH-dependent acetoacetyl-CoA reductase; 3, SCL PHA polymerase; 4, SCL PHA depolymerase; 5, D(−)-3-hydroxybutyrate-dimer hydrolase. is important that the granules are not dried prior to use as they would become crystalline. The latex may be applied as a spray to a material such as paper, dried and cross-linked using heat or uv light. The MCL PHAs are promising as coatings (29) since they are less crystalline than the SCL PHAs, and the microorganisms which synthesize them can introduce different functional groups (30).

Degradation of PHA

SCL PHA has been shown to degrade as rapidly as cellophane, much more rapidly than poly-L-lactic acid and aliphatic polyesters such as poly(butylene succinate) and poly(butylene succinate-*co*-ethylene succinate) under anaerobic conditions (31), faster than polycaprolactone under aerobic conditions, and faster than paper during composting (32). Although PHAs degrade rapidly in most nonsterile natural environments, they are much less susceptible to abiotic hydrolysis than most other "environmentally degradable" polymers. For example, although P(HB-*co*-HV) is less readily hydrolyzed under aseptic conditions (33), it generally degrades much more rapidly than polycaprolactone in septic environments.

PHA Biodegradability. One of the attractive features of PHAs products is that they can be biodegraded in a variety of environments including compost, soil, and sea water, under aerobic or anaerobic conditions. The rate of degradation in nature depends on environmental factors such as pH, temperature, moisture level, quantity of microorganisms capable of degrading PHAs, nutrients other than a carbon source, and on characteristics of the PHA material such as its thickness, surface area, molecular weight, crystallinity, and the presence of other components such as a filler. Standard methods for the determination of biodegradability have been developed for international standards organizations. For example, ISO/FDIS14855 is the compostability testing method. It is identical to ASTM D5338 and to the DIN (German) Standard.

Enzymatic Degradation of PHAs. The extracellular and intracellular depolymerases for the degradation of PHAs function differently. In both cases, the substrate is PHA but there is a difference in crystallinity. PHA granules inside the cell are amorphous (the native form). However in extracellular degradation, PHA has been removed from the cell and has been "processed," becoming a more crystalline material with both amorphous and crystalline regions. Intracellular depolymerases demonstrate low activity with semicrystalline PHA and extracellular depolymerases poorly attack amorphous PHA. Extracellular degradation is important in an environmental context as it would be the primary mechanism for the disappearance of a PHA product during composting or wastewater treatment.

Intracellular Degradation. Native PHB granules isolated from *Rhodospirillium rubrum* (34), *Azotobacter beijerinckii* (35), and *Zooglea ramigera* (36) were shown to be self-hydrolyzing while those of *Bacillus megaterium* (34) were not and those of *Alcaligenes eutrophus* (now called *Ralstonia eutropha*) did so at a very low rate (37). Depolymerization in *B. megaterium* requires a heat-labile factor associated with the granule and three soluble components: a heat-stable protein activator, PHB depolymerase, and a hydrolase. The concerted action of the first three components resulted in monomers and 15–20% dimers with the hydrolase converting the dimers to monomers.

Active intracellular depolymerases could lead to "turn over" of accumulated PHAs in the presence of excess carbon and/or PHA catabolism under carbon limitation. When *R. eutropha* containing PHB was placed in a nitrogen-free medium with valeric acid as the sole carbon source, many HB units were replaced by HV units or "turned over" (38). Similarly when cells containing P(HB-*co*-HV) were placed in the same medium with butyric acid as the sole carbon source, the HV content of the cells decreased.

The production of PHA depolymerase is repressed in most PHA-degrading bacteria when an easily degradable carbon source is present. When the carbon substrate is exhausted, the depolymerase synthesis is derepressed. Once the PHA monomers are released, they can be repolymerized, serve as a source of carbon and energy for growth or be excreted. If the microorganism is lacking the hydroxyalkanoic acid dehydrogenase or this enzyme has a low activity, the monomer will accumulate as hydroxycarboxylic acids. It has been demonstrated that this approach can be used to produce a high yield of pure enantiomers (39).

Extracellular Degradation. Although aqueous and enzymatic hydrolyses contribute to degradation in the environment, aqueous hydrolysis is very slow compared to enzymatic hydrolysis. It took about 16 weeks to produce a 30% weight loss of a P(HB-*co*-9%4HB) film (12 mm in diameter and 70 μm in thickness) in 0.01 *M* phosphate buffer at 70°C and pH 7.4 (16). Because of random hydrolytic chain scission, the number-average molecular weight (M_n) decreased from 226,000 to 13,000 in 55 days, with little change in actual weight (8%). At day 110, the extent of weight loss had increased to 30%. Degradation (usually monitored as weight loss) is typically much more rapid in the presence of active microorganisms. For example, a 75-μm-thick film completely degraded in anaerobic sewage in 1 week, in a well-watered soil at 25°C in 12 weeks, and in an estuarine sediment at 20°C in 8 weeks (40).

An initial sequence of events for a PHB film buried in a well-watered soil has been described (40). The first step is a wetting-out process, in which aqueous hydrolysis is probably responsible for the increase in the number of hydroxyl and carboxylic acid groups at the surface. After 1 week, the plastic surface becomes more hydrophilic. Bacterial and fungal colonization then occurs. Microbial attack (primarily due to extracellular enzymes) takes place at the surface (41,42) which becomes more pitted, increasing the surface area for degradation. Surface area is further increased by blending with a more rapidly biodegradable polymer such as starch. In a P(HB-*co*-19%HV)–starch composite, the degradation rate increased with the starch content (43). Starch was lost more rapidly than the P(HB-*co*-19%HV) starting at both surfaces, then toward the center. As the starch was removed, a larger internal surface area was available for PHA degradation. At least 31vol% starch granules is required to have continuity of all internal surfaces in a polyethylene–starch composite (44).

The mechanism of extracellular degradation of PHA is not yet well understood. A wide variety of microorganisms (fungi, aerobic and anaerobic bacteria) have been implicated but only *Pseudomonas lemoignei*, *Alcaligenes faecalis*, and *Comamonas* sp. have been studied in detail. Production of extracellular PHA depolymerases is induced by the presence of PHA as the sole carbon source. Generally, a PHB depolymerase acts from the hydroxyl terminus to form dimers (or trimers, depending on the depolymerase) and a trace amount of monomer. An

oligomer hydrolase further hydrolyzes the dimers (or trimers but not the polymeric material) to monomers which can then be used as a source of carbon and energy. Since the depolymerase acts at the hydroxyl end (sequentially removing monomers, dimers, or trimers), there should be a very slow change in the M_n. The rate of weight loss should not depend on the initial molecular weight and it has been shown that high and low molecular weight PHBs were indeed degraded at the same rate (41). There is no significant change in the molecular weight of the bulk of a film or blow-molded product as degradation takes place at the surface.

Although extracellular depolymerases act on semicrystalline PHA, the degradation rate has been shown to decrease with increasing crystallinity of PHB films (45). For a blow-molded, P(HB-*co*-16%HV) product (a 20-μm cross section was exposed to partially purified PHB hydrolase from *Penicillium funiculosum*), the degradation rate is faster at the less crystalline surface than at the more crystalline core (42). Furthermore, it has been shown that the amorphous regions on the surface of PHB films are degraded preferentially whereas microbial colonization takes place at spherical holes which tend to be at the crystal centers and at the boundary between spherulites (46).

The enzyme specificity depends to some extent on the composition of the PHA which induced the degradation. In general, enzymes induced by SCL PHAs will not act on MCL PHAs and those induced by MCL PHAs will not act on SCL PHAs. The specificity based on the composition of the PHA inducer is not as clear within each group of depolymerases. P(HB-*co*-HV) was degraded more slowly than PHB, and P(4HB) was degraded more quickly than PHB (41) by PHB-induced depolymerases. However, PHB, PHV, and P(HB-*co*-HV) were degraded at comparable rates by purified PHV depolymerase (PHV as sole carbon source) from *P. lemoignei* (47). It has been suggested that P(4HB) degraded faster because 4HB monomers were more sterically accessible to the enzyme than were 3HB monomers (41).

PHA Synthesis

Synthetically, PHB is produced from racemic 3-butyrolactone and P(HB-*co*-HV) is made from a mixture of 3-butyrolactone and 3-valerolactone, with triethylaluminum and water as catalyst (48). Although the stereospecificity of the resulting polymer can be controlled to a certain extent by adjusting the ratio of triethylaluminum and water, synthetic PHAs are usually optically inactive and hence only partially biodegradable.

SCL PHA Biosynthesis. During PHB synthesis, 3-ketothiolase catalyzes the condensation of two acetyl-CoAs to produce acetoacetyl-CoA which is stereospecifically reduced by an independent reductase to produce D(−)-3-hydroxybutyryl-CoA (35,49) (Fig. 3). First elucidated in *A. beijerinckii*, the presence of this synthetic route was confirmed in *R. eutropha*. These four-carbon monomers are then added to the growing PHB chain by a polymerase. If propionic acid is supplied during the fermentation, some of the acid is converted to proprionyl-CoA. A portion of this proprionyl-CoA is condensed with acetyl-CoA via 3-ketothiolase to produce five-carbon monomers (Fig. 3b). This is the most common pathway of P(HB-*co*-HV) production. Most PHB-accumulating bacteria will

produce P(HB-*co*-HV). Since acetate is needed for this synthetic route and some propionic acid is decarboxylated before monomer synthesis, usually less than 50% of the monomers will be HV even if a feed of pure propionic acid is added. This yield can be increased in *R. eutropha* by decreasing the dissolved oxygen concentration in the bioreactor during the accumulation phase (50).

High yields of HV are obtained when pentanoic acid is used because acetyl-CoA is no longer required since pentanoic acid is metabolized directly to L-(3)-hydroxyvaleryl-CoA which is subsequently racemized (at least in *R. eutropha*) to D-(3)-hydroxyvaleryl-CoA (51) (Fig. 3b). Although some acetate is produced, leading to HB monomer formation, PHAs with greater than 90% HV content can be obtained. SCL PHA producers have not been reported to accumulate monomers with side chains longer than C_2 or C_3 but can produce P(3HB-*co*-4HB) when fed 4-hydroxybutyric acid or 1,4-butanediol. *R. eutrophus* accumulates terpolyesters of 3HB, 3HV, and 5HV monomers when fed a mixture of pentanoic and 5-chloropentanoic acids. Even among SCL-accumulating microorganisms, there may be differences in the PHA synthetic pathway. For example, in *R. rubrum*, L-(+)-3-hydroxybutyryl-CoA is racemized to D-(−)-3-hydroxybutyrl-CoA using enoyl-CoA hydrases.

In most SCL PHA-accumulating bacteria, high intracellular levels of NADH and acetyl-CoA greatly stimulate the rate of PHA synthesis. Thus, if the growth rate is limited by a nutrient other than the source of carbon and energy, PHA is accumulated in the cell. By definition, the PHB content of the cells is stable under balanced growth conditions, while carbon and energy limitations increase depolymerase activity, leading to a decrease in cellular PHA content.

MCL PHA Biosynthesis. MCL PHA was first identified in mixed cultures in activated sludge (52) and marine sediments (53). The unusual manner in which these materials crystallized led to some debate as to whether they were copolymers or mixtures of homopolymers (54). The breakthrough in MCL PHA technology came when it was discovered that *Pseudomonas oleovorans* would accumulate MCL PHA when fed with the appropriate alkane, alkanoate, or alkanol (30,55,56). Shortly thereafter, several other ribosomal RNA homology group I pseudomonads were found that could also accumulate MCL PHA from the above substrates. Many pseudomonads can produce MCL PHA from simple carbohydrates such as glucose (57,58) although the yield is usually much lower. This led to the belief that MCL PHA could be derived from fatty acid synthesis as well as fatty acid degradation (59).

In fatty acid synthesis or degradation (Fig. 4), once the substrate is in the form of alkanoyl-CoA, a two-step process involving a 3-ketoacyl-CoA reductase and a PHA synthase occurs. The reduction step requires NADPH. A suitable supply of intracellular substrate appears to be the key factor controlling the rate of biosynthesis. If *P. oleovorans* is fed octanoate, it accumulates much more PHA than if hexanoate or dodecanoate are added. Nevertheless, the synthase is relatively nonspecific. *P. oelovorans* can accumulate polymers in which the side chain of the monomers contain double bonds, branches, cyclic structures, or even halogen atoms if the appropriate substrate is supplied.

Much less polymer is produced from carbohydrates (ie fatty acid synthesis) than from alkanes or related substrates (ie fatty acid degradation). This is possibly due to a shortage of acceptable substrate for the synthase. Pseudomonads

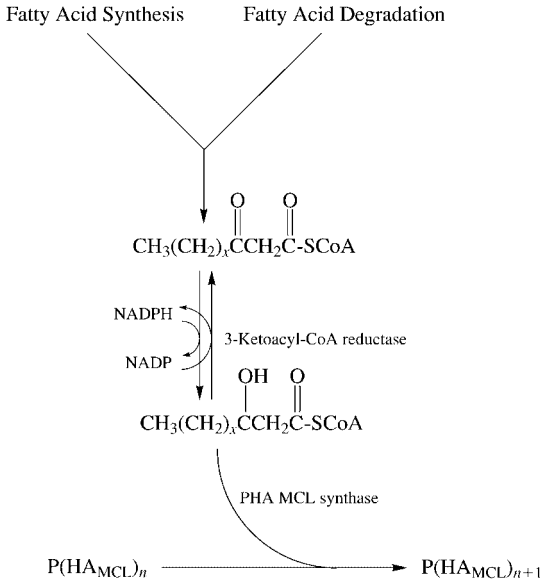

Fig. 4. Biosynthesis of MCL PHA. Substrate may result from fatty acid degradation, or from fatty acid synthesis. The substrate must be transferred from the acyl carrier protein (ACL) to Coenzyme A (CoA) if derived from fatty acid synthesis.

that produce PHA from glucose, accumulate a polymer where 3-hydroxydecanoate units dominate. They also frequently use 3-hydroxydecanoate as an intermediate metabolite for the synthesis of other materials such as biosurfactants (60). Blocking these pathways could result in increased polymer production.

The intracellular PHA depolymerase system can act very efficiently in MCL PHA producers. Carbon limitation often leads to extremely rapid depolymerization. The diversity of metabolic machinery among PHA-accumulating microorganisms indicates that unusual and potentially valuable PHA copolymers await discovery.

Synthesis in Transgenic Plants. PHB can be synthesized in plants in which the bacterial reductase and polymerase genes have been introduced. Although virtually all organisms possess the third gene in the SCL PHA pathway, coding for 3-ketothiolase, its activity and specificity vary, and it may not be present in all eucaryote organelles. Production is usually increased by cloning the 3-ketothiolase gene with the other two. Although transgenic plants are easily created, productivity remains problematic. The SCL PHA pathway was first cloned into *Arabidopsis thaliana*, the *Escherichia coli* of plant biotechnology (61). The yield was low, 0.1% dry weight, and the plants were stunted. However, granules similar to those found in bacteria were produced. The initial cloning strategy targeted the cytoplasm and granules were also found in the cell nucleus. Subsequent work has targeted the plastid which is also the site of starch and oil synthesis in plants. This has resulted in increased yields of up to 14% dry weight in the leaves of *A. thaliana*. These plants grew well but were chlorotic probably because of large amounts of PHB in the chloroplasts. Present research centers on oil and starch producing plants since these are already adapted to have large amounts of

storage material in the plastids (62), but other strategies are also being assessed. Although MCL PHA has been produced in transgenic plants (63), yield is low, partially because of a lack of understanding of the link between fatty acid synthesis and MCL PHA synthesis.

Separation of PHA from Biomass

All separation processes to date have been developed for microbial rather than plant biomass but many of these approaches could also be applied to recovery of PHA from plants. As a first step in the recovery from microbial biomass, the cells are separated from the fermentation broth usually by centrifugation or flocculation. In the latter case, the pH of fermentation broth is adjusted to 9 and the broth is heated; the pH is readjusted to 5 (64), and the biomass is recovered by centrifugation or filtration. The wet biomass may be freeze- or spray-dried to remove water. Processes to separate the intracellular PHA from the rest of the microbial biomass may be divided into two categories: (*1*) selective solubilization of PHA in an organic solvent, leaving the majority of the other biomass components in suspension and (*2*) destruction (eg enzymatic solubilization) of cellular components other than PHA, leaving the PHA granules in suspension. Physical treatments such as drying, heating, freezing and thawing, repeated centrifugation, and exposure to acids and organic solvents may result in crystallization of native PHA.

Solvent Extraction of PHAs. The majority of the patented separation processes describe the extraction of PHB from microbial biomass using organic solvents such as chlorinated hydrocarbons (eg chloroform or 1,2-dichloroethane), azeotropic mixtures [eg 1,1,2-trichloroethane with water (65)]; chloroform with methanol, ethanol, acetone, or hexane (66), and cyclic carbonates [eg hot (120–150°C) ethylene carbonate or 1,2-propylene carbonate (67)] in which the polymer is soluble. With the wider variety of PHAs which can be produced today, the choice of solvents should be carefully considered. In general, solvents which are suitable for PHB should be equally good for any SCL and MCL PHA. The reverse may not be true. For example, while semicrystalline PHB is insoluble in acetone, MCL PHA will dissolve in it.

Cells may be pretreated to make the polymer more accessible to the extraction solvent. This may involve washing in a hydrophilic solvent in which the polymer is insoluble (such as methanol or acetone for SCL PHA and methanol for MCL PHA), or physical disruption such as grinding, wet-milling, French press, or freezing and thawing cycles. Pretreatment with acetone has been shown to have the added advantage of removing certain polar lipid impurities and increasing the amount of PHB recovered (68).

After solvent extraction, the polymer solution is separated from the cellular residue by filtration or centrifugation. PHB is then precipitated from the chlorinated hydrocarbons or azeotropic mixtures with a cold nonsolvent, such as methanol. In the cases of ethylene carbonate and 1,2-propylene carbonate, the majority of the PHB precipitates on cooling (67).

PHA solutions become too highly viscous to process easily at concentrations of greater than 5 wt%. As a result, large amounts of solvent are required to obtain sufficiently dilute solutions to enable easy separation. A significant portion of

the PHB may remain unextracted in the biomass (68). Solvent extraction is not considered economical unless cheap solvent and energy for solvent recovery are available. However, solvent extraction is useful when the PHA content of the biomass is low or when high purity is required.

Although thermal degradation of PHB in air or a nitrogen atmosphere has been well studied (69), there are few examples which show that PHB degrades in organic solvents. The molecular weight is known to decrease in propylene carbonate and ethylene carbonate at 110–140°C (67), in chloroform–methanol mixtures at room temperature (70), and in methylene chloride, chloroform, and 1,2-dichloroethane at their boiling points (68).

Solvent extraction is a commonly used laboratory technique for PHA recovery, especially for molecular weight determination. Usually, methanol- (or ethanol-) pretreated, lyophilized biomass is heated in chloroform under reflux conditions for about 1 h. The polymer solution is recovered by filtration or centrifugation, and the polymer is precipitated in cold ethanol or methanol. The polymer may be further purified by redissolving in chloroform and reprecipitating in cold ethanol. It should be noted that about 25% of the "original" molecular weight (determined by chloroform extraction under ambient conditions) is lost when refluxed in chloroform for 1 h (68).

Removal of Cellular Components Other Than PHA.

Enzymatic Methods. Classical enzymatic treatment (involving lysozyme, proteinases, DNAses, etc) with or without a surfactant step can be used to remove the non-PHA biomass (71). Biologists have used these methods to prepare native PHB granules to study intracellular enzymatic degradation. On a commercial level, a process in which the fermentation broth may be first heated to 80°C to denature DNA and some proteins has been described (72). A series of enzymes [such as lysozyme, phospholipase, lecithinase, or alcalase (proteinase)] are then used to obtain a product which is 90–95% pure with 6–7% proteins and some peptidoglycan as major impurities. There may be a final wash with hydrogen peroxide to whiten the product. This was the method used for the production of P(HB-*co*-HV) (73), which was sold under the trade name Biopol by Zeneca, and later by Monsanto. When PHA granules recovered by enzymatic treatment are freeze-dried, they have a hard, crystalline shell and an amorphous core (6).

Chemical Methods. Strong oxidizing agents such as sodium hypochlorite at pH 10 have been used to dissolve the cellular biomass under conditions which result in significant loss of PHA molecular weight. However, by optimizing the operating conditions, PHB with a weight-average molecular weight of 600,000 g/mol and 95% purity has been obtained from *R. eutropha* biomass containing 50% PHB with an initial molecular weight of 1,200,000 g/mol. When the biomass is pretreated with a surfactant, less contact time with hypochlorite is needed to obtain PHB with the same purity. This allows an even higher molecular weight (800,000 g/mol) to be obtained (74). Never-dried granules obtained by surfactant-hypochlorite treatment also have an external crystalline shell and an amorphous core (75). Similar PHB recovery, molecular weights, and purity may be obtained when sodium hypochlorite is omitted and only an NaOH solution at pH 13 is used.

Physical Methods. Although there are many methods (eg reciprocating pump, ball mill) to physically disrupt microbial cells, there have been few processes which are based on these principles proposed for the large-scale recovery of PHAs. A process in which a biomass suspension was heated to 220°C

under nitrogen in an autoclave and then forced through a fire-jet into a tank of cold water has been patented (76). Cell breakage occurred, releasing PHB granules which were suspended in 50% aqueous acetone to remove lipids and to cause flocculation.

Commercial Production

PHB remained an academic curiosity until the fifties and sixties when W.R. Grace and Co. in the United States produced small quantities for commercial evaluation. They obtained patents for production processes and manufactured articles such as sutures and prosthetic devices (77) but eventually abandoned the project because of low PHB yields and difficulties in the separation process. About 10 years later, Imperial Chemical Industries (ICI) began a program in PHA production and product development. They patented (78) the first commercial process to produce SCL PHA copolymer (P(HB-*co*-HV)).

Choice of Production Strain and Process. The most important economic considerations are substrate costs, reactor productivity, and separations costs. SCL PHA can be produced from hydrolyzed starch (glucose), lactose (recombinant *E. coli* on cheese whey), cane or beet molasses (*Azotobacter vinelandii* or *Alcaligenes latus* on sucrose), waste wood (fermented hydrolyzed hemicellulose), methanol, and even mixtures of hydrogen and carbon dioxide (*R. eutropha*). Addition of an appropriate cosubstrate such as propionic acid results in P(HB-*co*-HV) synthesis in any of these processes although the percentage of HV can vary considerably depending on the bacterial strain. High productivity has been reported for several of these substrates. Using *R. eutropha* growing on glucose, 164 g/L of biomass containing 76% PHB has been produced in a fed-batch process in only 50 h (79). Densities well in excess of 100 g/L have been reported for fed-batch processes using *E. coli* strains with multicopy plasmids containing the key SCL PHA synthetic genes (80) as well as for methylotrophs growing on methanol (81). In recombinant *E. coli* strains, PHB content is frequently reported as being in excess of 90% of the biomass dry weight, making the separation process much simpler.

MCL PHA. The highest productivity results from using octanoic or nonanoic acids, but these are toxic at concentrations of several grams per liter and their low solubility may limit the growth rate because of poor mass transfer. Sodium salts of these acids are much more soluble but the final product concentration in fed-batch culture is limited by the accumulation of toxic concentrations of sodium ions in the medium. In any event, the present cost of both the salts and the acids prohibit their use in commercial production. Most microorganisms which make MCL PHA produce lipases and grow well on vegetable oils but the lipase concentration may limit the production rate. A *Pseudomonas putida* strain has been grown in fed-bath culture from oleic acid (a fatty acid commonly found in plant oils) to a biomass concentration of 92 g/L containing 45% PHA in 26 h (82). Because of their low density, these PHAs float to the surface after breakage of the bacterial cell and can thus be easily and cheaply separated from the rest of biomass.

Commercial Production Methods. Tredegar Industries has used recombinant *E. coli* to produce over 100 g/L of biomass containing at least 80% PHB by dry weight at the pilot-scale level. Mild detergent treatment and washing

steps followed by spray drying result in a white product which is 98% pure (83).

Fermentation and separation processes were developed for the pilot-scale production of PHB using an *A. latus* strain as well as its further processing into consumer products. Up to 1 ton/week of PHB was produced in Austria in a 15,000-L bioreactor (84). This technology is currently owned by the German company Biomer. The Biomer fermentation process is relatively simple with multistaging from the petri dish to a shake flask to a small fermentor which is then used to inoculate the production reactor (Fig. 5a). If sufficient carbon source (molasses) is added during the fed-batch process, up to 60 g/L of PHB may be obtained. The

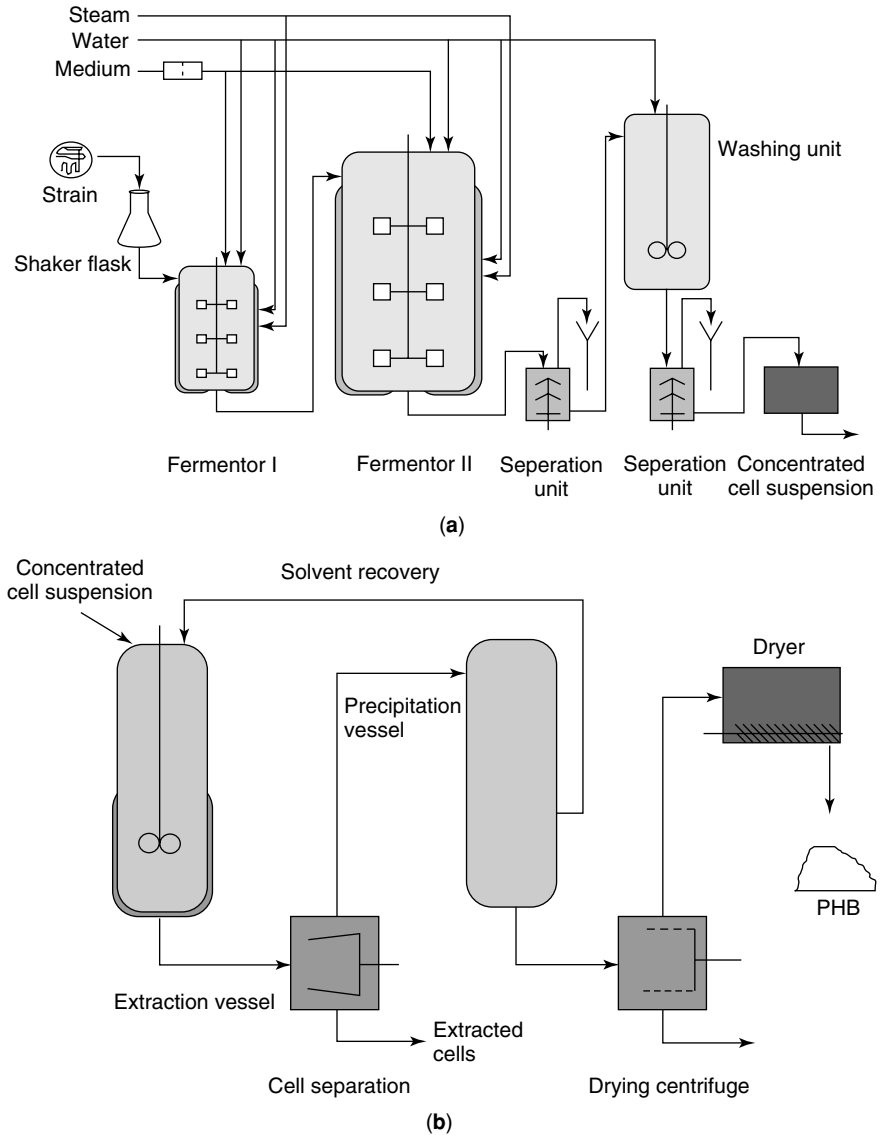

Fig. 5. (**a**) Biomer PHB fermentation process. (**b**) Biomer PHB separation process.

resulting biomass is washed in water. The concentrated cell suspension is then subjected to methylene chloride extraction (Fig. 5b). The resulting slurry is separated in a decanter. The solvent phase is then injected into hot water in a precipitation vessel where methylene chloride evaporates and PHB precipitates. After water removal (drying), PHB can then be processed into a marketable product.

Biopol [P(HB-*co*-HV)] has been produced from glucose and propionic acid in 35,000-L airlift reactors and in up to 200,000-L stirred tank reactors (85). Phosphate limitation (after about 60 h of growth) is used to trigger the accumulation phase in a strain of *R. eutropha*. Phosphate limitation was found to give better results than nitrogen limitation (86). Although solvents (chloroform or methylene chloride extraction after a hot methanol wash) may be used when high purity is required, the P(HB-*co*-HV) is usually obtained by treatment of the biomass with a series of surfactants, enzymes, and possibly oxidizing agents to dissolve the non-PHA biomass. The product is essentially a latex that may then be washed, spray-dried, compounded with nucleating agents and plasticizers, and extruded in the form of pellets. Until recently, several grades of Biopol were available at a cost of about 17.60/kg. Monsanto reported that Biopol production costs were 25–30% greater than those of polyolefins and has discontinued production.

Copersucar (Sao Paulo, Brazil) currently manufactures up to 5 tons of PHB per month in a fed-batch process using a 20,000-L fermentor equipped with a Frings aeration system. A *Burkholderia* sp. or *R. eutropha* mutant lacking PHA depolymerase is grown on inverted sugar and mineral salts. The PHB accumulation phase is triggered by phosphate limitation. The PHB is extracted in a mixture of boiling alcohols (a waste from ethanol distillation) under reflux. The cellular debris is removed and the polymer precipitates on cooling. Solvent is recovered by injecting the solvent/PHB paste on boiling water under vaccum. Copersucar may be able to sell PHB much more cheaply than its competitors as it has access to inexpensive carbon (sucrose) and energy (bagasse) sources.

Future Prospects

Cost of production is not a major consideration if PHA is to be used exclusively for specialty applications. However, if PHA is to be economically competitive with synthetic plastics, it must be produced on a far larger scale than any other aerobically produced microbial product. An additional problem arises from the fact that PHAs are intracellular products. Thus the amount that can be produced per cell has physical limitations.

In a typical PHA fermentation process, the cost is divided fairly evenly between substrate cost, capital, and operating expenditures in the fermentation process and the cost of separating the PHA from the microbial biomass. Typically the yield of dry biomass from a hexose sugar such as glucose is about 42% for *R. eutropha*. If the final biomass contains 75 wt% by weight of recoverable PHA, then the yield of PHA from the total amount of substrate supplied is about 32%. Thus, if carbon substrate was available at $500/t, the cost of the carbon source alone would be $1560/t, making the product twice as expensive as bulk synthetic plastics.

New methods such as the incorporation of temperature-sensitive plasmids for the production of autolytic enzymes should reduce separation costs. The direct

use of PHA-containing bacteria in melt processing (ie no separation process apart from water removal) has also been proposed. However, even assuming a negligible cost for the carbon source by using a waste material such as cheese whey permeate, and neglecting the separation costs, studies have shown that PHA produced in bioreactors could not be economically competetive with synthetic bulk plastics in the foreseeable future. The volumetric production rate cannot compete with chemical processes and this rate is limited by the oxygen transfer rate of present day bioreactors. New technologies must be developed for commercial PHA production.

In vitro synthesis of PHA granules from activated substrates may eventually become commercially feasible. In *R. eutropha*, the maximum rate of PHA synthesis occurs early in accumulation phase and deteriorates slowly thereafter. One would therefore expect that the maximum amount of PHA accumulation would depend on enzymatic activity or on NADPH or substrate supply. However the most detailed published study on this process points to a physical limitation (86) where polymer synthesis slows to a virtual stop simply because there is no more space available. If this is indeed the case, then the way around such a limitation is to produce the PHA granules outside the cells. This has been achieved (87,88). Commercial exploitation of this process requires a source of the biosynthetic enzymes (easily achievable through molecular biological techniques), substrates, NADP, and a method for NADP reduction already used in commercial steroid transformation processes. This would eliminate or greatly reduce separation costs. The present economic and technical barrier to this process is the lack of an inexpensive method to link coenzyme A to the appropriate carboxylic acid.

It is likely that in the near future, starch, oilseed, or leguminous plants will be used to produce PHAs. Other plant materials such as cellulose and starch are already used to make plastics or plastic-like materials. Hemicelluloses have been used directly and/or converted to organic acids for PHA production at a laboratory scale. Thus any waste from the separation of PHA from plants could be hydrolyzed, fermented to lactic, acetic, and propionic acids, and then fed into bioreactors for the production of specialty PHAs. Polylactides and other polymers of organic acids could be produced in the same plant as could polysaccharides. Plant materials may become a major source of plastic materials in the next century with PHAs leading the way.

POLY(TRIMETHYLENE TEREPHTHALATE)

Introduction

Poly(trimethylene terephthalate) (PTT, also abbreviated as 3GT) is an aromatic polyester made by the melt polycondensation of 1,3-propanediol (PDO) with either terephthalic acid (TPA) or dimethyl terephthalate (DMT). Although available commercially only since 1998, it was one of the three polyesters first synthesized by Whinfield and Dickson (1) in 1941. Two of which, the so-called even-numbered poly(ethylene terephthalate) (PET) and poly(butylene terephthalate) (PBT) for the number of methylene units in their chemical structures, are well-established high volume polymers. However, the odd-numbered PTT remained an obscure polymer. It was never commercialized until recently because PDO was very expensive and was available only as a small volume fine chemical.

In the early 1970s, there were interests to commercialize PTT (2–4); however, they were short-lived. Despite making significant progress in lowering PDO manufacturing cost, the economics was still not good enough. Interest was revived in the late 1980s when Shell Chemical Co. (5) and Degussa (6) had breakthroughs in PDO manufacturing technologies. Shell began selling PTT in 1998 and completed building a new PDO plant (7). It was followed by DuPont announcing the building of a PTT plant by first using PDO acquired from Degussa, and later using PDO from bioengineering route (currently under development) when it becomes available (8). More than half a century after it was first synthesized, PTT finally joined PET and PBT and became a commercial reality. PTT from Shell is trademarked as Corterra polymer and DuPont's trademark is Sorona 3GT.

1,3-Propanediol Monomer

1,3-Propanediol [504-63-2], also called trimethylene glycol, is a colorless, clear liquid with a boiling point of 214°C. The traditional synthesis route, practiced by Degussa, is to hydrate acrolein (9) under pressure with an acid catalyst such as acidic ion-exchange resin into 3-hydroxypropanal (3-HPA). This intermediate is not isolated. The aqueous solution is hydrogenated into PDO using Raney nickel catalyst. A new commercial route developed by Shell uses ethylene oxide (EO) as the starting raw material. Ethylene oxide is first hydroformylated into 3-HPA, using a combination of CO and H_2 synthesis gas with cobalt catalyst (5). 3-HPA is concentrated and hydrogenated into PDO. Commercial quantities of PDO are now available from both processes. A third route with the potential of further lowering PDO cost is by enzymatic fermentation (10,11) of glycerol and alcohol. This bio-route is under active development by DuPont and Genencore International. With advances in biogenetic engineering, new strains of engineered bacteria were reported to improve yield and selectivity that can be scaled up for commercial production.

Polymerization

PTT is melt-polymerized by either the transesterification of PDO with DMT or by the direct esterification of PDO with TPA. The process is similar to the polymerization of PET but with several important differences. Since the reactivity of PDO is much lower than that of ethylene glycol, "hot" catalysts such as titanium butoxide (12) and dibutyl tin oxide (13), normally too fast for PET, are used to polymerize PTT. Melt polymerization is carried out between 250 and 275°C, about 40°C lower than that used for PET. PTT has different polymerization side reaction products. Instead of cyclic trimers, PTT produces cyclic dimers. It also gives off acrolein and allyl alcohol instead of acetaldehyde gaseous by-products. Acrolein requires special handling and disposal.

Direct esterification of PDO with TPA is the preferred commercial route to polymerize PTT because it is more economical than using DMT. Figure 1 shows the reaction scheme. Because TPA has a melting point > 300°C and has poor solubility in PDO, esterification is carried out in the presence of a "heel" and under a pressure of 70–150 kPa at 250–270°C for 100–140 min. *Heel* is an oligomeric PTT melt with a degree of polymerization (DP) of 3–7 purposely left in the reaction vessel from a previous reaction to act as a reaction medium and to increase TPA solubility. The esterification step is self-catalyzed by TPA. After reaching a DP of about 3–7, 40–50% of the oligomers is transferred to the polymerization vessel. Titanium butoxide or dibutyl tin oxide catalyst (50–150 ppm) is added to initiate polymerization at 260–275°C. Vacuum (<0.15 kPa) is applied to remove the condensed water until the polymer reaches an intrinsic viscosity (IV) of 0.7–0.9 dL/g.

To obtain higher molecular weight PTT with IV > 1.0 dL/g, melt-polymerized chips are further solid-stated (14,15) at 180–210°C under nitrogen to prevent polymer yellowing from prolonged melt polymerization. Solid-stating also helps driving off residual gaseous by-products in the polymer chips; however, the molecular weight distribution is broadened from 2 to about 2.5.

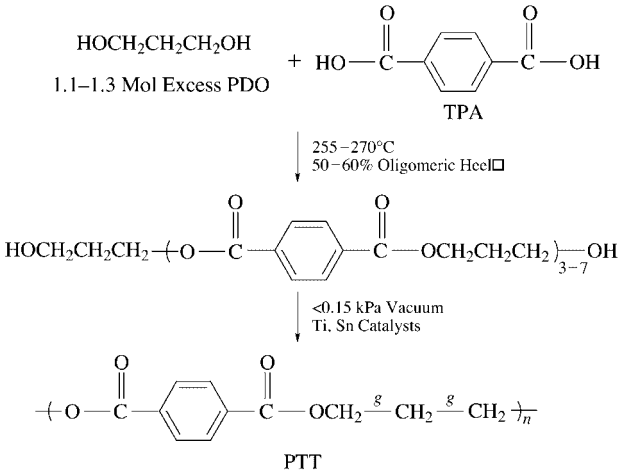

Fig. 1. PTT polymerization by direct esterification of TPA with PDO. *Gauche* conformation of PTT's methylene units is indicated by *g*.

Side Reactions and Thermal Degradation

PTT melt undergoes several side reactions during polymerization and melt processing. It has been proposed that PTT undergoes thermal degradation similar to PET via McClafferty rearrangement of the ester moiety (16,17). The carbonyl group abstracts a β-methylene hydrogen through a six-membered cyclic transition state, and this event is followed by chain scission giving terminal carboxyl and vinyl end groups in the fragmented chains. Further scission of the vinyl end gives allyl alcohol and its oxidative product acrolein. Under inert atmosphere, PTT has similar thermogravimetric weight loss profile as PET (18) with only one main decomposition step. Degradation in air was, however, different and involved two mechanisms. At about 300°C, degradation was decomposition-controlled. At a higher temperature, the rate increased and degradation changed to diffusion-controlled.

Cyclic oligomer is generated by chain backbiting similar to that in PET. Instead of cyclic trimer, PTT forms cyclic dimer with a melting point of 254°C. During polymerization, some PDO is dimerized into dipropylene ether glycol (DPG) and are incorporated in PTT as copolymer. Presence of DPG moiety lowers the polymer's melting point and affects the fiber's dye uptake. These side reactions could be suppressed to various extents by adding antioxidants and phosphites, using high purity PDO, and controlling the polymerization conditions (19).

Thermal Properties

PTT is a semicrystalline polymer with a glass-transition temperature T_g of 45°C and a melting point T_m of 228°C, both measured by a differential scanning calorimeter (dsc). The T_g of PTT is dependent on the polymer's crystallinity. It

Table 1. Thermal Properties of PTT

Property	Value	Reference
Melting point, °C	228	–
Equilibrium melting point, °C	244, 248	21,22
Heat of fusion ΔH_f, kJ/mol	30±2	23
Fully amorphous heat capacity, J/(K·mol)	94	23
Crystallization half-time @ 180°C, min	2.4	24
Cold crystallization temperature, °C	65	–
Glass-transition temperature, °C	45	–
Thermal diffusivity, m^2/s		
@ 25°C	1.36×10^{-7}	25
@ 140°C	0.99×10^{-7}	25

remains at 45°C up to about 30% crystallinity, and increases rapidly to about 70°C when crystallinity reaches 50% (20). The heat of fusion ΔH_f for a 100% crystalline PTT is 30 ± 2 kJ/mol. Other thermal properties are shown in Table 1. When PTT was rapidly quenched from the melt, the dsc heating scan showed a cold crystallization exotherm at about 65°C; however, a slowly cooled PTT does not cold crystallize. Therefore, the crystalline morphology is dependent on the melt quench history, and affects the drawing behavior of the polymer. The reversible and irreversible heat capacities were measured using adiabatic calorimetry, dsc, and temperature-modulated dsc (23,26). The measured heat capacities for both solid state and liquid state PTT agreed well with values calculated from the Tasarov equation based on polymer chain skeletal vibration contributions (Fig. 2).

Crystallization Kinetics

A comparison of the isothermal crystallization kinetics of PET, PTT, and PBT using a dsc showed that PTT has a crystallization rate in between those of PET and PBT (24). The Avrami rate constant K was of the order of 10^{-3}–10^{-2} min^{-n} when crystallized at 175–195°C. It is about an order of magnitude higher than PET but an order of magnitude lower than PBT when they were compared with the same degree of undercooling from the melt. PTT has a spherulitic growth rate of 117–4.7 μm/min, and it requires 4.8 kcal/mol of work for lamellae chain folding (22). On the basis of secondary nucleation analysis, a multiple nucleation crystallization mechanism transitioned from regime II to regime III at around 194°C was reported (22). Since the work of chain folding and the nucleation mechanism transition temperature were between literature values of PET and PBT, the three polyester crystallization rates rank in the same order.

A rapidly quenched PTT cold crystallizes when it is heated to above its T_g. It was found that PTT cold crystallized at a much faster rate than PET by following the increase in PTT crystalline band at 1220 cm^{-1} using rapid scanning Raman spectroscopy (27). At 71°C, PTT crystallized and reached 80% of its equilibrium crystallinity in <1 min whereas PET did not cold crystallize at all.

Molecular Weights

As a norm, molecular weight M of a polyester is given by its intrinsic viscosity (IV), also called limiting viscosity number $[\eta]$; M and $[\eta]$ are related to each other through the Mark–Houwink equation

$$[\eta] = KM^{\alpha} \tag{1}$$

where K and α are constants unique to the solvent and temperature used in measuring IV. Because of the fast crystallization rate, PTT chips have higher crystallinity than PET and are much more difficult to dissolve. A stronger solvent such as hexafluoroisopropyl alcohal (HFIPA) is used to dissolve PTT at room temperature. However, by heating to 110°C and taking care to ensure complete dissolution, mixtures of tetrachloroethane/phenol, typically used for PET, have been successfully used for PTT. Table 2 shows PTT's Mark–Houwink constants for various solvents (28,29), and the methods of molecular weight measurement.

In practice, IV is often measured using the simplified single-point method to save time. Simplified equations (30–33) gave good estimations of IV compared to the more rigorous Huggins or Kraemer plots to within ±3% when the solution concentration is kept at <0.005 g/dL (28).

Crystal Structure

Like PET and PBT, PTT crystallizes into the triclinic crystal structure (34–37). Unit cell dimensions obtained from wide-angle x-ray diffraction (waxd) are a=0.459, b=0.621, c=1.831 nm, $\alpha = 98°$, β=90°, γ=112° (34). The c-axis contains

Table 2. PTT Mark–Houwink Constants

Solvent	Temperature, °C	Molecular weight[a] determination[a] method[a]	K, 10^4 dL/g	α	Reference

60/40 Tetrachloroethane/ phenol	30	sals	5.36	0.69	24
50/50 Tetrachloroethane/ phenol	20	sals	8.2	0.63	25

[a]sals = small-angle light scattering.

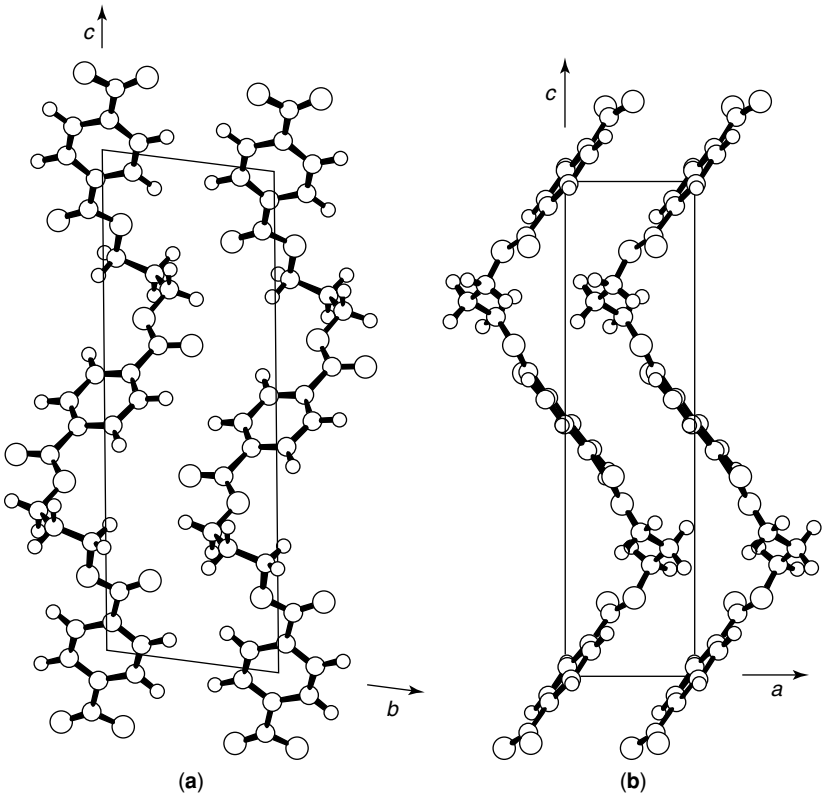

Fig. 3. Crystal structure of PTT viewed in the (**a**) *bc*-plane and (**b**) *ac*-plane showing the zizzag chain from the *gauche–gauche* conformation of the methylene units. Reprinted from Ref. 34, Copyright 1979, with permission from Elsevier Science.

two PTT repeating units with the methylene groups arranged in a *gauche–gauche* conformation. When viewed in the *ac*- and *bc*-plane, the chains are arranged in a highly contracted zizzag manner compared to that of PBT and PET (Fig. 3). There are disagreements in the reported crystal densities. Densities based on waxd crystal structures are much higher than those obtained by electron diffractions (38).

Measurements of the densities of a series of 19 PTT samples with dsc crystallinities from 14 to 35% gave an extrapolated crystal density of 1441 kg/m^3, in closer agreement to the waxd unit cell density (39). Until more work was done, the author's research group used 1432 kg/m^3 for crystallinity measurement, based on crystal structure parameters (34). Using a group contribution method, an amorphous density of 1295 kg/m^3 was calculated (25) in good agreement with the extrapolated value obtained by Ziabicki (39).

PTT waxd crystal orientation function f_c can be measured from the azimuthal scan of 010 reflection. The Herman orientation function equation using this reflection has been given by (38), and is based on Wilchinsky's treatment of uniaxial orientation:

$$f_c = 1 - 3\cos^2\phi_{010,Z} \tag{2}$$

where $\langle\cos^2\phi_{010,Z}\rangle$ is the average cosine angle of the normal of (010) plane made with the draw direction Z.

Mechanical Properties

Table 3 compares properties of PTT, PET, and PBT (40). They were measured on injection-molded samples using ASTM test methods. Tensile strength, flexural modulus, and notched Izod impact of PTT fall in between those of PET and PBT. All three polymers have similar electrical properties except for PET which has lower volume resistivity. The lower moisture absorptions of PTT and PBT are due to the high crystallinities from fast crystallization.

Dynamic Mechanical Properties. The PTT dynamic mechanical relaxation spectrum shows three viscoelastic relaxations (41). α-Relaxation occurs at -70°C and is the glass-transition temperature. T_g obtained by dynamic mechanical methods is usually higher than that from a dsc, and is frequency dependent.

Table 3. Comparison of PTT, PET, and PBT Properties

Property	PET	PTT	PBT
Tensile strength, MPa[a]	72.5	67.6	56.5
Flexural modulus, GPa[b]	3.11	2.76	2.34

[a] To convert MPa to psi, multiply by 145.
[b] To convert GPa to psi, multiply by 145,000.
[c] To convert J/m to ft·lbf/in., divide by 53.38.

α-Relaxation as high as 91°C has been reported (42). There are two subzero relaxations. β-Relaxation occurs at about −70°C. It originated from the amorphous phase (43), and has been attributed to the reorientation of the hydroxyl groups and local motions of the carboxyl groups. γ-Relaxation occurs at about −105°C and overlaps with the β-relaxation peak as a shoulder. This relaxation comes from the cooperative movement of the methylene segments containing at least three consecutive methylene units (44), and is therefore a low temperature motion of the trimethylene glycol portion of the polymer.

Elastic Recovery. The fiber industry has long been aware of PTT having the best tensile elastic recovery and resiliency among the three aromatic polyesters (45). This property is very desirable for fiber applications such as in carpets and textile apparels. The driving force for PTT's good elastic recovery comes from the response of its molecular chain to the applied strain.

It has been shown (46) that PTT has a very low theoretical crystal modulus, 2.59 GPa (375, 550 psi), compared to 107 GPa (1.55×10^7 psi) of PET (47) because of PTT's highly contracted helical-like conformation, whereas PET chain is fully extended with trans conformation. When a PTT fiber is stretched *in situ* in a waxd, the fiber period, measured from the Bragg d-spacing, increases immediately and is proportional to the applied strain up to 4% strain before deviating from affine deformation (48). Up to this critical strain the crystal deformation is reversible. The response of microscopic crystalline chains to macroscopic deformation explains why PTT has the best elastic recovery among the three aromatic polyesters. Further, PTT's elastic recovery and permanent set are nearly the same as nylon-6,6 up to 30% strain (25).

Melt Rheology. Figure 4 shows the melt viscosity as a function of shear rate for a 0.92 dL/g IV fiber grade PTT from 245 to 275°C (49). At 265°C, the melt viscosity profile is nearly the same as that of PET at a typical processing temperature of 290°C. At high shear rates of 10^3–10^4 s^{-1}, found in injection

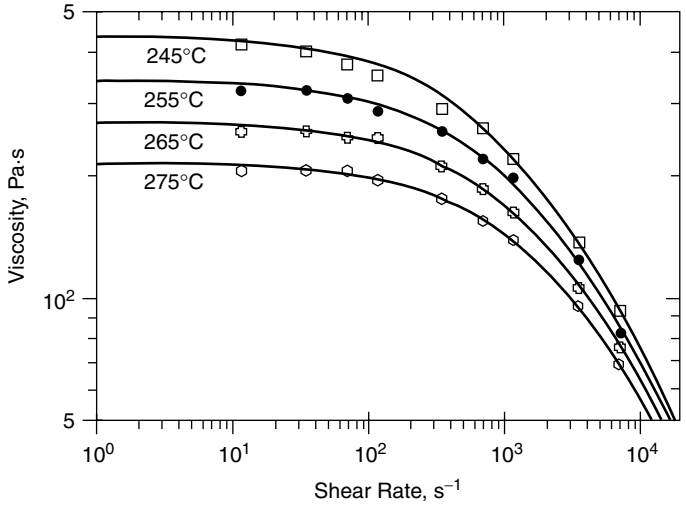

Fig. 4. Fiber grade 0.92 dL/g IV PTT capillary rheometer melt viscosity as a function of shear rate from 245 to 275°C. To convert Pa · s to P, multiply by 10.

molding and fiber spinning, the melt shear thins. It can be approximated as a power law fluid. However, PTT is more sensitive to shear thinning than PET with a non-Newtonian power law index n of 0.64 compared to 0.79 of PET (26).

Processing and Applications

Most of the developments to date have focused on textile and carpet fiber applications because PTT has a combination of several properties particularly suited for these applications. Table 4 compares PTT fiber properties with those of PET, nylon-6, and nylon-6,6 (20), (50), (51).

PTT fibers and yarns have bulk, resiliency, stretch-recovery, softness, hand, and drape similar to nylons and are much better than PET. As a polyester, it is inherently resistant to most stains that are acidic in nature because it does not have dye sites. It also has a lower static propensity. It is dyed with disperse dyes, but at a lower temperature than PET because of a lower T_g. The combinations of these properties are attractive to carpet and textile manufacturers for some applications where PTT could replace nylon or PET. It also offers the potential of creating new fiber products by using the unique combinations of these properties, which are not found in either nylon or PET.

Fiber end-use applications include (*1*) ready-to-wear, active-wear, intimate apparels, inner linings where stretch-recovery, softness, hand, and drape are the key attributes; (*2*) carpets where resiliency, newness retention, stain resistance, and low static generation provide values over currently used materials in some market segments; (*3*) automotive and home upholstery utilizing the easy dyeing, stain resistance, stretch-recovery properties. Within a short period of time since the polymer's commercialization, PTT ready-to-wear stretch apparels (52) and resilient floor coverings had already appeared in the market (since 1999).

Other applications are in monofilaments, nonwovens, films, engineering thermoplastics, and molded goods. Paper forming fabrics made with PTT monofilaments have been patented (53) for use in papermaking machines because PTT combines the chemical resistance of a polyester and the resiliency of the less chemical resistant nylon. PTT non-woven fabric shows better dimensional

Table 4. Comparison of PTT, PET, and Nylon Fiber Properties

Property	PTT	PET	Nylon
Yarn bulk and crimp	Excellent	Good	Excellent
Resiliency, stretch-recovery	Excellent	Fair	Excellent
Dyeing	Very good disperse-dyed at atmospheric boil without carrier	Good, disperse-dyed under pressure with carrier	Excellent, acid dyed
Stain resistance	Excellent	Excellent	Poor to very good
Electrostatic propensity	Excellent	Excellent	Poor to very good
Hand and softness	Excellent	Excellent	Very good
Drape	Excellent	Fair	Excellent

stability and is softer than polypropylene (54). Other applications include synthetic leathers (55) and flexible transparent film for packagings (56).

Fiber Processing. PTT used for fiber applications has IV of 0.80–0.92 dL/g ($M_n \approx$ 16,000–20,000). Prior to melt processing, the polymer chips must be dried to a moisture level of <30 ppm to avoid hydrolytic degradation. A close-loop hot air dryer is preferred. PTT is dried at 130°C and at a dew point of <−40°C for 6 h. Because of the faster crystallization rate, PTT chips are already semicrystalline after palletizing, and do not require a precrystallization step prior to drying as in PET.

The dried polymer is extruded at 250–265°C into fibers using conventional processing machines for bulk continuous filaments (BCF), partially oriented yarn (POY), spin-draw yarn (SDY), and staple fiber.

Carpets. The process of making PTT BCF carpets has been described in detail (57). The extruded yarn is drawn between sets of heated godets to a draw ratio 2.8–3.5 (58,59). It is then textured with hot air at 160–220°C and at a pressure of 0.6–1.0 MPa (87–145 psi) (60). Heat-setting with steam is at 135–145°C or at 175–195°C (61) when heat-set with the less effective heat conducting superheated steam. Tufted carpets are dyed with disperse dyes at atmospheric boil (62) in a continuous or a batch process. PTT carpets show excellent resiliency equivalent to a nylon in walk tests, have lower static charge of <3.5 kV, and are resistant to coffee, mustard, betadine, red acid dyes, and other stains (63).

Textile Fibers. PTT POY is spun using PET POY or SDY fiber spinning machines. Table 5 shows the tenacities and elongations of PTT fiber as a function of spinning speed (64). Tenacity increases while the elongation decreases with increasing speed. The PTT fiber stress–strain curve, unlike PET, has an inflexion point like a knee (45,65). A fully oriented PTT fiber has a modulus of 2.58 GPa (374,000 psi) compared to 9.15 GPa (1.33×10^6 psi) of PET (45).

PTT yarn has been textured by false-twist method at 140–160°C (64). Crimp development was almost twice as high as PET with crimp contraction reaching about 50%. When PTT yarns with a high level of crimp contraction are knitted into stretch fabrics, the amount of stretch achieved is equivalent to PET stretch fabrics incorporated with 6–8% of Spandex (66). In addition to stretch, PTT fabrics tend to have softer hand and better drape than PET. Since PTT does not absorb moisture like nylon, PTT fabrics also have a desirable dry touch and comfort.

Table 5. Tensile Properties of 150 dtex[a]/34-filament PTT Fiber as a Function of Spinning Speed

[b]To convert GPa to psi, multiply by 145,000.
[c]To convert J/m to ft·lbf/in., divide by 53.38.

Dyeing. Because of its low T_g, PTT is disperse-dyed at atmospheric boil without using carriers for plasticization (62,67,68). Most countries have legislations prohibiting or regulating the use of the environmentally harmful biphenyl type carriers. PTT is thus a much more environmentally friendly polymer than PET in this respect, although PET is now dyed under pressure at 130°C without using carrier. The dye uptake of PTT and PET fibers has been compared by measuring their Kulbelka–Munk, K/S, values as a function of dyeing temperature (68). PTT reached and leveled off at K/S of about 16 at 100°C whereas PET did not absorb much dye at this temperature. Dye uptake only leveled off at >120°C dyeing temperature with a less dense color shade K/S value of 13.

Injection Molding. Several patents describe the injection molding of PTT for applications as transparent heat-resistant bottles (69), impact, heat, and bending resistant electrical connectors (70) and others. Neat PTT can be injection molded at 250–260°C into a mold maintained at 70–80°C under a holding pressure of 3.1–4.2 MPa (450–609 psi) and a cycle time of 40 s (40). Colder mold temperature tends to cause uneven crystallization with the formation of an amorphous transparent skin and a highly opaque crystalline core. The spherulites formed ranged from small and disordered at the outer edges to more perfect and larger in the core with high stress-concentration interfaces. In extreme cases, the molded article could become brittle. Glass-filled PTT crystallizes at a much faster rate and reduces the cycle time to 30 s. Table 6 compares the properties of a 30% glass-filled PTT with PET and PBT (40). The heat distortion temperature is greatly improved by the glass from 59 to 216°C. Notched Izod impact is similar to that in PET and slightly better than in PBT.

Health and Safety

Since PTT is a new commercial product, Shell took up the responsibility of product stewardship (71) and registered the polymer on the chemical inventory lists of several countries. As a high molecular weight polymer, PTT is biologically inactive and requires safe handling like other commercial polymers.

When PTT is exposed to high heat such as during drying and melt processing, it releases acrolein, allyl alcohol, and cyclic dimer by-products (71). Among them,

acrolein is of special concern because it is a very strong lacrymator. It also irritates lung and respiratory tracts and affects breathing. The effects are acute and do not have cumulative long-term effects. OSHA industrial hygiene guidelines for time-weighted exposure limit of acrolein over a period of 8 h is 0.1 ppm, and the short-term exposure limit for 15 min is 0.3 ppm. Therefore, adequate ventilation must be provided to avoid acrolein exposure.

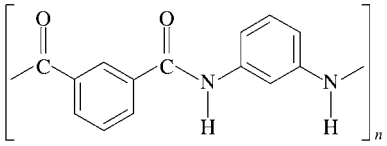
POLYAMIDES, AROMATIC

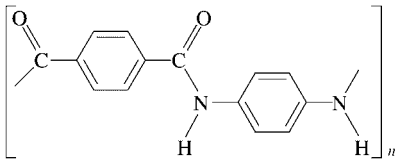
Introduction

Aromatic polyamides first appeared in the patent literature in the late 1950s and early 1960s, when a number of compositions were disclosed by researchers at DuPont (1–3). These polymers were made by the reaction of aromatic diamines with aromatic diacid chlorides in an amide solvent. Over 100 examples of aromatic polymers and copolymers described in patents were listed in a 1989 book (4). Another extensive list of polymers was provided in the previous edition of this encyclopedia (5).

Forty years later, after the expenditure of much time and money, the number of commercially important aromatic polyamide polymers has been reduced to three—two homopolymers, poly(*m*-phenylene isophthalamide) (MPDI) and poly(*p*-phenylene terephthalamide) (PPTA), and one copolymer, copoly(*p*-phenylene/3,4′-diphenyl ether terephthalamide) (ODA/PPTA) (6):

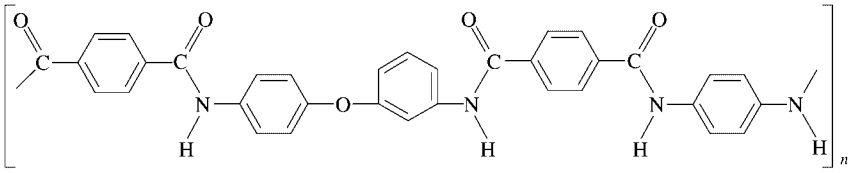


poly(*m*-phenylene isophthalamide) MPDI



poly(*p*-phenylene terephthalamide) PPTA

Encyclopedia of Polymer Science and Technology. Copyright John Wiley & Sons, Inc. All rights reserved.

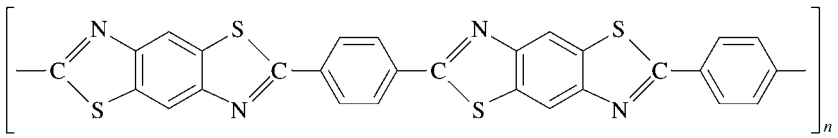


copoly(*p*-phenylene/3,4′-diphenyl ether terephthalamide ODA/PPTA

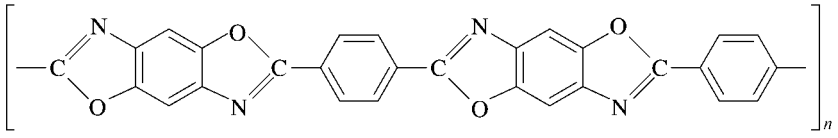
Because fibers from these aromatic polyamides have properties that differ significantly from the class of fibers known as polyamides (see Polyamides, fibers), the U.S. Federal Trade Commission adopted the term *aramid* as designating fibers of the aromatic polyamide type in which at least 85% of the amide linkages are attached directly to two aromatic rings.

The important properties of this class of polymers include thermal and chemical stability and the potential for high strength and modulus. Aliphatic polyamides melt at temperatures below 300°C, whereas most aromatic polyamides do not melt or melt above 350°C. Aramids also exhibit greater chemical resistance and low flammability. These properties derive from the aromatic character of the polymer backbone that can provide high chain rigidity. Aromatic polyamide fibers can have very high strength and modulus, and these properties persist at elevated temperatures. Because of their low density, aromatic polyamides have higher specific strength and modulus than steel or glass. In recent years, design engineers have been able to utilize these unique properties to create products which protect personnel from fire, bullets, and cuts, reduce the weight of aircraft and automobiles, and hold oil drilling platforms in place.

There are several other aromatic polymers, not polyamides, but which form fibers with high chain rigidity and similar properties. These would include poly(*p*-phenylene benzobisthiazole) (PBT) and poly(*p*-phenylene benzobisoxazole) (PBO) (Ref. 4, Chapt. VII):



poly(*p*-phenylene benzobisthiazole) PBT



poly(*p*-phenylene benzobisoxazole) PBO

There is no systematic nomenclature for aromatic polyamides; however, several codes can be found in the literature. Poly(*m*-phenylene isophthalamide) is referred to as MPD-I or MPDI, poly(*p*-phenylene terephthalamide) is referred to as PPTA or PPD-T, and copoly(*p*-phenylene/3,4′-diphenyl ether terephthalamide) is referred to as ODA/PPTA or HM–50. Another important polymer, although not

available in commercial quantities, is poly(*p*-benzamide), PBA. Codes will be used throughout the article to refer to these materials.

Sources of Ingredients

The principal ingredients for the manufacture of aromatic polyamides on a commercial scale are the diamine and diacid chloride monomers, plus the solvents used for the polymerization reaction. The chemical processes reported to be used for preparation of each of these ingredients are described in this section.

Solvents. The key polymerization solvents are readily available from several sources. They are dimethylacetamide (DMA), dimethylformamide (DMF), *N*-methyl-2-pyrrolidinone (NMP), and hexamethylphosphoramide (HMPA).

Monomers. *m*-Phenylene diamine (MPD) can be prepared by the continuous liquid phase hydrogenation of *m*-dinitrobenzene at moderate temperatures (7). One process employs a dispersion of the *m*-dinitrobenzene in water (8); another uses a solvent, such as DMF, which dissolves both the reactant and the MPD product (9). Catalysts for the hydrogenation include platinum, palladium, and nickel that must be recovered by filtration. Purification steps include vacuum distillation.

p-Phenylene diamine (PPD) can be made in a two-stage process (10). In the first stage aniline and sodium nitrite undergo diazotization to form benzenediazonium chloride, which in turn reacts with excess aniline to form the intermediate, diphenyltriazine. At low pH, diphenyltriazine is rearranged into *p*-aminoazobenzene. Finally, *p*-aminoazobenzene is cleaved by catalytic hydrogenation into PPD and aniline. The aniline is recycled to the first-stage reaction. The PPD then undergoes a series of purification steps, including vacuum distillation.

3,4′-Diaminodiphenyl ether (3,4′-ODA) can be prepared from 3,4′-dichlorodiphenyl ether by treatment with aqueous ammonia in the presence of an amide solvent (eg, NMP), using copper as a catalyst (11). Dichlorodiphenyl ether is prepared by treating the sodium salt of *p*-chlorophenol with *m*-dichlorobenzene in the presence of aqueous NaOH, followed by removal of the water and subsequent treatment with dimethylene glycol diethyl ether and CuCl (12).

Phthaloyl chlorides [isophthaloyl chloride (ICL) and terephthaloyl chloride(TCL)] are made by at least two processes, both involving the chlorination of phthalic acid. In the first (13), xylene is chlorinated by a photochemical reaction to form hexachloroxylene. The hexachloroxylene then reacts with phthalic acid to give the corresponding phthaloyl chloride and by-product HCl. Phthaloyl chloride is purified by double distillation. To produce ICL by this reaction, *m*-xylene and isophthalic acid are the starting materials. To produce TCL, the process starts with *p*-xylene and terephthalic acid. Phthaloyl chlorides can also be produced by reacting intermolecular anhydrides of the corresponding acids with phosgene, in the presence of an amide catalyst such as DMF or DMA (14).

Polymer Properties

A wide variety of aromatic polyamide polymers and copolymers have been disclosed in the patent literature. Table 1 provides a partial list of structures, the

Table 1. Examples of Aromatic Polyamides

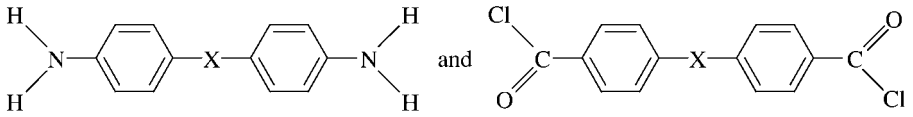
inherent viscosity of the polymer (a measure of molecular weight), and two thermal characteristics of the polymers. Many additional examples can be found in the literature (4,5).

With the exception of the A–B type polymer, poly(*p*-benzamide) (PBA), the polymerizations are of the A–A plus B–B type. A further distinction can be made between monomers with para orientation, eg, PPTA and those with meta orientation, eg, MPDI. The meta-oriented polymers are less easily crystallized, and therefore usually remain in solution throughout the polymerization. In some cases they can be spun into fibers directly from the polymerization medium. On the other hand, para-oriented polymers will tend to crystallize as they reach a certain chain length, so that they precipitate from the polymerization solution. This can limit the level of molecular weight that can be achieved, as will the nature of the solvent and the polymerization temperature.

Another important characteristic of the monomers is the presence of pendant groups attached to the aromatic ring. These pendant groups include alkyl, halogen, alkoxy, cyano, acetyl, and nitro. In addition to the simple phenylene compounds, diamines and diacid chlorides based on naphthalene and 4,4′-biphenyl have been used. A variety of monomers with bridging units of the following form have also been explored:



where X can be oxygen, sulfur, sulfone, keto, amine, or isopropylidene.

Thus, the number of chemical structures that could be (and has been) explored is quite large, especially when one considers the possible copolymer combinations.

Molecular Weight. The number-average molecular weight (M_n) of aromatic polyamides is generally in the range of 10,000–30,000, which is typical of condensation polymers. Because the measurement of M_n and M_w (weight-average molecular weight) is difficult and time consuming, the molecular weight of aromatic polyamides is commonly characterized by a dilute solution viscosity parameter termed *inherent viscosity* (η_{inh}). Inherent viscosity is an approximation of "intrinsic viscosity" ($[\eta]$), which, in turn, is classically related to molecular weight by the Mark–Houwink equation.

$$[\eta] = kM_w^a$$

Values of k and a in this equation have been measured for several aromatic polyamide solutions in 96% sulfuric acid (18,19).

PPTA	$k = 0.008$, $a = 1.09$
Poly(tetramethyl-*p*-phenylene terephthalamide)	$k = 0.0063$, $a = 0.96$
Poly(*p*-phenylene-2,5-dimethyl terephthalamide)	$k = 0.0021$, $a = 1.16$
MPDI	$k = 0.013$, $a = 0.84$

k has the units mL/g (divide by 100 to obtain the more commonly used units for η_{inh} of dL/g).

The viscosity/molecular weight relationship deviates from the Mark-Houwink equation at high levels of molecular weight (18). For PPTA this nonlinearity is pronounced above $M_w = 40{,}000$. Thus, at high levels of molecular weight, inherent viscosity will be somewhat misleading as an indicator of M_w.

Inherent viscosity is defined as

$$\eta_{inh} = \ln(t_{soln}/t_{solv})/c$$

where t_{soln} is the flow time for the polymer solution in the viscometer, t_{solv} is the flow time of the solvent, and c is the concentration of polymer in the solution specified as 0.5 g/dL (20). Thus, η_{inh} has the units of reciprocal concentration. Different solvents have been used. For the *para*-oriented polymers, the normal solvent is 96–98% sulfuric acid. For the meta-oriented polymers amide solvents are often used in place of sulfuric acid.

Molecular Weight Distribution. The polydispersity index (M_w/M_n) for PPTA has been estimated by gel permeation chromatography to be near 2 for low molecular weight polymers and nearer to 3 for polymers with $M_w > 35{,}000$ (18).

Thermal Properties. High melting point is one of the key distinguishing properties of aromatic polyamides. (In most cases the melting point exceeds the decomposition temperature, so that the material chars). A number of scientists have studied the thermal characteristics of aromatic polyamides by the differential thermal analysis (dta). Data for melting point are included in Table 1. The melting points of these polymers were empirically identified with the endothermic phase transitions from DTA measurements. One study did not detect a melting point for PPTA (15) while another (16) did (530°C). This has been attributed to molecular weight differences.

Thermogravametric analysis (tga) provides a measure of polymer thermal stability. In this test, polymer samples are heated at a programmed rate and sample weight is recorded as a function of temperature. Two studies (15,16) made tga measurements and reported the temperature for 10% weight loss (see Table 1). The thermal stability of these polymers is lower in air than in nitrogen.

Solubility. Solubility of selected aromatic polyamides in a variety of solvents has also been measured (15). In general, PPTA is soluble only in strong acids, such as sulfuric, hydrofluoric and methanesulfonic acids (all of the polymers cited are soluble in these acids). MPDI is also soluble in the amide solvents (DMF, DMA, and NMP) and in dimethyl sulfoxide, as are most of the substituted variations of these two polymers. Solubility in the amide solvents is increased by the addition of salts such as LiCl and $CaCl_2$. This class of polymers is generally not soluble in formic acid or *m*-cresol, which are common solvents for aliphatic polyamides.

Analytical and Test Methods. The properties described previously are all determined by well-known techniques in polymer chemistry. A description of each of the methods can be found in textbooks (20).

Laboratory Synthesis

Solution Polymerization. Most of the examples in the patent literature utilize solution polymerization. In this technique, an aromatic diamine is dissolved in an amide solvent and a stoichiometric quantity of an aromatic diacid chloride is added to the diamine solution while stirring vigorously. Important factors include monomer stoichiometry, ingredient and solvent purity, anhydrous conditions, diamine concentration (and therefore polymer concentration), and temperature of the starting diamine solution.

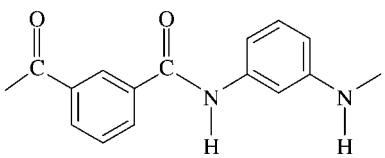
The primary polymer properties that are sought in these polymerizations are high polymer molecular weight and freedom from impurities that could impact the properties of products prepared from the polymer. All of the factors listed earlier can affect molecular weight. Stoichiometric imbalance will lead to excess ends that cannot react. Impurities, including water, can react with the active ends of one of the monomers. High temperature can lead to side reactions that produce unreactive ends. Since the reaction between an acid chloride and an amine is highly exothermic, the heat generated can significantly increase the temperature of the polymerizing solution. The extent of the temperature rise will depend on the diamine concentration and the degree of cooling.

For polymers that remain soluble in the polymerizing medium, such as MPDI in NMP, the reaction is rapid even at low temperature. For those that do not remain soluble, the choice of solvent becomes very important. More powerful solvents can produce polymers with higher molecular weights. Lower temperatures can also retard the precipitation of the polymer.

A 1965 book (21) discusses low temperature solution polycondensation at length, although it does not deal with the reaction of aromatic diamines with aromatic diacid chlorides by this method. The book also discusses interfacial polymerization.

A mechanism for these low temperature polymerizations has been proposed (Ref. 4, pp. 115–119). It involves an initial stage in which the amine reacts with an acid chloride liberating a molecule of HCl. The HCl, in turn, forms a complex with either an unreacted amine end or a molecule of solvent. An equilibrium is established between the amine hydrochloride and the solvent hydrochloride that depends on the basicity of the solvent. The first stage proceeds until half of the amine has reacted, at which point nearly all of the amine ends have formed an HCl complex. The second stage of the reaction is much slower and depends on the availability of free amine.

Poly(p-benzamide). PBA is an interesting case. One monomer from which a high molecular



weight polymer can be made is *p*-aminobenzoyl chloride hydrochloride. This monomer can be synthesized from *p*-aminobenzoic acid and thionyl chloride,

forming the intermediate, sulfinyl aminobenzoyl chloride, followed by treatment with dry HCl in ether (22). When this monomer is dissolved in an amide solvent such as DMA, an equilibrium is set up between the amine hydrochloride of the monomer and the solvent hydrochloride. Some free amine is formed and the polymerization proceeds. As one would expect, this monomer is extremely sensitive to water and heat.

Poly(m-phenylene isophthalamide). The formation of MPDI is an example of a polymerization in which the polymer remains soluble in the polymerizing medium. Suitable solvents are NMP and DMA with the possible addition of LiCl or $CaCl_2$. MPD is dissolved in anhydrous solvent at a concentration of up to 1.0 mol/L and cooled to 0°C, stirring vigorously. Solid ICL is added and the stirring is continued for 30 minutes. The resulting polymer remains in solution and has an η_{inh} of 1.8 (3).

Poly(p-phenylene terephthalamide). PPTA provides an example of a polymer that has very limited solubility in suitable solvents. In the laboratory, PPD is dissolved in an amide solvent in concentrations up to 0.5 mol/L. The solution is cooled to near 0°C, stirring vigorously. Solid TCL in an equal stoichiometric quantity is added and within a few minutes the solution becomes opalescent. Vigorous stirring is continued as the polymerizing mixture solidifies and then breaks into particles with the consistency of wet sawdust. This crumb can then be neutralized with dilute caustic, washed with water, and dried. The resulting polymers exhibit η_{inh} as high as 6.0 (23).

Because polymerization will proceed much more slowly when the polymer becomes insoluble, the selection of the solvent has an important effect on the level of molecular weight that can be achieved. Solvents using mixtures of HMPA and NMP or HMPA and DMA produce polymers with higher molecular weight than any of the three solvents alone (24). Similarly, salts can be added to amide solvents to increase the solubility of PPTA and thereby increase the η_{inh} level that can be obtained (24). The combination of NMP and $CaCl_2$ is especially useful for providing high molecular weight PPTA (25). Another approach for increasing the level of molecular weight that can be attained is the use of an acid acceptor, such as tertiary amines (26) and tributyl amine (27).

Copolymers. A large number of copolymer compositions have been prepared, many by low temperature solution polymerization, including ODA/PPTA (Ref. 4 pp. 145–172; 28,29).

Interfacial Polymerization. Some of the earliest reports of the preparation of aromatic polyamides employed interfacial polymerization. In this technique the diacid chloride is dissolved in a solvent with limited water solubility and then added to an aqueous solution of the diamine with vigorous stirring. The aqueous solution contains a base that neutralizes the HCl that is generated. One example is the preparation of MPDI using tetrahydrofuran as the solvent for ICL (2).

This process is difficult to develop at a commercial scale. A modified process for producing MPDI allows the ICL and MPD to react slowly in a solution without an acid acceptor. This reactive solution is then added to an aqueous solution containing an acid acceptor and stirred vigorously to build molecular weight in an interfacial-type polymerization. This process gives higher molecular weight than

solution polymerization techniques and therefore, improved fiber properties. This is the process that Teijin uses to produce the polymer for their MPDI product, Teijinconex® (30).

Vapor Phase Polymerization. PPTA can be formed by vapor phase polymerization at temperatures above 250°C (31). The polymer produced appears to have a high degree of branching, which makes the spinning of fibers with high strength more difficult. Improved products may be formed by using an acid acceptor that would permit shorter reaction times (32).

Commercial Polymerization Processes

There are relatively few commercial products based on aromatic polyamides. These are listed in Table 2. Processes for producing the polymers, for those products where reliable information has been published, are described.

MPDI. The commercial process for MPDI has been proposed (5) based on the patent literature (35). A block diagram of the process is shown in Figure 1.

The diamine noted in the figure is actually a 9.3% solution of MPD in DMA in the patent example, and the diacid chloride is molten ICL. The MPD solution is cooled to −15°C, while the molten ICL is supplied at 60°C. The heat of reaction brings the temperature of the effluent from the mixer to 74°C. This effluent is then cooled before $Ca(OH)_2$ is added to neutralize the HCl formed in the polymerization reaction. Finally, the polymer solution is blended, deaerated, and filtered before being pumped to storage for use in spinning. The MPDI of the patent example has an η_{inh} of 1.65.

A second polymer process is the modified interfacial polymerization described earlier (30). In this process, the polymer is isolated and dried, then redissolved for spinning, as shown in Figure 2.

PPTA. The commercial process for PPTA has been proposed (5) based on the patent literature (36,37). A block diagram of the process is shown in Figure 3.

Table 2. Commercial Products Based on Aromatic Polyamide Polymers

Polymer	Type of product	Trade name	Capacity,[a] t/year	Manufacturer
MPDI	Fiber	Nomex	15,900	E. I. du Pont de Nemours & Co.
MPDI	Fiber	Teijinconex	2,300	Teijin Co., Ltd.
MPDI	Fiber	Fenylon	900	Russian State Complex
PPTA	Fiber	Kevlar	29,900	E. I. du Pont de Nemours & Co.
PPTA	Fiber	Twaron	11,000	Accordis (Twaron Products bv)
PPTA	Fiber	Fenylon ST	1,300	Russian State Complex
ODA/PPTA	Fiber	Technora	800	Teijin Co., Ltd.
Aramid copolymer	Film	Mictron	400	Toray Industries, Inc.
PPTA	Film	Aramica	200	Asahi Chemical Industry, Ltd.

[a]Data for fiber capacities from SRI International (33); data for film capacities from *Japan Chemical Week* (34).

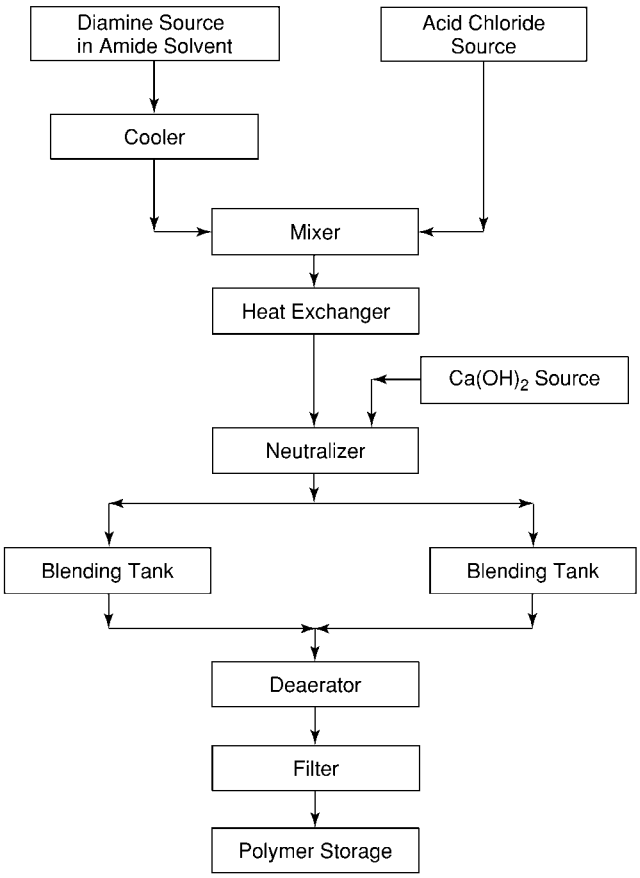


Fig. 1. Preparation of MPDI via low temperature solution polymerization (35).

In this process, PPD is dissolved in HMPA and then mixed with molten TCL in a series of mixers equipped to remove some of the heat of reaction. The polymer/solvent crumb is then washed with water, filtered, and dried. For health reasons, HMPA has been replaced by NMP/$CaCl_2$ as a solvent.

A similar process has been described for the production of PPTA for the Twaron process (10), although the polymerization reaction is done in batch reactors. The solvent is NMP containing $CaCl_2$. The polymer has a molecular weight (M_n) of 18,000–19,000.

ODA/PPTA. The polymerization process for producing ODA/PPTA has been described (6,28,29). PPD and 3,4′-ODA are dissolved in a solvent such as NMP and then reacted with TCL to form the copolyamide. The composition is likely 50% 3,4′-ODA and 50% PPD. When the reaction is complete the HCl formed is neutralized by the addition of $Ca(OH)_2$ to give a stable viscous solution that is suitable for spinning. The inherent viscosity is in the 2–3 dL/g range and the polymer concentration is around 6 wt%. The process is quite similar to that shown in Figure 1 after accounting for the use of two diamines.

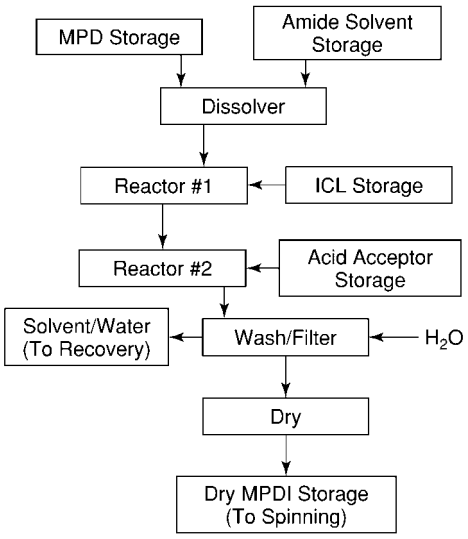

Fig. 2. Preparation of MPDI via interfacial polymerization (30).

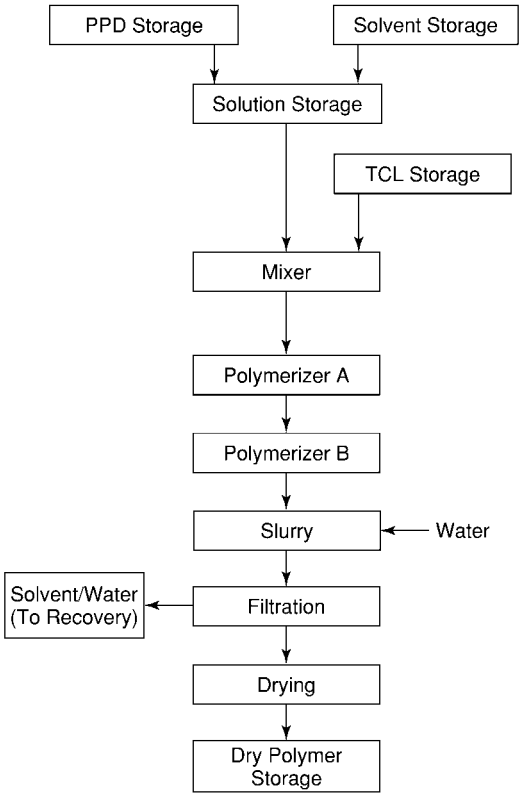

Fig. 3. Preparation of PPTA via low temperature solution polymerization (37).

Processing of Aromatic Polyamides

Most of the aromatic polyamides we have discussed so far have high melting points that prevent the type of melt processing common to aliphatic polyamides, polyolefins, and other polymers. Thus, most applications are based on forms of the polymer that can be prepared from solutions of the polymers. These would include fiber, films, and pulp.

Techniques for processing polymer solutions are well known (See Fibers) and include wet spinning and dry spinning of fibers and solution casting of films. In order to minimize the cost of commercial processes, large numbers of fibers must be handled together, at high speed, and with minimum interruptions to the operation. Commercial processes for forming aromatic polyamide products are described in this section, focusing on the types of solution that are employed and the methods used to coagulate the fibers and complete the development of the fiber structure.

Wet Spinning MPDI. A flow diagram for the wet spinning of MPDI to form Teijinconex is shown in Figure 4 (30).

The process involves dissolving the dry, salt-free polymer in an organic solvent at low temperature and then heating the dispersion to near 100°C to form a clear solution. This solution is wet spun into an aqueous solution containing a high concentration of an inorganic salt. The coagulated fiber is washed, and then drawn and post-treated. The fiber has excellent mechanical properties.

Figure 5 describes another wet spinning process for MPDI (38).

Dry Spinning MPDI. The dry spinning of MPDI from a DMF/$LiCl_2$ solution into an air column maintained at 225°C has also been described (3). After the

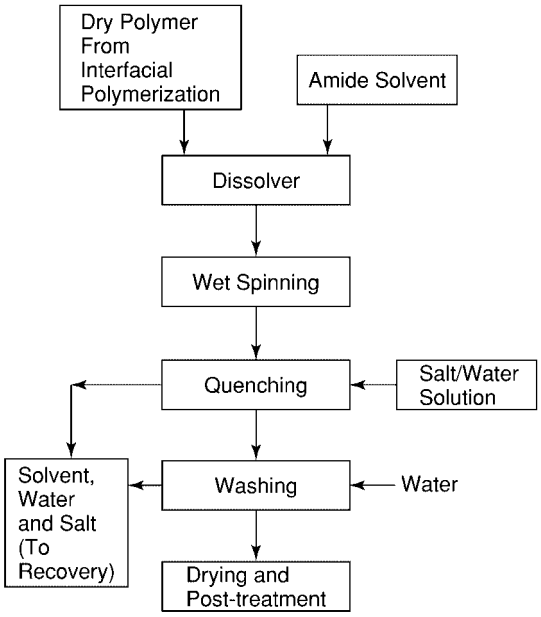

Fig. 4. Wet spinning of MPDI (30).

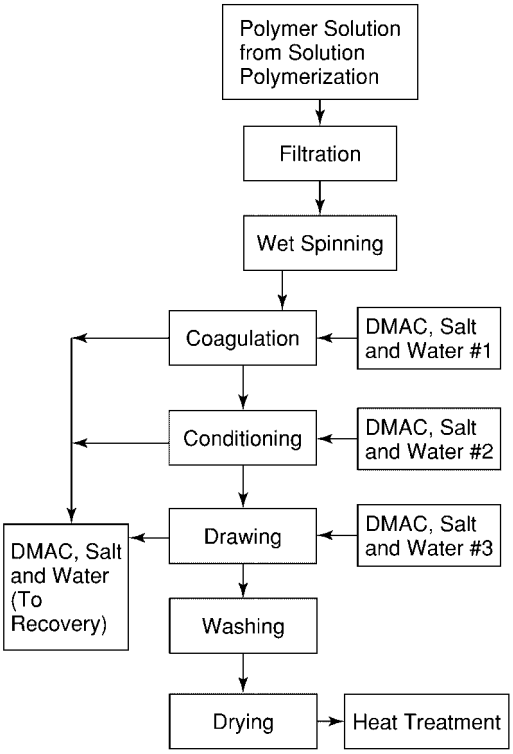

Fig. 5. Wet spinning of MPDI (38).

fibers thus formed are drawn 4.75× and the remaining solvent and salt removed by extraction in hot water, they exhibit a tenacity of 0.6 GPa and an elongation of 30%.

Spinning of PPTA. Unlike MPDI, high molecular weight PPTA is not soluble in amide solvents, with or without the addition of inorganic salts. Formation of fibers from PPTA became possible when it was discovered that concentrated solutions of the polymer in 100% sulfuric acid had relatively low viscosity, could be spun at moderate temperatures, and that the PPTA did not degrade rapidly at those conditions (36). This discovery was the result of the study of nematic solutions of PBA and PPTA (22,36) and substantiated the theoretical predictions of Flory (39). A schematic of such a process is shown in Figure 6.

The patent literature (36) describes a spinning process in which PPTA is dissolved in 98–100% sulfuric acid at a concentration of greater than 18%. The solution is pumped through a spinneret into an aqueous coagulating/quenching bath, with an air gap separating the spinnerets from the bath (40). The fiber is then washed thoroughly with water and dried.

Fibers formed by this spinning process are highly oriented even without the type of high temperature drawing common for other polyamide fibers, and have high stiffness (tensile moduli of 50–75 GPa). Even higher moduli (Kevlar 149 has a modulus of 180 GPa) can be obtained by subjecting the fibers to a stretching

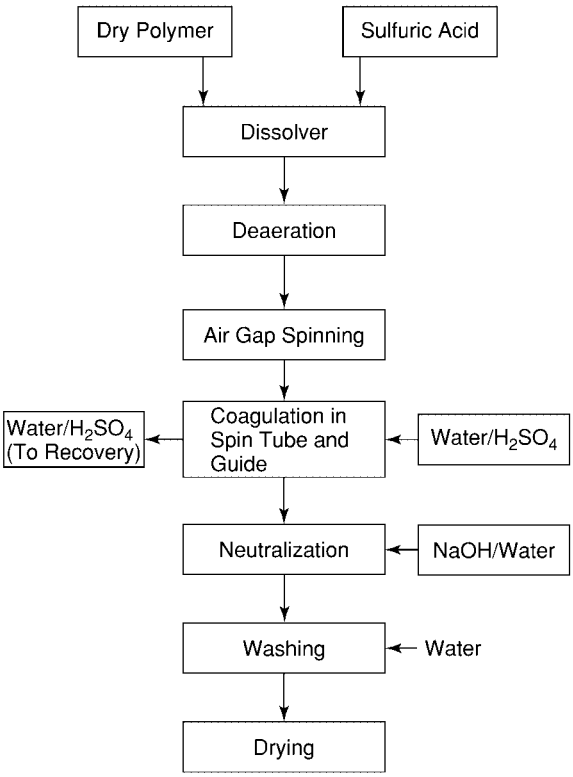

Fig. 6. Air gap spinning of PPTA (36).

process at high temperature (41–43). This would appear to be the basis for the high modulus versions of Kevlar and Twaron.

Wet Spinning of ODA/PPTA. The literature (28,29) describes the wet spinning of the copolyamide, ODA/PPTA, from a solution in NMP and $CaCl_2$ that had been filtered and deaerated. The solution is then pumped through a spinneret into a hot water/$CaCl_2$ bath. Next the filaments are washed with hot water and dried. The dried fibers are subjected to 8.5× stretch in a heated cell containing 510°C nitrogen. The fibers have tenacities in the 2.6–3.3 GPa range, depending on the ratio of DPE to PPD. The process is similar to that described in Figure 5.

Post-Spinning Processes. A significant portion of the aramid fiber sold in recent years has been in the form of staple, floc, or pulp products that are produced by the fiber manufacturer. Short fiber products are produced by cutting continuous filament yarn into lengths that range from about 1 mm to over 100 mm. Products in the 1- to 6-mm length range are referred to as *floc*, while the longer products are called *staple*. All of the continuous filament products described previously are also offered in cut-fiber forms.

Pulp is highly fibrillated, high surface area (7–15 m^2/g) short length product that is made by passing an aqueous slurry of cut PPTA fiber through a refiner

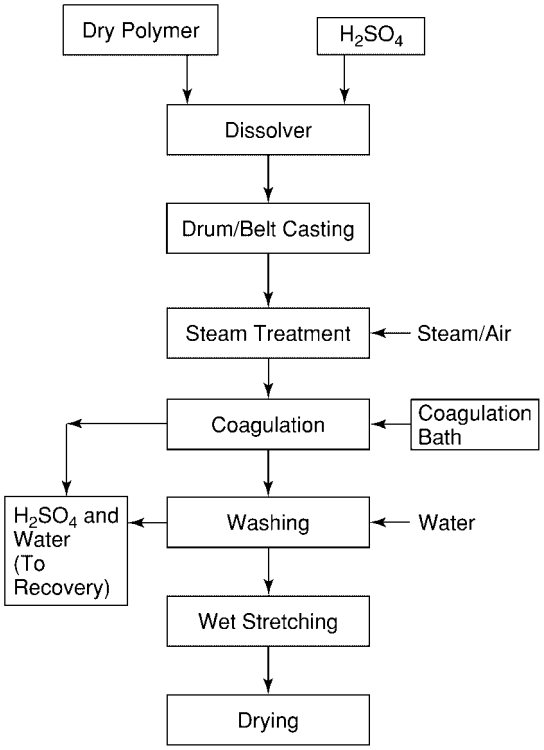

Fig. 7. Process for casting PPTA film (46).

(10). MPDI is not offered in pulp form, but methods for producing pulp have been disclosed (44,45).

Film Casting of PPTA. A technique has been developed for producing biaxially oriented PPTA film (46). A schematic of this process is shown in Figure 7.

This process involves dissolving PPTA in sulfuric acid at concentrations that produce a liquid crystal state. The viscous solution is extruded through a die onto a drum or belt where it is subjected first to high humidity warm air. This can convert the film from an anisotropic solution to an isotropic one. This is important for the production of a balanced film (machine direction or MD compared to transverse direction or TD), because anisotropic solutions of PPTA have a strong tendency to fibrillate. This solution is then dipped into a coagulating liquid, such as dilute sulfuric acid, which sets the film. Next the film is washed with water to remove the acid, after which it is biaxially stretched to provide orientation and then dried. Finally, the film is heat-treated while retaining the orientation.

Fiber and Film Properties

Physical, chemical, electrical, and mechanical properties of fibers are described in this section, with emphasis on commercially available fibers and the properties of importance in the markets they serve.

Table 3. Crystal Lattice Parameters of PPTA, PBA, and MPDI[a]

	PPTA	PBA	MPDI
Crystal system	Orthorhombic	Orthorhombic	Triclinic

Fiber Structure. An extensive description of the structure of PPTA (Kevlar) fibers has been provided in a 1993 book (47), including a description of the crystal lattice (48), estimates of apparent crystallite size and percent crystallinity, a description of fibrillar and pleat structure, and evidence of a skin-core structure. Crystal lattice structure and dimensions for PBA and MPDI (Nomex) fibers are also included, as shown in Table 3. The structure of Twaron is essentially the same (10), while the crystal structure of Teijinconex is nearly identical to the MPDI fiber in Table 3. PPTA fibers are highly crystalline, ranging from 68 to 95% crystalline depending on the heat treatment of the fiber and the crystallinity measurement technique. MPDI fibers are also highly crystalline, although the crystal lattice is quite different from that of PPTA (30).

It has been proposed that PPTA fibers have an unusual radial orientation of hydrogen-bonded sheets and a pleated structure (49). When this model is combined with proposals for a skin-core structure (50–52), one can visualize a comprehensive picture of PPTA structure.

Fiber Properties. Most commercially available fibers are now available in a variety of forms, including continuous filament yarns of different deniers, staple products of various lengths, pulp, paper products, and some nonwoven fabrics. Physical and chemical properties have most often been determined for the yarn products, with the understanding that these properties would usually apply to the other forms as well. While there is some variation in properties among the various deniers, it is usually not large. Representative properties of the major types of commercial yarn are shown in Tables 4 and 5. These properties are taken from the catalogs published by each manufacturer (53,54). Test methods are described in Table 6.

The products available commercially at this time fall into several categories. The MPDI products provide high temperature durability, low flammability, inherent dielectric strength, and excellent chemical resistance, combined with low modulus and high elongation. These products are well suited to fabrics for protective clothing, paper in electrical uses, and high temperature filtration applications.

[a]Measurements made after 3 months (2200 h) of exposure at room temperature.

PPTA and ODA/PPTA provide high tensile strength and modulus, coupled with high use temperature and low flammability. The high modulus versions of PPTA provide value in protective apparel, ropes, and fiber optic applications, while the standard versions are used in asbestos replacement and rubber reinforcement markets. Figure 8 shows modulus vs tenacity for a wide variety of fiber products.

Film Properties. The two commercial aramid films are both based on PPTA. Aramica is a homopolymer, while Mictron is most likely a copolymer or a terpolymer. They provide excellent strength and stiffness, along with high temperature stability. Table 7 lists some of the key properties of these materials.

Uses

The properties of aromatic polyamide fibers and films are sufficiently different from those of the products that preceded them that many new uses and

applications have been developed. Applications are summarized according to general market groupings, specifying the type of fiber or film used but not the specific product.

MPDI Fibers.

Textiles. MPDI fibers have found a substantial market as the fiber used to produce garments designed to protect workers from the hazard of fire. Obviously this includes firefighters and racecar drivers, but it is also becoming standard clothing for workers who operate in chemical factories and other places where the danger of flash fires is real. Key properties include its inherent flame resistance; abrasion, wear, and chemical resistance which allows clothing to be washed and worn many times; and high elongation and low modulus which allows the design of comfortable clothing. Antistatic properties and other characteristics can be incorporated by use of fiber blends.

MPDI fabrics have also been used as a fire blocking material in aircraft seat upholstery, where regulations require such functionality. They are finding increasing use as a fire block in hospitals and as upholstery where fire resistance is important.

Another major market for MPDI fabrics is as bag filters for a number of industries, such as power plants, cement factories, and steel factories, where the ability to withstand hot, corrosive gases is critical.

Paper. An equally important use of MPDI fiber are products in the form of paper. Paper can be made from a mixture of MPDI fibrids and floc (45). The mixture is slurried in water and processed on a conventional paper machine. The primary market for these papers is as electrical insulation in motors, generators, and transformers. The key properties are chemical resistance, good insulating characteristics, and high temperature stability.

Another significant market based on paper is that of honeycomb sandwich structures for aircraft interior floors and panels. The MPDI provides thermal stability during processing and, in the form of honeycombs, gives an exceptional stiffness to weight ratio.

PPTA and ODA/PPTA Fibers.

Protective Clothing. PPTA fibers have become the standard from which body armor for the protection of police and military personnel is made. The primary properties are high strength and light weight. These protective fabrics must be thicker than their fire protection cousins, but they still must be designed to be comfortable. PPTA is also used to make cut resistant fabrics for use in gloves and chain saw chaps.

Composites. High strength and low weight provides the basis for the use of PPTA reinforced composites for the strength members in aircraft, boats, the transportation industry, and sports equipment. Related applications would include providing the protective shielding in lightweight helmets for the military and as rigid armor in military vehicles, police cars, helicopters, and banks.

PPTA is also used in pulp form in a variety of automotive and industrial applications such as brake and clutch linings, gaskets, and nonwoven felts, where it has replaced asbestos. Key performance attributes are chemical resistance, thermal stability, and wear resistance.

Ropes and Cables. Here, again, high specific strength and stiffness are important. Cables based on PPTA fibers anchor oil rigs and provide ship to shore mooring lines. PPTA fibers also provide tension reinforcement for fiber optic cables, where high stiffness and dielectric properties are key advantages. ODA/PPTA fibers are used in a variety of applications where high strength and abrasion resistance are important.

Rubber Reinforcement. PPTA fibers were developed originally to replace polyester and steel as the reinforcing fiber in tires. That market continues to be important today, although it never reached the level envisioned in the 1960s. Key market segments today include high performance automobile tires, heavy-duty machinery and aircraft tires and, on the other end of the spectrum, puncture resistant, high performance bicycle tires. PPTA and ODA/PPTA are also used as reinforcement in rubber transmission belts and hoses.

Other Markets. PPTA fibers are used to form nonwoven sheet reinforcements that are used as substrate for printed wiring boards where low thermal expansion or the ability to use laser drilling technology are important. Other applications for aramid fibers include cement reinforcement, the engineered lumber

industry, boat sails, parachute fabrics, reinforcement in athletic shoes, pulp as a thixatropic agent, etc. Like most new materials, the development of new applications is a continuing process and is driven by the ingenuity of designers.

PPTA Films.

Recording Media. PPTA film provides a three- to fourfold advantage in tensile modulus over polyester film which is the preeminent material of the industry. High temperature stability is another important feature in this market. These property advantages offer the possibility of substantial miniaturization, and are the primary basis for the development of this film. At this time, the markets and products are still in the development stage.

Resin and Fibrid Forms. More recently commercialized product forms of PPTA and MPDI are respectively, resin and fibrid. The resin (polymer) form is finding utility as a reinforcing agent or as a wear additive in a variety of thermoplastic matrices. The high surface area fibrid form is used as a thixatrope and as a reinforcing agent in coating, sealant, plastic, elastomer, and composite applications.

Economic Aspects

Aramid products have now been commercially available for nearly 40 years. Table 2 provides a summary of current (as of 1999) capacities to produce these products, with total worldwide capacities of 19,000 t of *m*-aramid fiber, 43,000 t of *p*-aramid fiber, and 600 t of *p*-aramid film. Table 8 shows total world consumption of Aramid fibers between 1979 and 1998 (33), indicating sales near 90% of capacity for *m*-aramid and near 60% for *p*-aramid. Sales of both types have been increasing at a rate of over 4.5%/year for the past 10 years.

Prices of Aramid products vary widely depending on the denier of the product and the part of the world the product is sold. In general, *m*-aramids fall in the $20–60/kg range while *p*-aramids fall in the $10–30/kg range (33). Staple is less expensive than continuous filament yarn.

Table 8. Consumption of Aramid Fibers (thousands of metric tons)

Japan and Asia	1	1	3	3
Total	*6*	*14*	*19*	*25*

Health and Safety

No matter the process, the safety requirements in the production of aramid fibers and films are substantial. The monomers used in these processes are highly toxic and are sometimes handled at high temperatures (7). They require protective clothing and great care to avoid any contact. At least one potential solvent for the polymerization (HMPA) was found to be carcinogenic in rats (59) and was discontinued as the solvent for the commercial process. Sulfuric acid is used in the fiber formation of PPTA, and protective clothing is a requirement for all personnel who enter the spinning area. The high strength of PPTA fibers makes handling the yarn at high speed a hazardous enterprise, and special training of production workers is especially important.

PPTA and MPDI are relatively safe products that present minimal risk to human health and the environment. MPDI fabrics have been worn for over 30 years without significant effect on the skin, and PPTA products have a similar history. The Food and Drug Administration now provides that many forms of PPTA fiber may be safely used as components of articles that come in repeated contact with food.

During the processing of these fibers some respirable fibrous particles are always produced, and inhalation of these particles should be minimized. Adherence to good industrial hygiene practices for ventilation and cleanup will protect against significant exposure (60).

POLYAMIDES, FIBERS

Polyamide fibers are spun from linear thermoplastic polymers having recurring amide groups made from diamines and dicarboxylic acids $(CONH{-}R{-}NHCO{-}R')_n$ or lactams $(RCONH)_n$. Polyamides are generally referred to as nylons when R and R′ are essentially aliphatic, alicyclic, and less than 85% of the amide linkages are attached directly to two aromatic rings. When these linkages are equal to or greater than 85% aromatic, the fibers are referred to as aramids. Polyamides from the condensation of diamines and dicarboxylic acids are termed AABB type, and those from lactams, AB type. Aliphatic polyamides are identified by numerals that indicate the number of carbon atoms in the monomer. One number is used for the AB type and two numbers, the first designating the diamine, for the AABB type. For example, the polyamide made from caprolactam (six carbons) is nylon-6 [25038-54-4], and those from hexamethylenediamine and adipic acid, nylon-6,6 [9011-56-6]. Monomers containing ring structures are coded by either a single letter such as T for terephthalic acid (nylon-6,T) or an abbreviated form such as PACM for bis(*p*-aminocyclohexyl)methane, eg, PACM-12. In designating a random copolyamide, the components are named in order of decreasing percentages, followed by their weight percentages in parentheses. For example, if hexamethylenediamine adipic acid, sebacic acid, and dodecanedioic acid are copolymerized to give 50% nylon-6,6, 40% nylon-6,10, and 10% nylon-6,12, the product can be designated as nylon-6,6/6,10/6,12 (50/40/10). A block copolyamide, which is made by melt-blending two polyamides or a yarn consisting of fibers spun from two different polymer melt streams such as nylon-6,6 and nylon-6,10, can be designated as nylon-6,6//6,10 (50//50).

Wallace H. Carothers and his research team at DuPont discovered nylon-6,6, which is covered in his patents issued in 1937 and 1938. Diamines from C_2 to C_{18} were synthesized and reacted with aliphatic and aromatic dicarboxylic acids to make polyamides, which were then melt spun and evaluated as fibers. Nylon-6,6 was ultimately selected for scale-up and development because of its favorable

Encyclopedia of Polymer Science and Technology. Copyright John Wiley & Sons, Inc. All rights reserved.

melting point (~260°C), best balance of properties, and lower manufacturing cost. DuPont announced nylon-6,6 as the first synthetic fiber on Oct. 27, 1938, completed the pilot plant in Wilmington, Delaware, in July 1938, and introduced nylon to the market as Exton bristles for Dr. West's toothbrushes (1). The first nylon filament plant was built in 1939 at Seaford, Delaware, and nylon stockings went on sale nationally on May 15, 1940.

In 1929, while employed at the Agfa Film Factory near Leipzig, Germany, Paul Schlack discovered caprolactam, the intermediate for nylon-6 (2). He polymerized caprolactam to nylon-6 and was granted a patent in 1941 assigned to I. G. Farbenindustrie (3). Nylon-6 was developed and commercially introduced as Perlon in 1940 (4,5). I. G. Farbenindustrie had evaluated many polyamide constituents without finding an improvement over nylon-6 and nylon-6,6 (6). In Italy, Societa Rhodiaceta started making nylon-6,6 in 1939. In the United Kingdom, ICI and Coutaulds formed British Nylon Spinners in 1940 and started to manufacture nylon-6,6 in 1941. In the United States, Chemstrand started spinning nylon-6,6 in 1952, and by 1955 Allied Chemical, American Enka, and Industriale Rayon started spinning nylon-6 fibers.

Approximately 4×10^6 t of nylon fiber is produced annually worldwide; nylon-6 and nylon-6,6 account for about 98% of the total production. Nylon fibers are used in the flooring, apparel, industrial and transportation industries. The advantages of nylon fibers over other synthetic fibers are high strength, durability, resilience, ease of dyeability, and low specific gravity.

In 1998, the worldwide nylon fibers market was shared by DuPont with 27%; BASF, 9%; Rhodia, 9%; Solutia, formerly Monsanto fibers, 7%; AlliedSignal, 7%; and the remaining 41% by many smaller manufacturers (7). The downturn in the fiber business, worldwide recession, overcapacity, and competition from polyester fibers in the late 1980s led to acquisitions and merges. Some mills started to melt spin their own fibers, notably nylon-6, during this period (8,9).

Properties of Nylon-6 and Nylon-6,6

Both the inherent properties and those that can be engineered into the fiber and ultimately into the fabricated article account for the diverse end uses of nylon. For every end use, the fiber must offer performance and/or a perceived market value, meet mill acceptance standards, and have favorable economics.

The properties of textile fibers can be divided into three categories—geometric, physical, and chemical—which can be measured with available methods (10–12). Perceived values such as tactile aesthetics, style appearance of apparel fabrics, comfort of hosiery, as well as color, luster, and plushness of carpets are difficult to quantify and are not always associated with the properties of the fiber, but rather with the method of fabric construction and finishing.

The most useful synthetic fibers for textile applications are linear, semicrystalline, oriented polymers, whose properties are defined by molecular structure and molecular organization. The first level of molecular organization is the chemical structure that defines the structure of the repeating unit in the base polymer

and the nature of the polymeric link. This relates directly to chemical reactivity, dyeability, moisture absorption, and swelling characteristics, and indirectly to all physical properties. Macromolecular structure, the second level, describes the family of polymer molecules in terms of chain length, chain-length distribution, chain stiffness, molecular size, and molecular shape. The third level, supermolecular organization, describes the arrangement of the polymer chains in three-dimensional space. Levels two and three are directly related to the physical properties of textile fibers and have a significant bearing on some of their chemical characteristics. The chemical and macromolecular structures of polyamide fibers can be determined by chemical and instrumental analysis (13). The supermolecular organization of nylon-6 and nylon-6,6 have been defined in terms of crystallinity, crystalline and amorphous orientation, and chain folds by xrd, fiber density, dsc, and nmr methods (10,14–18).

Molecular chains in a polyamide fiber are held in specific structural configurations by weak van der Waal and strong intermolecular hydrogen-bonding forces between amide groups. An increase in the number of amide bonds raises the melting point in a homologous series, with the AABB type having the higher melting points T_m in the series (Fig. 1). AABB polymers have a more symmetrical repeating unit than AB. Other things being equal, the more symmetrical the repeating unit, the higher the T_m.

Nylon-6 and nylon-6,6 are isomers that share the same empirical formula, $C_6H_{11}NO$; density, 1.14 gm/cm^3; refractive index n_D, 1.530 (unoriented fiber); and many other properties (19). However, they differ in melting point by 40°C because of differences in the alignment of molecular chains and crystallization behavior (18). These parameters are important in fiber formation in melt spinning, but are not as significant as the glass-transition temperature T_g in the downstream processing of the fiber into a specific end-use article (20). The T_g which signifies a transition from a glassy to a rubbery state, plays a role in the drawing, texturing, and dyeing of a fiber. By controlling melt spinning and downstream processing, the fiber properties of both nylon types can be adjusted to accommodate a variety of end-use performance requirements.

Tensile Properties. Tensile properties of nylon-6 and nylon-6,6 yarns, shown in Table 1, are a function of polymer molecular weight, fiber spinning speed, quenching rate, and draw ratio. The degree of crystallinity and crystal and amorphous orientation obtained by modifying elements of the melt-spinning process have been related to the tenacity of nylon fiber (18).

Tensile properties of synthetic and natural fibers (or yarn) are measured from stress–strain curves as shown in Figure 2. These measurements are not only important in determining the suitability of a nylon fiber for a specific end use, but also in comparing it to other fiber types. Nylon staple generally has higher elongation but similar tenacity to regular nylon filament because of differences in melt-spinning conditions, such as draw ratio and quench rate, and because it is usually a crimped product. Both nylon fiber forms have a lower modulus than polyester, cotton, silk, Nomex and Kevlar; the last two are aramids produced by DuPont. Increasing the tenacity increases the modulus of nylon, but it is still lower than polyester and Kevlar. The toughness of nylon is approximately 20% higher than polyester and much higher than silk, cotton, wool, Nomex and Kevlar.

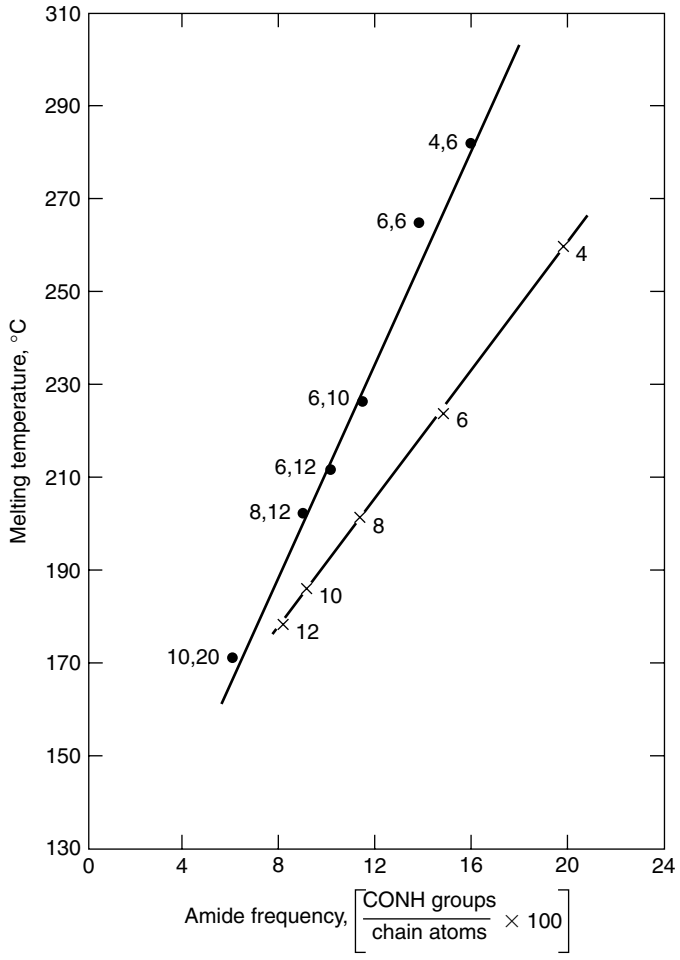

Fig. 1. Effect of amide frequency on the melting points of AB-type (×) and AABB-type (•) polyamides. The number on the curves indicate the specific nylon.

Definitions of the commonly measured tensile properties are as follows: *Linear density* (tex) is the weight in grams of 1000 m of yarn. *Tenacity* (N/tex). is the tensile stress at break and is expressed in force-per-unit linear density of unstrained specimen. *Knot tenacity* is the tensile stress required to rupture a single strand of yarn with an overhand knot tied in the segment of sample between the testing clamps. It is expressed as force-per-unit linear density and is an approximate measure of the brittleness of the yarn. *Loop tenacity* is the tensile stress required to rupture yarn when one strand of yarn is looped through another and broken. It is expressed as force-per-unit linear density. Loop tenacity is an indication of brittleness, but is not considered as sensitive as the knot test. Reported values are one-half the actual test values.

Breaking strength is the maximum load required to rupture a fiber. It is expressed in grams. *Tensile strength* is the maximum stress or load per unit area

[c]To convert N/tex to g/den, multiply by 11.33.
[d]To convert MPa to psi, multiply by 145.

in units of Pascal (1 MPa = 145 psi). Tensile strength (MPa) = tenacity (N/tex) × specific gravity × 1005. *Elongation at break* is the increase in sample length during a tensile test and is expressed as a percentage of original length. *Tensile modulus*, ie, Young's modulus, also called *initial modulus* or *elastic modulus*, is the load required to stretch a specimen of unit cross-sectional area by a unit amount. It is expressed as the ratio of the tensile stress divided by the tensile strain in the initial straight-line portion of the stress–strain curve, extrapolated to 100% sample elongation. *Work-to-break* is the actual work required to rupture the material. It is proportional to the total area under the stress–strain curve. *Yield point*, or *elastic limit*, is the point on the stress–strain curve where the load and elongation cease to be directly proportional. It is the point at which the stress–strain curve deviates from the tangent drawn to the initial straight-line portion of the curve, as in tensile modulus determinations.

Creep is the change in shape of a material while subject to a stress; it is time-dependent. *Elasticity*, the ability of a fiber to return to its original dimensions upon release of a deformation stress, is described by the tenacity of the yield point on the stress–strain curve. *Toughness*, the ability of a fiber to absorb work before it ruptures, is evaluated from the area under the total stress–strain curve. The toughness index is defined as one-half the product of the stress and strain at break

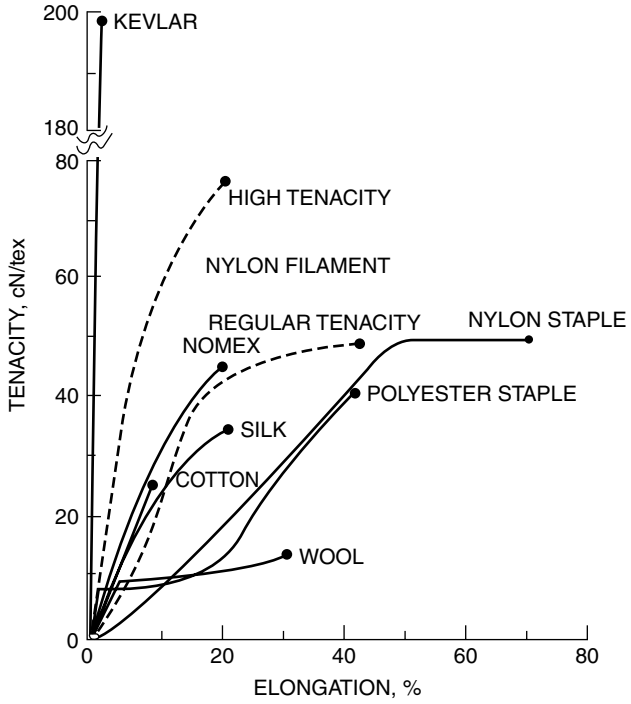

Fig. 2. Stress–strain curves of some textile fibers (22). To convert cN/tex to N-tex, divide by 100.

and is also in units of gram-per-unit linear density. *Creep and recovery* define the plasticity or plastic flow of a fiber in relation to load and time (21). At a critical applied load above the yield point, the fiber extends very rapidly and continues to extend at a much slower rate as time progresses, spanning from a few seconds to over a month. When the load is removed, the reverse process occurs. The fiber recovers part of its extension very rapidly and then begins to contract over a period of time (delayed recovery). The recovery is a relaxational phenomenon where the stress that generated the deformation is dissipated as a function of time, which in effect is complimentary to creep. The quantification of the plastic flow of a fiber resulting from molecular motions induced by the deformation and recovery processes is dependent on load, time, and temperature (22).

Elastic recovery is the ability of a fiber to regain its original form after being stretched at a specified percentage of its length. Shrinkage induced by hot–wet treatment of a fiber is also a form of stress relaxation. Compared to other fibers, nylon fibers have an outstanding degree of elasticity, recovering well from high loads and extension.

Temperature and Moisture Properties. Thermal treatment and moisture affinity significantly influence the physical properties of nylon fibers and fabrics. The absorption of water causes the fiber to swell, which alters its dimensions and in turn changes the size, shape, stiffness, and permeability of yarns and fabrics. It also alters the frictional and static behavior of yarns in mill processing as well as the performance of fabrics during use. Water, a powerful plasticizer for

nylon, preferentially penetrates the amorphous regions, readily hydrogen-bonds to the amide, and increases molecular chain mobility (23–28). As a result, the absorbed water lowers tensile modulus, the work to elongate and work recovery (29,30), and the glass-transition temperature (31). The crystallinity of nylon also increases as it absorbs water (32), which breaks up intermolecular hydrogen bonding and allows the hydrocarbon chain segments to pack better. Water also affects the heat setting properties of nylon yarns and fabrics (33,34). The moisture regain of nylon-6 and nylon-6,6 is shown in Table 1. For comparison, polyester has a moisture regain of approximately 0.4%, acrylic 1.5%, cotton 8%, and wool 16%.

Because of water's plasticizing effect, the water content of nylon fibers and fabrics must be known and controlled when measuring physical properties. Prior to the measurement, samples are conditioned at a specified temperature and relative humidity (rH) for at least 24 h.

Nylon-6 softens at 170°C and melts at 215–220°C. Nylon-6,6 softens at 234°C and melts at 255–260°C. Nylons also have thermal behavior properties between the melting and glass-transition temperatures that are important in fiber melt spinning and drawing and in fiber-to-fabric processing. These behavior properties are the result of relaxational phenomena due to the onset of mobility of the aliphatic chain segments in the amorphous and crystalline regions and occur between 70 and 180°C (28,35). Typical unrestrained nylon-6,6 fibers begin to shrink as the temperature increases from 25 to 70°C with the application of dry heat. At 70°C the fiber undergoes crystallization that tends to reduce chain mobility. From 70 to 115°C the fiber continues to shrink and at 115–125°C loses absorbed and bonded water. The crystal structure also changes from the triclinic to the hexagonal form. At 170–180°C, the hexagonal crystals begin to break up and the polymer chains take on a fluid-like mobility. Because of its higher temperature profile, nylon-6,6 requires higher fiber melt processing, texturing, heat setting (36), and end-use application temperatures (eg, thermal bonding) than nylon-6.

Electrical Properties. Nylon has low electrical conductivity (high electrical resistivity) and behaves like an insulator. Nylon-6 has a resistivity of 6×10^{14} Ω·cm when dry and a resistivity of 2×10^{8} Ω·cm when conditioned at 100% (RH) at 20°C (37); nylon-6,6 responds similarly.

Because of its insulating nature, nylon can accumulate positive or negative electrical charges on its surface when rubbed or in contact with other substances, followed by separation. These charges do not dissipate readily and can cause problems in fiber processing and certain end-use applications. Consequently, antistatic agents are added to spin finishes to facilitate fiber processing, conductive fibers are added to carpets to prevent static shock, and antistats are added to the fibers to prevent static cling of women's slips.

The dielectric constant of nylon-6,6 (at 1000 Hz) is 4.0 at 22°C and 18% (rH), and increases to 20.0 when wet (38).

Optical Properties. When light falls on a nylon fiber, it can be partially transmitted, absorbed, or reflected, depending on the cross-section shape and the nature of any second substance added during polymerization or melt spinning. Additive-free nylon with a standard round cross section has a translucent high sheen luster. The inherent luster of the fiber and the color introduced in dyeing are important optical properties that relate to a fabric's visual quality and its acceptance by the customer. Fibers that need to be opaque or to cover well in

certain applications such as apparel are melt spun from polymer containing TiO_2 delusterant.

Optical properties also provide useful structure information about chemically similar fibers. The orientation of the molecular chains of a fiber can be estimated from differences in the refractive indexes measured with the optical microscope, using light polarized in the parallel and perpendicular directions relative to the fiber axis (39,40). The difference of the principal refractive indexes is called the *birefringence*, which is generally used to monitor the orientation of nylon filament in melt spinning (43). Birefingence can also be used to distinguish nylon from other chemically dissimilar fiber types as illustrated:

	Refractive index		Birefringence
	$n_{\parallel}$	$n_{\perp}$	$(n_{\parallel}—n_{\perp})$
Nylon	1.578	1.522	0.056 (Strong)
Polyester	1.706	1.546	0.160 (Intense)
Acrylic	1.511	1.514	−0.003 (Weak)

Chemical Properties. The chemical reactivity of nylon is a function of the amide groups and the amine and carboxyl ends. The aliphatic segment of the chain is relatively stable.

Solvolysis and Reactivity. Generally, nylon is insoluble in organic solvents, but soluble in formic acid, some phenolic solvents, and fluorinated alcohols such as hexafluoro-2-propanol. Nylon is relatively inert to alkalies. Dilute solutions of strong mineral acids, such as sulfuric and hydrochloric, weaken nylon fibers and hydrolyze them at high concentration and elevated temperature. Strong oxidizing agents and mineral acids such as potassium permanganate solution and nitric acid degrade nylon. Nylon, however, can be bleached in most bleaching solutions common to household and commercial mill applications. Nylon can be hydrolyzed by water under pressure at 150°C and above. The amine end group of a nylon fiber can undergo the same reactions as primary amines, such as neutralization, acylation, and dehydrohalogenation of alkylbromides at elevated temperatures (41).

The amine ends also react with atmospheric contaminants, such as SO_2 and oxides of nitrogen and ozone, under ambient storage conditions (42). This phenomenon is referred to as aging and results in reduced acid-dye affinity.

Thermochemical Properties. Thermal oxidation of nylon-6 and nylon-6,6 starts to occur at 120–140°C, ultimately leading to product yellowing and strength loss. Prolonged exposure at 50–60°C above the melting point will cause crosslinking and the formation of gel, and in the case of nylon-6, depolymerization emitting caprolactam. Thermal degradation of polyamides involves complex chemical reaction paths that are a function of the chemical structure, temperature, length of time exposed, and levels of moisture and oxygen.

The preferred and also the most effective thermal stabilizers for nylon subjected to hot-stretching in tire cord manufacturing are salts and organic derivatives of copper (43–47). The copper salt is added before polymerization at concentrations that give 30- to 70-ppm Cu in the spun yarn. Alkali metal iodides or bromides are also added at 0.1–0.3% for synergism and stabilization of the

cuprous/cupric moieties during melt processing (48). Organic antioxidants such as hindered phenols alone and in combination with organic phosphites are moderately effective.

Photolytic Properties. The extent of photodegradation of nylon-6 and nylon-6,6 depends on the intensity and spectral distribution of the light source, the length of time exposed, humidity, air quality, and the presence of photosensitizers on and below the fiber surface. Photosensitizers include the degradation products created during melt spinning and high temperature fiber processing, TiO_2 (the standard fiber delusterant), iron salt contamination, as well as certain dyes and dye bath chemicals. The chemistry of the photodegradation of nylon is as complex as thermal degradation and has also been studied extensively (49,51–53).

Nylon-6 and nylon-6,6 fibers degrade when exposed directly to sunlight outdoors and under glass or to a source of uv radiation in the 300- to 400-nm wavelength range, resulting in the formation of hydroperoxides, chain scission, yellowing, and strength loss (53). In contrast, polyester, if shielded by glass, and acrylic fibers have outstanding resistance to direct sunlight. Polyester is therefore preferred for window curtain fabric and acrylic for outdoor furniture.

The prepolymer copper-based antioxidants described earlier are also effective photostabilizers for nylon and are used in yarns for parachutes. Soluble copper salts (eg, $CuSO_4$) can also be applied to fibers as part of the finish or to fabrics as post-treatments to protect against uv exposure.

The TiO_2 delusterant is photostabilized by adding manganese salts of pyrophosphorous acids, phosphites, and phosphates (54,56,57) in the prepolymer, or by using TiO_2 coated with a manganese compound (57,58).

Staple Properties. In contrast to continuous filament, spun nylon staple yarns have a softer, warmer tactile hand and a more natural appearance. Nylon staple is used as the pile material in plush carpets and woven velour automotive upholstery fabrics because of its high strength, abrasion resistance, and ease of recovery from pile crush and distortion. It is also used in blends with natural fibers and regenerated cellulosics and acrylics primarily to add strength in yarn spinning of both coarse and fine count yarns and for weaving apparel greige goods.

To accommodate the various uses in 100% form and in blends, the tenacities and elongations of the nylon staple offerings range from 0.3 to 0.6 N/tex (3–7 g/denier) and from 50 to 100% elongation. Most other fiber properties of nylon staple differ little from those of the continuous filament; property characteristics of nylon-6 and nylon-6,6 are similar.

The multiplicity of nylon blends, processing systems, and uses requires a large variety of staple types. Tex per filament may be 0.1–2 (1–20 denier), the cross section may be round or modified, the luster may be bright or dull, crimp may be present or absent, and the fiber may be heat-set or not, depending on its use. The staple length is about 4 cm for cotton system processing, 5–7 cm for the woolen system, 8–10 cm for the worsted system, and about 18–20 cm for carpet staple.

Preparation of Nylon-6 and Nylon-6,6 Polymer

Fiber quality polymer requires that ingredients have optimum purity; are protected from exposure to oxygen; the equipment be maintained, cleaned,

and purged; and new additives be pretested for melt stability and polymer reactivity.

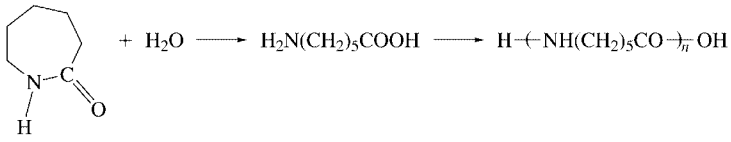
Hexamethylenediamine [124-09-4] and adipic acid [124-04-9] are used in the commercial production of nylon-6,6, and ε-caprolactam [105-60-2] is used for nylon-6.

Nylon-6,6 is made by the polycondensation of hexamethylene diamonium adipate salt with removal of water.

The diamine and diacid react in equimolar quantities to form a salt having a pH of 7–7.5 and stored as a 50–60% aqueous solution. Nylon-6,6 can be polymerized in either a batch or continuous process. In the batch process, the salt is transferred to an evaporator where it is heated at 150–160°C and concentrated to 80–85% by the removal of water. Additives such as chain terminators, dye modifiers, and antioxidants are introduced. The mixture is pumped into an autoclave purged with nitrogen and heated under pressure from 210 to 275°C until prepolymer having about 4000 molecular weight is formed. At this point, TiO_2 delusterant can be added. The pressure is gradually released and the temperature is maintained to remove more water in order to increase the degree of polymerization. After the molten polymer has equilibrated to the desired molecular weight, it is extruded under pressure in the form of a ribbon, which is quenched on a water-cooled casting wheel and cut into flakes of a specified size. The flake is dried in a flake conditioner and packaged.

The number-average molecular weight is adjusted in the 12,000–15,000 range for apparel fibers, >20,000 for high strength yarns for tires and industrial end uses.

Nylon-6 is the polyamide formed by the ring-opening polymerization of ε-caprolactam. The polymerization of ε-caprolactam can be initiated by acids, bases, or water. Hydrolytic polymerization initiated by water is often used in industry. The polymerization is carried out commercially in both batch and continuous processes by heating the monomer in the presence of 5–10% water to temperatures of 250–280°C for periods of 12 to more than 24 h. The chemistry of the polymerization is shown by the following reaction sequence.



Depending on the final polymerization conditions, an equilibrium concentration of monomers (ca 8%) and short-chain oligomers (ca 2%) remains (59). Prior to fiber spinning, most of the residual monomer is removed. In the conventional process, the molten polymer is extruded as a strand, solidified, cut into chip, washed with water to remove residual monomer, and dried. In some newer continuous processes, the excess monomer is removed from the molten polymer by vacuum stripping.

The addition of small, but specific, amounts of a monofunctional acid to the polymerization is often used to control molecular weights and catalyze reactions. The polymerization is controlled to produce a number-average molecular weight of 18,000–30,000, depending on the end use.

Nylon-6 can be easily polymerized at atmospheric pressure. A continuous process was developed in 1940, called the VK process, which in German stands for *vereinfacht kontinuierlich*, or simplified continuous (60). The VK process is widely used in industry in the 1990s, whereas batch processes, being less economical, are gradually phased out of use. Procedures are also available for making gram quantities of nylon-6 and nylon-6,6 in the laboratory (61).

Manufacture of Nylon-6 and Nylon-6,6 Fibers and Yarns

All commercial linear polyamides that melt at or below 280°C are melt—rather than solution—spun into fiber because melt spinning is more economical.

Polyamide fibers are manufactured by melt spinning (or extrusion), followed by drawing (or stretching). In spinning, the molten polymer is delivered from an extruder or a metal-grid melter, or directly from continuous polymerization located upstream of the spinning machine. The molten polymer passes through a filter and a spinnerette. The emerging molten filaments are quenched by cross-flow air in a vertical chimney, attenuated partially in the molten state to achieve the desired spun tex and partially in the solid state to develop some degree of orientation. The filaments are converged and a finish preparation is applied to the yarn to provide lubrication and static protection prior to winding on a bobbin. In a two-step process, the spun yarn packages are first lagged in a conditioned area to facilitate drawing and to maintain package integrity. The yarns are then drawn to approximately 130% (draw ratio of 1.3) up to 600% (draw ratio of 6.0) of their original length, resulting in higher tensile strength, lower elongation, and oriented crystallization. The drawing process is controlled and modified to achieve the yarn properties for specific end use. Conventional drawing is used for moderate tenacity apparel straight (flat) yarns and heat is applied, followed by a heat-relaxation step for the high tenacity, low shrinkage tire yarns. For carpets and some apparel applications, flat yarns are textured (crimped) to impart softness and fabric cover (bulk).

Combinations of two or more of the above steps into consecutive processes, such as spin–draw or spin–draw–texture, reduce manufacturing costs. In addition to continuous-filament yarn, nylon is also offered in staple, tow, and flock forms. Staple is made by cutting crimped continuous-filament yarn into 3- to 20-cm lengths. In manufacturing, tow is made by combining many yarn ends, either flat or crimped, to give a total tow size of 6–111 ktex. Flock is made by precision-cutting tow into 0·5- to 3-mm fiber lengths.

Spinning Continuous-Filament Yarns

In the first commercial process for melt-spinning nylon, polymer chips were stored under nitrogen pressure in a sealed hopper from which they flowed by gravity to a pancake coil heated by a central Dowtherm system (62). The nitrogen pressure

moved the molten polymer to a gear pump that forced the metered polymer stream through a sand-filled filter pack and a spinneret, both maintained at the desired temperature by the single Dowtherm system for the entire machine. The molten filaments were quenched by a cross flow of air at ambient temperature in a chimney with side panels to prevent outside air disturbances. The quenched filaments were converged over a ceramic guide to form the single threadline per spinnerette. Finish was applied by a roll and the threadline wound on friction-driven bobbins at speeds of a few hundred meters per minute. The spun yarn was taken to another machine, the draw twister, where it was drawn, given twist for coherence, and wound on shipping packages containing about 0.5 kg of yarn.

Over the years, fiber producers have improved on the basic design and developed more efficient spinning machines that have lowered manufacturing costs and improved yarn quality. In the early 1950s, the continuous polymerization (CP) process for nylon was combined directly with the spinning machine to eliminate the use of polymer chips. The capacity of a CP direct-spinning machine can be as high as 70,000 t/year and the machine is used in the production of apparel, carpet, industrial yarn, and staple. Extruders are also used to melt polymer chips. They can be horizontal or vertical, vented or unvented, having capacities up to 5000–7000 t/year.

Molten polymer must be delivered to the spinnerette in precisely metered amounts or the filaments will vary in size and give unacceptable products. A metering pump is installed after the extruder to discharge exact volumes of molten polymer per unit time against pressures as high as 70 MPa (10,000 psi) at temperatures in the 300°C range. The molten polymer is also filtered under high shear to remove gel particles and particulate matter that can clog spinnerette holes. A filtration-shear device is attached directly to the distribution plate and spinneret. The typical pack for spinning low tex yarns is a cylindrical cavity about 3.7 cm in diameter and 3.7 cm in height, filled with layers of sand, the finest on the bottom and the coarsest on top. Fine-mesh screens in the bottom and top of the cavity keep the sand in place. Specially designed screens and sintered metal are replacing the sand. Pack designs must avoid stagnant spots where polymer can be trapped and thermally degrade, thus increasing the pressure drop through the pack and shortening its life.

Early spinnerettes were 316-stainless steel disks, ∼5 cm in diameter, 0.5 cm in thickness, and with 13 round holes. Over the years, the increased productivity demands have led to as many as 500 holes for larger disk spinnerettes and 4000 holes for rectangular shape spinnerettes.

The molten filaments are extruded through the spinnerette down a vertical chimney where they are air-quenched. The filaments are then converged to form the threadline in the V shape formed by crossed ceramic pins or other similar devices. The threadline passes to the floor below where finish is applied and is wound up on the spin bobbins.

In earlier years, the windup speed was 275–375 m/min with 0.5 kg of yarn per bobbin. In the 1990s, winders are designed for 10- to 25-kg bobbins, two or more bobbins per winder, operating at speeds up to 6000 mpm, and equipped with automatic bobbin changers.

A conventional spinning apparatus is shown in Figure 3 (63). Polymer chips are melted in a larger extruder, which, in turn, feeds a manifold spinning line.

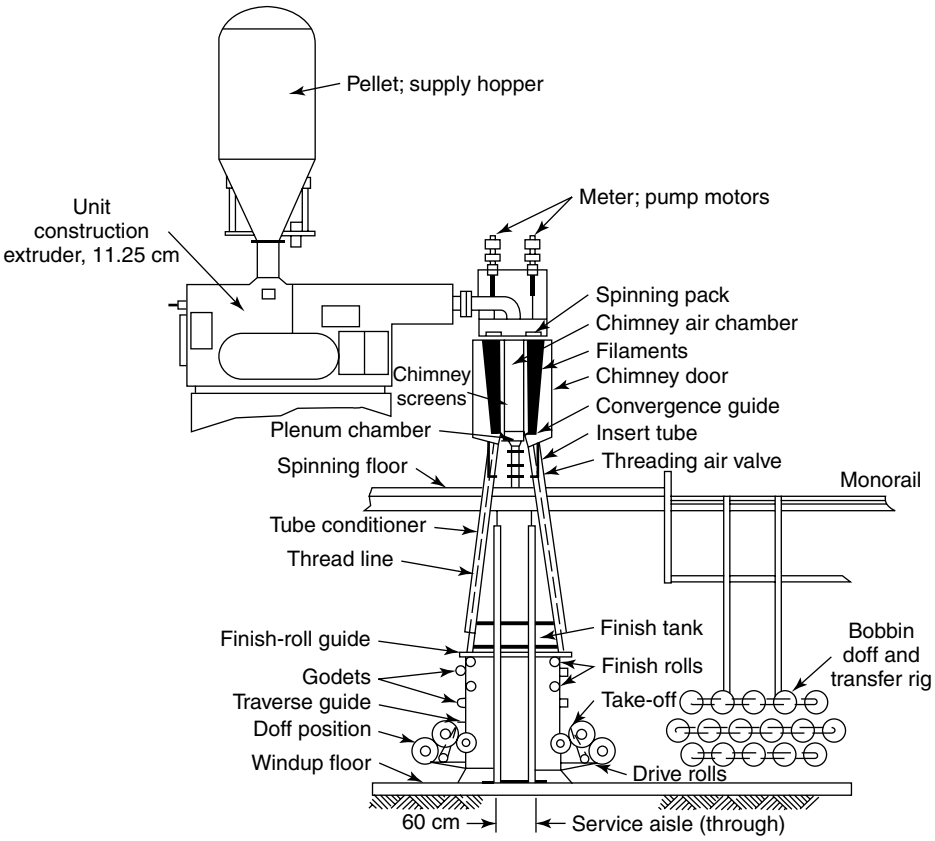


Fig. 3. Conventional melt spinning apparatus. Reproduced with permission from Ref. 66. Copyright © 1966 Noyes Publications.

The feed lines are made as short as possible and the polymer is distributed to a series of spin packs and chimneys where the yarn is quenched. The yarn passes to the tube conditioner, over finish rolls and take-up godet rolls, and then to winders. Spare winders switch over rapidly to a new roll during the doffing operation to avoid yarn loss. The yarns then pass on monorail conveyors to the drawing areas. In plant production, multiple yarns are spun simultaneously, each with many filaments. Efforts must be taken from polymer makeup through spinning to control the uniformity of each end of yarn and to minimize defects that can result in breaks and down time. A significant design trend in spinning has been toward modern short and ultrashort compact machines (64,65). The concept is to have one floor spinning where the maximum distance between spin die and winder is 1.3–2 m compared to conventional processes having up to 5 m between spinnerette plate and winder.

Draw–Twist Process. This is a two-step split process where yarn spun onto bobbins at 300–3000 m/min is lagged and then taken to a draw-twisting operation (Fig. 4a). The degree of drawing or stretching is accomplished by adjusting the speed of the draw rolls, which run faster than the feed rolls. The drawn yarn is

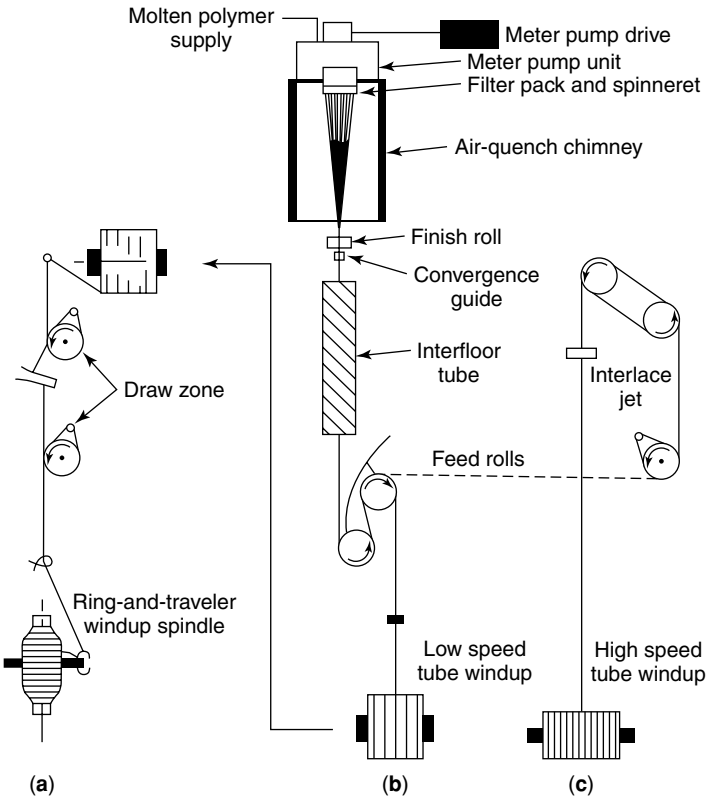

Fig. 4. Melt spin–draw processes for nylon yarn (**a**) draw–twist process, (**b**) conventional spinning process, and (**c**) coupled process.

then twisted for coherence and wound on a pirn with a standard ring-and-traveler mechanism. Yarns for apparel, hosiery, and industrial end uses have been made by this process.

Spin–Draw Process. In the early 1960s, a single-step process was commercialized in which the spinning and drawing steps were combined (Figs. 4b and 4c). This required the development of high speed drawing, winding technology, and air jet interlacing to tangle instead of twisting the yarn. For apparel and carpet yarn end uses, the process utilizes the conventional cold draw; for tire and high strength industrial yarn applications, heated-draw assists such as jets, rotating pins, shoes, roll chests, and yarn relaxation steps are added (66). The spin–draw process has also been combined with continuous polymerization. The double-sided unit in Figure 3 is commonly used where the stretch godets and draw assists are installed before the windup (67,68).

In the coupled process (Fig. 4c), the draw ratio, which affects the tenacity and elongation, lowers with increasing spinning speed. As draw ratio is increased, tenacity and initial modulus increase and elongation decreases.

New Developments in Spinning and Drawing. The continual effort by the fiber producers to increase production, lower manufacturing costs, and improve quality has led to a better understanding of the effects of the spinning and

drawing process on physical and molecular structure of fibers (69–77). The polymer factors that affect melt spinning are molecular weight and polydispersity index, which is the ratio of weight-average molecular weight M_w to number-average molecular weight M_n. M_w is determined by solution viscosity and M_n by end-group analysis. In spinning, the tensile stress of the extruded fiber is affected by the polymer melt viscosity, spinning speed, cooling rate, and its degree of structural orientation.

The earlier work cited was in the 100- to 2400-m/min spinning speed range, but the later effort is focused at 4000–6000 m/min (78,79). The effect of spinning speed on residual drawing was classified by the degree of fiber orientation (80). Low orientation yarns (LOY) have a high residual drawing, low crystallinity, and limited storage stability. These yarns are subsequently processed through the draw-twisting process. Medium oriented yarns (MOY) processed at 1800–2800 m/min are slightly more crystalline, but still have limited storage stability. Partially oriented yarns (POY) processed at 3000–4000 m/min are partially drawn (70–100% elongation) with some residual drawing, but still have low crystallinity. Partially or spin-oriented nylon feed yarns were developed in the early 1970s to meet the needs of increased false-twist texturing speeds (81). In processing, the drawing step is eliminated and the orientation required for draw texturing is controlled in spinning. POY yarns have also been used in the 1990s in the process of draw warping to make flat yarn warps for weaving and knitting (81–84). A process has been defined for making feed yarns that impart excellent uniformity with structure-sensitive large acid dye molecules in dyeing fabrics from warp-drawn yarns (85). Highly oriented yarns (HOY) spun at 4000–6000 m/min are not fully drawn (50–60% elongation). Fully oriented yarns (FOY) with elongations of 20–30% require spinning speeds of well over 6000 m/min.

Molecular weight has a strong effect on the properties of high speed melt-spun nylon. Generally, higher molecular weight leads to higher modulus and filament tenacity and lower elongation to break (86). In spinning POY nylon, the yarn bundle can be transferred directly to winders capable of 4500–6500 m/min, (which is referred to as godetless spinning), or through a set of driven godets (87). Improvements in the processing and properties of nylon-6,6 have been made by modifying quench and windup hardware (64,88), using higher than usual molecular weights (86,89), adding a trifunctional branching agent to increase melt viscosity (90), incorporating minor amounts of hydrogen-bonding agents in high molecular weight polymer (87), and adding pyrogenic silica to the polymer (91). The hydrogen-bonding agents include nylon-6 monomer or 2-methylpentamethylene diamine.

Texturing Processes. Texturing is the conversion of flat continuous-filament yarns to crimped ones so as to simulate properties inherent in natural and synthetic spun staple yarns, such as thermal insulation, fullness, cover (bulk), softness, and moisture transport. In texturing, the geometry and, to a degree, the surface of the filaments are mechanically deformed by bending, twisting, or compressing to introduce permanent wavy (crimp) loops and coils. Prior to the texturing step, heat is applied in the range of 100–190°C to soften the filaments. After texturing, the yarn is cooled to set the crimp and the mechanical deformation is removed by tensioning the yarn during package windup. Texturing affects the tensile properties, dyeability, and the macromolecular structure of the fibers in a

nonuniform way that can cause dye structure and barré problems in dyeing fabrics. Depending on how the filaments have been mechanically deformed and the temperature used, differential stresses and random disoriented molecular chains are set in specific configurations to give one of three classifications of textured yarns: stretch, modified stretch–bulk, or bulk. The textured stretch or bulk is developed when the yarn experiences a stress-relaxing environment under low or no tension, as in steaming hot air, or dyeing. Stretch yarns have high extensibility and good recovery, but only moderate bulk compared to modified stretch and high bulk-textured yarns.

Descriptions of the various texturing processes and latest machine modifications to increase quality, speed, and efficiency have been the subject of numerous reviews (92–96). In air jet or Taslan texturing, the yarn is introduced into a venturi tube in the air jet where the turbulence from a stream of compressed air cause the filaments to entangle and form surface loops. The product has bulk, but no stretch, and the process can be varied to give a range of bulk and novelty effects (97). In false-twist texturing, a specially made yarn is heated by a radiant or contact heater just below the melting point, twisted as high as 30–40 turns/cm, then untwisted and packaged at windup speeds as high as 1200 m/min. Draw-texturing is a continuous process where partially oriented yarns are drawn and false-twist-textured. A continuous high speed spin–draw–false-twist-texturing process for nylon has also been developed (98). False-twist-textured filaments are coiled, have good bulk, but are regarded primarily as stretch yarns.

In another form, bulked continuous-filament (BCF) yarns are spin-drawn and textured with a fluid jet in a continuous one-step process. After drawing, the yarn is heated over rolls in a hot chest and passed through a hot air or superheated steam jet under controlled conditions. In some designs, texturing is achieved by impinging the yarn onto a baffle plate, a screen, or the walls of a specially shaped chamber (99–102). BCF yarns have bulk with some stretch and each filament has a random, three-dimensional curvilinear crimp form. Edge crimping is accomplished by drawing a heated yarn over a knife edge that compresses (flattens) the edge side and stretches the outside of the filament. The metastable stresses so imposed are relaxed during heating, causing the yarn to crimp and coil to give a stretch yarn (103–105). Gear crimping is adaptable to draw-twisting or spin–draw–texture operation and generally used to texture high tex yarns. Stuffer-box crimping is used for both low and high tex yarns and for crimping tow for staple. Most of the crimped nylon made in the United States is stuffer-boxed, gear, false-twist, and air- or fluid-jet-crimped.

Commercial textured yarns cover a range of yarn sizes and end uses. The 1.7- to 3.3-tex (15- to 30-denier) yarns for hosiery are false-twist-textured, as is the 4.4- to 22.2-tex (40- to 200-denier) yarns for apparel. The 56- to 333-tex (500- to 3000-denier) yarns for carpets, upholstery, and soft-sided luggage are air- and fluid-jet-textured.

Most of the textured apparel and industrial yarns are woven or knitted directly into fabric. The carpet BCF yarns can be tufted directly off package into loop pile or velvet constructions. For the textured saxony constructions, the BCF and the spun staple yarns must be ply-twisted and heat-set. The heat-setting temperature for nylon-6 and nylon-6,6 is 180–220°C in hot–dry atmosphere, and 120–140°C in saturated steam. The yarns are twist-set in pressurized autoclaves

or continuously on the Superba and Suessen machines (106). Before setting the twist, the yarn is heated and relaxed for predevelopment of the bulk.

Staple Fiber. Staple manufacturing consists of spinning, drawing, crimping, cutting, and baling (107). The spun yarn from individual spinnerettes, ranging from several hundred to a few thousand filaments, are piddled into a can, lagged, the ends of which combined into a tow, and drawn. Finish is applied in spinning to help drawing, and is usually applied again after drawing to assist in the crimping and cutting operations. In crimping, multiple tow ends are forced continuously into a constricted stuffer box by preset feed rolls. The box is sealed by an adjustable hinged and weighted gate. The tow ends filling the chamber are arranged in uniform folds by compression. When the pressure in the stuffer box exceeds the pressure of the hinged gate, the gate rises to permit discharge of the crimped tow, and then falls, thereby repeating the process (108). Prior to cutting, water is applied to the crimped tow to reduce static and maintain wear life of the knives. The compact spinning systems, approximately 6 m high by 6 m wide and developed for nylon, polyester, and polypropylene, can be integrated into accommodating, designed downstream staple process operations (crimping, heat-setting, cutting, baling) to reduce space and cost as well as to expand product flexibility and improve quality (109). This process is a spin–draw type where tow is fed directly to drawing and then through the staple-making operations. The spinning and drawing speeds must be coordinated for proper performance. When utilizing the conventional low speed staple process, the spinning and drawing speeds must be reduced substantially. To compensate for the loss in throughput capacity per position, spinnerets having high number of holes (8000–75,000) are used. In another process where spinning and drawing are maintained close to conventional spinning, the stuffer-box crimper must be designed to process large tow titers, and to prevent the sticking of filaments on the roller and escaping of filaments that break loose from the bundle. Developed by Takehara, Japan, a high speed crimper capable of 6000 m/min avoids the problems encountered with the conventional roller (110). The Takehara Type T-K-K has a large-diameter ring roller that rotates in one direction, and an inner roller that lies on the inner surface of the ring roller and rotates with it in the same direction and with the same speed while holding the tow to be crimped (111).

Staple is used directly in the manufacturing of nonwoven fabrics and spun into yarn through the cotton, worsted, and woolen systems in 100% form or in blends with other synthetic or natural fibers.

Flock. *Flocking* is the mechanical and/or electrostatic application of finer fiber particles to adhesive-coated fabrics, paper, yarns, plastic, or metal objects (112). Flocking offers a soft, velvety surface for decorative and visual appeal and has a wide variety of functions: sound dampening, thermal insulation, friction reduction of sliding surfaces, increased surface exposure for evaporation and filtering, buffing and polishing, liquid retention or dispersal, cushioning of heavy objects, and even preventing the settling of barnacles on boat hulls (113).

Flock is made by precision-cutting drawn, uncrimped tow using a rotary or guillotine cutter into 0.3- to 6-mm lengths, depending on the denier per filament. The higher the denier per filament, the longer the tolerable length before curvature of the cut fiber becomes a problem in flock preparation. The tow presented to the cutter can be a combination of tow with lower total tow ktex creeled directly

out of shipping boxes or a tow that had been scoured, pad-dyed, rinsed, and treated with special finish on a continuous range. The tow size can be from 111 to 3889 ktex (1,000,000–35,000,000 denier) at the cutter.

Whether the process is continuous or batch, the flock must be similarly treated for electrostatic application. The spin finish is removed by scouring and then a finish mixture is applied to impart the following properties to the flock (114): (*1*) good siftability; (*2*) low interfiber adhesion needed for proper coverage, (*3*) good movement and orientation in the electrostatic field needed to get the flock to go straight into the adhesive coating, (*4*) correct level of conductivity appropriate to the strength of the field and compatible with an ac- or dc-applied voltage, and (*5*) good wetting-out properties in the adhesive. Fiber length has a great effect on flock properties; increasing the fiber length decreases the number of fibers sifted, the number of fibers flocked, and the percentage of maximum flock density (115).

Nylon is the preferred fiber for flocking because of its good chemical bonding to a wide range of adhesives, its toughness, and its ease of dyeability and printability. Nevertheless, the tow must be manufactured with the proper ktex, cohesion, and spin finish to be readily converted to flock.

Finishes. Fiber finishes are designed to provide fiber cohesion, lubricity, and static-free operability at low and high traverse speeds over a variety of metallic and ceramic surfaces encountered in fiber plant and mill operations (116–118). Fiber cohesion is important in that loose or protruding filaments can catch on processing equipment and cause snags and breaks, or become entrapped within a windup package, causing unevenness in texturing, knitting, and weaving. Finishes, consisting primarily of lubricants, emulsifiers, and antistatic agents, are generally applied as aqueous emulsions at concentrations giving a finish-on-yarn level of 0.3–1% after the evaporation of water.

In application, the aqueous-finish emulsion is pumped to a holding or storage tank from which it is circulated through a system that feeds the spinning machine. The finish is applied by passing the yarn either through the circulating finish across a constantly revolving "kiss" roll that is partially immersed in the emulsion, or through a slotted pin or guide in which the emulsion stream is metered through an orifice.

Modified Cross Sections. Nylon filaments are spun in a variety of cross-section shapes that include the conventional round to irregular solid and hollow shapes (Fig. 5). The cross-section shape is an important variant in designing the functionality and luster of fibers. The round cross section is used for strength in industrial applications and for subdued luster in apparel and upholstery. The multilobal cross sections are used to enhance bulk and for bright luster in both BCF and spun staple yarns for carpets and upholstery. The grooves in the multilobal shapes also enhance moisture transport by wicking water through capillary action. Flat-sided ribbon-like cross sections provide cover in apparel applications.

Bright (no delusterant) round and hollow fiber cross sections have a smooth sheen-like luster, whereas multilobal cross sections vary from bright sheen to bright glitter luster, depending on how they are designed to converge and transmit internally reflected light (119).

In spinning the different fiber cross sections, spinnerette orifice shape and dimensions must be made to exacting tolerances, and changes in polymer melt

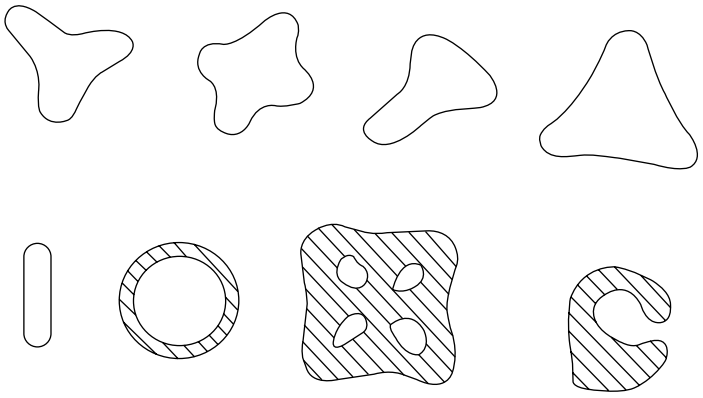

Fig. 5. Typical nylon fiber cross-section shapes.

viscosity, block temperature, and air quenching conditions must be anticipated to assure the desired shape, spinning continuity, and quality yarn. In spinnerette manufacture, the final orifice is produced after counterboring all but the thin sections of the spinnerette blank. Noncircular spinnerette orifice shapes are made by electron-beam milling and electrodischarge machining. For the solid, nonround shapes, a single orifice design is used. Various specific orifice shapes have been developed and fiber cross sections have been defined using mathematical relationships (120,121).

In making hollow fibers, both pre- and post-coalescent spinnerettes and spinning techniques can be used. The former requires injection of a gas through the capillary to create the void (122,123), whereas the latter involves entrapment of gas (air, nitrogen) by coalescence of the molten polymer spun exiting from a segmented orifice designed to give the desired number of cross-section holes, shape, and percent void (124,125).

The open hollow-fiber shape shown in Figure 5 is made by a unique process requiring bicomponent yarn technology (169). A yarn is spun with a water-soluble copolyester core and nylon sheath where the core is dissolved out with an alkali treatment in fabric dyeing.

Additives. Additives can be introduced in salt preparation, polymerization, or the molten polymer stream prior to extrusion of the filaments. Additives are used to alter the basic characteristics and performance of the fiber and can be classified by function.

Delusterants reduce the transparency, increase the whiteness, and alter the fiber's reflectance of light. TiO_2 is the delusterant of choice for all melt-spun fiber types because of its high cover, whiteness, and chemical and thermal stability. The anatase, not the rutile form of TiO_2, is preferred because it is softer and contributes less to abrasion wear of machine guides and rolls. Nylon is translucent and requires TiO_2 in most textile and home furnishing applications for the cover and to reduce objectionable sheen and gloss in fabrics. Semidull nylon yarns contain ca TiO_2, 0.3%; middull, ca 1.0%; and fulldull, ca 1.5–2.0%.

TiO_2 requires careful slurry preparation and introduction to the nylon to minimize the formation of agglomerates and to maintain an average particle size

of 0.1–0.5 μm in fiber. Otherwise, filter packs will clog and require frequent replacement. TiO_2 is added as an aqueous dispersion to the prepolymer in the manufacturing of nylon-6,6, and to the caprolactam in the manufacturing of nylon-6, frequently as a master batch containing up to 30% TiO_2 in low molecular weight polymer (127). Nonmelt-compatible polymeric materials such as poly(oxyethylenes), polystyrene (128), and poly(methyl pentene) (129) have also been used as delusterants.

Colorants can be introduced into the fiber by adding dyes and pigments in salt preparation, during polymerization, or into the molten polymer just before spinning (130). Pigmented fibers are referred to as mass-dyed, dope-dyed, solution-dyed, or producer-colored. Inorganic pigments are used more than the organics, especially where high color, light, and crock fastness are required, such as in upholstery and carpet for automotive interiors. The organic pigments have higher chroma, but are not as colorfast to heat and light. Nylon-6 can accommodate more pigments than nylon-6,6 because of its lower melt-processing temperatures. Like TiO_2, the pigments must be dispersible and heat stable in polymer and fiber manufacturing. A common and efficient approach to adding pigment to the base polymer in spinning is first to disperse the pigment as a concentrate in a carrier polymer, usually a lower melting copolymer. The concentrates range from 25 to 50% pigment content and are offered as a single color or a compounded color blend in pellet or flake form. The flake can be blended with the base polymer flake at a specified loading and charged to the feed hopper of the spinning process or remelted in a vessel that allows it to be metered directly into the molten polymer prior to spinning. Quality pigmented fibers are spun with processes equipped with mixing screws and volumetric or gravimetric automatic feeders. Typical pigments for nylon are carbon black, red iron oxide, aluminum cobalt blue, and phthalocyanine blue and green. Carbon black enhances nylon's resistance to photodegradation. A number of light-stable pigments that are also environmentally friendly are available (131).

Antioxidants are used to prevent thermal and oxidative degradation of nylon in manufacturing, post-fiber and fabric processing, and final use.

Antistats such as polyoxyethylenes (132,133) and *N*-alkyl polycarbonamide (134) are added to nylon to reduce static charge and improve moisture transport and soil release in fabrics. These additives also alter the luster of fiber spun from bright polymer. Static reduction in carpets is achieved primarily by the use of fibers modified with conductive carbon black.

Antimicrobial agents are used where there is a need to inhibit bacterial and fungal growth. The additives can consist of copper, germanium, zinc and zinc compounds, metal oxides or sulfides, metal zeolites, as well as silver and copper oxide coated inorganic core particles (135–140).

Flame retardants designated for nylon plastics, such as halogenated organic and phosphorous derivatives, are difficult to spin into fiber because of the high loading required for effectiveness and their adverse effects on melt viscosity and fiber physical properties.

Both fiber producers and fabric mills have realized that many of the performance variants that are difficult to incorporate into fiber melt spinning can be accomplished by post-treating yarns or fabrics. Mills can apply flame retardants, softeners, dye-fade inhibitors, and stain- and soil-resisting agents as part of the finishing of a fabric.

Dyeability

Nylon is atmospherically dyed using established trade procedures for staple (stock dyed), yarn (yarn dyed), fabric (piece dyed) for batch dyeing systems (becks, jets, kettles), for continuous dyeing systems [pad – dye, steam (fixation), rinse], and for printing systems (flatbed, rotary screen, roller and transfer) (141–143). Because of their physical and chemical structure, nylon-6 and nylon-6,6, unlike the principal synthetic and natural fibers, have an affinity for every dye class as summarized in Table 2 (144).

Commonly used dyes are the disperse, acid, and premetallized. Disperse dyes are easy to apply, but have marginal wash and lightfastness on nylon. Acid dyes, unlike the disperse dyes, are water soluble, interact with the amine ends, and, as expected, have better wash and lightfastness than the disperse dyes. There are two categories of acid dyes. Those containing one sulfonate group on the dye molecule are referred to as leveling acid dyes and those containing two or more sulfonates, nonleveling or critical acid dyes. Premetallized dyes are large metal complex molecules that respond like critical acid dyes. They have the best wash and lightfastness and are used for high uv-exposure end uses such as automotive upholstery. Leveling acid dyes are used in piece dyeing and wet roller and screen printing of carpets, upholstery, and apparel. Disperse dyes are used to dye carpets and for transfer printing primarily of flocked upholstery and carpets. In transfer printing, dyes printed on special papers are transferred to the fabric under heat and pressure.

Effect of Fiber Properties. Acid dyes are attracted to the accessible amine ends of the nylon chains located in the amorphous regions of the fiber. Acid dye affinity of nylon can be adjusted by adding excess diamine or diacid to the polymer salt or by changing the molecular weight in polymerization. A light acid-dyeable nylon-6,6 is spun with 15–20 amine ends, expressed in terms of gram equivalents per 10^6 grams of polymer. A medium or regular acid-dyeable nylon has 35–45 and a deep acid-dyeable nylon has 60–70 amine ends. Ultradeep acid-dyeable nylons have 80 amine ends or more and are made by adding basic compounds such as *N*-(2-aminoethyl)piperazine in polymerization to enhance the total available dye sites (145). Nylon-6,6 can also be made base-dyeable by

Table 2. Dye Affinity of Major Textile Fibers[a]

	Dye types[b]							
Fiber types	Direct	Vat	Reactive	Sulfur	Acid	Premet	Cationic	Disperse
Cellulose	D	D	D	D	S	S	–	–
Wool	S	SS	HS	S	D	D	–	D
Nylon	S	HS	HS/D	HS	D	D	D	D
Acetate	S	S	S	S	–	–	–	D
Acrylic	–	–	–	–	–	–	D	D
Polyester, 2GT	–	–	–	–	–	–	D	D
Polypropylene	–	–	–	–	–	–	–	–

increasing the level of carboxyl ends (146) or by introducing sulfonic acid groups through the addition of a copolymerizable dicarboxylic acid derivative to a polymer salt, such as the sodium salt of 3,5-dicarboxybenzene sulfonate (147). By using the proper dyes, dye-bath auxiliaries, and pH control, light, medium, and deep acid- and base-dyeable yarns can be dyed in combination in a single bath to give multitonal and two-color styling effects. This concept of differential-dyeing yarns is unique to nylon and is used extensively in the piece dyeing of carpet, apparel, and upholstery fabrics.

Macromolecular structure and supermolecular organization also affect dye affinity. Drawn (oriented) nylon-6 has more of a random open structure than nylon-6,6 (148). Nylon-6, therefore, dyes more rapidly than nylon-6,6, but is also more susceptible to color crocking, especially with disperse dyes. High dye rates can be achieved with nylon-6,6 by adding a minor random copolyamide component in polymerization. Also, any melt-spinning process adjustment or post-fiber and fabric treatment that decreases orientation in the amorphous domain increases dyeability. Examples are lowering the draw ratio, applying steam or swelling chemicals (eg, phenol), and texturing particularly with pre- or post-heat relaxation (149, 150). Nonuniform drawing or heat application can cause streaks with structure-sensitive nonleveling and premetallized dyes. Variations in fiber geometry and cross-section shape and yarn crimp level in texturing cause optically related color streaks. The streaks are caused by a single yarn or groups of yarns that appear to take up dye differently from neighboring groups of yarns. The yarns differing in heat history, amine-end sites, and/or processing tensions will cause streaks.

The appearance of streaks with leveling or nonleveling acid and premetallized dye can be subdued by increasing the dye-bath pH, at a sacrifice in dye exhaust, by adding chemical agents that retard the dye strike or, more effectively, by metering all or a portion of the dye in a concentrated solution at or near the dyeing temperature of the fiber (87.8–104.4°C) instead of at the usual 26.7–48.9°C practiced by the trade (151).

For end uses demanding high dye lightfastness such as automotive interior fabrics, select premetallized dyes and uv inhibitors are applied through the dye bath (152,153). Nylon can also be co-dyed with polyurethane elastomeric fibers, wool, acrylics, polyesters, and cellulosics (154).

Modified Nylon-6 and Nylon-6,6 Fibers

Bicomponent and Biconstituent Fibers. Bicomponent fibers consist of two polymers of the same generic class, eg, nylon-6 and nylon-6,10; biconstituent fibers consist of two dissimilar generic polymers, eg, nylon-6,6 and polyester. Both fiber types are made separately by melt-spinning the two different polymers through a common, specially designed spinneret such as the one in Figure 6 (155). The spinneret hole and block channels can be designed so that the two polymers emerge side by side, as sheath–core or conjugate fibers. The fibers are processed through conventional drawing or spin–draw operations. The original intent of the side-by-side bicomponent yarn was to impart stretch in tricot knit and hosiery applications. Nylon-6 and nylon-6,6 homopolymers were paired to a copolyamide on the basis of shrinkage difference as measured on the individually

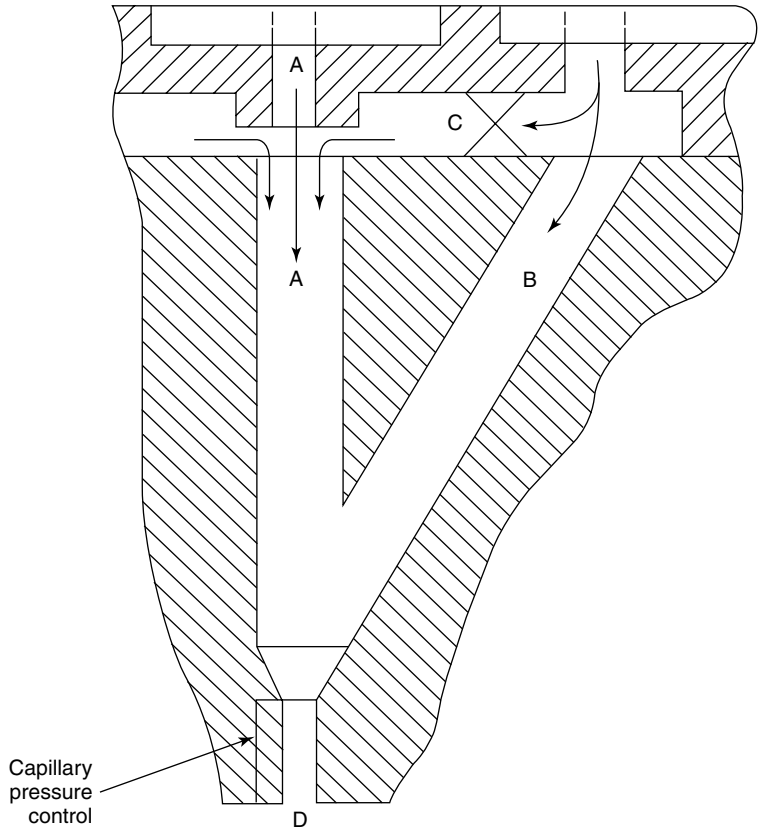

Fig. 6. Bicomponent spinneret for sheath-core fiber where A represents copolymer; B, homopolymer; and D, bicomponent fiber capillary exit. If side-by-side fiber is desired, the interconnecting channel C is sealed at X.

spun polymers. Depending on the differential shrinkage, the bicomponent yarn would assume a level of helical crimp in dyeing or steaming.

Examples of earlier bicomponent stretch yarns were spun with a nylon-6,6 sheath and core compositions of nylon-6,6/6,10 (50/50) and nylon-6,6/6 (80/20). Stretch was also achieved by spinning side-by-side two nylon-6,6 polymers having a relative viscosity difference of at least 15 units (156), and by spinning nylon-6 with a melt-spinnable polyurethane (157).

Most of the stretch hosiery today are made from textured POY and with elastomeric spandex fibers.

Bicomponent technology has been used to introduce functional and novelty effects other than stretch to nylon fibers. For instance, antistatic yarns are made by spinning a conductive carbon-black polymer dispersion as a core with a sheath of nylon (158) and as a side-by-side configuration (159). At 0.1–1.0% implants, these conductive filaments give durable static resistance to nylon carpets without interfering with dye coloration.

Dye selectivity can be altered by spinning a high amine-end nylon core with a sulfonate-containing nylon sheath (160). In standard dyeing conditions, the core

accepts leveling acid dyes, but not critical or basic dyes; the sheath accepts basic dyes. The effect creates a third color when dyed in combination with acid- and base-dyeable yarns.

Microdenier fibers, ie, very fine fibers, can be made by spinning biconstituent conjugate fibers such as those illustrated in Figure 7. The technology was developed by Kanebo and marketed under the fabric names Belseta and Glacem. The concept, referred to as alkalization, is to spin a readily alkali-soluble copolyester with nylon and then to dissolve away the polyester in the fabric stage. For example, the wedge-like nylon portion of the round 1.7-decitex (1.5 denier) filament in Figure 7 can split into eight components, each 0.20 decitex (0.18 denier) (161). The hexagonal cross-section fiber is of the "islands-in-the-sea" type where the orange wedge-shaped nylon "islands" in the copolyester "sea" connect slightly at the matrix center (162).

Microdenier nylon and polyester were a significant spinning breakthrough when demonstrated in 1985. The finer-than-silk fibers added a new dimension to fabric aesthetics, comfort, and performance. Microdenier nylons are used in weaving, warp knits, and weft knits for sports-, leisure-, and fashion-wear. Polyester can be melt spun at 0.55 decitex/filament, but the finest nylon is spun at 1.1 decitex/filament. The ultramicro staple nylons made by the polyester alkalization procedure are used to manufacture suede and water-resistant fabrics.

Copolymers. There are two forms of copolymers: block and random. A nylon block copolymer can be made by combining two or more homopolymers in the melt. The composition of the melt is a function of temperature and more so of time. Two homopolyamides in a moisture-equilibrated molten state undergo amide interchange where amine ends react with the amide groups. As time progresses, the two homopolyamides in the melt form a block and eventually a random copolymer as a result of amide interchange. Block copolymerization is a way of introducing a new variant into a base polymer without grossly affecting the spinning

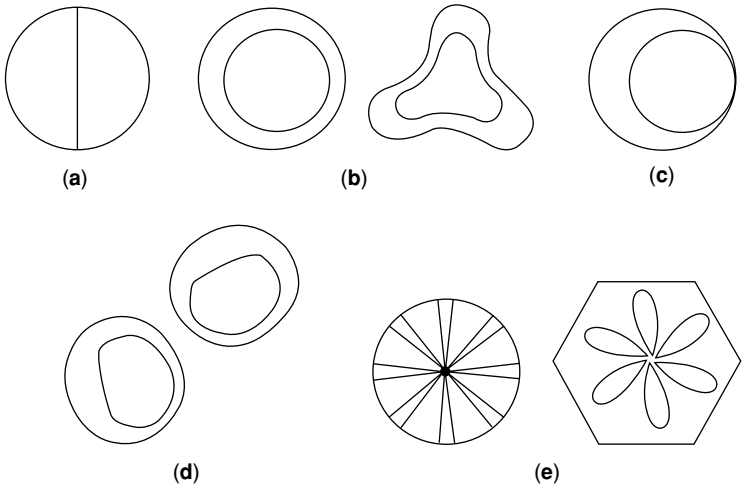

Fig. 7. Bicomponent cross-section forms: (**a**) side by side, (**b**) concentric sheath core, (**c**) eccentric sheath core, (**d**) kidney-shaped sheath core, and (**e**) conjugate.

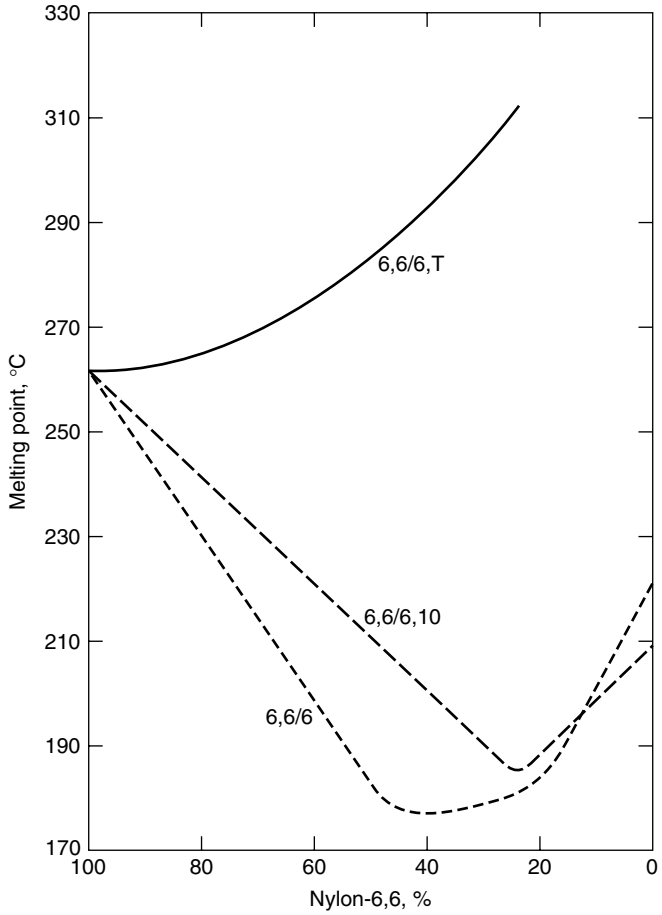

Fig. 8. Melting point–composition curves for random copolyamides of nylon-6,6.

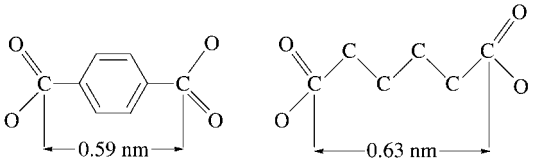
performance and physical properties of the yarn. The process requires careful control, however, to maintain the desired composition in order to ensure uniform product and spinning continuity. Examples of this technology are the block copolymers of poly(4,7-dioxadecamethyleneadipamide) and poly(dioxaarylamide) with nylon-6 (163,164) for hydrophilic nylons.

Random copolymers are made by combining two or more monomers in the polymerization process. The melting temperature of random copolymers are lowered as the regularity with which the monomer groups are spaced along the backbone is reduced. Hydrogen bonding between the amides is also reduced. This is illustrated in the melting point–composition relationship for nylon-6,6/6 and nylon-6,6/6,10 in Figure 8. Crystallinity and orientation are also reduced with increasing randomization. However, in the case of nylon-6,6/6,T, the crystallinity is not reduced because the copolyamide segment is similar in size to that which is replaced. Such monomers which can be exchanged or replace each other in the crystal lattice are often termed *isomorphic monomers*.



Random copolyamides that melt below 200°C are difficult to process through melt spinning because they are difficult to crystallize and consequently remain tacky through the windup. Copolyamides that melt above 300–310°C are also difficult to process because of their higher melt viscosities and greater susceptibility to thermal oxidation.

The general properties of random copolyamides are high dyeability (especially with nonleveling large dye molecules), lower melting and softening points, reduced dry and wet strength properties, high creep failure, and high shrinkage. The last property led to the use of the copolyamides in bicomponent self-crimping yarns. Copolyamides are also suitable for thermal bonding of fiber and fabrics because of their low softening temperature. Random copolyamides are also used to modify the dyeability of nylon-6,6. The addition of 0.5–2% comonomer increases the dyeing rate to almost that of nylon-6. Comonomers are also used as assists in the high speed godetless spinning of draw-texturing feed yarns. Nylon-6,6 copolyamides with ethyltetramethyleneadipamide, pentamethyleneadipamide, or 2-methylpentamethyleneadipamide units lower the gelation rate of nylon-6,6 at the spinning temperature of nylon-6,6 (165–167).

Graft Polymers. The grafting of polymers on nylon fiber surfaces as a means of altering chemical or physical properties has been explored and demonstrated over the years. However, a process has not yet been found that is safe, economical, and efficient for grafting yarns at conventional spinning speeds. Nevertheless, efforts continue because the property changes are dramatic and permanent, and because the process is more conducive to slower speed fabric-finishing processes. Vinyl monomers can be grafted to almost any nylon by ionizing radiation usually from a Co-60 source, high energy uv radiation, or chemical means. Radiation grafting of acrylonitrile on nylon-6 gives basic dyeability, and that of styrene, hydrophobicity (168). Nylon-6,6 can also be made basic-dyeable by chemically grafting acrylic or methacrylic acid with a water-soluble formaldehyde sulfoxylate salt (169). The friction of nylon fibers can be changed by grafting poly(dimethylsiloxane) macromolecules to the surface (170).

Nylon carpet fibers can be made to resist stain from certain acidic artificial and natural colorants found in soft drinks, juices, coffee, and red wines, by grafting a phenyl–vinyl and ether–maleic anhydride copolymer to the fiber surface using uv light and a photoactivator in the solution (171). However, there are other techniques for blocking the stain-sensitive amine ends that are more commercially applicable and efficient. They include (*1*) the post-treatment of nylon carpets with an alkali metal silicate in a phenol–formaldehyde product (172) or with a sulfonated naphthol or sulfonated phenol–formaldehyde product at a specific pH (173), (*2*) manufacturing of carpets with only cation-dyeable nylon yarn and dyeing or printing them to shade and acceptable lightfastness with premetallized or acid dyes

(177), and (*3*) melt-spinning of fibers–pigmented or producer-colored fibers–from nylon polymer containing a high level of a sulfonated derivative (174,175).

Other Nylons

Poly(tetramethylenediamine-*co*-adipic acid), nylon-4,6 [24936-71-8], polymer introduced as Stanyl by Dutch State Mines is spun into a high-temperature-resistant, high-tenacity filament yarn, Stanylenka 460 HRST, by Akzo Nobel Faser AG in Wuppertal, Germany. Stanylenka is intended for industrial applications including tire cord and automotive airbags because of its enhanced heat capacity, improved chemical resistance, better dimentional stability, and higher modulus than nylon-6,6 (176). The fiber melts at 285°C and has a density of 1.18 g/cm^3.

Poly(bis-[*p*-aminocyclohexyl]methane-*co*-dodecanedioic acid), PACM-12 [24936-74-1], introduced by DuPont as Qiana in 1968 was later withdrawn from the market. This diamine exists in several cis–trans and trans–trans isomeric forms that influence fiber properties, such as shrinkage and tenacity. The product offered silk-like hand and luster, dimensional stability, and wrinkle resistance similar to polyester. The yarn melted at 280°C, had a high wet glass-transition temperature of ∼85°C, and a density of 1.03 g/cm^3; the last was lower than that of nylon-6 and nylon-6,6. Qiana required a carrier for effective dyeing.

Poly(hexamethylenediamine-*co*-dodecanedioic acid), nylon-6,12 [24936-74-1], melts at 212°C, has a density of 1.06 g/cm^3, and has a lower moisture regain than that of nylon-6,6. Nylon-6,12 is used primarily for fishing lines and toothbrush bristles. It has a good apparel fiber properties, but is not as readily dyeable as nylon-6,6.

Poly(butyrolactam), nylon-4 [24938-566-27], melts at 268°C, has a density of 1.25 g/cm^3, and has a moisture regain of 6–9%, which is similar to cotton at 60% RH. It is easier to dye than nylon-6 and cotton, but is difficult to manufacture (177).

Applications

World production of nylon fibers is expected to reach 4×10^6 t in the year 2000 (178). Just under 50% of this volume will be produced in the United States and Western Europe, while future production growth will be predominantly in developing regions of China and southeast Asia (179). Production by polyamide type is about 70% nylon-6 and 30% nylon-6,6 (180).

Nylon and polyester make up almost 75% of world's synthetic fiber production (178). As the various market segments and end-use technologies have developed over the years for these maturing synthetic fibers, nylon has moved specifically into higher value applications where its unique properties justify the higher price. Nylon has grown more slowly than polyester, and now nylon filament production volume is one-third of polyester (179). Nylon filament prices are generally higher than those of polyester filament, for example, ranging from around 25% higher for tire reinforcement to over twice as much for some apparel yarns (181).

Principal market segments for nylon are carpet face yarns, which in the United States account for 70% share of nylon consumption; knit and woven apparel

at 18% share; industrial end uses such as tires and reinforced rubber products at 7%; and all other uses at 5% (182).

Nylon is the preferred fiber for carpets because of its excellent wear resistance, appearance retention, and ease of coloration. For a given appearance retention and wear life, particularly in plushes, less nylon (in terms of weight per unit area) is required than for polyester or polypropylene. Technical innovations such as soil and stain resistance and antistatic carpeting have contributed significantly to the growth of nylon in this industry. Branding or certification programs, including DuPont's Stainmaster∗, Solutia's Wear-Dated∗, Allied's Anso∗, and BASF's Zeftron∗, and others, have been used to grow volume and market share. In the 1990s, the industry also saw much push toward lower cost, nonbranded offerings, and significant industry integration, mergers, and reorganization. Nylon filament and staple have 60% share of carpet face fiber usage in the United States, exceeding 2 billion pounds per year; polypropylene filament has grown to almost 30% share, while staple fibers of polyester and other materials make up the rest (182).

Recycling of carpet components, especially the face fiber, has received much attention during the 1990s because over 4 billion pounds of post-consumer and manufacturing carpet-related waste is discarded annually, usually to landfills (183). The industry and major nylon fiber and carpet producers have demonstrated and are implementing collection methods, material management methods, and technologies to recycle waste carpet materials in a variety of bulk composites, reformed plastics via component separation and remelt, and recovered base polymer ingredients for both nylon-6 and nylon-6,6. Less than 1% of the discarded material is currently being recycled (183), but significant growth in recycled volume is expected during the next 5 years (184).

Two largest segments of industrial nylon applications are (1) reinforcing yarns in tires and (2) woven fabrics for airbags in automobiles. Because of its excellent strength, adhesion to rubber, and fatigue resistance, nylon is the preferred fiber in bias-ply industrial/commercial tires (eg, for short-distance trucks, construction/agricultural equipment, racing cars, and airplanes), in mini-spare passenger car tires, and in off-road vehicles tires. Polyester is the dominant fiber used in the carcass of radial passenger car tires because of its relative cost and higher modulus versus nylon. Nearly all high performance radial passenger car tires have nylon cap plies (above steel belts) to improve high speed durability.

In 1984 the U.S. Department of Transportation ruled that all new cars sold in the United States must be equipped with automatic crash-restraints for driver and front-seat passenger by 1990. This led to the adoption of the airbag concept, which created a new fabric opportunity for nylon industrial yarns. Airbag usage in light vehicles grew to over 110 million units by the year 2000, as frontal airbag installations for drivers and passengers reached 100% in the United States and approached 70% in Europe and Japan (185). Significant additional growth is expected as other regions adopt this concept, and adoptions of side-impact airbags increase. The air bag fabric is woven with high tenacity nylon industrial yarns, generally nylon-6,6, ranging from 47 to 94 tex (420–840 denier), in plain or rip-stop construction, and then scoured, heat-set, and coated with a neoprene formulation to protect the fabric from environmental pollutants and changes in temperature and humidity.

Other applications for the heavier denier, industrial grade nylon yarns include cordage, hose, webbing, sport goods, coated fabrics, belting, printer ribbon tapes, personal flotation devices, luggage, upholstery (automotive, contract), home furnishings, and papermaker felts (staple).

In apparel applications, nylon is preferred over polyester in warp knit fabrics for lingerie because of nylon's relatively fine denier, low weight, and softness; and in circular knit fabrics for sheer hosiery and pantyhose for these same reasons plus its superior textured yarn properties (especially stretch/recovery). Nylon is also the companion yarn of choice in stretch knit and woven constructions that incorporate elastane fibers, such as Dupont's Lycra∗ or Bayer's Dorlastan∗, because of textile processing compatibility (especially dyeing) versus polyester and elastane, in addition to nylon's preferred tactile aesthetics. Volume growth of nylon in apparel is expected to continue at relatively low rates, around 2.0% per year (186), but higher growth in value is expected as the recent consumer/retailer demands for high value, branded fabrics and garments continue (187). Examples of these specialty offerings are the stretch fabrics with elastane yarn, typically 5–20% of the composition; and branded offerings differentiated by aesthetics or functional performance, like Dupont's Tactel∗, Nylstar's Meryl∗, and BASF's Ultra Touch∗. Because of their softness, drape, and comfort, one denier per filament and microdenier yarns (less than 1 denier/filament) continue to gain popularity as compared to the workhorse 3 denier/filament yarns in previous years.

POLYAMIDES, PLASTICS

Introduction

The use of polyamides in plastic applications dates back to the original commercialization of this polymer. The first polyamide application was the introduction by DuPont in 1938 of nylon-6,6 for tooth brush filaments (1). Although fiber applications soon dominated, the use of polyamides as plastics grew steadily from the 1950s and is estimated to represent more than 25% of total polyamide use in the year 2000 or 1.65 million metric tons per year (2). Growth is about 8–9% per annum compared to less than 1.5% for fibers (3).

Polyamides were the first engineering plastics and still represent by far the biggest and most important class of these types of material. The combination of mechanical and thermal properties allows them to be employed for highly specified end uses and often for metal replacement applications (see Engineering Thermoplastics, Survey).

Polyamides comprise a range of materials, depending on the monomers employed. Nylon-6,6 [32131-17-2] and nylon-6 [25038-54-4] continue to be the most popular types, still accounting for more than 90% of nylon use. Table 1 gives a summary of the properties of the more common types which are currently commercially available. In recent years there has been increasing interest in polyamides with higher melting points to extend the boundaries of this polymer type to satisfy more stringent high temperature automotive and electronic applications. This has resulted in the development of nylon-4,6 and several semiaromatic nylons.

Physical Properties

The original development of polyamides, initially nylon-6,6 then nylon-6, concentrated on their potential as fiber-forming materials where strength, elasticity, and high dye uptake were considered the most important properties, along with the ability to withstand ironing temperatures. It soon became apparent, however, that the properties of the material held many advantages for use as a plastic. In particular, the relatively high tensile strength and stiffness, together with good toughness, high melting point (and therefore temperature stability), and good chemical resistance, all combined to allow a wide range of applications. The material soon came to be seen as an engineering plastic that could be used for metal replacement in structural or semistructural end uses. These properties are present to a greater or lesser extent in the entire semicrystalline polyamide family and form the basis for the continuing success and growth of these materials.

Appropriate choice of monomer can provide a balance of properties to meet particular types of applications. In general, the effects of different monomers and therefore the property balance of different types of nylon can be summarized as follows: lengthening the aliphatic segments between the amide groups results in lower moisture absorption, reduced strength and stiffness, and lower melting point (eg, nylon-11 or nylon-12 compared to nylon-6,6). The introduction of aromatic groups increases stiffness and strength but reduces moisture uptake and, to a lesser extent, impact strength. Some semiaromatic polyamides also have an increased melting point.

In addition to the semicrystalline nylons, which comprise the vast majority of commercial resins, nylon is also available in an amorphous form that gives rise to transparency and improved toughness at the expense of high temperature properties and chemical stress-crack resistance. Table 2 shows the properties of some different polyamide types.

Crystallinity. The presence of the polar amide groups allows hydrogen bonding between the carbonyl and NH groups in adjacent sections of the polyamide chains. For common nylons such as nylon-6,6 and nylon-6, the regular spatial alignment of amide groups allows a high degree of hydrogen bonding to be developed when chains are aligned together, giving rise to a crystalline structure in that region. These nylons are semicrystalline materials that can be thought of as a combination of ordered crystalline regions and more random amorphous areas having a much lower concentration of hydrogen bonding. This semicrystalline structure gives rise to the good balance of properties. The crystalline regions contribute to the stiffness, strength, chemical resistance, creep resistance, temperature stability, and electrical properties; the amorphous areas contribute to the impact resistance and high elongation. The crystallinity can be disrupted by substituents on the chains that interfere with the alignment process. Amorphous nylons are produced by deliberately engineering this effect, eg, nylon-NDT/INDT (also known as PA-6-3-T or PA-TMDT), which uses trimethyl-substituted hexamethylenediamine isomers combined with terephthalic acid.

Thermal Properties. The high melting point of polyamides such as nylon-6,6 is a function of both the strong hydrogen bonding between the chains and the crystal structure. This also allows the materials to retain significant stiffness above the glass-transition temperature (T_g) and almost up to the melting point.

The effect is further increased when reinforcements such as glass fiber are added, giving a high deflection temperature under load even at high loading. The effect also results in the sharp melting points of nylon as the majority of the hydrogen bonding rapidly breaks down at that temperature, giving a low viscosity, water-like melt. The melting point is mainly related to the degree of hydrogen bonding between the chains, which depends on the density of amide groups. The melting point therefore drops as the length of aliphatic groups between the amide links increases (eg, nylon-6,6 melting at 264°C, compared to nylon-6,12 at 212°C). The influence of structure on the melting point is further complicated by factors that affect the ease of crystallization. For even–even nylons such as nylon-6,6 and nylon-6,12, the monomers have a center of symmetry and the amide groups easily align to form hydrogen bonds in whichever direction the chains are facing when placed on top of one another. For even nylons, such as nylon-6, that have no center of symmetry, the amide groups are in the correct positions only if the chains are aligned in one particular direction (antiparallel). For this reason, nylon-6 has a melting point more than 40°C lower than nylon-6,6, despite having the same density of amide groups. It also has a slower crystallization rate and therefore wider processing window. Other types of nylon, such as even–odd and odd nylons, also differ from the above types for similar reasons of crystallization and crystal packing. In addition, crystallization is impeded and melting point reduced by copolymerization and substituents on the chains, although in certain cases isomorphism of comonomers avoids this effect, eg, terephthalic acid increases the melting point of nylon-6,6.

In recent years, polyamides have been increasingly used in higher temperature applications (mainly automotive) and in addition to the newer high melting point materials, glass-reinforced nylon-6,6, in specially modified formulations, has been shown to be suitable for use in replacing metals at temperatures which would not have been considered possible a few years ago (13).

Moisture Absorption. A characteristic property of nylon is the ability to absorb significant amounts of water (14) (Fig. 1). This again is related to the polar amide groups around which water molecules can become coordinated. Water absorption is generally concentrated in the amorphous regions of the polymer where it has the effect of plasticizing the material by interrupting the polymer hydrogen bonding, making it more flexible (with lower tensile strength) and increasing the impact strength. The T_g is also reduced. Moisture absorption, determined by both the degree of crystallinity and the density of amide groups, is, as with the melting point, reduced with increasing length of aliphatic groups in the chain. Aromatic monomers also reduce the moisture absorption. Nylon-6 has a higher moisture absorption than nylon-6,6 because of its lower crystallinity. The effect of moisture absorption on the mechanical properties of nylon-6,6 is included in Table 3.

Electrical Properties. Nylons are frequently used in electrical applications mainly for their combination of mechanical, thermal, chemical, and electrical properties. They are reasonably good insulators at low temperatures and humidities and are generally suitable for low frequency, moderate voltage applications. The relatively high dissipation factor of nylon causes problems under conditions of high electrical stress, particularly when moist, because of the likelihood of overheating. Dry nylon has volume resistivities in the 10^{14}–10^{15} Ω·cm region, but this decreases with increasing moisture and temperature. Dielectric

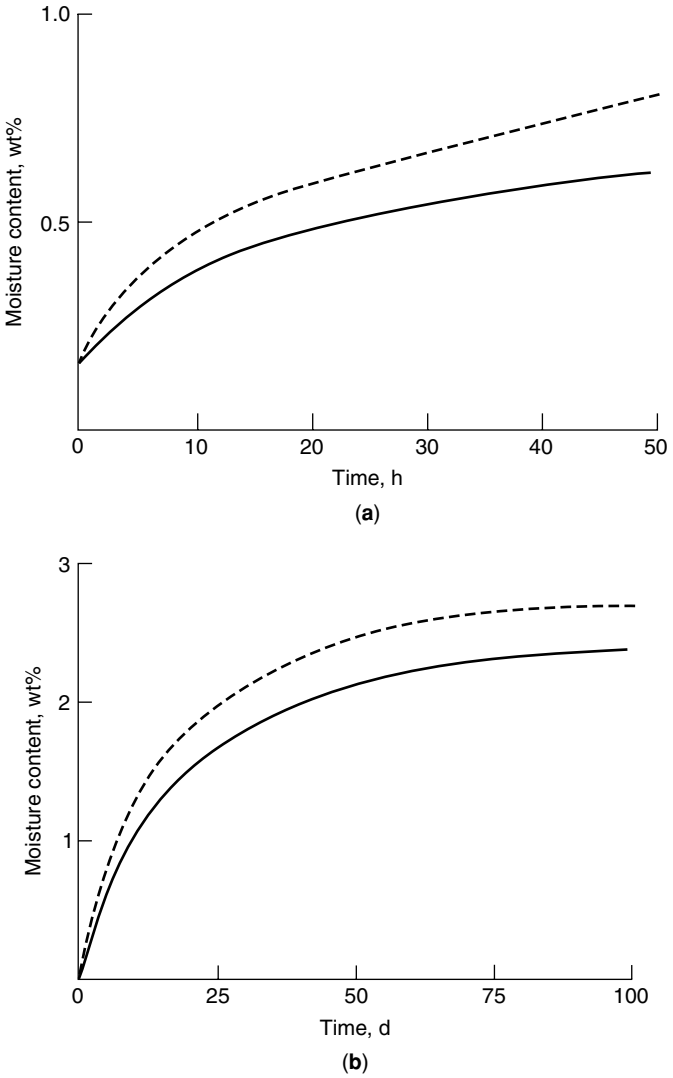

Fig. 1. Rate of moisture pickup for nylon-6,6 (——) and nylon-6 (—) granules at 50% rh and 23°C: (**a**) 0–48 h, (**b**) 0–100 days.

constant displays large increases with moisture and temperature. For moist nylon, however, the value decreases with increasing frequency, as the water molecules are less able to respond at higher frequencies.

Nylons have excellent arc and tracking resistance. Arc resistance is not affected by moisture or temperature up to about 100°C. Comparative tracking resistance of most unmodified nylons is greater than 600 V. Incorporation of additives such as flame retardants often reduces the electrical properties because of the introduction of ionic species.

Flammability. Most nylons are classified V-2 by the Underwriters' Laboratory UL-94 test, which means that these nylons are self-extinguishing within a

certain time scale under the conditions of the test. They achieve this performance by means of giving off burning drips. Inclusion of reinforcement such as glass fiber converts this behavior to HB, where the sample continues to burn as a result of the reinforcement holding it together. The flammability performance can be improved by adding flame-retardant additives that can eliminate burning drips and produce nylon that meets the most stringent UL-94 test (V-0), even with materials containing glass fibers.

Mechanical Properties

The semicrystalline structure of most commercial nylons imparts a high strength (tensile, flexural, compressive, and shear) as a result of the crystallinity and good toughness (impact strength) due mainly to the amorphous region. The properties of nylon are affected by the type of nylon (including copolymerization), molecular weight, moisture content, temperature, and the presence of additives. Strength and modulus (stiffness) are increased by increasing density of amide groups and crystallinity in aliphatic nylons; impact strength and elongation, however, are decreased. Nylon-6 having a lower crystallinity than nylon-6,6 has a

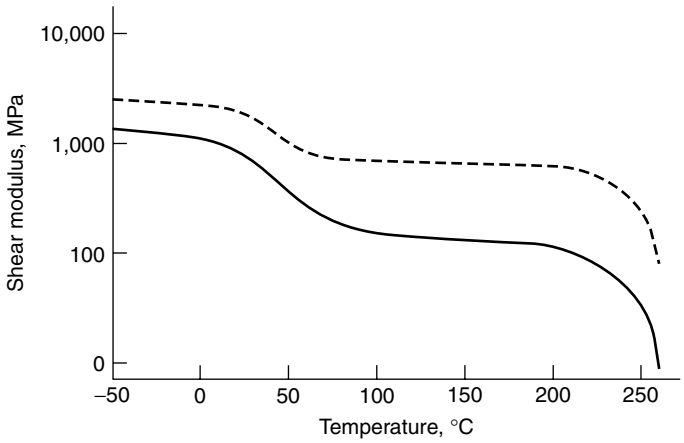

Fig. 2. Effect of temperature on the shear modulus of dry nylon-6,6 (——) and nylon-6,6 plus 30% glass fiber (—). To convert MPa to psi, multiply by 145.

higherimpact strength and slightly lower tensile strength. Nylons containing aromatic monomers tend to have increased stiffness and strength by virtue of the greater rigidity of the chains. Increasing molecular weight gives increased impact strength without having a significant effect on tensile strength. Moisture content affects the properties of nylon-6 and nylon-6,6; the effect is similar to that of temperature. Increasing moisture content reduces the T_g above which the modulus and tensile strength drop significantly; however, some polyamides with a high T_g, such as those containing aromatic monomers, have little change in properties with changing moisture as the T_g remains above room temperature. Increasing moisture for nylon-6 and nylon-6,6 also gives a steady increase in impact strength as a result of increasing plasticization, although at very low temperatures moisture can embrittle nylon. For nylons that absorb lower amounts of water, the effects on properties are less.

The effect of temperature on properties can be seen in Figure 2, which shows the effect on modulus of increasing temperature of unmodified and glass-reinforced nylon-6,6. Impact strength, however, shows a steady increase with temperature as it does with moisture.

Generally, nylon is notch-sensitive and the unnotched impact strength is dramatically reduced when a notch or flaw is introduced into the material. This needs to be considered when designing parts so that sharp angles are avoided where possible. This notch sensitivity can be considerably reduced by incorporating impact modifiers. For the most effective of these materials, the notched impact strength approaches the unnotched impact performance of the unmodified resin. The increased ductility of the material that accompanies impact modification does, however, reduce stiffness and strength. Moisture conditioning of moldings is often used to increase impact strength and flexibility before such operations as snap fitting or assembling cable ties, which can be avoided in some cases by using impact-modified resins. The effect of impact modifier on the properties of nylon-6,6 is shown in Table 3.

Properties such as stiffness and strength can be considerably increased by adding a reinforcing agent to the polymer, particularly glass or carbon fiber. Inclusion of a filler or reinforcement forces the material to fail in a brittle rather than ductile fashion. As a result, the unnotched impact strength and elongation are reduced, although the notched impact strength may be increased. These materials maintain their mechanical integrity under a high load almost up to the melting point of the nylon, eg, deflection temperature under load (see Table 3). Mechanical properties can also be modified by the inclusion of Plasticizers, which have a similar effect to that of water in breaking down hydrogen bonding in the amorphous region and increasing ductility, flexibility, and impact strength. Table 3 also shows the effect of glass and plasticizers on nylon-6,6 and nylon-12 properties, respectively.

As with most plastics the properties of nylons are time-dependent. The strain in a molding constantly under load increases with time (creep); equally, the load or stress required to maintain a constant deformation decays with time (stress relaxation). Some creep curves are given in Figure 3. Glass-fiber reinforcement considerably improves the creep performance. Nylons have good resistance to dynamic fatigue, ie, the application of cyclic loads. This is influenced both by the frequency and wave form imposed as well as by moisture, temperature, and the presence of notches. Again, glass-fiber reinforcement considerably improves the number of cycles that can be withstood. Nylon-6,6 has much better fatigue resistance than nylon-6, and it is claimed that nylon-4,6 is much better still (9). Nylon is also particularly resistant to damage from repeated impacts; much better, for example, than some metals that have a high impact resistance to a single blow.

Two more properties for which nylon shows particular advantages are abrasion resistance and coefficient of friction. These properties make the material suitable for use in, for example, unlubricated bearings and intermeshing gears;

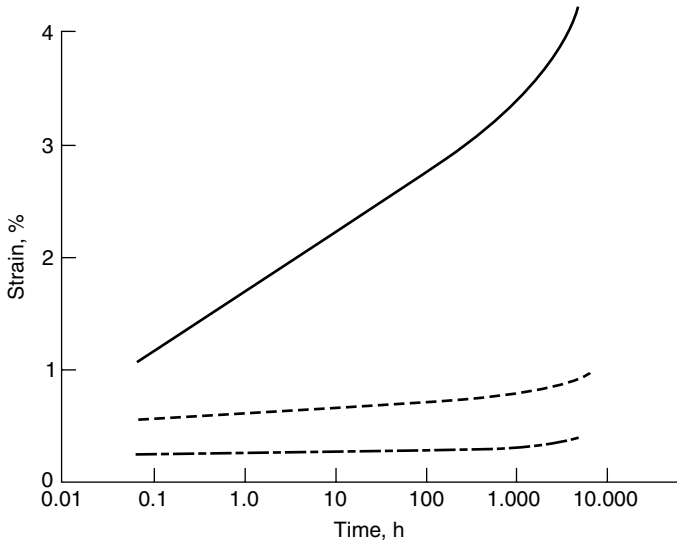

Fig. 3. Tensile creep of nylon-6,6 at 50% rh, 23°C, and 15 MPa (2175 psi) (——), reinforced by 15 wt% glass (—), and 33 wt% glass (– -).

nylon has been used in such applications from an early stage in its development. Wear and friction properties can be further improved by use of appropriate additives; for example, abrasion resistance can be increased considerably by the use of aramid-fiber reinforcement and PTFE, graphite or molybdenum disulphide have been used to significantly reduce friction (and often also wear) in moving parts.

Chemical Properties

Hydrolysis and Polycondensation. One of the key properties of polyamides relates to the chemical equilibrium set up when the material is polymerized. The polymerization of nylon is a reversible process and the material can either hydrolyze or polymerize further, depending on the conditions.

In the melt the material is in a dynamic situation and only at a certain (equilibrium) moisture content does the rate of hydrolysis equal the rate of polymerization. This equilibrium moisture content (in a sealed system) depends on the polymer, the temperature, the molecular weight, and the end group balance of the polymer. Below this moisture content, the melt increases in viscosity (polymerizes) and above it hydrolysis occurs with reduction in viscosity and molecular weight. For nylon-6,6, the equilibrium moisture content is close to 0.15% for most standard injection-molding resins; however, the figure is less for reinforced materials as less nylon is present per unit weight. For high molecular weight nylons used for extrusion applications, the equilibrium moisture content is less as the concentration of end groups is less; therefore, these materials need to be processed at lower moisture contents to avoid lowering the molecular weight. Nylons also polymerize in the solid form (solid-phase or solid-state polymerization) if heated significantly above 100°C in the absence of water. The equilibrium also means that nylons can hydrolyze when parts are exposed to aqueous environments for long periods at high temperatures, leading to loss of properties. However, this depends on the conditions of exposure. Nylon-6,6 has long been used successfully for automobile radiator end tanks and washing machine valves and has recently been used for pump housings for the boilers of domestic central heating systems (15). Nylons that absorb lower amounts of moisture have improved hydrolysis resistance, and semiaromatic nylons have been used for some higher temperature applications (16).

Thermal Degradation. Although nylons have good thermal stability, they tend to degrade in the melt when held for long periods of time or at high temperatures. This is particularly the case for nylons containing adipic acid such as nylon-6,6. The adipic acid segment can cyclize, leading to chain scission and the production of cyclopentanone and derivatives and evolution of carbon dioxide and ammonia. Alongwith reduction of molecular weight, cross-linking also occurs, and the material eventually sets into an intractable gel. This is normally not a problem with plastics processing operations where the residence time is relatively short, but loss of molecular weight during injection molding can occur as a result of this, particularly at high temperatures (over 300°C) or where the shot size is a small proportion of the machine capacity. Significant evolution of carbon dioxide also occurs. Processing machines should not be left containing molten nylon for any length of time but should be either emptied or purged out with, for example, a polyolefin.

Oxidation. All polyamides are susceptible to oxidation. This involves the initial formation of a free radical on the carbon alpha to the NH group, which reacts to form a peroxy radical with subsequent chain reactions leading to chain scission and yellowing. As soon as molten nylon is exposed to air it starts to discolor and continues to oxidize until it is cooled to below 60°C. It is important, therefore, to minimize the exposure of hot nylon to air to avoid discoloration or loss of molecular weight. Similarly, nylon parts exposed to high temperature in air lose their properties with time as a result of oxidation. This process can be minimized by using material containing stabilizer additives. Improvements in recent years have allowed nylons to be used at higher temperatures without problems, and formulations to minimize yellowing with aging have been developed.

Ultraviolet Aging. Nylon parts exposed to sunlight and uv rays undergo a similar free-radical aging process. Again, this can be reduced with appropriately stabilized materials.

Effect of Chemicals and Solvents. Nylons have excellent resistance to many chemicals, although the effect varies depending on the nature of the nylon. Generally, polyamides tend to be particularly resistant to nonpolar materials such as hydrocarbons. Resistance is least to strong acids and phenols which are most effective at disrupting the hydrogen bonding and which can sometimes dissolve the nylon. Highly polar materials such as alcohols are absorbed and sometimes dissolve the nylons containing lower concentrations of amide groups. Ethylene glycol, which is used in engine coolants, is absorbed by polyamide and dissolves nylon-6,6 (and nylon-6) above 160°C. Certain metal salts can attack nylon causing stress cracking, eg, zinc or calcium chloride, or even dissolve the material in alcoholic solution, eg, lithium chloride.

Manufacture

Solid-State Polymerization. There is a limit to the molecular weight that can be obtained in a melt-polymerization process as a result of degradation with long melt residence times and limits to the diffusion rate of moisture out of high viscosity melts. In order to produce high molecular weight resins to be used in, for example, extrusion operations, it is necessary to polymerize further by heating in the solid state. This is carried out under vacuum, steam, or inert gas. Nylon-6,6, for example, can be solid-state-polymerized in the temperature range of 150–240°C. Below the melting point, the hydrolysis rate is negligible compared to the reaction time, and degradation reactions are also much reduced. This process can be carried out by a batch or continuous process. The batch process involves tumbling granules in a heated rotating vessel under vacuum or a stream of inert gas. The continuous process uses a column with heating and cooling sections, granules enter at the top and exit at the bottom against a counter current of inert gas, and the residence time is set to give the molecular weight increase required.

Compounding. Although low levels of additives such as lubricants can often be incorporated during the polymerization process (internally or surface coated onto granules), in order to add the required higher levels of, eg, glass-fiber reinforcement, impact modifiers, or flame retardants, it is necessary for the nylon

to undergo a second manufacturing step to melt-incorporate the additives. This is carried out by extrusion compounding, which usually consists of a gravimetric feed of additives and nylon granules to a single- or twin-screw extruder. The screw conveys the mixture along a heated barrel and, by the action of shear on the polymer, melts the material and mixes in the ingredients. Twin-screw extruders usually have intermeshing co-rotating screws that are more effective at mixing the material than single-screws, and can be built up from modular components, allowing flexibility in selecting the average and localized shear/mixing regime along the screw. Additives such as glass fiber can be added along the barrel and into the melt in such designs; screw-side feeders can be used to do this. A vacuum line attached to a vent in the barrel allows the removal of moisture and volatiles. Material is extruded through a die into laces, which are water-cooled and pelletized. An alternative compounder is the co-kneader design which is a modification of a single-screw extruder but has axial motion as well as rotation and mixing pins engaging with the (modified) screw. This system allows a higher level of mixing to be achieved without generating excessive temperatures (particularly useful for temperature-sensitive additives) but requires a secondary crosshead or gear pump to develop pressure for lace extrusion (17).

Additives and Modifications. For plastics uses, nylon is only rarely employed as the pure polymer, and is almost always modified to some extent even if only with the addition of a small amount of lubricant. There has been a dramatic increase in the range and number of combinations of additives used to modify nylons, resulting in a huge expansion in the number of commercial grades available and the uses to which they can be put. It is not unusual to find formulations that contain less than 50% nylon and half a dozen or more additives.

Lubricants. Lubricants are used to improve the melt flow, screw feeding, and mold release of nylons. Long-chain acids, esters, and amides are used together with metal salts, eg, metal stearates. Improved melt flow is mainly a function of molecular weight reduction during molding. Mold release is improved by waxes of limited compatibility with nylon, which migrate to and lubricate the mold surface. High molecular weight silicones have also been used to improve flow and mold release of polyamide.

Nucleants. Although nylons crystallize quickly, it is often an advantage, particularly for small parts, to accelerate this process to reduce cycle time and increase productivity. Nylon-6, which crystallizes more slowly than nylon-6,6, particularly benefits from nucleation in unreinforced formulations. Nucleants are generally fine-particle-size solids or materials that crystallize as fine particles before the nylon. The materials, eg, finely dispersed silicas or talc, seed the molten nylon and result in a higher density of small uniformly sized spherulites; in nylon-6, the crystalline form is also changed. Nucleation increases tensile strength and stiffness but makes the material more brittle. Mold shrinkage is lower for nucleated resins.

Stabilizers. Stabilizers are often added to slow down the rate of oxidation and uv aging. Heat stabilizers can be organic antioxidants (such as hindered phenols or aromatic amines), hydroperoxide decomposers, or metal salts. The latter are most commonly used in the form of copper halide mixtures. This system, which has the side effect of discoloring the nylon, acts as a regenerative free-radical suppressor. Above about 120°C, the copper halide system is by far the most effective

and allows the use of glass-reinforced nylon-6,6 in high temperature automotive underhood applications. Ultraviolet stabilizers can be free-radical acceptors, uv absorbers, or hindered amine light stabilizers. Commonly, mixtures are used to give optimal performance, eg, a uv absorber such as a benzotriazole (or recently triazine) compound, to harmlessly absorb much of the uv energy, combined with a hindered amine light stabilizer (plus optionally a hindered phenol) to suppress reactive free radicals (18). The most common uv stabilizer, however, continues to be finely dispersed carbon-black pigment.

Impact Modifiers. Notched impact strength and ductility can be improved with the incorporation of impact modifiers, which can also lower the brittle–ductile transition temperature and give much improved low temperature toughness. Impact modifiers are rubbers (often olefin copolymers) that are either modified or contain functional groups to make them more compatible with the nylon matrix. Dispersion of the rubber into small (micrometer size) particles is important in order to obtain effective toughening (19). Impact modifiers can be combined with other additives, such as glass fiber and minerals, in order to obtain a particular balance of stiffness and toughness. Modified acrylics, silicones, and polyurethanes have also been proposed as impact modifiers.

Flame Retardants. Flame retardants are added to nylon to eliminate burning drips and to obtain short self-extinguishing times. Halogenated organics, together with catalysts such as antimony trioxide, are commonly used to give free-radical suppression in the vapor phase, thus inhibiting the combustion process. Additives that have been used are brorninated polystyrene, decabromodiphenyl oxide, and chlorinated dodecahydrodimethanodibenzocyclooctene (Dechlorane plus). In Europe, red phosphorus is widely used. It is effective at much lower levels and promotes char formation as well as inhibiting combustion, but is a more hazardous raw material to handle and the compounds are not available in light colors. Concern about the possibility of dioxin formation from resins containing halogenated organics, particularly those containing phenoxy groups, has led to increasing interest in nonhalogen, nonphosphorus flame retardants. Melamine derivatives have been widely used in unreinforced compositions and products have been developed based on magnesium hydroxide, although the high levels needed result in very poor mechanical properties. Recently nonhalogen, nonred phosphorus glass-reinforced flame retardant materials have been reported (20).

Plasticizers. Plasticizers are used to increase the flexibility of nylon and improve impact strength. They are most commonly used in nylon-11 and nylon-12 for such applications as flexible fuel hoses for automobiles. Plasticizers for polyamide are often sulphonamides, although others such as long-chain diols have been used as well as the caprolactam monomer in unextracted nylon-6. The latter material has been used for applications such as fishing lines.

Reinforcement. Nylon is particularly suitable for reinforcement and the melt incorporation of short glass fibers has long been practiced, being developed around 1960 by ICI in England (21) and Fiberfil Inc. in the United States (22). The tensile strength of nylon-6,6 is increased by more than 2.5 times and stiffness by almost 4 times by adding 30% glass fiber. Glass fiber also improves dimensional stability, notched impact strength, temperature performance and long-term creep, and is normally used in the 15–60 wt% range. The glass fibers used need to be treated with a specific sizing to enable bonding with the nylon and dispersion in

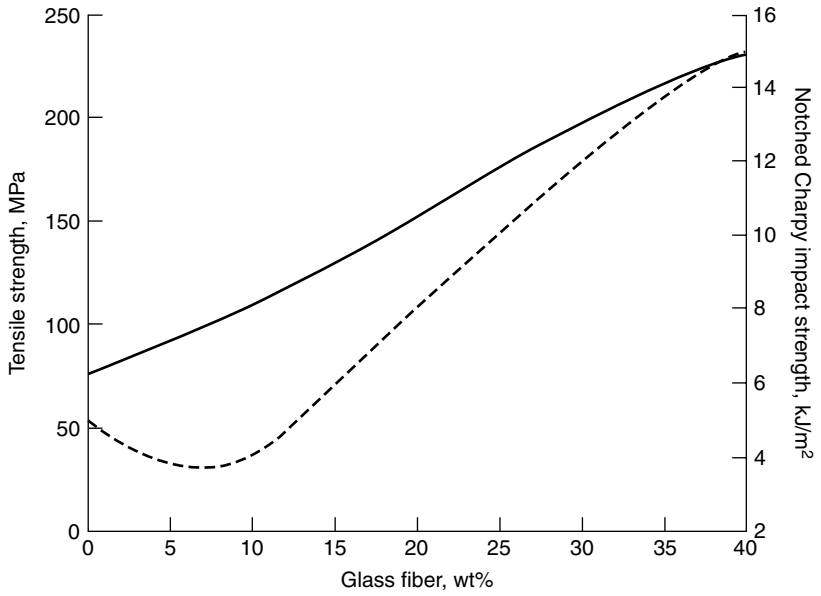

Fig. 4. Variation of tensile strength (——) and notched impact strength (—) with glass fiber level in nylon-6,6. To convert kj/m^2 to ft·lbf/in^2, divide by 2.10.

the melt; the size formulations are proprietary but often contain an aminosilane coupling agent and a polyurethane or acrylic binder. Special sizing compositions have been developed to improve the retention of properties of nylon-6,6 when exposed to hot engine coolant, and glass fibers further improved in this respect continue to be developed. The fibers are normally added as 3- or 4.5-mm chopped strands (bunches of filaments), but the fiber length in the final product drops to a fraction of a millimeter after dispersion in the extruder. Figure 4 shows the relationship between glass fiber content and typical properties in nylon-6,6.

A disadvantage of glass fibers is the warpage of flat moldings. This is the result of differential shrinkage caused by anisotropy from the glass fibers, which tend to align with the direction of melt flow. Mineral reinforcements are used to obviate this by stiffening the material with a more isotropic mixture. Properties are lower than for glass fiber. Minerals having a higher aspect ratio, such as talc and mica, tend to have higher stiffness and strength; surface-treated kaolin and wollastonite have better impact properties. Combinations with glass are also used. Other reinforcements include mineral fibers, carbon fiber, and para-aramid fibers (Kevlar). Carbon fibers give very high stiffness but are much more expensive than glass; aramid fibers increase abrasion resistance.

Nanocomposites. These are materials in which nanometer size silicate layers are uniformly dispersed into polyamides to give high levels of reinforcement at very low levels (eg, 5%). The layer-type clay minerals are treated to make the layers separate allowing them to be incorporated into the polymer structure (intercalation). Initial developments involved incorporation during nylon polymerization but extrusion compounding routes have now been developed. Some advantages of this technology are low density and isotropic shrinkage (23).

Polymer Blends. Commercial blends of nylon with other polymers have also been produced in order to obtain a balance of the properties of the two materials or to reduce moisture uptake. Blends of nylon-6,6 with poly(phenylene oxide) have been most successful, but blends of nylon-6,6 and nylon-6 with polyethylene or polypropylene have also been introduced (24).

Pultrusion. A special variant of compounding is pultrusion, which is used in the manufacture of long fiber reinforced polyamide materials. In this technique, fibers (eg, glass fibers) are pulled through polymer melt usually with some mechanism to spread the fibers to allow complete wetting. On cutting the resulting lace, the glass fiber length becomes equal to the length of the granule. These materials can give high stiffness and impact strength combined with lower warpage (25) but need to be processed carefully (large gate size, low back pressure) to avoid reducing the glass fiber length to that of a standard short glass fiber product.

Processing

Nylons need to be processed dry to avoid molecular weight loss and processing problems. Figure 5 indicates both the usable moisture range for nylon-6,6 and nylon-6 in injection molding and the relationship with temperature (26). Extrusion applications require lower moisture contents (max 0.1–0.15% for nylon-6,6 and nylon-6) as do some other nylon types (eg, max 0.1% for nylon-11 and nylon-12; 0.05% for nylon-4,6). The materials are normally supplied dry by the manufacturer

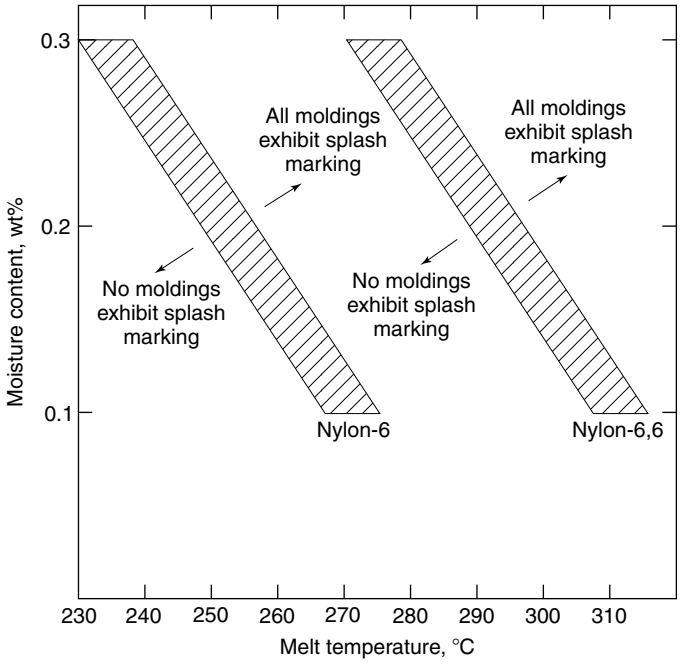

Fig. 5. Relationship between moisture content and temperature for an unvented cylinder during injection molding.

in moistureproof packaging such as foil-lined 25-kg bags or lined 1-ton boxes. Once opened, the material should be used within a few hours or resealed. Material that has absorbed some moisture can be redried using a vacuum oven at 80°C or a dehumidifier hopper drier.

Material should not be processed at too high a temperature, eg, preferably not above 310°C for nylon-6,6 or 290°C for nylon-6, in order to avoid degradation. Residence times at the higher temperatures should be kept to a minimum. Molten nylon should not be left in an idle machine for more than 30 min maximum. Exposure of molten and hot nylon to air should also be minimized to avoid discoloration.

Generally, nylon scrap or regrind can be reused satisfactorily, provided that it is dry. The level allowed depends on the amount of degradation and the specification of the final products.

Injection Molding. This is the largest single processing route for nylon, taking more than 60% of the material produced. This technique is generally carried out using a screw preplasticizing injection-molding machine (27–29) (see INJECTION MOLDING). Nylons can often be processed on general-purpose screws having a constant decreasing flight depth along the screw, but better performance can be achieved by a nylon-type screw having a sharp reduction in flight depth within a few flights in the compression or transition zone. This allows for the sharp melting point of semicrystalline nylons, which results in a rapid reduction in bulk density.

The sharp melting point and the low melt viscosity also mean that nylon can give problems with nozzle drool and/or premature freeze-off. For this reason, it is normally necessary to use either a reverse-taper nozzle (fitted with a heater to avoid freeze-off), a mechanical shut-off nozzle, or melt decompression. The design of molds should also take into account this low viscosity and sharp melting point. Mold surfaces should be well-mated to avoid flash.

Table 4 gives injection-molding temperatures for various nylons. Typical molding conditions for polyamides are as follows: average injection velocity, 100–300 mm/s; hold pressure, 70–90 MPa; hold pressure time, 20–30 s; maximum injection pressure, 70–90 MPa; cooling time, $\leq$10 s; and total cycle time, $\leq$50 s. Nylons generally require a fast injection speed and are particularly good for achieving fast cycle times because of the low viscosity and rapid setting-up.

Significant mold shrinkage occurs with nylon, mainly on account of the increase in density with crystallization. This can give rise to voiding and sink marks in moldings. The dimensional stability can be much improved by using reinforcing agents or nucleated materials.

Developments in injection molding that have become increasingly important include gas injection and fusible-core molding. Gas injection enables a saving in part weight and avoidance of sink marks in thick sections. This technique has recently been upgraded for use in tubing applications where the hollow core formed by the gas pushing out molten nylon from the center becomes the bore of the tube. Special materials are required to give a smooth internal surface. Fusible-core technology involves overmolding a low melting metal alloy core that is subsequently melted out in an oil bath. This technique allows much more complex moldings containing internal passageways to be produced. The method had become important for making automobile air inlet manifolds but is now being mainly overtaken in

Table 4. Injection-Molding Temperatures for Different Polyamides[a]

Polyamide	Melt temperature, °C[b]	Mold temperature, °C
Nylon-6	250–290	80
Nylon-6,6	290–300	80–100[b]
Nylon-4,6	315	120
Nylon-6,9 and nylon-6,10	270	80
Nylon-6,12	240–270	80
Nylon-11	210–260	80
Nylon-12	200–250	70–80[c]
Nylon-MXD,6	250–280	130
Nylon-NDT/INDT	280–300	80
Polyphthalamide[d]	327–332	135–150

[c]The lower mold temperature is used if >5% plasticizer.
[d]Ref. 31.

this application by vibration welded parts. Another very recent technique, which is really a development of gas injection, is water injection. In this process, water under high pressure replaces gas in ejecting molten nylon from the center of a part; the advantage is more efficient cooling, shorter cycle times, and the potential to produce larger diameter tubes (32).

Extrusion. Extrusion accounts for about 30% of nylon produced and is used in various processes (33). Nylons can be extruded on conventional equipment having the following characteristics. The extruder drive should be capable of continuous variation over a range of screw speeds. Nylon often requires a high torque at low screw speeds; typical power requirements would be a 7.5-kW motor for a 30-mm machine or 25-kW for a 60-mm one. A nylon screw is necessary and should not be cooled. Recommended compression ratios are between 3.5:1 and 4:1 for nylon-6,6 and nylon-6; between 3:1 and 3.5:1 for nylon-11 and nylon-12. The length-to-diameter ratio L/D should be greater than 15:1; at least 20:1 is recommended for nylon-6,6, and 25:1 for nylon-12.

Typical operating temperatures are shown in Table 5. Most extrusion operations require high viscosity (high molecular weight) nylon in order to give a high melt strength to maintain the shape of the extrudate. In the following sections,

Table 5. Typical Temperatures (°C) for Nylon Extrusion

Location	Nylon-6,6[a]	Nylon-6[a]	Nylon-12[b]
Screw			
Feed zone	265–275	220–230	185–205
Compression zone	275–285	235–250	190–215
Metering zone	285–295	245–265	190–220
Head	285–295	250–270	200–230
Die	285–295	250–270	195–230

[a]Ref. 33.
[b]Ref. 34.

reference is made to three broad viscosity ranges that correspond to these approximate number-average molecular weights when nylon-6,6 is used: high viscosity nylon ($M_n = 30{,}000$–$40{,}000$), medium viscosity (20,000–30,000), and standard viscosity (15,000–18,000, as used for injection molding).

Film. Nylon film can be produced as either tubular or cast film. In tubular film, melt is extruded through a screen pack and a tubular die, and a bubble is formed with air pressure. Total drawdown (extension of the melt) of the order of 10:1 to 20:1 is achieved. High viscosity nylon is required for this operation. A relatively stiff, hazy film is produced; nylon-6 has a lower haze level than nylon-6,6. Cast film is produced from medium viscosity nylon by extruding through a straight slot die and then rapidly quenching on highly polished rolls at a controlled temperature; speed of the rolls affects drawdown as above. Nylon film is also produced as coextruded multilayer structures mainly with olefin-type polymers. Nylon film has a low permeability to oxygen, nitrogen, and carbon dioxide, but a high permeability to water vapor (see BARRIER POLYMERS).

Tubing and Pipe. Medium to high molecular weight polymers are used for tube extrusion. Small bore tube (up to 10 mm) can be extruded through a conventional die and cooled in an open water bath. Air is injected into the center of the tube, using a torpedo to prevent the extrudate from collapsing and to adjust the wall thickness. For tubing larger than 10 mm, a pressure sizing die is used and tube is drawn into the water bath through a series of sizing plates in the end of the bath, 25–50 mm away from the die. A drawdown of about 2:1 is usually used, but this depends on the molecular weight and line speed. High molecular weight nylons require less drawdown than the less stiff lower molecular weight materials. Similar methods are used for large diameter pipe, for which high viscosity material is normally used, particularly with high wall thicknesses. As this is a slow operation, melt temperatures are kept up to 30°C above the normal melt temperature.

Monofilament. Standard and medium viscosity nylons are used. Close control of diameter is important and a gear pump is used before the die (after filtering through a fine filter pack) to minimize pressure variations. The die hole diameter is normally 1.5–2 times the diameter of the undrawn filament. The filaments are drawn through a quench tank at approximately 40°C, separated and then drawn by passing through two sets of rolls (running at different speeds) separated by a heated chamber. The drawn filament is set by passing through a final heated conditioning chamber.

Rod and Profiles. Medium to high viscosity grades are used. Accurate temperature control is important. For rods of diameters greater than 3 mm, slow solidification is essential to avoid voids and cracks caused by nonuniform shrinkage. Two processes are used. For rods up to 150 mm, a forming box is used whereby nylon is extruded under pressure through a water-cooled cylindrical tube. The tube is isolated from the die by a nonmetallic gasket, the rod is pulled off at a constant rate by a haul-off. The second process, which can be used for more complex shapes, involves extruding the nylon into a series of interconnecting open-ended molds.

Wire and Cable Coating. Nylons are widely used for wire covering and sheathing cable. In the latter application, nylon is usually overcoated onto insulation of another material, such as PVC, in order to provide cut and abrasion resistance. In a specialized application, nylon-11 and nylon-12 are used to provide

termite resistance. Amorphous polyamides have been used for sheathing of optical fiber cables.

Blow Molding. Blow Molding of nylons has become more important as a means of making large hollow moldings. In addition to high molecular weight nylon, resins modified to increase melt strength and containing glass fiber have been introduced, and impact modifiers are often used to increase melt elasticity. Blow molding of nylons is usually carried out by extrusion blow molding, whereby melt is produced in an extruder and formed into a tube called a parison (35). The molten parison is captured in a mold that pinches and seals the ends, and the rigid hollow part is formed by inflation under air pressure. Intermittent extrusion blow molding is most common, which involves the storing of melt in an accumulator die head until required to form the next parison, melt storage with a reciprocating screw or accumulator pot with ram is often used. Continuous blow molding and injection blow molding (for small parts) can also be used. The parison can also be inflated using suction blow molding and this technique is now becoming increasingly important. Suction blow molding is especially suitable for 3-D parts where the parison can be effectively pulled through complex mold shapes using vacuum. The design of the manifold and accumulator head should be such as to avoid material hold-up locations (giving degradation and gel formation), and should also incorporate even, carefully controlled heating. Adequate venting of the head is necessary to avoid buildup of gas.

Rotomolding. Nylon-6, nylon-11, and nylon-12 can be used in rotomolding and are generally supplied for these applications as a powder or with a small pellet size. The process involves tumbling the resin in a heated mold to form large, thin-walled moldings. Nylon-11 and nylon-12 use mold temperatures of 230–280°C and nylon-6 is processed at over 300°C. An inert gas atmosphere is preferred to avoid oxidation.

Reaction Injection Molding. RIM uses the Anionic polymerization of nylon-6 to carry out polymerization in the mold. A commercial process involves the production of block copolymers of nylon-6 and a polyether by mixing molten caprolactam, catalyst, and polyether prepolymer, and reacting in a mold (36,37).

Powder Coating. Nylon-11 and nylon-12 are used in powder form for anticorrosion coating of metals. Dip coating and electrostatic and flame spraying are used. Dip coating, which involves immersing a preheated article into fluidized nylon powder, is most suitable for automation.

Assembly Techniques. After molding, parts produced in more than one component can be assembled by snap fit, bolting, rivetting, welding, or gluing. Welding has become much more widespread in the last 10 years, with vibration welding in particular finding use to produce complex parts such as automotive air intake manifolds in a more cost effective manner than the capital intensive lost core process. Ultrasonic welding is also used (requires the nylon parts to be dry) and recently both hot plate and laser welding (38) have attracted considerable interest. Special polyamide materials have been developed for both these latter techniques. Polyamide parts can also be glued together, aided by the high surface energies of these polymers. Joint strengths are however much lower than when welded. Certain epoxy and polyurethane glues can be used sucessfully with polyamides although epoxies may give better resistance to temperature. Nylon–nylon joints are stronger than, for example, nylon–aluminum.

Table 6. Worldwide Polyamide Consumption in 1998 (10^3 t)[a]

Region	Auto	Electrical/electronic	Film	Other	Total

Applications

More than 60% of nylon is used in injection-molding applications. About 55% of this use is in the transportation industries, and most of this use is concerned with automobile production. Table 6 shows the split of applications for which nylon was used worldwide in 1998 (3). Descriptions of uses for polyamides, split into the principal application areas are given below.

Automotive. Not only is this the biggest single application area for polyamides but the rapid increase in the number of new applications is strongly influencing the overall growth rates for the polymer type. Metal replacement is being driven by both weight savings (and therefore fuel efficiency) and lower manufacturing costs.

Underhood. Polyamides have been used under the hood for a long time and applications such as radiator end tanks, filter housings, connectors and cable ties, together with nylon-11 and nylon-12 for fuel hoses have been long established. Certain applications such as filter housings may have mainly switched to lower cost polymers such as polypropylene but this has been far more than balanced by a huge growth in new uses. During the 1990s nylon air intake manifolds had essentially replaced aluminum and use of polyamides had extended to fuel rails, fans, fan shrouds, thermostat housings, and valve and engine covers. Some of the latest developments are front end modules (often nylon/metal hybrid structures) (39) and water tubes or water rails to replace rubber hoses in the coolant circuit. These tubing parts can potentially be made by either gas injection molding or blow molding, depending on the complexity and functionality required.

Interior. Again, polyamides have been used for some time for switches, handles, seat belt components, etc. Big new applications include air bag containers (very tough stiff resins are required to withstand the explosive inflation forces), pedals, and pedal boxes. Polyamides have also been used to replace metals in seat systems (39).

Exterior. Probably the biggest exterior application for polyamides is for wheel covers where mineral reinforced compositions are used to get the required degree of dimensional stability and flatness. Moves to use lower cost polymers have had limited success so far because of the better resistance of nylon to temperatures developed during braking. Other exterior applications include sun roof surrounds, door handles, fuel filler flaps, etc. One special application is the use of a nylon product (DuPont Selar®) as a fuel barrier material in polyethylene fuel tanks.

Electrical/Electronic. The electrical insulating properties of polyamides together with temperature performance, toughness, and inherent low flammability have long driven use in electrical and electronic applications. Uses include cable ties, connectors, light housings, plugs, and switches. Flame-retardant materials are also used for switchgear, housings, relays, circuit breaker components, and terminal strips. The advent of higher melting, higher heat-distortion temperature polyamides has allowed more temperature sensitive applications to convert to plastics. A new area for these types of products is for printed circuit boards using surface mount technology for which resistance to soldering temperatures is necessary. One additional application area is for housings for electronic equipment using products modified to provide an electromagnetic barrier and static dissipation.

Consumer. Polyamides are used in a number of consumer applications. A long-standing use is for power tool housings made from glass-reinforced nylon-6 or nylon-6,6 often containing impact modifier. A variation of this is a chain saw handle made using gas injection to reduce the weight; nylon monofilament is also used for strimmer cord. Sports equipment is one area in which polyamide use has expanded significantly and nylon has been used in ski boots and ski bindings, ice or roller skates, sports shoe soles, and tennis rackets (using carbon fiber reinforcement). Other miscellaneous applications include lighters, kitchen utensils, toothbrush filaments (nylon-6,12), chair bases and arms, spectacle frames, sewing thread, and packaging film (including cook-in-the-bag envelopes).

Industrial. This covers a huge range of unrelated areas of use. Nylon has been used from the early days in various gears and pulleys as well as in bearings and bearing cages, fasteners, and valves. Low melting nylon terpolymers are used as hot melt adhesives, nylon-12 for wire coating (including dish washer baskets), and amorphous nylons are used for transparent filter bowls and flow meters and for protecting optical fiber cables. Other uses have been stadium seats, sliding rails for conveyors, washing machine valves, castors, rail insulator pads, fishing lines, window thermal insulation, and film for medical applications. Some recent applications are pump housings for central heating systems (15) and an all-nylon shopping trolley (40).

Recycling

The issue of the recycling of polyamide parts has become a hotly debated issue since the second half of the 1990s. In the light of expected future legislation, a number of pilot schemes have been started to investigate collecting and recycling parts such as automotive components. The most advanced schemes however concentrate on reusing nylon carpets in plastic end uses. These processes are complex and expensive as considerable pretreatment of the post-consumer article is required before it can be reused in a plastics compounding process. The product can be recompounded directly (mechanical recycling) which invariably leads to a lower quality resin as contamination and/or unwanted ingredients cannot be entirely removed. The route to highest quality resin is achieved by chemical recycling in which the polyamide is taken back to monomer, purified, and repolymerized. A plant to chemically recycle nylon-6 had been started in the United States in 1999

(41) and a demonstration plant to recycle nylon-6,6 (as well as mixtures with nylon-6) was due to be commissioned in 2001 (42). The final development of recycling will probably involve a balance of part reuse, energy recovery, mechanical recycling, and chemical recycling.

Economic Aspects

The principal worldwide manufacturers of nylon resins are given in Table 7. Total sales of nylon plastics in the United States and Canada in 1998 were 495,000 t (3). West European sales were 572,000 t and sales in Asia Pacific (including Japan) were 335,000 t (3). Table 8 shows the variation of price across different polyamide types. Current estimates of growth for polyamide plastics are 9% p.a. for nylon-6 and 8.2% for nylon-6,6 (3). With fiber growth at 1.3% and 1.4% respectively, this represents a greater than 6 times higher growth rate for plastics. Published literature values for polyamide prices had remained stable through the second half of the 1990s (44) but in Europe at least, real prices had been dropping to the point at which major suppliers had needed to announce price increases in late 1999 and 2000 in order to get back to reinvestment economics (particularly in view of major oil and raw material cost increases).

Specifications, Standards, and Quality Control

Raw material specifications may be agreed between the supplier and the molder or end user, or they may be defined as requirements by an external body. The standards ASTM D4066 (45) and ISO 1874-1/2 identify how to classify and specify nylon materials and give details of tests and test methods that may be used, as well as required values. ASTM D5336 for polyphthalamides is also used. The tests include mechanical, thermal, electrical, and flammability properties as appropriate. In addition to these, it is normally necessary to specify the viscosity of the material, maximum moisture content, and ash content (if reinforced). Viscosity is generally measured as solution viscosity that corresponds directly to molecular weight, rather than melt viscosity, which is moisture-dependent. In the United States, solution viscosity is generally measured as relative viscosity (ASTM D789) or inherent viscosity (ASTM D2857), normally in 90% formic acid or *m*-cresol solvent. Elsewhere, viscosity measurements mainly use the internationally agreed viscosity number (ISO 307) in formic acid, sulfuric acid, or *m*-cresol. Moisture content is determined according to ASTM D789. The test employs a coulometric Karl Fischer titration technique using a nitrogen-flushed heated chamber to drive moisture into the solution. Commercial equipment is available to carry out this test. Manufacturer's quality control tests normally include tests for contamination, color, moisture, ash, viscosity, packaging (qv), and other properties as appropriate.

In recent years most polyamide suppliers have made data available using a common computer database software known as CAMPUS (Computer Aided Material Preselection by Uniform Standards). All data in this database is measured in common ISO format (ISO 10350 for single point and ISO 11403-1/2 for

POLYCYANOACRYLATES

Introduction

Cyanoacrylate polymers are commercially important materials as structural adhesives. They combine rapid curing and high strength and are widely used to bond a diverse range of substrate surfaces, including metals, ceramics, plastics, rubbers, and biologically derived materials. The corresponding monomers were first isolated in 1947 by Ardis at B. F. Goodrich (1). Subsequently, Eastman Kodak patented them as adhesive compositions in 1957 (2) and the first commercial adhesive formulation, based on methyl 2-cyanoacrylate, was introduced in 1958 (3). Today, cyanoacrylates represent a billion dollar industry serving medical, electronic, engineering, and consumer markets worldwide. Although adhesive compositions still constitute the major segment of the business, there is growing interest and activity in the use of these polymers in other areas. These include binding agents for the controlled delivery of drugs, coatings for lithographic printing plates, waveguides for optical sensors, photoresists, and holographic recording media.

Physical Properties of Monomers

Cyanoacrylate monomers are generally low viscosity, colorless liquids that are unstable in the absence of acidic stabilizers. The commercially important materials are lower alkyl esters of 2-cyanoacrylic acid including methyl, ethyl, *n*-propyl, allyl, *n*-butyl, isobutyl, 2-methoxyethyl, 2-methoxypropyl, and *n*-octyl derivatives. The structures of some of these monomers are shown in Figure 1. The physical properties of these and related monomers are reported in detail in several previous

publications (3–5). A summary of the bulk physical properties of some common monomers is presented in Table 1.

The lower esters of alkyl 2-cyanoacrylates (eg, methyl, ethyl esters) provide adhesives with excellent lap-shear strengths to a variety of different substrates (3). They are, however, brittle materials and generally require the addition of a rubber-toughening agent to improve peel strength and impact resistance (4). The low esters have pungent odors whereas the higher esters, in particular the alkoxyalkyl esters, are virtually odorless (3).

Chemical Properties of Monomers

The chemical properties of cyanoacrylate monomers are primarily determined by the highly electron-deficient nature of the alkene double bond. In the presence of catalytic amounts of basic or nucleophilic species they undergo rapid anionic bulk polymerization reaction and this chemistry is discussed in more detail later. Under neutral or acidic conditions, cyanoacrylates are good dienophiles and readily undergo [4+2] cycloaddition reactions with conjugated dienes such as butadiene or anthracene (6,7). However, in the presence of stiochiometric quantities of electron-rich monomers, such as vinyl ethers, they undergo heterodiene cycloadditions to give substituted dihydropyrans (8) (Fig. 2). The diene adducts

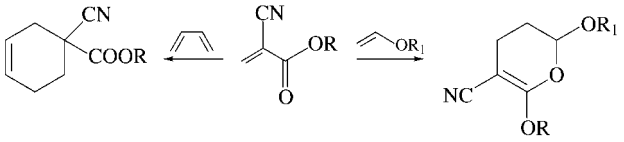

Fig. 2. Cycloaddition reactions of cyanoacrylates.

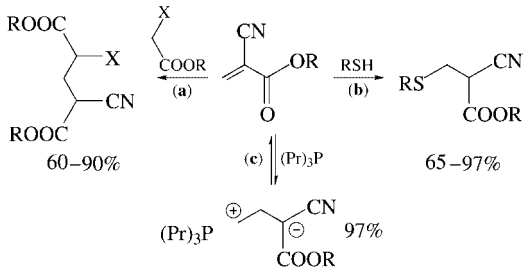

Fig. 3. Michael-type addition reactions to cyanoacrylates: (a) 5% piperidine, acetonitrile, 20°C, X = NO_2, CN, COR; (b) acetone, 3.5 h, 20°C, R = CH_2COOH, C_2H_4SH; (c) dry benzene, 3 h, 20°C.

are stable and are frequently used to characterize the more reactive monomers. In contrast, the dihydropyrans are unstable and are readily isomerized or polymerized (8,9).

Cyanoacrylates may also add to a variety of organic acids in piperidine-catalyzed Michael-type reactions (10–12). Thus nitro-, cyano-, and acetoacetates give the corresponding glutarate derivatives in moderate to high yields (Fig. 3a). However, as the acidity of the organic acid decreases, the yield of Michael adduct decreases and polymerization predominates. From a synthetic viewpoint the reaction is useful only for acids having $pK_a < 13$. Similarly, thiols and thiocarboxylic acids add to cyanoacrylate monomers to give the corresponding β-thioethers in high yields (11,12). This reaction proceeds at room temperature and does not require a catalyst (Fig. 3b). However, slow addition of monomer to thiol is required to ensure that polymerization does not occur. Similar techniques are used to prepare internal zwitterionic salts of cyanoacrylates and trialkylphosphines (Fig. 3c) (10,11,13). The salts are stable over several months, provided they are stored under anhydrous conditions.

Manufacture of Monomer

Cyanoacrylate monomers are usually prepared by a base-catalyzed Knoevenagel condensation of alkyl cyanoacetate and formaldehyde to give an intermediate low molar mass polymer which is then depolymerized under acidic conditions at elevated temperatures (14–17). Figure 4 depicts the process for the production of methyl 2-cyanoacrylate.

The condensation step is preferably carried out with paraformaldehyde in the presence of a nonaqueous solvent to facilitate the removal of water by azeotropic distillation (15). The reagents are generally employed in stiochiometric amounts,

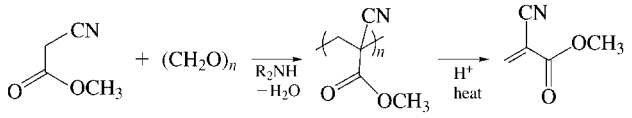

Fig. 4. Synthetic route for production of methyl 2-cyanoacrylate.

although a small excess of cyanoacetate may be employed to reduce the viscosity of the intermediate polymer solution, thus improving its processing characteristics (16). On completion of the condensation step, the solvent is removed and the oligomer treated with anhydrous acid, such as P_2O_5, to neutralize the catalyst and remove traces of residual water. The depolymerization reaction is carried out under reduced pressure at temperatures in the range 150–250°C and is facilitated by the addition of a nonreactive heat transfer medium, such as tricresyl phosphate (15). Acidic vapor-phase stabilizers, such as SO_2, and free-radical inhibitors, such as 1,4-hydroquinone, are also added to ensure stability of the monomer as soon as it is formed (15,16). On heating, the polymer decomposes to produce monomer vapor, which is passed through a distillation condenser and collected as a liquid. The crude monomer obtained in this way is then purified by redistillation and carefully stabilized with low levels of acidic inhibitors (18).

Other methods for the synthesis of cyanoacrylate monomers include pyrolysis of 3-alkoxy-2-cyanopropionates (1), transesterification of cyanoacrylates with alcohols (19,20), displacement of monomer from the corresponding anthracene Diels–Alder adduct by treatment with maleic anhydride (7,21), esterification of cyanoacrylic acid or cyanoacryloyl chloride with alcohols (22), and the oxidation of alkyl 2-cyanopropionate phenyl selenides with hydrogen peroxide (23). These alternative methods are particularly useful for the preparation of monomers not readily prepared by thermal decomposition of cyanoacrylate polymer.

Polymerization

Cyanoacrylate monomers undergo extremely rapid polymerization in the presence of catalytic amounts of anionic initiators or certain covalent bases such as tertiary amines and phosphines. The reaction is completely inhibited by strong acids and is thus anionic in nature. The kinetics of base-catalyzed solution polymerization has been studied in detail utilizing adiabatic calorimetry (24–35). These studies show that in the absence of strong acid the polymerization has no intrinsic termination reaction. The overall kinetics depends on the rate of initiation and may be distinguished between those reactions in which initiators exhibit very rapid rates of initiation (eg, hydroxyl ions or phosphines) and those where the initiation sequences are relatively slow (eg, acyclic amines or pyridine). With rapid initiators, nearly ideal living polymerization conditions exist and molecular weights are in close approximation to the theoretical values from the monomer/initiator ratios employed (25). For such cases a classical anionic polymerization mechanism is postulated (Fig. 5). With covalent bases such as tertiary amines, the initiation step involves one or more reversible monomer addition reactions before the propagation sequence becomes established and the polymerization proceeds via a zwitterionic mechanism (29,30).

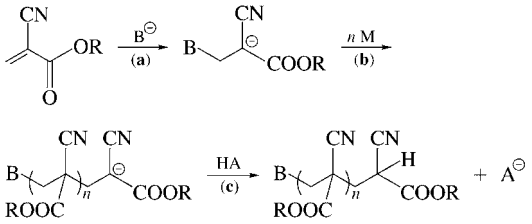

Fig. 5. Base (B)-catalyzed anionic polymerization mechanism of cyanoacrylate monomer (M): (a) initiation, (b) propagation, and (c) transfer/termination by acid (HA).

Although cyanoacrylate polymers are most commonly prepared by anionic polymerization, they may also be prepared by free-radical polymerization using conventional radical initiators (36–38), provided adequate amounts of anionic polymerization inhibitors are employed. Bulk photoanionic polymerization of cyanoacrylates has also been described by a number of workers (39–43). These systems rely on the *in situ* generation of an anionic initiator from a neutral species, following absorption of light of an appropriate wavelength. The zwitterionic and radical copolymerization of cyanoacrylates has also been reported for a number of comonomers including vinyl ethers (44), ketene acetals (45), furan (46), vinyl ketones (47), and ethylene (48).

Properties of Polymers

The physical properties of poly(alkyl 2-cyanoacrylates) are discussed in a recent review (49). The polymers are colorless and amorphous solids that readily undergo retropolymerization reactions at temperatures in the region 140–180°C (50). Glass-transition temperatures T_g vary depending on the method of measurement, conditions of synthesis, etc, with values typically in the range of −78 to +165°C (*n*-decyl and methyl cyanoacrylate polymers respectively). The solubility of methyl, ethyl, and *n*-butyl cyanoacrylate polymers were systematically determined in a wide range of common solvents (51). The polymers are generally soluble in polar aprotic solvents (eg, DMSO, DMF) and insoluble in both nonpolar solvents (eg, hexane, ether) and polar solvents (eg, methanol, water). Solubility improves as the size of the alkyl group increases. Intrinsic viscosities $[\eta]$ of ethyl and *n*-butyl cyanoacrylate polymers have been measured in a number of different solvents and found to give linear log–log relationships with number-average molecular weight M_n over approximately 2 orders of molecular weight range. The Mark–Houwink constants were determined and found to be internally self-consistent for a range of different solvents (51).

The thermodynamic properties of several cyanoacrylate polymers have been determined using precision adiabatic and isothermal calorimetry (52–55). The Gibbs free energy ΔG_0 estimated from the enthalpy ΔH_0 and entropy ΔS_0 of the bulk polymerization of various monomers showed that polymerization is thermodynamically feasible over the temperature range −270 to +160°C at standard pressure. Ceiling temperatures T_c for polymerization were derived from the thermodynamic data and represent the upper temperature limit of polymerization.

Table 2. Thermodynamic Parameters for Some Cyanoacrylate Polymerizations at 25°C and Atmosphere Pressure (101.3 kPa)

Parameter[a]	Ethyl	Allyl	*N*-Decyl
$-\Delta H_0$, kJ/mol	48	64	69
$-\Delta S_0$, J/mol·K	88	85	141
$-\Delta G_0$, kJ/mol	21	39	39
T_c, °C	267	307	217
T_g, °C	149	122	−78
Ref.	55	52	53

[a]To convert J to cal, divide by 4.184.

Glass transitions (T_g) were obtained from plots of heat capacity with temperature and clearly show a decrease in value as the size of the alkyl side chain increases. Typical data are presented in Table 2..

Cyanoacrylate polymers are also rapidly degraded in solution at temperatures substantially below T_c in the presence of basic species (56,57). Size exclusion chromatography showed that an initial high molecular solution of unimodal polycyanoacrylate degrades over 60s at ambient temperature to produce a lower molecular weight distribution following the addition of a catalytic amount of hydroxide ion. This degradation was attributed to a chain-end unzipping of monomer followed by its immediate repolymerization to produce an intermediate bimodal distribution of molecular weights.

Dynamical mechanical analyses are reported for a range of solvent cast films of cyanoacrylate polymers ranging in molecular weight from 75,000 to 330,000 (58). The storage moduli decrease with increasing size of the alkyl side chain and generally fall off sharply at temperatures above T_g. An exception to this trend is poly(allyl 2-cyanoacrylate), which exhibits an increase in modulus that is attributed to cross-linking through the unsaturated side group. Refractive indices of cyanoacrylate polymers are in the range 1.45–1.48 and dielectric constants vary from 3.3 to 5.4 at 1 MHz (3).

Economic Aspects

The principal manufacturers and suppliers of cyanoacrylate monomers include Henkel (Loctite Div.), National Starch, Toagosei, Sumitomo, and Three-bond. The largest market for these materials is in the formulation of so-called *instant adhesives* for which the U.S. production is now estimated in the region 2000 t annually. Although this represents a relatively small fraction of the total volume of adhesives business, it corresponds to a disproportionately high value due to the high costs of cyanoacrylate monomers.

Specifications and Standards

Cyanoacrylates are generally specified in relation to their intended end use (see section on Uses). For adhesives this will usually include details of the physical properties of uncured formulations (eg, viscosity, density, flash point), curing

performance and conditions in a standard joint configuration (cure time, effect of humidity, etc) and a variety of physical, chemical, and materials performance properties (T_g, adhesive strength, durability, chemical resistance etc). These data are generally available in technical product bulletins provided by the manufacturers and suppliers of the various monomers.

Analytical and Test Methods

Cyanoacrylate monomers and polymers are routinely characterized by all common chromatographic and spectroscopic techniques including ir, nmr, ms, gc, sec, and uv analytical techniques. The levels of acid stabilizers in monomers are usually determined by potentiometric titration. Microstructural assignments of anionically and zwitterionically polymerized poly(ethyl 2-cyanoacrylate) have been unambiguously determined using DEPT and ^{1}H–^{13}C HETCOR nmr analysis (59).

Health and Safety Factors

Volatile cyanoacrylate monomers, in particular methyl and ethyl cyanoacrylates, have characteristic acrid odors. Exposure to these materials at levels in the range of 1–5 ppm results in irritation to the eyes, nose, and throat (3). It is recommended that these monomers be used in a well-ventilated area, that skin and eye contact be avoided, and that the user be familiar with the relevant safety data supplied by product manufacturers. A recent epidemiological study in workers with occupational exposure to monomer vapors concluded that there was no increased risk of pulmonary obstruction (eg, asthma) on exposure to average short-time concentrations of less than 0.5 ppm (60). Polymerization of cyanoacrylates is rapid and exothermic and particular care should be taken to avoid burns, which can result from the unexpected bulk polymerization of inadequately stabilized or contaminated monomer samples.

Uses

Adhesives represent by far the most important use of cyanoacrylates. They are marketed throughout the world for both industrial and consumer use. They polymerize rapidly on contact with many surfaces and exhibit excellent adhesive strength to a wide variety of different materials. The beneficial adhesive properties are attributed to a combination of good wetting of surfaces by the monomers, the high polarity of the polymer, and the high molecular weight of the bulk polymer, which is frequently in excess of 10^6. The typical adhesive product comprises a mixture of monomers, stabilizers, and additives (such as thickeners, rubbers, fillers) to control the rheology of the uncured composition and properties of the cured adhesive. Several comprehensive reviews on cyanoacrylate adhesives have been published (3,4).

Traditionally cyanoacrylates have been used to facilitate the automated assembly of various devices and components including computers, calculators, electric motors, medical equipment, optical components, jewelry, and sporting

goods. More recently, cyanoacrylate adhesives are being used in surgical areas such as tissue adhesives for wound closure (61), sealing corneal perforations (62), and for the control of gastrointestinal bleeding (63). Cyanoacrylate adhesives are associated with a comparatively low incidence of post-operative infection and the cured polymers are generally considered to be biodegradable, biocompatible, nontoxic, and nonallergenic (61,63). Cyanoacrylate esters with higher alkyl group side chains (eg, *n*-butyl, *n*-octyl) are preferred for surgical applications, as they have been shown to be less toxic to surrounding tissues (62).

Cyanoacrylate polymers are also extensively used in the production of encapsulated colloidal nanoparticles for targeted drug delivery systems and are particularly useful in the treatment of certain cancers (64). Their good encapsulation properties, low toxicity, and satisfactory biocompatibility make them attractive for this application. By forming amphiphilic copolymers of cyanoacrylate and ethylene oxide, the therapeutic activity of entrapped compounds can be enhanced. The copolymer functions to prolong the circulation lifetime of the nanoparticles after they have been introduced into the bloodstream (65).

Other potential uses of cyanoacrylate polymers include the development and characterization of latent fingerprints by vapor-phase deposition of polymer (66) and the deposition and growth of plasma-resistant photoresist films by interfacial polymerization from the vapor phase (67). Potential applications in the optical area include the formation of high tilt angle alignment layers in liquid crystal devices (68), the production of holographic media for optical data storage (69), and the production of waveguide sensors for the detection of organic vapors (70). Polycyanoacrylate films containing infrared dyes are readily ablated on exposure to laser light and may be used to produce lithographic printing plates with good ink receptivity, adhesion, and wear resistance (71).

POLYESTERS, FIBERS

Introduction

Over 17,000 kt (>35 billion pounds) of polyester fiber are produced each year, making it the most widely used fiber in the world (1) (Fig. 1). Its commercial domination of textile and industrial markets is due to a unique blend of high performance, low cost, and benign impact on the environment. The polyester fiber industry shares raw material supplies with the large global markets for poly(ethylene terephthalate) (PET) beverage containers (recycleable into fibers) and automobile antifreeze and so it is based on a large and stable infrastructure. The public image of polyester fiber is less than glamorous, but it is unlikely that a more versatile and economical fiber will replace it anytime soon.

W. H. Carothers at DuPont invented the polymer family known as polyester over 70 years ago (2–5). The polyester fiber industry developed in the post-World War II period, along with other "miracle" synthetic fibers of the time. Synthetic fibers revolutionized the textile industry, providing a number of advantages over traditional plant and animal fibers:

(1) Increased fiber strength and uniformity allowed finer yarns, higher processing speeds, less waste, and a wider range of fabric possibilities.
(2) Better thermal stability enabled "permanent press" fabrics that were easier to care for.

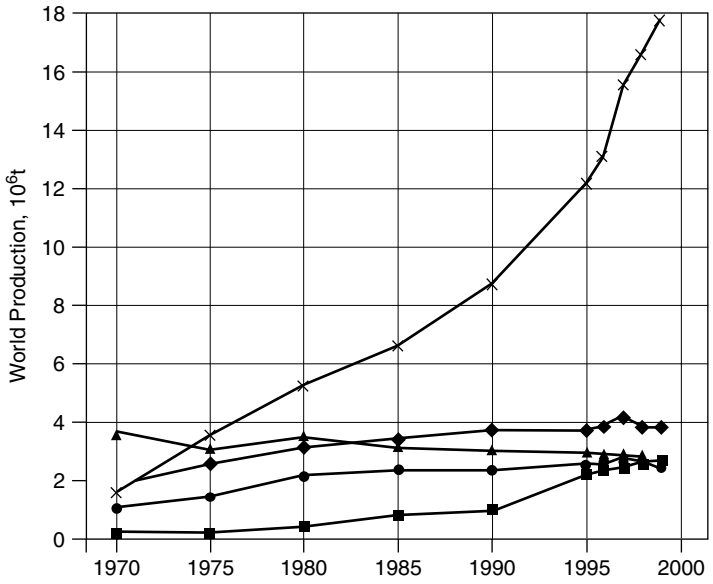

Fig. 1. Historical growth of polyester fibers (PES = PET). Synthetic fibers—World production by fiber class. PES, PA, Cellulose, PAC, and Misc. Reprinted with permission from Ref. 2.

Many of those synthetic fibers remain in special applications, but polyester has captured the largest share of the markets for cotton blending, apparel, and rubber reinforcement. With the economic advantage of large production scale, its dominance has continued to grow at the expense of natural and other synthetic fibers.

A polyester fiber is defined by the U.S. Federal Trade Commission as "A manufactured fiber in which the fiber forming substance is any long-chain synthetic polymer composed of at least 85% by weight of an ester of a substituted aromatic carboxylic acid, including but not restricted to substituted terephthalic units, $p(-R-O-CO-C_6H_4-CO-O-)_x$ and parasubstituted hydroxybenzoate units, $p(-R-O-CO-C_6H_4-O-)_x$."

Carothers' original polyesters used aliphatic dicarboxylic acids and had low melting points. Fibers made from these polymers were not commercially interesting. Nearly a decade later, J. R. Whinfield and J. T. Dickson working for Calico Printers Assoc., Ltd. produced a high melting point polyester from aromatic terephthalic acid and ethylene glycol. They assigned patent rights to ICI in 1947, and the PET industry was born. Today, the term "polyester" is nearly synonymous with PET, although other members of the family continue to be used in special applications.

Historical Development

A patent-sharing arrangement gave DuPont initial control over PET in the United States while ICI Chemicals dominated patents in the rest of the world (6–9).

The success of PET fibers encouraged opposition from wool and cotton producers, and competition from other chemical and textile firms. ICI sublicensed the PET technology to companies in Japan and Western Europe, and installed fiber plants with a number of affiliates around the world. DuPont built fiber plants in the Americas and Europe.

PET fibers rapidly became a worldwide venture, with each producer developing their own designs of fiber-making equipment and their own market segments. The large chemical firms, who could afford the R&D to develop the best products with the most efficient and reliable manufacturing processes, established industry leadership.

As the technology developed, PET fibers penetrated into a number of end-use areas, broadly classified as *staple fibers, textile filament*, and *industrial filament*. These end uses have different requirements in terms of fiber properties and physical geometry, and so different fiber manufacturing processes have evolved according to the special needs of each market segment.

Staple PET fibers are typically packaged in bales and blended with natural staples such as cotton or wool. They are designed with cut lengths and diameters similar to their blend partners, ∼30 to 100 mm in length and ∼10 to 20 μm in diameter. Fiber diameter is an important parameter affecting both bending stiffness and light reflection, which affect fabric feel and appearance. Staple fibers are formed into yarns by the ancient practice of fiber spinning, where the fibers are twisted together to form a continuous strand and the number of fibers in the cross section controls the fineness of the yarn. These yarns are formed into fabrics by the traditional methods of weaving or knitting. The protruding free ends of twisted staple yarns contribute to fuzzy fabric surfaces, which greatly impact the perceived comfort of apparel fabrics. PET staple fibers must possess three-dimensional structure (or "crimp") and surface lubricity to allow the fibers to be processed in textile machinery and to mingle evenly with other fibers in the blend.

Initially developed for textiles and apparel, staple fibers are finding increasing applications in nonwovens markets. In these applications, fibers are formed directly into fabrics through carding, dry-lay, or wet-lay forming processes and held together by entanglement, resin bonding, or thermal bonding. Such nonwoven products are used for filters, interliners, cushioning material, etc.

Textile filament yarns are continuous yarns, with fabric aesthetics akin to natural silk. Fiber diameter plays a strong role in fabric suppleness, and *texturing* of the yarn is also used to impart three-dimensional structure and pleasing fabric feel. In contrast to the high-volume, low-speed processes for staple fibers, continuous yarns are produced at relatively high speeds (∼100 m/s) and sold on bobbins; high speed winder technology has been a crucial factor in the growth of these markets. The world's current production of polyester fibers for textiles is split roughly evenly between staple and filament yarns (1).

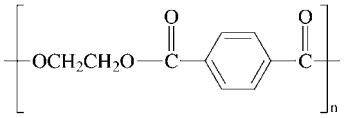
Industrial (nontextile) end uses constitute the third major market for PET fibers. *Industrial filament yarns* are used for reinforcement of rubber or high strength industrial fabrics. Most passenger car tires produced in the United States are reinforced with yarns made from high molecular weight PET polymers, processed to yield high strength and low shrinkage. Neither dyeability or appearance is important, but the physical and chemical properties of the fibers are critical.

The manufacturing processes for textile filament, staple, and industrial filament yarns have become so specialized that it is not possible to make one such

class of fibers on the others' equipment. Within these classes, there are production machines specialized for certain types of fibers for certain types of consumer products. Large machines designed to produce high volumes of commodity products (eg, staple for cotton blending) at high efficiency and low cost are not well suited to the efficient production of specialty staple variants (eg, fibers with special dyeing properties) and vice versa.

Additives and copolymers have extended the use of PET fibers into areas where the original commodity products had deficiencies in eg, soil-resistance, static protection, or poor dyeability. Newer members of the polyester family have found applications in markets where more stretchiness or resiliency were desired (using longer aliphatic chains) or to gain higher modulus, temperature resistance, and strength (with fully aromatic polymers).

Chemical and Physical Structure



Poly(ethylene terephthalate) (PET)

PET polymer is composed of repeating units of the above monomer, each unit having a physical length of about 1.09 nm and a molecular weight of about 200. Ideally, it is capped on the left by H—, and on the right by —OH when produced from ethylene glycol and terepthalic acid. Polymerization is thus accompanied by the production of water, which is removed under elevated temperature and vacuum. Accordingly, the presence of water in the molten state will rapidly depolymerize the structure, so that thorough drying of the polymer prior to melt spinning of fibers is a prerequisite.

The PET polymer structure can also be generated from the reaction of ethylene glycol and dimethyl terephthalate, with methyl alcohol as the by-product; a few producers still use this route. The aromatic ring coupled with the short aliphatic chain is responsible for a relatively stiff polymer molecule, as compared with more aliphatic structures such as polyolefin or polyamide. The lack of segment mobility in the polymer chains results in relatively high thermal stability, as discussed later.

Melt Behavior. The degree of polymerization is adjusted to yield the desired balance of molten viscosity (for fiber extrusion) and filament strength. A textile grade polymer will have an average number of ~100 repeat units per molecule so that the extended length of a typical polymer chain is about 100 nm with a molecular weight about 20,000. Higher levels of polymerization produce higher strength fibers, but the melt viscosity and stability of the melt to even tiny amounts of moisture become extreme. Measurement of the average degree of polymerization is typically accomplished by measurement of either the molten viscosity (eg, by measuring pressure drop through a calibrated orifice) or the viscosity of a dilute solution of the polymer in an appropriate solvent (10). The latter is a measure of polymer chain length known as "intrinsic viscosity" or IV. A typical IV level, in *o*-chlorophenol (OCP) solvent, for the aforementioned textile

grade polymer is 0.62. [Different solvents will generate different IV numbers (11)]. The IV in OCP is connected to the number-average molecular weight (M_n) of the polymer by the Mark–Houwink formula for PET (11):

$$IV_{OCP} = 1.7 \times 10^{-4} (M_n)^{0.83} \quad (1)$$

A useful formula to predict the (low shear) melt viscosity of PET from its IV is as follows:

$$\eta_0 = 0.0129 (IV_{OCP})^{5.35} \exp\left(\frac{6800}{T}\right) \quad (2)$$

where η_0 is the Newtonian melt viscosity (Paċs) and T the absolute temperature (K).

If moisture is present before the polymer is melted, hydrolytic degradation will occur. Each water molecule will break a chain, increasing the total number of polymer chains by one. The effect on the average molecular weight is as follows:

$$M_n' = \frac{M_n}{1 + \frac{xM_n}{1800}} \quad (3)$$

where M_n is the starting average molecular weight, M_n' the average molecular weight after reaction with water, and x the weight percent of water.

Equation (3) can be used with equations (1) and (2) to determine the effect of moisture on IV and melt viscosity.

It can be seen from these relationships that higher IVs produce rapid increases in melt viscosity, and increased sensitivity of the polymer to hydrolytic degradation. The technology required to process high IV (ca 0.9–1.0) materials used for industrial fibers is more demanding than that for textile materials. Pressure requirements for polymer flow, for example, are ~10 times higher.

In addition to hydrolytic degradation, random chain scissions will occur at elevated temperatures and these scissions lead to a gradual loss of average molecular weight in the polymer melt. The chemistry of thermal degradation is different from hydrolytic degradation; it results in different types of end groups on the polymer chains. The chemical species that are generated during thermal degradation reactions are deleterious to fiber properties, leading to loss of thermal stability and, in the presence of oxygen, to cross-linked gel particles.

Polymer Structure. In the absence of any mechanism to induce preferential orientation in the polymer molecules, PET will freeze as a clear, glassy solid with a specific gravity of 1.33 (11). The molecular structure is similar to that of a bowl of spaghetti, with the polymer chains randomly coiling about one another. The chains are attracted to each other through van der Waal forces. This attraction can be overcome with the addition of thermal energy, which induces molecular vibration and bond rotations. Some chain segments pack together more closely than others, particularly if they are run parallel to each other for a section of their lengths. Stronger bonds form in these regions. If sufficient molecular alignment is present, regions of the microstructure pack into an ordered, repetitive structure and become crystalline (Fig. 2).

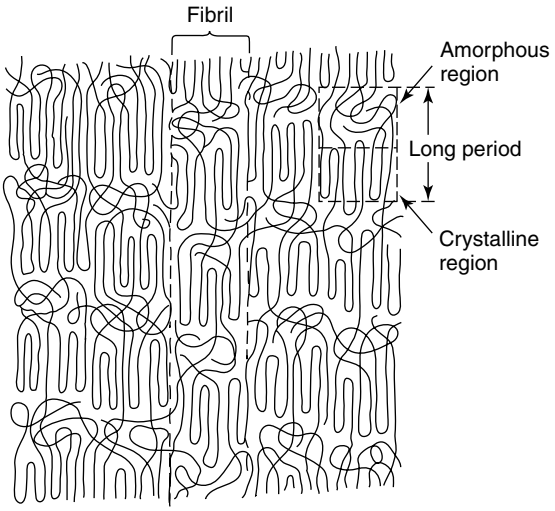


Fig. 2. Microstructure of an oriented, partially crystalline PET fiber (8).

An amorphous polymer in a state of molecular alignment is not a stable structure; it is metastable. It can change either to a more perfectly ordered, crystalline structure or to a more disordered, nonoriented structure. In either case, the free energy of the system is reduced. Given enough time and/or thermal energy, an oriented amorphous polymer will change in either or both of these directions.

The van der Waals attraction forces in the amorphous regions can be overcome at relatively low temperatures. The glass-transition temperature (T_g) is the characteristic temperature at which this occurs. At temperatures above T_g, spontaneous molecular rearrangement becomes easier, allowing plastic deformation and the generation of crystalline order with the release of heat. The stronger bonding forces in the crystalline phase require higher temperatures in order to be re-broken, and this phase transition represents a true melting point T_m. However, even this transition is not sharply defined in a real polymer because the melting temperatures depend on the size of the crystallites. Smaller crystallites melt more easily.

As determined from x-ray diffraction, the unit cell of crystalline PET is triclinic with a repeat distance of 1.075 nm along the major axis (11,12). This corresponds to >98% of the theoretical extended length of the monomer repeat unit (12). There is very little extensibility remaining in a PET crystal, resulting not only in high modulus but also a relatively short extension range over which the crystal can be extended and still recover elastically. The density of the crystalline structure is 9% higher than the amorphous structure, with SG = 1.45 (11).

A considerable amount of molecular orientation along the fiber axis is induced in the fiber manufacturing process, and crystallization will occur in regions where adjacent polymer chains are sufficiently extended and aligned so that bonds can form between adjacent chains. The rate of crystallization for oriented fibers under tension is thousands of times faster than for unoriented, quiescent melts. The length of the polymer chain which will be continuously entrapped within a

crystalline region is typically ~20 repeat units, before entanglement with another chain terminates the process. But crystalline regions do come in different sizes, and the size and distribution of these crystallites contribute to fiber properties such as dyeability and shrinkage. It is the crystalline regions that tie together the spaghetti-like polymer structure to give fibers with high strength and temperature stability (see Table 1).

Table 1. Properties of PET Fibers

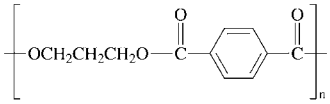
Diameter, μm	10–50
Tenacity, MPa[a]	
Textile fiber	450–750
Industrial fiber	850–1050
Elongation, %	10–50
Initial modulus, MPa[a]	
Textile fiber	$\leq$6,000
Industrial fiber	$\leq$14,500
Shrinkage @160°C, %	
Textile fiber	5–15
Industrial fiber	2–5
Specific gravity	
Molten	1.21
Amorphous	1.33
Crystalline	1.44
Glass transition, °C	
Amorphous	67
Oriented, crystalline	125
Crystalline melt point, °C	265–275
Heat capacity, J/(kg·K)[b]	
@25°C	63
@200°C	105
Heat of fusion, kJ/kg[b]	120–140
Thermal conductivity W/(m·K)	0.14
Thermal volumetric expansion, 1/°C	
30–60°C	1.6×10^{-4}
90–190°C	3.7×10^{-4}
Moisture regain, %	
65% rh	0.6
Total immersion	0.8
Refractive index	1.58–1.64
Dielectric constant	
60 Hz	3.3
1 GHz	2.8
Electric resistivity, ohm·cm	
Dry	10^{18}
0.5% moisture	10^{12}
Solvents	*o*-Chlorophenol, hexafluoroisopropyl alcohol, hot alkali
Nonsolvents	alcohol, gasoline, most acids

[a]To convert from MPa to psi, multiply by 145.
[b]To convert from J to cal, divide by 4.184.

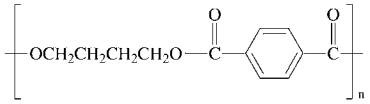
The T_g of amorphous PET is in the range of 65–75°C, and this can increase to ~125°C after being drawn and partially crystallized, reflecting the reduced rotational mobility of the chain segments. The crystallite melting points range from ~265 to 285°C. Usually, however, a single melt temperature is quoted for PET, eg, the temperature of maximum heat absorption in a differential scanning calorimeter (dsc).

Among the spectrum of melt-spinnable fibers such as polyolefins and nylons, PET stands at the upper end in terms of crystalline melt temperature and glass-transition temperature. This provides superior dimensional stability for applications where moderately elevated temperatures are encountered, eg, in automobile tires or in home laundering and drying of garments. It is generally agreed that the high thermal stability results from the aromatic rings that hinder the mobility of the polymer chain.

More elastic, less stiff polyesters can be prepared from diols with longer aliphatic chain lengths, eg, from propylene (3G) or butylene (4G) glycols in combination with terephthalic acid [see POLY(TRIMETHYLENE TEREPHTHALATE)]. These polymers crystallize in a form with significantly less extension of the molecule; approximately 75 and 87% of the fully extended form for the 3GT and the 4GT polymers, respectively (12).



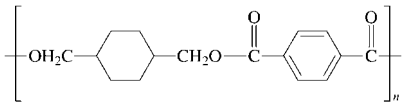
Poly(trimethylene terephthalate) (PTT)



Poly(tetramethylene terephthalate) (PBT)

Along with the increased softness and springiness of the polymers comes a reduction in melting points and glass-transition temperatures, not always welcome. These polyester variants command a higher price simply because they are more rare; their raw materials are more expensive because they are not produced on the massive scale of the PET raw materials.

One alternative to PET fiber which did compete historically was poly(1,4-cyclohexylene dimethylene terephthalete), commercialized under the name Kodel II by Eastman. This polyester gained an early footing because it was not covered by the existing patents, and was able to establish a raw material base from which it could compete both technically and economically [see POLY(CYCLOHEXYLENE TEREPHTHALATE)].



Poly(cyclohexylene dimethylene terephthalate)

This PCT fiber has better resiliency than PET, without compromising high temperature resistance. It successfully competes in the high-end carpet yarn market against nylon, where PET was limited by its relatively lower wear resistance. Recycling of PET bottles has provided a source of low cost resins that are used for carpets in less critical markets.

Fiber Geometry. Solid PET polymer is relatively hard and brittle. It must be formed into very fine fibers in order to exhibit bending stiffness that is low enough for textile materials. Most commercial PET fibers are produced in a diameter range of about 10–50 μm, considerably smaller than a human hair. Within this range lies a vast difference in the softness, drape, and feel of fabrics formed from the fibers, since bending stiffness of a cylindrical fiber depends on the 4th power of its diameter.

One key requirement in the commercial production of fibers is controlling fiber diameters within narrow ranges of the target. Another is controlling the internal structure of the fiber, particularly the orientation of the polymer molecules. It is orientation of the polymer molecules along the fiber axis that controls the morphology and hence the fiber properties such as dye uptake, shrinkage, and tensile strength.

The production process for fibers starts with the extrusion of molten PET through small holes at slow speeds, but the fibers will be stretched by hundreds of times their initial lengths before the production process is completed. The stretching process is responsible for diameter reduction and for alignment of the polymer molecules in the direction of the stretching. As this alignment proceeds, the polymer chains pack increasingly closer to each other, and the density of the material rises progressively, becoming crystalline in some regions. The fiber density is a guide to the amount of orientation present in the fiber; a finished PET fiber is typically ~50% crystalline.

Chemical and Physical Modifications

In many applications, modification of PET fiber properties is desirable in order to enhance certain features of the product or to enhance the process of converting fibers into finished goods. In these cases, most of the basic PET fiber properties are acceptable but certain enhancements are desired, even at the expense of other properties or costs that will be affected by the modification. These side effects are always present; it is the goal of fiber development personnel to engineer the best compromise.

What follows are some of the most common variations that have been applied to PET fibers; more complete information is available in the literature (13).

Low Pill Fibers. In staple yarns that do not contain high twist levels, it is relatively easy for individual fibers to work their way to the yarn surface under the influence of friction. This will cause long filaments to appear at the surface of the fabric, which then become entangled to form unsightly fuzz balls or "pills." With natural fibers, these pills readily break off after the attaching filament is repeatedly flexed. With PET, the attaching filaments are too tough to break, and the pills accumulate. It is difficult to prevent pills from forming and far easier to modify the PET fiber so that it will more readily break under repeated flexing. The simplest way to do this is to reduce the molecular weight of the polymer, thereby reducing fiber strength. This also reduces the melt viscosity, which can create some problems with the stability of the melt-spinning process.

Some anti-pill fibers are made by including a small amount of a cross-linking agent in the polymer (eg, pentaerythritol) (Fig 3). This increases melt viscosity

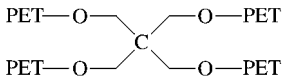


Fig. 3. Cross-linking of PET chains by reaction with pentaerythritol.

while embrittling the fiber and reducing its flex life. The penalty is a fiber that is somewhat weaker during processing and more subject to breakage during yarn and fabric formation. An alternative is to treat fabrics with an alkaline bath that partially dissolves the PET fibers to make them weaker; this also changes the hand of the fabric. The most elegant approach is to include a chemical cross-linker that is not activated until the fabric is formed and put into an activating bath.

Deep Dye Fibers. The PET polymer molecule contains no chemically active species for attachment of dye molecules. Instead, "disperse" dyes are used which diffuse into the fiber and become physically entrapped in the tangle of polymer chains in the amorphous regions. (The dye molecules are too large to fit within the more closely-packed crystalline regions.) In order to encourage rapid diffusion into the structure, it is common to use pressurized dye baths and/or "structure-opening" chemicals that encourage swelling of the amorphous regions. The presence of large amounts of crystallinity and/or high orientation (hence closer packing of polymer chains) in the amorphous regions will inhibit the dye diffusion process. Differences in fiber orientation cause differences in dye depth.

A common method to increase the dyeing rate is to inhibit the formation of crystalline regions during fiber manufacture. To this end, it is sufficient to break up the regularity of the repeating ET units of PET. Small amounts of *other* types of monomers which are incorporated into the chain will do this, as they form copolymers.

Monomer units for this purpose include adipic acid or isophthalic acid to substitute for some of the terephthalic acid (Fig. 4a). Similarly, propane or butane diol, or poly(ethylene glycol) can be substituted for some of the ethylene glycol.

The result is a fiber that is less crystalline and dyes more readily. The downside is an unavoidable reduction in transition temperatures, a less stable structure more prone to shrinkage, and the easier escape of dye molecules and oligomers which can deposit onto the surfaces of textile processing equipment. Depending

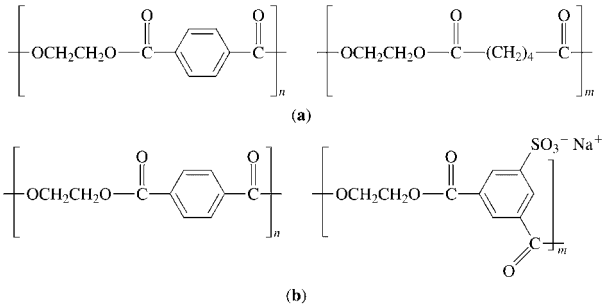

Fig. 4. (**a**) Deep-dye PET, modified by copolymerization with adipic acid and (**b**) Cat-dye PET, enabled by addition of sulphoisophthalic acid.

on level and type of comonomer used, increased problems with lightfastness or polymer degradation can also occur.

Ionic Dyeability. As noted earlier, PET has no dye attachment sites for chemically active dyes. It is possible to add ionic dyeability by forming copolymers of PET with monomer species that possess such sites, for example, on a pendent side chain. The most common of these has been the incorporation of a sodium salt of a dicarboxylic acid, eg, of 5-sulphoisophthalic acid. The acidic sulpho-group allows the attachment of cationic dye molecules, in addition to disperse dyes (Fig. 4b).

If both the modified and the unmodified fibers are put into a dye bath containing a mixture of disperse and cat dyes, they will emerge with two different colors. This is not only a good parlor trick, but is useful in the creation of specialty fabrics when the two different yarns are woven into fabrics with a predetermined pattern. The multicolored pattern emerges upon dyeing.

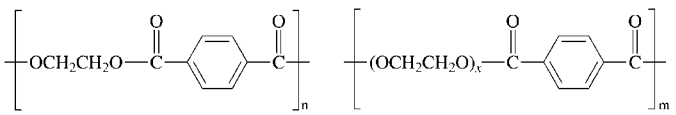
Since the basic structure of the modified fiber is a copolymer, rapidity of dyeing is also gained with these cat-dye fibers. Losses in fiber strength, temperature stability, and increased hydrolytic degradation are prices paid for the dyeability enhancement.

Some efforts have been made to incorporate sites into PET that accept *acid* dyes, but most of these alkaline-containing additives cause degradation and discoloration of the polymer. No acid-dye PET polymer has been commercially successful.

Antistatic/Antisoil Fibers. The nonionic character of the PET molecule makes the polymer hydrophobic and oleophilic. Without polar species, the ability to transport electrical charge along the fiber is poor. If excess static charges build up on PET fibers, as will happen unavoidably upon contact with other materials, these charges will not quickly leak away. The result can be clinging of fabrics to the skin or discharges of static electricity. (This problem is reduced at higher humidity levels because the small amount of water absorbed by the PET provides polar, charge-carrying molecules for quicker draining of the static charge.) PET's attraction for nonpolar, oily materials means that oils, which are difficult to remove, can easily stain fibers.

During the manufacture and processing of fibers, it is common to employ surface lubricants, wetting agents, and antistatic treatments to assist in processing. These are temporary, however, and a longer-term solution typically requires polymer additives or copolymers. (Copolymerization typically results in greater permanence than additives which can migrate to the fiber surface and be lost.)

Poly(ethylene glycol) (PEG) is frequently added to PET to confer antistatic and/or antisoil behavior. The ether groups running along the backbone of the PEG are sufficiently polar to attract moisture and to provide charge-transfer sites. This benefits both the electrical conductivity and the ability of water or detergent molecules to lift the oily stains. By using long-chain PEG additives, a block copolymer is formed. This avoids some of the thermal stability losses that occur with random copolymers.



PET copolymerized with poly(ethylene glycol)

It is also possible to add PEG at the last stages of polymerization, so that much of the additive remains agglomerated in a separate phase. In this case, subsequent scouring of the fibers removes much of the soluble PEG, leaving microscopic voids in the fibers. These voids can act as reservoirs for moisture, and will also decrease light transmission and increase the reflectance properties of the fibers.

High Shrink Fibers. Although high fiber shrinkage is not usually desirable, an exception is when high and low shrink fibers are intimately combined. As the yarn or fabric shrinks because of the high shrink component, the excess length in the low shrink component forms loops at the yarn and fabric surfaces, providing texture. In filament yarn fabrics, these projecting loops can mimic the feel and appearance of staple yarn fabrics. Lack of crystallization in oriented fibers allows high shrinkage so that copolymers or non-heatset (noncrystallized) PET fibers can be used for these purposes.

Low Melt Fibers. Noncrystalline polymers or copolymers can also be used to generate fibers with relatively low softening temperatures. Such fibers can be blended with regular fibers, eg, staples, and bonded together by applying sufficient heat to melt the low temperature component. Such fibers need not be exotic. The use of undrawn, amorphous fibers suffices for many such purposes, for example, bonded nonwoven webs formed from a mix of drawn and undrawn PET staple fibers. Without crystalline structure, the undrawn fibers will soften and become tacky at relatively low temperatures.

Bicomponent (Bico) Fibers. Bico fibers are a new class of fibers, rather than a subset of PET fibers. Bico fibers are formed from two different polymers, which are melted separately and then combined into a single fiber at the last moment before extrusion. In some cases the fibers are actually extruded separately, and then combined while they are still molten so that they fuse together after spinning.

The most common cross-sectional fiber shapes are core-sheath and side-side configurations (Fig. 5). By encasing a PET core in a modified sheath, it is possible

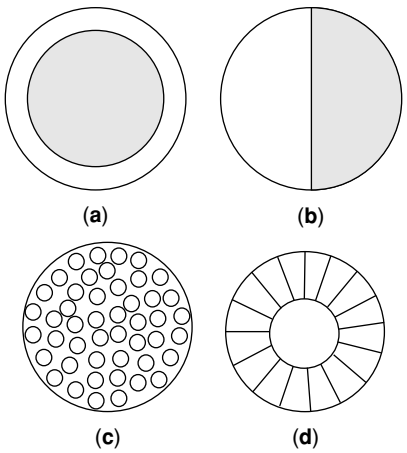


Fig. 5. (**a**) Cross-section of core/sheath bico fiber, (**b**) cross-section of side/side bico fiber, (**c**) "Islands-in-the-sea" bico fiber, and (**d**) segmented bico fiber.

to provide desirable surface characteristics (eg, antistatic/antisoil) with minimal effect on fiber strength. A popular application is to use sheath material with a lower melt point than the core. A nonwoven fabric can be formed from such fibers and then heated to a temperature sufficient to melt the sheath to bond the fibers together. Since the core component is not melted, the binder fiber retains its integrity and strength.

The side-side configuration is usually used to impart crimp to the fiber. If formed from fiber materials with differing shrinkage characteristics, and treated after fiber formation to develop the shrinkage, the differential lengths will cause the fibers to contract into a helical shape and develop three-dimensional crimp. Such self-crimping fibers provide a different type of bulk and hand than do conventionally crimped fibers.

Bico fibers have been available for at least 30 years, but only recently have they developed widespread applications. Bico production equipment is relatively more complex and expensive and so the fibers require higher selling prices. As these fibers become more common in specialty markets, production cost is decreasing and they are now beginning to find uses in commodity applications.

Hollow Fibers. In some applications it is desirable to generate increased bulk without adding weight, eg, for insulation or padding. A solution is to make fibers that are larger in diameter and stiffer, but with internal voids to reduce weight. (Think of a core-sheath heterofil with an air core.) By extruding hollow fibers, weight reductions of 20% or greater can be achieved, a not inconsiderable advantage. Foaming agents in the polymer (eg, dissolved CO_2) have also been used to generate microporous, lightweight fibers.

Microfibers. A PET microfiber is loosely defined as one with a decitex per filament below about 1. (Decitex is a measure of fiber size. If 10,000 m of fiber weighs x grams, the decitex of the fiber $= x$.) This translates to a fiber diameter of $\sim$10 μm or less. In fabric form, such fibers provide a very soft hand and a low luster appearance. They can also make moisture-repellant fabrics without sacrificing comfort or air porosity, ideal for sportswear. The larger fiber surface area also can be useful for filtration applications.

Traditional melt spinning is not the best way to make microfibers. Technical problems occur with very low mass throughputs, and economics suffer. By employing bico technology, it is possible to extrude larger shapes that can be separated into smaller components after extrusion.

The "islands-in-the-sea" approach uses bico technology to extrude filaments that contain a multiplicity of small fibrils encased in a soluble matrix (Fig. 5c). After fiber processing and fabric formation, the matrix is dissolved away to leave behind the microfibers. Fibers with submicron diameters can be produced. The process is expensive, but luxurious fabrics and nonwoven materials such as Ultrasuede® are made this way.

Bico technology can also be used to form composite fibers that can be broken apart, by using polymers with poor mutual adhesion (eg, polyolefin and PET). A fiber made with a dozen or more segments, alternating between two polymer types, can be post-processed to form separated fibrils of the two different materials. The shapes of the fibrils can affect the aesthetics of the fabrics, for example, sharp edges on the fibrils confer crispness and the sound of silk to fabrics.

Light Reflectance. The light reflectance of yarns and fabrics can be quite sensitive to the size and shape of the fibers. Two types of light interactions occur:

(1) Light is reflected from the surface of the fiber because of the change in refractive index from air into polymer (for PET, $n = 1.6$). This is specular reflection, similar to reflection from a mirror, and causes no coloration of the reflected light.
(2) Light that is transmitted through the fiber surface can interact with the molecular structure, eg, dye molecules, and thereby change its spectral character before being emitted back through the surface.

The mixture of these two types of light is what meets the eye, and the ratio of these two components affects the perceived depth of color. The more the specular reflection, the less the apparent color depth. Fine fibers of PET usually appear white, even though the polymer chips that they are made from may appear grey in color. This is a consequence of the high amount of specular reflection of ambient light, emanating from the large surface area of the fibers. Additionally, any relatively large surface areas of specular reflection can generate visible points of light when they are oriented to reflect from point sources; these cause the fibers or fabrics to glitter.

Larger diameter fibers have proportionally less surface to volume ratio and so proportionally less specular reflection; thus they appear darker than small fibers containing the same amount of dye. But larger fibers also have relatively flatter surfaces and are more prone to glitter. It has long been practiced to include microscopic fragments of highly reflective material in the polymer so as to opacify the fibers and diffuse surface reflections and glitter. Powdered titanium dioxide is the common additive used for this. It gains its reflective properties by means of exceedingly high refractive index. The quantity of TiO_2 in the polymer is controlled to produce "clear" or "dull," or "semi-dull" fibers for various types of fabrics.

It is possible to microscopically roughen the fiber surface to diffuse the surface reflections by other methods, eg, by chemically etching the surfaces with corrosive solvents. Many of these solvents will preferentially dissolve the amorphous regions, leaving the undissolved crystalline formations standing proud at the surface. Powdered materials with refractive indices similar to PET can be incorporated in the polymer to create rougher fiber surfaces with much less light reflectance from the additive/polymer interfaces. Cab-O-Sil®, a powdered silica, is one such material.

In addition to the aforementioned methods, fiber shape is exploited to produce differences in appearance. Surface lobes can break up smoothness and reduce glitter, and triangular or T shapes can generate subtle sheen effects to fabrics and yarns. Patent literature is filled with various cross-sectional shapes that have been used to provide visual and tactile effects that are not possible with natural fibers.

Surface Friction and Adhesion. Control of fiber friction is essential to the processing of fibers, and it is sometimes desirable to modify fiber surfaces for particular end uses. Most fiber friction modifications are accomplished by coating the fibers with lubricants or finishes. In most cases, these are temporary treatments that are removed in final processing steps before sale of the finished good.

In some cases a more permanent treatment is desired and chemical reactions are performed to attach different species to the fiber surface, eg, siliconized slick finishes or rubber adhesion promoters. Polyester's lack of chemical bonding sites can be altered by surface treatments that generate free radicals, such as with corrosive chemicals (eg, acrylic acid) or by ionic bombardment with plasma treatments. The broken molecular bonds produce more polar sites, providing increased surface wettability and reactivity.

The physical topology of the fiber surface also has a strong effect on friction. A microscopically smooth surface will generate more intermolecular attraction sites than will a roughened surface. It has been long known that including particulate additives (eg, TiO_2 or Cab-O-Sil) in the polymer reduces fiber friction, and that polished rolls generate more friction against PET fibers than do rougher rolls.

Antiflammability and Other Applications. Problems can occur with garments made from thermoplastic polymer fibers when they are exposed to flames; the molten polymer can stick to skin and cause burns. If the molten polymer itself supports continued combustion, the problem is worse. Additives that contain bromine or phosphorus have been used to reduce combustibility of PET, but these additives are typically expensive and/or deleterious to fiber properties. Here, bico technology is applicable so that antiflammable additives can be incorporated into the sheath without sacrificing the strength of the core of the fiber.

Other applications that have been developed for PET fibers include the incorporation of fragrances, antibacterial or absorbent additives, and also pigmented fibers for permanent coloration. Here again, the bico technology offers a route to such specialty fibers with lower raw material costs and fewer processing faults.

Melt Spinning of PET Fibers

A large part of the attractiveness of PET is that it is melt-spinnable into fibers, providing a clean, pollution-free manufacturing process. The goals of melt spinning include not only the stable formation of fine fibers but also the control of the microstructure of those fibers. Ideally, this is done at as high a throughput rate as possible for economic reasons.

Typical equipment used to make PET fibers is shown in Figure 6. Prior to melting, the polymer chips must be thoroughly dried, typically under vacuum at elevated temperature for several hours. The equilibrium moisture content of PET under ambient conditions is about 0.5% (11) and this much moisture would cause unacceptable levels of depolymerization. The dried polymer chips are fed to an extruder which melts the chips and forwards them to a metering pump, which delivers a volumetrically controlled flow of polymer into a heated spinning pack.

Modern large-scale PET fiber facilities have evolved to a continuous process of PET polymer production, and have integrated the processes of polymerization and fiber extrusion. This avoids the equipment, energy, and manpower needed to solidify and pelletize the polymer, dry it, and remelt it. In large plants that operate continuously for months at a time, huge quantities (more than 200 tons per day) of fiber are produced from a single line. Such fibers may be used, for example, in commodity markets such as woven or knitted apparel, or for tire reinforcement. For more specialized markets, which require modified polymers in

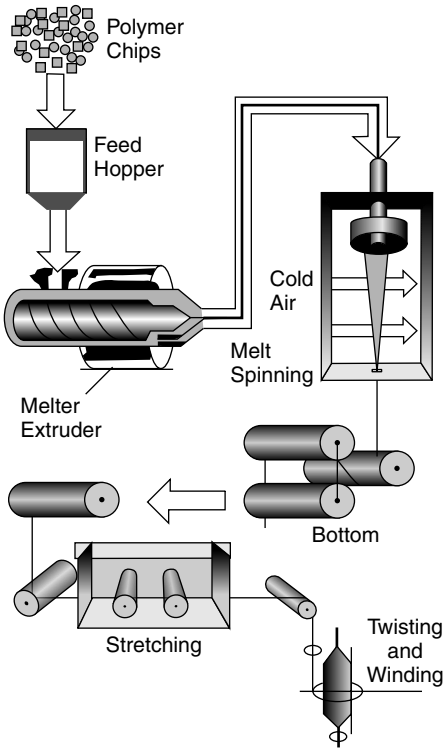

Fig. 6. Melt spinning process. From www.fibersource.com.

smaller quantities, the downtime and waste associated with changeovers of such large lines is prohibitive; smaller batch lines based on PET chips are preferred. Whether fed by a continuous polymerization (CP) process or by remelted chips, however, the spinning processes are basically the same.

Under typical conditions of 290°C spinning temperature, the molten viscosity is ca 200–2000 Paċs (2000–20,000 P) depending on average molecular weight. This is extremely viscous—similar to hot asphalt. The pump must provide a pressure of 10–20 MPa (∼100–200 bar) to force the flow through the pack, which contains filtration media (eg, a sand bed) to remove any particles larger than a few micrometers.

At the bottom of the pack, the polymer exits into the air through a multiplicity of small holes through a thick plate of metal (the spinneret). The number of holes can range up to several thousands per spinneret. Each spinneret hole is ca 0.2–0.4 mm in diameter with a typical flow rate in the range of about 1–5 g/min (less for fine fibers, more for heavy fibers). Although a round hole is most common, it is not unusual for the hole to have a complex shape intended to provide fiber cross sections of unusual shape, as noted earlier. The mass flow rate through the spinneret is controlled by metering pumps feeding the pack. A take-up device, typically a rotating roll system with a controlled surface speed, controls the final speed of the extruded filaments. Assuming the same flow rate to every spinneret

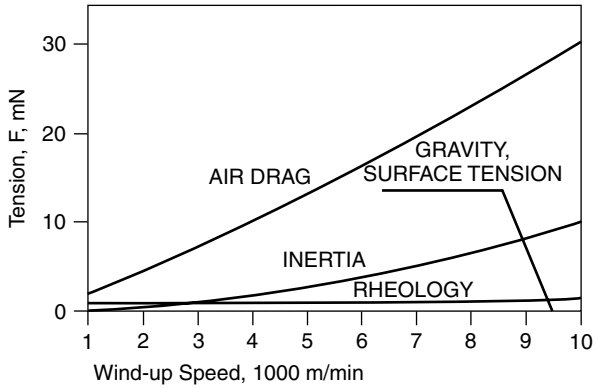

Fig. 7. Typical forces acting upon spinning threadline (14). To convert from mN to dyne, multiply by 100.

hole, the final diameter of the filaments is fixed by the flow rate and the take-up speed; the spinneret hole size does not affect fiber diameter.

The structure and properties of the filaments are controlled by the threadline dynamics, especially in the molten region between the exit from the spinneret and the freezing point of the fibers. After freezing, the fibers will be traveling at the take-up speed, which is typically 100–200 times faster than their exit speed from the spinneret hole. Thus, considerable acceleration (and stretching) of the threadline occurs after extrusion. The forces acting on the fibers in this transition region include gravity, surface tension, rheological drag, air drag, and inertia (Fig. 7). Because both temperature and threadline speed are rapidly changing, these force balances also change rapidly along the threadline. The dynamics of threadline formation are reasonably well understood and have been successfully modeled. Numerous references on the subject are available (15,16).

While traversing the spinneret hole (typically 1.5–5.0 times longer than it is wide), the molten fibers are in a state of viscous shear that induces molecular orientation along the fiber axis. Upon exit from the hole, the filaments slow down and bulge slightly, as the molecules relax and disorient. This is "die swell." From the die swell region onward, the filaments accelerate, and it becomes an ongoing competition between orientation (induced by extensional flow) vs thermal disorientation (due to molecular relaxation). Near the spinneret, the filament is still hot, the polymer is relatively fluid, and little net orientation is present in the threadline. Further down, the filament is cooler, the polymer more viscous, and thermal disorientation less; net orientation is higher. Orientation increases progressively and reaches a maximum as the threadline "freezes," ie, stops extending, usually within ∼1 m from the spinneret. The amount of orientation that is frozen into the spun fiber is directly related to the stress level in the fiber at the freeze point (15).

A key parameter which controls the rate at which orientation is being generated is the rate of extension

$$v' = \frac{dv}{dx} \tag{4}$$

where v is the local threadline velocity and x the distance along threadline.

For a Newtonian polymer, the stress required to deform the polymer at this extension rate is simply $\eta v'$, where η is the extensional viscosity of the polymer (which changes rapidly as the polymer cools) PET is not strictly Newtonian, else it could not be fiber-forming. Fiber forming polymers develop increasing tension because of retraction forces as they become oriented, so that localized necks do not grow and become discontinuities. An exception to this behavior occurs at high shear rates, and is discussed later.

The fiber extension also corresponds to acceleration of the material at a rate equal to vv', and the inertial resistance to this acceleration is responsible for a tension gradient along the filament. Finally, the air resistance of the fiber generates surface drag forces that increase with velocity so that a further tension gradient appears because of air drag. These are the three dominating forces—rheological, inertial, and air drag—that control spinning threadline dynamics and velocity profiles over the range of typical spinning speeds. Gravity and surface tension forces are relatively much smaller.

Starting with a more viscous polymer (whether due to higher molecular weight or lower extrusion temperature) will produce higher final orientation. And so will increasing the total amount of stretch, the "draw-down" ratio. The primary tool for controlling the net orientation, though, is the speed of the process, ie, the take-up speed. By increasing the velocity and extension rate of the filaments, the orientating mechanism becomes more dominant over the thermal relaxation mechanisms, and more net orientation is frozen into the fibers. Since molecular orientation is such a critical parameter, several methods have been developed to measure it. One of the most common is filament birefringence, taking advantage of the fact that oriented PET is a birefringent material. The refractive index for light polarized along the fiber axis is different than the index for polarization across the axis. The difference in these indices increases as the orientation increases. This difference can be measured by viewing fibers under a microscope with polarized light (17). This method requires only a very small sample of fibers, as compared with other methods that may depend on measurement of, for example, fiber shrinkage, shrinkage forces, or residual extensibility. Obviously, a higher level of v' corresponds to larger rheological and inertial forces, and higher v creates more air drag. Thus, high speed spinning is also high stress spinning.

The melt-spinning process for PET fibers can conveniently be divided into three regions of take-up speed:

(1) In low speed spinning (<1000 m/min), the spinning threadline forces are dominated by rheological deformation. Air drag may also play a role for fine filaments (with high surface–volume ratios), but drag is generally small in the fiber formation region near the spinneret where velocities are lower and diameters larger. The acceleration rate is too small for inertia to play a role. Only a small amount of residual orientation is frozen into the threadline, since thermal disorientation predominates over the orientating effects of fiber extension.

(2) In medium-speed spinning (ca 1000–4000 m/min), the air speed generates higher drag and faster cooling. The inertial effects are also greater, being proportional to velocity and extensional shear rate. The resulting higher

stress at the freeze point increases the orientation frozen into the spun fibers.

(3) At speeds beyond ~4000 m/min, inertial and air-drag effects become the dominant contributors to fiber stress. Sufficient orientation can be induced so that significant crystallization occurs in the as-spun fiber. The structure begins to partition into either highly oriented crystalline regions or amorphous regions of relatively low orientation. There is relatively less of the "oriented-amorphous" structure.

The structure-partitioning effect at high speeds is believed to arise from the scaffold of oriented regions that develop within the structure and support the fiber stress. This leaves the less-ordered regions free to relax and disorient so that a two-phase structure begins to appear where there was before a broad continuum of orientations. In this region, the highly ordered sections behave as a solid, with tensile stresses proportional to deformation, while the less-ordered regions behave more like a fluid with stresses proportional to *rate* of deformation. This is a mixture of solid and liquid phases.

It has been observed that, at speeds sufficient to induce crystallization, fiber deformation will become concentrated into a "neck" region where the final amount of stretching will occur over a very short distance. The origins of this neck have been a source of speculation and research (15,16) and efforts have been made to link necking and crystallization in a cause–effect relationship. Current evidence favors the explanation that this phenomenon is similar to necking behavior seen when cold-drawing plastic materials (14). This means that the molten filament passes through a stage where resistance to deformation decreases along the threadline. The decrease in resistance is initiated by "shear-thinning," where the apparent viscosity of the polymer decreases at increased shear rates. High shear rates promote a high level of molecular orientation within the melt, which then allows the molecules to slip by each other more easily. As the thinning process accelerates, the decrease in cross-sectional area concentrates the stress, while the overall tension remains constant. This produces a rapidly thinning neck. The necking stops when sufficient orientation has been induced so that further elongation requires additional force, and the resistance has become elongation-dependent rather than elongation rate-dependent. Classically, the liquid has become a solid. Coincidentally, the high levels of orientation allow crystallization to occur very rapidly after stretching has stopped.

Another feature of high speed spinning is that the fiber macrostructure becomes nonuniform, with more orientation and crystallinity near the fiber surface than in the interior. This is a result of nonuniform solidification, where rapid cooling generates lower temperature and higher viscosity at the surface. This leads to an oriented surface "skin" which supports the spinning stress, whereas higher temperatures in the interior allow more relaxation and disorientation.

The skin-core structure is a macroscopic analogue of the partitioned structure within the fiber. Since fiber stresses become concentrated in the oriented regions, there is a loss of participation of some of the interior molecules to resist subsequent strains. Under fiber extension, the taut molecules will break first, triggering rupture of the fiber before the unoriented molecules contribute much resistance. A loss of overall fiber strength and tenacity results.

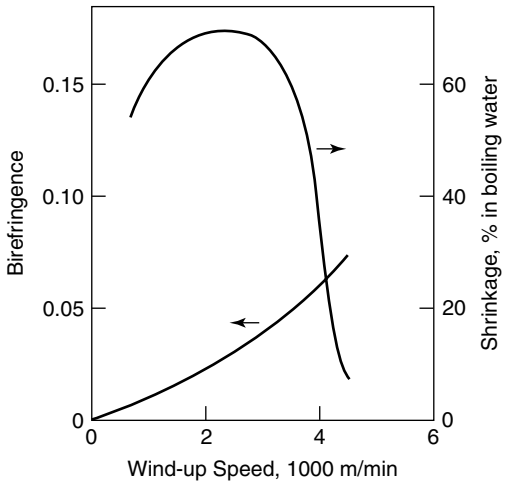

Fig. 8. Orientation and shrinkage of spun yarn vs spinning speed (18).

Insight into the spun yarn structure can be gained by observing its behavior in boiling water. The combination of elevated temperature and the plasticizing effect of the water molecules allows relaxation of the oriented regions, resulting in yarn shrinkage (Fig. 8). As spun orientation becomes greater, the spun yarn shrinkage will increase up to a point. At sufficiently high levels of orientation, the plasticizing effect of the heat and moisture will allow crystallization to proceed within the hot water, and this will inhibit shrinkage in the amorphous regions. This rate differential will increase at higher spinning speeds. Additionally, the reduction of amorphous orientation accompanying crystallization in high speed spun yarns will depress their shrinkage even further.

In summary, the strongest PET fibers are formed by slow-speed spinning processes. A benefit of high speed spinning is that it generates less of the intermediate "oriented-amorphous" structure that is prone to thermal shrinkage. The most thermally stable fibers are therefore formed by high speed spinning processes. It is possible to increase spinning speeds to the point that very little extensibility remains in the fibers, but the microstructure becomes so highly paritioned that little strength remains. Nearly all commercial spinning processes leave at least ~100% extensibility remaining in the spun fibers, and do further downstream processing at lower temperatures in order to develop the most useful fiber properties.

Spinning Process Control. There are a number of factors available for controlling the spinning process, to control thereby the properties of the fibers. These include melt viscosity (via temperature and/or polymerization level), hole diameter and throughput, spinning speed, and the cooling rate of the filaments after extrusion. In the ideal world, each fiber would have an identical history and microstructure. In reality, each filament is subjected to different thermal histories according to its position within the threadline relative to the flow of cooling air. Uneven heat losses from the spinneret face also lead to different extrusion temperatures among the filaments. Consequently, different filaments have different

average orientation levels. Additionally, any particular filament will have varying levels of orientation along its length because of microscale fluctuations in cooling rate, eg, air turbulence.

The fiber orientation uniformity is also affected by small-scale or timewise variations in polymer viscosity related to breakage of polymer chains during the extrusion process. The degradation occurs as a result of residual moisture that immediately reacts to break chains, and by thermal degradation that occurs more gradually over time (2). Different residence times and temperature histories within the laminar flow streamlines lead to different viscosities, and hence different orientation levels in the final fibers.

A primary goal of extrusion equipment and process design is to minimize the orientation variability among filaments, since variability can have undesirable effects on product uniformity (eg, dye uptake level) and on yarn strength and processing performance. As a rule, higher throughput rates and/or more filaments per spinneret create greater difficulties in achieving uniform cooling and fiber properties. There is a compromise between fiber uniformity and production economics, since larger scale processes are more economical.

This tradeoff between product uniformity and production economics has affected the process design for various types of PET fibers. Products such as textile filament yarn have a strong requirement for uniform dye uptake, within and between bobbins of yarn used for weaving or knitting. No opportunity is available for "blending out" dye differences with continuous filament (CF) yarns. Continuous filament yarns are made on spinning machines with a relatively small number and low density of holes per spinneret, and the supply of cooling air is controlled very carefully to minimize variability. These are relatively low throughput processes.

In contrast, staple fibers are always blended during the textile process, either among themselves or with other fibers. Small fiber orientation differences that might occur between various spinning machines, or over small periods of time, will be blended out so that dye uptake differences occur over such a fine scale as to be invisible to the eye in the final fabric. For this reason, tolerance for fiber nonuniformity is greater for staple than for filament products. Consequently, the spinning processes used for staple allow much higher throughput rates, with much higher numbers of holes per spinneret. This allows staple fiber to be produced at less cost than filament yarn, and the selling prices of the fibers reflect this; filament PET yarns command significantly higher prices than do commodity staples. Continuous filament products, however, do not require post-processing in order to be converted into yarns suitable for knitting and weaving.

Relative scales of the spinning processes for staple and filament products are depicted in Table 2. The industrial filament process is intermediate to the staple and textile filament processes, in terms of both spinning throughput and fiber

Table 2. Scales of Spinning for Various Products

	Staple filament	Industrial filament	Textile filament
Filaments per spinneret	6000	750	140
Pack throughput (kg/h)	240	100	12
CV of orientation	~15%	~10%	~5%

orientation uniformity (here measured by spun birefringence level). Industrial yarns must be uniform enough to be drawn to much higher tenacity levels than staple yarns, but are not dyed and therefore not subject to the more demanding uniformity requirements of textile yarns.

Although it is evident that fiber orientation level affects dye uptake, and that orientation uniformity translates to dye uniformity, it is less obvious that orientation uniformity will affect yarn strength. The breakage of fiber bundles is controlled by the "weak link" principle, where the early breakage of a few high orientation fibers will initiate a catastrophic failure sequence among surviving fibers within the bundle (19,20). This comes about as a result of load transfer from the broken fibers to the unbroken survivors via fiber–fiber friction, and hence stress concentration. Variable extensibility of the fibers within a yarn can thereby result in yarn strength that is much lower than the average strength of the component fibers.

Drawing of Spun Filaments

The purpose of drawing is to further align and stabilize the structure of the fibers. Additional diameter reduction occurs in this step. Drawing occurs at a much lower temperature than spinning, typically just above T_g, so that there is minimal thermal disorientation to compete with orientation induced during stretching. Fibers may have been extended by a factor of 100–200 during spinning, but a draw ratio in the range of about 2–5 is typically enough to induce the maximum amount of fiber orientation short of breakage. Drawing is more efficient at orienting the structure.

The amount of drawing used depends on (*1*) the amount of orientation already present from spinning and (*2*) the desired level of fiber properties. High levels of final orientation are desired for technical fibers where high tenacity and high initial modulus are needed. Less orientation may be needed for textile fibers, so that dye penetration is faster and the fibers are less stiff.

Figure 9 displays the stress–strain behavior of PET fibers that were prepared from the same spun yarn but drawn to different ratios. The curves represent the elongation and stress in terms of initial fiber area (decitex). The open circles represent true stress values, where stress values at break are corrected for the decreased area of the fiber after extension on the testing device.

As expected, the residual extensibility of the fiber decreases at higher draw ratios. What is not so predictable is that the true stress at failure increases as the draw ratio increases; fiber failure strength is improved by drawing the yarn. If a curve is drawn to connect the endpoints of the stress–strain curves, it is seen that there is an inverse relation between tenacity and elongation to break (e_b). The form of this relationship is

$$t = \frac{K}{e_b^{\alpha}} \tag{5}$$

where t is engineering tenacity, K and α are constants.

Experimentally, $\alpha \sim 0.3$. The value of K is a measure of inherent fiber strength and will depend on the molecular weight of the polymer. K will also increase if post-draw heatsetting is used to crystallize the structure.

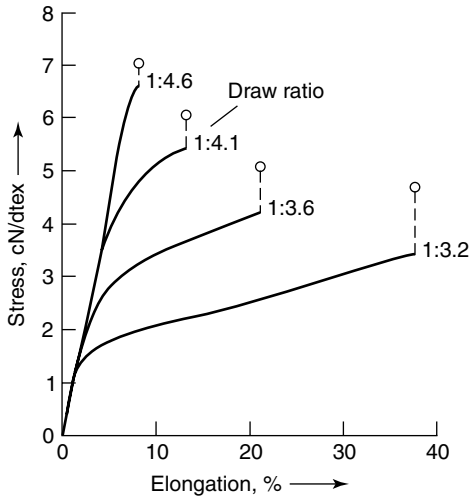

Fig. 9. Stress–strain curves of PET filaments drawn at different draw ratios (21). To convert cN/dtex to g·f/den, multiply by 113.

The presence of significant crystallinity in the fibers prior to drawing is detrimental to a smooth and continuous drawing process. Free extension of the polymer chains is inhibited by crystalline tie points, which must be disrupted for molecular extension to occur while drawing. If very high final fiber orientations are desired, then high drawing stresses may be generated, which can cause frequent breakouts of the drawing process at the sites of small fiber defects. Increasing the drawing temperature to compensate for the high tension will only hasten the crystallization process, compounding the problem. For most PET fiber production, inhibiting spun orientation is an advantage since it will allow a higher final draw ratio, which will allow higher spinning speed and throughput. An exception is when the final fiber properties require very high levels of thermal stability which can be provided by a network of small, very numerous crystallites that are "seeded" during the spinning process.

The use of a post-draw heatsetting (or annealing) step usually accompanies the drawing process. It is the purpose of this step to stabilize the structure and make it stronger. The level of yarn tension and the annealing temperature both can have significant effects on the final properties. Basically, there are two separate processes occurring during annealing: (*1*) crystallization in the most highly oriented regions and (*2*) chain disorientation via bond rotation in amorphous regions. The relative rates of these two processes are affected differently by tension and temperature and so a significant range of different fiber properties can be achieved according to the balance of these two variables.

High temperature (~200°C), high tension heatsetting promotes a high level of orientation in the amorphous regions and hence high fiber modulus and relatively lower dyeing rate. Dyeing rate can be improved by reducing the heatsetting temperature so that less crystallization occurs. If temperature is raised even higher, however, the structure can generate fewer larger crystals as the smaller ones melt and the larger ones become more perfect. This will also enhance

dyeability, since there are fewer crystallites to inhibit diffusion of the large dye molecules.

If the fibers are heated with low tension, then disorientation of the amorphous regions occurs and the fibers are left with low shrinkage forces (and modulus), but high dyeability. It may be desired to complete stress-relaxation while the filaments are held in some particular shape so that the memory of this shape is frozen into the microstructure. This might be done by twisting the yarn to form helical fibers, or by compressing them into random or regular modes of buckling. Such fibers retain crimp or texture, further enhancing their fabric aesthetics or their processability on textile machinery.

Commercial Drawing Processes. The drawing process can be continuous with spinning or it can be done as a separate step. The former simplifies handling, but can require very high final roll speeds since the drawing rolls must operate at several times the spinning speed. Such spin-draw processes are commonly used for high strength industrial yarns, at final speeds up to ca 8000 m/min (300 mph). This speed imposes severe demands on rolls and winders that can operate at high centrifugal forces (~10,000 g) and can control the yarn temperatures in the few milliseconds of contact time that are available.

At the other extreme are discontinuous staple fiber processes that operate at relatively slow speeds (<500 m/min). In order to obtain high throughput rates, the spun yarns from many spinnerets are collected and drawn in parallel. A modern staple line might process up to $\sim 5 \times 10^6$ filaments at a time, producing fiber at the rate of 200–300 tons/day. After crimping, such fibers are usually cut into short (<50 mm) lengths and baled. Depicted below is a modern drawing line for PET staple fibers. Such lines can be purchased as a package installation from equipment vendors, as can lines to produce the PET polymer and spin it into fibers (Fig. 10).

The third major PET fiber type is continuous filament textile yarn and this also uses a discontinuous production process. In this case the spun yarns are produced at speeds up to ~5000 m/min, precluding further in-line processing because of exceedingly high speed requirements. The spun yarns are highly oriented (known as POY, for Partially Oriented Yarn) and are wound onto packages then subsequently processed on another machine which provides the final orientation, texturing, and setting in an integrated process. Most commonly, POY yarns are heatset in a highly twisted configuration and then untwisted. The memory of twist produces a fiber bundle with helical filaments, providing bulk and stretchiness. Textured CF yarns may be knitted or woven directly into fabrics, eliminating the steps of blending and yarn formation used for staple fibers such as cotton or wool.

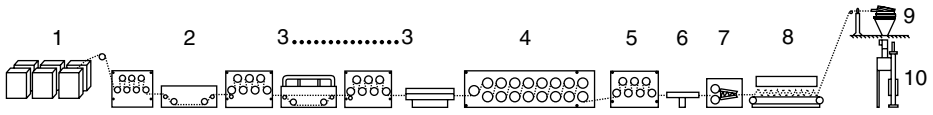

Fig. 10. Staple fiber line: (1) spun yarn supply cans, (2) lubricating bath, (3) two-stage drawing, (4) heatsetting, (5) cooling, (6) reheating, (7) crimping, (8) drying, (9) cutting, and (10) baling.

More akin to silk yarns, continuous filament POY produces lighter fabrics of 100% PET. Such yarns have provided a fertile field for imaginative engineering of cross-sectional shapes, fiber sizes, and combinations of color and texture. An entire field of specialty filament yarns called Shingosen has been developed in Japan (2), providing novel and luxurious fabrics that cannot be duplicated with natural fibers.

The Future of Polyester Fibers

From the proprietary developments by chemical industries in the mid-twentieth century, the technology for making PET fiber has become readily available. Entire plants can be purchased from machinery suppliers for textile or industrial fibers, continuous filaments, or staple. This has led to rapid expansion of PET fiber plants into developing countries by governments and/or large investment firms that supply fiber for labor-intensive fabric and apparel industries based in those countries. To an increasing degree, such apparel is imported back to the countries where the technology originated, displacing fiber and textile businesses there. This trend will continue as the world economy becomes more global.

Standardization of the world fiber business on PET guarantees that future fiber technology efforts will remain focused on this polymer. Costs and efficiencies will get better, and other fiber types will become even less competitive. Domination of the PET commodity fiber business by Asian countries will encourage more efforts by Western and Japanese producers to further expand into niche markets with special fiber types, and to further displace natural and other synthetic fibers from their markets.

The types of products that contain PET fibers will expand, especially in areas such as nonwoven fabrics used for disposable items, eg, industrial fabrics for diapers, disposable wipes, filters, etc. These are products that do not require much hand labor and are relatively protected from the low labor costs in developing countries. It is certain that bicomponent fibers based on PET will become more prevalent as the production technology becomes more widespread, where the bico approach can enhance properties or economics.

The domination of PET is likely to continue so long as the raw material costs remain low, and these are currently driven by the cost of oil. Although synthetic fibers use only ∼1% of the petroleum stream, they are in competition for that resource with fuels which use up to 50 times as much. Efforts are already in place for chemical producers to supply raw materials from renewable biological sources, and so it is possible that even the increasing cost of oil will not diminish the dominance of polyester. When contrasted with increasing costs of land and resources for natural fiber production, as food for an increasing population competes for the same land, the use of PET fibers will likely become even more prevalent than today.

POLYKETONES

Introduction

Nearly 40 years have evolved between the first discovery by Reppe of transition-metal-catalyzed CO/ethene copolymerization and the discovery in 1983, at Shell, of a class of highly active, high yield palladium catalysts for the synthesis of high molecular weight, perfectly alternating CO/ethene copolymers [PK-E, Fig. 1]. This class of catalysts is also active for the co- and terpolymerization of CO with alkenes other than ethene, both simple aliphatic and heteroatom functionalized, thus providing access to a family of completely new polyketone polymers.

The high activity catalysts have made it possible to produce perfectly alternating copolymers in an ultrapure state, with very low levels of catalyst residues. Extensive research efforts have subsequently provided further advances in the manufacture and stabilization of polyketones and led to the development of easily melt-processable polyketone grades. For the first time, the intrinsic physicochemical and mechanical properties of these polymers could thus be assessed.

Aliphatic polyketones described here are a family of semicrystalline thermoplastics obtained by co- or terpolymerization of CO and ethene and/or higher α-olefins. Main emphasis will be on CO/ethene/propene-based terpolymers [PK-EP]. These polymers can be produced with a wide range of compositions and molecular weights. Various aspects of polyketone catalysis, the polymerization process, the types and properties of polyketones, and their applications are reviewed. A number of reviews on polyketones have appeared in recent years (1–5).

In 1996, Shell started commercial production of a number of PK-EP engineering thermoplastic grades, marketed under the trade name of Carilon Polymer.

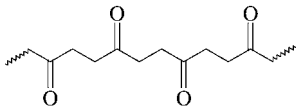

Fig. 1. CO/ethene-based PK-E. *Note:* Applied notation for perfectly alternating CO/α-olefin polyketones: PK-M_1M_2-n, in which M_1 and M_2 are abbreviations for the types of α-olefins incorporated in the co- or terpolymer chain [eg M = ethene (E), propene (P), butene (B), pentene (P), hexene (H), octene (O), decene (D), dodecene (Do), tetradecene (Td), hexadecene (Hd), octadecene (Od), icosene (Ic), and styrene (S)] and n, the molar monomer index $\{n = [100 \times [M_2]/([M_1] + [M_2])]\}$, is the percentage of M_2 (in mol%) on the total amount of α-olefin incorporated in the polymer backbone. For example, PK-E represents a copolymer build up of CO and ethene, while PK-EP-6 represents a terpolymer build up of CO, ethene, and propene in a molar ratio of 100:94:6.

Because of a strategic change in product portfolio initiated in 2000, Shell International Chemicals has announced its withdrawal from the engineering plastics market.

Physical Properties and Manufacture of Monomers

Ethene, propene, and CO are gases under ambient conditions. Their most important properties are given in Table 1. Ethene and propene are primarily obtained from cracking of higher hydrocarbons, or from dehydrogenation of ethane and propane, respectively. Carbon monoxide may be obtained by steam reforming of hydrocarbons (petroleum gas, natural gas, mineral oil, biomass) or gasification of coal into synthesis gas, followed by separation.

Copolymerization

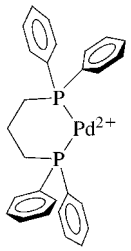
Perfectly Alternating Copolymers. Nickel was the first transition metal found to catalyze the copolymerization of ethene and CO. In the late 1940s, Reppe and Magin (BASF) showed that $K_2Ni(CN)_4$ in water catalyzed the production of low melting polyketone oligomers in addition to diethyl ketone and propionic acid, albeit with a poor activity of ~0.8 g PK-E/(g Ni·h) (6). Also, rhodium-based catalysts showed some activity (7,8). Palladium(II) systems were first disclosed by Gough (ICI). Although these palladium(II) dichloride complexes bearing monodentate phosphine ligands showed a moderate activity,

Table 1. Physical Properties of the Monomers

Physical property	Ethene	Propene	CO
Molecular weight	28.054	42.080	28.010
Boiling point, °C	−103.7	−47.7	−191.5
Melting point, °C	−169.2	−185.3	−204.0
Critical pressure, MPa[a]	5.12	4.65	3.50
Critical temperature, °C	9.9	92.0	−140.2

[a]To convert MPa to psi, multiply by 145.

~300 g PK-E/(g Pd·h), severe conditions were required (250°C, 200 MPa) (9). In the early 1980s, Sen reported that certain monodentate phosphine modified palladium(II) complexes containing the virtually noncoordinating tetrafluoroborate anion produced PK-E under very mild conditions. However, the reaction rates were very low, ~4 g PK-E/(g Pd·h), as were the molecular weights (10,11). The real breakthrough came in 1983, when Drent (Shell) discovered that palladium(II)-based catalysts modified with the combination of a diphosphine ligand (L_2) and weakly or noncoordinating anions (X, eg sulfonates), produce high molecular weight PK-E at high rates [up to 6000 g PK-E/(g Pd·h) for $Pd(dppp)X_2$ (**1**)], at relatively mild reaction conditions (90°C, 4–6 MPa) (12,13).



$Pd(dppp)^{2+}$ (**1**)

Copolymerization is carried out in methanol, which also constitutes an initiation and chain transfer reagent (eq. 1).

$$n\,CH_2{=}CH_2 + n\,CO + CH_3OH \longrightarrow H{-}[CH_2CH_2C(O)]_n{-}OCH_3 \qquad (1)$$

Although the catalysts L_2PdX_2 were initially prepared *in situ* (eq. 2), preformed complexes exhibit a similar performance (14–16).

$$Pd(OOCCH_3)_2 + L_2 + 2\,HX \longrightarrow L_2PdX_2 + 2\,CH_3COOH \qquad (2)$$

Since this finding, a large variety of transition-metal-based catalysts have been reported for the production of perfectly alternating aliphatic polyketones (17–27). Particularly suitable systems include palladium(II)- or nickel(II)-based complexes modified with a neutral or anionic bidentate chelating ligand and weakly coordinating anions X (such as OTs^-, OTf^-, TFA^-, BF_4^- and tetra-arylborates) (2,3,13).

Besides ethene, a variety of α-olefins can be effectively copolymerized with CO. These include

(1) propene and higher aliphatic α-olefins (2,14,15,28–35)
(2) functionalized α-olefins in which the functionality (eg $-CH_2OH$, $-CH_2CN$, $-CH_2Cl$, $-COOH$, $-COOR$, epoxide) is separated by at least one methylene group from the olefinic group (2,5,36–38).
(3) styrene and its (functionalized) derivatives (4,39–47)
(4) α,ω- and 1,2-dienes (48–53)

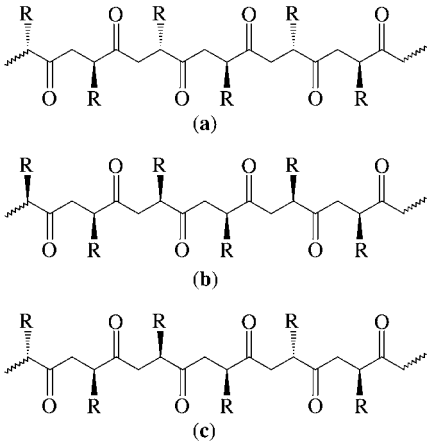


Fig. 2. Polyketone stereoisomers: (**a**) isotactic; (**b**) syndiotactic; (**c**) atactic.

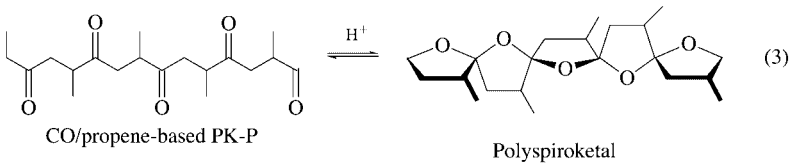
Additionally, certain *internal* olefins can be copolymerized with CO, albeit at much reduced rates. For example, by employing 2-butene, low molecular weight oligomers of poly(1,5-ketone) are obtained by a sequence of insertion and isomerization steps (54). Copolymers with *strained* internal olefins such as (functionalized) norbornene or norbornadiene can also be made (55).

Besides copolymers, a variety of perfectly alternating CO/olefin terpolymers have been produced (31,56–64). The two olefins are usually randomly incorporated in the polymer chain, to a degree which is equally proportional to their concentration and relative rate of incorporation.

Copolymerization of CO and α-olefins can be achieved with almost perfect control of the chemo-, regio- (via either 1,2- or 2,1-insertion), and stereoselectivity in nearly all cases (2–4,33). Syndio-, iso-, and atactic copolymers can be produced on purpose (Fig. 2). For propene, highly isotactic materials can be prepared using chiral ligands (33,65,66). For styrene, chain-end control results in syndiotactic structures for a suitable choice of ligands (39,41). This chain-end control can, however, be overruled by application of certain chiral ligands to give isotactic structures (67). Epimerization of syndio- or isotactic polyketones into atactic materials occurs by heating, or by treatment with a strong base or a strong acid (68).

Interestingly, the palladium-catalyzed copolymerization of propene and CO may yield a polyspiroketal product, which can be converted into a polyketone (PK-P) by heating or dissolution (69,70). This conversion is reversible (eq. 3). In the presence of an acid the polyspiroketal structure can be (partly) restored (4,54). Also copolymers of higher α-olefins tend to adopt the polyspiroketal form (4).



(3)

The choice of the most effective catalyst system is highly dependent on the type of olefin under consideration. Polymerization of CO and aliphatic α-olefines is most suitably carried out employing a catalytic system modified with a symmetrical, C_3-bridged aryldiphosphine ligand (2,71). However, these systems are not suitable for copolymerization of CO and styrene (41). For this reaction palladium(II)-based catalysts modified with a conjugated diimine (39,41), a bisoxazoline (43,44), a phosphine–phosphite (43), or a phosphine–imine ligand (43) have been employed, in, under chain-transfer conditions, combination with an oxidant promotor, such as 1,4-benzoquinone or 1,4-naphthoquinone (39–47,72), or a polar, acidic type of solvent (73,74).

Polyketone catalysis can be carried out in a wide variety of solvents, including water [using sulfonated ligands (75–79)], aprotic solvents [in which alumoxanes can be used as cocatalysts (80,81)], and even in solvent-free systems (62,82). However, methanol remains the solvent of choice for industrial polyketone production. Aliphatic polyketones can also be manufactured in a gas-phase process (83,84).

Nonperfectly Alternating Copolymers. Nonperfectly alternating polyketones, having a CO content of less than 50%, may be obtained either by a free-radical polymerization (3,85–87) or by application of certain *neutral* palladium(II)-based catalysts (88). However, the products are not identical. The nonperfectly alternating copolymers produced with a palladium(II)-based catalyst consist of a random combination of $-CH_2CH_2C(O)-$ and $-CH_2CH_2-$ units, while those produced by a free-radical polymerization also contain branched structure elements.

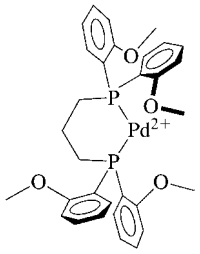
Catalyst Evaluation and Development. After the discovery of $(dppp)PdX_2$ [(**1**), dppp = 1,3-(diphenylphosphino)propane] as an efficient catalyst for CO/α-olefin copolymerization and Shell's decision to start process and product development work on this new engineering thermoplastic, an intensive search began toward the identification of more efficient catalyst systems for the production of PK-EP-6 [Shell's commercial polyketone grade, which contains 6 mol% of propene]. The target was not just to simply increase the activity, but also to find catalysts exhibiting an optimal balance on criteria including activity and stability of the catalyst, relative rate of propene/ethene incorporation, the molecular weight and molecular weight distribution of the terpolymer, product bulk density, particle size distribution, reactor fouling, the influence of residual catalyst on the melt-stability of the terpolymer, and the synthetic accessibility and manufacturing costs of the diphosphine ligand.

It had already been found that catalysts based on C_3-bridged aryldiphosphines (dppp) were more active than their C_2- or C_4-bridged counterparts (12,13). Substitution of the aryldiphosphines by alkyldiphosphines gives moderately active catalysts, but the molecular weight of the products is rather low (89). In 1986, it was discovered that replacement of the phenyl substituents on phosphorus by *o*-anisyl groups [$Pd(bdompp)X_2$ (**2**), bdompp 1,3-bis-(di-(2-methoxyphenyl)phosphino)propane], not only gave more active catalysts, but also produced co- and particularly terpolymers with a considerably higher molecular weight (Table 2) (90).

Table 2. Performance of Selected Catalysts in CO/Ethene Copolymerization[a]

Catalyst	Diphosphine ligand (L_2)	Rate, kg/(g Pd·h)	LVN,[b] dL/g
1	dppp	7.1	1.05
2	bdompp	12.7	1.58
3	diEt-XPhos	42.7	1.20

[a]Reaction conditions: Catalyst–$Pd(OAc)_2/L_2$/trifluoroacetic acid = 1/1.02/6, solvent = methanol, $T = 90°C$, $P_{tot} = 5$ MPA (50 bar), $CO/C_2^{=} = 1/1$ (gas cap), 6 wt% seed/methanol (C_2^2 = ethene).
[b]LVN = limiting viscosity number (see also Table 3).



$Pd(bdompp)^{2+}$(**2**)

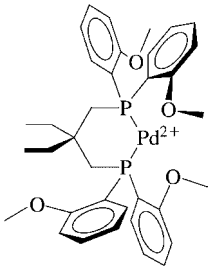
This finding offered the advantage of producing PK-EP-6 (LVN 1.7) at a much higher rate of 8–10 kg/(g Pd·h) (at 80°C) than with (**1**), which produces this material at a rate of only 1 kg/(g Pd·h) (at 45°C). At 80°C, the rate of (**2**) is first-order in ethene up to the highest partial pressures investigated (6 MPa), first-order in CO up to 0.5 MPa, and becomes zero-order in CO between 1 and 4 MPa. Taking the relative molar solubilities (inverse Henry constants) of CO, ethene, and propene in methanol at 80°C (1:5.4:11) into account, the ratio of rate constants for the incorporation of the three monomers by (**2**) was found to be

$$k_{co}:k_{c_2}:k_{c_3} = 1300:19:1$$

On a molecular scale this means that CO-insertion is much faster than ethene-insertion, while, in turn, propene-insertion is considerably slower than that of ethene. The rate constants for incorporation of other α-olefins are similar to that found for propene. The rate-dependency on the monomer concentration is highly dependent on the catalyst employed. For example, the rate of a Pd(dppp)-based catalyst (**1**) is first-order in CO over a much larger pressure span than that of (**2**) (91).

The structures of all further improved catalysts are based on modifications of this basic ligand concept: combination of a C_3-bridged disphosphine and *o*-anisyl groups on phosphorus. In 1987, it was found that substitution of the central carbon atom of the C_3-bridge by a $Si(CH_3)_2$ unit (diMe-Si-XPhos) gave the most active type of catalyst systems discovered thus far (92). In the 1990s, it was found that substitution of one or both protons at the central carbon atom of the C_3-bridge by aliphatic groups (eg diEt-XPhos, (**3**)) provided similar high activity catalysts

(93–95). Moreover, this type of catalysts exhibits a higher olefin/CO reactivity ratio, offering the advantage of using a lower olefin/CO ratio in the batch slurry polymerization process for PK-EP-6, thus lowering the olefin recycling costs.



$Pd(diEt\text{-}XPhos)^{2+}$ (**3**)

Recently, certain nickel(II)-based catalysts have been found to exhibit activities similar to that of the most active palladium(II)-based catalysts (96,97). However, thus far the industrial applicability of these low cost nickel catalysts is limited because of the poor rate of propene incorporation during CO/ethene/propene terpolymerization.

Reaction Mechanism of Polyketone Catalysis

Propagation. The catalytically active species in polyketone formation is a square-planar cationic palladium(II) complex, L_2PdR^+, where L_2 represents the bidentate ligand and R is the growing polymer chain. The fourth coordination site at palladium may be occupied by an anion, a solvent molecule, a carbonyl group of the chain (*vide infra*), or a monomer molecule. Model studies indicate that having a strongly coordinating group at this position strongly reduces the rates of the insertion steps (98–100). Thus, competition for the vacant site appears to be an important factor affecting the performance of the catalyst, and provides an explanation for the sensitivity to the choice of solvent and counterion.

The palladium–diphosphine-catalyzed copolymerization of CO with aliphatic olefins occurs in a perfectly alternating way, and propagation "errors" (double CO or olefin sequences) are not observed. The origin of the perfectly alternating nature of the copolymers has received ample attention, both in experimental (101–106) and in theoretical studies (107–110). The mechanism for copolymer chain growth involves two sequential propagation steps: the reversible migratory insertion of CO into the Pd–alkyl bond of the growing polymer chain, followed by the irreversible migratory insertion of ethene into the resulting Pd–acyl bond (Fig. 3). Various intermediates in the catalytic cycle have been isolated or were characterized spectroscopically (82,98–105,111,112). Double CO-insertion does not occur because it is thermodynamically uphill, while double ethene-insertion is kinetically hampered owing to the much higher affinity of cationic palladium(II)-centers for CO over ethene, combined with the much higher rate of CO-insertion in the Pd–alkyl bond over ethene-insertion.

Bidentate ligands give copolymerization catalysts which are far superior to those bearing monodentate ligands (1,2). The most obvious difference between

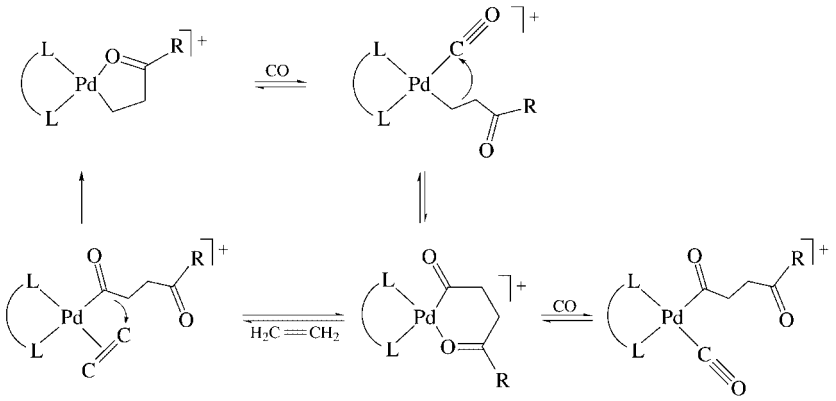


Fig. 3. Proposed propagation mechanism; R represents the growing copolymer chain.

mono- and bidentate ligands is that the latter are always cis-chelate coordinated at the d^8-square-planar palladium center, whereas the former can also coordinate in a trans fashion. If a bidentate ligand is used, the starting or growing copolymer chain and the "empty" fourth coordination site are always cis to each other, which is the ideal position for migratory insertion reactions. If a monodentate phosphine is used, both palladium(II)-alkyl and palladium(II)-acyl species prefer a trans position of the two phosphine ligands, which hampers migratory insertion reactions and facilitates termination.

Initiation and Termination (Chain Transfer). End-group analysis (^{13}C nmr) of CO/ethene copolymer produced in *methanol* showed the presence of 50% ester [-C(O)OCH_3, **E**] and 50% ketone [-C(O)CH_2CH_3, **K**] groups, in accordance with the average overall structure of the polymer molecule as given in equation 1. It is not a priori clear which group is the "head" and which is the "tail" of the polymer. Moreover, gc and ms analyses of oligomer fractions show, in addition to the expected keto-ester (**KE**) chains, the presence of diester (**EE**) and diketone (**KK**) compounds (13).

$CH_3CH_2[C(O)CH_2CH_2]_nC(O)OCH_3$ $\quad n \geq 0$
Keto-ester (**KE**)

$CH_3O[C(O)CH_2CH_2]_nC(O)OCH_3$ $\quad n \geq 1$
Diester (**EE**)

$CH_3CH_2[C(O)CH_2CH_2]_nH$ $\quad n \geq 1$
Diketone (**KK**)

At low temperatures ($\leq 85^\circ$C) employing $Pd(dppb)^{2+}$ as the catalyst, the majority of the polyketone chains are **KE**, with only small but balancing quantities of **EE** and **KK** chains (13). At higher temperatures, the same products are produced in a ratio (**KE**:**EE**:**KK**) close to 2:1:1. These observations have been rationalized by assuming two competing termination mechanisms (13); *protonolysis* (*H*), leading to the formation of a ketone end group (**K**) and *methanolysis* (*M*), giving an ester end group (**E**). After termination via protonolysis a Pd-*methoxy* species is

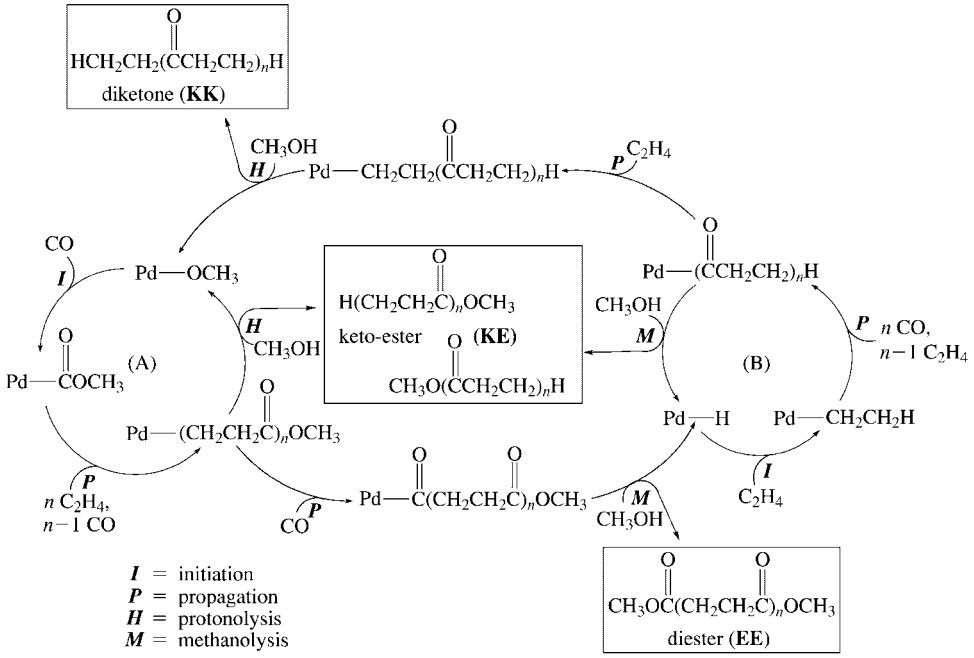

Fig. 4. Proposed chain transfer mechanisms, the *methoxy* cycle (A) and the *hydride* cycle (B) (reprinted in slightly adjusted form from Ref. 2).

obtained, which gives rise to the formation of an **E** end group at the start of the next copolymer chain it produces (cycle A), whereas after alcoholysis a Pd-*hydride* species is obtained, giving a **K** end group in the next chain (cycle B).

In Figure 4 the formation is summarized of the three possible polymeric chains, **KE**, **EE** and **KK**, formed by the two initiation–propagation–termination cycles A and B. Individually both cycles produce **KE** molecules, but the cycles are connected by the two "cross" termination steps which give **EE** and **KK** chains.

The formation of appreciable amounts of **EE** and **KK** at higher temperatures demonstrates that both chain transfer cycles contribute with comparable rates. The almost complete absence of the "crossover" products **EE** and **KK** at *lower* temperatures indicates that *one* cycle dominates. Rapid protonolysis and slow methanolysis would produce **KE** product via $PdC(O)OCH_3^+$ initiation (cycle A). Rapid methanolysis and slow protonolysis would produce the same product, but now via PdH^+ initiation (cycle B). Hence, product distribution alone is not sufficient to decide which cycle is responsible for the production of **KE** under these conditions. Crossover from A and B must have the same rate as termination within B, since the termination rate does not depend on how the chain started. Similarly, crossover from B to A has the same rate as termination within A. If the ratio of alcoholysis to protonolysis is k, the ratio of the products will be **EK**:**EE**:**KK** $= 1 + k^2$:k:k. A ratio of 2:1:1 implies that both termination steps contribute equally (k . Based on this finding, the ratio to which the chain transfer cycles A and B occur can be determined. The actual mechanism of alcoholysis has not been elucidated as yet.

In aprotic solvents and for CO/α-olefin- and CO/styrene-based copolymers, formation of vinyl-ketone [$R^1R^2C{=}C(R^3)C(O){-}$] and butenyl-ketone end groups has been reported (2,72,114).

Nature of the Catalyst in Polyketone Catalysis

Under actual slurry process conditions, 70–90°C; 5MPa (50 bar) CO/ethene, the nature of the initially homogeneous palladium(II)-based polyketone catalyst is rather complex. It may be present in at least three different states (I–III), each exhibiting its own kinetics. State I represents the running catalyst species, $[L_2Pd(CH_2CH_2C(O))_nCH_2CH_3]^+$ or $[L_2Pd(CH_2CH_2C(O))_nOCH_3]^+$, in the *homogeneous phase*, so being completely dissolved in methanol. Because of growth of the copolymer chain, the solubility of these species gradually decreases and at a certain chain length n, the running catalyst precipitates and becomes heterogeneous. Copolymer chain end-group analysis revealed that this phase transition occurs when n is about 13–20 and is accompanied by a change in the extent to which the two termination reactions, *alcoholysis* and *protonolysis* (*vide supra*), occur while the ratio of chain transfer vs propagation (k_t/k_p) increases (115).

The states II and III represent two types of heterogeneous catalyst species. Size exclusion chromatography showed the molecular weight distributions of CO/ethene-derived polyketone to be bimodal (116), indicating the presence of two different types of propagating catalyst sites that are not in fast equilibrium (117). The molecular weight distribution could be fitted with a combination of a Flory–Schulz distribution (type II; $M_w/M_n = 2$), typical of a homogeneous polymerization catalyst (118), and a Wesslau distribution (type III; $M_w/M_n \gg 2$), typical of a heterogeneous polymerization catalyst (119). It is conceivable that the catalytic sites producing a Wesslau distribution are sterically or physically congested, for example, because they are caught in the matrix or micropores of the polymer particles. The sites producing a Flory–Schulz distribution may be located on the external surface of the polyketone particles and therefore all face a similar environment. The ratio of polymer chains produced by the type II and III sites was found to be dependent on the copolymer particle size. Larger particles contain more of the longer chains produced by type III sites. Because of particle growth and agglomeration during a batch slurry run, the Wesslau contribution increases with time, and, as a consequence, the average molecular weight of the product gradually increases.

Manufacturing Process

The production of aliphatic polyketones at larger scale started in the market development unit (MDU; production capacity: 500 t/a) in Moerdijk, the Netherlands, in 1986 at Shell. The first commercial plant (capacity 7 kt/a) for the production of aliphatic polyketones came on stream in Carrington, U.K., in 1996. Production is carried out in a batch slurry process, by terpolymerization of CO, ethene, and propene in methanol at 70–90°C and 40–60 bar. The catalyst Pd(bdompp)$(TFA)_2$ (**2**) is suitably prepared in acetone by mixing palladium acetate,

1,3-bis-(di-(*o*-methoxyphenyl)phosphino)propane, and trifluoroacetic acid in a 1:1.02:4–10 ratio (see eq. 2).

The catalyst Pd concentration in the reaction solvent is usually about 5 ppm. The activity of the catalyst is about 8–10 kg terpolymer/(g Pd·h), throughout a batch run, typically lasting 8 h. The main commercial polyketone grades, PK-EP-6, contain about 6 mol% of propene and have a melting point of about 220°C and M_n = 37,000–52,000. After work-up and drying, the product is obtained as a snow white powder with a bulk density of 300–500 kg/m^3, and an average polymer particle size typically in the range of 200–600 μm, depending on the grade produced. The amount of Pd residue in the product is generally well below 10 ppmw.

The molecular weight of the various product grades is controlled mainly by the reaction temperature, the overall pressure, and the partial pressure ratio of the monomers. A small amount of water (2 vol%) is added to the reaction mixture to reduce the amount of methanol chemically bound to the terpolymer in the form of ketal groups. The initially encountered problems of extensive reactor fouling and low bulk density of the product were overcome simultaneously by introduction of a seed powder (typically 4–10 wt% PK-EP-6) in the reactor prior to the start of the polymerization and the use of an excess of acid in the catalyst solution. Both the seed powder and the excess of acid assist agglomeration of the newly formed terpolymer particles. The required excess of acid depends on the desired molecular weight.

A similar aliphatic polyketone product, Ketonex™, has been produced at pilot-plant scale by BP in Grangemouth, Scotland (120,121). Production was presumably carried out in a continuous slurry process.

Properties

Physical and Mechanical Properties. Perfectly alternating aliphatic polyketones based on ethene and CO, $-[CH_2CH_2C(O)]_n-$ (PK-E), have a relatively high melting point (T_m) of 257°C (122,123). This is about 125°C higher than the T_m of polyethylene, and reflects the strong polar group contribution, resulting from the regularly repeating ketone units. The alternating ketone groups in the polymer backbone confer polarity and high cohesive energy density to the polymer. The strong polar intermolecular forces, combined with a flexible polymer backbone, yield a semicrystalline material with a typical density of 1.24 g/cm^3 and a glass-transition temperature (T_g) near 15°C.

X-ray diffraction studies showed that the crystalline phase of PK-E may exist in two different forms, α and β (124,125). In both forms the copolymer chains are in an all-trans configuration, but the modes of chain packing differ. At room temperature, the crystalline phase exists primarily in the α-form. Depending on the way the material is prepared and pressure-treated, a phase transition takes place at about 120°C to the β-form. Above 120°C, the crystalline phase is exclusively in the β-form until it melts. This crystalline phase transition (CPT) is reversible, ie, upon cooling, the β-form (partly) transforms into the α-form again. The transition is accompanied by a volume change of about 5–7% (calculated densities for the α- and β-form are 1.383 and 1.297 g/cm^3, respectively) (124). In the differential scanning calorimetry thermogram, the CPT is observed as a small endotherm at 120°C

(126,127). The processes of spinning and drawing lead to the transformation of the β-crystalline part of PK-E into oriented α-crystalline material (128).

The crystallinity, T_m, and T_g of PK-E can be influenced by introduction of a third monomer such as propene (PK-EP) or a higher α-olefin such as decene (PK-ED) or dodecene (PK-EDo) (56–58). For example, random incorporation of 6 mol% propene in the polymer backbone (PK-EP-6) results in reduction of T_m from 257 to 220°C, while incorporation of 4 mol% dodecene (PK-EDo-4) reduces T_m to about 230°C. In PK-EP, propene is predominantly incorporated in the polymer chain in the 1,2- or 2,1-mode and, according to ^{13}C nmr in solution, only a small fraction is incorporated in the 1,3-mode.

Semicrystalline polyketones are insoluble in common organic solvents, and dissolve only in highly polar and acidic solvents such as hexafluoroisopropanol and *m*-cresol (>60°C). Related to this, polyketones demonstrate a high resistance to a broad range of chemicals and constitute good barriers both to small gases (such as oxygen) and to automotive fuels (129,130). Semicrystalline polyketones exhibit typical engineering thermoplastic characteristics, such as high impact strength, high heat distortion temperature, modulus (131), high resilience, and good wear and abrasion behavior. In a falling-weight impact test, PK-EP containing 3–6 mol% propene shows ductile failures down to −50°C. Replacement of the propene by 4 mol% dodecene (PK-EDo-4) lowers this temperature to −70°C. Also other mechanical properties of PK-EDo-4, such as stiffness, stability, and notched Izod impact strength, are significantly better than those of PK-EP-6.

Characteristics of typical low molecular weight (LMW) and high molecular weight (HMW) commercial grade materials of PK-EP-6 are given in Table 3.

The HMW grade is the standard grade for injection molding. The LMW grade is a high melt-flow injection molding grade and also the base material for compounding. Typical properties of the HMW grade are summarized in Table 4.

Relationships exist between T_g, T_m, and the type of termonomer introduced in the polymer and between T_g and the ductile to brittle temperature transition of polyketones in notched Izod or falling-weight impact strength test. For decene- or dodecene- containing grades T_m and T_g decrease simultaneously, while for propene-containing grades the opposite is observed (5).

Next to semicrystalline materials, perfectly alternating polyketones have also been manufactured, which exhibit amorphous, elastomeric, viscous, or side-chain liquid crystalline characteristics. An overview of some different types of polyketones is given in Table 5.

Oligomers of PK-P and PK-EP with a C_3/C_2 ratio of >0.4 are highly viscous liquids which can be cross-linked with a range of multifunctional reagents, such

Table 3. Characteristics of Two PK-EP-6 Grades[a]

Table 5. Overview of Various Types of Aliphatic Polyketones

Type	Monomers	Appearance	Potential uses	Source
PK-E	CO/C_2^{2-}	Semicrystalline; $T_m = 257°C$	Engineering thermoplast	10–13, 122
PK-EP	$CO/C_2^{=}/C_3^{2-}$ ($C_3 < 10$ mol%)[a]	Semicrystalline; $T_m = 180–250°C$	*Vide infra* (section D)	56
PK-EP	$CO/C_2^{=}/C_3^{=}$ ($C_3 > 20$ mol%)[a]	LMW: highly viscous	Thermosetting resins	132, 133
		$M_w > 10^5$ g/mol[b]: elastomeric	Films, adhesives	5, 58
PK-EDo	$CO/C_2^{=}/C_n^{2-}$ ($C_3 < 10$ mol%)[a]	Semicrystalline; $T_m = 180–250°C$	Engineering thermoplast	57
PK-P	$CO/C_3^{=}$	Atactic LMW: highly viscous	Thermosetting resins	132–134
		$M_w > 10^5$ g/mol: elastomeric[c]	Films, adhesives	5, 35
		Isotactic: semicrystalline	–	33, 64, 66
PK-S	CO/styrene	Syndiotactic: semicrystalline; $T_m = 280°C$	–	4, 39, 47
		Atactic: amorphous; $T_g \approx 100°C$	–	135
		Isotactic: semicrystalline; T_m = n.d.	–	
PK-ES	$CO/styrene/C_2^{=}$	Semicrystalline or amorphous	–	62, 64, 136
PK-Hd	CO/C_{16}^{2-}	$M_n \approx (5–8) \times 10^3$ g/mol,[d] highly viscous; $T_m = 13°C$	Wax crystal growth modifiers that lower the pour point of gas oils and crude oils	5, 137–139
PK-POd	$CO/C_3^{=}/C_n^{=}$ ($n = 18, 20$)	Elastomeric	Elastomers	5, 59

[a] On total amount of olefins. Olefins are represented C_n = where the superscript indicates a double bond and subscript n denotes the number of carbons in the olefin.
[b] Measured by gpc (rel. to polystyrene).
[c] Stereoirregular; regioregularity: 50–55% head-to-tail units.
[d] Measured by gpc (rel. to PMMA).

as diamines, to obtain new, both thermoset and thermoreversible, performance resin systems (79,132,133). These systems, marketed by Shell under the trade name Carilite, (can) find application in coatings, composites, and adhesives.

Product Stability. During melt-processing, polyketones undergo intermolecular and intramolecular aldol condensation reactions (140–144). The intermolecular degradation reactions (*cross-linking*) lead to an increase in the melt viscosity and limit the melt-processing window (145). These reactions are catalyzed by impurities, such as salts (ions) and catalyst residues (146). Because of the lower melting point, the PK-EP grades (with $T_m \approx 220^\circ C$) have a substantially improved melt-processing window compared to PK-E ($T_m \approx 257^\circ C$). This, in combination with the application of high turnover palladium catalysts, improved manufacturing techniques (147), and the discovery of efficient melt-stabilizers such as calcium hydroxy apatite (148,149) led to a significant reduction in cross-linking during melt-processing. As a result, polyketone thermoplastics have become readily processable using conventional techniques, such as injection molding, extrusion, blow molding, hot-plate molding, and fiber spinning.

During aerobic heat aging, aliphatic polyketones can undergo complex oxidation reactions, manifested in part by molecular weight loss. Specific hindered phenolic type antioxidants have been identified, which significantly reduce molecular weight loss, allowing maintenance of mechanical properties for a long period (150). The typical continuous use temperature or UL index of stabilized neat PK-EP is currently 90–95°C. [*Note*: *UL index* (Underwriters' Laboratory) is defined as the (service) temperature at which the polymer loses 50% of a certain property within an agreed period of time. The property selected is the most critical property in the application envisaged. UL indices are found by extrapolation in an Arrhenius plot of failure vs aging temperatures. Usually they are based on extrapolation to 11000 h.]

Because of the presence of carbonyl groups, aliphatic polyketones are prone to degradation upon exposure to uv light. The mechanisms are based on chain-scission reactions, described in the literature as Norrish type I and Norrish type II reactions (151). Addition of uv absorbers is required to improve the photostability of unpigmented polyketone polymers, but is less effective for maintenance of surface-related properties (152,153). Ultravioletabsorbing pigments such as carbon black can also be used to significantly retard photodegradation in aliphatic polyketones.

Filled and Reinforced Aliphatic Polyketone Compounds. Aliphatic polyketones can be compounded with inorganic fillers, reinforcing agents, and lubricants (154). Compounds are produced using a co-rotating twin-screw extruder, with a typical melt temperature of 260°C.

Within Shell Chemicals, a number of fillers have been evaluated. These include chopped glass fibers, mica, wollastonite (a calcium silicate mineral), and calcium carbonate (nonreinforcing mineral filler). In all cases improvements in flexural modulus, flexural strength, and heat distortion temperature were found, the levels corresponding to the reinforcing ability of the filler. Fiber glass gave the best improvement, followed in decreasing order by mica, wollastonite, and calcium carbonate. The notched Izod values followed this same order of ranking, with the exception that mica-filled PK-EP-6 exhibits the lowest impact values. The results demonstrate that aliphatic polyketones can be readily compounded

with traditional fillers at relatively high loading levels and that filled polyketones exhibit property relationships similar to those of other engineering thermoplastics.

Flame-Retardant Aliphatic Polyketone Compounds. In the electrical and electronic industries, there is an increasing demand for materials with good flame retardancy (UL-94 VO rating and limiting oxygen index $\geq$ 28%). This often necessitates the addition of flame-retardant additives into plastics. Various halogenated compounds are very effective flame retardants. In recent years, however, governmental, regulatory, and public pressures have supported the use of halogen- and red phosphorus-free flame retardants because of environmental, toxicity, corrosivity, and smoke generation concerns. In this context, much attention has been given to hydrated fillers, such as aluminum and magnesium hydroxide, which function by releasing water upon endothermic decomposition. Polyketones have been found to be excellent base materials for halogen- and red phosphorus-free flame retardants at loading levels much lower than generally required in other thermoplastics (20–30% vs typically 50–60% for polyolefins and polyamides). This low loading level helps to preserve mechanical properties and the ductility and toughness of the aliphatic polyketone. On account of its low viscosity, which facilitates filler incorporation, a relatively high melt-flow aliphatic polyketone is used as a base material for flame-retardant compositions. Since aliphatic polyketones are generally melt-processed at temperatures above the decomposition temperature of aluminum hydroxide, but below that of magnesium hydroxide, the latter was selected as flame retardant for polyketones (155). In addition, a unique mineral, partially hydrated magnesium calcium carbonate ($MgCaCO_3$) was found to exhibit good flame retardancy for polyketones, even at low loading levels.

Of the hydrated fillers evaluated, magnesium hydroxide is more efficient than $MgCaCO_3$. Surface modification of magnesium hydroxide preserves impact properties. Addition of glass fibers increases the strength, rigidity, and dimensional stability of halogen- and red phosphorus-free flame-retardant aliphatic polyketone compositions.

Uses

The processing advantages offered by aliphatic polyketones have proven to be particularly attractive. The polymer is suitable for many conventional melt-processing methods, without any need for predrying. Injection molding of aliphatic polyketones is characterized by fast setting, ensuring that molding times are short. Comparative tests with other engineering thermoplastics have shown that reductions in cycle time of up to 50% can be achieved by using aliphatic polyketones, without any compromise in the functionality of the molded parts or the overall balance of performance properties. The shrinkage of nonfilled grades is isotropic. Moldings exhibit an excellent mold definition and are marr-resistant. If molded correctly, even large, flat moldings are warp-free. Parts can be assembled "dry as molded" without any need for conditioning or annealing.

Automotive Applications. Aliphatic polyketones (PK-EP-6) are characterized by the following performance attributes: good thermal dimensional stability, good low temperature impact behavior, and excellent resistance to fuels

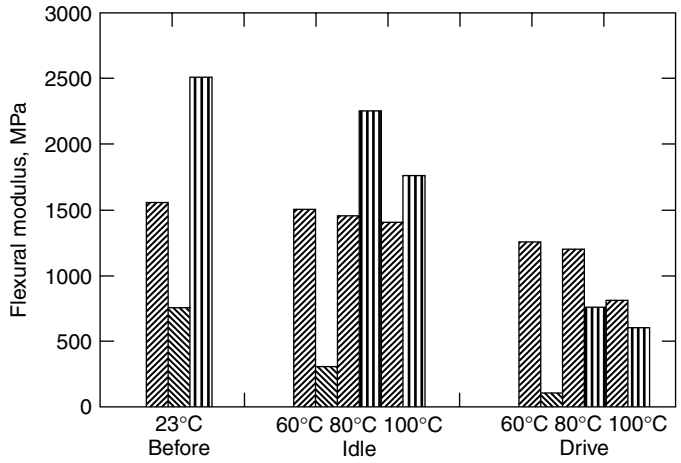

Fig. 5. Aging performance in diesel fuel (3000 h). ▨ PK; ▧ HDPE; ▥ POM. To convert Mpa to psi, multiply by 145.

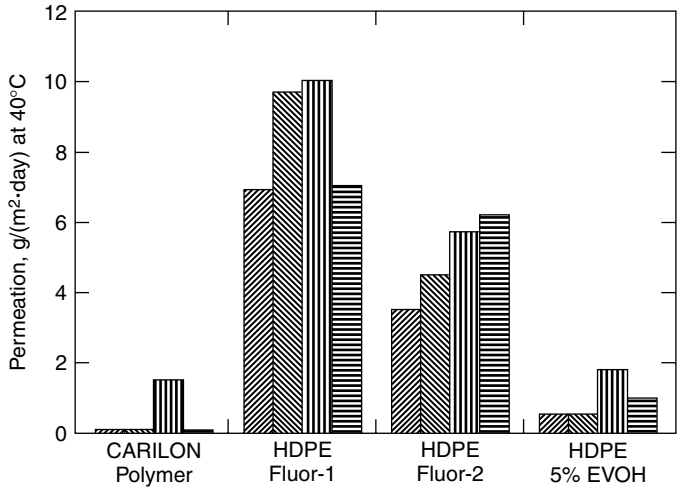

Fig. 6. Fuel permeation. ▨ Petrol; ▧ TF1; ▥ TF2; ▤ TF3. *Note:* Based on European standard fuel Halterman (CEC-RF-08-A-85). TF-1 = 90% + 10% EtOH, TF-2 = 92.5% + 7.5% EtOH, TF-3 = 95% + 5% EtOH. HDPE Fluor-1 and HDPE Fluor-2 refer to fluorinated HDPE fuel tanks from different suppliers. HDPE 5% EVOH is an HDPE, ethylene vinyl alcohol multilayer system.

(Fig. 5), coolants, transmission fluids, oils, and greases, with virtually no fuel permeation (Fig. 6). These attributes make these materials well suitable for a variety of automotive applications, such as fuel tanks, fuel system components, fuel pumps, fuel filters, injection rails, sensors, transmission seal rings, bearing cages, and rubber reinforcements (156). Only relatively small molecules capable of hydrogen bonding, such as water and methanol, give rise to a minor degree of

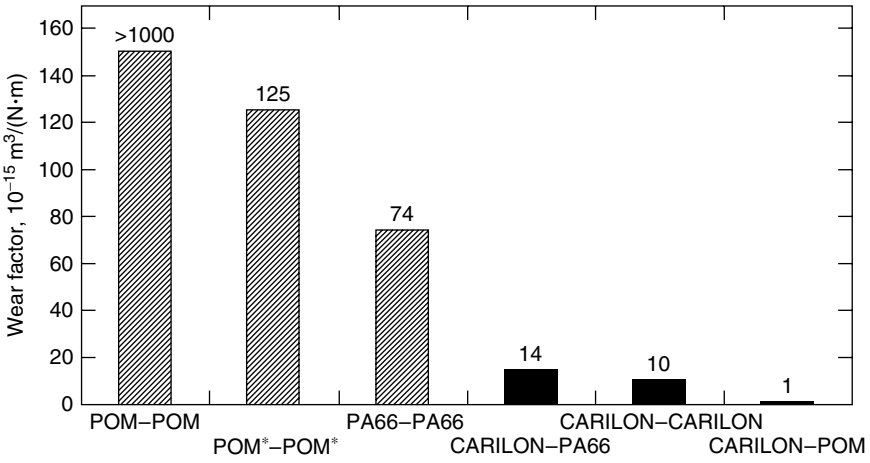

Fig. 7. Wear resistance of like and unlike polymer pairings. POM∗: POM, PTFE-modified.

swelling, exhibiting a plasticizing mechanism. PK-EP-6 is particularly resistant to aqueous media, including weak acids, bases, and salt solutions such as zinc chloride (up to 50%).

Polyketones can be considered for both monolayer and multilayer constructions. The combination of good barrier properties, dimensional stability in the presence of fuel, and high burst pressures affords the possibility of a simple monolayer construction. Should multiple layers be required, an inexpensive two-layer construction based on polyethylene and polyketones has been demonstrated to exhibit good structural strength, barrier performance, and interlayer adhesion, both with and without a tie layer.

Consumer Applications. The excellent wear resistance of aliphatic polyketones is a particularly interesting feature. Field experience has shown that tribological arrangements such as gear trains can become more attractive if at least one of the components is made from aliphatic polyketones (157) (Fig. 7). In plastic arrangements where lubrication is not desired, arrangements with aliphatic polyketones generate low wear and low noise. The wear characteristics of aliphatic polyketones in like polymer pairings is much lower than which would be achieved with polyamide–polyamide or polyacetal–polyacetal arrangements, and this even applies when comparisons are made with specially lubricated PTFE-modified materials.

Aliphatic polyketones are used in power lawn and garden industry because of the good wear resistance, insensitivity to water, chemical resistance, and ease of molding. Other application areas related to the good wear performance are in sports and recreational equipments. Outlets are also found in the medical sector because of the autoclavability, sterilizability, and chemical resistance of aliphatic polyketones. Polyketones are FDA-approved, which is important for food contact applications.

Electrical and Electronic Applications. Flame-retardant aliphatic polyketone compounds are formulated to meet UL-94 V-0 and V-1 classifications,

and offer a good balance between flame resistance, electrical properties, stiffness, toughness, and elongation at break. High tracking resistance is complemented by resistance to electrolytic corrosion, high glow wire temperature, and low smoke density. No corrosive flue gases are produced, and flame retardancy is achieved with mineral flame retardants. Aliphatic polyketone compounds have found outlets in connectors, cable ties, and electromechanical devices.

Industrial Applications. Aliphatic polyketones possess a combination of properties such as chemical resistance, resilience, snapability, tribological properties, and impact performance, that are important for industrial applications. Aliphatic polyketones are able to withstand cleaning processes such as spraying with hot and cold water, blowing with hot air, exposure to hot steam, and exposure to detergents or weak bleaches. Typical areas of application are bottling, cleaning, conveyor belting, pumps or offshore applications, pipe-liner applications, and industrial filters and brushes.

Fiber Applications. Aliphatic polyketones also offer high potential as an anisotropic material (158). The maximum stretch ratio which has been obtained for aliphatic polyketones is 26:1. This has been determined for fibers produced via solution-spinning (159,160), the spin technique allowing the largest degree of disentanglements. The maximum stretch ratio of aliphatic polyketones is higher than that of polyamides and polyesters (respectively 6:1 and 10:1), but lower than that of polypropylene and polyethylene (respectively 48:1 and 300:1) (161). This indicates the ease of stretching and the intrinsic ability of polyketones to obtain a more oriented molecular structure than polyamides and polyesters. Because of the presence of carbonyl groups, the level of secondary molecular interactions on the other hand is stronger than for polyolefins, allowing an oriented molecular structure to be maintained in use, a weakness for polyolefins, as is indicated by the poor creep resistance of polyolefins.

Although PK-EP-6 can be solution-spun with excellent results (162), the most feasible/economic way to produce fibers is via melt-spinning. Melt-spun aliphatic polyketone fibers can be stretched to high ratios, yielding high levels of molecular orientation, and so strong and stiff fibers, as is demonstrated in Figure 8.

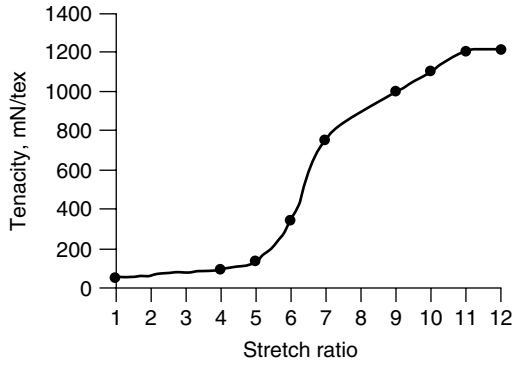

Fig. 8. Tenacity as a function of the stretch ratio of melt-spun aliphatic polyketones (PK-EP-6). To convert mN/tex to g·f/den, multiply by 11.33×10^{-3}.

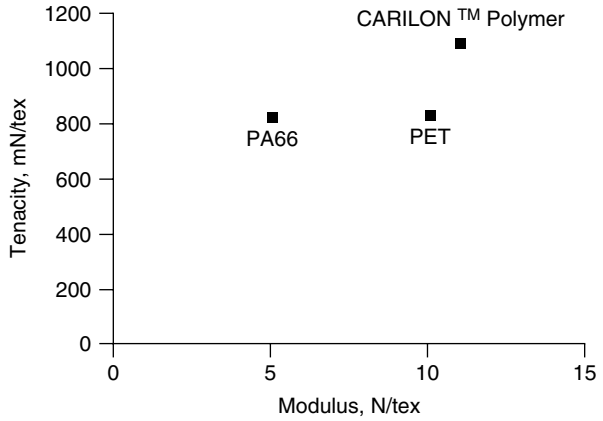

Fig. 9. Balance between tenacity and modulus for different fiber meterials. To convert mN/tex to g·f/den, multiply by 11.33×10^{-3}.

As Figure 9 shows, aliphatic polyketone fibers position well as compared to melt-spun polyamide-66 and poly(ethylene terephthalate) fibers.

The good tensile properties achievable with fibers made from PK-EP-6 make it an obviously attractive material for reinforcement in rubber applications, such as tires, hoses, and belts. In view of the inherent structure of aliphatic polyketones, which is vulnerable to photolytic attack if not adequately protected, direct exposure to sunlight should be limited, which is avoided in the case of rubber reinforcements.

The good chemical and hydrolytic resistance of aliphatic polyketone fibers, which has to be balanced with its thermal oxidative stability, provides them new opportunities as filter material, eg papermaking cloth or fuel filters.

Outlook

The development of aliphatic polyketones adds a new chapter to the history of polymers. These perfectly alternating co- or terpolymers are accessible by the transition-metal-catalyzed polymerization of readily available, cheap feedstocks, CO and olefins. The origin of the remarkable, perfectly alternating nature of the polymers can be found in a subtle interplay between thermodynamic and kinetic factors during catalysis, along with the interaction of the polar polymer chain-end with the electrophilic catalytic metal center. A parallel is noticed between polyketone catalysis and modern olefin polymerization catalyzed by early transition-metal or iron complexes. However, while in the latter, electrophilic activation of just one type of monomer, ie olefins, is involved, polyketone catalysis requires the simultaneous activation of two totally different types of monomers, ie CO and olefins, with different coordination capabilities and reactivity characteristics. It is therefore not surprising that the present, first generation of commercial palladium(II)-based polyketone catalysts show as yet a considerably lower activity than homogeneous polyolefin catalysts. Although the current catalyst activity is sufficiently high to make production of polyketones economically viable,

future catalyst research has to be directed toward the development of more active, more efficient, and (better) recyclable catalytic systems. Most recent research (*vide supra*) has already shown that subtle changes in catalyst structure can afford a huge boost in activity and monomer reactivity ratio, while a first high activity catalyst based on nickel(II) has just been discovered.

As shown, aliphatic polyketones present a broad new class of polymers with a wide range of properties and applications. An important additional asset of these polymers is their ecological friendliness. In production, their direct synthesis from readily available base-chemicals, principally accessible from renewable feedstocks such as ethanol or biomass, overcomes the synthesis of complex monomers, which is often unavoidably accompanied by the generation of significant waste streams, as in the case of other engineering plastics such as polyamides. In use, because of their unique balance of properties and associated wide range of applications, polyketones can play a vital role in the sustainable development of mobility by significant weight reduction of automotive vehicles, as well as by reduction of hydrocarbon emissions from these vehicles by the use of integrated nonhydrocarbon permeable polyketone fuel systems. In addition, polyketones can be recycled and, since they contain only C, H, and O-atoms, are perfectly suited for clean energy production or for recycling back to feedstock, eg by gasification, at the end of their service life.

Aliphatic polyketones are still in an early phase of product development and at present, only terpolymers based on CO, ethene, and propene are in a well-enough advanced state of development for use as engineering thermoplastics. Future research into the structure–performance relationships of co- and terpolymers based on these and other olefinic monomers will lead to a controlled molecular tailoring and designing of polymers with desired properties.

POLYNUCLEOTIDES

Introduction

Hereditary information is stored within the nucleic acids DNA and RNA. Natural nucleic acids are polymeric, consisting of monomers known as nucleotides, and hence the term "polynucleotide" can be used to refer to DNA and RNA. Information is encoded within the sequence of nucleotides in these polymers as specific tracts defined as genes. The information is passed on to progeny by replication and converted into protein products by *transcription*/*translation* (a process known as gene expression). While considerable progress in understanding the biological role of nucleic acids was made in the first half of the twentieth century, it was the proposal of the double-helical structure for DNA in 1953 (1) that allowed researchers to begin probing, mimicking, and manipulating the nucleic acids at the molecular level (2). The importance of this cannot be overstated: virtually all advances in molecular biology and biotechnology rest on the foundations of nucleic acid chemistry and biology.

This article describes the structural and functional properties of the polynucleotides, DNA and RNA., beginning with a description of how these polymers are synthesized through enzymatic catalysis or by stepwise, solid-supported chemical methods. Next, the structural features of DNA and RNA are described, followed by the most commonly used methods for studying the properties of polynucleotides.

A variety of synthetic polynucleotide analogues are presented next. Once the DNA structure and base-pairing rules were identified, synthetic chemists could begin preparing unnatural analogues. These compounds are important for testing various theories regarding the relationship between the primary structures of DNA/RNA and their tendency to fold into specific three-dimensional structures.

Encyclopedia of Polymer Science and Technology. Copyright John Wiley & Sons, Inc. All rights reserved.

In addition, synthetic analogues are finding increasing utility as diagnostic probes and therapeutic agents.

Next strategies for sequence-specific recognition of polynucleotides are described. Preservation and processing of the genetic information *in vivo* requires sequence-specific recognition of DNA and RNA by proteins and other nucleic acids. Unraveling biological mechanisms for recognition has led to several classes of compounds that can be designed to bind to most, if not all, sequences of DNA and RNA. The most successful of these compounds are themselves oligomeric or polymeric, reflecting the need for relatively large molecular structures to interact sequence specifically with polynucleotides.

The penultimate section of this article presents one of the truly paradigm-shifting discoveries of the late twentieth century: the demonstration that RNA could act as an enzyme, catalyzing a variety of chemical reactions. The extension of this work to the *in vitro* evolution of sequences with unique catalytic and binding properties represents the introduction of the nucleic acids into what was once thought to be the exclusive realm of proteins.

Finally, the article concludes with a description of how polynucleotides are finding applications in materials sciences. In particular, the sequence-specific molecular recognition mechanisms that define precise, relatively rigid three-dimensional structures have led materials scientists to adopt polynucleotides as construction materials for the noncovalent synthesis of intricate, ordered structures. Thus, the very molecules that fueled the biotechnological revolution are now being incorporated into the foundation of the next revolution, namely nanoscience and nanotechnology.

The following sections describe in fairly general terms the chemistry, biology, and physics of DNA, RNA, and their synthetic analogues. Key references to books, review articles, and the primary literature are provided to permit the interested reader to find more detailed descriptions of the various topics.

Polynucleotide Structure

The most widely recognized secondary structure for a biopolymer is the DNA double helix. However, DNA is capable of forming a variety of nonduplex secondary structures either transiently or at equilibrium. Moreover, the structural landscape available to RNA is vast, because RNA normally exists in the absence of a complementary strand. This allows RNA to fold into complex three-dimensional shapes, analogous to proteins, and exhibit many diverse functions. This section reviews the primary, secondary, and tertiary structures adopted by polynucleotides.

Primary Structure. The primary structure of DNA differs from RNA only in the absence of the 2′-OH group and the replacement of the uracil nucleobase with thymidine (Fig. 1). The monomer itself comprises a phosphate group, a ribose or deoxyribose sugar ring, and a nucleobase. Each of these components is important for the formation of the most common of DNA and RNA structures, the right-handed double helix. DNA and RNA polymers are polyelectrolytes by virtue of the anionic phosphate groups positioned at regular intervals along the phosphodiester backbone. These charges introduce to the polynucleotides intra- and interstrand electrostatic repulsive forces that affect the thermodynamic stabilities of various secondary and tertiary structures. Meanwhile, the backbone sugar rings

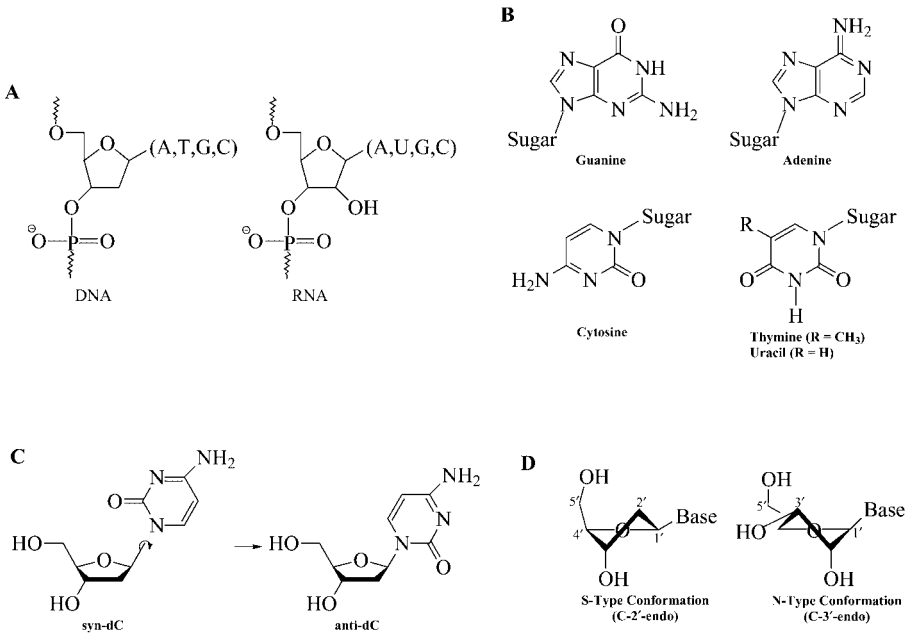

Fig. 1. Elements of DNA/RNA primary structure. (**A**) backbone units, (**B**) nucleobase structures, (**C**) glycosidic bond rotation interconverts syn and anti conformations, and (**D**) preferred sugar puckers for deoxyribose (left) and ribose (right).

can adopt two limiting conformations, the C3′-endo and the C2′-endo, that influence the orientation of the backbone and the base (Fig. 1). Also, the orientation of the nucleobase relative to the sugar ring (ie syn or anti) is variable but crucial to secondary structure formation (Fig. 1) (3,4).

The primary structure of oligonucleotides can be written using the notation 5′-dpApGpTpC-3′. The 5′ refers to the position of the exocyclic methylene carbon of the DNA backbone (Fig. 1). The "d" denotes that the sugar rings are deoxyribose; in the case of RNA the "d" will not be present. The "p" refers to the locations of the phosphate groups that create phosphodiester linkages to the 5′ and/or the 3′ sugar carbons of the adjacent monomers, and A, G, T, and C are abbreviations for adenosine, guanosine, thymidine, and cytidine respectively (U = uridine in RNA). In addition to the standard nucleobases, a variety of modified nucleobases are found in RNA, particularly transfer RNA. These modifications are introduced post-transcriptionally by enzymes.

Secondary Structure.

The Double Helix. The most common secondary structure formed by DNA and RNA is the double-stranded helix (1). The double helix places the negatively charged phosphate groups on the periphery where they are exposed to water, while the bases are π stacked in the interior with the nucleobases forming interstrand pairs through hydrogen-bonding interactions (Fig. 2) (5). Wrapping of the two strands around one another creates two concave surfaces, referred to as the *minor and major grooves*. The edges of the base pairs form the floors of the grooves, while the sugar rings and phosphate groups comprise the walls of the grooves.

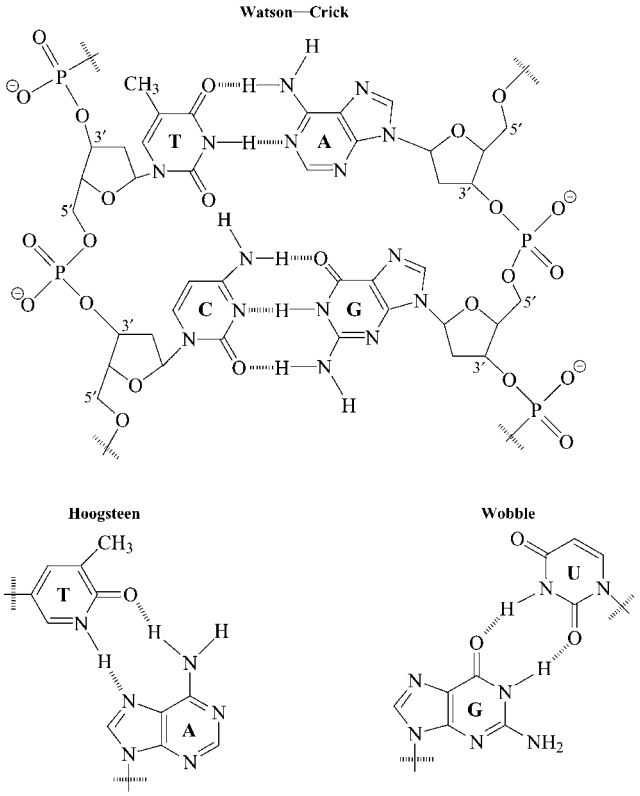

Fig. 2. Hydrogen-bonding patterns in polynucleotides, including Watson–Crick pairing characteristic of duplex DNA and RNA (top); Hoogsteen pairing formed in triplex structures (bottom left); and wobble pairing often found in RNA (bottom right).

The canonical Watson–Crick base pairs utilize NH and NH_2 groups of the nucleobases as hydrogen bond donors, while the electron pairs of carbonyl carbons and ring nitrogens serve as hydrogen bond acceptors (Fig. 2). The recognition of the purine bases (A and G) by the pyrimidine bases (T and C) establishes the fidelity of DNA transcription. Non-Watson–Crick base pairs have been observed, the most important of which are the Hoogsteen pairs and the "wobble" pairs (Fig. 2). These noncanonical base pairs give rise to triplex structures, and also allow for the considerable variations from the standard duplex form observed in many DNA and RNA sequences.

Given the conformational flexibility of the monomer units, it is no surprise that the double helical secondary structure can actually be subdivided into families of structurally distinct polymorphs (see Table 1 for helix parameters) (6). DNA double helices most commonly adopt the B-form, while A-form helices are the most common RNA secondary structures. These helices have a right-handed helix sense and utilize the Watson–Crick base pairing mentioned above (Fig. 3). In addition, both the A- and B-form orient the glycosidic bond in the anti conformation. A major difference between the A- and B-form structures is the positioning of the base pairs relative to the helix axis. In B-DNA the base pairs are centered

Table 1. Helix Parameters

Parameter	A-Form DNA	B-Form DNA	Z-Form DNA	A-Form RNA
Helix twist	Right	Right	Left	Right
Residues per turn	11	10.5	11.6	11
Helix diameter, nm	2.3	2.0	1.8	–
Sugar pucker	C3′-endo	C2′-endo	C2′-endo	C3′-endo
Glycosidic bond orientation	anti	anti	anti (A, T, C), syn (G)	anti
Displacement of bp from axis, nm	0.45	−0.002 to −0.18	−0.2 to −0.3	0.44
Major groove	Narrow, deep	Wide, deep	Flat, very shallow	1
Minor groove	Wide, shallow	Narrow, deep	Narrow, very deep	1

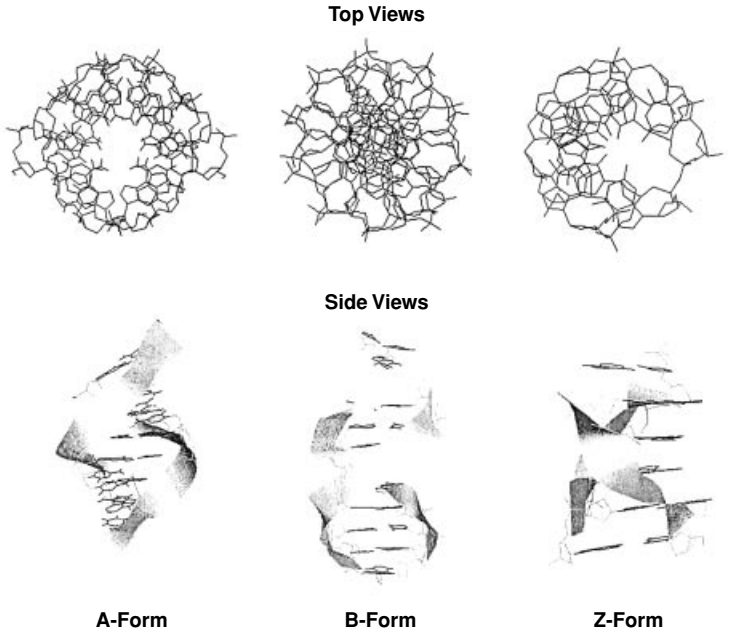

Fig. 3. Top and side views of three DNA double-helical conformations. In the side views, the base pairs are shown in black and ribbons are traced along the DNA backbones to illustrate the helicity.

on the helix axis and lie roughly perpendicular to the axis. In A-DNA the base pairs are shifted toward the minor groove by 0.45 nm and are tilted, leading to a deep and narrow major groove, but a shallow and wide minor groove relative to B-DNA (3,4). When viewed from the above, this leads to a "filled" cylinder for B-DNA, but an open channel running through A-DNA (Fig. 3).

Z-DNA is a left-handed double-stranded helix (Fig. 3) favored by high concentrations of NaCl or $MgCl_2$ and alternating G–C sequences. Z-DNA is less tightly wound (11.6 vs 10.5 base pairs per helical turn) and therefore forms a narrower helix than B-DNA. Z-DNA has a characteristic zigzag appearance to its backbone,

which arises from alternation between the syn and anti conformations of the guanine and cytosine bases respectively. This leads to a major groove that is extremely shallow (almost flat) and a minor groove that is very deep (7). Although B-form DNA is most common *in vivo*, the existence of Z-form DNA *in vivo* has led to intensive studies of its potential biological role (8).

The A-, B-, and Z-form helices are model helices that do not fully represent the range of helical structures observed by nmr and x-ray analysis of DNA and RNA. Each base sequence can have its own structure that will influence the curvature, rigidity, and even the groove widths and depths. While the degree to which the local structure of double-helical DNA varies with sequence has been recently questioned (9), extreme cases such as the highly curved structures of oligo(dA)–oligo(T) sequences are well-established (3,4). Moreover, biologically relevant properties such as hydration, flexibility, and the positioning of hydrogen-bond donor and acceptor groups in the two grooves are clearly sequence-dependent.

Triplexes and Beyond. Watson–Crick base pairing leaves hydrogen-bond donor and acceptor groups exposed in the major groove of B-form DNA. Oligonucleotides can bind within the major groove of B-form DNA to form triple-helical complexes stabilized by Hoogsteen hydrogen bonding (Fig. 2). These structures form most readily at homopurine–homopyrimidine sequences, using either homopurine or homopyrimidine third strands (10–12). Although most studies have utilized a separate third strand to form the triplex, certain sequences of duplex DNA can form triplexes by folding back of one strand into the major groove of the duplex at a remote site, leaving its partner strand unpaired. This structure, referred to as "H-DNA," (13) has not yet been identified *in vivo*, although speculation has focused on its possible involvement during genome replication.

Tetrahelical structures of DNA can also form from guanine-rich sequences (14). These structures are stabilized by G-tetrads formed via Hoogsteen hydrogen bonding of four guanines in a roughly square orientation (Fig. 4). Adjacent tetrads stack on top of one another, but with a potassium or magnesium cation sandwiched in between. Quadruplexes can form from four separate strands, two separate strands, or from the intramolecular folding of a single strand. It is postulated that G-quadruplexes are formed in the single-stranded extensions of chromosomes

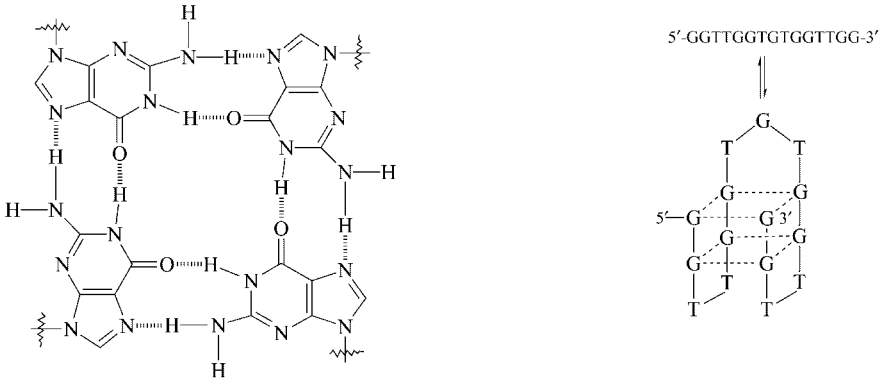

Fig. 4. Hydrogen bonding pattern in guanine (G)-tetrads (left) and intramolecular folding of a 15-base DNA sequence into a G-quadruplex motif (right).

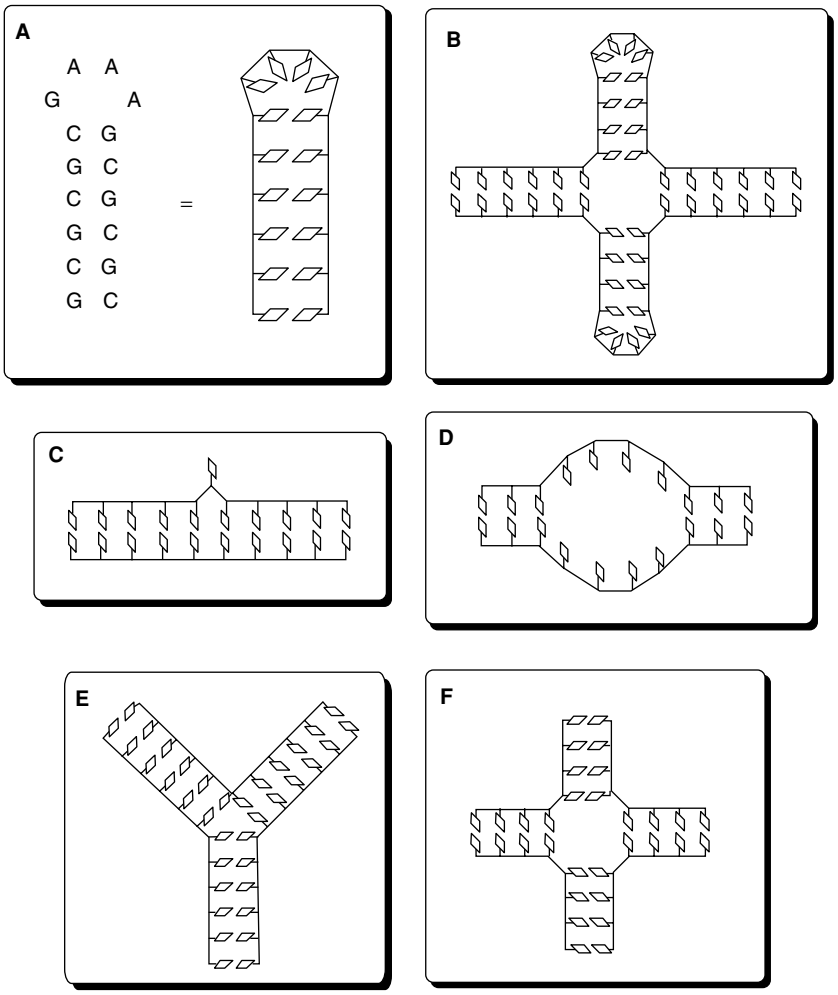

Fig. 5. Nonduplex polynucleotide secondary structures: hairpin (**A**), cruciform (**B**), bulge (**C**), bubble (**D**), three-way junction (**E**), and four-way junction (**F**).

known as telomeres. Telomeric DNA consists of thousands of repeats of a G-rich sequence that can form G-quadruplexes. Telomeric repeats are lost over the life cycle of somatic cells, and when the telomere becomes suitably short, cell death is triggered. This loss of repeats is compensated for by the enzyme telomerase, which extends the telomeres and therefore cell life. Telomerase activity has been observed in over 80% of all tumor types, suggesting a link with cell immortalization and tumorigenesis and spurring intense study of the G-quadruplex as a specific target for antitumor drugs (10).

Other Oligonucleotide Structures. DNA and RNA sequences can form many nonduplex secondary structures (Fig. 5). For example, bulges are formed when one or more unpaired bases are present within one strand of an otherwise base-paired structure. Unpaired bases present on both strands at a given

position are referred to as *bubbles*. Whether these non-hydrogen-bonded bases are stacked within the helix or flipped out toward the aqueous solvent is highly sequence-dependent. Bulges have been implicated in protein/RNA recognition and are sometimes necessary for the tertiary folding of catalytic RNAs (15,16).

Hairpins can form when there are complementary sequences within the same strand but separated by a noncomplementary region, such as the sequence 5′-CGCGCGCGAAAGCGCGCG-3′ where the central GAAA forms the loop and the underlined bases at the termini form the stem (Fig. 5). If a hairpin is formed within the context of double-stranded DNA, the complementary strand can also fold into a hairpin, yielding a cruciform structure, or remain unpaired. Such structures likely serve as binding sites for proteins. Furthermore, the hairpin motif is one of the most common secondary structure elements observed in RNA (17).

With appropriately designed sequences, three-way and four-way junctions can form (Fig. 5) (15). The four-way junction is particularly noteworthy, as it constitutes the key intermediate in homologous recombination, where the two chromosomes within a given pair mix with one another (18,19). Four-way junctions formed from synthetic oligonucleotides have provided useful models for these intermediates and have been used as design elements in nanoconstruction (*vide infra*).

Tertiary Structure. Unlike DNA, an RNA molecule normally exists *in vivo* in the absence of its complementary strand. This allows RNA to fold into a plethora of sequence-dependent three-dimensional structures. The secondary structures are based on loops, bulges, and helices, but many of these elements can bend, turn, and fold upon themselves, allowing for tertiary interactions to occur between unpaired hydrogen-bonding sites. For example, two complementary loop sequences can hybridize with one another to form a short Watson–Crick duplex that stabilizes an entropically unfavorable conformational restriction (Fig. 6). However, two secondary structure elements need not recognize one another through Watson–Crick base pairing. Certain loop sequences will bind tightly to helical regions in a sequence-specific manner. In many cases, these tertiary interactions are stabilized by hydrogen bonding involving the 2′-OH group from the ribose ring, a feature that is missing from a corresponding DNA polynucleotide (20). These long-distance (relative to the primary structure) interactions allow for many three-dimensional shapes to be formed (21,22). This leads to an almost endless variety of structure in DNAs and RNAs that allows for the specific recognition of biological macromolecules, and even reaction catalysis.

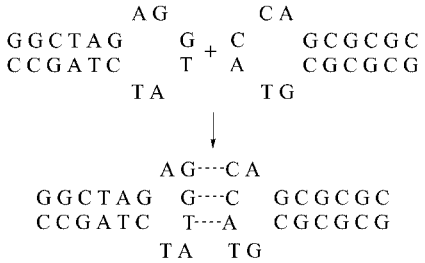

Fig. 6. Tertiary interaction between two complementary loops forms a "kissing complex" through Watson–Crick base pairing.
