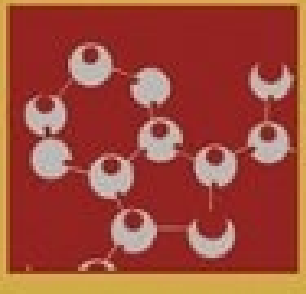
ENCYCLOPEDIA OF POLYMER SCIENCE AND TECHNOLOGY

THIRD EDITION



ACETYLENIC POLYMERS, SUBSTITUTED

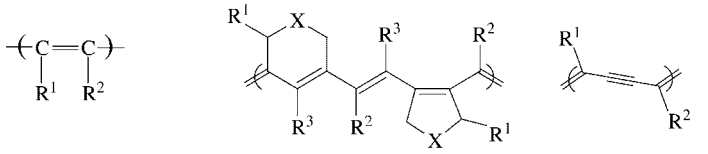
Introduction

Polymerization of acetylene was first achieved by Natta and his co-workers using a Ti-based catalyst (1). Because of the lack of processability and stability, early studies on polyacetylenes were motivated by theoretical and spectroscopic interests only. Then the discovery of the metallic conductivity of doped polyacetylene (2–6) stimulated research into the chemistry of polyacetylene, and now polyacetylene is recognized as one of the most important conjugated polymers. The finding by Natta and co-workers was followed by the modification of their catalytic system. An explosive expansion in polyacetylene chemistry has been caused by the entry of the Shirakawa catalyst $Ti(O\text{-}n\text{-}C_4H_9)_4$–$(C_2H_5)_3Al$. Its very unique ability to give a thin film of polyacetylene (7,8) has attracted the interest of solid-state physicists, which has significantly contributed to the fundamental chemistry of conjugated macromolecules.

Unfortunately, the intractability and unstability of polyacetylene strictly inhibit its practical applications. Thus, an introduction of substituents onto polyacetylene backbone has been investigated to improve its processability. Early attempts led to the conclusion that only sterically unhindered monosubstituted acetylenes can be polymerized with the Ti-based Ziegler–Natta catalysts. Traditional ionic and radical initiators also lack the ability to provide high molecular weight polymers from substituted acetylenes. In 1974 the first successful polymerization of substituted acetylene was achieved when it was found that "Group 6" transition metals are quite active for the polymerization of phenylacetylene to a polymer with molecular weight over 10^4 (9). After this finding, there has been much effort to develop highly active catalysts, to tune the polymer properties, and

Encyclopedia of Polymer Science and Technology. Copyright John Wiley & Sons, Inc. All rights reserved.

also to precisely control the polymer structure. These energetic studies have produced a wide variety of polymers from acetylene derivatives including mono- and disubstituted acetylenes, α,ω-diynes, and 1,3-diacetylenes. The carbon–carbon alternating double bonds in main chains of these polymers provide an opportunity to obtain unique properties such as conductivity, nonlinear optical properties, magnetic properties, permeability, photo- and electroluminescent properties, and so on, which are not accessible from the corresponding vinyl polymers.



Many papers in the literature have followed the finding by Masuda and coworkers (9). This article covers the literature from the mid-1980s up to mid-2000. As a result of the rapid growth in the area, the chemistry of polymers from acetylene, 1,3-diacetylenes, and α,ω-diacetylenes are excluded (see POLYACETYLENE; DIACETYLENE and TRIACETYLENE POLYMERS). The first focus is on the polymerization reaction of substituted acetylenes with various transition metal catalysts. The synthesis of functionally designed polyacetylenes is also covered. Readers are encouraged to access other reviews and monographs on polyacetylene (10–14), on 1,3-diacetylenes (15–19), and on α,ω-diynes (20,21). Previous review articles are also helpful to survey the chemistry of substituted polyacetylenes (10,13,22–29).

Polymerization Catalysts

A variety of transition metal catalysts have been found to polymerize substituted acetylenes. Effective catalysts range from Group 3 to Group 10 metals. Activity of catalysts greatly depends on monomer structure; therefore, it is quite important to recognize the characteristics of each catalyst. Table 1 lists recent representative examples for the polymerization of substituted acetylenes with various transition metal catalysts, which will help readers to understand the general features of catalysts.

Group 3 Transition Metals. Examples for the polymerization of substituted acetylenes with "Group 3" transition metals are rather limited (134). Ziegler–Natta catalysts based on Group 3 transition metals polymerize acetylene and its derivatives (32,33,62). The combination of Sc or lanthanide transition metals with trialkylaluminum, eg, M(naphthenate)– and M(phosphonate)–*i*-$(C_4H_9)_3Al$, has been proven to provide high molecular weight polymers from terminal aliphatic and aromatic alkynes. High molecular weight polymers (M_n > 30,000) are available from aliphatic linear alkynes such as 1-hexyne and 1-pentyne, whereas 1-alkynes with branching at α or β-position, eg, 3-methyl-1-pentyne and 4-methyl-1-pentyne, result in polymers in low yields (32,33). In a similar way, phenylacetylene polymerizes in the presence of a ternary

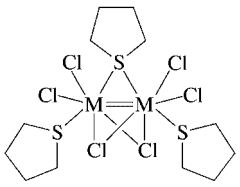
[g] Ring-opening polymerization.

Ln(naphthenate)–*i*-$(C_4H_9)_3Al$–C_2H_5OH catalyst (62). Sc- and Nd-based catalysts are relatively effective among the other Group 3 transition metals including 15 lanthanide elements. One of the characteristic points of these catalytic systems is the selective formation of cis-cisoidal polymers. Thus, poly(phenylacetylene) formed with Ln(naphthenate)–*i*-$(C_4H_9)_3Al$–C_2H_5OH is crimson, crystalline, and insoluble. The resultant poly(phenylacetylene) gradually dissolves into *o*-dichlorobenzene at 135°C (62), which probably results from the thermally induced cis-to-trans isomerization of the main chain.

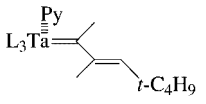
Group 5 Transition Metals. The most probable side reaction in the polymerization of acetylenes is cyclooligomerization that is well promoted by "Group 5" transition metals. For example, cyclotrimerization of 1-alkynes readily occurs in the presence of $NbCl_5$ (135–137). Thus, bulky substituents must be incorporated into the monomers for the successful formation of polymers by Group 5 transition metals. In other words, Ta and Nb catalysts suit the polymerization of disubstituted acetylenes.

The most convenient catalysts are $TaCl_5$ and $NbCl_5$. Both catalysts can polymerize disubstituted acetylenes such as 3-octyne (138) and 1-phenylpropyne (116). The use of cocatalysts such as *n*-$(C_4H_9)_4Sn$, $(C_2H_5)_3SiH$, $(C_6H_5)_3Sb$, $(C_6H_5)_3Bi$, and $(C_6H_5)_4Sn$ accelerates the polymerization and suppresses the polymer degradation, leading to the formation of ultra high molecular weight polymers. For example, polymers with molecular weight above 10^6 are obtained from 1-trimethylsilyl-1-propyne (113) and diphenylacetylenes (121) with $TaCl_5$–$(C_6H_5)_4Sn$. Without a cocatalyst, diphenylacetylenes give no polymers (120). It has been reported that well-characterized dinuclear Nb and Ta complexes (**1**) polymerize disubstituted acetylenes (139). Like $NbCl_5$ and $TaCl_5$, cyclooligomerization dominates over the polymerization in the case of monosubstituted acetylenes. The Nb version of (**1**) gives good yields of polymers compared with the Ta analogue. Ta carbene (**2**) induces living polymerization of 2-butyne (105).



M = Ta, Nb

1



(L = OC_6H_3-*o*, *o*-*i*-$(C_3H_7)_2$)

2

Monosubstituted acetylenes generally prefer cyclotrimerization to polymerization in the presence of halides of "Group 5" metals as described earlier (135–137). The polymerization of monosubstituted acetylenes by $NbCl_5$ and $TaCl_5$ catalysts is possible only in the case of sterically crowded monomers, which is exemplified by the polymerization of 3-trialkylsilyl-1-alkynes with the formula of HC≡CCH($Si(CH_3)_2R$)R′ (R = CH_3, *n*-C_6H_{13}, C_6H_5; R′ = *n*-C_3H_7, *n*-C_5H_{11}, *n*-C_7H_{15}) (45). Even *tert*-butylacetylene affords a low yield of polymer in the presence of $TaCl_5$ or $NbCl_5$. Additionally, the molecular weights of these Ta- and Nb-based poly(*tert*-butylacetylene)s are lower than those of the W-based ones. However, there has been a demonstration of the unique ability of

2,6-dimethylphenoxyo (dmp) complexes of Nb, $Nb(dmp)_nCl_{5-n}$ (dmp = OC_6H_3-*o,o*-CH_3, $n = 1$ or 2) with cocatalysts such as C_2H_5MgBr or $(C_2H_5)_3Al$, to polymerize terminal acetylenes such as *tert*-butylacetylene and phenylacetylene (30,31). From *tert*-butylacetylene, extremely high molecular weight polymers are available. Even poly(phenylacetylene) prepared with $Nb(dmp)Cl_4$–*t*-C_4H_9MgCl possesses relatively high molecular weight ($M_n = 19{,}000$). Such an exceptional ability of $Nb(dmp)_nCl_{5-n}$–cocatalyst originates from the presence of bulky aryloxo groups that have the same effect as bulkiness on the monomer.

Group 6 Transition Metals. This class is most widely employed because of their high ability to polymerize a wide range of substituted acetylenes (10,23,25, 26). We shall classify "Group 6" transition metals into the following four categories: metal halide catalysts, metal carbonyl catalysts, metal carbene catalysts, and metal alkylidene catalysts.

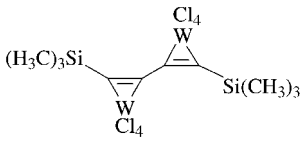
Metal Halide Catalysts. $MoCl_5$ and WCl_6, the most convenient "Group 6" transition metal catalysts, give high yields of polymers from various monosubstituted acetylenes, especially from bulkily monosubstituted acetylenes. In the case of sterically not very crowded monomers such as 1-*n*-alkyne and phenylacetylene, the yields and molecular weights of polymers are unsatisfactory ($M_n < 1 \times 10^5$) because of the unavoidable formation of cyclotrimers (140). In contrast, sterically crowded monomers like *tert*-butylacetylene and ortho-substituted phenylacetylenes selectively polymerize with $MoCl_5$ and WCl_6 to give high molecular weight polymers. $MoCl_5$ or WCl_6 alone are unfortunately inactive for disubstituted acetylenes.

Appropriate organometallic cocatalysts such as *n*-$(C_4H_9)_4Sn$, $(C_2H_5)_3SiH$, $(C_6H_5)_3Sb$, $(C_6H_5)_3Bi$, and $(C_6H_5)_4Sn$ remarkably activate $MoCl_5$ and WCl_6 catalysts and allow the effective polymerization of even disubstituted acetylenes such as 2-octyne (103) and 1-chloro-1-octyne (106). Living polymerization is also possible by applying this catalyst system (141). For example, in the presence of an appropriate protic additive (*e*g, C_2H_5OH, *t*-C_4H_9OH), $MoOCl_4$–*n*-$(C_4H_9)_4Sn$ gives polymers with narrow molecular weight distributions ($M_w/M_n < 1.1$) from various mono- and disubstituted acetylenes (25,27,28).

A systematic study was made on the nature of W-based catalysts, $W(dmp)_nCl_{6-n}$–cocatalyst ($n = 1$–4), in the polymerization of terminal acetylenes (30,31). The catalytic activity of $W(dmp)_nCl_{6-n}$ is generally lower than that of WCl_6 because the electron-donating phenoxy ligands reduce the Lewis acidity of the metal. However, these catalysts are characterized by the ease of fine-tuning of the activity, which can be simply performed by varying the number of ligands. $W(dmp)_nCl_{6-n}$ catalyzes the polymerization of *tert*-butylacetylene to give an extremely high molecular weight polymer in the presence of cocatalysts such as C_2H_5MgBr and $(C_2H_5)_3Al$. Emphasis should be placed on the fact that the enhanced bulkiness around W in $W(dmp)_nCl_{6-n}$ enables the polymerization of *n*-alkylacetylenes, leading to high molecular weight polymers. This contrasts to the feature of the WCl_6–catalyzed polymerization that generally results in low molecular weight polymers from the less sterically hindered monomers such as 1-alkynes ($M_n \sim 10^4$). For example, $W(dmp)_4Cl_2$–C_2H_5MgBr transforms 1-octyne into an elastomer with M_n of 350,000, while WCl_6 provides yellow viscous oil.

It has been reported that a stable W-based butadiyne complex (**3**) polymerizes ortho-substituted phenylacetylenes (142) and monosubstituted arylacetylenes

having condensed aromatic rings to give polymers having extended main-chain conjugation (89).



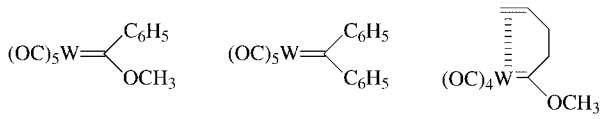
3

Metal Carbonyl Catalysts. Mo or W hexacarbonyl alone cause no polymerization of acetylenes. However, upon uv irradiation in halogenated solvents such as CCl_4, various substituted acetylenes readily polymerize with Mo and W hexacarbonyls (10,23,25,26). $Cr(CO)_6$ as well as other "Group 7" metal carbonyls such as $Mn_2(CO)_{10}$ and $Re_2(CO)_{10}$ yield no active species under similar conditions. CCl_4, used as a solvent, plays a very important role for the formation of active species, and therefore, cannot be replaced by toluene, that is often used for metal chloride-based catalysts. Although the activity of metal carbonyl catalysts is low compared with the metal halide catalysts, they provide extremely high molecular weight polymers. Another advantage of metal carbonyl catalysts is their stability, which facilitates the experimental procedure.

An alternative metal carbonyl catalyst, $(Mes)Mo(CO)_3$ (Mes = mesitylene), also catalyzes the polymerization of substituted acetylenes in CCl_4 (143). Photoirradiation is unnecessary for this system; the ligating mesitylene is readily released by heating, which allows the polymerization to proceed without photoirradiation. In a similar way, photoirradiation can be omitted by using $(CH_3CN)_3M(CO)_3$ as a catalyst (144).

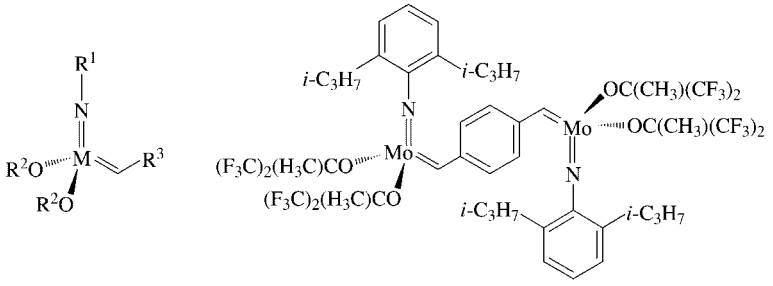
The use of $(C_6H_5)_2CCl_2$ enables the omission of CCl_4 in the metal-carbonyl catalyzed polymerization of acetylenes. For example, the polymerization of phenylacetylene with $W(CO)_6$ in the presence of $(C_6H_5)_2CCl_2$ in toluene proceeds homogeneously and gives a polymer with M_n of 17,000 in 68% yield upon photoirradiation (58,59). Very high molecular weight polymers ($M_w > 10^5$) are attainable from sterically bulky aromatic and aliphatic acetylenes. An alternative metal carbonyl catalyst, $MCl_2(CO)_3[As(C_6H_5)_3]$ (M = Mo, W), that catalyzes the ring-opening polymerization of norbornenes has been shown to polymerize *tert*-butylacetylene and ortho-substituted phenylacetylenes without photoirradiation or the use of CCl_4 (37).

Metal Carbene Catalysts. The first use of isolated single-component carbene catalysts showed that the Fischer (**4**) and Casey carbenes (**5**) polymerize phenylacetylene, *tert*-butylacetylene, and cyclooctyne in low yields (130). For example, the bulk polymerization of *tert*-butylacetylene with (**4**) gives a high molecular weight (M_n = 260,000) polymer in 28% yield. Polymer-supported Fischer carbene (**4**) is also active for the polymerization of phenylacetylene under photoirradiation (145). As a catalyst, the Casey carbene (**5**) is less stable but more active than the Fischer carbene (130). The Rudler carbene (**6**) readily releases the intramolecularly ligated double bond upon the approach of an acetylenic monomer. Thus, it is more active than the Fischer and Casey carbenes (146–148). These carbene complexes are, however, unable to control the polymerization.



4 5 6

The polymerization chemistry of substituted acetylenes has been explosively evolved by the development of well-characterized Mo- and W-based metal carbenes with the structure of (**7**). Although the preparation of these catalysts is somewhat tedious, they elegantly function as living polymerization catalysts for substituted acetylenes such as ortho-substituted phenylacetylenes (84,149) and α,ω-diynes (150–152). Since the initiation efficiency is quantitative, polymers with a desired molecular weight are available. The structure of both terminal ends can be controlled by using appropriate terminating agents. The bifunctional Schrock carbene (**8**) bisinitiates the polymerization of diethyl dipropargylmalonate, $(HC{\equiv}CCH_2)_2C(CO_2C_2H_5)_2$, giving telechelic living polymers (151). Details for the living polymerization are described herein.



7 8

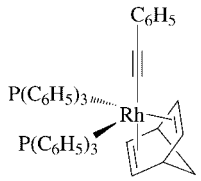
Metal Alkylidyne Catalysts. Metal alkylidyne complexes such as $(CO)_4BrW{\equiv}CC_6H_5$ (153) and $(t\text{-}C_4H_9O)_3Mo{\equiv}C\text{-}n\text{-}C_3H_7$ (131) serve as catalysts for the polymerization of substituted acetylenes. Speculated initiation mechanisms of $(CO)_4BrW{\equiv}CC_6H_5$-catalyzed polymerization involve its isomerization into a metal carbene species $(CO)_4W{=}CBrC_6H_5$. The complex, $(t\text{-}C_4H_9O)_3Mo{\equiv}C\text{-}n\text{-}C_3H_7$, which is formed by the reaction of $Mo_2(O\text{-}t\text{-}C_4H_9)_6$ with 4-octyne, catalyzes the polymerization of cyclic acetylene (131). The polymerization of cyclooctyne proceeds in a ring-opening fashion to give an insoluble linear polymer with M_n and M_w/M_n estimated to be 8600 and 7.0, respectively, after the hydrogenation of the polymer into polyethylene. Ring-opening polymerization of cyclooctyne is also achieved with a W catalyst, $W_2(O\text{-}t\text{-}C_4H_9)_6$ (132). The reaction of cyclooctyne with $W_2(O\text{-}t\text{-}C_4H_9)_6$ gives a bifunctional metal alkylidene complex *in situ* $(t\text{-}C_4H_9O)_3W{\equiv}C(CH_2)_6C{\equiv}W(O\text{-}t\text{-}C_4H_9)_3$; thus, bisinitiation takes place to give a polymer having active species at both terminal ends (132).

Group 8 Transition Metals. Iron-catalyzed polymerization of substituted acetylenes has a long history (22,25,60). Well-used iron catalysts have a general formula of $Fe(acac)_3{-}R_nAlCl_{3-n}$, and they are readily prepared *in situ*. $Fe(acac)_3{-}(C_2H_5)_3Al$ is employed most frequently. This is a heterogeneous catalyst and is able to polymerize sterically unhindered terminal acetylenes such as *n*-alkyl-, *sec*-alkyl-, and phenylacetylenes. On the contrary, monomers having bulky

substituents such as *tert*-alkylacetylenes and disubstituted acetylenes cannot be polymerized with the Fe catalysts. Although Fe catalysts cannot precisely control the polymerization, they show very high activity and often give very high molecular weight polymers. Poly(*n*-alkylacetylenes) obtained with Fe catalysts are orange-colored, soluble, rubbery, and have high molecular weights (154). Similar to the lanthanide catalysts as noted previously, Fe catalysts provide cis-cisoidal polymers, which was evidenced by the C—H out-of-plane deformation at 740 cm^{-1} in the ir spectrum. Thus, poly(phenylacetylene) formed with $Fe(acac)_3$–$(C_2H_5)_3Al$ is insoluble and crystalline (61). See later for the stereospecific polymerization with Fe catalysts.

Group 9 Transition Metals. A significant contribution to the recent tremendous strides in the chemistry of substituted polyacetylenes is undoubtedly based on the finding of excellent activity of Rh catalysts (25,26,29). The most characteristic feature of Rh catalysts is their very high activity for the polymerization of phenylacetylenes to give high molecular weight polymers with almost perfect stereoregularity (cis-transoidal). Furthermore, the excellent ability of Rh catalysts to tolerate various functional groups including amino, hydroxyl, azo, radical groups, and so on allows the production of highly functionalized polymers (Table 1).

The first example of the Rh-catalyzed polymerization employed $RhCl_3$–$LiBH_4$ for the polymerization of phenylacetylene (60). The use of protic solvent (ethanol) accelerates the polymerization, and a cis-transoidal polymer selectively forms. After this discovery, a variety of Rh catalysts have been developed (Table 2). Cationic Rh catalysts such as $(nbd)Rh^+[(\eta^6\text{-}C_6H_5)B^-(C_6H_5)_3]$ (38) and dinuclear Rh complexes, $[(nbd)RhCl]_2$ and $[(cod)RhCl]_2$ (29), are frequently employed. $[(nbd)RhCl]_2$ is usually more active and stable than $[(cod)RhCl]_2$ (64,157). The Rh-catalyzed polymerization proceeds in various solvents such as benzene, tetrahydrofuran, ethanol, and triethylamine (47,64). Among the solvents, ethanol and triethylamine are favorable for phenylacetylenes from the viewpoint of both polymerization rate and polymer molecular weight (64). The most widely applied catalyst is $[(nbd)RhCl]_2$–$(C_2H_5)_3N$ (29). Use of this catalyst allows the polymerization of phenylacetylenes to give excellent yields of stereoregular polymers with high molecular weights ($M_n > 10^5$). Living polymerization of phenylacetylenes is feasible using a well-characterized Rh catalyst such as $(nbd)C_6H_5C{\equiv}CRh(P(C_6H_5)_3)_2$ (**9**) (168–171). Multicomponent catalysts, $[(nbd)RhOCH_3]_2$–$P(C_6H_5)_3$ (172) and $[(nbd)RhCl]_2$–$LiC(C_6H_5){=}CPh_2$–$P(C_6H_5)_3$ (173), have been proven to be active for the living polymerization of phenylacetylenes. In the latter case, the initiation species is a vinylrhodium (**10**) that was isolated and well characterized by x-ray analysis (174). Details for the living polymerization are described in the next section.



9

Table 2. Rh Catalysts for the Polymerization of Substituted Acetylenes

Catalyst	Reference	Catalyst	Reference
$RhCl_3$–$LiBH_4$	60	$[(cod)Rh(SC_6F_5)]_2$	164,165
$[(cod)RhCl]_2$	(29,63,155,156)	$(cod)Rh(SO_3C_6H_4$-*p*-$CH_3)(H_2O)$	166
$[(nbd)RhCl]_2$	(29,47,64,157–160)	$[(nbd)Rh(acac)]_2$	167
$(cod)Rh^+B(C_6H_5)_4^-$–$HSi(C_2H_5)_3$	161	$(nbd)Rh^+[(\eta^6$-$C_6H_5)B^-(C_6H_5)_3]$	38
$(nbd)Rh^+(dbn)_2PF_6^-$	162	$(nbd)C_6H_5C{\equiv}CRh(P(C_6H_5)_3)_2$ (**9**)	168–170–171
(nbd)Rh(dbn)Cl	162	$[(nbd)RhOCH_3]_2$–$P(C_6H_5)_3$	172
	163	$[(nbd)RhCl]_2$–$(C_6H_5)_2C{=}C(C_6H_5)Li$–$P(C_6H_5)_3$	173
		$(nbd)(C_6H_5)_2C{=}C(C_6H_5)Rh(P(C_6H_5)_3)_2$ (**10**)	174
	(63,155,156)		175

Polymerization of phenylacetylenes is feasible even in aqueous media by using water-soluble catalysts. For example, $(cod)Rh^{+}(mid)_2PF_6^{-}$ (mid = *N*-methylimidazole) provides cis-transoidal poly(phenylacetylene) (cis 98%) in high yield (98%) (166). Other catalysts, $(cod)Rh(SO_3C_6H_4\text{-}p\text{-}CH_3)(H_2O)$ and $(nbd)Rh(SO_3C_6H_4\text{-}p\text{-}CH_3)(H_2O)$, work as water-soluble catalysts to produce cis-transoidal polymer (166). The polymerizations can be done under air; thus, a poly(phenylacetylene) thin film (thickness ca 250 nm) is readily obtained by dropping a dilute chloroform solution of phenylacetylene onto the water surface of a dilute aqueous solution of $(cod)Rh(SO_3C_6H_4\text{-}p\text{-}CH_3)(H_2O)$ in an open beaker (166).

Polymerization of phenylacetylene in compressed (liquid or supercritical) CO_2 has been studied using a Rh catalyst, $[(nbd)Rh(acac)]_2$ (167). Higher polymerization rate is obtained in CO_2 than in conventional organic solvents such as THF and hexane. Polymerization in the presence of a phosphine ligand, $\{p\text{-}[F(CF_2)_6(CH_2)_2]\text{-}C_6H_4\}_3P$, predominantly produces cis-transoidal polymers, while, without the ligand, both cis-transoidal and cis-cisoidal polymers are formed.

Rh catalysts have been recently applied to the polymerization of propiolic esters (47). Amines cannot be used as cocatalysts in this case because of the high reactivity of propiolic esters toward nucleophiles. Rh-catalyzed polymerization of propiolic esters is accompanied by unavoidable side reactions such as linear- and cyclooligomerizations; thus, the yields of poly(propiolic esters) are rather unsatisfactory (15–60%). Relatively high yields of poly(propiolic esters) with high molecular weights are accessible when the polymerization is conducted in alcohols or acetonitrile at high monomer and catalyst concentrations (50). A characteristic feature is the almost perfect stereoregularity of the polymers, which is in contrast to the Mo-catalyzed polymerization of propiolic esters (48). Stereoregular cis poly(propiolic esters) exist in a well-ordered helical conformation. See later for details for the synthesis of helical polyacetylenes.

A disadvantage of the Rh-catalyzed polymerization is recognized in the poor availability of monomer. Monomers that can be effectively polymerized are limited to phenylacetylene and its para- and meta-substituted derivatives and propiolic esters. $[(nbd)RhCl]_2$–$(C_2H_5)_3N$-catalyzed polymerization of monosubstituted acetylenes having bulky substituents such as *tert*-butylacetylene and ortho-substituted phenylacetylenes is sluggish, and the latter gives insoluble polymers in low yield. However, a cationic rhodium complex, $(nbd)Rh^{+}[(\eta^6\text{–}C_6H_5)B^{-}(C_6H_5)_3]$, shows higher activity than $[(nbd)RhCl]_2$–$(C_2H_5)_3N$, and is able to effectively polymerize bulky monomers including *tert*-butylacetylene and 3-phenyl-1-butyne (38). Disubstituted acetylenes cannot be polymerized with Rh catalysts. Only one exceptional example has been found by using cyclooctyne as a monomer whose very large ring strain (∼38 kJ/mol) enables very rapid polymerization with $[(nbd)RhCl]_2$, giving an insoluble polymer in good yield (133).

Group 10 Transition Metals. Group 10 transition-metal catalysts including Ni and Pd are generally not adequate for the polymerization of acetylenes because these catalysts tend to lead to the cyclooligomerization rather than the polymerization. Exceptional examples have been found by using $Ni(NCS)_2P(C_6H_5)_3$ (51) and $[Pd(C{\equiv}CR)_2(P(C_6H_5)_3)_2]$ (R = $Si(CH_3)_3$, CH_2OH, $CH_2N(CH_3)_2$) (52,176). Polymers with a relatively high molecular weight are formed with these late transition metal catalysts. Another successful polymerization of substituted acetylenes with "Group 10" metals is achieved by utilizing enhanced free energy

difference between the monomer and polymer. Namely, highly strained cyclooctyne readily polymerizes with Pd and Ni catalysts including $PdCl_2$, $Pd_2(dba)_3$, $Pd(CH_3CN)_2(OTs)_2$, $Ni(cod)_2$, and so forth (133).

Ionic Catalysts. Preparation of polyacetylenes having satisfactory molecular weights is impossible by ionic processes. For example, anionic polymerization of phenylacetylene is claimed to be accompanied by the electron transfer from the active center to the conjugated chain, which causes the formation of low molecular weight oligomers (177). Attempts to ionically polymerize acetylene derivatives have been made using zwitterionic monomers such as *N*-methyl-2-ethynylpyridinium salts (178–180) and phosphonium acetylenes ($C_6H_5C{\equiv}C^+P(C_6H_5)_3Br^-$) (181). The degree of polymerization is generally below 25. However, the ability of these monomers to anionically polymerize offers block copolymers with common vinyl monomers such as styrene, which would provide a new route to functional materials. Relatively high molecular weight polymers ($\sim$10,000) can be obtained by the *tert*-C_4H_9OK-initiated proton transfer polymerization of acetyleneamides (182). Much higher reactivity of acetyleneamides than that of acrylamides allows one to conduct the polymerization under the mild conditions to give formally alternating copolymers of acetylene with isocyanates.

Precision Polymerization

In these two decades remarkable progress has been made in the development of excellent catalysts for living and stereospecific acetylene polymerizations (10,26–28). The π-conjugated polymers prepared by the sequential polymerization are strictly limited to polyacetylenes, except for only a few examples. Thus, synthesis of tailor-made conjugated macromolecules such as end-functionalized polymers, block copolymers, star-shaped polymers is possible only in the case of substituted acetylenes.

General. As stated in the preceding section, diverse transition metals from Group 3 to Group 10 elements initiate the polymerization of substituted acetylenes. Catalysts that achieve living polymerization, however, are quite limited, which contrasts to a wide variety of living polymerization catalysts for vinyl monomers. The catalysts are classified into the following groups: (1) metal halide catalysts, (2) metal carbenes, and (3) Rh complexes. As described later, attention should be paid on the fact that the structure of monomers undergoing living polymerization significantly depends on the type of catalyst. Thus, appropriate catalysts must be selected in order to synthesize well-defined polymers from the individual monomer.

Living Polymerization by Metal Halide Catalysts. Metal halide-based living polymerization catalysts possess a general formula of MO_nCl_m–cocatalyst–ROH (M = Mo or W, $n = 0$ or 1, $m = 5$ or 4) (10,25–28). The most striking feature of these catalysts is the ease in preparation. One can readily generate these catalysts *in situ* just by mixing these three components. The living polymerization of substituted acetylenes has been achieved, for the first time, by using a Mo-based multicomponent catalyst. The ability of a protic additive, ethanol, to control the polymerization of 1-chloro-1-octyne with $MoCl_5$–*n*-$(C_4H_9)_4Sn$ in toluene has been demonstrated (141). Poly(1-chloro-1-octyne) with narrow molecular weight

distribution ($M_w/M_n < 1.2$) is attainable in the presence of $MoCl_5$–*n*-$(C_4H_9)_4Sn$–C_2H_5OH. The living nature was confirmed by the linear dependence of molecular weight on monomer conversion and by the successful initiation of the polymerization of second-charged monomers with the living prepolymer. The use of $MoOCl_4$ instead of $MoCl_5$ provides propagation species with a longer lifetime (183). For example, in the case of $MoCl_5$–*n*-$(C_4H_9)_4Sn$–C_2H_5OH, bimodal poly(1-chloro-1-octyne) is formed if the monomer is further added after the complete consumption of the initially fed monomer. On the other hand, the deactivation of the active chain end is not observed under the $MoOCl_4$–*n*-$(C_4H_9)_4Sn$–C_2H_5OH system, which leads to the formation of unimodal polymers after a similar multistage polymerization (184). Other cocatalysts including $(C_6H_5)_4Sn$, $(C_2H_5)_3SiH$, and $(C_6H_5)_3Bi$ do not induce living polymerization, and only *n*-$(C_4H_9)_4Sn$ and $(CH_3)_4Sn$ give living poly(1-chloro-1-octyne). Internal acetylenes such as 2-nonyne also undergo living polymerization (185). The living nature of the polymerization of 2-nonyne is remarkably enhanced by conducting the polymerization in anisole instead of toluene. Although the polymerization rate is not dependent on the length of alkyl chain, the position of the acetylenic triple bond drastically affects the polymerization rate; that is, the polymerization rate decreases in the order of 2-alkyne > 3-alkyne > 4 alkyne (185). In a similar way, $MoCl_5$–*n*-$(C_4H_9)_4Sn$–C_2H_5OH induces living polymerization of ring-substituted phenylacetylenes (141). Bulky substituents (*eg*, CF_3, $Si(CH_3)_3$, *i*-C_3H_7), however, should be incorporated into the ortho position in order to exclude cyclotrimerization (140,186–189). Thus, living nature is slightly low in the case of *o*-methylphenylacetylene (190). It is interesting that phenylacetylene derivative, HC≡CC_6F_4-*p*-*n*-C_4H_9, having no bulky ortho substituent polymerizes with $MoOCl_4$–*n*-$(C_4H_9)_4Sn$–C_2H_5OH in a living fashion to yield a polymer with low polydispersity (191).

Replacement of toluene with anisole as polymerization solvent remarkably improves the living nature, leading to both an increase in initiation efficiency and a decrease in polydispersity. For instance, the initiation efficiency of *o*-trifluoromethylphenylacetylene increases from 9 to 42% in anisole (192). The ability of anisole to improve the living nature enables living polymerization of 1-chloro-2-phenylacetylene (192); living polymer from this monomer is inaccessible in toluene (193).

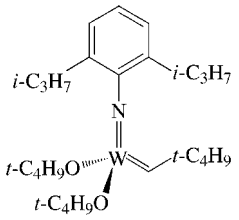
The effects of organometallic components have been systematically investigated. In toluene, only *n*-$(C_4H_9)_4Sn$ and $(CH_3)_4Sn$ cocatalyze living polymerization (184). However, the use of anisole expands the availability of cocatalyst; $(C_2H_5)_3Al$ (194), $(C_2H_5)_2Zn$ (195), and *n*-C_4H_9Li (196) can be used as cocatalysts. It is interesting that the addition of the third component, the protic additive, is not necessary in the case of *n*-C_4H_9Li. Variation of cocatalysts affects the initiation efficiency and block copolymerization behavior. Initiation efficiency decreases in the order of *n*-$(C_4H_9)_4Sn$ > $(C_2H_5)_3Al$ > $(C_2H_5)_2Zn$ > *n*-C_4H_9Li. Consequently, extremely high molecular weight polymers ($>10^5$) with very narrow molecular weight distribution (<1.03) are attainable by using $MoOCl_4$–*n*-C_4H_9Li (196). Block copolymerizations have been examined by using various monomers and cocatalysts (197). $MoOCl_4$–*n*-$(C_4H_9)_4Sn$–C_2H_5OH appears to be most effective for the selective formation of block copolymers from various monomers. For example, in the block copolymerization with $MoOCl_4$–$(C_2H_5)_3Al$–C_2H_5OH, reverse of the feed order often causes deactivation of the living chain end, giving a mixture of

homo- and copolymers. On the other hand, with $MoOCl_4$–*n*-$(C_4H_9)_4Sn$–C_2H_5OH, block copolymers with narrow molecular weight distributions selectively form from various substituted acetylenes even if the order of monomer addition is changed (197).

Tungsten-based multicomponent catalysts, $WOCl_4$–*n*-$(C_4H_9)_4Sn$–*t*-C_4H_9OH, $WOCl_4$–*n*-C_4H_9Li, and $WOCl_4$–C_2H_5MgBr, have been proven to achieve controlled polymerizations of *o*-trifluoromethylphenylacetylene, *o*-trimethylsilylphenylacetylene, HC≡CC_6F_4-*p*-*n*-C_4H_9, 3-decyne, and 5-dodecyne (198,199). On the other hand, analogous combinations of WCl_6 with cocatalysts are ineffective for living polymerization of these monomers.

$NbCl_5$ has been reported to polymerize 1-trimethylsilyl-1-propyne in nonpolar solvents such as cyclohexane, giving a polymer with low polydispersity (200). The molecular weight of this polymer increases in proportion to the monomer conversion. Either the replacement of $NbCl_5$ by $TaCl_5$ or the use of other solvents disrupts the living nature of the polymerization.

Living Polymerization by Single-Component Carbene Complexes. Much effort has been made to develop well-defined carbene complexes for the living polymerization of substituted acetylenes as well as cyclic olefins. The first example for the isolated metal-carbene catalyzed polymerization of acetylenes appeared in the literature for the acetylene oligomerization with a W-based carbene (**11**) (201). Soluble oligoacetylenes, $(C_2H_2)_n$ (n = 3–9), are obtained by the reaction of acetylene with (**11**) in the presence of quinuclidine. The living chain ends of these oligoacetylenes quantitatively react with pivaldehyde to give oligomers having *tert*-butyl groups at both ends. Trans geometrical main-chain structure dominates over the cis one. The living nature of this polymerization system allows selective formation of an ABA-type triblock copolymer of norbornene with acetylene.



11

After the work with W-based catalysts, Mo carbene catalysts (**7a–d**) were synthesized (Table 3) and have been proven to elegantly induce living cyclopolymerization of 1,6-heptadiynes (150,151). Mo carbenes ligated by bulky imido and alkoxy groups are quite effective. Because there is no significant difference between the propagation and initiation rates, the resultant polymers show relatively broad molecular weight distributions (∼1.25). However, these catalysts are able to quantitatively initiate the polymerization, which allows an easy control of the molecular weights simply by adjusting the monomer–initiator ratio. It is important to use appropriate solvent (DME) for selective cyclopolymerization; the polymerizations can be run in other solvents but give insoluble networked polymers. Bisinitiation of 1,6-heptadiynes is feasible if bifunctional initiator (**8**) is used (151). The ability of these Mo carbenes to tolerate polar functional groups

Table 3. Mo-Based Carbene Catalysts ((7)) for the Living Polymerization of Substituted Acetylenes

(**7**)	R^1	R^2	R^3	R^4
7a	C_6H_3-2,6-*i*-$(C_3H_7)_2$	$OC(CH_3)(CF_3)_2$	$C(CH_3)_2C_6H_5$	H
7b	C_6H_3-2,6-*i*-$(C_3H_7)_2$	$OC(CF_3)_3$	$C(CH_3)_2C_6H_5$	H
7c	1-Adm	$OC(CH_3)(CF_3)_2$	$C(CH_3)_2C_6H_5$	H
7d	C_6H_3-2-*t*-C_4H_9	$OC(CH_3)(CF_3)_2$	$C(CH_3)_3$	H
7e	C_6H_3-2-*t*-C_4H_9	$O_2C(C_6H_5)_3$	$C(CH_3)_3$	H
7f	C_6H_3-2-*t*-C_4H_9	$O_2C(C_6H_5)_3$	$C(CH_3)_2C_6H_5$	H
7g	1-Adm	$OCH(CF_3)_2$	$C(CH_3)_2C_6H_5$	H
7h	1-Adm	$OCH(CF_3)_2$	C_6H_5	CH_3
7i	1-Adm	$OCH(CF_3)_2$	C_6H_5	C_6H_5
7j	C_6H_3-2,6-$(CH_3)_2$	$OC(CH_3)(CF_3)_2$	$C(CH_3)_2C_6H_5$	H

permits living polymerization of functionalized monomers containing ester, sulfonic ester, and siloxy groups (151). Even a hydroxy group-containing monomer quantitatively provides a polymer. End-capping of the polymers is readily accomplished using aromatic aldehydes including *p-N,N*-dimethylaminobenzaldehyde and *p*-cyanobenzaldehyde. Cyclopolymerization of 1,6-heptadiynes with carbenes (**7a–d**) offers polymers having both five- and six-membered cyclic structures. In contrast, carbenes (**7e**) and (**7f**), which have bulky carboxylate ligands produce polymers bearing only six-membered rings (152).

Ring-substituted phenylacetylenes have been applied to the Mo carbene-initiated polymerization, leading to a finding that well-defined polymers are readily obtained with (**7g–i**) ligated by less bulky alkoxy groups (84,149). Unless an appropriate base is added, isolation of (**7g–i**) cannot be accomplished because of their instability. Like metal halide-induced living polymerizations, bulky ring substituents at the ortho position are required for controlled polymerization. The most characteristic point of these polymerization systems is that all the steps including initiation and propagation can be readily monitored by an nmr technique. For example, the detailed studies on the initiation step for various ring-substituted phenylacetylenes have revealed that the alkylidene groups of (**7**) selectively undergo α-addition onto *o*-trimethylsilylphenylacetylene. On the other hand, the selectivity of α-addition decreases with the decrease in the bulkiness of ortho substituents. Thus, the polymer main chain has both head-to-tail and head-to-head structures in the case of phenylacetylenes with small ortho substituents.

Metal-containing monomers, ferrocenylacetylene (**12**) and ruthenocenylacetylene (**13**) have been subjected to living polymerization with (**7j**) that has bulky alkoxide ligands (102). Living polymers are inaccessible with (**7g–i**) that suit ortho-substituted phenylacetylenes. Because of the insolubility of these polymers, the polymerization degree must be restricted below ca 40 in order to produce the soluble polymers. Similar metallocene-containing monomers, HC≡CC_6H_4-*o*-Fc (**14**), HC≡CC_6H_4-*p*-CH=CHFc (**15**), HC≡CC_6H_4-*p*-N=NFc (**16**), and HC≡CC_6H_4-*p*-C≡CC_6H_4-*p*-C≡CFc (**17**), polymerize in a living manner in the presence of (**7**) (87,88). The use of (**7j**) leads to successful formation of high molecular weight polymers ($\sim 10^4$) from terminal aliphatic acetylenes (202). Because the chain propagation is faster than initiation, narrow molecular weight distribution is not attained.

However, cyclotrimerization of 1-*n*-alkylacetylene can be completely suppressed, leading to the quantitative yields of polymers.

In addition to these Mo- and W-based carbene complexes, a Ta-based carbene (**2**) that is active for the living polymerization of 2-butyne has been developed (105). Again, the initiation efficiency is quantitative, and the living end can be endcapped with aromatic aldehydes. As polymers from symmetric acetylenes are generally insoluble, soluble poly(2-butyne) is accessible if the degree of polymerization is suppressed below 200. The nmr analysis of living oligomers of 2-butyne clearly indicates that both cis and trans structures exist in the main chain. This Ta carbene (**2**) is unfortunately ineffective for the polymerization of internal acetylenes having bulky substituents such as diphenylacetylene. Chain transfer inhibits the formation of polymers from terminal acetylenes with (**2**), giving oligomers having broad molecular weight distributions.

Stereospecific Living Polymerization by Rh Catalysts. As shown in the previous section, very high order of regulation for double bond geometry (cis-transoidal) is possible by using Rh catalysts. Although the presence of long-lived propagating species has been claimed in the Rh-catalyzed polymerization of phenylacetylene (157), the conventional Rh catalyst, $[(nbd)RhCl]_2$, cannot achieve well-controlled polymerization. Rh-catalyzed living polymerization was first accomplished in 1994 (168). The excellent ability of an isolated catalyst (**9**) to offer quantitative yields of poly(phenylacetylenes) with narrow molecular weight distribution was demonstrated (168) (Table 2). The structure of (**9**) was completely characterized by a single-crystal x-ray analysis, and more details of the polymerization have been disclosed (171). Polymerization of phenylacetylene with (**9**) in the presence of 4-(*N*,*N*-dimethylamino)pyridine (DMAP) provides a well-defined polymer having a long-lived active site at the propagation terminal. DMAP is indispensable, and without DMAP, the polydispersity increases to 1.3. High stability of the propagation centers allows the isolation of poly(phenylacetylene) having active propagation sites that can sequentially polymerize second monomers to give precisely controlled block copolymers (171).

One striking feature of the stereoregular polyacetylenes is their simple NMR spectral patterns, which facilitates investigation of the polymerization mechanism as well as the polymer structure. A copolymer of phenylacetylene with partly ^{13}C-labeled phenylacetylene ($C_6H_5{}^{13}C{\equiv}{}^{13}CH$) shows two doublet carbon signals with $J_{13C-13C}$ of 72 Hz, indicating the presence of $^{13}C{=}{}^{13}C$ bond in the polymer backbone (171). This is a clear indication of the insertion mechanism instead of the metathesis pathway. Solid-state NMR studies of poly(phenylacetylene) also verified the insertion mechanism for the Rh-catalyzed polymerizations (169).

After the finding of catalyst (**9**), further development of a new living polymerization system, $[(nbd)Rh(OCH_3)]_2$–$P(C_6H_5)_3$–DMAP, enabled the enhancement of the initiation efficiency from 35% to 70% (172). The polymerization with $[(nbd)Rh(OCH_3)]_2$–$P(C_6H_5)_3$–DMAP is 3–4 times faster than that with (**9**). The isolation of $[(nbd)Rh(OCH_3)]_2$ is not necessary; a simple mixture of commercially available $[(nbd)RhCl]_2$, $P(C_6H_5)_3$, $NaOCH_3$, and DMAP induces the living polymerization of phenylacetylene without broadening the polydispersity.

A new vinylrhodium complex (**10**) for the living polymerization of phenylacetylenes has been prepared, isolated, and fully characterized by x-ray analysis (174). Catalyst (**10**) polymerizes phenylacetylene and its para-substituted

analogues to give living polymers. Living polymerization is also possible even in the presence of water. The isolation of (**10**) is not necessary, and the complex formed *in situ* by the reaction of $[(nbd)RhCl]_2$ with $LiC(C_6H_5)=C(C_6H_5)_2$ and $P(C_6H_5)_3$ induces living polymerization in quantitative initiation efficiency (173). A remarkable feature of this polymerization system is the ability to introduce functional groups at the initiation terminal. For example, living poly(phenylacetylene) bearing a terminal hydroxy group is readily obtained by the polymerization with a three-component catalyst, comprising $[(nbd)RhCl]_2$, $LiC(C_6H_5)=C(Ph)C_6H_4$-*p*-$OSiCH_3$-*t*-C_4H_9, and $P(C_6H_5)_3$, followed by the desilylation of the formed polymer. Polymerization of β-propiolactone with the terminal phenoxide anion of this polymer gives a new block copolymer of phenylacetylene with β-propiolactone (203).

Stereospecific Polymerization with Fe Catalyst. As mentioned earlier, iron and lanthanide catalysts are able to form cis-cisoidal stereoregular polymers from phenylacetylenes. However, a quantitative discussion on the cis-cisoidal steric structure has not been made because of the insolubility of cis-cisoidal poly(phenylacetylene). Attempts have been made to prepare soluble cis-cisoidal poly(phenylacetylenes) by incorporating alkyl pendant onto the aromatic ring (65). nmr analyses of Rh- and Fe-based polymers from *p*-adamantyl-, *p*-*tert*-butyl-, and *p*-*n*-butylphenylacetylenes led to a conclusion that all of the Rh- and Fe-based polymers adopt cis-transoidal geometrical structure. From the NMR analysis, the cis content of these polymers was calculated to be more than 95% for Rh-based polymers. The cis content of Fe-based polymers significantly depends on the bulkiness of the ring substituents and decreased from 93 to 65% with an increase in the bulkiness. These data support the idea that cis-cisoidal polymers are specifically formed with Fe catalysts unless the ring substituents are extremely bulky. However, the thermodynamic instability of the initially formed cis-cisoidal conformation readily isomerizes the cis-cisoidal polymers into cis-transoidal ones upon dissolution.

Stereospecific Living Polymerization by Mo Catalysts. Apart from the stereospecific polymerizations through the insertion mechanism in the case of Rh and Fe catalysts, the metathesis approaches to stereoregular polymers are rather difficult. For instance, the cis content of poly(*o*-methylphenylacetylene) prepared with $MoOCl_4$–*n*-$(C_4H_9)_4Sn$–C_2H_5OH is 81% (190). A unique example for elegantly controlled stereospecific metathesis polymerization is limited to the Mo-catalyzed polymerization of *tert*-butylacetylene (36,204). Cis polymers are selectively obtained from *tert*-butylacetylene in the presence of $MoCl_5$. WCl_6 catalysts, in contrast, lead to less stereoregulation. Stereospecific living polymerization of *tert*-butylacetylene is possible with $MoOCl_4$–*n*-$(C_4H_9)_4Sn$–C_2H_5OH, which gives a polymer with a narrow molecular weight distribution (36). The cis content reaches 97% at a low temperature (−30°C). Cis content decreases if the polymerization is conducted with $MoOCl_4$ or $MoOCl_4$–*n*-$(C_4H_9)_4Sn$. A detailed nmr study on the stereoregularity of poly(*tert*-butylacetylene) showed that the cis content depends on the rate of Lewis-acid catalyzed isomerization from the cis to the trans form (205). That is, all catalysts including $MoOCl_4$, $MoOCl_4$–*n*-$(C_4H_9)_4Sn$, and $MoOCl_4$–*n*-$(C_4H_9)_4Sn$–C_2H_5OH specifically give cis polymers just after the polymerization. However, a rapid acid-catalyzed cis-to-trans isomerization reduces the cis content as well as the molecular weight after the completion of the polymerization. Thus, the difference in acidity of catalysts determines the rate of

isomerization and eventually influences the cis content of the polymer. The isomerization can be retarded by conducting the polymerization at low temperature or in poor solvents such as dichloromethane or anisole.

Functional Polyacetylenes

Thanks to the tremendous progress in the transition metal-catalyzed polymerization of substituted acetylenes as described in the previous sections, it is now possible to access various acetylene-based polymers having desired first-order structures. This, in combination with highly advanced organic synthetic technology, provides novel functional materials based on polyacetylenes, and the following surveys examples of the design and synthesis of functional substituted polyacetylenes.

Permeable Polyacetylenes. Application of substituted polyacetylenes as gas-permeable materials has been most intensively studied (206–213). These studies are motivated by the extremely high gas permeability of poly(1-trimethylsilyl-1-propyne) (**18**) (214). which is the most permeable material among the polymers available. Its oxygen permeability (P_{O2} = 1–2 mmol/(m·s·GPa), 3000–6000 barrers) is about 10 times larger than that of poly(dimethylsiloxane). In addition to its high permeability, the ability of (**18**) to give a free-standing film has attracted many membrane scientists. Poly(diphenylacetylenes) also exhibit large values for gas permeability (213). They are thermally very stable ($T_0 > 500^\circ$C) and possess film-forming ability. The ease in modifying ring substituents provides an opportunity to tune the permeability as well as the solubility and second-order conformation. Table 4 lists examples of the substituted polyacetylenes having high gas permeability. The permeability of poly(diphenylacetylenes) significantly depends on the shape of ring substituents. Generally, those with bulky ring substituents such as *tert*-butyl, trimethylsilyl, and trimethylgermyl groups exhibit very large P_{O2} values, up to 0.37–0.40 mmol/ (m·s·GPa) (1100–1200 barrers), which is about a quarter of that of (**18**) and approximately twice as large as that of poly(dimethylsiloxane). Poly(phenylacetylenes) tend to show lower permeability than poly(diphenylacetylenes).

Liquid crystalline Polyacetylenes. Several kinds of polyacetylenes with liquid-crystalline moiety in the side groups have been prepared with the motivation of improving main-chain orientation and effective conjugation through the alignment of the pendant mesogens. The polymer skeleton of poly(1-alkynes) shows liquid crystallinity, whereas poly(phenylacetylene)- based polymers exhibit poorer mesomorphism because of their high rigidity of the polymer backbone (71). Poly(1-alkynes) with phenylcyclohexyl mesogenic cores separated from the main chain by an alkylene spacer (**19**) have been synthesized (40,224). These polymers prepared with Fe and Mo catalysts show smectic A phase upon heating. Mo-based polymers show higher transition temperatures compared to the Fe-based polymers. X-ray diffraction (xrd) measurements indicate that these polymers adopt layered structures in the liquid crystalline state where the mesogenic side chains locate at both sides of the main chain (225). The main chain of the polymers has been claimed to comprise the head-head–tail-tail linkage from the xrd data. Novel photo-responsive liquid crystalline polyacetylenes (**20**) that have azobenzenes as

mesogens have also been prepared (41,226). Thermally induced transitions from glassy to smectic and isotopic phases take place at 38 and 87°C, respectively. Polymer (**20**) undergoes reversible photochemical trans-to-cis and cis-to-trans isomerizations.

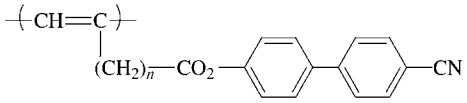
20

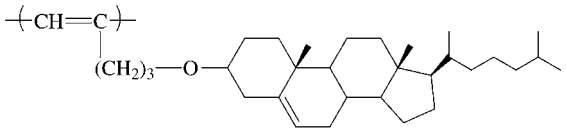
Similar liquid crystalline polyacetylenes (**21**) were synthesized. Polymers (**21**) possess 4′-cyano-4-biphenylyloxy mesogenic centers that are separated from

the main chain by long alkylene spacers (70). The cyano functionality does not deactivate the Mo- and W-based metathesis catalysts, and good yields of the polymers are obtained. All polymers (**21**) are mesomorphic, which was supported by the differential scanning calorimetry, polarizing optical microscopy, and x-ray diffraction analyses. The presence of a longer spacer favors better ordering of the mesogenic cores. These polymers adopt various morphologies, *e*g, monotropic nematicity, enantiotropic nematicity, and enantiotropic smecticity, depending on the length of the alkylene spacer.

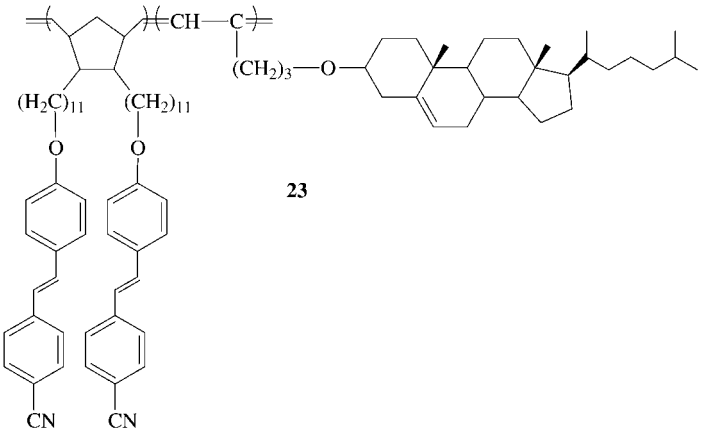


21 n = 2, 3, 8

A liquid crystalline-substituted polyacetylene bearing cholesteryl side groups (**22**) has been synthesized by using a well-defined Schrock-type catalyst (43). Upon cooling, the polymer exhibits a mesophase of the smectic A type before undergoing a glass transition. The ability of the Schrock catalyst to achieve the living polymerization of norbornenes provides a block copolymer (**23**) consisting of a mesogen-substituted polynorbornene and (**22**) (227). The acetylene-block exhibits a smectic A phase, while the polynorbornene domain is nematic. Thus, the block copolymer shows microphase separation retaining the mesophases of the homopolymers.



22



23

Polyacetylenes with Nonlinear Optical Properties. Substituted polyacetylenes are conjugated polymers; however, the repulsion between pendant

groups causes the twist of the main chain to reduce the degree of conjugation. Thus, many of substituted polyacetylenes show quite low unpaired-electron densities, which results in their poorer electrical conductivity (10,22–24,26). The main-chain conjugation can be improved by introducing ortho-substituents to monosubstituted arylacetylenes. For example, poly(phenylacetylenes) ortho-substituted by trimethylsilyl, trimethylgermyl, and trifluoromethyl groups are deeply colored and show large third-order nonlinear optical susceptibilities (228,229) (Table 5). Arylacetylenes bearing condensed aromatic rings such as naphthalene, anthracene, phenanthrene, and pyrene also belong to this category (52,90–95). Monomers designed so as to increase steric repulsion between the pendant groups and the main chain of the formed polymers give polymers having extremely expanded main-chain conjugation in the presence of W catalysts (94). Hence, 9-phenanthrylacetylene, 9-anthrylacetylene, and 1-pyrenylacetylene give deeply colored polymers in good yields with WCl_6–*n*-$(C_4H_9)_4Sn$. They show the absorption maxima around 600 nm, and the cut off wavelengths reach 800 nm. On the other hand, the less conjugated polymers are formed from 2-anthrylacetylene and 2-phenanthrylacetylene. Among the polymers from monosubstituted acetylenes, the polymer from 10-hexoxycarbonyl-9-anthrylacetylene (**24**) exhibits the largest third-order nonlinear optical susceptibility (230) (Table 5). Although the homopolymer of 9-anthrylacetylene obtained with W catalyst is insoluble (90), (**24**) is a soluble dark-purple polymer having an absorption maximum at 580 nm. The electric conductivity of I_2-doped (**24**) is 8.77×10^{-4} S/cm at 293 K. *N*-Carbazolylacetylene also polymerizes with W catalysts, giving a polymer with high degree of main-chain conjugation (95).

Luminescent Substituted Polyacetylenes. The luminescent property of conjugated polymers is one of the most important functions, and an energetic study of the photo- and electroluminescence of substituted polyacetylenes has been made (231–245). Polymers that show intense luminescence are those from diphenylacetylenes and 1-phenyl-1-alkynes, and so on. Only weak red emissions are observed from monosubstituted arylacetylene polymers (234,240). A systematic investigation on the luminescence of these kinds of polymers found that poly(diphenylacetylenes) exhibit photoluminescence around 530 nm and electroluminescence around 550 nm (232,242). In a similar way, poly(1-phenyl-1-alkynes) photochemically and electrochemically emit strong lights with spectral maxima located around 455 and 470 nm, respectively. Green and blue emissions are observed from the electroluminescent devices using poly(diphenylacetylenes) and poly(1-phenyl-1-alkynes) as the emission layers, respectively (235,236,240,242,243). The Stokes shift of photoluminescence of these polymers is quite large: 0.3 eV for poly(diphenylacetylenes) and 0.6 eV for poly(1-phenyl-1-alkynes). This series of studies varying the substituents on the polymers have revealed the following tendencies: (*1*) the introduction of bulky or long alkyl pendant groups enhances the efficiencies of the luminescence of poly(diphenylacetylenes) (235,242), and (*2*) the emission peaks blue-shift with the length of the alkyl pendant of poly(1-phenyl-1-alkynes) (234). Interestingly, both photo- and electroluminescences of the blend of blue emissive poly(1-phenyl-1-octyne) and green emissive poly(1-phenyl-2-*p*-*n*-butylphenylacetylene) vary between green and blue, which is dependent on the ratio of the two polymers (234,237). This result means that the emission

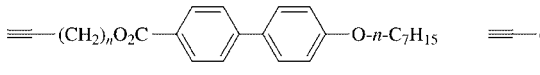
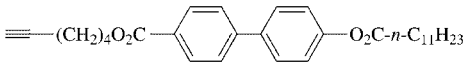
R^2 = CH_3, C_2H_5, $n\text{-}C_6H_{13}$, etc.

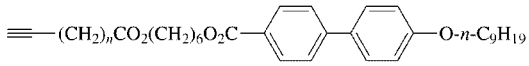
Polymers from monosubstituted terminal acetylenes strongly luminesce upon photoexcitation (246). Higher photoluminescent efficiency is observed for polymers (**25**) (**26**) (**27**), which emit strong deep-blue light (380 nm). This unexpected strong emission seems to originate from the ordering of the pendant mesogens that enhance the main-chain conjugation of the polymers. Similar to the case of other luminescent polyacetylenes, the increase in the length of the alkyl chain causes a slight blue-shift of the emission wavelength.



25 (n = 2–4, 9)



26



27 (n = 2, 8)

Chromic Substituted Polyacetylenes. In contrast to the extensive studies on the luminescent properties, less attention has been paid on the chromic properties of substituted polyacetylenes. The first demonstration of electrochromism was made using poly(*o*-trimethylsilylphenylacetylene) (247). Poly(*o*-trimethylsilylphenylacetylene) is cycled electrochemically between doped and undoped states. Upon electrochemical doping, poly(*o*-trimethylsilylphenylacetylene) film loses its red color to white. Similarly, poly[*p*-(*N,N*-diethylamino)phenylacetylene] can be electrochemically doped and exhibits a reversible color change between green ocher and deep blue (76).

Magnetic Substituted Polyacetylenes. Development of organic magnets is one of the most challenging and exciting targets for synthetic chemists. Theory predicts that free radicals in pendants of poly(phenylacetylene) are capable of ordering the ferromagnetic spin-interaction if the radicals conjugate with the phenyl rings. According to this theory many efforts have been made to prepare poly(phenylacetylenes) having stable radicals such as phenoxy, galvinoxyl, nitronyl nitroxide, and aminyl radicals. Figure 1 shows representative examples for poly(phenylacetylenes) having stable radicals such as phenoxy, galvinoxyl, nitronyl nitroxide, and aminyl radicals. Polymers (**28–31**) are prepared by the direct polymerization of the radical-containing monomers (99–101,248). Rh catalysts suit the polymerization of radical-containing monomers because the radical groups do not interfere with Rh catalysts. The other radical-containing polymers (**32–37**) are derived from the polymerization of the corresponding precursors followed by the oxidative polymer reaction (249–254). Under the appropriate

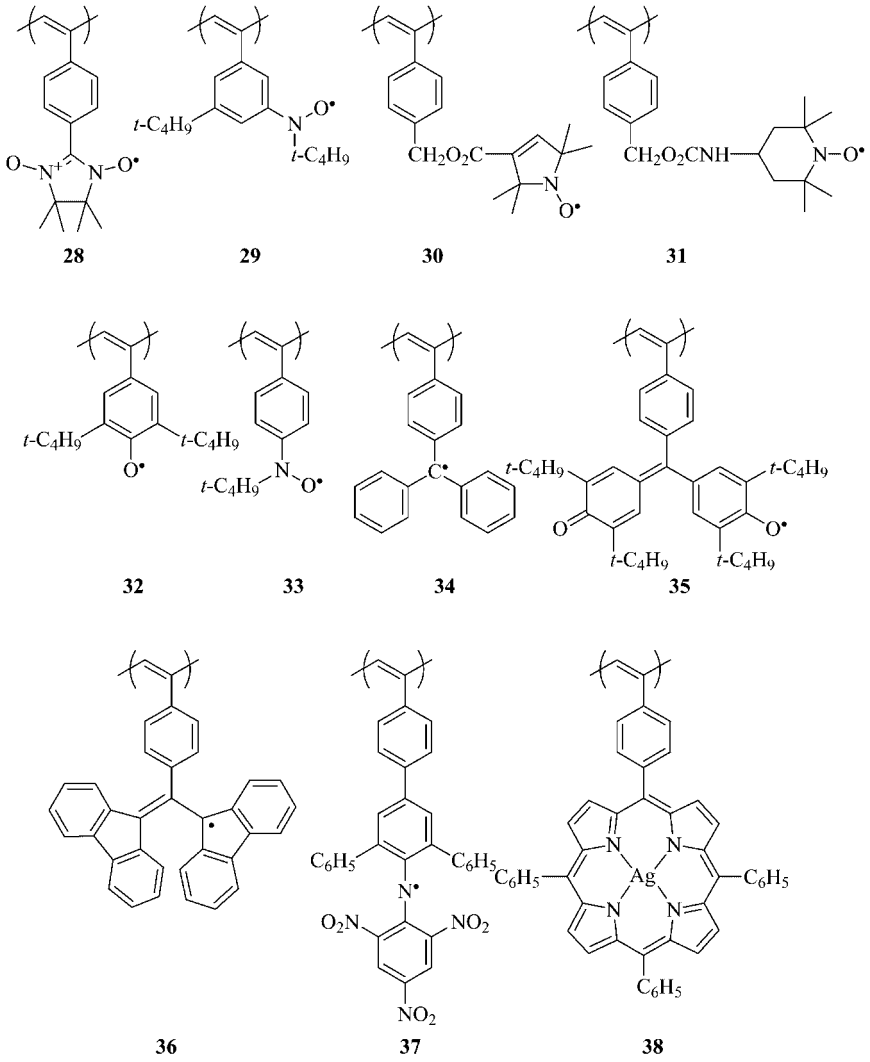


Fig. 1. Poly(phenylacetylenes) having stable radicals.

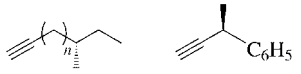
conditions, polymers with a very high spin concentration are available. Paramagnetic metalloporphyrins have been incorporated into poly(phenylacetylene) with the motivation of producing magnetically interacting polymers (**38**) (255). Unfortunately, no ferromagnetic interactions have been achieved because of the torsion in the polyene backbone. The twist of the main chain, caused by the steric repulsion between the pendants, inhibits the extended conjugative spin coupling through the alternating double bonds in the main chain.

Optically Active Substituted Polyacetylenes. The repulsion between the pendants in substituted polyacetylenes twists the main chain, which discourages the studies on the synthesis of acetylene-based polymer magnets. Recently, this main-chain torsion has been extensively applied to the synthesis of chiral

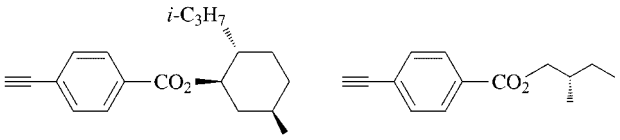
polymers having well-ordered helical conformations, which has expanded the potential utility of substituted acetylenes as the enantioselective permeable materials, polarization-sensitive electrooptical materials, asymmetric electrodes, and so on.

Helical Poly(1-alkynes). The first report of the synthesis of chiral substituted polyacetylenes involved the polymerization of terminal aliphatic acetylenes having a chiral pendant (**39**) with $Fe(acac)_3$ in the presence of trialkylaluminum (39). Relatively weak but clear Cotton effects appear in the electric absorption range of the main chain, suggesting the helical conformation of the polymers. The distance between the chiral carbon and the main chain remarkably influences the chiroptical properties of the polymers, and the intensity as well as the shape of the Cotton effects considerably changes with the variation of the number of methylene spacers between the chirogenic carbon and the main chain. A decrease in temperature results in the drastic enhancement of the Cotton effect, which indicates the short persistence length of the helical domain. Monomer (**40**) was polymerized with a cationic Rh catalyst, $(nbd)Rh^+[(\eta^{-6}\text{–}C_6H_5)B^-(C_6H_5)_3]$, to give a polymer displaying very intense Cotton effects (38). Thus, the increase in the bulkiness at the α-carbon is likely to advantageously induce helicity to the backbone.



39 **40**

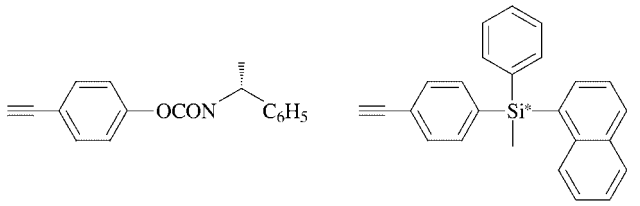
Helical Poly(phenylacetylenes). The most widely studied helical-substituted polyacetylenes are based on poly(phenylacetylene) with chiral ring substituents. Polymerization of chiral phenylacetylenes was first reported in 1995 (72). 4-(−)-Menthoxycarbonylphenylacetylene (**41**) was subjected to the polymerization with several transition metal catalysts such as $[(nbd)RhCl]_2$ and WCl_6. The resultant Rh-based polymer shows a large optical rotation and intense CD effects in the electric absorption region of the main chain. The polymer, thus, exists in a helical conformation with an excess of one-handed screw-sense. Poly(phenylacetylene) with small chiral pendants, poly(**42**), in contrast, displays poorer chiroptical properties. Interestingly, an increase in temperature steeply increases the optical rotation of poly(**41**) if the polymer is produced with a W catalyst. Such a drastic enhancement of chiroptical properties is not observed in the case of Rh-based poly(**41**).



41 **42**

The ability of the helical poly(phenylacetylene) to recognize chiral molecules has been demonstrated (73). A stereoregular phenylacetylene-based polymer, poly(**43**), prepared with Rh catalyst has been shown to adopt a helical conformation. The corresponding polymer with ill-controlled stereoregularity, that is,

W-based poly(**43**), shows no distinct CD effects. High stereoregularity (cis) is, thus, required for the construction of well-ordered helical structures. The molecular recognition ability was demonstrated by the chromatographic enantioseparation of various racemates using poly(**43**) as a chiral stationary phase.



43 **44**

The nature of the helical conformation of poly(phenylacetylene) has been studied in detail (74). The stability of the helical conformation of poly(phenylacetylenes) was estimated by the chiroptical properties of the copolymers from chiral and achiral phenylacetylenes. When the monomer possesses sterically less bulky ring substituents, a clear cooperative nature on the copolymerization is not observed. A chiral amplification phenomenon is attainable only when the monomers have bulky ring substituents. This result coincides with the poor chiroptical property of poly(**42**) (73) and also with the very intense CD effects of poly(**44**) having bulky chiral silyl groups (256). Computational simulations verified that, unlike polyisocyanates which have a long persistence length of helical structure because of their stiff main chain, the main chain of poly(phenylacetylene) is quite flexible and that, unless bulky substituents are incorporated, poly(phenylacetylene) exists in essentially randomly coiled conformation or in a helical conformation with very short persistence length.

In an elegant application of the unique nature of poly(phenylacetylene), a new method has been established for the transformation of the randomly coiled conformation of poly(phenylacetylene) into a well-defined helix by using external chiral stimuli (Fig. 2) (77,257–260). For example, poly(4-carboxylphenylacetylene) adopts a stable helical conformation with an excess of one-handed screw-sense when the carboxyl groups complex with chiral molecules (258). Very intense CD effects as a result of the helical conformation of the main chain are observed in the presence of chiral amines or aminoalcohols. The absolute configuration of chiral molecules determines the sense of the helix. For instance, addition of (*R*)-amines results in a positive first Cotton effect around 440 nm, whereas negative first Cotton effects appear in the presence of (*S*)-amines. This behavior is almost universal for a wide range of amines and aminoalcohols. Therefore, poly(4-carboxylphenylacetylene) functions as a probe for chiral molecules. A similar phenomenon is attainable for poly(phenylacetylenes) having amino (77) or boronic acid groups (258). The former recognizes chiral carboxylic acids and α-hydroxy carboxylic acids, and the latter can be applied as a probe for a wide variety of chiral molecules that include not only diols, aminoalcohols, amines, α- and β-hydroxy carboxylic acids but also steroids and carbohydrates.

Aminoalcohols more strongly complex with carboxylic acid than amines. This characteristic allows substitution of the chiral amines, initially complexed with poly(4-carboxylphenylacetylene), by achiral aminoalcohols (260). The most

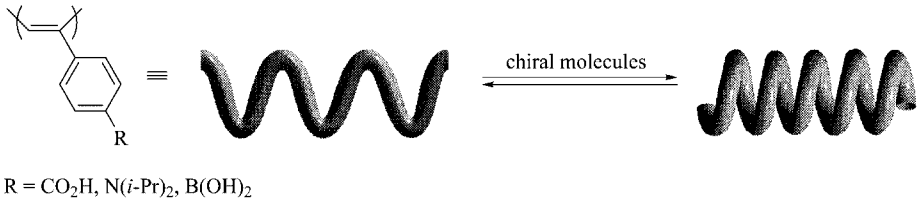


Fig. 2. Schematic illustration of the complexation of poly(phenylacetylenes) with chiral molecules.

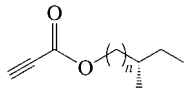
characteristic point of this process is that the helix sense, determined by the priory complexed chiral amines, is maintained even after complete substitution by achiral aminoalcohols. In other words, the memory of macromolecular helicity is possible.

Helical Poly(propiolic esters). Comprehensive studies of the helical nature of poly(propiolic esters) (**45**) have shown that, apart from the flexibility of the main chain of polymers from poly(1-alkynes) and poly(phenylacetylenes), poly(propiolic esters) possess a stiff main chain (50,261,262). The Mark–Houwink–Sakurada plots of the stereoregular (cis-transoidal) poly(propiolic esters) clearly indicate the stiff main chain of poly(propiolic esters) (262). For example, the slope of the Mark–Houwink–Sakurada plot of poly(hexyl propiolate) is 1.2, which is comparable to that of poly(hexyl isocyanate). The stiffness of poly(propiolic esters) originates from the helical conformation with a large helical domain size. In contrast to other substituted polyacetylenes, a clearer cooperative effect of helical structure is observed in the chiral/achiral and the R/S copolymerizations (262). Therefore, only a small amount of chiral substituents in the pendant groups leads to well-ordered helical poly(propiolic esters) with an excess of one-handed screw sense. The most important factor to affect the secondary conformation of poly(propiolic esters) is the structure of pendants, and an introduction of methylene groups at the α-position of the ester group is indispensable for the construction of well-ordered helical polymers (261). For the polymers having α-methylene groups (**44**), $n = 1$–5), remote control of the screw sense is possible if the chiral information positions within the ε-carbon from the ester group. Temperature variable CD spectra also suggest that, if the chiral carbon locates within the δ-position, one screw sense dominates over the counterpart even at room temperature. When the chiral substituent on the ester group is a long alkyl chain such as (*S*)-3,7-dimethyloctyl group, helix sense inversion takes place, which is driven by the change of temperature or solvent composition (77).



45 (n = 0–5)

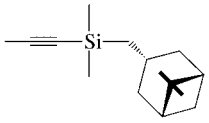
A simple NMR technique can estimate not only the activation energy of helix–helix interconversion ($\Delta G‡$), but also the free energy difference between the right- and left-handed conformations (ΔG_r) (**262**). In the NMR spectra of poly(propiolic esters) without α-branching, α-methylene protons give two diastereotopic signals. This peak separation is contributed by the slow interconversion process between

the right- and left-handed helical conformations. Thus, the temperature variable NMR measurements readily give the activation energy $\Delta G^{\ddagger}$ for the helix–helix interconversion (71–79 kJ/mol, 17–19 kcal/mol), which is comparable to that of polyisocyanates. This means that poly(propiolic esters) undergo rapid helix inversion at ambient temperature. The ΔG_r of poly(hexyl propiolate) was also estimated by NMR to be 6.65 kJ/mol (1.59 kcal/mol) at 22°C.

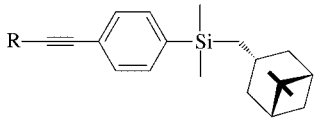
Helical Polymers from Disubstituted Acetylenes. In contrast to the energetic studies on the helical polymers from monosubstituted acetylenes, those from disubstituted acetylenes are very limited. One of the reasons is the difficulty in controlling and elucidating the stereoregularity of the polymers from disubstituted acetylenes. However, in contrast to the instability of polymers from monosubstituted acetylenes (263–269), those from disubstituted acetylenes are quite stable. Another advantage of polymers from disubstituted acetylenes is their excellent permeability to small molecules. Thus, chiral polymers from disubstituted acetylenes are potentially applicable to the chiral resolution membranes.

The first example of chiral polymer from a disubstituted acetylene is a poly(1-trimethylsilyl-1-propyne)-based polymer, poly(**46**), which was synthesized in moderate yields using $TaCl_5$–Ph_3Bi (112). Poly(**46**) displays small optical rotations, and its molar ellipticities of the Cotton effects are up to a few hundreds. The main chain of poly(**46**) is, therefore, not a well-ordered helix. This is probably because of the less controlled geometrical structure (cis and trans) of the polymer backbone. However, the free-standing film of this polymer achieves an enantioselective permeation of various racemates including alcohols and amino acids. For example, the concentration-driven permeation of an aqueous solution of tryptophan by poly(**46**) gives 81% enantiomeric excess (ee) of the permeate at the initial stage. A characteristic of the membrane of poly(**46**) is its ability to enantioselectively recognize 2-butanol and 1,3-butanediol, because the direct resolution of these racemates by hplc is impossible.

Other chiral polymers from disubstituted acetylenes are based on the poly(phenylacetylene) derivatives that are also recognized as one of the most permeable polymers. Diphenylacetylene having a dimethyl-(−)-pinanylsilyl group (**47a**) was polymerized with Ta and Nb catalyst to give an extremely high molecular weight polymer in good yield (124). The produced polymer exhibits a very large optical rotation ($[\alpha]_D > 2000°$), and complicated but very intense CD effects appear in its absorption region. Although the first order structure (cis or trans, head-to-head or head-to-tail) of the polymer is unknown, these very rich chiroptical properties are indicative of the main-chain chirality based on helical structure. Similar polymers from disubstituted acetylenes (**47b**) and (**47c**) have been obtained; however, their chiroptical properties are poorer in comparison with those of poly(**47a**).



46



47a; R = C_6H_5
47b; R = CH_3
47c; R = Cl

Although poly(**47a**) exhibits large chiroptical properties, its ability to enantioselectively permeate racemates is unexpectedly low. In contrast, poly(**47b**) that possesses small $[\alpha]_D$ and $[\theta]$ values achieves the resolution of racemic mixtures of tryptophan. The initial % ee of permeate reached 52%. Thus, the size of the void in the membrane of helical poly(**47a**) appears to be very large, which may inhibit the racemate to interact with the chiral environment originating from the chiral pendant.

ACRYLAMIDE POLYMERS

Introduction

The terminology used to describe acrylamide-containing polymers in the technical literature varies in its precision. In order to avoid confusion, throughout this article the term "poly(acrylamide)" is reserved for the nonionic homopolymer of acrylamide, whereas the term "polyacrylamides" or "acrylamide polymers" refers to acrylamide-containing polymers, including the homopolymer and copolymers. Specific nomenclature is used for particular copolymers, for example, poly(acrylamide-*co*-sodium acrylate).

The diverse class of water-soluble and water-swellable polymers comprising polyacrylamides contains some of the most important synthetic polymeric materials used to improve the quality of life in our modern society. Acrylamide-containing polymers fall into three main categories: nonionic, anionic, and cationic. The projected annual sales growth rate of polyacrylamides between 1999 and 2002 is 4–7% (1). The multi-billion-dollar global market value of this class of materials makes it an economically important segment of the chemical industry.

Poly(acrylamide) is made by the free-radical polymerization of acrylamide, which is derived from acrylonitrile by either catalytic hydrolysis or bioconversion. The unique chemistry of acrylamide, its favorable reactivity ratios with many comonomers, and the ability of poly(acrylamide) to be derivatized allows for a substantial variety of polymers to be tailor-made over a wide range of molecular weights (approximately 10^3–50×10^6 Da), charge densities, and chemical functionalities.

A very large number of applications for acrylamide-containing polymers have been extensively reviewed (2–7). One major application area for polyacrylamides is in solid–liquid separations. The largest market segments therein are for use

Encyclopedia of Polymer Science and Technology. Copyright John Wiley & Sons, Inc. All rights reserved.

as flocculants and dewatering aids for municipal wastewater, thickening aids for industrial wastewater, secondary clarification and clarification of potable water, solids removal from biological broths, and animal feed recovery from waste. Because of major concern for the environment, the allowable suspended solids in most effluent streams are becoming more restricted by government regulations. New technologies for producing cationic polymers with a wide range of charge levels, novel structures, and very high molecular weights have addressed this need. These polymers have greatly improved the dewatering performances of centrifuges, screw presses, and belt presses used for such purposes. This has resulted in drier dewatered solids, which has translated into lower costs to either landfill or incinerate the solids.

The largest volume applications for polyacrylamides in paper mills are in on-machine wet-end processes. Paper retention aids and drainage aids are used to flocculate or bind fillers, fibers, and pigments. Glyoxalated cationic polyacrylamides are used as strengthening agents and promoters for paper sizing. Other papermaking applications include off-machine processes for recovering fiber from recycled paper waste and for deinking.

High molecular weight polyacrylamides have also traditionally been used in the minerals processing industry. Recent polymer technology developments, including ultra high molecular weight and novel anionic polyacrylamides, have yielded important materials. These products are used as flocculants in coal mining, the Bayer process for alumina recovery (red mud flocculants), precious metals recovery, and the solid–liquid separation of underflow streams in a variety of mining processes. Novel chemical modifications of low molecular weight polyacrylamides have resulted in materials that are used as modifiers in the selective separation of metal sulfides and magnetite and as depressants and flotation aids.

One large market segment for anionic polyacrylamides had traditionally been in enhanced oil recovery. However, low oil prices have resulted in a large decline in such applications. Since 1990, polymer flooding has virtually disappeared in the United States. However, during 1999 crude oil prices started to increase.

Other significant application areas for polyacrylamides include soil conditioning and erosion control, drag reduction, sugar processing, additives in cosmetics, and superabsorbents.

Physical Properties

Solid Polyacrylamides. Completely dry poly(acrylamide) is a brittle white solid. It is nontoxic, unlike the monomer. Dry polyacrylamides (including copolymers) are commercially available as nondusting powders and as spherical beads. These products can contain small amounts of additives that aid in both the stability and dissolution of the polymers in water. Commercially available acrylamide copolymer powders, which are typically dried under mild conditions, will usually contain about 5–15% water depending on their ionicity. The powders are hygroscopic, and generally become increasingly hygroscopic as the ionic character of the polymer increases. Cationic polymers are particularly hygroscopic.

Some physical properties of nonionic poly(acrylamide) are listed in Table 1. The tacticity and linearity of the polymer chain is claimed to be dependent on

Table 1. Physical Properties of Solid Poly(acrylamide)

Property	Value	Reference
Density	1.302 g/cm^3 (23°C)	8
Glass-transition temperature (T_g)	195°C	9
Critical surface tension (γ_c)	52.3 mN/m (= dyn/cm) (20°C)	10
Chain structure	Mainly heterotactic linear or branched, some head-to-head addition	11–14
Crystallinity	Amorphous (high molecular weight)	15
Solvents	Water, ethylene glycol, formamide	16
Nonsolvents	Ketones, hydrocarbons, ethers, alcohols	17
Fractionation solvents	Water–methanol	18
Gases evolved on combustion in air	H_2, CO, CO_2, NH_3, nitrogen oxides	19

the polymerization temperature. Syndiotacticity is favored at low temperatures (20). Linear polymer chains are reportedly obtained below 50°C, but branching begins to occur as the temperature is increased above this level (21). A wide range of values of the glass-transition temperature (T_g) of poly(acrylamide) have been published. This is because the measured value is highly sensitive to the presence of water and also to the presence of nonacrylamide species along the polymer backbone. For example, small amounts of acrylate groups can arise from hydrolysis of the amide group during or after polymerization. This can dramatically change the T_g.

Solution Properties. The amide group (—$CONH_2$) in poly(acrylamide) provides for its solubility in water and in a few other polar solvents such as glycerol, ethylene glycol, and formamide. We can acquire a sense of poly(acrylamide)'s affinity for water by examining a few characteristic parameters. Theta (Θ) conditions for a polymer delineate a particular combination of solvent and temperature at which the polymer acts in an ideal manner (22), ie, the chains behave as random coils. The Θ temperature of poly(acrylamide) in water has been determined to be −8°C (23). Thus, water at 25°C is a solvent of intermediate quality for poly(acrylamide). Aqueous methanol (40 vol%), however, is a Θ solvent for poly(acrylamide) at 25°C (24). The Flory χ parameter, which is a measure of the relative affinity between the polymer segments with each other vs with the solvent, is 0.5 under Θ conditions. The Flory χ parameter of poly(acrylamide) has been determined to be 0.48 in water at 30°C (25). These and other properties of poly(acrylamide) in solution are collected in Table 2.

Poly(acrylamide) is soluble in liquid water at all concentrations, temperatures, and pH values. However, at high pH (>10.5) the polymer will begin to hydrolyze on standing (29). Poly(acrylamide) is generally soluble in most salt solutions but can phase separate in some highly concentrated salt solutions, such as $(NH_4)_2SO_4$. Each amide group in poly(acrylamide) has roughly 2 strongly bound water molecules (30) associated with it, whereas the entire first hydration sheath contains a total of about 4–5 water molecules per monomer (31). This may be compared to poly(sodium acrylate), which has 4 strongly bound water molecules

Table 2. Physical Properties of Poly(acrylamide) in Solution

Property	Value	Conditions	Reference
Steric hindrance parameter (σ)	2.72	Water @ 30°C	26
Characteristic ratio (C_∞)	14.8	Water @ 30°C	26
Persistence length (y)	1.52 nm	Water @ 25°C	–[a]
Partial specific volume (ν)	0.693 cm^3/g	Water @ 20°C	27
Theta temperature (Θ)	−8°C	Water	23
Theta conditions	0.40 v/v methanol/water	25°C	24
Flory χ parameter	0.48 ± 0.01	Water @ 30°C	25
Refractive index increment (dn/dc)		Water @ 25°C	28
	0.187 cm^3/g	$\lambda = 546.1$ nm	
	0.185 cm^3/g	$\lambda = 632.8$ nm	

[a]Calculated from the values of K_0 (Mark–Houwink–Sakurada prefactor under Θ conditions) and Θ_0 (viscosity constant) found in Ref. (21), using the relationship: $y = (\frac{M_n}{2b})(\frac{K_n}{\Theta_0})^{2/3}$, where M_0 is the monomer molecular weight (71 g/mol), and b is the monomer length (0.25 nm).

per repeat unit (32) and a total of 11 water molecules of hydration per repeat unit (33). Certain salts, however, can alter the hydrogen bonding between the primary amide groups and water in individual chains. For example, addition of potassium iodide [7681-11-0] to a poly(acrylamide) solution can increase the solution viscosity slightly (34). The inferred coil expansion involves a change in the hydration sheath of the polymer.

The amide group is capable of strong hydrogen bonding, which has effects on both the monomer and polymer properties. The relative rates of acrylamide polymerization in various organic solvents (35–37) are influenced by solvent–monomer interactions, which depend on the polarity and hydrogen bonding ability of acrylamide. Hydrogen bonding has been evidenced (with nmr) to occur mainly with the carbonyl oxygen in the acrylamide (38,39).

The hydrogen bonding ability of the amide group is also well worth considering when rationalizing the solution properties of polymers containing acrylamide. Two examples are presented here. The slow evolution of hydrogen-bonded aggregates (see the following) have been implicated in explaining the time dependence of the viscosities of poly(acrylamide) solutions in aqueous media (12,40). Second, it is well known that copolymers of acrylamide and sodium acrylate exhibit maximum values of the mean square radius (R_g), second virial coefficient (A_2), and intrinsic viscosity [η] at 60–70 mol% acrylate content (41). This can be rationalized from a consideration of intermolecular hydrogen bonding and electrostatic interactions.

Copolymers of acrylamide with ionic comonomers are also generally quite soluble in water. However, the solution properties of ionized copolymers of acrylamide are substantially different from those of the homopolymer. The incorporation of ionic comonomers leads to all of the traditional polyion effects such as chain expansion and viscosification at low ionic strength (polyelectrolyte effect), ionization-dependent dissociation constants, counterion condensation, ion exchange with charged surfaces, and specific binding of certain multivalent ions. For example, anionic copolymers containing carboxylate groups will precipitate at certain multivalent salt concentrations (42–44). Poly(sodium acrylate) can phase

separate in the presence of divalent salts when there are about 0.8 equivalents of the divalent cations (45). The phase behavior of acrylamide–acrylic acid copolymers in mixtures of mono and divalent salts has been studied (46). Trivalent cations (eg, Al^{3+} and Cr^{3+}) are even more efficient at precipitating polyions containing carboxylate groups (47). Under the right conditions, these physical crosslinks can be used to form a reversible gel. This strategy has been employed in mobility control systems used in oil recovery (48).

The rate of dissolution of polyacrylamides can depend on the agitation conditions, dissolved salts, the material form of the polymer (eg, solid or emulsion), state of hydration, and the presence of other components. While salts only weakly affect the dissolution rate of poly(acrylamide), ionic copolymers tend to dissolve decidedly more slowly in salt solutions than in pure water. Increasing the mechanical energy input typically speeds up the dissolution process; however, mechanical degradation (chain scission) of very high molecular weight chains can occur. Flows with elongational components (eg turbulent and porous media flows) are usually most egregious in this regard. The coil-to-stretched transition initiated at a critical elongation rate in these flows can be responsible for such phenomena as drag reduction (49) and apparent viscosity enhancement in porous media flow (50,51). However, chain scission can also occur at a second critical elongation rate. These critical elongation rates are functions of the degree of polymerization, the solvent quality, and the polymer concentration (52–56). Care is often taken to avoid mechanical degradation of the polymer during mixing [especially in impeller-type mixers (57), gear pumps, and orifice flow], filtration, and flow through a packed column [eg, in high performance size-exclusion chromatography (HPSEC) analysis], all of which expose the polymer chains to some elongational flow kinematics.

Linear polyacrylamides in solution adopt nearly random coil configurations that are partially permeable (draining) to solvent. The coils are unassociated in dilute solution. The average shape of the isolated coils has been described as an ellipsoidal or bean-shaped structure (58). The individual chains are quite flexible, as is common with most vinyl polymers. This is indicated from several parameters shown in Table 2, such as the persistence length, steric hindrance parameter (σ), and characteristic ratio (C_∞). The persistence length of 1.52 nm for poly(acrylamide) in water is quite similar to the average intrinsic (bare) persistence length ($\sim$1.4 nm) of many vinyl polymers (59).

One measure of the size of a polymer in solution is its mean square radius (R_g), sometimes referred to as its radius of gyration. The mean square radius scales with the weight-average molecular weight (M_w) to a fractional power (a_r) for a homologous series of polymers all within the same topology class (eg, linear chains); $R_g = K_r M_w{}^a r$. The K_r and a_r values depend on the polymer, solvent, and temperature. Suggested values derived from the literature for poly(acrylamide) and a few copolymers are listed in Table 3.

Solution Rheology. Solutions of polyacrylamides tend to behave as pseudoplastic fluids in viscometric flows. Dilute solutions are Newtonian (viscosity is independent of shear rate) at low shear rates and transition to pseudoplastic, shear thinning behavior above a critical value of the shear rate. This critical shear rate decreases with the polymer molecular weight, polymer concentration, and the thermodynamic quality of the solvent. A second Newtonian plateau at high shear rates is not readily seen, probably because of mechanical degradation of the chains

Table 3. Suggested R_g–M_w Correlations for Polyacrylamides in Solution $R_g = K_r M_w{}^a r$ (R_g in nm)

Polymer	Solvent	Temp., °C	MW range (10^6 Da)	10^2 K_r, nm	a_r	Reference
Poly(acrylamide)	Water	25	0.83–13.4	0.725	0.64	23

(12). Viscometric data for dilute and semidilute poly(acrylamide) solutions can often be fit to a Carreau model (63,64). It is wise to remember the cautions that were cited previously about mechanical degradation of the high molecular weight components of a polyacrylamide sample when analyzing rheological data.

The viscosities of fully dissolved, high molecular weight poly(acrylamide)s in aqueous solutions have often, but not always, been seen to change with time over the periods of days to weeks. Typically, the solution viscosity decreases with time. Extensive studies of this instability phenomenon have been made (12,40) and it was concluded that the evolution of intramolecular hydrogen bonds and the resulting change in macromolecular conformation were responsible for the time dependence, and not any molecular weight degradation. The instability can be avoided completely when the polymers are dissolved in formamide, aqueous ethylene glycol, or 2% 2-propanol in water. Competing viewpoints do exist about the interpretation of this solution aging (65,66).

The intrinsic viscosity $[\eta]$ of a polymer in solution is a measure of its molecular volume divided by its molecular weight. The $[\eta]$ value can be empirically correlated to the viscosity-average molecular weight (M_η) via the Mark–Houwink–Sakurada relationship (67): $[\eta] = K_\eta M_\eta a_\eta$. Poly(acrylamide) and ionic copolymers of acrylamide follow this empirical relationship, which is often used to estimate the polymer molecular weight. Table 4 lists suggested literature values of K_η and a_η for poly(acrylamide) and several copolymers in a variety of solvents.

At high concentrations of univalent ions ($\sim$1 M), the solution properties of ionic copolymers of acrylamide tend to resemble those of the homopolymer, but they are not exactly the same. Considering the intrinsic viscosity data, the exponents a_η for anionic and cationic polyacrylamides in high salt concentrations tend to cluster between 0.7 and 0.8, which is similar to that for poly(acrylamide) (12,23,60–62,71–75). However, the prefactors (K_η) vary over a larger range, and this cannot be rationalized simply by considering only the degree of polymerization. This means that there are real differences in the short-range interactions along the chains, which depend on the copolymer composition.

The polymer concentration (c) dependence of the zero-shear-rate viscosity (η_0) for aqueous poly(acrylamide) solutions of various viscosity-average molecular weights does not seem to follow the entanglement model, wherein polymer chain interpenetration would dominate the viscometric behavior, and a master curve should result when η_0 is plotted against cM_η. Instead, the data can be better described using a suspension model, wherein $c[\eta]$ correlates the η_0 data on a master plot. A concise presentation of the relationship between η_0, M_η, and c for poly(acrylamide) in water at 25°C has been made (12).

Solutions of poly(acrylamide) that are well in excess of the overlap concentration can display viscoelastic properties. Viscoelasticity of these polymeric fluids can be observed in a variety of ways, including the presence of a normal stress and/or flow irregularities (eg, vortices) in steady-shear flow, stress overshoot during shear flow startup, a measurable storage modulus (G') in oscillatory flow, an apparent shear thickening in flows with an elongational component (eg, porous media flow), a measurable elongational viscosity, or the ability to pull a solution "fiber" (tubeless siphon effect). A simple means for qualitatively assessing the molecular weight of a linear poly(acrylamide) in solution is to see how long a thread one can pull out of a semidilute solution of the polymer using a rod.

Table 4. Suggested Mark–Houwink–Sakurada Correlations for Polyacrylamides in Solution $[\eta] = K_\eta M_\eta a_\eta$ ($[\eta]$ in cm^3/g)

Polymer	Solvent	Temp., °C	MW range (10^6 Da)	$10^2\ K_\eta$, cm^3/g	a_η	Reference

Acrylamide Polymerization

Acrylamide [79-06-1] (2-propenamide, C_3H_5ON) readily undergoes free-radical polymerization to high molecular weight poly(acrylamide) [9003-05-8]. The synthetic methods have been reviewed extensively (12). Free-radical initiation can be accomplished using organic peroxides, azo compounds, inorganic peroxides including persulfates, redox pairs, photoinduction, radiation-induction, electroinitiation, or ultrasonication. Several reasons account for the ultrahigh molecular weights achievable. First, preparations of polyacrylamides are usually conducted in water, and the chain transfer constant to monomer and polymer appears to be zero in water (76). Second, the value of $k_p/k_t{}^{1/2}$, about 4.2, is unusually high (77) and is independent of the pH of the media. The rate of polymerization is proportional to the 1.2–1.5 power of the monomer concentration and to the square root of the initiator concentration (78–80). All this results in a high rate of propagation. Chain termination is primarily by disproportionation (81).

The large amount of heat (82.8 kJ/mol) that evolves during polymerization can result in a rapid temperature rise. One way in which this exotherm problem has been addressed in commercial high-solids and high-molecular-weight processes has been through the use of an adiabatic gel process in which the initiation temperature is 0°C. In another approach, controllable-rate redox polymerization of aqueous acrylamide-in-oil emulsions can be carried out at moderate temperatures of 40–60°C in order to accommodate the exotherm and to achieve very high molecular weights. At 70–100°C, a persulfate initiator can give a grafted or branched polymer (82). Additives greatly affect the rate and the kinetics of polymerization (83,84). These additives include metal ions, surfactants, chelating agents, and organic solvents. The high chain-transfer constant of compounds such as 2-propanol, bisulfite ion, or persulfate ion to active polymer has been reported (85). Chain-transfer agents have been used purposely to control molecular weight, minimize insoluble polymer, and control cross-linking and the degree of branching in commercial preparations.

Structural Modifications of Poly(acrylamide)

Poly(acrylamide) is a relatively stable organic polymer. However, poly(acrylamide) can be degraded (eg, molecular weight decreases) under certain conditions. The amide functionality is acidic in nature and is capable of undergoing most of the chemical reactions of primary amides. Consequently, acrylamide polymers can be functionalized by post-polymerization chemical reactions. Examples illustrated in the following constitute the most-used chemical modifications. To obtain anionic derivatives, poly(acrylamide) can be hydrolyzed with caustic. Sulfomethylated poly(acrylamide) can be prepared by reacting poly(acrylamide) with formaldehyde and sodium bisulfite under acidic conditions. Reacting poly(acrylamide) with hydroxylamine under alkaline conditions can yield hydroxamated poly(acrylamide). As an example of a cationic derivative, Mannich-base poly(acrylamide) can be obtained by reacting poly(acrylamide) with formaldehyde and dimethylamine to produce a cationic polymer with a charge that varies with pH. As an example of a nonionic derivative, poly(acrylamide) can be reacted with glyoxal to yield pendent

aldehyde functionality. These structurally modified polyacrylamides are successful commercial products.

Degradation. Dry poly(acrylamide) is relatively stable. The onset of dry poly(acrylamide) decomposition occurs at 180°C (86). Inter- or intra-amide condensation (87) to an imide can occur in acidic media at high temperatures (140–160°C). At temperatures above 160°C, thermal degradation, imidization, nitrile formation, and dehydration take place. Polymer stability is very important in actual applications in order to maintain consistent and excellent performance. In most applications, polymer solutions are prepared and used at moderate temperatures; however, there are exceptions such as in the harsh reservoir conditions (high temperature and high salinity) found in some enhanced oil recovery operations. Impurities such as residual persulfate from batch manufacturing can degrade the polymer (88,89). A residual Fe^{2+} EDTA complex in the product can also enhance degradation at both ambient and elevated temperatures (90–92). Hydroxy radicals, which can form in the presence of oxygen (93,94), can attack the polymer backbone. In the absence of oxygen, anionic polyacrylamide solutions were stable at 90°C for 20 months (95). Polyacrylamide in aqueous solution, in the presence of oxidizing agents such as $KMnO_4$, bromine, and $AgNO_3$, will degrade. The degraded polymer shows a reduced molecular weight, cross-linking, and chain stiffening (96). Recently, potassium peroxosulfate (97) was also reported to degrade hydrolyzed polyacrylamide. In the presence of ozone, very little degradation was found at low pH. However, random chain scission occurred at pH 10 (98). In the presence of sodium azide, a bactericide, a poly(acrylamide) in solution at room temperature showed no degradation for a long time (60). A combination of both pressure and elevated temperature can enhance polyacrylamide degradation. Polymer degradation can also occur under shear and elongational stresses (93,99). Backbone homolytic cleavage has been confirmed by a free-radical trap technique. Under certain shear conditions one macroradical per 12 monomer units can be formed.

Numerous types of oxygen scavengers are used to inhibit and prevent oxidative degradation. These stabilizers have been reviewed (96) extensively. Effective compounds are thio compounds, hydroquinone, bisulfite, phenolic compounds, hydroxylamine, hydrazine, and others.

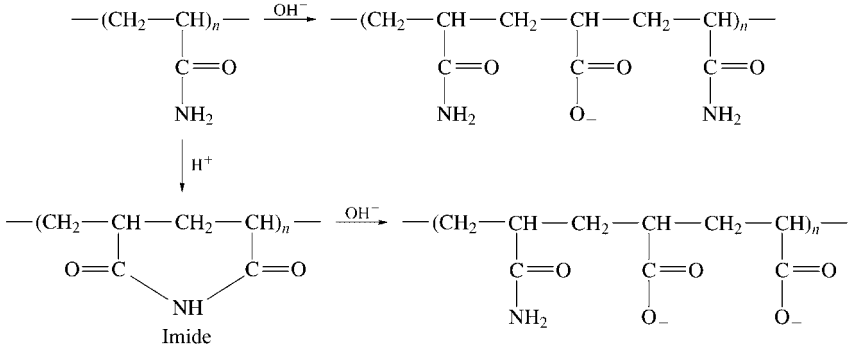
The biodegradability of poly(acrylamide) has not been definitively delineated in the literature (96). Recently, however, microorganisms (100), enterobacter agglomerans and azomonas macrocytogenes, were isolated from soil and the molecular weight of poly(acrylamide) in the presence of these microorganisms was found to undergo a 40-fold reduction as a result of chain degradation. The rate of biodegradation was equivalent to 20% of the carbon being consumed each day.

Hydrolyzed Polyacrylamide. Hydrolysis of poly(acrylamide) proceeds smoothly over a wide range of pH. Fundamental studies have been reviewed extensively (13,101–103). At alkaline pH, three reaction kinetics constants have been described, k_0, k_1, and k_2. The subscripts characterize the number of neighboring carboxylate groups next to the amide group being hydrolyzed. The rate constant k_0 is for no carboxylate neighbors, k_1 is for one carboxylate neighbor, and k_2 is for two carboxylate neighbors. Indirect evidence has shown that $k_0 > k_1 > k_2$. Under alkaline conditions, the rate of hydrolysis of poly(acrylamide) decreases with increasing conversion. The electrostatic repulsion from the increasing number of

carboxylate groups in the backbone polymer opposes the approaching hydroxyl ion. Consequently, further hydrolysis will be severely retarded. Only about 80% of the amide groups (104) can be hydrolyzed by excess hydroxide ion even at elevated temperatures.

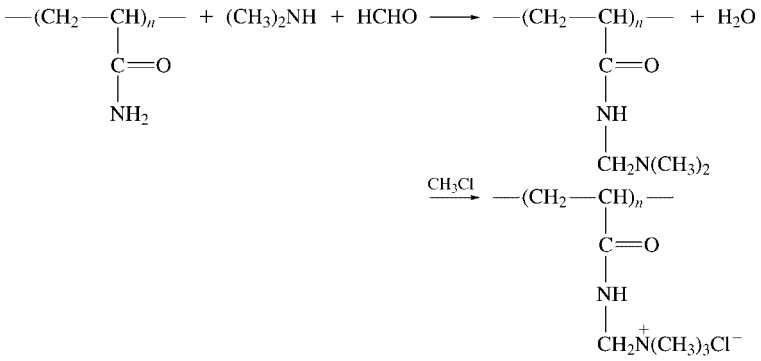
^{13}C nmr studies (105–107) have shown that hydrolysis at high pH results in a nearly random distribution of carboxylate groups. In one industrial process, a polyacrylamide with about 30 mol% hydrolysis is prepared by heating an aqueous poly(acrylamide) solution containing excess sodium carbonate [497-19-8] (108). Polymerization of acrylamide in a water-in-oil emulsion in the presence of sodium hydroxide has also yielded a copolymer with about 30 mol% hydrolysis (109). A method of preparing a hydrolyzed poly(acrylamide) (104) with a viscosity-average molecular weight greater than 30×10^6 Da was achieved in an inverse emulsion, in the presence of caustic, ethoxylated fatty amine, and oil.

Hydrolysis of poly(acrylamide) proceeds slowly under acidic conditions. The undissociated carboxylic acid groups are protonated, neutral species under those conditions. The intramolecular catalysis by means of undissociated—COOH groups at low pH has been proposed as the main mechanism (92). An imide structure has been proposed to be an intermediate in the low pH hydrolysis of poly(acrylamide), yielding short blocks of carboxyl groups distributed along the polymer chain. To date, there has been limited application of these block copolymer structures, and ones with high molecular weight have not been commercialized.



Under neutral conditions, the observed mechanism of hydrolysis cannot be explained by a simple superposition of the retardation kinetics at high pH and intramolecular catalysis at low pH (92).

Cationic Carbamoyl Polymers. Poly(acrylamide) reacts with formaldehyde [50-00-0], CH_2O, and dimethylamine [124-40-3], C_2H_7N, to produce aminomethylated polyacrylamide (a Mannich reaction). This reaction has been studied extensively (110–114). A wide range of substitution can be produced in solution or in water-in-oil emulsion. ^{13}C nmr studies (114) have verified that the Mannich substitution reaction follows second-order kinetics. The formation of the formaldehyde–dimethylamine adduct is very rapid. The high rate of Mannich substitution at high pH indicates a fast base-catalyzed condensation mechanism. The Mannich reaction is reversible and pH dependent. At low pH, the rate of substitution is very slow.



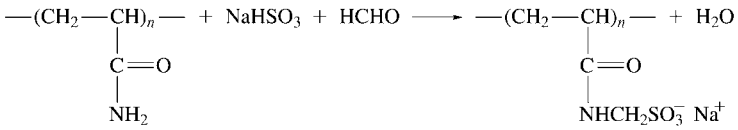
Mannich Reaction

Because of the simplicity of the process, the small capital investment for manufacturing equipment, and the low raw material costs, this group of cationic water-soluble polymers constitutes a substantial percentage of commercially important flocculants. Solution Mannich polyacrylamides are prepared and sold only at 4–6% solids, limited by the large solution viscosities and propensity for crosslinking on standing. The addition of formaldehyde scavengers such as guanidine compounds and dicyandiamide [461-58-5] (115) have improved the shelf stability. Aminomethylation of poly(acrylamide) is a reversible reaction. The reverse reaction can be retarded if the pendent amine groups are protonated by addition of an acid. Mannich base products protonated with organic acids or mineral acids have been patented (116). Low charge-density quaternized aminomethylated products are also sold at polymer solids less than 3% because of very high solution viscosities at higher polymer concentrations.

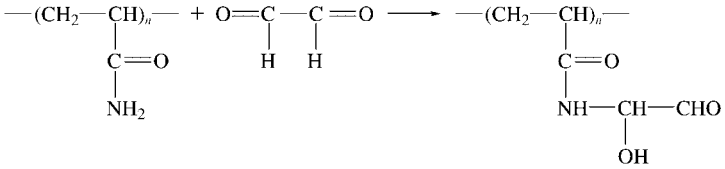
Several disadvantages of solution Mannich poly(acrylamide)s are the problem of handling high solution viscosities, the added expense of shipping low solids formulations, and the limitations to applications with low pH substrates because of the decrease in cationic charge with increasing pH. Quaternized aminomethylated products in water-in-oil emulsions with greater than 20% solids have been developed. The charges in both high and low charge products were nearly independent of pH (113,117–119). Microemulsion formulations have been developed and now they replace certain polymer macroemulsions. In one such case, poly(acrylamide) was functionalized in a microdroplet (∼100 nm in diameter) that contained only a few poly(acrylamide) molecules (120). Products based on this technology have been commercially successful as high performance cationic organic flocculants for municipal and industrial wastewater applications (121,122).

Sulfomethylation. The reaction of formaldehyde and sodium bisulfite [7631-90-5] with polyacrylamide under strongly alkaline conditions at low temperature to produce sulfomethylated polyacrylamides has been reported many times (123–125). A more recent publication (126) suggests, however, that the expected sulfomethyl substitution is not obtained under the previously described strongly alkaline conditions of pH 10–12. This nmr study indicates that hydrolysis of polyacrylamide occurs and the resulting ammonia reacts with the sodium bisulfite and formaldehyde to form sulfomethyl amines and hexamethylenetetramine

[100-97-0]. A recent patent describes a high pressure, high temperature process at slightly acid pH for the preparation of sulfomethylated polyacrylamide (127).



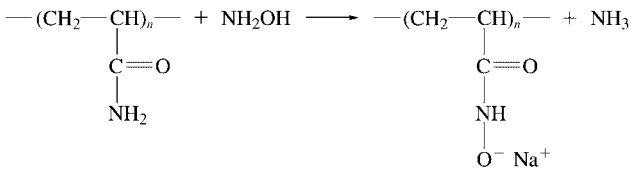
Reaction with Other Aldehydes. Poly(acrylamide) reacts with glyoxal [107-22-2], $C_2H_2O_2$, under mild alkaline conditions to yield a polymer with pendent aldehyde functionality.



The rate of this reaction can be controlled by varying the pH and reaction temperature. Cross-linking is a competing reaction. The reaction rate increases rapidly with increasing pH and with increasing polymer concentration. In a typical commercial preparation, a 10% aqueous solution of a low molecular weight polyacrylamide reacts with glyoxal at pH 8–9 at room temperature. As the reaction proceeds, solution viscosity increases slowly and then more rapidly as the level of functionalization and cross-linking increases. When the desired extent of reaction is achieved, before the gel point, the reaction is acidified to a pH below 6 to slow the reaction down to a negligible rate. These glyoxalated polyacrylamides are used as paper additives for improving wet strength (128).

A similar reaction occurs when poly(acrylamide) is mixed with glyoxylic acid [298-12-4], $C_2H_2O_3$, at pH about 8. This reaction produces a polymer with the CONHCH(OH)COOH functionality, which has found application in phosphate ore processing (129).

Transamidation. Poly(acrylamide) reacts with hydroxylamine [7803-49-8], H_2NOH, to form hydroxamated polyacrylamides with loss of ammonia (130).



This hydroxamation reaction occurs under alkaline conditions (131–133). Carboxyl groups can be produced because of the hydrolysis of the amide (131, 132). Acrylamide polymers can also be reacted with primary amines such as 2-aminoethanesulfonic acid (taurine) [107-35-7] at high temperature and acid pH to yield N-substituted copolymers containing sulfoethyl groups (134).

Hofmann Reaction. Polyacrylamide reacts with alkaline sodium hypochlorite [7681-52-9], NaOCl, or calcium hypochlorite [7778-54-3], $Ca(OCl)_2$, to form a polymer with primary amine groups (135). Optimum conditions for the reaction include addition of a slight molar excess of sodium hypochlorite, followed by addition of concentrated sodium hydroxide at low temperature (136). A two-stage addition of sodium hydroxide minimizes a side reaction between the pendent amine groups and isocyanate groups formed by the Hofmann rearrangement (137). Cross-linking sometimes occurs if the polymer concentration is high. High temperatures can result in chain scission. If long reaction times are used, NaOCl will cause chain scission and molecular weight decline. If very short reaction times are used at temperatures above 50°C, then polymers with high primary amine content can be obtained (138).

Reaction with Chlorine. Poly(acrylamide) reacts with chlorine under acid conditions or with NaOCl under mild alkaline conditions at low temperature to form reasonably stable *N*-chloropolyacrylamides. The polymers are water soluble and can provide good dry strength, wet strength, and wet web strength in paper (139).

Chemistry of Acrylamide Copolymers

Cationic Copolymers. The largest segment of the acrylamide polymer market has been dominated by cationic copolymers. The copolymers of acrylamide (AMD) and cationic quaternary ammonium monomers are manufactured by various commercial processes, which will be discussed in a later section. The most widely used of these cationic comonomers are cationic quaternary amino derivatives of (meth)acrylic acid esters or (meth)acrylamides, and diallydimethylammonium chloride.

The quaternary ammonium monomer contents in these copolymers are typically between 5 and 80 mol% for most applications. The composition actually employed depends on cost–performance relationships. Costs are largely dominated by the cationic monomer. Thus, the cationic demand of the substrate for each application has to be optimized. Normally, low- to medium-charge copolymers are used for paper waste applications and medium- to high-charge copolymers are used for sludge dewatering. The molecular weights for flocculants are usually 5×10^6 Da or greater. The higher molecular weight polymers often have the advantage of lower dosages in water treating and better fines capture in paper manufacture. Commercially important cationic comonomers, along with their reactivity ratios with acrylamide, are listed in Table 5.

Copolymers [69418-26-4] of acrylamide and AETAC (see Table 5, footnote *b*) are the most important flocculants because of a uniform sequence distribution of comonomers (140,141). Reactivity ratios obtained under very different free-radical copolymerization conditions can agree very well. For example, in one case, a free-radical copolymerization was initiated using potassium persulfate (KPS) [7727-21-1] in aqueous solution at pH 6.1 (141), while in the other case the copolymerization was initiated using a TBHP/MBS redox pair in an inverse emulsion stabilized with sorbitan monooleate (SMO) at pH 3.5 (140). The surfactant in an inverse emulsion may alter the reactivity of both AMD and AETAC. For

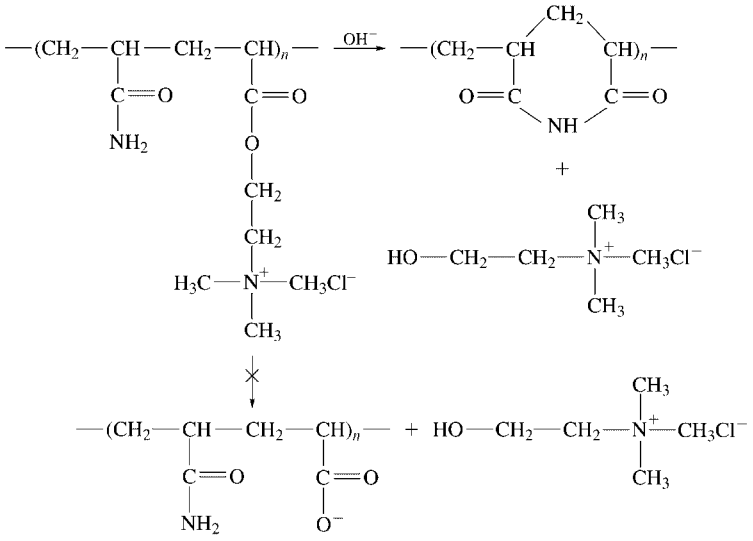
example, when SMO is utilized, in formulations made below the azeotropic monomer composition (ie, the copolymer composition is the same as the monomer feed composition, at about 58 mol% AETAC), AETAC is consumed slightly faster than AMD. On the other hand, if a block copolymeric surfactant, poly(ethylene oxide-*b*-12-hydroxysteric acid) (HB246), is utilized (148), then AMD is the faster reacting monomer. The results suggest that in the interfacial region near the discrete aqueous droplets, the AMD concentration is greater in the HB246 case than in the SMO case.

During AMD/MAETAC copolymerizations, MAETAC [5039-78-1] reacts with its own monomer significantly faster than with AMD. Consequently, copolymers [35429-19-7] can have severe compositional drift and often poor performance. How the sequence distribution can be improved if copolymerizations of AMD and MAETAC are conducted in water-in-oil microemulsion recipes has been studied (142). $K_2S_2O_8$-Na_2SO_3 redox initiator and the composite surfactants SMO and octylphenol ethoxylate were used. They found that reactivity ratios for AMD/MAETAC values were $r_{AMD} = 0.57$ and $r_{MAETAC} = 1.11$ (see Table 5).

Quaternary aminoester copolymers are very susceptible to base hydrolysis and are stable under very acidic conditions (140). In both manufacturing and in applications of these products, great care is needed to control the pH in order to prevent hydrolysis. These products should possess sufficient buffering acid to maintain very acidic conditions. The hydrolytic instability of ester copolymers is primarily attributed to a base-catalyzed ester cleavage reaction that forms cyclic imides between neighboring AMD and AETAC groups. The loss in cationic charge is not due to direct ester hydrolysis (149). The chemistry of the six-membered imide ring is shown below (140,150).



The effect of pH on hydrolytic stability of cationic ester–acrylamide copolymers has been long recognized (149). The decrease in viscosity and effectiveness, characteristic of this instability, do not take place in aqueous solutions at pH 2–5.

Cationicity loss in AETAC and MAETAC copolymers depends on both pH and composition. For example, in a 43 mol% AETAC copolymer, at least 95% of the ester groups have at least one AMD neighbor. The effect of pH on cationicity loss in this copolymer was minimal at a pH of 2–3 at 90°C for 9 h. Above pH 3, ester loss increased dramatically. Prolonged heating (24 h) resulted in a greater degree of ester loss. It was found that the rate of isolated ester hydrolysis was first order in hydroxide concentration at 60°C at constant buffer pH of 5.5. If there were neighboring acrylamide groups in the chain, then there was a second-order dependence of ester disappearance on hydroxide concentration. This indicated that the imidization reaction was also first order in hydroxide ion concentration. The percentage of esters cleaved increased as the number of AETAC groups with neighboring AMD groups increased. Polymers with esters and no AMD neighbors such as the homopolymers of AETAC or MAETAC were found to have a low degree of hydrolysis. The rate of hydrolysis of AETAC and MAETAC copolymers were the same only when both had the same number of AMD neighbors.

Cationic copolymers derived from amide monomers, such as MAPTAC [51410-72-1] and APTAC [45021-77-0], are reasonably random and are hydrolytically stable. However, they are more expensive. The molecular weights of high charge AMD/APTAC [75150-29-1] and AMD/MAPTAC [58627-30-8] copolymers typically do not reach the high molecular weights of AMD/AETAC copolymers because of impurities in the APTAC and MAPTAC. However, low charge AMD/MAPTAC copolymers, containing ∼3 mol% MAPTAC, are significant commercial products.

Diallydimethylammonium chloride (DADMAC) [7398-69-8] is the least expensive commercially available cationic monomer. This monomer has been successfully produced by reacting allyl chloride, dimethylamine, and sodium hydroxide in aqueous solution (151,152). Monomer solutions with solids of 60–70% can be achieved and used directly for polymerization without further isolation and purification. DADMAC is a nonconjugated diene monomer that was found to homopolymerize to high molecular weight linear cationic polymer without crosslinking (151,152). Poly(diallydimethylammonium chloride) (PDADMAC) [26062-79-3] was the first synthetic organic flocculant approved for potable water clarification by the U.S. Public Health Service (154). The polymerization of DADMAC is known as kinetically favorable to give 98% of inter–intra cycloaddition and 2% pendent double bonds (143). The initiator radical attacks the terminal carbon on one allyl group, and the radical formed attacks the internal carbon on the other allyl group in the same molecule to form a five-membered pyrrodinium ring with a cis-to-trans ratio of 6:1 (155).

The rate law for DADMAC polymerization in an aqueous system, when persulfate is used, is not simple: $R_p = (S_2O_8^{2-})^{0.8}(\text{DADMAC})^{2.9}$. A combination of complicated initiation reactions and dimeric DADMAC interactions can account for the unusually high exponent of the DADMAC concentration (156). High monomer concentrations (>1.5 mol/L) used in commercial processes result in greater rates of polymerization and higher molecular weights. PDADMAC with low residual unreacted monomer can be manufactured in water using either persulfate addition or ammonium persulfate with sodium metabisulfite (157). Polymerization of DADMAC has also been studied in water-in-oil emulsion in a continuous stirred tank reactor (158). In that case, the oil-soluble initiator,

2,2′-azobis(2,4-dimethylvaleronitrile) (ADVN), and the surfactants sodium di-2-ethylhexylsulfosuccinate (AOT) and SMO were used. The rate of polymerization was $R_p = k\,(\mathrm{ADVN})^{0.4}(\mathrm{AOT})^{0.5}(\mathrm{SMO})^{-0.4}(\mathrm{DADMAC})^3$. The negative order of SMO concentration was due to the fact that SMO is a radical scavenger. The influences of partitioning effects and ionic strength contributed to the third order in DADMAC concentration.

The molecular weight of PDADMAC is not as high as for acrylic polymers because of the large chain-transfer constant of allylic radicals. However, a molecular weight of 5×10^5 Da is sufficient for applications such as potable water clarification, color removal, and textile processing. These applications rely on the very high cationic charge of PDADMAC. This polymer is often used along with a high molecular weight anionic polyacrylamide in process-water clarification in paper deinking mills.

Anionic Copolymers. Anionic acrylamide copolymers such as poly(acrylamide-*co*-sodium acrylate) [25085-02-3], poly(acrylamide-*co*-ammonium acrylate) [26100-47-0], poly(acrylamide-*co*-sodium-2-acrylamido-2-methylpropanesulfonate) (AMD/NaAMPS) [38193-60-1], and poly(acrylamide-*co*-2-acrylamido-2-methyl-1-propanesulfonic acid) (AMD/AMPS) [40623-73-2] have considerable practical importance. They can be prepared in solution, inverse emulsion (144,145), and inverse microemulsion (146). Comonomer reactivity ratios of AMD with acrylic acid or acrylic acid salts are given in Table 5. Reactivity ratios vary with pH. At high pH the reactivity ratio for AMD is higher, but at low pH the reactivity ratio of acrylic acid is higher. At a pH of about 5, a random copolymer can be obtained. When AMD and sodium acrylate are copolymerized in a microemulsion at pH of about 10, copolymer composition is independent of conversion and the reactivity ratios are equal. The copolymer chain composition conforms to Bernoullian statistics (146). These copolymers are used extensively as industrial flocculants for water treating, mining and paper manufacture, drag reduction agents, and in secondary and tertiary oil recovery. Reasons for their extensive use include their low cost and very high molecular weights. Their limitations include poor solubility at low pH and precipitation of the salt form in the presence of calcium ions.

Comonomer reactivity ratios for AMD and NaAMPS are given in Table 5 (147). AMD/AMPS copolymers and AMD/NaAMPS copolymers maintain their anionic charge at low pH and have a high tolerance to many divalent cations. They are used as flocculants for phosphate slimes, uranium leach residues, and coal refuse. There are also many oilfield applications.

Commercial Processes

There are numerous laboratory methods to prepare polyacrylamides. However, there are only a few viable commercial processes used to manufacture materials that meet the necessary performance standards. There are many requirements for commercial materials: very low to very high molecular weights, low insolubles content, low residual monomer content, fast dissolution rate, ease of handling, minimal dusting (for dry solids), product uniformity, long-term storage stability (to ensure performance consistency), high solids (to reduce shipping costs), and

consistent performance characteristics. Several common commercial processes are summarized below.

Solution Polymerization. Commercial production of polyacrylamides by solution polymerization is conducted in aqueous solution, either adiabatically or isothermally. Process development is directed at molecular weight control, exotherm control, producing low levels of residual monomer, and control of the polymer solids to ensure that the final product is fluid and pumpable. A generic example of a solution polymerization follows.

An acrylamide monomer solution (2–30 wt% in water) is typically prepared, and deaerated by sparging it with an inert gas (eg, nitrogen) to reduce the oxygen content in solution. Stainless steel batch reactors or glass continuous stirred tank reactors are often used for solution polymerizations. A chelating agent is added to complex autopolymerization inhibitors such as copper or other metals, if they are present. The polymerization is then initiated using one of several free-radical initiator systems (azo, peroxy, persulfate, redox, or combinations) at concentrations ranging from 0.001 to 10 wt% on monomer. The rate of polymerization depends on reaction conditions, but it typically depends on the 1.2–1.6 order of monomer concentration and 0.5 order of initiator concentration. The heat evolved during polymerization (82.8 kJ/mol) can be removed by an external cooling system. For adiabatic processes, the temperature rise needs to be estimated and great care needs to be exercised to avoid exceeding the reflux temperature. Chain-transfer agents and inorganic salts can be added to improve processing and to reduce insolubles. Monomer-to-polymer conversions of 99.5% are achievable in 4–6 h of polymerization time. The products can have a molecular weight ranging from one thousand to four million. Polymer solids can be 2–30%. The process can be used in conjunction with thermal drying or precipitation methods in order to obtain products in either powder or granular form. Short residence times in drum drying have been used to avoid chain degradation and formation of insolubles. Precipitation in C_1—C_4 alcohols can be done to obtain nonsticky rubbery polymer gel that can be further extruded and then dried with hot air. The resulting granules can be milled and sieved to produce a uniform product. Care is taken to avoid very finely divided material that can cause dusting problems.

Some commercial low molecular weight polyacrylamides (LMPAM) are manufactured in solution and sold at 10–50% solids. For example, LMPAM containing DADMAC comonomer is made at 40% solids and can be reacted with glyoxal to produce a strengthening resin for paper. Furthermore, LMPAM hydrolyzed with sodium hydroxide to polyacrylate is manufactured at 30% solids and is used as an antiscalant. High molecular weight poly(acrylamide) is also prepared in solution at 2–6 wt% solids and is often further modified using, for example, the Mannich reaction.

Inverse Emulsion Process. A method of avoiding the high solution viscosities of high molecular weight water-soluble polymers comprises emulsifying the aqueous monomer solution in an oil containing surfactants, homogenizing the mixture to form a water-in-oil (inverse) emulsion, and then polymerizing the monomers in the emulsion. The resulting polymer latex can be inverted in water, releasing the polymer for use. A basic patent (159) illustrated this inverse emulsion process. Processes in which the inverse emulsion polymerization results in finely divided particles that are small enough to retard settling and can

be sold without further modification have been developed (160,161). Stability of the inverse emulsion to mechanical shear has recently been improved (162). Commercial production of inverse emulsion polymerization of AMD has been reviewed (163).

Polymerization on Moving Belts. Dry polyacrylamides are sometimes preferred, particularly when transportation distances are long. A variety of continuous processes has been developed for preparing dry polyacrylamides that consist of polymerizing aqueous acrylamide on a moving belt and drying the resulting polymer (164–166). In one such process (167), an aqueous solution of acrylamide and a photosensitizer is pumped onto a moving stainless steel belt, cooled on the underside by a water spray and covered on the upper side by a humid inert atmosphere. The belt passes under uv lamps that photoinitiate polymerization. The belt speed can be controlled so that the polymerization is complete when the polymer reaches the end of the belt. At the end of the belt the polymer gel that has formed can be sliced into small granules and dried in an oven. The dried polymer is then passed through a grinder to produce the desired particle size for handling and use.

Several recent patents describe improvements in the basic belt process. In one case, a higher solids polymerization is achieved by cooling the starting monomer solution until some monomer crystallizes, and then introducing the resulting monomer slurry onto a belt. The latent heat of fusion of the monomer crystals absorbs some of the heat of polymerization, which otherwise limits the solids content of the polymerization (168). In another patent, a concave belt that flattens near the end is described. This change is said to result in improved release of polymer from the belt (167).

Dry Bead Process. Dry polyacrylamides can also be prepared in the form of dry beads with bead sizes ranging from about 100–2000 μm (169,170). These beads are formed by azeotropically distilling water from inverse suspension polyacrylamides, collecting the beads by filtration, and further drying the beads in a fluid bed drier for short times. The resulting beads can be dissolved in water in a similar manner to other dry polyacrylamides. The size and shape of the beads prepared in the suspension polymerization process are a function of the types and amounts of surfactants and additives employed. Typically, 0.03–0.2 wt% (based on water plus polymer) of an oil-soluble polymeric surfactant is used to obtain the desired bead size. Greater amounts of surfactants lead to smaller beads (169). Certain water-soluble ionic organic compounds are said to be effective in improving the stability of the beads and providing a narrower bead size distribution when used in conjunction with the polymeric stabilizers (169). In the absence of the stabilizer, irregularly shaped, unstable particles can result. The choice of the stabilizer is considered to be dependent on the charge of the polyacrylamide being produced (169).

Microemulsion Polymerization. One inherent problem with water-in-oil emulsions of acrylamide-based polymers is the potential formation of unstable lattices both during production and in finished products. The coagulum that can form in the reactor can result in a time-consuming cleanout (171). Technology has continuously improved reactor configuration, types of agitation, proper cooling (171), and a proper balance of aqueous, oil, and emulsifier ratios (160,161). Microemulsion polymerization (qv) can provide improvements to address these

problems (172–182). Monomer microemulsions are thermodynamically stable systems comprising two liquids, insoluble in each other, and a surfactant. They form spontaneously without homogenization. The resulting polymer microlattices are typically nonsettling, transparent, and about 100 nm in diameter. These systems can have high emulsifier levels: more than 8 wt%, which is about 4–5 times more than emulsifier levels in conventional inverse emulsions. Consequently, the cost of producing microemulsions becomes less attractive. However, further refinements to technology lead to the development of cost-effective microemulsified Mannich acrylamide polymers (120–122,183). This technology was used to develop functionalized polyacrylamides (184). In one case, a poly(acrylamide) microlatex reacted with formaldehyde and dimethylamine (Mannich reaction), and then quaternized with methyl chloride to yield a very highly charged cationic carbamoyl polymer (120–122,185). These commercial products are widely used in many applications for solid–liquid separation. These products have been improved by treating them with buffer acid, a formaldehyde scavenger, and heat to produce a high performance cationic polymer (186).

Environmentally Friendly Polyacrylamides. In recent years, commercial processes that use biodegradable oils to replace petroleum hydrocarbons have received a great deal of attention. Also, there has been a great deal of interest in polymerization in supercritical fluids. These future directions for the manufacture of polyacrylamides are summarized in the following.

Dispersion Polymerization. Water-in-oil emulsions contain at least 30 wt% of a petroleum-based hydrocarbon that is a valuable natural resource. By using such formulations, oils are consumed unnecessarily and can enter the world's waterways as a source of secondary pollution. An aqueous polymer dispersion is one environmentally responsible formulation that contains no oil or surfactant, and near-zero amounts of volatile organic compounds. Dispersion polymerization can be used to prepare cationic, anionic, and nonionic polyacrylamides.

Inverse Emulsions with Biodegradable Oils. Some examples of inverse emulsion polymerization processes employing biodegradable oils include materials with aqueous phase monomer mixtures, such as AMD and AETAC or AMD and MAETAC, dispersed in a biodegradable oil, such as bis-(2-ethylhexyl)adipate (187), containing a polymeric emulsifier that is a copolymer of dimethylaminoethylmethacrylate and mixtures of methacrylates. A buffering acid, such as a dicarboxylic acid, is used to stabilize cationic copolymers. Aliphatic dialkylethers are also used as biodegradable oils (188), in conjunction with SMO as an emulsifier, to produce high-molecular-weight cationic copolymers.

Inverse Emulsion Polymerization Acrylamide in Near-Critical and Supercritical Fluid Conditions. Supercritical fluids exhibit both liquid-like properties (eg, solubilizing power), and gas-like properties (eg, low viscosities). Aqueous AMD has been dispersed and even microemulsified in near-supercritical ethane–propane mixtures using nonionic surfactants such as ethoxylated alcohols (eg, Brij 30 and Brij 52). Emulsion polymerization of AMD was then conducted at 60°C for 5 h and 379 bar, at the near-supercritical condition of certain ethane–propane mixtures (189). 2,2′-Azobis(isobutyronitrile) (AIBN) was used as the initiator. The resulting poly(acrylamide) had a low molecular weight in the range of $(2.7–5.8) \times 10^5$ Da. The ethane and propane can be easily recovered and recycled in a production plant.

Emulsion polymerization of AMD was also conducted at 60°C for 1 h and 345 bar in near-supercritical CO_2. AIBN was the initiator. An amide end-capped hexafluoropropylene oxide oligomer that has high solubility in the near-supercritical CO_2 was found to stabilize the dispersed particles (190–192). Only a few classes of polymers have good solubility in near-supercritical CO_2. The advantages of using carbon dioxide include very low viscosities during polymerization and ease of recovery.

Applications.

Dewatering. Polyelectrolyte-assisted dewatering constitutes one of the most important application areas of polyacrylamides (3). Solid–liquid separations in aqueous media can be enhanced by the flocculation of small suspended particles into larger aggregates, which increases separation rates. Floc formation requires a destabilization and adherence of the smaller particles. This is usually accomplished by means of surface charge neutralization, charge-patch formation, and/or polymer bridging (193). Acrylamide-containing polymers make ideal candidates for such flocculants because of the large molecular weights achievable with them. High molecular weight cationic copolymers are typically employed in wastewater treatment. Solid–liquid separations in mining industries often benefit from the use of anionic copolymers, or in some cases dual polymer systems (cationic and anionic in sequence). Various dewatering processes in the papermaking industry regularly make use of cationic, anionic, or dual addition systems (194). Nonionic poly(acrylamide) finds less use in solid–liquid separations, save for some mining applications.

Mineral Processing. Both synthetic and natural hydrophilic polymers are used in the mineral processing industry as flocculants and flotation modifiers. Most synthetic polymers in use are polyacrylamides. Nonionic polymers are effective as flocculants for the insoluble gangue minerals in the acid leaching of copper and uranium (195,196), for thickening of iron ore slimes (197), and for thickening of gold flotation tailings (198). In some uranium leach operations, a cationic polymer with a relatively low charge density is used along with the nonionic polymer to improve supernatant clarity.

Anionic polyacrylamides are extensively used in the mining industry. They are used as flocculants for insoluble residues formed in cyanide leaching of gold (199). Acrylamide–acrylic acid copolymers are used for thickening copper, lead, and zinc concentrates in flotation of sulfide ores. These copolymers, containing from 50 to 100% carboxylate groups, are used to flocculate fine iron oxide particles in the manufacture of alumina from bauxite at high pH (200). Hydroxamated polyacrylamides, prepared by reaction of nonionic polyacrylamide or anionic polyacrylamide with hydroxylamine salts, are also effective in this Bayer process (201). Other uses for hydroxamated polyacrylamides include reduction of titanaceous and siliceous scale in Bayer alumina processes (202) and flocculation of titanium or copper ore tailings in froth flotation processes (203). Copolymers [40623-73-2] of acrylamide and acrylamido-2-methylpropanesulfonic acid [15214-89-8] have been patented as phosphate slime dewatering aids (204).

Low molecular weight polyacrylamide derivatives with mineral specific functionalities have been developed as highly selective depressants for separation of valuable minerals from gangue minerals in froth flotation processes. These depressants have certain ecological advantages over natural depressants such

as starches and guar gums. The depressants provide efficient mineral recovery without flocculation. They are often used along with hydrophobic mineral collectors (eg, sodium alkyl xanthates) and froth modifiers. Partially hydrolyzed polyacrylamides with molecular weights of 7,000–85,000 can be used in sylvanite (KCl) recovery (205). Polymers having the functionality $-CONHCH_2OH$ are efficient modifiers in hematite–silica separations (206). Polymers containing the —CONHCH(OH)COOH functionality provide excellent selectivity in separation of apatite from siliceous gangue in phosphate benefication. Valuable sulfide minerals containing copper and nickel can be separated effectively from gangue sulfide minerals such as pyrite in froth flotation processes when acrylamide–allylthiourea copolymers or acrylamide–allylthiourea–hydroxyethylmethacrylate terpolymers are added to depress the pyrite (207). Acrylamide copolymers can be used as iron ore pellet binders (208). When the ore slurry in water has a pH above 8, anionic polymers are effective. If the ore is acid washed to remove manganese, then a cationic polymer is effective.

Paper Manufacture. Polyacrylamides are used as wet-end additives to promote drainage of water from the cellulose web, to retain white pigments and clay fillers in the sheet, to promote sheet uniformity, and to provide dry tensile strength improvements (209). An important advance in papermaking technology has been the use of microparticle retention aids. Organic microparticles, prepared from acrylamide and anionic comonomers by microemulsion polymerization, provide good sheet formation characteristics and controlled drainage (210,211). Cationic polyacrylamides that have been reacted with glyoxal are used to promote wet strength (212). These wet strength resins have been used in paper towels. Recently, these glyoxalated polymers have been modified so that they can be used in toilet tissue. These polymers provide an initial high wet tensile strength with rapid tensile strength decay in water so that sewers may not become clogged (213,214). Anionic polyacrylamides have been used with alum to increase dry strength (215). Primary amide functionality promotes strong interfiber bonds between cellulose fibers. Sometimes paper mills use dry strength additives so that recycled fiber, groundwood, thermomechanical pulp, and other low cost fiber can be used to produce liner board and other paper grades which must meet ICC requirements for burst strength and crush strength. Recently, there has been an increasing demand for writing papers and copy paper that have good print characteristics. Print quality can be improved by use of surface sizes combined with acrylamide polymers. The acrylamide polymer gives the paper sheet better surface strength (216). Details on paper manufacture can be found in Reference (217). All additives used for manufacture of food-grade papers are subject to FDA regulations and are listed in the *Code of Federal Regulations* [paragraphs 176.170, 176.180, 178.3400, and 178.3650] (1998).

Enhanced Oil Recovery. Polymer flooding is a potentially important use for anionic polyacrylamides having molecular weights greater than 5 million and carboxyl contents of about 30%. The ionic groups provide the proper viscosity and mobility ratio for efficient displacement. The anionic charge prevents excessive adsorption onto negatively charged pores in reservoir rock. Viscosity loss is observed in brines particularly when calcium ion is present. A primary advantage of anionic polyacrylamides is low cost (218). Profile modification is a process wherein flooding water is diverted from zones with high permeability to other zones of

lower permeability containing oil. Polymeric hydrogels are used for this. Metals such as chromium and aluminum can be injected with anionic polyacrylamides to cross-link the polymers in more permeable reservoir zones prior to the water flood (219,220). The development of new, more environmentally acceptable cross-linking systems has continued. A recent patent claims a composition consisting of hexamethylenetetramine [100-97-0] and 4-aminobenzoic acid [150-13-0] for this purpose (221).

Polyacrylamides are used in many other oilfield applications. These include cement additives for fluid loss control in well-cementing operations (222), viscosity control additives for drilling muds (223) and brines, and for fracturing fluids (224). Copolymers [40623-73-2] of acrylamide and acrylamidomethylpropanesulfonic acid do not degrade with the high concentrations of acids used in acid fracturing.

Hydrophobically Associating Polymers. Extensive research in the 1980s and 1990s focused on acrylamide copolymers containing small amounts of hydrophobic side chains. At zero or low shear rates, the apparent viscosity can be very large because of association of the hydrophobic groups between chains. In oil reservoir conditions, the polymers tolerate high salt concentrations while providing proper viscosifying properties (225). These associative thickeners are also used in coatings (226) and in oil spill cleanup (227). Reference (228) gives more information about associative polymers.

Hydrophobically associating acrylamide copolymers can be prepared by micellar polymerization. These copolymers have short blocks of hydrophobic groups randomly distributed in the backbone. A recent paper reviews the major advances in this area (229).

Superabsorbents. Water-swellable polymers are used extensively in consumer articles and for industrial applications. Most of these polymers are cross-linked acrylic copolymers of metal salts of acrylic acid and acrylamide or other monomers such as 2-acrylamido-2-methylpropanesulfonic acid. These hydrogel-forming systems can have high gel strength, as measured by the shear modulus (230). Sometimes, inorganic water-insoluble powder is blended with the polymer to increase gel strength (231). Patents describe processes for making cross-linked polyurethane foams that contain superabsorbent polymers (232,233). Recent patents describe grafted copolymers that are highly absorbent to aqueous electrolyte solutions (234).

Analytical Methods. Most of the traditional methods for polymer analysis (235) are applicable to polyacrylamides. We will only point out several special features regarding the use of some of these techniques for the analysis of polyacrylamides.

Oftentimes a preliminary step applied before many analytical methods is the isolation of the polymer. The isolation of polyacrylamides from the other components of the media in which they were prepared (eg, aqueous solution or inverse emulsion, with attendant surfactants and oil) is often readily accomplished by precipitation in short-chain alcohols or acetone. The individual solubilities of formulation components should be tested if there is any doubt. Experience shows that anionic copolymers are often best precipitated in the alcohols, and cationic copolymers in acetone (homopolyaminoesters are soluble in methanol). Since acrylamide is soluble in these organic solvents, it will also be separated from the polymer in this procedure.

Once the polymer is isolated, its chemical composition can be quantified using in or nmr spectroscopies (12,236). An nmr study can also give some information about chain architecture in the case of copolymers (237). Elemental analysis can be employed to confirm a composition. Ultraviolet spectroscopy is generally not used for compositional analysis per se; however, polymers containing acrylamide do absorb short-wavelength uv radiation, along with many other materials. A uv detector set around 215 nm is a common choice for measuring polymer concentration in the absence of interfering substances; many surfactants and some salts (eg, NO_3^-, SCN^-) are problematic in this regard. Differential refractometry is the logical alternative for concentration monitoring when uv-absorbing substances are present.

The extent of conversion during an acrylamide polymerization is most easily followed by determining the disappearance of the monomer. High performance liquid chromatography (hplc) is often found best for this purpose. An hplc method in which poly(acrylamide) inverse emulsions can be used directly has been developed (238). In the case of copolymers, hplc protocols that allow the simultaneous determination of all the unreacted monomers can be used to evaluate compositional drift as a function of conversion.

Global properties of the polymer chains (eg, molecular weight, coil dimensions, branching content) are most often evaluated using scattering, hydrodynamic, or viscometric techniques on dilute polymer solutions. The conventional methods appropriate for soluble polymeric materials typically apply equally well to polyacrylamides. In the case of high molecular weight polyacrylamides, the main difficulties in obtaining accurate information involve preparing a purified polymer solution that is in an equilibrium state, and passing it through the measurement device without substantially altering it in either process.

When using viscometric methods, experiment protocols can be designed to address any effects that instabilities may have on the viscosities of the polyacrylamide solutions, if not to alleviate the instabilities altogether. Mechanical degradation can also occur in high molecular weight polymers. This can happen during sample preparation (eg, mixing), purification (eg, filtration), or during the viscosity measurement itself (especially in elongational flows). In any case, one should estimate these handling effects for any set of protocols.

The presence of colloidal-size contamination ("dust") in polymer solutions can possibly affect either static or dynamic light scattering experiments (239,240). Neutron scattering is less afflicted by this kind of contamination (241). For high molecular weight polyacrylamides whose coil dimensions are roughly in the same size range as the colloidal contaminants, and which have a natural propensity to adsorb onto suspended materials (after all, many of these polymers are flocculants), any problem of sample purification should not be ignored. If one is simply looking for a clean sample, it is possible to exhaustively filter a solution in a recycle loop (242). Clarification of dilute polymer solutions by centrifugation is another method that can minimize mechanical degradation of the polymers. Centrifuging dilute solutions of high molecular weight linear polyacrylamides from 4 to 8 h in excess of $15{,}000 \times G$ is satisfactory in many instances. Good light scattering data can be acquired even in the case of a marginally clean polymer solution by attempting to "look through the dust." This is made easier by reducing the scattering volume, slowing (or stopping) the solution flow, and monitoring the scattering

volume (either manually or with the aid of a computer algorithm) for periods that are free of point scatterers.

The effects of sample clarification must be gauged when trying to preserve and analyze the polymer in its original form. This includes situations when samples are passed through packed columns, as in HPSEC analysis. A uv-absorbance study can be used to determine polymer loss if there are no interferences in the solution. A method that can monitor the molecular weight distribution (eg, HPSEC or dynamic light scattering), or one that is sensitive to the high molecular weight component (eg, elongational viscometry), can be used to assay for mechanical degradation.

The double extrapolation of light scattering data to zero polymer concentration and zero scattering angle yields an average property of the macromolecular ensemble: the weight-average molecular weight (M_w) from static light scattering and the z-average hydrodynamic radius ($<R_h>_z$) from dynamic light scattering. In some cases, the details of the distribution of these quantities are also of interest. Dynamic light scattering data can be analyzed directly to give a distribution of the hydrodynamic size distribution of a sample. How to derive molecular weight distributions from dynamic light scattering data has been demonstrated (243), but this involves knowing the correlation between the polymer diffusion coefficient and molecular weight, a relationship that is not always available.

Methods involving a physical separation of the components of the distribution, coupled with a method for measuring some feature of the macromolecules across this separated collection, find more use in determining molecular weight (or size) distributions. Size exclusion chromatography (sec) remains a popular way to separate macromolecular populations (244), including polyacrylamides (245). More recently, flow field flow fractionation (ffff) (246) has been shown to have some advantages over sec methods, especially for very high molecular weight polymers, including polyacrylamides. Since the fluid contact surface in ffff is a membrane, as opposed to a packed bed of finely divided particles in sec, there is less opportunity for altering the native distribution by means of polymer adsorption, retention, or mechanical degradation. High molecular weight cationic copolymers of acrylamide can be difficult to pass unaltered through commercial sec columns. Ultracentrifugation (63,247,248) has also been used to separate the components of polyacrylamide samples for subsequent analysis, but this is currently a less popular method than either sec or ffff.

The early approaches to characterizing the molecular weight distributions of samples separated using sec or ffff were based on retention time, requiring a correspondence to be made between the retention time and molecular weight. This was typically done by calibrating the separation device using fractionated (narrowly distributed) standards, which in some cases were only vaguely related chemically to the polymer of interest. More recently the use of in-line light scattering detectors for the purpose of directly determining M_w, R_g (static light scattering photometer), or R_h (dynamic light scattering photometer) for each "slice" of the separated distribution has been an alternative to these approaches (249). This has generally improved one's ability to characterize the details of the molecular weight or size distributions for many acrylamide-containing polymers, for which standards consisting of narrow fractions are not readily available.

Titration methods are mostly applicable to ionic copolymers of acrylamide. Typically, potentiometric titrations are used for high salt concentrations, and conductometric titrations are used for low salt concentrations. This kind of information can be important since ionogenic groups with weak acid or base properties will have both dissociation-dependent and salt-dependent pK_as when they are in a polymer chain. In addition to titrating ionic acrylamide copolymers with low molecular weight titrants, their titration with other oppositely charged polyelectrolytes has proven useful (250). For example, poly(potassium vinylsulfonate) can be used to titrate cationic copolymers of acrylamide. This titration gives information about the available charge on the host macromolecule. Usually the macroion titrant is of lower molecular weight than the polymer of interest. In any case, the conditions of the polyelectrolyte–polyelectrolyte complexation reaction must allow for complete 1:1 complex formation. Care must be taken such that the kinetics of the complex formation does not influence the results. The end point can be detected in any one of several ways, including turbidometrically, or using a dye indicator. The color change of the dye at the end point can be determined visually or spectrophotometrically with an "optrode."

Detecting Polyacrylamides. In order to detect low concentrations of polyacrylamides as part of an analysis scheme (251), to optimize the use of or to monitor the fate of these polymers in a variety of technological applications, an assay method for trace amounts of these polymers that remain in solution is usually needed. One approach, more appropriate for laboratory studies, has been to incorporate fluorescent groups in the polymer either by copolymerization or by postpolymerization derivatization. Acrylamide copolymers containing sodium fluorescein (252), various dyes [phenol red, or brilliant yellow (253)], *N*-2,4-dinitroanilineacrylamide (254), or a pyrene-labeled monomer (255) have been described. Early methods based on chemical derivatizations describe coupling fluorescein isothiocyanate to amine groups on Hofmann-reacted poly(acrylamide) (256,257). Various other approaches have been developed to add fluorescein (258), dansyl (259), 9-xanthydrol (260), and other fluorescent groups to acrylamide-containing chains (261).

A completely different approach to detecting low levels of high molecular weight polyacrylamides in solution without recourse to prelabeling the polymers has been used in a number of instances. Methods based on the flocculation capacity of these polymers are surprisingly sensitive. Both the turbidity and the settling rate of a suspension can change measurably after exposure to even low concentrations (several ppm) of a flocculant. Such changes were used in the settling rate of kaolin suspensions to assay for low levels of anionic polyacrylamides in runoff water from a soil amendment application involving those polymers (262). They were able to reliably detect residual polymer in the water at the ppm level.

Specifications, Shipping, and Storage. The amount of residual acrylamide is usually determined for commercial polyacrylamides. In one method, the monomer is extracted from the polymer and the acrylamide content is determined by hplc (263). A second method is based on analysis by cationic exchange chromatography (264). For dry products the particle size distribution can be quickly determined by use of a shaker and a series of test sieves. Batches with small particles can present a dust hazard. The percentage of insoluble material is determined in both dry and emulsion products.

Polyacrylamide powders are typically shipped in moisture-resistant bags or fiber packs. Emulsion and solution polymers are sold in drums, tote bins, tank trucks, and tank cars. The transportation of dry and solution products is not regulated in the United States by the Department of Transportation (DOT), but emulsions require a DOT NA 1693 label.

Under normal conditions, dry polymers are stable for 1 year or more. The emulsion and solution products have somewhat shorter shelf lives.

Safety and Health.

Commercial Polyacrylamides. Dry cationic polyacrylamides have been tested in subchronic and developmental toxicity studies in rats. No adverse effects were observed in either study. Chronic studies of polyacrylamides in rats and dogs indicated no chronic toxicity or carcinogenicity. Dry anionic and nonionic polyacrylamides (265) have acute oral (rat) and dermal (rabbit) LD_{50} values of greater than 2.5 and greater than 10 g/kg, respectively. Dry cationic polyacrylamides have acute oral (rat) and dermal (rabbit) LD_{50} values of greater than 5 and greater than 2 g/kg, respectively. Emulsion nonionic, anionic, and cationic polyacrylamides have both acute oral (rat) and dermal (rabbit) LD_{50} values of greater than 10 g/kg. Dry nonionic and cationic material caused no skin irritation and minimal eye irritation during primary irritation studies with rabbits. Dry anionic polyacrylamide did not produce any eye or skin irritation in laboratory animals. Emulsion nonionic polyacrylamide produced eye irritation in rabbits, while anionic and cationic material produced minimal eye irritation in rabbits. Emulsion nonionic, anionic, and cationic polyacrylamide produced severe, irreversible skin irritation when tested in rabbits that had the test material held in skin contact by a bandage for 24 h. This represents an exaggeration of spilling the product in a boot for several hours. When emulsion nonionic, cationic, and anionic polyacrylamides were tested under conditions representing spilling of product on clothing, only mild skin irritation was noted. Polyacrylamides are used safely for numerous indirect food packaging applications, potable water, and direct food applications.

Experimental Polyacrylamides. It is wise to treat any laboratory-prepared "experimental" polyacrylamide as if it contains substantial amounts of unreacted monomer unless it has been isolated and purified as described above.

Acrylamide is commercially available as a 50% solution in water with a copper salt as a polymerization inhibitor. Polymerization is very exothermic and autopolymerization can occur under certain conditions. In the interest of safety, acrylamide solutions should be stored under the following conditions:

(1) Maintain the storage temperature below 32°C (90°F) and above the solubility point.
(2) Keep the solution free of contaminants.
(3) Maintain the proper level of oxygen and Cu^{2+} inhibitors.
(4) Maintain the pH at 5.2–6.0.
(5) Store the solution in a container that is opaque to light.

It is recommended that these solutions be stored for no more than 3 months because of the depletion of the dissolved oxygen. All containers must be dated and no more than 93% full. Packaged acrylamide solutions should be consumed on a first-in, first-out basis.

Economic Aspects. Worldwide, there are many suppliers of polyacrylamides. Some of these are producers and some are repackagers. Suppliers are listed in Table 6. Selling prices for polyacrylamides vary considerably depending on the product form (solution, emulsion, dry), type (anionic, nonionic, cationic), and other factors. Prices on a polymer basis can range from as low as about $2/kg for simple dry nonionic polyacrylamides to $8/kg and more for highly charged cationic polymers. Prices in recent years have dropped because of price erosion and lower manufacturing costs of AETAC and DADMAC cationic monomers. In many applications, such as sludge dewatering in waste treatment, the need for increased performance has lead to increased functionalization (eg, higher cationicity) and increased cost.

In the United States, the major uses for polyacrylamides are in water treating, and paper manufacturing. For water treating, the best growth is expected to be for cationic copolymers because of use in dewatering equipment like belt presses that produce high solids sludge cakes that can be more easily incinerated or disposed of in scarcer landfills. For paper manufacturing, glyoxalated cationic copolymers for paper wet strength, high molecular weight retention aids, and drainage aids are considered to grow in use. Increased use of poly(acrylamide) flocculants in recycled paper mills, particularly in deinking mills where better process water clarification is necessary because of closed water circuits, is also expected. Polyacrylamides are beginning to be used along with surface sizes in paper to improve the control of ink adsorption and print quality. In the mineral process industry in the United States (and Australia), there has been a great

Table 7. Consumption of Polyacrylamides[a]

Year	Paper, %	Water treating, %	Mining, %	EOR, %	Other, %	Total 10^3 t

[a]From Ref. (1).

increase in the use of hydroxamated polyacrylamides in alumina manufacture. The market for polyacrylamides in enhanced oil recovery has decreased steadily in the United States. In 1985, the total market exceeded 10 million metric tons, but in 1999 the use has been almost none. Total consumption of polyacrylamides is expected to increase about 4% per year during the next few years after 1999 in the United States. In Europe, the use of water-treating chemicals on municipal sludge treatment will increase because of European Union legislation preventing sewage dumping. The treatment of wastewater is intensive, and many waste treatment plants and paper mills have closed circuits because of environmental concerns. The total consumption of poly(acrylamide)s is expected to increase about 3% per year in Europe. In Japan, the major consumption has been in paper manufacture (anionic and nonionic polyacrylamides) and water treatment (cationic and amphoteric copolymers). In municipal sludge treatment, highly cationic polyacrylamides are used for rapid flocculation in high speed centrifuges. The use of cationic copolymers is expected to grow at higher rates. Japan exports a considerable amount of polyacrylamides (and acrylamide monomer) to Asian and other markets. Another potential market will be enhanced oil recovery in China. Table 7 gives an estimated breakdown of polyacrylamide consumption (1).

ACRYLIC (AND METHACRYLIC) ACID POLYMERS

Introduction

Almost all acrylic polymers produced commercially contain acrylic acid and/or methacrylic acid at some level, which gives them a special property. Content of the acidic monomers ranges from <5 wt% present in many widely used emulsion copolymers to100 wt% in water-soluble homopolymers. Between these extremes, by the inclusion of a wide variety of comonomers, the copolymers may be water-soluble, soluble only in their neutralized forms, the so-called alkali-soluble polymers, or swollen gels if cross-linkers are present. The less expensive acrylic acid produced by a simpler process is now more commercially available than methacrylic acid and dominates the polymer market especially in nonemulsion areas. This article focuses chiefly on water-soluble, alkali-soluble, and water-swellable gels, based on homopolymers and copolymers since these are very important commercially and they contain significant levels of the acidic monomers. Acrylic emulsion polymers have low acid content and are widely used in industry and household paint formulations: they are included here in a selected limited fashion because they have been widely studied and the open and patent literatures are so voluminous.

Monomers

The structures of propenoic acid, commonly called *acrylic acid*, and 2-methylpropenioc acid, commonly called *methacrylic acid*, are shown below:

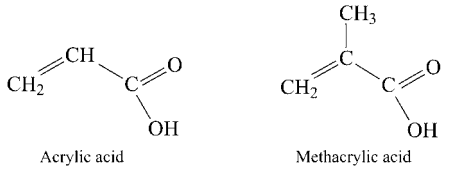
Table 1. Physical Properties of Acrylic and Methacrylic Acids

Property	Acrylic acid	Methacrylic acid
Formula weight	72.06	86.10
Melting point, °C	13.5	14.0
Boiling point, 101 kPa,[a] °C	141.0	159–163
Vapor pressure, 25°C, kPa[a]	0.57	0.13
Density, 25°C, g/mL	1.045	1.015
Heat of vaporization, J/g[b]	435	418
Heat of polymerization, kJ/g[b]	1.08	0.657
Heat of polymerization, kJ[b]/mol	76.99	56.32
Heat capacity, 25°C, J[b]/(g·°C)	2.1	2.1
Refractive index η_D	1.4185	1.4288
Viscosity, 25°C, mPa·s (=cP)	1.25	1.3
Flash point, tag closed cup, °C	50	67
Flash point, Cleveland open cup, °C	68	77
Surface tension, 25°C, mN/m (=dyn/cm)	–	26.5
Solubility in water	Miscible	Miscible
Autoignition temperature, °C	412	400
Dissociation constants (10^5)	5.5	2.2

[a]To convert kPa to mm Hg, multiply by 7.5.
[b]To convert J to cal, divide by 4.184.



Acrylic acid and methacrylic acid are selective oxidation products of propylene and isobutylene, respectively. The minor difference in structure between the two acids, the α-methyl substituent of methacrylic acid, results in minimal physical property differences as indicated in Table 1. However, this structural difference distinctly affects polymerization and copolymerization kinetics and the characteristics of the resulting polymers.

Acrylic acid was first reported in 1843 as a product of the air oxidation of acrolein, which is obtained from the high temperature cracking of glycerol (1) (Fig. 1). However, large-scale production of acrylic acid was not introduced until the 1930s when industrial manufacturing processes were developed and safe-handling procedures adopted for this very reactive monomer (2). Since then, commercial growth has been phenomenal and, today, the production and use in

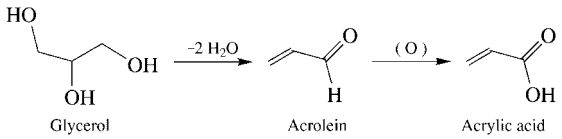


Fig. 1. Cracking of glycerol to acrylic acid.

polymerizations greatly predominates over methacrylic acid. This is due to its lower cost and relative ease of preparation by the oxidation of inexpensive propylene, and to a great extent to the global acceptance of superabsorbent acrylic acid-based polymers in diapers and feminine hygiene products.

Frankland and Duma first reported methacrylic acid in 1865 (3). However, like acrylic acid, its commercial development came many years later in 1933 (4). The development required pioneering chemistry on the monomer and its derivatives by Dr. Otto Rohm published in his doctoral thesis in 1901 and its evolution through the formation of the Rohm and Haas Co. in 1909 (5–8). Like the acrylic acid, methacrylic acid and its vinyl derivatives are used mainly in the preparation of polymers. There is little interest in small organic molecules based on the monomers.

Properties. The physical properties of the two acidic monomers are contrasted in Table 1. The major differences to note between the two acidic monomers with regard to polymerization reactions and polymer properties are the higher boiling point of the methacrylic acid and the higher heat of polymerization and higher acidity of acrylic acid.

Both monomers are bifunctional organic compounds, with each having carboxylic acid and conjugated unsaturated double bond functionalities. The carboxyl group undergoes all the reactions expected and readily forms salts and esters using conventional procedures. Caution must be exercised during these reactions because the conjugated unsaturation present in the molecules renders them susceptible to highly exothermic and potentially explosive Michael addition reactions and free-radical polymerizations under uncontrolled conditions. It is this high reactivity of the monomeric double bond that allows rapid carefully controlled polymerization to produce the expected result in polymerization reactions.

Manufacture of Acrylic Acid Monomer. Many synthetic routes to acrylic acid exist and are reported widely in the literature. However, the only currently commercially viable process is based on the direct high temperature gas-phase oxidation of propylene, as indicated schematically in Figure 2. This economical process, based on the availability and low cost of propylene, is expected to predominate commercially for many years. Other once practiced processes based on acrylonitrile, propiolactone, and ethylene cyanohydrin are no longer of importance (2).

The oxidation proceeds by the two-step catalytic process indicated above, without the isolation of the intermediate acrolein. Acrylic acid, obtained in high yield based on propylene, is isolated as an aqueous solution and purified by extraction and distillation. The principal impurities in the commercial monomer, termed glacial acrylic acid, that may affect subsequent polymerization reactions include acetaldehyde, acrolein, furfural, benzaldehyde, and acrylic acid dimer, 3-acryloxypropionic acid. Since these impurities are inhibitory in polymerization,

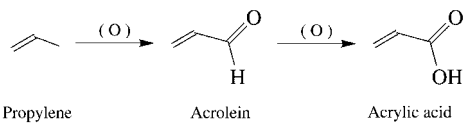

Fig. 2. Acrylic acid by propylene oxidation.

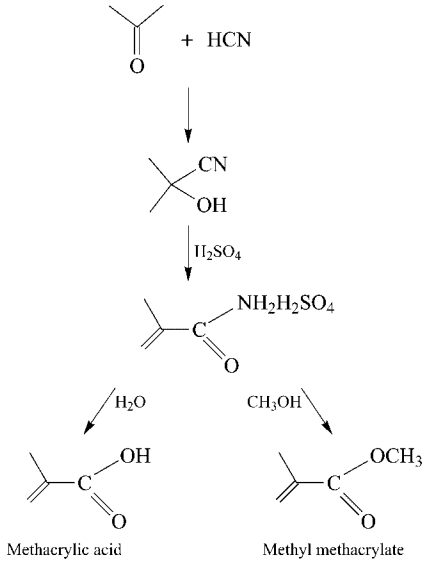

Fig. 3. Processes for methacrylic acid and methyl methacrylate.

they must be removed to facilitate the production of ultrahigh molecular weight polymers for use in superabsorbent manufacture, for example.

Manufacture of Methacrylic Acid Monomer. The commercial manufacture of methacrylates began in 1933 based on acetone cyanohydrin, which is still the basis for all current production (4). This well-established technology is based on the commercially inexpensive chemical starting compounds, acetone, hydrogen cyanide, and sulfuric acid. The process is represented by the schematic shown in Figure 3. Acetone reacts with hydrogen cyanide to form acetone cyanohydrin, which is readily converted into the methacrylamide sulfate salt in the presence of anhydrous sulfuric acid. This intermediate salt may be directly converted into either methacrylic acid or methyl methacrylate by reaction with water or anhydrous methanol, respectively. In commercial practice, the two steps are generally carried out simultaneously with an aqueous methanol solution to produce an ester rich mixture, since methyl methacrylate is the higher volume commercial product for the production of Plexiglas (Rohm and Haas Co.).

Handling and Storage of Acrylic and Methacrylic Acids. Acrylic acid is available commercially at 98%+ purity and contains a polymerization inhibitor such as hydroquinone (HQ), monomethylhydroquinone (MEHQ), or phenothiazine. Methacrylic acid, on the other hand, is available at 99%+ purity and is stabilized with either HQ or MEHQ. It is not usually necessary to purify the monomers to remove the inhibitors prior to polymerization, as the level of free-radical initiators used readily overwhelms them. However, where ultrahigh molecular weight polymers are required, for example in superabsorbent polymers, the impurities must be removed. The corrosiveness of the monomers toward many metals requires storage to be in stainless steel, glass, or aluminum or suitably lined vessels. Any metals leached from storage vessels could potentially promote dangerous runaway polymerizations in the presence of oxygen. Obviously, for

the same reasons, polymerization reactions must be carried out in similarly constructed equipment.

Since both acids have relatively high freezing points, 13–14°C, they must be prevented from freezing in cold conditions. If freezing occurs, thawing is a hazardous procedure since the distribution of inhibitor between solid and liquid is difficult to control, and runaway uncontrolled and potentially explosive polymerization of the liquid phase is always a threat. To avoid this potential hazard, monomer storage at temperatures in excess of their freezing points is recommended.

Health and Safety. Both acids are moderately toxic compounds when ingested or absorbed through the skin. Severe internal burns result from swallowing. Skin contact causes rapid tissue damage due to the highly corrosive nature of the monomers. The vapor of acrylic acid is more irritating to the eyes than that of methacrylic acid, but both may cause redness on prolonged exposure.

As with all industrial chemicals with similar characteristics, safe handling with suitable protection gear is highly recommended; gloves, facemask, and clothing are all important. These are all listed in the Material Safety Data Sheets (MSDS) that accompany the monomers and these sheets must be thoroughly read and understood before working with either monomer.

Polymerization of Acrylic and Methacrylic Acids

Dependence on pH. The rates of polymerization of both acidic monomers in dilute aqueous solutions are pH-dependent. The rate of polymerization is high at low pH for both monomers; it falls rapidly to a minimum at pH 6–7, and then increases to a maximum at pH 10 for acrylic acid and 12 for methacrylic acid (9–13). At high salt or monomer concentrations, the polymerization rate minimum at the pH range 6–7 becomes less pronounced.

The explanation of the observed rate minimum at pH 6–7 is generally considered to be due to the slower rate of propagation for the anion than for the free acid. However, as pH is increased, the rate of polymerization increases because of the decreased rate of termination of the radical anions promoted by coulombic repulsion (10). An alternative explanation of both the increase of polymerization with pH and the leveling of the rate by added salts at pH 6–7 is postulated to be due to the formation of terminal ion pair radicals with a propagation rate similar to that of the free-acid monomers (9).

Copolymerization. Acrylic and methacrylic acids readily copolymerize free radically with many vinyl monomers. This versatility results from a combination of their highly reactive double bonds and their miscibility with a wide variety of water- and solvent-soluble monomers. Reactivity ratios derived from copolymerizations with many monomers are tabulated in many books on polymerization, for example in Wiley's *Polymer Handbook* (14) (see also Wiley's Database of Polymer Properties). Q and e values are parameters that may be established for a monomer based on a large number of reactivity ratios with other monomers. These parameters are associated with interactions between the monomer and the growing chain via resonance (Q) and polar effects (e).

As mentioned, the rate of copolymerization of acrylic and methacrylic acids is dependent on pH effects and the resulting ionization as well as the comonomers.

Table 2. Comonomer Effects on Acidic Polymers

Comonomer	Polymer
None	Water-soluble
Water-soluble	Water-soluble
Water-insoluble, low level	Water-soluble
Water-insoluble, mid level	Alkali-soluble emulsion
Water-insoluble, high level	Emulsion polymer
Polyvinyl cross-linker	Gel

This conflict makes it difficult to describe the acidic monomers by single Q and e values derived from reactivity ratios. Neutralization changes both Q and e values. Particularly, e values reverse from a positive value to a negative value on neutralization (15). This is expected as e is a measure of electron-donating ability of the monomeric double bond and neutralization may be equated to a change from electron-withdrawing carboxylate group to an electron-donating carboxylate ion.

Alternative Synthesis of Acidic Polymers. There are two approaches to homo- and copolymers of acrylic and methacrylic acids. In addition to the conventional use of acrylic acid and methacrylic acid monomers, the main theme of this article, there exists the possibility of converting polymers of the derivatives of these two monomers to acidic polymers. There would obviously have to be very extenuating circumstances to take this route industrially because of cost penalties. However, there are situations where there is a reason to do this. Availability of monomers is a good example. Acrylonitrile was at one time more available than acrylic acid in some parts of the world and simple hydrolysis of the polymer gave poly(acrylic acid). Other potential routes exist from such homo- and copolymers of acrylamide, acrylic and methacrylic esters, and acid chlorides. Although not further discussed here, the reader is reminded that polymer synthesis with acrylic monomers is very versatile and forethought is always necessary before plunging ahead.

Polymerization Processes. A variety of processes are used commercially to homopolymerize and copolymerize acrylic acid and methacrylic acid. On the basis of economics and environmental considerations, water is generally the preferred industrial solvent or polymerization medium. However, the choice of process is usually dictated by the requirements of the polymer to be produced. As already indicated, pH influences the rate of polymerization. Comonomers and molecular weight of the polymer to be produced also have a profound effect on the type of polymerization process that can be used and on the type of product obtained. The contents of Table 2 indicate the change from water-soluble to alkali-soluble emulsions and ultimately emulsion polymers is dependent on the comonomers in copolymers of acrylic and methacrylic acids. This transition from water-soluble polymer to emulsion polymer as the acidic monomer is decreased depends on the hydrophobicity of the comonomer. Introduction of divinyl monomers causes transition to gel materials in all compositions. The gels may vary from highly swollen to tightly bound copolymers, depending on the cross-linker level.

The effect of molecular weight is very pronounced with the water-soluble polymers. The change of viscosity of aqueous solutions is shown schematically in Figure 4. A precipitous increase in viscosity occurs at lower concentrations with

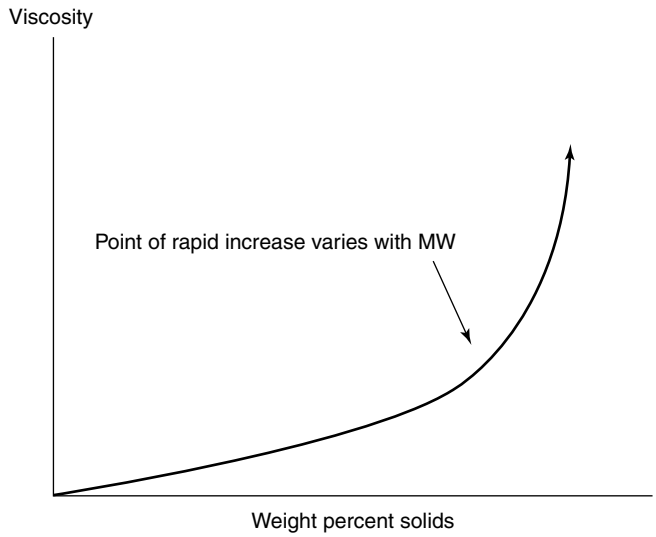

Fig. 4. Water-soluble polymers: viscosity/molecular weight in water.

higher molecular weights, essentially making it economically impossible to make polymer of greater than about 100,000 Da by aqueous solution polymerization. This can be controlled to some extent by polymerizing the monomers at lower concentration, but this becomes economically undesirable at some point, usually around 30 wt% solids. Hence, new technology is borne. Generally speaking, low molecular weight homopolymers, less than 100,000 Da, may be made in aqueous solution; higher molecular weights require technologies such as suspension and gel polymerization.

Copolymer synthesis suffers the same viscosity restrictions as the homopolymers when the comonomers are sufficiently water-soluble to produce water-soluble copolymers. When water-insoluble comonomers are used it is possible to resort to cosolvents with water or surfactants in micellar polymerizations to effect solubility to a limited degree, but this is only useful at low molecular weight and is undesirable environmentally. Higher molecular weight copolymers are usually made by emulsion, inverse emulsion, or suspension polymerization.

Polymer Characteristics

The polymer types considered here are primarily those that are soluble in water as prepared, soluble after neutralization of emulsion polymerized copolymers, the so-called alkali-soluble polymers, and cross-linked swellable gel polymers. Emulsion polymers are discussed in a limited fashion, as acrylic and methacrylic acids are used ubiquitously at low levels in almost all acrylic emulsion polymerizations to contribute some special characteristic. For example, the incorporation of acidic monomers contributes to such properties as adhesion, wettability, and emulsion polymer stability.

Emulsion Polymers.

Applications. Acrylic emulsion polymers containing insufficient acrylic or methacrylic acids to solubilize on neutralization are used in a myriad of applications including, coatings, floor polish, inks, dispersants, adhesives, and caulks. These are almost all thin film applications and the acid contributes hydrophilicity, stability, dispersancy, etc. The polymers are balanced by backbone hardness, hydrophobicity/hydrophilicity balance, functionality, all moderated by choice of comonomers and by molecular weight and morphology. Some examples from the literature of the use of emulsion copolymers containing low levels of acidic monomers include autodeposition coatings (16), paper saturants (17), wood coatings (18), corrosion-resistant coatings (19), printing ink binders with core-shell morphology (20), monodispersed particles for liquid toners (21), oil-repellent finishes based on fluoromonomers (22), dilatant dispersants for antistatic coatings (23), water-resistant coatings (24), water-dispersible polymers for building materials (25), surfactant-free emulsions for nonwovens (26), pressure-sensitive adhesives with good mechanical stability (27), water-resistant cosmetics (28), anticorrosion coatings for ferrous metals (29), hair styling shampoos (30), redispersible film-forming coatings (31), core-shell graft polymers for cement modifiers (32), coatings and inks (33), wood coatings (34), acrylic polyester hybrids (35), redispersible powders for cement (36), hair fixatives (37), redispersible core-shell polymers (38), core-shell coatings (39–42), coatings (43), pressure-sensitive adhesives (44), and emulsion paints (45).

Synthesis. The synthesis of emulsions is widely described in the literature, both patent and open. Ingredients are surfactants for setting particle size and stabilization of the emulsion, and initiators for polymerization. Leading reference books are by Blackley; although somewhat dated it is still an excellent book and another is Gilbert's recent publication (46). Other useful synthesis references include some specific interests, pressure-sensitive adhesives (47), styrene emulsion polymerization using alkali-soluble resins as emulsifiers (48), manufacture and use of curable emulsions (49), preparation of concentrated emulsions (50), multistage polymer preparation (51), core-shell vinyl acrylic emulsions (52), acrylic grafted to polyester emulsions (53), aqueous polymer dispersions (54), process for polyacrylate dispersions (55), sterically stabilized acrylic graft copolymers (56), polyacrylate dispersions without colloid protection (57) and with colloid protection (58), low VOC emulsions (59), design of latex polymers (60), random copolymers as emulsifiers (61), multihollow latex particles (62), modeling of acid distribution in lattices (63,64), modeling of microparticles and experimental verification (65), and effect of pH on properties of emulsion polymers (66). Since so many applications of acrylic emulsions are dependent interfacial science, film formation is very important and has received much interest (67–70).

Water-Soluble Polymers.

Synthesis. Water-soluble polymers are prepared by conventional free-radical polymerization methods with molecular weight control through the level of initiator and the use of chain transfer agents. Generally, molecular weights of the polymers range from a few thousand to several hundred thousand, which is useful in many applications from dispersants to rheology modifiers to thickeners to flocculants. The lower molecular weights from 1000 to about 30,000 have been most widely worked on. Typical initiators fall into two classes, the thermally activated

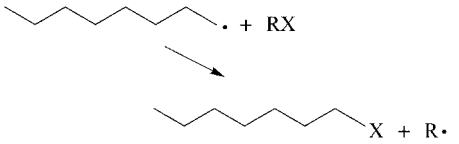

Fig. 5. Chain transfer in free-radical polymerization.

and the redox types. The thermally activated are persulfates, perphosphates, azos, hydroperoxides, etc, which are used in temperature ranges of 50–100°C. The redox initiators are generally designed for use at lower temperatures and function by using stoichiometric amount of reducing and oxidizing agents in the presence of a metal catalyst. The metal decomposes the peroxy compound to produce radicals for initiating polymerization and is converted to a higher oxidation state in the process; the reducing agent cycles the metal back to the lower oxidation state and the process is repeated.

Molecular weight control by using chain transfer agents (Fig. 5) results in the incorporation of the chain transfer agent at least on the polymer terminus.

RX is a general term for a chain transfer agent. The liberated R· radical then initiates another polymer chain and X, usually hydrogen from chain transfer agents, terminates the current chain. Phosphite chain transfer agents are exemplified in the aqueous preparation of low molecular weight acrylic homo- and copolymers (71,72). A similar utilization was patented by Coatex S. A. (73). Other chain transfer agents that have been used include alcohols such as isopropylalcohol (74), aminothiols (74), mercaptoethanol (75), mercaptoethanol (76), hypophosphorous acid (77), and copper salts that are extremely effective (78–82).

Other interesting polymerizations include the use of metal-activated hydrogen peroxide to deliver low molecular weight polymers (83,84), continuous polymerization of water-soluble monomers in extruders (85), dry polymerization of acrylic acid in super critical carbon dioxide (86,87) and on a powder bed (88), and the use of sodium nitrate mediated aqueous polymerization to allow high solids (89).

Transamidation allows the preparation of unique low molecular weight, water-soluble polymers from acrylic acid–acrylamide copolymers. The advantage is that functional amines such as sulfonic acid salts can be incorporated into preformed polymer to create new functional polymers without the need to synthesize new monomers (90–92).

Applications. Water-soluble homopolymers of acrylic and methacrylic acids and their copolymers are widely used in a myriad of applications. Poly(acrylic acid) and copolymers with maleic acid and other monomers are used in large quantities in solid detergents and dishwashing powders (80,93–107). Only minor modifications to composition and/or molecular weight to alter the balance of surface interactions allow use in many different applications. Changing hydrophile/hydrophobe ratio, charge density, introduction of other charged species, etc, all expand the application range. Scale formation in aqueous systems may be prevented by the presence of sulfonate groups (108–110) and allyloxy functionality (111,112). Cement additives used to reduce water requirements are based on acrylic acid copolymers with poly(ethylene oxide) acrylate monomers (113–116). Copolymers with acrylic alkyl esters are used in textile sizing agents (117).

Plant productivity in hydroponic media is reportedly enhanced by the presence of poly(acrylic acid) (118). Dispersing characteristics are imparted by copolymerizing a range of monomers and again they are used widely, for example, in inks (119), for inhibiting barium scale in seawater (120), ceramics (121,122), to disperse acrylic emulsion polymers (123), to disperse dyes (124). Copolymers are also used in oil drilling and recovery (125–129), in corrosion control (130–136), in paper for wet and dry strength (137), boiler water treatment (138–141), specialty cleansers (142–146), eliminating odor from animal excrement (147), reverse osmosis for scale inhibition (148), water clarification (149), soil conditioners (150), and seed coatings (151).

Environmental Issues of Water-Soluble Polymers. Because the water-soluble polymers based on acrylic and methacrylic acids are generally disposed off in the environment, there have been studies to determine their effect on the environment and to monitor their build. Acrylic acid polymers are not biodegradable except at the oligomer molecular weight, that is about 3 to 10 units (152). Elegant monitoring of low concentrations is available by two techniques, immunoassay (153) developed at Rohm and Haas, and fluorescence tagging (154). Tagging is useful both for environmental monitoring and for concentration control in applications.

Alkali-Soluble Polymers. Alkali-soluble polymers are generally emulsion polymers that have insufficient acid content to solubilize in water in the absence of neutralization. In addition to emulsion polymerization, polymerization in partial or complete organic solvents, as suspensions, and inverse emulsions are all reported. However, emulsion polymerization represents the most convenient route to these polymers, with suspension and inverse emulsions being very limited.

Alkali-soluble emulsion polymers were originally developed as thickeners based on copolymers of acrylic acid and methacrylic acid with simple acrylic and methacrylic esters, as exemplified by their preparation in patents to S.C. Johnson (155), BASF (156), and Goodyear (157). However, in the last two decades advanced hydrophobically modified alkali-soluble polymers have emerged as thickeners and rheology modifiers which function by association of their hydrophobic functionalities with themselves or other convenient centers in a formulation containing these polymers. Figure 6 represents this association schematically.

Both types of alkali soluble thickeners generally contain methacrylic acid rather than acrylic acid since this monomer is more readily incorporated into

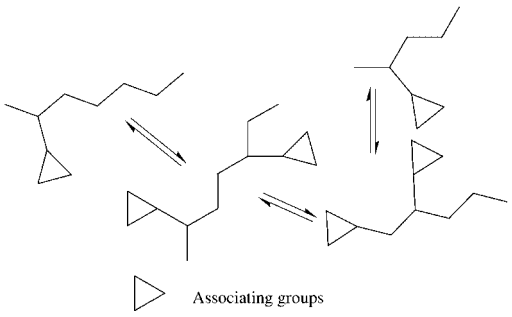

Fig. 6. Association of hydrophobic alkali-soluble polymers.

emulsion polymers, as it is more hydrophobic than acrylic acid and less likely to homopolymerize in the aqueous continuous phase. Patents to Dow (158), DeSoto (159), Union Carbide (160), and Rohm and Haas (161) represent the synthesis of hydrophobically modified alkali-soluble emulsion polymers. The hydrophobe may be attached to the acrylic polymer backbone by an ester or urethane linkage (162). The properties of hydrophobic associative thickeners and conventional thickeners in paint-making formulations have been compared (163). Several papers have appeared on the interactions of similar polymers in paint formulations (164–167) and on general hydrophobic interactions in water (168,169).

There are other less widely used syntheses of associative polymers including acid monomer grafting to poly(ethylene oxide) (170,171), inverse emulsion polymerization (172–174), suspension polymerization (175), micellar polymerization (176,177), and solid-phase extrusion polymerization (178).

Applications. In addition to latex paint applications already mentioned, applications include paper (179), oil spill clean-up (180), flocculants and mineral dewatering (181), emulsion polymerization stabilizers (182), and in mixed associative thickeners in paints (183).

Gel Polymers. Gel polymers based on the acidic monomers are high molecular weight (co)polymers that are cross-linked such that solubilization in water is prevented. The levels of swelling or gel formation are controlled by degree of cross-linking of the polymer. The major outlet for this chemistry is in the development of superabsorbent polymers now ubiquitous in diapers and feminine hygiene products. They have completely revolutionized a way of life for raising infants and caring for incontinent elderly. Hence, it is not surprising that most of the published information is patent literature that relates to manufacturing processes that have been or continue to be used for the preparation of superabsorbents. Some of these processes are referenced herein, but the patent literature is so voluminous that not all are included here.

Synthesis. Gel polymerization of acrylic acid with a polyvinyl cross-linking monomers in water is by far the most prevalent commercial process. Examples of cross-linkers used are triallylamine (184), *N*,*N*′-methylenebisacrylamide (185), tetraallyloxyethane (186,187), trimethylolpropane triacrylate (188), ethylene diamines (189), trimethylol triacrylate and diacrylate in combination (190), ethylene glycol diglycidyl ether (191), trimethylolpropane tris(3-aziridinylpropionate) (192), and poly(ethylene oxides) diacrylate (193). In an extension of cross-linking one process by Sanyo uses inefficient graft polymerization of acrylic acid onto starch as a source of the cross-linking required to introduce control over gel swelling (194).

Applications. Copolymers of acidic monomers and other water-soluble monomers obtained by gel polymerization for special effects, generally in medical applications, include hydroxyethyl methacrylate (195), hydroxypropyl methacrylate and acrylamide (196), and vinyl saccharides (197).

There has been a move from conventional granular gel materials to foamed (198) and flat plate (199) type superabsorbents based on poly(acrylic acid). In addition to superabsorbents for personal hygiene, the materials have wide ranging applications in many areas from biomedical to cosmetics. Some of these are petroleum recovery and sealing of sewer pipes when cross-linked with metals such as iron salts (200); flocculants in water purification (201); copolymers with

acrylamide in textile printing pastes (202); cosmetic gelling agents (203); surgical dressings (204); reversible gels (205); subterranean fault stabilization (206), and controlled release (207).

Block and Graft Polymers

Graft Synthesis. Free-radical-promoted grafting of acrylic and methacrylic acids and other water-soluble comonomers onto synthetic and natural substrates gives unique polymeric structures quite different from the random copolymers obtained in conventional copolymerization. These block and graft polymers bring a unique and different structure/property balance with applications in many areas.

Applications. Poly(ethylene oxides) are readily grafted with acrylic acid to give partially biodegradable detergent polymers (208–210). Grafts onto other substrates include poly(vinyl alcohol) (211), water-soluble maleic anhydride copolymers (212), polycaprolactone (213), and onto emulsion polymers of acrylates and methacrylates (214).

Natural substrates are often starch or cellulose derivatives. Grafts for detergent applications (215,216), thickening dispersions (217), leather tanning (218), water treatment (219), oil recovery (220), water-absorbents (221), and water-absorbents in fibers and sheets (222). More fundamental studies on grafting to polysaccharides have been published (223).

Block Synthesis. Water-soluble block copolymers are formed from the copolymerization of macromonomers of methacrylates with acrylic and methacrylic acid monomers and their solution properties compared with random copolymers of similar composition (224). Diblock and triblock copolymers may be prepared by a number of techniques and are also used on ink-jet inks (225) and scale inhibition in water boilers (226), respectively. Associative properties of block polymers to form micellar structures are well established (227,228). Triblock polyampholyte polymers are also known (229).

Inverse Emulsion Polymerization

Inverse emulsion polymerization is a term used for water in oil (monomer) dispersion polymerization as opposed to conventional emulsion polymerization where the monomer and polymer are largely insoluble and dispersed in water. The advantage is that high molecular weight polymers and copolymers of water-soluble monomers may be prepared without the attendant viscosity build mentioned earlier. The process chemistry is well established as indicated in the patent literature (230–233) but not widely used and likely to be less so as solvents are removed from processing. Spray drying is often used for polymer isolation (234).

ACRYLIC ESTER POLYMERS

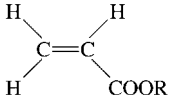
Introduction

The usage of acrylic esters as building blocks for polymers of industrial importance began in earnest with the experimentation of Otto Rohm (1). The first recorded preparation of the basic building block for acrylic ester polymers, acrylic acid, took place in 1843; this synthesis relied on the air oxidation of acrolein (2,3). The first acrylic acid derivatives to be made were methyl acrylate and ethyl acrylate. Although these two monomers were synthesized in 1873, their utility in the polymer area was not discovered until 1880 when Kahlbaum polymerized methyl acrylate and tested its thermal stability. To his surprise, the polymerized methyl acrylate did not depolymerize at temperatures up to 320°C (4). Despite this finding of incredibly high thermal stability, the industrial production of acrylic ester polymers did not take place for almost another 50 years.

The commercial discovery of acrylic ester polymers took place while Otto Rohm was conducting his doctoral research in 1901. Rohm obtained a U.S. patent in 1912 covering the vulcanization of acrylates with sulfur (5). Commercial production of acrylic ester polymers by the Rohm and Haas Co. of Darmstadt, Germany, commenced in 1927 (6).

Properties

The structure of the acrylic ester monomers is represented by the following:



Encyclopedia of Polymer Science and Technology. Copyright John Wiley & Sons, Inc. All rights reserved.

The R ester group dominates the properties of the polymers formed. This R side-chain group conveys such a wide range of properties that acrylic ester polymers are used in applications varying from paints to adhesives and concrete modifiers and thickeners. The glass-transition range for a polymer describes the temperature range below which segmental pinning takes place and the polymer takes on a stiff, rigid, inflexible nature. This range can vary widely among the acrylic ester polymers from -54°C for butyl acrylate (R = C_4H_9) to 103°C for acrylic acid (R = H). Film properties are dramatically influenced by this changing of the polymer flexibility.

When copolymerized, the acrylic ester monomers typically randomly incorporate themselves into the polymer chains according to the percentage concentration of each monomer in the reactor initial charge. Alternatively, acrylic ester monomers can be copolymerized with styrene, methacrylic ester monomers, acrylonitrile, and vinyl acetate to produce commercially significant polymers.

Acrylic ester monomers are typically synthesized from the combination of acrylic acid and an alcohol. The properties of the polymers they form are dominated by the nature of the ester side chain as well as the molecular weight of the product. Acrylic ester polymers are similar to others in that they show an improvement in properties as a function of molecular weight until a certain threshold beyond which no further improvement is observed. This threshold is reached at a molecular weight value of 100,000–200,000 for acrylic polymers.

Glass-Transition Temperature. The Glass Transition temperature (T_g) (qv) describes the approximate temperature below which segmental rigidity (ie, loss of rotational and translational motion) sets in. Although a single value is often cited, in reality a polymer film undergoes the transition over a range of temperatures. The reason for this range of temperatures for the glass transition is that segmental mobility is a function of both the experimental method used [dynamic mechanical analysis (dma) vs differential scanning calorimetry (dsc)] as well as the experimental conditions. Factors such as hydroplasticization in varying degrees of humidity can skew T_g results. Most polymers experience an increase in the specific volume, coefficient of expansion, compressibility, specific heat, and refractive index. The T_g is typically measured as the midpoint of the range over which the discontinuity of these properties takes place. Care should be taken when analyzing T_g data, however, as some experimenters cite the onset of the discontinuity as the T_g value.

The rigidity upon cooling below T_g is manifested as an embrittlement of the polymer to the point where films are glass-like and incapable of handling significant mechanical stress without cracking. If, on the other hand, one raises the temperature to which a film is exposed above the glass-transition range, the polymer film becomes stretchable, soft, and elastic. For amorphous acrylic polymers, many physical properties show dramatic changes after passing through the glass-transition temperature range. Among these physical properties are diffusion, chemical reactivity, mechanical and dielectric relaxation, viscous flow, load-bearing capacity, hardness, tack, heat capacity, refractive index, thermal expansivity, creep, and crystallization.

The most common thermal analyses used to determine the glass-transition temperature are dma and dsc. More information on these techniques and how to interpret the results are contained in References 7–9. The T_g values for the most common homopolymers of acrylic esters are listed in Table 1.

Table 1. Physical Properties of Acrylic Polymers

Polymer	Monomer molecular formula	CAS registry number	T_g, °C[a]	Density, g/cm^3 [b]	Refractive index, n_D
Methyl acrylate	$C_4H_6O_2$	[9003-21-8]	6	1.22	1.479
Ethyl acrylate	$C_5H_8O_2$	[9003-32-1]	−24	1.12	1.464

[a]Refs. 7 and 10.
[b]Ref. 11.

The most common way of tailoring acrylic ester polymer properties is to copolymerize two or more monomers. In this fashion, the balance of hard (high T_g) and soft (low T_g) monomers used to make up the overall composition will determine the overall hardness and softness of the polymer film. An estimate of the T_g, and therefore the film hardness, can be calculated using the Fox equation (eq. (1)) (12):

$$1/T_g = \Sigma W(i)/T_g(i) \quad (1)$$

The factor W in this equation refers to the weight, or percent composition, of a given monomer with a given T_g value for the homopolymer.

As can be seen in Table 1, the most common acrylic ester polymers have low T_g values and, therefore, soften films in which they are copolymerized with other vinylic monomers. This effect results in an internal plasticization of the polymer. That is, the plasticization effect from acrylic esters, unlike plasticizer additives which are not covalently bound, will not be removed via volatilization or extraction.

Nondestructive techniques such as torsional modulus analysis can provide a great deal of information on the mechanical properties of viscoelastic materials (8,13–25). For this type of analysis, a higher modulus value is measured for those polymers which are stiffer, harder, or have a higher degree of cross-linking. The regions of elastic behavior are shown in Figure 1 with curve A representing a soft polymer and curve B a harder polymer. A copolymer with a composition between these two homopolymers would fall between the two depicted curves, with the

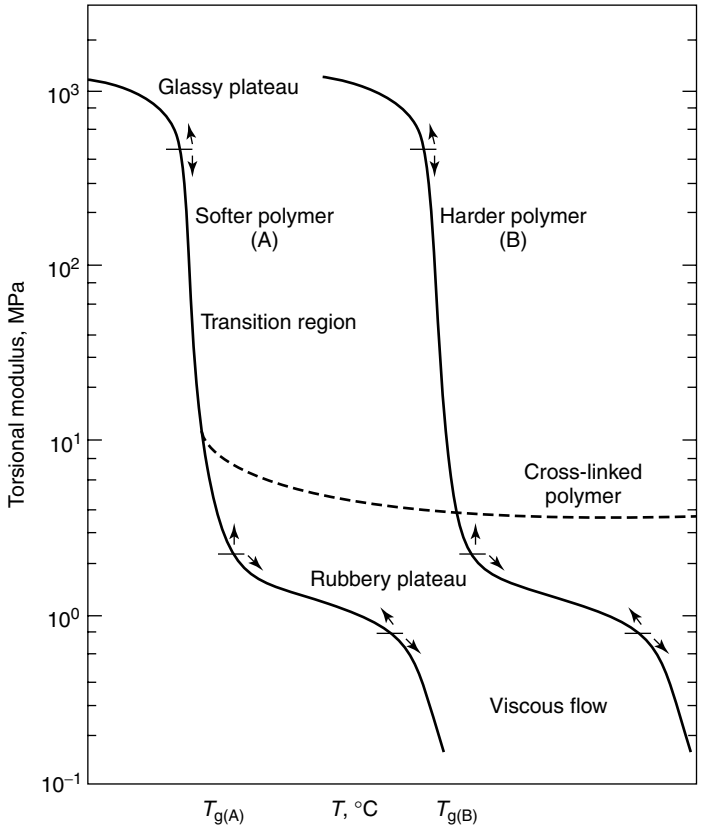

Fig. 1. Modulus–temperature curve of amorphous and cross-linked acrylic polymers. To convert MPa to kg/cm^2, multiply by 10.

relative distance from each curve determined by the similarity of the copolymer composition to one homopolymer or the other (26–28).

Acrylic ester polymers are susceptible to the covalent bonding of two or more polymer chains to form a cross-link (11,29–38). The above-described thermal analysis techniques are capable of distinguishing not only T_g but also varying degrees of cross-linking between polymers. A higher degree of cross-linking results in an elevation and extension of the rubbery plateau region. After a certain level of cross-linking is obtained, the segmental mobility of the polymer chains is impeded (23,25,28). This loss of mobility is measured as an increase in the T_g of the polymer. Further details on cross-linking within and between polymer chains can be found in References 11 and 29–38.

Molecular Weight. The properties of acrylic ester polymers (and most other types of polymers for that matter) improve as molecular weight increases. Beyond a certain level (100,000–200,000 for acrylic ester polymers) this improvement in polymer properties reaches a plateau. The glass-transition temperature can be described by the equation:

$$T_g = T_{gi} - k/M_n$$

Table 2. Mechanical Properties of Acrylic Polymers

Polyacrylate	Elongation, %	Tensile strength, kPa[a]
Methyl	750	6895
Ethyl	1800	228
Butyl	2000	21

[a]To convert kPa to psi, multiply by 0.145.

where T_{gi} is the glass-transition temperature for a polymer of infinite molecular weight and M_n is the number average molecular weight. Typical values of k fall in the range of 2×10^5 (39). Reference 40 summarizes the effect of molecular weight on polymer properties.

Mechanical and Thermal Properties. The mechanical and thermal properties of a polymer are strongly dependent on the nature of the ester side-chain groups of its composite monomers. With H as a side chain, poly(acrylic acid) is a brittle material at room temperature, which is capable of absorbing large quantities of water. The first member of the acrylic ester family, poly(methyl acrylate), is a tough, rubbery, tack-free material at room temperature. The next higher chain length material, poly(ethyl acrylate), is softer, more rubbery, and more extensible. Poly(butyl acrylate) has considerable tack at room temperature and is capable of serving as an adhesive material. Information on these homopolymers is summarized in Table 2 (41). Softness of these polymers increases with increasing chain length until one reaches poly(*n*-nonyl acrylate). Beginning with this chain length, the side chains start to crystallize, which leads to a stiffening of the polymer. This stiffening translates into an embrittlement of the polymer (42); poly(*n*-hexadecyl acrylate), for example, is a hard, waxy material at room temperature.

Acrylic ester polymers are quite resilient to extreme conditions. This resilience gives finished products the durability that has earned acrylic polymers their reputation for value over time. In contrast to polymers of methacrylic esters, acrylic esters are stable when heated to high temperatures. Poly(methyl acrylate) can withstand exposure to 292–399°C in vacuo without generating significant quantities of monomer (43,44). Acrylic ester polymers are also resistant to oxidation. Hydroperoxides can be formed from polymer radicals and oxygen under forcing conditions (45–47), but by and large this is a minor concern.

Solubility. Like most other properties, the side chain of acrylic ester polymers determines their solubility in organic solvents. Shorter side-chain polymers are relatively polar and will dissolve in polar solvents such as ether alcohols, ketones, and esters. With longer side-chain polymers, the solubility of a polymer shifts to the more hydrophobic solvents such as aromatic or aliphatic hydrocarbons. If a polymer is soluble in a given solvent, typically it is soluble in all proportions. Film formation occurs with the evaporation of the solvent, increase in solution viscosity, and the entanglement of the polymer chains. Phase separation and precipitation are not usually observed for solution polymers.

Solubility is determined by the free energy equation (the Flory–Huggins equation) governing the mutual miscibility of polymers (eq. (2)):

$$\Delta G_{Mix} = kT(N_1 \ln \nu_1 + N_2 \ln \nu_2 + \chi_1 N_1 \nu_2) \quad (2)$$

Table 3. Solubility Parameters of Acrylic Homopolymers Calculated by Small's Method[a]

Polymer	$(J/cm^3)^{1/2}$ [b]
Methyl acrylate	4.7
Ethyl acrylate	4.5
n-Butyl acrylate	4.3

[a] Refs. 23 and 53.
[b] To convert $(J/cm^3)^{1/2}$ to $(cal/cm^3)^{1/2}$, divide by 2.05.

where k is the Boltzmann's constant, T the temperature, N_1 the number of solvent molecules, N_2 the number of polymer molecules, ν_1 the volume fraction of the solvent, ν_2 the volume fraction of the polymer, and χ_1 the Flory–Huggins interaction parameter.

With this equation, polymer dissolution takes place when the free energy of mixing is negative. A polymer in solution always has a much higher entropy level than undissolved polymer since it is free to move to a far greater extent. This means the change in entropy term will always have a large positive value. Therefore, the factor which determines whether or not a polymer will dissolve in a particular solvent is the heat term. If the difference in the solubility parameters for two substances is small, dissolution will occur since the heat of mixing will be small and the entropy difference will be large (this translates into a negative overall energy of mixing). A polymer will dissolve in a particular solvent if the solubility parameters and the polarities for the polymer and the solvent are comparable (38,48–53). Some relevant solubility parameters are given in Table 3.

Polymer solution viscosity is a function of the polymer molecular weight, concentration in solvent, temperature, polymer composition, and solvent composition (9,54–56).

Chemical Resistance. Acrylic polymers and copolymers are highly resistant to hydrolysis. This property differentiates acrylic polymers from poly(vinyl acetate) and vinyl acetate copolymers. When exposed to highly extremely acidic or alkaline environments, acrylic ester polymers can hydrolyze to poly(acrylic acid) and the corresponding alcohol. Resistance to hydrolysis decreases in the order butyl acrylate > ethyl acrylate > methyl acrylate. Although it is the least hydrolytically stable, methyl acrylate is still far more resistant to hydrolysis than vinyl acetate (57,58).

Ultraviolet radiation is the other main stress encountered by polymers in the coatings arena. One hundred percent acrylic polymers are highly resistant to photodegradation because they are transparent to the vast majority of the solar spectrum (59). When uv-absorbing monomers, such as styrene, are incorporated into the polymer backbone, the uv-resistance of the resulting polymer decreases dramatically and a more rapid deterioration in polymer/coating properties is observed. On the other hand, a noncovalently bound uv absorber, such as hydroxybenzophenone [117-99-7], further improves the uv stability of 100% acrylic polymers (59).

Higher energy radiation such as from gamma ray or electron beam sources results in the scission of both main and side chains (60). The ratio of backbone to side-chain scission is determined by the nature of the side chain (61,62).

Acrylic Ester Monomers

A wide variety of properties are encountered in the acrylic monomers area. This range of properties is made accessible by the variability of the side chain for acrylic monomers. Some of the key physical properties of the most commercially important monomers are included in Table 4. A more complete listing of both monomers and their properties is found in the article Acrylic Acid and Derivatives.

The two most common methods for production of acrylic ester monomers are (*1*) the semicatalytic Reppe process which utilizes a highly toxic nickel carbonyl catalyst and (*2*) the propylene oxidation process which primarily employs molybdenum catalyst. Because of its decreased cost and increased level of safety, the propylene oxidation process accounts for most of the acrylic ester production currently. In this process, acrolein [107-02-8] is formed by the catalytic oxidation of propylene vapor at high temperature in the presence of steam. The acrolein intermediate is then oxidized to acrylic acid [79-10-7].

$$CH_2{=}CHCH_3 + O_2 \xrightarrow{\text{catalyst}} CH_2{=}CHCHO + H_2O$$

$$2\,CH_2{=}CHCHO + O_2 \xrightarrow{\text{catalyst}} 2\,CH_2{=}CHCOOH$$

Once the acrylic acid has been formed, the various acrylic ester monomers are synthesized by esterification of acrylic acid with the appropriate alocohol (63–66).

These monomers are then prevented from highly exothermic and hazardous autopolymerization processes during shipping and storage by the addition of a chemical inhibitor. The most common inhibitors currently used are hydroquinone [123-31-9], the methyl ether of hydroquinone (MEHQ) [150-76-5], and the newest member of the inhibitor family, 4-hydroxy TEMPO [2226-96-2]. 4-Hydroxy TEMPO, unlike the quinone inhibitors, does not require the presence of oxygen in order to be effective. Chemical inhibitors are only added at the $<$100 ppm level and are not typically removed prior to their commercial use. Finally, copper and its alloys can also function as inhibitors and should, therefore, be avoided when constructing a reactor for purposes of producing acrylic ester (co)polymers (67). With no inhibitor added, the monomers must be stored at temperatures below 10°C for no longer than a few weeks. Failure to exercise these precautions can result in violent, uncontrolled, and potentially deadly polymerizations.

Common acrylic ester monomers are combustible liquids. Commercial acrylic monomers are shipped with DOT (Department of Transportation) red labels in bulk quantities, tank cars, or tank trucks. Mild steel is the usual material of choice for the construction of bulk storage facilities for acrylic monomers; moisture is excluded to avoid rusting of the storage tanks and contamination of the monomers.

A variety of methods are available for determining the purity of monomers by the measurement of their saponification equivalent and bromine number, specific gravity, refractive index, and color (68–70). Minor components are determined by iodimetry or colorimetry for hydroquinone or MEHQ, Karl–Fisher method for water content, and turbidimetry for measuring trace levels of polymer. Gas–liquid chromatography is useful in both the general measurement of monomer purity as well as the identification of minor species within a monomer solution.

Although toxicities for acrylic ester monomers range from slight to moderate, they can be handled safely and without difficulty by trained, personnel, provided

Ethyl acrylate	760	1800	7.4	25
Butyl acrylate	3730	3000	5.3	

that the proper safety instructions are followed (67,71). Table 5 contains animal toxicity data for common acrylic ester monomers under acute toxicity conditions.

Because of their higher vapor pressures, liquid methyl and ethyl acrylate are the two most potentially harmful acrylic ester monomers. Threshold limit values (TLV) for long-term low level exposures to these monomers in industrial situations have been established by OSHA (Table 5). Local regulations and classifications sometimes apply, however, to these monomers. Ethyl acrylate, for example, has been labeled a known carcinogen by the State of California (71).

Radical Polymerization

Free-radical initiators such as azo compounds, peroxides, or hydroperoxides are commonly used to initiate the polymerization of acrylic ester monomers. Photochemical (72–74) and radiation-initiated (75) polymerization are also possible. At constant temperature, the initial rate of polymerization is first order in monomer and one-half order in initiator. Rate data for the homopolymerization of several common acrylic ester monomers initiated by 2,2′-azobisisobutryonitrile (AIBN) [78-67-1] have been determined and are contained in Table 6. Also included in this table are heats of polymerization and volume shrinkage data (76).

The polymerization of both acrylic and methacrylic ester monomers is accompanied by the release of a large quantity of heat as well as a substantial decrease in sample volume. Commercial processes must account for both these phenomena. Excess heat must be removed from industrial reactors by the use of high surface area heat exchangers. As for the shrinkage issue, the percent shrinkage encountered upon polymerization of the monomer is, in general, inversely proportional to the length of the monomer side chain. Mole for mole, the shrinkage amount is relatively constant (77).

Table 6. Polymerization Data for Acrylic Ester Monomers in Solution[a]

Acrylate	Concentration, solvent	k_{sp}, L/mol·h[b]	Heat, kJ/mol[c]	Shrinkage, vol%
Methyl	3 *M*, Methyl propionate	250	78.7	24.8
Ethyl	3 *M*, Benzene	313	77.8	20.6
Butyl	1.5 *M*, Toluene	324	77.4	15.7

[a] Ref. 76.

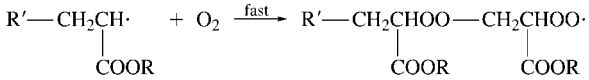
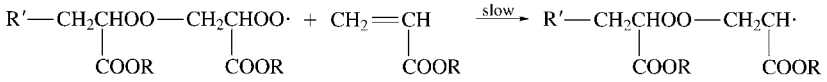
The free-radical polymerization of acrylic monomers takes place through the classical stepwise chain-growth mechanism, which is described as the head-to-tail addition of individual monomer units through attack of the monomer double bond and formation of a single bond between the newly incorporated monomer units.

This stepwise growth continues until either termination or chain transfer of the radical chain end takes place. Termination can occur by combination or disproportionation, depending on the conditions of the polymerization (78,79).

The addition step typically takes place as a head-to-tail process although head-to-head addition has been observed as well (80). Oxygen has a strong inhibitory effect on the rate of polymerization of acrylic ester polymers. Oxygen is, therefore, excluded from commercial reactors primarily through the use of positive nitrogen flow. The nature of the oxygen inhibition is known: an alternating copolymer can be formed between oxygen and acrylic ester monomers (81,82).



The oxygen chain end is relatively unreactive when compared to the acrylic chain end and reduces the overall rate of polymerization. Additionally, the peroxy radical undergoes a faster rate of termination than the standard acrylic-based radical:



One will observe a drop in overall reaction rate, a change in polymer composition and properties, as well as a decrease in polymer molecular weight if oxygen is not excluded from a reactor when polymerizing acrylic ester monomers (83).

The wide variety of acrylic ester monomers dictates that a wide variety of homopolymers with radically different properties are accessible. An even wider variety of polymers can be formed through the copolymerization of two or more acrylic ester monomers (84,85).

Acrylic ester monomers are, in general, readily copolymerized with other acrylic and vinylic monomers. Table 7 presents data for the free-radical copolymerization of a variety of monomers 1:1 with acrylic ester monomers. These numbers are calculated through the use of reactivity ratios:

$$r_1 = k_{11}/k_{12}$$
$$r_2 = k_{22}/k_{21}$$

For a binary copolymer, the smaller reactivity ratio is divided by the larger r value and multiplied by 100. Values greater than 25 indicate that

Table 7. Relative Ease of Copolymer Formation for 1:1 Ratios of Acrylic and Other Monomers, $\frac{r(\text{smaller})}{r(\text{larger})} \times 100$

Monomer 2	CAS registry number	Monomer 1

[a]Ref. 88.

copolymerization proceeds smoothly; low values for the ease of copolymerization can be helped through the adjustment of comonomer composition as well as the monomer addition method (86).

A growing chain with monomer 1 as the chain-end radical has a rate constant for self-addition of k_{11}; the rate for addition of monomer 2 is k_{12}. The self-addition rate for a terminal monomer 2 radical is given as k_{22}; the rate for addition of monomer 1 is k_{21}. The reactivity ratios can also be calculated from the Price-Alfrey measures (87) of resonance stabilization (Q) and polarity (e) which are shown for common acrylic esters in Table 8. NMR can also be used to determine the composition distribution characteristics of acrylic copolymers (88,89).

In addition to the standard side-chain variation discussed above, special functionality can be added to acrylic ester monomers by use of the appropriate functional alcohol. Through the use of small levels of functional monomers, one can allow an acrylic ester polymer to react with metal ions, cross-linkers, or other types of resins. Table 9 contains information on some of the more common functional monomers.

Bulk Polymerization

Bulk polymerizations of acrylic ester monomers are characterized by the rapid formation of an insoluble network of polymers at low conversion with a concomitant rapid increase in reaction viscosity (90,91). These properties are thought to

come from the chain transfer of the active radical via hydrogen abstraction from the polymer backbone. When two of these backbone radical sites propagate toward one another and terminate, a cross-link is formed (91).

Solution Polymerization

Of far greater commercial value than that of simple bulk polymerizations, solution polymerizations employ a co-solvent to aid in minimizing reaction viscosity as well as controlling polymer molecular weight and architecture. Lower polyacrylates are, in general, soluble in aromatic hydrocarbons, esters, ketones, and chlorohydrocarbons. Solubilities in aliphatic hydrocarbons, ethers, and

Table 10. Chain-Transfer Constants to Common Solvents for Poly(ethyl acrylate)[a]

Solvent	$C_s \times 10^5$
Benzene	5.2
Toluene	26.0
Isopropyl alcohol	260
Isobutyl alcohol	46.5
Chloroform	14.9
Carbon tetrachloride	15.5

[a]Refs. 79, 92, and 93.

alcohols are somewhat lower. As one moves to longer alcohol side-chain lengths, acrylics become insoluble in oxygenated organic solvents and soluble in aliphatic and aromatic hydrocarbons and chlorohydrocarbons. Solvent choices for acrylic solution polymerizations are made on the basis of cost, toxicity, flammability, volatility, and chain-transfer activity. The chain-transfer constants (C_s) for a variety of solvents in the solution polymerization of poly(ethyl acrylate) are shown in Table 10.

Initiators serve the dual role of beginning the polymerization of an individual chain as well as controlling the molecular weight distribution of a polymer sample. Initiators are chosen based on their solubility, thermal stability (rate of decomposition), and the end use for the polymer. Additionally, initiators can be used to control polymer architecture by cross-linking control; this property also allows initiators to serve a role in the regulation of molecular weight distribution. Levels of usage vary from hundredths of a percent to several percent by weight on the polymer formed. The types of initiators most commonly employed in solution polymerizations are organic peroxides, hydroperoxides, and azo compounds.

Molecular weight control can also be achieved through the use of a chain-transfer agent. The most commonly used species in this class are chlorinated aliphatic compounds and thiols (94). The chain-transfer constants (C_s at 60°C) for some of these compounds in the formation of poly(methyl acrylate) are as follows (87): Carbon tetrabromide, 0.41; Ethanethiol, 1.57; and Butanethiol, 1.69.

Because of the volatile nature of the monomers used and high temperatures often employed, solution polymerizations are typically performed in reactors which can withstand pressures of at least 446 kPa (65 psi). Standard materials of construction include stainless steeel (which may be glass-lined) or nickel. Anchor-type agitators are used for solution polymerizations with viscosities up to 1.0 Pa·s (1000 cP), but when viscosity levels move above this range, a slow ribbon-type agitator is used to sweep material away from the reactor walls. Improper agitation can result in the severe fouling of a reactor. Most industrial reactors are jacketed for steam heating and/or water cooling of a batch and contain a rupture disk to relieve pressure buildup. Additionally, there are numerous inlets in a typical industrial reactor as well as a thermocouple for monitoring temperature. A valve is placed in the bottom of the reactor to release polymerized material to storage containers.

Cooling within a reactor is typically provided by a reflux condenser. Since polymerization is a highly exothermic process, temperature control is a safety concern as well as a product integrity issue. Temperature control is primarily

obtained through the gradual addition of monomers into the reactor by gravity from storage containers close to the reactor. In this manner, the rate of monomer addition and reaction can be matched to the cooling capacity of the reactor so that temperatures remain relatively constant throughout the polymerization. If these measures fail to control the temperature of a particular batch, a chemical inhibitor, such as a hydroquinone, can be added to retard the rate of polymerization.

Oxygen can serve as an inhibitor of polymerization. Reactors typically maintain a blanket of nitrogen over the entire reactor kettle. In polymerizations with temperatures below reflux, nitrogen is used to purge the reaction solution; a nitrogen blanket is then placed over the reactor prior to the addition of the initiator. Total cycle times for solution polymerizations run in the range of 24 h (95).

A typical solution polymerization recipe is shown below:

Composition	Parts
Reactor charge	
Ethyl acetate	61.4
Benzoyl peroxide	0.1
Monomer charge	
Ethyl acrylate	36.5
Acrylic acid	2.0

This copolymer has an overall composition of 94.8% ethyl acrylate/5.2% acrylic acid with the monomer charged at a level of 39 wt% in a solution of ethyl acetate. Initially, the solvent and initiator, benzoyl peroxide in this case, are added to the reactor and heated to reflux (80°C). Forty percent of the monomer mixture is added to the reactor in one charge. Then, four equal aliquots of monomer are added 24, 50, 79, and 110 min after the initial charge. Reflux is maintained within the reactor overnight to ensure complete reaction; the product is then cooled and packaged the next morning (96).

Storage and handling equipment are typically made from steel. In order to prevent corrosion and the transfer of rust to product, moisture is typically excluded from solution polymer handling and storage systems (97). Because of the temperature-sensitive nature of the viscosity of solution polymers, the temperature of the storage tanks and tranfer lines is regulated either through prudent location of these facilities or through the use of insulation, heating, and cooling equipment.

Emulsion Polymerization

Emulsion polymerization is the most industrially important method of polymerizing acrylic ester monomers (98,99). The principal ingredients within this type of polymerization are water, monomer, surfactant, and water-soluble initiator. Products generated by emulsion polymerization find usage as coatings or binders in paints, paper, adhesives, textile, floor care, and leather goods markets. Because of their film-forming properties at room temperature, most commercial acrylic ester polymers are copolymers of ethyl acrylate and butyl acrylate with methyl methacrylate.

Lower acrylates are capable of polymerizing in water in the presence of an emulsifier and a water-soluble initiator. The polymeric product is typically a milky-white dispersion of polymer in water at a polymer solids content of 30–60%. Particle sizes for these latices fall in the range of 0.1–1.0 μm. Because of the compartmentalized nature of the process (99), high molecular weights are obtained with most emulsion polymerizations without the resulting viscosity build encountered with solution polymerizations. Additionally, the use of water as a dispersion medium provides attractive safety, environmental, and heat removal benefits when compared to other methods of polymerizing acrylic ester monomers. The emulsion polymerization of the higher (relatively water insoluble) acrylates can even be accomplished now through the use of a patented method for catalytically transferring monomer from droplets to the growing polymer particles (100).

The types of surfactants used in an emulsion polymerization span the entire range of anionic, cationic, and nonionic species. The most commonly used soaps are alkyl sulfates such as sodium lauryl sulfate [151-21-3], alkylaryl sulfates such as sodium dodecyl benzene sulfonate [25155-30-0], and alkyl or aryl polyoxyethylene nonionic surfactants (87,101–104). Product stability and particle size control are the driving forces which determine the types of surfactants employed; mixtures of nonionic and anionic surfactants are commonly used to achieve these goals (105–108).

Water-soluble peroxides, such as sodium or ammonium persulfate, are commonly used in the industrial arena. The thermal dissociation of this initiator (109) results in the formation of sulfate radicals which initiate polymer chains in the aqueous phase. It is possible to use other oxidants, such as hydrogen peroxide [7722-84-1] or persulfates in the presence of reducing agents and/or polyvalent metal ions (87). In this manner, a redox initiator system is formed which allows the experimenter to initiate polymer chains over a much broader range of temperatures (25–90°C) than simple thermal initiation (75–90°C) (110). The primary disadvantage of this initiation method is that greater level of salt impurities are introduced to the reactor which could, perhaps, adversely influence final polymer properties such as stability.

Emulsion polymerization batches on the industrial scale are typically run in either stainless steel or glass-lined steel reactors which can safely handle internal pressures of 446 kPa (65 psi). Agitation within the reactors is controlled by use of a variable speed stirring shaft coupled at times with a baffling system within the reactor to improve mixing. Care must be taken to avoid excessive mixing forces being placed on the latex as coagulum will form under extreme conditions. Temperature control of batches is maintained through the use of either steam or cold water jacketing. Multiple feed lines are necessary to provide for the addition of multiple streams of reactants such as initiators, monomer emulsions, inihibitors if necessary, and cooling water. Monitoring equipment for batches typically consists of thermocouples, manometers, sightglasses, as well as an emergency stack with a rupture disk in case of pressure buildup within the reactor. A typical industrial emulsion polymerization plant is shown in Figure 2.

There are numerous examples of typical industrial emulsion polymerization recipes available in the open literature (111,112). A process for the synthesis of a polymer with a 50% methyl methacrylate, 49% butyl acrylate, and 1% methacrylic acid terpolymer at a solids content of 45% is described below:

Charge	Parts
Monomer emulsion charge	
Deionized water	13.65
Sodium lauryl sulfate	0.11
Methyl methacrylate	22.50
Butyl acrylate	22.05
Methacrylic acid	0.45
Initiator charge	
Ammonium persulfate	0.23
Reactor charge	
Deionized water	30.90
Sodium lauryl sulfate	0.11

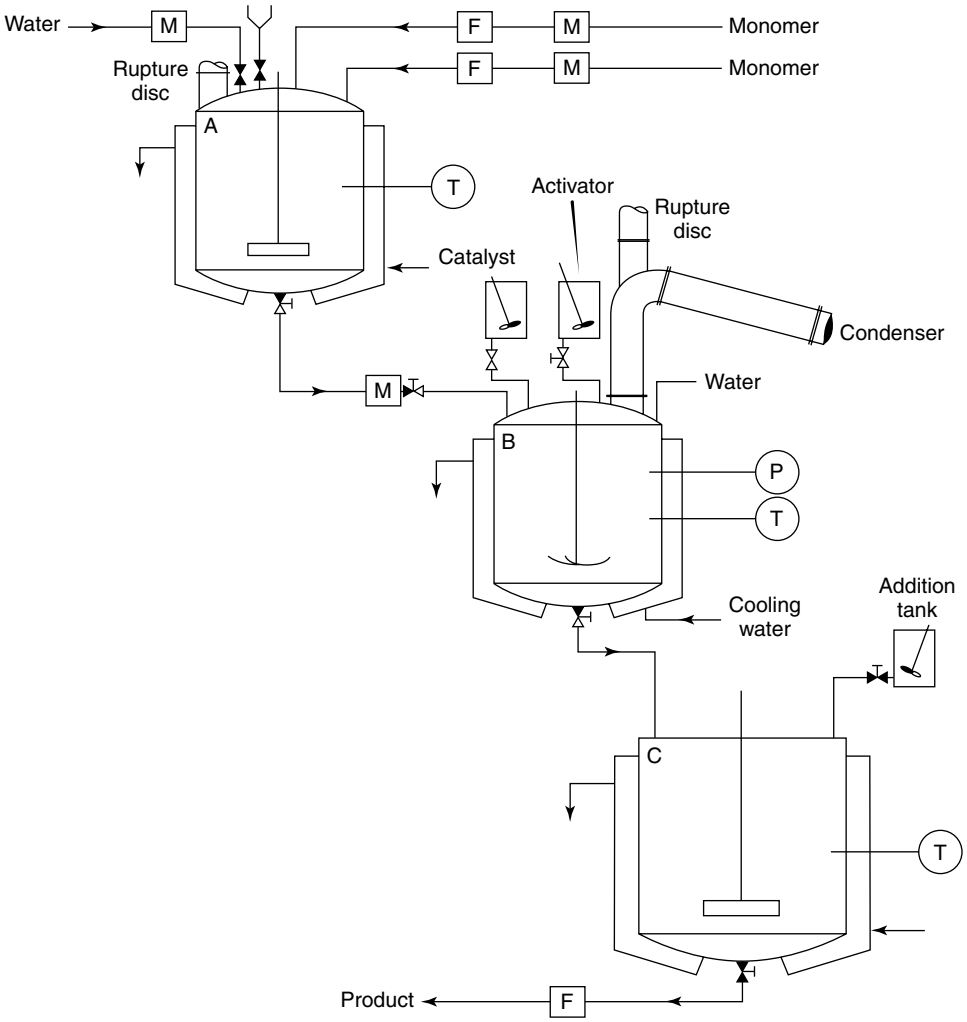

Fig. 2. Emulsion polymerization plant. A, Emulsion feed tank; B, polymerization reactor; C, drumming tank; F, filter; M, meter; P, pressure gauge; T, temperature indication.

The monomer emulsion is first formed in a separate agitation tank by combination of the water, soap, and monomer with a proper level of mixing. Care must be taken to avoid excessive levels of agitation in the monomer emulsion tank to avoid incorporating air into the emulsion. The reactor water is heated under a nitrogen blanket to a temperature of at least 75°C prior to the addition of the initiator. Following the addition of the initiator, the monomer emulsion is fed into the reactor over the course of approximately 2.5 h. Temperature control is maintained during this time through both control of the monomer feed rate as well as use of the reactor jacket heating/cooling system. After the monomer emulsion feed is completed, the temperature is held above 75°C for at least 30 min to reduce the level of residual standing monomer within the system. The product is then cooled, filtered, and packaged.

Once packaged, the storage of acrylic latices is a nontrivial matter; problems commonly encountered with these polymer colloids include skinning (surface film formation), sedimentation, grit formation within the latex, formation of coagulum on storage container walls, and sponging (aerogel formation). Exposure of the material to extremes in temperature is avoided through prudent location of these facilities or the use of insulation, heating, and cooling equipment. Acrylic emulsion polymers, like many other types of polymers, are subject to bacterial attack. Proper adjustment of pH, addition of bactericides, and good housekeeping practices (95) can alleviate the problems associated with bacterial growth. Some advances in the industrial application of emulsion polymerization have been described in the open literature (113).

Suspension Polymerization

Suspension polymers of acrylic esters are industrially used as molding powders and ion-exchange resins. In this type of polymerization, monomers are dispersed as 0.1- to 5-mm droplets in water and are stabilized by protective colloids or suspending agents. In contrast to emulsion polymerization, initiation is accomplished by means of a monomer-soluble agent and occurs within the suspended monomer droplet. Water serves the same dual purpose as in emulsion (heat removal and polymer dispersion). The particle size of the final material is controlled through the control of agitation levels as well as the nature and level of the suspending agent. Once formed, the 0.1- to 5-mm polymer beads can be isolated through centrifugation or filtration.

The most commonly used suspending agents are cellulose derivatives, polyacrylate salts, starch, poly(vinyl alcohol), gelatin, talc, and clay derivatives (95). The important function these agents must serve is to prevent the coalescence of monomer droplets during the course of the polymerization (114). Thickeners can also be added to improve suspension quality (95). Other additives such as lauryl alcohol, stearyl acid or cetyl alcohol lubricants and di- or trivinyl benzene, diallyl esters of dibasic acids, and glycol dimethacrylates cross-linkers are used to improve bead uniformity and bead performance properties.

Unlike emulsion polymerization, the initiators employed in suspension polymerization must not be water-soluble; organic peroxides and azo species are most commonly used. In similar fashion to bulk polymerization, the level of initiator

used directly influences the molecular weight of the product (95,115,116). Developments in the method of suspension polymerization have been reviewed in the open literature (117,118).

Graft Copolymerization

Polymer chains can be attached to a preexisting polymer backbone of a similar or completely different composition to form what is termed a graft copolymer. Acrylic branches can be added to either synthetic (119,120) or natural (121–124) backbones. Attachment of graft polymer branches to preformed backbones is accomplished by chemical (125–127), photochemical (128,129), radiation (130), and mechanical (131) means. The presence of distinct compositions in this branched geometry often conveys properties which cannot otherwise be attained (132,133).

Living Polymerization

One of the most exciting areas currently in the radical polymerization of acrylic ester monomers is the field of living polymerization. Living polymers are defined in Reference 134 as "polymers that retain their ability to propagate for a long time and grow to a desired maximum size while their degree of termination or chain transfer is still negligible." Because of these properties, exceptional control can be exercised over the topology (ie, linear, comb), composition (ie, block, graft), and functional form (ie, telechelic, macromonomer) of these polymers (135).

Atom-transfer radical polymerization (ATRP) and nitroxide-mediated (136–138) polymerization both show promise in terms of the ability to fine tune polymer architecture using living radical methods. ATRP has been successfully used in the polymerization of methyl acrylate (139,140) as well as functional acrylates containing alcohol (141), epoxide (142), and vinyl groups (143) on the side chain. The main drawbacks to the ATRP method of creating acrylic ester homo- and copolymers are the relatively long reaction times and the high levels of metal-containing initiator required (see LIVING POLYMERIZATION, RADICAL).

Radiation-Induced Polymerization

Coatings can be formed through the application of high energy radiation to either monomer or oligomer mixture. Ultraviolet curing is the most widely practiced method of radiation-based initiation (144–150); this method finds its main industrial applications in the areas of coatings, printing ink, and photoresists for computer chip manufacturing. The main disadvantage of the method is that uv radiation is incapable of penetrating highly pigmented systems.

To form a film via this method, a mixture of pigment, monomer, polymer, photoinitiator, and inhibitor are applied to a substrate and polymerized by controlled exposure to uv radiation. Polymers used as co-curing agents often have unsaturated methacrylate functionalities attached; higher order acrylates are often used as the solvent in photocure mixtures.

In order to avoid the problems associated with more highly pigmented systems, electron beam curing is employed (151). This high energy form of radiation is capable of penetrating through the entire coating regardless of the coating's pigment loading level.

Anionic Polymerization

The Anionic Polymerization of acrylic ester monomers is accomplished by use of organometallic initiators in organic solvents. The main advantage to the use of anionic polymerization as opposed to other methods is its ability to generate stereoregular or block copolymers. Some examples of this type of polymerization include the anionic formation of poyl(*t*-butyl acrylate) (152–155), poly(isopropyl acrylate) (156), and poly(isobutyl acrylate) (157,158). Solvent conditions primarily determine tacticity of the resulting polymer product with nonpolar solvents generating isotactic product and polar solvents resulting in the formation of syndiotactic polymers. The strikingly different physical properties and mechanistic discussions on the formation of these two different types of polymer have been described in the polymer literature (159–162).

The initiation step for anionic polymerizations takes place via a Michael reaction:

$$R_3C^-M^+ + CH_2{=}CHCOOR \longrightarrow R_3C{-}CH_2{-}\bar{C}H{-}COOR$$

A subsequent polymer growth occurs by head-to-tail addition of monomer to the growing polymer chain.

$$R_3C{-}CH_2{-}\bar{C}H{-}COOR + CH_2{=}CHCOOR \longrightarrow R_3C{-}CH_2{-}\underset{\displaystyle COOR}{CH}{-}CH_2{-}\underset{\displaystyle COOR}{\bar{C}H}$$

Because of cost constraints and toxicity issues involved with the organometallic initiators, anionic polymerization is of limited commercial significance. Both the living methods described above as well as DuPont's group-transfer polymerization method (163–167) are seen as alternative ways to achieve the same level of control over polymer architecture as that of anionic polymerization. All these methods offer the promise of narrow and controllable molecular weight distributions as well as the ability to form block copolymers through the sequential addition of monomers. Additionally, all the methods suffer from slow overall reaction rates and the difficulty of removing the specialty initiators after polymer formation has taken place.

Analytical Test Methods and Specifications

Emulsion Polymers. Current analytical methods allow for complete characterization of all crucial aspects of an acrylic latex (87). The main properties of interest are an acrylic latex's composition, percent solids content, viscosity, pH,

particle size distribution (168,169), glass-transition temperature, minimum film-forming temperature (170), and surfactant type. In addition to these basic properties, the stability of a latex with respect to mechanical shear, freeze-thaw cycles, and sedimentation on standing for long periods of time are of interest in commercial products.

Solution Polymers. A solution polymer's composition, solids content, viscosity, molecular weight distribution, glass-transition temperature, and solvent are of interest. Standard methods allow for all of these properties to be readily determined (171,172).

Environmental Health and Safety Factors

Acrylic polymers are categorized as nontoxic and have been approved for the handling and packaging by the FDA. The main concerns with acrylic polymers deal with the levels of residual monomers and the presence of nonacrylic additives (primarily surfactants) which contribute to the overall toxicity of a material. As a result, some acrylic latex dispersions can be mild skin or eye irritants.

During the manufacture of an acrylic polymer, precautions are taken to maintain temperature control (173). In addition to these measures, polymerizations are run under conditions wherein the reactor are closed to the outside environment to prevent the release of monomer vapor into the local environment. As for final product properties, acrylic latices are classified as nonflammable substances and solution polymers are classified as flammable mixtures.

Uses

Because of their wide property range, clarity, and resistance to degradation by environmental forces, acrylic polymers are used in an astounding variety of applications that span the range from very soft adhesive materials to rigid non-film-forming products (Table 11).

Coatings. Acrylic ester latex polymers are used widely as high quality paint binders because of their excellent durability, toughness, optical clarity, uv stability, and color retention. These properties allow acrylics to find use as binder vehicles in all types of paints (76): interior and exterior; flats, semigloss, and gloss; as well as primers to topcoats. Although all-acrylic compositions are most

favored in exterior applications because of their excellent durability (174), other types of copolymers such as vinyl-acrylics and styrene-acrylics benefit in terms of performance properties from the acrylic portion of the composition; methods of manufacturing acrylic-based paints have been described previously in the literature (175). Acrylic emulsion polymers even find use in the protection of structural steel (176) (see COATING METHODS, SURVEY).

The industrial finishing area sees both acrylic emulsions as well as solution polymers utilized in a wide variety of applications including factory finished wood (177,178), metal furniture and containers (179), and can and coil coatings (180). In order to harden acrylic polymers for this type of demanding application, the polymers are often cross-linked with melamines, epoxies, and isocyanates. The coatings are applied via spraying, roll dipping, or curtain coating. Radiation curing using uv radiation or electron beam radiation (181–186), powder coating (187–190), electrode deposition of latices (191–193), and the use of higher solids level emulsion (194) represent newer methods for applying acrylic coatings to form industrial finishes. Excellent reviews on the use of water-based emulsions (195,196) and solution acrylics (197–199) can be found in the open literature (see COATINGS).

Hydrophobically modified acrylics are finding extensive usage as thickening agents in the paints marketplace as well as the area of industrial finishes (200). Flow and leveling improvements are observed when changing a formulation over from hydroxyethylcellulose to acrylic-based thickeners. Unlike cellulosic thickeners, the modified acrylics act through an associative thickening mechanism; they stabilize the dispersed polymer phase rather than thickening the aqueous phase of a polymer latex. Two main types of modified acrylics are of commercial value: HASE (hydrophobically modified alkali-soluble emulsions) and HEUR (hydrophobically modified ethylene oxide urethane block copolymers). These acrylics compete with hydrophobically modified hydroxyethylcellulose in the marketplace (201–203).

Textiles. Because of their durability, soft feel, and resistance to discoloration, acrylic emulsion polymers find a variety of uses in the textiles area including binders for fiberfill and nonwoven fabrics, textile bonding or laminating, flocking, backcoating and pigment printing applications. *N*-Methylolacrylamide is often used as a self-cross-linker in acrylic textile binders to improve washing and dry cleaning durability as well as overall binder strength (204).

Polyester (205–208), glass (209), and rayon (210) nonwoven and fiberfill mats have been manufactured using acrylic binders to hold the mats together. In this process, the acrylic emulsions are applied to a loose web or mat and are then heated to form a film at the fiber crossover points which maintains the structural integrity of the mat. The final products generated using this technology include quilting, clothing, disposable diapers, towels, filters, and roofing (see NONWOVEN FABRICS).

Acrylic polymers find use in applications that take advantage of their exceptional resistance to environmental assaults such as uv radiation, ozone, heat, water, dry cleaning, and aging (211). Acrylics are often used as the backing material for automotive and furniture upholstery to improve the dimensional handling properties, prevent pattern distortion, prevent unraveling, and minimize seam slippage. Strike-through problems are averted through the use of foamed or

frothed acrylic coatings, which also yield a softer fabric and save on energy costs (212). Crushed acrylic latex foam are employed as backing materials for draperies. The foam protects the drapery from sun damage, mechanically stabilizes the fabric, improves drape, and gives a softer hand than conventional backing materials (213). Acrylics are also used as carpet-backings and to bond fabric-to-fabric, fabric-to-foam, and fabric-to-nonwoven materials (214).

The flocking process begins with the bonding of cut fibers to an adhesive-coated fabric to obtain a decorative and functional material (215). Acrylics can provide the softness and durability that are sought in flocked textiles; they also serve as binders for pigments in the printing of flocked fabrics (35,216,217).

The feel, soil release properties, and permanent-press behavior of a fabric can be finely tuned using acrylic as finishing polymers. Copolymers of acrylics with acrylic or methacrylic acid can be used as thickeners for textile coating formulation.

Adhesives. Acrylic emulsion polymers are used in a wide variety of adhesives. Pressure-sensitive Adhesives, which typically have T_g values less than 20°C, are the main type of acrylic adhesive. Acrylic polymers and copolymers find use as PSAs in tapes, decals, and labels. Along with their aforementioned superior chemical resistance properties, acrylics possess an excellent balance of tack, peel, and shear properties which is crucial in the adhesives market (218,219). Other types of adhesives that employ acrylics include construction formulations and film-to-film laminates.

Paper. Because of their excellent cost-performance balance, acrylic-vinyl acetate copolymer emulsion binders have been used as pigment binders for coated paper and boards. These binders provide higher brightness, opacity, coating solids, and improved adhesion versus styrene–butadiene copolymers (220,221). Acrylics also find usage as paper saturants with properties that compare favorably to natural rubber, butadiene–acrylonitrile, and butadiene–styrene (222). Finally, acrylic emulsion polymers are utilized in starch-latex-pigmented coatings (223) as well as size-press (224) and beater addition (225) applications.

Other Applications. The leather finishing area is a traditional stronghold of acrylic emulsion polymers (226). Acrylics are used throughout the entire process of pigskin leather production; the use of acrylics lends uniformity, break improvement, better durability, and surface resistance while preserving the natural appearance of the pigskin (227).

Acrylics have been used to impart impact strength and better substrate adhesion to cement (228). The ceramics industry uses both acrylic solution and emulsion polymers as temporary binders, deflocculants, and additives in ceramics bodies and glazes (229) (see CERAMICS).

Acrylics are used in the manufacture of aqueous and solvent-based caulks and sealants (230,231). Elastomeric acrylics are used in mastics to prevent uv radiation and chemical damage to the underlying polyurethane foam. Acrylics also impart hailstone resistance as well as flexibility over a broad temperature range (232). The manufacturing process for poly(vinyl chloride) uses acrylics as processing aids and plate-out scavengers in calendered and blown films. Acrylics allow for the manufacture of thick, smooth calendered vinyl sheets through modification of the melt viscosity of the vinyl sheet polymer (233). In the

agricultural area, thin layers of acrylic emulsions have been applied to citrus leaves and fruit to control "Greasy Spot," a disease which causes leaf-spotting and eventually leaf loss (234). Acrylics have found a great deal of use in the floor polish area; a guide to formulating these coatings has been published (235).

Acrylic polymers have been used as alternatives to nitrile rubbers in some hydraulic and gasket applications because of their excellent heat-resistance properties (236,237). Ethylene–acrylate copolymers have been used as transmission seals, vibration dampeners, dust boots, and steering and suspension seals (238).

ACRYLONITRILE AND ACRYLONITRILE POLYMERS

Introduction

Acrylonitrile (also called acrylic acid nitrile, propylene nitrile, vinyl cyanide, propenoic acid nitrile) is a versatile and reactive monomer (1) which can be polymerized under a wide variety of conditions (2) and copolymerized with an extensive range of other vinyl monomers (3). Since its U.S. commercial debut in 1940, acrylonitrile has been one of the most important building blocks of the polymer industry. This has been demonstrated by the steady production growth of acrylonitrile to more than 4,000,000 t produced worldwide each year. Today, over 90% of the worldwide acrylonitrile production each year uses the Sohio-developed propylene ammoxidation process. Acrylonitrile is among the top 50 chemicals produced in the United States, as a result of the tremendous growth in its use as a starting material for a wide range of chemicals and polymer products. Acrylic fibers remain the largest user of acrylonitrile. Other significant uses are in styrene–acrylonitrile (SAN) and acrylonitrile–butadiene–styrene (ABS) resins and nitrile elastomers, and as an intermediate in the production of adiponitrile and acrylamide.

Acrylonitrile Monomer

Physical Properties. Acrylonitrile (C_3H_3N, mol wt = 53.064) is an unsaturated molecule having a carbon–carbon double bond conjugated with a nitrile group. It is a colorless liquid, with the faintly pungent odor of peach pits. Its properties are summarized in Table 1. Acrylonitrile is miscible with most organic solvents, including acetone, benzene, carbon tetrachloride, ether, ethanol,

ethyl acetate, ethylene cyanohydrin, liquid carbon dioxide, methanol, petroleum ether, toluene, xylene, and some kerosenes. Table 2 lists the azeotrope compositions of acrylonitrile with some of those solvents. Other important properties are reported in the literature: vapor pressure, solubility in water, and partial vapor pressure over its aqueous solutions (4,5); the partition of acrylonitrile between water and styrene (6); vapor–liquid equilibria and boiling temperatures for acrylonitrile–acetonitrile–water systems (7); high pressure–volume isotherms and temperature–volume isobar (8); electron diffraction and infrared spectral data (4); and Raman and uv spectra (9).

Chemical Properties. The presence of both a double bond and an electron-accepting nitrile group permits acrylonitrile to participate in a large number of addition reactions and polymerizations. The chemical reactions of acrylonitrile have been discussed in great length and detail (10,11). A brief summary follows.

Reactions of the Nitrile Group.

Hydration and Hydrolysis. In concentrated 85% sulfuric acid, partial hydrolysis of the nitrile group produces acrylamide sulfate, which upon neutralization yields acrylamide; this is the basis for acrylamide's commercial production. In dilute acid or alkali, complete hydrolysis occurs to yield acrylic acid.

Table 2. Azeotrope Compositions of Acrylonitrile[a]

Other component	Boiling point, °C	Acrylonitrile, wt%
Benzene	73.3	47
Carbon tetrachloride	66.2	21

Methanol	61.4	39
2-Propanol	71.7	56
Tetrachlorosilane	51.2	11
Water	71	88

[a] Ref. 4.

Alcoholysis. Reactions with primary alcohols, catalyzed by sulfuric acid, convert acrylonitrile to acrylic esters. In the presence of alcohol and anhydrous halides, imido ethers are formed.

Reactions with Olefins and Alcohols. The Ritter reaction occurs with compounds such as olefins and secondary and tertiary alcohols which form carbonium ions in acid, and N-substituted acrylamides are formed.

Reactions with Aldehydes and Methylol Compounds. Catalyzed by sulfuric acid, formaldehyde and acrylonitrile react to form either 1,3,5-triacrylylhexahydro-*s*-triazine or *N*,*N*′-methylenebisacrylamide, depending on the conditions. Similarly, in the presence of sulfuric acid, *N*-methylolbenzamide reacts to yield mixed bisamides. *N*-Methylolphthalimide reacts to give *N*-phthalimidomethylacrylamide.

Reactions of the Double Bond.

Diels-Alder Reactions. Acrylonitrile acts as a dienophile with conjugated carbon–carbon double bonds to form cyclic compounds. On the other hand, acrylonitrile can act as a diene. For example, with tetrafluoroethylene 2,2,3,3-tetrafluorocyclobutanecarbonitrile forms; and with itself, dimers of *cis*- and *trans*-cyclobutanedicarbonitriles form at high temperatures and pressure. The activation energy for acrylonitrile cyclodimerization has been reported to be 90.4 kJ/mol (12).

Hydrogenation. With metal catalysts, an excellent yield of propionitrile is attained, which can be further hydrogenated to propylamine.

Halogenation. At low temperatures, halogenation proceeds slowly to produce 2,3-dihalopropionitriles. In the presence of pyridine, addition of chlorine forms 2,3-dichloropropionitrile quantitatively. At elevated temperatures, without uv light, 2,2,3-trihalopropionitrile is obtained; with uv light, both 2,2,3- and 2,3,3-isomers are formed. Simultaneous chlorination and alcholysis occur to give 2,3-dichloropropionic acid esters.

Hydroformylation. In a process also known as the oxo-synthesis, acrylonitrile reacts with a mixture of hydrogen and carbon monoxide, catalyzed by cobalt octacarbonyl, to give β-cyanopropionaldehyde. This reacts with hydrogen cyanide and ammonia, and then hydrolysis produces glutamic acid on a large commercial scale.

Hydrodimerization. The reductive dimerization of acrylonitrile can be done either chemically or electrochemically to form adiponitrile. Hydrodimerization with its derivatives also takes place.

Reactions with Azo Compounds. Meerwein reactions of diazonium halides with acrylonitrile take place at low temperatures, catalyzed by cupric chloride, to yield 2-halo-3-arylpropionitriles. Reactions with diazomethane compounds lead to pyrazolines and finally cyclopropanes. Reactions with 9-diazofluorene produce a cyanocyclopropane derivative, with the generation of nitrogen. Phenyl azide reacts with acrylonitrile to yield a heterocyclic nitrile at room temperature or an open-chain nitrile at elevated temperatures.

Reactions of Both Functional Groups. Hydrolysis of acrylonitrile catalyzed by hydrochloric acid yields 3-chloropropionic acid. Alcoholysis and chlorination occur simultaneously in the presence of sulfuric acid. Similarly, alcoholysis and hydrochlorination also occur. Addition of both ammonia and hydrogen produces both trimethylenediamine and propylamine. Treatment of acrylonitrile

with hydrogen peroxide at neutral to slightly alkaline pH, yields glycidamide. Similarly, treatment with water, containing ammonium sulfide or a weak base, forms bis(2-carboxamidoethyl)sulfide or poly(β-alanine).

Cyanoethylation Reactions (Michael-Type Additions). Most compounds with a labile hydrogen atom can add on the double bond of acrylonitrile to form cyanoethyl groups; that is, the primary products are 3-substituted propionitriles.

$$CH_2{=}CHCN + RH \longrightarrow RCH_2CH_2CN$$

A large number of useful reactions fall into this category. Examples of these reactions are carbon cyanoethylation in which aldehydes, ketones, esters, nitriles, nitro compounds, sulfones, aliphatic and aromatic hydrocarbons, or haloforms add to acrylonitrile; nitrogen cyanoethylation where amines, ammonia, anilines, or amides add; oxygen cyanoethylation where alcohols, phenols, water, hydroperoxides, oximes, or hydrogen peroxide react; sulfur cyanoethylation in which sulfides, bisulfides, or sulfhydryl compounds add; hydrogen halide cyanoethylaphonates, boranes, silanes, or tin hydrides. In addition, many natural and synthetic polymers possessing labile hydrogen atoms, such as cotton, jute, gums, lignin, proteins, modified cellulose, poly(vinyl alcohol) (PVC), and acetone–formaldehyde and methyl ethyl ketone–formaldehyde condensates, react with acrylonitrile to yield cyanoethyl derivatives.

Manufacture of Acrylonitrile. Acrylonitrile is produced in commercial quantities almost exclusively by the vapor-phase catalytic propylene ammoxidation process developed by Sohio (now BP Chemicals) (17).

$$C_3H_3 + NH_3 + 3/2\ O_2 \xrightarrow{\text{catalyst}} C_3H_3N + 3\ HO_2$$

A schematic diagram of the commercial process is shown in Figure 1. The commercial process uses a fluid-bed reactor in which propylene, ammonia, and air contact a solid catalyst at 400–510°C and 49–196 kPa (0.5–2.0 kg/cm^2) gage. It is a single-pass process with about 98% conversion of propylene, and uses about 1.1 kg of propylene per kg of acrylonitrile produced. Useful by-products from the process are HCN (about 0.1 kg per kg of acrylonitrile), which is used primarily in the manufacture of methyl methacrylate, and acetonitrile (about 0.03 kg per kg of acrylonitrile), a common industrial solvent. In the commercial operation the hot reactor effluent is quenched with water in a countercurrent absorber and any unreacted ammonia is neutralized with sulfuric acid. The resulting ammonium sulfate can be recovered and used as a fertilizer. The absorber off-gas containing primarily N_2, CO, CO_2, and unreacted hydrocarbon is either vented directly or first passed through an incinerator to combust the hydrocarbons and CO. The acrylonitrile-containing solution from the absorber is passed to a recovery column that produces a crude acrylonitrile stream overhead that also contains HCN. The column bottoms are passed to a second recovery column to remove water and produce a crude acetonitrile mixture. The crude acetonitrile is either incinerated or further treated to produce solvent quality acetonitrile. Acrylic fiber quality (99.2% minimum) acrylonitrile is obtained by fractionation of the crude acrylonitrile mixture to remove HCN, water, light ends, and high boiling impurities. Disposal of

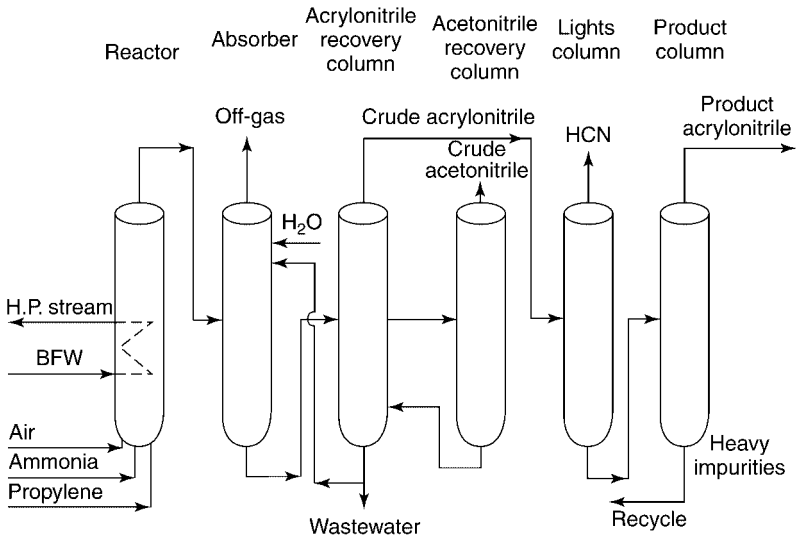

Fig. 1. Process flow diagram of the commercial propylene ammoxidation process for acrylonitrile. BFW is boiler feed water.

the process impurities has become an increasingly important aspect of the overall process, with significant attention being given to developing cost-effective and environmentally acceptable methods for treatment of the process waste streams. Current methods include deep-well disposal, wet air oxidation, ammonium sulfate separation, biological treatment, and incineration (18).

Although the manufacture of acrylonitrile from propylene and ammonia was first patented in 1949 (19), it was not until 1959 when Sohio developed a catalyst capable of producing acrylonitrile with high selectivity, that commercial manufacture from propylene became economically viable (20). Production improvements over the past 30 years have stemmed largely from development of several generations of increasingly more efficient catalysts. These catalysts are multicomponent-mixed metal oxides mostly based on bismuth–molybdenum oxide. Other types of catalysts that have been used commercially are based on iron–antimony oxide, uranium–antimony oxide, and tellurium–molybdenum oxide.

Fundamental understanding of these complex catalysts and the surface-reaction mechanism of propylene ammoxidation has advanced substantially since the first commercial plant began operation. Mechanisms for selective ammoxidation of propylene over bismuth molybdate and antimonate catalysts have been published (21). The rate-determining step is the abstraction of an α-hydrogen of propylene by oxygen in the catalyst to form a π-allyl complex on the surface (21–23). Lattice oxygens from the catalyst participate in further hydrogen abstraction, followed by oxygen insertion to produce acrolein in the absence of ammonia or nitrogen insertion to form acrylonitrile in the presence of ammonia (24–27). The oxygens removed from the catalyst in these steps are replenished by gas-phase oxygen, which is incorporated into the catalyst structure at a surface site separate from the site of propylene reaction. In the ammoxidation reaction, ammonia

is activated by an exchange with O^{2-} ions to form isoelectronic NH^{2-} moieties according to the following:

$$NH_3 + O^{2-} \longrightarrow NH^{2-} + H_2O$$

These are the species inserted into the allyl intermediate to produce acrylonitrile.

The active site on the surface of selective propylene ammoxidation catalyst contains three critical functionalities associated with the specific metal components of the catalyst (28–30): an α-H abstraction component such as Bi^{3+}, Sb^{3+}, or Te^{4+}; an olefin chemisorption and oxygen or nitrogen insertion component such as Mo^{6+} or Sb^{5+}; and a redox couple such as Fe^{2+}/Fe^{3+} or Ce^{3+}/Ce^{4+} to enhance transfer of lattice oxygen between the bulk and the surface of the catalyst. The surface and solid-state mechanisms of propylene ammoxidation catalysis have been determined using Raman spectroscopy (31,32), neutron diffraction (33–35), x-ray absorption spectroscopy (36,37), x-ray diffraction (38–40), pulse kinetic studies (26,27), and probe molecule investigations (41).

Other Acrylonitrile Processes. Processes rendered obsolete by the propylene ammoxidation process (42) include the ethylene cyanohydrin process (43–45) practiced commercially by American Cyanamid and Union Carbide in the United States and by I. G. Farben in Germany. The process involves the production of ethylene cyanohydrin by the base-catalyzed addition of HCN to ethylene oxide in the liquid phase at about 60°C, and subsequent dehydration.

A second commercial route to acrylonitrile used by DuPont, American Cyanamid, and Monsanto was the catalytic addition of HCN to acetylene (46). The reaction occurs by passing HCN and a 10:1 excess of acetylene into dilute HCl at 80°C in the presence of cuprous chloride as the catalyst. These processes use expensive C_2 hydrocarbons as feedstocks and thus have higher overall acrylonitrile production costs compared to the propylene-based process technology. The last commercial plants using these process technologies were shutdown by 1970.

Other routes to acrylonitrile, none of which achieved large-scale commercial application, are acetaldehyde and HCN (47), propionitrile dehydrogenation (48, 49), and propylene and nitric oxide (50,51).

Numerous patents have been issued disclosing catalysts and process schemes for the manufacture of acrylonitrile from propane. These include the direct heterogeneously catalyzed ammoxidation of propane to acrylonitrile, using mixed metal oxide catalysts (52–55).

A two-step process involving conventional nonoxidative dehydrogenation of propane to propylene in the presence of steam, followed by the catalytic ammoxidation to acrylonitrile of the propylene in the effluent stream without separation, is also disclosed (56).

Because of the large price differential between propane and propylene, which has ranged from $155/t to $355/t between 1987 and 1989, a propane-based process may have the economic potential to displace propylene ammoxidation technology eventually. Methane, ethane, and butane, which are also less expensive than propylene, and acetonitrile have been disclosed as starting materials for acrylonitrile synthesis in several catalytic process schemes (57,58).

Table 3. Worldwide Acrylonitrile Production,[a] 10^3 t

[a]Ref. 62.

Economic Aspects (Monomer). The propylene-based process developed by Sohio was able to displace almost all other commercial production technologies because of its substantial advantage in overall production costs, primarily due to lower raw material costs. Raw material costs, less by-product credits, account for about 60% of the total acrylonitrile production cost for a world-scale plant. The process has remained economically advantaged over other process technologies since the first commercial plant in 1960 because of the higher acrylonitrile yields, resulting from the introduction of improved commercial catalysts. Reported per-pass conversions of propylene to acrylonitrile have increased from about 65 to over 80% (17,59–61).

More than half of the worldwide acrylonitrile production is situated in Western Europe and the United States (Table 3). In the United States, production is dominated by BP Chemicals with the Sohio Process, with more than a third of the domestic capacity (Table 4). Nearly one-half of the U.S. production was exported in 1997 (Table 5), with most going to Far East Asia.

Far East Asian producers, especially in the People's Republic of China (PRC), have not been able to satisfy their increasing domestic demand in recent years. Consequently, the percentage of U.S. production exported grew from around 10% in the mid-1970s to approximately 42% in 1997.

In addition, the higher propylene costs relative to the United States generally makes it more economical to import acrylonitrile from the United States than to install new domestic production. Nevertheless, additions to Far East Asian acrylonitrile production capacity have been made in the 1990s, notably in South

Korea. Table 6 provides a breakdown of worldwide demand between 1986 and 1998. Growth in demand has averaged about 3% per year.

Analytical and Test Methods. Numerous instrumental and chemical techniques are available for the determination of acrylonitrile. The method of choice is directed by the concentration and the medium involved. For direct assay of acrylonitrile, titrimetric procedures are frequently used. Dodecyl mercaptan reacts with acrylonitrile under base catalysis; excess mercaptan is then back-titrated with an acid bromate-iodide solution (63), or alternatively, for colored solutions, with silver nitrate (64). Hydrolysis of the nitrile with strong base generates ammonia, which can then be determined by Nessler's reagent (65).

For dilute solutions, both gas chromatography (66) and polarography (67) are rapid, sensitive, and precise. Small amounts of acrylonitrile can be separated from other components by azeotropic distillation with alcohols, followed by polarographic (67,68) or chromatographic (69,70) analysis.

For monitoring of acrylonitrile in ambient air, a measured quantity of an air sample is drawn through a charcoal tube, followed by quantitative extraction with a carbon disulfide–acetone (98:2) mixture for gas chromatographic analysis. Reliable results can be attained even when <1-ppm acrylonitrile is present (71). A comprehensive review and a description of the development of environmental test methods for air, water, soil, and sediment samples have been done (72).

Storage and Transport. Acrylonitrile must be stored in tightly closed containers in cool, dry, well-ventilated areas away from heat, sources of ignition, and incompatible chemicals. Storage vessels, such as steel drums, must be protected against physical damage, with outside detached storage preferred. Storage tanks

and equipment used for transferring acrylonitrile should be electrically grounded to reduce the possibility of static spark-initiated fire or explosion. Acrylonitrile is regulated in the workplace by OSHA (29 CFR 1910).

Acrylonitrile is transported by rail car, barge, and pipeline. Department of Transportation (DOT) regulations require labeling acrylonitrile as a flammable liquid and poison. Transport is regulated under DOT 49 CFR 172.101. Bill of lading description is Acrylonitrile, Inhibited, 3, 6.1, UN 1093, PGI, RQ.

Health and Safety Factors. Acrylonitrile is absorbed rapidly and distributed widely throughout the body following exposure by inhalation, skin contact, or ingestion. However, there is little potential for significant accumulation in any organ, with most of the compound being excreted primarily as metabolites in urine. Acrylonitrile is metabolized primarily by two pathways: conjugation with glutathione and oxidation. Oxidative metabolism leads to the formation of an epoxide, 2-cyanoethylene oxide, that is either conjugated with glutathione or directly hydrolyzed by epoxide hydrolase.

The acute toxicity of acrylonitrile is relatively high, with 4-h LC_{50}s in laboratory animals ranging from 300 to 900 mg/m^3 and LD_{50}s from 25 to 186 mg/kg (73,74). Signs of acute toxicity observed in animals include respiratory tract irritation and two phases of neurotoxicity, the first characterized by signs consistent with cholinergic overstimulation and the second being CNS (central nervous system) dysfunction, resembling cyanide poisoning. In cases of acute human intoxication, effects on the CNS, characteristic of cyanide poisoning, and effects on the liver, manifested as increased enzyme levels in the blood, have been observed.

Acrylonitrile is a severe irritant to the skin, eyes, respiratory tract, and mucous membranes. It is also a skin sensitizer. Acrylonitrile is a potent tumorigen in the rat. Tumors of the CNS, ear canal, and gastrointestinal tract have been observed in several studies following oral or inhalation exposure. The mechanism of acrylonitrile's tumorigenesis in the rat and the relevance of these findings to humans are not clear. Available data are insufficient to support a consensus view or a plausible mode of action. There is evidence for weak genotoxic potential, but no evidence of DNA-adduct formation in target tissues.

Indications are that oxidative stress and resulting oxidative DNA damage may play a role. There is extensive occupational epidemiology data on acrylonitrile workers. These investigations have not produced consistent, convincing evidence of an increase in cancer risk, although questions remain about the power of the database to detect small excesses of rare tumors. In 1998, The International Agency for Research on Cancer reevaluated the cancer data for acrylonitrile and made a rare decision to downgrade the cancer risk classification (from "probably carcinogenic to humans" to "possibly carcinogenic to humans") based primarily on the growing epidemiology database (75).

Experimental evaluations of acrylonitrile have not produced any clear evidence of adverse effects on reproductive function or development of offspring at doses below those producing paternal toxicity. The results of genotoxicity evaluations of acrylonitrile have been mixed. Positive findings *in vitro* have occurred mainly at exposures associated with cellular toxicity, and the most reliable *in vitro* tests have been negative.

Acrylonitrile will polymerize violently in the absence of oxygen if initiated by heat, light, pressure, peroxide, or strong acids and bases. It is unstable in

the presence of bromine, ammonia, amines, and copper or copper alloys. Neat acrylonitrile is generally stabilized against polymerization with trace levels of hydroquinone monomethyl ether and water.

Acrylonitrile is combustible and ignites readily, producing toxic combustion products such as hydrogen cyanide, nitrogen oxides, and carbon monoxide. It forms explosive mixtures with air and must be handled in well-ventilated areas and kept away from any source of ignition, since the vapor can spread to distant ignition sources and flash back.

Federal regulations, (40 CFR 261) classify acrylonitrile as a hazardous waste and it is listed as Hazardous Waste Number U009. Disposal must be in accordance with federal (40 CFR 262, 263, 264, 268, 270), state, and local regulations, and occur only at properly permitted facilities. Strict guidelines exist for clean-up and notification of leaks and spills. Federal notification regulations require that spills or leaks in excess of 100 lb (45.5 kg) be reported to the National Response Center. Substantial criminal and civil penalties can result from failure to report such discharges into the environment.

Acrylonitrile in Air. As a consequence of the 1977 interim results of both the Dow and DuPont studies, OSHA issued an emergency temporary standard on Jan. 17, 1978, specifying that the 8-h time-weighted average exposure to airborne acrylonitrile should not exceed 2 ppm; prior to 1977, 20 ppm was allowed. This standard covered all workplaces manufacturing or using acrylonitrile as a raw material, as well as fabrication facilities processing acrylonitrile-based polymers.

The permanent OSHA standard was implemented on Nov. 2, 1980, and it establishes a maximum permissible exposure limit for the vapor of acrylonitrile at 2 ppm as an 8-h time-weighted average, a ceiling limit at 10 ppm as a 15-min time-weighted average, and an action level at 1 ppm as an 8-h time-weighted average. Eye and skin contact with liquid acrylonitrile is prohibited. Other provisions include notification of regulated areas, methods of compliance, respiratory protection, emergency situations, protective clothing and equipment, housekeeping, waste disposal, hygiene facilities and practices, medical surveillance, employee information and training, signs and labels, record keeping, observation of monitoring, etc (76).

Environmental monitoring around 11 U.S. industrial sites which produce acrylonitrile, acrylamide, acrylic and modacrylic fibers, ABS, SAN, and nitrile elastomers was conducted in 1977. Acrylonitrile in the air was very low, ranging from 0.1 to 325 ng/L (4.3 ppm); and in soils or sediments, none (72). Studies of the atmosphere surrounding several types of commercial equipment processing a high acrylonitrile copolymer (Barex 210) indicate no evidence of acrylonitrile under normal operating conditions (1163). Some typical emission sources in the acrylonitrile-polymerization industry have been identified, control techniques suggested, and plan of action discussed (72). Approaches to remedy toxic chemical problems and provide a safe environment have also been suggested (77).

Acrylonitrile in Polymers. The very low amount of residual acrylonitrile in finished resins or products (ca 1 ppm in acrylic and modacrylic fibers, 20–50 ppm in ABS and SAN) does not pose the threat of acrylonitrile migration or release under normal intended use and handling conditions. Materials made from acrylonitrile are exempt from OSHA regulations, provided they are not capable of releasing acrylonitrile in airborne concentrations in excess of 1 ppm as a 9-h time-weighted

average, under the expected conditions of processing, use, and handling, and not heated above 77°C. Thus, certain finished polymers and their fabricated products, such as ABS, SAN, nitrile barrier resins, solid nitrile elastomers, and acrylic and modacrylic fibers, are exempt. Polymers and copolymers of acrylonitrile per se are riskless, but there is concern regarding acrylonitrile in food containers (qv) because of the possibility of migration from the finished products to the contained foodstuff. Therefore, the use of the polymers for food-contact applications requires compliance with governmental regulations.

Well-sealed containers of carbon or stainless, tin-coated metals, or brown glass bottles can be used and labeled DANGER, CONTAINS ACRYLONITRILE, CANCER HAZARD. They should be properly grounded and stored in a well-ventilated area free of excessive heat, flames, sparks, or other sources of ignition. Contamination with strong acids or bases, peroxides, or other initiators should be avoided. Acrylonitrile should be handled in a hood or a ventilated area where the concentration will not exceed OSHA-regulated standards. Testing should be done according to OSHA standards to ensure personnel protection and compliance. Protective equipment such as rubber gloves and apron (or liquid-proof uniform), goggles, and face shield should be used. When acrylonitrile is at or above the action level of 1 ppm, respiratory protection should be implemented. A half-face respirator with organic vapor cartridge can provide adequate protection up to 20 ppm; full-face respirator, up to 100 ppm; and supplied air respirator in positive pressure mode with full-face piece, helmet, suit, or hood, up to 4000 ppm.

Uses. Historically, synthetic fibers consume more than half of the acrylonitrile produced throughout the world, and ABS–SAN copolymers are the second largest users (see Table 7). Nitrile elastomers have the longest history of acrylonitrile usage. Worldwide consumption of acrylonitrile increased from 2.5×10^6 in 1976 to 4.6×10^6 t/year in 1998. The trend in consumption over this time period is shown in Table 7 for the principal uses of acrylonitrile: acrylic fiber, ABS resins, adiponitrile, nitrile rubbers, elastomers, and SAN resins. Since the 1960s acrylic fibers have remained the major outlet for acrylonitrile production in the United States and especially in Japan and the Far East. Acrylic fibers always contain a comonomer. Fibers containing 85 wt% or more acrylonitrile are usually referred to as *acrylics, whereas fibers containing 35–85 wt% acrylonitrile are* termed modacrylics (see FIBERS, ACRYLIC). Acrylic fibers are used primarily for the manufacture of apparel, including sweaters, fleece wear, and sportswear, as well as for home furnishings, including carpets, upholstery, and draperies. Acrylic

Table 7. Worldwide Acrylonitrile Uses and Consumption, 10^3 t

Use	1998 (Estimated)	1997	1995	1990	1986
Acrylic fibers	2615	2628	2313	2242	2350
ABS resins / SAN	1095	1079	996	781	598
Adiponitrile	494	477	446	330	281
NB (AN/BD) Copolymers	144	143	134	143	125
Miscellaneous	269	264	249	243	189
Total consumptions	*4617*	*4591*	*4138*	*3739*	*3543*

fibers consume about 57% of the acrylonitrile produced worldwide. Growth in demand for acrylic fibers in the 1990s was modest, between 2 and 3% per year, primarily from overseas markets. Domestic demand was flat.

ABS resins and adiponitrile are the fastest growing uses for acrylonitrile. ABS resins are second to acrylic fibers as an outlet for acrylonitrile. These resins normally contain about 25% acrylonitrile and are characterized by their chemical resistance, mechanical strength, and ease of manufacture. Consumption of ABS resins increased significantly in the 1980s and 1990s with its growing application as a specialty performance polymer in construction, automotive, machine, and appliance applications. Opportunities still exist for ABS resins to continue to replace more traditional materials for packaging, building, and automotive components. SAN resins typically contain between 25 and 30% acrylonitrile. Because of their high clarity, they are used primarily as a substitute for glass in drinking cups and tumblers, automobile instrument panels, and instrument lenses. The largest increase among the end uses for acrylonitrile has come from adiponitrile, which has grown to become the third largest outlet for acrylonitrile. It is used by Solutia as a precursor for hexamethylenediamine (HMDA, $C_6H_{16}N_2$) [124-09-4] and is made by a proprietary acrylonitrile electrohydrodimerization process (78). HMDA is used exclusively for the manufacture of nylon-6,6 (see POLYAMIDES). The growth of this acrylonitrile outlet in recent years stems largely from replacement of adipic acid ($C_6H_{10}O_4$) [124-04-9] with acrylonitrile in HMDA production, rather than from a significant increase in nylon-6,6 demand. The use of acrylonitrile for HMDA production should continue to grow at a faster rate than the other outlets for acrylonitrile, but it will not likely approach the size of the acrylic fiber market for acrylonitrile consumption.

Acrylamide is produced commercially by heterogeneous copper-catalyzed hydration of acrylonitrile (79–82). Acrylamide is used primarily in the form of a polymer, polyacrylamide, in the paper and pulp industry, and in wastewater treatment as a flocculant to separate solid material from wastewater streams (see ACRYLAMIDE POLYMERS). Other applications include mineral processing, coal processing, and enhanced oil recovery in which polyacrylamide solutions were found effective for displacing oil from rock.

Nitrile rubber finds broad application in industry because of its excellent resistance to oil and chemicals, its good flexibility at low temperatures, high abrasion and heat resistance (up to 120°C), and good mechanical properties. Nitrile rubber consists of butadiene–acrylonitrile copolymers, with an acrylonitrile content ranging from 15 to 45%. In addition to the traditional applications of nitrile rubber for hoses, gaskets, seals, and oil well equipment, new applications have emerged with the development of nitrile rubber blends with PVC. These blends combine the chemical resistance and low temperature flexibility characteristics of nitrile rubber, with the stability and ozone resistance of PVC. This has greatly expanded the use of nitrile rubber in outdoor applications for hoses, belts, and cable jackets, where ozone resistance is necessary.

Other acrylonitrile copolymers have found specialty applications with good gas-barrier and chemical-resistant properties. An example is BP Chemicals' Barex resins which are acrylonitrile–methyl acrylate copolymers grafted on a nitrile rubber. Barex resins are unique barrier resins with the combinations of excellent oxygen barrier, good chemical resistance, and antiscalping properties.

Another application for acrylonitrile is in the manufacture of Carbon fibers. They are produced by pyrolysis of oriented polyacrylonitrile fibers and are used to reinforce composites for high performance applications in the aircraft, defense, and aerospace industries. These applications include rocket engine nozzles, rocket nose cones, and structural components for aircraft and orbital vehicles where light weight and high strength are needed. Other small specialty applications of acrylonitrile are in the production of fatty amines, ion-exchange resins, and fatty amine amides used in cosmetics, adhesives, corrosion inhibitors, and water-treatment resins. Examples of these specialty amines include 2-acrylamido-2-methylpropanesulfonic acid ($C_7H_{13}NSO_4$) [15214-89-8], 3-methoxypropionitrile (C_4H_7NO) [110-67-8], and 3-methoxypropylamine ($C_4H_{11}NO$) [5332-73-0].

Polymerization of Acrylonitrile

Homopolymerization. Pure acrylonitrile does not polymerize readily without initiators or light, but polymerization proceeds rapidly and exothermically in the presence of free radicals or anionic initiators. Oxygen is a very strong inhibitor and forms peroxides. If oxygen is allowed to react to exhaustion, polymerization may then proceed at a very high rate through the thermal decomposition of peroxides, and explosion can occur. Conventional peroxide initiators, such as benzoyl peroxide and hydrogen peroxide, and azo compounds, such as 2,2′-azobis(isobutyronitrile) and 2,2′-azobis(2,4-dimethylvaleronitrile), can be used at moderate temperatures below 100°C. Redox catalysis systems can be used in aqueous media at low temperatures. Initiation can also be induced by light (83) and radiation (84). Polymerization can be carried out in bulk, emulsion, suspension, slurry, or solution.

Continuous Bulk Process. Polyacrylonitrile is not soluble in its monomer and precipitates from the medium. The polymerization exhibits autocatalytic behavior, and as polymerization proceeds, it becomes increasingly difficult to remove the heat of polymerization as viscosity increases. Consequently, in a batch process, the polymerization can run out of control. Therefore, continuous operation is used to overcome the difficulties (85–87). As an example, the following streams are continuously charged into a 2.5-L reactor at 40°C, equipped with an agitator and filled initially with acrylonitrile to one-half of its volume:

(1) cumene hydroperoxide 10 g/h
(2) SO_2 (gas) 120 g/h
(3) dimethylacetomide 3.2 g/h
(4) 2-mercaptoethanol 8 g/h

After the first 10 min, acrylonitrile is fed into the reactor at 4000 g/h. The effluent from the reactor has 54.6% conversion of acrylonitrile (85). The mechanisms and kinetic models for acrylonitrile bulk polymerization have been described (88–91), as has the study of high pressure polymerization (8).

Continuous Slurry Process. This process is similar to bulk polymerization, but the monomer is isolated into small suspended droplets in an aqueous medium.

This provides heat-removal capability and commercial feasibility. In one example (92), a 60-L stainless steel cylindrical reactor is equipped with a turbine agitator and a pump to circulate a portion of the polymerizing medium from the bottom through a heat exchanger, thus removing the heat of polymerization. Three separate streams of a 0.3% H_2SO_4 aqueous solution, a catalyst solution (15% Na_2SO_3 and 4.22% Na_2ClO_3 in water), and a monomer solution (97% acrylonitrile and 3% water) are continuously charged into the reactor at the rates of 22.4, 1.0, and 11.8 kg/h, respectively. At 35°C and 1.69 h of residence time, the conversion is 90% and the polymer has an average molecular weight of ca 75,000.

Emulsion Process. In the following example, redox catalysis is used to achieve rapid polymerization at low temperatures (20–60°C), yielding a polymer with better color than that obtained by the use of other initiator systems where higher temperatures are required.

(1) water 270 parts
(2) emulsifier (23% sodium salt of sulfonated cumar resin) 26 parts
(3) ammonium persulfate 0.6 parts
(4) ammonium bisulfite 0.5 parts
(5) sodium dihydrogen phosphate 0.8 parts
(6) dilute H_2SO_4 As required to adjust the solution of pH 4.6

One hundred parts of this solution and 50 parts of acrylonitrile are charged into a reactor. It is then purged with N_2, sealed, and polymerized at 40°C for 2 hs, achieving 85% conversion (93). After polymerization is completed, the polymer is recovered by coagulation with salt (see EMULSION POLYMERIZATION).

Solution Process. The solution process is rather straightforward and is generally used to prepare acrylic polymers suitable for direct wet- or dry-spinning fiber manufacture. Dimethylformamide is one of the best solvents for polyacrylonitrile and is used extensively. In this medium, an overall activation energy for the polymerization has been estimated to be 86.6 kJ/mol (94). Other important solvents are dimethylacetamide, dimethyl sulfoxide, ethylene or propylene carbonate, and concentrated aqueous solutions of NaSCN, HNO_3, H_2SO_4, and ZnC_{l2}.

Copolymerization. Acrylonitrile copolymerizes readily with electron-donor monomers, and >800 acrylonitrile copolymers have been registered with *Chemical Abstracts*. A comprehensive listing of reactivity ratios for acrylonitrile copolymerizations is available (95). Copolymerization is carried out by bulk emulsion, slurry, or suspension processes. The arrangement of monomer units in acrylonitrile copolymers is most commonly random. Special techniques can be used to achieve specific arrangements.

Alternating Copolymers. Copolymerization of a strong acceptor monomer with a strong donor monomer yields alternating equimolar copolymers; for example, this is the case for maleic anhydride or vinylidene cyanide with styrene. Acrylonitrile, a weak electron acceptor, complexes readily with charge-transfer agents, such as organoaluminum or metallic halides. These complexes are strong electron acceptors, which interact with strong donor monomers to form ground-state

comonomer complexes and undergo polymerization to form alternating copolymers. The probable reaction mechanism is as follows:

$$A + CTA \longrightarrow A{-}CTA$$

$$D + A{-}CTA \rightleftharpoons (D{\rightarrow}A{\cdots}CTA) \rightleftharpoons D^{+}\ {}^{-}A{-}CTA$$

$$D^{+}\ {}^{-}A{-}CTA \longrightarrow (DA)_x\,(D^{+}\ {}^{-}A{-}CTA) \longrightarrow {-}(DA)_n{-}$$

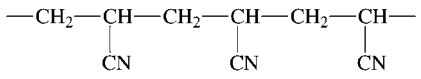
where A is acrylonitrile, CTA the charge-transfer agent, and D the strong electron-donor monomer.

The polymerization proceeds spontaneously at room temperature or elevated temperatures. The proposed matrix of the comonomer complexes is described in Reference 96. Examples of alternating acrylonitrile copolymerizations involve vinyl cyclohexanes with $AlEC_2H_5tCl_2$ (97), vinyl acetate with $ZnCl_2$ (98) or Ziegler–Natta catalyst (99), and styrene.

Block Copolymers. Several methods such as ultrasonics (100), radiation (101), and chemical techniques (102,103), including the use of polymer ions, polymer radicals, and organometallic initiators, are available to prepare Block Copolymers of acrylonitrile. Acrylonitrile can be used as either the first-or the second-phase monomer. Depending on the mechanism of termination, a diblock of the AB type and a triblock of the ABA type can be formed by disproportionation or transfer for the former, and recombination for the latter. Some of the comonomers are styrene, methyl acrylate, vinyl chloride, methyl methacrylate, vinyl acetate, acrylic acid, and *n*-butyl isocyanate. An overview and survey of alternating and block copolymers can be found in Reference 104.

Properties of Homopolymer

Polyacrylonitrile adopts the head-to-tail linkage of its monomer units, with nitrile groups on alternate carbon atoms at very close proximity:



By conventional polymerization methods, polyacrylonitrile forms both isotactic and syndiotactic configurations in approximately equal proportion. However, primarily the isotactic polyacrylonitrile is formed in the polymerization.

The compact size and strong polarity of the nitrile groups make them very interactive with their surroundings. The lone pair orbital on nitrogen is suitable for hydrogen bonding, as well as for electron-donor–acceptor complex formation. In addition, the electrons in the π-orbitals of the nitrile triple bond are available for interactions, for example, with transition-metal ions.

The polar nitrile groups exert intramolecular repulsion, compelling the molecules into an irregular helical conformation (105,106), but they ensure intermolecular attraction between polymer molecules. The interactions of polyacrylonitrile molecules and their relationship to macroscopic properties have been reviewed (106).

Table 8. Estimate of Phases in Polyacrylonitrile[a, b]

Sample[c]	Crystalline	Quasi-crystalline	Amorphous
PAN B molded at 200°C	0.47	0.25	0.28
PAN B molded-annealed	0.45	0.34	0.21
PAN B cast	0.42	0.10	0.48
PAN A cast-annealed	0.44	0.23	0.33

[a] Ref. 109.
[b] Made by emulsion free-radical polymerization.
[c] PAN A: 120,000 M_v, cast from DMF, PAN B: 328,000 M_v, cast from DMSO.

The prevailing polar nature of polyacrylonitrile provides its unique and well-known characteristics, including hardness and rigidity, resistance to most chemicals and solvents, sunlight, heat, and microorganisms, slow burning and charring, reactivity toward nitrile reagents, compatibility with certain polar substances, ability to orient, and low permeability toward gases. Physical constants and an infrared spectrum of polyacrylonitrile are available (107).

Morphology. The heterogeneous system of polyacrylonitrile contains crystalline, quasicrystalline, and amorphous phases (108,109). The ratio of these three phases has been estimated (Table 8); there is little change in the crystalline phase regardless of specimen preparations. This indicates that the crystals, even though destroyed when dissolved in the solvents, form again to the same extent upon casting from the solvents. However, large differences are shown for the quasicrystalline and amorphous phases, depending on the methods of preparation.

Three regions of transition are defined by dynamic mechanical measurements (109): the main transition for the amorphous phase at 157°C, the dipole–dipole interaction for the quasicrystalline phase at 99°C [generally considered as the Glass Transition], and the secondary transition for the amorphous phase at 79°C (see DYNAMIC MECHANICAL PROPERTIES). The high temperature transition is usually ascribed to concerted motions of the pendent nitrile groups and is very sensitive to modifications. When the polymer is heat-treated (110) to form a conjugated ring system from the nitrile groups, this high temperature transition disappears as in the case of the dielectric transition (111) (see DIELECTRIC RELAXATION). Furthermore, when a small amount (5–10%) of methyl methacrylate is introduced as a comonomer, the transition behavior changes drastically; the high temperature transition disappears (112). Multiple-transition phenomena have also been shown by birefringence (113), dielectric (114–117), and x-ray diffraction (qv) (118) measurements (see MORPHOLOGY).

Crystallization. Using fractionated polyacrylonitrile, crystallization has been carried out at various temperatures (119), and several morphological growth features have been observed, namely, rectangular single crystals, twinned crystals, ovals, and spherulites. The lamellae are vertically arranged in a manner similar to polyethylene ovals. As in thin-film polystyrene, natural rubber, and gutta-percha, crack-like structure or space between lamellae is found to be associated with fibrils. The growth mechanism for polyacrylonitrile spherulites is similar to that for other polymers (see SEMICRYSTALLINE POLYMERS; CRYSTALLIZATION KINETICS).

Amorphous Polyacrylonitrile. This polymer has been synthesized successfully, using bis(pentamethyleneimino) magnesium as catalyst and *n*-heptane as solvent (120,121). By converting the polymer into poly(acrylic acid) by alkaline hydrolysis, and comparing its infrared spectrum to those of poly(acrylic acid) prepared with azobisisobutyronitrile as initiator, this amorphous polyacrylonitrile has been shown to have the normal head-to-tail structure of the usual, more crystalline polyacrylonitrile described previously. Its density is 1.2% higher, and its configuration is primarily isotactic, like the polymer synthesized through a radiation-induced urea canal complex. Its solubility is remarkably different; it is easily soluble in propylene carbonate at room temperature and in formamide at elevated temperatures. In addition, the viscoelastic properties of the amorphous material show only a single transition at high temperatures of ca 170°C with the absence of the transition at ca 100°C. This fact supports the assignment of the high temperature transition to the molecular motion related to the amorphous region and the low temperature transition to the quasicrystalline region (see AMORPHOUS POLYMERS).

Melting Point. Because polyacrylonitrile decomposes before reaching its melting temperature, the determination of its melting point requires rather unusual approaches. A melting point of 317°C has been obtained by dilatometry (qv) (105). Using a heating rate of 40°C/min, which is sufficiently fast to achieve melting prior to degradation, a value of 326°C has been measured by dta (122). By wide-angle x-ray and stereoscan measurements, at a heating rate of >1000°C/min, a melting point of 320 ± 5°C has been deduced (123).

Water is known to depress the melting point of acrylonitrile polymer and its vinyl acetate copolymers strongly; degradation during measurement becomes insignificant, and scanning calorimetry has been used effectively to probe the structure of the polymers (124,125). Addition of water continually depresses the polymer melting point until a critical water concentration is reached, whereupon the molten polymer separates from the water, and no further reduction in melting point is observed (Fig. 2). Both the minimum melting point and the critical water concentration decrease with increasing comonomer content. The melting-point reduction by water is consistent with the Flory theory (126) and can be expected from the nitrile–water interaction, which results in the disruption of the nitrile–nitrile bonding. On the other hand, the depressions of both the melting point and the heat of fusion by the presence of the comonomer (Fig. 3) are attributable to the crystal defect model (127) in which the noncrystallizable comonomer enters the lattice as defects rather than being relegated to an amorphous phase. Thus, the degree of the depressions is interpreted as a measure of the regularity and strength of the intermolecular dipole–dipole bonds that stabilize the lattice.

When the draw ratio of the fiber is extended from 1 to 6 times, the heat of fusion increases from 1.88 to 2.5 kJ/mol, and a secondary endotherm appears at 147°C; the primary endotherm is at 156°C (Fig. 4). These changes are reversible upon relaxation of the fiber. The appearance of the secondary endotherm is interpreted as a disruption in the crystalline phase at high threadline stress, whereas the increase in the heat of fusion reflects the formation of dipole–dipole bonds upon orientation of the polymer chains in the amorphous region of the fiber.

Polarization. Polyacrylonitrile can achieve very high, persistent electrical polarization as inferred from thermally stimulated discharge analysis (128). This

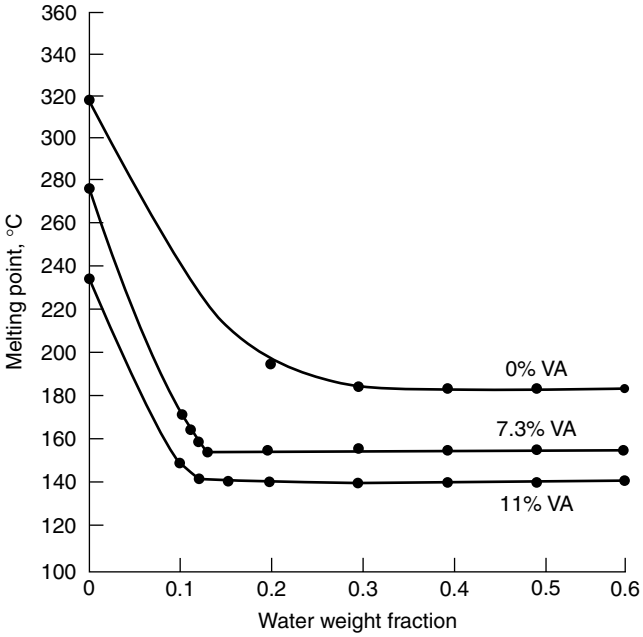


Fig. 2. Dependence of melting point of water content for acrylonitrile–vinyl acetate (VA) copolymer (125).

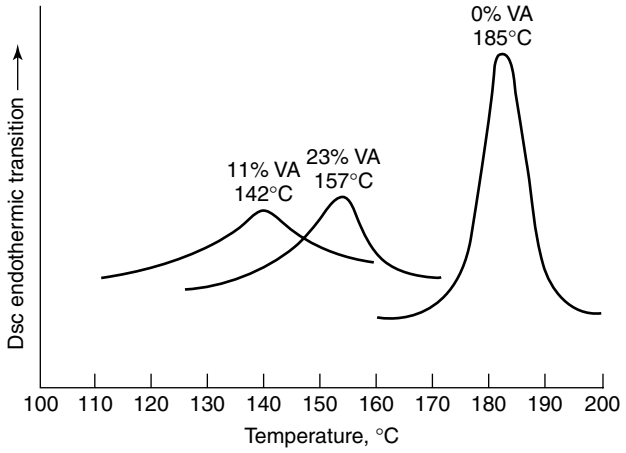

Fig. 3. Melting endotherms of acrylonitrile–vinyl acetate copolymers mixed with two parts of water (125).

can be explained by the strong dipole moment of the nitrile groups and the quasicrystalline nature of the polymer. Because of the strong dipole moment, an external electrical field can impose strong torque on the polymer chains and lead to a highly polarized state. Quasicrystallinity permits these chains to be rearranged

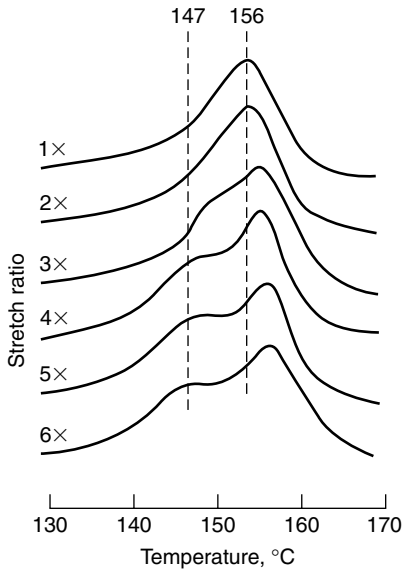

Fig. 4. Melting endotherms of acrylonitrile copolymer fiber (7% vinyl acetate) at different stretch ratios (124).

and packed together, providing a certain degree of molecular reorganization to store the energy. Both x-ray diffraction and high resolution internal-reflection infrared spectroscopy have been used to study the polarization characteristics of polyacrylonitrile films (129).

When the films are exposed to electric fields, x-ray diffraction indicates a densification of laterally ordered regions and an increase in the degree of local order or in the size of the ordered regions. Infrared spectroscopy suggests an intensification of dipolar bonding between adjacent nitriles, and the possibility of vibrational coupling among adjacent groups. It is envisioned that when polyacrylonitrile is subjected to thermoelectric treatment, the structural rearrangement of the polymer chains involves not only a biased orientation of dipoles, but also enhanced dipole–dipole associations forming dipolar clusters.

Solubility. Because of the properties of polyacrylonitrile, an active solvent capable of dissolving this polymer must satisfy some unique and critical chemical property of the polymer chains and, at the same time, separate the polymer molecules with a nonpolar segment. For example, dimethylformamide is an effective solvent, but formamide, methylformamide, and diethylformamide are not; dimethyl sulfone is, but diethyl sulfone is not. The following solvents are effective for polyacrylonitrile at either room temperature or elevated temperatures (107,130): dimethylformamide, dimethylthioformamide, dimethylacetamide, *N*-methyl-β-cyanoethyl formamide, α-cyanoacetamide, tetramethyl oxamide, malononitrile, fumaronitrile, succinonitrile, adiponitrile, α-chloro-β-hydroxypropionitrile, β-hydroxypropionitrile, hydroxyacetonitrile, *N*,*N*-di(cyanomethyl)aminoacetonitrile, ε-caprolactam, bis(β-cyanoethyl)ether, γ-butyrolactone, propiolactone, 1,3,5-tetracyanopentane, tetramethylene sulfoxide,

dimethyl sulfoxide, 2-hydroxythyl methyl sulfone, methyl ethyl sulfone, sulfolane, *m*-nitrophenol, *p*-nitrophenol, *o*-, *m*-, *p*-phenylene diamine, methylene dithiocyanate, trimethylene dithiocyanate, dimethyl cyanamide, ethylene carbonate, propylene carbonate, succinic anhydride, maleic anhydride, certain *N*-nitro- and nitrosoalkyl amines, some formylated primary and secondary amines, pyrrolidinone derivatives, concentrated sulfuric acid or nitric acid, and concentrated aqueous solutions of LiBr, NaCNS, or $ZnCl_2$. Copolymers of acrylonitrile are often soluble in dioxane, chlorobenzene, cyclohexanone, methyl ethyl ketone, acetone, dimethylformamide, butyrolactone, and tetrahydrofuran.

Barrier Properties. The remarkable barrier property of polyacrylonitrile to oxygen and carbon dioxide has been demonstrated (131), but high permeability toward helium is noticed. The high polarity of polyacrylonitrile leads to this high permeability and high sorption toward water vapor. This is perhaps the only limitation for the barrier application of the polymer. The activation energies for permeation and their preexponential factors for polyacrylonitrile are available (131). The value of the ratio of the permeabilities to helium and oxygen is exceptionally high; for example, the value for poly(vinylidene chloride), another high barrier polymer, is 58.5, whereas that for polyacrylonitrile is 1770. In addition, the activation energies for permeation are relatively low; for example, the activation energy for poly(vinylidene chloride) is 70.3 kJ/mol for nitrogen, while that for polyacrylonitrile is only 44.4. These two features suggest that the free volume of polyacrylonitrile for gas transport must be very small (see BARRIER POLYMERS; VINYLIDENE CHLORIDE POLYMERS).

The sorption of CO_2 has been studied at high pressures under various temperatures, and the characteristic dual-mode sorption isotherms (superposition of Henry's law and a Langmuir isotherm) of gas–glassy polymer systems have been observed (132). The Langmuir affinity constants and their enthalpy change are lower than expected. This is interpreted as resulting from the competition for available sites between CO_2 and the immobile residual in the film. The observed behavior suggests unique slow relaxations of polyacrylonitrile during the transient CO_2 permeation process, which are not observed in other glassy polymers. The sorption of water vapor has also been studied (133,134), and like CO_2, the water-vapor sorption follows the dual-mode model. At high vapor pressures, clustering of the penetrant molecules in nonrandom aggregation is suggested. Again, as in CO_2 sorption, non-Fickian time-lag behavior is observed, indicating relaxations of polyacrylonitrile during the transient sorption transport to accommodate the clustering process of the penetrant.

Chemical Reactions. Polyacrylonitrile is resistant to common solvents, oils, and chemicals, but its nitrile groups and α-hydrogens do react with certain reagents. Hydration with concentrated sulfuric acid forms a solution (135). Hydrogenation results in the formation of polymers with pendent aminonethylene groups (136,137). Hydrolysis with hot aqueous alkali yields a mixture which passes through a thick red stage and eventually becomes the yellow, water-soluble salt of poly(acrylic acid) (138) (see ACRYLIC (AND METHACRYLIC) ACID POLYMERS). Upon reaction with strong alkali in dilute dimethylformamide solution, rapid chain scission ensues (139). Reaction with hydroxylamine produces amidoximes and hydroxamic acids (140,141). Grafting with vinyl acetate proceeds in emulsion, with potassium persulfate as initiator (142). Irradiation induces free-radical sites

which initiate grafting or cross-linking (qv), depending upon the presence or the absence of a monomer (143).

Thermal Degradation. Upon heating, discoloration of polyacrylonitrile occurs; it first becomes yellow, then progressively red, and finally black. The mechanism of color formation is thought to be the reaction of the nitrile groups in forming a conjugated system. A comprehensive review of polyacrylonitrile color formation and thermal degradation reaction has been made (144). There are four main categories of Degradation reactions: chain scission, cross-linking, hydrogenation, and cyclization (145). Thermal degradation under reduced pressure, and in air at 200°C, has been studied using Fourier transform infrared spectroscopy (146). A mechanism involving imine–enamine tautomerism explains satisfactorily the observed spectral changes under reduced pressure (146). The reactions in air are more complex, and their interpretation is difficult.

The decomposition products of pure polyacrylonitrile yarn pyrolyzed at 400, 600, and 800°C in either air or nitrogen have been quantitatively analyzed using gas chromatography and gas chromatography–mass spectrometry (147). The main products are HCN, which is the predominant toxic product, and 16 other nitriles. At higher temperatures, the quantities of HCN, acetonitrile, acrylonitrile, and aromatic nitriles increase, whereas those of aliphatic dicyanides decrease. Ammonia is a decomposition product, but its toxicity is insignificant, compared to HCN, and has not been determined. The viscous condensates contain several homologous series of aliphatic nitriles. A similar study of polyacrylonitrile pyrolysis products in oxygen at 400, 700, and 900°C has shown the four chief products to be HCN, acetonitrile, acrylonitrile, and benzonitrile (148). The other 16 products are methane, acetylene, ethylene, ethane, propene, propane, 1,3-butadiene, ethyl nitrile, vinyl acetonitrile, crotonitrile, benzene, pyridine, dicyanobutene, adiponitrile, dicyanobenzene, and naphthalene. With increased temperature, the relative yields and complexity of products increase to a maximum of ca 700°C. Further increase in temperature produces thermally stable product, including low molecular weight nitriles and aromatic species.

Copolymers

Because of the combination of high melting point, high melt viscosity, and poor thermal stability, acrylonitrile homopolymer has little application. Even in synthetic fibers, small amounts of copolymers are incorporated to improve stability, dye receptivity, and certain other properties. By copolymerizing acrylonitrile with other monomers, the deficiencies of acrylonitrile homopolymer have been tempered and, at the same time, the unusual and desirable properties of acrylonitrile have been incorporated into various melt-processible resins. For general applications, acrylonitrile content ranges up to ca 50%; for barrier applications, to ca 75%. Acrylonitrile copolymer properties, such as rigidity, chemical resistance, melt viscosity, stability, and permeability, generally vary in proportion to the acrylonitrile content. However, the glass-transition temperature (T_g) shows unusual behavior; there is a maximum or a minimum T_g in certain cases, eg, for copolymers of styrene, vinylidene chloride, and methyl methacrylate.

The principal uses of acrylonitrile are in Acrylic fibers, copolymers with styrene (SAN), and in combination with butadiene and styrene (ABS). (see ACRYLONITRILE–BUTADIENE–STYRENE). SAN copolymers are discussed in detail in later sections of this article. Following are a few other copolymers and their properties.

Copolymers of Benzofuran. These alternating copolymers are optically active and are prepared in the presence of optically active aluminum compounds as complexing agents for acrylonitrile. Opposite signs of rotation are obtained using different complexing agents. The highest specific rotation of -8° has been attained with the stoichiometric ratio of menthoxyaluminum dichloride to acrylonitrile. The results indicate that the alternating dyad contributes to the optical activity, and the asymmetric configuration of the carbon atoms of the acrylonitrile unit influences the optical rotation. It is claimed that the optical activity is mainly induced by the copolymers themselves, not by the residual catalysts (149).

Copolymers of Carbon Dioxide. Copolymerization proceeds in the presence of triethylenediamine as initiator at 120–160°C under moderate pressure to yield an ester structure. The yield and molecular weight of the copolymers increase with initiator concentration, but the M_n of the synthesized copolymers is low, ie, 1500–2200. They are transparent viscous liquids or solids, depending on the molecular weight (150).

Copolymers of 2-Dimethylaminoethyl Methacrylate. The cationic nature of this copolymer has been shown to permit heparin attachment and cyclization of the nitrile groups with ethylene oxide gas for controlled structure alterations. The improved blood compatibility suggests Medical applications, including dialysis membranes, ultrafiltration membranes, and adsorbent coatings for hemoperfusion (151).

Copolymers of Methyl Acrylate. Barex® resins, commercial high barrier resins produced by BP Chemicals, are copolymers of acrylonitrile and methyl acrylate [96-33-3]. These resins are excellent examples of the use of acrylonitrile to provide gas and aroma/flavor barrier, chemical resistance, high tensile strength, stiffness, and utilization of a comonomer to provide thermal stability and processibility. In addition, modification with an elastomer provides toughness and impact strength. These materials have a unique combination of useful packaging qualities, including transparency, and are excellent barriers to permeation by gases, organic solvents, and most essential oils. Barex resins also prevent the migration and scalping of volatile flavors and odors from packaged foods and fruit juice products (152,153). They also provide protection from atmospheric oxygen. Barex resins meet FDA compliance for direct food contact applications. In April 2000, the FDA approved the use of Barex 210E resin for fruit/vegetable juices, ready-to-use teas, and other specified beverages for fill temperatures less than 150°F (66°C). This new ruling expands the application of Barex resins into the beverage market place.

Barex resin extruded sheet and/or calendered sheet (153) can be easily thermoformed into lightweight, rigid containers (152,154). Packages can be printed, laminated, or metallized. Recent developments in extrusion and injection blow molding (152,155), laminated film structures (152,156), and coextrusion (153,157) have led to packaging uses for a variety of products. Barex resins are especially well-suited for bottle production. These acrylonitrile copolymers also provide a

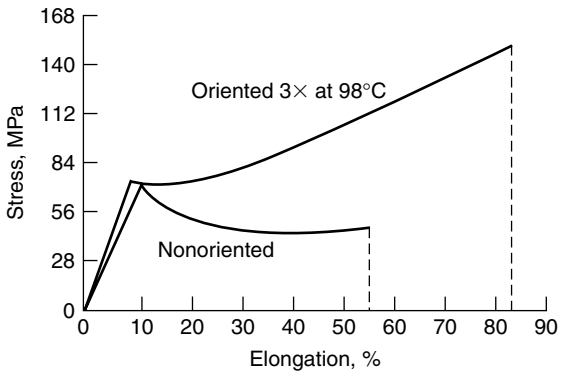

Fig. 5. Stess elongation of Barex 210 sheet (159). To convert MPa to psi, multiply by 145.

good example of the dependence of properties on the degree and temperature of orientation (158,159). Figure 5 illustrates the improvement in tensile strength, elongation, and the ability to absorb impact energy as a result of orientation (159) by Barex resins (for example, Barex 210). Tensile strength and impact strength increase with the extent of stretching, and decrease with the orientation temperature. Oxygen permeability decreases with orientation. These orientation properties have led to the commercialization of Barex resins to fruit juice containers in France (153). Some typical physical properties of Barex resins are shown in Table 9.

Table 9. Physicial/Mechanical Properties of Commercial Barex Resins[a]

Copolymers of Methyl Methacrylate. The glass-transition temperatures of these copolymers exhibit a minimum of ca 87°C at ca 40 wt% acrylonitrile; the T_g's of the homopolymers are ca 105°C. This unusual behavior is explained by the interactions of the dyads and well predicted by the sequence-distribution equation (160).

Copolymers of Styrene. For thermoplastic applications, the largest volume comonomer for acrylonitrile is styrene. Styrene–acrylonitrile copolymers are designated SAN. SAN copolymers are discussed in detail in the later part of this article.

Copolymers of Poly(vinyl alcohol) with Formaldehyde and Hydroquinone. These electron-exchange resins are condensation products of partially cyanoethylated poly(vinyl alcohol) and have a weak acidic nature and lustrous black appearance. The polar groups of acrylonitrile improve the redox capacities over a standard weak-acid electron exchanger, hydroquinone–phenol–formaldehyde (161).

Copolymers of 4-Vinylpyridine. Acrylonitrile improves the tensile strength of these reverse-osmosis membranes. Cross-linking quaternization of the copolymers with diiodobutane improves the performance of the membranes, achieving salt rejection of 95% and hydraulic water permeability of up to 30×10^{-15} $cm^2/(s \cdot Pa)$. The quaternized membranes also are anion exchangeable; more than two-thirds of iodide exchanges with chloride (162).

Copolymers of Vinylidene Chloride. The glass-transition temperatures of these copolymers vary nonlinearly with composition, as is the case for copolymers of methyl methacrylate, but these show a maximum. It is a broad maximum around 105°C at 55–80 wt% acrylonitrile. (The T_g of vinylidene chloride homopolymer is ca −20°C, whereas PAN's is ca 100°C.) Again, sequence distribution explains such behavior (163). These copolymers have good barrier properties and are used for surface Coatings. Acrylonitrile grafting on starch imparts hydrophilic behavior to starch and results in exceptional water absorption capability (164–167). These copolymers can also immobilize enzymes by entrapment or covalent bonding (168).

Grafting on Fibers. By treatment with sodium hydroxide and a low degree of cyanoethylation, the moisture retention of cotton can be improved by as much as 14% (169). X-ray diffraction reveals a decrease in the crystallinity of the cotton, which provides the improved moisture retention (170). Modifications of fibers by grafting with acrylonitrile, followed by hydrolysis, produce water-receptive and soil-repellent fibers (171). Such treatments to nylon result in significant protein-coupling efficiency (172). Grafting onto polypropylene fibers enhances moisture absorption and dye absorption (173).

Other Copolymers. Acrylonitrile copolymerizes readily with many electron-donor monomers other than the copolymers mentioned above. More than 800 acrylonitrile copolymers have been registered with *Chemical Abstract* and a comprehensive listing of reativity ratios for acrylonitrile copolymerizations is readily available (174). Some of the other interesting acrylonitrile copolymers follows: acrylonitrile–methyl acrylate–indene terpolymers, by themselves, or in blends with acrylonitrile–methyl acrylate copolymers, exhibit even lower oxygen and water permeation rates than the indene-free copolymers (175,176). Terpolymers of acrylonitrile with indene and isobutylene also exhibit excellent barrier

Table 10. Monomers Commonly Copolymerized with Acrylonitrile

Monomer	Molecular formula	Structural formula	CAS registry number
Methyl methacrylate	$C_5H_8O_2$	$CH_2{=}C(CH_3)COOCH_3$	[80-62-6]
Methyl acrylate	$C_4H_6O_2$	$CH_2{=}CHCOOCH_3$	[96-33-3]
Indene	C_9H_8		[95-13-6]
Isobutylene	C_4H_8	$CH_2{=}C(CH_3)_2$	[115-11-7]
Butyl acrylate	$C_7H_{12}O_2$	$CH_2{=}CHCOOC_4H_9$	[141-32-2]
Ethyl acrylate	$C_5H_8O_2$	$CH_2{=}CHCOOC_2H_5$	[140-88-5]
2-Ethylhexyl acrylate	$C_{11}H_{20}O_2$	$CH_2{=}CHCOOC_8H_{17}$	[103-11-7]
Hydroxyethyl acrylate	$C_5H_8O_3$	$CH_2{=}CHCOOC_2H_4OH$	[818-61-1]
Vinyl acetate	$C_4H_6O_2$	$CH_2{=}CHOOCCH_3$	[108-05-4]
Vinylidene chloride	$C_2H_2Cl_2$	$CH_2{=}C(Cl)_2$	[75-35-4]
Methyl vinyl ketone	C_4H_6O	$CH_2{=}CHCOCH_3$	[78-94-4]
α-Methylstyrene	C_9H_{10}	$CH_2{=}C(CH_3)C_6H_5$	[98-83-9]
Vinyl chloride	C_2H_3Cl	$CH_2{=}CHCl$	[75-01-4]
4-Vinylpyridine	C_7H_7N	$CH_2{=}CHC_5H_4N$	[100-43-6]
Acrylic acid	$C_3H_4O_2$	$CH_2{=}CHCOOH$	[79-10-7]

properties (177), and permeation of gas and water vapor through acrylonitrile–styrene–isobutylene terpolymers is also low (178,179).

Copolymers of acrylonitrile and methyl methacrylate (180) and terpolymers of acrylonitrile, styrene, and methyl methacrylate (181,182) are used as barrier polymers. Acrylonitrile copolymers and multipolymers containing butyl acrylate (183–186), ethyl acrylate (187), 2-ethylhexyl acrylate (183,186,188,189), hydroxyethyl acrylate (185), vinyl acetate (184,190), vinyl ethers (190,191), and vinylidene chloride (186,187,192–194) are also used in barrier films, laminates, and coatings. Environmentally degradable polymers useful in packaging are prepared from polymerization of acrylonitrile with styrene and methyl vinyl ketone (195).

Acrylonitrile multipolymers containing methyl methacrylate, α-methylstyrene, and indene are used as PVC modifiers to melt blend with PVC. These PVC modifiers not only enhance the heat distortion temperature, but also improve the processibility of the PVC compounds (196–200). The acrylonitrile multipolymers grafted on the elastomer phase provide the toughness and impact strength of the PVC compounds with high heat distortion temperature and good processibility (201,202). Table 10 gives the structures, formulas, and CAS registry numbers for several comonomers of acrylonitrile.

Although the arrangement of monomer units in acrylonitrile copolymers is usually random, alternating or block copolymers may be prepared using special techniques. For example, the copolymerization of acrylonitrile, like that of other vinyl monomers containing conjugated carbonyl or cyano groups, is changed in the presence of certain Lewis acids. Effective Lewis acids are metal compounds with nontransition metals as central atoms, including alkylaluminum halides, zinc halides, and triethylaluminum. The presence of the Lewis acid increases

the tendency of acrylonitrile to alternate with electron-donor molecules, such as styrene, α-methylstyrene, and olefins (203–207). This alternation is often attributed to a ternary molecular complex or charge-transfer mechanism, where complex formation with the Lewis acid increases the electron-accepting ability of acrylonitrile, which results in the formation of a molecular complex between the acrylonitrile–Lewis acid complex and the donor molecule. This ternary molecular complex polymerizes as a unit to yield an alternating polymer. Cross-propagation and complex radical mechanisms have also been proposed (208).

A number of methods such as ultrasonics (209), radiation (210), and chemical techniques (211–213), including the use of polymer radicals, polymer ions, and organometallic initiators, have been used to prepare acrylonitrile block copolymers. Block comonomers include styrene, methyl acrylate, methyl methacrylate, vinyl chloride, vinyl acetate, 4-vinylpyridine, acrylic acid, and n-butyl isocyanate.

Living radical polymerization (atom transfer radical polymerization) has been developed which allows for the controlled polymerization of acrylonitrile and comonomers to produce well defined linear homopolymer, statistical copolymers, block copolymers, and gradient copolymers (214–217). Well-defined diblock copolymers with a polystyrene and an acrylonitrile–styrene (or isoprene) copolymer sequence have been prepared (218,219). The stereospecific acrylonitrile polymers are made by solid-state urea clathrate polymerization (220) and organometallic compounds of alkali and alkaline-earth metals initiated polymerization (221).

Acrylonitrile has been grafted onto many polymeric systems. In particular, acrylonitrile grafting has been used to impart hydrophilic behavior to starch (124,222,223) and polymer fibers (224) as discussed above. Exceptional water absorption capability results from the grafting of acrylonitrile to starch, and the use of 2-acrylamido-2-methylpropanesulfonic acid [15214-89-8] along with acrylonitrile for grafting results in copolymers that can absorb over 5000 times their weight of deionized water (225). For example, one commercial product made by General Mills, Inc., Super Slurper, is a modified starch suitable for disposable diapers, surgical pads, and paper towel applications. Acrylonitrile polymers also provide some unique applications. Hollow fibers of acrylonitrile polymers as ultrafiltration membrane materials are used in the pharmaceutical and bioprocessing industries (226). Polyacrylonitrile-based electrolyte with $Li/LiMn_2O_4$ salts is used for solid-state batteries (227). Polyacrylonitrile is also used as a binding matrix for composite inorganic ion-exchanger (228).

SAN Copolymers

Because of the difficulty of melt processing the homopolymer, acrylonitrile is usually copolymerized to achieve a desirable thermal stability, melt flow, and physical properities. As a comonomer, acrylonitrile contributes hardness, rigidity, solvent and light resistance, gas impermeability, and the ability to orient. These properties have led to many copolymer application developments since 1950. The utility of acrylonitrile [107-13-1] in thermoplastics was first realized in its copolymer with styrene (C_8H_8) [100-42-5], in the late 1950s. Styrene is the largest volume of comonomer for acrylonitrile in thermoplastic applications. Styrene–acrylonitrile copolymers [9003-54-7] are inherently transparent plastics with high heat

resistance and excellent gloss and chemical resistance (229). They are also characterized by good hardness, rigidity, dimensional stability, and load-bearing strength (due to relatively high tensile and flexural strengths). Because of their inherent transparency, SAN copolymers are most frequently used in clear applications. These optically clear materials can be readily processed by extrusion and injection molding, but they lack real impact resistance.

The subsequent development of acrylonitrile–butadiene–styrene resins [9003-56-9], which contain an elastomeric component within a SAN matrix to provide toughness and impact strength, further boosted commercial application of the basic SAN copolymer as a portion of these rubber-toughened thermoplastics (see ACRYLONITRILE–BUTADIENE–STYRENE). When SAN is grafted onto a butadiene-based rubber, and optionally blended with additional SAN, the two-phase thermoplastic ABS is produced. ABS has the useful SAN properties of rigidity and resistance to chemicals and solvents, while the elastomeric component contributes real impact resistance. Because ABS is a two-phase system and each phase has a different refractive index, the final ABS is normally opaque. A clear ABS can be made by adjusting the refractive indexes through the inclusion of another monomer such as methyl methacrylate. ABS is a versatile material and modifications have brought out many specialty grades such as clear ABS and high temperature and flame-retardant grades. Saturated hydrocarbon elastomers or acrylic elastomers (230,231) can be used instead of those based on butadiene (C_4H_6) [106-99-0] as weatherable grade ABS.

SAN Physical Properties and Test Methods. SAN resins possess many physical properties desired for thermoplastic applications. They are characteristically hard, rigid, and dimensionally stable with load-bearing capabilities. They are also transparent, have high heat distortion temperatures, possess excellent gloss and chemical resistance, and adapt easily to conventional thermoplastic fabrication techniques (232).

SAN polymers are random linear amorphous copolymers. Physical properties are dependent on molecular weight and the percentage of acrylonitrile. An increase of either generally improves physical properties, but may cause a loss of processibility or an increase in yellowness. Various processing aids and modifiers can be used to achieve a specific set of properties. Modifiers may include mold release agents, uv stabilizers, antistatic aids, elastomers, flow and processing aids, and reinforcing agents such as fillers and fibers (232). Methods for testing and some typical physical properties are listed in Table 11.

The properties of SAN resins depend on their acrylonitrile content. Both melt viscosity and hardness of SAN resins increase with increasing acrylonitrile level. Unnotched impact and flexural strengths depict dramatic maxima at ca 87.5 mol% (78 wt%) acrylonitrile (233). With increasing acrylonitrile content, copolymers show continuous improvements in barrier properties and chemical and uv resistance, but thermal stability deteriorates (234). The glass-transition temperature (T_g) of SAN varies nonlinearly with acrylonitrile content, showing a maximum at 50 mol% acrylonitrile. The alternating SAN copolymer has the highest T_g (235,236). The fatigue resistance of SAN increases with acrylonitrile content to a maximum at 30 wt%, then decreases with higher acrylonitrile levels (237). The effect of acrylonitrile incorporation on SAN resin properties is shown in Table 12.

Table 11. Physical/Mechanical Properties of Commercial Injection-Molded SAN Resins[a]

SAN Chemical Properties and Analytical Methods. SAN resins show considerable resistance to solvents and are insoluble in carbon tetrachloride, ethyl alcohol, gasoline, and hydrocarbon solvents. They are swelled by solvents such as benzene, ether, and toluene. Polar solvents such as acetone, chloroform, dioxane, methyl ethyl ketone, and pyridine will dissolve SAN (239). The interactions of various solvents and SAN copolymers containing up to 52% acrylonitrile have been studied, along with their thermodynamic parameters such as the second virial coefficient, free-energy parameter, expansion factor, and intrinsic viscosity (240).

The properties of SAN are significantly altered by water absorption (241). The equilibrium water content increases with temperature while the time required decreases. A large decrease in T_g can result. Strong aqueous bases can degrade SAN by hydrolysis of the nitrile groups (242).

The molecular weight of SAN can be easily determined by either intrinsic viscosity or size-exclusion chromatography (sec). Relationships for both multipoint and single-point viscosity methods are available (243,244). The intrinsic viscosity and molecular weight relationships for azeotropic copolymers have been given (245,246):

(1) $[\eta] = 3.6 \times 10^{-4} M_w^{0.62}$ dL/g in MEK at 30°C

(2) $[\eta] = 2.15 \times 10^{-4} M_w^{0.68}$ dL/g in THF at 25°C

(3) $[\eta] = \frac{\eta_{sp}/c}{1+k_\eta \eta_{sp}}$, where $k^\eta = 0.21$ for MEK at 30°C and 0.25 for THF at 25°C

Chromatographic techniques are readily applied to SAN for molecular weight determination. Size-exclusion chromatography or gel permeation chromatography (247) columns and conditions have been described for SAN (248). Chromatographic detector differences have been shown to be of the order of only 2–3% (249). High pressure precipitation chromatography can achieve similar molecular weight separation (250). Liquid chromatography can be used with sec-fractioned samples to determine copolymer composition (251). Thin-layer chromatography will also separate SAN by compositional (monomer) variations (250).

Residual monomers in SAN have been a growing environmental concern and can be determined by a variety of methods. Monomer analysis can be achieved by polymer solution or directly from SAN emulsions (252), followed by "head space" gas chromatography (251,252). Liquid chromatography is also effective (253).

SAN Manufacture. The reactivities of acrylonitrile and styrene radicals toward their monomers are quite different, resulting in SAN copolymer compositions that vary from their monomer compositions (254). Further complicating the reaction is the fact that acrylonitrile is soluble in water and slightly different behavior is observed between water-based emulsion and suspension systems, and bulk or mass polymerizations (255). SAN copolymer compositions can be calculated from copolymerization equations (256) and published reactivity ratios (174). The difference in radical reactivity causes the copolymer composition to drift as polymerization proceeds, except at the azeotropic composition where copolymer composition matches monomer composition. Figure 6 shows these compositional variations (257). When SAN copolymer compositions vary significantly, incompatibility results, causing loss of optical clarity, mechanical strength, and moldability, as well as heat, solvent, and chemical resistance (258). The termination step has been found to be controlled by diffusion even at low conversions, and the termination rate constant varies with acrylonitrile content. The average half-life of the radicals increases with styrene concentration from 0.3 s at 20 mol% to 6.31 s with pure styrene (259). Further complicating SAN manufacture is the fact that both the heat (260,261) and rate (262) of copolymerization vary with monomer composition.

The early kinetic models for copolymerization, Mayo's terminal mechanism (263) and Alfrey's penultimate model (264), did not adequately predict the behavior of SAN systems. Copolymerizations in dimethylformamide and toluene indicated that both penultimate and antepenultimate effects had to be considered

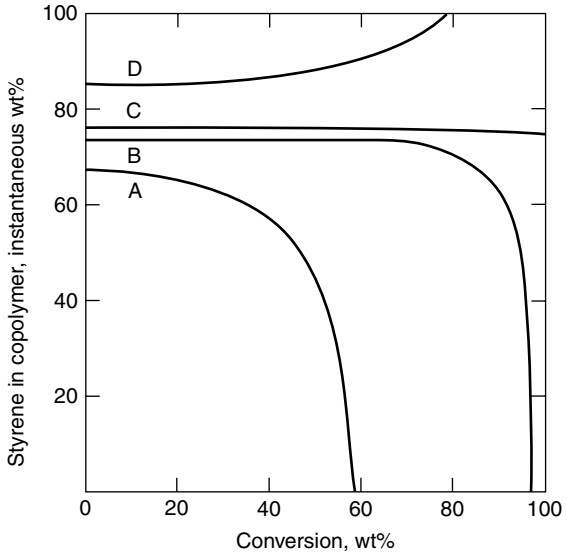

Fig. 6. Approximate compositions of SAN copolymers formed at different conversions starting with various monomer mixtures (256): S/AN = 65/36(A); 70/30(B); 76/24(C); 90/10(D).

(265,266). The resulting reactivity model is somewhat complicated, since there are eight reactivity ratios to consider.

The first quantitative model, which appeared in 1971, also accounted for possible charge-transfer complex formation (267). Deviation from the terminal model for bulk polymerization was shown to be due to antepenultimate effects (268). The work with numerical computation and ^{13}C- nmr spectroscopy data on SAN sequence distributions indicates that the penultimate model is the most appropriate for bulk SAN copolymerization (269,270). A kinetic model for azeotropic SAN copolymerization in toluene has been developed that successfully predicts conversion, rate, and average molecular weight for conversions up to 50% (271).

An emulsion model that assumes the locus of reaction to be inside the particles and considers the partition of acrylonitrile between the aqueous and oil phases has been developed (272). The model predicts copolymerization results very well when bulk reactivity ratios of 0.32 and 0.12 for styrene and acrylonitrile, respectively, are used. Commercially, SAN is manufactured by three processes: emulsion, suspension, and continuous mass (or bulk).

Emulsion Process. The emulsion polymerization process utilizes water as a continuous phase, with the reactants suspended as microscopic particles. This low viscosity system allows facile mixing and heat transfer for control purposes. An emulsifier is generally employed to stabilize the water insoluble monomers and other reactants, and to prevent reactor fouling. With SAN, the system is composed of water, monomers, chain-transfer agents for molecular weight control, emulsifiers, and initiators. Both batch and semibatch processes are employed. Copolymerization is normally carried out at 60–100°C to conversions of ~97%.

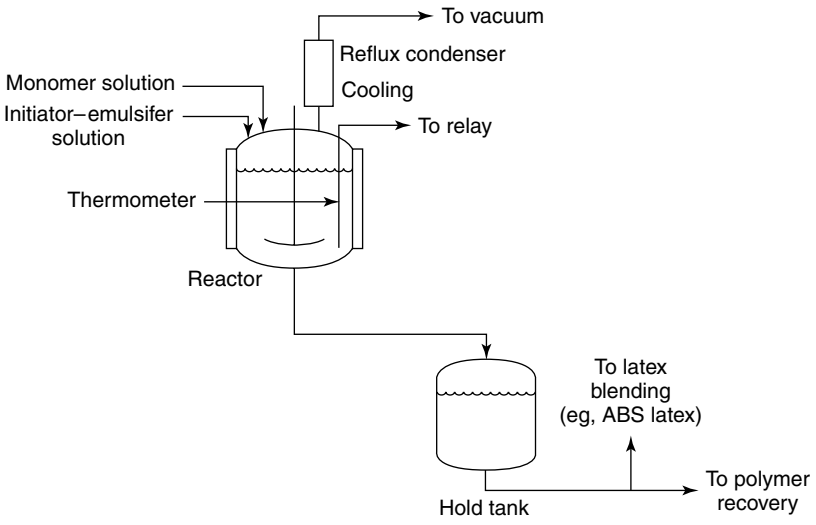

Fig. 7. SAN batch emulsion process (274).

Lower temperature polymerization can be achieved with redox-initiator systems (273).

Figure 7 shows a typical batch or semibatch emulsion process (274). A typical semibatch emulsion recipe is shown in Table 13 (275).

The initial charge is placed in the reactor, purged with an inert gas such as N_2, and brought to 80°C. The initiator is added, followed by addition of the remaining charge over 100 min. The reaction is completed by maintaining agitation at 80°C for 1 h after monomer addition is complete. The product is a free-flowing white latex with a total solids content of 35.6%. Compositional control for other than azeotropic compositions can be achieved with both batch and semibatch emulsion

Table 13. Semibatch-Mode Recipe for SAN Copolymers

Ingredient	Parts
Initial reactor charge	
Acrylonitrile	90
Styrene	111
Na alkanesulfonate (emulsifier)	63
$K_2S_2O_8$ (initiator)	0.44
4-(Benzyloxymethylene) cyclohexene (mol wt modifier)	1
Water	1400
Addition charge	
Acrylonitrile	350
Styrene	1000
Na alkanesulfonate (emulsifier)	15
$K_2S_2O_8$ (initiator)	4
4-(Benzyloxymethylene) cyclohexene (mol wt modifier)	10
Water	1600

processes. Continuous addition of the faster reacting monomer, styrene, can be practiced for batch systems, with the feed rate adjusted by computer through gas chromatographic monitoring during the course of the reaction (276). A calorimetric method to control the monomer feed rate has also been described (233). For semibatch processes, adding the monomers at a rate slower than that for copolymerization can achieve equilibrium. It has been found that constant composition in the emulsion can be achieved after ca 20% of the monomers have been charged (277).

Residual monomers in the latex are avoided either by effectively reacting the monomers to polymer or by physical or chemical removal. The use of *tert*-butyl peroxypivalate as a second initiator toward the end of the polymerization or the use of mixed initiator systems of $K_2S_2O_8$ and *tert*-butyl peroxybenzoate (278) effectively increases final conversion and decreases residual monomer levels. Spray devolatilization of hot latex under reduced pressure has been claimed to be effective (278). Residual acrylonitrile can also be reduced by postreaction with a number of agents such as monoamines (279) and dialkylamines (280), ammonium–alkali metal sulfites (281), unsaturated fatty acids or their glycerides (282,283) and their aldehydes, esters of olefinic alcohols, cyanuric acid (284), and myrcene (285).

The copolymer latex can be used "as is" for blending with other latexes, such as in the preparation of ABS, or the copolymer can be recovered by coagulation. The addition of electrolyte or freezing will break the latex and allow the polymer to be recovered, washed, and dried. Process refinements have been made to avoid the difficulties of fine particles during recovery (286,287).

The emulsion process can be modified for the continuous production of latex. One such process (288) uses two stirred-tank reactors in series, followed by insulated hold-tanks. During continuous operation, 60% of the monomers are continuously charged to the first reactor, with the remainder going into the second reactor. Surfactant is added only to the first reactor. The residence time is 2.5 h for the first reactor where the temperature is maintained at 65°C for 92% conversion. The second reactor is held at 68°C for a residence time of 2 h and conversion of 95%.

Suspension Process. Like the emulsion process, water is the continuous phase for suspension polymerization, but the resultant particle size is larger, well above the microscopic range. The suspension medium contains water, monomers, molecular weight control agents, initiators, and suspending aids. Stirred reactors are used in either batch or semibatch mode. Figure 8 illustrates a typical suspension manufacturing process while a typical batch recipe is shown in Table 14 (289). The components are charged into a pressure vessel and purged with N_2. Copolymerization is carried out at 128°C for 3 h and then at 150°C for 2 h. Steam stripping removes residual monomers (290), and the polymer beads are separated by centrifugation for washing and final dewatering.

Compositional control in suspension systems can be achieved with a corrected batch process. A suspension process has been described where styrene monomer is continuously added until 75–85% conversion, and then the excess acrylonitrile monomer is removed by stripping with an inert gas (291,292).

Elimination of unreacted monomers can be accomplished by two approaches: using dual initiators to enhance conversion of monomers to product (293,294)

Table 14. Batch-Mode Recipe for SAN Copolymers[a]

Ingredient	Parts
Acrylonitrile	30
Styrene	70
Dipentene (4-isopropenyl-1-methylcyclohexene)	1.2
Di-*tert*-butyl peroxide	0.03
Acrylic acid–2-ethylhexyl acrylate (90:10) Copolymer	0.03
Water	100

[a]Ref. 289.

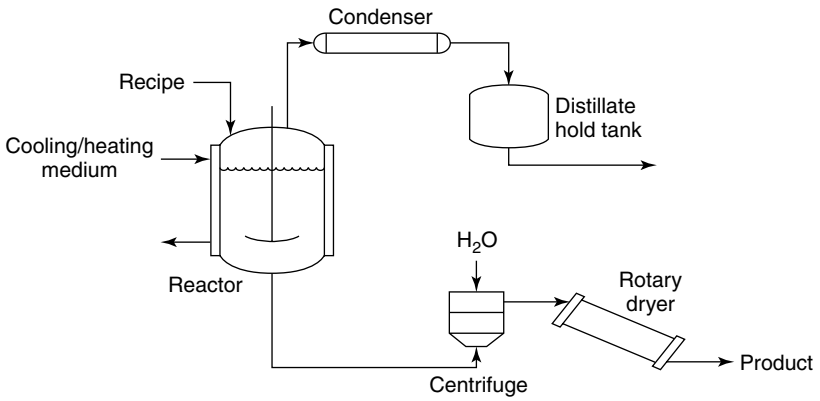

Fig. 8. SAN suspension process (289).

and steam stripping (290,295). Several process improvements have been claimed for dewatering beads (296), to reduce haze (297–300), improve color (301–305), remove monomer (306,307), and maintain homogeneous copolymer compositions (291,292,308).

Continuous Mass Process. The continuous mass process has several advantages, including high space-time yield, and good quality products uncontaminated with residual ingredients such as emulsifiers or suspending agents. SAN manufactured by this method generally has superior color and transparency, and is preferred for applications requiring good optical properties. It is a self-contained operation without waste treatment or environmental problems since the products are either polymer or recycled back to the process.

In practice, the continuous mass polymerization is rather complicated. Because of the high viscosity of the copolymerizing mixture, complex machinery is required to handle mixing, heat transfer, melt transport, and devolatilization. In addition, considerable time is required to establish steady-state conditions in both a stirred-tank reactor and a linear-flow reactor. Thus, system start-up and product grade changes produce some off-grade or intermediate grade products. Copolymerization is normally carried out between 100 and 200°C. Solvents are used to reduce viscosity or the conversion is kept to 40–70%, followed by devolatilization to remove solvents and monomers. Devolatilization is carried out from 120 to 260°C

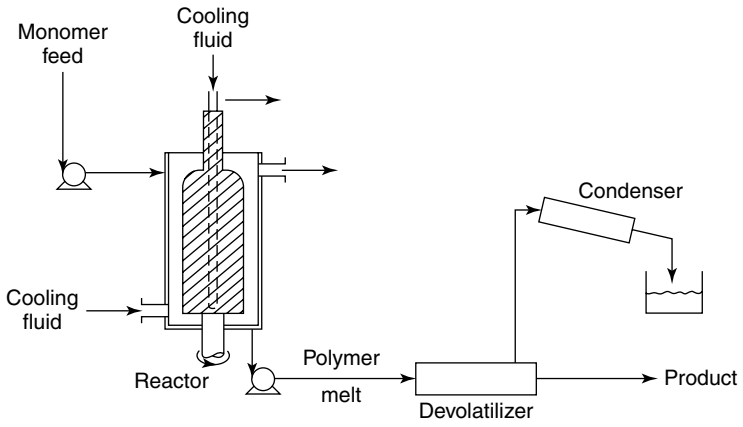

Fig. 9. SAN continuous mass process (309).

under vacuum at less than 20 kPa (2.9 psi). The devolatilized melt is then fed through a strand die, cooled, and pelletized.

A schematic of a continuous mass SAN polymerization process is shown in Figure 9 (309). The monomers are continuously fed into a screw reactor where copolymerization is carried out at 150°C to 73% conversion in 55 min. Heat of polymerization is removed through cooling of both the screw and the barrel walls. The polymeric melt is removed and fed to the devolatilizer to remove unreacted monomers under reduced pressure (4 kPa or 30 mm Hg) and high temperature (220°C). The final product is claimed to contain less than 0.7% volatiles. Two devolatilizers in series are found to yield a better quality product as well as better operational control (310,311).

Two basic reactor types are used in the continuous mass process: the stirred-tank reactor (312) and the linear-flow reactor. The stirred-tank reactor consists of a horizontal cylinder chamber equipped with various agitators (313,314) for mixing the viscous melt and an external cooling jacket for heat removal. With adequate mixing, the composition of the melt inside the reactor is homogeneous. Operation at a fixed conversion, with monomer make-up added at an amount and ratio equal to the amount and composition of copolymer withdrawn, produces a fixed composition copolymer. The two types of linear-flow reactors employed are the screw reactor (309) and the tower reactor (315). A screw reactor is composed of two concentric cylinders. The reaction mixture is conveyed toward the outlet by rotating the inner screw, which has helical threads, while heat is removed from both cylinders. A tower reactor with separate heating zones has a scraper agitator in the upper zone, while the lower portion generates plug flow. In the linear-flow reactors the conversion varies along the axial direction, as does the copolymer composition, except where operating at the azeotrope composition. A stream of monomer must be added along the reactor to maintain SAN compositional homogeneity at high conversions. A combined stirred-tank followed by a linear-flow reactor process has been disclosed (315). Through continuous recycle copolymerization, a copolymer of identical composition to monomer feed

can be achieved, regardless of the reactivity ratios of the monomers involved (316).

The devolatilization process has been developed in many configurations. Basically, the polymer melt is subjected to high temperatures and low pressures to remove unreacted monomer and solvent. A two-stage process using a tube and shell heat exchanger with enlarged bottom receiver to vaporize monomers has been described (311). A copolymer solution at 40–70% conversion is fed into the first-stage exchanger and heated to 120–190°C at a pressure of 20–133 kPa and then discharged into the enlarged bottom section to remove at least half of the unreacted acrylonitrile. The product from this section is then charged to a second stage and heated to 210–260°C at <20 kPa. The devolatilized product contains ~1% volatiles. Preheating the polymer solution and then flashing it into a multipassage heating zone at lower pressure than the preheater, produces essentially volatile-free product (310,317). SAN can be steam-stripped to quite low monomer levels in a vented extruder which has water injected at a pressure greater than the vapor pressure of water at that temperature (318).

A twin-screw extruder is used to reduce residual monomers from ca 50 to 0.6%, at 170°C and 3 kPa with a residence time of 2 min (313). In another design, a heated casing encloses the vented devolatilization chamber, which encloses a rotating shaft with specially designed blades (319,320). These continuously regenerate a large surface area to facilitate the efficient vaporization of monomers. The devolatilization equipment used for the production of polystyrene and ABS is generally suitable for SAN production.

Processing. SAN copolymers may be processed using the conventional fabrication methods of extrusion, blow molding, injection molding, thermoforming, and casting. SAN is hygroscopic and should be dried before use for best results. Small amounts of additives, such as antioxidants, lubricants, and colorants, may also be used. Typical temperature profiles for injection molding and extrusion of predried SAN resins are as follows (321):

(1) **Molding temperatures**

a. cylinder 193–288°C
b. mold 49–88°C
c. melt 218–260°C

(2) **Extrusion temperatures**

a. hopper zone water-cooled
b. rear zone 177–204°C
c. middle zone 210–232°C
d. torpedo zone and die 204–227°C

Health and Toxicology. SAN resins, in general, appear to pose few health problems, in that SAN resins are allowed by the FDA to be used by the food

and medical industries for certain applications under prescribed conditions (322). The main concern over SAN resin use is that of toxic residuals, eg, acrylonitrile, styrene, or other polymerization components such as emulsifiers, stabilizers, or solvents. Each component must be treated individually for toxic effects and safe exposure level.

Acrylonitrile is believed to behave as an enzyme inhibitor of cellular metabolism (323) and is classified as a possible human carcinogen of medium carcinogenic hazard (324), and can affect the cardiovascular system and kidney and liver functions (323). Direct potential consumer exposure to acrylonitrile through consumer product usage is low because of little migration of the monomer from such products. The concentrations of acrylonitrile in consumer products are estimated to be less than 15 ppm in SAN resins. OSHA's permissible exposure limit for acrylontrile is 2 ppm, an 8-h time-weighted average with no eye or skin contact; the acceptable ceiling limit is 10 ppm; and the action level, the concentration level that triggers the standard for monitoring, etc, is 1 ppm. Further information on the toxicology and human exposure to acrylonitrile is available (325–327).

Styrene, a main ingredient of SAN resins, is a possible human carcinogen (IARC Group 2B/EPA-ORD Group C). It is an irritant to the eyes and respiratory tract, and while prolonged exposure to the skin may cause irritation and CNS effects such as headache, weakness, and depression, harmful amounts are not likely to be absorbed through the skin. OSHA has set permissible exposure limits for styrene in an 8-h time-weighted average at 100 ppm, the acceptable ceiling limit (short-term, 15 min, exposure limit) at 200 ppm (328), and the acceptable maximum peak at 600 ppm (5-min max. peak in any 3 h). For more information on styrene environmental issues, see the CEH Styrene marketing research report (329,330).

In September 1996, the EPA issued a final rule requiring producers of certain thermoplastics to reduce emissions of hazardous air pollutants from their facilities. The final rule seeks to control air toxins released during the manufacture of seven types of polymers and resins, including SAN.

Economic Aspects (Polymers)

The first commercial applications of acrylonitrile polymers were developed by German scientists to provide oil- and gasoline-resistant rubbers during World War II. Although nitrile elastomers (Buna N) no longer account for a main portion of acrylonitrile use, they are still indispensable in many applications. Also, in response to the needs of the war, scientists at U.S. Rubber Company developed the forerunners of modern ABS, ie, tough, shatterproof blends of nitrile rubbers and SAN copolymers. Acrylic fiber manufacture was initiated around 1960, and world production of acrylonitrile has since increased to $>4.0 \times 10^6$ t. Historically, acrylic fibers have consumed >70% of the acrylonitrile in Europe, the Far East, and Latin America. In the United States, this outlet has been gradually decreasing from 50% to about a 30% share.

SAN Economic Aspects. SAN has shown steady growth since its introduction in the 1950s. The combined properties of SAN copolymers, such as optical

clarity, rigidity, chemical and heat resistance, high tensile strength, and flexible molding characteristics, along with reasonable price have secured their market position. Among the plastics with which SAN competes are acrylics, general-purpose polystyrene, and polycarbonate. SAN supply and demand are difficult to track because more than 75% of the resins produced are believed to be used captively for ABS compounding and in the production of acrylonitrile–styrene–acrylate (ASA) and acrylonitrile–EPDM–styrene (AES) weatherable copolymer (331). SAN is considered to be only an intermediate product and not a separate polymer in the production processes for these materials.

There are two major producers of SAN for the merchant market in the United States, Bayer Corp. and the Dow Chemical Co., which market these materials under the names of Lustran and Tyril, respectively. Bayer became a U.S. producer when it purchased Monsanto's styrenics business in December 1995 (332). Some typical physical properties of these SAN resins have been shown in Table 11. These two companies also captively consume the SAN for the production of ABS as well as SAN-containing weatherable polymers. The other two U.S. SAN producers, either mainly consume the resin captively for ABS and ASA polymers (GE Plastics) or toll produce for a single client (Zeon Chemicals). BASF is expected to become a more aggressive SAN supplier in the United States since its Altamira, Mexico, stryenics plant came on-line in early 1999. Overall, U.S. SAN consumption has been relatively stable for the last few years, ranging from 43×10^3 to 44.5×10^3 t (95–98 million pounds) between 1994 and 1996. Most markets for SAN are growing at only GDP rates. Consumption growth for SAN in 1996–2001 is expected

Table 15. U.S. Production/Consumption of SAN, 10^3 t (Dry-Weight Basis)

	Production	Consumption[a]
1985	39.5	34.1
1986	41.8	35.9
1987	57.3	38.6[b]
1988	67.3	41.4
1989	51.4	34.1
1990	61.4	37.3
1991	49.5	37.7
1992	51.4	38.2
1993	47.7	40
1994	62.7	44.5[c]
1995	59.1	43.6[c]
1996	55.5	43.6[c]
1997	43.6	–[c]

[a]Includes captive consumption for uses other than ABS compounding and ASA/AES polymers production.

[b]According to the SPI, 45 t of SAN resin was consumed domestically in 1987. Industry believes this figure to be incorrect. An estimate of 38.6 t is believed to be more accurate.

[c]Reported SPI data for 1996–1997 includes both U.S. and Canadian information and, therefore, are not included in this table. The stated CEH statistics represent consumption only.

to continue at an average annual rate approximation of GDP growth at 2%. Use for packaging will be flat and the automotive application may disappear altogether. Other markets, however, are expected to increase at annual rates between 2.3 and 5.9%. Production and consumption figures for SAN resin in recent years are shown in Table 15 (332).

Uses

Acrylonitrile copolymers offer useful properties, such as rigidity, gas barrier, chemical and solvent resistance, and toughness. These properties are dependent upon the acrylonitrile content in the copolymers. SAN copolymers offer low cost, rigidity, processibility, chemical and solvent resistance, transparency, and heat resistance, which provide advantages over other competing transparent/clear resins, such

Table 16. SAN Copolymer Uses[a]

Application	Articles
Appliances	Air conditioner parts, decorated escutcheons, washer and dryer instrument panels, washing machine filter bowls, refrigerator shelves, meat and vegetable drawers and covers, blender bowls, mixers, lenses, knobs, vacuum cleaner parts, humidifiers, and detergent dispensers
Automotive	Batteries, bezels, instrument lenses, signals, glass-filled dashboard components, and interior trim
Construction electronic	Safety glazing, water filter housings, and water faucet knobs battery cases, instrument lenses, cassette parts, computer reels, and phonograph covers
Furniture	Chair backs and furniture shells, drawer pulls, and caster rollers
Housewares	Brush blocks and handles, broom and brush bristles, cocktail glasses, disposable dining utensils, dishwasher-safe tumblers, mugs, salad bowls, carafes, serving trays, and assorted drinkware, hangers, ice buckets, jars, and soap containers
Industrial	Batteries, business machines, transmitter caps, instrument covers, and tape and data reels
Medical	Syringes, blood aspirators, intravenous connectors and valves, petri dishes, and artificial kidney devices
Packaging	Bottles, bottle overcaps, closures, containers, display boxes, films, jars, sprayers, cosmetic packaging, liners, and vials
Custom molding	Aerosol nozzles, camera parts, dentures, disposable lighter housings, fishing lures, pen and pencil barrels, sporting goods, toys, telephone parts, filter bowls, tape dispensers, terminal boxes, toothbrush handles, and typewriter keys

[a]Refs. 9 and 145.

as poly(methyl methacrylate), polystyrene, polycarbonate, and styrene–butadiene copolymers. SAN copolymers are widely used in goods such as housewares, packaging, appliances, interior automotive lenses, industrial battery cases and medical parts. U.S. consumption of SAN/ABS resins in major industrial markets is about 1095 t in 1998.

Acrylonitrile copolymers have been widely used in films and laminates for packaging (333–337) because of their excellent barrier properties. In addition to laminates (338–342), SAN copolymers are used in membranes (343–346), controlled-release formulations (347,348), polymeric foams (349,350), fire-resistant compositions (351,352), ion-exchange resins (353), reinforced paper (354), concrete and mortar compositions (355,356), safety glasses (357), solid ionic conductors (358), negative resist materials (359), electrophotographic toners (360), and optical recordings (361). SAN copolymers are also used as coatings (362), dispersing agents for colorants (363), carbon-fiber coatings for improved adhesion (364), and synthetic wood pulp (365). SAN copolymers have been blended with aromatic polyesters to improve hydrolytic stability (366), with methyl methacrylate polymers to form highly transparent resins (367), and with polycarbonate to form toughened compositions with good impact strength (368–371). Table 16 lists the most common uses of SAN copolymers in major industrial markets (232,319). Some important modifications of SAN copolymers are listed in Table 17.

Acrylonitrile has contributed the desirable properties of rigidity, high temperature resistance, clarity, solvent resistance, and gas impermeability to many polymeric systems. Its availability, reactivity, and low cost ensure a continuing market presence and provide potential for many new applications.

Table 17. Modified SAN Copolymers

Modifier	Remarks	Reference
Polybutadiene	ABS, impact resistant	[a]
EPDM rubber[b]	Impact and weather resistant	371,372
Polyacrylate	Impact and weather resistant	373,374
Poly(ethylene-*co*-vinyl acetate) (EVA)	Impact and weather resistant	375
EPDM+EVA	Impact and weather resistant	376
Silicones	Impact and weather resistant	377
Chlorinated polyethylene	Impact and weather resistant and flame retardant	378
Polyester, cross-linked	Impact resistant	379
Poly(α-methylstyrene)	Heat resistant	380
Poly(butylene terephthalate)	Wear and abrasion reisitant	381
Ethylene oxide–propylene oxide copolymers	Used as lubricants to improve processability	382
Sulfonation	Hydrogels of high water absorption	383
Glass fibers	High tensile strength and hardness	384

ACRYLONITRILE–BUTADIENE–STYRENE POLYMERS

Introduction

Acrylonitrile–butadiene–styrene (ABS) polymers [9003-56-9] comprise a versatile family of readily processable resins used for producing products exhibiting excellent toughness, good dimensional stability, and good chemical resistance. Special product features can also be obtained such as transparency, unique coloration effects, higher heat performance, and flame retardancy. ABS is comprised of particulate rubber, usually polybutadiene or a butadiene copolymer, dispersed in a thermoplastic matrix of styrene and acrylonitrile copolymer (SAN) [9003-54-7]. The presence of SAN chemically attached or "grafted" to the elastomeric particles compatabilizes the rubber with the SAN component. Altering structural and compositional parameters allows considerable versatility in the tailoring of properties to meet specific product requirements.

Physical Properties

Typical mechanical properties of some commercially available ABS materials are listed in Table 1. It is indicated that a wide range of mechanical and impact properties are achievable for ABS materials.

These property variations are obtained through comonomers, additives, or by making structural changes such as the following: rubber content, extent of rubber cross-linking, rubber particle size and distribution, grafted SAN level and composition, and the composition and molecular weight of the matrix. Depending on the polymerization technique, SAN can be controlled to varying levels as the continuous phase, as grafted polymer attached to the rubber particles, and as

Table 1. Material Properties of ABS Grades

Properties	ASTM method	Medium impact	High impact	Heat resistant	Flame retardant	High modulus[a]
Notched Izod impact at rt, J/m[b]	D256	160–270	270–530	75–300	140–320	50–150
Tensile yield strength, MPa[c]	D638	35–50	30–45	35–60	35–45	65–95
Elongation at break, %	D638	20–40	25–80	10–60	10–30	2–5
Flexural yield strength, MPa[c]	D790	55–75	50–75	55–90	55–75	95–160
Flexural modulus, GPa[d]	D790	2–3	1.5–2.5	2–3	2–2.5	4–9
Heat deflection[e], °C at 1825 kPa[f]	D648	75–90	75–85	90–110	70–80	95–105
Vicat softening pt, °C	D1525	100–110	95–105	110–125	85–100	100–110
Rockwell hardness	D785	100–115	80–110	105–115	95–105	110–115

[a] Filled with ~10–30% glass.
[b] To convert J/m to ft·lbs/in., divide by 53.4.
[c] To convert MPa to psi, multiply by 145.
[d] To convert GPa to psi, multiply by 145,000.
[e] Unannealed at 6.35-mm thickness.
[f] To convert kPa to psi, multiply by 0.145.

occlusions contained within the rubber particles. Thus, both the rubber content and the "rubber phase" (defined as rubber that may contain occluded SAN) volume fraction at a given rubber weight fraction can be independently controlled. Because of the capability to vary such structural and compositional parameters for property enhancements, ABS is a versatile engineering thermoplastic that can be customized to provide a wide range of mechanical and flow properties.

Structural and Compositional Effects. Being a multiphase polymer blend, the effects of the compositional and structural features in ABS are complex and interdependent. However, to a first approximation, the rubber phase contributes toughness, the styrene component contributes rigidity and processability, and the acrylonitrile (AN) phase contributes chemical resistance.

Effect of Dispersed Rubber Phase. The impact toughness of ABS is one of many properties affected by the rubber phase volume fraction, particle size and size distribution, and structure. SAN alone is quite brittle—it is the presence of the uniformly distributed rubber phase (ranging in size from 50 to 2000 nm) that imparts the ductility observed in ABS resins. It is widely reported that rubber particles induce plastic deformation in the SAN phase on a microscopic scale in the form of crazing and shear yielding accompanied (in most cases) by rubber voiding (1–4). A maximum in impact energy seems to occur when the micro deformation process is dominated by shear yielding at the deformation rates involved. The impact strength of ABS increases with rubber phase content usually leveling off at ~30% rubber by weight. Most commercial ABS resins have a rubber content in the range of 10–35 wt%. The volume fraction of the rubber phase at a given rubber level can be much higher for products manufactured by the mass (or sometimes termed a "bulk ABS") vs emulsion process because of the much higher level of occluded SAN produced in the mass process (see Figs. 1 and 2).

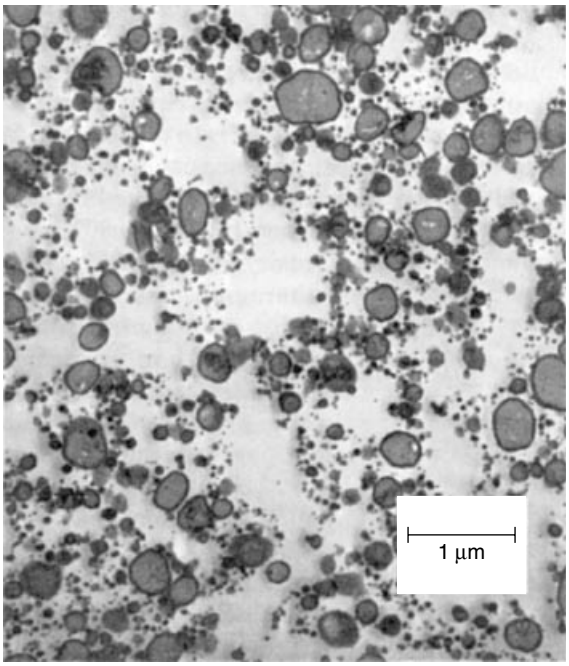

Fig. 1. Transmission electron micrograph of ABS produced by an emulsion process. Staining of the rubber bonds with osmium tetroxide provides contrast with the surrounding SAN matrix phase. To convert J/m^2 to ft·lbf/in.^{2}, divide by 2100.

The rubber phase size and size distribution is also affected by the manufacturing process. Typically, the size of the rubber phase averages ∼200–400 nm for resin produced by an emulsion process and ∼1000–2000 nm for resin produced by mass polymerization. The size distribution of the rubber particles can be very broad, narrow monomodal, or bimodal. The dependence of the impact toughness of ABS on rubber phase particle size and size distribution can be of a complex nature because of the interactions with the graft interface. A maximum impact is reported (1) to occur for emulsion ABS at a mean rubber particle size of about 300 nm for a matrix SAN containing 25% AN.

It has been reported (5) that the elastic modulus of ABS resins prepared by either mass or emulsion polymerization can be represented by a single relationship with the dispersed phase volume fraction. This is in agreement with the theory that the modulus of a blend with dispersed spherical particles depends only on the volume fraction and the modulus ratio of particles to matrix phase. Since the modulus of rubber is almost 1000 times smaller than the modulus of the matrix SAN, the rubber particle volume fraction alone is the most important parameter controlling modulus values of ABS resins. Even for rubber particles containing a high occlusion level, as in ABS produced by mass polymerization, the modulus of the composite particle still remains unchanged from pure rubber, suggesting a unique relationship between modulus and dispersed phase volume fraction. Also, the modulus of a material is a small strain elastic property and is independent of particle size in ABS. The effects of rubber content on modulus and on tensile

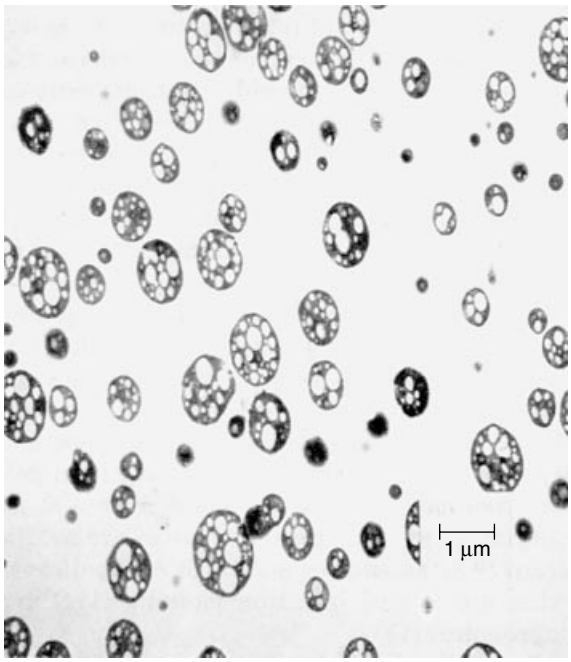

Fig. 2. Transmission electron micrograph of ABS produced by a mass process. The rubber domains are typically larger in size and contain a higher concentration of occluded SAN than those produced by emulsion technology. To convert J/m to ft·lbf/in., divide by 53.4.

and flexural yield stress are shown in Figures 3 and 4 for an emulsion produced ABS. As illustrated, the tensile and flexural yield stress values are also strongly affected by the rubber volume fraction, although—unlike modulus—the stress values are not independent of rubber particle size. It is known that tensile yield stress decreases at a given rubber volume fraction with an increase in particle

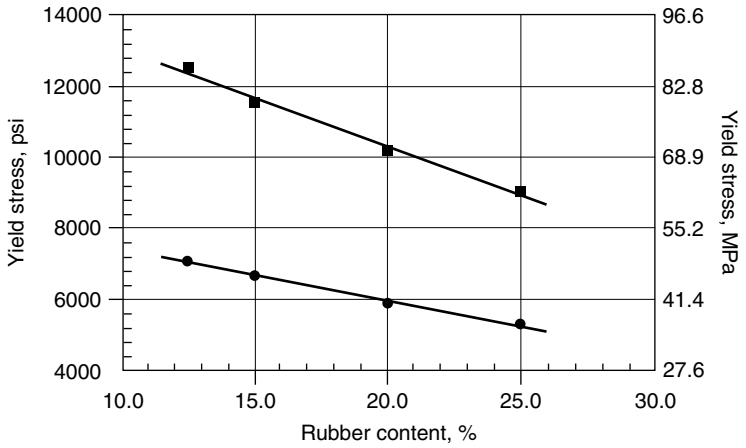

Fig. 4. Effect of rubber content on tensile and flexural yield stress of emulsion ABS at a fixed rubber particle size. ● Tensile stress and ■ flex stress.

diameter; this behavior is explained on the basis of having an increased volume of matrix SAN under higher stress near rubber particles (6).

Effect of Matrix SAN Composition and Molecular Weight. At a given rubber content and grafted rubber particle size and distribution, the mechanical properties of ABS are also strongly affected by the molecular weight and composition of the SAN present as the continuous, matrix phase. Increasing the molecular weight of the matrix SAN increases impact toughness, an effect which tends to level off at molecular weights higher than a number-average molecular weight (M_n) of ~60,000. If the SAN M_n is less than 25,000, no significant amount of crazing deformation is indicated, and therefore, no significant toughening takes place with rubber addition. Yield stress and modulus values of ABS appear to be independent of the molecular weight of the SAN, consistent with the observation that the craze initiation stress value for SAN is independent of molecular weight above an M_n of ~25,000 (7). A similar relationship between craze initiation stress and molecular weight has been reported for polystyrene (8).

The AN content of SAN has a significant influence on the environmental stress-cracking resistance of ABS, and it is generally observed that increasing AN content increases the stress-cracking resistance of ABS. Most general-purpose ABS materials contain SAN with AN content of 20–30%, whereas improved chemical resistance ABS grades employ SAN with AN content of about 35%. It is also indicated that AN in SAN improves the crazing resistance of SAN, which can explain the increased ductility of ABS as compared to rubber-modified polystyrene (high impact polystyrene). Creep and fatigue performance also improve as the AN content of the SAN is increased. In addition to the AN content of SAN matrix, the AN content of the grafted SAN plays an important role in ABS materials prepared by the melt blending of grafted rubber with SAN pellets. If the difference between AN levels of matrix SAN and grafted SAN is over 5%, some immiscibility and partial phase separation can take place (9), which can cause rubber aggregation during compounding and processing steps. Surface gloss of final article may

be lowered although mechanical properties and impact toughness can be maintained with an AN mismatch of as high as 10% between the grafted SAN and matrix SAN. Surface appearance can also be affected if two different matrix SAN components having a differing AN content are mixed because of the surface of the molded part becoming enriched with the SAN of lower AN content (10).

Effect of Grafted SAN. The extent of grafting is a critical parameter as well. If the level of grafted SAN is lowered, a nonuniform dispersion of rubber may occur, affecting toughness and aesthetic properties (eg, gloss). Furthermore, the rubber aggregates will also have an increased tendency to undergo deformation during processing, resulting in the loss of toughness, mechanical, and aesthetic properties. In commercial ABS materials, SAN molecular weight and composition, graft amount, and rubber particle size and structure are properly balanced to achieve an optimal balance of mechanical properties, toughness, melt viscosity, and aesthetics.

Rheology. The ABS manufacturer controls rheological properties through structure variations which can have a complex effect dependent on shear rate. Effects of structural variations on viscosity functions are more evident at lower shear rates (<10/s) vs higher shear rates. At high shear rates, the melt viscosity is controlled primarily by the composition and molecular weight of the ungrafted SAN and by the percentage of the grafted rubber phase. The modulus curves correspond in their shape to that of the ungrafted SAN component, and the rubber particle type and concentration have little effect on the temperature dependence of the viscosity function (11). The extrudate swell, however, becomes smaller with increasing rubber concentration (12).

By contrast, the graft phase structure has a marked effect on viscosity at small deformation rates. The long time relaxation spectra are affected by rubber particle–particle interactions (13,14), which are strongly dependent on particle size, grafting, morphology, and rubber content. Depending on particle surface area, a minimum amount of graft is needed to prevent the formation of three-dimensional networks of associated rubber particles (14). At low shear rates, the associated rubber particles behave similar to a cross-linked rubber; the network structure, however, is dissolved by shearing forces. Extensive studies on the viscoelastic properties of ABS in the molten state have been reported (11–18). Effects of lubricants and other nonpolymeric components have also been described (19). Techniques for characterizing melt-flow differences include melt-flow rate, melt index, spiral flow, and capillary rheometry.

High shear rate viscosity (eg, 1000/s) is considered more relevant to injection-molding applications, and, in general, molding grades have lower melt viscosities than extrusion grades. Designers are striving to further reduce costs through thinwall design. ABS exhibits both low melt viscosity and good impact strength, key characteristics making ABS suitable for thinwall applications (20).

Gloss. Surface gloss values can be achieved ranging from a very low matte finish at <10% (60° Gardner) to high gloss in excess of 95%. Gloss is dependent on the specific grade and the mold or polishing roll surface. Low gloss is achieved either through the use of large rubbery domains, aggregates of smaller rubber particles, or through the addition of dulling agents.

Thermal Properties. Higher heat ABS grades are achieved through copolymerization with monomers (eg, alpha methyl styrene or *N*-phenyl

maleimide) in the matrix phase or through the use of ABS as a base polymer in high performance alloys. Most common are ABS–polycarbonate alloys which extend the property balance achievable with ABS to offer even higher impact strength and heat resistance (21).

Color. ABS is sold as an unpigmented powder, unpigmented pellets, precolored pellets matched to exacting requirements, and "salt-and-pepper" blends of ABS and color concentrate. Color concentrates can also be used for on-line coloring during molding.

Transparency. Standard ABS grades are opaque because of the refractive index mismatch between the dispersed rubber phase and the continuous SAN matrix. However, ABS-type systems are available as transparent grades for clear applications, with transparency achieved by the matching of the refractive index of the rubber and matrix phases through the incorporation of comonomers. Typically, refractive index of the rubber phase is increased through the use of styrene–butadiene rubber and the matrix phase reduced and matched to the rubber phase through terpolymerization with methylmethacrylate.

Chemical Properties

The behavior of ABS may be inferred from consideration of the functional groups present within the polymer.

Chemical Resistance. The term *chemical resistance* is generally used in an applications context and refers to resistance to the action of solvents in causing swelling or stress cracking as well as to chemical reactivity. Environmental stress cracking can be assessed by applying a chemical to a prestressed sample and determining its stress-crack resistance over a specified period of time. As previously discussed, the presence of AN enhances environmental stress-cracking resistance. In ABS, the polar character of the nitrile group reduces interaction of the polymer with hydrocarbon solvents, mineral and vegetable oils, waxes, and related household and commercial materials. Good chemical resistance provided by the presence of AN as a comonomer combined with relatively low water absorptivity ($<1\%$) results in high resistance to staining agents (eg, coffee, grape juice, beef blood) typically encountered in household applications (22).

Similar to most polymers, ABS undergoes stress cracking when brought into contact with certain chemical agents under stress (22,23). Injection-molding conditions can significantly affect chemical resistance, and this sensitivity varies with the ABS grade. Certain combinations of melt temperature, fill rate, and packing pressure can significantly reduce stress-cracking resistance, and this effect is interactive in complex ways with the imposed stress level that the part is subjected to in service. Both polymer orientation and stress appear to be considerations; thus, critical strains can be higher in the flow direction (24). Consequently, all media to be in contact with the ABS part during service should be evaluated under anticipated end-use conditions.

Processing Stability. Processing can influence resultant properties by chemical and physical means (25,26). Degradation of the rubber and matrix phases has been reported under very severe conditions (27). Morphological changes may become evident as agglomeration of dispersed rubber particles during injection

molding at higher temperatures (26). Physical effects such as orientation and molded-in stress can have marked effects on mechanical properties. Thus, the proper selection and control of process variables are important to maintain optimum performance in molded parts. Antioxidants added at the compounding step have been shown to help retention of physical properties upon processing (25).

Appearance changes evident under certain processing conditions include color development (25), changes in gloss (27), and splaying. Discoloration may be minimized by reducing stock temperatures during molding or extrusion. *Splaying* is the formation of surface imperfections elongated in the direction of flow and is typically caused by moisture, occluded air, or gaseous degradation products; proper drying conditions are essential to prevent moisture-induced splay.

Techniques for evaluating processing stability and mechanochemical effects include using a Brabender torque rheometer (28,29), injection molding (26,28), capillary rheometry (26,28), and measuring melt index as a function of residence time (25).

Thermal Oxidative Stability. ABS undergoes autoxidation and the kinetic features of the oxygen consumption reaction are consistent with an autocatalytic free-radical chain mechanism. Comparisons of the rate of oxidation of ABS with that of polybutadiene and SAN indicate that the polybutadiene component is significantly more sensitive to oxidation than the thermoplastic component (30–32). Oxidation of polybutadiene under these conditions results in embrittlement of the rubber because of cross-linking and the introduction of polar oxidized groups; such embrittlement of the elastomer in ABS results in the loss of impact strength. Studies have also indicated that oxidation causes detachment of the grafted SAN from the elastomer, which contributes to impact deterioration (33).

Examination of oven-aged samples has demonstrated that substantial degradation is limited to the outer surface (33), ie, the oxidation process is diffusion limited. Consistent with this conclusion is the observation that oxidation rates are dependent on sample thickness (31). Impact property measurements by high speed puncture tests have shown that the critical thickness of the degraded layer at which surface fracture changes from ductile to brittle is about 0.2 mm. Removal of the degraded layer restores ductility (33). A demonstration of the effects of an embrittled surface on impact was achieved using ABS coated with SAN (34). Rates of oxidation can be significantly affected by additives such as colorants (31).

Test methods for assessing thermal oxidative stability include oxygen absorption (30,31,35), thermal analysis (36,37), oven aging (33,38,39), and chemiluminescence (40,41). Such techniques primarily reflect the reactivity of the rubber component in ABS with oxygen.

Antioxidants have been shown to improve oxidative stability substantially (42,43). Hindered phenols, thiodipropionates, and phosphites can be effective in improving processing or end-use stability (44). In multiphase systems like ABS, stabilizers can partition between the component phases. Thus, the additive concentration in each phase can differ significantly from the added or average concentration potentially influencing additive effectiveness. The use of rubber-bound stabilizers to permit concentration of the additive in the rubber phase has been reported (45–47). Scanning electron microscopy (sem) using xeds (energy dispersive x-ray analysis) has been used to determine the partitioning behavior of stabilizers in ABS. The partitioning of various conventional stabilizers between the rubber

and thermoplastic phases has been shown to correlate with solubility parameter values (48).

Photo-oxidative Degradation. Unsaturation present as a structural feature in the polybutadiene component of ABS (also in high impact polystyrene, rubber-modified PVC, and ABS–polycarbonate blends) increases lability with regard to photo-oxidative degradation (49–51), which can result in discoloration and loss of impact. Applications involving outdoor exposure require protective measures to maintain an optimum level of performance. Light stabilizers provide some measure of protection (52,53), as illustrated by the very successful use of ABS in interior automotive trim. Colorants have a significant effect on light stability and can either increase or decrease color fastness, depending on colorant type. For extended outdoor exposure, the best protection is provided by a protective coating which can be either paint or a cap layer of a weatherable polymer such as a thermoplastic acrylic, cast acrylic, or ASA (acrylonitrile–styrene–acrylate terpolymer). A cap layer of ASA vs acrylics (PMMA) minimizes brittle surface layer effects. The cap layer is applied by coextrusion over ABS, resulting in a laminate sheet which can be thermoformed into parts providing a favorable balance of cost and part performance that includes excellent weatherability.

The photodegradation of ABS typically occurs in the outermost layer (54,55). Impact loss upon irradiation is due to embrittlement of the rubber and possibly scission of the grafted SAN (49,56). Appearance changes such as yellowing are caused by chromophore formation in both the polybutadiene and SAN components (49,57). Mechanisms describing the photo-oxidative degradation of ABS have been proposed (51,52,58). Oxidation studies with singlet oxygen have shown that initial attack on ABS occurs on the polybutadiene component (59). Weathering studies have been conducted using artificial (60,61) and outdoor exposure (60) conditions. Light wavelength dependence has been studied, and photodegradation of the polybutadiene component has been reported to be primarily initiated by wavelengths below 350 nm (62) but can extend into the visible region (63). For discoloration, photochemical yellowing is caused primarily by wavelengths between 300 and 360 nm, and maximum bleaching of yellow colored species is reported to occur in the 475- to 485-nm region (62). For the above reasons, any spectral difference between accelerated aging and actual exposure could lead to a lack of correlation, affecting predictive capability by accelerated techniques. Xenon arc is preferred vs other test methods (eg, carbon arc, HPUV) because of the closer simulation of the spectral distribution of sunlight by Xenon arc if the appropriate filter combination is used. Oxidative degradation induced by processing may also affect photosensitivity (49,64). A comparative study on the weathering of ABS and other acrylic-based plastics has shown that elastomer type and SAN phase composition are two key factors affecting both color and impact retention (65).

Test methods that have been used to determine the effects of light aging on embrittlement of ABS include Izod impact, Charpy impact, flexural tests, falling dart, and dynamic mechanical measurements. Because photodegradation occurs only on the outer surface and the interior of the sample remains essentially unaffected, a pendulum type of notched impact will not be sensitive to changes in surface embrittlement. Falling dart types of testing increase sensitivity to surface changes; the use of a high speed puncture test has been described for determining the effect of outdoor exposure on crack-initiation energy values for ABS (65).

Flammability. The general-purpose grades are usually recognized as 94 HB according to the requirements of Underwriters' Laboratories UL94. Flame-retardant (FR) grades (V0, V1, and V2) are also available which meet Underwriters' UL 94/94 5V and Canadian Standards Association (CSA) requirements. Flame retardancy is typically achieved by utilizing halogenated additives in combination with antimony oxide or by alloys with PVC or PC (66–68). A wide variety of brominated flame retardants have been used in ABS with tetrabromobisphenol-A (TBBPA) and brominated epoxy oligomers (BEOs), currently in widespread use. Both are melt-blendable and can be well dispersed on most commercial equipment. TBBPA is very cost effective, providing excellent flame retardancy and good flow properties; however, products formulated with TBBPA generally have poorer light stability and a lower heat-deflection temperature. Although TBBPA exhibits low thermal stability, processing is usually not an issue if recommended guidelines are followed. Flame-retardant ABS grades formulated with BEOs are preferred if reduced color shift upon light exposure is required.

Polymerization

All manufacturing processes for ABS involve the polymerization of styrene and acrylonitrile monomers in the presence of an elastomer (typically polybutadiene or a butadiene copolymer) to produce SAN that has been chemically bonded or "grafted" to the rubber component termed the "substrate."

Rubber Chemistry. The rubber substrate is typically produced by the free-radical polymerization of butadiene. The radical source can be provided by either thermal decomposition or oxidation–reduction (redox) systems. The primary product is primarily 1,4-polybutadiene with some 1,2-polybutadiene, which contains a pendent vinyl group. Cross-linking of polymer occurs at high conversion through abstraction of reactive allylic sites or by copolymerization through double bonds (especially the double bonds in the more sterically accessibly pendent vinyl groups). Rubber cross-linking is controlled by the use of chain-transfer agents and the concentration and type of the intiator used; the reaction can also be affected by chain transfer to emulsifiers. For emulsion ABS, the rubber is typically both produced and subsequently used for grafting as a latex.

Graft Chemistry. Grafting of styrene and acrylonitrile onto a rubber substrate is the essence of the ABS process. Grafting is a free-radical process initiated by the abstraction of allylic hydrogens on the rubber substrate or by copolymerization through double bonds that are pendent or internal in the rubber substrate, as illustrated in Figure 5 (69). Initiator level and type affects the extent of grafting (69–75) with oxyradicals yielding a higher degree of grafting than carbon radicals because of higher rates of abstraction from the rubber substrate. Chain-transfer agents are also used in controlling overall degree of grafting and graft molecular weight.

Ungrafted SAN is formed concurrently with grafted SAN, with the ratio controlled by factors that include temperature, chain-transfer agent, pendent vinyl content of rubber, initiator level, and initiator type (69–77). As previously described, occlusions of SAN can also form within the rubber particles with the mass process leading to significantly higher occlusion levels than the emulsion

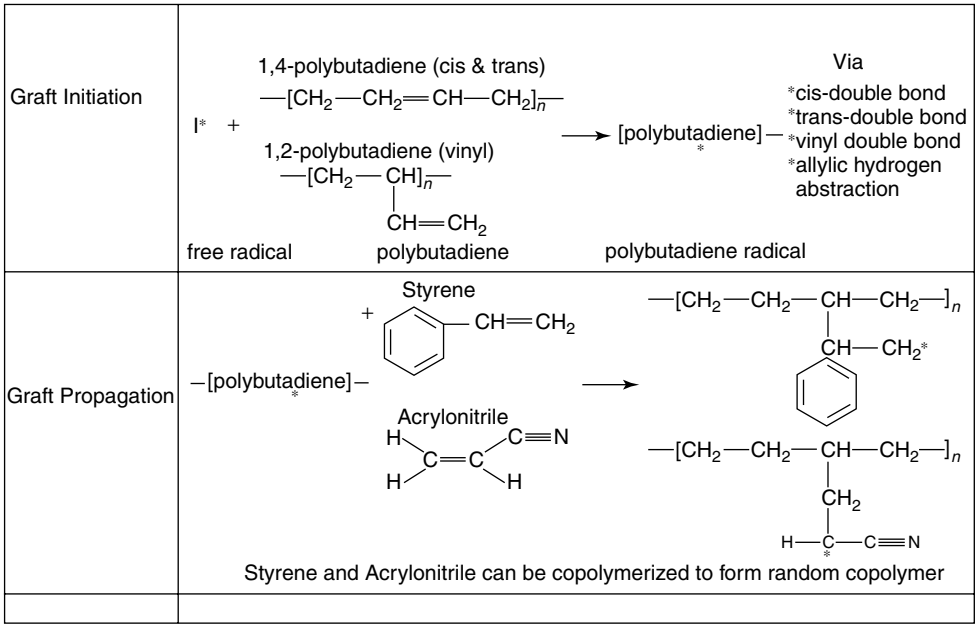

Fig. 5. Mechanisms of graft SAN formation.

process (78,79). In the mass process, block copolymers of styrene and butadiene can be added to obtain unusual particle morphologies (eg, coil, rod, capsule, cellular) (78).

Emulsion Process. The emulsion process for making ABS has been commercially practiced since the early 1950s. Its advantage is the capability of producing ABS with a wide range of compositions, particularly higher rubber contents than are possible with other processes. Mixing and transfer of the heat of reaction in an emulsion polymerization is achieved more easily than in the mass polymerization process because of the low viscosity and good thermal properties of the water phase. The energy requirements for the emulsion process are generally higher because of the energy usage in the polymer recovery area. The emulsion polymerization process is typically a two-stage reaction process (80,81), as illustrated in Figure 6.

In the first stage, a rubber substrate, primarily composed of polybutadiene, is made using an emulsion polymerization process. The desired particle size of the rubber is either obtained by direct growth during polymerization or by an agglomeration process subsequent to polymerization. In a second-stage reaction, styrene and acrylonitrile are grafted onto the rubber substrate by emulsion polymerization. After the graft reaction is complete, the polymer can be recovered from the graft latex and compounded into a final pellet product (81–86).

Rubber Substrate Process. The rubber substrate can be made by a variety of different reaction processes including batch, semi-batch, and continuous (87). Butadiene monomer is primarily used in the substrate reaction, but comonomers such as styrene and acrylonitrile are common (84,85). The amount

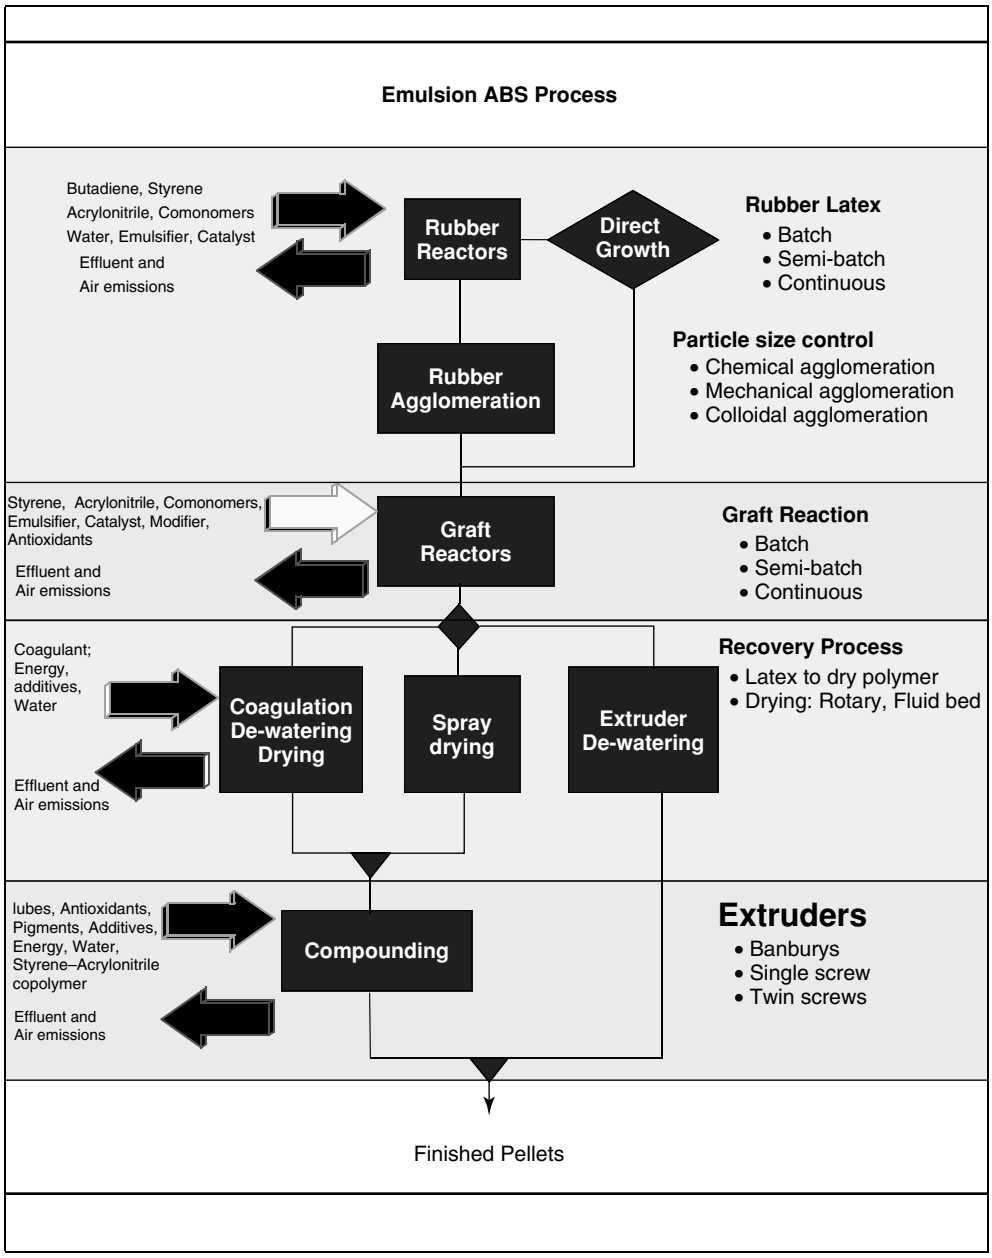

Fig. 6. Emulsion ABS process.

and type of comonomer employed will affect the glass transition of the rubber substrate and, thereby, influence the impact properties of the ABS polymer. Oxidation–reduction systems (eg, hydrogen peroxide and iron) or thermal initiators (eg, potassium persulfate or azobisisobutyronitrile) are used to initiate polymerization. Cross-link density is controlled by type and level of initiator, type and

level of chain-transfer agent, reaction temperature, degree of conversion, or by the addition of comonomers. It is important to note that the graft process also can affect the cross-link density of the rubber. Various surfactant types can be employed to emulsify the monomer and stabilize the latex particles. Standard fatty acid soaps and derivatives are the most common emulsifiers employed; however, detergents such as sodium dobenzyl sulfonate and sodium lauryl sulfate can also be used. The use of nonionic surfactants has been reported (88). The "soap-free" emulsion polymerization of butadiene is possible using reactive surfactants (89), functional monomers such as acrylic acid (90), or high levels of potassium persulfate (91). The incorporation of surfactants into the polymer backbone provides the advantage of minimizing low molecular by-products in the final polymer that could result in mold buildup or juicing.

The incorporation of comonomers into the rubber substrate can be useful in achieving specialized performance of the final ABS polymer, such as adjusting the refractive index of the rubber phase to better match the continuous SAN phase to achieve a clear or more translucent ABS product (92). The incorporation of polymerizable antioxidants or uv stabilizers has also been reported (93). Typically, these modifications increase the cost of ABS and are only employed for specialized applications.

Reactor productivity can be effected by various factors including initiator type, latex particle size, monomer purity, chain-transfer agents, and reaction temperature (87). As previously described, rubber particle size and distribution are important factors controlling the final properties of the ABS polymer. Large particles can be obtained by direct growth in the reactor, but much longer reaction times are needed. Comonomers such as AN can be added to speed the reaction rate and achieve relatively large particles in less time (94,95). Productivity can also be improved by the use of antifouling agents to minimize buildup of polymer on reactor heat-transfer surfaces (96–98). These antifouling agents improve heat transfer and minimize the time the reactor is down for cleaning.

Graft Process. Grafted SAN is critical to achieving effective dispersion of the rubber in the matrix phase, with key factors being SAN composition and rubber particle surface coverage. The composition of the grafted SAN depends on the monomer-feed composition and the monomer reactivity ratio. The composition of the polymer formed will equal the feed at the azeotropic composition, which occurs at ~3/1 mass ratio of styrene-to-acrylonitrile (80,88), and compositional drift will occur at monomer feed compositions other than the azeotropic concentration. Note that in aqueous systems, the difference in water phase solubility of acrylonitrile vs styrene can also perturb monomer concentrations at the reaction site and, thus, affect compositional drift. Polymerization techniques such as continuous vs batch processes and controlling pump rates can be used to control compositional drift (99–105). Surface coverage is controlled by rubber particle surface area and is effected by factors including initiator type, monomer feed to rubber level, and chain-transfer agents.

Resin Recovery Process. Typically, the polymer is recovered by the addition of coagulants which destabilize the ABS latex. Different coagulants are used depending on the surfactant. Thus, strong and weak acids work well with fatty acid soaps, and metal salts are used with acid stable soaps (106). The use of nonionic coagulants has also been reported (107,108). Acrylic latices have been

used to control the coagulation process and obtain a narrow resin particle-size distribution (109).

Once coagulated, the resulting slurry can then be filtered or centrifuged to recover wet ABS resin, which is then dried to a low moisture content. A variety of dryers can be used for ABS, including tray, fluid bed, and rotary kiln-type dryers. Other methods of recovery have been employed such as spray drying (110) and extruder dewatering (111). Spray drying allows for good control of the final particle size of the resin, but uses a significant amount of energy in the drying process. In extruder dewatering, the latex is either directly fed into the extruder or is first coagulated and then fed into the extruder. Extruder dewatering allows for more efficient stripping and recovery of unreacted monomer than standard drying processes.

Air and Water Treatment. The emulsion process exerts a greater demand on wastewater treatment than other processes (suspension or mass) because of the quantity of water used, and air emissions may be higher because of the types of process equipment employed. Recent federal and state EPA regulations governing air emission from ABS facilities affect the level of styrene, acrylonitrile, butadiene, and other volatile organic compounds that can be emitted into the air or sent to wastewater treatment facilities. In some cases, effluent water can be recycled and reused, but ultimately the water must be discharged, requiring treatment of the water prior to discharge. Air emissions from an emulsion ABS process can be reduced by improving the conversion of the monomers (112), the installation of equipment to strip and recover monomers, or the installation of end-of-pipe controls. End-of-pipe controls such as regenerative catalytic oxidation, regenerative thermal oxidation, fixed and fluid bed carbon absorption, and biofiltration are viable means of addressing air emission issues (113).

Mass Polymerization Process. In the mass (114–122) ABS process, the polymerization is conducted in a monomer medium rather than in water, usually employing a series of two or more continuous reactors. The rubber used in this process is most commonly a solution polymerized linear polybutadiene (or copolymer containing sytrene), although some mass processes utilize emulsion-polymerized ABS with a high rubber content for the rubber component (123). If a linear rubber is used, a solution of the rubber in the monomers is prepared for feeding to the reactor system. If emulsion ABS is used as the source of rubber, a dispersion of the ABS in the monomers is usually prepared after the water has been removed from the ABS latex.

In the mass process (124) using linear rubber, the rubber initially dissolved in the monomer mixture will phase separate, forming discrete rubber particles as SAN polymerization procedes. This process is referred to as phase inversion since the continuous phase shifts from rubber to SAN during the course of polymerization. Special reactor designs are used to control the phase inversion portion of the reaction (115,117–120). By controlling the shear rate in the reactor, the rubber particle size can be modified to optimize properties. Grafting of some of the SAN onto the rubber particles occurs as in the emulsion process. Typically, the mass-produced rubber particles are larger than those of emulsion-based ABS and contain much larger internal occlusions of SAN. The reaction recipe can include polymerization initiators, chain-transfer agents, and other additives. Diluents are sometimes used to reduce the viscosity of the monomer and polymer mixture to

facilitate processing at high conversion. The product from the reactor system is devolatilized to remove the unreacted monomers and is then pelletized. Equipment used for devolatilization includes single- and twin-screw extruders and flash and thin film/strand evaporators. Unreacted monomers are recovered and recycled back to the reactors to improve the process yield.

The mass ABS process was originally adapted from the mass polystyrene process (125). Mass produced ABS typically has very good unpigmented color and is usually somewhat more translucent because of the large rubber phase particle size and low rubber content. Increased translucency can reduce the concentration of colorants required. The extent of rubber incorporation is limited to approximately 20% because of viscosity limitations in the process; however, the mass-produced grafted rubber can be more efficient (on an equal percent rubber basis) at impact modification than emulsion-grafted rubber because of the presence of high occlusion levels in the rubber phase. The surface gloss of the mass-produced ABS is generally lower than that of emulsion ABS because of the presence of the larger rubber particles, but recent advances provide additional flexibility to achieve higher gloss (115–119).

Suspension Process. The suspension process utilizes a mass (126) or emulsion reaction (127,128) to produce a partially converted mixture of polymer and monomer and then employs a batch suspension process (129) to complete the polymerization. When the conversion of the monomers is approximately 15–30% complete, the mixture of polymer and unreacted monomers is suspended in water with the introduction of a suspending agent. The reaction is continued until a high degree of monomer conversion is attained and then unreacted monomers are stripped from the product before the slurry is centrifuged and dried, producing product in the form of small beads. The morphology and properties of the mass suspension product are similar to those of the mass-polymerized product. The suspension process retains some of the process advantages of the water-based emulsion process, such as lower viscosity in the reactor and good heat removal capability.

Compounding. ABS either is sold as an unpigmented product, in which case the customer may add pigments during the forming process, or it is colored by the manufacturer prior to sale. Much of the ABS produced by the mass process is sold unpigmented; however, precolored resins provide advantages in color consistency. If colorants, lubricants, fire retardants, glass fibers, stabilizers, or alloying resins are added to the product, a compounding operation is required. ABS can be compounded on a range of equipment, including batch and continuous melt mixers, and both single- and twin-screw extruders. The device must provide sufficient dispersive and distributive mixing dependent on formulation ingredients for successful compounding, and low work or low shear counterrotating twin-screw extruders as used in PVC are not recommended. In the compounding step, more than one type of ABS may be employed (ie, emulsion and mass-produced) to obtain an optimum balance of properties for a specific application. Products can also be made in the compounding process by combining emulsion ABS having a high rubber content with mass- or suspension-polymerized SAN.

Analysis. Analytical investigations may be undertaken to identify the presence of an ABS polymer, characterize the polymer, or identify nonpolymeric

ingredients. Fourier transform infrared (ftir) spectroscopy is the method of choice to identify the presence of an ABS polymer and determine the ABS ratio of the composite polymer (130,131). Confirmation of the presence of rubber domains is achieved by electron microscopy. Comparison with available physical property data serves to increase confidence in the identification or indicate the presence of unexpected structural features. Identification of ABS by pyrolysis gas chromatography (132) and dsc (133) has also been reported. Detailed compositional and molecular weight analyses involve determining the percentage of grafted rubber; determining the molecular weight and distribution of the grafted SAN and the ungrafted SAN; and determining compositional data on the grafted rubber, the grafted SAN, and the ungrafted SAN. This information is provided by a combination of phase-separation and instrumental techniques. Separation of the ungrafted SAN from the graft rubber is accomplished by ultracentrifugation of ABS dispersions (134,135), which causes sedimentation of the grafted rubber. Cleavage of the grafted SAN from the elastomer is achieved using oxidizing agents such as ozone [10028-15-6] (135,136), potassium permanganate [7722-64-7] (137), or osmium tetroxide [20816-12-0] with *tert*-butyl-hydroperoxide [75-91-2] (138). Chromatographic and spectroscopic analyses of the isolated fractions provide structural data on the grafted and ungrafted SAN components (139). Information on the microstructure of the rubber is provided by analysis of the cleavage products derived from the substrate (135,137). The extraction of ungrafted rubber has also been reported (140). Additional information on elastomer and SAN microstructure is provided by ^{13}C nmr analysis (141). Rubber particle composition may be inferred from glass-transition data provided by thermal or mechanochemical analysis. Rubber particle morphology as obtained by transmission or scanning electron microscopy (142) is indicative of the ABS manufacturing process (78) (see Fig. 1).

The isolation and/or identification of nonpolymerics has been described, including analyses for residual monomers (131,143,144) and additives (131,145–147). The determination of localized concentrations of additives within the phases of ABS has been reported; the partitioning of various additives between the elastomeric and thermoplastic phases of ABS has been shown to correlate with solubility parameter values (48).

Processing

Good thermal stability plus shear thinning allow wide flexibility in viscosity control for a variety of processing methods. ABS exhibits non-Newtonian viscosity behavior. For example, raising the shear rate one decade from 100/s to 1000/s (typical in-mold shear rates) reduces the viscosity by 75% on a general-purpose injection-molding grade. Viscosity can also be reduced by raising melt temperature; typically increasing the melt temperature 20–30°C within the allowable processing range reduces the melt viscosity by about 30%. ABS can be processed by all the techniques used for other thermoplastics: compression and Injection Molding, Extrusion, calendering, and Blow Molding. Clean, undegraded regrind can be reprocessed in most applications (plating excepted), usually at 20% with

virgin ABS. Post-processing operations include cold forming; thermoforming; metal plating; painting; hot stamping; ultrasonic, spin, and vibrational welding; and adhesive bonding.

Material Handling and Drying. Although uncompounded powders are available from some suppliers, most ABS is sold in compounded pellet form. The pellets are either precolored or natural to be used for in-house coloring using dry or liquid colorants or color concentrates. These pellets have a variety of shapes including diced cubes, square and cylindrical strands, and spheroids. The shape and size affect several aspects of material handling such as bulk density, feeding of screws, and Drying. Very small particles called fines can be present as a carryover from the pelletizing step or transferring operations; these tend to congregate at points of static charge buildup. Certain additives can be used to control static charges on pellets (148).

ABS is mildly hygroscopic. The moisture diffuses into the pellet and moisture content is a reversible function of relative humidity. At 50% relative humidity, typical equilibrium moisture levels can be between 0.3 and 0.6% depending on the particular grade of ABS. In very humid situations moisture content can be double this value. Although there is no evidence that this moisture causes degradation during processing, drying is required to prevent voids and splay (149) and achieve optimum surface appearance. Drying down to 0.1% is usually sufficient for general-purpose injection molding and 0.05% for critical applications such as plating. For nonvented extrusion and blow-molding operations a maximum of 0.02% is required for optimum surface appearance.

Desiccant hot air hopper dryers are recommended, preferably mounted on the processing equipment. Tray driers are not recommended, but if used the pellet bed should be no more than 5 cm deep. Many variables affect drying rates (150,151); the pellet temperature has a stronger effect than the dew point. Most pellet drying problems can be a result of actual pellet temperatures being too low in the hopper. Large particles dry much more slowly than pellets, thus regrind should be protected from moisture regain. Supplier data sheets should be consulted for specific drying conditions. Several devices are available commercially for analytically determining moisture contents in ABS pellets (152–154). Alternatives to pellet drying are vented injection molding (155) and cavity-air pressurization (counterpressure) (156).

Injection Molding.

Equipment. Although plunger machines can be used, the better choice is the reciprocating screw injection machine because of better melt homogeneity. Screws with length-to-diameter ratios of 20:1 and a compression ratio of 2–3:1 are recommended. General-purpose screws vary significantly in number and depth of the metering flights; long and shallow metering zones can create melt temperature override which is particularly undesirable with FR grades of ABS. Screws with a generous transition length perform best because of better melting rate control (157). Good results have been realized with a long transition “zero-meter” screw design (158). Some comments on the performance of general-purpose and two-stage vented screws used for coloring with concentrates is given in Reference 159. Guidelines for nozzle and nonreturn valve selection as well as metallurgy are given in References 160 and 161. Gas-nitrided components should be avoided; ion-nitrided parts are acceptable.

A variety of mold types can be used: two-plate, three-plate, stack, or runnerless. Insulated runner molds are not recommended. If heated torpedoes are used with hot manifold molds, they should be made from a good grade of stainless steel and not from beryllium copper. Molds are typically made from P-20, H-13, S-7, or 420 stainless; chrome or electroless plating is recommended for use with FR grades of ABS. Mold cavities should be well vented (0.05 mm deep) to prevent gas burns. Polished, full round, or trapezoidal runners are recommended; half or quarter round runners are not. Most conventional gating techniques are acceptable (160,161). On polished molds a draft angle of 0.5° is suggested to ease part ejection; side wall texturing requires an additional 1° per 0.025 mm of texture depth. Mold shrinkage is typically in the range of 0.5–0.9% (0.005–0.009 cm/cm) depending on grade, and the shrinkage value for a given grade can vary much more widely than this because of the design of parts and molding conditions.

Processing Conditions. Certain variables should be monitored, measured, and recorded to aid in reproducibility of the desired balance of properties and appearance. The individual ABS suppliers provide data sheets and brochures specifying the range of conditions that can be used for each product. Relying on machine settings is not adequate. Identical cylinder heater settings on two machines can result in much different melt temperatures. Therefore, melt temperatures should be measured with a fast response hand pyrometer on an air shot recovered under normal screw rpm and back-pressure. Melt temperatures range from 218 to 268°C depending on the grade. Generally, the allowable melt temperature range within a grade is at least 28°C. Excessive melt temperatures cause color shift, poor gloss control, and loss of properties. Similarly, a fill rate setting of 1 cm/s ram travel will not yield the same mold filling time on two machines of different barrel size. Fill time should be measured and adjusted to meet the requirements of getting a full part, and to take advantage of shear thinning without undue shear heating and gas burns. Injection pressure should be adjusted to get a full part free of sinks and good definition of gloss or texture. Hydraulic pressures of less than 13 MPa (1900 psi) usually suffice for most moldings. Excessive pressure causes flash and can result in loss of some properties. Mold temperatures for ABS range from 27 to 66°C (60–82°C for high heat grades). The final properties of a molded part can be influenced as much by the molding as by the grade of ABS selected for the application (162). The factors in approximate descending order of importance are polymer orientation, heat history, free volume, and molded-in stress. Izod impact strength can vary severalfold as a function of melt temperature and fill rate because of orientation effects, and the response curve is ABS grade dependent (163). The effect on tensile strength is qualitatively the same, but the magnitude is in the range of 5–10%. Modulus effects are minimal. Orientation distribution in the part is very sensitive to the flow rate in the mold; therefore, fill rate and velocity-to-pressure transfer point are important variables to control (164). Dart impact is also sensitive to molding variables, and orientation and thermal history can also be key factors (165). Heat-deflection temperature can be influenced by packing pressure (166) because of free volume considerations (167). The orientation on the very surface of the part results from an extensionally stretching melt front and can have deleterious effects on electro-plate adhesion and paintability. A phenomenon called the mold-surface effect, which involves grooving the nonappearance half of

the mold, can be employed to reduce unwanted surface orientation on the noncorresponding part surface (168–170). Other information regarding the influence of processing conditions on part quality are given in References 171–175.

Part Design. For optimum economics and production cycle time, wall thicknesses for ABS parts should be the minimum necessary to satisfy service strength requirements. The typical design range is 0.08–0.32 cm, although parts outside this range have been successfully molded. A key principle that guides design is avoiding stress concentrators such as notches and sharp edges. Changes in wall thickness should be gradual, sharp corners should be avoided, and generous radii (25% of the wall thickness) used at wall intersections with ribs and bosses. To avoid sinks, rib thickness should be between 50 and 75% of the nominal wall. Part-strength at weld lines can be diminished; thus, welds should be avoided if possible or at least placed in noncritical areas of the part (176). Because of polymer orientation, properties such as impact strength vary from point to point on the same part and with respect to the flow direction (162). Locations of highest Izod impact strength can be points of lowest dart impact strength because of the degree and direction of orientation. ABS suppliers can provide assistance with design of parts upon inquiry and through design manuals (177). There are a number of special considerations when designing parts for metal plating to optimize the plating process, plate deposition uniformity, and final part quality (178). ABS parts can also be designed for solid–solid or solid–foam co-injection molding (179) and for gas-assisted-injection molding (180) (see INJECTION MOLDING).

Extrusion.

Equipment. Since moisture removal is even more critical with extrusion than injection molding, desiccant hot-air hopper drying of the pellets to 0.02% moisture is essential for optimum properties and appearance. The extruder requirements are essentially the same for pipe, profile, or sheet. Two-stage vented extruders are preferred since the improved melting control and volatile removal can provide higher rates and better surface appearance. Barrels are typically 24:1 minimum L/D for single-stage units and 24 or 36:1 for two-stage vented units. The screws are typically 2:1 to 2.5:1 compression ratio and single lead, full flighted with a 17.7° helix angle. Screen packs (20–40 mesh = 840–420 μm) are recommended.

For sheet, streamlined coat-hanger type dies are preferred over the straight manifold type. Typically, three highly polished and temperature controlled rolls are used to provide a smooth sheet surface and control thickness (181). Special embossing rolls can be substituted as the middle roll to impart a pattern to the upper surface of the sheet. ABS and non-ABS films can be fed into the polishing rolls to provide laminates for special applications, eg, for improved weatherability, chemical resistance, or as decoration. Two rubber pull rolls, speed synchronized with the polishing rolls, are located far enough downstream to allow sufficient cooling of the sheet; finally, the sheet goes into a shear for cutting into lengths for shipping.

Pipe can be sized using internal mandrels with air pressure contained by a downstream plug or externally using a vacuum bushing and tank. Cooling can be done by immersion, cascade, or mist. Water temperatures of 41–49°C at the sizing zone reduce stresses. Foamcore pipe has increased in market acceptance significantly over the last few years, and cooling unit lengths must be longer than for solid pipe. Drawdown should not exceed 10–15%.

Profile dies can be flat plates or the streamline type. Flat-plate dies are easy to build and inexpensive but can have dead spots that cause hang-up, polymer degradation, and shutdowns for cleaning. Streamlined, chrome-plated dies are more expensive and complicated to build but provide for higher rates and long runs. The land length choice represents a tradeoff; long lands give better quality profile and shape retention but have high pressure drops that affect throughput. Land length to wall thickness ratios are typically 10:1. Drawdown can be used to compensate for die swell but should not exceed 25% to minimize orientation. Sizing jigs vary in complexity depending on profile design; water mist, fog, or air cooling can be used. The latter gives more precise sizing. Also, water immersion vacuum sizing can be used. Accurate, infinitely adjustable speed control is important to the takeoff end equipment to guarantee dimensional control of the profile.

With sheet or pipe, multilayer coextrusion can be used. Solid outer-solid core coextrusion can place an ABS grade on the outside that has special attributes such as color, dullness, chemical resistance, static dissipation, or fire-retardancy over a core ABS that is less expensive or even regrind. Composites can be created in which the core optimizes desired physical properties such as modulus, whereas the outer layer optimizes surface considerations not inherent in the core material. Solid outer-foam core can provide composites with significant reductions in specific gravity (0.7). Dry blowing agents can be "dusted" onto the pellets or liquid agents injected into the first transition section of the extruder.

Extrusion processing conditions vary depending on the ABS grade and application; vendor bulletins should be consulted for details. Information for assistance in troubleshooting extrusion problems can be found in Reference 182 (see EXTRUSION).

Calendering. The rheological characteristics of the sheet extrusion grades of ABS easily adapt them to calendering to produce film from 0.12 to 0.8 mm thick for vacuum forming or as laminates for sheet. The advantages of this process over extrusion are the capability for thinner gauge product and quick turnaround for short runs.

Blow Molding. Although ABS has been blow molded for over 20 years, this processing method has been gaining popularity recently for a variety of applications (183). Better blow-molding grades of ABS are being provided by tailoring the composition and rheological characteristics specifically to the process. While existing polyolefin equipment can often be easily modified and adjusted to mold ABS, there are some key requirements that require attention.

Pellet predrying is required down to 0.02–0.03% moisture. High shear polyolefin screws must be replaced with low shear 2.0:1 to 2.5:1 screws with L/D ratios of 20:1 to 24:1 to keep the melt temperature in the 193–221°C optimum range. The land length of the tooling can be reduced to 3:1 to 5:1 because ABS shows less die swell; this also helps to reduce the melt pressure resulting from the higher viscosity. The accumulator tooling should be streamlined to reduce hang-up and improve re-knit, and be capable of handling the higher pressures required with large programmed parisons. Mold temperatures of 77–88°C provide good surface finish. It is recommended that the material vendor be consulted to confirm equipment capability and provide safety and processing information (184) (see BLOW MOLDING).

Secondary Operations.

Thermoforming. ABS is a versatile thermoforming material. Forming techniques in use are positive and negative mold vacuum forming, bubble and plug assist, snapback and single- or twin-sheet pressure forming (185). It is easy to thermoform ABS over the wide temperature range of 120–190°C. As-extruded sheet should be wrapped to prevent scuffing and moisture pickup. Predrying sheet that has been exposed to humid air prevents surface defects; usually 1–3 h at 70–80°C suffices. Thick sheet should be heated slowly to prevent surface degradation and provide time for the core temperature to reach the value needed for good formability. Relatively inexpensive tooling can be made from wood, plaster, epoxies, thermoset materials, or metals. Tools should have a draft angle of 2° to 3° on male molds and 0.5° to 1° on female molds. More draft may be needed on textured molds. Vacuum hole diameters should not exceed 50% of the sheet thickness. Mold design should allow for 0.003–0.008 cm/cm mold shrinkage; exact values depend on mold configuration, the material grade, and forming conditions. Maximum depth of draw is usually limited to part width in simple forming, but more sophisticated forming techniques or relaxed wall uniformity requirements can allow greater draw ratios. Some definitions for draw ratios are given in Reference 186. Pressure forming, with well-designed tools, can make parts approaching the appearance and detailing obtained by injection molding. Additional information on pressure forming is given in Reference 187 (see THERMOFORMING).

Cold Forming. Some ABS grades have ductility and toughness such that sheet can be cold formed from blanks 0.13–6.4 mm thick using standard metalworking techniques. Up to 45% diameter reduction is possible on the first draw; subsequent redraws can yield 35%. Either aqueous or nonaqueous lubrication is required. More details are available in Reference 188.

Other Operations.

Metallizing. ABS can be metallized by electroplating, vacuum deposition, and sputtering. Electroplating (qv) produces the most robust coating; progress is being made on some of the environmental concerns associated with the chemicals involved by the development of a modified chemistry. An advantage to sputtering is that any metal can be used, but wear resistance is not as good as with electroplating. Attention must be paid to the molding and handling of the ABS parts since contamination can affect plate adhesion, and surface defects are magnified after plating. Also, certain aspects of part design become more important with plating; these are covered in References 169 and 178.

Fastening, Bonding, and Joining. Often parts can be molded with various snap-fit designs (189) and bosses to receive rivets or self-tapping screws. Thermal-welding techniques that are easily adaptable to ABS are spin welding (190), hot plate welding, hot gas welding, induction welding, ultrasonic welding, and vibrational welding (191,192). ABS can also be nailed, stapled, and riveted. There are a variety of adhesives and solvent cements for bonding ABS to itself or other materials such as wood, glass, and metals; for more information, contact the material or adhesives suppliers. Joining ABS with materials of different coefficients of thermal expansion requires special considerations when wide temperature extremes are encountered. An excellent review of joining methods for plastics is given in Reference 193.

Table 2. Markets for ABS Plastics by Region in 1999, 10^6 lb

Market	United States and Canada	Western Europe	Japan	Total	%
Transportation	374	397	132	903	21
Electrical[a]	501	569	415	1485	34
Miscellaneous[b]	869	457	679	2005	46
Total	1744	1423	1226	4393	100

[a]Electrical includes consumer electronics, business equipment, and appliances.
[b]Miscellaneous includes construction, pipe, consumer, and others.

Applications

Its broad property balance and wide processing window has allowed ABS to become the largest selling engineering thermoplastic. ABS enjoys a unique position as a "bridge" polymer between commodity plastics and other higher performance engineering thermoplastics. Table 2 summarizes estimates for 1999 regional consumption of ABS resins by major use (194). In 1999 the single largest market for ABS resins worldwide was transportation. Uses are numerous and include both interior and exterior applications. Interior injection-molded applications account for the greatest volume. General-purpose and high heat grades have been developed for automotive instrument panels, consoles, door post covers, and other interior trim parts. ABS resins are considered by many the preferred material for components situated above the "waistline" of the car. Exterior applications include radiator grilles, headlight housings, and extruded/thermoformed fascias for large trucks. ABS plating grades also account for significant ABS sales and include applications such as knobs, light bezels, mirror housings, grilles, and decorative trim. Appliances were the second largest market segment for ABS. The majority of this consumption was for major appliances; extruded/thermoformed door and tank liners lead the way. Other applications in the appliance market include injection-molded housings for kitchen appliances, power tools, vacuum sweepers, sewing machines, and hair dryers. Transparent ABS grades are commonly used in refrigerator crisper trays, vacuum sweeper dirt cups, and other applications requiring premium aesthetics.

A large "value-added" market for ABS is business machines and other electrical and electronic equipment. Although general-purpose injection-molding grades meet the needs of applications such as telephones and ink jet printer covers, significant growth exists in more demanding FR applications such as computer housings and displays.

An emerging application base for ABS products has been in consumer applications requiring differentiation through aesthetic appeal vs mechanical performance. A wide range of options featuring inherent aesthetic looks such as metalic, sparkle, metamerism, or even thermochromatic color change can be found in products ranging from computers to telephones.

Pipe and fittings remain a significant market for ABS, particularly in North America. ABS foam core technology allows ABS resin to compete effectively with PVC in the primary drain-waste and vent pipe market.

Table 3. Worldwide Capacity for ABS Plastics 1994–2000 by Region, 10^3 t

Region	1994	1995	1996	1997	1998	1999	2000
Western Europe	841	838	865	882	1000	1000	990
Eastern Europe	80	80	81	81	82	82	82
Africa	0	0	0	0	0	0	0
North America	931	894	894	934	1083	1098	1098
Latin America	128	115	127	129	126	230	267
Middle East	0	0	0	0	0	0	0
Asia-Pacific	2130	2535	3158	3292	3712	3857	3977
Total	*4110*	*4462*	*5125*	*5318*	*6003*	*6267*	*6414*

Table 4. World Capacity of Leading ABS Producers

Producer	2000 Capacity, 10^3 t	Largest producer in
GE Plastics	855	North America
Bayer	766	Europe
Chi Mei Industrial	1120	Pacific

Other uses of ABS include consumer and industrial applications such as luggage, toys, medical devices, furniture, shower stalls, and bathroom fixtures.

Economic Aspects

Capacity. Estimated ABS capacity worldwide in 2000 is given in Table 3 (195). Accurate ABS capacity figures are difficult to obtain because significant production capability is considered "swing" and can be used to manufacture polystyrene or SAN as well as ABS. From a regional standpoint, Asia-Pacific has the largest ABS nameplate production capability at 3977 t. The United States has approximately 17% of the world's capacity at 1068 t. Most suppliers have multiple facilities with the largest producers regionally being GE in North America, Bayer in Europe, and Chi Mei in the Pacific. As shown in Table 4, these three producers account for almost 50% of the world's capacity (195).

Table 5. U.S. Unit Sales Values for ABS Resins

Year	Value, $/kg	Year	Value, $/kg
1986	1.56	1993	1.83
1987	1.68	1994	1.87
1988	1.93	1995	2.03
1989	2.03	1996	1.86
1990	1.95	1997	1.67
1991	1.92	1998	1.48
1992	1.86	1999	1.76* est.

Price. The price history of ABS in the United States is presented in Table 5 for the period from 1986 to 1998 (196). The cyclical nature of prices during this period reflects both the cyclical nature of key feedstocks (197–199) and the increased global capacity available. The change also represents the changing mix of ABS resins and blends toward higher value, higher performance applications. Since late 1999, prices have risen appreciably because of dramatic increases in raw material feedstocks and stronger global demand.

Although ABS resins have a long history by industry standards, the products are anything but mature. ABS resins and blends are, and are expected to remain, the engineering thermoplastics of choice for a wide array of markets.

ADDITIVES

Introduction

Plastics additives are typically organic molecules that are added to polymers in small amounts (typically 0.1–5.0 wt%) during manufacture, processing, or converting so as to improve the inherent properties of the polymer resin. Additives can be categorized in three major segments: polymer modifiers, performance enhancers, and processing aids. Pigments and Colorants are not included in this overview. Antiozonants, accelerators, and vulcanizing agents, used in large volumes in elastomers, are also excluded (see RUBBER CHEMICALS). The global market for plastics additives in 1998 has been estimated to be of the order of $15–16 billion in value and 7–8 million tons in volume (1). Poly(vinyl chloride) (PVC) and polyolefins are the largest consumers of additives and drive the growth rates of 4–5% on average.

Polymer modifiers, accounting for about half of the total value (4.5 million tons globally in 1999), are added primarily to alter the physical and mechanical properties of the plastic. These include plasticizers, foaming (blowing) agents, coupling agents, impact modifiers, organic peroxides, and nucleating/clarifying agents. Plasticizers, used primarily in flexible PVC, are the highest volume additives (see PLASTICIZERS). Coupling agents are among the fastest growing additives (6–7%) in this class (see SILANE COUPLING AGENTS).

Performance enhancers are added to plastics to provide functionality not inherent to polymer itself. These include flame retardants (FRs), Heat Stabilizers for PVC, Antioxidants, light stabilizers, biocides, and Antistatic Agents. Performance enhancers for 40% of the total global market for additives are led by FRs with a total value of $2 billion. Among performance enhancers, light stabilizers show above average growth rates of 6–7% (2) (see UV STABILIZERS).

Encyclopedia of Polymer Science and Technology. Copyright John Wiley & Sons, Inc. All rights reserved.

Processing aids are typically surface-active agents that are added by the plastics converters/transformers to improve throughput and alter the surface properties of the finished article. Additives in this class include lubricants, slip agents, antiblocks, and mold-release agents (see RELEASE AGENTS).

A key driver of change and new product development in the plastics additives markets is a host of environmental concerns. This is seen most dramatically in PVC where concerns over the use of heavy-metal heat stabilizers based on lead have led to a widespread conversion to tin-based materials and even to nonmetallic stabilizers. The widely used phthalate-based Plasticizers for flexible PVC have come under fire because of concerns over their potential adverse effects on the human reproductive systems. Concerns over the potential for brominated FRs to form dioxins are fueling the development of new halogen-free systems.

Plastics additives are used extensively in food packaging and as such are regulated by the U.S. Food and Drug Administration (FDA) (and related international agencies) as indirect food additives. Regulation by the FDA of a new additive requires submission of toxicity, as well as migration data from the polymer in question into a variety of food stimulants so as to calculate estimated daily intake. The level of migration and anticipated annual usage determines the extent of toxicity testing that is required. Information on the petition process for obtaining regulations as well as a directory of all indirect food additives can be obtained through the FDA website www.fda.gov.

Additives are incorporated into polymer matrixes by a variety of methods and at various points in the manufacturing process. Polymer producers typically incorporate additives as single components or as blends of two or more additives during the pelletization/isolation step. Converters and transformers often introduce additives as a concentrate or masterbatch. *Concentrate is a mixture* is a mixture of an additive dissolved in a polymer resin carrier at fairly high (10–30%) concentrations. A *masterbatch* is a blend of additives and often pigments in a resin carrier designed for a specific end-use application.

Modifiers

Plasticizers. Plasticizers, through their use in flexible PVC, are the largest volume polymer additives used in plastics. Flexible PVC accounts for nearly 90% of the volume of plasticizers used in plastics. Plasticizers are added at very high loadings (up to 80%) depending on the degree of flexibility required. Plasticizers are added to inherently hard thermoplastics to increase the flexibility, softness, and/or extensibility. In addition, secondary benefits of improved processability, greater impact resistance, and higher ductility can often be achieved. Plasticizers are often used as carriers for pigments and are the liquid vehicle for PVC plastisols. Plasticizers are predominately esters produced through the reaction of an acid or anhydride with a linear or branched alcohol (3).

Dialkyl phthalates produced by the reaction of phthalic anhydride [85-44-9] with alcohols varying in chain length from C_4 to C_{11} with 2-ethyl-1-hexanol [104-76-7] and 1-octanol [111-87-5] typically used, are the most commonly used plasticizers. While somewhat interchangeable, performance properties such as low temperature flexibility, volatility, processability, and extractability are governed

by chain length and degree of branching. For example, in interior automotive PVC applications, the octyl phthalates have been replaced by isodecyl phthalates because of their lower volatility and thereby enhanced fogging resistance.

The remaining plasticizers are more specialty in nature. Aliphatics are typically 2-ethylhexyl esters of dibasic acids, such as glutarates, adipates, or sebacates. The primary use of aliphatics is when low temperature flexibility and crack resistance is required. When very low volatility and low migration is required, the plasticizers of choice are based on esters of trimellitic anhydride [552-30-7]. A typical application for mellitates is in PVC wire and cable jacketing, which requires excellent long-term heat aging properties and extraction resistance. For particularly demanding performance applications, dibasic acids are polymerized with diols to produce low molecular weight polymeric plasticizers. Esters of phosphorus oxychloride [10025-87-3], the phosphate esters, are typically used as FRs and also impart plasticizing properties. A final class are the epoxies, with epoxidized soybean oil [8013-07-8] (ESBO) being the most common (epoxies based on tall oils and linseed oil are also available). While primarily added as secondary thermal stabilizers in PVC because of their ability to scavenge HCl generated during processing, as plasticizers they exhibit excellent extraction resistance and low migration.

Typically the large producers of plasticizers are backward integrated into either alcohol and phthalic anhydride or both. The key suppliers of the commodity plasticizers in North America are ExxonMobil (Jayflex), BASF (Pluronic), Eastman (Eastman), and Aristech (PX). About 2.5 billion pounds of plasticizer are consumed in North America.

Foaming (Blowing) Agents. *Chemical blowing agents* are inorganic or organic additives that produce a foamed structure. They are used extensively in PVC but also in polyethylene (PE), polypropylene (PP), and polystyrene (PS) to improve properties and appearance (insulation against heat and noise, better stiffness, removal of sink marks in injection-molded parts, and improved electrical properties) as well as to reduce weight. Chemical-blowing agents can be classified as either physical or chemical. They are typically added via a concentrate or masterbatch. The total market for blowing agents in North America is 6800 tons (4,5).

Physical blowing agents are volatile liquids or compressed gasses that are dissolved in the polymer and change state during processing to form a cellular structure. Chemical blowing agents (CBAs) decompose thermally during processing to liberate gasses that form a foamed product. Organic CBAs typically are solid hydrazine derivatives that generate nitrogen in an exothermic reaction. Most common is azodicarbonamide [123-77-3], which in pure or modified form accounts for up to 80% of all CBAs. It begins to decompose at 390°F. Other types are the sulfonyl hydrazides {most common is 4,4′-oxybis(benzenesulfonyl hydrazide) [80-51-3] which is used for low temperature applications} and *p*-toluene semicarbazides {most common is *p*-toluenesulfonylsemicarbazide [10396-10-8] which is used in high temperature applications such as acrylonitrile–butadiene–styrene (ABS), poly(phenylene oxide) (PPO), nylon, and high impact polystyrene (HIPS)}. High gas yields and pressures for exothermic CBAs make them useful in applications such as cross-linked PE and extruded products. Uniroyal Chemical (Celogen, Expandex) is the major producer of these products in North America. Endothermic

CBAs are based on blends of inorganic carbonates and polycarbonic acids. Proper combination of these materials allows for operating temperature ranges of 150–300°C. A common commercial system is based on citric acid [77-92-9] and sodium bicarbonate [144-55-8]. Endothermic CBAs generally produce a lower gas yield providing foams with smaller cell structure than exothermic CBAs do. Clariant (Hydrocerol) is the leading supplier of endothermic CBAs.

Coupling Agents. Coupling agents promote adhesion between polymers and inorganic fillers by forming stable chemical bonds between the organic matrix and the surface of the filler. The highest usage of coupling agents is in the treatment of glass fibers for use in thermosets such as epoxies and polyesters. Other fillers include clay, silica, mica, wollastonite, calcium carbonate and aluminum trihydrate (ATH).

The most common type of coupling agent is the organosilanes. Silanes have the general structure $RSi(OR')_3$, where R is a functionalized organic group that binds to the polymer matrix (ie, amino, epoxy, acrylate, or vinyl) and R′ is typically methyl or ethyl. The methoxy or ethoxy groups hydrolyze to silanols which react with surface hydroxyl groups on the inorganic fillers to form oxane bonds. The result is improved mechanical or electrical properties. Amino silanes are typically used for epoxy and phenolic resins, epoxy silanes for epoxy resins, and methacrylate silanes with unsaturated polyesters. Fillers are typically pretreated with an aqueous dispersion of silane at levels of 0.2–0.75%. The treated fillers are then reacted with the polymer matrix during compounding. The silane improves wetting during the compounding process, thereby reducing the surface tension of the organic–inorganic interface for better dispersion. The filled compound has much improved moisture resistance. Dow Corning, Crompton, and Degussa-Huels (Sivento) are major suppliers of silanes in North America with an estimated market value of $70–100 million.

In addition to silanes, a variety of organometallics (primarily titanates, but also zirconates, aluminates, and zircoaluminates) are used as coupling agents, although in significantly lower volumes. While mechanistically similar, titanates are more versatile than silanes because they can react with a broader range of fillers (ie, calcium carbonate). However, they are more susceptible to hydrolysis. Titanates are often used as dispersing agents for fillers in polyolefins by reducing the surface energy of the filler, resulting in better impact strength, lower melt viscosity, and better aged mechanical properties. DuPont and Kenrich are the primary suppliers of organometallics.

A specialty class of coupling agent are the maleated polyolefins (6). The pendant maleic anhydride unit reacts with surface hydroxyl groups (or siloxy group in the case of pretreated fillers) while the polymeric portion cocrystallizes with the polymer matrix. Their main applications are in glass-filled PP composites and in non-halogenated FR wire and cable applications. The addition of 1–2% maleated PP can improve the tensile strength of a 30% glass-filled PP by up to 40%. In FR applications, 4% maleated PE in a PE/EVA (polyethylene/ethylene–vinyl acetate) blend containing 65% ATH gives up to three times improvement in elongation. The maleic anhydride reacts with the basic inorganic FR, fillers, ATH, and magnesium hydroxide. Maleated polyolefins are marketed in North America by DuPont (Fusabond) and Uniroyal (Polybond).

Organic Peroxides. Organic peroxides are used in the plastics industry to catalyze polymerization reactions or to modify the properties of polymers (7,8). On the polymerization side, peroxides are used as initiators for PVC, low density polyethylene (LDPE), PS, and acrylics. As modifiers of existing polymers, peroxides are used for the curing of unsaturated polyester resins, as cross-linkers of PE, silicones, and a variety of ethylene-based elastomers (9) and to break down the molecular weight of PP in a process known as *visbreaking* or *controlled rheology* (10). Peroxides function through the thermal decomposition of the unstable peroxide bond to generate two free radicals. The reactivity of the peroxide is modified by altering the organic substituents attached to the peroxide or through the use of coadditive promotors. The reactivity of the peroxide is defined by the *10-h half-life temperature*, or the temperature at which one-half of the peroxide decomposes in a 10-h period. The lower the 10-h half-life temperature, the more reactive the peroxide. Organic peroxides fall into seven basic groupings depending on the organic substituent. These are dialkyl peroxides, diacyl peroxides, hydroperoxides, ketone peroxides, peroxydicarbonates, peroxyesters, and peroxyketals. The following table categorizes organic peroxide by grouping and chemical process:

The choice of organic peroxide used for initiating polymerizations is dictated by the polymerization temperature used to produce the polymer. The low temperatures used for PVC polymerization, for example, dictate the use of organic peroxides with low 10-h half-life temperatures. For the higher polymerization temperatures used for LDPE, an organic peroxide with a higher 10-h half-life temperature may be used. When used as polymerization catalysts, organic peroxides are typically used in the 0.1–0.5% range. Approximately half of all organic peroxides are used in the various polymerization processes.

Unsaturated polyesters are produced through the cross-linking of low molecular weight polyester resins and comonomers such as styrene in the presence of 1.0–2.5% based on resin weight. Fillers, pigments, and reinforcements such as glass fiber are often added as well. Depending on the cure temperature, promotors are often used. For room-temperature cures and resin-transfer molding, organic cobalt and copper promotors are added to the ketone peroxides, which are typically used. Unsaturated polyester resin production is the largest single application of organic peroxides, accounting for 30–40% of total consumption.

For the cross-linking of ethylene-based polymers for applications such as wire and cable jacketing and tubings, peroxides are added during compounding/processing at levels of 0.2–0.4%. In the visbreaking of controlled-rheology PP, to reduce the molecular weight and melt viscosity of the polymer, similar levels are used. Controlled-rheology PP is particulary common for fiber and extrusion grades. When peroxides are used together with other additives, particularly antioxidants, a careful balance of concentrations must be chosen since the radicals formed during thermal decomposition can react with the other additives, lowering the effective concentrations of each.

Key suppliers of organic peroxides in North America include Akzo Nobel (Trigonox, Perkadox), LaPorte, and AtoFina (Luperox).

Impact Modifiers. Impact modifiers function by absorbing the impact energy and dissipating it in a nondestructive fashion. Typically elastomers, they are added to a wide range of thermoplastic materials at levels up to

20%. The major types of impact modifiers are acrylics, styrenics including methacrylate–butadiene–styrene (MBS) copolymers and Acrylonitrile-Butadiene-Styrene Polymers, chlorinated polyethylene (CPE), EVA copolymers, and the ethylene–propylene copolymers and terpolymers (EPR and EPDM respectively). The major market for impact modifiers is in PVC, although they are used in a wide range of other polymers such as polyolefins and engineering polymers.

MBS is the highest volume of the styrenic types. These terpolymers consist of an elastomeric core with a hard outer shell, which provide good impact resistance together with excellent processability. Typically used in transparent PVC packaging because of its good clarity, its market growth has slowed as PET and polyolefins have replaced PVC in packaging applications. Because of poor weatherability owing to the butadiene component, outdoor applications are limited. Kaneka Texas and Rohm & Haas are the major producers.

ABS is used in a variety of resins with PVC again being the major market. Like MBS, ABS suffers from poor weatherability and is therefore useful in outdoor applications only when a uv-resistant capstock is applied. GE Specialty Chemicals is the leading producer in North America.

Acrylics are the fastest growing impact modifiers because of their usage in exterior PVC siding and profile. While they function in the same way as MBS and ABS, the graft phase is based on butyl or ethylhexyl acrylates which are far more uv-stable than butadiene. Rohm & Haas and AtoFina are the major producers in North America.

EPDM and EPR are used to modify polyolefins, primarily in the automotive industry. The largest volume is in automotive PP bumpers. This application is gradually being replaced by impact-resistant polymers produced by metallocene technology, providing better performance and economics. DuPont Dow and Exxon are leading producers in North America. When used with plastics such as nylon, PET, and PBT, the EPDM and EPR are often modified with a functionalized monomer to allow them to react with the plastic. Additionally, the shell of a core-shell modifier can also be modified to include a reactive group. Suppliers of functionalized modifiers include Rohm & Haas, AtoFina, Shell, and Exxon.

CPE is again most widely used in PVC, although it does find applications in polyolefins. It can only be used in opaque applications but it does have excellent weatherability, making it useful for PVC pipe, siding, and profiles. DuPont Dow is the leading producer in North America.

Nucleating/Clarifying Agents. Materials added to semicrystalline plastics prior to processing and fabrication, which affect the rate of cystallization and spherulite size, are referred to as *nucleating agents*. These are typically insoluble or immiscible materials which provide sites for crystal formation. The main benefit for the addition of nucleating agents is improved cycle time during injection molding. When the addition of nucleators decreases the size of the crystallites to less than the wavelength of visible light, these agents are referred to as *clarifying agents* because they reduce haze and improve transparency (11).

For nucleation of nylon and PP, sodium benzoate [532-32-1] is the traditional material of choice. Use levels are of the order of 0.1% with injection-molded packaging closures being a major application. Sodium benzoate does not impart any improvement in optical properties. Low molecular weight polyolefins, ionomers,

as well as plasticizers such as ESBO are used for nucleation of semicrystalline plastics such as PET. Modified benzylidene sorbitols dominate the market for nucleation and clarification of PP. They are used at 0.1–0.3% levels in both homo- and copolymers, with injection-molded housewares, medical devices such as syringes, and other packaging being the major applications. Metal salts of organic phosphates have also been introduced for nucleation/clarification of PP. In North America, Milliken (Millad), Ciba Specialty Chemicals (Irgaclear), and Amfine (AdekaStab North America) are key suppliers. Talc and other minerals are often used as nucleators.

Property Extenders

Antimicrobials/Biocides. Biocides are used to provide protection against mold, mildew, fungi, and bacterial growth on the surface of polymers. Since they function by being toxic to the microorganisms which cause growth, they are considered as pesticides under the Federal Insecticide, Fungicide and Rodenticide Act and as such are carefully regulated by the U.S. EPA. All end-use applications and related performance claims must be registered through the EPA and supported with toxicity, safety, handling, environmental, as well as efficacy data. Since microorganisms grow at the surface of plastics, in order to be effective biocides must migrate. Their rate of migration is closely related to their efficacy (12,13).

The primary use of biocide additives is for flexible PVC which accounts for over 70% of the total demand. While PVC is inherently resistant to microbial attack, the phthalate plasticizers are quite susceptible. Moisture contact and external factors such as uv-exposure can increase susceptibility by providing surface crazing/defects as sites for growth. Typical applications for biocide use in PVC are pool and pond liners, outdoor furniture, marine upholstery, roofing membranes, garden hoses, shower curtains, and wire and cable jacketing. Use of biocides in polyolefins is growing with applications such as children's toys and furniture, kitchen utensils, cutting boards, and trash bins. Biocides are also used in a variety of engineering polymers (PET, PA) and in PUR foams.

A variety of organic and inorganic biocides have been developed for use in plastics, including arsines, isothiazolinones, chlorinated phenols, silver, and zinc compounds. Among the arsines, 10,10′-oxybisphenoxyarsine [58-36-6] is most common and is used at an active level of 0.02–0.05%. A typical isothiazalone is 2-*n*-octyl-4-isothiazolin-3-one [26530-20-1]. These are used at levels of 0.1–0.15% and are available in a 4% concentrate in a plasticizer (either dialkylphthalate or ESBO). Zinc-2-pyridinethianol-1-oxide [13463-41-7] (commonly known as omacide or zinc omadine) and trichlorophenoxyphenol [3380-34-5] (Triclosan) are other common biocides. In North America, Morton/Rohm & Haas (Vinyzene) is the market leader in terms of volume and breadth of product line. Other key players include Akros Chemicals (Intercide), Arch Chemical, and Ferro. The global market for biocides used in plastics is of the order of 23,000 tons.

Antioxidants. Polymers may be oxidized during processing, fabrication, and end use resulting in loss of aesthetic and mechanical properties. This thermally induced autoxidation results in the formation of free radicals which will react with oxygen to form hydroperoxides. These hydroperoxides are themselves

thermally unstable and their ensuing decomposition results in chain scission, cross-linking, and the formation of chromophores. In order to inhibit the initiation of polymer oxidation and to retard the resulting destructive chemical processes Antioxidants are added during manufacture, processing, and/or during fabrication of plastic articles (14–16). The global market for antioxidants is estimated to be 227,000 tons or $1.3 billion (1) (see ANTIOXIDANTS).

Traditional antioxidants are classified as either primary or secondary types depending on their mode of action. Primary antioxidants act by trapping free radicals, usually hydroperoxy radicals, through donation of a labile hydrogen to the radical species. Secondary antioxidants interfere with the propagation steps of autoxidation by decomposing hydroperoxides to form stable, nonradical species. It is quite common for a combination of primary and secondary antioxidants to be used to provide the maximum stabilization of a plastic. Use of antioxidants in plastics is ubiquitous, since nearly all resin types require some form of stabilization in order to provide useful and durable materials.

The two most common classes of primary antioxidants are the aromatic amines and hindered phenols. Aromatic amines, such as substituted diphenylamines are extremely effective, acting as both radical chain terminators and peroxide decomposers. A major drawback of aromatic amines is their tendency to form highly discolored oxidation products during use (staining). As a result their use is restricted to applications where discoloration is not an issue, such as carbon black filled or pigmented systems. As such their major usage is in the rubber industry. In plastics a major application is black wire and cable jacketing. Flexsys (Santonox), Goodyear (Wingstay), and BF Goodrich (Agerite) are among the leading suppliers of aromatic amines. For stabilizing end-use articles, relatively high levels of amine are used—typically 0.5–1.0 wt%. When used as a storage stabilizer for polyols which in turn are used in polyurethane (PUR) manufacture, lower levels (typically 200–1000 ppm) are used. The standard primary antioxidants used in plastics are based on hindered phenols which in turm are usually based on derivatives of 2,6-di-*t*-butylphenol [128-39-2] (BHT). One of the most common phenols is 2,6-di-*t*-butyl-4-methylphenol [128-37-0] (BHT). While highly effective, it is relatively volatile and is susceptible to discoloration upon oxidation. In order to improve on the properties of BHT, a host of analogues have been developed These modifications generally involve either altering the hindering alkyl groups or changing the substituent in the 4-position. In order to improve on the volatility of BHT, antioxidants with two, three, and four hindered phenols linked together are available and commonly used. Hindered phenols are effective both during polymer processing and during end use. Typically they are used in combination with a secondary antioxidant to maximize their effectiveness during high temperature processing and to minimize color formation resulting from the overoxidation of the phenol. Use levels of 0.1–0.5% are common. Hindered phenols are available from a number of producers, with Ciba Specialty Chemicals (Irganox), Great Lakes Chemical (Anox, Lowinox), and Cytec (Cyanox) being key suppliers in North America. Recently Vitamin E (α-tocopherol) [10191-41-0], a high molecular weight but extremely reactive phenol, has found niche use primarily in food-contact applications because to its effectiveness at low levels (100–200 ppm) and its "green" image. Its major limitation is its tendency to form highly discoloring chromophores upon oxidation. While primarily used to provide

uv-stability, hindered-amine light stabilizers (HALS) can be used as antioxidants when use temperatures are below 135°C. The primary benefit of HALS when used as an antioxidant is that unlike aromatic amines or hindered phenols, their oxidation products are colorless. Since they do not provide high temperature stability, they must be used in conjunction with phosphites or some other melt-processing stabilizer.

Secondary antioxidants generally fall into two classes: the organophosphites and thioesters. Organophosphites are typically trivalent arylphosphites which react with hydroperoxides in the polymer to generate a pentavalent phosphate and a nonreactive alcohol. Phosphites are effective at the high temperatures used in polymer processing but do not provide any stabilization during end- use. As such they are nearly always used with hindered phenols in practical applications. Trisnonylphenylphosphite [26523-78-4] is commonly used but is slowly being replaced by more complex arylphosphites with improved hydrolytic stability. Typical use levels are in the range of 500–1500 ppm. Ciba (Irgafos), GE Specialty Chemicals (Ultranox), and Clariant (Sandostab) are major suppliers. Thioesters are derivatives of 2,2′-thiobispropionic acid [5811-50-7], the most common being the lauryl esters, dilaurylthiodipropionate [128-28-4], and stearyl esters, distearylthiodipropionate [693-36-7]. In contast to the arylphosphites, thioesters are active at the lower end-use temperature range 125–150°C and are often used in combination with hindered phenols to stabilize polyolefins for under-the-hood applications. They are not active as melt-processing stabilizers. The primary drawback of thioesters is poor organoleptic properties, which limit their use in food-contact applications. Typical use levels are in the range of 1.0–1.5%. Cytec (Cyanox) and Crompton (Argus) are major suppliers in North America.

Newer developments (17) have focused on higher performing stabilizers which can be used at low levels with enhanced ancillary properties such as low color and odor. Dialkylhydroxylamines used in combination with HALS provide an excellent, low color stabilization system for PP fibers. Arylbenzofuranones have been shown to boost the performance of traditional hindered phenol/phosphite stabilization systems at use levels of 150 ppm.

Antistats. As a result of their low electrical conductivity (surface resistivity in the order of $10^{15} - 10^{17}$ Ω/sq), plastics are known for their ability to accumulate electrostatic charges. The static charge can be generated during processing, transportation, handling, or final use, and typically occurs because of friction between the plastic and another material. The build up of static charge leads to a number of undesirable properties such as dust/dirt buildup, solids buildup on walls of plastic containers during filling, clinging effects during fabrication or conversion of films, destruction of electronic parts packaged in plastic materials, and ignition of vapors or particulates. A number of approaches have been developed to address these problems including topically applied antistatic additives, carbon black and other conductive fillers, intrinsically conductive polymers, and the classical migratory additives such as ethoxylated amines and glycerol monostearates (18). The total market for antistats in North America is estimated to be $30 million. Polyolefins, styrenics, and PVC consume the majority of Antistatic Agents.

For nondurable applications, topical, external antistats can be applied to the finished plastic article through dipping or spraying of the part. The most

common type is the quaternary ammonium salts or "quats," which are typically applied as a water or alcohol solution. Since these materials are easily removed during handling or use, they are only effective for relatively short duration. For more durable applications, internal antistats added during compounding have been developed. The classical systems have a lipophilic tail and a hydrophobic head which migrates to the polymer surface to form a moisture-absorbing layer allowing for static dissipation. These systems rely on migration of the additive and sufficient humidity to form the moisture layer. The most common type of migratory antistat is the nonionics, essentially surfactants. This class is dominated by the ethoxylated fatty alkylamines and the ethoxylated alkylamides. These antistats are effective at lower loadings (<2%), require at least 50% relative humidity, have an induction time before being active, can ultimately be wiped or washed from the surface affecting permanence, and can have adverse surface effects such as plate-out and poor printability. To achieve the optimum blend of performance characteristics (permanence vs fast induction) blends of fast and slow migrators are typically used. Key suppliers of migratory antistats in North America are Ciba SC (Atmer), Akzo (Armostat), and Crompton (Kemamine).

In order to improve on the performance of the classical migratory antistats with respect to permanence and humidity sensitivity, a number of newer approaches have been developed. These include hydrophilic polymers, inherently conductive polymers, and conductive fillers. The most common ICPs are based on polyaniline, a highly conjugated polymer which is converted to a cationic salt with an organic acid. The relatively high cost has relegated these materials to niche applications. Fillers such as carbon black and nickel-coated graphite have good permanence but can affect mechanical properties and are highly colored. Finally, the hydrophilic polymers are the most rapidly growing of the permanent technologies. These are based typically on polyether/polyamide block copolymers and develop a conductive network when used at 10–30% loadings. These types of permanent antistats are available from Atofina (Pebax) and Ciba (Irgastat). Typical applications are in business machines such as fax and copier parts, typically HIPS and ABS (see ANTISTATIC AGENTS).

Flame Retardants. Added to plastics to inhibit ignition and retard the spread of flame, mechanistically, flame retardants (FRs) can be categorized as one of the following (19,20):

(1) **Char formers:**

Typically phosphorus-based organic compounds which when burned provide a physical and insulating barrier between the flame and the fuel or polymer

(2) **Heat absorbers:**

such as ATH or magnesium hydroxide which decompose at high temperature to generate water which in turn removes heat from the system through evaporation. Additionally they form glassy oxide barrier layers.

(3) **Radical sources:**

typically brominated or chlorinated hydrocarbons; they act by interfering with the radical-chain mechanism occurring in the gas phase. High energy hydroxyl and oxygen radicals formed during the chain-branching phase of combustion are trapped in the gas phase and replaced by much lower energy halogen radicals.

(4) **Antimony synergists:**

antimony trioxide [1309-64-4] which shows no FR activity on its own, synergizes with halogen-containing compounds through the formation of antimony trichloride.

By chemical class, FRs can be categorized as follows.

Brominated Hydrocarbons. Accounting for the highest dollar value, these consist of additives such as decabromodiphenyloxide [1163-19-5] and tetrabromobishphenol A [79-94-7] and derivatives. These products are used in engineering resins primarily (HIPS, ABS, and PC) for the business machine market. Typically they are used with antimony oxide [1309-64-4] as a synergist in a ratio of 3:1 respectively. Major suppliers of brominated FRs are Great Lakes Chemical Co. (GLCC), Albemarle (Saytex), and Dead Sea Bromine.

Chlorinated Hydrocarbons. The chlorinated paraffins are used as FRs/plasticizers for PVC, in PUR foams, and in certain elastomeric materials. Dover Chemical (Chlorez) is a key supplier. Dechlorane [2385-85-5] (Occidental) has its main application in polyolefin wire and cable jacketing. A reactive type, chlorendic acid and anhydride chlorendic [115-28-6] (Occidental) is used primarily in unsaturated polyester. Typically the chlorinated compounds can also be used with antimony synergists.

Phosphate Esters. The phosphate esters can be subdivided into halogenated and non-halogenated versions. Halogenated phosphate esters are used almost exclusively in PUR foams. Rhodia (Antiblaze) and Akzo Nobel (Fyrol) are key suppliers. The non-halogenated phosphate esters are primarily aryl esters and are used in engineering plastics. They are widely used in lubricants and as plasticizers in PVC. Rhodia, GLCC, and Akzo Nobel are the key producers.

Antimony. Antimony trioxide is the primary product but sodium antimonate and antimony pentoxide are also used to a minor extent. Antimony compounds are used as synergists with halogens, with GLCC (Anzon) and Occidental (Laurel) as the major producers.

Aluminum Trihydrate. Since aluminum trihydrate (ATH) [21645-51-2] begins to decompose at relatively low temperature, it can only be used in polymers which can be processed at temperatures not exceeding 200°C for long periods of time (polyolefins, acrylics, unsaturated phosphate esters, and PVC. When higher temperature processing is required, magnesium hydroxide can be substituted. It is used at very high loading levels (60 wt% or greater). These high loadings can

have a detrimental effect on physical properties. Major producers are Alcoa, Alcan, and Martinswerke (Lonza).

FRs are a greater than $2 billion global business (1), with bromine-based products accounting for nearly half of the value, followed by phosphate esters.

Heat Stabilizers. Chlorinated polymers, primarily PVC, decompose during processing to liberate HCl via dehyrochlorination reactions. The liberated HCl catalyzes the dehydrochlorination leading to rapid discoloration, embrittlement, and loss of mechanical properties. Primary Heat Stabilizers act by trapping the liberated HCl and also by reacting with labile chlorines on the polymer chain formed during polymerization (eg, allylic chlorines) (21). There are three major types of primary heat stabilizers: lead compounds, mixed metal salts, and organotins. Major producers in North America include Crompton/Witco (Mark), AtoFina (Thermolite), Rohm & Haas/Morton (Advastab), Ferro (Synpron, Thermcheck), Akcros (Akcrostab), and Baerlocher (Baerostab). The total market in North America is 110,000 tons or $500 million. Globally the heat stabilizer market is valued at $1.8 billion and 500,000 t (1).

Lead Compounds. These may be either organic or inorganic with dibasic lead stearates and phthalates, tribasic lead sulfate, and dibasic lead phosphite and carbonate as common examples. Their primary usage is in wire and cable insulation because of their nonconductive properties due to the water insolubility of the lead chloride which is produced during thermal processing. Once extensively used in a wide variety of applications, they have largely been replaced by mixed metals and tins because of intense regulatory pressure. Only in wire and cable have lead compounds persisted since no suitable technical replacement is available despite significant R&D activity. The major producer in North America is the Hammond Group (Halstab).

Mixed Metal Salts (or Soaps). These consist of Ba/Cd salts (once the most widely used because of their effectiveness but now declining owing to regulatory pressure), Ba/Zn, and Ca/Zn salts. The efficacy of these "mixed metal salts" as thermal stabilizers follows that order. Mainly used in flexible or semirigid PVC, they are available in solid and liquid versions. Solids are typically salts of fatty acids such as stearates and laurates while liquid versions are octoate, phenolate, and neodecanoate salts. Mixed metal salts are almost always used in the presence of secondary stabilizers such as organophosphites, epoxies (eg, epoxidized soyabean oil), and β-diketones. This is particularly the case for the less active Ba and Ca/Zn. The ratio of metal salt to secondary stabilizer is typically 4:1. Mixed metal salts or soaps are available from Akros, Baerlocher, Ferro, and Rohm & Haas in North America.

Organotins. Primarily used in rigid PVC, the most widely used types are the dibutyl and octyltin mercaptides. While excellent stabilizers, they suffer from odor, staining, and poor uv-stability. Sulfur-free organotins which include the dibutyltin maleates are useful in applications requiring good weatherability such as extruded siding and profile. Methyl tins are the most active (particularly at high temperature and shear) and are favored from a toxicity and regulatory perspective. Crompton, AtoFina, and Rohm & Haas are the leading suppliers in North America.

Light Stabilizers. Most polymers degrade as a result of photo-induced oxidation so that for durable applications requiring weatherability it is necessary

to add light stabilizers. Ultraviolet induced degradation results in the loss of both aesthetic (color, gloss, clarity) as well as mechanical properties. The uv-portion of sunlight has sufficient energy to break chemical bonds in polymers resulting in the formation of free radicals. Light stabilizers interfere with these processes, slowing the harmful effects of uv-radiation (16,22,23).

Light stabilizers fall into three general classes: ultraviolet absorbers (UVAs), nickel quenchers, and HALS. While the largest consumption of light stabilizers is in polyolefins, there are significant usages in engineering resins, styrenics, PURs, and in coatings. HALS account for approximately half of the sales of light stabilizers and has approximately double the growth rates of UVAs in total. The global light stabilizer market is valued at $530 million and is growing at 6–7%/year (1).

UVAs are organic molecules that preferentially absorb uv-radiation and dissipate it in the form of heat. They are transparent in the visible region so as to not impart color and are highly photostable in order to provide long-term protection. UVAs fall into two major classes: 2-hydroxy-4-alkoxybenzophenones and substituted 2-hydroxybenzotriazoles. A wide variety of modifications have been made to these basic types to provide for enhanced ancillary properties such as reduced volatility, better polymer compatibility, and enhanced photostability. Benzophenones are widely used in PVC and polyolefins. Because of their superior performance, benzotriazoles are used in high performance resins such as PC, nylon, and acrylics. Other minor types include benzoates, salicylates, and diphenyl acrylates. More recently a high performance class based on 2-(2-hydroxyphenyl)-1,3,5-triazines have been introduced. These products have superior inherent photostability to the standard types making them suitable for applications such as automotive and construction having high weatherability requirements. Ciba Specialty Chemicals (Tinuvin, Chimassorb), Cytec (Cysasorb), and Great Lakes Chemcal (Lowilite) are the major suppliers of UVAs in North America. UVAs are added to polymers at levels of 0.2–0.5%.

Nickel quenchers such as nickel dibutyldithiocarbamate [13927-77-0] and 2,2′-thiobis-(4-octylphenolato)-*n*-butylamine nickel (II) [14516-71-3] deactivate excited chromophores which act as sensitizers for the photolysis of hydroperoxides (24). Once widely used in pp fibers, they have been replaced almost entirely by HALS. Because of their high resistance to pesticides used in greenhouses, these products are widely used in PE agrofilm applications. Their usage is gradually declining, however, because of concerns over the toxicity of nickel. Cytec remains the leading producer of nickel quenchers.

The other important light stabilizers, the HALS, are based on substituted 2,2,4,4-tetramethylpiperidines. During initial light exposure, HALS are converted to nitroxyl radicals which are effective scavengers of the free radicals formed during weathering. A wide range of variations of HALS are available to optimize volatility and migration and to minimize interaction with other additives. For example, high molecular weight HALS have been developed to minimize volatility from high surface area PP fibers. Recent developments have centered on modifying the piperidine nitrogen with alkyl or alkoxy groups to reduce basicity, and hence interaction with other additives such as FRs, thioester antioxidants, and environmental agents such as pesticides and acid rain. HALS major application is in polyolefins but they are also used extensively in styrenics and acrylics. Typical use levels are from 0.15 to 0.3%. Ciba Specialty Chemicals and Cytec are the major

producers in North America, with Great Lakes Chemical and Clariant (Sanduvor) significant on a global basis.

Because HALS and UVAs function via different mechanisms, they are often used together for synergistic performance and optimum weatherability.

Processing Aids

Lubricants. Lubricants are added to polymers during processing to improve their flow characteristics. While primarily acting as processing aids to reduce energy consumption and enhance the surface properties of extruded articles, they provide additional benefits in terms of mold release, improved antistatic properties, and better pigment dispersion. These additives act either "internally" as friction modifiers between polymer chains to decrease melt viscosity or "externally" by coating or treating the metal surfaces of the processing equipment, thereby reducing the friction at the polymer–metal interface. A wide variety of chemical classes of lubricants are available, including metal stearates, fatty amides, fatty acid and glyceral esters, waxes of various types, and flouropolymers. Depending on the application, many of these exhibit both external and internal lubricating properties (25,26).

Metal stearates, including predominately calcium stearate as well as zinc stearate, are the most widely used lubricants. In PVC calendering and extrusion, the stearates provide heat stabilizing effects as well as act as an internal lubricant. In polyolefins, stearates act as external lubricants as well as deactivators of catalyst residues. Ferro (Synpro, Petrac), Baerlocher (Hydense), and Crompton (Witco) are the major producers of metal stearates in North America.

Fatty amides provide multifunctionality, acting both as external lubricants and as slip agents and antiblocks. Primary amides such as oleamide [301-02-0], erucamide [112-84-5], and stearamide [1309-64-4] are primarily used as slip and mold-release agents for polyolefins. The higher molecular weight ethylene bisstearamide is used as a lubricant in both rigid and flexible PVC and in engineering polymers such as polyacetal, nylon, and ABS. Croda (Crodamide) is a major supplier of amides in North Amercia.

Fatty alcohols are used primarily in rigid PVC where their excellent compatibility makes them useful where clarity is important Fatty acids, represented by stearic acid, find some use in calendered and blow-molded PVC. Fatty esters, such as glycerolmonostearate [31566-31-1], function as either internal or external lubricants depending on molecular weight (compatibility). Again, PVC is the primary substrate but PC, PS, and PUR can be processed with these materials.

Polyethylene and paraffin waxes are used widely as external lubricants for PVC because of their high level of incompatibility. They are often used in combination with calcium stearate in unplasticized PVC pipe formulations. Honeywell (A-C Wax), Petrolite (Baker Petrolite), and Clariant (Hoechst Wax) are leading suppliers of waxes.

Fluoropolymers, a small but high value type of external lubricant/processing aid, are based on tetrafluoroethylene (27). These materials form monomolecular layers on metal surfaces and are primarily used in PE-blown film applications to

reduce "shark-skin" and gels. These materials are growing rapidly as the use of metallocene PE resins increases, which is more difficult to process than conventional resins. DuPont Dow (Viton), 3M/Dyneon (Dynamar), and AtoFina (Kynar) supply these types of lubricants.

Slip/Antiblock Agents. Slips and antiblocks are used primarly in PE films to modify the inherent self-adhesion which causes the film layers to stick together. In the case of antiblocks, inorganic particles such as silk, talc, and diatomite (processed diatomaceous earth) are added at the compounding step to form a roughness at the surface which prevents the films from sticking (28). Slip agents, primarily migratory fatty acid amides, are added to provide a lubricity or reduced coefficient of friction at the surface, allowing a plastic film to slide over itself or another plastic (29). Erucamide [112-84-5], a C-22 fatty amide, is the most widely used slip agent because of its slower migration rate and better thermal stability than the stearamides and oleamides, accounting for over half of the total consumption. In North America, the major suppliers of slip agents are Akzo Nobel (Armoslip), Crompton (Kemamide), Croda (Crodamide), and Ciba Specialty Chemicals (Atmer SA). In polyolefin films a combination of slip and antiblock agents are used to impart desirable surface properties in such consumer applications as packaging and garbage and other bags.

ADHESION

Definition of Adhesion and Adhesive Joint

Adhesion is the attraction between two different condensed phases when they are in contact. Attractive forces range in magnitude from strong chemical bonds (≈25–100 kcal/mol) to much weaker physical forces, known as van der Waals interactions. An adhesive joint is a structure usually consisting of two bodies (adherends, substrates), which are held together by adhesion. The bodies may be directly bonded to each other, or coupled by an adhesive layer. The science of adhesion is multidisciplinary and can be divided into two parts: one dealing with surfaces and interfaces and the other with the fracture of adhesive joints. The former is largely concerned with bond formation and predicting attractive forces and energies, whereas the latter deals with test methods to measure joint strength.

One of the most important findings in adhesion science is that the *mechanical* energy required to fracture an adhesive joint (so-called *work of detachment* or *interfacial fracture energy*) is larger than the *intrinsic* interaction energy holding the joint together. The latter is a reversible quantity—equal to the *minimum* energy needed to disrupt an interface or the energy gained upon forming it. However, in general, the fracture of an adhesive joint is not a reversible process. When a joint is loaded, only some of the input mechanical energy is available (stored) to disrupt the interface and the rest is converted (dissipated) into increased molecular motion (heat). Additional input energy is required to attain sufficient elastic energy at the interface to disrupt it. Thus, bulk energy dissipation augments joint strength and causes the mechanical work of detachment to be larger than the interfacial interaction energy.

To judge the intrinsic adhesion at an interface by the measured fracture energy may be misleading. For example, if an adhesive is modified by adding fillers

Encyclopedia of Polymer Science and Technology. Copyright John Wiley & Sons, Inc. All rights reserved.

or tackifiers, and the modified adhesive gives a higher fracture energy than the unmodified one, it is tempting to conclude that intrinsic adhesion has been enhanced. But, by adding filler, the bulk properties of the adhesive are also modified and the improved performance may reflect merely a higher dissipation of mechanical energy within the adhesive layer.

Adhesion is important in many technologies (eg, adhesives, coatings, composites) and usually involves bringing solid and liquid surfaces, or two liquid surfaces, into contact. This article begins by considering characteristics of solid and liquid surfaces and then proceeds to discuss their contact to form interfaces and interphases. Next, the various types of adhesive bonds are discussed as well as the thermodynamics of adhesion. This is followed by a section on surface treatments to enhance the bondability of plastics and metals, and one dealing with the special case of elastomer tack. Two final parts deal with test methods to measure joint strengths and a discussion of the relationship between joint fracture energy and intrinsic adhesion.

Surfaces

Solids. Nearly all solid surfaces are rough at dimensions of a few nanometers. They may contain asperities, pores, projections, depressions, etc. In addition, surface regions of solids generally have different compositions than their bulk. All metals that have been exposed to the atmosphere have an oxide layer on them (1). The thickness of the oxide depends on the nature of the metal and the environment. Some metals, eg, aluminum and titanium, form thin, tough, tenaciously adhering oxides, which passivate the surface and prevent continued oxidation. Others, like iron, have oxides which continue to grow, especially in a humid environment.

In practice, metal oxides are covered with organic molecules and water adsorbed from the atmosphere (2). Other common sources of surface contamination are residual processing oils and lubricants. Another source of surface species is from the bulk. For example, iron containing only 10 ppm of carbon has been shown to form a carbon-rich structure on its surface upon heating or straining. In addition to carbon, other species, including sulfur, nitrogen, boron, and oxygen, have been shown to diffuse from the interior of metals to their surfaces (1).

It is also common for polymeric compounds to form surface regions with compositions different from the bulk material, by selective diffusion of components. This process is termed *blooming* when the surface component is solid, and *bleeding* if it is liquid. Sulfur and fatty acid blooms can inhibit adhesion in rubber laminates (3). Laser desorption mass spectroscopy has been employed to identify surface species on vulcanized rubber (4). X-ray scattering methods for the study of polymer surfaces and interfaces have been reviewed (5). Other surface analysis techniques commonly used with polymers include attenuated total reflectance (6–8), electron microprobe (9), Auger electron spectroscopy (10), x-ray photoelectron spectroscopy (11), and scanning probe microscopic methods (12). Overviews on polymer surface analysis have been published (13,14).

Liquids. Consider a pool of a simple, pure, low molecular weight liquid. Its molecules are mobile and diffusing about. Molecules in the bulk of the liquid interact with other molecules in all directions, while those at the surface

experience a net attraction tending to pull them toward the interior. This causes surface molecules, on average, to be at greater spacing than bulk molecules and possess greater free energy. This gives rise to a surface tension, as the liquid behaves as if it has an elastic skin. Moreover, since nature seeks to minimize free energy, a volume of liquid in the absence of other forces takes a spherical shape to minimize the number of surface molecules. At constant temperature and pressure, the increase in Gibbs free energy accompanying a unit area increase in surface area of a liquid is, by definition, its surface tension γ. Alternatively, γ may be viewed as the force per unit length, tending to contract the surface and cause a liquid to resist spreading.

Real adhesive liquids are often complex mixtures, and, like solids, may have surface compositions different from their bulk. In addition, practical adhesive liquids are often reactive and/or polymeric.

Interfaces, Interphases, and Weak Boundary Layers

Schematically, Figure 1 shows two "real" materials, say A and B, that are composed of molecular components a_i and b_i, respectively. These are located in the bulk (a_{ib}, b_{ib}), at the surface (a_{is}, b_{is}), and/or within the near surface region (a_{in}, b_{in}). Upon contacting A and B under ambient conditions, the *interface*, defined as the locus of interactions between the two materials, initially involves the surface species on each and any entrapped air. In general, the interface will not be continuous at first. Entrapped air and surface rugosity prevent immediate, full molecular contact, although applied pressure can speed interface formation. With time, depending on the particular system, the region between the two bulk materials, the so-called *interphase*, changes. Along with increased molecular contact, diffusion of surface and near-surface species can change the composition and structure of the interface and interphase. For example, the interface may thicken by interdiffusion and chemical reactions may occur. (Specific examples are considered later.) If the interphase contains a mechanically weak layer (weak boundary layer), it may be the site of fracture when the adhesive joint is loaded. Weak boundary layers (WBLs) may originate on or near the surface of materials before they are contacted, or they may develop *in situ* during the dynamic conditions of contact.

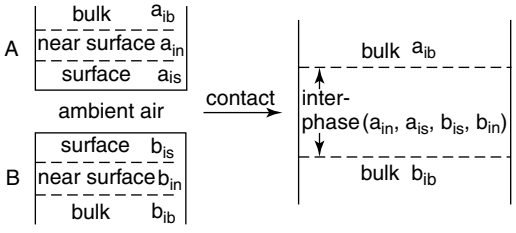

Fig. 1. Two hypothetical "real" materials A and B: (**a**) prior to contact and (**b**) after contact. Surface and near surface components form the interphase, which contains the interface(s) as well as (gradient) compositions and structures different from the bulk materials. In general, the interphase is quite complex. See text for further description.

To provide a strong joint, the *structural* components, ie, those responsible for the cohesive strengths of A and B, must interact well at the final interface, and a WBL must not be present. WBLs may be removed prior to bonding or be disrupted by diffusion during bonding.

After an adhesive contacts a solid substrate, it is normally necessary to convert it to a hardened state (setting) so that the joint will be capable of supporting stress. However, since setting severely reduces the molecular mobility required to achieve true contact and good bond formation, it should not take place too quickly. Many weak adhesive joints can be traced to rapid setting before sufficient interface formation. Setting of adhesives can occur by physical or chemical means. In order to minimize internal stresses in a joint, there should not be a large change in volume of the adhesive during solidification, and the thermal expansion coefficients of the adhesive and adherends should be similar. This is especially important when the solid adhesive has a high modulus. Furthermore, joints with plane interfaces have been suggested (15) to be more sensitive to adhesive shrinkage than are joints made with complex, high surface area adherends. Solvent-based adhesives experience the most shrinkage during setting compared to those which harden by cooling (hot melt) or by chemical reaction (usually thermosets). The fact that epoxy resins shrink only about 3% upon setting is one reason for their good performance. Another advantage of epoxy solidification reactions compared to many other condensation polymerizations is that no small molecules, eg, water, which can interfere with bonding, are created during setting. Polyurethane reactions are also favorable in this regard.

Some inorganic substances adhere exceptionally well because they expand upon freezing. For example, ice will adhere to almost any surface, even those not wetted well by water (16). When water freezes in a depression in a solid surface, expansion causes it to lock against the sides of the depression and form a strong joint. Attempts (17,18) have been made to develop organic adhesives, based on ring opening polymerizations, that expand upon setting.

Bond Classification

When two different materials are contacted, a complete description of the interaction between them requires understanding the number, type, and distribution of bonds formed. This depends on surface topography and the extent of molecular mixing between the materials. In the following subsections, we classify various types of adhesive bonds. It is beyond the intent of this article to consider all the detailed possibilities, which become apparent from the previous discussion of interface and interphase complexity. Rather, we primarily discuss relatively simple systems, from which general principles may be gleaned.

Adsorption on Planar Substrates. The simplest type of adhesive bond occurs when a liquid is contacted with a planar solid with which it is totally immiscible and into which it cannot diffuse. Bonding is limited to physical and/or chemical adsorption at specific sites on the substrate surface. A sharp and planar interface is formed. This is the usual situation when an organic adhesive adheres to a very smooth inorganic substrate. The time-dependent process during which interfacial bonds form is called *wetting*. In general, it involves an increase in the

number of interactions (more actual contact area) and/or a change in the type of interactions.

Surface species can be a hindrance to wetting. Many polar substrates such as glasses or metals, which have been exposed to ambient air, have several molecular layers of adsorbed moisture on them. Wetting is expected to be speeded if the liquid readily solubilizes surface moisture. Perhaps this is one role of polar groups in a typical adhesive. Certainly an adhesive that is completely incapable of displacing or solubilizing surface moisture (or other surface contaminants) would find it difficult, if not impossible, to attain molecular contact with the actual substrate. Furthermore, air entrapped during contact may slow wetting.

Adsorption on Substrates with Complex Surface Topography. As in the previous case, the substrate is completely immiscible with the liquid adhesive, so that adhesive–substrate interactions are limited to adsorption at surface sites. However, the substrate surface topography is now rough and complex. The interface is still two-dimensional and sharp, but now has the complex shape of the substrate surface. Because of pores, depressions, and/or asperities, there are many more surface sites available to interact with an adhesive as compared to a planar substrate. Thus, if the adhesive has sufficient mobility and the wetting forces are high enough, the extent of adhesion may be increased by surface roughening. On the other hand, very viscous adhesives may form relatively few interactions with roughened substrates, especially if the (wetting) time from adhesive application to solidification (setting) is short.

Another consequence of a complex topography is mechanical interlocking between the adhesive and substrate. This is analogous to fastening with a "hook" and "eye" or with Velcro®, where a resistance to separation is present without intrinsic adhesion. Of course, joint strength is improved if both mechanical interlocking and intrinsic adhesion are operative. Mechanical interlocking plays an important role in bonding wood, textiles, and paper because of their finely divided and porous nature. In addition, many metals and plastics are etched before bonding so that the adhesive can penetrate and lock into them. When mechanical interlocking is substantial, the region around the interface forms a composite interlayer within the interphase.

Interdiffusion. When two polymers are contacted, the interface will not be two-dimensional, but rather will become a region (volume) consisting of interdiffused molecules from each material (19,20). The thickness of this interlayer depends on the thermodynamic compatibility of the materials, the contact time, and molecular diffusion rates. Molecular interdiffusion is quite different from mechanical interlocking. The former is analogous to a homogeneous solution and involves interpenetration at the molecular level, whereas in the latter case, analogous to a heterogeneous mixture, the bulk adhesive flows into and around surface features of the substrate that are much larger than molecules. Interdiffusion increases the number of interactions among dissimilar chains, and, if the interdiffused distance is sufficient, interchain entanglements develop. Reviews on polymer interdiffusion have been written (21,22).

When two incompatible polymeric melts A and B are contacted, the equilibrium interface width a_I is dependent on the Flory–Huggins interaction parameter χ and the molecular weights of each polymer. A mean field approach has been used (23,24) to predict that a_I is given by

$$a_I = \frac{2b}{\sqrt{\chi \cdot c}} \frac{1}{\sqrt{1 - 2\ln 2\left(\frac{1}{\chi N_A} + \frac{1}{\chi N_B}\right)}} \quad (1)$$

where b is the statistical segment chain length, and N_A and N_B are the degrees of polymerization of A and B, respectively. The parameter $c = 6$, when a_I is small compared to the chain radius of gyration, R_g, while $c = 9$ in the limit $a_I \gg R_g$ (25). Neutron reflectivity experiments (26,27) have established the validity of Helfand's mean field approach.

When two pieces of the same material are contacted, their bonding is termed *autohesion* (or *self-bonding*) (19). This has also been called *healing* (28). Using reptation theory (29), chain interdiffusion across the original contact junction has been analyzed. The crossing density, which is the number of times the interdiffusing molecules intersect the contact plane per unit area after a time t, has been calculated (30,31) as has the average interpenetration distance (28,32–34). Both measures of healing are predicted to be proportional to $t^{1/2}$. Furthermore, for polybutadienes with different vinyl contents it has been shown that the tensile strengths of autohesion increase linearly with $t^{1/2}$ (see Fig. 2) before reaching plateau values (35). Further discussion of autohesion is delayed until a later section, in which pressure-sensitive tack and time/temperature effects are also considered.

Effect of Interdiffusion on Joint Strength. The joint strength of a thermodynamically compatible adherend pair [poly(methyl methacrylate) and poly(vinyl chloride)] has been found to be quite high, while that for an incompatible pair [poly(butyl methacrylate) and poly(vinyl chloride)] was low (36). Furthermore, using electron microscopy, it was shown that the interfacial thickness for the compatible pair was about 0.1 μm, whereas the incompatible pair formed a much sharper interface, too narrow to be determined experimentally. In principle,

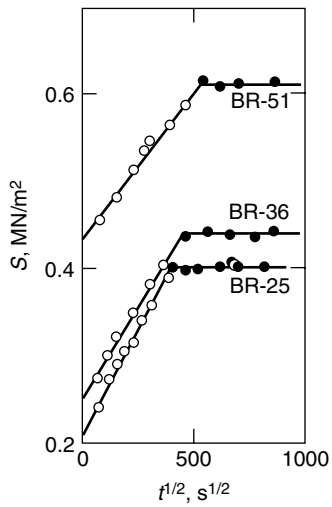

Fig. 2. Development of tensile strength S of autohesion with time of contact for different types of polybutadiene (35) ($MN/m^2 = MPa$). To convert MN/m^2 to psi, multiply by 145.

compatible polymer pairs will form an interface thickness that will continue to increase as long as the adherend molecules remain mobile. On the other hand, the equilibrium width of the interface between incompatible polymers is typically in the range of 2–50 nm (37).

The effect of interdiffusion on the autohesion of rubbery adherends has been studied using a peeling geometry (38). Two layers, each composed of a butyl rubber network and miscible, unattached (non-network) polyisobutylene (PIB) chains, were contacted for 14 h at 60°C. The PIB chains were free to diffuse through the butyl network and across the contact junction. Joints were peeled apart over a wide range of rates and temperatures, and peel energies G were superposed to form a mastercurve covering eight decades of reduced rate. At intermediate peel rates, G was about 10 times the value obtained for a butyl network control containing no PIB. However, at both sufficiently low and high reduced rates, autohesion was little affected by PIB. The behavior at low rates was attributed to ready disentanglement of interdiffused PIB molecules from the network, while, at high rates, it was proposed that interdiffused molecules had little influence on joint strength, because they broke during separation rather than disentangling. The authors hypothesized that disentanglement of interdiffused PIB chains takes place at intermediate rates, with substantial viscous energy expended in the process.

Ellipsometry (39) has been used to determine the interface thickness between layers of poly(methyl methacrylate) (PMMA) and poly(styrene-*co*-acrylonitrile) (SAN) contacted at 130°C. PMMA and SAN are miscible when the SAN contains 9.5–33 wt% acrylonitrile, but they are immiscible outside this composition range. Figure 3 shows interfacial thicknesses for both miscible and immiscible cases. The interface thickness for the miscible pair grows linearly with $t^{1/2}$. On the other hand, the interfacial thickness for the immiscible pair quickly reaches a value of about 20 nm and remains constant even after contacting for 12 h above T_g. Figure 4 shows tensile strengths of adhesion (normalized with respect to the tensile strength of the weaker SAN) for the compatible adherends plotted against the square root of the interface thickness. The data are linear and a surprisingly high

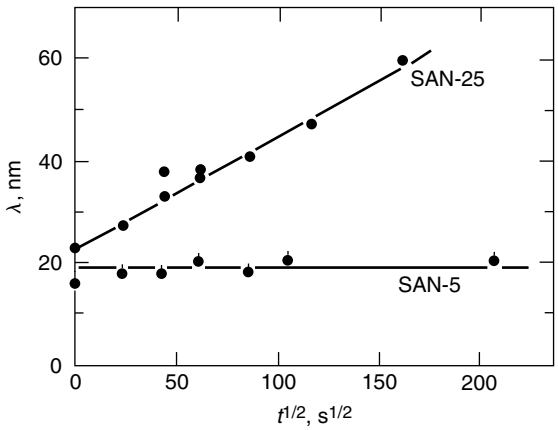

Fig. 3. Interface thickness after various contact times for miscible (PMMA/SAN-25) and immiscible (PMMA/SAN-5) pairs (39).

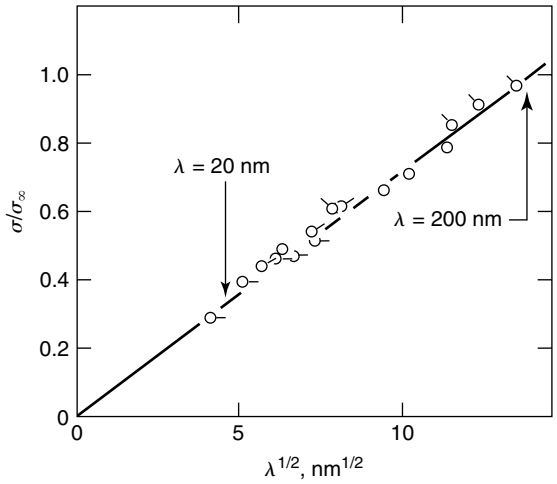

Fig. 4. Normalized strength of PMMA/SAN joints as a function of interface thickness (39).

interface width of about 200 nm is necessary for the joint strength to reach the tensile strength of the SAN.

Autohesion between two uncross-linked layers of polybutadiene has been studied (40). The self-diffusion coefficient was measured using small-angle neutron scattering, and T-peel specimens were used to determine joint strengths. The contact time required to reach the cohesive strength was 3 orders of magnitude greater than the time required for a diffusion distance equal to the chain radius of gyration. The authors speculated that low autohesion, even with significant interdiffusion, was due to different diffusion rates of branched and linear chains within the polybutadiene. Branched chains were proposed to impart increased bond strength, but have suppressed interdiffusion. Therefore, during the early stages of contact, the interdiffusion layer is rich in linear chains, resulting in lower strength. A much longer time is required for branched chains to interdiffuse and for the joint to obtain the full cohesive strength. There appears to be a difference in structure between bulk chains and the interdiffused layer during the initial stage of healing.

Forward recoil spectroscopy has been employed to determine interdiffusion widths for the autohesion of a polyimide film (41). In addition, fracture energies G were measured by T-peel testing. When a_I was less than 20 nm, G was so low ($<$10 J/m^2) that it was difficult to measure. At larger extents of interdiffusion, G increased linearly with a_I. Again, an unexpectedly large interdiffusion distance of at least 200 nm was required before complete healing was attained.

Adhesion between the nearly compatible pair, polystyrene and poly(*p*-methyl styrene), has been investigated (42). Variations in annealing temperature and molecular weight were used to change interface widths, which were measured by neutron reflectivity. Fracture energies, determined using double cantilever beam test-pieces, increased linearly from about 100 to 450 J/m^2 as a_I increased from 9 to 11 nm. The large, fourfold increase in G over this rather narrow range of a_I was

attributed to increased energy dissipation with the onset of sufficient interchain entanglements to induce crazing.

Bonding Involving Diffusion and Chemical Reaction. A number of technologically important adhesive bonds are formed by contacting materials which have components that diffuse to the interfacial region and chemically react. The strength of the reaction product and its interaction with each material controls joint strength. The generality and success of the approach will be demonstrated by discussing industrially important examples involving polymer/polymer, polymer/inorganic glass, and polymer/metal bonding.

Nitrile Rubber/Polypropylene. Nitrile rubber (NBR), a copolymer of butadiene and acrylonitrile, is quite incompatible with polypropylene (PP) and forms a very weak bond when contacted with it. As a result, a blend of these two polymers, prepared by melt mixing, produces a heterogeneous material that processes poorly and has very low strength and extensibility. Adhesion between the phases can be increased by adding to the blend a small amount of two reactive components: a telechelic, amine-functionalized NBR oligomer and an anhydride-terminated PP (43). These materials react *in situ* to form an NBR/PP block copolymer, which is thought to locate at the interface and increase bonding between the NBR and PP phases. The modified blend processes easily and has excellent strength. A similar methodology has been used to promote bonding between nitrile rubber and butyl rubber (44). An analogue of this approach is interfacial polymerization (45), in which immiscible phases (aqueous and organic) containing reactive components (diamine and diacid chloride) are contacted and polymer forms at the interface (so-called nylon-rope trick). Similarly, immiscible polymers may contain certain reactive components which can diffuse to the interface and form a product that increases adhesion between phases.

Adhesion between immiscible polymers has also been increased by using already prepared block or graft copolymers composed of segments of each polymer. In one approach (46), the copolymer is added to one or both of the adherends before contacting them. However, here, the copolymer may itself phase separate *away* from the interface. In another approach (47), the copolymer is spun-coated sparingly on one of the adherends to assure its presence at the interface.

In general, a third component, "technological compatibilizer," may couple phases in different ways. The compatibilizer may

(1) phase separate, at least in part, as a distinct layer *between* the two phases. In this case, the cohesive strength of the layer and its interaction with each phase are important;
(2) locate at the interface and form a "monolayer" or less coverage. In this case, the degree to which the compatibilizer alters the bonding between phases will depend on its concentration at the interface and the extent to which it is entangled and/or linked to each phase;
(3) dissolve in each phase and increase the thermodynamic compatibility between the phases, thereby causing the interface to thicken.

The compatibilizer may not be *directly* involved in improving interphase bonding, but rather cause the molecules of each phase to interdiffuse more

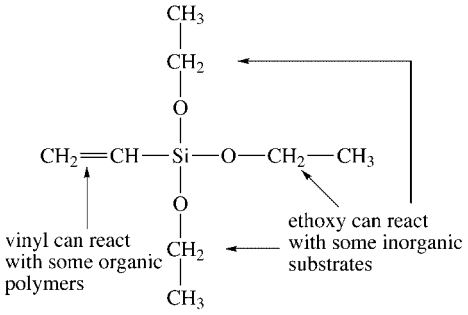

Fig. 5. Vinyltriethoxysilane coupling agent.

extensively. (Analogous behavior is known with small molecules. For example, an immiscible mixture of water and benzene forms one phase upon the addition of methanol.) This mechanism may explain the increased adhesive tack and cured adhesion of dissimilar elastomers containing certain tackifier resins and so-called bonding agents.

Silane Coupling Agents. Silane coupling agents are very effective in promoting the adhesion of various polymers to inorganic glasses and are widely used in composites as well as joined structures (48–50). Silanes may be directly applied to substrates or may be added to a polymer prior to bonding. In the latter case, the silane diffuses to the glass–polymer interface and reacts as discussed next.

Silane coupling agents have four functional groups as shown in Figure 5. The three alkyloxy groups undergo hydrolysis to become silanols, which are capable of reacting with glass or self-condensing to form a polysiloxane. The fourth functional group reacts with the polymer. Thus, an *in situ* polysiloxane layer forms between the glass and polymer and couples them together. Table 1 gives several types of silane coupling agents and some polymers commonly used with them.

Brass/Rubber. When rubber containing sulfur curatives is pressed into contact with brass (typical alloy ~65% copper, 35% zinc) and then vulcanized, copper diffuses to the brass surface and reacts with sulfur to form cuprous sulfide (51). This interlayer grows outward from the brass surface, strongly interlocking into the rubber phase (52,53). Again, diffusion to an interface and *in situ* reaction to form a "coupling" interlayer is employed to provide bonding. Joint strength can

Table 1. Silane Coupling Agents

Type	Formula	Used With
Vinyl triethoxysilane	$CH_2{=}CHSi(OCH_2CH_3)_3$	Cross-linked polyethylene, thermosetting polyester, diene elastomers
γ-Glycidoxypropyl trimethoxy silane	$CH_2OCHCH_2O(CH_2)_3Si(OCH_3)_3$	Epoxy, urethane, poly(vinyl chloride), phenolic
γ-Aminopropyl triethoxysilane	$NH_2CH_2CH_2CH_2Si(OCH_2CH_3)_3$	Epoxy, melamine, nylon, polycarbonate, polyimide
γ-Mercaptopropyl trimethoxysilane	$HSCH_2CH_2CH_2Si(OCH_3)_3$	Epichlorohydrin, urethane, polyvinylchloride

be very high, and, because of this, steel cords used to reinforce tires are brass-plated.

Thermodynamics of Adhesion

Contact Angle. The degree to which a liquid wets a solid is measured by the contact angle θ (Fig. 6). When $\theta = 0$, the liquid spreads freely over the surface and is said to completely wet it. This occurs when the molecular attraction between the liquid and solid molecules is greater than that between similar liquid molecules (54). Surface tensions are related to the contact angle by an expression from equilibrium considerations (55):

$$\gamma_{sv} = \gamma_{sl} + \gamma_{lv}\cos\theta \tag{2}$$

where γ_{sv} is the solid–vapor surface tension, γ_{sl} is the solid–liquid interfacial tension, and γ_{lv} is the liquid–vapor surface tension.

The surface tension γ_{sv} of a solid that has adsorbed a layer of vapor is generally less than that of the solid in vacuo γ_s and this reduction is termed the spreading pressure π_s:

$$\pi_s = \gamma_s - \gamma_{sv} \tag{3}$$

However, liquid surface tension is little affected by the vapor phase so that $\gamma_{lv} \approx \gamma_l$.

Whether or not a given liquid will wet a solid surface depends on the surface tension of both substances. The ability of a liquid to wet a solid is often described by the spreading coefficient S_{sl}:

$$S_{sl} = \gamma_{sv} - \gamma_{sl} - \gamma_{lv} \tag{4}$$

A large positive S_{sl} implies that a liquid will spontaneously wet the solid. A negative S_{sl} indicates incomplete wetting and $\theta > 0$.

A widely used method for determining γ_s was developed using contact angle measurements (56). A plot of $\cos\theta$ against surface tensions for a homologous series of liquids can be extrapolated to give a critical surface tension γ_c at which

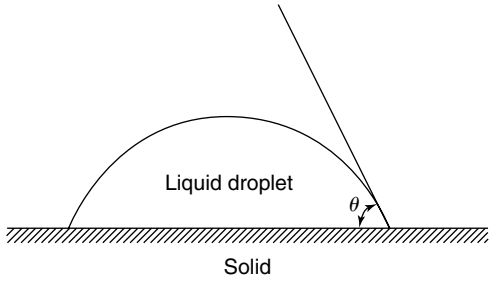

Fig. 6. Contact angle of a liquid droplet on a planar solid surface.

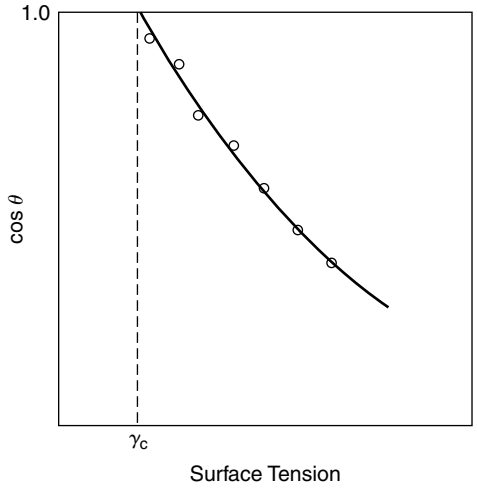

Fig. 7. Zisman plot for a particular solid surface and a homologous series of liquids.

cos $\theta = 1$; such a plot is shown in Figure 7. Any liquid with a surface tension less than γ_c completely wets the solid surface. γ_c has been taken as an approximate measure of γ_s. It should be noted, however, that the value of γ_c is generally dependent on the particular series of liquids used to determine it. A series of polar liquids, such as alcohols, will give a higher γ_c than a series, such as simple hydrocarbons, which interacts less strongly with the same surface (57).

Thermodynamic Work of Adhesion. If a liquid is placed on a solid surface with which it has no interaction, then the interfacial tension between them is simply the sum of the surface tensions of the liquid and the solid. However, in all real systems, there are at least van der Waals attractions between the molecules of the liquid and those of the solid. This interaction decreases the interfacial tension so that $\gamma_{sl} < \gamma_l + \gamma_s$. The extent of the decrease is a direct measure of the interfacial attraction, and is termed the thermodynamic work of adhesion W_a:

$$W_a = \gamma_l + \gamma_s - \gamma_{sl} \tag{5}$$

This expression, first given by Dupré (58), states that the reversible work W_a of separating a liquid and a solid in vacuo must be equal to the free energy change of the system. (In wetting phenomena, the surface free energies are given directly by the surface tensions.)

Another expression relates γ_{sl} to the individual surface tensions of the liquid and solid (59):

$$\gamma_{sl} = \gamma_s + \gamma_l - 2\phi^{(\gamma_s\gamma_l)}1/2 \tag{6}$$

The last term represents the reduction in interfacial tension owing to molecular attraction between the liquid and solid. The term ϕ is defined by

$$\phi = \frac{W_a}{(W_{cl}W_{cs})^{1/2}} \tag{7}$$

where W_{cl} and W_{cs} are the work of cohesion of the liquid and solid, respectively, ie, the thermodynamically reversible work required to create a unit area of new surface in each material. For simple interfaces, ϕ is approximately unity, but for systems in which there are different types of intermolecular force in the two substances, ϕ may be appreciably less than unity.

By combining equations (2),(3), and (6), an expression for γ_s is obtained:

$$\gamma_s = \frac{[\gamma_{lv}(1+\cos\theta)+\pi_s]^2}{4\phi^2\gamma_{lv}} \tag{8}$$

If $\pi_s \approx 0$, as has been suggested for high energy liquids on low energy surfaces (60,61) then equation (8) reduces to

$$\gamma_s = \frac{\gamma_{lv}(1+\cos\theta)^2}{4\phi^2} \tag{9}$$

From the preceding discussion, as $\theta \to 0$, then $\gamma_{1v} \to \gamma_c$ (Zisman plot). Substituting this condition into equation (9), it is found that

$$\gamma_c = \phi^2\gamma_s \tag{10}$$

Thus, γ_c is predicted to be approximately equal to γ_s only when $\phi \approx 1$, ie, for simple interfaces for which

$$\gamma_s = \frac{\gamma_{1v}(1+\cos\theta)^2}{4\phi^2}$$

When γ_s and γ_l have values appropriate to simple nonpolar substances, about 25 mJ/m^2, W_a is only about 50 mJ/m^2, or less. The work for detaching one adhering substance from another has been found to be much larger than this, in the range 1 J/m^2 to 10 kJ/m^2. Thus, other contributions to the mechanical strength, from dissipative processes within the joint, greatly outweigh the intrinsic adhesion. Nevertheless, dissipative contributions depend upon the intrinsic adhesion, and in some instances, they are directly proportional to its magnitude (62,63). If there is no affinity between the adherends, there is certainly no mechanical strength of an adhesive bond.

Surface Treatment

In order to obtain a strong and durable adhesive joint, the surfaces of adherends are often treated before bonding. In general, these treatments alter the surface region in one or more of the following ways: removal of a weak boundary layer, change in surface topography, change in chemical nature of the surface, or modification of the physical structure of the surface.

Polyolefins, Polyester.

Corona Discharge. The material is exposed to a corona discharge, usually in air and at atmospheric pressure. Polyethylene treated in this way experiences surface oxidation (64). Figure 8 gives xps spectra for a treated surface of low density polyethylene. The appearance of the O 1s peak indicates the formation of

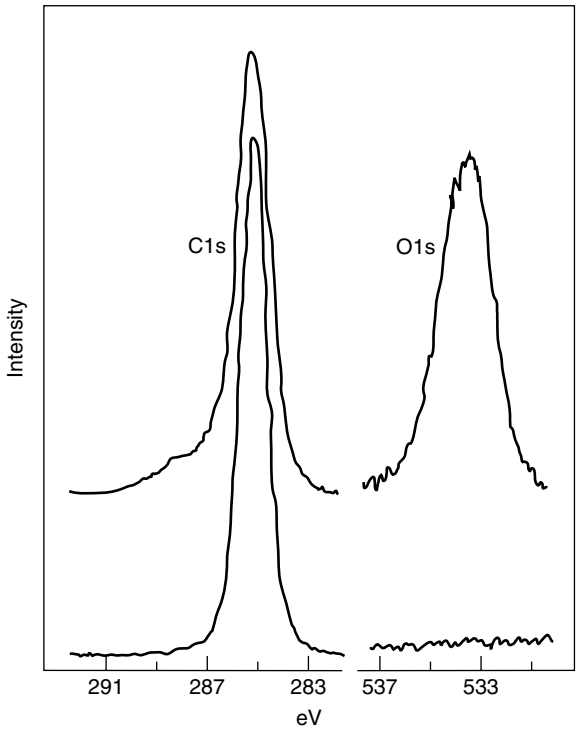

Fig. 8. ESCA spectra of low density polyethylene before (lower curve) and after (upper curve) treatment with a corona discharge (64).

surface oxidation products. These are capable of dipolar or even perhaps acid–base interactions with polar adhesives. In addition, there is fine-scale roughening of the surface (65). This indicates that the corona has degraded and removed portions of the surface in a nonuniform way. Since polyethylene has both crystalline and amorphous regions, it is likely that the corona selectively attacks the more vulnerable amorphous regions. The enhanced bonding of polar adhesives to corona-treated polyethylene is attributed both to the increase in surface roughness and to an increase in surface energy. Only a small degree of oxidation is needed to markedly increase the adhesion of polyethylene to an epoxy adhesive. Oxidation not only increases the *specific energy* of interaction with the epoxy, but also increases the *number* of interactions because of more interdiffusion. Thus, bonding is enhanced autocatalytically by surface oxidation.

The wettability, and hence ability to bond, of oxidized polyethylene decreases quickly upon heating it to 85°C (66). Apparently, oxygen-containing groups in the surface spontaneously turn inward toward the bulk of the sample, so that the surface energy of the material is reduced and the hydrocarbon character of the surface is increased. At room temperature, the loss of bondability is slower since the chains have less mobility for this redistribution.

Acid Etching. Chromic acid is used to treat polyolefins before bonding. This causes selective removal of portions of the surface region and hence surface

roughening (67). In addition, hydroxyl, carbonyl, carboxylic acid, and sulfonic acid groups are introduced (68). Bond strengths of epoxy adhesives are dramatically improved after short exposure to a chromic acid etch solution, and quickly become comparable to the cohesive strength of the polyolefin substrate. As with corona discharge treatment, the increase in joint strength after acid etching is attributed both to the introduction of polar groups and to the increased surface roughness. Extended treatment times are detrimental to joint strength because extensively etched polymer becomes a weak boundary layer.

Flame treatment. Polyester and polyethylene films are commonly exposed to flame treatment to increase bondability. Here, an oxidizing flame briefly ($\sim$0.01–0.1 s) impinges on the surface (69,70). XPS analysis (71) has shown that amide surface groups are generated, as well as typical oxidation functionality. Flame-treated films maintain bondability better than those that have been given corona treatment. Moreover, for all types of treatment, it is best to bond surfaces as soon as possible after treatment.

Surface Grafting. Rather than allowing the active species formed at a surface to simply combine with ambient oxygen, it is possible to have a reactive monomer present and form grafts to a surface. In one study (72), radicals and ions were created in a polyethylene surface by irradiation with γ rays in the presence of vinyl acetate monomer. The resulting polyethylene–vinyl acetate graft showed excellent bonding with an epoxy adhesive. Other researchers (73) have grafted acrylic acid onto polyethylene using electron beam irradiation. Adhesion to aluminum was increased about 10-fold.

Fluorocarbon Polymers. Fluorocarbon polymers require treatment with powerful etchants before they can be strongly bonded. Metallic sodium dissolved in either a mixture of naphthalene and tetrahydrofuran, or in liquid ammonia, is effective (74,75). These reagents reduce the polymer surface by defluorination (76). Initially, the surface is discolored, and it will form a carbonaceous black residue if treatment is continued too long. XPS analyses have shown the presence of unsaturation, and carbonyl and carboxyl functionality after treatment (76). Wettability and joint strengths are dramatically improved. Care must be taken not to treat the polymer too long, since substantial degradation of the surface region would generate a weak boundary layer and lower joint strength.

An interesting technique to improve the bonding of an epoxy adhesive to polytetrafluoroethylene (PTFE) has been demonstrated (77,78). Two adherends are abraded in the presence of liquid adhesive. These are then brought into contact and the adhesive allowed to set. The shear strength of the joint is about seven times that obtained if the adherends are abraded in air before applying the adhesive. Presumably, when abrasion is carried out in the presence of the adhesive, active species are created in the PTFE surface as a result of chain rupture and they react directly with the adhesive. When abrasion takes place in air, these species may decay away before the adhesive is applied.

Metals. A metal that has been exposed to air invariably forms an oxide layer on its surface. This oxide layer may be intrinsically weak or it may adhere poorly to the underlying metal, leading to weak adhesive joints in either case. Furthermore, usually there are organic contaminants present on the surface, ie, residual lubricants from the manufacturing process or substances adsorbed from the atmosphere. In order to prepare a metal surface for bonding, etching

techniques have been developed that remove both the surface contaminant and the existing oxide layer. Under controlled conditions, a new oxide layer is then formed, which is strong and adheres firmly to the underlying metal.

Chemical etching removes some of the underlying metal as well. The metal near the surface may have quite a different physical structure from the bulk as a result of the particular process used in forming. For example, if the surface was created by a cutting action, then the metal near the cutting blade, now the surface region, is subjected to high stresses that can cause local yielding and plastic deformation. Because the state of deformation of the surface material influences its reactivity with oxygen, the oxide formed is different from that which would have formed on a strain-free surface. Also, the structure of the deformed surface varies because of the inevitable nonuniformity in local deformations during cutting. After removing the irregular oxide layer by etching, a new oxide with improved uniformity and strength can be formed in a controlled way.

Aluminum. The treatment of aluminum to enhance bonding has received considerable attention because of the widespread use of aluminum/epoxy bonds in aircraft. It is a relatively simple matter to prepare an aluminum substrate so that it will initially bond tenaciously to epoxy adhesives. An aluminum/epoxy lap-shear joint in which the aluminum has been degreased and grit-blasted before bonding is so strong that it fails within the epoxy layer when stressed (79). However, upon modest exposure to a moist environment, bond strength falls and the locus of failure changes to the interfacial region. The decrease in strength is more rapid if the adhesive joint is also stressed while exposed to moisture (80). (The accelerated action of an environmental degradant caused by stress is an important general phenomenon in materials science and has been called mechano-chemical degradation.) The oxide (Al_2O_3) on aluminum may change into the hydroxide (AlOOH), boehmite, on exposure to a humid atmosphere (81). Boehmite is weaker than the original oxide and adheres less strongly to the aluminum beneath it. This leads to the decrease in joint strength upon exposure to moisture (82–84). Auger electron spectroscopic analysis of joints broken after exposure to high humidity has shown that fracture occurs at or near the boehmite–metal interface (84).

Both the physical structure of the oxide and its resistance to moisture can be changed by special surface treatments. One treatment is the Forest Products Laboratory (FPL) process (85). This consists of degreasing, alkaline cleaning, and etching in a solution containing $Na_2Cr_2O_7{\cdot}2H_2O$, H_2SO_4, and H_2O in a 1:10:30 ratio by weight. Specimens are then thoroughly rinsed and air-dried. Joints made from FPL-etched aluminum bonded with epoxy adhesives are much more resistant to degradation by moisture compared to joints made with unmodified aluminum. Part of the increase in durability is attributed to the physical structure of the oxide layer, which consists of a uniform layer about 5 nm thick with long oxide spikes (ca 40 nm) protruding outward (86). It is proposed that the adhesive can flow around the protrusions, thereby increasing the area of interaction between the oxide and the adhesive, and also providing mechanical interlocking.

A further enhancement in aluminum/epoxy joint durability in a moist environment is obtained by anodizing the aluminum after FPL treatment (80). Typically, samples are anodized for several minutes in an aqueous solution of phosphoric acid (phosphoric acid anodization or PAA) before rinsing and drying in warm air. The process produces a thin, uniform oxide layer near the bulk metal and a

much thicker (400 nm) porous layer on top of it (86). This upper layer is much thicker than that formed using the FPL process alone, and, in addition, after PAA a monolayer of $AlPO_4$ is present on top of the Al_2O_3 (87). The high durability of joints containing PAA-treated aluminum is again attributed, at least in part, to the microporosity of the oxide layer into which the adhesive may flow and solidify. Water molecules that diffuse to the interfacial region and therefore swell the adhesive within the pores may actually cause it to press more firmly against the cell wall and tend to enhance joint strength. An additional mechanism that may confer high durability on joints containing PAA-treated aluminum is the resistance to moisture provided by the $AlPO_4$ top layer. This will protect the oxide and delay the formation of the undesirable hydration product, boehmite (87).

Copper. The bonding of polyethylene to copper provides another example of the importance of oxide topography on joint strength (88,89). If copper is first cathodically cleaned or chemically polished, then polyethylene adheres rather poorly. However, if copper is given a wet oxidation treatment with sodium chloride, sodium hydroxide, and sodium phosphate solution before bonding, then polyethylene adheres tenaciously. In the former cases, the oxide layer is rather smooth and uniform, whereas the latter treatment produces a thick, black dendritic oxide that adheres strongly to polyethylene by mechanical interlocking. The bond strength is enhanced by plastic deformation of the composite interlayer, consisting of the fibrous oxide embedded in polyethylene, which interlinks the bulk copper and polyethylene (90).

Steel. Not all metal adherends require chemical surface treatments in order to optimize joint durability. With mild steel, removal of soluble contaminants by vapor degreasing followed by grinding or grit blasting is sufficient (91). However, the freshly created surface of steel is very reactive and reoxidizes almost instantly. It will continue to oxidize, especially in the presence of moisture, eventually forming a visible rust. The treated surface must be coated with a primer or adhesive before the oxide layer becomes too thick, otherwise joint strength and durability will be poor (92).

Tack

Some rubbery materials adhere firmly to themselves (autohesive tack or autohesion) or to a different surface (adhesive tack) after brief contact under light pressure. They have a liquid character which results in rapid bond formation, yet, without setting, they resist detachment like a solid, ie, they are *str*ong and so*ft*. (Tacky substances are "stroft," like toilet paper.) Typically, adhesive tack involves bonding to a hard substrate and interdiffusion is absent or minimal. Adsorption is the principal mechanism of adhesion. On the other hand, autohesion involves both molecular contact and interdiffusion. Autohesion is important in the manufacture of articles, such as tires, which are built by laminating rubbery components.

Adhesive Tack. Adhesives that exhibit adhesive tack are often called *pressure-sensitive* adhesives (PSAs), since joint strengths depend on the pressure applied during bonding. In practice, PSAs are usually carried on a backing; tapes and labels are examples. In order to secure rapid wetting on common surfaces, a PSA must have a creep compliance after 1 s greater than about 10^{-6} m^2/N

(93). When the compliance is greater than this value, the forces of attraction between molecules of the adhesive and substrate are sufficient to pull the adhesive into intimate contact with the substrate surface, even when that surface is irregular on a microscopic scale. Furthermore, in order to provide a strong joint, a PSA should have a long yield plateau followed by hardening at large strains. Yielding blunts the separation front, reduces stresses, and therefore inhibits detachment. Strain-hardening prevents continued flow and easy rupture of the adhesive. This distinguishes a good PSA from a simple liquid. Both may readily attain molecular contact, but although liquids easily flow apart at low stresses, suitable elastomeric formulations will resist relatively large tensile stresses before rupturing. Some elastomers are self-strengthening upon deforming, by virtue of the steric regularity of their molecules, which allows them to rapidly crystallize on stretching. Since this mechanism is inactive at low strains, it imparts strength without hindering wetting. Natural rubber strain-crystallizes and is widely used in pressure-sensitive adhesive formulations.

Thus, in brief, a successful pressure-sensitive adhesive not only has low resistance to small strain deformation in order to facilitate wetting, but also it can resist large strains without flowing apart easily. Certain neat elastomers such as acrylate-based PSAs possess these features and are intrinsically tacky without additives. Other PSAs are formulated by diluting high molecular weight rubbers with special resins called tackifiers.

Tackifiers. *Tackifiers* are solid resins added to elastomers to improve pressure-sensitive adhesion. They generally have molecular weights in the 500–2000 range, with broad molecular weight distributions. Tackifiers are glassy, with softening points varying from 50 to 150°C, and they often have limited compatibility with the elastomer to which they are added (94,95). Common tackifiers include rosin derivatives, coumarone-indene resins, terpene oligomers, aliphatic petroleum resins, and alkyl-modified phenolics (96). In order to impart tack to an elastomer, a substantial portion of the tackifier must dissolve in the elastomer, thereby reducing entanglements and softening it, without excessive weakening. This requires control of the molecular weight of the tackifier. If it is too high, the tackifier becomes an incompatible filler—stiffening and strengthening, but preventing rapid wetting. On the other hand, if molecular weight is too low, the tackifier becomes a low T_g liquid and acts as a plasticizing solvent. In addition, tackifiers in PSAs have been reported to have marginal compatibility with the elastomer, often resulting in migration of some tackifier to the surface (97).

The effect of adding tackifiers on the rheological properties of elastomers has been investigated (98–100), and the results are instructive in understanding how a tackifier functions. Figure 9 shows a plot of the shear storage modulus G' of natural rubber with and without a tackifying resin (98). When the resin is present, the resistance to deformation is reduced at low rates, ie, lower G'. This results from a reduction in the rubber entanglement density and facilitates wetting on contact. At the same time, when measuring the strength of the bond at higher rates of deformation, the modulus G' is high, reflective of the tackifier's high T_g, and the material is stronger. This behavior can be contrasted with the effects of adding a filler or a simple plasticizer. A filler would increase G' over the entire range of rates of deformation, leading to difficulties in bond formation. A simple plasticizer unduly lowers the cohesive strength of an adhesive, so that, at

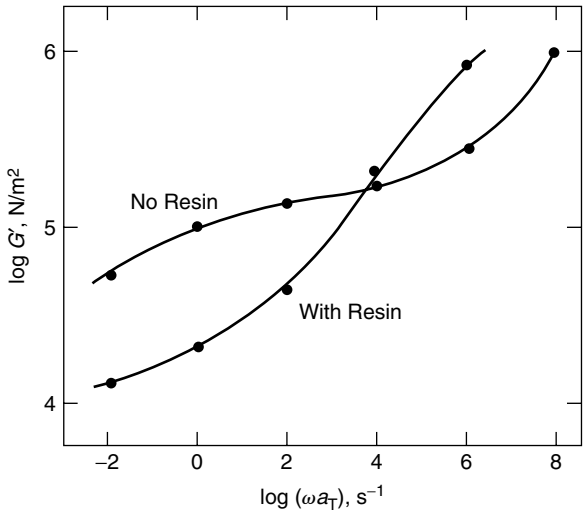

Fig. 9. Effect of a tackifier on the dynamic modulus G' of natural rubber as a function of reduced deformation frequency ωa_T (98). To convert N/m^2 to psi, multiply by 1.45×10^{-4}.

high dilution, a plasticized rubber is very weak. In contrast, a highly tackified rubber, though soft, nonetheless resists easy fracture (97).

Rate and Temperature Effects. Pressure-sensitive adhesives are soft elastomeric semisolids. Their peel strength depends strongly upon the rate of peel and the test temperature, as shown for a simple model system in Figure 10 (101). At low rates, the peel force increases with rate, and failure takes place entirely within the adhesive layer, which fails by flowing apart. The peel strength is primarily a measure of the work of extending a viscoelastic liquid to the point of rupture. Although the local stress required to disentangle the molecules at low rates is

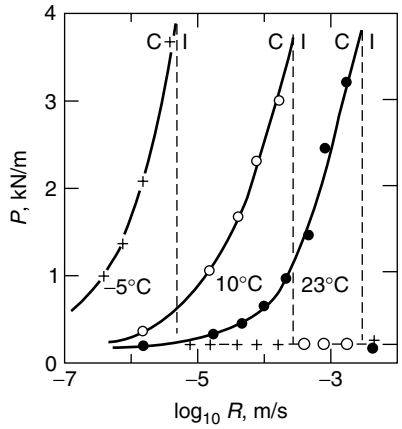

Fig. 10. Peel–force vs. rate of peeling for an elastomeric layer adhering to a polyester film. *C* and *I* denote cohesive and interfacial failure modes, respectively (101). To convert kN/m to ppi, divide by 0.175.

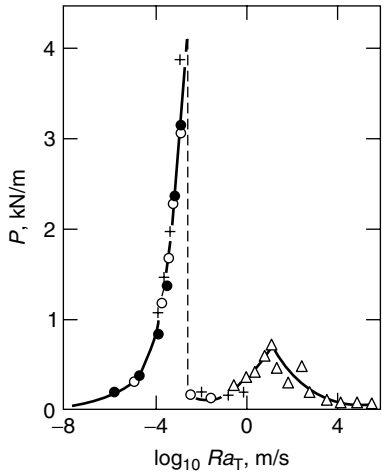

Fig. 11. Results from Figure 10 replotted against the reduced rate of peeling at 23°C, obtained by WLF time–temperature superposition (101). To convert kN/m to ppi, divide by 0.175.

relatively small, the work expended in ductile flow is large and the peel force, which measures the work of separation, is correspondingly high. At a critical rate of peel, which increases as test temperature increases, an abrupt transition takes place to interfacial fracture between the adhesive and substrate. This transition occurs when the rate of deformation of the adhesive layer at the peeling front becomes so high that the adhesive molecules do not disentangle and flow apart like a liquid. Instead, the molecules remain intertwined and respond like an elastic solid. In the elastic state, the work of separation is expended nearer to the interface, and is relatively small.

The rate of peel and test temperature at which the abrupt transition occurs are directly dependent upon the rate of Brownian motion of molecular segments. Simple viscoelastic adhesives therefore obey the WLF rate–temperature equivalence (102). Applying this principle to the data in Figure 10 results in the mastercurve shown in Figure 11. Thus, it is possible to predict the rate dependence of the peel strength over a wide range of peel rates, using only limited data obtained over a narrow range of rates at various temperatures.

Autohesive Tack (Autohesion). For two layers of the same elastomer to resist separation after being brought into brief contact, the basic criteria already outlined for adhesive tack must be satisfied. The two surfaces must come into intimate molecular contact and the materials themselves must resist high stresses without flowing apart. However, there is an important difference between the two types of tack. Pressure-sensitive adhesives based on hydrocarbon rubbers *always* contain substantial amounts (∼50% or more) of tackifier to allow them to readily achieve wetting. As discussed earlier, this is attributed to the need for the adhesive to be sufficiently compliant so that it will be quickly "pulled" by adsorption forces into intimate molecular contact with common hard substrates. Neat hydrocarbon rubbers exhibit very little adhesive tack, but they can exhibit very strong autohesion. For example, unmodified natural rubber is a poor pressure-sensitive

adhesive, but its autohesion is high. When interdiffusion is active, a high resistance to separation develops quickly in spite of relatively low compliance. Although interdiffusion cannot occur until molecular contact has been established, it appears that interdiffusion somehow speeds molecular contact. This apparent paradox is addressed next.

When two layers of the same elastomer are pressed together, molecular contact is not generally complete, but develops in a progressive manner. Thus, after a brief contact time t, some microscopic areas may not have achieved molecular contact and other areas will have achieved intimate contact at times varying from 0 to t. The overall bond strength, then, is the sum of many interactions of varying magnitude at the contact sites, together with interfacial defects (noncontacted regions). As t increases, the defects "close-up." Perhaps, interdiffusion at contact sites can speed the closing-up of interfacial defects around them.

Finally, it should be noted that the barriers to molecular contact may be different for adhesive tack and autohesion. Surface impurities, eg, from bloom, may readily redissolve into the bulk elastomer during autohesive bonding. On the other hand, impurities on common substrates, such as surface moisture, may not be readily displaced by an adhesive that is too stiff. Molecular mobility and microscopic flow are expected to aid displacement of impurities.

Molecular Weight. The effect of molecular weight on the autohesion and cohesive strength of natural rubber (NR) is shown in Figure 12 (103). As the molecular weight is increased, the cohesive strength rises because of a greater number of molecular entanglements per chain. On the other hand, the autohesion after a given contact time passes through a broad maximum with increasing molecular weight. At the lowest molecular weights, contact and interdiffusion are rapid. (*Relative autohesion*, defined as autohesion divided by cohesive strength, is unity.) Still, the autohesion is low because of the poor cohesive strength. At the highest molecular weights, both contact and diffusion are slow owing to restricted molecular mobility. Thus, the autohesion again is low. Qualitatively, similar results are found for other elastomers.

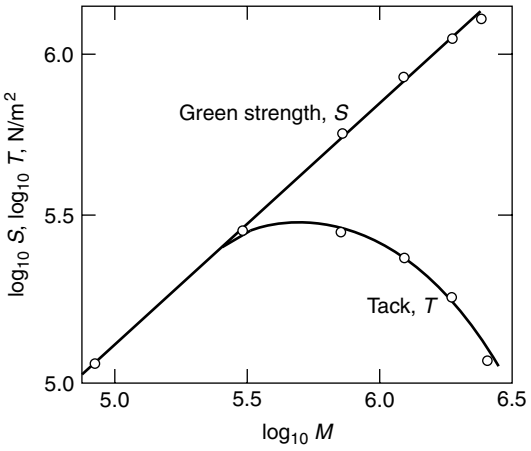

Fig. 12. Tensile strengths of autohesion (tack T) and cohesion (green strength S) of natural rubber as a function of molecular weight M (103).

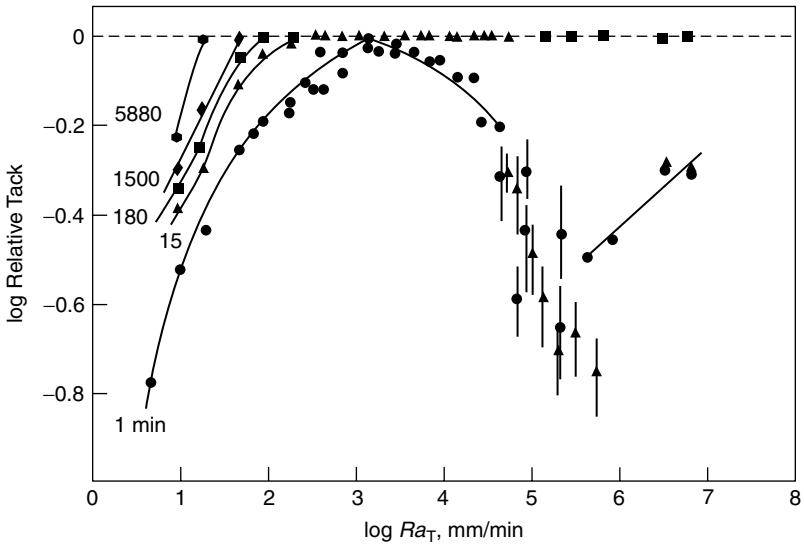

Fig. 13. Mastercurves of relative tack of an SBR versus reduced test rate at 23°C for various contact times, given in minutes for each curve. Ends of vertical lines are extreme values when failure was stick-slip (104).

Dried NR latex has very high molecular weight and low autohesion. However, NR undergoes molecular scission upon mastication and moderate amounts of milling improve autohesion as the molecular weight is reduced (Fig. 12). However, the cohesive strength, and hence, maximum achievable autohesion, becomes low after prolonged milling. Other elastomers, eg, styrene–butadiene rubber (SBR), are less susceptible to shear degradation, and autohesion is less altered by mastication. Nonetheless, shearing conditions used to prepare specimens for testing of autohesion should be well controlled.

Rate and Temperature Effects. Like adhesive tack, autohesion of elastomers is strongly dependent on test rate and temperature. Furthermore, as shown in Figure 13 for the T-peel autohesion of a cold emulsion SBR, relative autohesion P_r (for a given time and pressure of contact) is not unique, but it too depends markedly on test conditions (104).

Figure 13 is a mastercurve of relative autohesion after various contact times versus reduced test rate Ra_T at 23°C. The dotted line, log $P_r = 0$, ie, $P_r = 1$, is the maximum value that relative autohesion can attain. When data lie on this line, tack is equal to the cohesive strength, ie, the joint is as strong as the fully healed one. Of course, if healing were complete, data for all Ra_T would fall on the dotted line. Remarkably, as seen in Figure 13 and discussed below a tack joint may behave as if it was fully healed at certain Ra_T ($P_r = 1$), even though healing is actually quite incomplete ($P_r \ll 1$ at other Ra_T).

After 1 min of contact, $P_r \ll 1$ at the lowest test rates. Clearly, healing is incomplete. However, P_r increases with rate and reaches a value of one at a reduced test rate of about 1.6 m/min [log Ra_T (mm/min) ≈ 3.2]. At higher rates, P_r decreases to a minimum and the peel response becomes stick-slip. (Ends of the vertical lines

in Fig. 13 are extremes of P_r when the peel force oscillates in a regular stick-slip manner.) Thereafter, P_r increases again at the highest peel rates. As contact time is increased, the range of reduced rates where $P_r = 1$ broadens, but even after 100 h of contact, the junction is not fully healed, since, at the lowest test rate, P_r is still less than one. This is probably indicative of a very high molecular weight fraction in this cold-emulsion SBR, with an extremely slow interdiffusion rate. Nonetheless, after just 1 min of contact, the junction behaves as though it were fully healed under certain test conditions. At slow test speeds, substantial interdiffusion is required to attain a high value of P_r, whereas it appears that only limited interdiffusion is sufficient to give $P_r = 1$ at somewhat higher rates.

For contact times of 1 or 15 min, P_r increases with rate to a value of one, then decreases markedly and the failure becomes stick-slip. It has been hypothesized that this decrease is associated with the presence of small, non-contacted regions or interfacial flaws, which act as stress-raisers, when the elastomer is deformed at sufficiently high rate. If this is correct, then the abrupt decrease in P_r at high rates should be eliminated when the contact time and pressure are sufficient to cause the disappearance of these "defects." Indeed, after 180 min of contact, the decrease in P_r at high rates no longer occurs. After P_r becomes unity at some critical rate, it retains this value at all higher rates. Furthermore, if, after 180 min of contact, the contact pressure is removed while further healing proceeds, then the autohesion increases as if the pressure had been maintained for the entire contact period. However, for contact times less than 15 min, if pressure is removed for an interval during the contact period then autohesion is reduced. It appears that full molecular contact of surface elastomeric chains takes place between 15 and 180 min of contact. Then, autohesion becomes independent of pressure, since interdiffusion rates are insensitive to light pressures. With full contact, P_r remains equal to one at high rates and there is no stick-slip region where P_r falls off.

There has been disagreement in the literature whether molecular contact is sufficient to give high autohesion or whether substantial chain interpenetration is required (105). The previous results indicate that the answer may depend on the test rate and temperature. At high rates, complete, intimate molecular content may be sufficient, whereas molecular interdiffusion becomes relatively more important when the debonding rate is low.

Relating Joint Fracture Energy to Intrinsic Adhesion

In an earlier section, it was noted that the mechanical fracture energy G per unit of bonded area is greater, sometimes by several orders of magnitude, than the interfacial interaction energy holding the joint together. This section discusses this important feature in more detail.

Many basic studies attempting to relate fracture energy and intrinsic adhesion have involved the detachment of lightly cross-linked elastomers, usually over a broad range of test rates and temperatures. Work expended irreversibly in stressing these joints up to the point of failure is included in the total work of detachment. To focus attention on interfacial bonding it is therefore necessary to minimize any dissipative processes in the adherends. A simple cross-linked

elastomer can no longer flow like a liquid, but it is still not perfectly elastic because of internal friction between moving molecular segments. However, internal losses can be minimized by raising test temperature, so that molecular Brownian motion is more rapid, and by detaching the adhering layer at very low speeds. Under these "threshold" conditions the adhering layer is almost perfectly elastic, and the minimum fracture energy G_0 is determined.

In some simple cases of an amorphous elastomeric network adhered to a hard substrate, it has been found (62,106,107) that the fracture energy obeys the following equation:

$$G = G_0[1 + \phi(Ra_T)] \tag{11}$$

where ϕ is a quantity reflective of bulk energy losses, and dependent on test rate R and temperature T through the WLF factor a_T. ϕ has been related to an elastomer's loss modulus (108). For cross-linked rubbery materials, if the locus of failure stays the same, ϕ generally increases as the test rate is increased and tends to zero as Ra_T becomes sufficiently low. The (total) detachment fracture energy must also be equal to the sum of the ways in which energy is expended during fracture (109):

$$G = G_0 + H \tag{12}$$

where H is the hysteretic energy loss per unit area as a result of irreversible deformation in the *bulk* of the bonded components. Combining these two equations it is seen that

$$H = G_o\phi(Ra_T) \tag{13}$$

so that it is implicit in equation (11) that bulk energy losses depend directly on G_0.

Gent and Schulz (62) demonstrated that detachment energy was the product of an intrinsic strength and a loss function dependent on molecular mobility. Peeling of a cross-linked SBR from a polyester substrate was carried out at various rates both in air and in several wetting liquids. Values of G were equal to W_a (which had been determined from wetting experiments) times a much larger dissipative factor. Using a similar, lightly cross-linked SBR, the tensile fracture energy to separate the elastomer from various plastic substrates that had different surface energies was measured (106,107). In accord with equation (11), double-log plots of fracture energy versus reduced rate were parallel.

Although equation (11) is obeyed for certain cases of simple rubbers bonded to hard substrates, deviations from this relationship have been reported (110–112). One reason is that G_0 itself may sometimes be rate dependent (38,112,113). Furthermore, bulk dissipative losses may not be proportional to intrinsic adhesion, especially for joints containing components which can yield during fracture (112).

Next, we consider the relationship between G_0, the minimum mechanical energy required to disrupt an interface, and W_a, the equilibrium, thermodynamic work of adhesion. Firstly, however, we discuss the corresponding quantities for the *cohesive* fracture of a lightly cross-linked rubber. These are G_{0c}, the threshold tearing energy (114), and W_c, the reversible fracture energy of the bonds

acting across the cohesive fracture plane. Values of G_{0c} are of the order of 50 J/m^2 (0.024 ft·lbf/in.^{2}) (115,116). This value is much greater than W_c, which is calculated to be only about 2 J/m^2 (0.001 ft·lbf/in.^{2}). Thus, the minimum mechanical energy to fracture an elastomeric network is about 25 times that needed to (chemically) dissociate the carbon–carbon bonds crossing the fracture plane. The reason for this is that even under threshold conditions, in order to break just one backbone bond in a network chain, it is necessary to stretch all of the bonds in the chain essentially to their breaking point. Energy is not only expended in breaking bonds, but it is also lost within the broken, recoiling network strands. This idea was first proposed by Lake and Thomas (117). In mechanical rupture of a (strong) covalent network, the minimum dimension in which energy is expended away from the fracture plane is equal to the distance between cross-link points. On the other hand, cleaving bonds chemically does not require deformation and hence involves the minimum amount of energy to create new surface.

Although the Lake and Thomas analysis was carried out for cohesive fracture, the principles have been found to apply to the peeling detachment of a cross-linked polybutadiene layer bonded to glass (110). The amount of interfacial bonding was varied in a systematic way by changing the proportions of vinyltriethoxysilane and ethyltriethoxysilane used to treat a glass surface. Vinyltriethoxysilane is capable of forming covalent bonds with polybutadiene during free-radical cross-linking (118), whereas ethyltriethoxysilane is unreactive and interacts with the elastomer only by relatively weak van der Waals forces. The amount of interfacial covalent bonding between the elastomer and the glass surface was thus varied from only van der Waals forces, when ethyltriethoxysilane was used alone, to increasing amounts of interfacial chemical bonding, as increasing proportions of vinyltriethoxysilane were used. The detachment work was found to increase steadily with the amount of interfacial chemical bonding. Furthermore, values of G_0 were about 20–30 times higher than the calculated W_a. For instance, when the glass was treated with ethyltriethoxysilane, G_0 was 1.5 J/m^2, whereas the thermodynamic work of adhesion calculated from the surface energies of the treated glass and the elastomer was only about 0.05 J/m^2. Similarly, for glass treated with vinyltriethoxysilane, G_0 approached the threshold cohesive fracture energy of the elastomer, about 50 J/m^2, about 25 times greater than the calculated value for rupture of a plane of C—C bonds.

Andrews and Kinloch (106,107) also determined fracture energies for a lightly cross-linked elastomer bonded to various substrates. However, unlike Ahagon and Gent (110), they found approximate agreement between G_0 and W_a. The discrepancy in the two cases may be related to differences in test geometry. Andrews and Kinloch employed a cleavage mode, whereas peeling, which requires more severe bending, was used by Ahagon and Gent.

An easier way to measure G_0 for weakly adhering soft elastomers is the JKR (Johnson, Kendall, Roberts) technique (119,120), which usually involves contacting a hemispherical cap of elastomer with a planar substrate. Contact mechanics are employed to relate contact area to intrinsic adhesion. Using the JKR technique, a value of G_0 has been obtained of 0.12 J/m^2, about a factor of 2 higher than the expected work of adhesion (121). In other works (122,123) JKR experiments have been employed to determine threshold adhesion energies as low as 0.05 J/m^2.

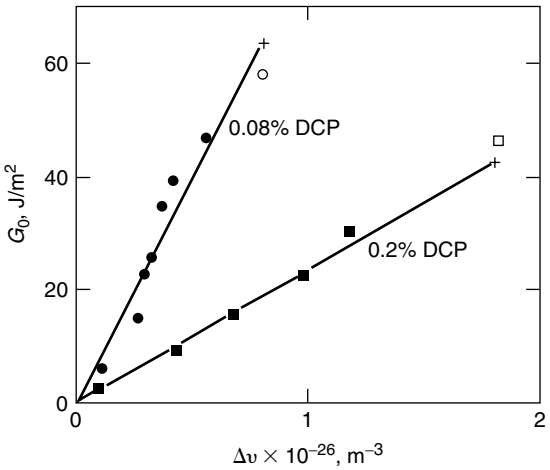

Fig. 14. Threshold work of detachment as a function of interfacial cross-link density for an elastomer (DCP = dicumyl peroxide) (124). To convert J/m^2 to lbf/in., divide by 175.

In other experiments (124) the density $\Delta\upsilon$ of chemical bonds between two layers of the same elastomer was varied by partially cross-linking the layers before contacting them and completing the cure. In Figure 14, G_0 is plotted against the increase $\Delta\upsilon$ in cross-linking while the two sheets were in contact. $\Delta\upsilon$ is a measure of the amount of interfacial bonding. As can be seen, the threshold work of detachment increased in direct proportion to $\Delta\upsilon$, up to the measured tear energy of the elastomer, denoted by crosses. Thus, there appears to be a direct relation between the mechanical strength, ie, work of detachment, obtained under threshold conditions and the density of chemical bonds at the interface.

However, it is noteworthy that the bond strengths for sheets prepared with more cross-linking agent were lower than those prepared with a smaller amount. The joints were weaker in adhesion (o and □) and weaker in tearing in the fully bonded state (+). This again points to the importance of the length of the molecular strands between cross-links. When the strands are long, they contain a large number of bonds that must be highly stressed in order to break or detach one of them. Thus, when the material is highly cross-linked and the molecular strands are short, then it is also less extensible and weaker.

The theoretical relation for the threshold bond strength (117,125), supported by the experimental results, is

$$G_0 = 1.0(C_\infty U/a^{1/2})L^{3/2}\Delta\upsilon \tag{14}$$

where C_∞ is the characteristic ratio of the molecule, generally lying between 2 and 10, a is the length of a C—C bond, U is its dissociation energy, and L is the contour length of the molecular strand between interlinks. Note that the strand length L is as important as the number $\Delta\upsilon$ of connecting strands in determining the strength of interlinked layers.

Strength of Adhesives and Joints

Fracture Mechanics of Simple Joints. In general, the strength of an adhesive joint is a function of the mode of loading and the dimensions and elastic properties of the bonded components, as well as the intrinsic strength of the interface. Fracture mechanics is used to relate the breaking load to these factors. One criterion for fracture assumes that a characteristic amount of energy is required to break apart the interface. Originally proposed for the brittle fracture of elastic solids (126), an energy criterion for fracture has been successfully applied to highly elastic materials (127), to materials that become locally dissipative (128,129), and to the separation of two adhering solids (130–142). An alternative criterion for fracture assumes that a critical *stress* is set up at the site of fracture (143). The two criteria are fundamentally equivalent, but energy calculations are often easier to perform.

In applying either criterion to predict the fracture of an adhesive bond, it is, in most cases, necessary to identify an initial failure site, usually a flaw at the interface. Failure is then assumed to take place by growth of this initial debond until the joint is completely broken. When an energy criterion is adopted for fracture, an energy balance is formulated in which changes in the strain energy of the joint and in the potential energy of the loading device when the debond grows by a small amount are equated to the work required for detachment. Strain energy is supplied by a loading device and stored in the deformable material. It is expended at failure in two ways: in supplying the work of fracture or detachment, and in deforming material that was previously undeformed or deformed less. By equating the energy made available to that required, the magnitude of the stored strain energy at the moment of fracture is deduced, and hence the breaking stress σ_b.

Modes of Failure.

Peeling. The peel test is particularly simple to analyze because the elastic energy of the deformed adherends does not change much as peeling proceeds. Most adhering layers do not stretch significantly under peel forces, and the amount of material subjected to bending does not alter. Thus, for flexible and inextensible adherends, the work of detachment is provided directly by the loading device. For peeling at 90° (Figure 15a), the peel force P per unit width is given by

$$P = G_a \tag{15}$$

where G_a denotes the work of detachment per unit area of interface. For peeling at 180° (Figure 15b),

$$P = G_a/2 \tag{16}$$

(The factor of 2 arises in this case because the point of loading moves through twice the distance of the detachment front.)

The contribution of plastic yielding to the measured peel force has been analyzed for an elastic–plastic adherend (144,145). If the adherend has a thickness greater than about $6EG_a/\sigma_y^2$, where σ_y is the yield stress, then no plastic deformation occurs and the peel force is unaffected. But if the adherend is thinner

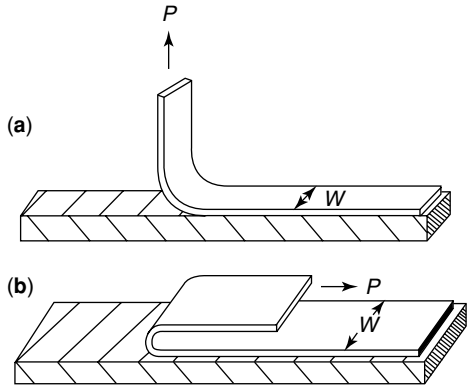

Fig. 15. Peel tests: (a) 90°; (b) 180°.

than this, it undergoes plastic deformation during peeling. The dissipated energy is provided directly by the peel force, which increases by a factor of up to about 3. However, for much thinner adherends the peel force falls again because now there is less material undergoing plastic deformation and less energy dissipated. Thus, the peel force is higher for adhesives that are capable of dissipating large amounts of energy during detachment, and for thicker adhesive layers, since this provides a greater volume of material in which dissipation occurs.

Lap Shear. Two simple examples of failure in lap shear are considered here. In the first, the adhering layer itself is elastic and stretchable (Fig. 16). The detachment force, applied parallel to the bond plane, stretches the detached layer and uses energy in doing so. For a linearly elastic layer, the relationship between the detachment force P per unit width and the work G_a of detachment per unit of bonded area is

$$P^2 = 2tEG_a \tag{17}$$

where E is Young's modulus of elasticity in tension for the detaching layer and t is its thickness (137). The corresponding tensile stress σ_b in the detaching layer is

$$\sigma_b^2 = 2EG_a/t \tag{18}$$

We note that equation (18) does not contain the size of the debonded zone. Shearing detachment is therefore predicted to take place at a constant force that depends on the elastic modulus and thickness of the adhering layer but not on the length

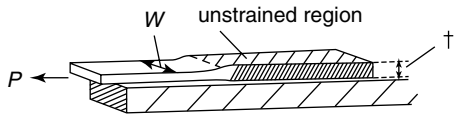

Fig. 16. Detachment of an adhering layer by a force parallel to the interface.

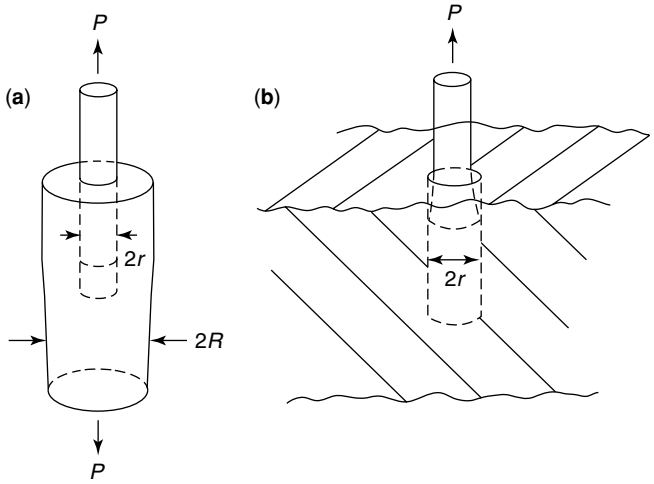

Fig. 17. Pullout of (**a**), an inextensible rod from an elastic cylinder and (**b**) an elastic rod from an inextensible block.

of the bonded region or on the extent of debonding. These features have been verified experimentally for adhering elastomeric layers (137), and the theory has been extended to deal with short overlaps, when bending deformations become important (137), with adherends of unequal thickness (137), and with prestressed layers (146). The success of a simple energy criterion for detachment confirms its general validity.

Pullout of Inextensible Fibers. By applying the same principle of energy conservation during detachment, it can be shown (141) that the pullout force P for an inextensible fiber of radius r embedded in a cylindrical elastic block of radius R (Fig. 17a) is given by

$$P^2 = 4\pi^2 R^2 r E G_a \tag{19}$$

When a bonded elastic cylinder of radius r is pulled out from a cylindrical cavity (Fig. 17b), then the pullout force is also given by equation (19) in the special form (142)

$$P^2 = 4\pi^2 r^3 E G_a \tag{20}$$

Experimental results with rubber cylinders have confirmed the general validity of equations (19) and (20). Measurements of failure loads in compression and torsion and in the presence of friction at the interface have been successfully analyzed in the same way (142). Moreover, a transition from pullout to fracture is expected when the strength of adhesion G_a is relatively large compared to G_c. The transition takes place at a critical ratio of the diameter of the embedded fiber to the diameter of the elastic cylinder in which it is embedded (147). An analysis along these lines also accounts for the brittleness of well-bonded laminar

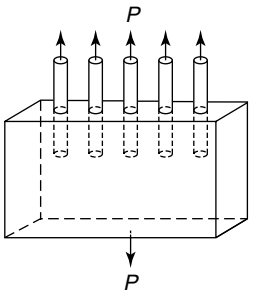

Fig. 18. Pullout of n fibers simultaneously from an elastic block.

composites compared to weakly bonded ones (138). Thus, again, energy considerations account for the principal features of the strength of adhesive joints.

When a number n of fibers are embedded in a single block of elastomer and they are all pulled together (Fig. 18), then the work required for detachment is obviously larger than for a single fiber by a factor of n. The strain energy stored within the block must therefore be larger than before, by a factor of n, and the total force applied for pullout must be increased by a factor of $n^{1/2}$. Thus, energy considerations immediately lead to the surprising conclusion that the total force required to pull out n fibers simultaneously from a single elastic block will increase in proportion to $n^{1/2}$. This prediction has been verified experimentally for 1–10 cords embedded in a rubber block (141). This is a striking example of the success of simple energy calculations in accounting for important features of the strength of joints and structures.

Shear Failure of an Adhesive Layer. Another type of shear failure occurs in a thin adhesive layer that is bonded and sheared between two rigid adherends (Fig. 19). Assuming that the adhesive is an elastic solid, the condition for growth of a debond that is long compared to the adhesive thickness t is (148)

$$G_a = tW \tag{21}$$

where W is the strain energy stored by the shear deformation, per unit volume. Thus, a thinner adhesive layer with higher elastic modulus will be more resistant to growth of a debond. However, the relation for short debonds is more complex. Initially, the value of G_a falls as the debond grows and the rate of debonding therefore slows, but when the debond length approaches t, G_a rises again to reach the value given by equation (21).

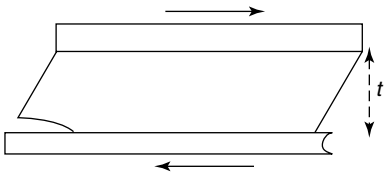

Fig. 19. Debonding in simple shear.

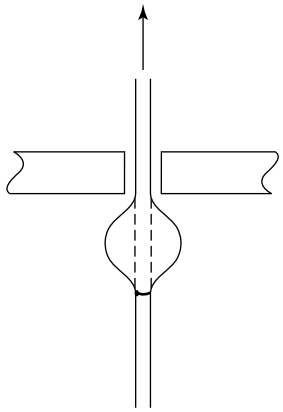

Fig. 20. Shearing a resin droplet from a fiber.

Other Shear Tests. A common test method for examining the strength of bonds between a resin and a fiber is the microdroplet test (149), shown in Figure 20. A droplet of resin about 20 μm in diameter is applied to a single fiber and then stripped away by pulling the fiber through a narrow aperture. Originally, the stripping force divided by the total bond area was regarded as the failure stress in shear. Later, the microdroplet test was reevaluated using the concepts of fracture mechanics and the stripping force was reinterpreted in terms of the fracture energy required for growth of an initial debond (150–152). It has recently been found necessary to take into account the effects of friction between the fiber and the resin droplet after debonding (153).

Another test method for resin–fiber bond strength employs a single fiber embedded within a long resin bar (154). As the bar is stretched, the less-extensible fiber breaks into smaller and smaller fragments with a final mean length of l_c. Originally, l_c was interpreted in terms of a characteristic failure stress σ_s of the resin–fiber bond in shear (155):

$$\sigma_s = \sigma_f(r/2l_c) \tag{22}$$

where r is the fiber radius and σf is its breaking stress in tension. Attempts have been made to reinterpret the repeated fractures of the fiber in terms of the energy required for both debonding and frictional sliding (156,157).

Tensile Detachment from a Rigid Plane. For a circular debonded patch at the interface between a half-space of an elastic material and a rigid substrate (Fig. 21), the applied stress σ_b sufficient to cause growth of the debond is (158)

$$\sigma_b^2 = 2\pi EG_a/3r \tag{23}$$

The same result is obtained for a pressurized debond, ie, a blister, of radius r at the interface between an elastic half-space and a rigid plane (159) because a tensile stress σ_b applied at infinity is equivalent to a pressure σ_b applied to the inner surface of the debonded region if the material is incompressible in bulk, as is assumed here.

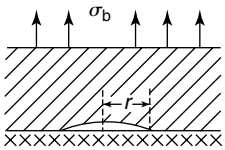

Fig. 21. Penny-shaped debond in a butt tensile test geometry.

Detachment from a Spherical Inclusion. A relation analogous to equation (23) has been deduced for the applied stress required to detach an elastic matrix from a rigid spherical inclusion (Fig. 22). The relation obtained is (140)

$$\sigma_b^2 = 4\pi EG_a/3r\sin 2\theta \tag{24}$$

where r now denotes the radius of the inclusion and 2θ denotes the angle subtended by an initially debonded patch located in the most favorable position for growth, ie, in the direction of the applied tensile stress (Fig. 22).

It is clear that σ_b will be extremely large for inclusions of small radius r, even if the level of adhesion, represented by G_a, is relatively small, only of the order of magnitude of van der Waals attractions. For example, when E is assumed to be 2 MPa, representative of soft elastomers, and G_a is given the relatively low value of 10 J/m^2, then the critical applied stress for detachment is predicted to reach a magnitude similar to E when the radius of the inclusion is reduced to about 20 μm, even if the initially debonded zone is as large as feasible, $\theta = 45^\circ$. These considerations appear to account for some features of reinforcement of elastomers by particulate fillers Fillers (140).

It is noteworthy that equation (24) predicts a decrease in detachment stress as the radius of the spherical inclusion is increased. This trend is in striking contrast to the result for a single fiber (eq. (19)), where the pullout force is predicted to increase as the radius of the inclusion is increased. Both trends are predicted

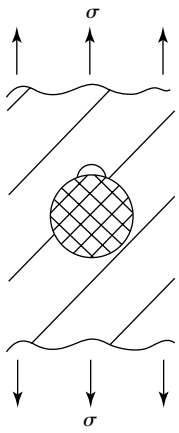

Fig. 22. Detachment from a rigid spherical inclusion.

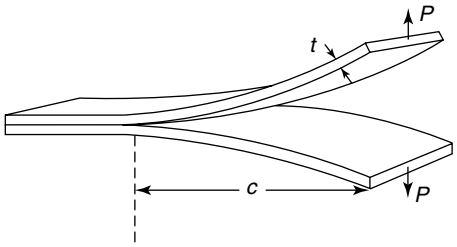

Fig. 23. Cleavage separation of two adhering plates.

by the theoretical analysis, and both are confirmed by experiment (141,160). The surface area to be debonded and the energy required to debond are both greater for fibers of larger diameter and, as a result, the pullout force is increased. For spherical inclusions, on the other hand, the amount of highly stressed material in the vicinity of the debond, which provides the energy needed for propagating the debond in this case, also increases with the size of the inclusion. The highly stressed volume grows in proportion to r^3, whereas the area to be debonded only grows in proportion to r^2. In consequence, it is easier to propagate a debond on a larger inclusion than on a smaller one.

Fracture Mechanics for Bonds between Relatively Stiff, Elastic Adherends. Two test methods are now discussed that are particularly convenient for use with relatively stiff adherends. They are denoted cleavage failure and torsional failure. At first sight, a cleavage experiment, shown in Figure 23, resembles simple peeling but the mechanics of separation are quite different. In peeling, the peeled strip is long and flexible, and bends around into alignment with the peel force, as sketched in Figure 15. In a cleavage experiment, on the other hand, the bonded plates are relatively stiff so that they do not deform greatly under the cleavage force (Fig. 23). They bend only slightly so that the cleavage force continues to act effectively at right angles to the plane of the plates, even when the separation distance c is fairly long.

In peeling, the strain energy due to bending the peeled strips does not change as peeling proceeds, because the degree of bending remains constant. Therefore, elastic strain energy does not feature in the relation between work of peeling and work of detachment, equations (15) and (16). On the other hand, in cleavage the bending energy stored in the separated portions of the plates is a function not only of the applied force P but also of the debonded length c. Thus, as debonding proceeds and the debonded length increases, the plates, regarded as long elastic cantilevers, become more compliant. When the corresponding change in strain energy is taken into account, the following relation is obtained between peel force P per unit width and work G_a of detachment:

$$P^2 = Et^3 G_a / 12c^2 \tag{25}$$

Note that the cleavage force P required to propagate the debond decreases continuously as the debond propagates. If, on the other hand, a constant deflection δ is imposed, then the energy available for debonding is given by

$$G = 3Et^3\delta^2/c^4 \tag{26}$$

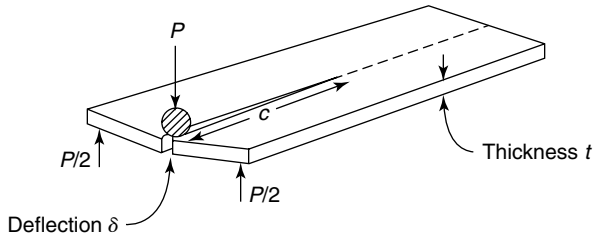

Fig. 24. Propagating a debond between two adhering plates by torsional loading (161, 162).

which decreases strongly as the debond length c increases. Thus, the initial debond will grow until there is no longer a sufficient amount of stored elastic energy to propagate it. This is an attractive feature of cleavage experiments: they can be employed to study the minimum (threshold) strength of the joint.

However, it is experimentally inconvenient to measure the debond length continuously as the debond grows, in order to calculate the energy available for debonding from equation (25) or (26). Another experimental arrangement has been proposed for stiff adherends that does not have this disadvantage. It is sketched in Figure 24. Two plates are adhered together partway along their narrow edges and the unbonded portions are twisted by a load P applied at one end point of the common interface. As the debond is forced to propagate, the debonded portions of the plates increase in length and in torsional compliance, in direct proportion to the distance c debonded. This feature leads to a fracture force P that is, in principle, independent of the distance c debonded (161):

$$P^2 = 2G_a t/C' \tag{27}$$

where C' denotes the torsional compliance of a unit length of the debonded portions of the adhering plates and t is the thickness of the bond itself. Note that the value of C' can be determined from the slope of the linear relation between deflection and applied load before the initial debond starts to propagate. This test technique has also been modified using a pulley arrangement to apply torsional deflections of much greater magnitude (162).

Because the fracture force P is, in principle, constant, it will only fluctuate if the bond strength itself is variable. Thus variations in the fracture force can be directly associated with variations in the strength of adhesion.

Both of the test techniques considered in this section depend on the adherends being linearly elastic. If this is not the case, then the relations given (eq. (26) and (27)) no longer apply. (This is the case for all of the relations given in this chapter: the adherends are assumed to be perfectly elastic so that energy expended in deforming them is available for fracture.) However, it is sometimes possible to bond fully elastic backing plates (eg, of spring steel) to the adherends under study and thus to convert plastic or yielding adherends into effectively elastic ones.

ADHESIVE COMPOUNDS

Introduction

An adhesive is a material that is used to join two objects through nonmechanical means. It is placed between the objects, which usually are called *adherends* when part of a test piece or *substrates* when part of an assembly, to create an adhesive joint. Although some adhesives form joints that nearly immediately are as strong as they will be in actual use, other adhesives require further operations for the adhesive joint to reach its full strength. Adhesives can be made in several different physical forms, and the form of a given adhesive will define the possible methods of its application to the substrate.

An adhesive is comprised of a base chemical or a combination of chemicals which define its general chemical class. Most adhesives contain a curing agent or catalyst that will cause an increase in the molecular weight of the system and frequently the formation of a polymeric network. Nearly all adhesives also contain additives or modifiers which fine tune the adhesive and may significantly influence its behavior before and after formation of the adhesive joint. These additives include solvents, plasticizers, tackifiers, fillers, pigments, toughening agents, coupling agents, stabilizers, and so on. Additives or modifiers increasingly are chosen for their ability to provide more than one benefit, for example, a pigment may not only color but may also reinforce an adhesive. In some cases, the process used to combine these diverse ingredients will strongly influence the properties of an adhesive. Although inorganic adhesives do exist, this article will be restricted to organic polymeric adhesives.

Consumers, designers, and engineers generally choose between adhesive bonding and mechanical or thermal methods when deciding how to join one object to another. Mechanical methods utilize bolts, screws, and rivets. Thermal methods include welding, soldering, and brazing. Adhesive bonding is the obvious choice

Encyclopedia of Polymer Science and Technology. Copyright John Wiley & Sons, Inc. All rights reserved.

for joining in cases in which the substrate is thin and relatively weak, for example, paper, or strong but relatively brittle, for example, glass. Use of adhesives in these situations avoids formation of stress concentration points and possible damage to the substrates. Even where the substrates will bear mechanical fastening, the geometry of certain parts sometimes makes welding or bolting more costly if not entirely impossible, as in the case of the aluminum honeycombs used in aerospace structures or tube-to-tube joining used in motor vehicle frame construction. Because they are usually applied so as to cover the entire joined surface in a continuous rather than point-by-point fashion, adhesives can provide a measure of environmental protection and mechanical reinforcement or stiffening well beyond the capabilities of mechanical fasteners. Stresses in adhesive joints are distributed over a relatively large area, which generally increases the mechanical and cosmetic integrity of joined parts. The energy damping capability of many polymeric adhesives contributes a mechanical damping component to joints that can increase their toughness and impact resistance. Adhesives are a great help in reducing the weight of structures because they add little weight and can facilitate the use of thinner substrates. Joining of dissimilar materials for reasons of economics, weight, or performance is frequently accomplished using adhesive bonding, providing properties already mentioned as well as electrical and thermal insulation, protection against galvanic corrosion, and acoustic damping. In some cases, adhesives are used in conjunction with joining methods such as welding and riveting, via weld bonding and rivet bonding, respectively, in order to maximize stiffness, strength, and fatigue resistance of joints.

Where an adhesive is the obvious choice, it is often the least expensive choice as well. In industrial situations where the performance expected of the adhesive is high and broad and its cost is that of a specialty rather than a commodity material, it is common to see users take a systems approach to make the best choice of joining method or the best choice of adhesive, if adhesive bonding is seen to be the best joining method. The systems approach to choosing adhesives goes well beyond comparing the cost per gallon of adhesives. It considers the number of parts to be joined, the time and cost constraints of assembly, spatial limitations, the need for substrate surface cleaning or preparation, the cost of all application, fixturing, and curing equipment, environmental and safety requirements, disposal costs, and, finally, part performance and lifetime.

Market Economics

In 1996, the global adhesive and sealant industry was estimated to have a size of about 7.5 million metric tons. The monetary value of this volume was considered to be about US$20.0 billion (1). The value of the market was estimated to be $28.0 billion in 1998 led by North America with a 33% share followed by Europe (30%), the Far East (19%), and the rest of the world (18%) (2). By 2002, the same marketplace is expected to grow to 16.7 million metric tons (3). Adhesives make up over 80% of the adhesives and sealants market. It has been estimated that the global use of adhesives will continue to grow annually by 3–4% from 2000 through 2005, but for some types of adhesives and for some markets, the growth could be much larger.

In the United States, the adhesive and sealants business was producing about US$1 billion from sales in 1972. By 1999, the U.S. adhesive business was estimated to be nearly 6.9 million tons in size with an approximate value of US$9.5 billion. The size of the U.S. adhesive market is anticipated to grow to 7.9 million tons by 2004 (4). The largest markets for adhesives in the United States are construction, primary wood bonding, textiles, and packaging. Markets that command some of the highest prices for adhesives include dental, aerospace, and microelectronics.

The late 1990s were marked by significant numbers of consolidations and partnerships in the adhesive industry that are expected to continue into the twenty-first century. In 1999, only seven companies produced 49% of the adhesives sold in the world (5). The remainder of the adhesive industry is highly fragmented; in the United States alone, there are about 500 adhesive companies. North American and European adhesive companies have partnered to serve the global operations of automotive OEMs expecting worldwide service. Several companies have formed joint ventures in the People's Republic of China (6) in anticipation of large market growth in that country. Such arrangements are expected to increase in number as makers of adhesives accelerate their pursuit of greater market share and opportunities in the most lucrative markets. Concurrently with these changes, many large resin suppliers have spun off their adhesive resin operations into new companies or sold off their adhesive raw materials divisions to established companies. An active adhesive formulator must keep track of raw materials sources and be prepared to trace older materials to their new sources.

The adhesives industry has been affected by environmental and regulatory concerns regarding health and safety issues of adhesive ingredients, use of solvents, and other issues. Less than 5% of the adhesives used in the United States in 1999 contained organic solvents. The use of adhesives with solvents is decreasing by about 2% annually. All other adhesives are waterborne or contain no carrier solvent. Recycling of adhesives has become more important as paper recycling has become very common, and the quality of recycled paper depends in part on the nature of adhesive residues present in recycle feedstock (7). Historically, certain adhesives have been based on natural products such as starch, natural rubber, and animal glue, and many adhesives still use as modifiers various tree-based rosins and terpenes, but there has been a strong shift away from naturally derived adhesives. Between 1972 and projected out to 2003, the value of U.S. adhesives made of synthetic resin and rubbers will have increased almost eight times while the value of U.S. adhesives made from natural bases will have increased only about five times (8). In the 1920s, nearly all primary wood bonding was done with adhesives produced from natural products (9). By the 1970s, that need was filled almost entirely by synthetic adhesives. As the price of crude oil rises and oil reserves dwindle, there is increasing interest in making more adhesives from renewable resources (10).

Principles of Adhesives and Adhesive Formulation

An adhesive is designed to perform certain functions. These functions are common to all adhesives, but the details as they relate to a given ultimate use can vary considerably.

First, the adhesive must be able to be conveniently applied to the substrate using a manual or mechanized method of application. Second, the adhesive must wet the surface to which it is applied. Third, the adhesive must achieve a permanently solid state via evaporation of a solvent, removal of pressure, a drop in temperature, or the occurrence of chemical reaction. The conversion must occur within a time period amenable to the use of the bonded part. Fourth, before it is put into service, the adhesively bonded part must have been provided with a bond that is strong enough to resist normally imposed stresses. The stresses normally imposed on a sealed envelope are very different from those imposed on a tiled wall or a bonded vehicle frame. Fifth, the adhesive must maintain the bond through the joint's functional lifetime, withstanding all environments to which the joint is normally exposed.

Methods of Adhesive Application. Until the twentieth century, adhesives and sealants were applied by hand using fingers, sticks, trowels, brushes, spatulas, shovels, and similar implements. These tools are still used by many do-it-yourselfers, craftspeople, and construction workers. Other relatively simple means of applying adhesives involve the use of squeeze bottles, spray cans, rollers, and squeeze tubes. Manual and pneumatic guns are often used to dispense adhesives, sealants, and caulks. For this type of application, the adhesive is supplied in a plastic cartridge to which can be affixed a tip or applicator to help control the shape and size of the adhesive bead as it is expelled. The adhesive is expressed from the cartridge by pressurization of a sealing piston. Such guns can be used to dispense two-part adhesive systems as well as one-parts, which are commonly called 2K and 1K adhesives, respectively, probably in reference to the German *komponent*. In the case of 2K adhesives, a mixing nozzle will be attached to the cartridge. This device consists of a tube and an inserted mixing element through which the two parts of the adhesive flow in a tortuous path, folding over on each other and becoming well mixed. For low volume applications in the industrial sector, 2K epoxy adhesives are often supplied in double-barreled plastic cartridges for application using manual or pneumatic dispensing guns.

High volume applications of adhesives generally dispense adhesives out of containers having volumes up to at least 1135 L (300 gal). Through proper choice of pump design and material choice, bulk dispensing is possible for both liquid and high viscosity paste adhesives whether 1K or 2K (11,12). For some industries, dispensing guns will be handheld and manually operated. In the automotive industry, hem flange adhesives, cosmetic sealers, antiflutter sealants, gap-filling adhesives, and other viscous materials are dispensed in high volumes using computer-controlled guns mounted on robot arms which zip about a part in a few seconds to lay down dollops or linear beads of adhesive or sealant. Gun-robot coordination must be precise. To lay down enough but not too much adhesive in a well-defined area in a controlled fashion, adhesive dispensing companies provide extrusion, spray, streaming, and swirling patterns of adhesive delivery. The adhesive is sometimes heated to lower its viscosity.

Hot-melt adhesives are also dispensed using guns. Hobbyists and do-it-yourselfers use small electric handheld guns into which they insert the adhesive sticks. The gun heats the adhesive, and the operator squeezes a trigger to dispense it. High volume dispensing systems for hot-melts generally include a stirred melting tank and a hot pumping system that delivers the adhesive to the application

device, which may be a spray gun, a roller, a brush, or a film die. Application methods include rotating pick-up wheels, transfer from a hot bar, and release from extrusion heads facilitated by spring ball valves (13).

The invention of pressure-sensitive tapes in the early 1930s provided a novel means of delivering an adhesive where it was needed. Adhesive tapes were first sold as rolls in boxes or cans and were unrolled by hand to be cut with scissors or a blade. This was followed by the design of tape dispensers that range from single-use, all-plastic disposables, to sand-weighted desk-top models fitted with metal blades, and on to the semiautomated dispensers used at large packing plants. Recent advances include dispensers of pre-cut adhesive strips that can be worn on one's wrist and the development of hand-tearable tapes. Solid curable adhesive films are available in roll, strip, and pre-cut forms of various shapes and thicknesses, with or without liners. These are typically somewhat tacky and are generally hand-applied.

Bond Formation. Adhesion science has established several mechanisms by which adhesion will occur. These are sometimes referred to as theories of adhesion, and they represent a means of explaining adhesion phenomena and increasingly provide guiding principles by which adhesion can be predicted to some extent and controlled to a larger extent. These theories are covered in most general texts on adhesives and adhesion science, many of which point out specific examples relevant to the scope of the text, for example, aerospace aluminum bonding or wood bonding. The theories of adhesion include the following:

(1) Electrostatic theory
(2) Diffusion theory
(3) Mechanical interlocking theory
(4) Acid–base theory or specific adhesion/interaction theory
(5) Covalent bonding theory

Regardless of which theory or theories are manifest in an adhesive bond, establishing an adhesive bond requires that first there be sufficient contact between the adhesive and the substrate. This can be accomplished only if the adhesive intimately wets the substrate. Although there are many types of adhesives, in order to form this necessary contact each must flow under the influence of gravity, pressure, heat, or presence of a solvent to wet any asperities on the substrate surface. This wetting is necessary for establishment of a bond, but it is ordinarily insufficient for establishment of the strongest or most durable bond. (Conversely, the area of contact may be controlled to minimize adhesion.) Adhesion science, one of the most interdisciplinary of all sciences, has established several tenets for wettability which are applicable to adhesives, coatings, and other substances whose adherability is of interest. The first is that the surface energy of the wetting material will ideally be lower than that of the substrate. Methods for establishing surface energies of liquids are well established, and tabulations of such data are readily available. Obtaining the surface energy of a solid is somewhat more problematic, but methods do exist, most based on the determination of critical surface tension from measurement of contact angles made by various liquids, and these have been

shown to have merit on a fundamental basis. Any surface roughness or surface contaminants will greatly influence the results of such measurements; however, the methods used are valuable in characterizing the wettability of ceramics and polymers, which generally have smooth surfaces.

The bulk properties of the adhesive and its ability to effect the transfer of stress across the adhesive–adherend interface will strongly dictate the measured strength of the bond, often described in terms of *practical adhesion*. The durability of the bond will be governed by the physical and chemical nature of the interfacial region formed, aptly called the *interphase*. The failure of a bond is usually characterized as being *adhesive* in the case where the failure is between the adhesive and the substrate and *cohesive* where the failure is within the adhesive. Failure may also be *mixed* mode, and other subtleties of the failure mode should be noted during testing or in the field. If surface analysis will be carried out to determine details of failure, failed bonds should be closed until that analysis can be performed.

Ideally the adhesive formulator will have at least a rudimentary knowledge about substrates, be they metals, ceramics, or polymeric materials. Whenever possible, testing of adhesives should be done on the same material being used in practice. If this is not possible, a nominally identical substitute should be used. The surface of the substrate should be what it will be in use. The state of that surface will affect adhesive wet-out, interfacial area, stress distribution, and the likelihood of chemical reaction. It is highly recommended that surfaces be as clean as possible, and it is often recommended that surface treatments be used. The most basic of all surface treatments is cleaning.

Simple cleaning methods include blowing away debris with canned or filtered air, wiping with a dry cloth or a cloth wet with ethanol, cleaning with a water-based citrus cleaner and rinsing with distilled water, and dipping in methyl ethyl ketone or petroleum ether and drying with a clean cloth. Vapor degreasing is used when the volume of parts to be cleaned can justify its installation. Until the early 1990s, chlorinated solvents were used widely for degreasing, but health and environmental concerns have shifted interest to other organic solvents and aqueous degreasers. Other environmentally acceptable cleaning methods that have been investigated include grit blasting, ultrahigh water jetting (14), and excimer laser treatments (15–17).

In some cases, cleaning of a surface is not sufficient for adequate bond formation. For metal bonding, this is especially true in situations where the adhesive joint will undergo exposure to severe environmental conditions such as moisture, salt spray, and high temperatures. The coupling of these environments with mechanical stresses can lead to failures at loads much lower than those at which the same joint would fail in a milder environment. In these situations, it is common to use a wet chemical surface treatment which removes all surface contamination as well as any poorly adhering oxides and converts the newly exposed surface to a durable oxide, preferably with a texture that encourages mechanical interlocking with an applied adhesive. Pretreatments for aluminum have been the subject of considerable research (18). In partnership with adhesive suppliers, aerospace users of aluminum have advanced the state of the aluminum-bonding art on a continuous basis for many years and often use the steps of alkaline cleaning,

phosphoric acid anodizing, and application of epoxy–phenolic primers to prepare aluminum for bonding. For industries in which failure may have less devastating results, organosilanes, sol–gel coatings, and gas plasmas have become the basis of a number of surface treatments.

Polymeric materials often present significant challenges to adhesive bonding. This is particularly true when bonding polymers with low surface energies such as polyethylene, polypropylene, and polytetrafluoroethylene; however, it is also true for bonding high surface energy polymers such as poly(ethylene terephthalate). Reliable wet chemical treatments continue to be used for plastics, but dry chemical treatments are well established as primers for adhesive bonding. These treatments include corona discharge, plasma, flame, and excimer laser.

Cleaning methods chosen should remove rather than redistribute contamination. Some methods which are ostensibly meant to clean may also contribute something in the way of a surface treatment via chemical or physical changes of a substrate. Methods which treat a surface chemically often also change surface texture, coupling roughness and chemical surface modification and making it difficult to separate their independent effects. Microscopic surface texturing can favorably enhance adhesion.

Adhesive users should not assume that meticulous cleaning and costly surface treatments will always be needed to ensure reliable adhesive bonding; however, as in all adhesive applications, the better the user understands what the adhesive must do, the more readily the need for cleaning and surface treatments can be assessed. Cleaning and surface treatment of substrates is not always economically feasible nor is it necessarily environmentally desirable. There have been considerable advances with respect to pressure-sensitive and structural adhesives which form strong durable bonds on oily metals and untreated plastics.

Adhesive Testing. The lifetime of an adhesive includes shipping and compounding of its components, storage and shipping of the adhesive in its final form, application to a surface or surfaces, service use, and a number of methods of disposal along the way and at its end. Adhesive raw materials are tested for certain characteristics at their source and then tested to some minimum standard by the adhesive manufacturer at the manufacturing site. The manufacture of adhesives is either a bulk or continuous process, as appropriate to the form and type of adhesive. After manufacture, there is testing to known standards based on customer and manufacturer requirements. Tests done on the as-manufactured adhesive include both bulk tests of the adhesive which are relevant to its handling and dispensing and tests of the adhesive as a bonding agent. Even before any of this testing occurs, there will often have been extensive laboratory testing of the adhesive to customer specifications, only a very small part of which is repeated on each lot subsequent to manufacturing. In bulk testing of both cured and uncured adhesives, attention to detail is of paramount importance. Consistency of preparation and test conditions can have a profound effect on final results, which are increasingly subjected to statistical analysis during development and through various manufacturing processes.

A variety of standardized tests have been published for adhesive testing. The American Society for Testing and Materials (ASTM), the Technical Association of the Pulp and Paper Industry (TAPPI), the Society of Automotive Engineers (SAE), the Pressure Sensitive Tape Council (PSTC), and the International Organization

for Standardization (ISO) have developed and published many different tests of interest to the technical community. Many academic and corporate libraries have bound collections of these standards. One can search the standard titles at each organization's website, respectively: www.astm.org, www.tappi.org, www.sae.org, www.pstc.org, and www.iso.ch. These organizations and their volunteer working committees actively update existing methods, standardize new methods, and obsolete older methods no longer in wide use. Additional standards are also published by or available from other professional organizations as well as specific companies and institutions. One will find that similar tests have been published by more than one organization or by the same organization; it is therefore useful to consult the source closest to one's interests and to review all applicable methods to find the one closest to one's needs. Variation from these standard methods, which is not uncommon, should be noted whenever reporting results from a given test. In cases where a specific test has not been published, these standards often provide help in developing needed tests. Numerous tests are also described in the open technical literature.

Bulk Testing. The chemical fingerprint, identity of, or contaminants present in bulk uncured adhesives can be obtained by any of the chemical tests routinely performed on other chemicals, including Fourier-transform infrared spectroscopy, mass spectrometry, and elemental analysis. Many adhesives are tested for their water or solvent content using weight loss or expansion tests or one of the analytical methods available. Percent solids are sometimes determined using mass measurements made before and after treatment in an ashing furnace. Volatile organic content is measured using weight loss tests done under relevant conditions. Measurement of the flow properties of adhesives is very important. Rheological tests include simple empirical tests that measure quantities such as the time needed to flow a certain volume a certain distance down an inclined plane or through a pressurized orifice, rotating-spindle tests that determine the relative viscosity of a liquid, and more advanced methods using cone-and-plate and parallel-plate methods that directly measure viscosity, yield stress, and flow activation energy at a variety of shear rates and temperatures. Density of paste adhesives can be measured using calibrated pycnometers. Thicknesses of solid adhesives, tapes, and related products can be measured manually or with methods such as x-ray fluorescence. Qualitative tests performed on adhesives include those addressing color, odor, consistency, foreign particulates, separation, and skinning. Shelf-life tests of bulk adhesives generally track how one or more of these many adhesive characteristics changes with time and temperature.

Testing of cured adhesives in the bulk state has become more widespread because of increasing use of adhesives in engineered structures. Concurrently, modelling of adhesive joints has become more commonplace, and for such work, measurement of the bulk mechanical and solid fracture properties in a variety of modes is essential. Developers of adhesives are also increasingly aware that testing of cured adhesives in the bulk state can provide information relevant to their performance in bonded joints.

Tests in common use for bulk characterization of adhesives include ASTM D816, *Standard Test Methods for Rubber Cements*; SAE J1524, *Method of Viscosity Test for Automotive Type Adhesives, Sealers, and Deadeners*; ASTM D638, *Standard Test Method for Tensile Properties of Plastics*; ASTM D3983, *Standard*

Test Method for Measuring Strength and Shear Modulus of Nonrigid Adhesives by the Thick-Adherend Tensile-Lap Specimen; and ASTM D2979, *Standard Test Method for Pressure-Sensitive Tack of Adhesives Using an Inverted Probe Machine*.

Adhesive Bond Testing. Practical adhesion is quantified in terms of the force or energy per unit area needed to separate a bonded joint. The most commonly used bonded joint configurations are the asymmetric and symmetric overlap shear and 90° and 180° peel. Many special or use-specific adhesive joint tests are also done. Adhesive tests based on fracture mechanics are increasingly used for their relevance to engineering design. Commonly used adhesive bond tests include ASTM D1002, *Test Method for Apparent Shear Strength of Single-Lap-Joint Adhesively Bonded Metal Specimens by Tension Loading (Metal-to-Metal)*; ASTM D2095, *Standard Test Method for Tensile Strength of Adhesives by Means of Bar and Rod Specimen*; ASTM D950, *Standard Test Method for Impact Strength of Adhesive Bonds*; ASTM D1780, *Standard Practice for Conducting Creep Tests of Metal-to-Metal Adhesives*; ASTM D2294-96, *Standard Test Method for Creep Properties of Adhesives in Shear by Tension Loading (Metal-to-Metal)*; ASTM D1876, *Standard Test Method for Peel Resistance of Adhesives (T-Peel Test)*; and ASTM D3330/D3330M, *Standard Test Method for Peel Adhesion of Pressure-Sensitive Tape*.

The testing of adhesives for their initial bonding characteristics makes up but one portion of adhesive testing. Testing of adhesive bonds under sustained mechanical loads and aggressive environments (moisture, heat, salt spray, saline soaks, solvent soaks, etc) comprises a significant part of testing. Repeated cycling of adhesive bonds through three or more environments, with or without a sustained load, is widely used although there is not always as much a strong scientific basis for the design of such test regimens as there is an experience base that suggests that such tests are predictive. Impact and dynamic or fatigue testing of adhesive bonds have become important components of adhesive testing.

Classification of Adhesives

There are many ways to classify adhesives. These include chemical class, joint strength, bulk modulus, physical form, ultimate use, general market, method of application, and price. Another classification scheme involves considering the activation of an adhesive and the driving force for its change from a liquid-like system to a solid-like system. Each of these methods of classification provides a framework within which to understand adhesives.

The primary chemical classes from which adhesives are made include epoxies, acrylics, phenolics, urethanes, natural and synthetic elastomers, amino resins, silicones, polyesters, polyamides, aromatic polyheterocyclics, and the various natural products such as carbohydrates and their derivatives as well as plant- and animal-based proteins. Chemical class was once a relatively clean differentiator of adhesives, but so many adhesives now are hybrids, designed to take advantage of specific attributes of more than one chemical class or type of material. Hybridization can be accomplished by incorporating into an adhesive a nonreactive resin of a different chemical class; adding another type of reactive monomer, oligomer,

or polymer; or chemically modifying an oligomer or polymer prior to adhesive compounding.

The measured overlap shear strength or peel strength of an adhesive joint is sometimes used to classify adhesives. The choice of substrate is a key element of such a comparison, certain aluminums or steels being most commonly chosen as standards, but glass, polyolefins, and other substrates are also used. Pressure-sensitive adhesives will be found at the low end of the bond strength spectrum, and structural adhesives will be found at the high end. In the middle will be found materials that are strong but not necessarily structural in nature; these are often called semistructural adhesives. Many sealants are strongly adherent, and some of these are referred to as adhesive sealants.

Market is a useful category for those interested in the buying and selling of adhesives, but market-based categories can be very broad. Construction adhesives, for example, include joint compound, carpet glues, ceramic and vinyl tile adhesives, a variety of wood-bonding adhesives, and double-sided foam tapes for hanging architectural glass. Although the adhesives used in some of these product categories are relatively standardized, there are many choices in other product categories. Similar breadth and depth would be encountered among adhesives used in the automotive, medical, and electronics industries. Within each of these market areas and most other market areas there will be found both commodity and specialty adhesives.

Most of those who develop adhesive compositions consider the form and ultimate use of an adhesive to be the most useful categories because these guide and direct adhesive development. The ability of the adhesive formulator to satisfy an end use will be very much related to the completeness of the information available concerning performance attributes required or expected. Price is a category of immense interest to the adhesive developer as it helps to define the raw materials from which the formulator may choose. The adhesive development team often must work closely with the customer to learn what is really needed from an adhesive.

Forms and Types of Adhesives

As supplied, adhesives can be found in the form of low viscosity liquids, viscous pastes, thin or thick films, semisolids, or solids. Before application to a substrate, an adhesive need not be sticky or otherwise particularly adherent. A distinct exception is the pressure-sensitive adhesive (PSA), which is inherently tacky when first made. Such an adhesive is applied as a thin film with or without a backing, the combination of the adhesive and the backing defining an adhesive tape. The PSA remains throughout its useful lifetime essentially the same material it was when first made. All other forms and types of adhesives undergo a transformation which is central to their function as an adhesive. This transformation is usually carried out through imposition of time, heat, or radiation, either actively or passively.

By loss of liquid, an adhesive applied as a true solution or a dispersion of solids will dry through loss of water or another solvent, leaving behind a film of adhesive. A reactive adhesive system will form internal chemical bonds through

the process of cross-linking, chemical reaction that joins dissimilar long-chain molecules, or polymerization, chemical reaction that joins similar monomer units. Solid adhesives are heated in order to be applied and then on cooling become functional adhesives. The transformation from a liquid, paste, or semi-solid to a functional adhesive is loosely termed *curing*. Additional general terms that refer to this transformation include *setting up* and *hardening*. Adhesives may also cure in stages. The first stage of curing is sometimes referred to as the B stage, and adhesives which have undergone some level of precure in their manufacture are often said to have been *B-staged*. For many adhesive applications, the ability of an adhesive to gel, precure, or develop green strength or handling strength is a key characteristic, being most important for parts which will be bonded and then transported to the next step in their processing. *Adhesives* are referred to as such before and after cure.

Pressure-Sensitive Adhesives. Pressure-sensitive adhesives (PSAs) are inherently and permanently soft, sticky materials that exhibit instant adhesion or tack with very little pressure to surfaces to which they are applied. The level of adhesion may build with time and be surprisingly high. PSAs generally have a high cohesive strength and often can be removed from substrates without leaving a residue. Some applications take advantage of a PSA's ability to quickly form a strong bond and under stress, force failure elsewhere in a system, an attribute used to advantage in tamper-proof packaging and price stickers. At the other end of the spectrum lie PSAs that can be repeatedly repositioned. The primary characteristics used to describe the performance of PSAs are tack, adhesion strength in peel, and resistance to shear forces.

PSAs can be sold in bulk or solution for later coating by product manufacturers. Most PSAs, however, are sold as components of tapes or labels. PSAs are also used to make protective or masking films, some of which also function as conventional tape products. PSAs are sold in the form of aerosol sprays for graphic arts work. Tape products join one object to another, as when one wraps a gift, seals a box, or puts up a notice. They consist of a film or web carrier coated on one or both sides with a PSA. The carrier is usually a paper or synthetic polymer made in the form of a solid or a foamed film. It is a key component of the tape. Such a construction is usually slit and wrapped on itself to form rolls of adhesive tape from which sections of the desired length can be removed. A release coating is sometimes added to the backside of the tape backing so that the tape can be removed from the roll cleanly, easily, and quietly without splitting the adhesive from the backing. Double-sided tapes that have no release liner effect release through opposite pairing of chemically different adhesives which are chemically incompatible or through use of adhesives of different levels of cross-linking which are physically incompatible. There also may be a primer on one or both sides of the tape carrier to ensure better adhesion of the PSA or the release coating. Some tapes are sold with release liners that must be removed after the tape is taken off its roll. Tapes can be applied manually or via mechanized tape dispensers for packaging, splicing, and other applications. Labels are sold with the PSA already present for their attachment to a variety of surfaces. Transfer tapes are PSAs that are provided on a liner from which the adhesive film can be transferred to another surface. PSAs that are effectively sticky hot-melt adhesives can be applied

in discrete lines, dots, or other shapes using manual and automated equipment. The convenience and adaptability of PSAs has gained them wide use in diverse applications in virtually every market served by adhesives.

Many PSA compositions contain a base elastomeric resin and a tackifier, which enhances the ability of the adhesive to instantly bond as well as its bond strength. The elastomer may be useful without cross-linking but will often require either chemical or physical cross-linking for establishment of sufficient cohesive strength. Heat or uv or radiation is usually the activator of the cross-linking, and suitable catalysts are used, their choice depending on the base resin. Small amounts of epoxy or hydroxy functionality are sometimes added to allow uv cures if the base resins are not themselves uv-curable. Electron beam curing has received attention but tends to be more costly than uv curing. Elastomers used as the primary or base resin in tackified multicomponent PSAs include natural rubber, polybutadiene, polyorganosiloxanes, styrene–butadiene rubber, carboxylated styrene–butadiene rubber, polyisobutylene, butyl rubber, halogenated butyl rubber, and block polymers based on styrene with isoprene, butadiene, ethylene–propylene, or ethylene–butylene. Any of these resins may be blended with each other to alter or optimize properties. Polychloroprene, *cis*-polyisoprene, and some waxes are rarely used as the main components in PSAs but have found some use as modifiers. Natural rubber grafted with methyl methacrylate, styrene–acrylonitrile copolymers, and other elastomers have been found useful as components of primers for PSA products. Polymers which can be useful as PSAs without tackification but may be modified beneficially with their addition include poly(alkyl acrylate) homopolymers and copolymers, polyvinylethers, and amorphous polyolefins. Comonomers useful for acrylate PSAs include acrylic acid, methacrylic acid, lauryl acrylate, and itaconic acid.

Much of the art of making PSAs rests in the choice of tackifier and the balance between base resins and tackifiers, of which there are numerous choices (19). Tackifiers commonly used with natural rubber, butyl rubber, and polyacrylates include rosins and rosin derivatives manufactured from pine tree gums. The styrenic block polymer base resins respond well to tackification with aliphatic and partially aromatic materials miscible with their continuous nonstyrenic phase or phases. Materials useful as PSA tackifiers have a lower molecular weight than the base resin. They are useful because they lower the modulus of the bulk adhesive in the rubbery region of the modulus–temperature spectrum, that is, above the glass-transition temperature. Tackifiers also tend to raise the glass-transition temperature of the system. Tackifiers which react with PSA resins have been introduced to counteract tendencies of tackifiers to migrate, bloom, or volatilize; these kinds of tackifiers are based on isocyanato-reactive or vinyl functional groups (20). Plasticizers are mentioned somewhat synonymously with tackifiers as modifiers for PSAs, but their use is recommended cautiously as any improvements they provide in tack can be quickly offset by losses in strength if the glass-transition temperature of the material is lowered too much.

Silicone PSAs are blends or reaction products of the combination of a polyorganosiloxane, such as poly(dimethyl siloxane) or its copolymers with diphenylsiloxane or methylphenyl siloxane, with a polysiloxane resin, which is largely inorganic. Pendant vinyl groups may also be incorporated into silicone PSAs,

making cross-linking possible with peroxide and other kinds of cures. These kinds of PSAs are most often tackified with additional silicone gums and siloxane resins of varying molecular weight. The silicone PSAs are unique in their resistance of temperatures up to 400°C; performance at elevated temperatures can be optimized using the siloxane resins and rare earth or transition-metal esters (21) (see PRESSURE SENSITIVE ADHESIVES).

The large bulk of PSAs are coated onto continuous webs or films to make pressure-sensitive tapes, labels, and so on. While many PSAs continue to be coated out of organic solvents, many have been converted to water-based formulations or are extruded as hot-melt adhesives, which upon cooling retain their tack. Aqueous emulsions of carboxylated styrene–butadiene and various acrylate copolymers are among the most useful as bases for water-based PSAs. The complexity of latex chemistry introduces additives such as chain-transfer agents and defoamers (22) into some emulsion-based PSAs. Proper coating of these kinds of PSAs can require addition of thickening agents based on water-soluble polymers. Other additives that may be found in PSAs include cross-linking agents, catalysts, heat stabilizers, antioxidants, photoinitiators, depolymerizers (or peptizers), and various fillers. Reinforcing agents such as phenolics and higher molecular weight relatives of the tackifiers are sometimes added to improve cohesive strength. As made, PSAs are generally colorless or off-white in appearance but are sometimes pigmented for color adjustment or become pigmented through addition of a colored filler such as titanium dioxide, talc, or silver.

Hot-Melt Adhesives. Hot-melt adhesives are solid adhesives that are heated to a molten liquid state for application to substrates, applied hot, and then cooled, quickly setting up a bond. The largest uses of hot-melt adhesives are in packaging, bookbinding, disposable paper products, wood bonding, shoemaking, and textile binding. The advantages of hot-melt adhesives include their easy handling in solid form, almost indefinite shelf life, generally nonvolatile nature, and, most importantly, ability to form bonds quickly without supplementary processing. They are considered friendly to the environment and are expected to see expanded use on a worldwide basis as the market continues to move away from solvent-based adhesives. The disadvantages of hot-melts lie in their tendency to damage substrates which cannot withstand their application temperatures, limited high temperature properties, and only moderate strength.

Application temperatures typically used for hot-melts range from about 65–220°C. Although the industry still refers to most temperature-sensitive adhesives as hot-melts, one will see references to warm-melt adhesives that soften at about 121°C and cool-melt adhesives that soften below about 100°C, but these terms are somewhat arbitrarily applied. Decreases in the application temperatures for hot-melts have lessened safety concerns associated with this type of adhesive. While most hot-melts are supplied as sticks or pellets, they are also produced as flat films or sheets, rolls, fibrous nonwovens, powders, strings, bulk masses, or dots or lines on liners.

Hot-melts generally are based on one or more thermoplastic resins. The largest portion of commercial hot-melt adhesives has for many years been based on ethylene–vinyl acetate copolymers having a vinyl acetate content of about 20–40%. The styrenic block polymers which are thermoplastic elastomers also make up a large portion of hot-melts. Other resins that have been found useful as bases

for hot-melts are synthetic elastomers, ethylene–ethyl acrylate copolymers, amorphous polyolefins, branched polyethylenes, polypropylene, polybutene-1, phenoxy resins, polyamides, polyesters, and polyurethanes. Combinations of these resins allows for property and cost adjustments. Tackifiers and plasticizers are commonly added to hot-melts to improve their flow and adhesion to substrates. Examples include synthetic hydrocarbons, natural terpenes, rosins, and various phthalates. Polybutene is occasionally used as the base resin for hot-melts having good cold flow and high wet-out characteristics, but it may also be used as a flexibilizer or plasticizer. Waxes are important hot-melt ingredients, lowering melt viscosity and improving wet out of the substrate. Reactive tackifiers exist to address migration. The polyamide, polyester, and polyurethane hot-melts are often classed separately from the other resins on which hot-melts are based. All are the result of condensation reactions, and they are frequently used with few additives, their properties instead being adjusted by changing the starting ingredients of the polymers. They may, however, contain additives that make them better suited to specific uses. Adhesives based on these polymers are considered to deliver higher performance by virtue of better high temperature resistance and higher strength and may provide better adhesion to polar substrates than the other largely hydrocarbon hot-melt adhesives (23).

Conventional hot-melt adhesives cool to set and do not chemically cross-link. Such systems have an open time of a few seconds to a few minutes. The need for more heat-stable adhesives and stronger bond strengths has driven the development of reactive hot-melts which undergo cross-linking. These are primarily based on polyurethane hot-melts with residual isocyanate groups that react with water after application to form a thermoset adhesive material. Water is provided by the surrounding air and substrate. Cure of these hot-melts is nearly complete within 24 h, but time for full cure will depend on temperature and ambient and substrate moisture content. An extension of the water-activated isocyanate cross-linking reaction is found in the use of polyurethanes which have been silylated to provide active hydrogens for reaction with residual isocyanates in polyurethanes (24). The acceptance of reactive polyurethane hot-melts has led to development of reactive block polymer and acrylate hot-melts which rely on radiation cure through activation of epoxy or vinyl groups (25,26); these are used primarily as PSAs.

Hot-melt adhesives are usually clear, off-white, white, or amber. Colored versions are available for nonbonding decorative use, for example, arts and crafts. Good color retention with heat aging is an important feature of a heat-stable hot-melt system, and antioxidants and heat-stabilizers are common ingredients in hot-melt adhesives. Photoinitiators are frequently present when uv or other radiation curing will be used. Other useful additives include fillers and reinforcing agents. When there is some lack of cohesiveness in blends of base resins, compatibilizers may be used to improve the apparent miscibility of these resins (27). Hot-melts can be based on either amorphous or semicrystalline resins. Particularly in the case of semicrystalline resins, the rate of cooling can dramatically affect adhesion to a substrate (28). To control the development of crystallinity, nucleating agents may be added to formulations based on crystallizable polymers such as polyesters.

Solution Adhesives. Adhesives delivered out of solutions are typically used for joining large areas destined for nonstructural or semistructural service.

The solution may be made with an organic solvent or with water or may be an aqueous dispersion. It is important that the liquid carrier have some means of escaping from the bondline in order for the proper bond strength to develop. It should be appreciated that many PSAs are made by casting out of liquids, but when put into use as components of tapes or labels, these adhesives are soft solids containing virtually no liquid.

Solvent-Based Solution Adhesives. Contact adhesives, activatable dry-film adhesives, and solvent-weld adhesives make up the solvent-based adhesives. Contact adhesives are solutions of high polymers which are applied to all surfaces to be joined via spray or brush, allowed to dry partially, and then given time under pressure to allow the adhesive layers to fuse. Heat is sometimes used to increase tack or accelerate drying. These adhesives are commonly used to join wood veneers to wood bases, synthetic laminates to particleboard countertops, and paper products to other materials. The major dry-film adhesive is solvent-applied natural rubber, which is unique in its ability to adhere to itself without tackification and useful for self-sealing envelopes and similar employment. After being coated on to paper or another substrate, dry-film adhesives must be wiped or sprayed with a liquid to regain their adhesiveness; the activating liquid now is nearly always water. Solvent-weld adhesives are used to join plastic parts such as PVC piping. The adhesive is usually a solution of PVC or chlorinated PVC that is applied to the outer surface of the pipe and the inner surface of a connector piece that are joined firmly together before the solvent has evaporated.

The most widely used contact adhesive is a solution of polychloroprene or modified polychloroprene in solvent blends of aromatic hydrocarbons, aliphatic hydrocarbons, esters, or ketones, for example, toluene–hexane–acetone. Viscosity, dry time needed before bonding, bond strength, and price are affected by the solvent. Using various combinations of the isomeric forms of polymerized 2-chlorobutadiene permits a fine-tuning of the crystallization rate of the dissolved polymer as the solvent evaporates. The polychloroprene may also be modified by the incorporation of methacrylic acid or mercaptans. Metal oxides (MgO and ZnO) that scavenge acids are often part of polychloroprene adhesives and also may act as cross-linking agents. Oxygen scavengers such as butylated hydroxytoluene (BHT) [128-37-0] or naphthylamines [25168-10-9] are added to prevent dehydrochlorination. To build initial handling strength, the solvent-based polychloroprene contact adhesives may be modified with alkyl phenolics, terpene phenolics, or phenolic-modified rosin esters, the first of these being the most effective and least deleterious (29). Chlorinated rubbers are sometimes added to these adhesives to improve their adhesion to plasticized PVC and other plastics. Added just before adhesive application, isocyanates are useful in modification of polychloroprene contact adhesives, reacting perhaps through hydrolysis of the pendant allylic groups present from the small number of 1,2 isomeric segments (30). The remainder of the solvent-based contact adhesives are comprised of polyurethane, SBR, styrene–butadiene–styrene block polymers, butadiene–acrylonitrile rubber, natural rubber, or various acrylic or vinyl resins in suitable solvents.

Water-Based Solution Adhesives. Solution adhesives based on water dispersions and aqueous emulsions are steadily gaining in use largely at the expense of solvent-based adhesives. These are rarely true solutions, with the exception of the viscosity modifiers often used to adjust flow characteristics. Dispersions

of polyurethanes in water find use in bonding of plastic sheets and films, cloth, shoe parts, foams, PVC veneers, and carpets. Other water-dispersible resins can be added to the polyurethane dispersion to lower costs and modify performance characteristics. The largest group of water-dispersed or water-dissolved adhesives are made of natural products, which are covered separately. At one time, vegetable gums were used widely as water-activatable adhesives, but poly(vinyl alcohol) has replaced them in envelope sealing and similar areas.

Poly(vinyl acetate) emulsions, the basis of the ubiquitous household white glues, are among the most familiar water-based adhesives. These are widely used for paper and wood bonding. They contain a substantial percentage of vinyl alcohol content, formed via partial hydrolysis from the vinyl acetate homopolymer as vinyl alcohol itself is not a stable molecule. Such latices are stabilized through the use of surfactants, one choice being well-hydrolyzed poly(vinyl acetate). After application to the substrate, latex adhesives cure by the evaporation of water accompanied by the coalescence of the latex particles. On the porous substrates with which these are most frequently used, the water exits the bondline through the substrate as well as the adhesive, preventing voiding or foaming which might weaken the bond. Subtle changes in properties can be engineered through the use of other comonomers or the use of liquid plasticizers. Glyoxal [107-22-2] or other cross-linking agents can be added to poly(vinyl acetate) latex adhesives to combat creep (31).

Polychloroprene latex adhesives have been available for many years. They are stable at pH values between about 10 and 12. The latex particles are usually lightly cross-linked. Except for the substitution of water for the organic solvent, the ingredients in these kinds of adhesives are similar to those found in their solvent-based counterparts. Terpene–phenolics are particularly effective as tackifiers for contact adhesives based on polychoroprene latices but rosin acids, rosin esters, hydrocarbons, and coumarone–indenes are also useful, particularly where heat-assisted bonding is not possible. Dehydrochlorination leading to acid generation is particularly possible with the water-based polychloroprene adhesives. Like other water-based adhesives, these may require addition of biocides or preservatives to prevent the breeding of microorganisms (32).

Structural Adhesives. Structural adhesives are designed to bond structural materials. Nearly any adhesive giving shear strengths in excess of about 7 MPa (about 1000 psi) may be called a structural adhesive. Structural adhesives are generally the first choice when bonding metal, wood, and high strength composites to construct a load-bearing structure. Bonds formed with structural adhesives cannot be reversed without damaging one or the other substrate. They are the only kind of adhesive that might be expected to be able to sustain a significant percentage of its initial failure load in a hot and humid or hot and dry environment. Any one of these descriptors names structural adhesives the strongest and most permanent type of adhesive. For good reason, they are sometimes referred to as engineering adhesives. The strength and permanence of structural adhesives is largely achieved using reactive adhesives, a term which has become something of a synonym for structural adhesives. Epoxies are the most widely used class of structural adhesive chemistry, but acrylates, urethanes, phenolics, and other classes have been used to great advantage, and the combination of these different chemical classes to create hybrid adhesives propagates the best virtues of each.

Reactive adhesive systems which are arguably not always considered structural adhesives but are conveniently grouped here are also reviewed in this section.

Epoxy Resins. Epoxy resins have a long and distinguished record as structural adhesives. Their use dates to 1950 or earlier, and their utility for adhesives was recognized upon their development. Most epoxy adhesives are resins based on what is commonly known as the diglycidyl ether of bisphenol A (DGEBPA). These resins are based on the reaction of 4,4′-isopropylidene diphenol (bisphenol A) [80-05-7], $C_{15}H_{16}O_2$, and epichlorohydrin [106-89-8], C_3H_5ClO. The molecular weight of the commercial difunctional resins formed by this reaction will vary with the molar ratio of the reactants. At a molecular weight of about 400 or less, these resins are viscous liquids which are immensely useful in epoxy adhesives. Commercially viable solid resins based on DGEBPA have molecular weights ranging up to about 4000. Many epoxy adhesives will also contain a small amount of an epoxy diluent having low viscosity and a more flexible structure; this resin adjusts the flow of the system and also helps to wet out the fillers that are usually present.

A wide variety of epoxy resins are commercially available: monofunctional or polyfunctional, aliphatic, cyclic, or aromatic. Brominated epoxies may be useful where flammability is a concern. An oxirane functionality is all that is needed to make an epoxy resin, and structural adhesives are only one of over a dozen different uses for epoxy resins. Many epoxy resins on the market will not necessarily be suitable for adhesives, but their availability does expand the choices available for adhesive formulators. The specialty epoxy resins developed specifically for adhesive use sometimes will be more costly than the DGEBPA resins but may provide the basis for a specialty adhesive that can meet a unique need and therefore command a proportionally higher price. Examples of these are epoxy-functional dimer acids, urethanes, and various elastomers.

Epoxy resins based on DGEBPA usually are quite stable at temperatures up to 200°C. Curing agents, sometimes called hardeners, must be added to the epoxy so as to cause cross-linking and chain extension to occur and a bond to form. Certain types of curing agents will be favored over others for each of the three types of epoxy structural adhesives: one-part (1K) epoxy paste adhesives, 2K epoxy paste adhesives, and 1K epoxy film adhesives. The strained oxirane ring is reactive with functional groups having either nucleophilic (basic) or electrophilic (acidic) character. Acid anhydrides, carboxylic groups, and hydroxyl groups react very slowly with the oxirane ring and are usually used with catalysts that accelerate their reaction with epoxies. Those groups which readily react without catalysts but often benefit from their use include amines and mercaptans. Both the epoxy resin and the curative package (curing agent plus catalyst) will influence final cure speed.

One-part (1K) paste adhesives usually consist of a DGEBPA resin, a reactive diluent, and latent curing agents that are insoluble with the resin at room temperature but dissolve at elevated temperatures to trigger cure. These kinds of adhesives are in use in the aerospace, automotive, and electronics industries. Dicyanodiamide or dicyandiamide [461-58-5], $C_2H_4N_4$, is the most frequently mentioned latent curing agent for cures occurring in the range of 170–180°C; practitioners refer to this material as *dicy*. Also useful in this range are metal-complexed imidazoles, complexes of Lewis acids (eg, boron trifluoride with amines), and diaminodiphenylsulfone. Cure temperature can be lowered by

using micronized dicyanodiamide ground to a particle size of 5–15 μm. Cure can be accelerated by use of aromatic tertiary amines, imidazole derivatives, and epoxy resin adducts with tertiary and other amines. Substituted ureas such as Monuron [150-68-5], $C_9H_{11}ClN_2O$, and nonchlorinated substituted ureas such as 3-phenyl-1,1-dimethylurea [101-42-8], $C_9H_{12}N_2O$, have also found use as accelerators in 1K epoxy adhesives. Dihydrazides offer a range of melting points depending on structure, their cure temperatures with epoxies beginning as low as 100–110°C. Adducts of dicyanodiamide which melt at temperatures in the 115–120°C range are available. Accelerated 1K epoxies show faster cures once heated but suffer from decreased shelf lives; after manufacture, they are usually stored in refrigerators or preferably freezers although this is usually impractical for drum quantities. For these same reasons, their manufacture is carried out at temperatures well below their activation temperatures and at low shear rates to avoid viscous heating.

The low viscosity two-part (2K) epoxy adhesives sold in hardware stores as 5-min epoxies are based on cure with polymercaptans regulated with amines to control worklife. The human nose can sense some mercaptans in air at the ppb level, making them valuable as gas odorants, but they are tremendously useful as curing agents, particularly when used in thin films as for adhesives. Their low toxicity is also an advantage. Capcure 3-800 [101359-87-9] is a commonly found polymercaptan. Low odor polymercaptans have been developed which combine strategies of odor masking, odor counteracting, and absorbency to stabilize polymercaptans, reducing the level of odor by about 75% (33). Higher molecular weight versions of the polymercaptans are useful as the base resins of polysulfide sealants, which are sometimes categorized as adhesives. In full formulation, the polysulfide base resins are blended with curing agents such as manganese dioxide or sodium perborate, accelerators or retarders, fillers, plasticizers, thixotropes, adhesion promoters, and pigments (34). These materials are used primarily in the construction and aerospace industries.

Many useful 2K epoxies utilize curing agents that are the reaction products of amines of low molecular weight with fatty acids. These are variously known as polyamidoamines, polyamides, and amidoamines and sold in a range of molecular weights under trade names such as Versamid and Ancamide. The fatty acid portion of these amines gives them larger bulk than the lower molecular weight amine curing agents, which facilitates formulation of adhesives having mix ratios closer to 1:1 by volume, which is of benefit for both packaging and off-ratio tolerance. Curing with polyamidoamines generally produces relatively flexible adhesives having good chemical resistance. Because they typically cure slowly, they are frequently used in combination with other amines such as diethylenetriamine (DETA), triethylenetriamine (TETA), tetraethylenepentamine, aminoethylpiperazine, modified imidazolines, and oligomeric amine-terminated polyethers. Some of the amines in this group are used as sole curing agents, and others, such as DETA and TETA, are used as epoxy adducts to reduce toxicity and increase stability. Aromatic amines, although useful for epoxy resin composite matrices, find little use in epoxy adhesives.

Another family of curing agents is based on substituted phenols such as tris(dimethylamino)phenol [31194-38-4], $C_{12}H_{21}N_3O$, and tris[(dimethylamino)methyl]phenol [90-72-2], $C_{15}H_{27}N_3O$. These tertiary amines

can produce rather brittle adhesives if used as sole curing agents, but are valuable as accelerators for other amines. They act as catalysts for dicarboxylic acid anhydride cures. Amines are also useful as accelerators for the oxirane–alcohol reaction, which is sluggish at room temperature but with catalysis will proceed above 120°C. Imidazoles are also generally useful as catalysts or cocuring accelerators for epoxy reactions with amines, hydroxyls, and thiols. Organic and inorganic salts sometimes find use in epoxy adhesives, coatings, and encapsulating compounds. Acid catalysts such as boron trifluoride–amine complexes find some use in epoxy adhesives but tend to require long cures, even at elevated temperatures, which normally works against their use in adhesives. Epoxy resins react slowly with acid anhydride curing agents but can be accelerated with acids or bases, imidazoles being used most often; however, anhydrides are not often used as curing agents in epoxy adhesives.

Epoxy film adhesives are 1K adhesives in film form. They are formulated much like 1K paste adhesives but often contain solid epoxy resins and additional resins that provide binding properties. These may be partially cured (B-staged) to provide a more dimensionally stable film. Epoxy film adhesives have been widely used in the aerospace industry where their relative stability accommodates the long build times needed for aircraft manufacture. Their cured properties can be outstanding in terms of strength, toughness, and durability. They can be supplied in film form and cut to size or provided as tapes in convenient slit widths. They may be made to be tacky using rubber resins and other mild tackifiers or they may be dry. Film adhesives of a more aggressive pressure-sensitive character have been developed by coating or laminating with pressure-sensitive formulations or formulating such that the bulk adhesive (35) is a PSA in its own right but can be cured to a semistructural or structural strength. Epoxy film adhesives based on thermoplastic polyamide resins are very tough when cured but can be susceptible to moisture absorption.

In addition to resins and curing agents, epoxy adhesives will contain many functional additives and modifiers. Flexibilizers and toughenersuch as polysulfides, epoxidized fatty acids, epoxidized polybutadiene, and amine- and carboxy-terminated acrylonitrile butadiene polymers react with the epoxy network. Flexibilizers remain in phase with the epoxy while toughenersypically phase separate to form domains, the result producing a tougher adhesive with more or less strength reduction relative to an unmodified system. Particulate toughenersay also be added to epoxy adhesives. These include core-shell resins, functionalized elastomeric particles, and ground reclaimed rubber. Positive aspects of structural adhesives based on epoxy resins include good adhesion to many substrates, no emission of volatiles upon cure, low shrinkage, and a broad formulating range based on a history of use dating to the 1940s. The lack of outgassing allows most curing to be done at ambient pressure although clamping till cure is standard protocol for any adhesive bonding operation. Shrinkage can be further decreased with use of appropriate fillers, harder fillers by some reports providing the lowest shrinkage.

Acrylics. Historically, acrylics offer several useful characteristics as structural adhesives. Most well known is their relatively high speed of reaction via free-radical polymerization. The details of their reaction provide a useful division

of the different classes of acrylic structural adhesives into redox-activated adhesives, encompassing both anaerobic acrylics and nonaerobic structural acrylics, and Polycyanoacrylates. These will be considered in turn.

Oxygen inhibits the polymerization of acrylic monomers to a useful extent, and its exclusion kicks off polymerization of monomeric acrylates. Early versions of anaerobic acrylics relied solely on this mode of initiation and polymerization, containing little besides acrylate monomers and diacrylic esters (36). Later it was found that if hydroperoxides were incorporated into the acrylic monomer, small amounts of free metal ions from metal substrates could help to create free radicals that initiated polymerization of the acrylate monomers. Only small amounts of metal ions are needed, iron, nickel, zinc, and copper being some of those of major industrial interest. Even though a major alloying element, for example, aluminum, may not be capable of helping to generate free radicals via the redox reaction, minor alloying elements, such as copper, may be available which can act in this capacity. The speed of reaction is limited by the ability of the metal ion to reduce the peroxide. Free-radical initiators used in anaerobic acrylics have included cumene hydroperoxide, *t*-butyl hydroperoxide, and potassium persulfate [7727-21-1], $K_2S_2O_8$. Other useful initiators for this cure are combinations of saccharin [81-07-2] with aromatic amines such as *N*,*N*′-diisopropyl-*p*-toluidine [24544-09-0] or 1-acetyl-2-phenylhydrazine [114-83-0]; such combinations were originally thought to be accelerators useful only with peroxide initiators until it was found that they were themselves initiators (37). Various accelerators can be used with initiators to hasten cure of these adhesives; classes of compounds useful as accelerators include cyclic peroxides, amine oxides, sulfonamides, and triazines (38).

A key ingredient in anaerobic acrylic adhesives is the acrylate monomer or monomers. These include primarily acrylic acid and methacrylic acid and their many and various esters such as lauryl acrylate, cyclohexyl methacrylate, methyl methacrylate, hydroxyalkyl methacrylates, and tetrahydrofurfuryl methacrylate. These monomers vary in their volatility, reactivity, and cost, the less volatile monomers forming the basis of low odor acrylic adhesives. In addition to the monomer acrylates, there generally is also present a diacrylate which acts as a cross-linker, the alkyl glycol dimethacrylates being widely used in this function. Other ingredients used in these adhesives include stabilizers or polymerization inhibitors such as phenols or quinones, chelating agents that snatch up trace metals to prolong shelf life, and various modifiers such as inert fillers, inorganic and polymeric thickeners, elastomers to improve toughness, and bismaleimides that improve high temperature performance (39).

The low viscosities and good wetting properties of these adhesives allow them to penetrate and flow in tight spaces. This is taken advantage of in many of their uses. Threadlocking and sealing are primary applications. When applied to the threads of bolts or pipes, to flanges, and to other tight-fitting machine parts which are later screwed into or pressed against a mating surface, the adhesive cures because of the exclusion of air and the formation of free radicals via the reaction of metal ions with the initiator. Other applications include bonding of optical fibers, impregnation of porous parts, crimp-bonding of electrical parts, and fastening of press-fit parts. Anaerobic adhesives are one-part adhesives, usually packaged in

small oxygen-permeable plastic containers which have not been entirely filled, this arrangement providing a sufficient supply polymerization-inhibiting oxygen to ensure good shelf life.

The non-aerobic structural acrylic adhesives are two-part adhesive systems. They are generally less oxygen-inhibited than the non-aerobic acrylics and do not rely on metal surface activation in the same way as the anaerobics. These adhesives are very similar in formulation to the non-aerobics, each borrowing technology from the other as it has developed. Lower oxygen sensitivity is accomplished through higher concentrations of accelerators and initiators. The accelerators and initiators are usually redox couples such as the commonly used hydroperoxide/amine–aldehyde condensates (oxidant/reductant), which react to form alkoxy radicals. The most widely used condensate is a polymeric resin [9003-37-6]. Produced by reaction of *n*-butyraldehyde [123-72-8] with aniline [62-53-3]. This material has a complex structure, the major component and active ingredient apparently being dihydropyridine [27790-75-6] (40). Another common redox couple is based on hydroperoxide coupled with an alkyl aromatic amine such as *N*,*N*-dimethylaniline [121-69-7]. A number of 2K acrylic formulations include metals, metal oxides, or metal salts (41).

The 2K non-aerobic acrylic adhesives can be used in any of three ways. The first is as a no-mix two-part, the use of which involves applying a thin layer of accelerator (in dilute solution) to one mating surface, flashing off the solvent, applying the adhesive to the second mating surface, and joining the two surfaces. It is perhaps a poor choice of terms, but the accelerator contains the initiator (eg, peroxide) or may contain a redox couple. As long as the bondline thickness is no more than about 500 μm (0.020 in.) for one-side activation or about 1000 μm for two-side activation, cure is expected to be adequate. 2K acrylics which are meant to be mixed before application utilize a different kind of accelerator that contains the catalyst system in a carrier resin such as an epoxy and perhaps a diluent. These can be used in a fashion similar to the no-mix adhesives, but this approach may not produce optimal properties. Typically, the 2K acrylics are made by mixing the accelerator into the one-part acrylics and immediately applying this mixture to the substrate. Volume mix ratios will range from about 2:1 to about 20:1. Additional ingredients commonly found in these compositions include various elastomeric polymeric toughenersuch as chlorosulfonated polyethylene, butadiene–acrylonitrile elastomers, and polyurethane acrylates. These toughenersare usually incorporated into the adhesives by dissolution in the acrylic monomers, creating adhesives sometimes referred to as second-generation acrylics. Their development by DuPont (42) and others marked the entry of acrylic structural adhesives into a large number of new applications.

Because of their high reactivity, these 2K acrylic adhesives are used in many situations where fast ambient cure is important. Since the incorporation of the redox couple catalysts, acrylic adhesives have advanced their use on metals as well as plastics, woods, and ceramic substrates. As a class, they tend to be fairly accommodating of oily metal and unprepared plastics and composites. Offensive odors often accompany the common forms that use the less expensive lower alkyl acrylates. Colors of these materials are clear, off-white, white, and amber. They are not often intentionally pigmented, although they may be tinted by functional metal additives or aluminum powders.

A very important class of acrylic adhesives, the cyanoacrylates are distinguished by their relative simplicity of formulation and their nearly instant bonding properties. The name recognition of "super glue" surpasses that of nearly any commercial adhesive though it is now known by a variety of other ungenericized trademarks. First discovered in the 1940s during World War II, cyanoacrylates were rediscovered and first truly appreciated in the 1950s and brought to the market in 1958. Then as now they were largely based on ethyl and methyl cyanoacrylate. Other monomers of interest have been the isopropyl, butyl, allyl, ethoxyethyl, methoxyethyl, methoxypropyl, and fluoroalkyl esters (see POLYCYANOACRYLATES).

Cyanoacrylate adhesives cure by polymerizing anionically. They are catalyzed by mild nucleophiles (bases), such as an OH^- ion, which can readily be found in small quantities on many surfaces. Strong acids, found in many woods and acid-treated metals, can inhibit polymerization. As long as the adhesive film thickness is as low as possible, that is, practically zero, sufficient catalyst provided by the substrate will be available, hence the usual directive to apply the adhesive sparingly and to avoid using it as a void filler or to bond porous surfaces. Bond thicknesses higher than about 13 μm (0.005 in.) are not recommended unless appropriate surface activators are used. As the conversion to a cured adhesive is a polymerization, it passes through and is subject to the same stages as any addition polymerization: initiation, propagation, chain transfer, and chain termination. Like the anaerobic adhesives, these adhesives are conveniently initiated by coating onto surfaces suitable initiators such as alcohols, epoxides, various amines, caffeine, and other heterocyclic compounds (43). Compositions may also incorporate accelerators as well as inhibitors, the latter usually being either phenolics designed to inhibit premature polymerization because of heat or light or anionic polymerization inhibitors consisting of sulfur dioxide, other acid gases, or complexes of sulfur dioxide with organic or inorganic compounds. Normally quite brittle, cyanoacrylate adhesives can be flexibilized using monomers having longer alkyl side chains (2-octyl cyanoacrylate) or by incorporating plasticizers such as acetyl tributyl citrate (44). Various approaches have been taken to toughening the cyanoacrylates (45). As uncross-linked thermoplastic adhesives, the cyanoacrylates begin to soften and flow at about 80°C and will also depolymerize. Their durability in hot moist environments is considered to be poor, especially on metals. This has been addressed through introduction of difunctional or bifunctional cross-linkers, addition of heat-resistant adhesion promoters, and various other strategies aimed at improving moisture resistance. The last important component of the cyanoacrylate adhesive is the thickener, which is usually polymeric in nature.

Cyanoacrylates have long been known to be effective adhesives for human skin and other soft human tissues. They are effective when used for sutureless wound closures and hemorrhage prevention, the butyl cyanoacrylate being most widely used (46) based on a good balance between biodegradability and inflammatory response. Flexibilizers as well as aids to biodegradation are added to make these more suitable for tissue bonding. In everyday use, the outstanding capability of cyanoacrylate adhesives to instantly bond human skin is seen as a negative feature. Skin-adhesion inhibitors that have been found useful include alkanols, carboxylic acid esters (47), and copolymers of maleic acid, vinyl chloride, and vinyl

acetate (48). These slow the adhesive's reaction rates against human skin or at least lower adhesion to it.

Urethanes. The core of a urethane adhesive is an isocyanate compound (see POLYURETHANES). Isocyanates react with a variety of functional groups having active hydrogens to generate a variety of linkages which give the resulting polymers their names. These include reaction with alcohols to form urethanes [R—NH—CO—O—R′], with amines to form ureas [R—NH—CO—NH—R′], with thiols to form thiocarbamates [R—NH —CO—S—R′], with amides to form acylureas [R—NH —CO—N(R′)—CO—R″], with urethanes to form allophanates [R—NH—CO—N(R′)—CO—O—R″], and with ureas to form biurets [R—NH—CO—N(R′)—CO—NH—R″]. Isocyanates can also react with water, generating carbon dioxide through the degradation of the unstable carbamic acid [R—NH—COOH]. This last reaction is the basis for the making of polyurethane foams. To a great extent, what is classified as urethane chemistry encompasses the entire chemistry available to isocyanates (see ISOCYANATE-DERIVED POLYMERS).

Most polyurethane structural adhesives are two-part systems based on the reactions of isocyanates and polyisocyanates with oligomers or polymers having at least two hydroxyl groups, which are generically referred to as diols or polyols. Although part of many earlier adhesive formulations, toluene diisocyanate (TDI) is now decreasing in use while use of diphenylmethane diisocyanate (MDI) is growing. Other common diisocyanates include 1,6-hexamethylene diisocyanate (HMDI or HDI) and isophorone diisocyanate (IPDI). Also available are the modified MDIs, multifunctional isocyanates often termed polyisocyanates, polymeric polyisocyanates, and isocyanate-capped oligomers which are often referred to as urethane prepolymers (49). Materials now available which have very low monomeric isocyanate content are expected to bring about increased use of urethanes in adhesives (50). Hydroxyl-functional materials useful in urethane adhesives have molecular weights between about 500 and 3000 and functionalities between 2 and 3. The base oligomer is usually a polyester, polyether, polycarbonate, or polydiene such as polybutadiene. Cross-linked polyurethanes can be made with the use of trifunctional isocyanates and triols or through reactions of urethanes with urethanes, ureas, or isocyanates to yield the trimer isocyanurate.

In many cases, as polyurethanes are formed, long-chain and short-chain diols alternate along the chain to form segments which are either "soft" or "hard." On a microscope scale, the soft and hard segments coexist in a domain morphology characteristic of what are known as segmented polyurethanes. The very good impact and fatigue resistance of polyurethanes is attributed to this phase-separated microstructure. Because it is the integral component of the soft segment, the particular diol or polyol chosen will greatly influence the rubbery and impact-resistance properties of the polyurethane. Likewise, the isocyanate chosen will strongly influence the strength, modulus, and hardness of the polyurethane. The domain morphology of segmented polyurethanes is most pronounced for systems containing no chemical cross-linking. In contrast to most adhesive systems, low levels of cross-linking tend to degrade the properties of polyurethane adhesives because of disruption of the domain morphology.

Because isocyanates react with so many different organic functional groups and can also react with water, which is found nearly everywhere, catalysts are

very important for the control of isocyanate reactions. Many of the catalysts used may push one reaction over another, but they do not necessarily entirely block unwanted reactions. Tertiary amines, principally bis(dimethylaminoethyl)ether, are frequently used to promote the isocyanate–water reaction, producing a blowing or foaming that generally would not be desirable for adhesives. Compounds that drive the isocyanate–hydroxyl action without substantially encouraging the isocyanate–water reaction include organometallic complexes such as dibutyltin dilaurate and stannous octoate. At temperatures higher than 100°C, urethanes and ureas will react with isocyanates to form the allophanates and biurets described previously, but above 130°C, these groups will decompose. Dimerization of isocyanates to form uretidiones is catalyzed by bases such as trialkylphosphines, pyridines, and tertiary amines. Formation of the trimer of isocyanates, isocyanurates, is favored through use of phosphines, amines, and various metal salts such as potassium acetate.

One-part urethane adhesives have been used for many years as high performance sealants. In this capacity they provide a useful combination of strength, flexibility, and elastic recovery. As adhesives, these systems have limited use unless formulated to overcome their inherent disadvantages. One-part polyurethane adhesives are typically moisture-cured and rely on a multistep reaction sequence as follows: isocyanate reacts with water to form carbamic acid, the unstable carbamic acid loses carbon dioxide and generates an amine, the amine reacts with additional isocyanate to form a urea, and the urea reacts with additional isocyanate to form a biuret, which includes a cross-link. Unless it diffuses out of the system, the CO_2 can cause foaming. Formulators learn to minimize the isocyanate content (%NCO) of a system in order to balance cure speed with foam control. Cure speeds—and foaming rates—of these systems decrease from the outside in and vary with the amount of atmospheric moisture in the air, which changes hourly and seasonally.

A different kind of moisture-activated 1K urethane adhesive utilizes a moisture-activated curing agent such as oxazolidine (51). Oxazolidines are formed by dehydration and subsequent ring closure of aminoalcohols by aldehydes or ketones. When the presence of water causes that reaction to reverse, hydroxyl and amine groups are formed. These react readily and directly with isocyanates. Monooxazolidines are useful primarily as water scavengers, but bisoxazolidines can participate in the curing reactions of urethane adhesives.

More sophisticated 1K urethane adhesives use blocked isocyanates along with polyol curing agents. Useful blocking compounds include phenols, malonates, methylethylketoxime, and caprolactam. These react with isocyanates, but at high temperatures or in the presence of strong nucleophiles, the reaction reverses, freeing the isocyanate. Such systems do not rely on water for reaction, nor do they suffer from the detriments of CO_2 generation, but they do require heat for cure. Another approach to a stable 1K urethane is to use a solid polyol, such as pentaerythritol, that melts at elevated temperatures and then reacts with the isocyanate (52). Other schemes for 1K urethanes have been described (53).

As a class, urethane adhesives have somewhat poorer thermooxidative and moisture resistance than acrylic and epoxy structural adhesives. This has historically limited their expansion into certain areas of use. A 2K adhesive having the ability to survive automotive paint oven temperatures, which run as high as 205°C,

uses polyols with high percentages of hydroxyl groups, an acrylonitrile-grafted triol, a phosphorus adhesion promoter, and a DABCO trimerization catalyst (54). 1K adhesives made with blocked isocyanates tend to be unable to withstand high temperatures because of volatility of the blocking agents, and other approaches are also unsatisfactory for high temperature stability. Use of micronized dicyanodiamide as a latent catalyst and curing agent for isocyanates has produced 1K urethane adhesives showing some capability to tolerate heating to well over 250°C while bonding well to fiber-reinforced plastic (FRP) (55). Sensitivity to hydrolysis has been another of the historic disadvantages of traditional urethane structural adhesives.

Two-part polyurethane adhesives will usually contain fillers and may contain pigments that facilitate visual qualitative off-ratio mixing detection. To increase cure speed, polyamines are sometimes added to the polyol curative, which also contains the catalysts. In addition to their primary ingredients, one-part moisture-curing urethane adhesives will typically contain fillers and perhaps pigments. Arguably the largest user of urethane structural adhesives is the transportation industry, which uses urethane structural adhesives for bonding of automotive parts made of sheet molding compound, FRP, and reinforced reaction injection molding composites and plastics. One-part urethanes are widely used for bonding of windshields to automotive vehicle frames. Although 1K urethanes are not conventionally considered to be structural in nature, automotive engineers hold that the windshield is part of the primary structure of the vehicle, conferring on these one-part urethanes the status of a structural adhesive. Wood bonding is another significant market for polyurethane structural adhesives.

As a group, polyurethane structural adhesives produce bond strengths on the lower end of the strength scale for structural adhesives, but their high flexibility, usually strong peel strength, and generally good impact and fatigue resistance recommend their use when these characteristics are important. A variety of adhesives have been developed which incorporate polyurethanes into acrylic or epoxy structural adhesives (56–59). Inclusion is done through use of isocyanate-functional ingredients or polyurethanes end-capped with a nonisocyanato functional group. The broad reactivity of isocyanates offers many other options for hybridization.

Phenolics. Phenolic Resins were the basis of the first synthetic structural adhesives. They are formed by the reaction of phenol [108-95-2], C_6H_6O, and formaldehyde [50-00-0], CH_2O. There are two types of phenolic resins, resoles and novolaks (or novolacs), the former being comprised of methylol-terminated resins and the latter of phenol-terminated resins. Resoles result from use of basic reaction conditions and an excess of formaldehyde and will cure via self-condensation at 100–200°C with loss of water. Novolaks are produced using acidic reaction conditions and formaldehyde/phenol molar ratios of 0.5–0.8, and they require addition of a curing agent for cure. Hexamethylenetetramine [100-97-0], $C_6H_{12}N_4$, is a widely used novolak curing agent. Resoles and novolaks are sometimes referred to as one-step and two-step resins, respectively.

Formulators can choose from a variety of commercially available phenolic compounds, including, in addition to phenol itself, the isomers of cresol, the isomers of xylenol, resorcinol, catechol, hydroquinone, bisphenol A, and various alkylphenols. Formaldehyde is usually used as the second major component, but acetaldehyde, furfuraldehyde, and paraformaldehyde (the polymer of

formaldehyde) have been used sometimes alone and sometimes along with formaldehyde. The reactions of these various components are complex but have been elucidated by painstaking research (60).

Like epoxies, the phenolics are very brittle unless modified by toughening. The first successful toughening were poly(vinyl formal) resins which were added as a powder sprinkled over a layer of resole phenolic applied out of solution. These Redux adhesives were the first toughened thermoset adhesives and were the basis of the first durable adhesive bonding technology for aerospace aluminum in the 1940s and 1950s. These were superseded in the 1960s by film adhesives formed from liquid phenolics filled with poly(vinyl formal) powders. Other toughening followed: poly(vinyl butyral), nitrile rubbers, polyamides, acrylics, neoprenes, and urethanes. Epoxy–phenolics are important hybrid adhesives and offer an immensely useful combination of strength, toughness, durability, and heat resistance. Phenolic structural adhesives as a class of materials are highly resistant to most chemicals.

Phenolic adhesives are found as powders, liquids, pastes, and supported and unsupported films. Among the pastes, both 1K and 2K systems are available. Fillers are commonly used in paste adhesives. Support of film adhesives is provided by glass, cotton fabric, nylon, or polyester scrims. The novolaks are almost exclusively powders in pure form, but the resoles often are found as liquids. The resole systems are usually cured at temperatures exceeding 170°C. The condensation cure of the resole phenolics systems requires that they be cured under high pressures to minimize evolution of bubbles from water vapor. This is usually done in autoclaves or hot presses at pressures of about 200 to nearly 1400 kPa (29–203 psi) (61). Cure times range from 1 to 4 h depending on temperature. The cure conditions required for the resole phenolic adhesives have limited their use, and to a great extent they as well as the relatively brittle novolak phenolics have been displaced by epoxies for aerospace aluminum bonding applications for which they were once the first choice. Nitrile–phenolic adhesives have a long history of use not only in aerospace applications but also in automotive applications such as the bonding of brake linings and the friction materials used in transmissions. Resole phenolic resin adhesives are widely used in the making of plywood and particleboard as both binders and for laminating of veneers; resorcinol is frequently used along with phenol or as the sole hydroxyl compound. In wood bonding, the porosity of the wood allows escape of the water vapor generated during curing of the adhesive and is believed to facilitate mechanical anchoring of the adhesive in the wood. Phenolics are also widely used as foundry resins for making sand-shell molds.

Urea–Formaldehyde and Related Adhesives. Urea–formaldehydes (UF) are the most significant members of the class of materials known as the Amino Resins or aminopolymers. These are the polymeric condensation products of the reaction of aldehydes with amines or amides. A molar excess of formaldehyde is used, and this along with the temperature and the pH dictate the properties of the final product. The initial reactions of urea and formaldehyde to form mono- and dimethylolureas can be catalyzed by either acids or bases, but the final condensation reactions will proceed only under acid conditions. These adhesives are widely used to make plywood and particleboard in processes utilizing heated hydraulic presses with multiple outlets for water vapor release. Temperatures up to 200°C

may be used. UF adhesives in the first use contain hardeners composed of ammonium chloride or ammonium sulfate solutions or mixtures of urea and ammonium chloride plus fillers such as grain and wood flours. Particleboard adhesives, which are really binders, contain similar hardening agents, a worklife extender (ammonia solution), insecticides, wax emulsions, and fire-retarders. The slow hydrolysis of the methylenebisurea [13547-17-6], $NH_2CONHCH_2NHCONH_2$, has been linked to the slow release of formaldehyde from UF adhesives (62). The wood industry has been under increasing pressure to reduce and eliminate unreacted and evolved formaldehyde from these products and has made great efforts to do so. Melamine–formaldehyde (MF) and the less expensive melamine–urea–formaldehyde (MUF) resins are the bases of high performing wood-bonding adhesives. Their resistance to water is superior to that of the UF resins, but their higher cost has limited their use. The urea in the MUF resins decreases the cost of the MF resins. Uses of these are similar to those for the UF resins with the addition of paper-laminates for wood panels. Melamine reacts more easily with formaldehyde than does urea, making possible full methylolation of melamine (63). Condensation of methylolated melamine with formaldehyde does occur under both acidic and slightly alkaline conditions, but acid catalysts or compounds generating acids are usually used in MF adhesives. Compounds such as acetoguanamine, ε-caprolactam, and *p*-toluenesulfonamide are often added to combat inherent brittleness and decrease stiffness. Ammonium salts are useful in making bulk wood products, but laminates can be adversely affected by these compounds; a complex of morpholine and *p*-toluenesulfonic acid is one hardener employed for this particular kind of MUF or MF adhesive. Defoamers and judicious amounts of release or wetting agents may also be used.

High Performance Adhesives. A number of adhesive needs exist which require resistance to very high temperatures and other environmental stressors such as certain gases, solvents, radiation, and mechanical loads. The upper temperature limits of the most durable epoxy and phenolic adhesives lie between about 200 and 250°C. The aerospace industry requires adhesives that are resistant to temperatures of nearly 400°C for hundreds of hours or about 150°C for much longer times. Heterocyclic polymers such as polyimides and polyquinoxalines have been the basis of most heat-resistant adhesives. Microelectronics adhesives sometimes also must deal with high heat, but they must also conduct heat away from heat-sensitive parts. This has been the inevitable result of increasing miniaturization. Epoxies continue to be the basis of many microelectronics adhesives, but adhesives based on stiff-chained thermoplastic resins such as polyethersulfone and polyetheretherketone have made some inroads. Electrical conductivity is most commonly enhanced with silver flake or powder, but nickel, copper, and metal-coated metals are also being used in this function (64). Thermal conductivity is usually adjusted through incorporation of aluminum, aluminum nitride, or other metals or ceramics (65).

Adhesives made from Natural Products. The first adhesives developed by humans were based on naturally available materials such as bone, blood, milk, minerals, and vegetable matter. Beginning with the commercial development of Baekeland's phenolic resin adhesives by the General Bakelite Co. around 1910, synthetic adhesives began to replace natural product adhesives for existing applications. The use of adhesives by industry began to grow and diversify over the

ensuing decades. In certain industries, among them furniture, food, bookbinding, and textiles, adhesives based on natural products continue to be used to a significant extent. These adhesives can be divided into those based on proteins, carbohydrates, and natural rubbers or oils. Historically, *glue* is a term used to refer to adhesives made from animal matter or vegetable-based protein.

Protein-Based Adhesives. The protein sources for these adhesives include mammals, fish, milk, soybeans, and blood. Animal and fish parts that yield useful proteins include hides, skins, bones, and collagen from cartilage and connective tissues. Most animal proteins are extracted using water and vary considerably in molecular weight, amino acid sequence, and inorganic impurities. For those proteins that are not already soluble in water, such as collagen, solubilization is accomplished by imposition of heat, pressure, or, most commonly, addition of acids or alkalis. Final molecular weights are in the range of 10,000–250,000 (66). Following solubilization, the protein solution is boiled down and dried to a final moisture content of 10–15%. Milk and cheese yield the relatively simple mixture of proteins called casein [9000-71-9]. Proteins are extracted from milk through direct acidification following decreaming and may also be generated through fermentation of lactose by bacteria to create lactic acid. Blood is almost entirely made up of proteins and after spray drying to remove water, can be stored for an extended period of time. Soybeans are important sources of both proteins and triglyceride oils. Proteins for adhesives are obtained from harvested soybeans by extracting or pressing out oils and then heating the remaining matter no higher than 70°C lest its alkaline solubility be compromised. Soybean meal is approximately 45–55% protein, the balance consisting of carbohydrates (∼30%) and ash (67).

Proteins are highly susceptible to changes in their structure through changes in pH, and the process of denaturation used when necessary to unfold protein molecules and break down their molecular weight to effect solubilization must only go far enough to obtain those effects but not deteriorate their adhesive qualities. Additional acids and bases are used in preparation of working adhesives made from proteins. Formulations of protein-based adhesives, in general, include the dried protein, water, an alkali compound which helps dispersion, and a hydrocarbon oil defoamer. Hydrated lime and sodium silicate solutions are usually added to modulate viscosity and to improve water resistance. Plasticizers are sometimes added as are fillers, biocides, preservatives, and fungicides. Protein-based adhesives are widely used for bonding of porous substrates such as wood, and as water is removed from the adhesive by absorption, air drying, and the optional application of heat, the proteins become fully denatured and the adhesive is set. A variety of denaturing and curing agents or cross-linkers can be used with protein-based adhesives, including hexamethylenetetramine, carbon disulfide [75-15-0], thiourea [62-56-6], dimethylolurea, and various metal salts. Blood glues may contain aldehydes and alkaline phenol–formaldehydes as cross-linkers. Although very strong, protein-based adhesives have been largely restricted to nonstructural interior wood-bonding applications and other uses where their susceptibility to water and moisture do not jeopardize their stability, and the use of the various cross-linkers is targeted primarily at improving their water resistance. The most water-resistant protein-based adhesives are the blood or blood-soybean blends, but even they are not fully weatherproof. Casein or casein–soybean blends are next in line, and soybean and animal hide glues exhibit the least water

resistance. The use of blood and casein adhesives is limited by the low yield of adhesive-grade dried blood from drying processes and the lack of appreciable suppliers of casein in the United States alongside a large number of diverse global sources. There has been a strong push from the soybean industry to have soy products more widely accepted in various industrial uses, but considerable work remains to be done in this area. Protein-based fibrin sealants have been the subject of considerable interest as medical adhesives and are considered by some to have many advantages when compared to cyanoacrylates and other types of adhesives (68), but their development has been limited because of human blood contamination issues.

Carbohydrate-Based Adhesives. Carbohydrates are available from a wide variety of plants, the shells of marine crustaceans, and bacteria. The raw adhesive materials obtained from these sources include cellulose, starch, and gum. Cellulose [9004-34-6] is a semicrystalline polymeric form of glucose having a molecular weight of less than 1000 to nearly 30,000. It is present in plant matter at a level between about 30 and 90%. Like some of the naturally occurring proteins, cellulose must be chemically treated in order to be used as an adhesive. Reaction of its hydroxyl groups is used to convert cellulose to cellulose esters and ethers. Important cellulose esters include cellulose nitrate, cellulose propionate, cellulose butyrate, cellulose acetate propionate, and cellulose acetate butyrate (69). The most important cellulose ethers include carboxymethylcellulose, ethylcellulose, methylcellulose, and hydroxyethylcellulose. The cellulose adhesives are film formers having a thermoplastic nature. A typical adhesive formulation includes a few percent of the cellulose, less than a percent each of a plasticizer and a natural protein, and the great balance of water or another solvent. Methylcellulose is the basis of a common nonstaining water-based wallpaper adhesive. Celluloses are very effective aqueous solution thickeners and are sometimes used in that capacity, so their solubility is limited by viscosity increases. Starches are the most significant class of carbohydrate adhesives. The source of the basic materials is broad and includes corn, wheat, rice, and potatoes as well as seeds, fruits, and roots from which starch is isolated by hot water leaching. Starch is a naturally occurring polymer of glucose. It occurs for the most part in either of two forms or something intermediate between the forms: amylose [9005-82-7], which is highly linear and has a degree of polymerization of 500–700, and amylopectin [9037-22-3], which is branched and has a degree of polymerization of about 1500–2000. Starch is also semicrystalline in nature, and its tightly packed granules must be opened to make it suitable for adhesive use. This is accomplished through heating, oxidation, or alkali or acid treatment. Colloidal suspensions of starches can be made by heating in water, but these have a tendency to solidify on cooling. Treatment with an alkali such as sodium hydroxide can lower the gelation temperature. Treatment with a mineral acid plus heat followed by neutralization with a base degrades the amorphous regions of the starch granule but does not disturb the crystalline regions, allowing a higher percentage of solids to be used in making an aqueous solution called a thin-boiling starch. Oxidation with alkaline hypochlorite produces a material similar to acid-treated starch but having better tack and adhesive properties. Dry roasting of starch in the presence of an acid catalyst produces dextrin [9004-53-9], which ranges in color from white to yellow to dark brown and shows different tendencies to repolymerize depending on the temperatures, times, and

catalyst concentrations used. Additives used in dextrin adhesives include tackifiers such as borax [1303-96-4], viscosity stabilizers, fillers, plasticizers, defoamers, and preservatives. Formaldehyde-precondensates and other compounds are added to improve water resistance. Starch-based adhesives are used in corrugated cardboard, paper bags, paper or paperboard laminates, carton sealing, tube winding, and remoistenable adhesives. Gums are naturally occurring polysaccharides obtained from various plants or microorganisms and usually prepared as adhesives by dispersion in either hot or cold water. Although they find use in applications similar to those mentioned for starches, they are more often found as additives in synthetic adhesives in which they act as rheology modifiers.

Other Nature-Based Adhesives. The use of natural rubber, an important adhesive component obtained from the rubber tree, is discussed under the section on Pressure-Sensitive Adhesives. Tannins are polymeric polyphenols isolated as one of two products from the bark of conifers and deciduous trees. Lignin is widely available as a waste material from pulp mills and has a complex structure. Tannin-based adhesives have attained some level of success in the marketplace. Despite considerable interest in and work toward more commercial use of lignins in adhesives for wood bonding, they have not yet succeeded in capturing market share. A vinyl-functionalized sugar has been developed for use in products including, most prominently, adhesives (70). Modification of sugars to make liquid epoxy resins has also been accomplished (71). Use of whey and whey by-products as adhesive components has been investigated (72). Modification of natural materials to make polyols and diisocyanates has been pursued in both the United States and the United Kingdom (73,74). It can be expected that additional plant-based monomers and polymers will be developed as the chemical industry comes to terms with the limited supply and rising costs of petrochemicals, making "green adhesives" a not-uncommon reality in the not-too-distant future (75).

Direct Bonding

Strictly speaking, direct bonding does not include the use of conventional adhesives or seemingly any adhesive at all. However, the joining of two extremely smooth solid surfaces into a spontaneous bond requires careful preparation and surface treatment which reflect the sophisticated use of chemistry, physics, and engineering. Practitioners of direct bonding consider its gluelessness to be a considerable benefit within its primary areas of applications, optics, electronics, and semiconductors, which benefit from minimal or no contamination (76). Such bonds are also considered jointless because of the atomic distances between the joined surfaces. The most prominent use of direct bonding may be wafer bonding, a key part of the silicon-on-insulator technology behind the making of integrated circuits, that is, computer chips (77). Another important use of direct bonding is construction of waveguides for optical devices.

The inclusion of direct bonding among a list of adhesive types reflects the supposition that conventional adhesives of any composition are useful because they compensate for the shortcomings of most surfaces one might wish to join. Indeed, if smooth enough, even polytetrafluoroethylene will adhere to itself. In the case of what is called stiction, direct bonding is not seen as desirable, and steps

are taken to prevent it from occurring (78). Redesign can be used to avoid material contact altogether. Surfaces can be roughened on a fine scale using chemical treatments.

Adhesive Formulation and Design

A 1999 compilation of chemicals used in adhesives listed 6300 materials (79), but the total number of compounds available for adhesive formulating is well in excess of this figure. Formulators of adhesives are in constant search of unique adhesive ingredients and their unusual combinations in order to satisfy the ever-increasing needs of their customers. In the interests of competition, many vendors of adhesive raw materials continue to protect the proprietary nature of their products by providing coded product names, a practice which though entirely understandable runs contrary to the need for the educated formulator to know the chemistry and structure of raw materials rather than relying on vague descriptions of the effects of a raw material in some standard formulation on some standard substrate.

Formulating adhesives is both a skill and an art. The novice formulator will find it invaluable to seek out other formulators in the same organization and learn from them as much as possible or at least whatever their time and patience allow. Maintaining such relationships over time can provide great benefit to the beginner as well as the veteran formulator, who will soon start learning from the former novice. The written and electronic literature of many vendors of adhesive raw materials includes information on formulating, including starting formulations. To the extent possible, one can also consult with vendor technical staff. The open technical literature, encompassing technical and trade journals, conference proceedings, and patents, provides considerable information on formulations, and its age should not discourage one from reading it as there is much to be learned from the older literature. The literature on nonadhesive polymer-based products, such as coatings, molding plastics, and composite matrix materials, may prove helpful in describing interesting raw materials not commonly used in adhesives. Likewise, components commonly used in one class of adhesives may be found to be useful in modifying adhesives of another class. The best teacher of formulating is experience, that is, trial and error.

Adhesive formulation involves more than the combining of various raw materials. The formulator must be a multidimensional technical professional able to juggle several different fields of science and engineering, legal issues, environmental considerations, computer hardware and software, and business concerns. It is not unusual to create a remarkable adhesive only to find that a key ingredient is unstable or too expensive for the intended market or poses unacceptable health and safety risks. Some customers have lists of ingredients which will not be allowed in items sold to them. Government entities require increasingly stricter labeling of adhesives and other chemical products, the requirements varying from country to country.

Better tools for adhesive formulation have been developed with the onset of the personal computer and computer workstations. These include software for design of experiments, databases used to track endless variations in adhesive recipes, mixtures design software for faster product optimization, and simple and

complex spreadsheets used to determine cost at the front end of development. Online searching of and access to the scientific and patent literature as well as the information on business trends and supplier's products available on the Internet have made information gathering easier. Adhesive development accelerates more each year, and the savvy formulator must keep pace.

AGING, PHYSICAL

Introduction

All glasses, including polymeric glasses, undergo a process known as physical aging or structural recovery. The origin of physical aging can be understood on a macroscopic level by examining the volume versus temperature path of an amorphous polymer, as shown in Figure 1. On cooling from the liquid state, the amorphous material does not crystallize because of kinetic or steric constraints and its volume decreases along the equilibrium density line. As the volume decreases, the molecular mobility also decreases. At the glass temperature or glass-transition temperature (T_g), the molecular mobility is such that the material can no longer maintain equilibrium density on the time scale of cooling and the material deviates from the equilibrium line onto the glass line. Although the glass temperature is often reported as a single number, its value depends on the cooling rate; faster cooling rates giving higher T_g values and higher glass lines. Independent of which glass line the material is on, the glass is not at equilibrium. Physical aging, which is also called structural recovery particularly when the evolution of thermodynamic variables is being referred to, is shown by the downward arrow in Figure 1 at aging temperature T_a.

The driving force for physical aging is the attempt to achieve equilibrium density through configurational rearrangements on a molecular scale. Corresponding to these changes on the molecular scale, we observe a decrease in volume, a decrease in enthalpy, an increase in modulus, and an increase in brittleness. The time scale for physical aging (ie, the time required to reach equilibrium) can be as short as several hundred seconds at aging temperatures in the vicinity of the nominal T_g and increases to years or millennia as the temperature decreases. According to the Gibbs and DiMarzio theory of the glass temperature (1–3), there

is an underlying thermodynamic transition, often associated with the Kauzmann temperature 52°C below T_g (4).

Physical aging and structural recovery are reversible phenomena. There is no change in chemical structure during physical aging. The changes in physical and mechanical properties that accompany structural recovery are caused by the densification associated with the approach to equilibrium. The changes can be erased by heating the material above the glass temperature to a temperature where the material is again at equilibrium. Cooling the material from the equilibrium state will result in reestablishment of the glass. This reversibility is often exploited in physical aging research as is mentioned later in this article.

The importance of structural recovery and physical aging lies in the changes in material properties that accompany the phenomena. These changes can in many instances adversely affect performance and lifetime. Consequently, structural recovery and physical aging impact the design, processing, and performance of polymers in many applications, including, but not limited to, aerospace and automotive applications, xerographic applications, and glass-to-metal seals (5). In addition to the practical effects of physical aging, an understanding of glasses and the effects associated with structural recovery is important from a fundamental scientific viewpoint. In fact, Nobel laureate P. W. Anderson claimed that the glass transition was one of the greatest unsolved problems of condensed matter physics (6). Although the basic phenomenology associated with glasses is known and models exist which describe structural recovery and physical aging, researchers are not yet able to predict a priori experimental observations.

In this article on physical aging, the phenomena associated with structural recovery and physical aging are described, starting with discussion of volume recovery, enthalpy recovery, viscoelastic properties, and failure. There are more in-depth reviews of the phenomena and models associated with the glass transition (7) and enthalpy recovery (8). See also GLASS TRANSITION, AMORPHOUS POLYMERS, and VISCOELASTICITY.

Volume Recovery

The decrease in volume during physical aging is specifically known as *volume recovery* or *volume relaxation*. Volume recovery experiments include down-jump, up-jump, and memory experiments. The results of these experiments, which are shown and discussed later, demonstrate that structural recovery is both nonlinear, nonexponential and path-dependent.

The simplest volume recovery experiment performed is the down-jump. In this experiment, a material initially above T_g and at equilibrium is subjected to a temperature down-jump to an aging temperature T_a below T_g. The isothermal evolution of volume at T_a, as indicated by the downward arrow in Figure 1, is monitored with time via length or volume dilatometry. Figure 2 shows typical data replotted from Kovacs data (9) for a series of aging temperatures for poly(vinyl acetate). These curves, called intrinsic isotherms, are plotted as the relative departure from equilibrium δ versus the logarithm of time, with δ defined as

$$\delta = \frac{v - v_\infty}{v_\infty} \tag{1}$$

where v is the volume at a specific aging time and v_∞ is the volume at equilibrium density. The relative departure from equilibrium has a nonexponential shape and approaches zero asymptotically at long times as equilibrium is attained. As might be expected, the times required to reach equilibrium increase as the aging temperature decreases.

The total change in delta during aging depends on the magnitude of the temperature jump and is related to the initial departure from equilibrium (δ_0):

$$\delta_0 = \Delta\alpha\,(T_{fo} - T_a) \tag{2}$$

where $\Delta\alpha$ is the difference in thermal expansivities between the liquid and glass ($=\alpha_l - \alpha_g$, where subscripts l and g refer to the liquid or equilibrium and glassy regimes, respectively). T_{fo} is the initial fictive temperature and it equals the value of the glass temperature associated with the rate of the quench to T_a. A more general definition of T_f is given later. For a perfect quench, T_{fo} is equal to the temperature at which the quench was made, although experimentally this is never the case. Although Figure 2 shows that Kovacs plotted his original data versus $(t - t_i)$ where t_i is the time at which the quench was initiated, modeling work (10) has indicated that this is incorrect. For capillary dilatometers (10), taking time zero at the beginning of the quench resulted in insignificant error in the data on a logarithmic time scale compared to the results of a perfect quench for times greater than approximately two times the thermal equilibration time. Hence, data should be plotted versus time, with time zero being the time at which the quench is initiated. This is in agreement to Struik's earlier suggestion (11).

The total change of volume during volume recovery is small, generally being smaller than 1%, ie, the change in δ is generally less than 10×10^{-3}. For example, for the data shown in Figure 2, the volume changed approximately 0.05% at the highest temperature and 0.5% at the lowest temperature. These changes,

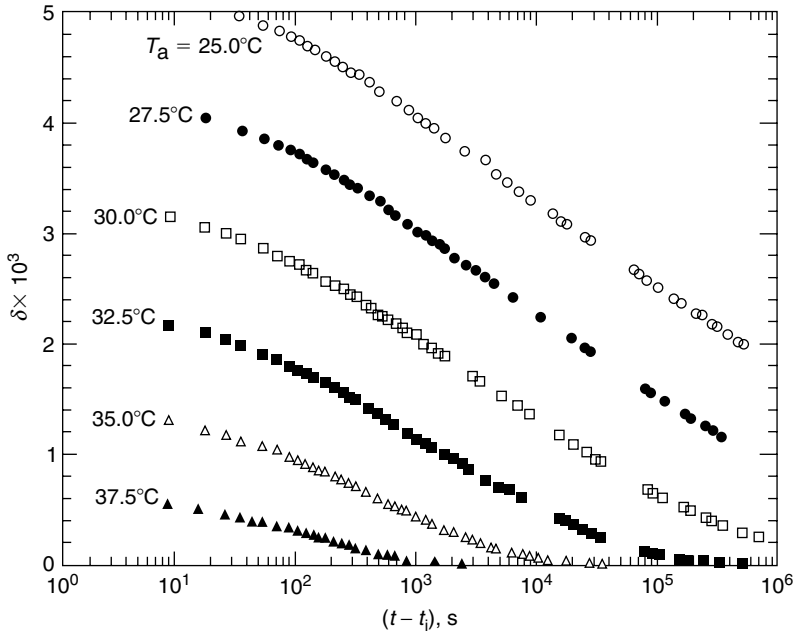

Fig. 2. Intrinsic isotherms for poly(vinyl acetate) from the data sets of Kovacs (replotted after Ref. 9). The departure from equilibrium is plotted vs time after thermal equilibration. Down-jumps were performed from 40°C to various isothermal aging temperatures ranging from 37.5 to 25°C.

in themselves, are not significant for dimensional stability in most applications. However, the associated changes in mechanical properties, and in particular in failure modes, can be significant in practical applications as is discussed later. It is noted that measurement of volume changes of this order indicates the need for high precision in the measurements. Resolution to 2×10^{-5} cm^3/g is desired and can be achieved with both traditional and automated capillary dilatometers. One source of noise in the measurements is the temperature fluctuations in the bath; preferably these fluctuations should be of the order of ± 0.01 K or less.

In addition to the down-jump volume recovery experiments, up-jumps can also be performed. In the up-jump experiment, the material is first equilibrated at a temperature T_i below T_g. It is then subjected to an up-jump in temperature to an aging temperature which may or may not be below the nominal glass temperature. During aging, the volume now increases with time as the material attempts to achieve equilibrium density. Kovacs' data (published originally in Ref. 12) for an up-jump to a single aging temperature after equilibration at the temperatures indicated are shown in Figure 3 for poly(vinyl acetate). Also shown in Figure 3 are the results of down-jumps to the same aging temperature from several initial temperatures.

The data in Figure 3 demonstrate what is known as the asymmetry of approach. For the same magnitude jump, the up-jump response is delayed relative to the down-jump and the time required to reach equilibrium is longer. The asymmetry of approach is considered to be a manifestation of the nonlinearity of the

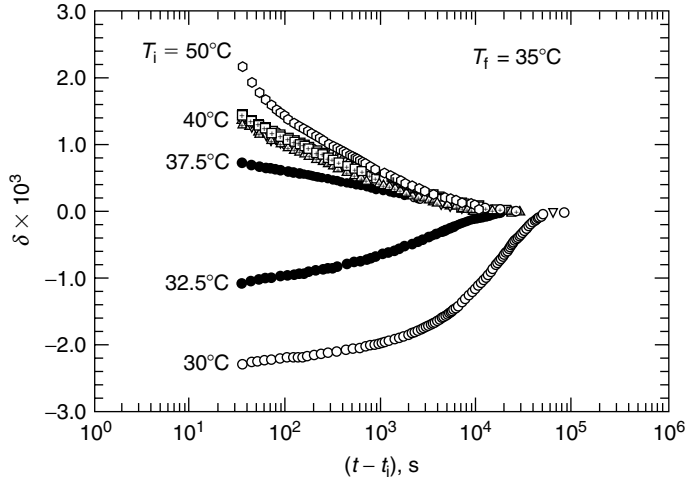

Fig. 3. The asymmetry of approach for poly(vinyl acetate) from the data sets of Kovacs and first published in Reference 12. The isothermal aging temperature is 35°C. Down-jumps and up-jumps were initiated at the temperatures T_i as shown.

relaxation process as was first recognized by Tool (13). In other words, the rate of volume recovery depends on some characteristic relaxation time (τ), which in turn depends on the instantaneous volume, which in turn depends on the rate of volume change (after Ref. 14):

$$v \rightarrow \tau \rightarrow \left(\frac{\partial v}{\partial t}\right)_{T_a} \tag{3}$$

Hence, the down-jump response is autoretarded on a logarithmic time scale with the characteristic relaxation time increasing with the time of aging, whereas the up-jump response is autoaccelerated with the characteristic relaxation time decreasing with the time of aging. For a small enough temperature jump, the response would be linear. In the linear case, the relaxation time would not change during the recovery, and the down-jump and up-jump responses would be mirror images.

The third type of volume recovery experiment, termed the memory or crossover experiment, demonstrates that the relaxation behavior is dependent on the prior thermal history of the material. In this experiment, the material is aged partially into equilibrium at temperature T_1 and then heated to a temperature T_a where the volume initially lies on the equilibrium line. Because the volume departure from equilibrium at T_a is initially zero, no evolution of volume might be expected. However, the observation is that the volume increases away from equilibrium and then decreases back to equilibrium. The thermal history involved in the memory experiment is depicted schematically in Figure 4. The experimental results of Kovacs for poly(vinyl acetate) (PVAc) (9) are shown in Figure 5 for several T_1, in addition to the down-jump response. The memory experiment is attributable to a distribution of relaxation times; for example, if at T_1 the fastest relaxing regions reached equilibrium density by the time the jump

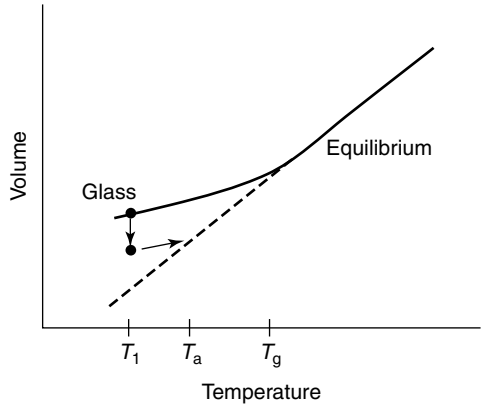

Fig. 4. Schematic of the memory experiment for volume (or enthalpy). The material is aged at T_1 such that the material is initially at equilibrium at T_a following an up-jump from T_1 to the final aging temperature T_a.

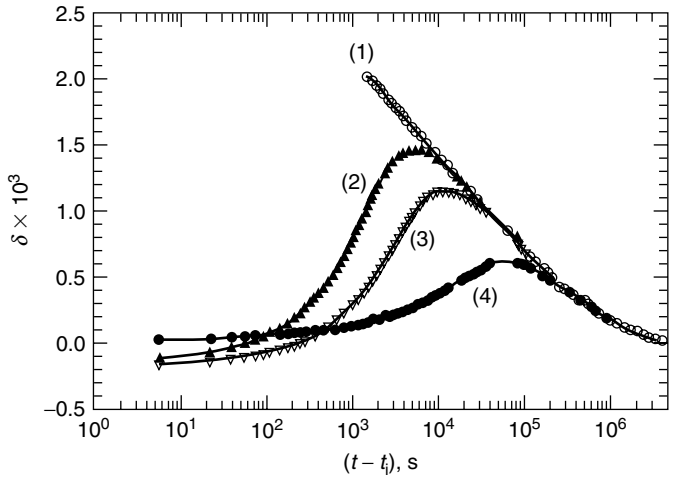

Fig. 5. Isothermal volume relaxation of poly(vinyl acetate) data of Kovacs (replotted after Ref. 9) showing the results of memory experiments. Sample 1 shows the response at 30°C after a quench from 40°C. For samples 2, 3, and 4, the material was initially quenched from 40°C and held at T_1 for a time t_1 before jumping up to T_a of 30°C. Sample 2: $T_1 = 10$°C for $t_1 = 160$ h; Sample 3: $T_1 = 15$°C for $t_1 = 140$ h; Sample 4: $T_1 = 25$ °C for $t_1 = 90$ h.

to T_a was made whereas the slowest regions had not, then at T_a the fast regions would expand to get to their equilibrium volume at this higher temperature resulting in the increase in volume away from equilibrium, and at longer times, the slowest regions would finally contract to their equilibrium density returning the material to equilibrium volume. Whether this picture is physically correct or not is unclear. However, it is clear that a single exponential relaxation function cannot reproduce the memory effect.

The majority of volume recovery experiments performed to date have been carried out close to the glass transition. The temperature range near T_g is convenient because the entire relaxation is accessible and equilibrium is attainable in reasonable times. However, glass-forming materials are often used deep in the glassy state. It is unclear whether extrapolation of volume recovery rates to temperatures far below T_g is valid. Recent work (15) on polycarbonate (PC) suggests otherwise. At low aging temperatures, volume recovery appeared to be higher than expected (15). In addition, there was a sharp transition from a slow rate of volume recovery to a much faster aging rate at 10^7 s. The observations have been confirmed qualitatively for polycarbonate but not for polystyrene (PS) (16). The significance of these results and whether current models of structural recovery can predict them is not yet clear.

Enthalpy Recovery

The decrease in enthalpy during physical aging is specifically called *enthalpy recovery* or *enthalpy relaxation*. The enthalpic response of a glass is similar to the volumetric response in that the enthalpy decreases after a down-jump in temperature. The most common way to measure enthalpy relaxation is with differential scanning calorimetry (dsc). However, the evolution of enthalpy cannot be measured *in situ* using dsc because of the small amount of heat given off and the long time scales over which the relaxation occurs. Consequently, the change in enthalpy because of aging is measured after aging for specified times. An explanation of the approach is shown schematically in Figures 6a and b. Enthalpy versus temperature is shown in Figure 6a. The diagram looks similar to that of volume versus temperature. At high temperatures the material is at equilibrium. During cooling from equilibrium, the enthalpy decreases and the molecular mobility of the material decreases. At the glass temperature (T_g), the material is no longer able to maintain equilibrium within the time scale of cooling, and the enthalpy departs from the equilibrium line and moves onto the glass line. The solid curve shows the behavior on cooling. On heating, the dashed curve is observed for an unaged glass, ie, a glass in which no relaxation occurred isothermally in the glassy state or during heating. Some small hysteresis in the vicinity of T_g is observed between the cooling and heating traces. On the other hand, the dash–dot line shows the behavior on heating of an aged glass. Since the aged glass has lower molecular mobility (corresponding to its increased density), the enthalpy often overshoots the equilibrium line during heating such that the rapid increase to equilibrium occurs at a temperature considerably above the glass temperature, as shown. The corresponding heat flow (P) or apparent heat capacity (C_p) for the aged and unaged glasses is shown in Figure 6b. For the unaged material, there is an endothermic step change in the heat flow at T_g (often with a small degree of overshoot). For the aged glass, on the other hand, a significant annealing peak or endothermic overshoot is observed. The difference between the area under the unaged and aged materials is the difference in enthalpy between the glass lines for the unaged and aged glasses (ΔH_a). In traditional dsc, ΔH_a is obtained by performing a temperature scan for an aged glass to obtain the aged response, then quenching the material at a given rate (generally the same rate that was used during the

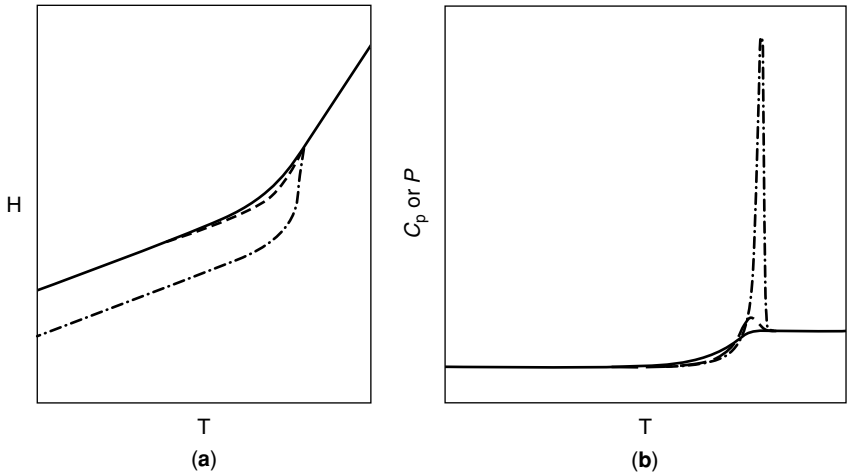

Fig. 6. (**a**) Schematic of enthalpy vs temperature. The solid line shows the response on cooling from the equilibrium state, whereas the dashed line shows the heating curve for an "unaged" glass in which there is a small hysteresis effect. The dash–dot line shows the heating curve for an "aged" glass; (**b**) Schematic of heat capacity vs temperature. The solid line shows the response on cooling from the equilibrium state, whereas the dashed line shows the heating curve for an "unaged" glass showing a small overshoot at the nominal glass temperature. The dash–dot line shows the large annealing peak observed in the heating curve for an "aged" glass.

down-jump to T_a), and performing a second temperature scan without aging the material to obtain the unaged response (17). Early suggestions that ΔH_a could also be obtained from the nonreversing heat flow using one heating scan with temperature-modulated dsc (18–20) have been shown to not be valid (21,22).

The results of typical dsc heating scans after isothermal aging are shown in Figure 7 for poly(ether imide) (PEI) for various aging times (23). In this case, one sample was used for all experiments, and isothermal aging was performed in the dsc itself. It is noted that if isothermal aging is performed in the dsc, isothermal calibration of the instrument must be performed.

As shown in Figure 7, as the time of aging increases, the overshoot peak temperature shifts to higher temperatures because of the increase in the relaxation time with aging. The area under the peak also increases. When equilibrium is reached, both the peak temperatures and the areas under the peaks stop evolving. Figure 8 shows the evolution of the departure of equilibrium for enthalpy versus the logarithm of time for poly(ether imide) for selected aging temperatures replotted from the data presented in Reference 23. The departure from equilibrium for enthalpy is defined as

$$\delta = \Delta H_{a\infty} - \Delta H_a \tag{4}$$

where $\Delta H_{a\infty}$ is the change in enthalpy at equilibrium. Each data point represents the average of three points. The intrinsic isotherms for enthalpy recovery are analogous to those for volume recovery. The times required to reach equilibrium increase as the aging temperature decreases and the initial departure

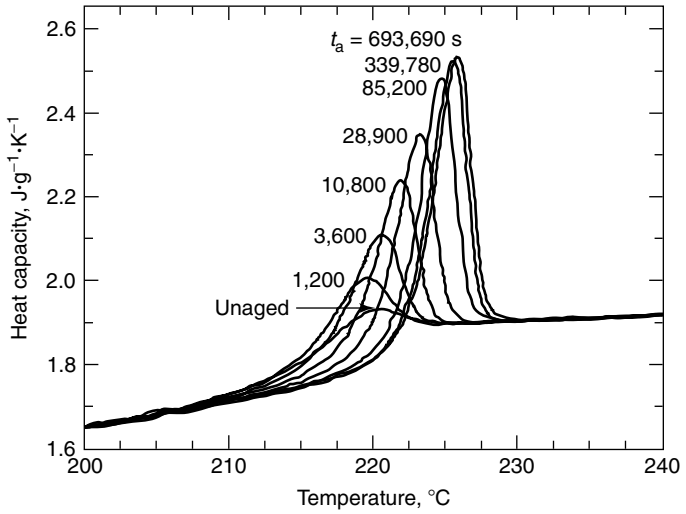

Fig. 7. DSC scans of heat capacity vs temperature for poly(ether imide) after isothermal physical aging at 201.3°C for the various aging times indicated. Scans were made on heating at 10°C/min. The data were corrected to agree with absolute C_p measurements in the liquid state. Data are replotted from Ref. 23.

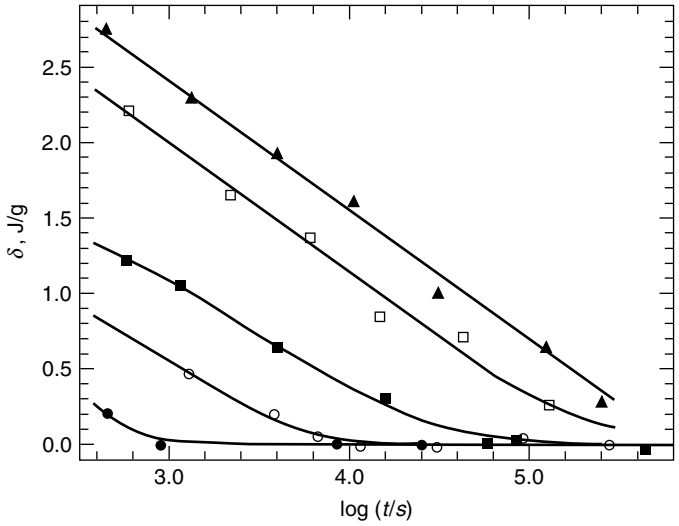

Fig. 8. Relative departure from equilibrium for enthalpy ($\Delta H_\infty - \Delta H_a$) vs the logarithm of aging time for poly(ether imide). Data are replotted from Ref. 23. T_a (°C) = (▲) 201.3, (□) 202.5, (■) 206.3, (○) 207.5, and (●) 211.3.

from equilibrium also increases as the aging temperature decreases. For a perfect quench, the initial departure from equilibrium for enthalpy (δ_0) depends on the magnitude of the temperature jump through the difference in heat capacity in the liquid $\Delta C_p = C_{pl} - C_{pg}$:

$$\delta_0 = \Delta C_p (T_{fo} - T_a) \tag{5}$$

where T_{fo} is the initial fictive temperature for the enthalpy down-jump and equals the glass temperature associated with the cooling rate used in the quench.

The asymmetry of approach and the memory effect should be observable for enthalpy although the dsc is not convenient for making such measurements. Enthalpy relaxation has been measured *in situ* using an adiabatic calorimeter in isothermal mode and asymmetry of approach data has been obtained by Oguni and co-workers (24,25). An inherent problem with adiabatic calorimetry, however, is the difficulty of the measurements, the large thermal equilibration time, and the drift of the instrument for long-time measurements. It should also be noted that the analysis performed by Oguni et al. on their asymmetry of approach data (24,25) neglected the concept of nonlinearity. The interpretation of their data must be viewed with skepticism for this reason.

Evolution of the Viscoelastic Properties

Corresponding to the changes in volume and enthalpy observed following a temperature down-jump from equilibrium, the viscoelastic properties are also observed to evolve. Changes in the dynamic mechanical properties with time of aging below the glass temperature were first reported in 1963 by Kovacs et al. for poly(vinyl acetate) (26). Subsequently, Struik published his thesis in 1978 in which periodic creep measurements were used to follow the effects of physical aging on the creep compliance (14). Figure 9 is a schematic of the stress, strain, and temperature history for the periodic creep experiment after a down-jump in temperature. The experiment consists of quenching the sample from above T_g to an aging temperature T_a below T_g and applying a load at approximately equal logarithmic increments of aging time (14). Hence, there are two time scales in the experiment: the aging or elapsed time (t_e) which begins at the moment of the quench (but often is taken as the time at which the sample reaches T_a) and the

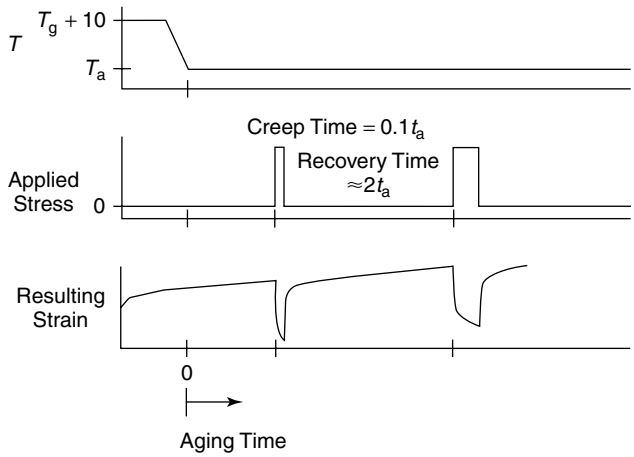

Fig. 9. Schematic of the creep experiment for monitoring physical aging.

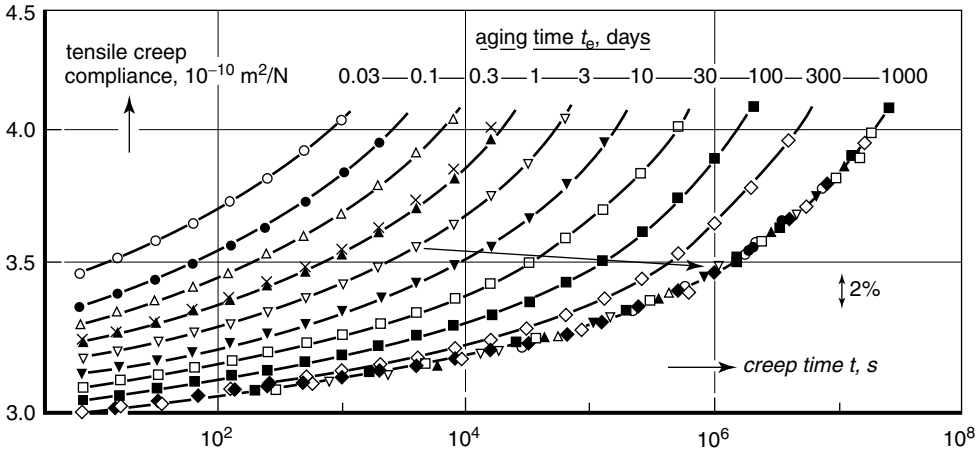

Fig. 10. Small-strain tensile creep curves for rigid poly(vinyl chloride) quenched from 90°C to 20°C and aged at 20 ± 0.1°C for a period of 4 years. The *x*-axis is the creep time. The times above the curves indicate the aging times at which each individual creep experiment was performed. The reduced curve was obtained by shifting the data to the longest aging time response as indicated by the arrow. The data are from Ref. 14, courtesy of L. C. E. Strvik.

creep time (t) which begins at the moment of loading. Creep times are generally performed for less than 10% of the aging time (0.1 t_e) in order to ensure that no appreciable aging occurs during the creep test. Hence, the creep response measured is a "snap shot" of the viscoelastic response at that particular aging time. The time between creep tests generally doubles or triples, allowing sufficient time for creep recovery; the time between measurements should be long enough that the strain change due to creep recovery from one loading is negligible compared to the subsequent loading. The time-dependent viscoelastic response to an up-jump is measured in a similar fashion. Small stresses are used to ensure that the viscoelastic response is linear.

Figure 10 shows the evolution of the creep compliance for poly(vinyl chloride) at 20°C over the course of four years (14). The T_g for poly(vinyl chloride) is around 70°C and so the aging temperature is approximately 50°C below T_g. As the material ages, the creep curves march to longer and longer times, indicating an increase in the characteristic relaxation time as aging progresses. If equilibrium were reached, the response would become independent of aging time (27). In sequential stress relaxation experiments, small strains rather than small stresses can similarly be used to probe the effect of aging on the viscoelastic response. In general, the creep or stress relaxation response due to the applied load or strain is the data analyzed in these experiments as indicated by the creep curves shown in Figure 10. A continuous test data method has recently been suggested, which involves analyzing both load and unload responses for the periodic creep experiment (28). This analysis can potentially yield a more accurate model of the mechanical response (since significantly more data is analyzed); however, the fact that in very few instrumental set-ups the load is actually zero in the unload portion of the experiment must be accounted for.

Time-aging time superposition can generally be used to reduce the curves by shifting them horizontally to superpose. A small vertical shift is sometimes needed as indicated by the slight downward slope of the arrow in Figure 10. The reduced curve is shown at the longest aging time in Figure 10. Struik has maintained that satisfactory time-aging time reduction of data infers that the structural–rheological simplicity is maintained, ie, the retardation spectrum shifts to longer times without a change in shape (14). Time-aging time superpositions have also been performed for poly(vinyl chloride), poly(methyl methacrylate) (PMMA), and polycarbonate creep data obtained by Read and co-workers over fourteen decades in time using several experimental techniques, and the satisfactory reduction of that data in the α-transition region has been interpreted as an indication of structural–rheological simplicity (29–31). On the other hand, Roe and Millman it was found that time-aging time superposition did not work for a polysytrene sample aged for several months at temperatures significantly below T_g and this was attributed to alteration of the shape of the relaxation time spectrum (32). It should be clear that a lack of time-aging time superposition indicates breakdown of structural–rheological simplicity. However, whether time-aging time superposition is sufficient to prove structural–rheological simplicity is less obvious. In order to clarify this point the concepts of time–temperature and time-aging time superpositions are briefly reviewed.

Reduction of linear viscoelastic data is based on the principles of time–temperature and time-aging time superpositions. The principle of time–temperature superposition is widely used to reduce creep or stress relaxation curves obtained at equilibrium density (33,34). The principle implies thermorheological simplicity, ie, the shape of the relaxation time spectrum does not change with temperature although the spectrum shifts to shorter times at higher temperatures. It has been demonstrated, however, that even for what was considered an ideal system, polyisobutylene, time–temperature superposition is not strictly observed (35). In addition, the ability to perform time–temperature superposition should be considered a necessary but not sufficient requirement for thermorheological simplicity because the relatively small experimental time scales over which data is usually obtained, coupled with the uncertainty in the data, leave open the possibility that time–temperature superposition is at best only a good approximation of the behavior over a large time scale. Indeed, it has been shown that although time–temperature superposition appears to be an empirically successful data reduction method for stress relaxation of semicrystalline polypropylene, the reduced stress relaxation curve is not consistent with dynamic mechanical data, and hence cannot be used to predict long-term viscoelastic performance (36). For a more in-depth discussion of time–temperature superposition, the reader is referred to the article on Viscoelasticity.

It is suggested that time-aging time superposition should similarly be considered a necessary but not sufficient requirement for structural–rheological simplicity, particularly since the basis for both shift factors is not well understood. The time-dependent compliance can often be described by

$$J(t) = J_g + J_d\psi(t) + t/\eta \tag{6}$$

where $J(t)$ is the time-dependent creep compliance, J_g refers to the glassy (zero time) compliance, and t is the time of creep. The viscous term (t/η) in equation (6),

where η is viscosity, is generally negligible during physical aging due to the high viscosity of the glass although this is not always the case as is discussed later. J_d in equation (6) is equal to $J_s - J_g$, where J_s is the steady state compliance which is equal to the long-time limiting value of the recoverable compliance for a non-cross-linked system. $\psi(t)$ is the normalized memory function for the compliance, and it goes from $\psi(0) = 0.0$ to $\psi(\infty) = 1.0$. The normalized memory function can often be described using the generalized Kohlrausch–William–Watts (KWW) (37,38) or stretched exponential function:

$$\psi(t) = 1 - e^{-(t/\tau)^{\beta}} \tag{7}$$

Equation (7) is also only valid for a short-term creep experiment in which the time of creep is short relative to the time scale of aging such that the characteristic relaxation time is constant. It is noted that the relaxation function of equation (7) has the correct limits and differs from the Kohlrausch compliance function ($J = J_s\, e^{(t/\tau)\beta}$) which was suggested initially by Struik (14) and which is not physically meaningful at long times (28).

The horizontal and vertical shift factors for reduction of two aging creep curves are defined as

$$\log a_{te} \equiv \log t_{ref} - \log t_1 \tag{8}$$

$$\log b_{te} \equiv \log J(t_{ref}) - \log J(t_1) \tag{9}$$

where $J(t_{ref})$ is the creep compliance at creep time t_{ref} on the reference curve (generally the curve obtained at longest aging times) to which all other curves are being shifted. $J(t_1)$ is the creep compliance at time t_1 which will be shifted to J(t_{ref}) and t_{ref}. By definition, the shift factors cannot depend on the creep time at which the shift is performed (ie, on the value of t_{ref}) since for a valid reduced curve the shift factors must be the same for all times along a given creep curve. For structural–rheological simplicity (eg, β = constant in eq. 7), the shift factors are given by those that Struik has reported (14):

$$a_{te} = \tau_{ref}/\tau_1 \tag{10}$$

$$b_{te} = J_{s_{ref}}/J_{s_1} \tag{11}$$

It should be noted that in addition to the criteria of structural–rheological simplicity, equation (11) is valid only when the glassy compliance J_g is negligible relative to the steady-state compliance.

Similarly, the stress relaxation modulus can often be described using the stretched exponential function:

$$G(t) = G_e + \left(G_g - G_e\right) e^{-(t/\tau)^{\beta}} \tag{12}$$

where G_g is the glass (or zero time) value of the modulus and G_e is the equilibrium (long-time) value of the modulus. For viscoelastic liquids, G_e is zero. For structural–rheological simplicity, the horizontal shift factor is given by equation (10) and the vertical shift factor is given by the following for viscoelastic liquids (39):

$$b_{te} = \frac{G_{g_{ref}}}{G_{g_1}} \tag{13}$$

When structural–rheological simplicity does not hold and, for example, β in equation (7) changes with physical aging, exact reduction of the creep or stress relaxation curves cannot be accomplished. However, it is estimated by the author that a change in the KWW β parameter of approximately 5–10% would result in a deviation of the logarithm of the aging time shift factor ($\log a_{te}$) of ± 0.05 over two decades in time scale. Scatter in reduced curves of this order of magnitude is often observed because of the scatter in the creep or stress relaxation data (23,39,40). Researchers have not systematically looked for such small deviations in their reduced curves.

In addition, structural–rheological simplicity might not be expected to be perfectly valid since the breadth of the relaxation time distribution is known to change with temperature at equilibrium (41,42) and along the glass line (43). Following a down-jump then, the breadth of the relaxation time distribution at equilibrium may be expected to differ between the initial and final temperatures and part of this change might be expected to occur during physical aging (as opposed to during the quench). A change in β with aging time of the order of 0.01–0.02 for polystyrene close to T_g has been inferred Recently by Ediger et al. (44). Based on the estimation above, such a change appears to be consistent with the majority of creep data in the literature (especially since researchers are not looking for such small deviations from superposition). For example, in a previous work on polycarbonate by McKenna (40) the value of β was observed to be invariant with aging time over the time scales investigated (up to 18 h for temperatures from 111°C below to 6°C below the nominal glass temperature). However, the error in β based on the error in the fit was reported to range from 4 to 7% at 70°C. In addition for two data sets at 135°C, β values equaled 0.47 ± 0.04 and 0.43 ± 0.02 at the longest aging time when a free fit was allowed (45). The point is that small systematic deviations in β may not be easily observable. The ability to obtain time-aging time superposition does not necessarily indicate that the shape of the spectrum is not changing with aging time.

According to equation (11), the vertical shift factor is suggested to be due to changes in the steady-state compliance, J_s, during physical aging. Such changes would arise if the steady-state compliance were temperature-dependent. J_s has been found to be independent of temperature in the range from 1.2 T_g to 2.0 T_g for several amorphous polymers (46,47). However, in the vicinity of T_g, J_s decreases with decreasing temperature for low molecular weight polystyrenes. (47) In the same work, J_s was predicted to also decrease for polystyrenes of higher molecular weight based on free volume arguments (47). This would suggest that in a down-jump experiment, J_s should decrease with aging time with the result that the vertical shift factors should be negative. Negative vertical shift factors are generally the case although two cases for positive shifts have been reported (14). However, positive vertical shift factors seem not to have a theoretical basis based on all measurements made to date on J_s.

In order to measure how the steady-state creep compliance and viscosity evolved during physical aging, a new interrupted creep experiment has been developed by plazek and co-workers (48). This experiment consists of applying a

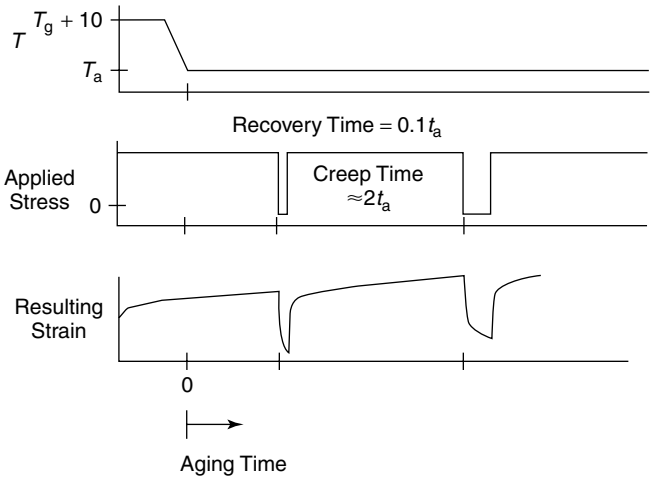

Fig. 11. A schematic of the intermittent creep experiment developed by Bernatz, Giri, Simon, and Plazek (Ref. 48).

constant load above T_g for a time long enough to reach steady state. Once in steady state, the material is quenched to the aging temperature T_a while maintaining the constant load. Successive creep-recovery measurements are made at logarithmic time increments. A schematic of the experiment for a temperature down-jump is shown in Figure 11. The rate of creep is monitored until the first creep-recovery measurement when the load is removed. After the first test, the load is reapplied and the creep rate is again monitored to ensure that adequate time has passed before the next measurement. The length of each creep-recovery measurement and the time between subsequent measurements follows the Struik protocol (14) for conventional or periodic creep experiments. The viscosity can be obtained as a function of aging time from the steady-state creep (or quasi steady-state creep for materials in which the steady-state creep compliance is temperature-dependent). The evolution of the steady-state compliance with aging time can be calculated from the horizontal shift factor (assuming β is constant, which should only be considered a first approximation):

$$a_{te} = \frac{\tau_{ref}}{\tau_1} = \frac{\eta_{ref} J_{s_{ref}}}{\eta_1 J_{s_1}} \tag{14}$$

Interpretation of the data from the interrupted creep experiment is based on the assumption that once the material reaches steady-state creep, a change in temperature will not disturb this condition if J_s is independent of temperature. Work by Leaderman on polyisobutylene above on T_g (49), as well as Plazek's work on 1,3,5-tri-α-naphthylbenzene (48), indicates this to be the case. Using the interrupted creep test, the evolution of both J_s and η for a polystyrene of 3400 molecular weight have been measured (48). This work confirms that for materials with temperature-dependent J_s, J_s will decrease during physical aging. The interrupted creep experiment may also make it possible to experimentally verify the relationship between the vertical shift factors and J_s.

Effects of Physical Aging on Failure

The most important effect of physical aging, from a practical standpoint, may well be its impact on failure and material lifetime. Physical aging has been found to cause transformation from ductile to brittle failure in many polymers, including poly(ethylene terephthalate) (50–52), polycarbonate (53–55), poly(ether imide) (56), and poly(phenylene oxide) (PPO) (57). In general, physical aging results in a decrease in the time to failure (58), as well as an increase in the yield stress and a decrease in the strain to break (50–57,59–66). A decrease in the impact fracture energy is also generally observed (63,66–69).

The effects of physical aging on craze growth are less clear. It has been found that craze breakdown and ultimate failure are accelerated by physical aging (61) in spite of the fact that the times to craze increase (61,62). However, other researchers found no effect of physical aging on the craze growth rates in polystyrene–polybutadiene diblock copolymers (70) and in polycarbonate (71). Complicating the picture, a transition from a high to low craze growth rate regime at long aging times for low aging temperatures in a styrene–acrylonitrile copolymer has been observed (72). The transition occurred over a narrow aging time window, with craze growth being relatively independent of aging time on either side of the transition. Higher aging temperatures showed only the low craze growth rate regime, leading to speculation that the transition occurred at aging times too short to be measured.

The effects of physical aging on fatigue crack propagation are even less well-documented than the effects on ultimate properties and crazing. Results seem to indicate that fatigue crack propagation depends very little on the degree of physical aging (69,73). The reason for this is suggested to be due to yielding occurring in the plastic zone (73). This is consistent with the fact that the lower yield stress which corresponds to the onset of generalized plastic flow has been observed to also be little affected by physical aging (60).

The Effect of Large Stresses on Physical Aging: Rejuvenation

The effect of large stresses on physical aging are controversial and not completely resolved. The term rejuvenation was coined by McKenna and Kovacs (74) to describe the observation that the aging time shift factor required to superpose large deformation responses was smaller than that required to superpose small deformation responses for the same thermal history. Strvik and others have interpreted this data as erasure of the previous aging by deformation-induced free volume (14,75–79). Other researchers have invoked rejuvenation to explain various observations (64,80). However, McKenna et al. have shown that although mechanical stimuli do induce a short-time volume response, the underlying volume relaxation is unperturbed by the deformation (81). This is contrary to what would be expected if rejuvenation were the case. In addition, it was found that the time required to reach equilibrium at temperatures near T_g was independent of the applied stress, suggesting that large stresses do not cause erasure of aging (82). It has been argued that the rejuvenation response is simply a result of nonlinear viscoelasticity, ie, the large deformation response is affected less by volume

(or enthalpy) changes than in the linear viscoelastic case (83,84). In fact, using the nonlinear viscoelastic Bernstin–Kearsley–Zapas (BKZ) constitutive equation (85) which includes an aging clock that depends upon the deformation magnitude, the rejuvenation response can be reproduced quantitatively without invoking any type of deformation-induced "erasure" effect (86).

There are two alternatives to the rejuvenation hypothesis: mechanical–structural decoupling which much of McKenna's work suggests (86,87) and the accelerated aging hypothesis suggested some time ago by Sternstein (88). There is some recent evidence of mechanically enhanced aging of polycarbonate (PC) at room temperature (89). Although consistent with Sternstein's ideas (88), more work is needed to directly test the accelerated aging hypothesis. It is important that this be done, however, in the context of nonlinear viscoelasticity.

Relative Time Scales for Relaxation of Different Properties

There are a number of reports in the literature on the relative time scales of relaxation for different properties (10,23,32,64,65,80,87,90–101) Table 1 summarizes experimental results on polymeric glasses. For nonpolymeric materials, Scherer (102) has summarized the relative values of characteristic equilibrium relaxation times obtained by Moynihan through modeling the relaxation behavior of various properties of low molecular weight glasses, as well as the experimental results of Rekhson on volume and stress relaxation of low molecular weight glasses. The results shown in Table 1 are seemingly contradictory at first glance, with some researchers finding that the time scales are the same for different properties and some groups finding that they differ. The time scale for relaxation is defined differently by different researchers. It has been suggested (10,23,99) that the time required to reach equilibrium may be the best measure of the relaxation time scale in spite of the fact that the relaxation response approaches equilibrium asymptotically. Most of the results reported in Table 1 reflect the relative approach to equilibrium for different properties. The rate of approach can differ for different properties because of differences in thermal history in different measurements and also because of differences in the sensitivity of the properties to the molecular changes associated with physical aging. This is the case even when the time required to reach equilibrium is the same (10,99). Hence, the assertion that the time required to reach equilibrium (rather than some characteristic relaxation time based on the shape of the relaxation response) is the appropriate time scale. McKenna et al. investigated the times required to reach equilibrium, and their results suggested that the relative time scales for stress relaxation and volume recovery depend on the physical aging temperature and the magnitude and direction of the jump from equilibrium to the aging temperature (87,90). On the other hand, the early results of Simon and co-workers on poly(ether imide) indicated that the time required to reach equilibrium for volume, enthalpy, and creep were identical (23,99). Subsequent experiments on polystyrene found that time scales to reach equilibrium were again the same for volume and enthalpy at temperatures where equilibrium was reached (10). However, model extrapolations to lower temperatures indicate that the relaxation times for enthalpy diverge from those of volume, and are shorter. The divergence might be dismissed as being due to problems

Table 1. Relative Time Scales for Evolution of Various Properties During Structural Recovery for Polymers

Material	Experiments	Findings	Reference
DGEBA[a]/PPO	Volume recovery and evolution of stress relaxation (up- and down-jumps)	Times to reach equilibrium differ: volume is faster in up-jump, slower in down-jump relative to mechanical property.	87,90
DGEBA[a]/DDS[b]	Volume recovery (up- and down-jumps) and creep (equilibrium)	Shift factors for data reduction are the same.	91
PS	Volume and enthalpy recovery	Times to reach equilibrium are the same near T_g; model calculations predict times to reach equilibrium differ: enthalpy faster than volume.	10
PS	Volume and enthalpy recovery (up- and down-jumps)	Rates of approach to equilibrium are related by a constant for volume and enthalpy.	92
PS	Volume and enthalpy recovery (double temperature jumps)	Times to reach maximum differ: volume is slower than enthalpy.	93
PS	Enthalpy recovery, and room temperature creep evolution (down-jumps)	Times to reach equilibrium differ: enthalpy is faster than mechanical property.	32
PS	Volume and enthalpy recovery (after cooling under pressure)	Times to reach specified percent recovery differ: volume is faster relative to enthalpy.	95
PMMA	Volume and enthalpy recovery (after cooling under pressure)	Times to reach specified percent recovery differ: volume is slower relative to enthalpy.	95
PMMA	Volume and enthalpy recovery, and dynamic mechanical analysis (down-jumps)	Decay functions differ: enthalpy is fastest, followed by volume, followed by mechanical property.	96
PMMA	Enthalpy recovery, and stress relaxation (down-jumps)	Model parameters for enthalpy relaxation comparable to experimental stress relaxation times.	97
PVAc	Volume and enthalpy recovery (down-jumps), dynamic mechanical analysis and dielectric analysis (equilibrium)	Equilibrium relaxation times obtained from modeling data differ: largest for enthalpy, smallest for mechanical property.	94
PVAc	Volume and enthalpy recovery (down-jumps)	Effective retardation times differ: smaller for volume relative to enthalpy.	98

Table 1. (Continued)

Material	Experiments	Findings	Reference
PVAc	Volume and dynamic mechanical analysis (up- and down-jumps)	Relaxation time from fit is smaller for volume than mechanical property on down-jump; activation energy is larger for volume.	80
PVAc	Volume, enthalpy recovery, and stress relaxation (down-jumps)	Mechanical property reaches equilibrium while volume and enthalpy are still evolving.	100,101
PEI	Enthalpy and volume recovery and creep evolution (down-jumps)	Times to reach equilibrium are the same but volume relaxes faster initially relative to enthalpy.	23,99
PC	Enthalpy recovery, creep, and yield (down-jumps)	Rate of change of enthalpy and creep are different; equilibrium is not reached.	64
PI	Enthalpy recovery and creep evolution (down-jumps)	Relaxation times from fit of data are longer for enthalpy than for creep.	65

[a]DGEBA: diglycidyl ether of bisphenol A.
[b]DDS.: 4,4′-diamino diphenyl sulfone.

with the model (see later on the TNM model and problems associated therewith), if it were not for the fact that our most recent data on the glass former selenium appears to show the divergence for temperatures at which equilibrium was reached (103). Figure 12 shows the times required to reach equilibrium as a function of the distance from the glass temperature (with T_g defined at 0.2°C/min) for polystyrene, poly(ether imide), and selenium. The selenium data is offset from the polystyrene and poly(ether imide) data because the temperature dependence of the times required to reach equilibrium differs. The symbols are the measured times required to reach equilibrium, whereas the dashed lines are the times required to reach equilibrium based on extrapolations using the Tool–Narayanaswamy–Moynihan (TNM) model for polystyrene and using a linear extrapolation for selenium (which is expected to give a lower bound for the time required to reach equilibrium). At temperatures in the vicinity of T_g all three properties appear to come to equilibrium at the same time within the scatter of the data. At lower temperatures, the times required to reach equilibrium appear to diverge for the various properties, with enthalpy reaching equilibrium before volume and creep. The divergence appears to occur closer to T_g for selenium than for polystyrene. Although the origin of the divergence in time scales is not known, it appears that this general framework is consistent for the three materials which we have studied and with the other data in the literature. We note that other researchers (80) have claimed a difference in activation energies for the characteristic relaxation time obtained from a fit of the stretched exponential to the relaxation data, resulting in a picture similar to what we observe but for the characteristic relaxation time. The two pictures are consistent; the primary difference is that we suggest that the

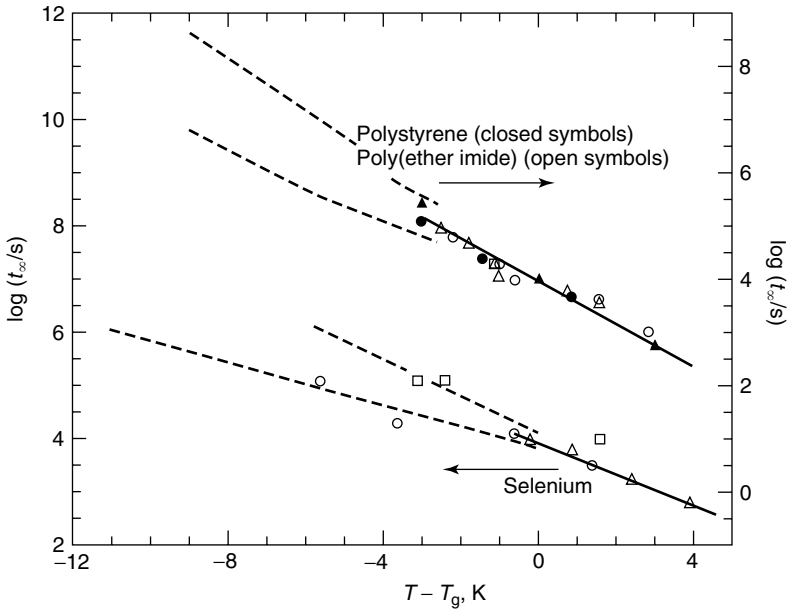

Fig. 12. The times required to reach equilibrium for polystyrene, poly(ether imide), and selenium vs the departure from T_g, where T_g is defined as the value obtained dilatometrically on cooling at 2°C/min. Data are replotted from Refs. 10, 23, 99, and 103 ▲ & △ Volume, □ Creep, and ● & ○ Enthalpy.

time required to reach equilibrium is a better parameter of the time scale because it is less influenced by magnitude of the temperature jump and the resulting shape of the relaxation response.

Temperature Dependence of the Relaxation Time at Equilibrium

The temperature dependence of the characteristic relaxation time is described by the (Williams–Landell–Ferry) (WLF) equation (104), or the equivalent Vogel–Tammann–Hesse–Fulcher (VTHF) (105–107) expression. These equations are valid from the nominal glass temperature to approximately 100–150°C above T_g. Far above the glass temperature, the temperature dependence decreases and becomes Arrhenius or follows a different WLF dependence (108). The temperature dependence of the relaxation time along the glass line below T_g is known to deviate from WLF behavior and follows what appears to be Arrhenius temperature dependence with a very low activation energy (14). What is not as well-known, however, is that below the glass temperature, the temperature dependence of the equilibrium relaxation time also appears to deviate from the WLF relationship with a lower apparent activation energy than expected based on extrapolation of the WLF equation.

The first convincing data depicting the change from WLF to an Arrhenius-type temperature dependence for the equilibrium relaxation time at T_g is the work

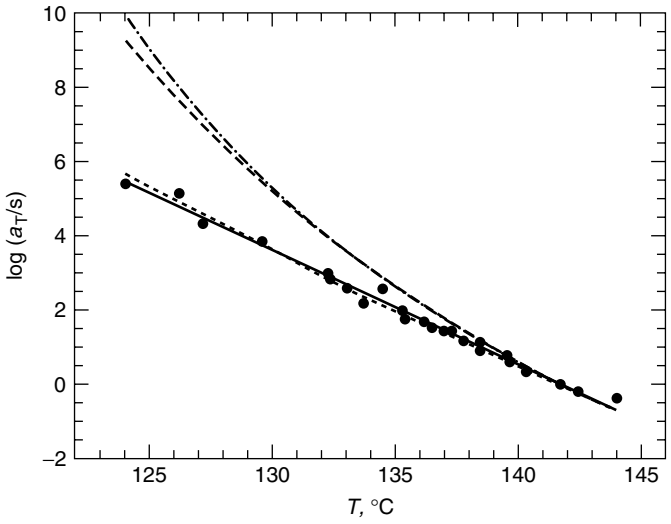

Fig. 13. The temperature dependence of the shift factors for stress relaxation of polycarbonate obtained at equilibrium. The data shows a significant deviation from the expected WLF temperature dependence; the dashed and dash–dot lines are the "universal" WLF temperature dependence and that which fits the polycarbonate data above T_g. The data are replotted from the data of Ref. 39. —●— Experimental data and linear fit, — — — WLF ($C_1 = 17.44$, $C_2 = 51.66$ K, $T_{ref} = 142^\circ$ C), – · – · – WLF ($C_1 = 14.42$, $C_2 = 43.97$ K, $T_{ref} = 142^\circ$ C), and ------- WLF ($C_1 = 49.71$ $C_2 = 174.6$ K, $T_{ref} = 142^\circ$ C).

on polycarbonate by O'Connell and McKenna in which equilibrium was reached at temperatures 17°C below the nominal glass temperature (109). This data is shown in Figure 13. Similar results were found for polystyrene (10). Similar behavior might be interpreted from earlier works on various organic liquids (110,111), although it is not clear in the early work that the measurements reported are all equilibrium measurements or that the reported Vogel fits are correct since in one case (111) T_∞ was very near T_g. Recent theoretical work by Di Marzio and Yang (112) predicts a change in the temperature dependence of the equilibrium relaxation time at T_g from WLF-type dependence to an Arrhenius temperature dependence. The non-WLF temperature dependence below T_g for the equilibrium state has major implications for modeling and predicting the effects of structural recovery, especially for aging deep in the glassy state, since knowledge of the value of the relaxation time at equilibrium is critical for accurate predictions.

Physical Aging in Semicrystalline Polymers

The effects of structural recovery are not limited to fully amorphous materials. In semicrystalline polymers, the amorphous regions physically age in a similar manner to the process in fully amorphous materials. Obviously, however, the change in properties will be only a fraction of that found in fully amorphous materials since the amount of amorphous material makes up only a fraction of the

semicrystalline material. One difference between aging in semicrystalline materials and fully amorphous materials, however, is the temperature range over which physical aging is observed. In amorphous materials, aging occurs only below the time or frequency dependent glass temperature, whereas in semicrystalline materials, physical aging has been observed at temperatures above the nominal T_g (14,113–118). The explanation is that the crystalline domains constrain the glass in the vicinity of the crystallite, increasing its T_g, and thereby increasing the temperatures at which physical aging is observed (113–116). However, above T_g secondary crystallization and/or crystal reorganization can take place. Results for physical aging of syndiotactic polystyrene above T_g suggest that in contrast to many semicrystalline polymers, the recrystallization phenomenon is the primary mechanism for physical aging above T_g (118).

Modeling Structural Recovery

Models of structural recovery include the Kovacs–Aklonis–Hutchinson–Ramos (KAHR) model (119), Moynihan's model (120), and Ngai's coupling model (121). These models are based on work done originally by Narayanaswamy (122), incorporating the ideas of Tool (13). The models of structural recovery reflect the nonlinear and nonexponential effects observed experimentally. The historical development of these equations has been detailed (7,8); only a brief description follows. The KAHR formulation (119), which is written in terms of a departure from equilibrium δ rather than in terms of T_f, is conceptually easier to use when the full three-dimensional PVT surface is considered:

$$\delta = \int_0^t \frac{d\delta}{dt} \exp\left[-\left(\int_{t'}^t \frac{dt''}{\tau} \right)^{\beta} \right] dt' \tag{15}$$

where for volume the departure from equilibrium is given by the definition in equation (1), whereas for enthalpy, the definition in equation (4) is used. τ is known as the characteristic relaxation time (although it is actually a retardation time), β is the nonexpontiality or stretching parameter, and $d\delta/dt$ is the rate of change of δ in arbitrary pressure or temperature histories:

$$\frac{d\delta}{dt} = \left(\frac{\partial \delta}{\partial P} \right)_T \frac{dP}{dt} + \left(\frac{\partial \delta}{\partial T} \right)_P \frac{dT}{dt} \tag{16}$$

For the case of isobaric temperature jumps or isothermal pressure jumps, these equations revert to the KAHR equations for volume recovery using $(d\delta/dP)_T = -\Delta\kappa$ and $(d\delta/dT)_P = \Delta\alpha$. $\Delta\kappa$ is the difference in the compressibilities of the liquid and glass at T_g. For enthalpy recovery, $(d\delta/dP)_T = VT\Delta\alpha$ and $(d\delta/dT)_P = \Delta C_p$.

The nonexponentiality of the structural recovery process is described by the nonexponentiality parameter β in equation (15); the history dependence is accounted for by the integral of the reduced time (dt/τ); and the nonlinearity is incorporated into the model by allowing the characteristic relaxation time τ

to be a function of temperature, pressure, and structure, the latter of which is often characterized by the fictive temperature (T_f), the fictive pressure (P_f), or the departure from equilibrium (δ). The fictive temperature is defined as the temperature at which a material would reach equilibrium if heated (or cooled) along the glass line. It is related to δ at constant pressure through the difference between the liquid and glass thermal expansion coefficients ($\Delta\alpha$) for volume and through the difference between the liquid and glass heat capacities (ΔCp) for enthalpy:

$$T_f = T_a + \frac{\delta}{\Delta\alpha} \quad \text{for volume recovery} \tag{17}$$

$$T_f = T_a + \frac{\delta}{\Delta C_P} \quad \text{for volume recovery} \tag{18}$$

Hence, at equilibrium, the fictive temperature is equal to the aging temperature. The fictive pressure has an analogous definition with respect to glass and liquid lines in pressure space.

Various phenomenological equations have been used to describe the dependence of the characteristic relaxation time on temperature and structure and sometimes pressure, including the TNM equation (120), equations derived by Hodge (123) and Scherer (124), both based on the approach of Adam and Gibbs (125), the KAHR and similar equations (119,126), equations based on free volume, and several others (127,128). The essential idea in all of these equations is that the characteristic relaxation time depends on the instantaneous state of the material (ie, temperature, pressure, and some measure of structure—volume, δ, T_f, and/or P_f). The most widely used form is the TNM equation for isobaric structural recovery:

$$\ln \tau_0 = \ln A + \frac{x\Delta h}{T} - \frac{(1-x)\,\Delta h^*}{T_f} \tag{19}$$

where x partitions the effects of temperature and structure and determines the degree of nonlinearity, and $\Delta h*$ and A are constants. Although this equation is unable to describe the observed WLF (104) or the equivalent VTHF (105–107) temperature dependence in the equilibrium limit when $T_f = T$, it is often thought to be a valid approximation to the narrow range of temperature over which data is modeled. Although this may be the case for modeling isothermal structural relaxation data, this assumption is suspect for modeling dsc temperature scans. To accurately model the poly(ether imide) data shown in Figure 8, the dependence of the characteristic relaxation time is needed as a function of structure and temperature from 201°C (where aging took place) to 230°C where the enthalpy overshoot returns to the baseline. The linear approximation of equation (19) is not valid over this temperature range above T_g (207°C) where the WLF equation is valid, let alone below T_g where the temperature dependence of the equilibrium relaxation time is expected to change (10,109). Consistent with the fact that equation (19)

is not a valid representation over the range of temperatures of interest when modeling dsc temperature scans, Schick and co-workers (129) have recently found that description of the loss and storage heat capacity obtained from slow temperature-modulated dsc cooling scans could only be done well by using an equation based on Adam and Gibbs which is consistent with WLF behavior above T_g.

There are unresolved issues pertaining to the models, including an apparent dependence of model parameters on thermal history and an inability to predict structural recovery for deep quenches (5,7,8,130–138). Simple fixes have been found not to resolve these problems (5,133,136,138,139). To make rational improvements to the models and to determine what "essential ingredients" (140) are needed to predict structural recovery, systematic investigation of model assumptions is now needed. The basic assumptions underlying current models of structural recovery include (*1*) thermorheological simplicity, (*2*) structural–rheological simplicity, (*3*) the assumption that the placement of the relaxation time spectrum on the time scale (ie, the mobility) depends only on the instantaneous state of the glass, and (*4*) the assumption that the relationship between glassy structure and temperature and pressure history can be described using Boltzmann superposition in a way that is analogous to viscoelasticity.

In contrast to the KAHR, TNM, and Ngai models of structural recovery, which were developed based on extending the formalism developed for viscoelasticity and an understanding of the relationship between the volume (or enthalpy) relaxation kinetics and the volume (or enthalpy), the thermoviscoelastic model developed in Caruther's group at Purdue (141) is based on Coleman's thermodynamic theory, also known as rational mechanics (142,143). It is one of the first advances in the development of equations to describe structural recovery to appear in about 20 years (144). Caruther's model begins with a free energy functional which is differentiated to obtain the time- and path-dependent nonequilibrium thermodynamic functions. The thermoviscoelastic constitutive model is the only theory which can qualitatively describe structural recovery, yield in tension and compression, multiaxial yield, nonlinear creep and stress relaxation, and constant rate of cooling isobaric studies with a single set of material parameters which can be independently obtained (145). The model is covered in detail in the Viscoelasticity article of this encylopedia.

Of particular importance to structural recovery models is the idea that the apparent mobility may depend on the temperature/pressure/stress path rather than on the instantaneous state of the material. This differs from all of the phenomenological equations for the characteristic relaxation time, including equation (19), which are presently used in other models of structural recovery. The dependence of the relaxation on the unique state has been investigated by Strvik (146), and although it was claimed that the relaxation time only appeared to depend on the instantaneous volume, there is considerable scatter in the data and the relationship appears to depend not only on the final aging temperature but also on the sample history (ie, the magnitude of down- and double-temperature jumps). The scatter may be due to the measurements of volume and relative relaxation time being made in separate instruments such that the thermal history of the samples were not identical. Alternatively, it may be an indication of a more complicated

relationship between the characteristic relaxation time and the instantaneous state as Caruther's model suggests.

Current Challenges in Physical Aging Research

One of the greatest unsolved challenges in physical aging research is understanding the relationship between the evolution of various properties, including failure, and the ability to predict time-dependent properties from limited data over, for example, the lifetime of a material. We are not at the point yet where we can predict changes in thermodynamic properties from one another, let along predict mechanical behavior from thermodynamic variables. Issues such as whether spectral shape changes during physical aging, how to correctly incorporate nonlinearity into the models of structural recovery, and how many ordering parameters exist are also not resolved.

Part of our problem lies in the absence of a universally accepted theory of the glass transition itself. For this reason, the interpretation and modeling of experimental results takes place within a weak theoretical framework. It is important that the fundamental questions associated with the glass transition be addressed, including, but not limited to, the assumptions underlying the Adam–Gibbs theory, the ability to calculate the configurational entropy, and the existence or lack thereof of an underlying thermodynamic glass transition.

ALKYD RESINS

Introduction

Although no longer the largest volume vehicles in coatings, alkyds still are of major importance. Alkyds are prepared from polyols, dibasic acids, and fatty acids. They are polyesters, but in the coatings field the term polyester is reserved for "oil-free polyesters." The term *alkyd* is derived from *alc*ohol and a*cid*. Alkyds tend to be lower in cost than most other vehicles and tend to give coatings that exhibit fewer film defects during application. However, durability of alkyd films, especially outdoors, tends to be poorer than films from acrylics, polyesters, and polyurethanes.

There are several types of alkyds. One classification is into *oxidizing* and *nonoxidizing* types. Oxidizing alkyds cross-link by the same mechanism as drying oils. Nonoxidizing alkyds are used as polymeric plasticizers or as hydroxy-functional resins, which are cross-linked by melamine–formaldehyde (MF), by urea–formaldehyde (UF) resins, or by isocyanate cross-linkers. A second classification is based on the ratio of monobasic fatty acids to dibasic acids utilized in their preparation. The terminology used was adapted from terminology used to classify varnishes. Varnishes with high ratios of oil to resin were called *long oil varnishes*; those with a lower ratio, *medium oil varnishes*; and those with an even lower ratio, *short oil varnishes*. Oil length of an alkyd is calculated by dividing the amount of "oil" in the final alkyd by the total weight of the alkyd solids, expressed as a percentage, as shown in equation (1). The amount of oil is defined as the triglyceride equivalent to the amount of fatty acids in the alkyd. The 1.04 factor in equation (2) converts the weight of fatty acids to the corresponding weight of triglyceride oil. Alkyds with oil lengths greater than 60 are *long oil alkyds*; those with oil lengths from 40 to 60, *medium oil alkyds*, and those with oil lengths less

Encyclopedia of Polymer Science and Technology. Copyright John Wiley & Sons, Inc. All rights reserved.

than 40, *short oil alkyds*. There is some variation in the dividing lines between these classes in the literature.

$$\text{Oil Length} = \frac{\text{Weight of Oil}}{\text{Weight of Alkyd} - \text{Water Evolved}} \times 100 \quad (1)$$

$$\text{Oil Length} = \frac{1.04 \times \text{Weight of Fatty Acids}}{\text{Weight of Alkyd} - \text{Water Evolved}} \times 100 \quad (2)$$

Another classification is *unmodified* or *modified alkyds*. Modified alkyds contain other monomers in addition to polyols, polybasic acids, and fatty acids. Examples are styrenated alkyds and silicone alkyds. Since they are closely related to alkyd resins, uralkyds and epoxy esters are also discussed.

Oxidizing Alkyds

Oxidizing alkyds can be considered as synthetic drying oils. They are polyesters of one or more polyols, one or more dibasic acids, and fatty acids from one or more drying or semidrying oils.

Film Formation. Most of the studies of the chemistry of cross-linking have been with drying oils and not the alkyds derived from them, but the mechanisms are applicable to both. Films exposed to air undergo autoxidative cross-linking. In nonconjugated unsaturated oils, the active group initiating drying is the diallylic group (—CH=CHCH$_2$CH=CH—) from esters of (*Z*,*Z*)-9,12-octadecadienoic acid [60-33-3] (linoleic acid) and (*Z*,*Z*,*Z*)-9,12,15-octadecatrienoic acid [463-40-1] (linolenic acid). They have one and two diallylic groups per molecule, respectively. Drying is related to the average number of diallylic groups per molecule. If this number is greater than about 2.2, the oil is a drying oil and if it is moderately below 2.2, the oil is a semidrying oil; there is no sharp dividing line between semidrying oils and nondrying oils. Since diallylic groups are the sites for cross-linking, it is convenient to relate the average number of such groups per molecule to the number average functionality $\bar{f}_n$ of the triglyceride or synthetic drying oil. It is probable that some of the sites are involved in more than one cross-linking reaction.

The methylene groups are activated by their allylic relationship to two double bonds and are much more reactive than methylene groups allylic to only one double bond. The $\bar{f}_n$ of a typical linseed oil is 3.6; it is a drying oil. The $\bar{f}_n$ of a typical soybean oil is 2.07; it is a semidrying oil. The higher the $\bar{f}_n$ of a drying oil, the more rapidly a solvent-resistant, cross-linked film forms on exposure to air.

The reactions taking place during drying are complex. Cross-linked films form from linseed oil in the following stages: (*1*) an induction period during which naturally present antioxidants (mainly tocopherols) are consumed, (*2*) a period of rapid oxygen uptake with a weight gain of about 10% (ftir shows an increase in hydroperoxides and appearance of conjugated dienes during this stage), and (*3*) a complex sequence of autocatalytic reactions in which hydroperoxides are consumed and cross-linked film is formed. In one study, steps 1, 2, and 3 were

far along in 4, 10, and 50 h, respectively, when catalyzed by a drier (1). Cleavage reactions to form low molecular weight by-products also occur during the latter stages of film formation. Slow continuing cleavage and cross-linking reactions through the lifetime of the film lead to embrittlement, discoloration, and slow formation of volatile by-products. Oils with significant quantities of fatty acids with three double bonds, such as linolenic acid, discolor to a particularly marked degree.

When a film is applied, initially naturally present hydroperoxides decompose to form free radicals. At first, these highly reactive free radicals react mainly with the antioxidant, but as the antioxidant is consumed, the free radicals react with other compounds. Hydrogens on methylene groups between double bonds are particularly susceptible to abstraction, yielding a resonance-stabilized free radical that reacts with oxygen to give predominantly conjugated peroxy free radicals. The peroxy free radicals can abstract hydrogens from other methylene groups between double bonds to form additional hydroperoxides and generate free radicals. Thus, a chain reaction is established, resulting in autoxidation. At least part of the cross-linking occurs by radical–radical combination reactions forming C—C, ether, and peroxide bonds. These reactions correspond to termination by combination reactions in free-radical chain-growth polymerization. Reactions analogous to the addition step in chain-growth polymerization could also produce cross-links.

Studies of the reactions of ethyl linoleate with oxygen in the presence of driers by ^{1}H and ^{13}C nmr showed that the predominant cross-linking reactions were those that formed ether and peroxy cross-links (2,3). Mass spectroscopic studies showed that only about 5% of the cross-links were new C—C bonds (2). Substantial levels of epoxy groups were detected in the reaction mixture, rising to a maximum in about 5 days and virtually disappearing in 100 days; it is suggested that epoxy groups may react with carboxyl groups to form ester cross-links.

Rearrangement and cleavage of hydroperoxides to aldehydes and ketones, among other products, lead to low molecular weight by-products. The characteristic odor of oil and alkyd paints during drying is attributable to such volatile by-products, as well as to the odor of organic solvents. Undesirable odor has been a factor motivating replacement of oil and alkyds in paints with latex, particularly for interior applications. The reactions leading to these odors have been extensively studied in connection with flavor changes of vegetable cooking oils (4). Aldehydes have been shown to be major by-products from the catalyzed autoxidation and from curing of drying-oil-modified alkyd resins (2,5). It has also been shown that C_9 acid esters remain in the nonvolatile reaction mixture (5).

Dried films, especially of oils with three double bonds, yellow with aging. The yellow color bleaches significantly when exposed to light; hence, yellowing is most severe when films are covered, such as by a picture hanging on a wall. The reactions leading to color are complex and are not fully understood. Yellowing has been shown to result from incorporation of nitrogen compounds and is markedly increased by exposure to ammonia. It has been proposed that ammonia reacts with 1,4-diketones formed in autoxidation to yield pyrroles, which oxidize to yield highly colored products (6).

The rates at which uncatalyzed nonconjugated drying oils dry are slow. Many years ago, it was found that metal salts (driers) catalyze drying. The most widely used driers are oil-soluble cobalt, manganese, lead, zirconium, and calcium salts of

octanoic or naphthenic acids. Salts of other metals, including rare earths, are also used. Cobalt and manganese salts, so-called top driers or surface driers, primarily catalyze drying at the film surface. Lead and zirconium salts catalyze drying throughout the film and are called through driers. The surface-drying catalysis by cobalt and manganese salts results from the catalysis of hydroperoxide decomposition. The cobalt cycles between the two oxidation states. The activity of through driers has not been adequately explained.

Combinations of metal salts are almost always used. Mixtures of lead with cobalt and/or manganese are particularly effective, but as a result of toxicity control regulations, lead driers can no longer be used in consumer paints sold in interstate commerce in the United States. Combinations of cobalt and/or manganese with zirconium, frequently with calcium, are commonly used. Calcium does not undergo redox reactions; it has been suggested that it may promote drying by preferentially adsorbing on pigment surfaces, minimizing adsorption of active driers. The amounts of driers needed are system specific. Their use should be kept to the minimum possible level, since they not only catalyze drying but also catalyze the reactions that cause post-drying embrittlement, discoloration, and cleavage.

Oils containing conjugated double bonds, such as tung oil, dry more rapidly than any nonconjugated drying oil. Free-radical polymerization of the conjugated diene systems can lead to chain-growth polymerization, rather than just a combination of free radicals to form cross-links. High degrees of polymerization are unlikely because of the high concentration of abstractable hydrogens acting as chain-transfer agents. However, the free radicals formed by chain transfer also yield cross-links. In general, the water and alkali resistance of films derived from conjugated oils are superior, presumably because more of the cross-links are stable carbon–carbon bonds. However, since the (*E*,*Z*,*E*)-9,11,13-octadecatrienoic acid [506-23-0] (α-eleostearic acid) in tung oil has three double bonds, discoloration on baking and aging is severe.

The most commonly used polyol in preparing alkyds is 1,2,3-propanetriol [56-81-5] (glycerol), the most commonly used dibasic acid is 1,3-isobenzofurandione [85-44-9] (phthalic anhydride) (PA), and a widely used oil is soybean oil. Let us consider a simple, idealized example of the alkyd prepared from 1 mol of PA, 2 mol of glycerol, and 4 mol of soybean fatty acids. A typical fatty acid composition data for soybean oil is as follows: saturated fatty acids [hexadecanoic acid [57-10-3] (palmitic acid) and octadecanoic acid [57-11-4] (stearic acid)], 15%; (*Z*)-9-octadecenoic acid [112-80-1] (oleic acid), 25%; linoleic acid, 51%; and linolenic acid, 9%. Any oil with an $\bar{f}_n$ higher than 2.2 is a drying oil. Although soybean oil is a semidrying oil, this alkyd would have an $\bar{f}_n$ of 2.76 per molecule and, therefore, would dry to a solid film. The alkyd would form a solvent-resistant film in about the same time as a 2,2-bis(hydroxymethyl)-1,3-pentanediol [115-77-5] (pentaerythritol), ester of soybean fatty acids, since they have the same $\bar{f}_n$. However, the alkyd would form a tack-free film faster because the rigid aromatic rings from PA increases the T_g of the film.

If the mole ratio of PA to glycerol were 2 to 3, 5 mol of soybean fatty acid could be esterified to yield an alkyd with an $\bar{f}_n$ of 3.45. This alkyd would cross-link more rapidly than the 1:2:4 mole ratio alkyd and would also form tack-free films even faster because the ratio of aromatic rings to long aliphatic chains would be 2:5 instead of 1:4. As the ratio of PA to glycerol is increased further, the average

functionality for autoxidation increases and the T_g after solvent evaporation increases because of the increasing ratio of aromatic to long aliphatic chains. For both reasons, films dry faster.

A theoretical alkyd prepared from 1 mol each of glycerol, PA, and fatty acid would have an oil length of about 60. However, if one were to try to prepare such an alkyd, the resin would gel prior to complete reaction. Gelation would result from reaction of a sufficient number of trifunctional glycerol molecules with three difunctional PA molecules to form cross-linked polymer molecules, swollen with partially reacted components. Gelation can be avoided by using a sufficient excess of glycerol to reduce the extent of cross-linking. When the reaction is carried to near completion with excess glycerol, there are few unreacted carboxylic acid groups, but many unreacted hydroxyl groups.

There have been many attempts, none fully successful, to calculate the ratios of functional groups and the extent of reaction that can be reached without encountering gelation. The problem is complex. The reactivity of the hydroxyl groups can be different; for example, glycerol contains both primary and secondary alcohol groups. Under esterification conditions, polyol molecules can self-condense to form ethers and, in some cases, can dehydrate to form volatile aldehydes. Reactivity of the carboxylic acids also varies. The rate of formation of the first ester from a cyclic anhydride is more rapid than formation of the second ester. Aliphatic acids esterify more rapidly than aromatic acids. Polyunsaturated fatty acids and their esters can dimerize or oligomerize to form cross-links. The dimers form by a mechanism similar to that encountered in the drying of the oils. Of the many papers in the field, that by Blackinton recognizes the complexities best (7). In addition to the above complexities, particular emphasis is placed on the extent of formation of cyclic compounds by intramolecular esterification reactions. Equations have been developed that permit calculation of ratios of ingredients theoretically needed to prepare an alkyd of any desired oil length, number-average molecular weight, and hydroxy content (8). Just like in other equations, the important effect of dimerization of fatty acids is not included as a factor in these equations. In practice, alkyd resin formulators have found that the mole ratio of dibasic acid to polyol should be less than 1 to avoid gelation. How much less than 1 depends on many variables.

For medium oil alkyds, the ratio of dibasic acid to polyol is not generally changed much relative to alkyds with an oil length of about 60, but the fatty acid content is reduced to the extent desired. This results in a larger excess of hydroxyl groups in the final alkyd. It is commonly said that as the oil length of an oxidizing alkyd is reduced below 60, the drying time decreases to a minimum at an oil length of about 50. However, this conventional wisdom must be viewed cautiously. The ratio of aromatic rings to aliphatic chains continues to increase, increasing T_g after the solvent evaporates from the film tending to shorten the time to form a tack-free film. However, at the same molecular weight, the number of fatty acid ester groups per molecule decreases as the oil length decreases below 60, since more hydroxyl groups are left unesterified. Therefore, the time required to achieve sufficient cross-linking for solvent resistance increases.

Long oil alkyds are soluble in aliphatic hydrocarbon solvents. As the oil length decreases, mixtures of aliphatic and aromatic solvents are required, and oil lengths below about 50 require aromatic solvents, which are more expensive than

aliphatics. The viscosity of solutions of long oil alkyds, especially of those with oil lengths below 65, is higher in aliphatic than in aromatic solvents; in medium oil alkyds, which require mixtures of aliphatic and aromatic solvents, viscosity decreases as the proportion of aromatic solvents increases. In former days, and to some extent still today, it was considered desirable to use a solvent mixture that gave the highest possible viscosity; then, at application viscosity, the solids were lower and the raw material cost per unit volume was less. Accordingly, alkyds were designed to have high dilutability with aliphatic solvents. This was false economy, but it was a common practice and is still being practiced to some extent. Increasingly, the emphasis is on reducing volatile organic compounds (VOC) and so the question becomes how to design alkyds with low solvent requirements rather than high dilutability potential. Furthermore, the aromatic solvents are on the hazardous air pollutants (HAP) list. High solids alkyds are discussed in a later section.

Monobasic Acid Selection. Drying alkyds can be made with fatty acids from semidrying oils, since the $\bar{f}_n$ can be well above 2.2. For alkyds made by the monoglyceride process, soybean oil is used in the largest volume. Soybean oil is economical and supplies are dependable because it is a large-scale agricultural commodity; alkyd production takes only a few percent of the world supply. For alkyds made by the fatty acid process, tall oil fatty acids (TOFA) are more economical than soybean fatty acids. Both soybean oil and TOFA contain roughly 40–60% linoleic acid and significant amounts of linolenic acid. White coatings containing linolenic acid esters gradually turn yellow. Premium cost "nonyellowing" alkyds are made with safflower or sunflower oils, which are high in linoleic acid but contain very little linolenic acid.

Applications in which fast drying and high cross-link density are important require alkyds made with drying oils. The rate of oxidative cross-linking is affected by the functionality of the drying oils used. At the same oil length and molecular weight, the time required to achieve a specific degree of cross-linking decreases as the average number of diallylic groups ($\bar{f}_n$) increases. Linseed long oil alkyds therefore cross-link more rapidly than soybean long oil alkyds. The effect is especially large in very long oil alkyds and less noticeable in alkyds with oil lengths around 60, where $\bar{f}_n$ is very high even with soybean oil and the effect of further increase in functionality by using linseed oil is small. Because of the large fraction of esters of fatty acids with three double bonds in linseed alkyds, their color and color retention are poorer than that of soybean alkyds. Tung oil based alkyds, because of the high proportion of esters with three conjugated double bonds, dry still faster. Tung oil alkyds also exhibit a high degree of yellowing. Dehydrated castor alkyds have fairly good color retention, since they contain only a small proportion of esters of fatty acids with three double bonds; they are used primarily in baking coatings.

Drying oils and drying oil fatty acids undergo dimerization at elevated temperatures. Dimerization occurs concurrently with esterification during alkyd synthesis; it generates difunctional acids, increasing the mole ratio of dibasic acids to polyol. The rate of dimerization is faster with drying oils having a higher average number of diallylic groups per molecule and with those having conjugated double bonds. Thus, the molecular weight, and therefore viscosity of an alkyd made with the same ratio of reactants, depends on the fatty acid composition. The higher the

degree of unsaturation, the higher the viscosity because of the greater extent of dimerization. Linseed alkyds have higher viscosities than soybean alkyds made with the same monomer ratios under the same conditions. The effect is particularly marked with tung oil. It is difficult to prepare straight tung alkyds because of the risk of gelation; commonly, mixed linseed–tung alkyds are used when high oxidative cross-linking functionality is desired.

A critical factor involved in the choice of fatty acid is cost. Drying oils are agricultural products and, hence, tend to be volatile in price. By far, the major use of many vegetable oils is for foods. Depending upon relative prices, one drying oil is often substituted for another in certain alkyds. By adjusting for functionality differences, substitutions can frequently be made without significant changes in properties.

Fatty acids are not the only monobasic acids used in making alkyds. Benzoic acid is also used, especially to esterify some of the excess hydroxyl groups remaining in the preparation of medium oil alkyds. The benzoic acid [65-85-0] increases the ratio of aromatic to aliphatic chains in the alkyd, thus contributing to a higher T_g of the solvent-free alkyd and more rapid formation of a tack-free film. At the same time, the reduction in the free hydroxyl content may somewhat reduce water sensitivity of the dried films. Rosin can also be used in the same fashion. Although rosin is not an aromatic acid, its polynuclear ring structure is rigid enough to increase T_g. If the critical requirement in drying is rapid development of solvent resistance, such benzoic acid and rosin modifications do not serve the purpose; they only reduce tack-free time. Frequently, benzoic acid-modified alkyds are called chain-stopped alkyds. The implication of the terminology is that the benzoic acid stops chain growth. This is not the case; the benzoic acid simply esterifies hydroxyl groups that would not have been esterified if the benzoic acid were absent. The effect on degree of polymerization is negligible.

Polyol Selection. Glycerol is the most widely used polyol because it is present in naturally occurring oils from which alkyds are commonly synthesized. The next most widely used polyol is pentaerythritol. In order to avoid gelation, the tetrafunctionality of pentaerythritol must be taken into account when replacing glycerol with pentaerythritol. If the substitution is made on a mole basis, rather than an equivalent basis, chances for gelation are minimized. As mentioned earlier, the ratio of moles of dibasic acid to polyol should be less than 1, and generally, a slightly lower mole ratio is required with pentaerythritol than with glycerol. At the same mole ratio of dibasic acid to polyol, more moles of fatty acid can be esterified with pentaerythritol. Hence, in long oil alkyds, the average functionality for cross-linking is higher, and the time to reach a given degree of solvent resistance is shorter for a pentaerythritol alkyd as compared to a glycerol alkyd. Because off this difference, one must be careful in comparing oil lengths of glycerol and pentaerythritol alkyds.

When pentaerythritol is synthesized, 2,2′-[oxybis(methylene)]-bis[2-hydroxymethyl)-1,3-propanediol [126-58-9] (dipentaerythritol) and 2,2-bis{[3-hydroxy-2,2-bis(hydroxymethyl)propoxy]methyl}1,3-propanediol [78-24-0] (tripentaerythritol) are by-products, and commercial pentaerythritol contains some of these higher polyols. Consequently, care must be exercised in changing sources of pentaerythritol, since the amount of the higher polyols may differ. Because

of the very high functionality, dipentaerythritol and tripentaerythritol (F = 6 and 8, respectively) are useful in making fast drying low molecular weight alkyds.

To reduce cost, it is sometimes desirable to use mixtures of pentaerythritol and 1,2-ethanediol [107-21-1] (ethylene glycol) or 1,3-propanediol (propylene glycol). A 1:1 mole ratio of tetra- and difunctional polyols gives an average functionality of 3, corresponding to glycerol. The corresponding alkyds can be expected to be similar, but not identical. 2-Ethyl-2-(hydroxymethyl-1,3-propanediol [77-99-6] (trimethylolpropane, TMP) can also be used, but the rate of esterification is slower than with glycerol. Although all of TMP's alcohol groups are primary, they are somewhat sterically hindered by the neopentyl structure (9). Trimethylolpropane, however, gives a narrower molecular weight distribution, which provides alkyds with a somewhat lower viscosity than the comparable glycerol-based alkyd. A kinetic study demonstrated that esterification of one or two of the hydroxyl groups of TMP has little effect on the rate constant for esterification of the third hydroxyl group (9). It can be speculated that pentaerythritol behaves similarly.

Dibasic Acid Selection. Dibasic acids used to prepare alkyds are usually aromatic. Their rigid aromatic rings increase the T_g of the resin. Cycloaliphatic anhydrides, such as hexahydrophthalic anhydride, are also used. While they are not as rigid as aromatic rings, the cycloaliphatic rings also increase T_g.

By far, the most widely used dibasic acid is phthalic anhydride (PA). It has the advantage that the first esterification reaction proceeds rapidly by opening the anhydride ring. The amount of water evolved is lower, which also reduces reaction time. The relatively low melting point (the pure compound melts at 131°C) is desirable, since the crystals melt and dissolve readily in the reaction mixture. In large-scale manufacturing, molten PA is used, which reduces packaging, shipping, and handling costs.

The next most widely used dibasic acid is 1,3-benzenedicarboxylic acid [121-91-5] (isophthalic acid, IPA). Esters of IPA are more resistant to hydrolysis than are those of PA in the pH range of 4–8, the most important range for exterior durability. On the other hand, under more alkaline conditions esters of phthalic acid are more resistant to hydrolysis than isophthalic esters. The raw material cost for IPA is not particularly different from PA (even after adjusting for the extra mole of water that is lost), but the manufacturing cost is higher. The high melting point of IPA (330°C) leads to problems getting it to dissolve in the reaction mixture so that it can react. High temperatures are required for longer times than with PA; hence more dimerization of fatty acids occurs with IPA resulting in higher viscosity. The longer time at higher temperature also leads to greater extents of side reactions of the polyol components (11). Thus, when substituting IPA for PA, one must use a lower mole ratio of IPA to polyol in order to make an alkyd of similar viscosity.

2,5-Furandione [108-31-6] (maleic anhydride) is sometimes used with PA to give faster drying alkyds with little color. Aliphatic acids, such as 1,6-hexanedioic acid [124-04-9] (adipic acid), are sometimes used as partial replacements for PA to give more flexible films.

Chlorinated dibasic acids, such as 3,4,5,6,7,7-hexachloroendomethylene-1,2,3,6-tetrahydrophthalic anhydride (chlorendic acid), are used in making alkyds for fire-retardant coatings (12).

High Solids Oxidizing Alkyds. The need to minimize VOC emissions has led to efforts to increase solids content of alkyd resin coatings. Since xylene is on the HAP list, its use is being reduced. Some increase in solids can be realized by a change of solvents. Aliphatic (and to a somewhat lesser degree, aromatic) hydrocarbon solvents promote intermolecular hydrogen bonding, especially between carboxylic acids, but also between hydroxyl groups, thereby increasing viscosity. Use of at least some hydrogen-bond acceptor solvent, such as an ester or ketone, or hydrogen-bond acceptor–donor solvent such as an alcohol, gives a significant reduction in viscosity at equal solids.

The molecular weight of conventional alkyds is usually greater than 50,000. Solids can be increased by decreasing molecular weight, which is easily accomplished by decreasing the dibasic acid to polyol ratio. Alkyds with solids in the range of 60–80% are commercially available with molecular weights in the range of 12,000–20,000 (13). High solids alkyds tend to have lower functionality for crosslinking and a lower ratio of aromatic to aliphatic chains. Both changes increase the time for drying. There is also a decrease in branching with the higher hydroxyl excess.

The effect of longer oil length on functionality can be minimized by using drying oils with higher average functionality. Use of oils containing linolenic or α-eleostearic acid is limited by their tendency to discolor. One can use safflower oil, which has a higher linoleic acid content and less linolenic acid than soybean oil. Proprietary fatty acids with 78% linoleic acid are commercially available. Early hardness of the films can be improved by using some benzoic acid to esterify part of the free hydroxy groups. As noted earlier, the rigid rings of benzoic acid increase T_g to increase hardness after solvent evaporation.

Different drier combinations are recommended for use with high solids alkyds. A study of a variety of driers and drier combinations with high solids coatings has been published (14). Cobalt, neodymium, aluminum, and barium carboxylic acid salts were of particular interest. Performance was enhanced by adding bipyridyl as an accelerator. The author reports that the best drier system was 0.04% Co, 0.3% Nd with 0.07% bipyridyl (percentages based on the vehicle solids). Reference 15 reports studies of mechanisms of action of cobalt and mixed cobalt/zirconium driers.

Using optimized resins, good quality air dry and baking alkyd coatings can be formulated with VOC levels of 280–350 g/L of coating. A 250-g/L level is attainable only with some sacrifice of application and film properties; still lower limits of permissible VOC are projected.

Solids can be increased by making resins with narrower molecular weight distributions. For example, one can add a transesterification catalyst near the end of the alkyd cook; this gives more uniform molecular weight and a lower viscosity product. To study the effect of molecular weight distribution, model alkyds with very narrow molecular weight distribution were synthesized by using dicyclohexylcarbodiimide, which allows low temperature esterification (9). With the same ratio of reactants, the number-average molecular weight and polydispersity were lower than that of the conventional alkyd control. These differences resulted from less dimerization through reactions of the double bond systems of the fatty acids and avoidance of self-etherification of polyol in the low temperature preparation. It was found that the solids could be 2–10% higher

than with the conventionally prepared alkyd of the same raw material composition. The model alkyds dried more rapidly, but their film properties, especially impact resistance, were inferior to those obtained with control resins with the usual broad molecular weight distribution (16). Conventionally prepared TMP alkyds had lower molecular weights and viscosities than the glycerol alkyds. This difference may result from less self-etherification of TMP as compared to glycerol.

High solids alkyds for baking applications have been made using tripentaerythritol. The high functionality obtained using this polyol ($F = 8$) gives alkyds that cross-link as rapidly as shorter oil length, higher viscosity glycerol alkyds (17). However, for air dry applications, the lower aromatic to aliphatic ratio lengthens the tack-free time. Presumably, progress could be made using a high functionality polyol with some combination of phthalic and benzoic acid, together with fatty acids with as high functionality fatty acids as possible. The cost of such an alkyd would be high.

Another approach to high solids alkyds is to use reactive diluents in place of part of the solvent. The idea is to have a component of lower molecular weight and much lower viscosity than the alkyd resin, which reacts with the alkyd during drying, and so it is not part of the VOC emissions. The use of reactive diluents is reviewed in Reference 18; 2,7-octadienyl maleate and fumarate are reported to be particularly effective. The use of diethers prepared from conjugated linoleic gives faster drying reactive diluents (19).

Several other types of reactive diluents have been used to formulate high solids alkyd coatings. Polyfunctional acrylate monomers (eg, trimethylolpropane trimethacrylate) have been used in force dry coatings (coatings designed to be cured in the range of 60–80°C) (20). Another example is use of dicyclopentadienyloxyethyl methacrylate [70191-60-5] as a reactive diluent (21). It is difunctional because of the easily abstractable allylic hydrogen on the dicyclopentadiene ring structure and the methacrylate double bond. The compound coreacts with drying oil groups in the alkyd. Mixed acrylic and drying oil fatty acid amides of hexa(aminomethoxymethyl)melamine have been recommended as reactive diluents (22,23). They contain high functionalities of $>NCH_2NHCOCH{=}CH_2$ and $>NCH_2NHCOC_{17}H_x$ moieties and promote fast drying. A recent patent discloses use of a reactive diluent prepared by reacting drying oil fatty acids with excess dipentaerythritol and then with 3-isocyanato-1-isocyanatomethyl-1,3,3-trimethylcyclohexane [4098-71-9] (isophorone diisocyanate) (24).

Waterborne Alkyds

As with almost all other resin classes, work has been done to make alkyd resins for coatings that can be reduced with water. One approach that has been more extensively studied in Europe than in the United States is the use of alkyd emulsions (25,26). The emulsions are stabilized with surfactants and can be prepared with little, if any, volatile solvent. Some problems limit use of alkyd emulsions (27). Coatings prepared using alkyd emulsion loose dry time on storage because of absorption of cobalt drier on the surface of pigments and precipitation of cobalt hydroxide. Best results were obtained with a combination of cobalt neodecanoate

and 2,2′-bipyridyl. It was shown that the surfactant tends to bloom to the surface of films formed from emulsions of long oil alkyds, washing a dry film tends to leave pits in the film showing a hexagonal pattern.

It is common to add a few percent of an alkyd-surfactant blend to latex paints to improve adhesion to chalky surfaces and, in some cases, to improve adhesion to metals. It is important to use alkyds that are as resistant as possible to hydrolysis. Hybrid alkyd–acrylic latices have been prepared by dissolving an oxidizing alkyd in the monomers used in emulsion polymerization, yielding a latex with an alkyd grafted on the acrylic polymer (28,29). Nonyellowing waterborne alkyds based on rosin–fatty acid modified acrylic latices have been reported (30).

Another approach has been to make alkyds with an acid number in the range of 50, using secondary alcohols or ether alcohols as solvents. The acid groups are neutralized with ammonia or an amine. The resultant solution can be diluted with water to form a dispersion of solvent swollen aggregates in water. Molecular weight can be higher than in the case of high solids alkyd because the major factor affecting viscosity at application solids is the volume fraction of internal phase of the dispersion rather than the molecular weight of the polymer. Use of primary alcohol solvents should be avoided because they can more readily transesterify with the alkyd during resin production and storage, leading to reduction in molecular weight and $\bar{f}_n$ (31). Hydrolytic stability can be a problem with water-reducible alkyds. If the carboxylic acid groups are half esters from PA or 1,3-dihydro-1,3-dioxo-5-isobenzofurancarboxylic acid [552-30-7] (trimellitic acid anhydride), the hydrolytic stability will be poor and probably inadequate for paints that require a shelf life of more than a few months. Because of the anchimeric effect of the neighboring carboxylic acid group, such esters are relatively easily hydrolyzed. As hydrolysis occurs, the solubilizing acid salt is detached from the resin molecules, and the aqueous dispersion loses stability. A more satisfactory way to introduce free carboxylic acid groups is by reacting a completed alkyd with maleic anhydride. Part of the maleic anhydride adds to the unsaturated fatty acid esters. The anhydride groups are then hydrolyzed with amine and water to give the desired carboxylate salt groups, which are attached to resin molecules with C—C bonds and cannot be hydrolyzed off. There is still a hydrolytic stability problem with the alkyd backbone, but hydrolysis does not result in destabilization of the dispersion. Similarly, acrylated fatty acids can be used to synthesize water-reducible alkyds with improved hydrolytic stability (32). Another approach to improving package stability is to react some of the free hydroxyl groups of an alkyd with isophorone diisocyanate and 3-hydroxy-2-(hydroxymethyl)-2-methylpropanoic acid [4767-03-7] (dimethylolpropionic acid, DMPA) (33) or with 1,3-bis(2,2-dimethyl-2-isocyanato)benzene (tetramethylxylylene diisocyanate) and DMPA (34).

After the film is applied, the water, solvent, and amine evaporate, and the film cross-links by autoxidation. Since there are a fairly large number of residual carboxylic acid groups left in the cross-linked binder, the water resistance and particularly the alkali resistance of the films are reduced, but are still satisfactory for some applications (35). Early water resistance can be a problem if, for example, a freshly painted surface is rained on before all the amine has evaporated from the film. Commonly, ammonia is used as the neutralizing amine because it is

assumed that ammonia volatilizes faster than any other amine. This assumption is not necessarily valid; if the T_g of the alkyd film is sufficiently high before all of the amine has volatilized, loss of amine becomes controlled by diffusion rate. The rate of diffusion of amine through the carboxylic acid-functional film is affected by the base strength of the amine. A less basic amine, such as morpholine, may leave the film at a faster rate than ammonia even though its volatility is considerably lower.

Modified Alkyds

Oxidizing alkyds have been modified by reacting with a variety of other components; vinyl-modified, silicone-modified, phenolic-modified, and polyamide-modified alkyds are the most common examples.

Oxidizing alkyds can be modified by reaction with vinyl monomers. The most widely used monomers are ethenylbenzene [100-42-5] (styrene), 1-ethenyl-2-methylbenzene (vinyl toluene), and 2-methyl-2-propenoic acid methyl ester (methyl methacrylate), but essentially any vinyl monomer can be reacted in the presence of an alkyd to give a modified alkyd. Methyl methacrylate imparts better heat and weather resistance than styrene but at higher cost.

In making styrenated alkyds, an oxidizing alkyd is prepared in the usual way and cooled to about 130°C in the reactor; then styrene and a free-radical initiator such as dibenzoyl peroxide [94-36-0] (benzoyl peroxide) are added. The resulting free-radical chain process leads to a variety of reactions, including formation of low molecular weight homopolymer of styrene, grafting of polystyrene onto the alkyd, and dimerization of alkyd molecules. The reaction is generally carried out at about 130°C, which favors decomposition of benzoyl peroxide to form phenyl free radicals; phenyl radicals have a high tendency to abstract hydrogen, which favors grafting. After the reaction is complete, the resin is diluted with solvent. The ratio of alkyd to styrene can be varied over a wide range; commonly 50% alkyd and 50% styrene is used. The ratio of aromatic rings to aliphatic chains is greatly increased, and as a result, the T_g of styrenated alkyd films is higher and tack-free time is shorter. Styrenated alkyds give a dry film in 1 h or less versus 4–6 h for the counterpart nonstyrenated alkyd. However, the average functionality for oxidative cross-linking is reduced, not just by dilution with styrene, but also because the free-radical reactions involved in the styrenation consume some activated methylene groups. As a result, the time required to develop solvent resistance is longer than for the counterpart alkyd. The fast drying and low cost make styrenated alkyds very attractive for some applications, but in other cases, the longer time required for cross-linking is more critical, in which case styrenated alkyds are not appropriate.

Styrenated alkyd vehicles are often used for air dry primers. One must be careful to apply top coat almost immediately or not until after the film has had ample time to cross-link. During the intermediate time interval, application of top coat is likely to cause nonuniform swelling of the primer, leading to what is called lifting of the primer. The result of lifting is the development of wrinkled areas in the surface of the dried film. End users who are accustomed to using alkyd

primers, which do not give a hard film until a significant degree of cross-linking has occurred, are particularly likely to encounter problems of lifting if they switch to styrenated alkyd primers.

Silicone resins have exceptional exterior durability but are expensive. Silicone modification of alkyd resins improves their exterior durability. The earliest approach was simply to add a silicone resin to an alkyd resin in the reactor at the end of the alkyd cook. While some covalent bonds between silicone resin and alkyd might form, probably most of the silicone resin simply dissolves in the alkyd. Exterior durability of silicone-modified alkyd coatings is significantly better than unmodified alkyd coatings. The improvement in durability is roughly proportional to the amount of added silicone resin; 30% silicone resin is a common degree of modification. Further improvements in exterior durability are obtained by coreacting a silicone intermediate during synthesis of the alkyd. Such intermediates react readily with free hydroxyl groups of the alkyd resin. Silicone resins designed for this purpose may contain higher alkyl, as well as methyl and phenyl, groups to improve compatibility. Alkyd coatings modified with high phenylsilicone resins are reported to have greater thermoplasticity, faster air drying, and higher solubility than high methylsilicone modified alkyds. These differences result in the higher rigidity of the aromatic rings, which leads to a solid film at an earlier stage of cross-linking. Less cross-linking in the phenylsilicone-modified coatings makes them more thermoplastic and soluble. Since IPA-based alkyd resins have better exterior durability than PA alkyds, they are generally used as the alkyd component. Silicone-modified alkyds are used mainly in outdoor air dry coatings for which application is expensive (eg, in a top coat for steel petroleum storage tanks).

Phenolic-modified alkyds are made by heating the alkyd with a low molecular weight resole phenolic resin based on *p*-alkylphenols. Presumably, the methylol groups on the phenols react with some of the unsaturated groups of the alkyd to form chroman structures. The resins give harder films with improved water and chemical resistance as compared to the unmodified alkyd.

Polyamide-modified alkyds are used as thixotropic agents to increase the low shear viscosity of alkyd resin based paints. Typically, about 10% of a polyamide resin made from diamines such as 1,2-ethanediamine (ethylenediamine) with dimer acids is reacted with an alkyd resin. High solids thixotropic alkyds based on polyamides made with aromatic diamines have been developed, which give superior performance in high solids alkyd coatings (36).

Nonoxidizing Alkyds

Certain low molecular weight short-medium and short oil alkyds are compatible with such polymers as nitrocellulose and thermoplastic polyacrylates. Therefore, such alkyds can be used as plasticizers for these polymers. They have the advantage over monomeric plasticizers (eg, dibutyl or dioctyl phthalate) in that they do not volatilize appreciably when films are baked. It is generally not desirable to use oxidizing alkyds, which would cross-link and lead to embrittlement of the films, especially on exterior exposure. Therefore, nondrying oil fatty acids (or oils) are used in the preparation of alkyds for such applications. For exterior acrylic

lacquers, nonanoic acid (pelargonic acid) alkyds combine excellent resistance to photodegradation with good compatibility with the thermoplastic acrylic resins. An interesting sidelight on terminology is that these pelargonic alkyds have been called *polyesters* rather than alkyds because the word *polyester* connotes higher quality than the word *alkyd*. Castor-oil-derived alkyds are particularly appropriate for nitrocellulose lacquers for interior applications, since the hydroxyl groups on the 12-hydroxy-(*Z*)-9-octadecenoic acid [141-22-0] (ricinoleic acid) promote compatibility.

All alkyds, particularly short-medium oil and short oil alkyds, are made with a large excess of hydroxyl groups to avoid gelation. These hydroxyl groups can be cross-linked with MF resins or with polyisocyanates. In some cases, relatively small amounts of MF resin are used to supplement the cross-linking during baking of medium oil oxidizing alkyds. To achieve compatibility, butylated MF resins are used. Such coatings provide somewhat better durability and faster curing than alkyd resins alone, with little increase in cost. The important advantage of relative freedom from film defects common to alkyd coatings can be retained. However, the high levels of unsaturation remaining in the cured films reduce resistance to discoloration on overbake and exterior exposure and cause loss of gloss and embrittlement on exterior exposure. These difficulties can be reduced by using nondrying oils with minimal levels of unsaturated fatty acids. Coconut oil has been widely used; its performance can be further enhanced by hydrogenation of the small amount of unsaturated acids present in it.

Since isophthalic (IPA) esters are more stable to hydrolysis in the pH range of 4–8 than phthalate esters, the highest performance exterior alkyd-MF enamels use nonoxidizing IPA alkyds. Exterior durability of such coatings is satisfactory for automobile top coats with opaque pigmentation. The films have an appearance of greater depth than that of acrylic-MF coatings. The films are perceived to be thicker than films of acrylic-MF coatings of comparable thickness and pigmentation. However, for many applications, alkyd-MF coatings have been replaced with acrylic-MF or polyester-MF coatings to improve the overall balance of film properties.

Synthesis of Alkyd Resins

Various synthetic procedures, each with many variables, are used to produce alkyd resins; the general reference and References 37 and 38 provide useful reviews of manufacturing procedures. Alkyds can be made directly from oils or by using free fatty acids as raw materials.

Synthesis from Oils or Fatty Acids.

Monoglyceride Process. In the case of glycerol alkyds, it would be absurd to first saponify an oil to obtain fatty acids and glycerol, and then reesterify the same groups in a different combination. Rather, the oil is first reacted with sufficient glycerol to give the total desired glycerol content, including the glycerol in the oil. Since PA is not soluble in the oil, but is soluble in the glycerol, transesterification of oil with glycerol must be carried out as a separate step before the PA is added; otherwise, glyceryl phthalate gel particles would form early in the process. This two-stage procedure is often called the monoglyceride process.

The transesterification reaction is run at 230–250°C in the presence of a catalyst; many catalysts have been used. Before the strict regulation of lead in coatings, litharge (PbO) was widely used; the residual transesterification catalyst also acted as a drier. Examples of catalysts now used in the United States are tetraisopropyl titanate, lithium hydroxide, and lithium ricinoleate. The reaction is run under an inert atmosphere such as CO_2 or N_2 to minimize discoloration and dimerization of drying oils. Rather than using glycerol, the transesterification can also be carried out with higher functionality polyols such as pentaerythritol.

While the process is called the monoglyceride process, the transesterification reaction actually results in a mixture of unreacted glycerol, monoglycerides, diglycerides, and unconverted drying oil. The composition depends on the ratio of glycerol to oil and on catalyst, time, and temperature. In general, the reaction is not taken to equilibrium. At some relatively arbitrary point, the PA is added, beginning the second stage. The viscosity and properties of the alkyd can be affected by the extent of reaction before the PA addition. While many tests have been devised to evaluate the extent of transesterification, none is very general because the starting ratio of glycerol to oil varies over a considerable range, depending on the oil length of the alkyd being made. (In calculating the mole ratio of dibasic acid to polyol, the glycerol already esterified in the oil must also be counted.) A useful empirical test is to follow the solubility of molten PA in the reaction mixture. This test has the advantage that it is directly related to a major requirement that must be met. In the first stage, it is common to transesterify the oil with pentaerythritol to obtain mixed partial esters. The second stage, esterification of the monoglyceride with PA, is carried out at a temperature of 220–255°C.

Fatty Acid Process. It is often desirable to base an alkyd on a polyol (eg, pentaerythritol) other than glycerol. In this case, fatty acids must be used instead of oils, and the process can be performed in a single step with reduced time in the reactor. Any drying, semidrying, or nondrying oil can be saponified to yield fatty acids, but the cost of separating fatty acids from the reaction mixture increases the cost of the alkyd. A more economical alternative is to use TOFA, which have the advantage that they are produced as fatty acids. Tall oil fatty acid composition is fairly similar to that of soybean fatty acids. Specially refined tall oils with higher linoleic acid content are available, as are other grades that have been treated with alkaline catalysts to isomerize the double bonds partially to conjugated structures. Generally, when fatty acids are used, the polyol, fatty acids, and dibasic acid are all added at the start of the reaction, and the esterification of both aliphatic and aromatic acids is carried out simultaneously in the range of 220–255°C.

Process Variations. Esterification is a reversible reaction; therefore, an important factor affecting the rate of esterification is the rate of removal of water from the reactor. Most alkyds are produced using a reflux solvent, such as xylene, to promote the removal of water by azeotroping. Since the reaction is run at a temperature far above the boiling point of xylene, less than 5% of xylene is used. The amount is dependent on the reactor and is set empirically such that there is enough to reflux vigorously, but not so much as to cause flooding of the condenser. Some of the xylene is distilled off along with the water; water is separated and xylene is returned to the reactor. The presence of solvent is desirable for other reasons: vapor serves as an inert atmosphere, reducing the amount of inert gas

needed, and the solvent serves to avoid accumulation of sublimed solid monomers, mainly PA, in the reflux condenser.

Reaction time is affected by reaction temperature. Higher temperatures obviously accelerate the reaction. If the reaction is carried too far, there is a major risk of gelation. There are economic advantages to short reaction times. Operating costs are reduced, and the shorter times permit more batches of alkyd to be produced in a year, increasing capacity without capital investment in more reactors. Therefore, it is desirable to operate at as high a temperature as possible without risking gelation.

A critical aspect of alkyd synthesis is deciding when the reaction is completed. Disappearance of carboxylic acid is followed by titration to determine acid number, and increase in molecular weight is followed by viscosity. Determination of acid number and viscosity both take some time. Meanwhile, in the reactor, the reaction is continuing. After it is decided that the extent of reaction is sufficient, the reaction mixture must be dropped into a larger tank containing solvent. When a 40,000-L batch of alkyd is being made, a significant time is required to get the resin out of the reactor into the reducing tank; meanwhile, the reaction is continuing. The decision to start dropping the batch must be made so that the acid number and viscosity of the batch will be right after the continuing reaction that occurs between the time of sampling, determination of acid number and viscosity, and discharging of the reactor. The time for these determinations becomes the rate-controlling step in production. If they can be done rapidly enough, the reaction can be carried out at 240°C or even higher without overshooting the target acid number and viscosity. On the other hand, if the control tests are done slowly, it may be necessary to run the reaction at only 220°C, which may require 2 h or more of additional reaction time. Automatic titration instruments permit rapid determination of acid number and so the usual limit on time required is viscosity determination. While attempts have been made to use viscosity of the resin at reaction temperature to monitor change in molecular weight, the dependence of viscosity on molecular weight at that high temperature is not sensitive enough to be very useful. The viscosity must be determined on a solution at some lower standard temperature. Since viscosity depends strongly on solution concentration and temperature, these variables must be carefully controlled.

In alkyd production, viscosity is commonly determined using Gardner bubble tubes. The cook is continued until the viscosity is high enough so that by the time the resin batch is dropped into the solvent and the batch cooled, its viscosity will be what is called for in the specification. This means starting to discharge the reactor when the test sample is at some lower viscosity. It is not possible to generalize how large this difference should be; it depends on the specific alkyd composition, the temperature at which the reaction is being run, the time required to do the determination, the time required to empty the reactor, and so on. Viscosities can be determined more rapidly using a cone and plate viscometer than with bubble tubes; the very small sample required for a cone and plate viscometer can be cooled and equilibrated at the measurement temperature more quickly.

Many variables affect the acid number and viscosity of alkyds. One is the ratio of reactants: The closer the ratio of moles of dibasic acid to polyol approaches 1, the higher the molecular weight of the backbone of the resin, but also the greater the likelihood of gelation. A useful rule of thumb for a starting point is to

use a mole ratio of 0.95. The final ratio is determined by adjustments such that the combination of acid number and solution viscosity come out at the desired levels. The greater the ratio of hydroxyl groups to carboxylic acid groups, the faster the acid groups are reduced to a low level. The degree of completion of the reaction is an important factor controlling the viscosity, as well as the acid number. It is usually desirable to have a low acid number, typically in the range of 5–10.

The composition of the fatty acids is a major factor affecting the viscosity, and compositions of an oil or grade of TOFA can be expected to vary somewhat from lot to lot. Dimerization and oligomerization of the unsaturated fatty acids occur in the same temperature range at which the esterification is carried out. Fatty acids with conjugated double bonds dimerize more rapidly than those with nonconjugated bonds, and dimerization rates increase with the level of unsaturation. At the same ratio of phthalic to polyol to fatty acids, alkyds of the same acid number and solution concentration will increase in viscosity in the order soybean < linseed < tung.

Some volatilization of polyol, PA, and fatty acids out of the reactor will occur depending on the design of the reactor, the rate of reflux of the azeotroping solvent, the rate of inert gas flow, and the reaction temperature, among other variables; the amount and ratio of these losses affect the viscosity at the standard acid number. The exact ratio of reactants must be established in the reactor that is actually used for synthesis. Since gelation can occur if the ratio of dibasic acid to polyol is too high, it is better not to put all the PA into the reactor in the beginning. If the viscosity is too low when the acid number is getting down near the standard, more PA can easily be added. The amount of PA held back can be reduced as experience is gained cooking a particular alkyd in a particular reactor.

Side reactions can affect the viscosity–acid number relationship. Glycerol and other polyols form ethers to some degree during the reaction. Glycerol can also form acrolein by successive dehydrations. When these reactions occur, the mole ratio of dibasic acid to polyol increases and the number of hydroxyl groups decreases; therefore, at the same acid number, the molecular weight will be higher. Excessively high viscosity and even gelation can result. Ether formation is catalyzed by strong protonic acids; therefore, it is desirable to avoid them as catalysts for the esterification. Monobutyltin oxide has been used as an esterification catalyst; presumably, it does not significantly catalyze ether formation. As noted earlier, pentaerythritol and TMP seem less vulnerable than glycerol to undesirable side reactions such as ether formation, and glycerol is the only polyol that can decompose to form acrolein. A hydroxyl group on one end of a growing polyester chain can react with a carboxylic acid group on another end of the same molecule, leading to ring formation. Transesterification of chain linkages can have the same result. Since cyclization reactions reduce chain length, their net effect is to reduce viscosity.

Many alkyd resins have broad, uneven molecular weight distributions. It has been shown that even modest changes in reaction conditions can cause large differences in molecular weight distribution, which can have significant effects on final film properties (39). In many alkyds, very small gel particles (microgels) are formed. It has been shown that these microgels play an important role in giving greater strength properties to final films (39). Process changes that may make

the alkyd more uniform may be undesirable. For example, allowing glycerolysis to approach equilibrium before addition of PA and using transesterification catalysts in the final stages of esterification both favor narrower molecular weight distributions and lower viscosities, but films made from the more uniform alkyds may exhibit inferior mechanical properties.

Urethane Derivatives

Uralkyds are also called urethane alkyds or urethane oils. They are alkyd resins in which a diisocyanate, usually 2,4(6)-toluene diisocyanate [584-84-9] (TDI), has fully or partly replaced the PA usually used in the preparation of alkyds. One transesterifies a drying oil with a polyol such as glycerol or pentaerythritol to make a monoglyceride (see section Synthesis from Oils or Fatty Acids) and reacts it with some PA (if desired) and then with somewhat less diisocyanate than the equivalent amount of N=C=O based on the free OH content. To assure that no N=C=O groups remain unreacted, methyl alcohol is added at the end of the process. Just like alkyds, uralkyds dry faster than the drying oil from which they were made, since they have a higher average functionality (more activated diallylic groups per average molecule). The rigidity of the TDI aromatic rings also speeds up the drying by increasing the T_g of the resin.

Two principal advantages of uralkyd over alkyd coatings are superior abrasion resistance and resistance to hydrolysis. Disadvantages are inferior color retention (when aromatic isocyanates used) of the films, higher viscosity of resin solutions at the same percent solids, and higher cost. Uralkyds made with aliphatic diisocyanates have better color retention, but are more expensive and have lower T_g. The largest use of uralkyds is in architectural coatings. Many so-called varnishes sold to the consumer today are based on uralkyds; they are not really varnishes in the original sense of the word. They are used as transparent coatings for furniture, woodwork, and floors: applications in which good abrasion resistance is important. Since they are generally made with aromatic isocyanates, they tend to turn yellow and then light brown with age; yellowing is acceptable in clear varnishes, but would be a substantial drawback in light-colored pigmented paints.

Water-reducible polyunsaturated acid substituted aqueous polyurethane dispersions are also being used (40). They can be made by reacting a diisocyanate with a polyol, monoglyceride of a drying oil, and dimethylolpropionic acid. The carboxylic acid groups are neutralized with a tertiary amine and dispersed in water. If aliphatic isocyanates are used, good color retention can be obtained. They are much more resistant to hydrolysis than conventional alkyd resins. Films also have excellent abrasion resistance. Cost can be reduced by blending in 10–20% of acrylic latex.

Epoxy Esters

Bisphenol A (BPA) epoxy resins can be converted to what are commonly called epoxy esters by reacting with fatty acids. Drying or semidrying oil fatty acids are used so that the products cross-link by autoxidation. The epoxy groups undergo

a ring-opening reaction with carboxylic acids to generate an ester and a hydroxyl group. These hydroxyl groups, as well as the hydroxyl groups originally present on the epoxy resin, can esterify with fatty acids. They are generally made by starting with a low molecular weight epoxy resin (ie, the standard liquid resin, $n = 0.13$) and extending with 4,4′-(1-methylethylidene)bisphenol [80-05-7] (BPA) by the advancement process to the desired molecular weight. Off-specification epoxy resin is often used to reduce cost. The fatty acids are added to the molten, hot resin, and the esterification reaction is continued until the acid number is low, usually less than 7 mg of KOH per gram of resin. In the esterification reaction with fatty acids, the average number of sites for reaction is the n value, corresponding to the number of hydroxyl groups on the resin, plus twice the number of epoxy groups. The esterification is carried out at high temperatures (220–240°C). The rate of esterification slows as the concentration of hydroxyl groups diminishes, and side reactions occur, especially dimerization of the drying oil fatty acids (or their esters). It is not practical to esterify more than about 90% of the potential hydroxyl groups, including those from ring opening the epoxy groups. The lower useful limit of the extent of esterification is about 50%. This is required to ensure sufficient fatty acid groups for oxidative cross-linking.

Tall oil fatty acids are commonly used because of their low cost. Linseed fatty acids give faster cross-linking coatings because of higher average functionality. However, their viscosity is higher because of the greater extent of dimerization during esterification, and their cost is higher. For still faster cross-linking, part of the linseed fatty acids can be replaced with tung fatty acids, but the viscosity and cost are still higher. The color of epoxy esters from linseed and linseed–tung fatty acids is darker than the tall oil esters. Dehydrated castor oil fatty acids give faster curing epoxy esters for baked coatings. The rate of formation of a dry film from epoxy esters depends on two factors: the average number of diallylic groups $\bar{f}_n$ and the ratio of aromatic rings to long aliphatic chains. The $\bar{f}_n$ can be maximized by using higher molecular weight BPA epoxy resin and by using enough fatty acid to react with a large fraction of the epoxy and hydroxyl groups. The ratio of aromatic rings to fatty acids can be maximized by using high molecular weight epoxy resin and esterifying a smaller fraction of epoxy and hydroxyl groups.

Epoxy esters are used in coatings in which adhesion to metal is important. While the reasons are not completely understood, it is common for epoxy coatings, including epoxy esters, to have good adhesion to metals and to retain adhesion after exposure of the coated metal to high humidity, a critical factor in corrosion protection. A distinct advantage of epoxy esters over alkyd resins is their greater resistance to hydrolysis and saponification. The backbone of alkyds is held together with esters from PA and the polyol, whereas in epoxy esters, the backbone is held together with C—C and ether bonds. Of course, the fatty acids are bonded to the backbone with ester groups in both cases, but the fraction of polymer bonds in a dry film subject to hydrolysis is substantially lower in the case of epoxy esters. On the other hand, exterior durability of epoxy ester coatings is poor, as is the case with all films made with BPA epoxy resins. As a result of these advantages and disadvantages, the major uses for epoxy resins are in primers for metal and in can coatings, such as for crowns (bottle caps), in which the important requirements are adhesion and hydrolytic stability. In baking primers, it is sometimes desirable

to supplement the cross-linking through oxidation by including a small amount of MF resin in the formulation to cross-link with part of the free hydroxyl groups on the epoxy ester.

Epoxy ester resins with good exterior durability (better than alkyds) can be prepared by reacting epoxy-functional acrylic copolymers (made with glycidyl methacrylate) with fatty acids. The product is an acrylic resin with multiple fatty acid ester side chains. By appropriate selection of acrylate ester comonomers and molecular weight, the T_g of the resin can be designed so that a tack-free film is obtained by solvent evaporation; then the coating cross-links by autoxidation. For an application like repainting an automobile at ambient temperatures, the cross-linking can proceed relatively slowly and need not be catalyzed by metal salt driers. The rate of cross-linking is slower without driers, but exterior durability is better.

Epoxy esters can also be made water-reducible. The most widely used water-reducible epoxy esters have been made by reacting maleic anhydride with epoxy esters prepared from dehydrated castor oil fatty acids. Subsequent addition of a tertiary amine, such as 2-(dimethylamino)ethanol [108-01-0], in water results in ring opening of the anhydride to give amine salts. Like other water-reducible resins, these resins are not soluble in water but form a dispersion of resin aggregates swollen with water and solvent in an aqueous continuous phase. The hydrolytic stability of these epoxy esters is better than corresponding alkyds and sufficient for use in electrodeposition primers until anionic primers were replaced by cationic primers. Water-reducible epoxy esters are still used in spray applied baking primers and primer-surfacers. They are also used in dip coating primers in which nonflammability is an advantage. Their performance equals that of solvent-soluble epoxy ester primers.

Uses

In 1997, the U. S. consumption of alkyds was approximately 310,000 t and projected use in 5 years is estimated to be 280,000–290,000 t (41). Coatings are the largest market with use in 1997 of approximately 250,000 t (42). European and Japanese consumption of alkyd coating resins in 1996 has been reported to be 360,000 and 110,000 t, respectively (42). Use of alkyds has been declining at about 2% a year and is projected to decline further as they are replaced with resins with higher performance and lower volatile emissions. Higher solids alkyds have been replacing conventional solids alkyds. In 1997, about 81,000 ton with solids of 50–60% and 16,000 tons of greater than 60% were used in the United States in comparison with 150,000 t of alkyds with lower than 50% solids. Only 10,000 t of waterborne alkyds were used (41).

The principal advantages of alkyds are low cost, low toxicity, and low surface tension. The low surface tension permits wetting of most surfaces including oily steel. Also the low surface tension minimizes application defects such as cratering. The principal limitations are generally poorer exterior durability and corrosion protection than alternative coating resins. While high solids and waterborne alkyd

resins are manufactured, their properties are generally somewhat inferior to conventional solvent-borne alkyds.

The largest use for alkyds in coatings is in architectural paints, particularly in gloss enamels for application by contractors. Contractors tend to prefer alkyd enamels over latex enamels because coverage can be achieved with a single coat. Also, alkyd paints can be applied at low temperatures whereas latex paints can only be applied at temperatures above about 5°C. The do-it-yourself market is served primarily with latex paints because of ease of cleanup and lesser odor. While initial gloss of alkyd enamels is higher than of latex enamels, the latex enamels exhibit far superior gloss retention in exterior applications. Alkyd primers provide better adhesion to chalky surfaces than most latex paints. The next largest use is in aerosol paints.

The largest use of alkyds in industrial applications is in general industrial coatings for such applications as machinery and metal furniture. Significant amounts are used with UF resins in coatings for wood furniture. Alkyd resin/chlorinated rubber based coatings are used in traffic paints, but use is decreasing because of high VOC content. An approach to overcoming this problem is the use of solvent-free alkyds in hot melt traffic paints (43). Some alkyds are still used in refinish paints for automobiles since they give high gloss coatings with a minimum of polishing. An example of recent work in formulating refinish coatings is preparing an alkyd by reacting tris(hydroxyethyl)isocyanurate with drying oil fatty acids and formulating with trimethylolpropane trimethacrylate as a reactive diluent (44).

About 39,000 t of uralkyds were used in the United States in 1997 (41). The largest use for uralkyds is as the vehicle for so-called urethane varnishes for the do-it-yourself market. The abrasion resistance of such coatings is greatly superior to that obtained with conventional varnishes or alkyd resins. Epoxy esters give coatings with markedly superior corrosion protection as compared with alkyd resins while retaining the advantage of low surface tension. However, as with any BPA epoxy system, exterior durability is poor. They are used primarily in primers for steel and in flexible coatings such as for metal crowns. Maleated epoxy esters give primers with equivalent properties of solvent-borne epoxy ester coatings and are widely used in formulating waterborne primers for steel.

Noncoatings applications include foundry core binders and printing inks, especially lithographic inks.

AMINO RESINS AND PLASTICS

Introduction

Amino resins are thermosetting polymers made by combining an aldehyde with a compound containing an amino ($-NH_2$) group. Urea–formaldehyde (U/F) accounts for over 80% of amino resins; melamine–formaldehyde accounts for most of the rest. Other aldehydes and other amino compounds are used to a very minor extent. The first commercially important amino resin appeared about 1930, or some 20 years after the introduction of phenol–formaldehyde resins and plastics (see PHENOLIC RESINS).

The principal attractions of amino resins and plastics are water solubility before curing, which allows easy application to and with many other materials, colorlessness, which allows unlimited colorability with dyes and pigments, excellent solvent resistance in the cured state, outstanding hardness and abrasion resistance, and good heat resistance. Limitations of these materials include release of formaldehyde during cure and, in some cases, such as in foamed insulation, after cure, and poor outdoor weatherability for urea moldings. Repeated cycling of wet and dry conditions causes surface cracks. Melamine moldings have relatively good outdoor weatherability.

Amino resins are manufactured throughout the industrialized world to provide a wide variety of useful products. Adhesive Compounds, representing the largest single market, are used to make plywood, chipboard, and sawdust board. Other types are used to make laminated wood beams, parquet flooring, and for furniture assembly.

Some amino resins are used as additives to modify the properties of other materials. For example, a small amount of amino resin added to textile fabric imparts the familiar wash-and-wear qualities to shirts and dresses. Automobile tires are strengthened by amino resins which improve the adhesion of rubber to

Encyclopedia of Polymer Science and Technology. Copyright John Wiley & Sons, Inc. All rights reserved.

tire cord. A racing sailboat may have a better chance to win because the sails of Dacron (Du Pont) polyester have been treated with an amino resin (1). Amino resins can improve the strength of paper even when it is wet. Molding compounds based on amino resins are used for parts of electrical devices, bottle and jar caps, molded plastic dinnerware, and buttons.

Amino resins are also often used for the cure of other resins, such as Alkyd Resins, and reactive acrylic polymers. These polymer systems may contain 5–50% of the amino resin and are commonly used in the flexible backings found on carpets and draperies, as well as in protective surface coatings, particularly the durable baked enamels of appliances, automobiles, etc.

The term *amino resin* is usually applied to the broad class of materials regardless of application, whereas the term *aminoplast* or sometimes *amino plastic* is more commonly applied to thermosetting molding compounds based on amino resins. Amino plastics and resins have been in use since 1920s. Compared with other segments of the plastics industry, they are mature products, and their growth rate is only about half of that of the plastics industry as a whole. They account for about 3% of the U.S. plastics and resins production.

History. The basic chemistry of amino resins was established as early as 1908 (2), but the first commercial product, a molding compound, was patented in England (3) only in 1925. It was based on a resin made from an equimolar mixture of urea and thiourea and reinforced with purified cellulose fiber and was trademarked Beetle (indicating it could "beat all" others). Patent rights were acquired by the American Cyanamid Company along with the Beetle trademark, and by 1930 a similar molding compound was being marketed in the United States. The new product was hard and not easily stained and was available in light, translucent colors; furthermore, it had no objectionable phenolic odor. The use of thiourea improved gloss and water resistance, but stained the steel molds. As amino resin technology progressed the amount of thiourea in the formulation could be reduced and finally eliminated altogether.

In the early 1920s, experimentation with urea–formaldehyde resins [9011-05-6] in Germany (4) and Austria (5,6) led to the discovery that these resins might be cast into beautiful clear transparent sheets, and it was proposed that this new synthetic material might serve as an organic glass (5,6). In fact, an experimental product called Pollopas was introduced, but lack of sufficient water resistance prevented commercialization. Melamine–formaldehyde resin [9003-08-1] does have better water resistance but the market for synthetic glass was taken over by new thermoplastic materials such as polystyrene and poly(methyl methacrylate) (see METHACRYLIC ESTER POLYMERS; STYRENE POLYMERS).

Melamine resins were introduced about 10 years after the Beetle molding compound. They were very similar to those based on urea but had superior qualities. Henkel in Germany was issued a patent for a melamine resin in 1936 (7). Melamine resins rapidly supplanted urea resins and were soon used in molding, laminating, and bonding formulations, as well as for textile and paper treatments. The remarkable stability of the symmetrical triazine ring made these products resistant to chemical change once the resin had been cured to the insoluble, crosslinked state.

Prior to the rapid expansion of thermoplastics following World War II, amino plastics served a broad range of applications in molding, laminating, and bonding.

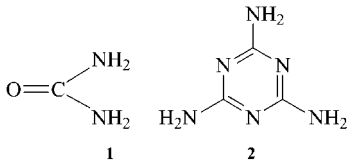
As the newer and more versatile thermoplastic materials moved into these markets, aminos became more and more restricted to applications demanding some specific property best offered by the thermosetting amino resins. Current sales patterns are very specific. Urea molding powders find application in moldings for electrical devices and in closures for jars and bottles. Melamine molding compound is used principally for molded plastic dinnerware. Urea resins have retained their use in electrical-wiring devices because of good electrical properties, good heat resistance, and an availability of colors not obtainable with phenolics. Urea–formaldehyde resins are useful as closures because of their excellent resistance to oils, fats, and waxes often found in cosmetics, and their availability in a broad range of colors. Melamine plastic is used for molded dinnerware primarily because of outstanding hardness, water resistance, and stain resistance. Melamine–formaldehyde is the hardest commercial plastic material.

Aminoplasts and other thermosetting plastics are molded by an automatic injection-molding process similar to that used for thermoplastics, but with an important difference (8). Instead of being plasticized in a hot cylinder and then injected into a much cooler mold cavity, the thermosets are plasticized in a warm cylinder and then injected into a hot mold cavity where the chemical reaction of cure sets the resin to the solid state. The process is best applied to relatively small moldings. Melamine plastic dinnerware is still molded by standard compression-molding techniques. The great advantage of injection molding is that it reduces costs by eliminating manual labor, thereby placing the amino resins in a better position to compete with thermoplastics (see INJECTION MOLDING).

The future for amino resins and plastics seems secure because they can provide qualities that are not easily obtained in other ways. New developments will probably be in the areas of more highly specialized materials for treating textiles, paper, etc, and for use with other resins in the formulation of surface coatings, where a small amount of an amino resin can significantly increase the value of a more basic material. Additionally, since amino resins contain a large proportion of nitrogen, a widely abundant element, they may be in a better position to compete with other plastics as raw materials based on carbon compounds become more costly.

Raw Materials

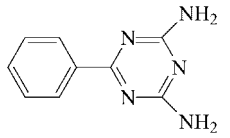
Most amino resins are based on the reaction of formaldehyde [50-00-0] with urea [57-13-6] [1] or melamine [108-78-1] (2).



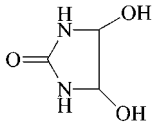
1 2

Although formaldehyde will combine with many other amines, amides, and aminotriazines to form useful products, only a few are used and are of minor

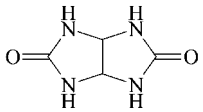
importance compared with products based on urea and melamine. Benzoguanamine [91-76-9] [3], for example, is used in amino resins for coatings because it provides excellent resistance to laundry detergent, a definite advantage in coatings for automatic washing machines. Dihydroxyethylene urea [3720-97-6] [4] is used for making amino resins that provide wash-and-wear properties in clothing. Glycoluril [496-46-8] (5) resins provide coatings with high film flexibility.



3



4



5

Aniline–formaldehyde resins were once quite important because of their excellent electrical properties, but their markets have been taken over by newer thermoplastic materials. Nevertheless, some aniline resins are still used as modifiers for other resins. Acrylamide occupies a unique position in the amino resins field since it not only contains a formaldehyde reactive site, but also a polymerizable double bond. Thus it forms a bridge between the formaldehyde condensation polymers and the versatile vinyl polymers and copolymers (see ACRYLAMIDE POLYMERS).

In the sense that formaldehyde can supply a methylene link between two molecules, it is difunctional. Each amino group has two replaceable hydrogens that can react with formaldehyde; hence, it also is difunctional. Since the amino compounds commonly used for making amino resins, urea, and melamine contain two and three amino groups, they are polyfunctional and react with formaldehyde to form three-dimensional, cross-linked polymer structures. Compounds with a single amino group such as aniline or toluenesulfonamide can usually react with formaldehyde to form only linear polymer chains. However, in the presence of an acid catalyst at higher temperatures, the aromatic ring of aniline may react with formaldehyde to produce a cross-linked polymer.

Urea. Urea (carbamide), CH_4N_2O, is the most important building block for amino resins because urea–formaldehyde is the largest selling amino resin, and urea is the raw material for melamine, the amino compound used in the next largest selling-type of amino resin. Urea is also used to make a variety of other amino compounds, such as ethyleneurea, and other cyclic derivatives used for amino resins for treating textiles. They are discussed later.

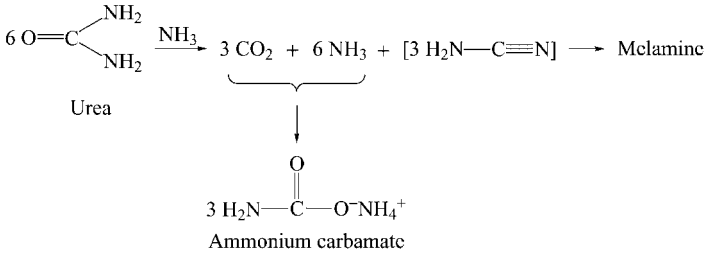
Urea is soluble in water, and the crystalline solid is somewhat hygroscopic, tending to cake when exposed to a humid atmosphere. For this reason, urea is frequently *pelletized* or *prilled* (formed into little beads) to avoid caking and making it easy to handle.

Only about 10% of the total urea production is used for amino resins, which thus appear to have a secure source of low cost raw material. Urea is made by the reaction of carbon dioxide and ammonia at high temperature and pressure to yield a mixture of urea and ammonium carbamate; the latter is recycled.

$$CO_2 + 2\,NH_3 \longrightarrow NH_2CONH_2 + H_2O \rightleftharpoons H_2NCOONH_4$$

Melamine. Melamine (cyanurotriamide 2,4,6-triamino-*s*-triazine), $C_3H_6N_6$, is a white crystalline solid, melting at approximately 350°C with vaporization, only slightly soluble in water. The commercial product, recrystallized grade, is at least 99% pure. Melamine was synthesized early in the development of organic chemistry, but it remained of theoretical interest until it was found to be a useful constituent of amino resins. Melamine was first made commercially from dicyandiamide [461-58-5] is now made from urea, a much cheaper starting material (9–12).

Urea is dehydrated to cyanamide which trimerizes to melamine in an atmosphere of ammonia to suppress the formation of deamination products. The ammonium carbamate [1111-78-0] also formed is recycled and converted to urea. For this reason the manufacture of melamine is usually integrated with much larger facilities making ammonia and urea.



Since melamine resins are derived from urea, they are more costly and are therefore restricted to applications requiring superior performance. Essentially all of the melamine produced is used for making amino resins and plastics.

Formaldehyde. Pure formaldehyde, CH_2O, is a colorless, pungent smelling reactive gas. The commercial product is handled either as solid polymer, paraformaldehyde (13), or in aqueous or alcoholic solutions. Marketed under the trade name Formcel, solutions in methanol, *n*-butanol, and isobutyl alcohol are widely used for making alcohol-modified urea and melamine resins for surface coatings and treating textiles.

Aqueous formaldehyde, known as formalin is usually 37 wt% formaldehyde, although more concentrated solutions are available. Formalin is the general-purpose formaldehyde of commerce supplied unstabilized or methanol-stabilized. The latter may be stored at room temperature without precipitation of solid formaldehyde polymers because it contains 5–10% methyl alcohol. The uninhibited type must be maintained at a temperature of at least 32°C to prevent the separation of solid formaldehyde polymers. Large quantities are often supplied in more concentrated solutions. Formalin at 44, 50, or even 56% may be used to

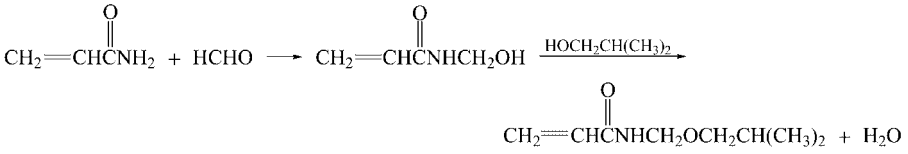
reduce shipping costs and improve manufacturing efficiency. Heated storage tanks must be used. For example, formalin containing 50% formaldehyde must be kept at a temperature of 55°C to avoid precipitation. Formaldehyde solutions stabilized with urea are used (14), and various other stabilizers have been proposed (15,16). With urea-stabilized formaldehyde the user need only adjust the U/F ratio by adding more urea to produce a urea resin solution ready for use.

Paraformaldehyde [30525-89-4] is a mixture of polyoxymethylene glycols, $HO(CH_2O)_nH$, with n from 8 to as much as 100. It is commercially available as a powder (95%) and as flake (91%). The remainder is a mixture of water and methanol. Paraformaldehyde is an unstable polymer that easily regenerates formaldehyde in solution. Under alkaline conditions, the chains depolymerize from the ends, whereas in acid solution the chains are randomly cleaved (17). Paraformaldehyde is often used when the presence of a large amount of water should be avoided as in the preparation of alkylated amino resins for coatings. Formaldehyde may also exist in the form of the cyclic trimer trioxane [110-88-3]. This is a fairly stable compound that does not easily release formaldehyde; hence, it is not used as a source of formaldehyde for making amino resins.

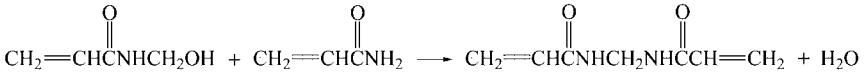
Approximately 25% of the formaldehyde produced in the United States is used in the manufacture of amino resins and plastics.

Other Materials. Benzoguanamine and acetoguanamine may be used in place of melamine to achieve greater solubility in organic solvents and greater chemical resistance. Aniline and toluenesulfonamide react with formaldehyde to form thermoplastic resins. They are not used alone, but rather as Plasticizers for other resins including melamine and urea–formaldehyde. The plasticizer may be made separately or formed in situ during preparation of the primary resin.

Acrylamide [79-06-1] is an interesting monomer for use with amino resins; the vinyl group is active in free-radical-catalyzed addition polymerizations, whereas the—NH_2 group is active in condensations with formaldehyde. Many patents describe methods of making cross-linked polymers with acrylamide by taking advantage of both vinyl polymerization and condensation with formaldehyde. For example, acrylamide reacts readily with formaldehyde to form *N*-methylolacrylamide [924-42-5], which gives the corresponding with isobutyl alcohol.



This compound is soluble in most organic solvents and may be easily copolymerized with other vinyl monomers to introduce reactive side groups on the polymer chain (18). Such reactive polymer chains may then be used to modify other polymers including other amino resins. It may be desirable to produce the cross-links first. Thus, *N*-methylolacrylamide can react with more acrylamide to produce methylenebisacrylamide, a tetrafunctional vinyl monomer.



Chemistry of Resin Formation

The first step in the formation of resins and plastics from formaldehyde and amino compounds is the addition of formaldehyde to introduce the hydroxymethyl group, known as *methylolation* or *hydroxymethylation*:

$$R{-}NH_2 + HCHO \longrightarrow R{-}NH{-}CH_2OH$$

The second step is a condensation reaction that involves the linking together of monomer units with the liberation of water to form a dimer, a polymer chain, or a vast network. This is usually referred to as *methylene bridge formation*, *polymerization*, *resinification*, or simply *cure*, and is illustrated in the following equation:

$$RNH{-}CH_2OH + H_2NR \longrightarrow RNH{-}CH_2{-}NHR + H_2O$$

Success in making and using amino resins largely depends on the precise control of these two chemical reactions. Consequently, these reactions have been much studied (19–30).

The first reaction, the addition of formaldehyde to the amino compound, is catalyzed by either acids or bases. Hence, it takes place over the entire pH range. The second reaction joins the amino units with methylene links and is catalyzed only by acids. The rates of these reactions have been studied over a broad range of pH (28). The results are presented in Figure 1.

The same study also examined some of the subsequent reactions involved in the formation of more complex U/F condensation products. Rate constants for these reactions at 35°C are shown in Table 1.

The methylol compounds produced by these reactions are relatively stable under neutral or alkaline conditions, but undergo condensation, forming polymeric products under acidic conditions. Consequently, the first step in making an amino plastic is usually carried out under alkaline conditions. The amino compound and formaldehyde are combined and form a stable resin intermediate that may be used as an adhesive or combined with filler to make a molding compound. The second step is the addition of an acidic substance to catalyze the curing reaction, often with the application of heat to cure the amino resin to the solid cross-linked state. In this reaction, the methylol group is probably protonated and a molecule

Table 1. Urea–Formaldehyde (U/F) Reaction Rate Constants

Reaction at 35°C and pH 4.0	k, L/(mol·s)
$U + F \rightarrow U/F$	4.4×10^{-4}
$U/F + U \rightarrow U{-}CH_2{-}U$	3.3×10^{-4}
$U/F + U/F \rightarrow U{-}CH_2{-}U/F$	0.85×10^{-4}
$U/F_2 + U/F \rightarrow FU{-}CH_2{-}U/F$	0.5×10^{-4}
$U/F_2 + U/F_2 \rightarrow FU{-}CH_2{-}U/F_2$	$<3 \times 10^{-6}$

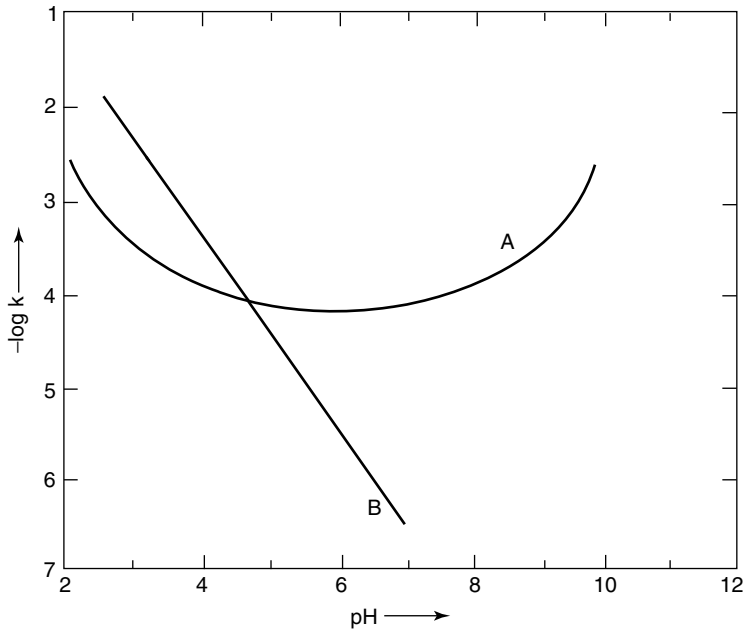


Fig. 1. Influence of pH on (**A**) the addition reaction of urea and formaldehyde (1:1), and (**B**) the condensation of methylolurea with the amino hydrogen of a neighboring urea molecule. Temperature = 35°C; 0.1 *M* aq. [Full View].

of water lost, giving the intermediate carbonium–imonium ion. This then reacts with an amino group to form a methylene link.

$$RNHCH_2OH + H^+ \rightleftharpoons RNHCH_2\overset{+}{O}H_2$$

$$RNHCH_2\overset{+}{O}H_2 \rightleftharpoons RNH\overset{+}{C}H_2 + H_2O$$

$$RN\overset{+}{H}CH_2 + H_2NR' \rightleftharpoons RNHCH_2H_2\overset{+}{N}R'$$

$$RNHCH_2H_2\overset{+}{N}R' \rightleftharpoons RNHCH_2HNR' + H^+$$

In addition to the two main reactions, ie, methylolation and condensation, there are a number of other reactions important for the manufacture and uses of amino resins. For example, two methylol groups may combine to produce a dimethylene ether linkage and liberate a molecule of water:

$$2\ RNHCH_2OH \rightleftharpoons RNHCH_2{-}O{-}CH_2NHR + H_2O$$

The dimethylene ether so formed is less stable than the diamino–methylene bridge and may rearrange to form a methylene link and liberate a molecule of formaldehyde.

$$RNH{-}CH_2O{-}CH_2NHR \longrightarrow RNH{-}CH_2{-}NHR + HCHO$$

The simple methylol compounds and the low molecular weight polymers obtained from urea and melamine are soluble in water and quite suitable for the manufacture of adhesives, molding compounds, and some kinds of textile treating resins. However, amino resins for coating applications require compatibility with the film-forming Alkyd Resins or copolymer resins with which they must react. Furthermore, even where compatible, the free methylol compounds are often too reactive and unstable for use in a coating-resin formulation that may have to be stored for some time before use. Reaction of the free methylol groups with an alcohol to convert them to alkoxy methyl groups solves both problems.

The replacement of the hydrogen of the methylol compound with an alkyl group renders the compound much more soluble in organic solvents and more stable. This reaction is also catalyzed by acids and usually carried out in the presence of considerable excess alcohol to suppress the competing self-condensation reaction. After neutralization of the acid catalyst, the excess alcohol may be stripped or left as a solvent for the amino resin.

The mechanism of the alkylation reaction is similar to curing. The methylol group becomes protonated and dissociates to form a carbonium ion intermediate which may react with alcohol to produce an alkoxymethyl group or with water to revert to the starting material. The amount of water in the reaction mixture should be kept to a minimum since the relative amounts of alcohol and water determine the final equilibrium.

Another way of achieving the desired compatibility with organic solvents is to employ an amino compound having an organic solubilizing group in the molecule, such as benzoguanamine. With one of the $-NH_2$ groups of melamine replaced with a phenyl group, benzoguanamine–formaldehyde resins [26160-89-4] have some degree of oil solubility even without additives. Nevertheless, benzoguanamine-formaldehyde resins are generally modified with alcohols to provide a still greater range of compatibility with solvent-based surface coatings. Benzoguanamine resins provide a high degree of detergent resistance, together with good ductility and excellent adhesion to metal.

Displacement of a volatile with a nonvolatile alcohol is an important reaction for curing paint films with amino cross-linkers and amino resins on textile fabrics or paper. Following is an example of a methoxymethyl group on an amino resin reacting with a hydroxyl group of a polymer chain:

$$RNHCH_2OCH_3 + HOCH_2{-}\underline{\S} \longrightarrow RNHCH_2OCH_2{-}\underline{\S} + CH_3OH$$

A troublesome side reaction encountered in the manufacture and use of amino resins is the conversion of formaldehyde to formic acid. Often the reaction mixture of amino compound and formaldehyde must be heated under alkaline conditions. This favors a Cannizzaro reaction in which two molecules of formaldehyde interact to yield one molecule of methanol and one of formic acid.

$$2\,HCHO + H_2O \longrightarrow CH_3OH + HCOOH$$

Unless this reaction is controlled, the solution may become sufficiently acidic to catalyze the condensation reaction causing abnormally high viscosity or premature gelation of the resin solution.

Manufacture

Precise control of the course, speed, and extent of the reaction is essential for successful manufacture. Important factors are mole ratio of reactants, catalyst (pH of reaction mixture), and reaction time and temperature. Amino resins are usually made by a batch process. The formaldehyde and other reactants are charged to a kettle, the pH adjusted, and the charge heated. Often the pH of the formaldehyde is adjusted before adding the other reactants. Aqueous formaldehyde is most convenient to handle and lowest in cost.

In general, conditions for the first part of the reaction are selected to favor the formation of methylol compounds. After addition of the reactants, the conditions may be adjusted to control the polymerization. The reaction may be stopped to give a stable syrup. This could be an adhesive or laminating resin and might be blended with filler to make a molding compound. It might also be an intermediate for the manufacture of a more complicated product, such as an alkylated amino resin, for use with other polymers in coatings.

The flow sheet (Fig. 2) illustrates the manufacture of amino resin syrups, cellulose-filled molding compounds, and spray-dried resins.

In the manufacture of amino resins every effort is made to recover and recycle the raw materials. However, there may be some loss of formaldehyde, methanol, or other solvent as tanks and reactors are vented. Some formaldehyde, solvents, and alcohols are also evolved in the curing of paint films and the curing of adhesives and resins applied to textiles and paper. The amount of material evolved in curing the resins may be so small that it may be difficult to justify the installation of complex recovery equipment. However, in the development of new resins for coatings and for treating textiles and paper, emphasis is being placed on those compositions that evolve a minimum of by-products on curing. The moist amino resin adhesive absorbs the high frequency radiation more readily than dry wood, thereby concentrating the heat in the glue line where it is needed. Hot pressing may be conducted in a hydraulic press comprising a large number of steam-heated platens, usually 5 cm thick. Pressures usually range from 1 to 2 MPa (150–300 psi). Hot-press temperatures for urea and melamine–urea are usually 115–132°C.

In plywood production with ureas, the spread veneers should be pressed as soon as possible. The time between spreading and pressing, usually called assembly time, should never exceed 1 h. With some formulations, the permissible assembly time may be no longer than 15 min. Melamine formulations and uncatalyzed melamine–urea combinations, however, can be spread and stored for as much as a week before use.

Ureas are not satisfactory for prolonged water immersion or for continuous exposure to warm and excessively humid conditions, although they are fairly resistant to normal humidity. Somewhat more durable bonds are obtained by heat

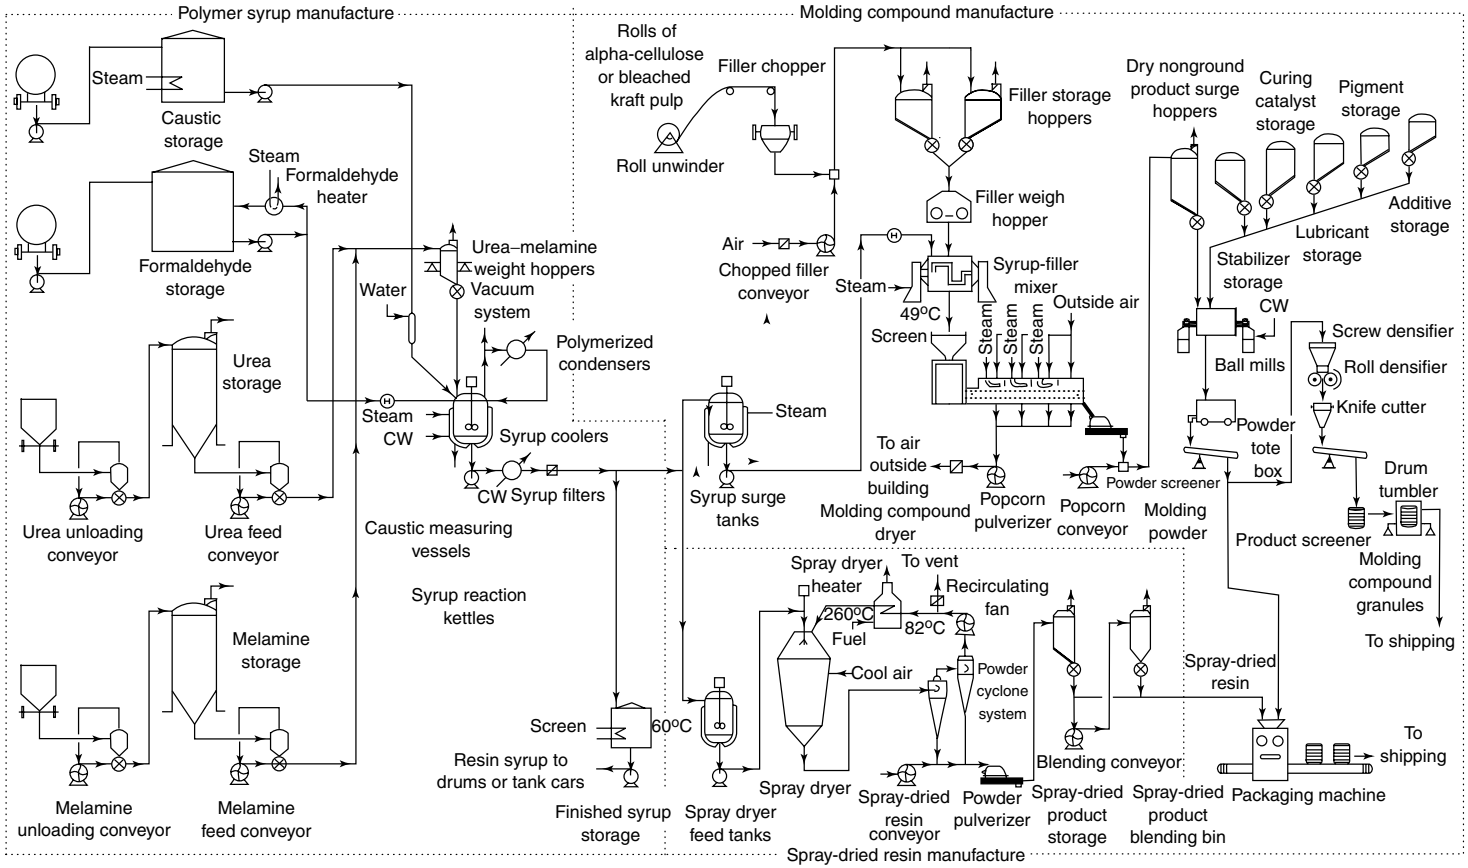

Fig. 2. Urea–formaldehyde and melamine–formaldehyde resin manufacture. CW: cold water. Courtesy of Stanford Research Institute.

setting. Ureas can be extended with wheat or rye flour, using as much as 150 parts flour to 100 parts dry resin. The extended glue still retains a fair degree of moisture resistance. Melamine resins have excellent water resistance, but cannot be cured at room temperature. Durable laminated wood beams used in building construction usually employ microwave technology for heat curing.

Continuous production of urea–formaldehyde resins has been described in many patents. In a typical example, urea and formaldehyde are combined and the solution pumped through a multistage unit. Temperature and pH are controlled at each stage to achieve the appropriate degree of polymerization. The product is then concentrated in a continuous evaporator to about 60–65% solids (31).

Laminating Resins

Phenolic and melamine resins are both used in the manufacture of decorative laminated plastic sheets for counters and tabletops. The phenolic is functional, being used in the backing or support sheets, whereas the melamine resin performs both decorative and functional roles in the print sheet and the protective overlay. Hardness, transparency, stain resistance, and freedom from discoloration are essential, in addition to a long-lasting working surface. Transparency is achieved because the refractive index of cured melamine-formaldehyde resin approaches that of the cellulose fibers and thus there is little scattering of light. Low cost and good mechanical properties are provided by the phenolic backing layers. In this instance, the combination of phenolic and amino resins achieves an objective that neither would normally be capable of performing alone. Developments in modified melamine resins have contributed to commercialization of premium priced through-color decorative laminates in which the dark color phenolic backing layers are replaced by color layers matching the full range of surface colors.

Phenolic resins are generally used in alcoholic solution, whereas melamine resins are best handled in water or water–alcohol mixtures. The paper or cloth web is passed through a dip tank containing resin solution, adjusted for pickup on squeeze rolls, and then passed through a heated drying oven. Once dried, the treated paper or cloth is fairly stable and, if stored in a cool place, it may be kept for several weeks or months before pressing into laminated plastic sheets.

A melamine laminating resin used to saturate the print and overlay papers of a typical decorative laminate might contain 2 mol of formaldehyde for 2 mol of melamine. In order to inhibit crystallization of methylol melamines, the reaction is continued until about one-fourth of the reaction product has been converted to low molecular weight polymer. A simple determination of free formaldehyde may be used to follow the first stage of the reaction, and the buildup of polymer in the reaction mixture may be followed by cloud-point dilution or viscosity tests.

A particularly interesting and useful test is run at high dilution. One or two drops of resin are added to a test tube half full of water. A cloudy streak as the drop sinks through the water indicates that the resin has advanced to the point where the highest molecular weight fraction of polymer is no longer soluble in water at that particular temperature. At this high dilution, the proportion of water to resin is not critical; hence the only measurement needed is the temperature of the water. The temperature at or below which the drops give a white streak is known

as the *hydrophobe temperature*. This test is particularly useful with melamine resins.

Laminates are pressed in steam-heated, multiple-opening presses. Each opening may contain a book of as many as 10 laminates pressed against polished steel plates. Curing conditions are 20–30 min at about 150°C under a pressure of about 6900 kPa (1000 psi).

Molding Compounds

Molding was the first big application for amino resins, although molding compounds are more complex than either laminating resins or adhesives. A simple amino resin molding compound might be made by combining melamine with 37% formalin in the ratio of 2 mol of formaldehyde/1 mol of melamine at neutral or slightly alkaline pH and a temperature of 60°C. The reaction should be continued until some polymeric product has been formed to inhibit crystallization of dimethylolmelamine upon cooling. When the proper reaction stage has been reached, the resin syrup is pumped to a dough mixer where it is combined with alpha-cellulose pulp, approximately one part of cellulose to each three parts of resin solids. The wet, spongy mass formed in the dough mixer is then spread on trays where it is combined with alpha-cellulose in a humidity-controlled oven to produce a hard, brittle popcorn-like intermediate. This material may be coarsely ground and sent to storage. To make the molding material, the cellulose–melamine resin intermediate is combined in a ball mill with a suitable catalyst, stabilizer, colorants, and mold lubricants. The materials must be ground for several hours to achieve the uniform fine dispersion needed to get the desired decorative appearance in the molded article. The molding compound may be used as a powder or it may be compacted under heat and pressure to a granular product that is easier to handle (32). A urea molding compound might be made in much the same way using a resin made with 1.3–1.5 mol of formaldehyde/1.0 mol of urea.

Amino molding compounds can be compression-, injection-, or transfer-molded. Urea molding compound has found wide use and acceptance in the electrical surface wiring device industry. Typical applications are circuit breakers, switches, wall plates, and duplex outlets. Urea is also used in closures, stove hardware, buttons, and small housings. Melamine molding compound is used primarily in dinnerware applications for both domestic and institutional use. It is also used in electrical-wiring devices, ashtrays, buttons, and housings.

The emergence of a new amino application is rare at this point in its relatively long life, but one such application has appeared and is growing rapidly. Because of the relative hardness of both urea and melamine moldings, a unique use has been developed for small, granular-sized particles of cut up molded articles. It is the employment of a pressurized stream of plastic particles to remove paint without damaging the surface beneath, and can be compared with a sandblasting operation. This procedure is gaining wide acceptance by both commercial airlines and the military for the refinishing of painted surfaces. It does not harm the substrate and eliminates the use of chemicals formerly used in stripping paint.

To speedup the molding process, the required amount of molding powder or granules is often pressed into a block and prewarmed before placing it in the mold.

Rapid and uniform heating is accomplished in a high frequency preheater, essentially an industrial microwave oven. The prewarmed block is then transferred to the hot mold, pressed into shape, and cured.

Production of decorated melamine plastic dinner plates makes use of molding and laminating techniques. The pattern is printed on the same type of paper used for the protective overlay of decorative laminates, treated with melamine resin and dried, and then cut into disks of the appropriate size.

To make a decorated plate, the mold is opened shortly after the main charge of molding compound has been pressed into shape, the decorative foil is laid in the mold on top of the partially cured plate, printed side down, and the mold closed again to complete the curing process. The melamine-treated foil is thus fused to the molded plate and, as with the decorative laminate, the overlay becomes transparent so that the printed design shows through yet is protected by the film of cured resin.

The excellent electrical properties, hardness, heat resistance, and strength of melamine resins make them useful for a variety of industrial applications. Some representative properties of amino resin molding compounds, including the industrial-grade melamines, are listed in Table 2.

Coatings

Cured amino resins are far too brittle to be used alone as surface coatings for metal or wood substrates, but in combination with other film formers (alkyds, polyesters, acrylics, epoxies) a wide range of acceptable performance properties can be achieved. These combination binder coating formulations cure rapidly at slightly elevated temperatures, making them well-suited for industrial baking applications. The amino resin content in the formulation is typically in the range of 10–50% of the total binder solids.

A wide selection of amino resin compositions is commercially available. They are all alkylated to some extent in order to provide compatibility with the other film formers, and formulation stability. They vary not only in the type of amine (melamine, urea, benzoguanamine, and glycoluril) used, but also in the concentration of combined formaldehyde, and the type and concentration of alkylation alcohol (*n*-butanol, isobutyl alcohol, and methanol).

On curing, amino resins not only react with the nucleophilic sites (hydroxyl, carboxyl, amide) on the other film formers in the formulation, but also self-condense to some extent. Highly alkylated amino resins have less tendency to self-condense (33,34) and are therefore effective cross-linking agents, but may require the addition of a strong acid catalyst to obtain acceptable cure even at bake temperatures of 120–177°C.

Amino resins based on urea have advantages in low temperature cure response and low cost. However, they are not as stable to uv radiation as melamine resins, and have poorer heat resistance; therefore, they have been successful primarily in interior wood finishes. Melamine resins, on the other hand, are uv stable, have excellent heat resistance, film hardness, and chemical resistance. They therefore dominate amino resin usage in OEM automotive coatings, general metals finishes, container coatings (both interior and exterior), and prefinished metal

applications. Glycoluril resins have also found use in prefinished metal, primarily because of their high film flexibility properties. Unalkylated glycoluril resins are unique in that they are stable under slightly acidic conditions and have therefore found use in low temperature cure waterborne finishes. Benzoguanamine resins have historically been successful in appliance finishes because of their superior chemical resistance and specifically their detergent resistance. However, they have both poor uv resistance and economics, which have limited their use in other application areas.

When first introduced to the coatings industry, amino resin compositions were partially butylated and relatively polymeric in nature, with degrees of polymerization of 4–6. However, the dominant amino resin in today's industrial coating is based on a highly methylated, highly monomeric (degrees of polymerization of 1.4–2.6) melamine cross-linking agent. Variations of extent of methylolation and methylation exist along with a number of co-ethers, where the melamine molecule is both methylated and either *n*-butylated or isobutylated. This type of composition dominates because it best addresses the pollution (low volatile organic compounds) and performance requirements of today's industrial finishes (see COATINGS).

Methylation provides fast cure response, improved exterior exposure, high weight retention on curing, and suitability for both solvent and waterborne systems. Waterborne systems, in most instances, provide lower pollution than solvent-based formulations. High monomer content reduces the viscosity of the amino resin, again lowering pollution particularly when used in solvent-based systems, and also improves film flexibility and recoat adhesion. When some butylation is included as part of the alkylation, the viscosity of the amino resin is lowered, thereby lowering pollution (of the formulated coating), improving recoat adhesion, and improving wetting and flow characteristics. An amino resin is usually selected on the basis of specific performance properties required or performance to be emphasized.

Stability in storage is an important property for coating systems containing amino resins. If the amino resin undergoes self-condensation or reacts at room temperature with the alkyd or other film-forming polymer, the system may become too viscous or thicken to a gel which can no longer be used for coating. Alkyds usually contain sufficient free carboxyl groups to catalyze the curing reaction when the coating is baked, but this may also cause the paint to thicken in storage. Partial neutralization of the acid groups with an amine can greatly improve storage stability yet allow the film to cure when baked, since much of the amine is vaporized with the solvent during the baking process. 2-Amino-2-methyl-1-propanol [124-68-5], triethylamine [121-44-8], and dimethylaminoethanol [108-01-1] are commonly used as stabilizers. Alcohols as solvent also improve storage stability. Catalyst addition just before the coating is to be applied permits rapid curing and avoids the problem of storage stability. A strong acid soluble in organic solvents such as *p*-toluenesulfonic acid is very effective and may be partially neutralized with an amine to avoid premature reaction.

A butylated urea–formaldehyde resin for use in the formulation of fast-curing baking enamels might be made beginning with the charge: urea (1 mol), paraformaldehyde (2.12 mol), and butanol (1.50 mol). Triethanolamine is added to make the solution alkaline (about 1% of the weight of the urea), and the mixture is refluxed until the paraformaldehyde is dissolved. Phthalic anhydride is added to

give a pH of 4.0, and the water removed by azeotropic distillation until the batch temperature reaches 117°C. Cooling and dilution with solvent is done until the desired solids content is reached (35).

A highly methylated melamine–formaldehyde resin for cross-linking with little or no self-condensation might be made as follows (36). A solution of formaldehyde in methyl alcohol is charged to a reaction kettle and adjusted to a pH of 9.0–9.5 using sodium hydroxide. Melamine is then added to give a ratio of 1 mol of melamine/6.5 mol of formaldehyde, and the mixture is refluxed for 1.5 h. The reaction is then cooled to 35°C, and more methanol added to bring the ratio of methanol per mole of melamine up to 11. With the batch temperature at 35°C, enough sulfuric acid is added to reduce the pH to 1. After holding the reaction mixture at this temperature and pH for 1 h, the batch is neutralized with 50% NaOH and the excess methanol stripped to give a product containing 60% solids, which is then clarified by filtration. A highly methylated resin, such as this, may be used in water-based (37) or solvent-type coatings. It might also be used to provide crease resistance to cotton fabric.

The principal problems facing amino resins in the industrial coatings of the 1990s are formaldehyde emission and low temperature cure performance. Significant progress has been made in reducing the residual free formaldehyde in the amino resin, but formaldehyde generation on baking must still be addressed. Concerning low temperature cure performance, emphasis is being placed on catalyst selection. Amino resins cure at bake temperatures as low as 71–82°C, but at these bake temperatures they require high concentrations of acid catalyst, which negatively affect hydrolysis resistance or water sensitivity of the cured film. The development of improved catalysts is the most promising solution to low temperature cure performance enhancement.

Textile Finishes

Most amino resins used commercially for finishing textile fabrics are methylolated derivatives of urea or melamine. Although these products are usually monomeric, they may contain some polymer by-product.

Amino resins react with cellulosic fibers and change their physical properties. They do not react with synthetic fibers, such as nylon, polyester, or acrylics, but may self-condense on the surface. This results in a change in the stiffness or resiliency of the fiber. Partially polymerized amino resins of such molecular size that prevents them from penetrating the amorphous portion of cellulose also tend to increase the stiffness or resiliency of cellulose fibers.

Monomeric amino resins react predominantly with the primary hydroxyls of the cellulose, thereby replacing weak hydrogen bonds with strong covalent bonds, which leads to an increase in fiber elasticity. When an untreated cotton fiber is stretched or deformed by bending, as in forming a crease or wrinkle, the relatively weak hydrogen bonds are broken and then re-form to hold the fiber in its new position. The covalent bonds that are formed when adjacent cellulose chains are cross-linked with an amino resin are five to six times stronger than the hydrogen bonds. Covalent bonds are not broken when the fiber is stretched or otherwise deformed. Consequently, the fiber tends to return to its original condition when

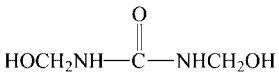
the strain is removed. This increased elasticity is manifested in two important ways:

(1) When a cotton fabric is cross-linked while it is held flat, the fabric tends to return to its flat condition after it has been wrinkled during use or during laundering. Garments made from this type of fabric are known as wash-and-wear, minimum care, or no-iron.
(2) A pair of pants that is pressed to form a crease and then cross-linked tends to maintain the crease through wearing and laundering. This type of garment is called *durable-press* or *permanent press*.

This increased elasticity is always accompanied by a decrease in strength of the cellulose fiber, which occurs even though weak hydrogen bonds are replaced by stronger covalent bonds. The loss of strength is not caused by hydrolytic damage to the cellulose. If the cross-linking agent is removed by acid hydrolysis for example, the fiber will regain most, if not all, of its original strength. The loss in strength is believed to be due to intramolecular reaction of the amino resin along the cellulose chain to displace a larger number of hydrogen bonds, resulting in a net loss in strength. The intramolecular and intermolecular reactions (cross-linking) both occur at the same time.

Although there are many different amino resins used for textile finishing, all of them impart about the same degree of increase in elasticity when applied on an equal molar basis. Elasticity can be measured by determining the recovery from wrinkling. Although all these products impart about the same degree of improvement in elasticity, they also may impart many other desirable or undesirable properties to the fabric. The development of amino resins for textile finishing has been aimed toward maximizing the desirable properties and minimizing the undesirable ones. Most of the resins and reactants used in today's textile market are based on urea as a starting material. However, the chemistry differs considerably from that employed in early textile-finishing operations.

The first amino resins used commercially on textiles were the so-called urea–formaldehyde resins, dimethylolurea [140-95-4] [6], or its mixtures with monomethylolurea [1000-82-4].



6

Their performance falls short of most present finishes, particularly in durability, resistance to chlorine-containing bleaches, and formaldehyde release, and they are not used much today. Both urea and formaldehyde are relatively inexpensive, and manufacture is simple; ie, 1–2 mol of formaldehyde as an aqueous solution reacts with 1 mol of urea under mildly alkaline conditions at slightly elevated temperatures.

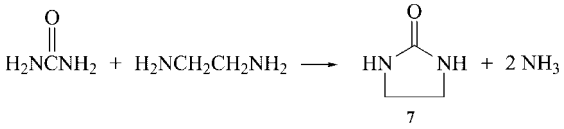
Since the methylolurea monomers have limited water solubility (about 30%), they were usually marketed in dispersed form as soft pastes containing 55–65% active ingredient in order to decrease container and shipping costs. By

increasing the temperature and using slightly acidic conditions, dimethylolureas can be made as a series of short polymers that have infinite water solubility and can be marketed at concentrations as high as 85%. However, because these result in increased fabric stiffness, they cannot be used interchangeably with the monomeric materials. Both forms polymerize readily in storage and, unless kept under refrigeration, become water insoluble within a few weeks at ambient temperatures.

To overcome stability and water solubility problems, methylolurea resins are frequently alkylated to block the reactive hydroxyl groups. For reasons of economy the alkylating agent is usually methanol. In this process, 2 mol of aqueous formaldehyde reacts with 1 mol of urea under alkaline conditions to form dimethylolurea. Excess methanol is then added, and the reaction continued under acidic conditions to form methoxymethylurea. Both methylol groups can be methylated by maintaining low concentrations of water and using a large excess of methanol; however, methylation of only one of the methylol groups is sufficient to provide adequate shelf-life and water solubility. Upon completion of the methylation reaction, the resin is adjusted to pH 7–10, and excess methanol and water are removed by distillation under reduced pressure to provide syrups of 50–80% active ingredients.

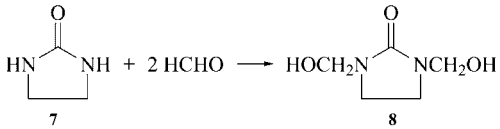
Like methylolureas, cyclic ureas are based on reactions between urea and formaldehyde; however, the amino resin is cyclic rather than linear. Many cyclic urea resins have been used in textile-finishing processes, particularly to achieve wrinkle resistance and shrinkage control, but the ones described below are the most commercially important. They are all in use today to greater or lesser extents, depending on specific end requirements.

Ethyleneurea Resins. One of the most widely used resins during the 1950s and 1960s was based on dimethylolethyleneurea [136-84-5] [1,3-bis(hydroxymethyl)-2-imidazolidinone], commonly known as ethyleneurea resin. Ethyleneurea resin [28906-87-8] is most conveniently prepared from urea, ethylenediamine, and formaldehyde. 2-Imidazolidinone [120-93-4] [7] (ethyleneurea) is first prepared by the reaction of excess ethylenediamine [107-15-3] with urea (38) in an aqueous medium at about 116°C.



7

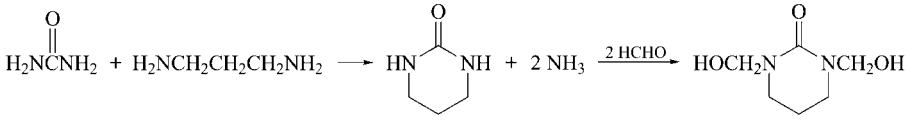
A fractionating column is required for the removal of ammonia and recycle of ethylenediamine. The molten product (mp 133°C) is then run into ice water to give a solution that is methylolated with 37% aqueous formaldehyde to form dimethylolethyleneurea [8].



7 8

The resin, generally a 50% solution in water, has excellent shelf-life and is stable to hydrolysis and polymerization.

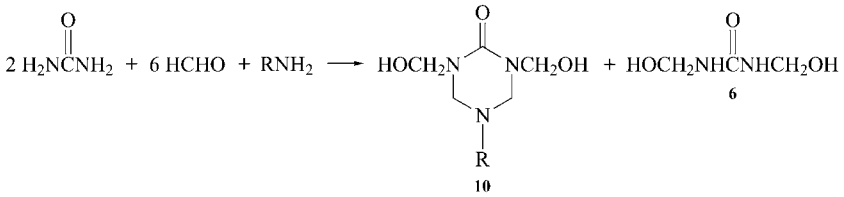
Propylene Urea Resins. Similar to the product from ethyleneurea [7], dimethylolpropyleneurea [3270-74-4] [9] 1,3-bis(hydroxymethyl)tetrahydro-2-(1*H*)-pyrimidinone] is the basis of propyleneurea–formaldehyde resin [65405-39-2]. Its preparation is from urea, 1,3-diaminopropane [109-76-2], and formaldehyde.



9

This resin was temporarily accepted, primarily because of its improved resistance to acid washes. However, the relatively high cost of the diamine precluded widespread commercial acceptance.

Triazone. Triazone is the common name for the class of compounds corresponding to the dimethylol derivatives of tetrahydro-5-alkyl-*s*-triazone [10]. They can be made readily and cheaply from urea, formaldehyde, and a primary aliphatic amine. A wide variety of amines may be used to form the six-membered ring (39); however, for reasons of cost and odor, hydroxyethylamine (monoethanolamine) is used preferentially. Since the presence of straight-chain methylolureas causes no deleterious effects to the fabric finish, the triazones typically are prepared with less than the stoichiometric quantity of the amine. This results not only in a less costly resin but also in improved performance (40).

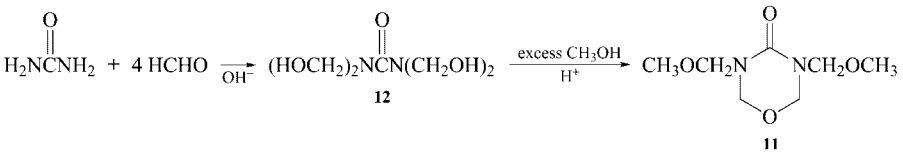


10 **6**

The resin is simply prepared by heating the components together. Usually the urea and formaldehyde are first charged to the kettle and heated under alkaline conditions to give a mixture of polymethylolureas, followed by the slow addition of the amine with continued heating to form the cyclic compound. The order of addition can be varied as can the molar ratios so as to yield a range of chain-ring compound ratios. The commercial resin is usually sold as a 50% solids solution in water.

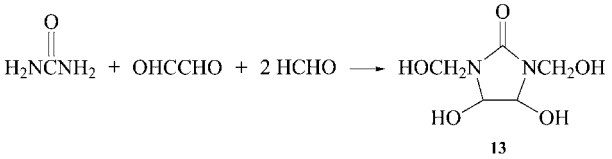
Uron Resins. In the textile industry, the term uron resin *uron resin* usually refers to the mixture of a minor amount of melamine resin and so-called uron, which in turn is predominantly *N,N′*-bis(methoxymethyl)uron [7388-44-5] [11] plus 15–25% methylated urea–formaldehyde resins, a by-product. *N,N′*-bis(methoxymethyl)uron was first isolated and described in 1936 (41), but was commercialized only in 1960. It is manufactured (42) by the reaction of 4 mol of formaldehyde with 1 mol of urea at 60°C under highly alkaline conditions to form

tetramethylolurea [2787-01-1] [12]. After concentration under reduced pressure to remove water, excess methanol is charged and the reaction continued under acidic conditions at ambient temperatures to close the ring and methylate the hydroxymethyl groups. After filtration to remove the precipitated salts, the methanolic solution is concentrated to recover excess methanol. The product (75–85% pure) is then mixed with a methylated melamine–formaldehyde resin to reduce fabric strength losses in the presence of chlorine, and diluted with water to 50–75% solids. Uron resins do not find significant use today because of the greater amounts of formaldehyde released from fabric treated with these resins.



12 11

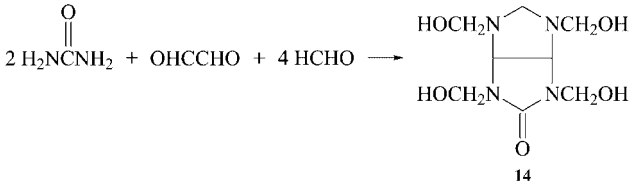
Glyoxal Resins. Since the late 1960s, glyoxal resins have dominated the textile-finish market for use as wrinkle-recovery, wash-and-wear, and durable-press agents. These resins are based on 1,3-bis(hydroxymethyl)-4,5-dihydroxy-2-imidazolidinone, commonly called dimethyloldihydroxyethyleneurea [1854-26-8] (DMDHEU) [13]. Several methods of preparation are described in the literature (43). On a commercial scale, DMDHEU can be prepared inexpensively at high purity by a one-kettle process (44): 1 mol of urea, 1 mol of glyoxal [107-22-2] as 40% solution, and 2 mol of formaldehyde in aqueous solution are charged to the reaction vessel. The pH is adjusted to 7.5–9.5 and the mixture heated at 60–70°C. The reaction is nearly stoichiometric; excess reagent is not necessary.



13

Glyoxal resins are generally sold at 45% solids solutions in water. Resin usage for crease-resistant fabrics had increased to well over 60×10^6 kg by 1974 and over half of this was DMDHEU for durable-press garments. In the early 1980s glyoxal resins modified with diethylene glycol [111-46-6] became prominent in the marketplace. These products are either simple mixtures of diethylene glycol and DMDHEU in water solution or the reaction product of diethylene glycol and DMDHEU. Rarely, ethylene glycol has been used in place of diethylene glycol. The diethylene glycol-modified DMDHEU products have the advantage of releasing significantly less formaldehyde from the finished fabric after resin curing than from fabric treated with DMDHEU. On the other hand, durable-press performance and shrinkage control are somewhat less with the glycol-modified resins.

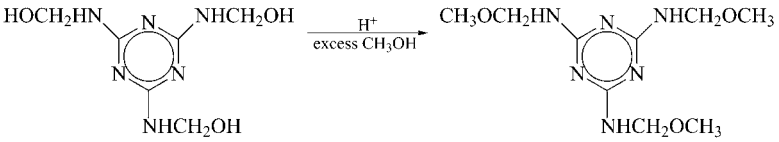
A less important glyoxal resin is tetramethylolglycoluril [5395-50-6] [14] (tetramethylolacetylenediurea) produced by the reaction of 1 mol of glyoxal with 2 mol of urea and 4 mol of formaldehyde.



14

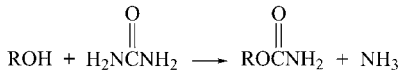
This resin was most popular in Europe, partly because of its lower requirements of glyoxal. However, because of increased availability and lower glyoxal costs plus certain application weaknesses, it has been generally replaced by DMDHEU.

Melamine–Formaldehyde Resins. The most versatile textile-finishing resins are the melamine–formaldehyde resins. They provide wash-and-wear properties to cellulosic fabrics, and enhance the wash durability of flame-retardant finishes. Butylated melamine–formaldehyde resins of the type used in surface coatings may be used in textile printing-ink formulations. A typical textile melamine resin is the dimethyl ether of trimethylolmelamine [1852-22-8], which can be prepared as follows:



Under alkaline conditions, 3 mol of formaldehyde react with 1 mol of melamine at elevated temperatures. Since water interferes with the methylation, methylolation is carried out in methanol with paraformaldehyde and by simply adjusting the pH to about 4 with continued heating. After alkylation is complete the pH is adjusted to 8–10, and excess methanol is distilled under reduced pressure. The resulting syrup contains about 80% solids.

Miscellaneous Resins. Much less important than the melamine–formaldehyde and urea–formaldehyde resins are the methylol carbamates. They are urea derivatives since they are made from urea and an alcohol.



(R can vary from methyl to a monoalkyl ether of ethylene glycol). Temperatures in excess of 140°C are required to complete the reaction and pressurized equipment is used for alcohols boiling below this temperature; provision must be made for venting ammonia without loss of alcohol. The reaction is straightforward and, in the case of the monomethyl ether of ethylene glycol [109-86-4], can be carried out at atmospheric pressure using stoichiometric quantities of urea and alcohol (45). Methylolation with aqueous formaldehyde is carried out at 70–90°C under alkaline conditions. The excess formaldehyde needed for complete dimethylolation remains in the resin and prevents more extensive usage because of formaldehyde odor problems in the mill.

Other amino resins used in the textile industry for rather specific properties have included the methylol derivatives of acrylamide (46), hydantoin [461-79-3] (47), and dicyandiamide (48).

Textiles are finished with amino resins in four steps. The fabric is (*1*) passed through a solution containing the chemicals, (*2*) through squeeze rolls (padding) to remove excess solution, (*3*) dried, and (*4*) heated (cured) to bond the chemicals with the cellulose or to polymerize them on the fabric surface.

The solution (pad bath) contains one or more of the amino resins described above, a catalyst, and other additives such as a softener, a stiffening agent, or a water repellant. The catalyst may be an ammonium or metal salt, eg, magnesium chloride or zinc nitrate. Synthetic fabrics, such as nylon or polyester, are treated with amino resins to obtain a stiff finish. Cotton or rayon fabrics or blends with synthetic fibers are treated with amino resins to obtain shrinkage control and a durable-press finish.

Normally, fabrics are treated in the sequence outlined above. The temperature of the drying unit is 100–110°C and the temperature of the curing unit can vary between 120 and 200°C but usually ranges from 150 to 180°C. The higher temperatures are employed to polymerize the resins on synthetic fabrics and at the same time to heat-set the fibers. Temperatures up to 180°C are used to allow the amino resins to react with cellulosic fibers alone or blended with synthetic fibers. The fabric is held flat but with minimum tension during drying and curing, and always tends to become flat when creased or wrinkled during use or laundering. The resin-treated cellulose absorbs less water and swells less than untreated cellulose. This reduced swelling along with little or no tension induced during drying minimizes shrinkage during laundering.

The steps followed in the precure are repeated in the postcure process, except that after the drying step the goods are shipped to a garment manufacturer who makes garments, presses them into the desired shape with creases or pleats, and then cures the amino resin on the completed garment. It is important that the amino resins used in the postcure process should (*1*) not react with the fabric before it has been fashioned into a garment, and (*2*) release a minimum amount of formaldehyde into the atmosphere, especially while the goods are in storage or during the cutting and sewing operations. These requirements are met, at present, with the diethylene glycol-modified DMDHEU resin.

Tire Cord. Melamine resins are also used to improve the adhesion of rubber to reinforcing cord in tires. Textile cord is normally coated with a latex dip solution composed of a vinylpyridine–styrene–butadiene latex rubber containing resorcinol–formaldehyde resin. The dip coat is cured prior to use. The dip coat improves the adhesion of the textile cord to rubber. Further improvement in adhesion is provided by adding resorcinol and hexa(methoxymethyl)melamine [3089-11-0] (HMMM) to the rubber compound which is in contact with the textile cord. The HMMM resin and resorcinol cross-link during rubber vulcanization and cure to form an interpenetrating polymer within the rubber matrix, which strengthens or reinforces the rubber and increases adhesion to the textile cord. Brass-coated steel cord is also widely used in tires for reinforcement. Steel belts and bead wire are common applications. Again, HMMM resins and resorcinol [108-46-3] are used in the rubber compound which is in contact with the steel cord so as to reinforce

the rubber and increase the adhesion of the rubber to the steel cord. This use of melamine resins is described in the patent literature (49).

Amino Resins in the Paper Industry

Paper is a material of tremendous versatility and utility, prepared from a renewable resource. It may be made soft or stiff, dense or porous, absorbent or water repellent, textured or smooth. Some of the versatility originates with the fibers, which may vary from short and supple to long and stiff, but the contribution of chemicals should not be underestimated.

Amino resins are used by the paper industry in large volume for a variety of applications. The resins are divided into two classes according to the mode of application. Resins added to the fiber slurry before the sheet is formed are called wet-end additives and are used to improve wet and dry strength and stiffness. Resins applied to the surface of formed paper or board, almost invariably together with other additives, are used to improve the water resistance of coatings, the sag resistance in ceiling tiles, and the scuff resistance in cartons and labels.

The requirements for the two types of resins are very different. Wet-end additives are used in dilute fiber slurries in small amounts. After the sheet is formed, most of the water is drained away and some of the remaining water is pressed out of the sheet before it is dried. The amino resin must be retained (absorbed) on the surface of the cellulose fibers so that it will not be washed away. On a typical paper machine, fiber concentration in the headbox would be about 1%. If the amount of wet-strength resin used is 1% of the weight of the fiber, the concentration of resin in the headbox would be only 0.01%. If no mechanism for attaching the resin to the fiber is provided, only a trace of the resin added to the slurry would be retained in the finished sheet. Good retention is achieved with the amino resin by making the resin cationic. Since the cellulose surface is anionic because of the carboxylic acid groups present, the cationic charge on the resin makes it substantive with the fiber leading to good retention of the resin when applied in the wet-end. Resins for application to the surface of preformed paper are not required to be substantive to cellulose and they may be formulated for adhesion, cure rate, viscosity, compatibility with other materials, etc, without concern for retention.

The integrity of a paper sheet is dependent on the hydrogen bonds which form between the fine structures of cellulose fibers during the pressing and drying operations (see CELLULOSE). The bonds between hydroxyls of neighboring fibers are very strong when the paper is dry, but are severely weakened as soon as the paper becomes wet. Bonding between the hydroxyls of cellulose and water is as energetic as bonding between two cellulose hydroxyls. As a consequence, ordinary paper loses most of its strength when it is wet or exposed to very high humidity. The sheet loses its stiffness and bursting, tensile and tearing strength.

Many materials have been used over the years in an effort to correct this weakness in paper. If water can be prevented from reaching the sites of the bonding by sizing or coating the sheet, then a measure of wet strength may be attained.

Water molecules are so small and cellulose and so hydrophilic that this solution usually affords only temporary protection. Formaldehyde, glyoxal, polyethylenimine, and, more recently, derivatized starch (50) and derivatized cationic polyacrylamide resins (51) have been used to provide temporary wet strength. The first two materials must be applied to the formed paper, but the other materials are substantive to the fiber and may be used as wet-end additives. Carboxymethylcellulose–calcium chloride and locust-bean gum–borax are examples of two-component systems applied separately to paper that were used to a limited extent before the advent of the amino resins. Today three major types of wet-strength resins are used in papermaking: polyamide–polyamine resins cross-linked with epichlorohydrin (52) are used in neutral to alkaline papers; cationic polyacrylamide resins cross-linked with glyoxal are used for acid to neutral papers; and melamine–formaldehyde resins are used for acid papers.

During the 30-year period following the introduction of synthetic wet-strength additives to papermaking in 1942, most paper was made at acid pH. Low molecular weight (or even monomeric) trimethylolmelamine [1017-56-7], when dissolved in the proper amount of dilute acid and aged, polymerizes to a colloidal polymer that is retained well by almost all types of papermaking fiber, and produces high wet strength under the mild curing conditions easily attained on a paper machine (53,54). This resin, introduced by American Cyanamid in 1942, is still extensively used when rapid cure, high wet strength, and good dry strength are important in acid paper. Some processing improvements have been made, including a report (55) describing the formation of a stable melamine resin acid colloid using formic and phosphoric acids. The chemistry of this reaction is quite interesting.

Melamine–formaldehyde acts as an amine when dissolved in dilute acid, usually HCl. During polymerization, between 20 and 80 monomeric units combine to form a polymer of colloidal dimensions (6–30 nm) with the elimination of water and HCl (56,57). The development of cationicity is associated with the loss of HCl, since a unit of charge on the polymer is generated for every mole of acid lost, and the pH decreases steadily during the polymerization. In a typical formulation at 12% solids at room temperature, polymerization is complete in about 3 h. The initially colorless solution develops a light blue haze and shows a strong Tyndall effect.

Such a colloidal sol is highly substantive to all papermaking fibers, kraft, sulfite, groundwood, and soda. For its successful use in paper mills, the pH must be kept low, both to prevent precipitation of the resin in an unusable form and to promote curing of the resin; and the concentration of sulfates in the white water on the paper machine must not be allowed to exceed 100 ppm, again because the resin is precipitated in an inactive form by high concentrations of sulfates. High sulfate concentrations may build up in mills using large amounts of alum for setting size or sulfuric acid for controlling pH.

The problem of sulfate sensitivity was solved by adding formaldehyde to the aged colloid, which improved wet-strength efficiency and reduced sensitivity to sulfates (58). Later, equivalent results were obtained by adding the extra formaldehyde before the colloid was aged. The additional formaldehyde acts like an acid during the aging process and, unless compensated for by a reduction in the amount of acid charged, lowers the pH to a point where polymerization to the

Table 3. Formulations for Regular and HE Colloid Resins

	Regular MF_3	HE MF_8

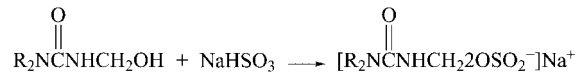
colloids is inhibited. The high efficiency (HE) resins have been used in mills with sulfate concentrations so high that use of regular trimethylolmelamine (MF_3) colloids would be uneconomical. Sulfate tolerance is a function of the amount of extra formaldehyde present. For best cost-performance, a family of HE colloids is necessary with composition varying from MF_4, for moderate sulfate concentrations, to MF_9, for very high sulfates.

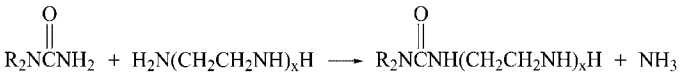
Formulations for regular and HE colloids are shown in Table 3 (59). The materials are added, in the order listed, to a 454-L (120-gal) tank provided with good agitation and ventilation. Formaldehyde fumes are evolved even from the regular colloid. The colloids develop only after aging and freshly prepared solutions are ineffective for producing wet strength. Stability of the colloids depends on temperature and concentration. Colloids at 10–12% are stable at room temperature for at least 1 week; stability may be extended by dilution after the colloids have aged properly.

Both regular and HE colloids increase the wet strength of paper primarily by increasing adhesion between fibers; the strength of the individual fiber itself is unaffected (60). The resin appears to improve the adhesion between the fibers, whether they are wet or dry, by forming bonds that are unaffected by water. The excess formaldehyde in the HE colloid appears to function by increasing the amount of formaldehyde bound in the colloid (59). The regular colloid, starting with about 3 mol of formaldehyde/1 mol of melamine, has about 2 mol bound in the colloid and 1 mol free. By mass action, the additional formaldehyde increases the amount of bound formaldehyde in the colloid. When an HE colloid is dialyzed or stored at very low concentrations (0.05%), it loses the extra bound formaldehyde and behaves as a regular colloid.

The first urea–formaldehyde resins used to any extent as wet-strength agents were anionic polymers made by the reaction of a urea resin with sodium bisulfite ($NaHSO_3$) (61). Attempts to use nonionic urea–formaldehyde polymers were unsuccessful; the neutral charge on the polymer made it unsubstantive to fiber resulting in lack of retention. The sulfomethyl group introduced by reaction with $NaHSO_3$ gave the polymers strong anionicity, but substantivity was largely restricted to unbleached kraft pulp. Lignin residues probably provided sites for absorption of the polymer. The use of alum as a mordant was essential, since both the resin and the fiber were anionic. The reaction of bisulfite with the urea–formaldehyde polymer may be represented as



In 1945, cationic urea resins were introduced and quickly supplanted the anionic resins, since they could be used with any type of pulp (62). Although they have now become commodities, their use in the industry has been steadily declining as the shift toward neutral and alkaline papermaking continues. They are commonly made by the reaction of urea and formaldehyde with one or more polyethylene–polyamines. The structure of these resins is very complicated and has not been determined. Ammonia is evolved during the reaction, probably according to the following:



Formaldehyde may react with the active hydrogens on both the urea and amine groups and therefore the polymer is probably highly branched. The amount of formaldehyde (2–4 mol/1 mol urea), the amount and type of polyamine (10–15%), and resin concentration are variable and hundreds of patents have been issued throughout the world. Generally, the urea, formaldehyde, polyamine, and water react at 80–100°C. The reaction may be carried out in two steps, with an initial methylolation at alkaline pH, followed by condensation to the desired degree at acidic pH, or the entire reaction may be carried out under acidic conditions (63). The product is generally a syrup with 25–35% solids and is stable for up to 3 months.

The cationic urea resins are added to paper pulp preferably after all major refining operations have taken place. The pH on the paper machine must be acidic for reasonable rates of cure of the resin. Urea resins do not cure as rapidly as melamine–formaldehyde resins and the wet strength produced is not as resistant to hydrolysis. Furthermore, the resins are not retained as well as the melamine resins. On a resin-retained basis, however, their efficiency is as good. The lower retention of the urea–formaldehyde resins is due to their polydisperse molecular weight distribution. High molecular weight species are strongly absorbed on the fibers and are large enough to bridge two fibers. Low molecular weight species are not retained as well because of fewer charge sites. Attempts to improve the performance of urea–formaldehyde resins by fractionating the syrups by salt or solvent precipitation, or selective freezing or dialysis have been technically successful but economically impractical. The process for production of resins is sufficiently simple so that some paper mills have set up their own production units. With captive production, resins with higher molecular weights and lower stability may be tolerated.

The recovery of fiber from *broke* (off-specification paper or trim produced in the paper mill) is complicated by high levels of urea–formaldehyde and melamine–formaldehyde wet-strength resin. The urea resins present a lesser problem than the melamine resins because they cure slower and are not as resistant to hydrolysis. Broke from either resin treatment may be reclaimed by hot acidic repulping. Even the melamine resin is hydrolyzed rapidly under acidic conditions at high temperature. The cellulose is far more resistant and is not harmed if the acid is neutralized as soon as repulping is complete.

The TAPPI monograph (64) is an excellent source of additional information on technical and economic aspects of wet strength. An informative overview of the chemistry and mechanisms involved in wet strength chemistry can be found in Reference 65.

Wet-strength applications account for the majority of amino resin sales to the paper industry but substantial volumes are sold for coating applications. The largest use is to improve the resistance of starch–clay coatings to dampness. In offset printing, which is becoming ever more important in the graphic arts, the printing paper is exposed to both ink and water. If the coating lifts from the paper and transfers to the plate, it causes smears and forces a shutdown for cleaning. A wide variety of materials have been added to the coatings to improve wet-rub resistance, including casein, soya protein, poly(vinyl acetate), styrene–butadiene latices, glyoxal–urea resins, and amino resins. Paper coatings are applied at as high a solids content as possible to ease the problem of drying. Retention is not a problem since the resin is applied to a preformed sheet. The important characteristics for coating resins are high solids at low viscosity, high cure rates, and high wet-rub efficiency. Urea and melamine resins or mixtures are sold as high solids syrups or dry powders. They are used with starch-pigment coatings with acidic catalysts or with starch-pigment–casein (or protein) coatings usually without catalysts. The syrups are frequently methylated for solubility and stability at high solids. All of the resins are of intrinsically low molecular weight to reduce viscosity for ease of handling (see COATINGS).

Closely allied to resins for treating paper are the resins used to treat regenerated cellulose film (cellophane) which does not have good water resistance unless it is coated with nitrocellulose or poly(vinylidene chloride). Adhesion of the waterproofing coating to the cellophane film is achieved by first treating the cellophane with an amino resin. The cellophane film is passed through a dip tank containing about 1% of a melamine–formaldehyde acid colloid type of resin. Some glycerol may also be present in the resin solution to act as a plasticizer. Resins for this purpose are referred to as *anchoring agents*.

Other Uses

Water-soluble melamine–formaldehyde resins are used in the tanning of leather in combination with the usual tanning agents. By first treating the hides with a melamine–formaldehyde resin, the leather is made more receptive to other tanning agents and the finished product has a lighter color. The amino resin is often referred to as a *plumping agent* because it makes the finished leather firmer and fuller.

Urea–formaldehyde resins are also used in the manufacture of foams. The resin solution containing an acid catalyst and a surface-active agent is foamed with air and cured. The open-cell type of foam absorbs water readily and is soft enough so that the stems of flowers can be easily processed into it. These features make the urea resin foam ideal for supporting floral displays. Urea–formaldehyde resin may also be foamed in place. A special nozzle brings the resin, catalyst, and foaming agent together. Air pressure is used to deposit the foam where it is desired,

eg, within the outside walls of older houses to provide insulation. This application might be expected to grow as energy costs increase, if undesirable odors can be controlled.

Urea–formaldehyde resins are also used as the binder for the sand cores used in the molds for casting hollow metal shapes. The amino resin is mixed with moist sand and formed into the desired shape of the core. After drying and curing, the core is assembled into the mold and the molten metal poured in. Although the cured amino resin is strong enough to hold the core together while the hot metal is solidifying, it decomposes on longer heating. Later, the loose sand may be poured out of the hollow casting and recovered.

Regulatory Concerns

Both urea– and melamine–formaldehyde resins are of low toxicity. In the uncured state, the amino resin contains some free formaldehyde that could be objectionable. However, uncured resins have a very unpleasant taste that would discourage ingestion of more than trace amounts. The molded plastic or the cured resin on textiles or paper may be considered nontoxic. Combustion or thermal decomposition of the cured resins can evolve toxic gases, such as formaldehyde, hydrogen cyanide, and oxides of nitrogen.

Melamine–formaldehyde resins may be used in paper which contacts aqueous and fatty foods according to 21 CFR 121.181.30. However, because a lower PEL has been established by OSHA, some mills are looking for alternatives. Approaches toward achieving lower formaldehyde levels in the resins have been reported (66,67); the efficacy of these systems needs to be established. Although alternative resins are available, significant changes in the papermaking operation would be required in order for them to be used effectively.

Economic Aspects

Japan produces more amino resin than any other country; the United States is next, with the Commonwealth of Independent States, (CIS) France, the United Kingdom, and Germany following.

Many large chemical companies produce amino resins and the raw materials needed, ie, formaldehyde, urea, and melamine. Some companies may buy raw materials to produce amino resins for use in their own products, such as plywood, chipboard, paper, textiles, or paints, and may also find it profitable to market these resins to smaller companies. The technology is highly developed and sales must be supported by adequate technical service to select the correct resin and see that it is applied under the best conditions.

During the past 10 years (the 1990s) there has been considerable changes in the suppliers of amino resins as a result of acquisitions, spin-offs, and withdrawal of some of the smaller companies from the business. The following is a representative list of those currently in the business: Badische Aniline and Soda-Fabrik (BASF), Ludwigshafen, Germany; Berger International Chemicals, Newcastle upon Tyne, England; Borden Chemical Division, Columbus, Ohio; Casella

Farbwerk Mainkur AG, Frankfurt-Fechenheim, Germany; Cuyahoga Plastics, Cleveland, Ohio; Cytec Industries, West Patterson, N.J.; DSM Coating Resins, Zwolle, Holland; Dainippon Ink, Ltd., Tokyo, Japan; Dynamic-Nobel, AG, Troisdorf-Koln, Germany; Fiberite Corp., Winona, Minn.; Georgia-Pacific Corp., Atlanta Ga.; Gulf Adhesives, Lansdale, Pa.; Hitachi Chemical Co., Ltd., Tokyo, Japan; Matsushita Electric Works, Ltd., Osaka, Japan; McWhorter Technologies, Carpentersville, Ill. (Division of Eastmen Chemical Co., Kingspot, Tenn.); Melamine Chemicals, Donaldson, La. (Division of Borden Chemical, Columbus, OH); Mitsui-Toatsu Chemicals Ltd., Tokyo, Japan; Mitsui-Cytec, Ltd., Tokyo, Japan; Montedison SpA, Milan, Italy; Pacific Resins, Tacoma, Wash.; Perstorp AB, Perstorp, Sweden; Perstorp Compounds, Inc., Florence, Mass.; Reichhold Chemicals, White Plains, N.Y. (Division of Dainippon Ink, Tokyo, Japan); Solutia, Inc., St. Louis, Mo.; Sumitomo Ltd., Tokyo, Japan; Vianova Resins GmbH & Co., Wiesbaden, Germany (Division of Solutia, St. Louis, Mo.).

ANTIFOAMING AGENTS

Introduction

The control or elimination of the foam that occurs in many industrial processes is a vital factor in their efficient operation. Additives for this purpose are the largest single category of process aids used in the chemical industry (1). They are used in low concentration to achieve this effect and are known variously as defoamers, antifoaming agents, foam inhibitors, foam suppressants, air release agents, and foam control agents. Defoaming implies breaking a preexisting foam, whereas antifoaming or foam inhibition indicates prevention of the formation of that foam. Such distinctions call for different product features. A defoamer is expected to exhibit rapid knockdown of a foam, whereas longevity of action might be the key requirement in many antifoam applications. Despite these varying performance features, many applications require both preventive and control functions, and in practice the same types of materials are used for both antifoaming and defoaming. For this reason, the general term *defoamers*, as used in this article, is meant to encompass all product types and degrees of action encountered with such process aids. The topic is sometimes known as chemical or physicochemical foam control as opposed to thermal and mechanical foam control approaches, such as centrifuging or spraying of the foam or the use of ultrasound, which are not covered here.

Many industries rely on the efficient and economical use of defoamers both as a process aid in product manufacture and to increase the quality of the finished product in its subsequent application. The most obvious use of defoamers

Encyclopedia of Polymer Science and Technology. Copyright John Wiley & Sons, Inc. All rights reserved.

as process aids is to increase holding capacity of vessels and improve efficiency of distillation or evaporation equipment. They are also used to improve filtration, dewatering, washing, and drainage of suspensions, mixtures, or slurries. Examples of industrial operations that benefit in these ways from the use of defoamers include oil well pumping; gas scrubbing at petrochemical plants; polymer and chemical synthesis and processing, particularly in monomer stripping; textile dyeing and finishing; leather processing; paint and adhesive manufacture; phosphoric acid production; control of wastewater and sewage; food preparation, notably the refining of sugar; the brewing of beer; and penicillin production by fermentation. Among the finished products that are improved in quality or efficacy by the proper inclusion of defoamers are lubricants, particularly cooling lubricants in metal working; diesel fuel, hydraulic and heat-transfer fluids; paints and other coatings; adhesives; inks; detergents; and antiflatulence tablets.

The use of vegetable and mineral oils as defoamers has been known for a long time. However, most modern defoamers are complex, formulated specialty chemicals, whose composition is often proprietary. Numerous reviews of the field have appeared since the previous edition of this article, notably the comprehensive book on the subject by Garrett (2). Other useful reviews include some on foam control principles (3–5), coatings applications (6), and silicones (7,8). Companies involved in the production of defoamers range from large, basic polymer producers to small regional formulators. In addition to control of foam and associated features such as rate of foam knockdown and the persistence of the effects, other frequently needed application requirements of these specialty materials include adequate shelf life, absence of adverse effects on and by the products being treated, ease of handling, lack of toxicity to manufacturing personnel and users, environmental acceptability, and cost-effectiveness. Defoamers range from relatively inexpensive mineral oils to costly fluorinated polymers. However, it is not the cost per kilogram of defoamer that matters, but rather the cost per unit produced using this processing aid that does. Another factor that strongly influences the choice of a specific defoamer is its ancillary surface properties such as wetting, dispersion, and leveling.

Defoamer Components

Modern defoamers contain numerous ingredients to meet the diverse product requirements for which they are formulated, including a variety of active ingredients in both the solid and liquid states and numerous ancillary agents such as emulsifiers, spreading agents, thickeners, preservatives, carrier oils, compatibilizers, solvents, and water. Not all defoamers contain all classes of components; some complex formulations contain several different materials in a particular category.

Active Ingredients. These are the components of the formulation that do the actual foam control work. Traditionally, defoamers were single-component liquids or homogeneous solutions of vegetable or mineral oils, but nowadays hydrophobic solids are the most effective active ingredients.

Liquid-Phase Components. The four most common liquid-phase components found in defoamers are hydrocarbons, polyethers, silicones, and fluorocarbons.

Many hydrocarbon fluids such as kerosene and other paraffinic and naphthenic mineral oils and vegetable oils such as linseed oil [8001-26-1], corn oil, soybean oil [8001-22-7], peanut oil, tall oil [8000-26-4], and castor oil [8001-79-4] are used as defoamers. Liquid fatty alcohols, acids and esters from other sources, and poly(alkylene oxide) derivatives of oils such as ethoxylated rosin oil [68140-17-0] are also used. Organic phosphates are valuable defoamers and have particular utility in latex paint applications. Another important class of hydrocarbon-based defoamer is the acetylenic glycols (9), such as 2,4,7,9-tetramethyl-5-decyne-4, 7-diol which are widely used in water-based coatings, agricultural chemicals, and other areas where excellent wetting is needed.

Among other organic polymers that have been proposed as foam control agents are polyisobutylene [9003-27-4], poly(alkyl acrylates), polyalkylene polyamines, and polyalkyleneimines. Poly(alkylene oxide) homopolymers and copolymers are frequently encountered in liquid-phase antifoam components. For example, copolymers [106392-12-5] of poly(ethylene oxide) and poly(propylene oxide) are used to reduce foam in the acid–gas scrubbing process (10). High molecular weight adducts of propylene oxide and polyhydric alcohols such as glycerol [56-81-5] and pentaerythritol [115-77-5] have also been reported to have useful antifoaming properties (11). Sometimes the polyether is mixed with other liquids, eg, poly(propylene oxide) [25322-69-4] and polydimethylsiloxane (PDMS) [9016-00-6]; sometimes the two materials are copolymerized.

Silicone oils are particularly effective antifoaming agents in nonaqueous systems because of their low surface tension and incompatibility. Polydimethylsiloxane (PDMS) is the most important silicone and is widely used in products for the petroleum industry, where its good thermal stability is very advantageous (12). Other useful silicone defoamers are polytrifluoropropylmethylsiloxanes [25791-89-3] and other fluorosilicones, which are very effective in nonaqueous foaming systems such as organic solvents and crude hydrocarbon stocks. Fluorocarbons are the most expensive class of antifoam fluid. Fluorocarbon oils and fluorine-containing amides such as the *N*-(alkylamino-trimethylene)perfluorooctanamides are used as antifoaming additives to lubricants and jet fuels (13).

Solid-Phase Components. Dispersed solids are vital ingredients in commercial antifoam formulations. Much of the current theory on antifoaming mechanism ascribes the active defoaming action to this dispersed solid phase with the liquid phase primarily a carrier fluid, active only in the sense that it must be surface-active in order to carry the solid particles into the foam films and cause destabilization. For example, PDMS, despite its considerable effectiveness in nonaqueous systems, shows little foam-inhibiting activity in aqueous surfactant solutions. It is only when compounded with hydrophobic silica [7631-86-9] to give the so-called silicone antifoam compounds that highly effective aqueous defoamers result. The three main solid-phase component classes are hydrocarbons, silicones, and fluorocarbons.

A variety of waxy hydrophobic hydrocarbon-based solid phases are used including fatty acid amides and sulfonamides, hydrocarbon waxes such as montan wax [8002-53-7], and solid fatty acids and esters. The amides are particularly important commercially. One example is the use of ethylenediamine distearamide [110-30-5] as a component of latex paint and paper pulp black liquor defoamer (14). Hydrocarbon-based polymers are also used as the solid components of

antifoaming compositions; examples include polyethylene [9002-88-4], poly(vinyl chloride) [9002-86-2], and polymeric ion-exchange resins.

In most cases, these active defoaming components are insoluble in the defoamer formulation as well as in the foaming media, but there are cases which function by the cloud-point mechanism (15). These products are soluble at low temperature and precipitate when the temperature is raised. When precipitated, these defoamer-surfactants function as defoamers; when dissolved, they may act as foam stabilizers. Examples of this type are the block polymers of poly(ethylene oxide) and poly(propylene oxide) and other low HLB (hydrophilic–lipophilic balance) nonionic surfactants. The use of soluble foam control agents has increased in recent years (7).

Pure silicone solids, such as silicone resins, are used in defoamer formulations, but the key material in this category is surface-treated silica, made hydrophobic by treatment with a silicone polymer or silane monomer. The development of these hydrophobic silicas (16) is widely acknowledged as one of the most significant advances in antifoam technology. They are used with a considerable variety of liquid components including hydrocarbons, polyethers, and silicones. The three most common ways of preparing the hydrophobic silica are to spray the silica with silicone oil and heat at 250–350°C, to treat with organochlorosilane vapors in an autoclave, and to disperse the silica in a silicone oil at elevated temperatures. Hydrophobic silica can also be produced by treatment with alcohols, fatty amines, and hydrocarbon waxes. The application of hydrophobic silica formulations as antifoaming agents has been reviewed with an emphasis on mechanism and use in textile dyeing (17).

Fluorocarbon solids are rare in defoamer compositions, presumably on account of their cost. Solid fluorine-containing fatty alcohols and amides are known. The most familiar fluorocarbon solid is polytetrafluoroethylene [9002-84-0]. It is not very effective in conventional hydrocarbon oil defoamer formulations because the particles aggregate strongly together, but in lower surface tension fluids such as silicone and fluorocarbon oils, the powdered polytetrafluoroethylene particles are much better dispersed and its performance is better (18).

Ancillary Agents.

Surface-Active Materials. The active defoamer components are necessarily surface active materials, but this ancillary category covers the surfactants that are often incorporated in the formulation for other effects such as emulsification or to enhance dispersion. Emulsifiers are essential in the common oil-in-water emulsion systems, but they are also required where mixtures of active liquid components are used. For example, specialized oil-in-oil emulsifiers are needed in defoamers based on silicone/polyether mixtures. oil-in-water emulsifiers are incorporated in some defoamers even when the final product contains no water. This is to promote emulsification (self-emulsifiable) or dispersion into aqueous foaming systems. These additives increase the speed of foam decay by promoting rapid dispersion of the defoamer throughout the foaming media. Examples of emulsifying agents used in defoamer compositions are fatty acid esters and metallic soaps of fatty acids; fatty alcohols and sulfonates, sulfates, and sulfosuccinates; sorbitan esters; ethoxylated products such as ethoxylated octyl or nonylphenols; and silicone-polyether copolymers.

Carriers. The function of a carrier is to provide an easily handleable, readily dispersible system for delivering the active defoamer components to the foaming

system and also to tie the complex defoamer formulation together, ie, coupling agents, compatibilizers, or solubilizers. Sometimes the carrier is used simply as an extender to lower the cost of the final product. Many of the low viscosity organic solvents that are used also exhibit some antifoaming properties in cases where they are both insoluble and of lower surface tension than the medium to which they are applied. Any of the usual paraffinic, naphthenic, aromatic, chlorinated, or oxygenated organic solvents can be used, but aliphatic hydrocarbons are the most common. Water is often used as a carrier fluid. In these cases, the defoamer product is typically an oil-in-water emulsion. With growing concern over unrecovered solvents, this has become a preferred type of defoamer formulation. Such products usually require preservatives to prevent bacterial spoilage in storage.

Sometimes the defoamer is required in a solid form, for example, to be suitable for incorporation into a low-sudsing detergent powder or agricultural chemical composition. Water soluble inorganic sorbent carriers such as sodium sulfate [7757-82-6], sodium carbonate [497-19-8], or sodium tripolyphosphate [7758-29-4] are used, as well as organic polymers such as methylcellulose [9004-67-5]. Sometimes the particles are further encapsulated with a coating that preserves the integrity of the defoamer formulation in storage with the detergents but allows disruption on contact with water in the wash process. When both the antifoam and the solid support are food-grade materials, they can also be used in food processing, brewing, and pharmaceutical applications.

Commercial Sources

The defoamer market is large and very specialized; suppliers differ markedly in orientation and in range of product lines. Some suppliers are large, international polymer producers with a basic manufacturing capability for the specific type of defoamer material they supply, whereas others are small, often regional, formulators who focus on the concerns of particular industries. The diversity of manufacture, supplier, product type, and application makes it impossible to present a comprehensive listing of commercial sources. Some compilations (19) are a useful source of available products. Table 1 shows significant defoamer suppliers (over five listings) in this compilation, together with one or two of their associated trade names.

Defoaming Theory

Foams are thermodynamically unstable. To understand how defoamers operate, the various mechanisms that enable foams to persist must first be examined. There are four main explanations for foam stability: (*1*) surface elasticity; (*2*) viscous drainage retardation effects; (*3*) reduced gas diffusion between bubbles; and (*4*) other thin-film stabilization effects from the interaction of the opposite surfaces of the films.

The stability of a single foam film can be explained by the Gibbs elasticity E, which results from the reduction in equilibrium surface concentration of adsorbed surfactant molecules when the film is extended (20). This produces an increase in equilibrium surface tension that acts as a restoring force. The Gibbs elasticity

Table 1. Commercial Defoamer Examples

Supplier	Trade name
Air Products and Chemicals, Inc.	Surfynol
Akzo Nobel Chemicals, Inc.	Propomeen

is given by equation (1) where σ is surface tension and A is surface area of the film.

$$E = 2A\mathrm{d}\sigma/\mathrm{d}A \tag{1}$$

In a foam where the films are interconnected, the related time-dependent Marangoni effect is more relevant. A similar restoring force to expansion results because of transient decreases in surface concentration (increases in surface tension) caused by the finite rate of surfactant adsorption at the surface. Such nonequilibrium surface tension effects are best described in terms of dilatational moduli. The complex dilatational modulus ε^* of a single surface is defined in the same way as the Gibbs elasticity as in equation (2) (the factor 2 is halved as only one surface is considered).

$$\varepsilon^* = A\mathrm{d}\sigma/\mathrm{d}A \tag{2}$$

In a dilatational experiment, where the surface is periodically expanded and contracted, ε^* is a function of the angular frequency (ω) of the dilatation

Table 2. Dilatational Elasticities and Viscosities of Crude Oil at 1 MHz[a]

Crude oil	Additive[b] identity	Additive viscosity, mm^2/s (= cST)	ε_d, mN/m (=dyn/cm)	η_d, mNs/m^2[c]

as in equation (3) where ε_d is the dilatational elasticity and η_d the dilatational viscosity.

$$\varepsilon^*(i\omega) = |\varepsilon|\cos\theta + i|\varepsilon|\sin\theta = \varepsilon_d(\omega) + \omega\eta_d(\omega) \tag{3}$$

A stable foam possesses both a high surface dilatational viscosity and elasticity (21). In principle, defoamers should reduce these properties. Ideally a spread duplex film, one thick enough to have two definite surfaces enclosing a bulk phase, should eliminate dilatational effects because the surface tension of an insoluble, one-component layer does not depend on its thickness. This effect has been verified (22). Silicone antifoams reduce both the surface dilatational elasticity and viscosity of crude oils as illustrated in Table 2. The PDMS materials are Dow Corning Ltd. polydimethylsiloxane fluids, SK 3556 is a Th. Goldschmidt Ltd. silicone oil, and FC 740 is a 3M Co. Ltd. fluorocarbon profoaming surfactant.

Both high bulk and surface shear viscosity delay film thinning and stretching deformations that precede bubble bursting. The development of ordered structures in the surface region can also have a stabilizing effect. Liquid crystalline phases in foam films enhance stability (23). In water-surfactant-fatty alcohol systems the alcohol components may serve as a foam stabilizer or a foam breaker, depending on concentration (23). Alcohol/surfactant ratios less than that corresponding to the liquid crystalline phase enhance film stability; higher ratios produced by contact with alcohol droplets disrupt this phase and cause film instability. Liquid-phase defoamer components may dilute or destroy such stabilizing phases or they may simply contribute lower surface shear viscosities than the foam stabilizing surfactant (profoamer). For example, the very low surface shear viscosity of PDMS (24) is often cited as a contributing factor to its effectiveness in defoamer compositions. On the other hand, too rigid a surface will also be prone to rupture. Thus, dilatational moduli that are too high will also result in foam instability, as in the case of diesel fuel antifoaming with a fluorosilicone antifoam agent (25).

Reduced gas diffusion between bubbles delays collapse by retarding bubble-size changes and the resulting mechanical stresses. Consequently, single films persist longer than the corresponding foam, but it seems to be a minor factor in

practical defoaming situations. The same is true of other thin-film stabilization effects from the interaction of the opposite surfaces of the film. These comprise both electric double-layer repulsion for ionic surfactants and entropic repulsion of polymer chains in the surface for nonionic materials. These effects are of paramount importance in determining the stability of very thin (less than 10 nm) films, but in practice the real challenge is usually to defoam films of at least several hundred nanometers in thickness where such effects have not begun to be significant.

All these mechanisms except high bulk viscosity require a stabilizer in the surface layers of foam films. Accordingly, most theories of antifoaming are based on the replacement or modification of these surface-active stabilizers. This requires defoamers to be yet more surface active; most antifoam oils have surface tensions in the 20–30 mN/m range, whereas most organic surfactant solutions and other aqueous foaming media have surface tensions between 30 and 50 mN/m. This is illustrated in Table 3.

Table 3. Surface Tensions of Surfactants and Defoamers

Material	CAS registry number	Surface tension,[a] mN/m (=dyn/cm)	Temperature, °C	References
Surfactants

In addition to having a lower surface energy than the foaming medium, defoamers must be insoluble in that medium, but also readily dispersible in it. There are five basic processes involved in the rupture of foam films by defoamers (7): entering, spreading, bridging, dewetting, and rupture.

The entering and spreading processes are governed by the entering coefficient E and the spreading coefficient S defined in equations (4) and (5), respectively (7), where σ_f is the surface tension of the foaming medium, σ_a the surface tension of the defoamer, and σ_{af} the interfacial tension between them.

$$E = \sigma_f + \sigma_{sf} - \sigma_a \tag{4}$$

$$S = \sigma_f - \sigma_{sf} - \sigma_a \tag{5}$$

The lower the value of σ_a, the more likely it is that E and S are positive, indicating a thermodynamic tendency for the processes to occur.

The displacement of the foam stabilizer and the mechanical disruption caused by these processes is sufficient to explain the function of defoamers which consist only of insoluble liquids such as silicone fluids used in the defoaming of crude oil. However, practical experience shows that blends of hydrophobic solids dispersed in the insoluble oil are generally necessary to control aggressive foaming, particularly in aqueous foam systems. Materials such as hydrophobic silica (17) or high melting point hydrocarbon amides such as ethylenediamine distearamide are notably effective. As an antifoam particle in a foam film approaches the air interface, an unsymmetrical thin film, known as a pseudoemulsion film (33), forms between the antifoam particle and the air phase. This psuedoemulsion film has a high stability in strongly foaming aqueous systems. Introduction of the hydrophobic particle into the oil drops destabilizes the pseudoemulsion film.

In such systems, bridging and dewetting effects are crucial to the defoaming mechanism. Once a defoamer particle such as hydrophobic silica has entered into a foam lamella, only then can it bridge the film. Subsequent dewetting of the particle by the foam film can then cause collapse by causing a small hole to form in the film. This hole rapidly expands, driven by surface tension effects, resulting in rupture of the film (34). The mechanical shock of this event can help propagate the defoaming action. For complete dewetting to occur, the contact angle must be greater than 90°, a requirement for defoamer action that has been well correlated for silicone-treated silica in hydrocarbon oil (35). Such dewetting helps thin the film and promote instability, and is particularly effective when sizes are such that the particle occupies both surfaces of the film. In this bridged situation, if the contact angle is large enough, a capillary pressure drop that pushes liquid away from the particle is developed (34). This flow results in migration of the air–liquid–solid interfaces toward each other until they meet and the film ruptures as it pinches off the particle. This concept offers an explanation for observed particle size and shape effects (2,18). Cinephotomicrographic studies are consistent with these dewetting ideas (36).

Debate continues about the detailed mechanisms of antifoaming by these synergistic combinations of insoluble oils and hydrophobic particles. These dewetting ideas imply that the hydrophobic particles become detached from the carrier

fluid. This separation accounts for the familiar experience of performance of antifoam compositions diminishing with time. Further additions of defoamer are needed to maintain effective foam control. Adsorption of antifoam components on other available surfaces, particularly in systems containing suspended solids, mutual saturation of foamer and defoamer changing the spreading and dewetting pressures, and coalescence of antifoam emulsions also contribute to this progressive loss of effectiveness. It has recently been demonstrated that exhausted or deactivated oil/silica defoamers segregate into two distinct populations of globules (silica-free and silica-enriched), neither of them being active defoamers (37). In addition, the spread oil layer disappears from the foam solution surface. The defoamer can be reactivated by addition of fresh oil without silica (37) which allows the entering and spreading mechanisms to function again, carrying in particles which can then bridge and dewet. Another interesting aspect of the dewetting/bridging action is its location. Most researchers explain the defoaming action in the foam films, although others (38) claim it occurs in the plateau borders of the foam. This theory can account for the fact that the typical size of antifoam drops (3–50 μm) is much larger than a typical foam lamella thickness, and also that smaller antifoam droplets are ineffective foam breakers.

Applications

The main industries and broad product groups that utilize defoamers are indicated by the subheadings in this section. These examples illustrate the wide variety of defoamer applications. Other application areas worthy of mention are agriculture and medical, particularly the use of antiflatulence tablets.

Adhesives and Sealants. Most industrial adhesives contain surface-active components and additives, and air entrainment during their mechanical application can significantly reduce joint strength. Defoamers are usually formulated into adhesives to protect users against such difficulties. Additional benefits such as improved uniformity of products, increased throughput, and reduced labor costs can also result from the use of defoamers during adhesive application. The footwear and nonwoven fabric industries are extensive users of defoamers in this way.

Chemical Processing. Agitation, distillation, and pressure differences are commonplace in many chemical processes. These are conducive to foam formation, and even when the plant design minimizes these problems it is still often necessary to employ defoamers. A review of this field (39) lists numerous problems encountered with unwanted foam in chemical processes: increased cost of coping with safety hazards from slippery floors, corrosive residues or flammable liquids; interference with process instruments, pumps, etc; slow drainage of liquids from products being dried; product rejection due to incompletely filled containers; reduced capacity in vats; premature failure in bearings and other mechanical devices because of loss of lubrication; separation and segregation of critical process ingredients; and perceived negative environmental impact and poor community relations on discharge.

Cleaning Compounds. A growth area for defoamers is in the formulation of low-foaming detergents and cleaners. This is in response to automation of

cleaning equipment and the need to operate it optimally. Changes in detergent composition and washing machine design have also had a significant impact on the need for foam control in this application (40). Incorporating defoamers in detergents in such a way that the low-foaming property does not drift with storage time is a considerable challenge. The antifoam composition has to survive storage with the surfactants, builders, bleaches, and other auxiliary agents, and yet function properly as soon as the detergent is added to the wash water. The solution is to prevent the defoamer from migrating within the detergent powder matrix such that the droplet size of the defoamer released into the wash water is the same regardless of storage conditions. Numerous patent examples of the four general ways in which this can be achieved have been provided (41): encapsulation in a water-soluble or water-dispersible wax, adsorption onto a carrier prior to wax coating, microencapsulation with film-forming polymers, and adsorption onto specially prepared inorganic salts.

Construction. Polymer dispersions in cements, mortars, and plastics are being increasingly used in the construction industry (11). Their plasticizing effect allows reduced amounts of water to be used, and they also confer strength and adhesion benefits in certain situations. The emulsifiers and dispersants used in these products can cause air entrainment problems with a detrimental effect on the ultimate stability of the construction. Powdered defoamers that can be directly added to the cement are commonly used. They are usually high surface area, highly absorbent inorganic fillers that have been treated with liquid defoamer compositions, similar to the products used in low-foaming detergents. Another approach to this problem is for the latex manufacturers to formulate low-foaming polymer dispersions with appropriate defoamers having good long-term stability.

Fermentation Processes. The efficient production of penicillin, yeasts, and single-celled protein by fermentation requires defoamers to control gas evolution during the reaction. Animal fats such as lard [61789-99-9] were formerly used as a combined defoamer and nutrient, but now more effective proprietary products are usually employed. Defoamer application technology has also improved. For example, in modern yeast production facilities, the defoamers are introduced by means of automatic electrode-activated devices. One concern in the use of defoamers in fermentation processes is the potential fouling of membranes during downstream Ultrafiltration. Silicone antifoams (42) seem less troubled by this problem than other materials.

Fertilizers. The fertilizer industry for many years has used tall oil fatty acids for the production of phosphoric acid [7664-38-2] by the digestion of phosphate-containing rocks with sulfuric acid. Carbon dioxide is liberated and presents a difficult, highly acidic foaming problem. Formulated products, many of which continue to contain tall oil fatty acids but which also contain emulsifiers and wetting agents such as dioctyl sodium sulfosuccinate [577-11-7], which greatly increase their effectiveness, are now used. Partially wetted gypsum particles contribute to the foam stabilization, and it is the modification of the gypsum wettability by these wetting agents that makes them so effective in this application.

Food and Beverages. Defoamer applications in the food and beverage industry include uses in both the preparation and processing of foodstuffs and in the cleaning and disinfecting of containers. Poly(alkylene oxide)-based defoamers

have played an important role in satisfying the foam control demands of this industry (43). The sugar beet industry is a prolific user of defoamers. This is now a fully mechanized automated procedure. The sugar is extracted with hot water, treated with limewater and carbon dioxide, filtered, and the filtrate subjected to evaporation. Foaming occurs in many of these steps. Another food processing area with considerable foam problems is the production of chips, fries, mashed potatoes, and potato starch. Proteins, starch, and other natural products in potatoes cause troublesome foams in wash baths. Beers and wines are also produced with the aid of defoamers. They permit more efficient use of vats and containers, and permit more controllable bottling procedures. The growth in returnable bottles and the widespread use of automated mechanical cleaning equipment has increased use of defoamers in this industry. They can be used directly or incorporated in low-foaming cleaning agents. It is important to note that foams occurring in food processing are generally stabilized by surface-active macromolecules, such as proteins or starch, instead of the more usual small-molecule surfactants, and this is reflected in the composition of defoamer products for these applications.

Leather. Almost every stage in leather processing, from the initial rawhide preparation, through tanning and dyeing and other finishing treatments, has the potential for causing foaming difficulties. Many of the preparations used in these steps contain wetting agents and other surfactants, or are applied in the form of emulsions or dispersions. The trend, as with many other defoamer applications, is to formulate the defoamer into the treatment product rather than deal with numerous optimized defoamers at each of the several processing steps.

Metal Working. The metal working industry encounters considerable foaming problems with the cutting oils and coolants that are sprayed onto the tool–workpiece interface to provide cooling, controlled lubrication, corrosion protection, and increased tool life. These coolants are provided as mineral oil/emulsifier concentrates that are diluted with water by the user. For many years, this industry tolerated the foam difficulty in its many milling, drilling, grinding, rolling, and drawing operations, but now uses defoamers such as formulated silicones and dispersions of fatty amides in mineral oils. Calcium soaps are also used as foam inhibitors in coolants. They are formed as a finely divided suspension of insoluble particles when the soaps present in the cooling lubricant concentrate react with hardening agents added to the dilution water.

Oil and Petrochemicals. There are a variety of uses for defoamers in oil recovery. They are used in some of the materials used in oil extraction, such as in drilling muds and cement lining, and also directly with the crude oil itself. In its natural state, crude oil contains dissolved gases held by high reservoir pressure. When this live crude oil is extracted and passed into the low pressure environment of a gas–oil separator, the dissolved gases are liberated and can cause troublesome foam that leads to oil losses via the gas stream and downstream equipment damage (44). Foaming is a problem in other petrochemical operations including distillation, cracking, coking, and asphalt processing. Defoamers are also used in the downstream petroleum market in lubricating oils and diesel fuel. The areas involving the application of oil and petrochemicals and the area of coatings(discussed below), are ones where not only the elimination of foam is important, but also the elimination of individual bubbles. This problem of deaeration

can only be dealt with using specifically designed products. Foam control agents can break foam lamellae once they are formed between bubbles but the defoamer generally cannot remove or accelerate the movement of individual air bubbles.

Coatings. Foam problems occur both during the preparation of paints and coatings and in their application. The use of ball mills and other equipment for pigment dispersion provides ideal conditions for mixing in air, and the presence of surfactants in the formulations assures considerable persistence of the foams that are generated. These problems may be controlled during manufacture by mechanical means, but a defoamer is almost always required for foam control during application since application methods vary considerably, for example, roller, brush, dip, or spray methods. The proper choice and minimum use of surfactants such as dispersants, flow agents, and wetting agents can minimize but not eliminate the use of defoamers to prevent surface defects during application such as cratering, pinholes, fisheyes, and orange peel. In addition to the final dried film appearance, the defoamer must not detract from other properties such as color acceptance, gloss, and adhesion.

Polymers. Foam is often a particular problem in the production of polymers. There are numerous situations where foam can reduce the production capacities of vats and vessels and cause problems in pumps, meters, and other equipment, particularly distillation and evaporation equipment. Foam is frequently a problem when stripping off a monomer from a polymer. Examples are in the production of styrene–butadiene [9003-55-8] and acrylonitrile–butadiene [9003-18-3] rubber latices. These latices are stabilized by surfactants that greatly contribute to foaming difficulties. Another problem foam area is in the stripping of unreacted monomer from poly(vinyl chloride) suspensions. In this process, vinyl chloride [75-01-4], a gas at room temperature, is liquefied by pressure, emulsified in water with surfactants and catalysts, and heated to bring about polymerization. The recovery of unpolymerized monomer by distillation from this mixture produces a severe foaming problem.

Pulp and Paper. The critical and troublesome foam problems of this industry have led the way in the use of defoamers. It is the world's biggest single user of defoaming agents (45). Early use of large amounts of kerosene or fuel oil has given way for ecological and cleanliness reasons to much more effective formulated defoamers. Foams are encountered at every stage from pulping, through paper fabrication and coating, to printing. A variety of wastewater streams are generated that are very prone to foaming because of the presence of dissolved soaps. Specific defoamer products are often tailored for each different stream. The so-called black-liquor defoamers were the first hydrophobic silica in hydrocarbon oil products that were then extended to other industries. The use of these defoamers has allowed some Kraft pulp mills to exceed original designed capacity.

Textiles. Defoamers are required in the jet dyeing of textiles (17). This process, which is mainly used with polyester fibers, is carried out at elevated temperature and pressure, and involves pumped recirculation of the dyeing medium from the reservoir through the jets. When the operation is complete and the pressure released, severe foaming can result in the absence of an effective defoamer. Foam control is needed in other dyeing processes also (17), such as continuous dyeing and beck dyeing. For example, in the dyeing of knitted fabrics of textured

polyester fibers, foaming of the dye liquor can cause the material to float, resulting in uneven application of the dye. Various surfactant mixtures are used in this area and bring additional benefits such as wetting and solubilization as well as foam control. Acetylenic glycols are very useful in this context (9). Dyeing is only one of several steps where foaming can cause difficulties with fiber processing. Defoamer may be required when any size or finish is applied to a textile material. One example is the pretreatment step in the processing of cotton. The fabric is exposed to strongly alkaline sodium hydroxide and anionic surfactant solution. Phosphate ester defoamers are much used in this application. Textile operations are also notorious for their wastewater foam problems.

Wastewater Treatment. Defoamers are used extensively to treat wastewater in many municipal and industrial treatment facilities and also in mining and mineral processing. Benefits are aesthetic, environmental, and economic. Aeration basins are rid of unsightly, troublesome foam, and water and energy are conserved by allowing more efficient use of mechanical equipment. Most foaming problems occur either at the biological treatment step or the effluent discharge step (46). Aeration is necessary in biological treatments to allow microorganisms to breathe, but the agitation produces foam. Defoamers that do not disrupt this process must be selected. Some of the upstream processes may depend on foaming and other surface-active phenomena such as flotation and flocculation steps, and care must also be taken to use defoamers that do not interfere with these processes if treated streams are recycled. Effluent foam discharge is illegal in some countries including the United States where the EPA prohibits discharge of floatable materials in the effluent stream (46).

Economic Aspects

Accurate information on the size of the defoamer market is impossible to obtain. There are too many types of materials and suppliers involved. Particularly for the more common oils and surfactants, defoaming is a very small part of their total usage, and no public information is available on what fraction of manufacturers' sales is in the area of foam control. Even for more expensive materials such as the poly(alkylene oxide) block copolymers, there is no way of distinguishing between their use as defoamers and other significant surfactant uses such as de-emulsifiers.

In 1993 the Encyclopedia estimate for a market for defoamers of all types was 150,000–170,000 t per year in the United States, with the rest of the world slightly exceeding that amount. The principal use area of pulp and paper accounts for between a third (47) and a half (45) of this usage. With modest growth in some markets offset by improvements in efficiency in others, the 1993 estimate remains an adequate one for 2000. No typical selling price for defoamers can be quoted because of the wide diversity of active materials and product types. The cheapest unformulated defoamer types cost as little as $0.6/kg in bulk quantities, whereas some custom-tailored defoamers cost over $5.0/kg. Usages vary from less than 0.1 kg of defoamer per ton of product to over 2.0 kg/ton of product, and it is not the unit cost of the defoamer that matters but the cost per unit of product produced that does. It often occurs that the controlled use of a relatively expensive

defoamer results in a lower cost per unit of product than use of an inexpensive defoamer.

Test Methods

The ultimate test of a defoamer is an actual field trial, and occasionally this is the only testing carried out. More usually some laboratory-scale evaluation of several different products is conducted before a recommendation is made for a suitable, economical defoamer for a specific application. Although suppliers have their chosen standard foaming surfactants, it is usual to work with the potential customer's foaming medium. Often, this work is done at the plant site to obtain fresh foaming liquors. Establishing that a given defoamer is effective in a particular application is only part of the testing required. The absence of any adverse effect on the final product and the manufacturing and use environments must also be determined. In addition, to be marketable the defoamer must be cost-effective and convenient and easy to handle for the customer. A useful account of the practical selection of defoamers has been given (39).

There are many laboratory methods for testing the relative merits of one defoamer against another. It is a simple matter to measure foam height as a function of time to compare the performance of various foam surfactants and defoamers. Unfortunately, this simplicity has led to a wide variety of methods and conditions used with no standard procedure that would make the measurement of foaminess as characteristic of a solution as its surface tension or viscosity. It has been suggested that the time an average bubble remains entrapped in the foam Σ is such a quantity (48), but few workers in the defoamer industry have adopted this proposal. One reason for this is that the measurement is not practical with strongly foaming materials, the steady-state foam height being very high and hard to reach. Nishioka et al. (49) describe dynamic methods for measuring Σ in their review of fundamental methods for measuring foam stability. They also observe that the decay of static foam is measured, most fundamentally, by the change with time in the size distribution of bubbles in a foam. This can be done by photomicroscopy of flash-frozen samples, a method that although somewhat tedious, is recommended for periodic confirmation of other less direct methods whenever possible. In practice, a wide variety of simpler methods are used that generally fall into one of five main categories:

(1) **Pneumatic methods.**

Gas introduction is controlled by injection through capillary tubes, sintered-glass spargers, diffuser stones, and the like.

(2) **Dynamic methods.**

This is a subdivision of the pneumatic class; foam heights or volumes are monitored while the gas continues to produce bubbles.

(3) **Shaking methods.**

Agitation is the easiest way of producing foam, but the results are very dependent on the details of the shaking procedure. Foam height, or for more viscous fluids specific gravity changes, are usually measured.

(4) **Pour methods.**

The liquid is poured or drained from one vessel into another. This approach is best limited to foams produced from dissolved gases in the liquid.

(5) **Stirring and blending methods.**

Like shaking methods, these are very dependent on procedural and equipment details, but they are simple to use and are widely employed for comparative purposes.

This diversity of test methods is reflected in ASTM recommendations (50). Pour (D1173-53 [reapproved 1986]), shaking (D3601-88), and blending (D3519-88) methods are suggested for aqueous solutions. Pneumatic methods are recommended for lubricating oils (D892-89) and engine coolants (D1881-86). Despite their omission by ASTM, dynamic methods are probably the most satisfactory for defoamer evaluation (12,41). The foaming solution is usually recirculated through a vertical cylinder where foam heights can be measured as a function of time. In such a device, a steady state can be achieved with a given foamer system and defoamer metered in at selected concentrations. The test enables various important defoamer characteristics to be measured such as the knockdown time, the time taken to collapse a preformed foam, and the persistence or hold-down time, the time taken for the foam to recover to some agreed level such as half its original height (defoamer half-life).

Health and Safety Factors

Defoamers are usually added at low bulk concentrations ranging from a few to a thousand parts per million of the foaming medium. Often the health risk posed by such additives is negligible compared to that of the material being defoamed. Such is the case in the defoaming of asphalt (qv) and phosphoric acid. Sometimes a specific defoamer type/foaming medium combination presents a particular problem and, so the supplier should always be involved in defoamer selection. Examples are the increase in flammability of polyester textiles with free PDMS (17), and the possibility that mineral oil antifoams may contain precursors that form dioxins in bleached pulp after chlorination (51). Health and safety concerns arise primarily in applications in the food and drug industries. Defoamers can be incorporated directly into these products, as in the production of sugar from sugar beets or in the

defoaming of fats for frying potato products, and indirectly, as in the manufacture of paper or plastic packaging materials.

U.S. government regulations governing the use of additives such as defoamers in food and drugs are listed in the Code of Federal Regulations (CFR). Title 21 contains the rules established by the Food and Drug Administration; Title 40 covers those that are the concern of the Environmental Protection Agency. For example, part 173.340 of Title 21 deals with defoamers that may be safely used in processing foods, whereas Part 180.1001 of Title 40 lists those materials exempt from the requirement of tolerance levels in pesticide chemicals, including defoamers used therein. Other parts of Title 21 that cover defoamer uses include 176.200 on coatings and 176.210 on the manufacture of paper and paperboard. One defoamer is also used as an active drug ingredient—the antiflatulent silicone, Simethicone [8050-81-5]. Such use is regulated by the FDA under part 332 of Title 21. Regulations are subject to change and the CFR is revised at least once each calendar year. It is also kept up-to-date by the individual issues of the *Federal Register*, a daily government publication.

Although the intent may be the same, the details of regulatory practice differ in other countries, and a multitude of regulations exist worldwide. Under the auspices of the Joint Expert Committee on Food Additives of the FAO–WHO, efforts are being made to establish international guidelines. However, given the changing regulatory climate, the differences in practice between countries, and the wide range and regional differences of antifoam components available, the best advice for those interested in health and safety aspects of defoamers is to contact the producers directly. Their skill and experience are the best defenses against safety hazards associated with the use of defoamers.

ATOMIC FORCE MICROSCOPY

Introduction

From their early beginnings in thermoset resins to the breakthrough thermoplastics of the mid-twentieth century and the liquid crystalline materials and other high performance materials of the 1970s to the present, polymers have established key roles in all sectors of human endeavor. From transportation to construction, microelectronics, and packaging, use of polymeric materials contributes to prosperity and performance. Development of new polymers for use as stand-alone materials, polymer solutions, blends, or composites is at the core of macromolecular science. It is in this arena where the disciplinary efforts of synthesis, structure, properties, and performance hybridize into a tetrahedral coordination of interdisciplinary research and engineering. While confirmation of chemical fidelity is highly advanced, the ability for structure and property determination at submicrometer scales is lacking. Most recently, the advantages of Nanocomposites are becoming clear (1) and this trend will continue only to the extent of the ability to characterize these new materials. Moreover, processing of polymer materials is critical to device performance, and affects the microstructure of semicrystalline castings as well as the nanostructure of mechanically strained or drawn films (2). The atomic force microscope enables characterization of these materials and therefore the development of more new materials.

The microscope is an invaluable tool to the materials scientist. There are two quantities that enable microscopy: contrast and resolution. Sensitivity is not inherently an issue in microscopy: signal level is not limiting because it is now possible to count single photons and electrons. Contrast and resolution determine one's ability to see at all scales. Contrast is the ability to measure changes in signal with a detector. The detector can be your eye, a CCD camera, or an

Encyclopedia of Polymer Science and Technology. Copyright John Wiley & Sons, Inc. All rights reserved.

electronic amplifier. The contrast of the signal can be from intensity changes, spectral changes, phase differences, scattering of electrons or ions, transmission of tunneling electrons, or force on an atom from a probe, amongst others. Without contrast there can never be resolving power. Resolution is defined as the smallest distance between two points in a sample, that one can detect as a change in signal. There are two modes to operate a microscope. The difference between far-field detection mode and near-field detection mode is that in the former the detector is "far" away from the signal source. When the source-to-detector distance is several times the wavelength of the signal, the system displays its wave character and is therefore subject to the diffraction limit of light. This is a fundamental limit and is a result of Heisenberg's uncertainty principle (3), which is of course a result of one of the postulates of quantum mechanics. Near-field detection does not require wave propagation of the signal. Therefore, resolution is determined by the size of the probe or pinhole detecting the signal. To increase the resolving power of the microscope, the tip of the probe needs to be smaller. This is the concept that drives the maturing area of scanning probe microscopy and is what makes the scanning tunneling microscope and atomic force microscope so powerful.

Since the development of the scanning tunneling microscope (stm) in 1982 by Binnig and Rohrer (4) (Recipients of the 1986 Nobel Prize in Physics for this discovery), the capabilities of microscopy in general have been pushed to previously unrealizable capabilities. The enhanced resolving power of the stm is attributed to the special contrast mechanism it employs. An stm operates in the near-field detection mode and is therefore not limited by diffraction as described above. In fact, only the interaction area of a local probe with the sample determines the limit of its resolution. This interaction area is actually difficult to access and strongly depends on the experimental method and the sample under study. The contrast mechanism of the stm is due to changes in the local density of electronic states at the sample. This results in a position sensitive quantum mechanical tunneling current flowing between the metal stm tip and the electrically conducting sample. Polymers, in general, are not good conductors and are therefore not typically examined with an stm. Fortunately the concepts and the technology of the stm have been applied to many other contrast mechanisms. This class of scanning probe microscope (spm) has revolutionized surface science and has enabled a nanotechnology already yielding useful new advanced materials.

Various contrast mechanisms have been deployed toward studies of materials and polymers. In general, any physicochemical signal that can be measured by a probe or through an aperture can be developed into an spm, where the resolution of the subsequent microscope is governed by the sample-to-probe distance dependence of the measured signal. Specifically the "P" in spm can be replaced by "near-field optical" (5) or "capacitance" (6,7) or "magnetic force" (8) or "thermal" (9) or "acoustic" (10) or "electron spin resonance" (11) or "nuclear magnetic resonance" (12) or "thermovoltage" (13–16). Other variants are too numerous to be inclusive. The late 1980s to early 1990s can be thought of as the renaissance period of spm inventions.

Microscopy of polymer surfaces and their high spatial resolution analysis is accomplished typically with the atomic force microscope (afm) used in various modes of operation. The contrast mechanism of the afm is the interatomic forces between the scanning probe and the sample's surface. The forces are measured

easily and result from the mean pairwise potential energies of the interacting atoms. Extracting the exact form of the potential energy versus tip-to-sample position is difficult with regard to the microscopic detail. However, it is generally described by a steep attractive interaction followed by a very steep repulsive interaction at closer separation. It is the shortness of range of this interaction energy that enables the near atomic resolution commonly provided by the afm.

Analysis

Synthesis and processing are integrally important when designing for the properties and performance of a polymer system. Bulk characterization of the system is often not enough to predict, control, and maintain desired system performance when surface interactions and particle incorporation are significantly involved. The discovery, development, and optimization of new polymeric systems (eg, composites, films, or fibers) often require ensembles of analytical investigation; no one technique is enough. The cohort of surface analytical techniques is voluminous and not appropriately reviewed here (17). It is, however, important to realize that the spatial resolution of an analysis is both technique- and sample-dependent. Atomic force microscopes are versatile analytical tools. They excel at topographic characterization of surfaces. Moreover, they can be used to probe the identity of chemical constituents at a surface and the mechanical properties of the near-surface region, both with high spatial resolution.

Imaging. Mechanical design and control of the afm is now mature. Early in its development there were some design constraints similar to all models (7,18–24). Notably, reduction of environmental noise, sharpness of the tip-probe asperity, and sensitivity of the force transducer are the most critical design elements. By far, the most commercially successful afm design is based on the laser-diode optical lever (24) coupled to an integrated micromachined Si or SiN cantilever and tip (25), as illustrated in Figure 1. There are several limitations to the resolving power of an afm; noise being one of the more benign and easily removed. Since the tip is not infinitely sharp and the tip or samples are not infinitely hard (ie, they have measurable Young's moduli), the resultant micrograph will be a convolution of the chemical, physical, and topographic properties of the entire system. This is a very important point since an artifact is only realized in hindsight.

For the idealized case of hard materials, an extremely small/sharp tip and a relatively flat sample, the principal concern is tip–sample convolution artifacts (26). Typical, commercially available afm probes have tips with radii of curvature of the order of 30 nm and with varying aspect ratios. As the topographical relief of the surface increases so must the aspect ratio of the tip. A common artifact found in samples of high relief is that the sample is actually imaging the shape of the tip instead of the converse. Since the quality of a tip varies with manufacturability and with use, overinterpretation of image structure without knowledge of tip-shape is ill-advised. A second common artifact, for the idealized sample, is observed when there is significant thermal drift, and nanometer spatial resolution is desired. Polymers have large coefficients of thermal expansion (eg, several hundred ppm/°C). Image acquisition with the afm is accomplished by raster scanning the probe across the sample. The scanner displaces the probe relative to the

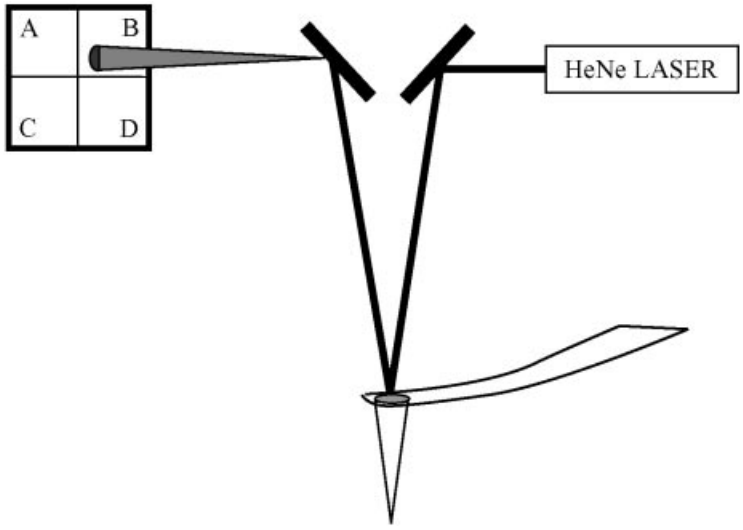

Fig. 1. Commercial afm design.

sample, one line at a time. Each line is typically scanned at a rate of many hundreds of nanometers per second in the "fast-scan" direction. After the scanner repositions the probe to the beginning of the first line, it steps down the "slow-scan" direction. This process is linear and slow. Therefore, any thermal drift will be convoluted mainly with the slow-scan direction. The effect will be to distort the image. This artifact is corrected for by subtracting out thermal drift (assuming it is constant) or by rotating the scan direction by 90°. Another common misinterpretation of afm images occurs when periodic structure is being investigated. In general, any periodic structure that is either parallel to or perpendicular to the scanning direction should never be believed. Sinusoidal noise in any number of the system's components will look like periodic structure perpendicular to the scan direction. Since the noise will most likely be out of phase with the scanning frequency, the image will appear to have a "crystalline" structure. Rotating the scan direction will not change the image. Also, spm data should not be accepted as true unless it has been reproduced at several scan speeds, several scan dimensions, a couple of scan directions, and in several areas of the sample. An afm is very powerful and can be made to generate any possible image, regardless of its validity.

There are several operating modes where the afm can generate microscopic contrast. These various modes can help deconvolute topographic relief from chemical and mechanical surface inhomogeneity. Topographic information is most precisely obtained in "contact" mode where the afm probe is very close to the sample and interacts with the repulsive potential energy of the surface. This is arguably the point at which the probe "touches" the sample. As long as the cantilever force transducer is significantly softer than the material being scanned over, such that excessive (force)/(contact area), that is pressure, does not perturb the sample, the afm will accurately trace the surface. This is an idealized situation since there will always be some deformation of the polymer surface by the probe even at static,

zero applied force F conditions. The perturbed contact area of radius a is described in the Johnson–Kendal–Roberts (JKR) (27) theory of adhesion mechanics as

$$a^3 = \frac{R}{K}\left[F + 3\pi R W_{\text{tip-sample}} + \sqrt{6\pi R W_{\text{tip-sample}} F + \left(3\pi R W_{\text{tip-sample}}\right)^2}\right]$$

where R is the mean radius of curvature of the tip and sample, $W_{\text{tip-sample}}$ is the tip–sample surface energy, and K is the weight averaged elastic moduli (28). For typical polymer systems, this result would predict a "contact" radius of 1–2 nm even for zero applied force. This seems to preclude atomic resolution with the afm; however, the JKR theory does break down at these small length scales. The afm can resolve atoms on "soft" materials, but it is difficult. Nanometer scale spatial resolution is more easily obtained, and in general, the resolution is inversely proportional to a material's elastic moduli.

While in contact mode, the user can collect both sample height and probe force information as the probe scans across the surface. In feedback mode (or height mode), the afm tries to maintain a constant applied force by driving together or retracting apart the tip from the sample as the probe is scanned. Ideally this would follow the topography of the sample, as the force would remain constant. This "height mode" has two advantages over the "force mode" with the feedback control turned off. Since the system is trying to keep a constant force, it is less likely to damage soft polymer surfaces having significant topographic relief. Moreover, the height mode provides a direct measure of the sample's topography. When the afm is operated in force mode (still addressed as contact afm), the probe-to-sample distance is not changed rapidly with varying topography. Therefore, as the tip travels over higher areas of the sample, the interatomic forces increase, resulting in the upward bending of the probe's cantilever. This mode has the advantages of allowing high scanning speeds and providing images with less noise and scanning artifacts. These come at the expense of not being able to acquire accurate and direct height measurements of the sample, and there is the possibility of more damage by the tip onto the polymer surface than when running in height mode. If only qualitative microscopy is required, force mode is the more useful technique.

An afm cantilever is flexible in several directions (29); it can be bent up and down to measure vertical displacement of a sample and it can be torqued about its long axis because of the moment applied to the end of the scanning tip. Because of the phenomena of friction and Newton's third law, there will be a measurable force applied to the tip, which is perpendicular to the load force applied normal to the sample. While the probe is scanning, this results in the twisting of the cantilever. Modern afms detect the reflection of a diode-laser from the end of the cantilever onto a position sensitive four-quadrant photodetector. The laser spot deflection is illustrated in Figure 2. The total laser power on the detector is the sum of the signal from each quadrant, $T = A + B + C + D$. Changes in sample height will cause the cantilever to deflect up or down, and the signal is recorded as $\delta H = [(A + B) - (C + D)]/T$. Simultaneously the cantilever may twist because of the frictional drag on the tip as it is pulled over the sample. The torque will deflect the laser beam horizontally and the "friction" signal is recorded as $\delta f = [(A + C) - (B + D)]/T$. Since friction is related to both surface chemistry and surface roughness, the two signals may not be independent. Variations in surface

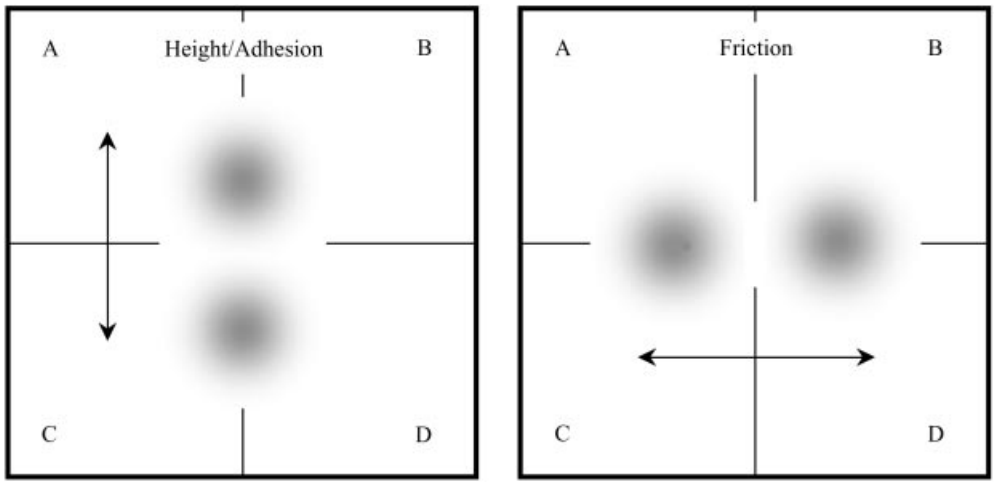

Fig. 2. Laser spot deflection.

composition are easily detected in force mode, whereas the topography signal may not detect any change in the surface character (30–33). Although differences in surface composition are sought with friction mode afm, friction forces can be dominated by the near-surface yield strength of the polymer and by any adsorbed water vapor forming a meniscus at the tip–sample contact (33).

By chemically modifying the surface of the tip with self-assembled monolayers of alkanethiols, the surface free energy and therefore the frictional drag on the system can be reduced. This technique has been used to obtain superior images of biaxially oriented PET films that are typically degraded by standard contact afm (34). Friction force studies provide another viable contrast mechanism for high spatial resolution microscopy of inhomogeneous polymer surfaces. However, it is very difficult to get absolute friction forces and thereby the coefficient of friction. Relative changes in frictional drag are measurable and aesthetic. Chemical modification of afm tips used in friction mode defines another category of "chemical force" microscopy. Selecting the terminal group at the surface of the tip (ie, making it more hydrophilic or hydrophobic) enhances the contrast of friction studies on chemically inhomogeneous surfaces (35). Even when there is no apparent change in topography, chemical force microscopy can define nanometer scale domains on polymer surfaces. Since friction is an energy dispersion phenomenon, we expect variations with surface temperature. In fact, scanning friction microscopy can be used to measure the viscoelastic properties of the near-surface region of poly(ethylene terephthalate), poly(methyl methacrylate), and polystyrene (PET, PMMA and PS, respectively) (32). As the temperature of a polymer surface increases, there are more available energy modes to dissipate the energy absorbed during the tip sliding process. These modes are intrinsic to the chemical composition near the surface.

Contact mode afm inherently damages soft materials. This is useful when trying to study wear resistance; however, it is deleterious to image quality and surface processing studies. Alternatively, the afm can interact with the attractive

potential energy, just above the surface and therefore not "touch" the surface or be dragged across it during a scan. The attractive force microscope was developed early in the evolution of the spm (19) explicitly to minimize sample perturbation from the scanning probe. It is difficult to maintain a stable mechanical system when the tip is being held a few nanometers away from and being attracted to the surface. Thermal fluctuations, scanning irregularities, sample inhomogeneity, and most importantly, capillarity affects from adsorbed water layers all contribute to this instability where the tip suddenly and unintentionally snaps onto the surface. To improve the attractive force mode, stiffer cantilevers were used. For contact afm of polymer surfaces, the softest cantilever that gives reliable scanning should be used. However, for noncontact mode, system stability requires that the force constant of the cantilever be greater than the force gradient $\partial F/\partial z$ felt by the tip near the surface, which gets larger as tip–sample separation z decreases. Moreover, lateral resolution decreases rapidly with increasing separation. For these and other mechanical design criterion, very high force constant ($k > 100$ N/m) cantilevers should be used. The trade-off in using stiff levers is that they do not deflect enough to detect the already small tip-surface forces (Recall Hook's law for a spring, $F = kz$). Various techniques were deployed to increase the sensitivity of the stiffer systems. Of these ac detection schemes, the most sensitive was heterodyne interferometry (8,23).

AC detection techniques in afm are similar in that they all oscillate the cantilever by driving the damped spring system with a sinusoidal input. The amplitude of oscillation of the free "undamped" probe A_0 is frequency dependent and reaches a maximum at its resonance frequency $\omega_0 = \sqrt{k/\mu}$ where μ is the effective mass of the probe. When the cantilever is very far from the surface, the undamped tip oscillation lags behind the sinusoidal driving signal by 90°. As the probe is brought closer to the surface, the attractive van der Waals forces pull down on the tip during the approach phase of the oscillation. This drag damps out the amplitude of oscillation by changing the effective mass of the cantilever, thereby moving the system off resonance with the driving frequency. Since the amplitude change is very sensitive to the average tip–sample separation, it can then be used to generate sample contrast and be deployed as a feedback mechanism to track sample topography. The principal disadvantage of this technique is the loss in lateral resolution because of the more gentle slope of the potential energy versus distance curve at these necessarily larger separations.

A significant advance in the development of "noncontact" afm is a new "tapping mode" afm (tmafm) (36,37). The required equipment for tmafm is similar to that for attractive force afm; however, the amplitude of oscillation A_0 is set to be much larger (typically >20 nm vs <5 nm for attractive force mode). Because of the larger amplitude, there is more energy stored in the cantilever as it accelerates away from the surface, thereby reducing the sticking instability discussed above. TMAFM actually intermittently "touches" the sample and the repulsive portion of the interatomic potential therefore affecting its motion, whereas noncontact afm involves only the attractive portion (38,39). As the oscillating tip is brought closer to the sample and starts to tap the surface, the system undergoes a transition from attractive mode to tapping mode and the "damped" oscillation amplitude decreases linearly and sensitively with average tip-surface separation. Again, this decrease in amplitude is used as a set point for feedback control of the

probe. Interatomic potential functions rise very steeply in the repulsive regime. Since the tmafm tip contacts the surface at each oscillation (>10,000 samples per second), the lateral resolution found in contact mode afm is regained or surpassed (40). As with contact mode, tmafm can also operate in liquids (40,41) although interpretation of the images is less clear because of the mechanical response of the fluid. To reduce friction-induced surface damage from contact mode afm, samples and probes are typically immersed in a liquid, which reduces the attractive capillarity force loading the tip onto the sample. With tmafm the tip contacts the sample for a very small percentage of the time and the repulsive forces at contact are still as small, or smaller, than those found in contact afm. Since the tip is most likely not contacting the surface when the probe is scanned laterally, there will be no frictional drag, effectively eliminating friction-induced damage. TMAFM has solved many of the damage and scanning artifact issues present in afm imaging of soft materials (eg, polymers, monolayers, and biological materials). Tapping mode is far superior to other afm modes for imaging and is currently the recommended state of the art. A good example of tmafm is illustrated in Figure 3 where the height and phase mode images of gelatin films on polystyrene (PS) and on mica are examined (42).

Mechanical Analysis. In addition to the wonderful imaging capabilities of afm, the tip–cantilever system can be used to extract mechanical properties of soft surfaces with the highest of spatial resolution. Since the mechanical behavior of bulk material can be dominated by the properties of the microstructure, aggregation, and domain segregation, analysis of these at length scales smaller than the surface inhomogeneity is critical for advanced materials design and characterization. Essentially, by "pushing" on the surface with the probe, one can extract a form of the Young's modulus (compliance), degree of plastic deformation, scratch and wear resistance, and the tribology of the viscoelastic nature of polymer surfaces. There are three ways to extract a relative Young's modulus E. The most accurate, easy to interpret but time-consuming method to get E (or something that looks like compliance) is with force–distance curves (FCs). As illustrated in Figure 4, the force on the cantilever is measured as a function tip–sample distance for a polystyrene/poly(vinyl methyl ether) (PS/PVME) blend (31). Initially, the tip is far from the surface and is driven toward the sample. In general this is a relative displacement; either the tip or sample is moved (typically the sample is moved, not the tip). As the tip experiences the attractive forces near the surface (mainly because of capillarity if the sample is exposed to air) it is deflected downward, toward the surface. To get accurate mechanical properties, each afm probe must be calibrated to determine its force constant (they vary greatly from designed specification) and the radius of curvature R of the tip. With knowledge of k, cantilever deflections are converted to actual forces. As the tip is driven further toward the sample the resultant force gradient exceeds the value of k; therefore, the system becomes mechanically unstable and snap to contact the surface. Once in contact with the surface and interacting with repulsive forces, further driving of the tip toward the sample results in both the upward deflection of the cantilever, p, and the downward elastic deformation of the sample, s, where the total displacement is $z = p + s$. To extract Young's modulus of soft samples (significantly softer than the afm tip material), FC contact data are fit to $F(z) = k[z - F(h)^{2/3}\left(D^2/R\right)^{1/3}]$, where $D = 3(1 - \nu^2)/(4E)$ and ν is Poisson's ratio (43). In general, the elastic

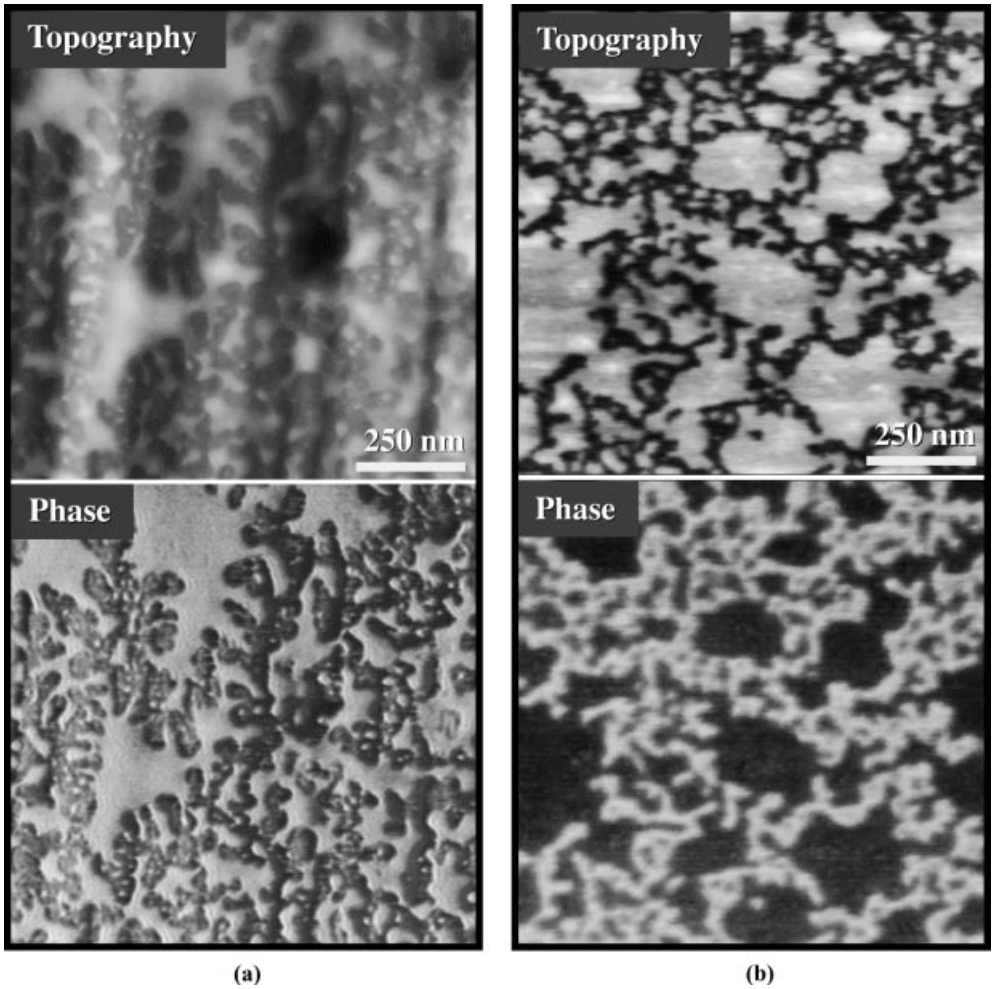

Fig. 3. Examples of tmafm. Reprinted from Ref. 42, Copyright (1998), with permission from Excerpta Media Inc.

modulus is proportional to the magnitude of the slope of the FC contact data. For soft materials there is typically an hysteresis observed during the retraction of the tip from the sample. This hysteresis is more pronounced for softer materials because of the longer relaxation time of compliant polymer films. As the tip is retracted further, still it does not release itself from the surface at the same distance where it snapped into contact initially. Adhesive interactions hold the tip onto the surface until the cantilever-induced force exceeds the adhesive force, which is related to the surface energies, the contact area, and surface roughness, and it subsequently snaps away back to its original undamped state. The difference between the force at the snap to contact point and the adhesive force has been shown to correlate with observed frictional forces (31). This is naively counterintuitive since adhesive interactions are parallel with load direction, and friction is measured perpendicular to the load; they should be uncoupled. Obviously friction

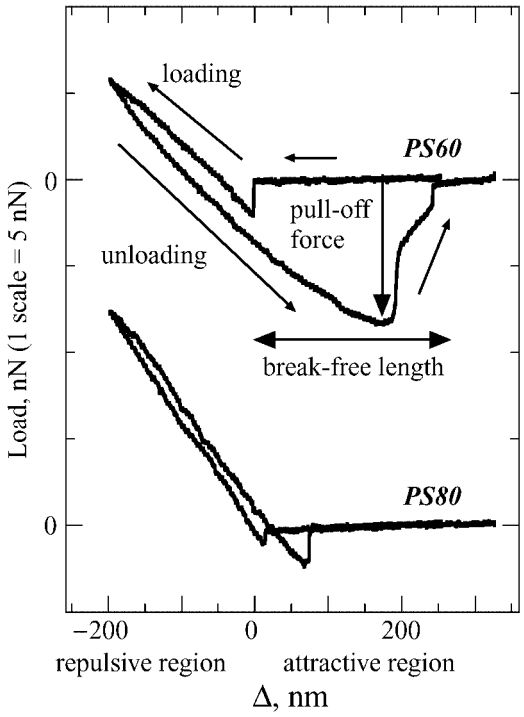

Fig. 4. Force–distance curve for a polymer blend. Reprinted from Ref. 31, Copyright (2000), with permission from AIP.

on soft materials deforms the surface and the tip pulls on the material as the surface yields.

Although FCs are useful and they can be quantitative, they are time-consuming, especially if one is mapping out the surface at each pixel (>10,000 FCs). A faster, and more convenient to visualize, method to obtain rheological information is with "force modulation" microscopy (fmm). This is a contact mode afm experiment where the sample's height is modulated by a sinusoidal signal. This is similar to tmafm except that the sample is driven while the tip remains in contact and that the oscillation frequency for fmm is an order of magnitude lower. As the tip is scanned laterally, both its height and its oscillation amplitude are recorded, where more compliant materials will absorb more energy, damping out the tip's oscillation (44,45). It can also be useful to measure the dynamic mechanical (DMA) properties of the near-surface region (see DYNAMIC MECHANICAL PROPERTIES). Polymers are typically characterized by DMA to yield frequency-dependent behavior. This technique is coupled to an afm by sweeping the oscillation frequency of the fmm experiment. By disabling the slow-scan direction and incrementing the oscillation frequency after each fast-scan line, an fmm amplitude versus position and frequency map is generated (44).

Since fmm is a contact mode technique it subjects the sample's surface to possibly destructive lateral forces as the tip scans. A less destructive alternative is to operate in the tapping-mode regime (46). Changes in mechanical properties

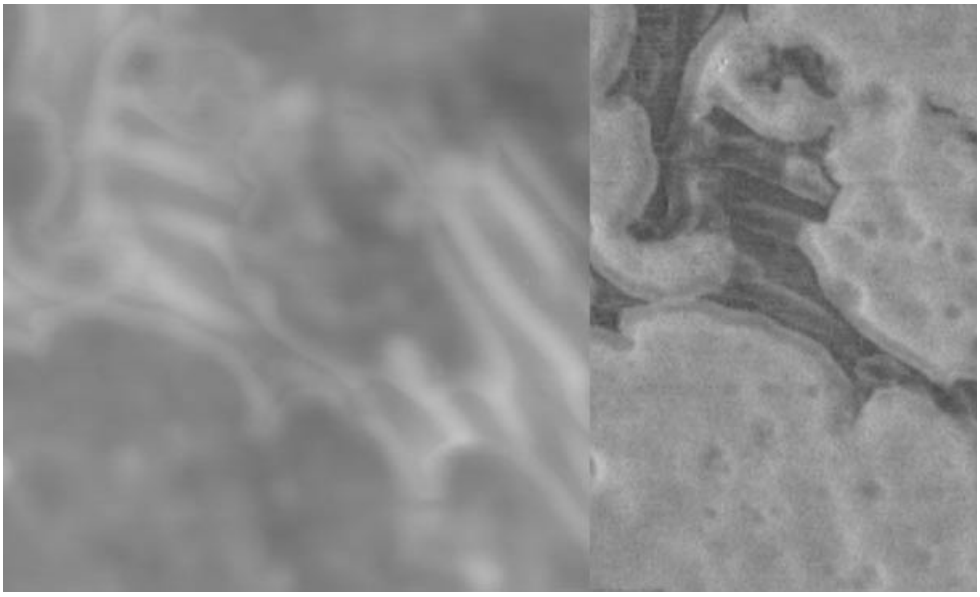

Fig. 5. Example of phase imaging for a polymer blend. Reprinted from Ref. 48, Copyright (1999), with permission from AIP.

near the surface will alter both the tip's amplitude of oscillation in tmafm and also the phase shift between the probe and the oscillating signal driving its vibration. This phase angle, ϕ, is sensitive to the oscillation frequency driving the probe and will lead or lag by $\pm 90^{\circ}$ on either side of the resonant frequency of the free cantilever. For a given frequency and driving amplitude the phase shift will increase or decrease as the compliance of the material changes. Currently this technique is limited to qualitative imaging. Since there is a reversal in contrast as experimental parameters of the tapping tip change, it is difficult to quantify these observations. However, because of the ease at which the phase images are acquired and the nondestructive nature of tmafm, this technique is now prevalent and found on all modern afm instrumentation (47). A clear demonstration of the qualitative advantage provided by phase imaging is shown in Figure 5, which compares the height (right) and phase (left) images of a doped polyanaline/cellulose acetate blend (48).

Much effort has been directed toward minimizing damage on the surface because of the scanning probes. This implies that it is quite easy to use the afm for studies of indentation and wear as illustrated in Figure 6 where a nano-scratch into a poly(ether ether ketone)(PEEK) matrix shows its relative poor wear resistance as compared to graphite (49). Using the stiff cantilevers required for tmafm, while in contact mode, softer polymer surfaces and their resultant composite systems can be plastically deformed and scratched. Indentation studies (ie, Vickers Hardness testing) are obtained by simply pushing harder than usual during an FC. With the stiffer probe pushing on the elastically deforming sample, it will eventually reach the polymer's yield strength. At this point the sample will plastically deform, leaving a tip-shaped indentation as the probe is pulled away from

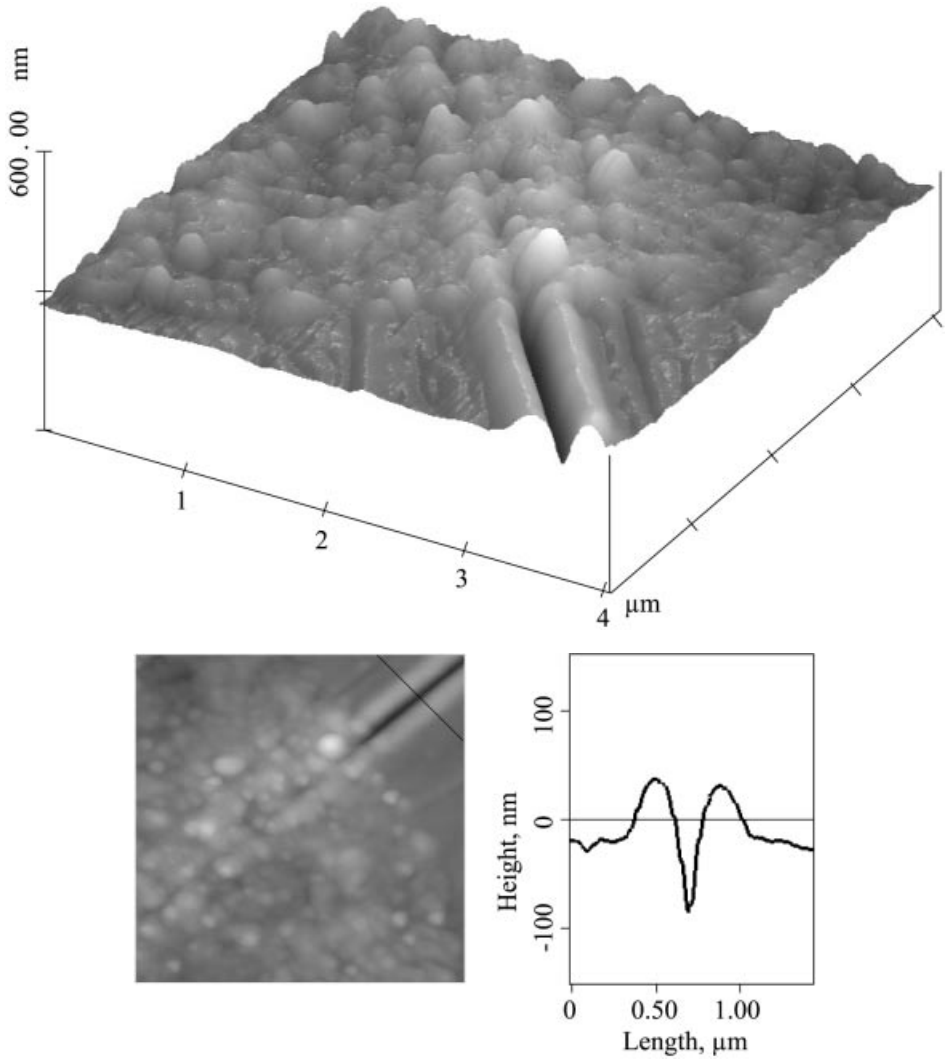

Fig. 6. Nanoscratching of a PEEK matrix sample. Reprinted from Ref. 49 (Fig. 3), Copyright (1999), with kind permission from Kluwer Academic Publishers.

the sample (50). After the indentation is formed, the same afm tip is used to scan over the new topography of the surface. Typical results exhibit a tip-shaped pit surrounded by pushed-up material. Since the elastic modulus of a standard tip is several hundred times larger than that for typical soft polymers, it can be assumed that most of the deformation is confined to the sample and that the shape of the tip is not deleteriously affected. Young's moduli and the materials tensile yield stress are extracted by modeling the contact and deformation geometry using Hertzian mechanics. The principles of nanotribology have been extensively reviewed elsewhere (51). More interesting still is the afm's ability to measure wear resistance with nanometers resolution. The contact area of the tip dragging across the sample, typically 10–100 nm, limits the spatial resolution of wear

resistance studies. Using appropriate software, the afm probe is directed across the surface to scratch out a pattern. Wear resistance versus scratch speed and tool pressure can be very useful when designing polymer blends and/or composites where low compliance and low adhesion are materials trade-offs and need to be optimized (49). This method has also been considered for pattern transfer applications. By scratching through thin, soft layers of a protective coating with the afm tip, a desired pattern can be lithographically transferred to the underlying substrate. Although direct write techniques are unacceptably inefficient, they do show promise for some limited ultrahigh resolution applications (52).

Developing Techniques. During the unloading segment of an FC on soft polymers, the tip pulls off of the surface and typically snaps back to its free position. Occasionally, however, the tip retracts in several steps, or sometimes pulls away such that the force versus distance curve is only mildly sloped. These observations are a result of polymer chain interaction with the tip (53). Material adsorbs to the afm tip during the compression and requires time to untangle itself from the chains on the substrate during pull-off (31). This phenomenon has shed light on another outstanding capability of the afm: its ability to perform single-molecule force studies. By properly functionalization of an afm tip and appropriate surface preparation, individual long-chain molecules can be manipulated and extended, again revolutionizing polymer mechanics and dynamics. Studies have yielded single-molecule force versus extension curves of poly(vinyl alcohol) (PVA) (54), polysaccharides (55,56), poly(acrylic acid) (57), and biological polymers as well (58). A typical single-molecule FC is shown in Figure 7, where a single PVA

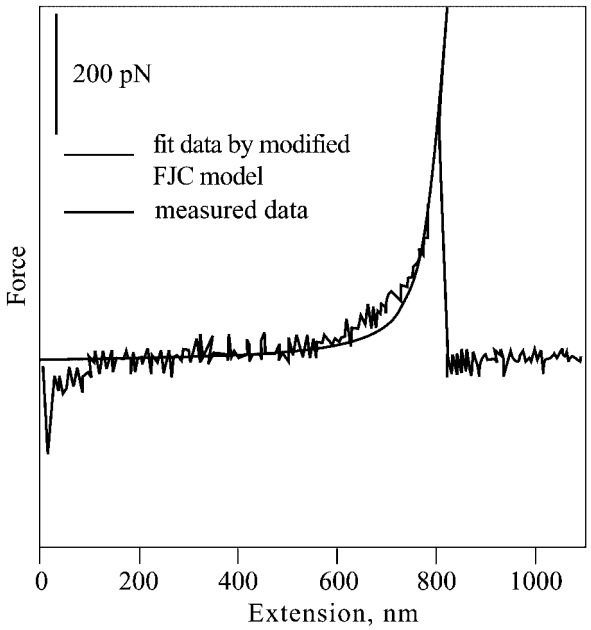

Fig. 7. A single-molecule force–distance curve for PVA. Reprinted from Ref. 54, Copyright © 1998, John Wiley & Sons, Inc.

chain is extended by an afm probe, and these data are modeled well by a freely jointed chain up to the force that causes bond rupture (54). Common to many of these studies is an apparent conformational change of the polymer strand as it is extended, followed by conversion to a significantly stiffer "crystalline" strand and then finally by bond scission. As the dimensions of nanostructured polymeric materials are reduced, single-molecule mechanics should directly correlate with these processed devices. It can be expected that the promise of chemistry's molecular fidelity finally enables true structure–function relationships for condensed materials in the near future.

In addition to imaging and mechanical analysis, researchers are now pursuing thermal analysis microscopy of polymer surfaces. Although this area is developing rapidly and has been well reviewed (59), only the state-of-the art available on commercial systems will be presented here. At the heart of scanning thermal microscopy (sthm) is the heat transfer process at the tip–sample "contact." Variations in heat transfer result in appropriate signal contrast where lateral resolution is limited by variations in thermal conductivity. Although thermal noise is quite low and signal sensitivity high, it is doubtful that the sthm will ever attain subnanometer resolution. Resolution of thermal contrast of approximately 100 nm is now common. There are several modes of operation, but typically a thermocouple or thermister is integrated into an afm probe where the tip of the temperature transducer is also the scanning tip. The system operates in contact mode and either the sample or the tip is heated. AC detection of an oscillating temperature increases signal sensitivity. This is most easily achieved by modulating the output power of a laser incident on the system. If the spectral absorption of the sample is spatially inhomogeneous, this too can be measured by scanning the wavelength of the light source at each, or some, of the scanning positions on the surface (60,61).

A more useful probe for sthm is the resistive wire (62). Instead of heating the sample and measuring the temperature with the tip, the tip itself is heated and its temperature is measured, via changes in its electrical resistance. Changes in local thermal conductivity of the sample will result in changes of the tip's temperature for a constant power through the wire. Dissipation of heat at the tip–sample "contact" and through inhomogeneous samples is convoluted, making quantitative measurements poorly understood. Thermal inhomogeneity in a polymer film can be laterally across and or longitudinally through the sample. Since the thermal diffusion length of a typical polymer is of the order of a micron, nanoscale calorimetry will approach a fundamental limit. However, micron-resolved thermal conductivity of domains in a poly(vinyl chloride)/polybutadiene (PVC/PBD) polymer blend have been clearly demonstrated in the literature (63). This type of microscopy can be more relevant on composites where fine tuning of thermal and mechanical properties is desired.

In addition to thermal conductivity, modifications of the sthm can yield thermal capacity or more specifically differential scanning calorimetry (dsc). Instead of heating the resistive wire with a constant power, its temperature is modulated with an ac current. The resultant amplitude and phase shift of the wire's temperature is measured with a lock-in-amplifier. Simultaneously, the temperature of the tip and sample are ramped up slowly so as to measure the change in heat dissipation per change in temperature, dq/dT. This measure is, of course, related to the local heat capacity of the sample and is correlated with expected phase

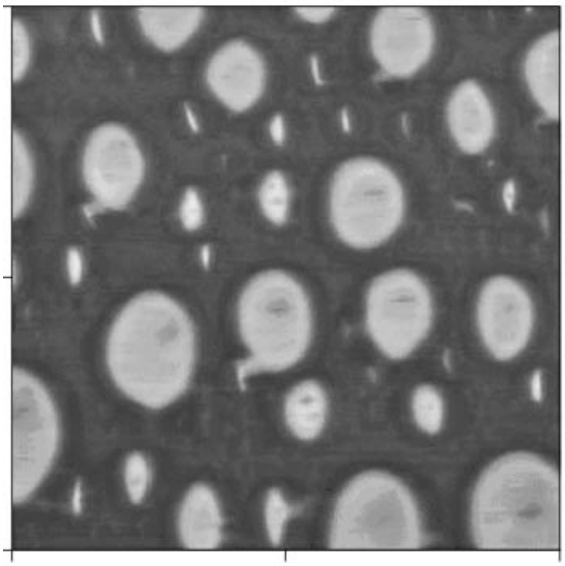

Fig. 8. A sthm scan of a PVC/PBD blend. Reprinted from Ref. 63, Copyright (1996), with permission from AIP.

transitions of the material. Plotting the first derivative of the phase shift versus sample temperature looks very similar to the bulk DSC as shown in Figure 8 for a sample of thermally quenched PET (63). Variations of glass-transition temperatures in micrometetr-sized domains could be critical as device dimensions shrink.

Since the afm is peerless at measuring vertical expansion, and the ac sthm can measure temperature, it should be possible to extract coefficients of thermal expansion (CTE) on thin films, which is nearly impossible with conventional thermal mechanical analysis (TMA). By modulating the sample's temperature the longitudinal composite expansion can be measured by the deflection of the sthm cantilever as the probe scans the sample (64). These capabilities are critically important when developing multilayered thin-film materials. Expansion of PMMA film insulating a gold interconnect line is measured and illustrated in Figure 9 (64). These data show that the theoretically expected expansion deviates from those observed, implying that this additional thermal fatigue could lead to premature device failure.

As mentioned above, the spm is mostly limited to sampling the near-surface region of a polymer system. A new technique based on tmafm has been developed to enable volume imaging with the spm. This study tracked a series of height and phase images of a styrene–butadiene–styrene (SBS) triblock polymer microdomain as the surface was being removed 7.5 nm at a time with a plasma etcher. These data are illustrated in Figure 10 (65).

Prior to the development of the spm, and all its derivatives, scaling of physical properties from the macroscopic to the nanoscopic was speculative at best. "Experiments are the only means of knowledge at our disposal. The rest is poetry and imagination" (Max Plank). The afm has opened the door of exploration into the varied complexities of advanced polymeric materials. In the following,

observations on various molecular systems and the surface characteristics intrinsic to them and their processing are discussed.

Systems

LB Films. Use of Langmuir–Blodgett (LB) film techniques have been shown to be an effective method for producing thin layers of materials for thermomechanical evaluation. Morphological description of such samples by afm has been used with success in a wide range of polymer systems. Individual chains of phthalocyaninepolysiloxane shish kabob molecules were deposited on metal nanoelectrodes using LB techniques (mixed with isopentyl cellulose) and then dispersed on the surface of an LB trough. The deposition surface was dipped into the dispersion to deposit the polymer mixture. The authors demonstrated that the structures of these semiconductive polymers are not disturbed by raised patterns on the electrode (66). Polystyrene/poly(ethylene oxide) (PS/PEO) diblock copolymers of differing fractional compositions were used to produce LB films. Polystyrene aggregates were observed to accumulate on the surface of the films; the features of these aggregates were directly proportional to the PS content in the starting diblock copolymer. Hence, by manipulation of the starting polymer, controlled patterning of the film surface could be accomplished without use of any lithographic methods (67) (see LANGMUIR–BLODGETT FILMS).

Changes in the environment in which polymer LB films are produced can result in significant structural changes of the deposited materials. LB films of poly(γ-benzyl-L-glutamate) produced from a number of solvents were imaged. Solvent polarity strongly influenced the self-assembly process and is manifest as thickness and height variations of individual fibers (which formed on the mica substrate), and in the lateral globular dimensions of the polymer absorbed from

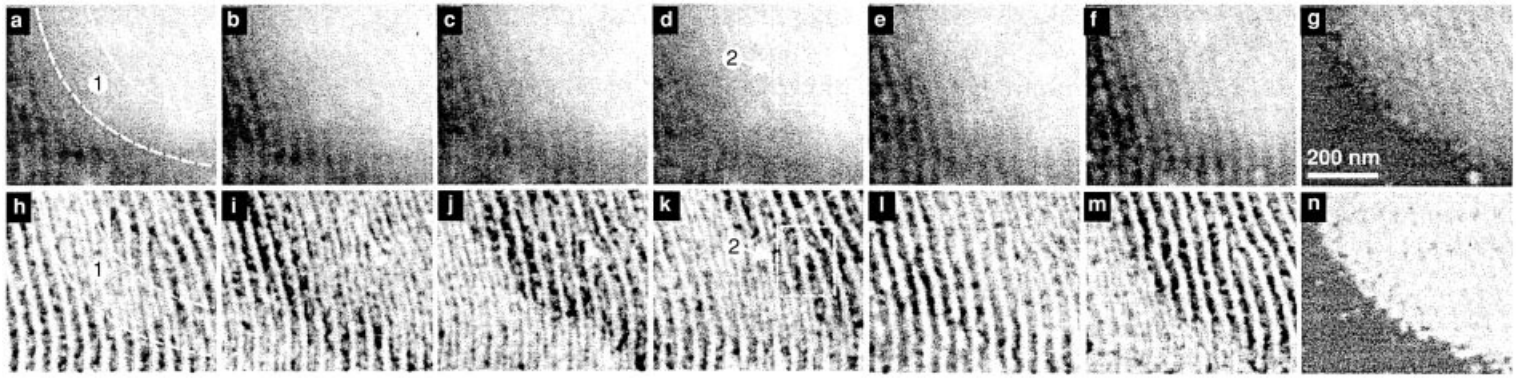

Fig. 10. TMAFM study of an SBS triblock polymer, as its surface was removed. Reprinted from Ref. 65, Copyright (2000) by the American Physical Society.

dilute solution. AFM allowed for the quantification of these structural differences, and was used to suggest a mechanism for self-assembly of polymer chains into fibrils (68). Varying the pH at which LB films of poly(linoleic acid) were produced resulted in major morphological changes within the deposited film. Tapping mode afm shows spherical particles lacking any regular pattern when depositing from a subphase solution with a pH of 6.0. As the pH is increased to 6.3 and 6.6, increasing organization into a network structure was observed. At pH 6.9, much of this structure was observed to be absent; it is at this pH that a step change in chemical reactivity of the polymer film is observed as well. Therefore, this method allows for a correlation between film structure and chemical properties (69).

Morphological differences in LB films result from small compositional changes in the polymers used, and from the difference in processing between LB and freestanding thick films. Formation of LB films from salts produced from polyamic acid and a variety of alkylamines were examined by afm. Unique morphologies were obtained, as the chemical structure of the amine was varied (70). The structure of LB films of polyaniline (PA) was shown by afm to possess preferential orientation, but with much lower levels of porosity than which had been previously observed within freestanding films. Increases of surface roughness in LB films were observed by afm when the ratio of low molecular weight PA to cadmium stearate in the subphase solution was increased, while domain sizes varied inversely with organic content (71). Varying the side chains of poly(*N*-alkyl acrylamides) was also demonstrated to produce major differences in morphologies in LB films. When decyl side chains were incorporated into the polymer film, these groups were observed to adopt random orientations. Increasing the chain lengths to octadecyl resulted in highly ordered two-dimensional crystals that were imaged by afm (72).

Monolayers (Self-Assembly of Oligomers). The degree of ordering, which results from molecular self-assembly of polymer systems, is readily ascertained using afm. Thin layers of an acetylenic phospholipid were demonstrated by afm to self-assemble into lamellar structures when cast as thin films. Uv polymerization of these films produced polymers with well-packed structures (73). Alternating layers of positively charged poly(diallyldimethylammonium chloride) and negatively charged montmorillonite clay were self-assembled onto various substrates. AFM was used to quantify the smoothing of initial surface roughness with each successful layer assembled to the surface, and to develop a representation of how clay platelets and polymer chains associate in layers (74). AFM imaging was used to determine the morphologies of nitro-containing diazoresin, as a function of deposition time, and of bilayer and multilayer assemblies of the diazoresin and poly(sodium *p*-styrene sulfonate). Flat, stable multilayer structures were demonstrated upon uv-irradiation (which resulted in replacement of the diazo group with C—C bonds between layers of polymers), and regular structures were shown to be maintained (75).

Biopolymers. Ranging from individual chains of deoxyribonucleic acid (DNA) to the "high performance" fibers produced by spiders for their use as draglines, afm has been used to provide insights into biopolymers, much as it has for synthetic systems (see POLYNUCLEOTIDES; SILK).

Solutions of single- and double-stranded DNA (as well as several synthetic polymers) were electrosprayed onto a mica surface and imaged. Each polymer

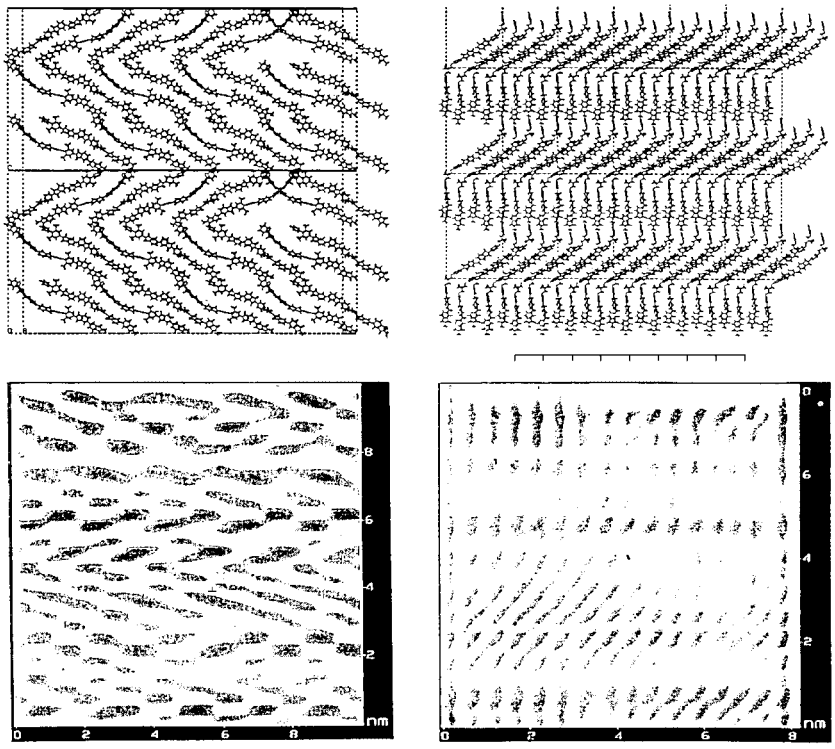
could be generated and analyzed in globular or fibrillar forms, depending on conditions of the electrospray processing of the solutions. Increasing polymer concentration in the water solutions led to formation of the globular structures. Changes in electrode potential used in the electrospraying was shown to also play a role in the morphology of the biopolymer (76).

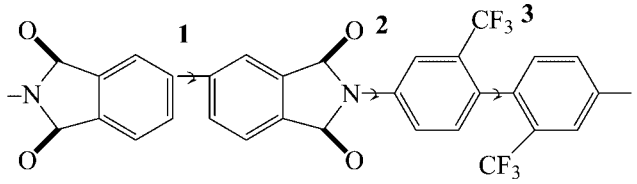
Both stretched and unstretched silk threads from the Black Widow spider were imaged. Two types of fibers were observed within the threads (thicker, 300 nm in diameter, oriented parallel to the thread axis; thinner, 10–100 nm fibrils oriented across the thread axis). With increasing strain, mean fiber and fibril diameters were found to decrease and fibrils aligned themselves more closely with the thread axis. The authors were able to relate these structural features to models of secondary and tertiary structure and organization in spider silk (77).

Thermosets. Structure determination in thermoset polymer systems can at times be problematic because of their relative insolubilities and large molecular weights. Direct observation of structural details by afm has been advantageous for such systems, describing both inherent material properties as well as the impact of processing steps on final structure properties.

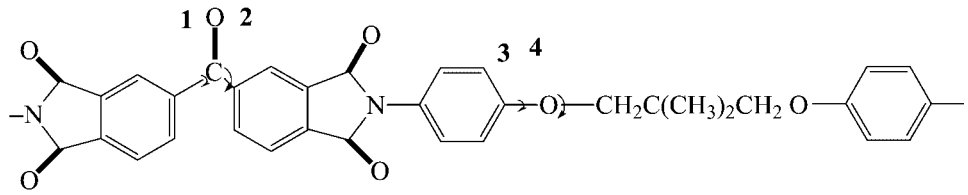
The role of processing of thermosets in determining ultimate polymer structure is well studied using afm. The morphological structures of fibers and films produced from segmented Polyimides were shown to match closely those predicted by molecular modeling (Fig. 11). In these systems, two-dimensional arrays of ordered polymer chain backbones were observed. For fibers, the polymer chain backbones were found to be oriented at a definite angle with respect to the fiber machine axis, where this angle is hypothesized to be due to differential shrinkage of the core and surface of the fiber during solvent removal and heat treatment of the fibers (78). AFM imaging of carbon fibers revealed extrusion lines, as well as the presence of "dirt" inclusions. A correlation between the concentration of these particles and the strength of the fibers was observed, providing a structural basis for optimizing the fiber-making process (79).

Inherent polymer morphologies have been determined using afm imaging. This technique was used to discover a parallel-rod structure on the surface of fluorinated polyimide films produced by vapor deposition polymerization; these structural details were not apparent by scanning electron microscopy (sem). When spin-cast films of the same polymer were imaged, a rough structure lacking the rod-like morphology was observed. The authors concluded that the parallel-rod morphology resulted from both polymer–polymer and polymer–substrate interactions (80). Cleaved surfaces of the polyacetylene poly(2,4-hexadiyne-1,6-diol bis(*p*-toluene sulphonate)) were imaged, revealing *bc*- and *ab*-planes consistent with the crystal structure of the polymer. An overall zig-zag morphology, with step heights corresponding to one polymer chain's width, was resolved clearly. Substituents on one side of the polymer backbone were observed to stick out diagonally from the surface, while other side chains were observed to be located underneath the substituents of a neighboring polymer chain (81). Thermoset epoxy resins modified with nanoclays were imaged using phase contrast afm. These images showed interlayer distances that were noticeably smaller than those measured by wide-angle x-ray scattering (waxs); the authors speculate that the mechanical deformation of the clay silicate layers by the afm tip may be the cause of this discrepancy, challenging the notion that the clays serve as rigid reinforcing layers in the composite (82).





BPDA-PFMB (3,3 ,4,4 -biphenyltetracarboxylic dianhydride + 2,2 -bis(trifluoromethyl) 4,4 -diaminobiphenyl)



BTDA (1,3-bis(4-aminophenoxy)-2,2-dimethylpropane + 3,3 ,4,4 -benzophenontetracarboxylic dianhydride)

Fig. 11. Morphology of segmented polyimide structures. Reprinted from Ref. 78 (Figs. 1c, 1f, 3 and Scheme 3), Copyright (1992), with permission from Springer-Verlag.

Chemical modifications of thermoset resins have been documented, using afm as an analytical tool. Ion beam modification of polyimide surfaces were imaged in contact mode, which showed a reduction in surface roughness with increasing irradiation, and generation of a graphitic structure in the degraded polymer (83).

Thermoplastics. The largest body of afm structural studies to date in the area of organic polymers has probed the details of commodity thermoplastic materials. Within this work, both support and extension of knowledge gained by other techniques, such as electron microscopy, as well as new insights into the structure–property differences which result from melt processing and/or thermal treatment have been gained. Specifics of thermoplastic surfaces, important in controlling transport and adhesion phenomena, have also richly benefited from afm studies. Structural studies of combinations of these thermoplastics is discussed later.

Polyethylene. AFM imaging of thermoplastics has been widely used to corroborate and expand knowledge obtained using other structural methods, such as x-ray crystallography and electron microscopy. Direct observation of folded chain lamellar crystals of polyethylene (PE) was provided by afm. Spacings appropriate for the (known crystallographic) orthorhombic unit cell, and for the monoclinic unit cell that can be produced by mechanical deformation, were observed (84) as were boundaries between regions of differently oriented folded chains (85) (see ETHYLENE POLYMERS, HDPE).

Cold extruded PE was imaged at scales ranging from 700 nm $\times$ 700 nm down to atomic scale resolution. Fibrillar morphology was observed for uniaxially oriented materials, with microfibrils in the 20–90 nm range, aligned with the extrusion axis. Individual polymer chains and extended chains were also observed (86).

Extruded high density polyethylene (HDPE) pipe was cooled on the outside with water, while the internal surface was allowed to cool in ambient air. As a result of this cooling gradient during fabrication, a range of crystal structures could be anticipated. AFM imaging of sections across the pipe confirmed major morphological differences that arose from the differential cooling. At all locations, spherulitic structures were observed, but spherulite size, band period, and lamellae thickness increased within the pipe from the cooled to uncooled sides (Table 1) (87).

Polypropylene and Polystyrene. As with PE, afm has yielded important structural details for the different grades of polypropylene (PP) and Polystyrene (PS). Syndiotactic polystyrene (sPS) was imaged (Fig. 12), showing a spherulitic

Table 1. Morphological Differences Arising from Differential Cooling of HDPE

Imaged area	Spherulite size, μm	Band period, nm
Cooled edge	2–3	400–500
Intermediate	4–5	800–900
Middle	6–8	1000–1100
Intermediate	8.5–10.5	1200–1400
Uncooled edge	10–13	1600–2000

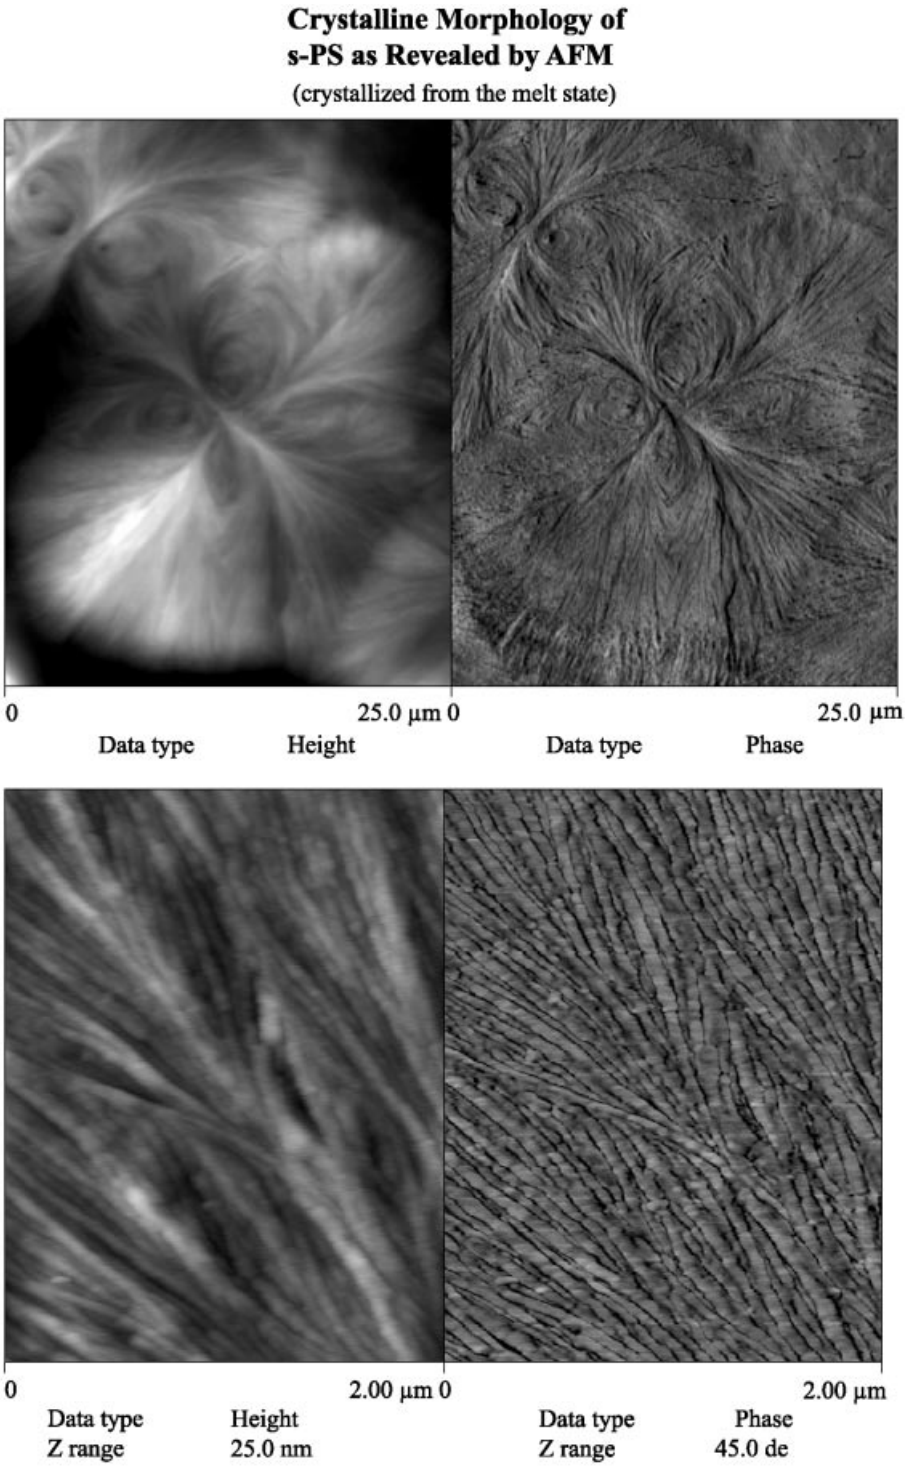


Fig. 12. Structural details of sPS. From Ref. 89, courtesy of Prof. S. Nazarenko.

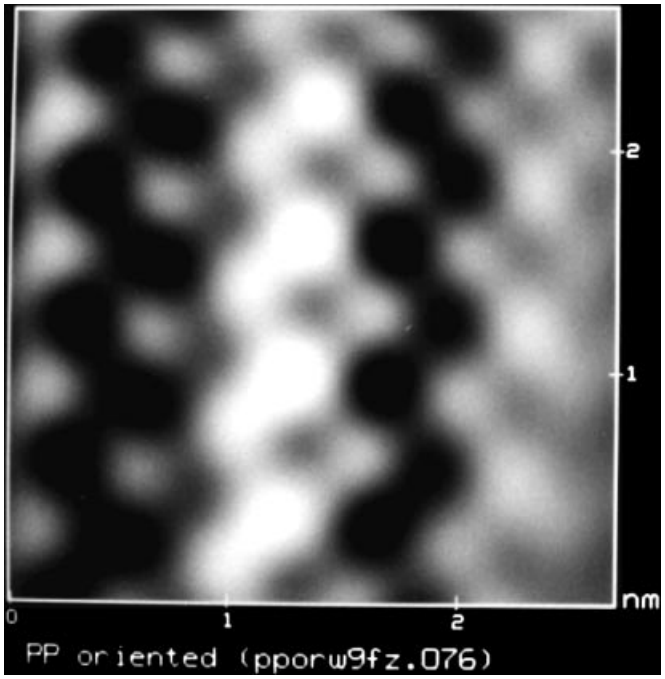

Fig. 13. Detailed structure of iPP. Reprinted from Ref. 91, Copyright (1994), with permission from Elsevier.

structure consistent with prior sem work. The radially arranged fibrils in the spherulites were shown to consist of small lamellar crystals. The observed spherulites were also twisted. Epitaxial crystallization of sPP on *p*-terphenyl created a laminar structure, such that the lamellae stand on end, with an average thickness of 20 nm (88). Similar structural details have been observed for syndiotactic polypropylene (sPP) (89).

Uniaxially oriented isotactic polypropylene (iPP) was imaged using afm, showing microfibrils and macromolecules. Fibrils with an average diameter of 150 nm were observed. Individual polymer chains with 1.17 nm chain–chain distance were seen. The authors propose that the (110) crystal plane was being resolved with this work (90). Other workers, who were able to clearly resolve right- and left-handed helices (Fig. 13) with pendant methyl groups visible, accomplished atomic scale resolution of iPP (91).

The metastable β-phase of iPP was imaged in another study, where epitaxial crystallization was found to result in a biaxial orientation that could not be achieved mechanically because of the $\beta \rightarrow \alpha$ transition that occurs during orientation. A lateral periodicity of 1.9 nm was found in the (110) face, corresponding to the distance between three chains, and is indicative of the frustrated packing of the β-phase of iPP. Variability in the image suggested the possibility of two distinct frustrated phases existing in the samples (92).

The effects of processing conditions on polymer structure have been demonstrated clearly using afm images of PP. Polypropylene fibers spun using three

different processes, gravity spinning, melt spinning, and melt blowing, were imaged by afm, and the structures resulting from each of these different processing methods compared. The surface of gravity-spun PP was found to be entirely covered with spherulites consisting of polycrystalline aggregates formed from a radiating array. Each branch of the spherulites were composed of lamellae and are connected by regions of amorphous material, consistent with general lack of orientation along the fiber axis. Similar structures were observed for melt-blown PP fibers. Analysis of images showed that spherulite diameter versus fiber diameter for melt-blown and gravity-spun fibers are correlated, which is very useful for developing polymer processors. The intercept of this correlation line is related to the amount of amorphous material in the polymer, and the slope to the number of spherulites that can fit along the circumference of the fiber. For the melt-spun fibers, no spherulites were observed. Spherulites generally grow on nonmoving surfaces since the transfer of stress to the growing threadline leads instead to the also well-known shish kabob structure in this case, consistent with polymers crystallized under strain (93).

Thermoplastic Polyesters. The effect of substrate structure upon applied polymer layer morphology was well illustrated with a thermoplastic polyester. Poly(ethylene terephthalate) films were formed on the surface of oriented poly(tetrafluoroethylene) (PTFE) and on silicon surfaces. The PTFE surface was characterized by ridges 0.1–0.2 μm wide, running parallel to the PTFE draw direction. The silicon wafer showed regular, two-dimensional roughness features. When PET film was overlaid on these two surfaces, its morphology was surface-induced. PET applied directly to the silicon wafer exhibited random, two-dimensional roughness, whereas the PET applied to the oriented PTFE surface aligned itself in parallel ribbons approximating the PTFE structure (94).

Specific chemical structures have been reported when near atomic scale resolution is obtained. When PET surfaces were imaged down to the nanometer scale, triads of roughly circular structures, 0.29 nm in diameter, corresponding to the expected size of terephthalate phenyl groups were observed (Fig. 14). The authors propose that the structures may indeed be terephthalate phenyl groups in the polymer (95).

Insights into the chemical properties of polyesters have also been obtained using afm imaging as a tool. The diffusion/deposition of oligomers to the surface of PET copolyesters was demonstrated by imaging hard nodules on the polyester surfaces as a function of copolymer composition. The frequency of these hard nodules observed by afm correlated with the levels of oligomer that could be solvent-extracted from the copolymers (96).

Other Thermoplastics. Polyoxymethylene (POM) was imaged by afm, revealing oriented polymer chains parallel with the machine axis of sample extrusion (Fig. 15). Atomic scale resolution of the chains demonstrated the helical nature of the polymer chains. Long-range correlation between polymer chains was observed as well (97). Imaging of extended chain crystals of POM closely matched molecular models for this material, allowing for the molecular packing and order in the extended chain crystal to be well understood. The authors were able to describe the polymer chain orientations with respect to the crystal (98).

Poly(tetrafluoroethylene) was imaged after a mechanical deposition method. Parallel rows of approximately 0.5 nm spacing were resolved (99). The PTFE

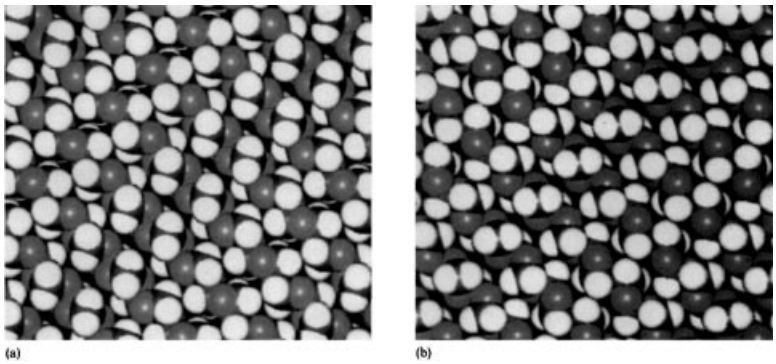

Fig. 15. Extended chain crystals of POM, showing polymer chain orientation with respect to the crystal. Reprinted from Ref. 98, Copyright (1994), with permission from Elsevier.

imaging demonstrated that because of its softness, the majority of observations with this material often are due to artifacts, rather than actual polymer structure. Operating in tapping mode, afm images of PTFE revealed structures comparable to those obtained with sem. The results of this work showed that PTFE is capable

of supporting large forces on the millisecond time scale, but is subject to creep at longer time frames (100).

Ultrahigh molecular weight polyethylene (UHMWPE) tapes were imaged under water to minimize operating repulsive forces and contact area between probe and sample. Highly regular fibular structures were obtained. Periodic contrast variations along the stretching axis were found on drawn tapes only under stronger operation forces, suggestive that these variations are a function of surface hardness, rather than of surface topology (101). Gel-drawn UHMWPE films showed bundles of microfibrils between 4 and 7 μm in diameter, depending upon the elongation, microfibrils between 0.2 and 1.2 μm in diameter, depending upon draw ratios employed, nanofibrils which form the microfibrils, and regular chain patterns on the molecular scale which correspond to the crystalline packing of the polymer chains at the surface of the nanofibrils (102).

While normally amorphous, and generally featureless on a micron scale, crystallization of polycarbonate was solvent-induced with butyl acetate, generating a disc-like spherulitic structure of ca 10 μm in diameter surrounded by an amorphous matrix. Within the spherulite, the twisted fibrils emanating from the point of nucleation were observed in these afm images, and is consistent with known lamellar growth mechanisms (103).

Liquid Crystalline Polymers. The high degree of stereoregularity associated with liquid crystalline polymer systems has been observed using afm. Effects of method of sample preparation, of post-extrusion heat treatment of the sample, and of interchain hydrogen bonding upon morphological structure have all been investigated. Lytropic poly(*p*-phenylene terephthalamide) (PPTA) was dry-jet wet-spun from sulfuric acid into a coagulant bath, and imaged as spun, after heat treatment. The authors obtained atomic scale resolution of both forms of the fibers, observing changes in periodicity in the structures resulting from the heat treatment (104,105). Thermotropic liquid crystalline polyesters were imaged (Fig. 16), showing ribbon-like fibrils; atomic-scale details of the fibril surfaces were also obtained. In polymers capable of hydrogen bonding between chains, a greater degree of chain-to-chain cohesion, which the authors propose could result from some degree of self-assembly, was observed (106).

When macromolecular cholesteric liquid crystals were imaged, a twisting of molecular orientation, which translated into a periodic lamellar structure in the materials, was found. Good agreement between afm and tem (transmission electron microscopy) was obtained in determining the widths of the lamellae. When the same polymer was processed from an isotropic solution, a homogeneous and nodular structure, lacking the periodicity of the cholesteric structure, was obtained (107).

Hyperbranched Polymers and Dendrimers. The rapid growth of knowledge in the area of Hyperbranched Polymers and dendrimers has been aided by the direct observation of large-scale structure from afm (see DENDRONIZED POLYMERS). Workers in this area have observed the nature of growth and distribution of polymeric branches as a function of both the chemical structure of the materials as well as that of surfaces on which the materials are grown. Further control of such structures, by introduction of additional, space-filling materials, has been observed by afm, as has general structural features of these complex polymers. Hyperbranched polyacrylic acid (PAA) films were imaged and it was found that

rms roughness declined as one progressed from zero to three dendrimer "generations," and then increased monotonically up through generation six when bonded to a rough gold substrate. When a smooth gold substrate was used, increasing roughness was observed starting with the first generation of hyperbranched PAA. The authors attributed this phenomenon to a sequential masking of roughness in the nonsmooth starting gold substrate through three generations. However, once a uniform surface smoothness is established, the dendrimer could then be randomly deposited on that surface, where subsequent layers would favor deposition

at those sites which contain the highest chain ends to bond to, and hence, increasing roughness is developed. With the smooth substrate, the first generation would be deposited randomly, and each successive generation of hyperbranched polymer favors addition to those areas containing high concentrations of acidic polymer chain ends, thereby increasing roughness with each added generation (108). Polyimidoamine starburst dendimers were similarly adsorbed on Au(111) surfaces. The relatively deformable fourth generation dendrimer, and the larger, more spherical and more rigid eighth generation dendrimer were tested. Directly adhered to the gold surface, the individual fourth generation dendrimers were shorter than those of the eighth generation material. Pretreating the gold surface with hexadecane thiol, which occupies surface space, led to growth of pillars of dendrimers on unoccupied surface sites, which could be imaged with afm (109). Diaminobutane dendrimers bearing outer layers of ferrocene were imaged. Circular features were seen that are thought to correspond to individual dendrimer units (110). Dendronized PS was imaged with afm, showing multilayer films made of densely packed nanorods. The cylindrical dendrimers were grouped in domains in which they are kept parallel to each other, with a periodicity of approximately 5 nm (88).

Filled Composites. Use of afm in characterizing filled composite materials has ranged from determination of composite morphology as a function of fabrication method to examination of the morphological effects of the reinforcing agent upon the matrix resin, and static and dynamic mechanical properties of the composites.

Poly(hydroxybenzoic acid)/copolyesterether elastomer microcomposites were imaged and it was shown that time and the solvent used to make the composite result in different morphologies. When solvents with high affinities for the elastomer were used, the resultant composite showed uniform dispersion of that material. With poor solvents, the elastomer was observed to aggregate into nonuniform aggregates (111).

Sheet molding compound thermoset materials were imaged by afm; it was found that fiber reinforcement, as much as 1 μm under the surface, had an effect on surface morphology (112). AFM scratch tests conducted on carbon fiber-reinforced PEEK/PTFE blends demonstrated that reinforcing carbon fibers are harder and more scratch-resistant than graphite or the matrix resins (113). Styrene–butadiene rubber (SBR) vulcanizates containing carbon black were imaged under conditions of different levels of extension (0–700%). The authors found that filler particles tend to align in the force field into string-like arrays; surface cracks develop between these filler arrays, and may play an important role in crack propagation (114).

Microporous Membranes. Microporous membranes pose two separate opportunities for afm to contribute structural knowledge of these materials. The technique is of course capable of describing the polymeric structures on scales ranging from micrometers down to tenths of nanometers, but is also able to describe the nature of the pores which modify the transport properties of membranes.

Nafion® perfluorinated sulfonic acid polymer was imaged, showing a nodular structure with 45-nm spherical domains, which in turn contained 11-nm spherical grains. Interstitial "pores" in the polymer were found to contain lower densities of polymer, but were not completely void. The authors showed that a nonuniform

distribution of the grains, with wide and deep rifts, occur when the polymer is swelled with tributyl phosphate (115).

Polysulfone membranes were imaged and the microstructure and microporosity characterized. Through this work, it was determined that two different modes of phase separation existed during the formation of the membrane. Hence, the specific details of membrane processing were shown to influence morphology and final performance of the product (116). Linear and branched aromatic polyamide membranes were imaged by both afm and field-emission sem. The sem work established molecular structure/morphological relationships, while the afm was used to determine the surface roughness of the membranes. A strong correlation between molecular structure and roughness was determined, with meta- substituted molecules giving rougher, less regular structures. Correlations between this surface roughness and water permeability were determined as well, providing the authors with a molecular structure to polymer morphology to membrane performance working model (117).

Polymer Blends, IPNs, Latexes, and Block Copolymers. When two or more dissimilar materials are combined in the absence of covalent bonds, as is the case for polymer blends, interpenetrating polymer networks (IPNs) and latices, or through direct chemical bonds, as with block and Graft copolymers, a number of important questions are raised that can be addressed by afm. The bulk morphology of these molecular combinations, as well as the specific chemical interactions within and between species, can provide important guidance for the design of improved materials. Variations in structural and mechanical properties of the blends and copolymer components, which result from the combining of materials or from some environmental force, which the materials are exposed to, again are important information for designers of such materials.

Blends. Blends of iPP with poly(styrene)-*block*-poly(ethylene-*co*-1-butene) were prepared under various conditions and imaged by afm, where macrophase separation because of incompatibility of the components was observed (Fig. 17). The degree of phase segregation was shown to be dependent on the thermal history of the sample (118). Blends of iPP and different poly(ethylene-butene) (PEB) copolymers were imaged. The authors found that iPP and PEB containing 88% butene were miscible, and PEB containing <88% butene were partially to totally immiscible, and polybutene (100% butene) was partially miscible. So, there is a narrow window of miscibility for these blends (119).

Thin films of blended deuterated polystyrene (dPS) and poly(vinyl methyl ether) (PVME) were imaged as a function of the dPS:PVME ratio. Near the critical composition of 35% dPS, an undulating, spinodal-like structure was observed, whereas for compositions away from the critical mixture ratio, regular mounds or holes (ϕdPS $< \phi_{crit}$ and ϕdPS $> \phi_{crit}$, respectively) were present. These variations were assigned to surface tension effects (120). Blends of PBD, SBR, isobutylene-brominated *p*-methylstyrene, PP, PE, natural rubber, and isoprene–styrene–isoprene block rubbers were imaged (Fig. 18). Stiff, styrenic phases and rubbery core–shell phases were evident as the authors utilized force-modulated afm to determine detailed microstructure of blends, including those with fillers such as carbon-black and silica (121).

Incompatible PS/PMMA/PVP [poly(2-vinyl pyridine)] blend films were imaged. Combining afm and selective dissolution of the film surface, the

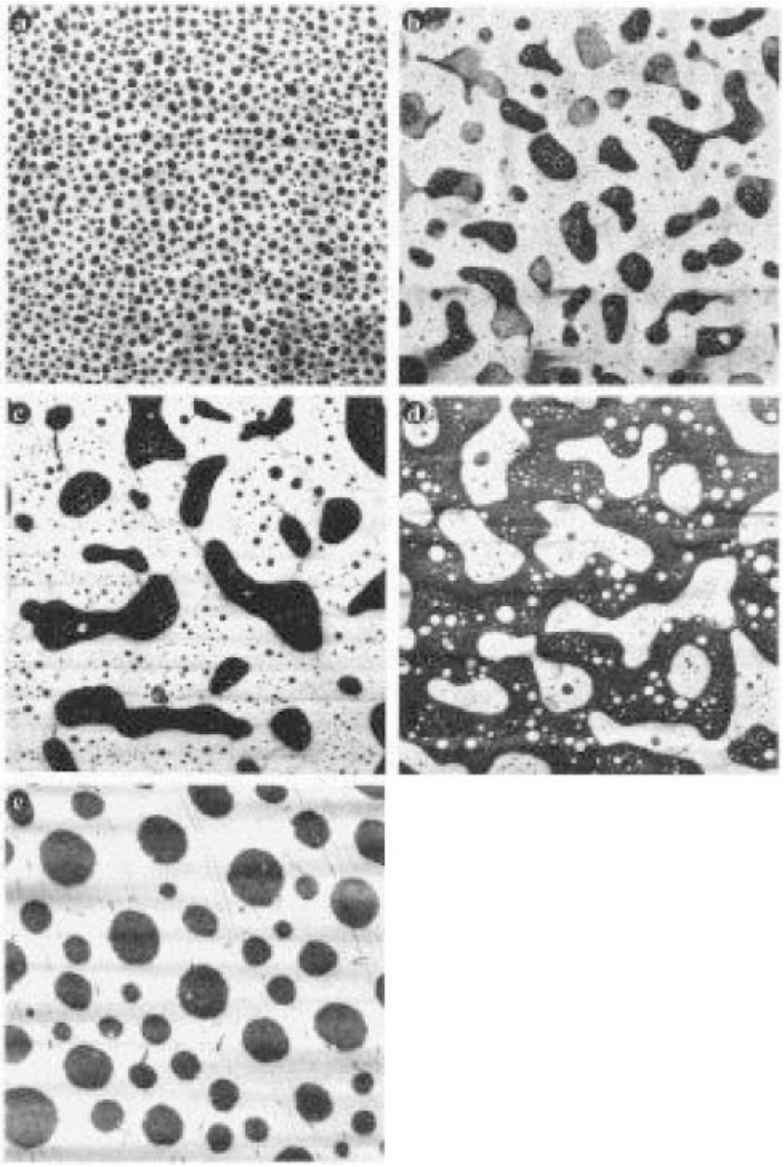

Fig. 17. Phase separation of incompatible blends of iPP and PEB, as a function of thermal history. Reprinted with permission from Ref. 118. Copyright (1998) American Chemical Society.

compositional distribution of polymers was determined. The PMMA was observed to act as a compatibilizer for the more incompatible PS and PVP domains, preventing the formation of high energy interfaces. Molecular simulation for a ternary blend of polymers with distinctly different surface energies closely models the observed morphology (122). Tapping mode imaging of triblock PS–PE–PBD and iPP showed the boundary between the materials to act as a nucleating agent,

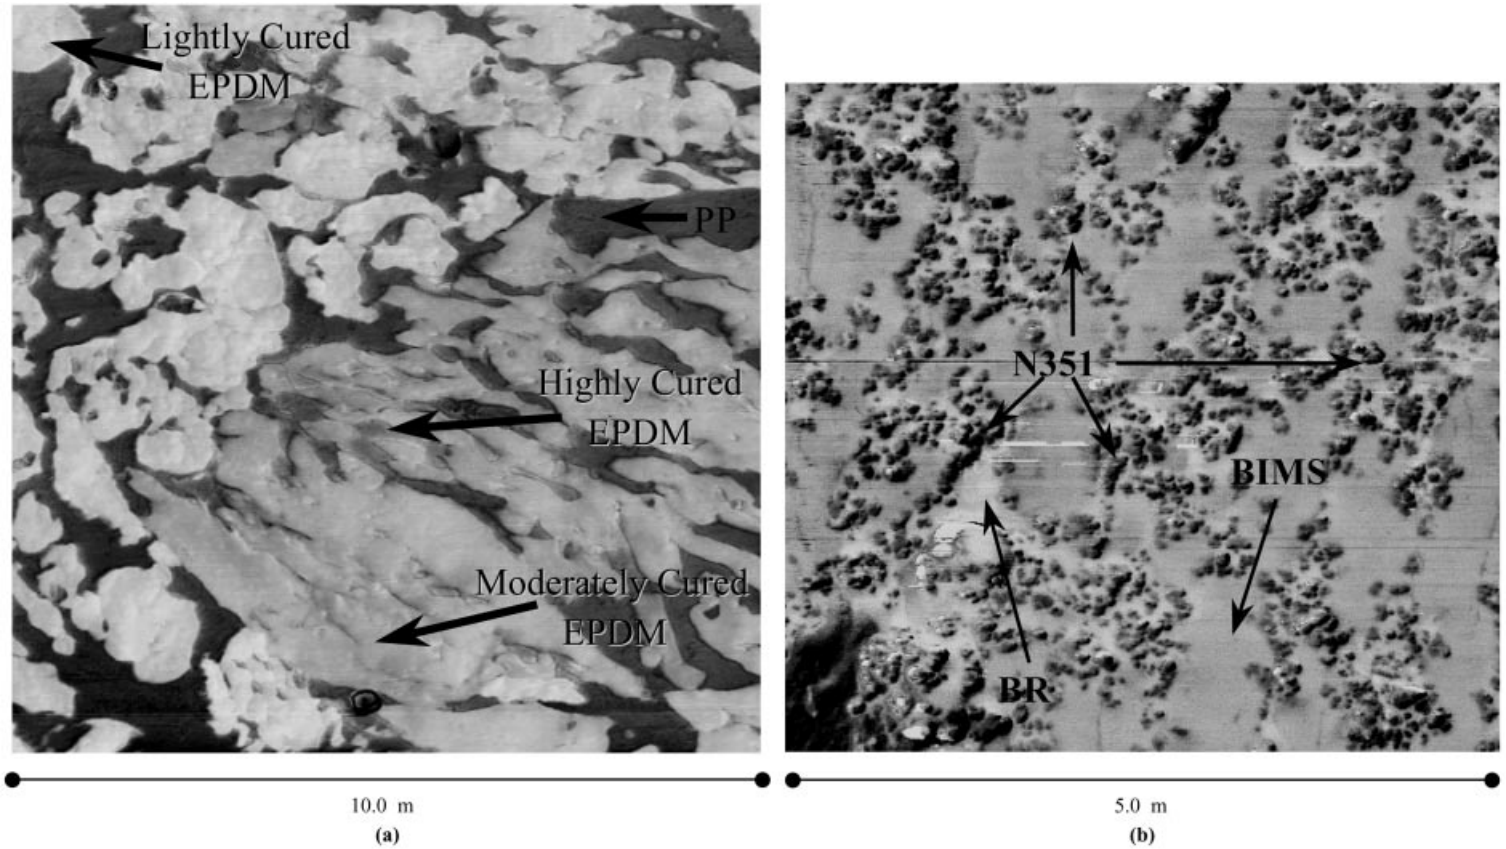

Fig. 18. Phases present in filled polymer blends. From Ref. 121, Copyright © 1997. John Wiley & Sons Limited. Reproduced with permission.

where iPP lamellae grew primarily in a direction perpendicular to the interface (123). Blends of acrylonitrile–butadiene (AB) rubber and ethylene–propylene–diene (EPD) rubber were shown to be incompatible without and compatible with a compatibilizer, such as chlorinated PE. The change in phase morphology with added compatibilizer was shown clearly by afm (124). Blends of conductive PA with plasticized cellulose acetate (CA) were imaged. The fibrillar structure of the PA in the amorphous CA matrix was evident and was correlated to electrical properties of the composite (125). Blends of poly(vinylidine difluoride) (PVDF) and PMMA or PVA were made and imaged, showing that different crystalline phases of the PVDF could be stabilized and therefore preferentially selected for use in blends with different amorphous polymers (126).

IPN. Interpenetrating networks of unsaturated polyester propylene glycol/maleic anhydride/phthalic anhydride (PG/MA/PAH) and polyurethane (PU) were imaged across a range of compositions. The afm image of unsaturated polyester was flat and featureless; however, with addition of 20% PU, phase separation of the polymers was observed. With increasing PU content, surface roughness and heterogeneity increased, whereas PU was preferentially dispersed on the surface of the matrix in clumps or circular plates of widely varying sizes (127).

Latexes. Poly(butyl acrylate)/poly(methyl methacrylate) (PBA/PMMA) core/shell latex particles were imaged. Contact mode afm was inappropriate because of excessive roughness and the associated artifacts typical to these types of experiments. However, in tapping mode, core/shells of varying compositions were imaged nicely. At 90/10 PBA/PMMA, the core is partially covered by PMMA and at 80/20, the PMMA microbeads are joined together into subparticles. At a 70/30 ratio, the subparticles merge into an intact shell (128). Tapping mode afm of perfluorooctylethyl methacrylate/poly(butylmethylacrylate) (PFMA/PBMA) latex blends showed that a film of PBMA was formed containing dispersed PFMA nanoparticles (65°C). Annealing to 100°C caused accumulation of PFMA at the surface of the film (129).

The morphology of rubber latex formation was followed as a function of time during the maturation of prevulcanization, and morphological features were shown to correlate with cross-link densities. Inhomogeneous latex particles cross-linked on the surface with uncross-linked cores were obtained during this process. It is proposed that these hard-shell/soft core structures coalesce to form the characteristic dimpled surface films (130).

Block Copolymers. The phase-separated diblock copolymer of PS–PMMA was imaged by afm during annealing. Cylinders of PMMA were observed parallel to the plane of the sample film. The evolution of defects in the structure was followed as a function of annealing time, thus giving insights into mobility and structural changes (131). Phase-separated diblocks of polyparaphenylene–poly(methyl methacrylate) (PPP/PMMA) were imaged over a range of compositions. With increasing PPP concentrations, stripes or lamellae emerged within the images. The width of these stripes was interpreted to correspond to that of the PPP in the copolymer (132) (see BLOCK COPOLYMERS).

Triblock poly(styrene-*block*-ethylene/butylene-*block*-styrene) was imaged giving a repeating series of hills and valleys. The surface area fraction of the hills increased with PS content in the copolymer. The local stiffness of the hills was higher than that of the valleys, measured by force versus displacement curves

generated with the afm probe. The authors conclude that the hills are PS and the valleys are ethylene/butylene (133). Triblock PS–PBD–PMMA was imaged showing the PS/PMMA lamellae to be mainly oriented perpendicular to the observed surface. PBD-spheroids (approximately 14 nm in diameter) are separated at the lamellar PS/PMMA interfaces. The microstructure is explained on the basis of surface energies (88).

Random block copolyamide-ethers (hard–soft block elastomers) were imaged, showing that thicker films contain much larger crystals of the hard block segments than those obtained with thin films (30-nm films had crystals of approximately 7 nm $\times$ 50–100 nm; 20-μm films had crystals of about 12 nm $\times$ 200 nm). Further analysis also suggested that within the thicker films, more soft-segment is available at the surface compared to the thinner films (134).

Hybrid Organic-Inorganic Polymers. Hybrid organic–inorganic polymers, typically produced by sol–gel inorganic polymerization–derivatization of organic polymers, are materials currently under investigation for a wide range of industrial, consumer, and military applications. With regard to afm imaging, such materials represent the combination of studies of organic polymer systems, and of inorganic polymers, most often for heterogeneous catalysts. For these emerging hybrid materials, afm has been shown to be able to discriminate between organic and inorganic phases, and to describe the boundary regions therein.

Nanophase-segregated morphologies of linear, sulfonated polystyrene–polyisobutylene–polystyrene triblock copolymers were demonstrated to act as templates for directing *in situ* sol–gel polymerizations of tetraethylorthosilicate (TEOS) around PS regions using domain-specific solvents and certain counterions. Suitable cations in conjunction with a solvent that swells only the PS domains allowed for hydrolyzed TEOS monomers to migrate to targeted ionic domains where sol–gel reactions occur. The morphology of these organic–inorganic hybrids consisted of rod-like, silicate-containing PS domains having inter-rod distances of tens of nanometers (Fig. 19). The rods were structured in essentially parallel arrays in micron-sized "grains" as is shown in the afm image (135,136). Poly(methyl methacrylate)–silica hybrid materials, prepared by sol–gel chemistry, were imaged. Fracture surfaces of optically transparent hybrids were found to exhibit very low levels of roughness, suggesting that the organic and inorganic phases are not separated, whereas the translucent variants showed significant roughness (suggestive of phase separation) (137). Poly(tetramethylene oxide)–silica hybrid materials were also prepared by sol–gel chemistry. Semi-IPNs were then produced from these materials and poly(methacrylic acid). Imaging of these revealed microphase-separated polysilicate domains (138). Similar polysilicate domains have been observed with poly(vinyl pyrrolidone)–silica hybrids (139). Silicate glass fibers, used in the reinforcement of organic polymers, were imaged (*1*) without any treatment, (*2*) with organosilane coupling agent treatment only, and (*3*) with complete emulsion-based fiber-sizing complexes. The untreated fibers were relatively smooth. Addition of a coupling agent only resulted in a rougher surface because segments of the coupling agent were torn from the glass fiber when individual fibers were separated from one another. Treatment with the complete fiber-sizing emulsions result in largely homogeneous surfaces that were smoother than those of the starting glass fibers (140). Ladder-like polyvinylsiloxane polymers were imaged, with the highly regular, two-dimensional network structure

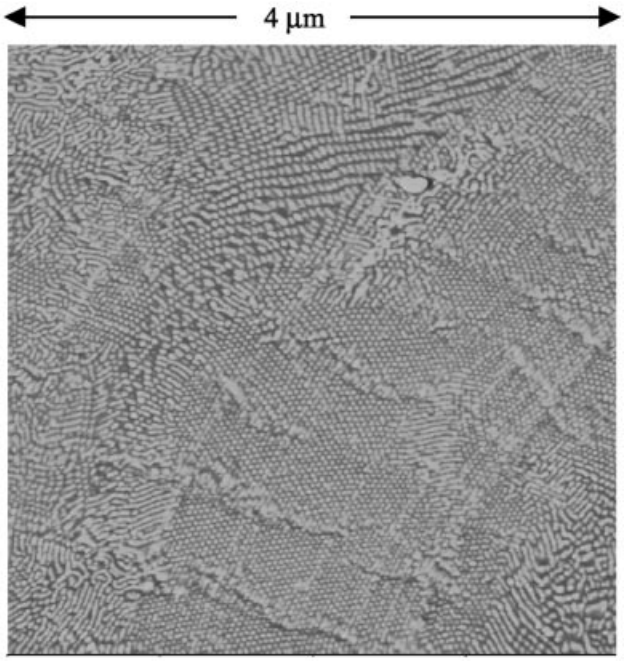

Fig. 19. Morphology of a hybrid silicate-PS molecular composite. From Ref. 135, courtesy of Prof. K. Mauritz.

clearly resolved by afm. Three-dimensional nanotubular structures from these polymers, and supermolecular structures resulting from these nanotubes, were also imaged (141).

Gels. The relative softness of most gels exacerbates the problems associated with the use of a mechanical force-based probe in determining morphology and structure. Such structural details are often scarce, given the high functionality associated with many gels. Thus, both a technical challenge and a suitable reward are associated with the use of afm with polymeric gels.

Poly(*N*-isopropylacrylamide) (PIPA) gels in water were imaged. The thickness of the gel-constrained sample geometry, cross-linking density, and osmotic pressure were all demonstrated to play a role in the observed structure. The surface microstructure, as well as the nanometer scale structure, was associated with the gel-phase transition, and there is potential, through this understanding, to control gel domain sizes. As cross-linking density was increased, the amplitude (in the afm) due to sponge-like domains is less clear. The authors hypothesize that the cross-links create local imperfections in the swelled structure (142–144).

Independently synthesized gel microspheres of PIPA were incorporated into PIPA matrix networks at the time of gelation. AFM imaging of these networks was used to visualize the microspheres, quantifying their degree of swelling as a function of temperature changes under constrained geometry. The authors found that this response was sensitive to the level of gel microspheres present in the macrogel; when a sufficient level of microspheres were present in the system, aggregation into three-dimensional domains of microspheres was observed (145).

Surface Characteristics

Roughness. Given that afm is a surface topographical technique, it should not be surprising that this method can be used to quantify the roughness of polymer surfaces, giving insights into irregularities inherent in the polymer, or resultant from chemical or mechanical action on the polymer, or from heterogeneous additives.

Surface roughness of biaxially oriented PET magnetic tape with and without metal oxide particles exhibited features down to 1 nm, including some attributed to the manufacturing process (a degree of alignment of magnetic particles along the machine axis of the films that exceeds statistical behavior). Magnetic particles, 1 μm $\times$ 0.1 μm, were observed and the surface roughness was fitted to a fractal geometry. The starting PET film surface was shown to be relatively flat and featureless at this length scale. The features observed by afm were not discernable by a noncontact optical profiler (146).

Surface roughness of PS and PS/PVME blend thin films before and after rubbing with velour cloth were measured and correlated with angle-dependent total-reflection x-ray fluorescence (TXRF). The TXRF failed to discern polymer surface changes because of rubbing, although it did characterize the underlying nickel substrate. On the other hand, afm revealed anisotropic grooves and ridges for the rubbed PS film, and isotropic, sinusoidal roughness for the rubbed blend. The anisotropy of the blend was said to be typical of phase-separated blends. Similar rms roughness of 6.1 nm and peak to peak distances of 170 nm were observed for the rubbed samples (147).

Morphology and Polymer Orientation. Morphology of polymer systems can be indicated by surface afm measurements. Of great interest in this area is the study of phase-segregated blends, blocks, and partially crystallized materials. Recently, the interpenetration of poly(butylenes succinate) lamella with the spherulites of the poly(vinylidene chloride-*co*-vinyl chloride) blend was determined by afm (148). Significant morphological changes occur in diacetylene LB films upon the addition of polyallylamine to the subphase during LB deposition (149). This addition was shown to produce microfibular structures in the resultant film consisting of "fingerprint" like features. Morphologically interesting phase segregation of phthalocyaninato-polysiloxane with poly(isobutylvinyl ether) have been measured with contact mode afm (150).

The morphology of polymer surfaces can also be influnced by electrostatics, rubbing and stretching of the materials. Polydiacetylene nanocrystals (151) and ferroelectric liquid crystalline elastomers (152,153) have been observed by afm. The morphology of these thin films yield interesting photoreactive and photoresponsive behavior. These morphologies are also affected by the rubbing (154) or stretching (153) of the materials. Understanding of molecular alignment is critical for liquid crystal display technology using polymer networks as the active matrix.

Adhesion. As mentioned previously, the afm force transducer can also be used to determine adhesion and frictional properties at surfaces. Because of the nature of afm cantilever–polymer surface interactions, it is possible to modify the cantilever tip with chemical agents, and then quantitatively probe the adhesion of these agents to the polymeric material in question. Modified afm tips were produced by attaching glass spheres to afm cantilevers. To the glass spheres,

sulfonated polysulfone was applied. The interactions between this sulfonated polysulfone and aminosilanes (which had been applied to silicon wafers) were measured using the afm. Treatment of the aminosilane with boiling water, which destroys the silane network, was shown to significantly reduce silane–polymer adhesive forces (155). Similarly, the authors showed correlation between maximum adhesive forces and silanol and sulfonic acid groups as well as mechanical entanglements (156). Adhesion between glass and HDPE or LDPE (low density polyethylene) was measured using afm. Grafting of chlorosilane-terminated PE onto the glass, to produce an amorphous interphase, was shown to enhance adhesion (157). Adhesion versus temperature was measured using afm FCs for a surface of poly(*tert*-butyl acrylate) near its glass–rubber transition (158). By studying compliance and adhesion, these authors concluded that the activation energy for molecular relaxation was the same for bulk versus free surface measurements. This indicates that afm surface measurements are accurate and useful measures of molecular scale viscoelasticity, and that when the surface properties do differ from the bulk then the afm can characterize these properties with near molecular spatial resolution. Moreover, when applied to ultrathin adsorbed polymer layers, the afm can be used for "nanorheology" so as to understand molecular lubricants at this important length scale (159).

Friction. To measure the frictional characteristics of a surface, the afm is used in contact mode, where the tip is "dragged" across the surface. The frictional force induced from the load of the tip, torques the cantilever. Higher frictional forces result in higher lateral deflection of the optical lever; these relative changes in deflection can be interpreted as changes in the coefficient of friction, μ, of the sample. In contrast to bulk measurements, afm studies of friction often contradict Amonton's "law" whereas the coefficient of friction does depend on load. This is especially true for polymer systems that exhibit significant viscous flow under load such as Hydrogels. Various hydrogels were studied by afm and μ did depend on load and also correlated with measured adhesive forces indicating a molecular chain attachment and entanglement model (160).

Friction, and more significantly wear, is an exceedingly important parameter for developing advanced polymer materials that must withstand sliding contact operations. Mechanisms of friction involve intermolecular forces, molecular adhesion, subnanometer topography of the sliding contact surfaces, and the elastic and yield moduli of the near-surface region. While studying the friction and adhesion of various polymer bearings (PS, polyacetal, Tarnamid T-27, etc) against a glass-fiber loaded, polyamide composite shaft, the resultant nanometer scale afm topography was correlated with μ (161). The high spatial resolution topographs of these worn polymer surfaces enabled a far more accurate computational model of the wear process.

Often, new materials are developed from composites, or mixed polymer systems. Since friction has been shown to be a molecularly driven mechanism, a simple weighted average of the material's constituents will not yield accurate predictions of measured tribological properties. The afm as a frictional transducer has resolved the submicrometer domains of PS/PMMA blends (162). To accentuate the sensitivity of the afm probe to very small differences in surface energy and μ, the afm tip can be functionalized. Hydroxylated tips are far better at discerning these surface changes when contrasting polar versus nonpolar blend components (163).

Table 2. RMS Roughness of Polymers Before/After Acrylamide Grafting

Polymer	Rms roughness, nm Unmodified surface	Acrylamide grafted
HDPE	308	290
PET	17	15
PTFE	165	120
PI	52	44
XPA	10	6.3

Modifications. As a method capable of describing both gross polymer features and placement of individual molecules (and small groups of atoms), afm has been shown to be an important probe in relating chemical and morphological structures. At these varying levels of magnification, afm has been demonstrated to be able to discern changes in polymers, which result from chemical modification of the starting monomer material.

A series of polymers, including HDPE, PET, PTFE, PI (polyimide), and XPA (cross-linked polyaniline) were imaged before and after Argon plasma or ozone treatment and acrylamide grafting. The basic surface features of the untreated substrates were retained after grafting. In each case, the rms roughness of the surfaces was reduced, as shown in Table 2, because the acrylamide grafts covered surface features (such coverage is similar to that described for monolayer coverage of hyperbranched polymers on inorganic surfaces). A broadening of lamellar distances was also observed upon grafting, suggesting that the grafted groups push between the existing lamellae (164).

Corona treatment of iPP (both oriented and biaxially oriented) led to the generation of spherical-shaped features on the sample surface. The size of these features was correlated to the corona dose level, as were the degree of surface oxidation, and the loss of molecular weight. Peel strength also correlated with the surface morphology (165). Poly(vinyl chloride) was oxidized using both air plasma and corona discharge. Significant differences in the surface morphologies of these two oxidized materials were imaged, with the air plasma producing smaller, regular surface nodules, and the corona producing a lower number of much larger features. The authors postulate that the plasma was more effective at removing plasticizer and other additives present in PVC, whereas the corona-generated features were the result of radical chain scissions and subsequent cross-linking of the oxidized polymer chains (166). Cross-linked, unsaturated polyester resins were treated with CF_4 under plasma conditions to produce a fluorinated surface exhibiting a greater moisture barrier than the unmodified resin. Changes in the surface were imaged, showing changes from a rough to a nodular surface upon treatment (167). LDPE and HDPE were also treated with CF_4 under plasma conditions. The degree of surface modification was found to decrease with the cystallinity level of the polymers. The lamellar surface of LDPE was converted into a uniform, nanoporous structure; this change was not observed on the HDPE. In neither case did the modification have any effect beyond the surface region (168). Polyethylene was plasma-treated in the presence of allyl alcohol, to give a hydroxylated surface, followed by silation. AFM shows that the silated surfaces are

similar to one another and consist of much higher levels of graininess than with the allyl alchol or argon plasma treatments alone. Image analysis suggested to the authors that the silane coverage might be greater than a monolayer (169).

The effectiveness of different wavelengths of light at producing the photochemical cross-linking of poly(ethynyl)carbosilane fibers was probed using afm. As the light frequency was changed, the depth of photochemical products also changed. Using broadband $\lambda > 300$ nm, photochemical products were observed to a depth of 100 nm, or about 125 molecular layers. When $\lambda = 254$ nm light was used, penetration of the photochemistry to 115 nm (130 layers) was observed. This level of detail is not readily obtained using techniques such as nmr or x-ray structural analysis (170).

BIOTECHNOLOGY APPLICATIONS

Introduction

The most important components of living cell, proteins, carbohydrates, and nucleic acids are polymers. Even lipids, which have lower molecular weights, can be regarded as methylene oligomers that have a polymerization degree of around 20. Nature uses polymers as constructive elements and parts of complicated cell machinery. The salient feature of functional biopolymers is their all-or-nothing or at least highly nonlinear response to external stimuli. Small changes happen in response to varying parameters until the critical point is reached; then a transition occurs in the narrow range of the varied parameter, and after the transition is completed, there is no significant further response of the system. Such nonlinear response of biopolymers is warranted by highly cooperative interactions. Despite the weakness of each particular interaction in a separate monomer unit, these interactions, when summed through hundreds and thousands of monomer units, provide significant driving forces for the processes in such systems.

Not surprisingly, understanding the mechanism of cooperative interactions in biopolymers has opened the floodgates for attempts to mimic the cooperative behavior of biopolymers in synthetic systems. Recent decades witnessed the appearance of synthetic functional polymers, which respond in some desired way to a change in temperature, pH, electric or magnetic fields, or some other parameters. These polymers were nicknamed stimuli-responsive. The name "smart polymers" was coined because of the similarity of the stimuli-responsive polymers to biopolymers (1). Nature has always striven for smart solutions in creating life. The goal of scientists is to mimic biological processes, and therefore understand them better, and also to create novel species and invent new processes.

Applications of polymers in biotechnology and medicine are discussed in this article. The highly nonlinear response of smart polymers to small changes in the external medium is of critical importance for the successful functioning of a system. Most applications of polymers in biotechnology and medicine include biorecognition and/or biocatalysis, which take place principally in aqueous solutions. Thus, only water-compatible smart polymers are considered; smart polymers in organic solvents or water/organic solvent mixtures are beyond the scope of the article. The systems discussed in the article are based on either soluble/insoluble transition of smart polymers in aqueous solution or on the conformational transition of macromolecules physically attached or chemically grafted to the surface. Systems that have covalently cross-linked networks of macromolecules, called hydrogels, are not considered (see HYDROGELS).

One could define *smart polymers* used in biotechnology and medicine as macromolecules that undergo fast and reversible changes from hydrophilic to hydrophobic microstructure triggered by small changes in their environments. These microscopic changes are apparent at the macroscopic level as precipitate formation in solutions of smart polymers or changes in the wettability of a surface to which a smart polymer is grafted. The changes are reversible, and the system returns to its initial state when the trigger is removed.

Polymers Used in Biotechnology and Medicine

The highly nonlinear transitions in smart polymers are driven by different factors, for example, neutralization of charged groups by either a pH shift (2) or the addition of an oppositely charged polymer (3), changes in the efficiency of hydrogen bonding and an increase in temperature or ionic strength (4), and critical phenomena in hydrogels and interpenetrating polymer networks (5). The polymer systems that have highly nonlinear response can be divided into three general groups: pH-sensitive polymers, thermosensitive polymers, and reversibly cross-linked networks.

pH-Sensitive Polymers. The first group of smart polymers consists of polymers whose transition between the soluble and insoluble state is created by decreasing the net charge of the polymer molecule. The net charge can be decreased by changing the pH to neutralize the charges on the macromolecule and hence to reduce the hydrophilicity (increase the hydrophobicity) of the macromolecule. Copolymers of methyl methacrylate (hydrophobic part) and methacrylic acid (hydrophilic at high pH when carboxy groups are deprotonated but more hydrophobic when carboxy groups are protonated) precipitate from aqueous solutions by acidification to pH around 5, and copolymers of methyl methacrylate (hydrophobic part) with dimethylaminoethyl methacrylate (hydrophilic at low pH when amino groups are protonated but more hydrophobic when amino groups are deprotonated) are soluble at low pH but precipitate in slightly alkaline conditions (6) (see METHACRYLIC ESTER POLYMERS). Hydrophobically modified cellulose derivatives that have pending carboxy groups, for example, hydroxypropyl methyl cellulose acetate succinate, are also soluble in basic conditions but precipitate in slightly acidic media (7).

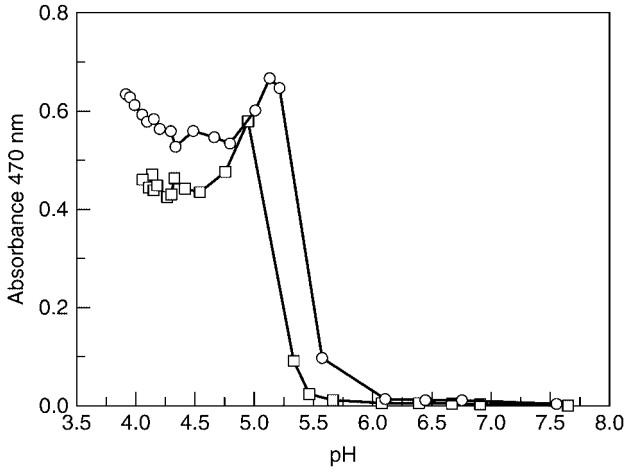

Fig. 1. pH-induced precipitation of a random copolymer of methacrylic acid and methacrylate (commercialized as Eudragit S 100 by Röhm Pharma GMBH, Weiterstadt, Germany) (open squares) and *p*-amino-phenyl-α-D-glucopyranoside-modified copolymer (open circles) measured as turbidity at 470 nm. Some decrease in turbidity at lower pH values is caused by flocculation and sedimentation of the polymer precipitate. Redrawn from Ref. 8.

The pH-induced precipitation of smart polymers is very sharp and usually requires a change in pH of not more than 0.2–0.3 units (Fig. 1). When some carboxy groups are used to couple a biorecognition element, for example, noncharged sugar, the increased hydrophobicity of the copolymer results in precipitation at a higher pH (8). The copolymerization of *N*-acryloyl sulfametazine with *N*,*N*-dimethylacrylamide results in a pH-sensitive polymer whose reversible transition is in the physiological range of pH 7.0–7.5 (9) (see ACRYLAMIDE POLYMERS).

The charges on the macromolecule can also be neutralized by adding an efficient counterion, for example, a low molecular weight counterion or a polymer molecule of opposite charges. The latter systems are combined under the name of polycomplexes. The cooperative nature of interaction between two polymers of opposite charges makes polycomplexes very sensitive to changes in pH or ionic strength (10). The complex formed by poly(methacrylic acid) (polyanion) and poly(*N*-ethyl-4-vinyl-pyridinium bromide) (polycation) undergoes reversible precipitation from aqueous solution at any desired pH value in the range 4.5–6.5 that depends on the ionic strength and polycation/polyanion ratio in the complex (Fig. 2) (11). Polyelectrolyte complexes formed by poly(ethylene imine) and poly(acrylic acid) undergo soluble–insoluble transition in an even broader pH range of 3–11 (12).

The pH of the transition of pH-sensitive polymers such as poly(methyl methacrylate-*co*-methacrylic acid) or poly (*N*-acryloyl sulfametazine-*co*-*N*,*N*-dimethylacrylamide) is strictly fixed for the given composition of comonomers. Thus, a new polymer should be synthesized for each desired pH value. The advantage of polyelectrolyte complexes is that by using only two different polymers and mixing them in different ratios, reversible precipitation can be achieved at any desired pH value in a rather broad pH range (see POLYELECTROLYTES).

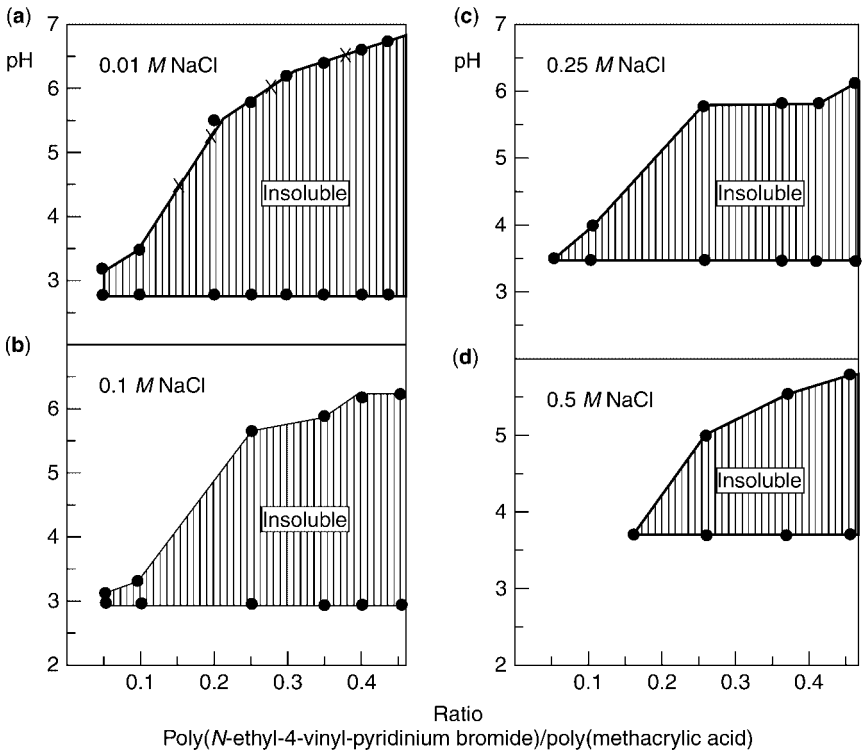

Fig. 2. Phase diagram for the polyelectrolyte complex formed by poly(*N*-ethyl-4-vinyl-pyridinium bromide) (polymerization degree 530) and poly(methacrylic acid) (polymerization degree 1830). The dots (represent pH values at which the turbidity of the polymer solutions was first observed at 470 nm. Ionic strength was 0.01 *M* NaCl (**a**), 0.1 *M* NaCl (**b**), 0.25 *M* NaCl (**c**), and 0.5 *M* NaCl (**d**). Dashed area represents pH/composition range where the complex is insoluble. Reproduced from Ref. 11 with permission.

Thermosensitive Polymers. The reversible solubility of thermosensitive polymers is caused by changes in the hydrophobic–hydrophilic balance of uncharged polymers induced by increasing temperature or ionic strength. Uncharged polymers are soluble in water because of hydrogen bonding with water molecules. The efficiency of hydrogen bonding lessens as temperature increases. The phase separation of a polymer occurs when the efficiency of hydrogen bonding becomes insufficient for the solubility of macromolecule.

When the temperature of an aqueous solution of a polymer is raised above a certain critical temperature (which is often referred to as the transition temperature, lower critical solution temperature (LCST), or "cloud point"), phase separation takes place. An aqueous phase that contains practically no polymer and a polymer-enriched phase are formed. Both phases can be easily separated by decanting, centrifugation, or filtration. The temperature of the phase transitions depends on the polymer concentration and molecular weight (Fig. 3) (13,14). The phase separation is completely reversible, and the polymer dissolves in water when the temperature is reduced below the transition temperature.

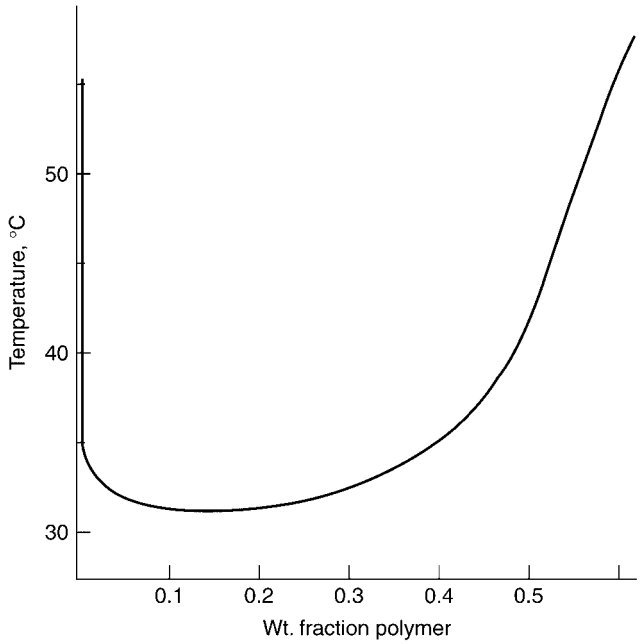

Fig. 3. Phase diagram for poly(NIPAAM) in aqueous solution. The area under the binodal curve presents the range of temperatures/polymer concentrations for homogeneous solution. Separation into polymer-enriched and polymer-depleted phases takes place for any polymer concentration/temperature above the binodal curve. Reproduced from Ref. 14 with permission.

Two groups of thermosensitive smart polymers are most widely studied and used:

(1) Poly(*N*-alkyl substituted acrylamides) and the most well-known of them, poly(*N*-isopropyl acrylamide) (poly(NIPAAM)), whose transition temperature is 32°C (14), and
(2) Poly(*N*-vinylalkylamides) such as poly(*N*-vinylisobutyramide) whose transition temperature is 39°C (15) or poly(*N*-vinyl caprolactam) whose transition temperature is 32–33°C (depending on the molecular weight of the polymer) (13)

A variety of polymers that have different transition temperatures from 4–5°C for poly(*N*-vinyl piperidine) to 100°C for poly(ethylene glycol) are available at present (16).

pH-Sensitive smart polymers usually contain carboxy or amino groups that can be used for covalent coupling of biorecognition or biocatalytic elements (ligands). Thermosensitive polymers, on the contrary, do not have inherent reactive groups which could be used for ligand coupling. Thus, copolymers that contain reactive groups can be synthesized. *N*-Acryloylhydroxysuccinimide (17) or glycidyl methacrylate (18) have often been used as active comonomers in copolymerization with NIPAAM, allowing further coupling of amino-group-containing ligands

to the synthesized copolymers. The use of an initiator of polymerization (19) or chain-transfer agent (20) that has an active group results in a polymer modified only at the end of the macromolecule. An alternative strategy is to incorporate a polymerizable double bond into the ligand, for example, by modification with acryoyl group, and then to copolymerize the modified ligand with NIPAAM (21,22).

An increase in the hydrophilicity of the polymer-accompanied incorporation of hydrophilic comonomers or coupling to hydrophilic ligands increases the transition temperature, whereas hydrophobic comonomers and ligands have the opposite effect (4). The pH-induced change in ligand hydrophobicity could have a dramatic effect on the thermoseparation of the ligand–polymer conjugate. A copolymer of NIPAAM and vinyl imidazole precipitates at about 35°C at pH 8 where imidazole moieties are noncharged and relatively hydrophobic, but no precipitation occurs even when heating the polymer solution to 80°C at pH 6 where imidazole groups are protonated and very hydrophilic (23).

Ligand–ligand interactions in a ligand–polymer conjugate also have a significant effect on the thermoseparation. The precipitation temperature for the previously mentioned copolymers of NIPAAM and vinyl imidazole increases as the imidazole content in the copolymer increases. On the contrary, the precipitation temperature decreases as the increase of imidazole content increases, when the polymer forms a Cu(II) complex (23). Each Cu(II) ion interacts with two to three imidazole groups to cross-link the segments of the polymer molecule (24). The restricted mobility of the polymer segments results in a lower precipitation temperature.

Block copolymers that have a thermosensitive "smart" part that consists of poly(NIPAAM) form reversible gels on an increase in temperature, whereas random copolymers separate from aqueous solutions by forming a concentrated polymer phase (25). Thus, the properties of polymers that are important for biotechnological and medical applications could be controlled by the composition of comonomers and also by the polymer architecture.

The phase transition of thermosensitive polymers at increased temperature results from hydrophobic interactions between polymer molecules. Because hydrophobic interactions are promoted by high salt concentrations, the addition of salts shifts the cloud point to lower temperatures. When the transition temperature is below room temperature, polymer precipitation is achieved by the addition of salt, without any heating. The addition of organic solvents, detergents, and chaotropic agents increases the transition temperature because these compounds deteriorate hydrophobic interactions.

Reversibly Cross-Linked Polymer Networks. Systems that have reversible noncovalent cross-linking of separate polymer molecules into a polymer network belong to the third group of smart polymers. When formed, reversibly cross-linked polymers either precipitate or form a physical gel. Polymers that have sugar ligands cross-linked by lectins with multibinding sites (26) and boronate-polyols (27–29) are the most widely used systems of this type. The reversible response in these systems is achieved by addition/removal of a low molecular weight analogue of the polymer. For example, small sugars added at high concentrations compete with sugar-containing polymers for binding to lectin and destroy intrapolymer cross-links that result in disengagement of the network.

Heterogeneous Systems Using Smart Polymers. A solid surface acquires new properties when modified by adsorption or chemical grafting of polymers. Smart polymer, that have terminal (only single-point) or random (multipoint) attachment possible could be covalently coupled to the respective active groups on the surface (30). Single-point attachment could also be achieved by covalent modification of the surface using an initiator of polymerization and then carrying out polymerization of monomers in the solution that surrounds the support. The growth of polymer chains occurs only at the sites where initiator was coupled (31). Alternatively, the solid support is irradiated by light (32) or a plasma beam (33) when monomer is in the surrounding solution. Active radical sites on the surface, which appear as a result of irradiation, initiate the growth of polymer macromolecules. As a rule, irradiation methods give a higher density of grafted polymer, but polymerization is less controlled as in covalent coupling or using a covalently coupled initiator. Irradiation, especially at high monomer concentrations, could produce a cross-linked polymer gel attached to the solid support (34).

A separate group of smart polymers is represented by particulate systems. Liposomes that reversibly precipitate on salt addition and removal were prepared from a synthetic phospholipid that had a diacetylene moiety in the hydrophobic chain and an amino group in the hydrophilic head of the phospholipid, followed by polymerization of diacetylene bonds (35). Latices composed of thermosensitive polymers or a layer of thermosensitive polymer at the surface represent another example of insoluble but reversibly suspended particulate systems that respond to increasing/decreasing temperature (31).

Applications Overview

There are numerous potential applications for polymers in biotechnology and medicine. The main commercial application of polymers is the production of "smart" pills where the (aside from medical plastics) polymer shell protects the pill from the harmful action of the stomach contents but allows the pill to dissolve in the intestine. There is not yet any other product on the market that applies smart polymers, but the interest in these applications is growing in both the academic community and industry. The following applications are considered in this article:

(1) smart pills that have an enteric coating
(2) smart polymers for affinity precipitation of proteins
(3) aqueous two-phase polymer systems formed by smart polymers and their application for protein purification
(4) smart surfaces for mild detachment of cultivated mammalian cells
(5) smart chromatographic matrices that respond to temperature
(6) smart polymers for controlled porosity of systems – "chemical valve"
(7) liposomes with triggered release of their contents

(8) smart polymers for bioanalytical applications
(9) reversibly soluble biocatalysts

Smart Pills That Have an Enteric Coating. Peroral introduction of medical preparations is the most convenient method compared to subcutaneous or intravenous injection and even to nasal sprays or eye droplets. The absorption of a swallowed pill takes place predominantly in the intestine and to reach the intestine the medicine must pass unharmed through the stomach that has a very low pH value of 1.4 and abundant hydrolytic enzymes that can degrade a broad variety of chemical structures. Many medicines are susceptible to damage in the stomach environment. The ideal condition for peroral introduction is to have a smart pill, which is insoluble in the stomach and hence passes through the stomach unaffected but easily dissolves at the higher pH in the intestine where the medicine is absorbed. Smart polymers provide the solution. Hydrophobic polymers such as poly(methyl methacrylate) or hydrophobically modified celluloses are insoluble in water per se, but the introduction of carboxy groups (either by partial hydrolysis of ester groups in methyl methacrylate or modification of cellulose HO groups by dicarboxylic acids such as succinic or phthalic acid) endows the polymers with pH-dependent solubility. The pill covered by a shell of such a polymer (enteric coating) is insoluble at low pH when the carboxy groups are protonated and uncharged, but is easily soluble at a pH above 6 when carboxy groups are protonated and charged. Industrially produced polymers for enteric coating belong to two main groups, synthetic copolymers of methyl methacrylate and methacrylic acid and modified derivatives of cellulose, a natural polymer (Table 1). The first group of polymers is used mainly by European and U.S. manufacturers, and the second group is more popular in Japan.

Table 1. Industrially Manufactured Polymers for Producing Smart Pills

Polymer	Trade name	Manufacturer	Country
Poly(methacrylic acid-*co*-methyl methacrylate) 1:1 monomer ratio, MW 135,000	Eudragit L	Röhm Pharma GmBH	United States, Germany
Poly(methacrylic acid-*co*-methyl methacrylate) 1:2 monomer ratio, MW 135,000	Eudragit S	Röhm Pharma GmBH	United States, Germany
Carboxymethylcellulose	CMEC	Freund Sangyo Co., Ltd.	Japan
Cellulose acetate phthalate	CAP	Wako Pure Chemicals Ltd.	Japan
Hydroxypropylmethyl cellulose phthalate	HP-50, HP-55	Shin-Etsu Chemical Co., Ltd.	Japan
Hydroxypropylmethyl cellulose acetate succinate	ASM, AS-H	Shin-Etsu Chemical Co., Ltd.	Japan
Poly(diethylaminoethyl methacrylate-*co*-methyl methacrylate) MW 150,000	Eudragit E	Röhm Pharma GmBH	United States, Germany

Whenever the charge-bearing comonomer has an amino group instead of a carboxy group, the solubility of the polymer acquires opposite pH-dependence. The polymer is soluble at low pH values but insoluble in neutral and alkaline media. Poly(diethylaminoethyl methacrylate-*co*-methyl methacrylate) (commercialized as Eudragit E) is an example of such a polymer. The shell that is composed of this polymer protects the tablet against dissolution in the neutral saliva, and the mouth is not affected by the unpleasant taste of bitter medicine, but the polymer dissolves readily in the stomach.

Bioseparation Applications

Affinity Precipitation. All bioseparation processes include three stages: preferential partitioning of target substance and impurities between two phases (liquid–liquid or liquid–solid), mechanical separation of the phases (eg, separation of the stationary and mobile phases in a chromatographic column), and recovery of the target substance from the enriched phase. Because smart polymers can undergo phase transitions, they could facilitate the second and the third stages of bioseparation processes.

The ability of smart polymers to form *in situ* heterogeneous systems is exploited in affinity precipitation (Fig. 4). The technique is based on using a conjugate of a smart polymer that has a covalently coupled biorecognition moiety, that is, a ligand specific for a target protein. The conjugate forms a complex with

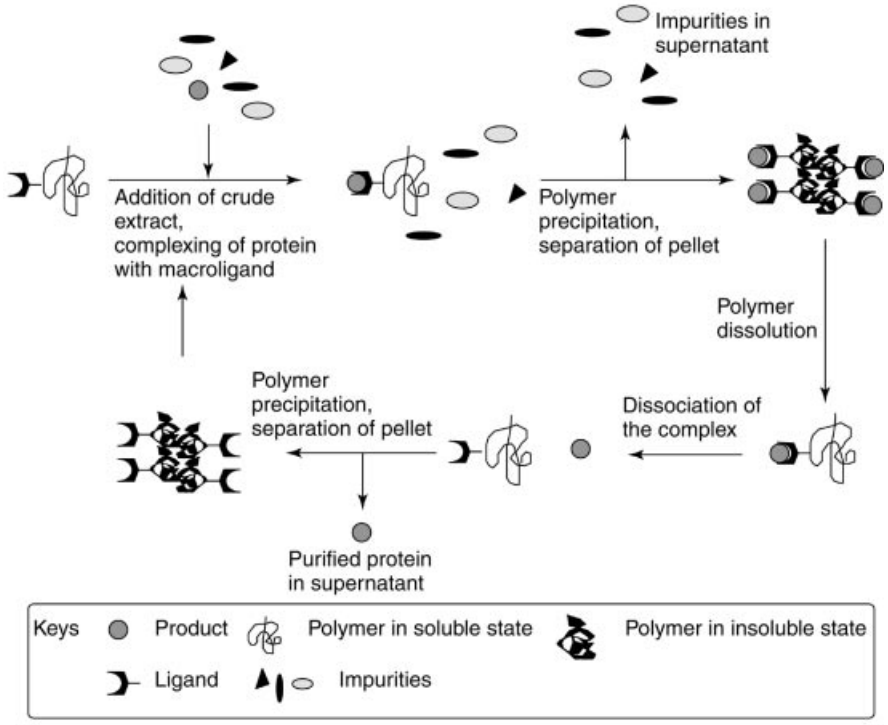

Fig. 4. Schematic of affinity precipitation technique for protein purification.

the target protein but not with the other proteins in the crude extract. Phase separation of the complex is triggered by small changes in the environment, resulting in transition of the polymer backbone into an insoluble state. The target protein specifically coprecipitates with the smart polymer, and the impurities in the crude extract remain in solution. Then, the target protein is either eluted from the insoluble macroligand–protein complex or the precipitate is dissolved. The protein is dissociated from the macroligand, and the ligand–polymer conjugate is precipitated again. Now without the protein that remains in the supernatant in purified form. A variety of different ligands such as triazine dyes, sugars, protease inhibitors, antibodies, nucleotides, double- or single-stranded DNA, and chelated metal ions were successfully used for affinity precipitation (36). After elution of the target protein the ligand–polymer conjugate could be recovered and used in the next purification cycle (37).

Triazine dyes, robust affinity ligands for many nucleotide-dependent enzymes, were successfully used in conjugates with the pH-sensitive copolymer of methacrylic acid and methyl methacrylate which precipitates when pH decreases (Eudragit S 100) for purification of dehydrogenases from various sources by affinity precipitation (38,39). Sugar ligands constitute another attractive alternative and have been used in combination with Eudragit S 100 for bioseparation of lectins (40). Restriction endonuclease Hind III was successfully isolated using the thermosensitive conjugate of poly(NIPAAM) with phage λ DNA (21). Human IgG was specifically precipitated with a conjugate of protein A and galactomannan. Galactomannan polymer was reversibly precipitated by adding tetraborate (41).

The efficient precipitation of Cu(II)-loaded poly(*N*-vinylimidazole-*co*-NIPAAM) by high salt concentrations at mild temperature is very convenient for metal affinity precipitation of proteins that have inherent histidine residues at the surface or for recombinant proteins artificially provided with histidine tags (usually four to six residues). High salt concentration does not interfere with protein–metal ion–chelate interaction, and, on the other hand, it reduces the possibility of nonspecific binding of foreign proteins to the polymer both in solution and when precipitated (23). The flexibility of polymer chains in solution allows several imidazole ligands on a polymer molecule to come close enough to interact with the same Cu(II) ion and thus to provide sufficient strength of polymer–Cu(II) interactions to purify a variety of histidine-containing proteins (37).

Polyelectrolyte complexes that have pH-dependent solubility were successfully used in different bioseparation procedures. When an antigen, inactivated glyceraldehyde-3-phosphate dehydrogenase, from rabbit was covalently coupled to a polycation, the resulting complex was used to purify monoclonal antibodies specific toward inactivated glyceraldehyde-3-phosphate dehydrogenase (11). The successful affinity precipitation of antibodies using glyceraldehyde-3-phosphate dehydrogenase bound to a polyelectrolyte complex indicates that the ligand is exposed to the solution. This fact was used to develop a new method for producing monovalent Fab fragments of antibodies. Traditionally, Fab fragments are produced by proteolytic digestion of antibodies in solution followed by isolation of Fab fragments. In the case of monoclonal antibodies against inactivated subunits of glyceraldehyde-3-phosphate dehydrogenase, digestion with papain resulted in significant damage of binding sites of the Fab fragment. Proteolysis of monoclonal antibodies in the presence of the antigen–polycation conjugate followed by (*1*)

precipitation induced by adding polyanion, poly(methacrylic acid), and a pH shift from 7.3 to 6.5, and (*2*) elution at pH 3.0 that resulted in 90% immunologically competent Fab fragments. Moreover, the papain concentration required for proteolysis was 10 times less for antibodies bound to the antigen–polycation conjugate compared to that for free antibodies in solution (42). Active glyceraldehyde-3-phosphate dehydrogenase from rabbit muscle was separated from the inactivated enzyme by using monoclonal antibodies specific for the inactivated enzyme covalently coupled to the polyanion component of the polyelectrolyte complex. This system can be regarded as a simplified model of chaperone action in living cells that assist in separating active protein molecules from misfolded ones (43).

Apart from specific interactions between a target protein and a ligand–polymer conjugate, nonspecific interactions of protein impurities with the polymer backbone could take place. The nonspecific interactions limit the efficiency of the affinity precipitation technique, and significant efforts were made to reduce these interactions. The advantage of polyelectrolyte complexes as carriers for affinity precipitation is low nonspecific coprecipitation of proteins when the polymer undergoes a soluble–insoluble transition (10).

Smart particles capable of reversible transition between aggregated and dispersed states were used for affinity precipitation of proteins. Thermosensitive (44) or pH-sensitive latices (45) or salt-sensitive liposomes that have polymerized membranes (35) are examples of such systems.

Two elements are required for successful affinity precipitation. The backbone of a smart polymer provides precipitation at the desired conditions (temperature, pH, ionic strength), and the biorecognition element is responsible for selective binding of the protein of interest. By proper choice of a smart polymer, precipitation could be achieved practically at any desired pH or temperature. For example, poly(*N*-acryloylpiperidine) terminally modified with maltose has an extremely low critical temperature (soluble below 4°C and completely insoluble above 8°C) and was used to purify thermolabile α-glucosidase (46).

Partitioning in Aqueous Polymer Two-Phase Systems. Two aqueous polymer solutions become mutually incompatible when the threshold concentrations of polymers are exceeded. Both of the polymer phases formed contain about 90% water and hence present a very friendly environment for proteins and other biomolecules. Proteins partition selectively between two phases depending on their size, charge, hydrophobicity, nature, and the concentration of the phase-forming polymers. The partitioning could also be directed by adding some salt or coupling an affinity ligand specific for a given protein to one of the phase-forming polymers (47). The selective partitioning of proteins between the two phases formed has proven to be an efficient tool for purifying proteins and some low molecular weight substances. The main problem of the method—how to separate the target protein from the phase-forming polymer—has not yet been completely solved. Smart polymers provide an elegant solution to this problem—simple precipitation of the phase-forming polymer leaves protein in the supernatant (Fig. 5): (*1*) the crude protein extract is mixed with the aqueous two-phase polymer system, and the conditions are selected so that the protein of interest partitions into a phase formed by a smart polymer (for example by coupling affinity ligand to the smart polymer), and the impurities concentrate in the other phase; (*2*) the phases are separated mechanically and the phase formed by the smart polymer is

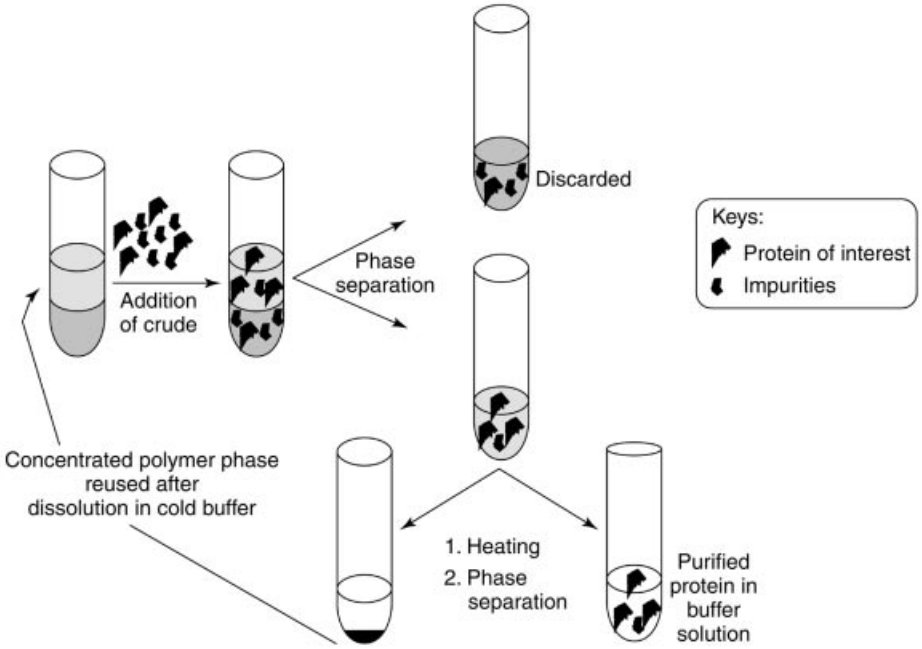

Fig. 5. Schematic presentation of protein partitioning in aqueous two-phase polymer system formed by a smart (thermosensitive) polymer. Reproduced from Ref. 140 with permission.

subjected to conditions (pH or temperature) where the polymer undergoes phase separation; and (*3*) two new phases are formed, a polymer-enriched phase of high polymer and low water concentration, which contains practically no protein, and a polymer-depleted aqueous phase that contains most of the purified protein and minute amounts of the polymer left after phase separation.

pH-Sensitive acrylic copolymers (48) or thermoresponsive polymers, poly(ethylene oxide-*co*-propylene oxide) (49,50) or poly(*N*-vinyl caprolactam-*co*-vinyl imidazole) (51), form two-phase systems with relatively hydrophilic polymers such as dextran or modified starch and have been successfully used for protein purification. The pH- or thermoprecipitated polymer in contrast to dextran could be regenerated by dissolution at a lower temperature or by changing pH. Quite recently, an aqueous two-phase polymer system was developed where both phase-forming polymers, poly(*N*-isopropylacrylamide-*co*-vinyl imidazole) and poly(ethylene oxide-*co*-propylene oxide) end modified by hydrophobic $C_{14}H_{29}$ groups, are thermoresponsive and could be recycled (52).

Smart Surfaces

Cell Detachment. The driving force behind phase separation of smart polymers is a sharp increase in hydrophobicity after a small change in

environmental conditions. The hydrophobic "collapsed" polymer aggregates form a separate phase. When grafted to the surface, macromolecules of the smart polymer cannot aggregate, but the conformational transition from the hydrophilic to the hydrophobic state endows the surface with regulated hydrophobicity: the surface is hydrophilic when the smart polymer is in the expanded "soluble" conformation and hydrophobic when the polymer is in the collapsed "insoluble" conformation. The change of hydrophobicity of the surface by grafted poly(*N*-isopropylacrylamide) was demonstrated by contact angle measurements (53) and water absorbency (54) (see SURFACE PROPERTIES).

The transition temperature for adsorbed (presumably via multipoint attachment) poly(NIPAAM) molecules is lower than that in bulk solution, and the properties of the layer of collapsed macromolecules formed above the transition temperature depend strongly on the speed by which the temperature increases. At a low speed of temperature increase, the "liquid-like" polymer layer is formed, whereas at high speeds, the polymer layer has more "solid-like" properties (55). When cooling, the collapsed polymer molecules return to the initial loopy adsorbed conformation via transitional extended conformation. The relaxation process for the extended-to-loopy adsorbed conformational transition occurs slowly and depends on the temperature obeying an Arrhenius law. Kinetic constraints, it is proposed, play an important role in this transition (56).

The change of surface properties from hydrophobic above the critical temperature of the polymer grafted to hydrophilic below it has been successfully used for detaching mammalian cells. Mammalian cells are normally cultivated on a hydrophobic solid substrate and are detached from the substrate by protease treatment, which often damages the cells by hydrolyzing various membrane-associated protein molecules. The poly(NIPAAM)-grafted surface is hydrophobic at 37°C because this temperature is above the critical temperature for the grafted polymer and those cells that are growing well on it. A decrease in temperature results in transition of the surface to the hydrophilic state, where the cells can be easily detached from the solid substrate without any damage. Poly(NIPAAM) was grafted to polystyrene culture dishes using an electron beam. Bovine hepatocytes, cells that are highly sensitive to enzymatic treatment, were cultivated for 2 days at 37°C and detached by incubation at 4°C for 1 h. Nearly 100% of the hepatocytes was detached and recovered from the poly(NIPAAM)-grafted dishes by low temperature treatment, whereas only about 8% of the cells was detached from the control dish (57). The technique has been extended to different cell types (58,59). It is noteworthy that hepatocytes recovered by cooling retained their native form, had numerous bulges and dips, and attached well to the hydrophobic surface again, for example, when the temperature was increased above the conformational transition of poly(NIPAAM). On the contrary, enzyme-treated cells had a smooth outer surface and had lost their ability to attach to the surface. Thus, cells recovered by a temperature shift from poly(NIPAAM)-grafted surfaces have an intact structure and maintain normal cell functions (58).

The molecular machinery involved in cell-surface detachment was investigated using temperature-responsive surfaces (60). Poly(NIPAAM)-grafted and nongrafted surfaces showed no difference in attachment, spreading, growth, confluent cell density, or morphology of bovine aortic endothelial cells at 37°C. Stress fibers, peripheral bands, and focal contacts were established in similar ways.

When the temperature was decreased to 20°C, the cells grown on poly(NIPAAM)-grafted support lost their flattened morphology and acquired a rounded appearance similar to that of cells immediately after plating. Mild agitation makes the cells float free from the surface without a trypsin treatment. Neither changes in cell morphology nor cell detachment occurred on ungrafted surfaces. Sodium azide, an ATP synthesis inhibitor, and genistein, a tyrosine kinase inhibitor, suppressed changes in cell morphology and cell detachment, whereas cycloheximide, a protein synthesis inhibitor, slightly enhanced cell detachment. Phalloidin, an actin filament stabilizer, and its depolymerizer, cytochalasin D, also inhibited cell detachment. These findings suggest that cell detachment from grafted surfaces is mediated by intracellular signal transduction and reorganization of the cytoskeleton, rather than by a simple change in the "stickiness" of the cells to the surface when the hydrophobicity of the surface is changed.

One could imagine producing artificial organs using temperature-induced detachment of cells. Artificial skin could be produced as the cells are detached from the support not as a suspension (the usual result of protease-induced detachment) but preserving their intercellular contacts. Fibroblasts were cultured on the poly(NIPAAM)-collagen support until the cells completely covered the surface at 37°C, followed by a decrease in temperature to about 15°C. The sheets of fibroblasts detached from the dish and within about 15 min floated in the culture medium (57). The detached cells could be transplanted to another culture surface without functional and structural changes (34). Grafting of poly(NIPPAM) onto a polystyrene surface by photolithographic technique creates a special pattern on the surface, and by decreasing temperature, cultured mouse fibroblast STO cells are detached only from the surface area on which poly(NIPAAM) was grafted (61). Lithographed films of smart polymer present supports for controlled interactions of cells with surfaces and can direct the attachment and spreading of cells (62). One could envisage producing artificial cell assemblies of complex architecture using this technique.

Temperature-Controlled Chromatography. Surfaces that have thermoresponsive hydrophobic/properties have been used in chromatography. HPLC columns with grafted poly(NIPAAM) have been used for separating steroids (63) and drugs (64). The chromatographic retention and resolution of the solutes was strongly dependent on temperature and increased as temperature increased from 5 to 50°C, whereas the reference column packed with nonmodified silica displayed much shorter retention times that decreased as temperature decreased. Hydrophobic interactions dominate in retaining solutes at higher temperature, and the preferential retention of hydrogen-bond acceptors was observed at low temperatures. The effect of temperature increase on the retention behavior of solutes separated on the poly(NIPAAM)-grafted silica chromatographic matrix was similar to the addition of methanol to the mobile phase at constant temperature (65).

The temperature response of the poly(NIPAAM)-silica matrices depends drastically on the architecture of the grafted polymer molecules. Surface wettability changes dramatically as temperature changes across the range 32–35°C (corresponding to the phase-transition temperature for NIPAAM in aqueous media) for surfaces where poly(NIPAAM) is terminally grafted either directly to the surface or to the looped chain copolymer of NIPAAM and *N*-acryloylhydroxysuccinimide which was initially coupled to the surface. The wettability changes for the

loop-grafted surface itself were relatively large but had a slightly lower transition temperature (~27°C). The restricted conformational transitions for multipoint grafted macromolecules are probably the reason for the reduced transition temperature. The largest surface free energy changes among three surfaces was observed for the combination of both loops and terminally grafted chains (30).

Introduction of a hydrophobic comonomer, butyl methacrylate, in the polymer resulted in a decreased transition temperature of about 20°C. Retention of steroids in poly(NIPAAM-*co*-butyl methacrylate)-grafted columns increases as column temperature increases. The capacity factors for steroids on the copolymer-modified silica beads was much larger than that on poly(NIPAAM)-grafted columns. The effect of temperature on steroid retention on poly(NIPAAM-*co*-butyl methacrylate)-grafted stationary phases was more pronounced compared to supports modified with poly(NIPAAM). Furthermore, retention times for steroids increased remarkably as the butyl methacrylate content increased in the copolymer. The temperature-responsive elution of steroids was strongly affected by the hydrophobicity of the grafted polymer chains on silica surfaces (63).

The mixture of polypeptides, consisting of 21–30 amino acid residues (insulin chain A, β-endorphin fragment 1–27, and insulin chain B) could not be separated at 5°C (below the transition temperature) on copolymer-grafted matrix. At this temperature, the copolymer is in an extended hydrophilic conformation that results in decreased interactions with peptides and hence short retention times insufficient to resolve them. The mixture has been easily separated at 30°C, when the copolymer is collapsed, hydrophobic interactions are more pronounced, and retention times are sufficiently long for resolving polypeptides (66). Large protein molecules such as immunoglobulin G demonstrate less pronounced changes in adsorption above and below the transition temperature. Only about 20% of the protein adsorbed on poly(NIPAAM)-grafted silica at 37°C (above the LCST) were eluted after decreasing temperature to 24°C (below the transition temperature) (67). Quantitative elution of proteins adsorbed on the matrix via hydrophobic interactions has not yet been demonstrated, although protein adsorption on poly(NIPAAM)-grafted matrices could be somewhat controlled by a temperature shift. A successful strategy for temperature-controlled protein chromatography proved to be a combination of temperature-responsive polymeric grafts and biorecognition element, for example, affinity ligands (see CHROMATOGRAPHY, AFFINITY).

The access of the protein molecules to the ligands on the surface of the matrix is affected by the transition of the polymer macromolecule grafted or attached to the chromatographic matrix. Triazine dyes, for example, Cibacron Blue, are often used as ligands for dye-affinity chromatography of various nucleotide-dependent enzymes (68). Poly(*N*-vinyl caprolactam), a thermoresponsive polymer whose critical temperature is about 35°C interacts efficiently with triazine dyes. Polymer molecules of a molecular weight of 40,000 are capable of binding up to seven to eight dye molecules, and hence, the polymer binds via multipoint interaction to the dye ligands available on the chromatographic matrix. At elevated temperature, polymer molecules are in a compact globule conformation that can bind only to a few ligands on the matrix. Lactate dehydrogenase, an enzyme from porcine muscle, has good access to the ligands that are not occupied by the polymer and binds to the column. Poly(*N*-vinyl caprolactam) macromolecules undergo transition to

a more expanded coil conformation as temperature decreases. Now, the polymer molecules interact with more ligands and begin to compete with the bound enzyme for the ligands. Finally, the bound enzyme is displaced by the expanded polymer chains. The temperature-induced elution was quantitative, and was the first reported in the literature when temperature change was used as the only eluting factor without any changes in buffer composition (69). Small changes in temperature, as the only eluting factor, are quite promising because there is no need in this case to separate the target protein from an eluent, usually a competing nucleotide or high salt concentration in dye-affinity chromatography.

Controlled Porosity, "Chemical Valve". Environmentally controlled change in macromolecular size from a compact hydrophobic globule to an expanded hydrophilic coil is exploited when smart polymers are used in systems of environmentally controlled porosity, so-called chemical valves. When a smart polymer is grafted to the surface of the pores in a porous membrane or chromatographic matrix, the transition in the macromolecule affects the total free volume of the pores available for the solvent and hence presents a means to regulate the porosity of the system (see MEMBRANE TECHNOLOGY).

Membranes of pH-sensitive permeability were constructed by grafting smart polymers such as poly(methacrylic acid) (70), poly(benzyl glutamate), poly(2-ethylacrylic acid) (71), poly(4-vinylpyridine) (72), which change their conformation in response to pH. Thermosensitive chemical valves have been developed by grafting poly(*N*-acryloylpyrrolidine), poly(*N*-*n*-propylacrylamide), or poly(acryloylpiperidine) (73); poly(NIPAAM) alone (33,74); or in copolymers with poly(methacrylic acid) (74) inside the pores. For example, grafted molecules of poly(benzyl glutamate) at high pH are charged and are in extended conformation. The efficient pore size is reduced, and the flow through the membrane is low ("off-state" of the membrane). As pH decreases, the macromolecules are protonated, lose their charge, and adopt a compact conformation. The efficient pore size and hence the flow through the membrane increases ("on-state" of the membrane) (71). The fluxes of bigger molecules (dextrans of molecular weights 4400–50,600) across a temperature-sensitive, poly(NIPAAM)-grafted membrane were effectively controlled by temperature, environmental ionic strength, and degree of grafting of the membrane, while the flux of smaller molecules such as mannitol was not affected by temperature even at high degree of membrane grafting (75). The on-off permeability ratio for different molecules (water, Cl^- ion, choline, insulin, and albumin) ranged between 3 and 10 and increased as molecular weight increased (76). An even more abrupt change of the on-off permeability ratio was observed for a membrane that had narrow pores formed by heavy ion beams when poly(NIPAAM) or poly(acryloyl-L-proline methyl ester) was grafted (77).

Different stimuli could trigger the transition of the smart polymer making it possible to produce membranes whose permeabilities respond to these stimuli. When a copolymer of NIPAAM with triphenylmethane leucocianide was grafted to the membrane, it acquired photosensitivity—uv irradiation increases permeation through the membrane (78). Fully reversible, pH-switchable permselectivity for both cationic and anionic redox-active probe molecules was achieved by depositing composite films formed from multilayers of amine-terminated dendrimers and poly(maleic anhydride-*co*-methylvinyl ether) on gold-coated silicon (79).

When the smart polymer is grafted inside the pores of the chromatographic matrix for gel permeation chromatography, the transition of grafted macromolecules regulates the pore size and, as a result, the elution profile of substances of different molecular weights. As the temperature is raised, the substances are eluted progressively earlier indicating shrinking of the pores of the hydrogel beads composed of cross-linked poly(acrylamide-*co*-NIPAAM) (80) or porous polymer beads with grafted poly(NIPAAM) (81).

When using a specific biorecognition element, which recognizes specific substances and translates the signal into a change of physicochemical properties, for example, pH, a smart membrane that changes its permeability in response to particular substances can be constructed. Specific insulin release in response to increasing glucose concentration, that is, an artificial pancreas, presents an everlasting challenge to bioengineers. One of the potential solutions is a "chemical valve" (Fig. 6). The enzyme, glucose oxidase, was used as a biorecognition element,

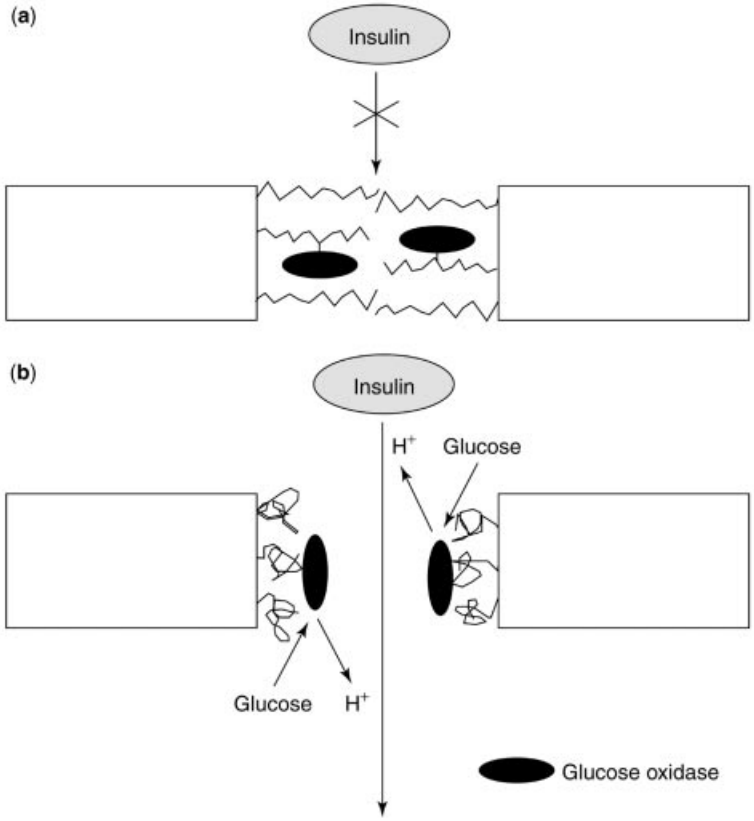

Fig. 6. Schematic of a "chemical valve." Glucose oxidase is immobilized on a pH-responsive polyacrylic acid grafted onto a porous polycarbonate membrane: (**a**) poly(acrylic acid) is in an expanded conformation that blocks insulin transport; (**b**) the oxidation of glucose is accompanied by a decrease in pH and the transition of poly(acrylic cid) into a compact conformation that results in opening of the pores and transport of insulin. Redrawn from Ref. 82.

capable of specific oxidation of glucose accompanied by a decrease in pH. The enzyme was immobilized on pH-responsive poly(acrylic acid) graft on a porous polycarbonate membrane. In neutral conditions, polymer chains are densely charged and have extended conformation that prevents insulin transport through the membrane by blocking the pores. Under exposure to glucose, the pH drops as the result of glucose oxidation by the immobilized enzyme, the polymer chains adopt a more compact conformation that diminishes the blockage of the pores, and insulin is transported through the membrane (82). Systems such as this could be used for efficient drug delivery that responds to the needs of the organism. A membrane that consists of poly(2-hydrohyethyl acrylate-*co*-*N*,*N*-diethylaminomethacrylate-*co*-4-trimethylsilylstyrene) undergoes a sharp transition from a shrunken state at pH 6.3 to a swollen state at pH 6.15. The transition between the two states changes the membrane permeability to insulin 42-fold. Copolymer capsules that contain glucose oxidase and insulin increase insulin release fivefold in response to 0.2 *M* glucose. After glucose removal, the rate of insulin release falls back to the initial value (83).

Alternatively, reversible cross-linking of polymer macromolecules could be used to control the porosity in a system. Two polymers, poly(*m*-acrylamidophenylboronic acid-*co*-vinylpyrrolidinone) and poly(vinyl alcohol) form a gel because of strong interactions between boronate groups and the hydroxy groups of poly(vinyl alcohol). When a low molecular weight polyalcohol such as glucose is added to the gel, it competes with poly(vinyl alcohol) for boronate groups. The boronate–poly(vinyl alcohol) complex changes to a boronate–glucose complex that results in eventual dissolution of the gel (84). In addition to a glucose oxidase-based artificial pancreas, the boronate–poly(vinyl alcohol) system has been used for constructing glucose-sensitive systems for insulin delivery (29,85–87). The glucose-induced transition from a gel to a sol state drastically increases the release of insulin from the gel. The reversible response to glucose has also been designed using another glucose-sensitive biorecognition element, Concanavalin A, a protein that contains four sites that can bind glucose. Polymers that have glucose groups in the side chain, such as poly(vinylpyrrolidinone-*co*-allylglucose) (26) or poly(glucosyloxyethyl methacrylate) (88), are reversibly cross-linked by Concanavalin A and form a gel. The addition of glucose results in displacing the glucose-bearing polymer from the complex with Concanavalin A and dissolving the gel.

Reversible gel-formation of thermosensitive block copolymers in response to temperature could be utilized in different applications. Poly(NIPAAM) block copolymers with poly(ethylene oxide) which undergo a temperature-induced reversible gel–sol transition were patented as the basis for cosmetics such as depilatories and bleaching agents (89). The copolymer solution is liquid at room temperature and easily applied to the skin where it forms a gel within 1 min. Commercially available ethyl(hydroxyethyl)celluloses that have cloud points of 65–70°C have been used as redeposition agents in washing powders. Adsorption of the precipitated polymer on the laundry during the initial rinsing period counteracts readsorption of dirt when the detergent is diluted (90).

Liposomes That Trigger Release of the Contents. When a smart polymer is attached somehow to a lipid membrane, the transition in the macromolecule affects the properties of the membrane and renders the system sensitive to

environmental changes. To attach a smart polymer to a lipid membrane, a suitable "anchor" which could be incorporated in the membrane should be introduced into the macromolecule. This could be achieved by copolymerizing poly(NIPAAM) with comonomers that have large hydrophobic tails such as *N*,*N*-didodecylacrylamide (91), using a lipophilic radical initiator (92), modifying copolymers (93) or polymers that have terminally active groups (94) with a phospholipid. Alternatively, smart polymers have been covalently coupled to the active groups in the hydrophilic heads of the membrane-forming lipid (95).

Interesting and practically relevant materials for studying the behavior of smart polymers attached to lipid membranes are liposomes, self-assembled 50–200 nm vesicles that have one or more (phospho)lipid bilayers which encapsulate a fraction of the solvent. Liposomes are stable in aqueous suspension because of the repulsive forces that appear when two liposomes approach each other. Liposomes are widely used for drug delivery and in cosmetics (96).

The results of a temperature-induced conformational transition of a smart polymer on the liposomal surface depend significantly on the fluidity of the liposomal membrane. When the membrane is in a fluid state at temperatures both above and below the polymer transition temperature, the collapse of the polymer molecule forces anchor groups to move closer together by lateral diffusion within the membrane. The compact globules of collapsed polymer cover only a small part of the liposomal surface. Such liposomes have a low tendency to aggregate because the most of their surface is not covered by the polymer. Naked surfaces contribute to the repulsion between liposomes. On the other hand, when the liposomal membrane is in a solid state at temperatures both above and below the polymer transition temperature, the lateral diffusion of anchor groups is impossible, and the collapsed polymer cannot adopt a compact globule conformation but spreads over most of the liposomal surface (97). Liposomes whose surfaces are covered to a large degree by a collapsed polymer repel each other less efficiently than intact liposomes. The stability of a liposomal suspension is thereby decreased, and aggregation and fusion of liposomes takes place, which is often accompanied by the release of the liposomal content into the surrounding medium (98).

When the liposomal membrane is perturbed by the conformational transition of the polymer, both the aggregation tendency and liposomal permeability for incorporated substances are affected. Poly(ethacrylic acid) undergoes a transition from an expanded to a compact conformation in the physiological pH range of 7.4–6.5 (99). The pH-induced transition of poly(ethacrylic acid) covalently coupled to the surface of liposomes formed from phosphatidylcholine results in liposomal reorganization into more compact micelles and concomitant release of the liposomal content into the external medium. The temperature-induced transition of poly(NIPAAM-*co*-*N*,*N*-didocecylacrylamide) (100) or poly(NIPAAM-*co*-octadecylacrylate) (101), incorporated into the liposomal membrane, enhanced the release of the fluorescent marker, calcein, encapsulated in copolymer-coated liposomes. Liposomes hardly release any marker at temperatures below 32°C (the polymer transition temperature), whereas the liposomal content is released completely within less than a minute at 40°C. To increase the speed of liposomal response to temperature change, the smart polymer was attached to the outer and inner sides of the lipid membrane. The polymer bound only to the outer surface if the liposomes were treated with the polymer after liposomal formation. When

the liposomes were formed directly from the lipid–polymer mixture, the polymer was present on both sides of the liposomal membrane (91).

Changes of liposomal surface properties caused by polymer collapse affect liposomal interaction with cells. Liposomes modified by a pH-sensitive polymer, partially succinilated poly(glycidol), deliver calcein into cultured kidney cells of the African green monkey more efficiently compared to liposomes not treated with the polymer (102). Polymeric micelles formed by smart polymers and liposomes modified by smart polymers could be used for targeted drug delivery. Polymeric micelles have been prepared from amphiphilic block copolymers of styrene (forming a hydrophobic core) and NIPAAM (forming a thermosensitive outer shell). The polymeric micelles were very stable in aqueous media and had long blood circulation because of small diameter, unimodal size distribution (24 ± 4 nm), and, a low critical micellar concentration of around 10 μg/mL. At temperatures above the polymer transition temperature (32°C), the polymer chains that form an outer shell collapse, become more hydrophobic, and allow aggregation between micelles and favoring binding interactions with the surface of cell membranes. Thus, hydrophobic molecules incorporated into the micelles are delivered into the cell membranes. These micelles are capable of site-specific delivery of drugs to the sites as temperature changes, for example, to inflammation sites of increased temperature (103).

Bioanalytical Applications

Because smart polymers can recognize small changes in environmental properties and respond to them in a pronounced way, they could be used directly as sensors of these changes, for example, a series of polymer solutions that have different LCSTs could be used as a simple thermometer. As salts promote hydrophobic interactions and decrease the LCST, the polymer system could "sense" the salt concentration needed to decrease the LCST below room temperature. A poly(NIPAAM)-based system that can sense NaCl concentrations above 1.5% was patented (104). The response of the polymer is controlled by a balance of hydrophilic and hydrophobic interactions in the macromolecule. Using a recognition element that can sense external stimuli and translate the signal into the changes of the hydrophilic/balance of the smart polymer, the resulting system presents a sensor for the stimulus. If the conjugate of a smart polymer and a recognition element has a transition temperature T_1 in the absence and T_2 in the presence of stimuli, fixing the temperature T in the range $T_1 < T < T_2$ allows achieving the transition of a smart polymer isothermally by the external stimulus (105). An example of such a sensor was constructed using trans–cis isomerization of the azobenzene chromophore when irradiated by uv light. The transition is accomplished by an increase in the dipole moment of azobenzene from 0.5 D (for the trans-form) to 3.1 D (for the cis-form) and hence a significant decrease of hydrophobicity. Irradiation with uv light results in increasing the LCST from 19.4 to 26.0°C for the conjugate of the chromophore with poly(NIPAAM). The solution of the conjugate is turbid at $19.4°C < T < 26.0°C$, but when irradiated, the conjugate dissolves because the cis-form is below the LCST at this temperature. The system responds to uv light by transition from a turbid to transparent solution. The termination of uv irradiation results in a slow return

of the system to its initial turbid state (105). A few other light-sensitive systems were proposed that use different chromophores: triarylmethylcyanide (106) and leuconitriles (107).

The hydrophobicity of the recognition molecule was also changed by chemical signals. Poly(NIPAAM) containing 11.6 mol% of crown ether 9 has a LCST of 31.5°C in the absence of Na^+ or K^+ ions, 32°C in the presence of Na^+, and 38.9°C in the presence of K^+. Thus, the introduction of both Na^+ and K^+ ions leads to the dissolution of the insoluble polymer at that temperature. At 37°C, this effect is achieved only by K^+ ions (108).

From better understanding of ligand–host interactions and development of new highly selective binding pairs (eg, by using combinatorial libraries to find ligands of high affinity for particular biomolecules), one could expect that smart polymer systems will be used as "signal amplifiers" to visualize a physicochemical event, which takes place in a recognition element, by a pronounced change in the system—conversion of a transparent solution into a turbid one or vice versa.

Antibody–antigen interactions present nearly ideal analytical selectivity and sensitivity developed by nature. Not surprisingly, they are increasingly used for a broad variety of bioanalytical applications. Different analytical formats have been developed. The common feature of most of them is the requirement for separating an antibody–antigen complex from a nonbound antibody or antigen. Traditionally, the separation is achieved by coupling one of the components of antibody–antigen pair to a solid support. The binding step is followed by washing nonbound material. Interactions of the soluble partner of the binding pair with the partner coupled to the support are often accompanied by undesired diffusional limitations, and hence, incubation times of several hours are required for analysis. Because smart polymers can undergo transition from the soluble to the insoluble state, they allow combining the advantages of homogeneous binding and, after the phase transition of the smart polymer has taken place, easy separation of the polymer precipitate from the supernatant. The essential features of an immunoassay that uses smart polymers (named PRECIPIA) are as follows. The covalent conjugate of poly(NIPAAM) with monoclonal antibodies to the κ-chain of human immunoglobulin G (IgG) are incubated for 1 h at room temperature (below the LCST of the conjugate), and the IgG solution is analyzed. Then plain poly(NIPAAM) (to facilitate thermoprecipitation of polymer–antibody conjugates) and fluorescently labeled monoclonal antibodies to the γ-chain of human IgG are added. The temperature is raised to 45°C, the precipitated polymer is separated by centrifugation, and fluorescence is measured in the supernatant (109). Immunoassay systems that use temperature-induced precipitation of poly(NIPAAM) conjugates with monoclonal antibodies are not inferior in sensitivity to the traditional heterogeneous immunoassay methods, but because the antigen–antibody interaction takes place in solution, the incubation can be shortened to about 1 h (110,111). The limitations of PRECIPIA as an immunoassay technique are essentially the same as those of affinity precipitation, namely, nonspecific coprecipitation of analyzed protein when poly(NIPAAM) precipitates. Polyelectrolyte complexes that have a low degree of nonspecific protein coprecipitation have also been successfully used as reversibly soluble carriers for PRECIPIA-type immunoassays (112). The conjugate of antibody and polyanion poly(methacrylic acid) binds to the antigen within a few minutes, and the polymer hardly exerts

any effect on the rate of antigen–antibody binding. Subsequent addition of a polycation, poly(*N*-ethyl-4-vinyl-pyridinium bromide) in conditions where the polyelectrolyte is insoluble, results in quantitative precipitation of the antibody–polymer conjugate within 1 min. The total assay time is less than 15 min (10).

In principle, PRECIPIA-type immunoassays could be used for simultaneous assay of different analytes in one sample, provided that conjugates specific toward these analytes are coupled covalently to different smart polymers that have different precipitating conditions, for example, precipitation of one conjugate by adding a polymeric counterion, followed by thermoprecipitation of the second conjugate by increasing temperature.

Reversibly Soluble Biocatalysts

The transition between the soluble and insoluble state of stimuli-responsive polymers has been used to develop reversibly soluble biocatalysts. A reversibly soluble biocatalyst catalyzes an enzymatic reaction in a soluble state and hence could be used in reactions of insoluble or poorly soluble substrates/products. As soon as the reaction is completed and the products are separated, the conditions (pH, temperature) are changed to promote precipitation of the biocatalyst. The precipitated biocatalyst is separated and can be used in the next cycle after dissolution. The reversibly soluble biocatalyst acquires the advantages of immobilized enzymes (ease of separation from the reaction mixture after the reaction is completed and the possibility for biocatalyst recovery and repeated use in many reaction cycles) but at the same time overcomes the disadvantages of enzymes immobilized onto solid matrices such as diffusional limitations and the impossibility of using them in reactions of insoluble substrates or products.

Biocatalysts that are reversibly soluble as a function of pH have been obtained by the covalent coupling of lysozyme to alginate (113); of trypsin to poly(acrolein-*co*-acrylic acid) (114); and of cellulase (115), amylase (115); α-chymotrypsin, and papain (116) to poly(methyl methacrylate-*co*-methacrylic acid). A reversibly soluble cofactor has been produced by the covalent binding of NAD to alginate (117). Reversibly soluble α-chymotrypsin, penicillin acylase, and alcohol dehydrogenase were produced by coupling to the polycation component of polyelectrolyte complexes formed by poly(methacrylic acid) and poly(*N*-ethyl-4-vinyl-pyridinium bromide) (118).

Biocatalysts that are reversibly soluble as a function of temperature have been obtained by the covalent coupling of α-chymotrypsin and penicillin acylase to a partially hydrolyzed poly(*N*-vinyl caprolactam) (119) and of trypsin (120), alkaline phosphatase (121), α-chymotrypsin (122), and thermolysin (123,124) to NIPAAM copolymers that contain active groups suitable for covalent coupling of biomolecules. Lipase was coupled to a graft copolymer composed of NIPAAM grafts on a poly(acrylamide-*co*-acrylic acid) copolymer (125). No significant differences in biocatalytic properties were found for α-amylase coupled to poly(NIPAAM) via single-point or multipoint mode. Both enzyme preparations demonstrated increased thermostability and the absence of diffusional limitation when hydrolyzing starch, a high molecular weight substrate (126). The temperature of a protein–ligand interaction was controlled by site-directed coupling of terminally modified

poly(NIPAAM) to a specifically constructed site (close to a biotin binding site) on a genetically modified streptavidin (127).

Biocatalysts which are reversibly soluble as a function of Ca^{2+} concentration were produced by covalent coupling of phosphoglyceromutase, enolase, peroxidase, and pyruvate kinase to α_{s1}-casein. The enzyme casein conjugates are soluble at a Ca^{2+} concentration below 20 mM but precipitate completely at a Ca^{2+} concentration above 50 mM. The precipitate redissolves when EDTA, a strong Ca^{2+}-binding agent, is added (128).

The reversible flocculation of latices has been used to produce thermosensitive reversibly soluble (more precisely reversibly dispersible) biocatalysts using trypsin (129), papain (130), and α-amylase (131). Latices sensitive to a magnetic field have been used to immobilize trypsin and β-galactosidase (132). Liposomes that have a polymerized membrane reversibly aggregate on changing salt concentration and have been used to immobilize α-chymotrypsin (133).

The most attractive application of reversibly soluble biocatalysts is repeated use in a reaction which is difficult or even impossible to carry out using enzymes immobilized onto insoluble matrices, for example, hydrolysis of water-insoluble phlorizidin (134); hydrolysis of high molecular weight substrates such as casein (123,130) and starch (115); hydrolysis of insoluble substrates such as cellulose (135) and raw starch (corn flour) (7,134,136–138); production of insoluble products such as peptide, benzyloxycarbonyl-L-tyrosyl-N^{ω}-nitro-L-arginine (116), and phenylglycine (139).

The hydrolytic cleavage of corn flour to glucose is an example of successfully using a reversibly soluble biocatalyst, amylase coupled to poly(methyl methacrylate-*co*-methacrylic acid), in an industrially interesting process (136). The reaction product of the process (glucose) inhibits the hydrolysis. The use of a reversibly soluble biocatalyst improves the efficiency of the hydrolysis which is carried out at pH 5, at which the amylase–polymer conjugate is soluble. After every 24 h, the pH is reduced to 3.5, the unhydrolyzed solid residue and the precipitated conjugate are separated by centrifugation, the conjugate is resuspended in a fresh portion of the substrate at pH 5, and the hydrolysis is continued. The conversion achieved after five cycles is 67%, and the activity of the amylase after the fifth cycle was 96% of the initial value (136).

BLOCK COPOLYMERS, TERNARY TRIBLOCK

Introduction

Self-assembly of matter (or the formation of superstructures by means of noncovalent bonds) is a fascinating field of research. The formation of crystals and liquid crystals by atoms or molecules is just one example. Also within a larger molecule with a lot of conformational freedom, such as a polyamide chain or a protein, certain conformations are stabilized by secondary interactions, such as hydrogen bonds, which is essential for their properties (eg, mechanical properties of polyamides and functional properties of proteins). Secondary interactions in supramolecular structures play an important role for many processes in living cells (1). Various aspects of self-assembly have been presented in books (2–4) and in a recent review (5). This article deals with the self-assembly (or self-organization) of synthetic macromolecules, namely block copolymers, principally terning triblocks (see BLOCK COPOLYMERS).

Synthetic polymeric materials have gained increasing importance in the last couple of decades. The task of polymer chemistry has always been to design polymeric materials for certain applications and with time, a number of monomers has become very important commercially. There is an ongoing research in the area of new monomers for the design of polymers with special properties, and the environmental problems related to new chemicals are also receiving increasing attention. Because the development of new monomers as well as the up-scaled production of the corresponding polymers is rather expensive and time-consuming, other strategies to obtain polymeric materials with well-defined properties are important.

The combination of different polymers into composites or blends can provide materials with desirable properties, and many successful examples have been

Encyclopedia of Polymer Science and Technology. Copyright John Wiley & Sons, Inc. All rights reserved.

reported (6). However, because of thermodynamics most blends of polymers turn out to be phase-separated, since the free-energy contribution by the gain of mixing entropy for long-chain molecules is very small as compared to free-energy contribution by even slight repulsive interactions between the segments (as expressed by the Flory–Huggins–Staverman parameter χ) of different chains, because χ multiplied by the usually large degree of polymerization, N, yields a dominating positive mixing enthalpy between dissimilar chains (7). The length scale of this phase separation is typically much larger than the length of the polymer chains; *macro*phase separation is discussed later. The tendency to phase-separate thereby depends not only on the thermodynamics, but also to a large extent on the processing, ie, kinetic parameters such as viscosity, for example. Also, an initially homogeneous blend can phase-separate after a temperature change via spinodal decomposition or via a nucleation and growth process (8). The size of the domains and the mechanical strength of their interface are some of the important parameters determining the properties of the final product.

In order to obtain fine-disperse phase-separated blends, compatibilizers can be added, which self-assemble at the interface between the incompatible blend components and prevent the blend from macrophase separation. Such compatibilizers consist of at least two parts: one is compatible with one of the blend components, and the other part is compatible with the other blend component. Thus, block copolymers composed of at least two different blocks are suitable for such applications (9–11). Because of the connectivity of their blocks, these materials undergo a *micro*phase separation when their blocks segregate from each other. Besides their use as compatibilizers in polymer blends, block copolymers have also a wide range of other applications. Examples are their use as viscosity modifiers (12), surfactants (13), light-emitting devices (14), or photonic crystals on optical length scales (15,16). Block copolymers have also been used as templates for designing novel ceramic structures (17,18) and as hosts for colloidal metals (19). The formation of vesicular structures in solution also makes block copolymers interesting as carriers of drugs or for cosmetic applications (20). Thermoplastic elastomers based on hard and soft blocks are prominent examples, where block copolymers have also received importance as bulk materials (9,21). Among multiblock copolymers with hard and soft segments polycondensates such as polyester-urethanes, polyether-urethanes, or polyester-amides should be mentioned. Also thermoplastic elastomers based on poly(butylene terephthalate) as hard segments and poly(ethylene oxide)-*block*-poly(ethylene-*co*-butylene)-*block*-poly(ethylene oxide) triblock copolymers as soft segments have been reported (22).

For the synthesis of block copolymers the reader is refered to a previous article in this series (23) and some other works describing the application of various controlled polymerization techniques for their synthesis, such as anionic polymerization (24–26), cationic polymerization (27,28), controlled radical polymerization (29,30), as well as combinations of various techniques (31–34). Synthetic procedures for star copolymers have been reviewed (35). The first synthesis of a heteroarm star terpolymer with three immiscible blocks has been described in Reference 36.

In this paragraph, some references concerning a few important aspects of block copolymers are given, which are not discussed further in this contribution. Crystallization within microdomains and the interplay between crystallization

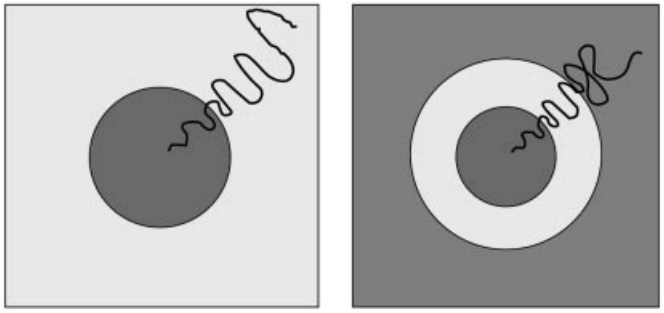

Fig. 1. Schemes of a chain in a cylindrical morphology of a diblock copolymer (left) and a core–shell cylindrical morphology of a ternary triblock copolymer (right).

and morphology formation is an ongoing topic since the beginning of research on di- and triblock copolymers (23,37–42). Also block copolymers with liquid crystalline blocks are investigated (43,44). Block copolymers in solution can form a variety of superstructures such as micelles, rods, vesicles (20,23,45–50), and tubular aggregates (51). At higher block copolymer concentrations lyotropic liquid crystalline phases can be found (52,53). Macroscopic alignment of block copolymers by mechanical (54–62) or electrical fields (63–67), orientation via directional crystallization (68), or orientation by evaporation of a solvent (69,70) are other interesting topics. However, to cover all these different aspects is beyond the scope of this contribution. There are reviews on the phase behavior (71) and dynamics (72) of diblock copolymers available. An overview of the research mainly done in the field of diblock copolymers is given in Reference 73. Here focus is mainly on the morphological behavior of ternary block copolymers consisting of amorphous blocks and their blends with other block copolymers in the bulk state.

As mentioned before, because of the connectivity of different blocks, block copolymers can only undergo a microphase separation when the different blocks become incompatible with each other (74,75). As an example, Figure 1 shows the cross section of a cylindrical diblock copolymer and a core–shell cylindrical triblock copolymer.

There are basically two different contributions to the free energy of a given microphase-separated block copolymer. On one hand the system tends to minimize the interface between connected blocks, and on the other hand the conformational entropy tends to a random coil conformation of the blocks, leading to a weak segregation between the blocks. As a result, a morphology with an interface larger than the minimal one is formed between the blocks. In contrast with polymer blends, chemically well-defined block copolymers self-assemble into regular crystal-like lattices when microphase separation occurs (as shown in Figs. 2 and 3 for diblock and triblock copolymers) (76).

The lattice sizes of block copolymer morphologies being typically in the range of approximately 10–100 nm, transmission and scanning electron microscopy (tem, sem) (77,78), scanning force microscopy (sfm) (79), and small angle x-ray (80,81) or neutron scattering (82) (saxs, sans) in many cases are powerful tools to investigate the morphology of these materials.

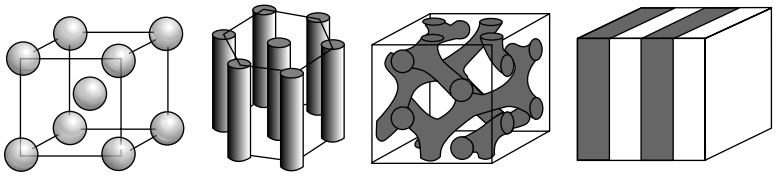

Fig. 2. Microphase-separated morphologies of diblock copolymers. From left to right: spheres, cylinders, double gyroid, lamellae. From Ref. 76. Copyright (2000) Wiley-VCH Verlag GmbH.

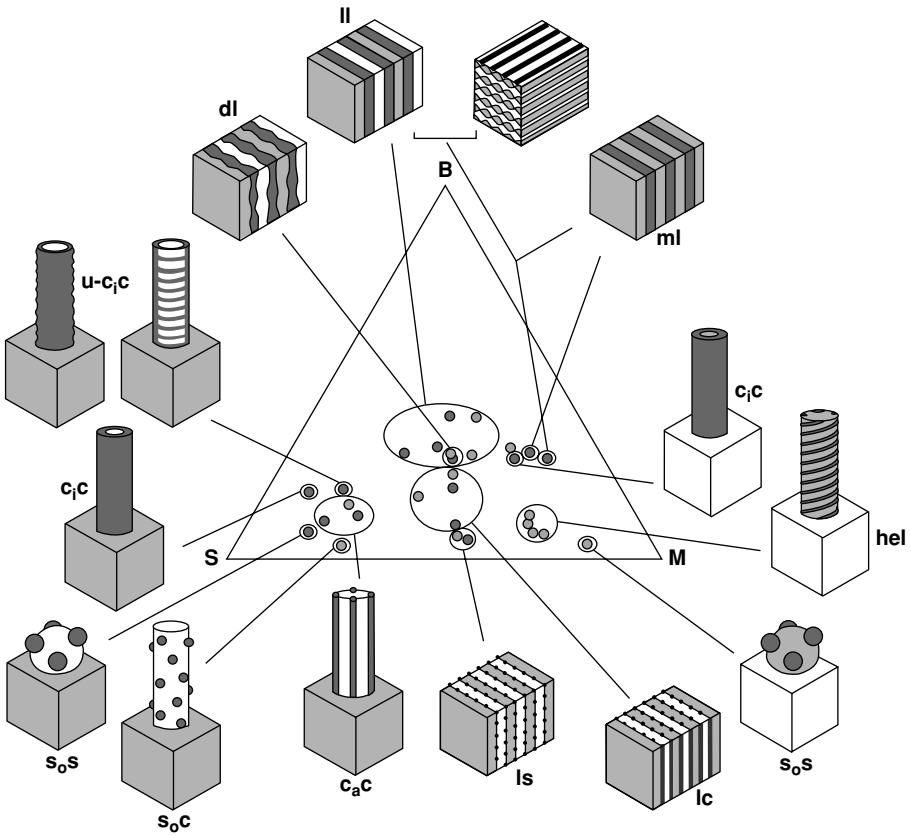

Fig. 3. Microphase-separated morphologies on the example of polystyrene-*block*-polybutadiene-*block*-poly(methyl methacrylate) (SBM) triblock copolymers (OsO_4, see Table 1). From Ref. 76. Copyright (2000) Wiley-VCH Verlag GmbH.

The aim of this contribution is to access the extremely rich phase behavior of ternary block and star copolymers by asking the following questions:

(1) How does the composition influence the morphology of ABC terpolymers?
(2) How does the chain topology influence the morphological behavior of ABC terpolymers?

Table 1. Colors of Different Components in Bright-Field TEM Images Used in the Morphological Schemes[a]

Polymer	OsO_4	RuO_4	OsO_4/CH_3I
Polystyrene	w	b	w
Polybutadiene	b		b
Polyisoprene	b		b
Poly(methyl methacrylate)	w	w	w
Poly(*tert*-butyl methacrylate)	w	w	w
Poly(cyclohexyl methacrylate)	w	w	w
Poly(methacrylic acid)	w	w	w
Poly(ethylene-*stat*-butylene)	w/g	w/g	
Poly(ethylene-*alt*-propylene)	w/g	w/g	
Poly(2-vinylpyridine)	w		g

[a] w: white, g: grey, b: black.

(3) What happens when one or two blocks of an ABC triblock copolymer are chemically modified?

(4) How does blending of ABC triblock copolymers with other block copolymers affect their morphological properties?

These questions are discussed in the sections after the next one, where first some theoretical basics are given to understand the thermodynamics of block copolymers.

The nomenclature of the block copolymers is as follows: $A_xB_yC_z{}^M$ is a block copolymer composed of the blocks A, B, and C, where subscripts denote the weight fraction (%) and M is the number-averaged overall molecular weight (kg/mol). Heteroarm star terpolymers are indicated by an asterisk ($A_xB_yC_z{}^{M*}$). The morphological schemes are presented in such a way that the typical colors found in tem images of correspondingly stained samples are used (Table 1).

Theoretical Descriptions of Block Copolymer Morphologies

Before going further into a discussion of the morphological behavior of these materials, consider the driving forces for the formation of such morphologies in some more detail. It is not intended to give a complete description of the theoretical efforts undertaken to describe this fascinating class of materials, but only to shed some light onto basic ideas of different theoretical approaches. The first focus is on diblock copolymers before switching to linear ternary triblock copolymers. The assumptions used for those materials can also be transferred to block copolymers of other topologies, although this leads to more complicated expressions.

There are two different limiting situations found in microphase-separated block copolymers. In the so-called weak segregation limit (WSL), a broad smeared interface separates neighboring microdomains; ie, there is a smooth transition of the composition across the domain boundary. On the contrary, within the so-called strong segregation limit (SSL), there is a sharp interface separating the domains and therefore an abrupt change of the composition across the domain boundary. The two situations are schematically shown in Figure 4 (83).

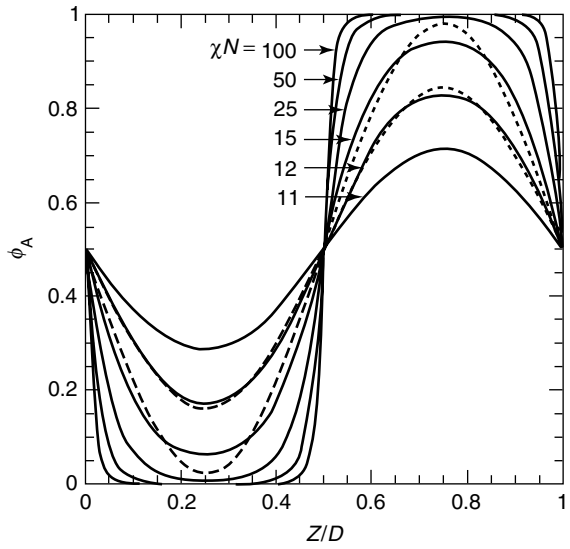

Fig. 4. Composition profile of a diblock copolymer across the domain boundary for various degrees of incompatibility. Reprinted with permission from Ref. 83. Copyright (1996) American Chemical Society.

First consider the SSL for a diblock copolymer. Here the follwing contributions to the free energy of n block copolymer chains are considered: the interfacial energy F_{int} originating from the interfacial tension γ between the incompatible blocks and the elastic contributions of the different blocks, F_{el}.

$$\begin{aligned}\frac{F}{nk_{\text{B}}T} &= F_{\text{el}}^{\text{A}}+F_{\text{el}}^{\text{B}}+F_{\text{int}} \\ &= \alpha^{\text{A}}\left(\frac{R}{aN^{1/2}}\right)^2+\alpha^{\text{B}}\left(\frac{R}{aN^{1/2}}\right)^2+\beta\,(\chi N)^{1/2}\left(\frac{R}{aN^{1/2}}\right)^{-1}\end{aligned} \tag{1}$$

The coefficients $\alpha^{\text{A,B}}$ corresponding to the elastic contributions and β corresponding to the interfacial contribution to the free energy are dependent on the morphology. R is the characteristic domain radius, and a is the statistic segment length (Kuhn length). For simplicity it is assumed that all blocks have similar statistical segment lengths. Different segment lengths of the blocks have also been treated theoretically and lead to asymmetric phase diagrams (84). For spheres, cylinders, their coronas, and for lamellae of AB diblock and ABA triblock copolymers, expressions for the free energy have been given (75,85).

While the interfacial tension ($\gamma \propto \chi^{1/2}$) (86) leads to a minimization of the interface between adjacent blocks, the conformational entropy of the different blocks favors a larger interface. As a compromise, there is an interface larger than the minimal one and the conformations of the blocks are reduced; ie, the blocks are stretched to a certain extent, leading to an elastic energy.

The minimum free energy for a given morphology is found by optimizing the radius of the domain, R, from the condition $\partial F/\partial R = 0$:

$$\frac{F}{nk_{\mathrm{B}}T} = \frac{3}{2}\left[2\left(\alpha^{\mathrm{A}} + \alpha^{\mathrm{B}}\right)\beta^2\chi N\right]^{1/3} \tag{2}$$

For the disordered state it is just the enthalpic part similar to the Flory–Huggins–Staverman free energy of polymer blends:

$$\begin{gathered}\frac{F}{nk_{\mathrm{B}}T} = \chi N f\left(1-f\right) \\ f = \phi_{\mathrm{A}}(r) \\ \sum_i \phi_i(r) = 1\end{gathered} \tag{3}$$

where f is the space-averaged volume fraction of component A and the system is considered to be incompressible. It should be noted that there are ongoing discussions on the influence of the junction point between blocks and the end groups on the interaction parameter, which is found to differ between blends of A and B homopolymers on one side and the corresponding AB block copolymer (87). However, this point is left out of this discussion, since it does not change the picture from a qualitative viewpoint.

The WSL approach for the description of the order–disorder transition, ie, the transition between the microphase-separated block copolymer and the disordered melt, where the two blocks mix with each other, has been developed (74,88,89) using the random phase approximation. This transition is often called the microphase separation transition (MST), and T_{ODT} is the temperature at which the order–disorder transition occurs. In this picture the system is described by a so-called order parameter, which is related to the space-dependent volume fraction or segment density of one of the components, say, component A. Again, the system is considered to be incompressible. The order parameter is then given by the deviation of the local segment density from the mean composition value.

$$\delta\phi_{\mathrm{A}}(r) = \phi_{\mathrm{A}}(r) - f \tag{4}$$

While in the disordered state the order parameter vanishes, it takes finite values in the ordered phases. The Fourier transform of the pair correlation function of the order parameter

$$\begin{gathered}S(q) = \int_{-\infty}^{\infty} S(r-r')^{-2\pi q(r-r')}\mathrm{d}(r-r') \\ S(r-r') = \frac{1}{k_{\mathrm{B}}T}\delta\phi_{\mathrm{A}}(r)\delta\phi_{\mathrm{A}}(r')\end{gathered} \tag{5}$$

is called the structure function and is directly related to the scattering intensity observed by saxs or sans. For the structure function of diblock copolymers in the disordered state

$$\begin{gathered}\frac{S(x) = N}{F(x,f) - 2\chi N} \\ x = q^2R_{\mathrm{g}}^2 = q^2\frac{Na^2}{6}\end{gathered} \tag{6}$$

where $\boldsymbol{q}$ is the scattering vector ($q = 4\pi/\lambda \sin\theta$, λ is the wavelength of the radiation within the sample, and 2Θ is the scattering angle) and a is the Kuhn length of the repeating units. R_g is the radius of gyration of the macromolecule.

$$F(x,f) = \frac{g(1,x)}{g(f,x)g(1-f,x) - \frac{1}{4}\left[g(1,x) - g(f,x) - g(1-f,x)\right]^2} \tag{7}$$

where $g(f, x)$ are the correlation functions of ideal noninteracting chains, which can be described by Debye functions:

$$g(f,x) = \frac{2}{x^2}\left(e^{-fx} - 1 + fx\right) \tag{8}$$

The maximum intensity occurs at

$$x^* = \left(q^* R_g\right)^2 = 3.873 \tag{9}$$

and diverges for a symmetric diblock copolymer ($f = 0.5$) at a critical value of $(\chi N)_{crit} = 10.495$

$$\left[1/S(x^*)\right]_{crit} = 0 \tag{10}$$

For the symmetric diblock copolymer a second-order transition between lamellar and disordered phase was predicted, while at all other compositions a first-order transition between disordered state and a body-centered cubic phase of spherical domains formed by the minority component was predicted, which changes into hexagonally packed cylinders and finally into lamellae upon further increasing χN. It has already been noted by Leibler's that his approach does not include fluctuation effects, which become important for finite degrees of polymerization (74). Fredrickson and Helfand accounted for this problem by modifying Leibler's theory in the following way (90):

$$S(x) = \frac{N}{\varepsilon + F(x,f) - F(x^*,f)} \tag{11}$$

At the MST for a symmetric diblock copolymer the correction parameter is $\varepsilon = 8.1114\, N^{-1/3}$ and $(\chi N)_{trans} = 10.495 + 41.022\, N^{-1/3}$.

As a consequence, the structure factor no longer diverges at the MST, but reaches a finite value, leading to a first-order phase transition also for the symmetric diblock copolymer. Moreover, there is a finite composition region where a direct transition between disordered and lamellar phase is predicted and the fluctuation effects disappear for infinite large N. However, it has been noted that the fluctuation corrections are only valid for $N > 10^4$ (90).

$$\left[\frac{S(x^*)}{N}\right]_{max} = 0.12328 N^{1/3} \tag{12}$$

Figure 5 shows the structure factor from both mean-field theory (Leibler) and the fluctuation correction (Fredrickson–Helfand) for a symmetric diblock

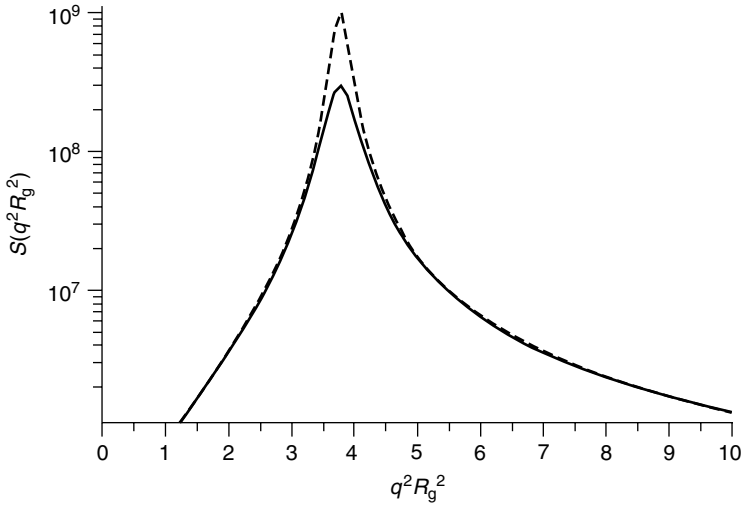

Fig. 5. Structure factor following from different theories. Note that the structure factor following Leibler's theory at $\chi N = 10.495$ would diverge. - - - - - Leibler ($\chi N = 10.49$); ——— Fredrickson–Helfand ($\chi N = 10.495 + 41.022\, N^{1/3}$).

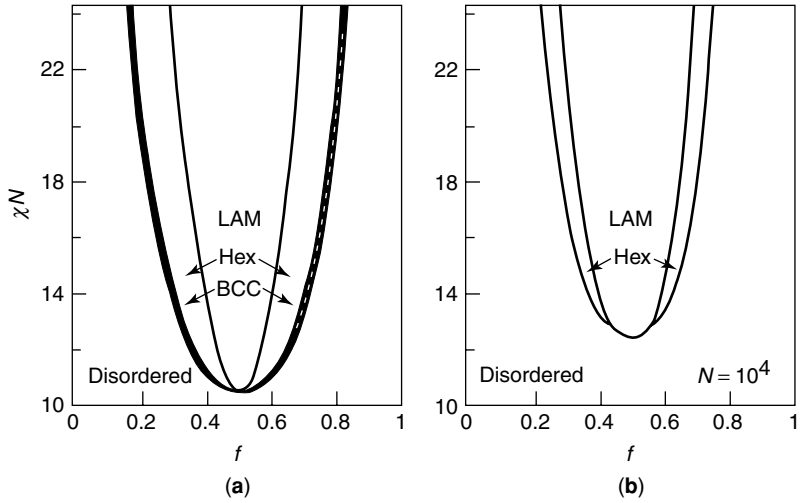

Fig. 6. Phase diagram of a diblock copolymer according to Leibler's theory (left) and including fluctuation corrections according to Fredrickson and Helfand (right). From Ref. 91. Copyright (1990) American Institute of Physics.

copolymer with $N = 10^7$ and $f = 0.5$. The phase diagrams taking into account lamellar, cylindrical, and spherical morphologies besides the disordered state were calculated and are shown in Figure 6 (91).

For these calculations the order parameter of the system was developed as a function of characteristic wave vectors, which correspond to the scattering vectors of reflections observable in a scattering experiment. These phase diagrams considered only the classical microphase morphologies (spheres, cylinders, lamellae), which are characterized by interfaces with a constant mean curvature H:

$$H(r) \equiv \frac{1}{2}(C_1 + C_2) \tag{13}$$

Here C_1 and C_2 are the two principal curvatures characterizing the shape of the interface at the location **r**. To be more precise, H is only constant for lamellae, while curved interfaces always show certain deviations from the idealized shape. For example, the cross section of cylinders is deformed hexagonally for matching the entropic requirements of the matrix-forming block: to fill space homogeneously and to avoid dissimilar stretching of different matrix blocks, the core cylinder has to be deformed to allow for almost similar distances between the interface and the borderline of the Wigner–Seitz cell ($L_1 = L_2$; see Fig. 7) (92). The deviation from the ideal symmetry of the core domain increases upon decrease of the matrix-forming block and increasing segregation.

Also nonclassical morphologies are discussed in the vicinity of the hexagonal and lamellar phase, which show a nonconstant mean curvature, even for the

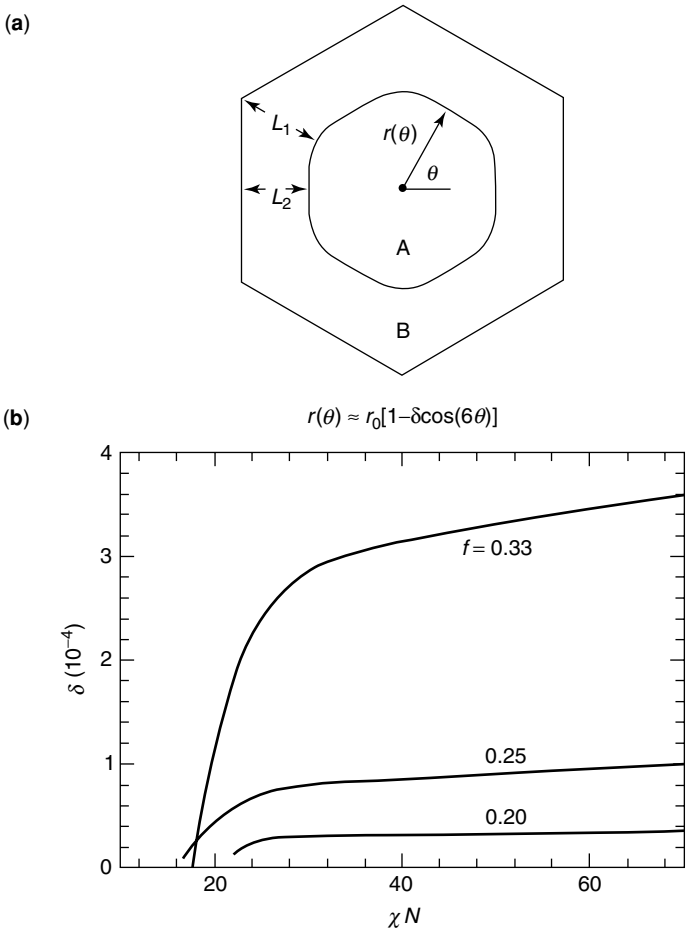

Fig. 7. (**a**) Nonconstant mean curvature of a cylindrical morphology. (**b**) The deviation from constant mean curvature δ as a function of incompatibility for various compositions. From Ref. 92. Copyright (1997) American Institute of Physics.

Copyright (1997) American Institute of Physics.

ideal case (large matrix-forming block). These are the double gyroid, the double diamond, and the hexagonally perforated lamellae (92). The double gyroid morphology was investigated theoretically by different groups in the WSL (93,94). This particular morphology belongs to a whole class of structures, the free energies of which differ only slightly and have not been distinguished experimentally so far (95,96). Only the double gyroid is considered to be a stable morphology, while the other two are metastable, as follows from self-consistent field theory (SCFT) calculations (92,97). The SCFT has also been used to cover the bridge between the WSL and the SSL leading to the phase diagram shown in Figure 8 (92).

Within the SCFT, the free energy is described by contributions of the internal energy U and entropy contributions by the junction points and the different blocks S_J and $S_{A,B}$, respectively (92).

$$F = U - T(S_J + S_A + S_B) \tag{14}$$

with

$$\begin{aligned}
\frac{U}{nk_BT} &= \frac{\chi N}{V}\int \mathrm{d}r\,\phi_A(r)\,\phi_B(r) \\
-\frac{S_J}{nk_B} &= \frac{1}{V}\int \mathrm{d}r\,\rho_J(r)\ln\rho_J(r) \\
-\frac{S_A}{nk_B} &= -\frac{1}{V}\int \mathrm{d}r\left[\rho_J(r)\ln q(r,f) + W_A(r)\,\phi_A(r)\right] \\
-\frac{S_B}{nk_B} &= -\frac{1}{V}\int \mathrm{d}r\left[\rho_J(r)\ln q^+(r,f) + W_B(r)\,\phi_B(r)\right]
\end{aligned} \tag{15}$$

where V is the overall volume of n block copolymers, ρ_J is the junction point density, q and q^+ are the partition functions of the A and B blocks which are influenced

by the fields W_A and W_B, respectively. Within the SSL, different contributions can be assigned to the quantities defined before. For ordered states these are

$$\frac{U}{nk_BT} \approx \frac{F_{int}}{2};\ -\frac{S_J}{nk_B} \approx 0;\ -\frac{S_A}{nk_B} \approx F_{el}^A + \frac{F_{int}}{4};\ \frac{S_B}{nk_B} \approx F_{el}^B + \frac{F_{int}}{4} \tag{16}$$

and for the disordered state it was given before (eq. 3).

Also binary block copolymers of other topologies have been studied. For symmetric ABA triblock copolymers in the WSL, a critical value of $\chi N = 18$ was determined (98), and this result was confirmed in works dealing with ABA triblock copolymers having arbitrary ratios between the two endblocks (99,100). The phase behavior of multiblock copolymers was studied by SCFT for asymmetric segment lengths also. Higher values for the critical value of χN were found here too (101). For heteroarm star copolymers with the same number of arms of both species A_nB_n, a symmetric phase diagram with a critical value of $\chi N = 10.5$ was obtained (99). Starblock copolymers $(AB)_n$ for various n and also for asymmetric segment lengths showed a lower value for critical χN by SCFT as compared to AB diblock copolymers (102). Heteroarm star copolymers with different numbers of arms A_nB_m $(m \neq n)$ (89,103–105) have also been described theoretically.

While the phase behavior of amorphous binary block copolymers, in particular diblock copolymers, has been investigated for a long time and most of the fundamental problems seem to be explored, ternary triblock copolymers, especially linear and star terpolymers have been addressed to a much lower extent (106). In contrast to the morphology of AB diblock copolymers, which is mainly determined by one interaction parameter χ and one independent composition variable such as the volume fraction ϕ_A, the morphology of ternary triblock copolymers is mostly determined by three interaction parameters χ_{AB}, χ_{BC}, χ_{AC} and two independent composition variables ϕ_A, ϕ_B. Because of the larger number of independent parameters, it is not surprising that ternary triblock copolymers show a huge variety of morphologies. The SCFT has also been used for symmetric ABC triblock copolymers $(\phi_A = \phi_C)$ (107). It was shown that a gyroid morphology with interpenetrating A and C tripod networks in a B matrix is more stable than a corresponding diamond lattice with interpenetrating A and C tetrapod networks in a B matrix. For such triblock copolymers, tetragonally packed A and C cylinders in a B matrix, as well as cubic lattices of spheres, were also described. The core–shell double gyroid morphology was described by this method, too (108).

With the exception of the cocontinuous morphologies, which are stable (in the case of gyroids) or metastable in a weak or intermediate segregation regime, the strong segregation theory gives qualitatively a good understanding of various morphologies, and therefore, it is often used for complictaed structures found in ABC triblock copolymers. In comparison to SCFT, it is much less intensive in terms of numerical calculations. In the following, the focus is on descriptions of the free energy of ABC triblock copolymers within the SSL.

If R_B is used as the characteristic dimension of the morphology (R_B being the half diameter of the B domain), F_{int} and F_{el} can be written as (109)

$$\begin{aligned} F_{int} &= \frac{N_B v_B}{R_B} K_{int} \\ F_{el} &= \frac{R_B^2}{N_B} K_{el} \end{aligned} \tag{17}$$

Fig. 9. where K_{int} and K_{el} are constants characterizing a particular morphology and $N_B v_B$ is the volume occupied by the B block. Upon minimization of the free energy with respect to R_B ($\partial F/\partial R_B \equiv 0$), the minimized free energy of the morphology per chain is obtained (109):

$$F = \frac{3}{2}\left(2N_B K_{el}\right)^{1/3}\left(v_B K_{int}\right)^{2/3} \tag{18}$$

Expressions for K_{int} and K_{el} have been given for various lamellar and cylindrical morphologies.

Figures 9 and 10 show transition lines between different lamellar (109,110) and cylindrical (111) morphologies of polystyrene-*block*-polybutadiene-*block*-poly(methyl methacrylate) (SBM) triblock copolymers and their hydrogenated analogues, polystyrene-*block*-poly(ethylene-*co*-butylene)-*block*-poly(methyl methacrylate) (SEBM) triblock copolymers.

Arguments based on such type of description of the free energy were also used for block copolymers showing no long-range order of A and C cylinders in a B matrix (112), as well as the stability of a spherical morphology, where one outer block forms a sphere in the matrix of the other outer block and the middle block forms either spheres on the interface or a shell (113). The free energies of ABC triblock copolymers within the SSL were also discussed by other groups (114–117).

When comparing ABC triblock with AC diblock copolymers, it is interesting to investigate the influence of the middle block on the miscibility of the two outer blocks; ie, the miscibility of A and C in an ABC triblock copolymer differs from the miscibility of these two blocks in an AC diblock copolymer. In order to answer

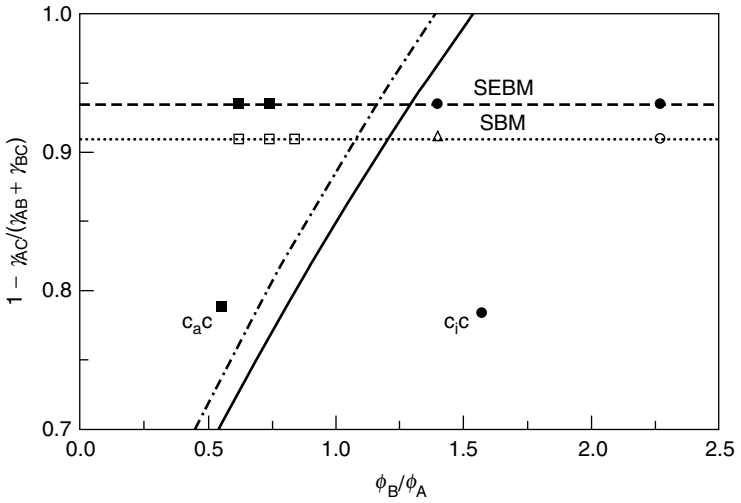

Fig. 10. Morphological transition lines between c_ac (cylinder at cylinder) and c_ic (cylinder in cylinder) morphologies for $\phi_C = 0.7$ (——) and $\phi_C = 0.6$ (.....) in comparison with experimental results on SBM and SEBM triblock copolymers. this question, the phase diagram of a diblock copolymer was calculated in the SSL by setting the free energy of a microphase-separated morphology equal to the free energy of the homogeneuos phase (118). From these calculations the volume fractions where spheres transform into cylinders and cylinders into lamellae were obtained in good agreement with experimental data on diblock copolymers. Also the critical value of the product χN, where a symmetric lamellar diblock copolymer transforms into the disordered phase, was obtained in good agreement with the weak segregation theory (74). Terms accounting for mixing energy have to be included when two of the three blocks of an ABC triblock copolymer become miscible with each other. Here a system with a strongly incompatible middle block and two less incompatible endblocks (χ_{AB}, $\chi_{BC} > \chi_{AC}$) is considered. For a given repulsive interaction $\chi_{AC}N_{AC}$ between the two outer blocks, their miscibility should be enhanced as compared to the corresponding AC diblock copolymer. One reason is a gain of conformational entropy for the middle block, since the confinements for the localization of the block junction points become similar to an ABA triblock copolymer; ie, both junction points can be localized anywhere on the surface of the middle block domain rather than being restricted to the part of the interface which connects B with A domains or B with C domains, respectively (Fig. 11).

Besides the introduction of an enthalpic contribution, the elastic energy terms of the spheres or cylinders located at lamellar interfaces have to be changed in the corresponding expressions for spheres or cylinders in a diblock copolymer. For a lamellar B block, there is no gain of conformational entropy upon mixing of the A and C blocks within this simple model. In addition the mixing entropy of the junction points S_J at the AB and BC interfaces has to be considered as another

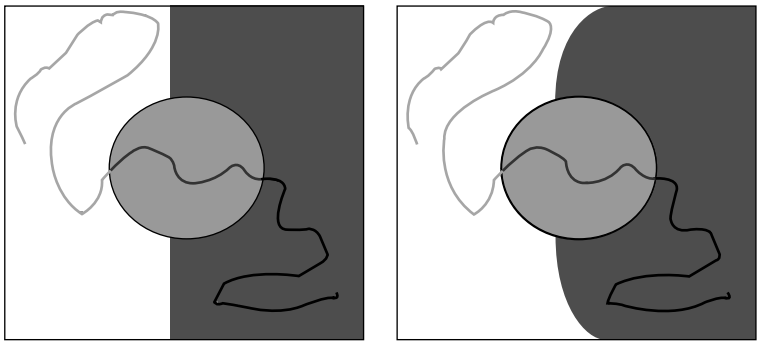

Fig. 11. ABC triblock copolymer with a demixed (left) and mixed (right) corona around the B domain.

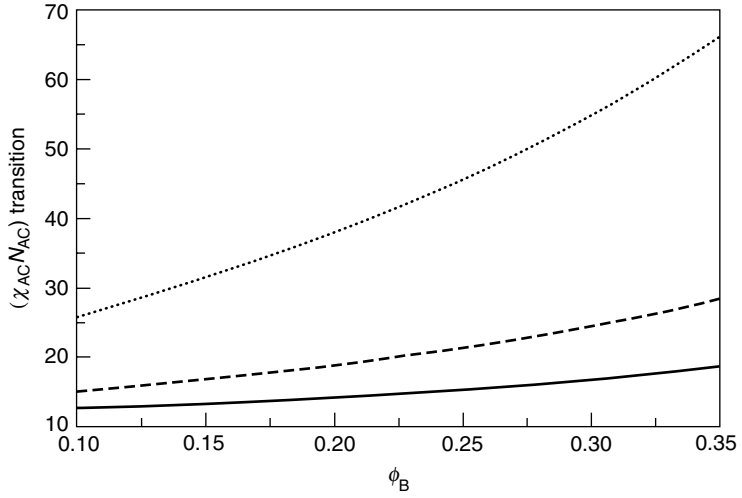

Fig. 12. Critical degree of incomaptibility between the endblocks of a symmetric ABC triblock copolymer ($\phi_A = \phi_C$) as a function of middle block content. $\chi_{AC}/(\chi_{AB} + \chi_{BC})$ with $\chi_{AB} = \chi_{BC}$: ——— 0.5; ..... 0.1; ..... 0.01. reason for enhancing miscibility of the two outer blocks. This can be expressed by (118)

$$\frac{S_J}{nk_B} = -\frac{f_A}{f_A+f_C}\ln\left(\frac{f_A}{f_A+f_C}\right) - \frac{f_C}{f_A+f_C}\ln\left(\frac{f_C}{f_A+f_C}\right) \tag{19}$$

Comparing the free energies of two morphologies with mixed or demixed A and C domains allows the calculation of the critical value of $\chi_{AC}N_{AC}$ for the order–order transition between these two morphologies. As an example, $\chi_{AC}N_{AC}$ of the transition between a morphology of B cylinders in a mixed AC matrix and a morphology of B cylinders at a lamellar AC interface (lc-morphology) is shown in Figure 12 (118).

The enhanced miscibility of the outer blocks is reflected by the larger critical value of $\chi_{AC}N_{AC}$ as compared to $\chi N = 10.495$ for a symmetric AC diblock copolymer. Qualitatively, these results on the influence of a short but strongly interacting middle block on the miscibility behavior of the two outer blocks were confirmed by a theoretical investigation within a weak segregation approach (119) and stimulated new experiments on the order–disorder transition of an ABC triblock copolymer (120).

All these approaches still suffer from the principal problem that in order to calculate the free energy of a morphology its corresponding symmetry needs to be put into the calculation. In other words, a new morphology can never be predicted from calculations of this type. In principle, Monte Carlo simulations could overcome this problem but have limitations due to finite size effects (121). An SCFT has been proposed without assuming a symmetry by solving self-consistent equations in real space in order to find the minimum of the free energy (122). An approximate free-energy functional has been minimized using an arbitrary unit cell, where both the local volume fraction and the unit cell can vary (123). Especially the possibility for the unit cell to vary during the minimization procedure avoids the occurrence of strain energy contributions, which would lead to another (wrong) equilibrium structure. In that approach the free energy is given as a function of the order parameters $\delta\phi_\alpha$, with α corresponding to the different blocks A, B, ...:

$$\begin{aligned} F\{[\delta\phi_\alpha(r)]\} &= F_{ref} + \Delta F \\ F_{ref} &= \frac{nk_BT}{V}\sum_\alpha \int dr \left(\frac{\phi_\alpha(r)}{f_\alpha}\ln\phi_\alpha(r)\right) \\ \Delta F &\cong \frac{nk_BT}{2}\sum_{\alpha,\beta,q\neq 0} S^{-1}_{\alpha\beta}(q)\,\delta\phi_\alpha(q)\,\delta\phi_\beta(-q) - F_{ref} \\ \delta\phi_\alpha(q) &= \frac{1}{V}\int dr\,[\delta\phi_\alpha(r)\exp(-iqr)] \end{aligned} \tag{20}$$

The structure factor $S_{\alpha\beta}$ is taken from Leibler's work. The following minimizations are then carried out simultaneously:

$$\begin{aligned} \left[\frac{\partial F}{\partial \delta\phi_\alpha(n_s)}\right] &= 0 \\ \left[\frac{\partial F}{\partial D_s}\right] &= 0 \end{aligned} \tag{21}$$

where s stands for the Cartesian coordinates x, y, z, and n_s is an integer number of the periodicity D_s in direction s. This approach was first demonstrated on examples of linear and star ABC block copolymers (123).

Influence of the Composition on the Morphology of ABC Terpolymers

In most of the experimental research carried out in this field so far, the phase behavior of linear ABC triblock copolymers was investigated as a function of

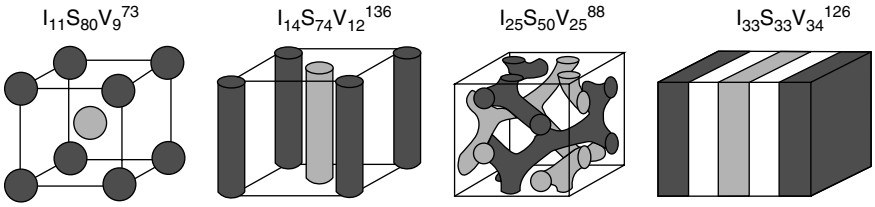

Fig. 13. Different morphologies found for symmetric ISV triblock copolymers with strongly incompatible endblocks (OsO_4/CH_3I, see Table 1).

composition for given sets of monomers (109,111,113,124). The core–shell morphologies in ABC triblock copolymers were first reported in Reference 125. A scheme for the dependence of the morphologies on composition for ABC triblock copolymers has also been proposed, where spherical, cylindrical, and lamellar morphologies were considered (125). For lower ratios of ϕ_B/ϕ_A, core–shell spheres and core–shell cylinders with a C matrix, and lamellae of all three components were proposed, while at larger ratios of ϕ_B/ϕ_A, the A component forms many little spheres within a B sphere surrounded by C matrix or, in the case for lamellae, A forms spheres within a B lamella. Some of these morphologies were found by this group in polystyrene-*block*-polyisoprene-*block*-poly(methyl methacrylate) (SIM) triblock copolymers. Polystyrene-*block*-polyisoprene-*block*-poly(4-vinylbenzyl)dimethylamine triblock copolymers have been reported, where a strong influence of the casting solvent on the morphology of the investigated films was found (126). A systematic study on polyisoprene-*block*-polystyrene-*block*-poly(2-vinylpyridine) (ISV) triblock copolymers has been presented, with $\phi_I \approx \phi_V$. Starting from $\phi_I \approx \phi_V \approx \phi_S$ and then increasing ϕ_S, they obtained lamellae, cylinders of both I and V arranged on a tetragonal lattice, and finally I and V spheres on a cubic lattice (Fig. 13) (124). Between the lamellar and cylindrical region also, a cocontinuous morphology was found, which was assigned to an ordered tricocontinuos double diamond structure (OTDD), in which one of the tetrapod lattices is formed by I and the other one by V, separated by the S matrix. However, a few years later the OTDD was ruled out (107), as it happened to the corresponding ordered bicontinuous double dimaond lattice (OBDD) discussed for binary block copolymers before (92). Instead of the OBDD the double gyroid structure was found to fit all experimental data for binary block copolymers, where two tripod-lattices of the minority component interpenetrate each other. In the ISV triblock copolymer with gyroid morphology, one tripod is formed by I while the other is formed by V and S separates them from each other (Fig. 13).

Stadler's work in the field of linear ABC triblock copolymers based on polystyrene (S), polybutadiene (B), and poly(methyl methacrylate) (M) led to the discovery of a number of new morphologies (110–113,127–130). The initial studies dealt with systems where the volume fractions of the outer blocks, ϕ_S and ϕ_M, were kept approximately equal. However, in contrast to Matsushita's work, the volume fraction of the outer blocks were kept large while ϕ_B was decreased, and only lamellar morphologies were obtained, where between the S and M lamellae B spheres (ls), B cylinders (lc), or a B lamella (ll) was embedded with increasing ϕ_B (Fig. 14).

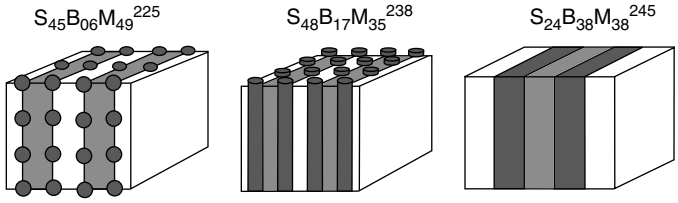

Fig. 14. Lamellar morphologies found in symmetric SBM triblock copolymers (OsO_4, see Table 1).

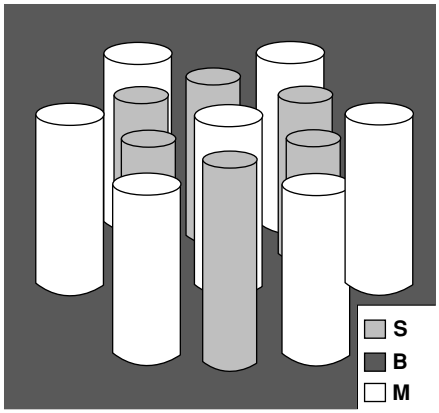

Fig. 15. Hexagonally arranged microphase-separated S and M cylinders of an SBM triblock copolymer (OsO_4, see Table 1). Reprinted with permission from Ref. 130. Copyright (1998) American Chemical Society.

An increase of ϕ_B also leads to morphologies with cylindrical domains of the endblocks. However, because of the smaller repulsion between S and M as compared to I and V of Matsushita's system, microphase separation was not complete between the different endblocks. Using a special solvent mixture, a novel hexagonal morphology was found, where both endblocks are arranged on a hexagonal lattice (Fig. 15) (130).

A symmetric linear polystyrene-*block*-poly((4-vinylbenzyl)dimethylamine)-*block*-polyisoprene triblock copolymer (131) showed a morphology with the same symmetry when cast from a particular solvent. This example underlines the influence of the preparation conditions on the bulk morphology of block copolymers. Since this type of morphology is found in coexistence with other morphologies, it might be a physically pinned nonequilibrium structure. In some ABC heteroarm star terpolymers long-range ordered structures with the same symmetry are observed, indicating that in those cases this structure is an equilibrium structure owing to the other chain topology (compare with the right scheme in Fig. 17).

Among the most spectacular morphologies found in these systems was a helical morphology (111,129), where the middle block forms helices around a cylinder formed by one endblock while the other endblock forms the matrix. This morphology is inherently noncentrosymmetric; however, no favored orientation was observed. It belongs to a whole group of morphologies with spheres or cylinders

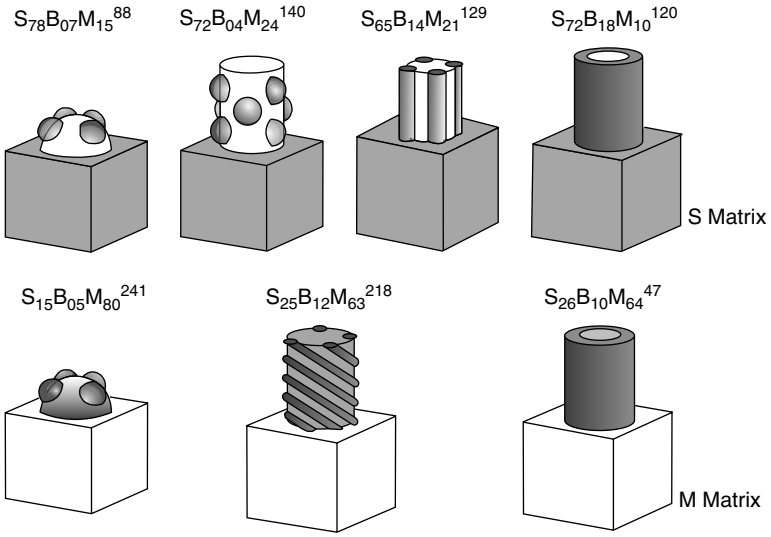

Fig. 16. Various spherical and cylindrical morphologies found in SBM triblock copolymers (OsO_4, see Table 1).

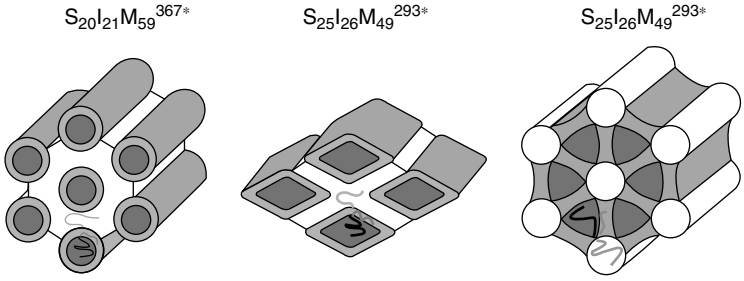

Fig. 17. Various cylindrical morphologies found in SIM heteroarm star terpolymers (OsO_4, see Table 1).

formed by one outer block in a matrix of the other outer block, with the middle block forming spherical, helical, cylindrical domains, or a shell around the core cylinder (Fig. 16) (111).

It is interesting to note that both the "sphere on sphere"(s_os) and the "cylinder in cylinder"(c_ic) morphologies were found with S and with M matrix, while the other morphologies shown in Figure 16 were found only with S or M matrix so far.

Much less work has been reported on ABC heteroarm star copolymers because of their rather difficult synthesis. Among the different publications in this field there are only a few dealing with a systematic investigation of the morphology in dependence of composition (132–135). An interesting problem of this chain topology is the location of the junction point. While in linear block copolymers junction points of incompatible blocks are more or less confined to a two-dimensional interface (depending on the degree of segregation), in incompatible ABC heteroarm star terpolymers the junction point is expected to be located along a line (one-dimensional). Of course, this means a strong entropic confinement and

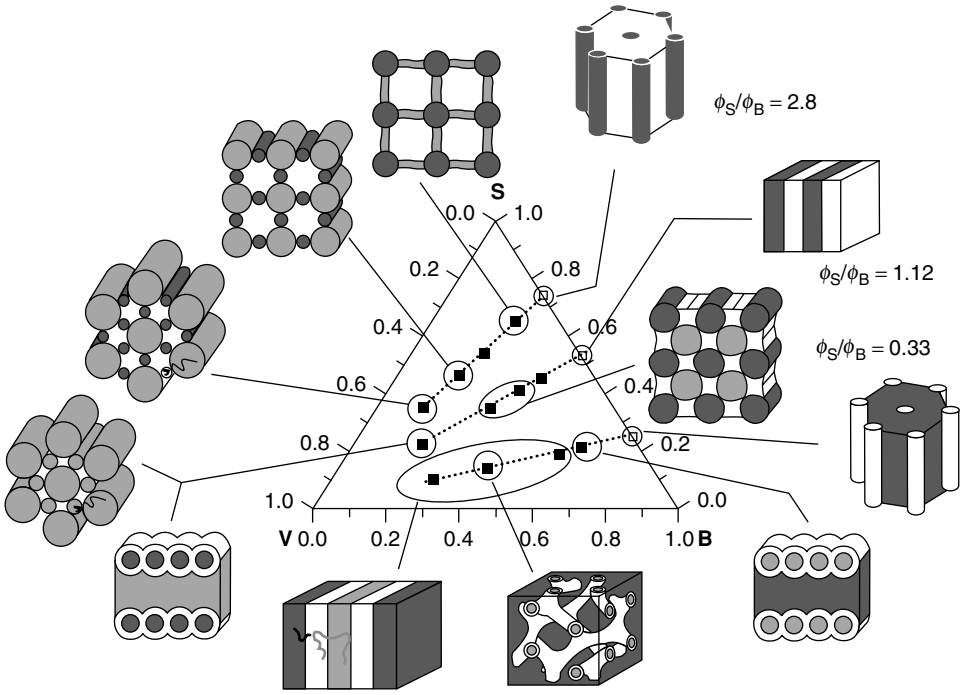

Fig. 18. Microphase-separated morphologies on the example of polystyrene-*arm*-polybutadiene-*arm*-poly(2-vinylpyridine) (SBV) heteroarm star terpolymers (OsO_4/CH_3I, see Table 1).

it may lead to a certain degree of mixing in the neighborhood of the junction point in order to reduce the stretching energy of the confined arms. For heteroarm star terpolymers of polystyrene (S), polyisoprene (I), and poly(methyl methacrylate) (M), three types of morphologies were described (133,134) (Fig. 17).

For systems with $\phi_S \approx \phi_I < \phi_M$, hexagonally packed core–shell cylinders were found when $\phi_M > 0.5$ (Fig. 17, left). For smaller volume fractions of M, tetragonally deformed core–shell cylinders were formed, where because of the short matrix-forming M block the interface adopts a nonconstant mean curvature (Fig. 17, middle). In these systems S forms a shell around the I cylinders, since $\chi_{SM} < \chi_{SI} \ll \chi_{IM}$. The S shell indicates that the junction points are not located on lines in these morphologies. Finally, systems with approximately similar amounts of all three constituents form a cylindrical morphology with a hexagonal symmetry and interfaces with nonconstant mean curvatures (Fig. 17, right). Here the junction points seem to be located along lines. A way to favor their location on lines is to use components with a stronger incompatibility. In another study SBV heteroarm star terpolymers were investigated. Because of the synthetic route, series of polymers with a constant ratio between S and B and just varying amount of V could be obtained (135). In this system the repulsive interactions are stronger as compared to the SIM system and related in the following way: $\chi_{SB} \approx \chi_{SV} \ll \chi_{BV}$. Figure 18 shows three rows of morphologies obtained for the volume ratios $\phi_S/\phi_B = 2.8$, 1.12, and 0.33 from the corresponding SB diblock copolymers, respectively.

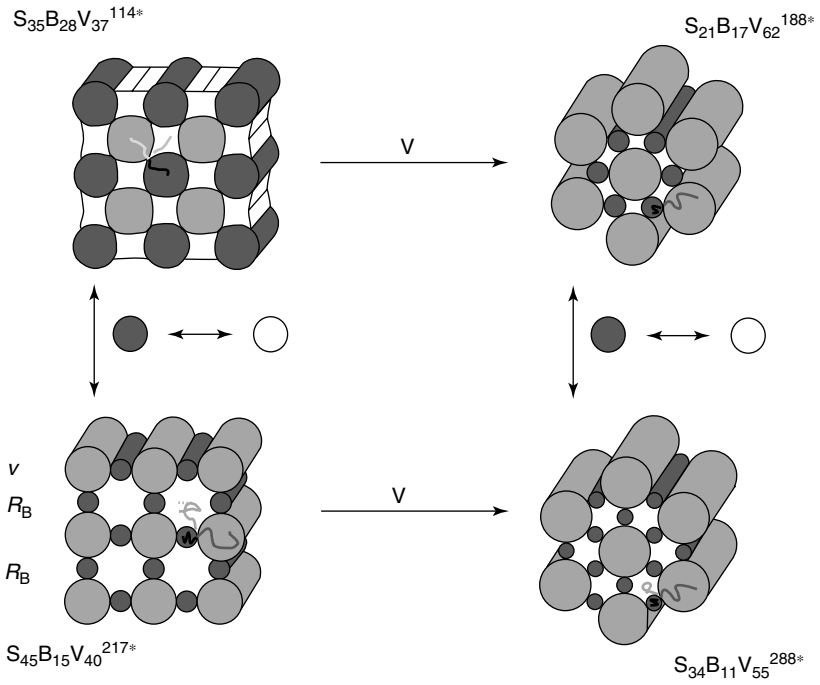

Fig. 19. Tetragonal (left column) and hexagonal morphologies (right column) of SBV heteroarm star terpolymers. The two lines are different by the symmetry positions of the B and S domains (OsO_4/CH_3I, see Table 1).

In the first two series ($\phi_S/\phi_B = 2.8$ and 1.12) mostly cylindrical morphologies are obtained, where because of the strong incompatibility between B and V these domains have a very small contact area, while the interfaces between S and B as well as between S and V are larger. These cylindrical morphologies allow the following crude consideration, as pictured in Figure 19: in tetragonally packed systems on the left side it is possible to exchange the symmetry positions of S and B by changing their relative composition (ie, the "coordination number" of the corresponding neighboring domains is exchanged). The same is true for the hexagonally packed systems on the right side. These hexagonal morphologies have the same symmetry as the symmetric SIM heteroarm star terpolymer (134). (Fig. 17, right) and the linear ABC triblock copolymers discussed in connection with Figure 15.

A similar comparison holds for the lamellae-like morphologies shown in Figure 20, where basically B and V exchange their symmetry properties when exchanging their volume fractions. However, it should be kept in mind that $S_{21}B_{17}V_{62}^{188*}$ shows two coexisting morphologies (compare with Fig. 18).

In the morphologies shown in Figure 20 as well as in the lamellar and core–shell double gyroid morphologies (136) shown at the bottom of Figure 18, the S blocks always separate the B from the V domains. Thus, in these morphologies the junction point is by no means restricted on a one-dimensional location, but it is distributed in the S domains.

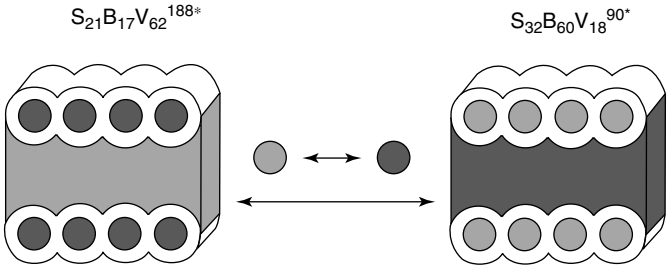

Fig. 20. Lamellar morphologies of two SBV heteroarm star terpolymers, which differ by the symmetry positions of the B and V domains (OsO_4/CH_3I, see Table 1).

Influence of the Chain Topology on the Phase Behavior of ABC Terpolymers

In this section the question of how the morphology is influenced by changing the block sequence for a given overall composition in linear ternary block copolymers is discussed. At the end of this section linear block copolymers are compared with their heteroarm star terpolymer analogues.

For a given composition and set of three monomers, the controlling factor is the interaction parameters χ_{AB}, χ_{BC}, and χ_{AC} between the middle and the two outer blocks. The latter interaction parameter plays a role only if the volume fraction of the middle block, ϕ_B, is so small that a direct interface between both outer blocks could become favorable because of a larger conformational entropy.

A core–shell cylindrical morphology with a nonconstant mean curvature of an SIV block copolymer with similar amounts of all three blocks has been reported (137). For a similar system with reversed block sequence (ISV), a lamellar morphology was found (124). Recently a systematic comparison of SBV and BSV triblock copolymers was reported (138). While the interaction parameters between the middle and the two outer blocks are comparable with each other in ISV and BSV triblock copolymers, this is not the case for SIV and SBV triblock copolymers. In the latter the much larger repulsive interaction between B (or I) and V as compared to the interaction between B (or I) and S leads to the systems' tendency to form a small interface between B (or I) and V, while the interface between B (or I) and S may be larger. So this type of triblock copolymers can form morphologies with curved interfaces (such as core–shell cylinders and core–shell double gyroids) at compositions where the corresponding BSV (or ISV) triblock copolymers form lamellae. The formation of lamellae for the latter copolymers is favored, since the repulsive interactions between S and B (or I) and between S and V are comparable and strong, while the repulsion between B (or I) and V is very strong. Note that the lamellar interface is the smallest possible interface between blocks. Figure 21 shows the different morphologies found for SBV and BSV triblock copolymers of Reference 138.

To some extent SBM triblock copolymers behave similar to BSV triblock copolymers. Since the interactions between B and S on one side and between B and M on the other side are comparable and strong, but the repulsive interactions

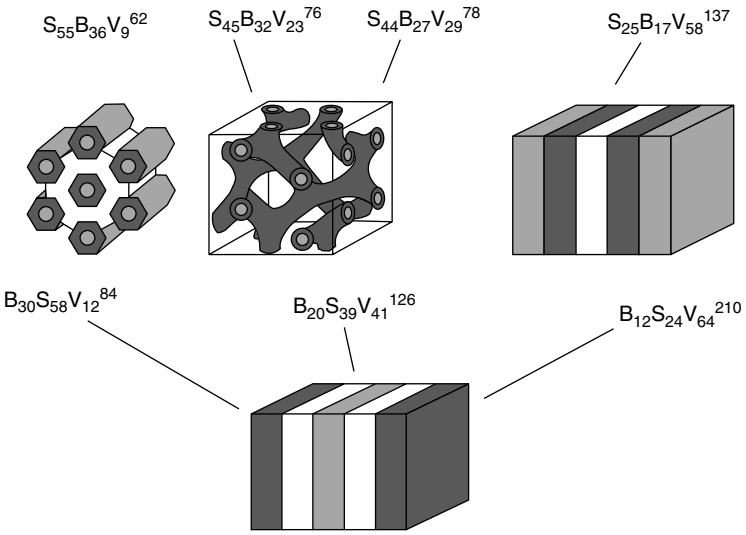

Fig. 21. Influence of the block sequence on the morphology in SBV and BSV triblock copolymers (OsO_4/CH_3I, see Table 1).

between S and M are weak, a system with similar volume fractions of S and M ($\phi_S \approx \phi_M > 0.3$) forms lamellae with B forming either a separating lamella between them ($\phi_B \approx 0.3$), or cylinders ($\phi_B \approx 0.17$) or spheres ($\phi_B \approx 0.06$) for smaller volume fractions of B, which leads to a direct interface between the S and M domains (Fig. 14). By the appearance of a direct A/C interface these block copolymers differ from the BSV system. The morphologies of BSM triblock copolymers are comparable to the morphologies observed in SBV triblock copolymers. While an SBM system composed of equal amounts of the three components forms lamellae, the corresponding BSM triblock copolymer cast from chloroform forms core–shell double gyroids (in coexistence with lamellar regions), which again is due to the dissimilarity of the interactions between the middle block and the two outer blocks (76,138). A further reason for the formation of the core–shell double gyroid morphology in this case may be the slight selectivity of chloroform for the M block. As discussed before, the solvent also plays an important role in the formation of the final morphology on block copolymers cast from solution (131). A solvent with lower polarity, such as toluene, leads to a more disordered morphology, while a more polar solvent, such as butanon (methyl ethyl ketone), results in a morphology of B cylinders in a matrix of S and M. Here the B domains precipitate first from the solution, while S and especially M are still swollen to a larger degree by the solvent (139).

Finally the morphologies of ternary linear block copolymers and heteroarm star terpolymers are compared. Here systems containing I or B are also compared, since these two polymers show rather similar interactions toward the other blocks (see Table 2 for solubility parameters). Figure 22 shows in the left column symmetrically composed SIM heteroarm star terpolymers (134) and linear BSM and SBM triblock copolymers (76). In the right column corresponding SBV (135) and SIV (144) heteroarm star terpolymers are compared with their linear compositional

analogues (124,137,138). In all systems the thermodynamically most unfavorable interaction leads to the smallest interface of that particular system, ie, between I (or B) and M (left column) and between I (or B) and V (right column). The lower incompatibility between S and M as compared to between that between S and V leads to a larger interface in the SIM star terpolymer, which forms a hexagonal morphology. The similar interactions between S and I (B) and between S and V lead to an SBV and SIV star terpolymer with a tetragonal morphology, where the interfacial areas between S and the other two blocks are of approximately similar size. For the linear block copolymers the stronger repulsive interactions between B (I) and V as compared to those between B and S leads to a stronger curvature (cylinders) for SBV and SIV triblock copoylmers, while the corresponding BSM triblock copolymer shows coexisting core–shell double gyroids and lamellae. Finally, the triblock copolymers with approximately similar interactions between the middle and the two endblocks lead to lamellae. This discussion neglects the possible influences by different segment lengths of the different components, which might lead to different entropic contributions of the different blocks, even if they have the same volume fractions. However, the differences of the segment lengths are small for these monomers.

Morphological Changes Induced by Chemical Modification of Linear ABC Triblock Copolymers

The relative change of the χ parameters between the middle block and the two outer blocks of ABC triblock copolymers can induce morphological changes without induction of miscibility between the outer blocks. Among the previous works on SBM triblock copolymers there were three examples where a morphological change was observed after hydrogenation of the B middle block to poly(ethylene-*co*-butylene) (EB) (Fig. 23). In two cases an SBM triblock copolymer with B spheres (109) or cylinders (145) at a lamellar interface between S and M after hydrogenation transformed into a hexagonal morphology of S cylinders surrounded by EB rings in an M matrix. The other example was the "knitting pattern" morphology (kp-morphology), which was formed after hydrogenation of a slightly asymmetrically composed lamellar SBM triblock copolymer (ll-morphology) (110). The composition range of the kp-morphology has been investigated in more detail later, and from those investigations, where the preparation conditions were also carefully studied, it is now assumed that the kp-morphology is metastable (146). This morphology was observed only in samples cast from chloroform solutions, while the samples cast from toluene formed distorted lamellae. While chloroform is a good solvent for S, B, and M, it is not a good solvent for EB; this fact leads to a segregation of EB domains from the solution, which are embedded in highly swollen S and M domains. On the other hand, toluene is a better solvent for EB than for M, which could be the reason for the formation of distorted lamellae in films cast from this solvent.

Another type of polymer analogous reaction has been applied in order to modify triblock copolymers. Polystyrene-*block*-polybutadiene-*block*-poly(*tert*-butyl methacrylate) (SBT) triblock copolymers were transformed to SBA triblock copolymers [A: poly(methacrylic acid)] by saponification of the T block (147). Both

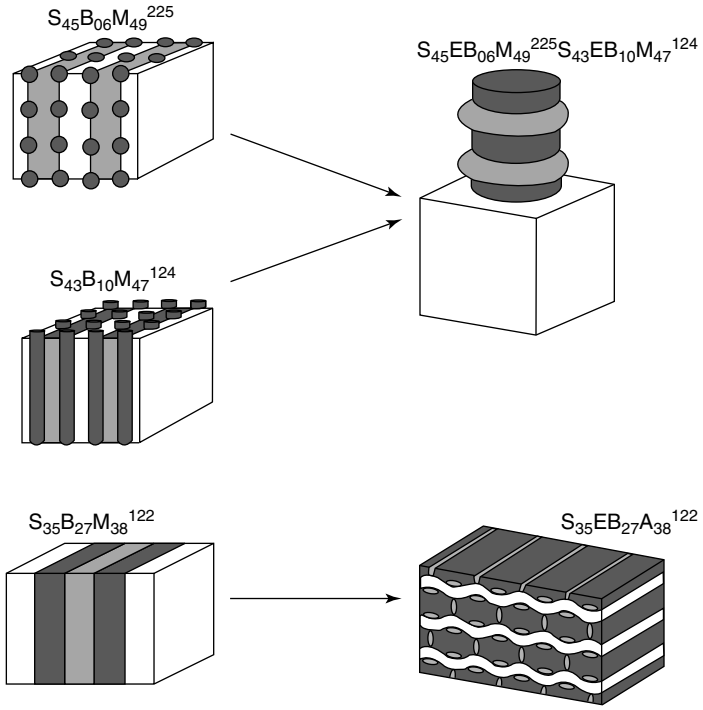

Fig. 23. Morphological changes induced via hydrogenation in SBM triblock copolymers. SBM: OsO_4, see Table 1; SEBM: RuO_4, see Table 1.

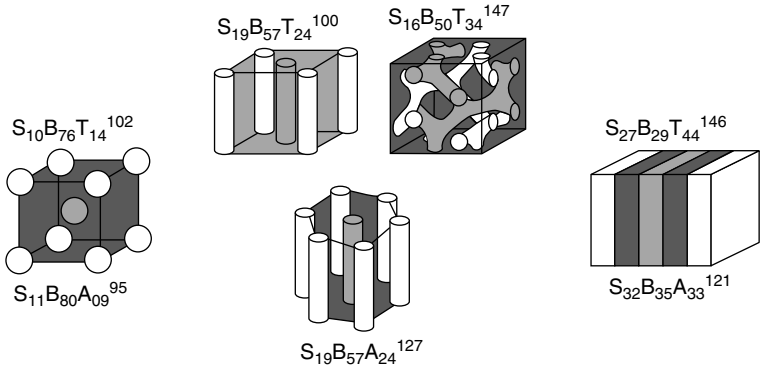

Fig. 24. Morphologies of SBT and SBA triblock copolymers.

systems are characterized by strong incompatibilities between all components. Figure 24 shows the morphologies of corresponding SBT and SBA triblock copolymers with slightly asymmetric endblocks, $\phi_S \approx \phi_{T,A}$. While the SBT triblock copolymers adopt the same morphologies already discussed for the ISV triblock copolymers with $\phi_I = \phi_V$, the SBA triblock copolymers show a different behavior. For increasing B content the morphology changes from lamellae to the same hexagonal motif for an SBM triblock copolymer (130). Upon further increase of the B

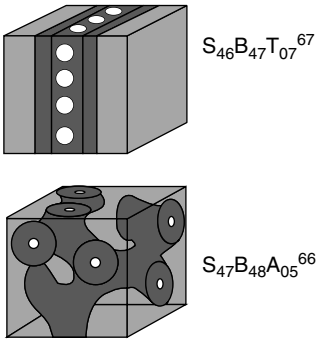

Fig. 25. Morphologies of an SBT and an SBA triblock copolymer with a short third block.

content, a lamellar structure is obtained, where B lamellae may alternate with lamellae being composed of S and A cylinders. However, the morphology of that polymer is not well characterized and therefore not shown in Figure 24. It turns out that $S_{19}B_{57}A_{24}{}^{127}$ (the product of the saponified $S_{16}B_{50}T_{34}{}^{147}$) corresponds to $S_{19}B_{57}T_{24}{}^{100}$ in terms of the mass fractions. Further increase of B then finally leads to a morphology where both endblocks form spheres, as does the corresponding SBT.

For an SBT triblock copolymer with $\phi_S = \phi_B$ and a very short T block, a lamellar structure is observed, where T spheres are embedded within the B lamellae. The corresponding SBA triblock copolymer forms a gyroid morphology, where the increased repulsive interaction between A and B (as compared to between T and B) may explain the behavior (Fig. 25). The change from a lamellar-like to a gyroid morphology can be interpreted as a decrease of incompatibility between the two major blocks S and B, which is driven by changing the interaction of a short endblock. It has been predicted that a strongly interacting endblock can also modify the order–disorder transition of the attached diblock copolymer in such a way that the region of the disordered phase is increased (119). As mentioned for the kp-morphology, in these systems also the selectivity of the solvent could explain the morphological transitions. A block has the lowest solubility and therefore may segregate as the first block from the solution.

In another work, the ls-morphology was used as a host for transition-metal complexes, which should be located selectively in the B domains (148). While the hydrogenation mentioned before was a quantitative polymer-analogous reaction, it was assumed that only a slight modification of the B domains with transition-metal complexes (based on Pd and Fe, respectively) would not lead to any change of the morphology. However, the morphology was changed in a dramatic way. While the complexation of a few percent of the B units with $PdCl_x$ led to a double gyroid morphology, complexation of a few percent of the B units with $Fe(CO)_3$ led to a cylindrical morphology. Like in the unmodified triblock copolymer, in both modified block copolymers the middle block forms spherical objects at the interface between the outer blocks. An explanation for this behavior is the induction of curvature of the interface between the two outer blocks by the fact that the middle block domain centered on the lamellar interface approximately along its equatorial plane in the SBM triblock copolymer moves out of that plane after chemical modification

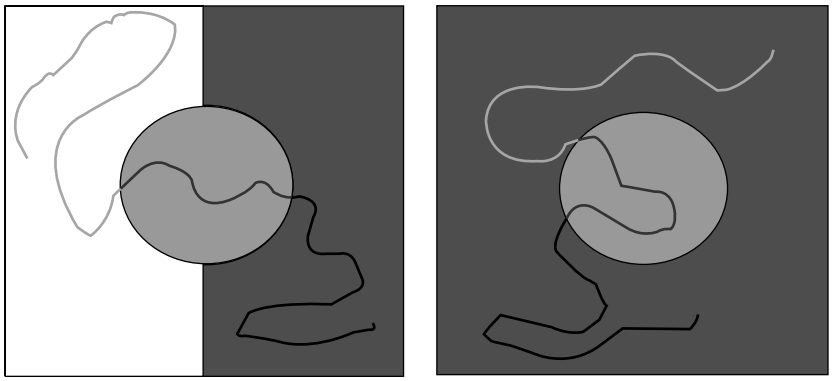

Fig. 26. Change of curvature in $S_{45}B_6M_{49}$[225] by modification of the middle block with a transition-metal complex.

(Fig. 26). This should be due to a change of the relative incompatibilities between the middle and the two outer blocks, which in turn leads to a change of the balance between the elastic energy contributions of the different blocks and the interface between them. Neglecting the small middle block, the overall morphology in this system changes from lamellae via double gyroid to a cylindrical morphology; although in terms of the outer blocks the system is composed almost symmetrically. Such behavior is unknown for amorphous diblock copolymers, where the corresponding morphologies are stable only at different compositions at a given temperature. Thus, an increasing asymmetry of the interactions between middle and outer blocks of a triblock copolymer with similar sized outer blocks and a short middle block leads to an increasing interfacial curvature driving the system from a lamellar morphology to curved morphologies; ie, the outer blocks become less incompatible with each other because of the changed balance between entropic and enthalpic contributions (Fig. 27). This behavior seems to agree qualitatively with the theoretical estimations discussed before (118,119).

Up to this point, morphological changes due to chemical changes have been presented. In the last part of this section discussion turns to a system, in which rather weak incompatibilities also play a role, which can be reduced sufficiently in order to achieve miscibility between the corresponding blocks by increasing the temperature. This system is composed of a symmetric diblock copolymer attached to a stronger incompatible third block of varying length. The chosen

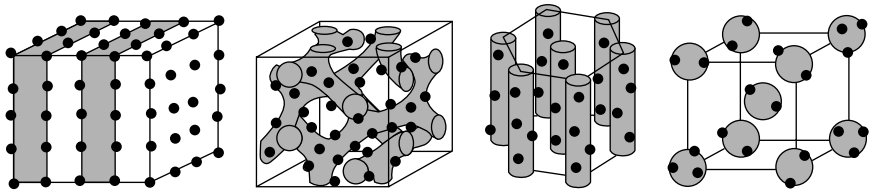

Fig. 27. Increasing curvature of the interface between the grey A and white C domains of an ABC triblock copolymer for increasing asymmetric interactions of the black B domains.

example consists of poly(ethylene-*alt*-propylene)-*block*-poly(ethylene-*co*-butylene)-*block*-polystyrene (EPEBS), which was obtained after hydrogenation of IBS triblock copolymers. This system was chosen because the order–disorder transition of EPEB diblock copolymers had been widely investigated before (149). It is well known that I and B homopolymers form single-phase blends with each other up to very large degrees of polymerization (150). Thus the corresponding IB diblock copolymers form disordered melts as well. While the IBS triblock copolymers behave like microphase-separated diblock copolymers with the compatible I and B blocks forming one microdomain and S forming the other one at low temperatures, at higher temperatures the order–disorder transition occurs and all three blocks form a disordered phase. This was monitored by dynamic mechanical spectroscopy (151). Especially the appearance of master curves in plots of the storage versus the loss modulus served as an indicator of the formation of the homogeneous disordered phase (152). This technique was also applied to EPEB diblock and the corresponding EPEBS triblock copolymers (153). While the order–disorder transitions of the EPEB diblock copolymers could be determined by this method, the order–order transition related to the onset of miscibility between these two blocks in the EPEBS triblock copolymer could not be resolved. A system with a short S block located in spherical domains (as proven by tem), $EP_{50}EB_{44}S_6$[48], showed an order–disorder transition around 70°C, which could be confirmed by the disappearance of the maximum in the saxs curve at that temperature. It is not obvious whether this system undergoes a phase transition from three microphase-separated domains into one homogeneous phase, or whether there is another order–order transition prior to the order–disorder transition. Because of the lack of sufficient electron density contrast between the two elastomeric blocks EP and EB, saxs only monitors EP and EB together in contrast to S. A system with a larger S block, $EP_{46}EB_{38}S_{16}$[74], shows rhombohedrally packed S cylinders at room temperature. At elevated temperatures a phase transition to a system with hexagonally packed S cylinders occurs. This indicates a mixing of the two elastomeric blocks at significantly larger temperatures as compared to the order–disorder transition of the corresponding EPEB diblock copolymer (order–disorder transition < 20°C), and hence the conclusion that the grafting of a diblock copolymer to an incompatible surface leads to an increase of its order–disorder transition. This can be explained by the fact that the system cannot gain as much entropy as a free diblock copolymer because of the fixed end of one block (EB) at the interface with the immiscible third block (S). Moreover, the penetration of the EP block into the EB domain necessarily leads to an increase of the interface between S and the mixed elastomeric domain, which results in an increase of interfacial energy, unless a temperature-induced reduction of the interfacial tension compensates this enthalpic hindrance.

Comparing the morphologies of the IBS and EPEBS triblock copolymers, a shift from the disordered state toward the lamellae upon hydrogenation could be observed. This is shown in Figure 28. Upon hydrogenation of the two elastomeric blocks they become incompatible (or less compatible), which changes the conformation of the elastomeric corona around the microphase-separated S domains. The appearance of a new interface (even if it is not sharp) confines the junction point between the elastomeric blocks, and as a result of the repulsive interaction the interfacial area tends to get reduced, in order to reduce the number of

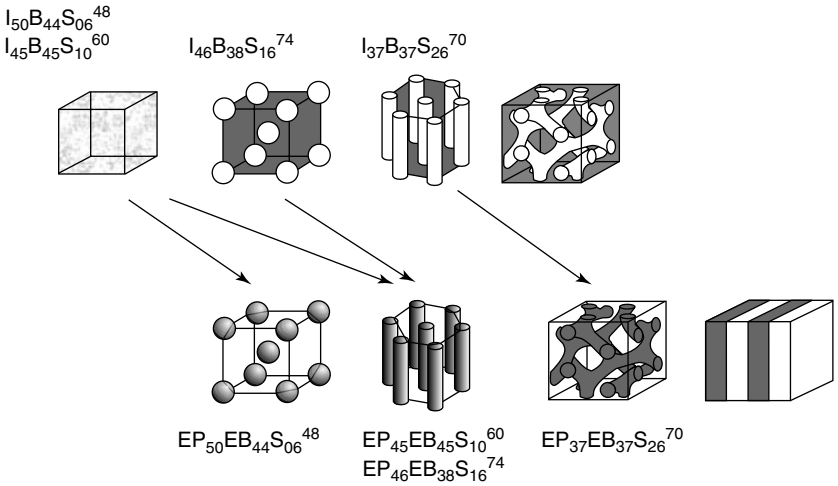

Fig. 28. Change of the morphologies of IBS triblock copolymers via hydrogenation to EPEBS triblock copolymers.

contacts between dissimilar segments. This leads to a stretching which reduces the curvature of the interface toward the S domains. For simplicity in Figure 28 the morphologies are shown as obtained from tem and saxs. Both methods cannot distinguish between the two elastomeric blocks, but distinguish only S from the I, B or EP, EB, respectively.

Blends of ABC Triblock Copolymers with Other Block Copolymers

Three articles of this encyclopedia consider only the morphological behavior of pure block copolymers in their bulk state by changing their topology or the thermodynamic properties of their blocks. Another interesting possibility to control block copolymer morphologies is given by blending block copolymers with other polymers or block copolymers. It is well known that free polymer chains can penetrate into grafted polymer chains under certain conditions (154). A block located at the interface of a microphase-separated block copolymer can be considered as a grafted chain. For chemically similar chains penetration is possible, when the free chains are shorter than the grafted chains. In such a case the gain of mixing entropy (or translational entropy of the free chains) is larger than the reduction of conformational entropy of the grafted chains induced by the chain stretching accompanied by mixing (Fig. 29).

The stretching in a grafted chain (or polymer brush) is a function of the distance to the interface. While close to the interface the stretching may be very large (depending on the interfacial tension), it vanishes at the surface of the polymer brush, where the chain approaches a random coil conformation. A certain interpenetration of similar chains always occurs when brushes with chemically similar chains are in contact with each other, as it is in the case of microphase-separated block copolymers in the bulk state. Since the interpenetration in these cases occurs

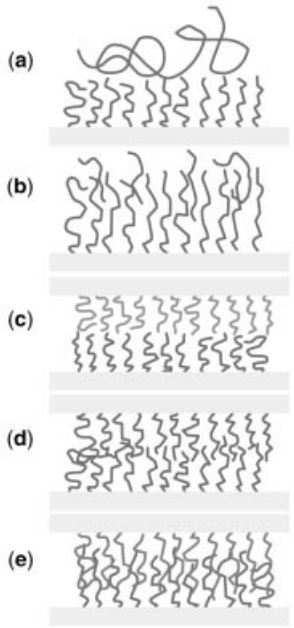

Fig. 29. Different situations of polymer brushes in contact with free chains or other polymer brushes. (**a**) Dry brush: long free chain cannot interpenetrate the brush; (**b**) Wet brush: short free chain interpenetrates brush; (**c**) $\chi > 0$: no interpenetration, phase separation; (**d**) $\chi = 0$: some interpenetration; (**e**) $\chi < 0$: stronger interpenetration.

between chemically similar chains, the driving force of this chain interpenetration is of pure entropic origin. While interpenetration will be suppressed when the interactions between different brushes are repulsive, attractive interactions will enhance the interpenetration (Fig. 29). This latter effect was used, for example, when compatibilizing blends of two polymers with a diblock (10) or triblock (11) copolymer, where each of the outer blocks shows selective attractive interactions to one of the other blend components.

Blends of microphase-separated binary block copolymers, mainly diblock copolymers, have been investigated for a long time (155). Blends of diblock copolymers were used to determine the stability region of the double gyroid morphology, which exists in a relatively narrow composition window in the weak and intermediate segregation regimes for binary block copolymers (156). In all these blends and also in blends of an AB diblock copolymer with an A homopolymer (157), only those morphologies were found which were similar to the morphologies found for a diblock copolymer with the same or slightly different overall composition; ie, no qualitatively different morphologies exist in these systems. A more dramatic effect has been reported in Reference 158, in which blends of different starblock copolymers, which all contained 25% S, were investigated. For some of these blends a lamellar morphology was found, which is very different from the stability region of the lamellar phase in diblock copolymers (158). Also an investigation of blends composed of SI diblock copolymers with various molecular weights and

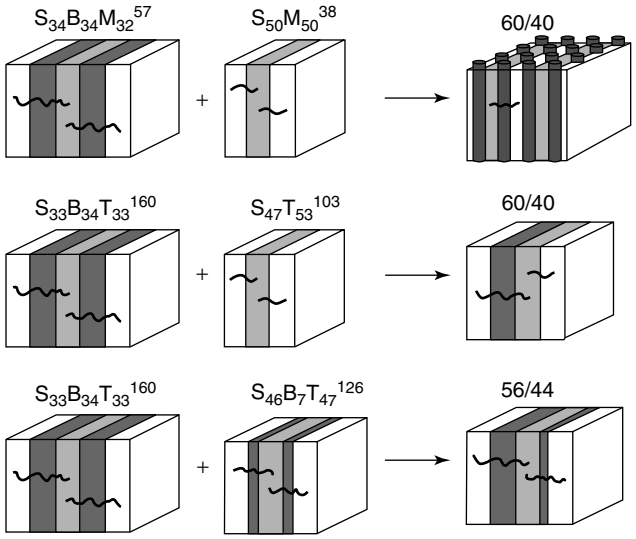

Fig. 30. Scheme of blends of various lamellar ABC and AC block copolymers forming the "cylinder at lamellar interface" and "noncentrosymmetric lamellae." Weight ratios of the blends are indicated in the figure (OsO_4, see Table 1).

various compositions showed a significant shift of the stability regions of different morphologies (159), which could be explained by a change of the interfacial curvature of the large block copolymer by swelling with the small diblock copolymer (160). In comparison, blending of ABC triblock copolymers with other block copolymers (ABC, AC) turned out to generate also new morphologies with symmetries not accessible in pure ABC or AC systems.

An idea proposed for periodic noncentrosymmetric layers in order to obtain longitudinal ferroelectric smectics was to use a structural sequence of α–β–γ–α (161). While ABC triblock copolymers self-assemble in a centrosymmetric way, ie, $\cdots$ABC CBA ABC$\cdots$, the idea of Reimund Stadler was to blend lamellar ABC with AC block copolymers to get a structure with the sequence $\cdots$ABC CA ABC$\cdots$, which is noncentrosymmetric (76,162,163). The initial attempts toward such a morphology were carried out on lamellar SBM and SM block copolymers (163). However, no composition and no molecular weights of components of such blends were found where the desired morphology was formed. Either macrophase separation between the pure triblock and diblock copolymers occurred for large molecular weights ($M_{SBM} \approx 150$ kg/mol, $M_{SM} \approx 100$ kg/mol) or a centrosymmetric superlattice was formed, where the B blocks were located in cylinders in a lamellar matrix of S and M (like lc-morphology) (Fig. 30).

From that result it was concluded that the repulsive interaction between the two outer blocks need to be increased, in order to force the system to suppress direct interfaces between the two outer blocks of the triblock copolymer. In the blend the effective volume fraction of the middle block is decreased by the swelling of the two outer blocks of the triblock copolymer by the corresponding blocks of the diblock copolymer. Thus a system is required where all three components form

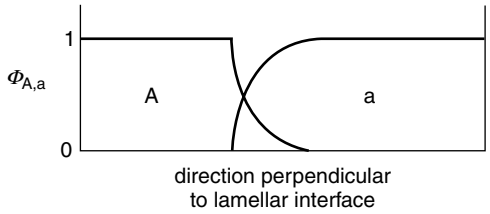

Fig. 31. Concentration profile of asymmetric interpenetration in a mixed lamella of A and a blocks from ABC and ac block copolymers.

lamellae, even for small volume fractions of the middle block. This is true for SBT. The blend of an SBT and ST block copolymer in fact formed the desired periodic noncentrosymmetric lamellar superlattice (Fig. 30) (76,162,163).

The driving force for the formation of such an arrangement has been discussed (164), and it was shown that the different stretching of the S and T blocks of the two block copolymers should be the reason for the formation of mixed domains for the two types of S and T blocks, respectively. The more stretched chains of the diblock copolymer can reduce their stretching when mixing with the corresponding less stretched chains of the triblock copolymer. This different degrees of stretching lead to an asymmetric concentration profile of A blocks coming from a diblock copolymer (a) and a triblock copolymer (A) (Fig. 31).

The best condition for ABC and ac block copolymers with $N_A = N_C = N_{ABC}$ and $N_a = N_c = N_{ac}$ to form a periodic noncentrosymmetric lamellar superlattice was found (164) to be

$$\left(\frac{X_{ac}}{X_{ABC}}\right)^3 = \frac{2N_{ac}^4}{N_{ABC}^3\,(N_{ABC} + N_B/\kappa)}\,\frac{\gamma_{ac}}{\gamma_{ABC}} \tag{22}$$

with $X = N\Sigma a/v$ (N is the degree of polymerization of the block, Σ is the interfacial area per chain, a is the segmental length, v is the monomeric volume, κ is a coefficient of the elastic energy in the order of unity, and $\gamma_{AB} = \gamma_{BC} = \gamma_{ABC}$). For a symmetric triblock copolymer ($N_B = N_{ABC}$) the best conditions for the formation of alternating triblock and diblock lamellae (periodic noncentrosymmetric lamellae) is with $X_{ac} = X_{ABC}$:

$$\frac{N_{ABC}}{N_{ac}} = \left(\frac{\gamma_{ac}}{\gamma_{ABC}}\right)^{1/4} \tag{23}$$

It is difficult to compare this formula quantitatively with the experimental results because the values of the interfacial tensions are not known to a high level of certainty. The solubility parameter of T reported in literature does not differ very much from B (Table 2). This would indicate a vanishing surface tension betwen B and T in the SBT triblock copolymer but is in contradiction with the microphase separation experimentally found in BT diblock copolymers.

The energy reduction of the diblock chains is higher than the increase of elastic energy of the triblock chains, leading to an overall reduction of the free

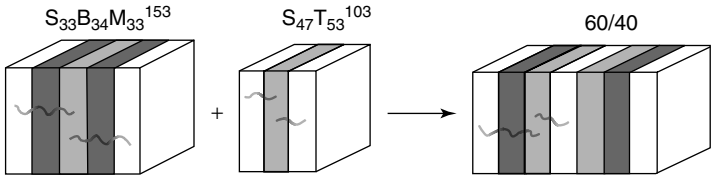

Fig. 32. Scheme of a blend of SBM and ST in a weight fraction of 60/40 forming periodic double lamellae (OsO_4, see Table 1).

energy of the system. Following this idea, a periodic noncentrosymmetric lamellar structure could also be generated when blending two SBT triblock copolymers with very different sizes of the middle blocks but similar lengths of the outer blocks (Fig. 30) (76). The different length of the middle block leads to different interfacial areas between the middle block and the outer blocks. As a result, the degree of chain stretching of the outer blocks is different in a similar way as discussed for the blend of SBT with ST. The noncentrosymmetric blend of two SBT triblock copolymers offers the possibility to introduce different functionalities into the two different B domains via chemical modifications of the two SBT triblock copolymers prior to their mixing.

While noncentrosymmetric superstructures can be obtained in blends of ABC and AC under favorable conditions, it may be expected that centrosymmetric double lamellar superstructures can be obtained in blends of ABC with AD, where D is incompatible with all other blocks. Such a structure is shown in Figure 32 and was obtained for a blend of lamellar SBM and ST block copolymers, while a corresponding blend of SBT with SM macrophase-separated (139). A similar structure was found for a blend of a lamellae-forming SBT triblock copolymer with a symmetric poly(2-vinylpyridine)-*block*-poly(cyclohexyl methacrylate) (VC) diblock copolymer, in which S and C form a mixed lamellar domain because of attractive interactions (165).

Blending of two SBM triblock copolymers which are also different in their middle block molecular weights (one forms the ll-morphology and the other forms the lc-morphology) leads to the kp-morphology (Fig. 33) (76,166). This again is an example that blending of block copolymers may lead to morphologies which are not observed for one of the pure components at any composition. Note that the kp-morphology was only observed for certain SEBM triblock copolymers, but it was never found in the non-hydrogenated SBM triblock copolymers (167). While there are indications that the kp-morphology is only metastable for SBM triblock copolymers, this is still an open question for the block copolymer blend (166).

Another type of block copolymer blends consisted of ABC and BC block copolymers. Here a situation can be imagined where the BC diblock chains align parallel to the BC blocks of the triblock chains, which leads to an increase of the effective volume fractions of B and C with respect to A. Blending of lamellar SBM with BM block copolymers of similar block sizes leads to core–shell morphologies. Depending on the blend ratio core–shell cylinders or core–shell double gyroid morphologies can be obtained, with S forming the core domains (76,168). Also coexistence of the different morphologies can be observed (see Table 2 of Ref. 168). For

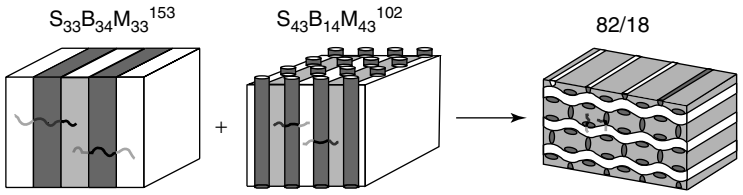

Fig. 33. Schemes two SBM triblock copolymers forming the kp-morphology in a blend with weight fractions of 82/18 (OsO_4, see Table 1).

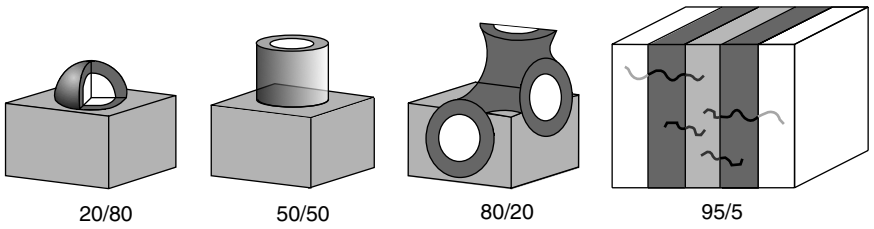

Fig. 34. Schemes of the core–shell analogues of diblock copolymer morphologies in a blend of $S_{33}B_{34}T_{33}^{160}$ and $S_{69}B_{31}^{71}$ block copolymers, with increasing weight fraction of the triblock copolymer from left to right (OsO_4, see Table 1).

comparison, blends of symmetric $S_{33}B_{34}M_{33}^{153}$ with symmetric $S_{49}B_{51}^{87}$ block copolymers show macrophase separation (76). Reducing the molecular weight of B of the SB diblock copolymer again leads to miscible blends of $S_{33}B_{34}M_{33}^{153}$ and $S_{69}B_{31}^{71}$. Depending on the blend ratio, either a morphology with S cylinders surrounded by four B cylinders in an M matrix (50/50, c_ac-morphology; see Figs. 3 and 16: there the locations of S and M are reversed) or an lc-morphology is observed for smaller amounts of diblock copolymer (80/20) (76).

With increasing amount of triblock copolymer, blends of lamellar SBT triblock copolymers with the asymmetric SB diblock copolymer form core–shell spheres, core–shell cylinders, core–shell double gyroids, and lamellae (Fig. 34). T forms the core domains in these morphologies, which can be considered as core–shell analogues of the well-known diblock copolymer morphologies (76).

In the blends of triblock and diblock copolymers presented so far only lamellae-forming triblock copolymers were used. Thus, the blend morphologies showed an increasing curvature of the interfaces with increasing amount of diblock copolymer (from lamellae toward core–shell spheres). As discussed before, the symmetrically composed $B_{32}S_{35}M_{33}^{196}$ triblock copolymer forms a core–shell double-gyroid morphology with B cores as a result of the asymmetric interactions between the middle and the two outer blocks. Adding a symmetric $S_{49}B_{51}^{87}$ diblock copolymer of comparable block lengths reverses the interfacial curvature: depending on the relative composition, lamellae or the inverted core–shell double gyroid morphology with M cores and S shells are formed (76) (Fig. 35).

Thus, blends of SBM with BM and BSM with SB (all blocks being of comparable size) form mixed superstructures, while the blend of SBM with SB macrophase-separates. The formation of mixed lamellar superstructures of ABC and AB block

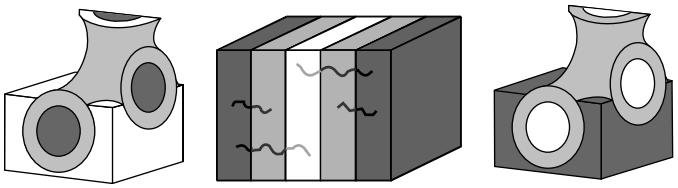

Fig. 35. Schemes of blends of $B_{32}S_{35}M_{33}$[196] with $S_{49}B_{51}$[87] with increasing weight fraction of SB from left to right (OsO_4, see Table 1).

copolymers in the SSL has been investigated (169,170). The chemical potential of the diblock copolymer in the mixed superstructure and in the pure state was compared in order to determine an approximate critical molar fraction of the triblock copolymer, q^*_{appr}, below which further diblock copolymers cannot be incorporated into the triblock copolymer domains. For the case where the A and B blocks of the diblock copolymer are shorter than the corresponding blocks of the triblock copolymer ($N_a < N_A$, $N_b < N_B$), the following critical composition is obtained:

$$q^*_{appr} = \left(\frac{\gamma_{BC}}{\gamma_{AB}} \frac{Y_a + Y_b}{Y_A + Y_B + Y_C - Y_a - Y_b} \right)^{1/3} \tag{24}$$

with $Y = Nv^{5/3}/a$ [N is the degree of polymerization of the block, v is the monomer volume, and a is the segmental length (Kuhn length)]. The critical composition becomes larger when the block lengths of the diblock and triblock copolymers are similar; ie, the incorporation of diblock copolymer chains becomes less favorable, which is in qualitative agreement with the experimental results:

$$q^*_{appr} = \left(\frac{\gamma_{BC}}{\gamma_{AB}} \frac{Y_A + Y_B}{Y_C} \right)^{1/3} \tag{25}$$

where $Y_A = Y_a$ and $Y_B = Y_b$.

Thus, the incorporation of diblock chains into triblock lamellae is favorable for a system with similar block lengths under the condition that the interfacial tension within the AB diblock copolymer is larger than the interfacial tension of the BC interface in the ABC triblock copolymer:

$$\frac{\gamma_{AB}}{\gamma_{BC}} > 1 \tag{26}$$

Other mixed superstructures were not considered in detail, but it is obvious that they may become stable with respect to mixed lamellae or macrophase separation at blend compositions with even larger amounts of the diblock copolymer.

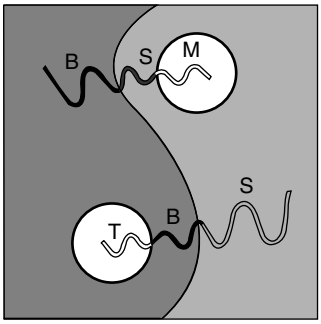

Fig. 36. Scheme of the tetracontinuous gyroid morphology in a blend of $B_{32}S_{35}M_{33}{}^{196}$ and $S_{33}B_{34}T_{33}{}^{160}$ at a ratio of the weight fractions of 50/50 (OsO_4, see Table 1). From Ref. 76. Copyright (2000) Wiley-VCH Verlag GmbH.

The concept of parallel alignment of the diblock copolymer chains with the corresponding blocks of the triblock copolymer was also extended to blends of two triblock copolymers. In a blend of $B_{32}S_{35}M_{33}{}^{196}$ and $S_{33}B_{34}T_{33}{}^{160}$ with comparable lengths of all blocks, a sequence of domains such as $\cdots$MSBTBSM$\cdots$ can be expected. In fact, such sequence is observed besides domains containing the pure components. Both S and B form a single gyroid interface dividing half of the unit cell (Fig. 36) (76) which was not observed in any system before. Both M and T form core gyroids in the S and B shells, respectively (76). In comparison to the tricontinuous double gyroid morphology of two components in diblock copolymers and the pentacontinuous core–shell double gyroid morphology of three components in triblock copolymers or block copolymer blends, this morphology shows a tetracontinuous gyroid morphology of four components. These cocontinuous morphologies have recently attracted stronger interest as possible candidates for membrane materials or for photonic applications (16).

The preparation of blends of microphase-separated block copolymers, which self-assemble in common superstructures, is easier as compared to mixed homopolymer or random copolymer blends. The latter often macrophase-separate during processing (for example during evaporation of a common solvent). This is due to a selectivity of the solvent–polymer interactions in favor of one of the blend components. This problem is present to a much lesser extent in blends of block copolymers where at least one of the blocks is chemically similar in both block copolymers and thus the selectivity problem in many cases is less important. In some cases, however, macrophase separation is observed at intermediate length scales. Systems where the incompatibility between SI and S(I-*stat*-EP) diblock copolymers was adjusted by the degree of hydrogenation of the latter one have been reported (171). Different structures were observed depending on whether first microphase separation between S and I or I-*stat*-EP, or the macrophase separation between the different elastomeric components, occurred leading to so-called macrophase separation within microphase separation. Blends of lamellar SBM (ll- or lc-morphology) with the analogous SEBM triblock copolymers both show a macrophase separation, where the S and M lamellae are continuous across both block copolymer domains, but the B and EB domains are well separated from each

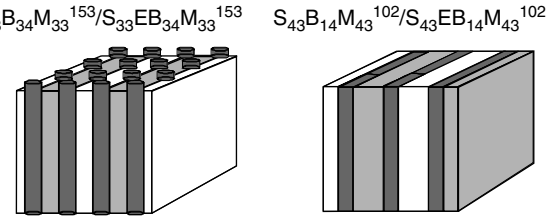

Fig. 37. Macrophase separation in blends of morphologically similar SBM and SEBM triblock copolymers: macrophase separation of cylindrical (left) and lamellar middle block domains (right) (OsO_4, see Table 1).

other (Fig. 37) (76). The control of macrophase separation in such block copolymer blends is thus a further way to design morphologies in these materials.

BLOCK COPOLYMERS

Introduction

Block copolymers are useful in many applications where a number of different polymers are connected together to yield a material with hybrid properties. For example, thermoplastic elastomers are block copolymers containing a rubbery matrix (polybutadiene or polyisoprene) containing glassy hard domains (often polystyrene). The block copolymer, a kind of polymer alloy, behaves as a rubber at ambient conditions, but can be molded at high temperatures because of the presence of the glassy domains that act as physical cross-links. In solution, attachment of a water-soluble polymer to an insoluble polymer leads to the formation of micelles in amphiphilic block copolymers. The presence of micelles leads to structural and flow characteristics of the polymer in solution, that differ from either parent polymer.

A block copolymer molecule contains two or more polymer chains attached at their ends. Linear block copolymers comprise two or more polymer chains in sequence, whereas a starblock copolymer comprises more than two linear block copolymers attached at a common branch point. Polymers containing at least three homopolymers attached at a common branching point have been termed *mixed arm block copolymers*, although they can also be viewed as multigraft copolymers (see GRAFT COPOLYMERS).

In this article, block copolymers prepared by controlled polymerization methods only are considered, primarily di- and triblock copolymers. Multiblock copolymers such as poly(urethanes) and poly(urethane-ureas) prepared by condensation polymerization are not discussed (see POLYURETHANES (PUR)). Although these materials do exhibit microphase separation, it is only short range in spatial extent due to the high polydispersity of the polymers.

Encyclopedia of Polymer Science and Technology. Copyright John Wiley & Sons, Inc. All rights reserved.

A standard notation for block copolymers is becoming accepted, whereby X-*b*-Y denotes a diblock copolymer of polymer X and polymer Y. However, sometimes the *b* is replaced by the full term *block*, or alternatively is omitted, and the diblock denoted X–Y.

A number of texts covering general aspects of block copolymer science and engineering have appeared in the last 30 years eg, References 1 and 2. More recently specialized reviews have appeared on block copolymer melts and block copolymer solutions, and these are cited in appropriate following sections. The burgeoning interest in block copolymers is illustrated by contributions covering various aspects of the subject in a review journal (3) and in an edited book (4).

Since the last edition of the Encyclopedia there have been many advances in the field of block copolymer science and engineering, including new synthesis methods, developments in the understanding of phase behavior, and the investigation of structure and dynamics in thin films. Many of these advances are likely to lead soon to novel applications.

Synthesis

The main techniques for synthesis of block copolymers in research laboratories around the world are presently anionic polymerization and living polymerization, cationic and radical. The older technique of anionic polymerization is still used widely in the industrial manufacture of block copolymers. Cationic polymerization may be used to polymerize monomers that cannot be polymerized anionically, although it is used for only a limited range of monomers. A summary of block copolymer synthesis techniques has been provided (5).

Anionic Polymerization. Anionic polymerization (qv) is a well-established method for the synthesis of tailored block copolymers. The first anionic polymerizations of block copolymers were conducted as early as 1956 (6). To prepare well-defined polymers, the technique is demanding, requiring high purity starting reagents and the use of high vacuum procedures to prevent accidental termination due to the presence of impurities. In the laboratory, it is possible to achieve polydispersities $M_w/M_n < 1.05$ via anionic polymerization. However, the method is also used industrially to prepare several important classes of block copolymers including SBS-type thermoplastic elastomers (S = polystyrene, B = polybutadiene) and polyoxyethylene-*b*-polyoxypropylene-*b*-polyoxyethylene Pluronic amphiphilic copolymers (4). There are a number of reviews that cover the application of anionic polymerization to block copolymers (7–11). Recent advances have mainly been directed toward the synthesis of block copolymers with exotic architectures, such as mixed arm stars (12–14), H-shaped copolymers (12), and ring-shaped (cyclic) block copolymers (15). All of these require the careful choice of multifunctional initiators (see BLOCK COPOLYMERS, TERNARY TRIBLOCKS; DENDRONIZED POLYMERS; HYPERBRANCHED POLYMERS).

Living Radical Polymerization. Undoubtedly the main advance in block copolymer synthesis in the last decade has been the development of techniques of living radical polymerization (sometimes termed controlled radical polymerization). The principle of controlled radical polymerization methods is to establish a dynamic equilibrium between a small fraction of growing free radicals and a

large majority of dormant species. Generated free radicals propagate and terminate as in conventional radical polymerization, although the presence of only a small fraction of radicals prevents premature termination. Among living polymerization methods, atom transfer radical polymerization (ATRP) has been used most extensively to synthesize block copolymers. Here, the radicals are generated through a reversible redox process catalyzed by a transition-metal complex that undergoes a one-electron oxidation with the abstraction of a halogen atom from the dormant species. The ATRP method, and its application to the synthesis of block copolymers, has recently been reviewed (16).

ATRP has been used to prepare AB diblock, ABA triblock, and most recently ABC triblock copolymers (17). To date, the technique has been used to create block copolymers based on polystyrene and various polyacrylates (16). However, it is possible to synthesize a so-called macroinitiator by other polymerization mechanisms (anionic, cationic, etc), and use this in the ATRP of vinyl monomers. Examples, such as the anionic polymerization of PEO macroinitiators for ATRP synthesis of polyethylene oxide/polystyrene block copolymers, are discussed in Reference 16.

Other Methods. Sequential living cationic polymerization is primarily used to prepare block copolymers containing a vinyl ether block, or polyisobutylene (18–20). It can also be coupled with other techniques (18,20). However the range of monomers that may be polymerized by this method is comparatively limited and consequently living cationic polymerization is only used in prescribed circumstances.

Ring-opening metathesis polymerization has also been exploited to build blocks from cyclic olefins, especially polynorbornene (5). The development of ring-opening metathesis polymerization for block copolymer synthesis has recently been facilitated by the introduction of functional group tolerant metathesis catalysts (21).

Block Copolymer Melts

The interest in the phase behavior of block copolymer melts stems from microphase separation of polymers that leads to nanoscale-ordered morphologies. This subject has been reviewed extensively (1,22–24). The identification of the structure of bicontinuous phases has only recently been confirmed, and this, together with major advances in the theoretical understanding of block copolymers, means that the most up-to-date reviews should be consulted (1,24). The dynamics of block copolymer melts, in particular rheological behavior, and studies of chain diffusion via light scattering and nmr techniques have also been the focus of several reviews (1,25,26).

The phase behavior of block copolymer melts is, to a first approximation, represented in a morphology diagram in terms of χN and f (1). Here f is the volume fraction of one block and χ is the Flory–Huggins interaction parameter, which is inversely proportional to temperature, that reflects the interaction energy between different segments. The configurational entropy contribution to the Gibbs energy is proportional to N, the degree of polymerization. When the product χN exceeds a critical value $(\chi N)_{\mathrm{ODT}}$ (ODT = order–disorder transition), the block copolymer microphase separates into a periodically ordered structure, with a

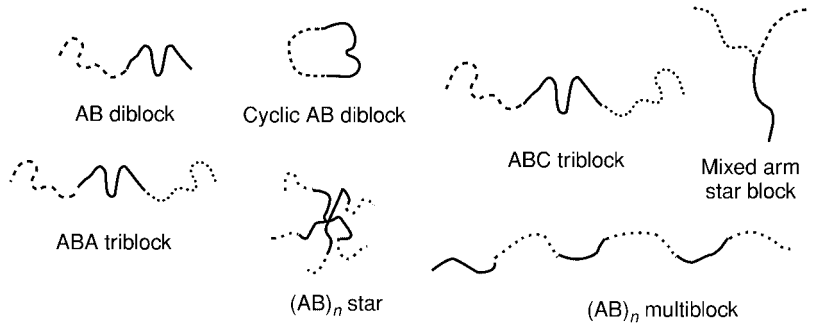

Fig. 1. Block copolymer architectures.

length scale ~5–500 nm. The structure that is formed depends on the copolymer architecture and composition (1) (see Fig. 1). For diblock copolymers, a lamellar (lam) phase is observed for symmetric diblocks ($f = 0.5$), whereas more asymmetric diblocks form hexagonal-packed cylinder (hex) or body-centered cubic (bcc) spherical structures. A complex bicontinuous cubic gyroid (gyr) (space group $Ia\bar{3}d$) phase has also been identified (27,28) for block copolymers between the lam and hex phases near the ODT, and a hexagonal-perforated layer (HPL) phase has been found to be metastable in this region (29–31). A useful compilation is available of studies on the morphology of block copolymers of various chemistries (32).

The main techniques for investigating block copolymer microstructures are transmission electron microscopy and small-angle x-ray or neutron scattering. Transmission electron microscopy provides direct visual images of the structure, albeit over a small area of the sample. Usually samples are stained using the vapors from a solution of a heavy metal acid (OsO_4 or RuO_4) to increase the contrast for electrons between domains (33). Small-angle scattering probes the structure over the whole sample volume, giving a diffraction pattern. The positions of the reflections in the diffraction pattern can be indexed to identify the symmetry of the phase (1,22). The preparation method can have a dramatic influence on the apparent morphology, for example whether solvent casting or melt processing is performed. Numerous cases of mistaken identification of "equilibrium phases" have appeared in the literature, when the phase was simply an artifact. For instance, different morphologies were obtained by varying the preparation conditions for a polyolefin diblock (34). In other cases, phases such as HPL have been observed (29) which although reproducible, have turned out to be only long-lived metastable phases, ultimately transforming to the equilibrium gyr phase (30,31). The ODT in block copolymers can be located by a number of methods—from discontinuities in the dynamic shear modulus (35–37) or small-angle scattering peak shape (38,39) or from calorimetry measurements (40).

To establish relationships between different block copolymer phase diagrams and also to facilitate comparison with theory, it is necessary to specify parameters in addition to χN and f. First, asymmetry of the conformation of the copolymer breaks the symmetry of the phase diagram about $f = 0.5$. For AB diblocks, conformational asymmetry is quantified using the "asymmetry parameter" $\varepsilon = (b_A{}^2/v_A)/(b_B{}^2/v_B)$ (41,42), where b_J is the segment length for block J and v_J is the segment volume. Composition fluctuations also modify the phase diagram, and

this has been accounted for theoretically by the Ginzburg parameter $\bar{N} = Nb^6\rho^2$, where ρ is the number density of chains (43,44). The extent of segregation of block copolymers depends on the magnitude of χN. For small χN, close to the ODT (up to $\chi N = 12$ for symmetric diblocks for which $\chi N_{\mathrm{ODT}} = 10.495$), the composition profile (density of either component) is approximately sinusoidal. This is termed the weak segregation limit. At much larger values of χN ($\chi N > \sim 100$), the components are strongly segregated and each domain is almost pure, with a narrow interphase between them. This is the strong segregation limit.

The first theories for block copolymers were introduced for the strong segregation limit (SSL) and the essential physical principles underlying phase behavior in the SSL were established in the early 1970s (1). Most notably, Helfand and coworkers (45–47) developed the self-consistent field (SCF) theory, thus permitting the calculation of free energies, composition profiles, and chain conformations. In the SCF theory, the external mean fields acting on a polymer chain are calculated self-consistently with the composition profile. The theory of Leibler (48) describes block copolymers in the weak segregation limit. It employs a Landau–Ginzburg approach to analyze the free energy, which is expanded with reference to the average composition profile. The free energy coefficients are computed within the random phase approximation. Weak segregation limit theory can be extended to allow for thermal composition fluctuations. This changes the mean field prediction of a second-order phase transition for a symmetric diblock copolymer to a first-order transition. This effect for block copolymers has been studied, and it was shown that composition fluctuations, incorporated via the renormalization method of Brazovskii, lead to a "finite size effect," where the phase diagram depends on $\bar{N}$ (43). A powerful new method to solve the SCF equations for block copolymers has been applied to analyze the ordering of many types of block copolymer in bulk and in thin films (49–52). The strong and weak segregation limits are spanned, as well as the intermediate regime where the other methods do not apply. This implementation of SCF theory predicts phase diagrams and other quantities such as domain spacings, in good agreement with experiment, and represents an impressive state of the art for modeling the ordering of soft materials. Accurate liquid state theories have also been used to model block copolymer melts (53,54), although they are hard to implement and consequently the method is often regrettably overlooked (1). Recently, a method has been developed to directly simulate field theories for polymers without introducing approximations such as mean field approaches and perturbation expansions (55). This technique holds much promise for examining the thermodynamics of block copolymers in the limit of low molecular weight where approximate methods such as mean field theory or renormalization techniques break down.

A phase diagram computed using self-consistent mean field theory (49,51) is shown in Figure 2. The figure shows the generic sequence of phases accessed just below the ODT temperature for diblock copolymers of different compositions. The features of phase diagrams for particular systems are different in detail, but qualitatively they are similar, and well accounted for by SCF theory.

The phase behavior of ABC triblocks is much richer (24) than that of two-component diblocks or triblocks, as expected because multiple interaction parameters (χ_{AB}, χ_{AC}, and χ_{BC}) result from the presence of a distinct third block.

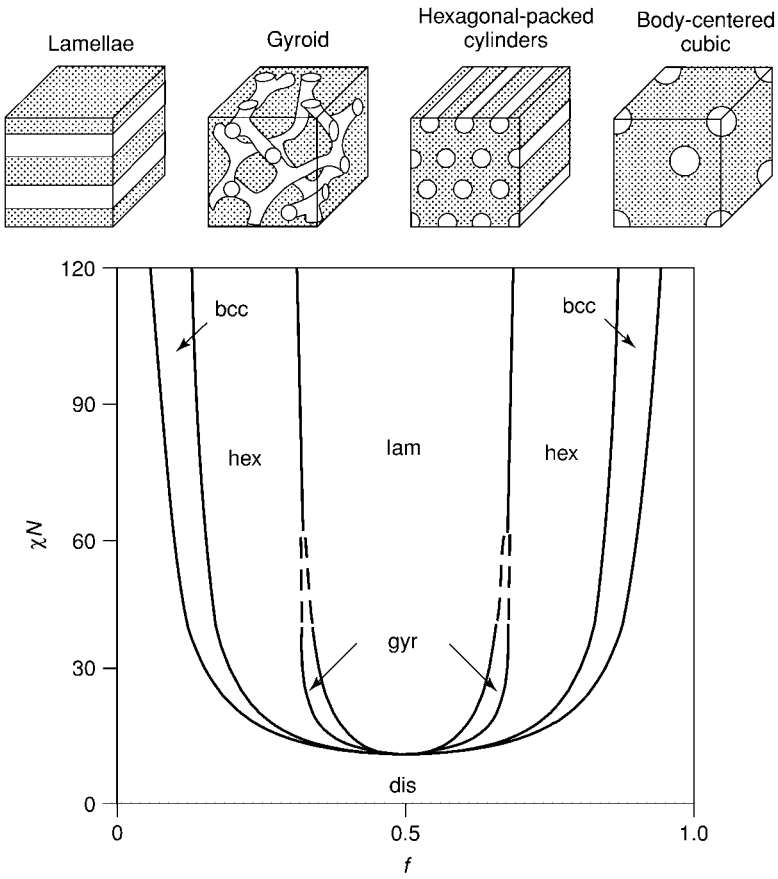

Fig. 2. Phase diagram for a conformationally symmetric diblock copolymer, calculated using SCF theory (49,51), along with illustrations of the equilibrium morphologies. In the phase diagram, regions of stability of disordered (dis), lamellar (lam), gyroid (gyr), hexagonal (hex), and body-centered cubic (bcc) phases are indicated.

Summaries of work on ABC triblock morphologies have appeared (1,56) and these systems are considered separately elsewhere in this encyclopedia (see BLOCK COPOLYMERS, TERNARY TRIBLOCKS). Because of the large number of possible morphologies, theorists are presently working to predict the phase behavior of these copolymers by using methods that do not require a priori knowledge of the space group symmetries of trial structures (57,58).

During processing block copolymers are subjected to flow. For example thermoplastic elastomers formed by polystyrene-*b*-polybutadiene-*b*-polystyrene (SBS) triblock copolymers, are molded by extrusion (see ELASTOMERS, THERMOPLASTIC). This leads to alignment of microphase-separated structures. This was investigated in the early 1970s by Keller and co-workers (22,59) who obtained transmission electron micrographs from highly oriented specimens of Kraton SBS copolymers following extrusion. Examples are included in Figure 3. Work on the effect of flow on block copolymer melts has been reviewed (1,25,61,62). Because of the

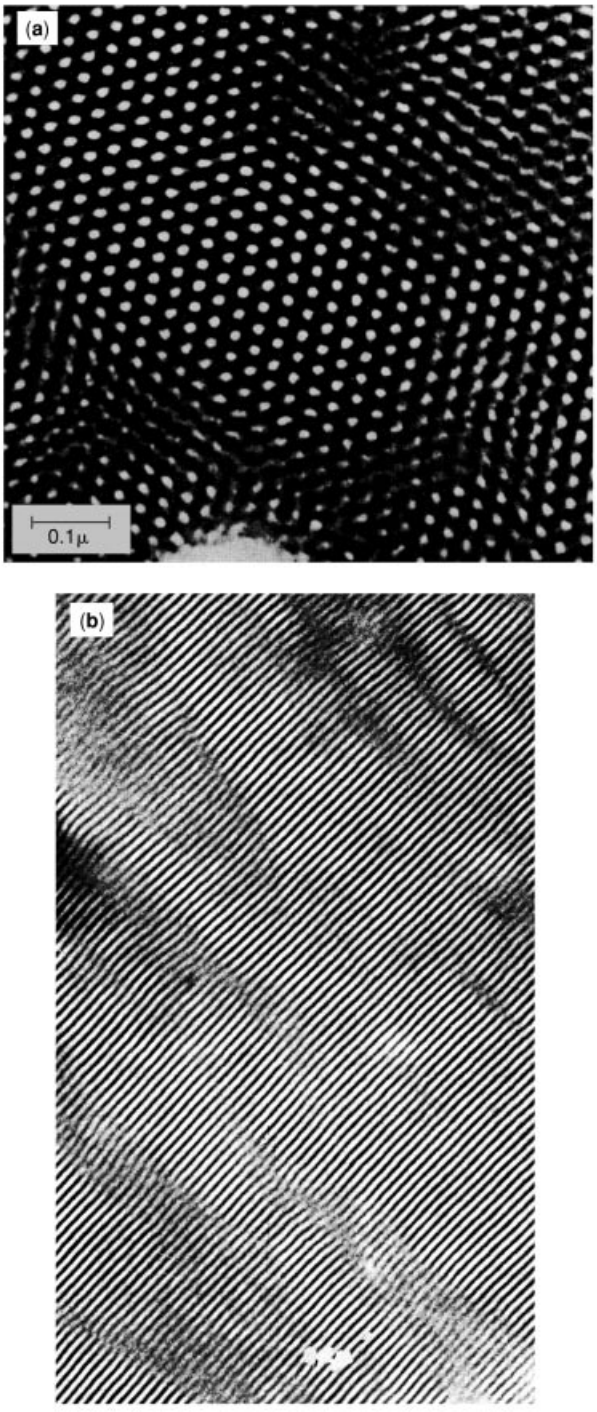

Fig. 3. Transmission electron micrographs from a hexagonal-packed cylinder structure subjected to flow during high temperature extrusion. The sample was a PS–PB–PS tribock (Kraton D1102) (60). (**a**) Perpendicular to the extrusion direction, (**b**) a parallel section.

convenience and well-defined nature of the shear geometry, most model studies have exploited this type of flow. The application of shear leads to orientation of block copolymer microstructures at sufficiently high shear rates and/or strain amplitudes (in the case of oscillatory shear). Depending on shear conditions and temperature, different orientations of a morphology with respect to the shear plane can be accessed. This has been particularly well studied for the lamellar phase where so-called parallel (lamellar normal along shear gradient direction) and perpendicular (lamellar normal along the neutral direction) orientations have been observed (63). Distinct orientation states of hexagonal and cubic phases have also been investigated, details being provided elsewhere (62). The ability to generate distinct macroscopic orientation states of block copolymers by shear is important in future applications of block copolymers where alignment will be important (reinforced composites, optoelectronic materials, and separation media). Shear also influences thermodynamics, since the ODT shifts upwards on increasing shear rate because the ordered phase is stabilized under shear (64,65).

The phase behavior of rod–coil block copolymers is already known to be much richer than that of coil–coil block copolymers, because the rod block can orient into liquid crystal structures (1). The rod block may be analogous to a biomacromolecule; for example, poly(benzyl glutamates) (66,67) and poly(peptides) (68) forming helical rod-like blocks have been incorporated in block copolymers. Possible applications of these materials arising from their biocompatibility are evident.

Block Copolymer Films

Microphase separation by block copolymers in thin films has been investigated from several perspectives. First, the physics of self-assembly in confined soft materials can be studied using model block copolymer materials for which reliable mean field statistical mechanical theories have been developed (69). Second, interest has expanded due to potential exciting applications that exploit self-organization to fabricate high density data storage media (70), to lithographically pattern semiconductors with ultrasmall feature sizes (71,72), or to prepare ultrafine filters or membranes (73). Research in this field is growing at a rapid pace, and the field has not been reviewed since 1998 (1,74), since when many new developments have occurred.

Block copolymer films can be prepared by the spin-coating technique, where drops of a solution of the polymer in a volatile organic solvent are deposited on a spinning solid substrate (often silicon wafers are used because of their uniform flatness). The polymer film spreads by centrifugal forces, and the volatile solvent is rapidly driven off. With care, the method can give films with a low surface roughness over areas of square millimeters. The film thickness can be controlled through the spin speed, the concentration of the block copolymer solution, or the volatility of the solvent, which also influences the surface roughness (75). Dip coating is another reliable method for fabricating uniform thin films (76). Whatever the deposition technique, if the surface energy of block copolymer is much greater than that of the substrate, dewetting will occur. The mechanism of dewetting has been investigated (77–79).

In thin films, the lamellae formed by symmetric block copolymers can orient either parallel or perpendicular to the substrate. A number of possible arrangements of the lamellae are possible, depending on the surface energies of the blocks and that of the substrate, and whether the film is confined at one or both surfaces. These are illustrated in Figure 4. In the case that a different block

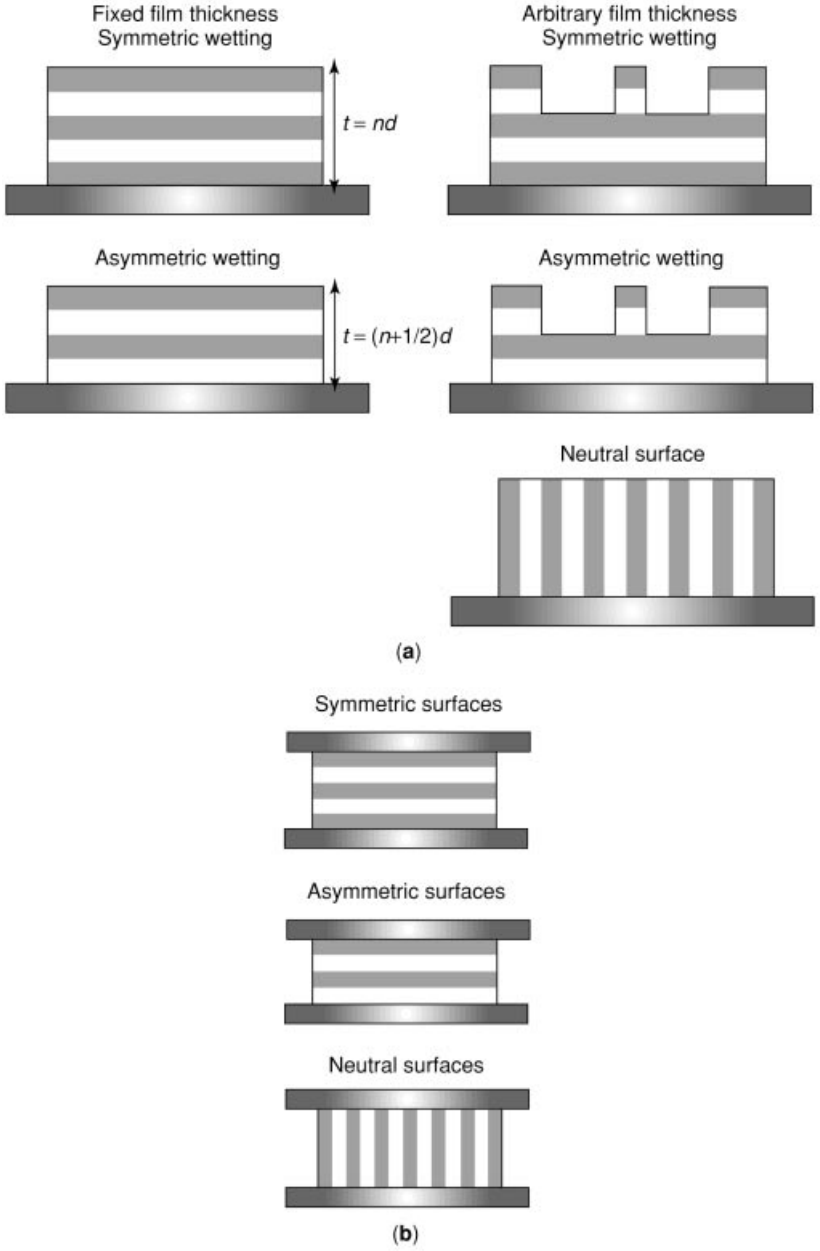

Fig. 4. Possible configurations of lamellae in block copolymer films: (**a**) confined at one surface and (**b**) confined at both surfaces.

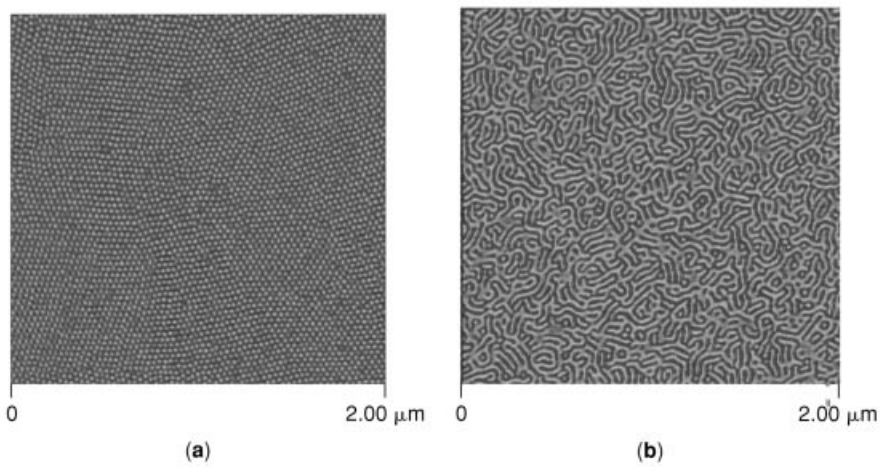

Fig. 5. Hexagonal and stripe patterns observed via atomic force microscopy (Tapping Mode). Phase contrast images of (a) polystyrene-*b*-poly(ethylene-*co*-butylene)-*b*-polystyrene, Kraton G1657 and (b) Kraton G1650 (82).

preferentially wets the interfaces with substrate and air, wetting is asymmetric and a uniform film has a thickness $(n+\frac{1}{2})d$. If the initial film thickness is not equal to $(n+\frac{1}{2})d$, then islands or holes (quantized steps of height d) form to conserve volume (80). In addition to leading to distinct orientations, confinement of block copolymers can change the thermodynamics of ordering, in particular surface-induced ordering persists above the bulk ODT (81).

Asymmetric block copolymers which form hexagonal or cubic-packed spherical morphologies in the bulk, form stripe or circular domain patterns in two dimensions, as illustrated in Figure 5. The stripe pattern results from cylinders lying parallel to the substrate, and a circular domain surface pattern occurs when cylinders are oriented perpendicular to the substrate, or for spheres at the surface. Bicontinuous structures cannot exist in two dimensions; therefore the gyroid phase is suppressed in thin films. More complex multiple stripe and multiple circular domain structures can be formed at the surface of ABC triblocks (83). Nanostructures in block copolymer films can be oriented using electric fields (if the difference in dielectric permittivity is sufficient), which will be important in applications where parallel stripe (84) or perpendicular cylinder configurations (85) are desired.

The morphology of block copolymers on patterned substrates has attracted recent experimental (86,87) and theoretical (88–90) attention. It has been shown that block copolymer stripes are commensurate with striped substrates if the mismatch in the two length scales is not too large.

The surface morphology of block copolymer films can be investigated by atomic force microscopy. The ordering perpendicular to the substrate can be probed by secondary ion mass spectroscopy or specular neutron or x-ray reflectivity. Suitably etched or sectioned samples can be examined by transmission electron microscopy. Islands or holes can have dimensions of micrometers, and consequently may be observed using optical microscopy.

Theory for block copolymer films has largely focused on the ordering of lamellae as a function of film thickness. Many studies have used brush theories for block copolymers in the SSL (91,92), although SCF theory has also been employed (69,89,93). Theory for weakly segregated block copolymers has been applied to analyze surface-induced order above and below the bulk ODT of a lamellar phase (94) and surface-induced layering in a hexagonal block copolymer film (95). Computer simulations using the dynamic self-consistent mean field method have predicted a range of "perforated lamellar" morphologies (96).

Block Copolymers in Solution

In a solvent, block copolymer phase behavior is controlled by the interaction between the segments of the polymers and the solvent molecules as well as the interaction between the segments of the two blocks. If the solvent is unfavorable for one block, this can lead to micelle formation in dilute solution. The phase behavior of concentrated solutions can be mapped onto that of block copolymer melts (97). Lamellar, hexagonal-packed cylinder, micellar cubic, and bicontinuous cubic structures have all been observed (these are all lyotropic liquid crystal phases, similar to those observed for nonionic surfactants). This is illustrated by representative phase diagrams for Pluronic triblocks in Figure 6.

The main classes of block copolymer examined in solution are those based on polyoxyethylene, which is water soluble and is the basis of most amphiphilic block

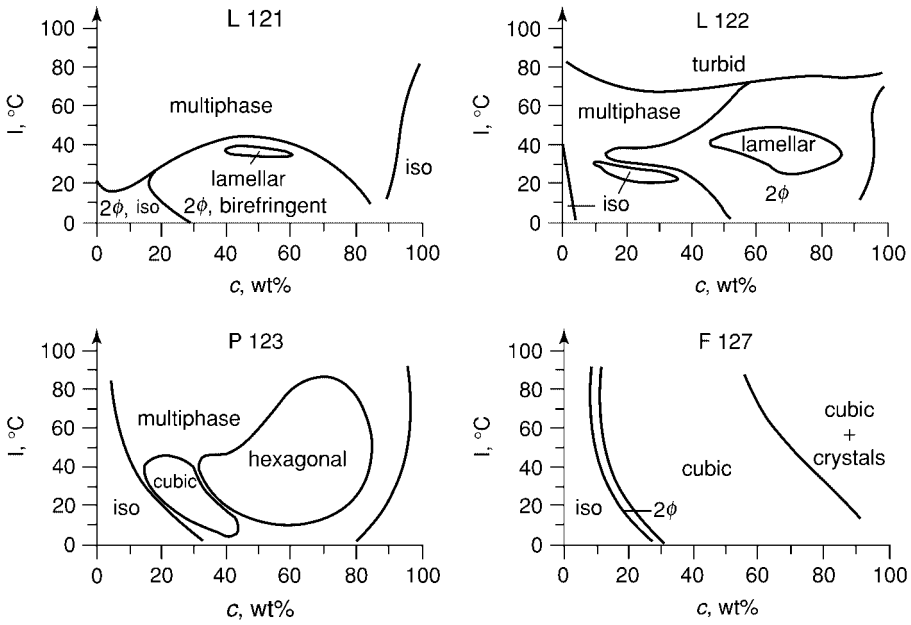

Fig. 6. Phase diagrams in water of $E_mP_nE_m$ (E = polyoxyethylene, P = polyoxypropylene) Pluronics with $n = 69$ and $m = 4$ (Pluronic L121), $m = 11$ (Pluronic L122), $m = 20$ (Pluronic P123) and $m = 99$ (Pluronic F127) (98). Two phase regians are denoted 2ϕ.

copolymers, and styrenic block copolymers in organic solvents. Selected studies on these systems up to 1998 have been summarized (1). Polyoxyethylene-based block copolymers include those of polyoxyethylene (E) with polyoxypropylene (P), especially EPE triblocks (commercial name: Pluronic or Synperonic), which are widely used commercially as surfactants in detergents and personal care products (99), and also in pharmaceutical applications, especially drug delivery (100–102). A number of edited books on water-soluble polymers cover applications of block copolymers (103–108). Related copolymers include those with a polyoxybutylene hydrophobic block (109,110). Work on styrenic block copolymers in organic solvents has also been reviewed (1,111). Block copolymers containing a polyelectrolyte chain have attracted attention from a number of research teams [(112,113) and references therein], copolymers containing a well-studied polyelectrolyte such as poly(styrene sulfonate) (114) or a polyacrylate (112) often being chosen.

Like surfactants, block copolymers form micelles above a critical concentration. The critical micelle concentration can be located by a variety of techniques (115), the most commonly used being surface tensiometry where the *critical micelle concentration* is located as the point at which the surface tension becomes essentially independent of concentration. The primary methods to determine micelle size and shape are light scattering and small-angle x-ray or neutron scattering. The thermodynamic radius (from the thermodynamic volume which is one eighth of the excluded volume) of micelles can be obtained from static light scattering experiments using the Carnahan–Starling equation for hard spheres to the Debye function (110). This procedure can be used in place of Zimm plots when the angular dependence of the scattered intensity is weak, which is usually the case for block copolymer micelles, which are much smaller than the wavelength of light (110). Static light scattering also provides the association number (from the micellar mass) and the second virial coefficient (1,110,116). Dynamic light scattering provides the hydrodynamic radius from the mode corresponding to micellar diffusion obtained from the intensity distribution of relaxation times [usually obtained from analysis of the intensity autocorrelation function using the program CONTIN (117)]. The Stokes–Einstein equation can then be used to calculate the hydrodynamic radius from the diffusion coefficient (1,110). Small-angle x-ray scattering or neutron scattering can be used to extract information on intra- and inter-micellar ordering (1). Neutron scattering has the advantage compared to x-ray scattering that the contrast between different parts of the system (eg, within the micelle or between the micelle and the solvent) can be varied by selective deuteration of solvent and/or one of the blocks. In dilute solution, only intramicellar structure contributes to the scattered intensity (the so-called form factor) and this can be modeled to provide information on micelle size and shape. The simplest model is that of a uniform hard sphere (118), although more sophisticated models are usually required for high quality data fitting (118–121). The intermicellar structure factor dominates at higher concentrations. It can be analyzed using the hard sphere model (118,122,123) to give information on the micellar radius and the micellar volume fraction. Where attractive interactions between micelles are significant, these also influence the structure factor and this can be modeled using the “sticky sphere” approximation (120).

A diverse range of theoretical approaches have been employed to analyze the structure of block copolymer micelles, and for micelle formation (1). The first models were based on scaling relationships for polymer "brushes" and give predictions for the dependence of micelle dimensions on the size of the blocks, as well as the association number of the micelle. A "brush" theory by Leibler and coworkers enables the calculation of the size and number of chains in a micelle and its free energy of formation (124). The fraction of copolymer chains aggregating into micelles can also be obtained. Self-consistent field theory was first applied to predict the critical micelle concentration of a diblock in a homopolymer matrix, and then applied to block copolymers in solution (1). The lattice implementation of SCF theory has been applied to analyze the dimensions of micelles for specific (Pluronic) block copolymers (125).

In addition to applications as surfactants and in personal care products, block copolymer micelles have been extensively investigated as nanoparticles for solubilizing active agents for drug delivery (100,101,126,127), or as "nanoreactors" for the production of inorganic nanoparticles, eg, of metals with potential applications in catalysis (128,129). An alternative approach is to form vesicles (bilayers wrapped round into a spherical shell) (130,131). These may be cross-linked or polymerized to form hollow shell nanoparticles (132–134).

At higher concentrations, block copolymers in solution form a variety of lyotropic mesophases (1,135–138). Because such phases possess a finite yield stress and so usually do not flow under their own weight, these are often termed gels. However, it must be emphasized that the gel properties result from the ordered microstructure rather than any cross-links between polymer chains as in a conventional polymer gel. The symmetry of the ordered phase formed largely depends on the interfacial curvature, as for conventional amphiphiles (115); however, the phase behavior can also be understood by mapping it onto that for block copolymer melts (97). Shear can be used to orient block copolymer gels as for block copolymer melts. The effects of shear on lyotropic lamellar, hexagonal-packed cylindrical micellar, and cubic micellar phases have all been investigated (135,139,140). Large amplitude oscillatory shear or high shear rate steady shear both lead to macroscopic orientation of the structures. In the case of cubic phases in particular, the flow mechanisms are complex, as is the rheological behavior with interesting nonlinear effects such as plateaus in the flow curve (141,142).

Theory for the phase behavior of block copolymers in semidilute or concentrated solution is less advanced than that for melts or dilute solutions because of the complexity of interactions between polymer and solvent. The two main methods developed have been (*1*) SCF theory for density profiles and domain spacings and (*2*) weak segregation limit calculations of the shift in ODT temperature with changing concentration. An overview of both approaches can be found elsewhere (1). SCF theory calculations have produced phase diagrams for specific Pluronic copolymers in aqueous solution that are in remarkably good agreement with those observed experimentally (143,144). Simulations using the dynamic density functional theory (commercially available as the Mesodyn module of Cerius^2 from Accelerys) have also yielded surprisingly accurate predictions for the sequence of phases obtained on varying concentration (145).

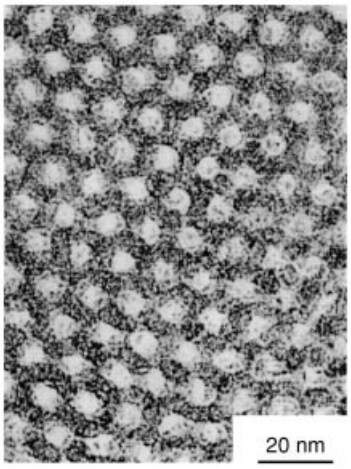

Fig. 7. Transmission electron micrograph of calcined silica structure templated using an acidic solution of Pluronic poly(oxyethylene)-*b*-poly(oxypropylene)-*b*-poly(oxyethylene) triblock. From Ref. 212.

Lyotropic block copolymer mesophases can be used to template inorganic materials such as silica (146,147), thus producing materials with a high internal surface area that could be useful in catalysts or separation technology. Figure 7 shows a transmission electron micrograph of hexagonal mesoporous silica, templated using a Pluronic block copolymer.

Crystallization in Block Copolymers

In semicrystalline block copolymers, the presence of a noncrystalline block enables modification of the mechanical and structural properties compared to a crystalline homopolymer, through introduction of a rubbery or glassy component. Crystallization in homopolymers leads to an extended conformation, or to *kinetically controlled* chain folding. In block copolymers, on the other hand, *equilibrium* chain folding can occur, the equilibrium number of folds being controlled by the size of the second, noncrystallizable block. The structure of block copolymers following crystallization has been reviewed (1,149) (see SEMICRYSTALLINE POLYMERS).

The most important crystallizable block copolymers are those containing polyethylene (PE) or poly(ethylene oxide) (PEO) (systematic name polyoxyethylene). Polyethylene in block copolymers is prepared by anionic polymerization of poly(1,4-butadiene) (1,4-PB), followed by hydrogenation, and has a melting point in the range 100–110°C. This synthesis method leads to ethyl branches in the copolymer, with on average 2–3 branches per 100 repeats. These branches induce lengths for folded chains which are set by the branch density and not by the thermodynamics of crystallization. The melting temperature of PEO in block copolymers is generally lower than that of PEO homopolymer (melting temperature $T_m =$ 76°C for high molecular weight samples). In contrast to PE prepared by hydrogenation of 1,4-PB, there is no chain branching in these copolymers and the fold

length depends on the crystallization procedure. Molecules with 1, 2, 3, . . . folds can be obtained by varying the crystallization protocol (quench depth, annealing time, etc). Crystallization has been investigated for other block copolymers, in particular those containing poly(ε-caprolactone) (PCL) ($T_m = 57^\circ$C). The morphology in block copolymers where both blocks are crystallizable has also been investigated. It has been found that co-crystallization occurs in diblock copolymers, in contrast to blends of crystallizing homopolymers (150). However, one block can influence the crystallization of another as shown by studies on polystyrene-*b*-polyethylene-*b*-poly(ε-caprolactone) ABC triblocks (151). A suppression of the crystallization temperature of the poly(ε-caprolactone) block was noted when the polyethylene block crystals were annealed before crystallization of PCL at lower temperatures (151), this effect being termed "antinucleation."

It is now firmly established that confinement of crystalline stems has a profound influence on crystallization in block copolymers. Confinement can result from the presence of glassy domains or simply strong segregation between domains. In contrast crystallization can overwhelm microphase separation when a sample is cooled from a weakly segregated or homogeneous melt (152–154). The lamellar crystallites can then nucleate and grow heterogeneously to produce spherulites (152,155), whereas these are not observed when crystallization is confined to spheres or cylinders.

Crystallization confined by glassy blocks leads to a drastic slow down in crystallization kinetics and a reduction in the corresponding Avrami exponent (156,157). Poly(ethylene) crystallites in a strongly segregated diblock have been observed to nucleate homogeneously within the PE spheres, leading to first-order kinetics, ie, exponential growth in the degree of crystallinity (158). Confined crystallization was first observed for a lamellar phase with glassy lamellae (159,160), and later in cylinders confined in a glassy matrix (161). Crystallization of the PE matrix in the inverse structure (ie, a phase containing rubbery or glassy cylinders) occurs without disrupting the melt microstructure (162).

Chain folds can exist in equilibrium in block copolymers, in contrast to homopolymers, because of the finite cross-sections of the blocks at the lamellar interface, which have to be matched if space is to be filled at normal densities. The equilibrium fold diagram has been mapped out for PEO-based block copolymers in the melt (163) and in solution (164). Nonequilibrium states of highly folded chains can also be trapped kinetically (164,165).

The orientation of crystalline stems in block copolymers depends on the morphology of the structure and the crystallization protocol. A parallel orientation of PE stems with respect to a lamellar interface was reported for a series of polyethylene-*b*-polyethylethylene diblocks (166), and a similar orientation was later reported (159,160) for a series of PE-containing diblocks based on simultaneous small-angle x-ray scattering/wide-angle x-ray scattering (saxs/waxs) experiments, as shown in Figure 8. SAXS on aligned specimens gives the lamellar orientation, whereas WAXS provides information on unit cell orientation. Samples may be aligned in the melt, for example using large amplitude oscillatory shear (159,167). In constrast to these studies showing parallel stem orientation, a perpendicular orientation of PE stems was proposed in a series of polyolefin diblocks (152). Again using the combination of saxs and waxs, it was found that PE stems generally orient perpendicular to the cylinder axis, although tilted stems were

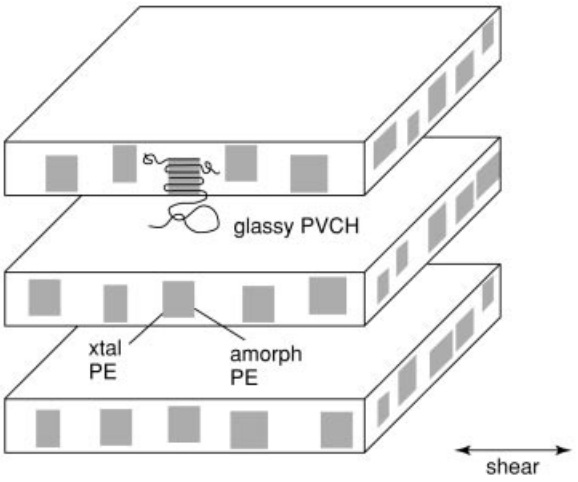

Fig. 8. Model for confined crystallization in a lamellar phase formed by a polyethylene-*b*-poly(vinylcyclohexane) diblock (159).

observed when crystallization was confined by strong segregation or by a glassy matrix (168). These apparently conflicting observations of parallel and perpendicular stem orientations can be rationalized when it is recognized that in both orientations the *b* axis of the PE crystals is the fast growth direction—in the lamellar plane and along the cylinder axis, respectively. Recently, the orientation of PE stems in a PS-*b*-PEO diblock forming a lamellar phase was investigated using saxs and waxs (167). Four regimes were identified: (*1*) A random stem orientation for a deep quench into liquid nitrogen, (*2*) stems parallel to lamellae for a crystallization temperature $-50^{\circ}\mathrm{C} \leq T_c \leq -10^{\circ}\mathrm{C}$, (*3*) stems inclined with respect to lamellae for $-5^{\circ}\mathrm{C} \leq T_c \leq -30^{\circ}\mathrm{C}$, and (*4*) stems perpendicular to lamellae for $T_c \geq 35^{\circ}\mathrm{C}$. For PEO cylinders formed in a PS–PEO diblock, the parallel orientation of stems was not observed, although the states (*1*), (*3*), and (*4*) were confirmed (169). These conclusions were supported by a separate study of the correlation lengths (apparent crystallite sizes) obtained from SAXS for different crystal orientations (170). In this report it was also noted that it is the initial growth stage that determines the final crystal orientation in nanoconfined lamellae rather than the primary nucleation step. Crystal orientation and changes in lamellar thickness of a related diblock were examined in a companion paper, in which the change in the crystallization kinetics for confined and unconfined crystallization were deduced from Avrami plots of the degree of crystallinity (171).

Theories for semicrystalline block copolymers are able to provide predictions for the scaling of amorphous and crystal layer thickness with chain length (1,149). A brush-type theory was developed by DiMarzio and co-workers (172) and an SCF theory by Whitmore and Noolandi (173). The latter approach predicts a scaling for the overall domain spacing $d \sim NN_a^{-5/12}$ (where N is the total degree of polymerization and N_a is that of the amorphous block) which is in good agreement with experimental results (174), as detailed elsewhere (1,149). Approaches used for crystallization in homopolymers may be used to calculate the change in melting temperature due to finite crystal thickness (Thompson–Gibbs equation)

and lamellar crystal surface energies (Flory–Vrij theory), and also growth rates (kinetic nucleation theory). Details can be obtained from Reference 1.

The morphology of thin films of crystallized block copolymers can be probed most conveniently at the microscopic scale by atomic force microscopy, whereas spherulites can be observed optically. Crystallization in thin films of PE-*b*-PEO diblocks has recently been investigated (175,176). For a diblock containing 45% PEO, parallel lamellae were observed in the melt but lamellae oriented perpendicular to the substrate upon crystallization at a large undercooling were observed using Atomic (Force) Microscopy (176). This was ascribed to a kinetically trapped state of chain-folded PEO crystals. However, ultimately the morphology evolved into the equilibrium parallel one, which was also observed for three other diblocks with a higher PEO content (176). Films of these copolymers were characterized by islands and holes at the surface because of an incommensurability between the film thickness and an integral number of lamellae, as discussed earlier. The island and hole structure was retained upon crystallization, although craters and cracks appeared in the lamellae. Within craters, terracing of lamellar steps was observed, from which the lamellar thickness could be extracted. Terracing of crystal lamellae oriented parallel to the substrate was also reported for a PEO-*b*-PBO diblock and a PEO-*b*-PBO-*b*-PEO triblock, probed by AFM (177). In this work a comparison of the lamellar thickness was also made with the domain spacing obtained from saxs and a model of tilted chains was proposed (fully extended for the diblock, once folded for the triblock). However, this is not in agreement with recent simultaneous saxs/waxs results that indicate PEO chains oriented perpendicular to lamellae in a PEO-*b*-PBO diblock (178).

Blends Containing Block Copolymers

In blends of block copolymer with homopolymer, there is an interplay between macrophase separation (due to the presence of homopolymer) and microphase separation (of the block copolymer). Which effect predominates depends on the relative lengths of the polymers and on the composition of the blend.

Macrophase separation can be detected by light scattering or via turbidity measurements of the cloud point since macrophase separation leads to structures with a length scale comparable to the wavelength of light. Regions of macrophase and microphase separation can also be distinguished by transmission electron microscopy or via small-angle scattering techniques. Microphase separation leads to a scattering peak at a finite wavenumber q, whereas macrophase separation is characterized by $q = 0$. The segregation of block copolymers to the interface between polymers in a blend can be determined in bulk from small-angle scattering experiments or transmission electron microscopy. In thin films, neutron reflectivity, forward recoil spectroscopy, and nuclear reaction analysis have been used to obtain volume fraction profiles, which quantify the selective segregation of block copolymers to interfaces.

An important application of block copolymers is as compatibilizers of otherwise immiscible homopolymers. There are a number of useful reviews of work in this area (179–182). The morphology of blends of polymers with block copolymer and theories for this have been reviewed (1). The influence of added homopolymer

on block copolymer structure has also been investigated, as have binary blends of block copolymers, and these systems are also considered in this section.

Blends of Block Copolymer with One Homopolymer. Block copolymers can solubilize homopolymers up to a certain amount, beyond which phase separation occurs. This ability to continuously swell block copolymer microstructures is the basis of a number of potential and actual applications in optoelectronics where the periodicity of the block copolymer structure is extended up to 0.1–1 μm which corresponds to wavelengths for reflection or guiding of light. The limit for macrophase separation in blends of block copolymer with homopolymer depends on the relative chain lengths, ie, on $\alpha = N_{Ah}/N_{Ac}$, where N_{Ah} is the degree of polymerization of the homopolymer (A) and N_{Ac} is the degree of polymerization of the same component of the copolymer. Work by two groups (183–186) has led to the identification of three regimes (1). If $\alpha < 1$, the homopolymer tends to be selectively solubilized in the A domain of the microphase-separated block copolymer, and is weakly segregated toward the domain center. If $\alpha \approx 1$, the homopolymer is still selectively solubilized in the A microdomains. However, it does not significantly swell the A block chains and tends to be more localized in the middle of the A microdomains. If $\alpha > 1$, macrophase separation occurs, with domains of microphase-separated copolymer in the homopolymer matrix. A transmission electron micrograph of the structure formed by a phase-separated lamellar diblock is shown in Figure 9.

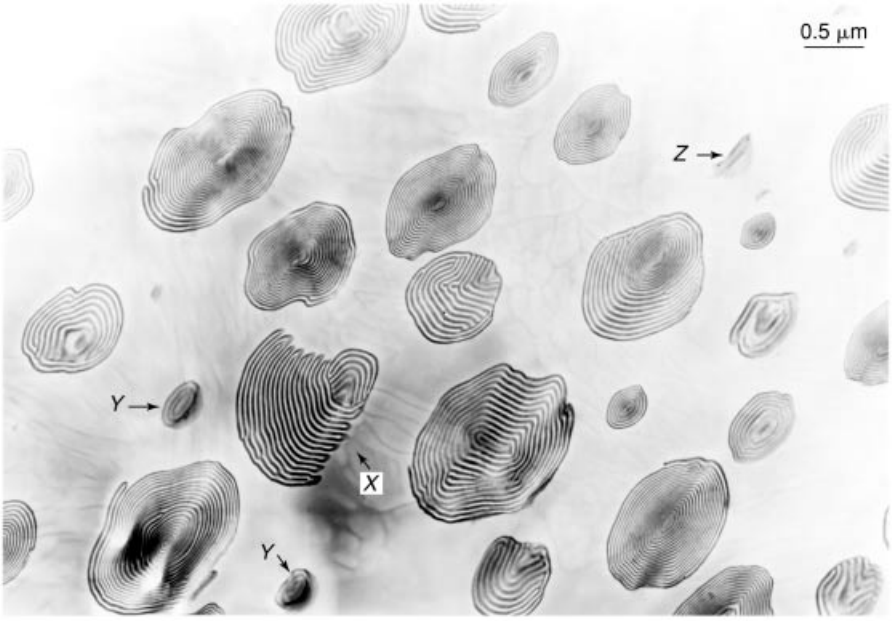

Fig. 9. Electron micrograph showing macrophase separation of domains of microphase-separated polystyrene-*b*-polyisoprene block copolymer (M_n = 100 kg/mol, $f_{PS} = 0.46$) in a PS homopolymer (M_n = 580 kg/mol) matrix (187).

Another important aspect of adding homopolymer to a block copolymer is the ability to change morphology (without synthesis of additional polymers). Furthermore, morphologies that are absent for neat diblocks such as bicontinuous cubic "double diamond" or HPL phases have been predicted in blends with homopolymers (188), although not yet observed. Transitions in morphology induced by addition of homopolymer are reviewed elsewhere (1), where a list of experimental studies on these systems can also be found.

Blends of Block Copolymer with Two Homopolymers. The ability of block copolymers to act as compatibilizers is now established. However, a debate has occurred in the literature as to whether block copolymers are more effective compatibilizers that random copolymers. For example, it has been reported that polystyrene/poly(2-vinylpyridine) random copolymers act to compatibilize the parent homopolymers (189), but that random polystyrene/poly(methyl methacrylate) copolymers are much less effective than corresponding block copolymers (190). The key appears to be the blockiness of the copolymer, which is much higher for the latter (191). Theory suggests that compositional polydispersity is also important for effective compatibilization (191,192). It leads to a greater gradation in composition across the interface, and consequently a lower configurational entropy of the homopolymers (192). In practice, polymers are compatibilized during melt processing. Then kinetic quantities such as the rate of diffusion of the copolymers to the interface and the shear rate are important. It has been shown that the coalescence of polymer droplets is inhibited by diffusion of block copolymers (193). The molar mass must be low enough so that diffusion occurs rapidly but not too low to prevent entanglements at the interface. On the other hand, copolymers with a molar mass that is too high get stuck in micelles.

Block copolymers act as compatibilizers by reducing the interfacial tension between homopolymers. Recent work shows that block copolymers can reduce the interfacial tension between homopolymers to the extent that polymeric microemulsions can be formed where the copolymer forms a continuous film between spatially continuous homopolymer domains (194–196). A transmission electron micrograph of a microemulsion formed in a blend of two polyolefins and the corresponding symmetric diblock is shown in Figure 10. A bicontinuous microemulsion forms in the mixture composition range where mean field theory predicts a Lifshitz point (197). A *Lifshitz point* is defined as the point along the line of critical phase transitions at which macro- and microphase branches meet (1). The observation of a microemulsion shows that mean field theory breaks down owing to the existence of thermal composition fluctuations. Although a theory for these composition fluctuations has not yet been developed, it has been shown that some properties of the microemulsion (elastic constants, composition profiles) can be modeled using an approach where the effective interaction between copolymer monolayers is computed (192,198,199). Both SCF and SSL theories have been employed (199). The effect of shear on polymeric microemulsions has recently been investigated, and it was shown that macrophase separation can be induced at sufficiently high shear rates (200). The connection between microemulsions formed by block copolymers and those containing conventional amphiphiles (which can be used to stabilize oil/water mixtures) has been emphasized (195,201) because of the importance of this aspect of block copolymer phase behavior to applications.

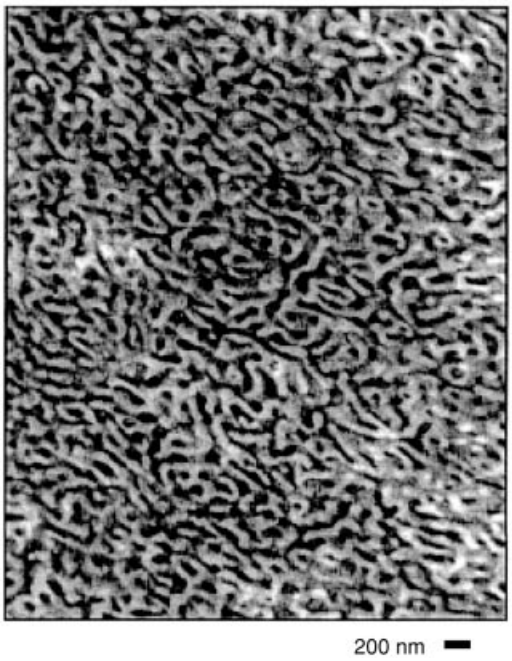

Fig. 10. Transmission electron micrograph of a microemulsion formed in a ternary blend of polyethylene, poly(ethylene–propylene), and a symmetric diblock of these two polymers. From Ref. 195.

Blends of Block Copolymers. Macro- versus microphase separation in blends of block copolymers has been investigated in particular for blends of polystyrene-*b*-polyisoprene diblock copolymers (202–206). Writing the ratio of molecular weights as $\delta = N_1/N_2$, it was found that blends of lamellar diblocks are miscible for $\delta < 5$, whereas for $\delta > 5$, the mixtures are only partially miscible (202,205). The same limiting value of δ was obtained using SCF calculations (207). The miscibility of pairs of asymmetric diblocks with the same (203) or complementary (203,204,208) compositions has also been investigated. By blending complementary diblocks (ie, those with composition f and 1-f), it is possible to induce a lamellar phase even for mixtures of asymmetric diblocks forming cylinder phases when pure (203,208). Blends of diblocks with similar compositions and molecular weights can be used to map the phase diagram by interpolation in the composition range spanned (146). By blending, the synthesis requirements to obtain a full phase diagram are reduced. The validity of this so-called single-component approximation has been tested using SCF theory. It was found that phase boundaries in the (f_1, f_2) plane (where f_1 and f_2 are the compositions of the two diblocks) map onto those of the corresponding pure diblock, if f_1 and f_2 do not differ too much (209,210). In the case that either f_1 or f_2 becomes close to zero or unity, this approximation completely breaks down (210). Thus, the one-component approximation is useful, although evidently the phase diagram of binary blends will contain biphasic regions.

Motivated by the possibility to prepare "exotic morphologies" exhibited by ABC triblocks (Block Copolymers, Ternary Triblocks) just by blending diblocks, researchers have investigated phase diagrams of strongly interacting AB and BC diblocks where the common B block is polyisoprene and the other two blocks are polystyrene and poly(ethylene oxide) (211,212). Although exotic phases were not found, regions of miscibility and immiscibility were mapped out. The phase diagrams obtained were in surprisingly good agreement with the predictions of a simple random phase approximation calculation of the spinodals (213).

BLOW MOLDING

Introduction

Blow molding is defined as a plastic process whereby a thermoplastic material is heated to its forming temperature, which is below that of the plastic materials being used; at its melting point it is made to form a hollow tube called a parison or preform. This heated homogeneous plastic material is then placed between two female molds that are cooled through some medium. The two female molds close on the heated parison or preform and a gas, usually air, enters via an open end of the parison via a blow pin or needle; the gas is blown into the closed female mold halves, taking the shape of the internal female closed mold, allow to cool, and is then sent out through an exhaust. The two female molds are then separated and the cooled, shaped hollow part is then ejected or allowed to drop out for the cycle to repeat.

In the first attempt over 100 years ago, to blow-mold hollow objects, two sheets of cellulose nitrate were clamped between two female mold halves. Steam injected between the sheets softened the material, sealed the edges, and expanded the heated sheets to form the inside shape of the two female mold halves. The high flammability of cellulose nitrate, however, limited the usefulness of this technique.

In the early 1930s, more suitable materials, such as cellulose acetate and polystyrene (PS), were developed; these led to the introduction, by Plax Corp. and Owens-Illinois, of automated equipment based on glass-blowing techniques. Unfortunately, the high cost and poor performance of these materials discouraged rapid development; they offered no advantage over the glass bottles. Finally, the introduction of low density polyethylene (LDPE) in the mid-1940s provided the advantage of squeezability, which glass could not match.

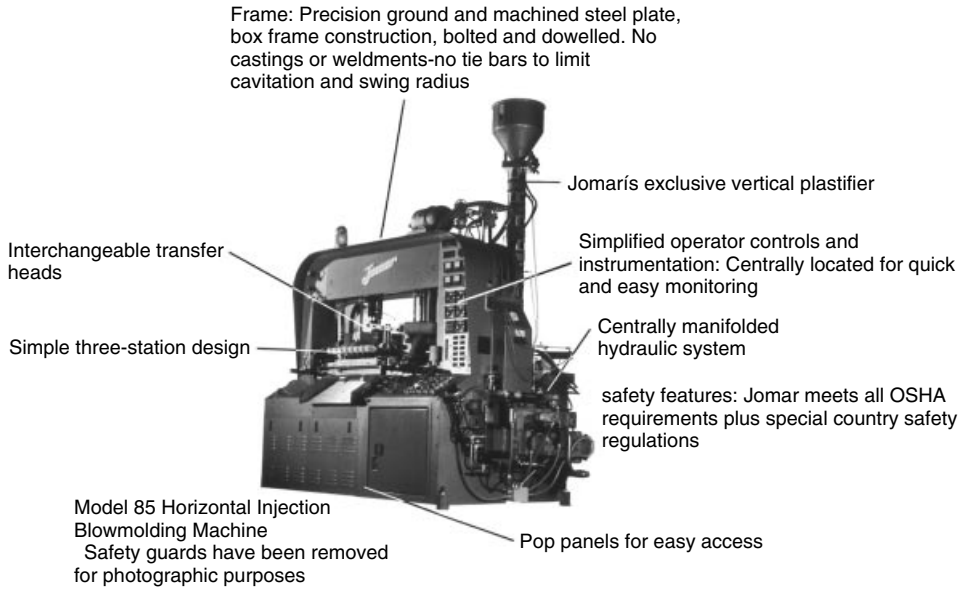

Fig. 1. Three-station injection blow-molding machine utilizing a vertical screw produced by Jomar, Pleasantville, N.J., U.S.A.

The first item to use LDPE was an underarm deodorant named Stoppette; the bottle was blow molded by the Plax Corp. In the first year, over 5 million units were sold and the blow-molding industry was born.

In the early 1950s, high density polyethylene (HDPE) was developed and today blow molding is the largest user of HDPE, which is the largest volume thermoplastic produced in the world, with over a billion pounds produced worldwide.

Blow molding, until the last few years, was the main plastic process utilized to produce a hollow object. In the past few years, other plastic processes, such as rotational molding and twin sheet thermoforming, have evolved with technical achievements and plastic raw materials improvements to where today, they can compete with blow molding for many uses as toys, gasoline tanks, holding tanks, etc.

The injection blow-molding (IBM) machines shown in Figures 1 and 2, even though produced by different injection blow-molding machinery manufacturers, can use tooling designed for either machine with slight mold design changes because of the bolt pattern or the platens used by each independent IBM machinery producer. There is no standard bolt pattern in the blow-molding industry for mounting the necessary tooling in the machines.

Resins

Most thermoplastic resins in use in the plastics industry can be blow-molded. Naturally, several resins are the leaders. HDPE is used in over 57% of the blow-molding market. In the year 2000, there was over 7021 million pounds of HDPE produced domestically. Poly(ethylene terephthalate) (PET) follows with over 33%

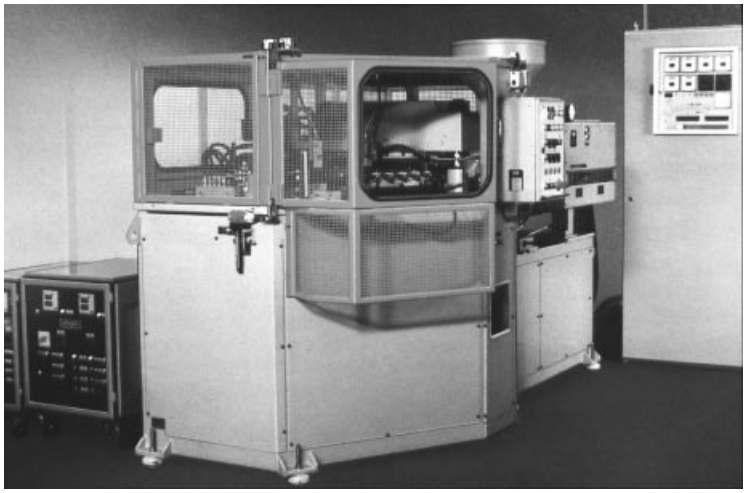

Fig. 2. Three-station injection blow-molding machine utilizing a horizontal reciprocating screw produced by Bekum, Berlin, Germany.

of the blow-molding market. In the year 2000, there was over 1720 million pounds of PET produced domestically.

Thus, these two plastic resins are used in slightly over 90% of the blow-molding industry. All the other thermoplastic resins such as polypropylene (PP), polystyrene (PS), poly(vinyl chloride) (PVC), acrylic–butadiene–styrene (ABS), acetal, polycarbonate (PC), low density polyethylene (LDPE), polysulfone, and others, all combine for the other uses in the approximate 10% blow-molded industry.

Examples would be gallon milk containers (HDPE), soft drinks (PET), gasoline tanks (HDPE), detergents, bleach, household chemicals (HDPE), automotive interiors (PP and ABS), mascara containers (ABS, PVC, HDPE), gas tanks for small yard mowers (nylon) to familiarize the reader with various markets. Naturally, the choice of resin used is based on performance, cost, barrier, availability, cleanliness, processing, transparency, and strength. The fastest growing markets at present are the automotive gasoline tanks, the 55-gallon drums (both HDPE) and the 20-oz soft drink products, the pint milk bottle (both PET). The beer market is just starting with specialty marketing.

Processes

There are three main processes used by the blow-molding industry to supply containers and hollow products to the blow-molding market: injection blow molding, extrusion blow molding, and stretch blow molding.

Generally, injection blow molding is used for small bottles and parts less than 500 mL in volume. The process is scrap-free, with extremely accurate control of weight and neck finish. However, part proportions are limited and the method is impractical for containers with handles and tooling costs are relatively high.

Extrusion blow molding, the most common process, is used for bottles or parts 250 mL in volume or larger. Tanks as large as 1040 L (275 gal) weighing

Table 1. Injection Blow Versus Extrusion Blow

Injection blow	Extrusion blow
Injection molded neck finish	Blown neck finish or calibrated neck finish
Scrap free	Must trim off tail and moilles
No pinch mark	Pinch mark which can be an area of the container for failure
Fast cycles for high output	Slower cycle
Tool cost relatively expensive	Tool cost relative low with use of aluminum molds
No handle ware	Handle ware of many sizes and shapes
Excellent surface finish or texture	Good surface area or texture
No die lines	Possible die lines due to extrusion of parison
Ease of automation for decorating and packing	Automation may be cumbersome and use large floor space
Small floor space	Greater floor space utilized

120 kg (265 lb) have been blow-molded; tooling is less expensive, and part proportions are not severely limited. Containers with handles and off-set necks are easily fabricated. On the other hand, flash or scrap resin must be trimmed from each part and recycled. Operator skill is more crucial to the control of part weight and quality. The two processes are compared in Table 1.

Stretch blow molding is used for bottles between 237 L (8 oz) and 2 L (67.6 oz) in size, and occasionally as large as 25 L (6.6 gal). The molecular biaxial orientation of certain resins enhances stiffness, impact, and barrier performance, and permits weight reduction.

Injection Blow Molding

In injection blow molding, melted plastic resin is injected into a parison cavity and around a core rod. This test-tube-shaped parison, while still hot, is transferred on the core rod to the bottle blow-mold cavity. Air is then passed through the core rod, expanding the parison against the cavity, which, in turn, cools the part.

Early injection blow-molding two-position techniques used adaptations of standard injection-molding equipment fitted with special tooling. The Piotrowski method used a 180° rotating arbor with two sets of core rods and one set of parison and bottle cavities. The Farkas, Moslo, and Gussoni methods used an alternating shuttle with two sets of core rods, one set of parison cavities, and two sets of bottle cavities. The difficulty with these methods was that the injection-mold and blow-mold stations stood idle while the finished parts were removed. In 1961 in Italy, Gussoni developed the three-position method, which used a horizontal 120° indexing head with split-mold parison and bottle cavities and three sets of core rods. The third station was intended for removal of the part, and the parison- and bottle-molding phases were completed simultaneously. A special machine was required, and by the late 1960s, this technique was perfected; it is the principal system used today. A layout of the standard three-station machine is seen in Figure 3.

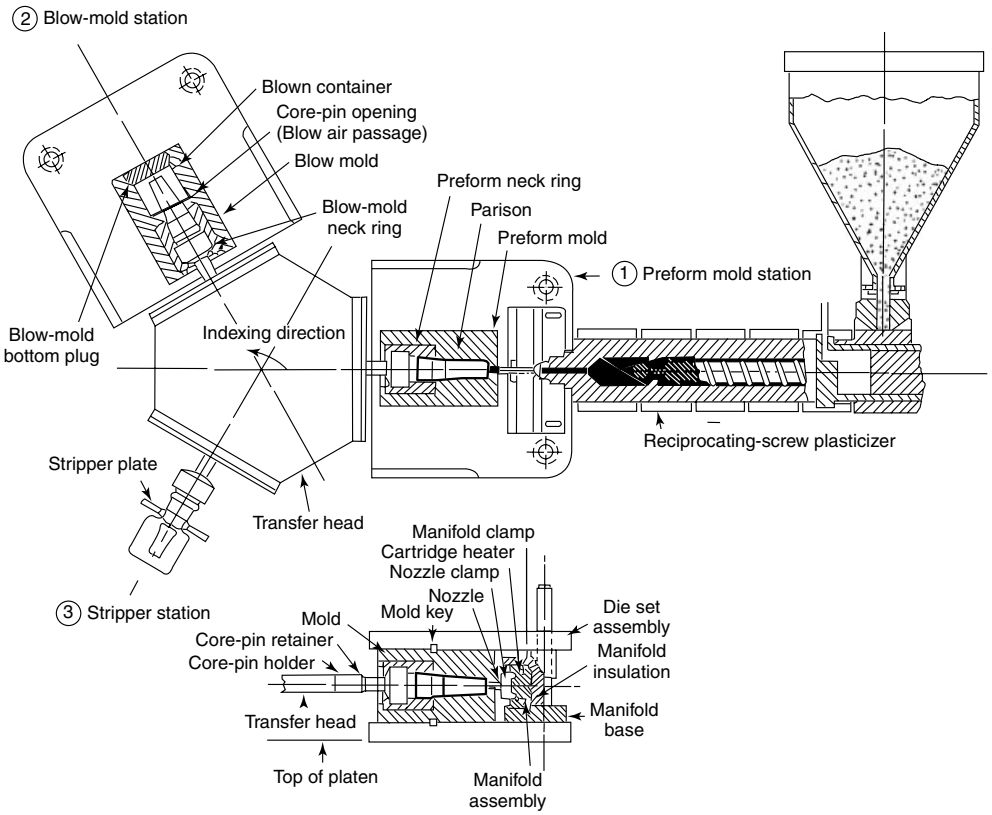

Fig. 3. A typical three-station injection blow-molding machine. Courtesy of Rainville Operation, Hoover Universal, Inc.

The three-position injection blow molding machine was upgraded to have four stations through companies as Larson Mardon Wheaton, Bekum, and Uniloy Milacron. The addition of the fourth station allowed for faster cycle times since the rotating table containing the core rods only indexed 90° instead of 120° as on the third station. The addition of fourth station was placed after the eject station and prior to the injection station. This additional station also could be used as a safety station to ensure the core rods were free of any debris. This station could also be used for in-mold decoration and also for conditioning the core rods prior to moving to the inject station to have a parison injection molding onto each core rod. The four-station machine is depicted in Figure 4.

One of the main features one should always be cognizant of is the dry cycle time of the machine. The *dry cycle time* is the time that it takes to open the clamp, raise the rotating table, index to the next station, drop the rotating table into position, and close the clamp or mold halves. There is no processing during the dry cycle. Processing time will add to the dry cycle time. Normally, on a three-station machine, the dry cycle time will vary from 2.8 to 3.5 s. On a four-station machine the dry cycle may range from 1.8 to 2.6. s. Larson Mardon Wheaton has taken this a step farther by designing and building their own all-electric machine. Their new all-electric four-station machine can dry cycle from 1.1 to 1.8 s depending

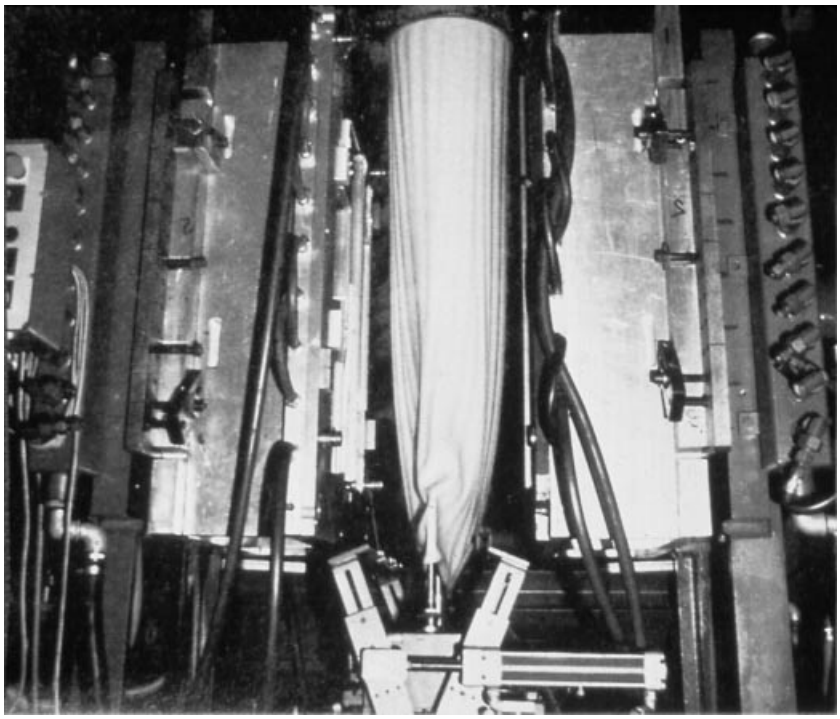

Fig. 4. Four-station layout.

on the size of the machine, whether it be a 15 or 180 ton. The tonnage relates to the clamp tonnage at the inject station plus the addition of the blow-mold clamp station. The injection station utilizes the greater tonnage. For example, a Larson Mardon Wheaton four-station may have 150 ton at the inject station and 30 ton at the blow-mold station. Together, the machine is rated at 180 ton. The Uniloy Rainville (85-3) three-station machine has 68-ton clamp at the injection station and 17-ton clamp at the blow-mold station, which added together to be the 85-ton machine. Figure 5 is a typical time or cycle sequence for an injection blow-molding machine.

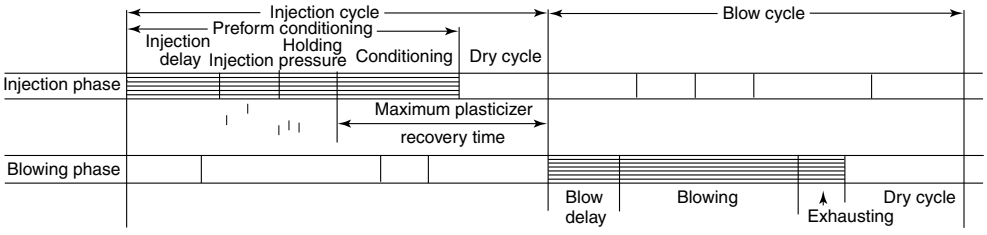

Fig. 5. Time sequence of injection blow molding. Courtesy of Rainville Operation, Hoover Universal, Inc.

Injection blow-molding machines are manufactured by Uniloy Milacron, JOMAR, Nissei, and Bekum for sale in the blow-molding industry. Several companies produce and use their own as Larson Mardon Wheaton and Captive Plastics and are not offered for sale. Injection blow-molding is normally considered when the container to be produced is 8 ounce (0.24 L) or under. The advantages and disadvantages of injection blow molding when compared to extrusion blow molding are listed in Table 1.

Injection Blow-Mold Tooling

Injection blow-molding requires two molds: one for molding the preform or parison, and the other for molding the bottle. The preform mold consists of the preform cavity, injection nozzle, neck-ring insert, and core-rod assembly. The blow mold consists of the bottle cavity, neck-ring insert, and bottom-plug insert (see Figs. 6–10).

The preform cavity design is governed by four basic rules or constraints. The first rule concerns the core-rod or cavity length-to-diameter ratio, which ideally approximates 10:1 or less. This ratio is frequently based on the overall height and the neck-finish diameter of the bottle. It ensures a minimum of core-rod deflection from injection pressures, which, in turn, provides uniform wall distribution and heat. Higher ratios have been used, but often require sliding pins to momentarily center the end of the core rod during the injection phase.

The second rule concerns the ratio of preform size to maximum bottle size, ie, blow-up ratio, which ideally is 3:1 or less. Most often, it is based on the maximum bottle diameter, width, or depth, and the neck-finish diameter. Maintaining this ratio provides uniform and consistent bottle cross-sectional wall distribution. If

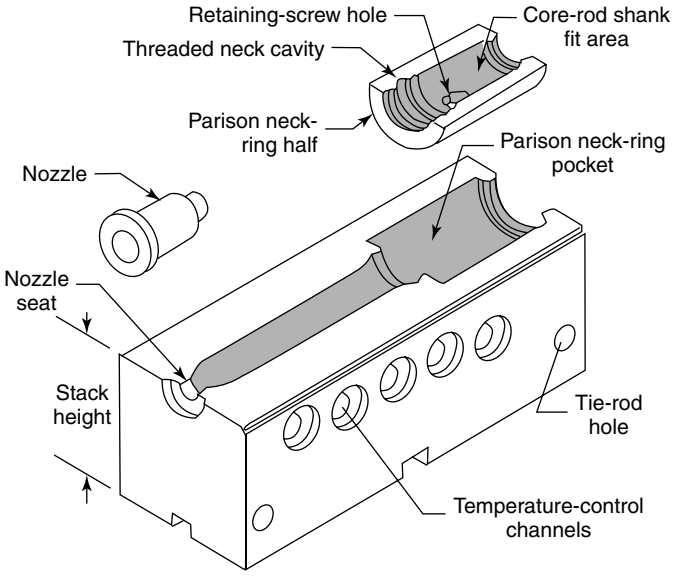

Fig. 7. Exploded view of one-half of a parison-mold cavity, with nozzle and neck-ring details.

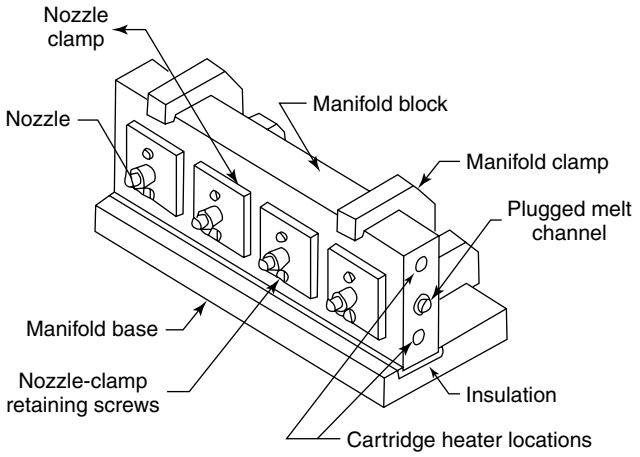

Fig. 8. Injection manifold for injection molding of parisons. Individual nozzles are clamped to the manifold block, which houses a hot runner for the melt.

the ratio is higher, the parison tends to float around during expansion, which therefore increases the chances of an eccentric wall distribution.

The third rule concerns the parison wall thickness, ideally between 2 and 5 mm. A wall thicker than 6 mm is difficult to temperature-condition and may act unpredictably during expansion. A wall less than 2-mm thick may also act unpredictably. For a given weight, a thin wall also increases the projected area, and thus possibly exceeds the capacity of the press.

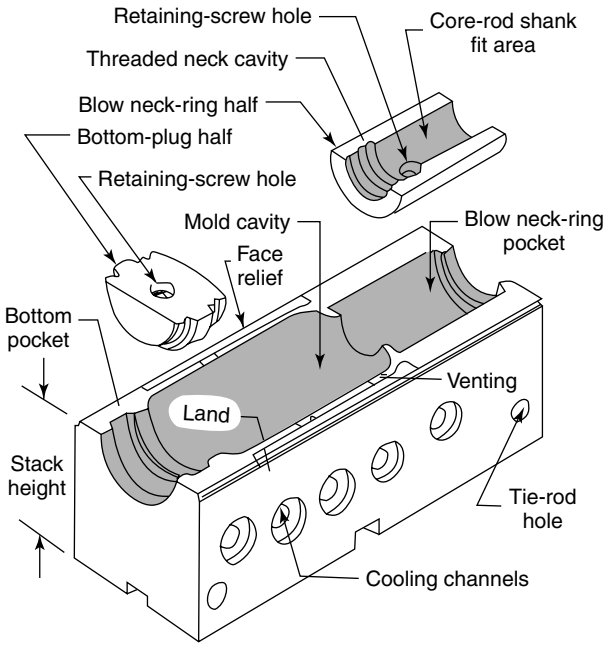

Fig. 9. Exploded view of one-half of an injection blow mold, with details of bottom plug and neck ring.

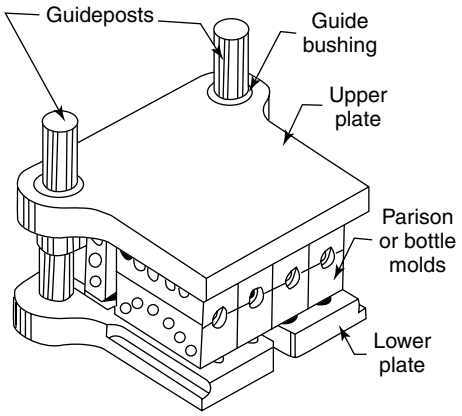

Fig. 10. Die set for manufacturing position and alignment of injection blow-mold cavities.

An important advantage of injection blow molding is the diametrical and longitudinal programming of the parison by shaping the parison mold cavity or core rod, or both. This is particularly important with oval bottles and leads to the fourth rule: in an annular cross-section, the heaviest area should not be more than 30% thicker than the lightest area. Generally, the shaping is done in the cavity and the core rod is round. With a higher ratio, the selective fill of material during the injection phase causes a vertical weld line in the bottle. Avoiding this

condition, in turn, restricts the bottle ovality to 2:1, that is, the width should not exceed two times the depth.

In multiple-cavity arrangements, each parison cavity is fitted with an injection nozzle of decreasing sizes. Material flow through the injection manifold is balanced, thus allowing each cavity to be filled at an equal rate.

The neck-ring insert has four functions: (*1*) it forms the finish or threaded neck section of the bottle; (*2*) because it is an insert, it provides a relatively low cost, easy method to change the size or style of the finish; (*3*) it firmly centers and locates the core rod in the parison cavity; and (*4*) it provides venting and a thermal break.

During the process, the neck-finish area of the parison must be cooled to retain its shape; the remainder of the parison is kept hot for later expansion in the bottle cavity. Depending on the plastic molding material, the temperature of the parison is between 65 and 135°C. The neck-ring insert is at times cooled as low as 5°C. The water lines for both the cavity and the neck-ring are usually drilled as closely together as possible, perpendicular to the cavity axis. The water flows from one cavity to the next.

The core-rod assembly also have four functions: (*1*) it forms the interior of the preform; (*2*) it supports the parison or the bottle during transfer; (*3*) it supplies the valve where air enters to expand the parison (the valve is located in the shoulder area or the tip, depending on the shape of the bottle or the ratio of the core-rod length to diameter; wide-mouth bottles, ie, core rods with low length-to-diameter ratios, are usually equipped with a shoulder valve); and (*4*) it has a "blow by" groove. This annular groove, located near the seating shank, 0.1–0.25 mm deep, is needed to seal the parison to prevent excessive air loss during blowing and to eliminate elastic retraction of the parison during the transfer between cavities.

Various materials are used to construct the parison cavity and core rods. For nonrigid polyolefin resins, the parison cavity is made of prehardened P-20 tool steel with a hardness of 31–35 HRC. For rigid resins, the parison cavity is made of A-2 tool steel, air hardened to 52–54 HRC. The neck-ring insert for most resins is made of A-2 tool steel. The core rod, for greater strength, is made of L-6 tool steel, hardened to 52–54 HRC. In all cases, the cavity surfaces are highly polished and chromium-plated, except for the neck-ring insert for polyolefin resins, which is occasionally sandblasted with a No. 120 grit.

The cavity defines the final shape of the bottle. The only design constraint is that the cavity width should not exceed two times the depth. To compensate for resin shrinkage after molding, the cavity dimensions are slightly enlarged. Specific shrinkage rates vary with the resin type and process conditions. For nonrigid polyolefin resins, shrinkage is between 1.6 and 2.0%; for rigid resins, 0.5% shrinkage is added. Slightly higher rates are usually applied to the heavier neck-finish dimension than to the body.

Vents are placed along the mold-parting surface to allow the escape of trapped air between the expanding parison and the cavity. If these are too deep, an objectionable mark is left on the bottle. Because an air pressure of 1 MPa (145 psi) is used in injection blow molding, these vents are kept less than 0.05-mm deep.

The neck-ring insert is used in the bottle cavity in a manner similar to its use in the parison cavity, although they are not identical. The thread diameter dimensions in the bottle cavity are 0.05–0.25 mm larger than in the parison cavity.

Unlike the parison neck-ring, the bottle neck-ring does not form the finish detail, but only secures the already-formed neck. The additional size provides clearance, reducing the change of distortion.

The bottom-plug insert forms the bottom or push-up area of the container; in some molds, this insert must be retractable. Generally, the push-up of polyolefin bottles can be stripped without side action if the height is less than 5 mm. With rigid resins, this height is reduced to 0.8 mm. When side action is required, an air cylinder, cam, or spring mechanism is used.

Aluminum, steel, or beryllium–copper is used for the bottle cavity and neck ring. For polyolefin resins, aluminum No. 7075, as well as QC-7, is used. The surface is usually finished with No. 120-grit sandblast, which increases the venting of trapped air. For rigid resins, A-2 tool steel air-hardened to 52–54 HRC is used. The surface finish is highly polished with chromium plating. Cast beryllium-copper is often used for minute detail. As with the parison cavity, water lines are drilled as closely together as possible, perpendicular to the cavity axis.

The parison and bottle molds are mounted onto a die set, which is then mounted to the platens of the injection blow molder. Keyways in two directions, on the upper and lower platens, are used to precisely position the cavities. Guideposts and bushings maintain precise alignment between the plates. To speed the operation, the entire die set or mold assembly is exchanged during a job change. It is considered false economy to reuse the die set with another mold set.

Injection blow-mold tooling must be designed for very precise tolerances, with dimensions often held to ± 0.015 mm, otherwise bottle quality will be inconsistent. For example, the core rods must be located closely fore and aft, and left and right of centerline of the parison and bottle cavities. If too tight, the mold could be damaged or the assembly might bind. If too loose, resin could flash around the shank area of the core rod, or the core rod could shift sideways, causing uneven wall distribution. In addition, many parts and sections of the mold setup must fit together and be interchangeable. Several core rods must fit the pocket of the parison or bottle cavities. These core rods are stacked alongside each other on a face bar. Clearly, the need for precision is the most crucial factor in the high cost of injection blow-mold tooling. However, once properly assembled, the injection blow-mold process can provide high yield and trouble-free production. Additional tooling for setup of the injection blow-molding machine would include the stripper plate (see Figs. 11 and 12) for stripping the formed containers from the core rods. The stripper consists of a stripper base and a stripper plate plus the screws and washers. On most machines the stripper is able to rotate 90° downward to

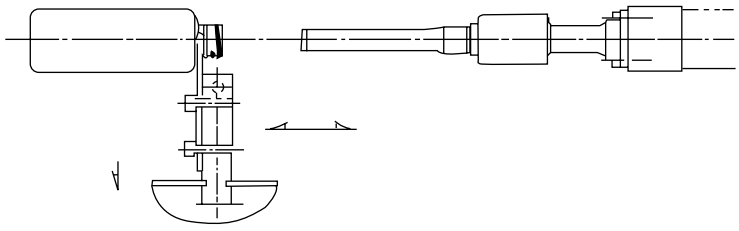

Fig. 11. Stripper action.

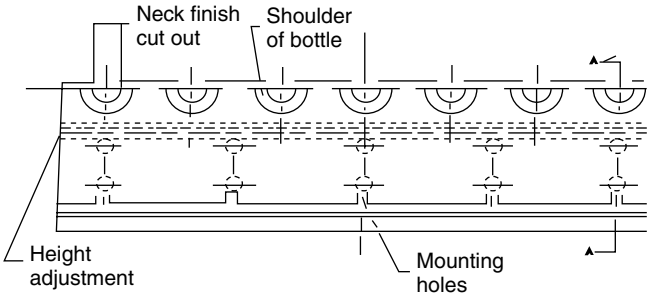

Fig. 12. Stripper plate.

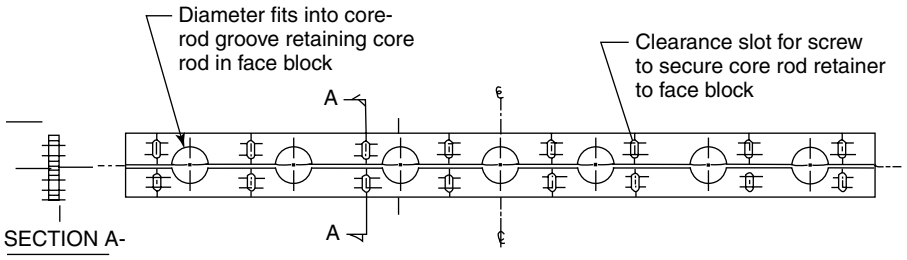

Fig. 13. Face bar.

deposit the product onto a conveyor, etc. We refer to this stripper as a stripper/tipper.

Figure 11 shows the blown bottle being ejected with the stripper moving out, and once the bottle is dropped into a container or on a conveyor belt, the stripper returns for the next cycle. Figure 13 shows a face bar which mounts to the rotating table (three-station machine requires three face bars and a four-station machine requires four face bars) to hold the core rods.

Figure 14 shows the retainers that fit over the rear shank of the core rod and hold the core rod in place on the face bar. In some instances, possibly because of core rod damage it may be necessary to use a face block plug. However, the manifold also has to be plugged for this same cavity.

By reviewing all the tooling essential for injection blow-molding, one can easily understand why it is more expensive than the extrusion blow-molding process. However, the injection blow-molding process yields a process that produces scrap-free, high volume containers that have the best neck finish dimensions and details in the blow-molding industry. Roll-on-deodorant containers are evidence of this statement.

Troubleshooting Injection Blow Molding. Injection blow-molding is no different than any other plastic process as to troubleshooting the process. One should first analyze as to what you feel is the problem and then approach the problem systematically. In approaching the problem, you should only make one change at a time and after the change, provide adequate time for the change you made to show its effect.

Below is a list of items or problems that are some-what common in the injection blow-molding process with possible solutions to the happening. The list is a

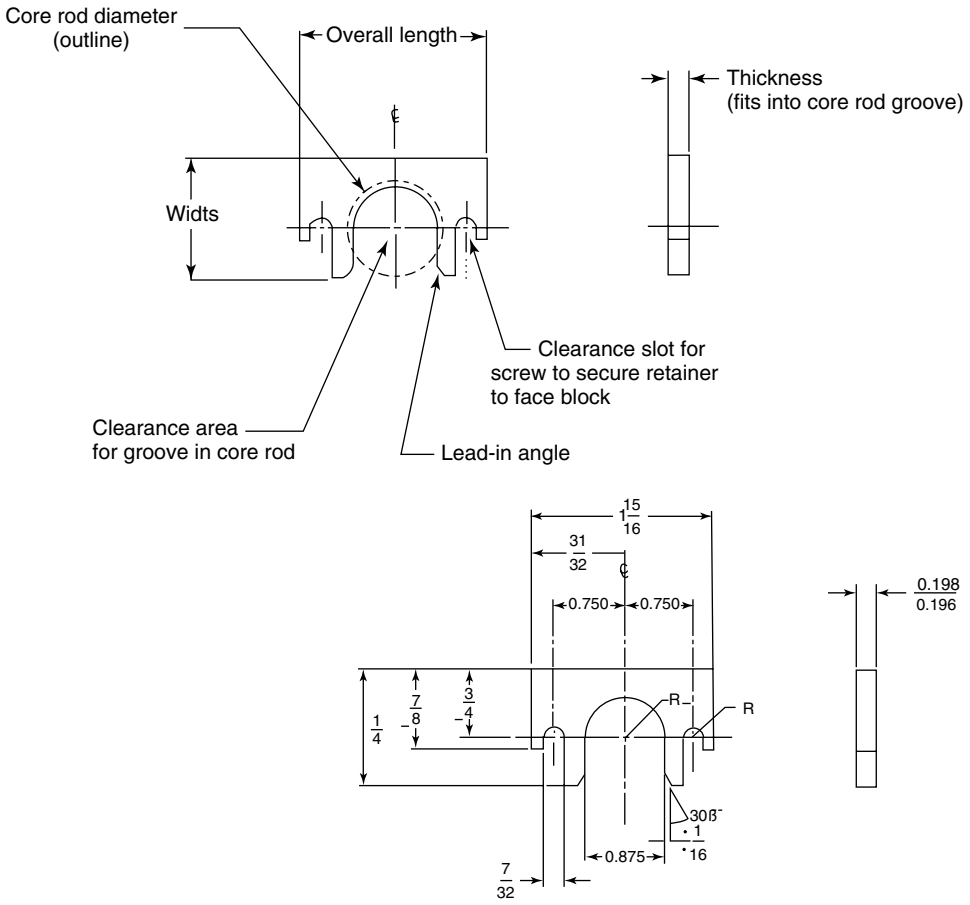

Fig. 14. Core-rod retainer.

guide and is not inclusive as machines and materials change along with controls. Always keep in mind, your injection-molding parisons and if you make a good parison, you should make a quality container.

Problem	Solution
Short shots	Out of material in the barrel
	Hopper out of material
	Material is budging
	Material slide not open
	Material too cold
	Secondary gates dirty or not large enough
	Inadequate venting
	Shot size not adequate
Sink marks in parison	Material not homogeneous
	Not adequate packing time or pressure
	Inadequate venting

Problem	Solution
Streaks in parison	Mold dirty
	Regrind or material fines
	Cavity damaged
	Melt not homogeneous
	Injection pressure too high or too fast
Stringing of gate of parison	Melt temperature is too high in secondary nozzle or manifold
	Secondary gate too large
Parison stuck to core rod	Melt temperature too hot
	Parison mold coolant not adequate or at proper temperature
	Core rod cooling not adequate
Parison tip too large to compress	Reduce land in secondary gate
	Move secondary nozzle in toward the parison
	Reduce land in end cap on spherical nozzles
Product torn	Lower gate temperature
	Check core rods
	Check nozzle seats
	Check parting line of parison and blow mold
	Add injection time
	Replace nozzle
Weak spot in center of product	Lower gate temperature
	Check parison body temperature
	Lower parison body temperature
	Add more injection time and pack time
	Lower injection pressure
	Decrease back pressure
Heavy section in product	Raise gate temperature
	Decrease core rod cooling
	Raise temperature in parison body
Push up not consistent	Increase blow time
	Increase blow pressure
	Increase bottom plug cooling
	Reduce gate temperature
	Add core rod tip cooling
	Lengthen cycle time
	Check vents
Rocker bottoms	Flash
	Vent
	Improper cooling
	Mold dirty
	Increase cycle time
	Check exhaust-possibly add exhaust time
	Check core rod openings
Bottom folds	Increase blow pressure
	Check core rod openings
	Reduce injection pressure
	Increase temperature in parison mold at fold location

Problem	Solution
Surface finish	Dirty molds
	Venting
	Material not homogeneous
	Temperature of parison too cold
	Increase blow pressure
	Increase cycle time
Dips in finish	Parison not packed
	Vents
	Neck rings too cold
	Increase pack time
Cracked necks	Raise melt temperature
	Increase parison neck ring temperature
	Retainer grooves on core rod too deep
Cocked necks	Increase blow pressure
	Increase blow time
	Check bottom plug movement
	Increase cooling on blow mold products body
Shrinkage	Increase blow time
	Decrease blow mold temperature
	Increase pack pressure
	Increase pack time
	Lower parison mold temperature
Flash	Melt too hot
	Injection pressure too high
	Molds not flat
	Vents too deep
	Clamp not adequate
	Platens not aligned
	Mold damaged
Parison sag (parison parting line and blow mold parting line do not overlap)	Decrease melt temperature
	Redo parison cooling lines for more balance
	Venting
	Add packing pressure
	Melt not homogeneous
	Check for nozzle uniform flow
Nozzle freeze-off	Contamination
	Damaged nozzle
	Temperature too low
	Manifold dirty
	Thermocouple malfunctioning
Stripping	Decrease blow time
	Retainer grooves too deep
	Increase pressure to stripper
	Lubricate stripper
	Check core rods for damage
Weld lines	Raise manifold temperature
	Raise parison mold temperature
	Raise injection pressure

Problem	Solution
Parting line	Increase pack time Increase secondary nozzle opening Molds damaged Molds not aligned Molds not flat Clamp pressure inadequate

Setup for Injection Blow Tooling. When doing a setup, whether it be for injection molding, blow molding, or extrusion, one should always strive to do the setup so that there are areas that can be used if needed in the process. Short cuts should not be taken in doing your setup.

In setting up the injection parison mold, a separate cooling line should be used for the neck rings, the parison end cap, and the zone immediately above the end cap. The temperature of the parison that is going to be blown needs to be controlled as uniformly as possible. If core-rod cooling is utilized, then a separate cooling unit should be utilized for the core rods.

In the blow mold, a separate cooling line should be used on the neck rings, the bottom plug, and the containers body.

It is recommended that all secondary nozzles from the manifold to the parison injection mold have a smooth bore so no material can be stagnant or hung up, nor be sheared. Each secondary nozzle should have its own heater band and thermocouple control. The manifold should have two deep well thermocouples that are averaged together to ensure that the manifold maintains an even melt temperature.

It is a good idea to have all the die sets nickel-coated plus the water lines. This will prevent rust within the die sets, which leads to pitting of the machine platen. This also prevents rust and mineral deposits from forming in the mold water lines.

The future of injection blow-molding will see a 3–5% growth. The machines will be redesigned to be all-electric based on the all-electric injection machines. The shortage of electrical power and its rising costs will force machine producers plus their customers to reduce energy use and costs. It is well documented that the all-electric injection machines reduce energy use by 30–35%, thus injection blow will follow the injection-molding machine lead into this industry.

Extrusion Blow-Molding

In extrusion blow molding, homogeneous melted thermoplastic resin is extruded as a tube into the air. This tube, called a parison, is captured between two mold halves that are of the female type. Gas usually air, enters as the female molds are closed, either through a blow pin or needle, and expands the homogeneous melted thermoplastic into the female mold halves, taking design of whatever is cut into the two female mold halves, alllowed to cool, then the gas is exhausted, the molds

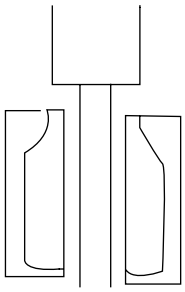

Fig. 15. Extrusion blow-molding process.

open, and exits the cooled desired product. Unlike injection blow molding, this process produces flash or trim off, that has to be trimmed and reclaimed. This excess is formed when the heated parison is pinched together at the bottom and top of this heated hollow tube. In some cases, there can be flash or trim on the entire periphera of the product to be formed (ie, automotive gasoline tanks) (See Fig. 15).

There are basically two different machines offered in the extrusion blow-molding industry. They are intermittent and continuous.

In continuous extrusion blow molding, the extruder or plastifier is running continuously and forming a parison continuously. The continuous extrusion provides the most homogeneous heated parison as the heated thermoplastic material is moving constantly with the least amount of residence time on the heated thermoplastic material. This method is employed to produce containers as on Bekum & Kautex; shuttle blow-molding machines such and on large industrial machines

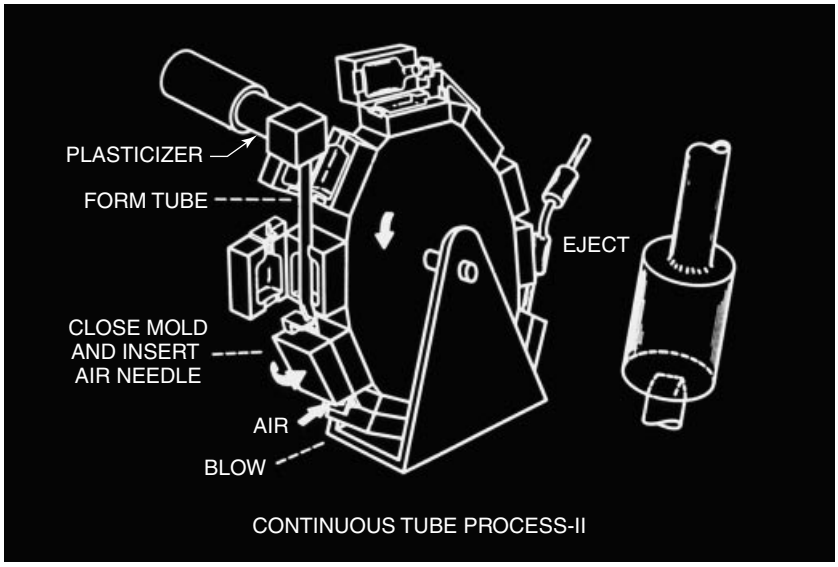

Fig. 16. Schematic of a rotary or wheel machine with continuous extrusion of the parison. Number of blow molds depends on size of wheel diameter and extruder size for output.

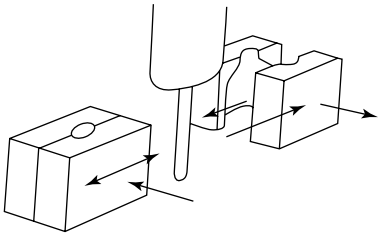

Fig. 17. Depicts a continuous extruded parison with blow molds that shuttle right or left, cut the parison, capture the cut parison in the closed blow mold and move right or left to blow the container.

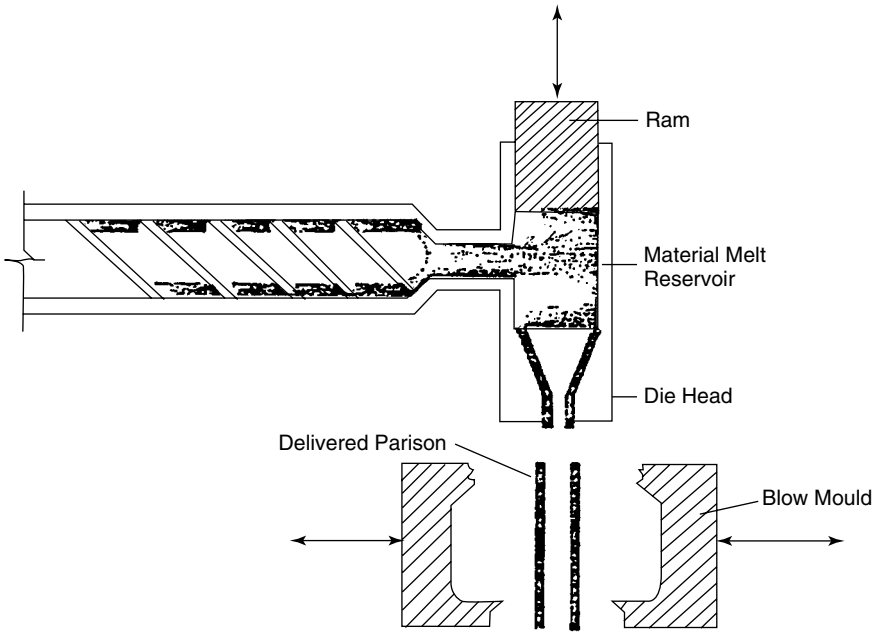

Fig. 18. Intermittent extrusion blow molding.

such as wheels produced by Uniloy Milacron, Plastipak, Graham & Owens Brockway. It is also used by Bekum, Kautex, Wilmington, Uniloy Milacron, Graham, Davis Standard, and Jackson Machinery to produce containers such as automotive gasoline tanks, holding tanks, 55-gal drums (see Figs. 16 and 17).

A reciprocating screw extrusion blow-molding machine sketch is shown in Figure 18. This is the process where the parison is extruded, then the blow molds cut the parisons and close, and the containers are then blown. Only after the blow molds open and the blown containers exit the machine is the parison once again extruded (see Fig. 18).

In intermittent extrusion blow molding, the parison is formed immediately after the blow-molded product is removed from the blow mold in most machines. In some large machines, the parison is cut and closed within the blow mold and then

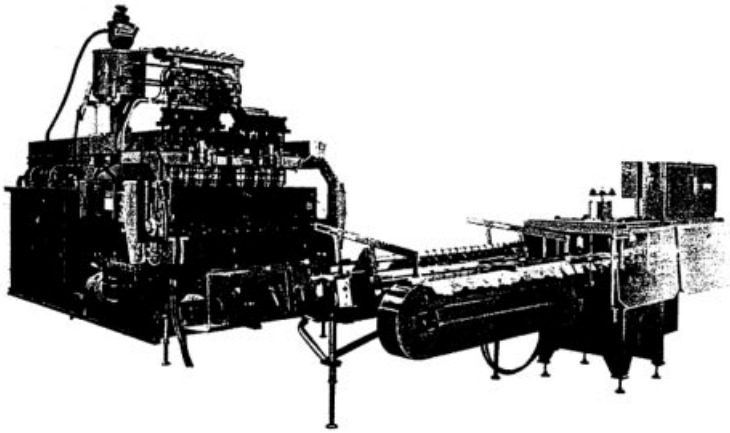

Fig. 19. Uniloy 350R2 8-head intermittent extrusion blow molder for the manufacture of 2-L (0.5-gal) milk bottles with handles. Production rates of over 65 bottles/min have been achieved; also shown is the flash trimmer. Courtesy of Hoover Universal, Inc..

the blow mold moves out from under the parison head tooling to allow another parison to be formed. Because of the stop and start of the parison, this method is normally not employed to use heat-sensitive materials, such as PVC. It is more suitable for heat-stable materials, such as HDPE, and ABS. Examples are gallon milk containers, automotive ducts, 5-gal water containers (polycarbonate).

The intermittent process utilizes a reciprocating-screw plastifier. After the parison is formed, the screw moves back (or recovers) accumulating new homogeneous melt in front of its tip. Once the blow mold exits the product, the signal is given for the plastifier to form a new parison. The screw will then move forward as a ram forcing the plastic melt through the extrusion head forming the next parison. At present, up to 12 parisons can be formed simultaneously. A reciprocating screw extrusion blow molder for a dairy bottle is shown in Figure 19.

Another modification is the ram-accumulator method, although no longer in widespread use. It is intended for parts weighing 2 kg or more. This system, much like the reciprocating-screw method, is used to extrude quickly heavy parisons that might sag or be deformed by their own weight. The accumulator is a reservoir mounted alongside the extruder. A piston or plunger pushes the melt through the extrusion head. In this method, unlike the reciprocating-screw process, melt that enters the reservoir first is last to leave. As a result, melt history of the resin is not uniform.

The accumulator head (see Fig. 20) has replaced the ram accumulator in its application for heavy parts. The tubular reservoir is a part of the extrusion head itself. Plastic melt that enters the head first is first to leave. A tubular plunger quickly extrudes the melt from the head annulus with a low, uniform pressure, which helps reduce the stresses found in other systems.

Related to extrusion blow molding is the extrusion-molded neck process (see Fig. 21). Still used by Owens-Illinois, this proprietary process can be traced to glass-blowing technology. In an unusual approach, the neck of the bottle is injection-molded and the bottle body is extrusion blow-molded. The two halves of

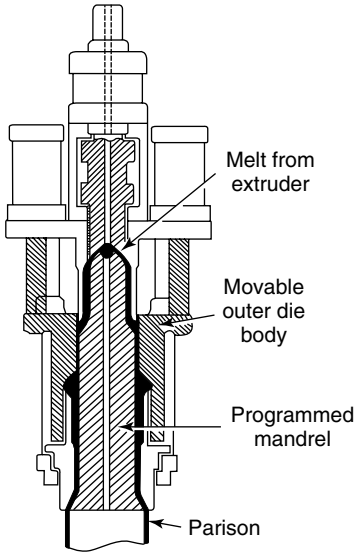

Fig. 20. Typical accumulator head.

the neck-finish cavity or neck ring are mounted to an actuating-head assembly, which intermeshes with the two halves of the blow-mold cavity. The process cycle begins with the main-body mold cavity open and the neck-ring cavity closed. The actuating-head assembly moves downward to contact the extrusion die head. When in position, extrusion pressure fills the neck section with plastic melt. After holding for 1–2 s, the head assembly moves upward while the parison is extruded. When the head assembly reaches the top of its stroke, the blow-mold cavity closes on the parison. The remaining steps of flash pinch-off, blowing, and part removal follow conventional techniques. Although the production cycle is somewhat slow, the process offers the advantages of an accurately molded neck and of a parison held at both ends. The other advantage is that only tail scrap is to be reground whereas in standard extrusion, both neck and tail scrap are to be reground.

Preference for a specific type and manufacturer of a blow-molding machine is based on experience, exposure to specific extrusion blow-molding methods, and different manufacturer equipment.

There are many blow-molding machine manufacturers, and choice should be based on the following criteria: cost, energy usage, floor space, reliability, output, service, manufacturer's reputation, controls–user friendly, cleanliness, world class design, height, maintenance, options available, dry cycle time, mold open and mold close time, and CFM usable per cycle with gauge and reservoir.

On any extrusion blow-molding machine, the buyer or user should know or test to have answers to the following:

(1) pound per hour output – actual
(2) plastifier – $\frac{L}{D}$ barrel

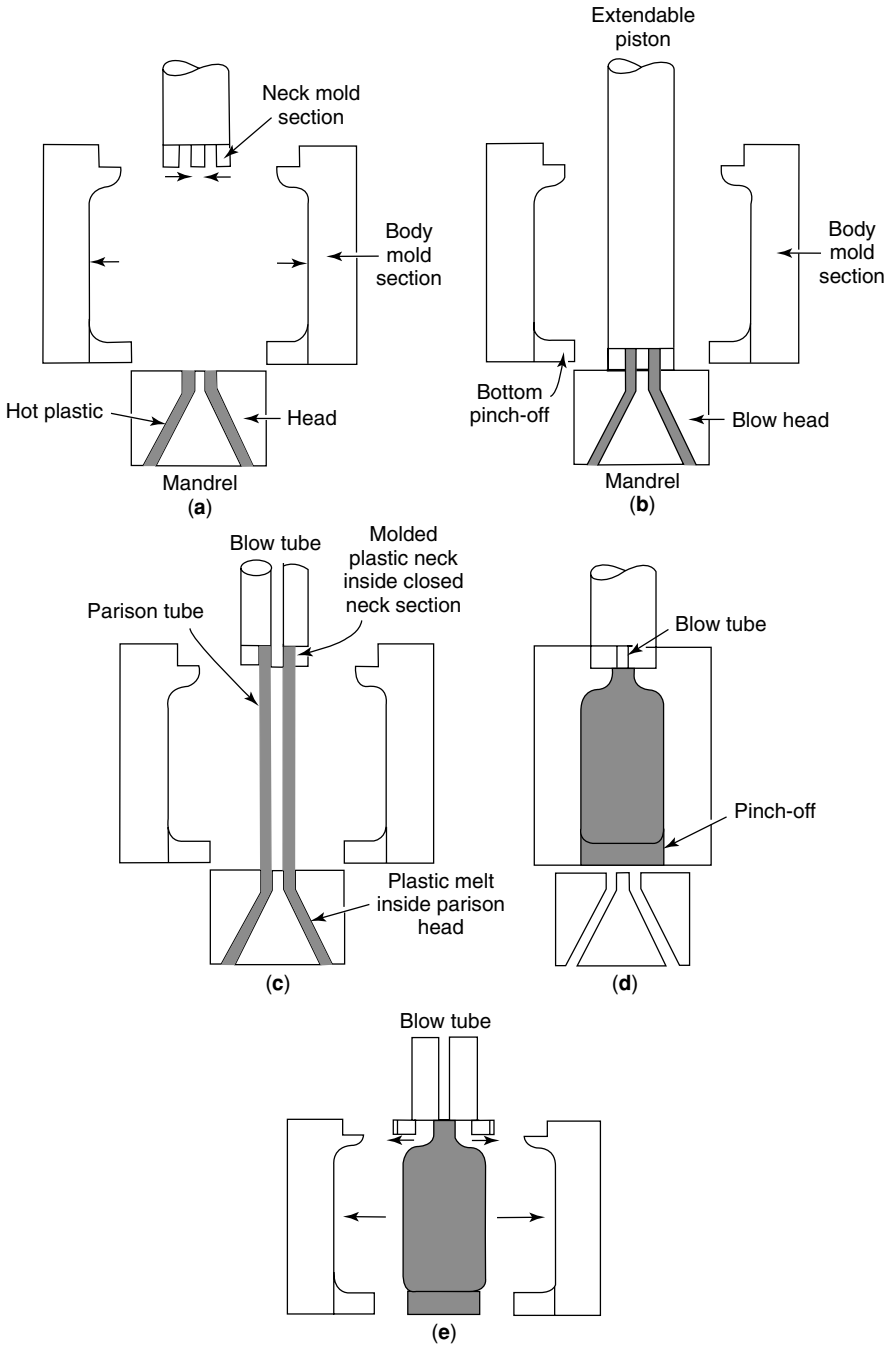

Fig. 21. Extrusion-molded neck blow-molding process. (a) Body section open, neck section closed, neck section retracted; (b) neck section extended to mate with parison nozzle (plastic fills neck section); (c) neck section retracted with parison tube attached; (d) body section closed, making pinch-off (parison blown to body sidewalls); (e) body molds open, neck molds open, bottle about to be ejected.

(3) compression ratio of the screw
(4) what type of screw—general-purpose, barrier screw or specific to one type resin
(5) barrel heating or cooling
(6) number of zones for heating the barrel
(7) location of the thermocouples
(8) Is there an extrudate temperature readout? Where is it located?
(9) Does it have a grooved feed throat on the barrel?
(10) Are the heater bands rotated so there is not an area on the barrel or head tooling that could have a cold area due to all the heater band endings aligned?
(11) Is accumulator type first in, first out or first in, last out.
(12) Is the tooling converging or diverging
(13) Is the head tooling center-fed or side-fed?
(14) How many points can be programmed rising the parison programmer?
(15) Can the blow molds be mounted safely and quickly?
(16) Can the clamp tonnage be adjusted for large or small blow molds?
(17) How is the parison cut?
(18) Is coextrusion possible?

In any extrusion blow-molding process, there is off-fall or trim that has to be reclaimed. How a production plant handles their off-fall or trim can make a difference as to profit or loss. Use of regrind, as well as the use of color additives and lubricants, will have a major effect on parisons repeatability.

The screw of the plastifier is designed to pick-up pellets (virgin pellets), not chopped and screened chop of the resin. In grinding, a uniform ground chop is not achieved. You and up with strings, fines, and various chopped sizes of plastic. Thus, the feed hopper of the machine is being fed a different bulk density because of the grinding, the virgin, and the colorant additive, all being of different sizes. The plastifier is nothing more than a pump and with a different bulk density being fed to the screw, the plastic melt has a differential of pressures within its melt stream causing short and long parisons, excessive sag, black specks, streaks, gels, and different die smells, and the result is poor efficiency.

Fines are in the virgin resin as received. Fines are generated when any plastic is ground in a grinder. Fines do not melt at the same melting temperature as the virgin resin nor the regrind. Their molecular weight is different. Fines should always be eliminated. They can clog the dryers, cause streaks, black specks, star bursts, and tear drops in the parison and in the blown product. A separating type grinder should be used in the regrind area. It is also good practice to pass your virgin plastic material through a fine eliminator system as it is being fed to the machine hopper.

Any blender should be checked for accuracy of delivery. Weigh blenders are preferred in today's blow-molding plants.

Formulas. In extrusion blow-molding, there are some definite formulas you should be aware of and use.

The blow up ratio (BUR) is defined as the blow mold diameter (product) divided by the parison outer diameter.

$$\text{BUR} = \frac{\text{Inside largest diameter inside blow mold}}{\text{parison outer diameter}}$$

Generally, this value is between 1.5 and 3; however, it can be up to 7 in unusual cases.

The amount of stretching a parison is subjected to is a function of the part size and configuration in relation to the parison size and orientation. In general, this can be expressed as follows:

$$\text{Average part thickness} = \frac{\text{parison surface area} \times \text{parison thickness}}{\text{product surface area}}$$

High blow pressure, greater than 60 psi, is necessary to achieve a good surface finish on the product, to pick up the mold detail, and to ensure the material is against the blow-mold surface to be cooled. Low blow pressure will increase the shrinkage of the product and will increase the cycle time since the mold cooling is not being utilized effectively. With some resins, such as polypropylene, a pressure of 100 psi has been found to be very satisfactory. However, the new procedure is to use low pressure of 80–120 psi and once the product is formed, then use high pressure of air (220–250 psi). Lower cycle times are achieved and an improved product is formed.

In PET stretch blow molding, single-stage machines, such as the Nissei, use a maximum pressure of 300 psi. In the two-stage method for PET, two-stage blow air is used. The low blow pressure would be approximately 220–250 psi and high blow pressure as high as 650 psi is used. Thus, the back plates and the blow mold must withstand these blow pressures and clamp closing forces.

Clamp Tonnage Required.

The required clamp tonnage is the sum of the blow pressure tonnage and pinch-off tonnage required with a 25% safety factor calculated as follows:

Production part projected area (IN^2) $\times$ Blow pressure $\times$ 1.25 $\div$ 2000 lb/ton = Blow pressure tonnage required with a 25% safety factor.

Pinch-off area (IN^2) (length $\times$ width) $\times$ pressure (lb/IN^2) $\times$ 1.25 $\div$ 20,000 lb/ton = Pinch-off tonnage required with a 25% safety factor.

Approximate pinch-off pounds per inch (ppi) for specific resins: PVC, 400/500; HDPE, 600–700; PP, 700–800; and PC, 1000.

Units. There is no uniform rating by the machinery manufacturers for clamp tonnage units nor is there a uniform use of nomenclature. One might see U.S. tons listed followed by KN and both are listed. Sometimes the multiplier is 10, so a 42 ton clamp will also show as 420KN. Other times a clamp will show 67 tons and 600KN which means a multiplier of 8.95 was used. Also, sometimes the U.S. tons are also given in metric eg, Cincinnati Milacron does this. The best conversion would be to rate in U.S. and metric tons with the U.S. tons being divided by 1.1 to yield metric tons.

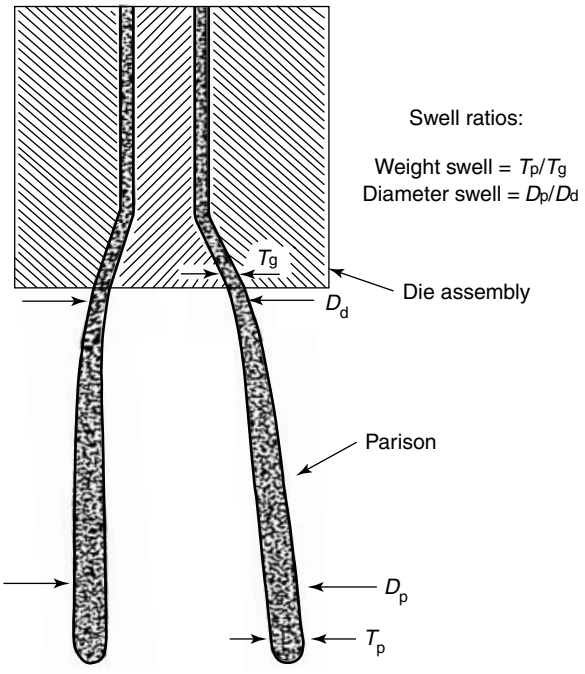

Fig. 22. Swelling behavior of viscoelastic material in parison formation.

Die/Weight Swell. The extrudate will swell as it exits the die. The swelling behavior is a result of the elastic component of the resin's flow. It is quite possible to measure the resins swell as it exits the die and to use this to ascertain the tooling sizes, and to determine if the resins can be used in producing the product.

There is also a weight swell of the resin and this is a result of the temperature, length of parison, speed of parison, drop, hang time of the parison, and the hot melt strength of the resin to be used. Swell ratios are defined in Figure 22.

Heat Extraction Load. The heat extraction load or the amount of heat to be removed from the product must be determined. This is important, as the amount of heat taken out by the blow mold must be known if the process is to be economically predictable. The amount of heat to be removed, Q, is determined by the material's temperature and the amount of plastic being delivered to the mold. It is calculated as follows:

$$Q = Cm\Delta t$$

where, Q is the total change desired during molding (J), C is the specific heat (J/g·°C) of the plastic material being processed, m is the amount (g) of plastic per hour to be cooled, and $\Delta t = (T_0 - T_f)$ is the initial plastic parison temperature into the mold minus final (demolding) temperature of the plastic (°C). As an example, for determining the heat load for a typical mold, the following data are used:

(1) C, specific heat for polyethylene = 2.5 J/g·°C.
(2) m, amount of PE to be cooled = 32 shots/h × 8.5 kg/shot × 0.80 shot reduction length = 218 kg/h

(3) T_0, parison temperature = 215.6°C (420°F).
(4) T_f, demolding temperature = 37.8°C (100°F).
(5) Δt, material temperature change = $T_0 - T_f = 215.6 - 37.8 = 177.8$°C

Thus,

$$Q = Cm\Delta t$$
$$= (2.3)(218{,}000)(177.8)$$
$$= 89\,\text{MJ}(84{,}440\,\text{BTU/h per mold, avg})$$

Assume 75% efficiency for heat transfer between chilled water and PE. Then,

$$\text{Cooling required} = \frac{119\,\text{MJ}}{0.75}(112{,}600\text{BTU/h})$$

With polyolefins, it is frequently desirable to run the molds as cold as possible, 4.5–15.5°C or lower. Condensation or moisture on the mold can cause outside surface defects when mold cooling temperatures are below dew point. To reduce or eliminate these, either the mold heat transfer fluid temperature can be increased, or it is possible with recently developed techniques to dehumidify the immediate blowing area to eliminate the condensation and maintain good surface appearance at a fast cycle. Effective dehumidification systems can be installed on existing equipment very satisfactorily, permitting ready access to the blow area while providing the dehumidification necessary to prevent condensation. Savings of 20–30 % have been reported through the use of this system.

Utilization of existing water temperatures in plants can be supplemented to improve cooling conditions through the use of turbulent flow of fluid through the mold channels. Depending upon the channel sizes, the greater the volume and the higher the pressure of the fluid put through the channels, the greater is the heat transfer. A turbulent flow wipes the side walls of the channels, permitting better heat transfer than that obtained with laminar flow of the fluid through the channels. This laminar flow characteristic tends to have reduced heat transfer at the channel circumference, whereas a turbulent flow enables more heat to be removed quicker with higher fluid temperatures, which also reduces the possibility of condensation.

A large-capacity temperature control unit (eg, with 2–7.5 HP pumping capacity, depending on the mold and channel sizes) can not only provide the desire turbulent flow, but can also assist in maintaining uniformity of control throughout the mold on an automatic basis. Production reports indicate that temperature variations of no more than 0.6–1.1°C are readily obtained with this approach, even with intricate molds.

To determine the proper flow for each mold, the Reynolds number should be determined. The Reynolds number ($N = DVP/M$, where D is pipe diameter, V is fluid velocity, P is fluid density, and M is fluid viscosity) is a nondimensional parameter used to determine the nature of the flow along surfaces. Numbers between 2100 represent laminar flow, numbers from 2100 to 3000 represent transitional flow, and numbers above 5000 represent turbulent flow.

The cooling time of parts is related to the wall thickness of the part. Tests on HDPE bottles have shown that wall thickness increases of 50% can increase the required cooling time as much as 200%. This increase of time is necessary to prevent warpage and to control shrinkage of the final product outside the molding cycle.

Because of the broad range of material, and part sizes, specific sizes and location of channels can be subjected to debate. To avoid this it would be better to state that channels should be as large as possible to provide high velocity flow for good heat transfer. They should be located approximately 0.5 in. from mold surface, depending upon mold size. These factors are highly desirable to ensure proper circulation through the work area to heat and cool the mold as rapidly as possible.

A roughened cavity surface is very helpful in blow-molding PE to assist in the movement of trapped air to the mold vents and to improve heat transfer rates.

Water, with its excellent heat transfer characteristics, is used primarily as the heat transfer medium for polyolefin blow-molding, but for the newer engineering resins a synthetic heat transfer fluid that operates up to temperatures of 121–149°C or more at low pressure is highly desirable because of the safety factor. Because the heat transfer characteristics of the synthetic fluid are not as effective as water, care must be exercised to use proper fluids in a safe manner to obtain as efficient production cycles as possible. Compromises sometimes are necessary, depending upon the required temperatures.

The most common material used for blow molds is aluminum. Aluminum has good conductivity, is lightweight, and has low mold costs. In considering the thermal conductivity, as measured in calories per square centimeter per centimeter per degree centigrade per second (cal/cm^2·cm·C·s) [or collecting terms, calories/(s·cm·°C)], aluminum has a thermoconductivity of 0.37, beryllium–copper 0.21 to 0.61, Kirksite 0.25, and steel 0.12–0.14. (In SI units of W/m·K the values are Al, 155; Be–Cu 88–255; Kirlisite, 105; and steel, 50–59). Aluminum is soft, however, and to protect against wear to specific points in the molds, steel or beryllium–copper inserts are used in production applications. The introduction of dissimilar materials, no matter how closely they are machined and mated, affects the heat transfer characteristic of the molds. Kirksite is less frequently used for inserts because of its weight and mass.

Metals Used in Blow Molds

Predominately, the choice of raw material for the main body of a blow mold is a high grade aluminum such as QC-7 or Alumnel 89.

With today's CADAM and CNC equipment, the blow-mold industry is producing large blow molds via machining rather than cast aluminum (Table 2). However, there are some industries that because of the blow-mold cost and short run volumes rely solely on cast aluminum blow molds. They also live with the problem of aluminum pinch-offs, rather than insert steel or beryllium–copper.

Aluminum is approximately eight times better in conductivity than steel. In some cases, blow molds are (for PVC or for inserts or cams) made of stainless steel (420,430).

Table 2. Some Metal Properties

Metal	Cast/cut	Upper cm^3	Durability	Resistance to PVC	Heat conductivity
Zinc	Cast	4.24	Fair	None	0.0017
Aluminum 70/75T6	Cut	1.60	Good	Fair	0.002
Aluminum	Cast	[a]	Fair (−)	Fair (−)	[a]
Brass	Cut	4.98	Good	Fair (+)	0.0015
Beryllium-copper	Cut	5.24	Very good	Very good	0.004
Beryllium-copper	Cast	5.24	Very good	Very good	0.004
Stainless steel 300	Cut	4.75	Fair	Very good	0.0006
Stainless steel 400	H.T. cut	4.75	Good	Fair	0.0003

[a]Depends on density of casting.

Pinch-offs can be produced from BeCu, Ampcoloy 940, or steel. S-7 are preferred for pinch-offs and 54–56 Rc for long life.

Shrinkage

Because molding is executed with a melt which is then solidified, shrinkage and warpage are experienced with most materials. Higher crystallinity polymers have higher shrinkage values (Table 3). Shrinkage is dependent upon the wall thickness because of the different cooling rates. The cycle time to cure the product will be what it takes to cool the thickest wall section. Cooling of a plastic part consists of three separate transfer mechanisms:

(1) Conduction of heat in wall of part
(2) Conduction of heat in mold wall
(3) Convective transfer of heat in cooling fluid

Step 1 is dependent upon resin type, temperature, and wall thickness. Step 2 depends upon the mold material's thermal properties, porosity, and mold/cooling

Table 3. Shrinkage and Other Properties of Some Common Blow-Molding Materials

Polymer	Shrinkage,[a] %	Linear coefficient of thermal expansion, $(10^{-4}\ K^{-1})$	Specific Volume, cm^3/g (at 20°C)
LDPE	1.2–2	2.3 (20°C)	1.09
HDPE	1.5–3	2.0 (20°C)	1.05
Polyacetal	1–3	1.3	0.7–0.71
PP	1.2–2.2	1.6	1.10
PS	0.5–0.7	0.7–0.8	0.89–0.95
PVC	0.5–0.7	0.8	0.81

[a]Measured on an axially symmetrical test bottle with an average wall thickness of 0.7–1 mm, by method of R. Holzmann, Kautex-Werke, Hangelar.

layout geometry. Some thermal properties of selected resins are shown in Table 3. Step 3 can be optimized with regard to temperature, fluid flow rate, and prevention of scale formation on the liquid side. The cooling rate of most processes is limited more by the rate of conduction within the plastic than by the rate of conduction in the mold. The cycle time of a part is usually strongly dependent on its wall thickness.

Venting

All blow molds have to be vented. The air that first occupied the product area must escape more rapidly than the rate at which the hot plastic is blown to fill the product area within the closed blow mold. This is known as venting.

In some cases it is very hard to ascertain that improper venting is the production problem that is keeping consistent quality parts from being produced in each cycle. Olefins will show burn signs and in some cases, carbon residue on the blown product, if the venting is really insufficient. There may be no burning of the plastic evident; however, the part produced just does not totally reproduce the blow-molding surface. In blow molding styrene and particularly PET, the resin will cool and just quit stretching since the compressed air, due to it being trapped, results in higher pressure than what is inside the heated parison or preform.

Well-designed molds are vented, as entrapped air in the mold prevents good contact between the parison and the mold cavity surface. When air entrapment occurs, the surface of the blown part is rough and pitted in appearance. A rough surface on a shampoo bottle, for example, is undesirable because it can interfere with the quality of decoration and can detract from the overall appearance. Molds are easily vented by means of their parting line, with face vents and with small holes. A typical mold parting line venting system is shown in Figure 23.

The venting is incorporated only in one mold half. This type of venting can be used on all sizes of molds. When certain areas of the mold cavity are prone to trap air, core vents as shown in Figure 24 can be used.

Venting in the mold cavity should be anticipated in the mold design and layout of the cooling channels so that provisions can be made for their locations.

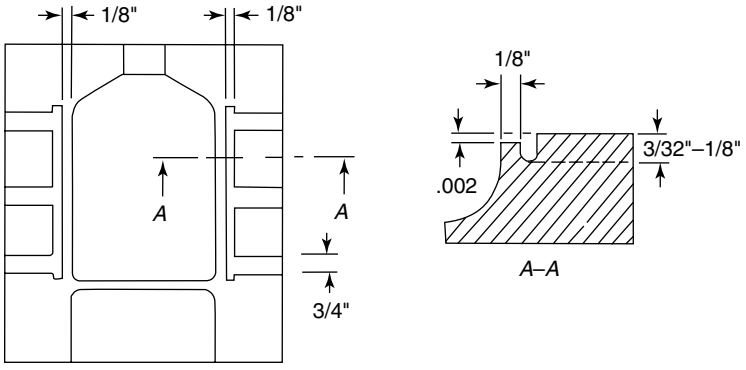

Fig. 23. Parting line venting.

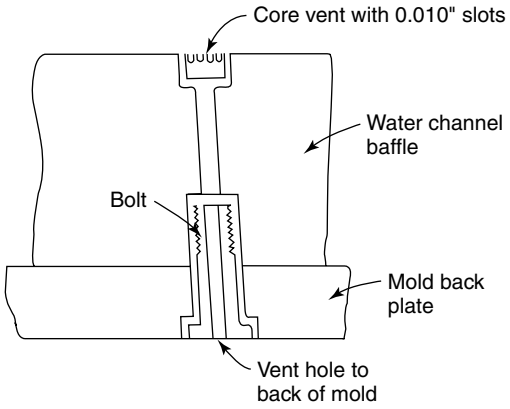

Fig. 24. Core venting.

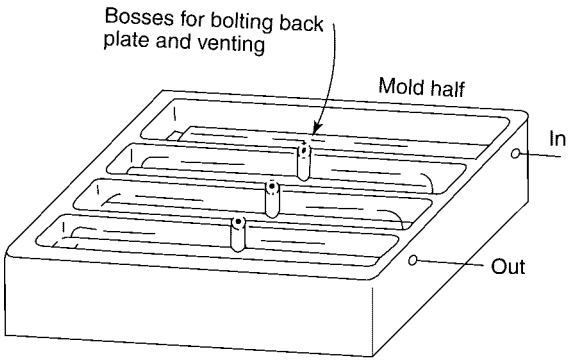

Fig. 25. Location of vents in baffles.

For the cast mold, the cooling channel baffles can be located over areas to be vented, as shown in Figure 25.

The vent opening will pass through a boss in the baffle to the back or outside of the mold. In machined molds, care must be taken so that vents miss the drilled cooling channels. When core vents cannot be used because the slots mark on the blown part will show, small drilled holes can be used. The effect of the size of hole on the surface of the part is shown in Figure 26.

If the hole is too large, a protrusion will be formed; if it is too small, a dimple will be formed on the part. Venting also can be incorporated in molds that are made in sections. A 76–250 μm (3–10-mil) gap between the two sections with venting to the outside of the mold is a very effective vent. For small containers, a 5–7.6 μm (0.2- to 0.3-mil) opening is used, and up to a 250μm (10-mil) opening has been used on large parts such as a 20-gal garbage container.

The mold cavity surface has an important bearing on mold venting and on the surface of the molded part. For PEs and PPs, a roughened mold-cavity surface is necessary for the smoothest surface. Grit blasting with 0.25–0.17 mm (60–80 mesh) grit for bottle molds and 0.59–0.42 mm (30–40 mesh) grit for larger molds is

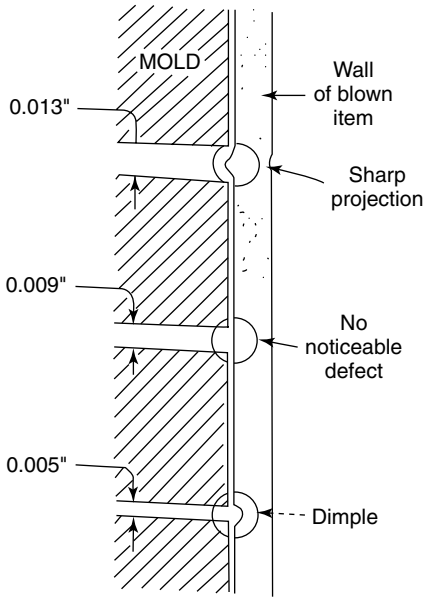

Fig. 26. Effect of vent hole size on part surface.

a common practice. The clear plastics such as PVC and styrene require a polished mold cavity for the best surface. A grit-blasted surface will reproduce on some clear plastics, an effect that is not normally desirable.

The pinch-off areas pinch the ends of the plastic parison and seal the edges together when the mold closes. These surfaces are subject to more wear than any other part of the mold. The high-heat-conductive metals preferred for blowing molds, such as aluminum and copper alloys, generally are less wear-resistant than steel. Steel inserts often are used for the pinch-off areas of the molds. An additional advantage of pinch-off inserts is that they can be made replaceable in the event of wear or damage. A neck pinch-off insert is sketched in Figure 27.

Generally, in volume production, pinch-off inserts are made of hard steel with the other portions of the blow mold produced from a nonferrous metal. The

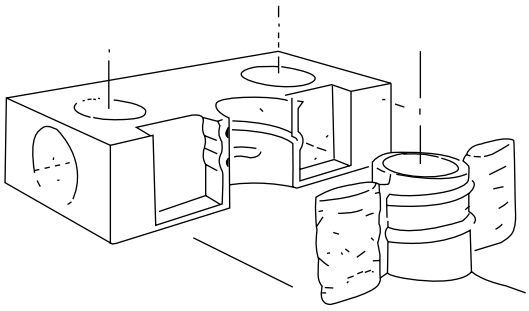

Fig. 27. Replaceable neck insert pinch-off.

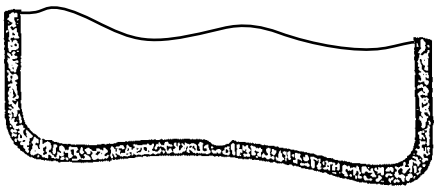

Fig. 28. Poor weld line (weak) pinch-off had knife edge; relief angle was either too large or too small.

pinch-off edge should not be similar to a knife edge, or it will tend to act as a cutter and will yield a "V" groove where the tail or pinch-off area of the parison is forced to bond (See Fig. 28).

The parts of the mold that weld the ends, and sometimes the interior portions, of the parison together, and also cut it or facilitate its removal are called the pinch-offs. Pinch-offs design has an important effect on the success of a blow-molding product because the weld seams are usually the weakest parts of the container. The pinch-off must be designed to maximize the strength of the blown product in this area. The results of a pinch-off optimization study for various grades of olefins are listed in Table 4 and also in Figure 29. A quality type pinch-off is depicted in Figure 30.

In bottle blow molds, there will be a hardened steel insert with a land of 0.076–0.13 mm (0.003–0.005 in.), a relief angle of 20° with a total depth of 0.76 mm (0.030 in.) measured from the inside bottom of the blow mold, and then a 45° cut to the bottom of the relief section in the pinch-off area. Normally, the total of this relief section will be 90% of the parison wall thickness to be pinched (see Fig. 31). This design will also minimize residual flash. It is best to design the pinch land at 0.25–0.4 mm (0.010–0.015 in.) and have metal to remove, if the pinch is not adequate.

Many different designs have been used in the pinch-relief sections. Two typical ones are shown in Figure 32. Design A is probably the one most widely used. In some instances, however, where the mold must pinch on a relatively thin portion of the parison and next to this pinching edge the parison must expand a large amount, the plastic will thin down and may even leave a hole on the parting line. This defect is sometimes seen near the finger hole on containers having handles. To prevent thin sections and holes, Design B is sometimes employed. The shallower angle of 20° has a tendency to force plastic to the inside of the blown

Table 4. Optimization Study Results for Various Grades of Olefins

Container volume (V), L	Pocket Opening Angel, (a), deg	Welding edge width b, mm	Pocket Width, (c), mm
≤1	30	0.6–1	2d
1–30	30	1–3	2d
30–250	30	3–5	1d–1.5d
250–2000	30	5–7	1d–1.5d

part and increase the wall thickness at the parting line rather than pushing the excess material back into the pinch relief. Another method used for increasing the wall thickness at the parting line employs a restriction or dam in the pinch relief similar to that shown in Figure 33. The pinch-off must be designed to maximize the strength of the weld. Some different types of pinch-off designs are shown in Figure 34.

Troubleshooting Extrusion Blow Molding

Problem	Suggested solution
Low gloss	Increase material temperature
	Increase mold temperature
	Improve mold venting
	Increase air pressure
	Increase air blowing rate
Excessive cycle	Decrease material temperature
	Decrease mold temperature
	Decrease part wall thickness
	Improve mold coring
	Increase material density
	Increase air pressure
	Increase melt index (with decreased stock temperature)

Problem	Suggested solution
Die lines	Clean the die
	Smooth and polish the die
	Increase mold temperature
	Increase air pressure
	Increase air blowing rate
	Increase purge time when changing materials
	Improve die streamlining
Low bottle weight	Increase due to mandrel clearance
	Decrease material temperature
	Increase extrusion speed
	Decrease extrusion die temperature
Surface roughness	Increase stock temperature
	Decrease extrusion speed
	Increase die temperature
	Improve die streamlining
Weak pinch	Adjust material temperature
	Increase pinch blade land width
	Decrease rate of mold closing
Parison curl	Adjust and center die-parison curls toward thin area
	Improve die and head heat uniformity
	Dirty die head
Wall thickness non-uniform	
vertically sag	Decrease material temperature
	Increase extrusion speed or accumulator ram pressure
	Lower melt index
	Increase material density

	Improve head and die heat uniformity
	Adjust and center the die
Excessive thinning at parting line	Decrease wall thickness, or make more uniform
	Decrease mold temperature
	Increase air pressure
	Decrease material temperature
	Decrease density
	Improve mold coring
Excessive shrinkage	Increase material temperature
	Decrease mold temperature
	Increase air pressure
	Decrease material temperature
	Decrease density
	Improve mold coring
Excessive parison swell	Increase material temperature
	Increase die temperature
	Decrease extrusion speed
	Increase melt index
	Reduce die size
Doughnut formation	Wait for mandrel temperature to reach die temperature
	Clean the lower surface of the die

Problem	Suggested solution
Warped top and bottom	Slow the cycle
	Decrease mold temperature
	Decrease stock temperature
	Decrease part weight
	Improve mold coringJ
Variable bottle weight	Finer extruder screen pack
	Increase screw cooling
	Raise rear extruder heats
	Decrease extruder rate

Coextrusion

A growing trend in extrusion blow molding is to coextrude parisons that contain up to seven layers of different materials. However, as of this time, coextrusion is limited to machines that only use one (1) parison as on a wheel and the continuous-type machine. Since the different materials combine in the head tooling (see Fig. 35), the use of manifolds for multiple cavity is not feasible, nor are accumulator machines (see COEXTRUSION).

Coextrusion blow-molding machines are very expensive and demand skilled operators. Coextrusion is used to produce containers having a view stripe and more recently for 55-gal drums and the plastic gasoline tanks that are in passenger cars, sport utility vehicles, or pick-up trucks. The plastic gasoline tanks are produced from a coextruded parison that contains six layers of different resins. For example, HDPE/adhesive/EVOH/adhesive/regrind/HDPE (see Fig. 35).

Major companies are finding that they can coextrude parisons that not only make use of their regrind, but also use less color additive. It is very feasible to extrude a virgin layer with no color additive on the inside of the

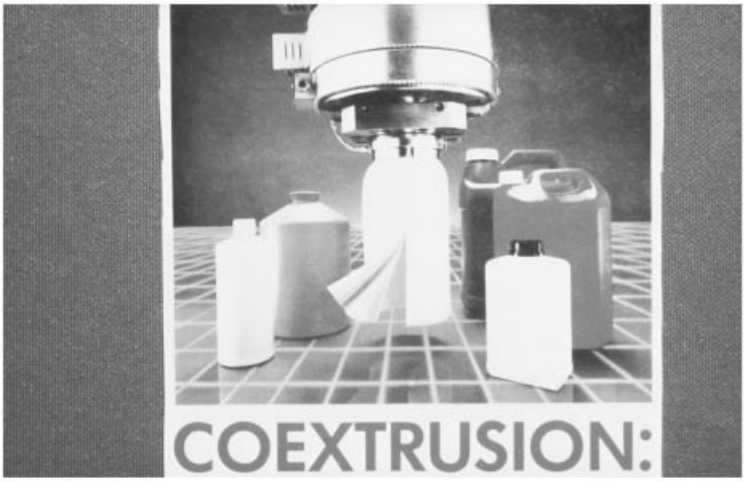

Fig. 35. Coextrusion head.

parison that is against the product to be packaged. The second layer is for the off-fall or regrind. The outer layer would be virgin with color additive, which would make up a three-layer coextruded parison. A six- or seven- layer coextruded parison may be HDPE/adhesive/EVOH/adhesive/regrind/virgin or HDPE/regrind/adhesive/EVOH/adhesive/regrind/virgin as examples.

Stretch Blow Molding

For stretch blow molding, mainly PET, PVC, PP, and PAN are used. In this process, based on the crystallization behavior of the resin, a parison or preform is temperature-conditioned and then rapidly stretched and cooled. For best results, the resin must be conditioned, stretched, and oriented just above the glass-transition temperature. At this point, the resin can be moved without the risk of crystallization (see Figs. 36 and 37).

Stretch blow molding is the most significant development since the development of the two piece can. This process improves produce performance, such as bottle-impact strength, cold strength, transparency, surface gloss, stiffness, and gas barrier. The bottles are lighter and less costly, and products that otherwise would not be suitable can be packaged. The process uses injection-molded, extruded, or extrusion blow-molded parisons in one or two steps.

In the one-step method, parison production, stretching, and blowing take place in the same machine. In the two-step method, the parison is produced separately from stretching and blowing. The main advantage of the one-step approach

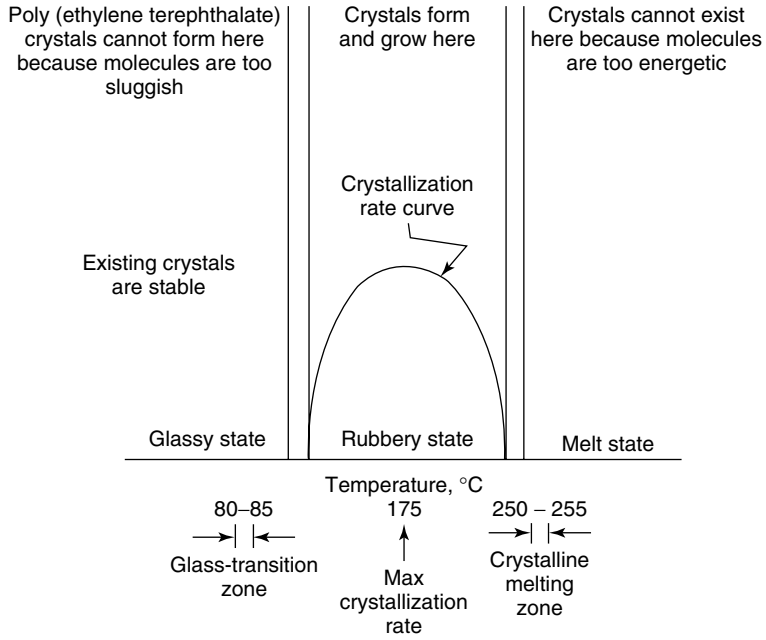

Fig. 36. Molders' diagram of crystallization behavior (8). Courtesy of the Society of Plastics Engineers.

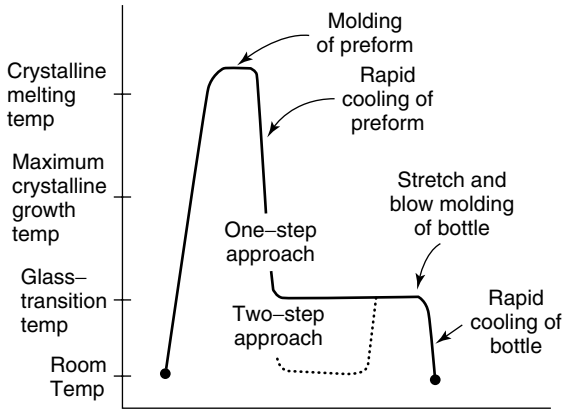

Fig. 37. Basic stretch blow mold process. Courtesy of Jerome S. Schaul.

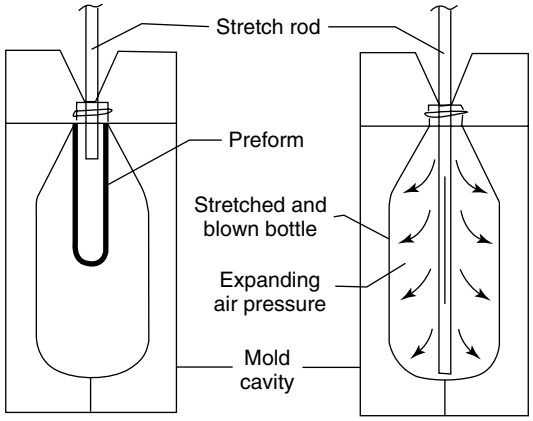

Fig. 38. A temperature-conditioned preform is inserted into the blow-mold cavity and is rapidly stretched. A rod is often used to stretch the preform in the axial direction, and air pressure to stretch the preform in the radial direction.

is the savings in energy as the parison is rapidly cooled to the stretch temperature. In the two-step approach, the parison is cooled to room temperature and reheated to the stretch temperature (see Fig. 38). On the other hand, production in the two-step method is more efficient, and a minor breakdown in one of the steps does not stop the other. The optimum balance of design vs output is also easier to achieve with the two-step approach. Limits on parison production, for example, do not force a compromise in parison design to achieve higher bottle production. For optimum performance, each bottle design has a unique parison-design and temperature-conditioning requirement which may or may not fit, for optimum productivity, the assumptions used in the design of the one-step equipment, which are virtually the same.

In the two-step method, the parison is injection-molded in a separate machine, sorted, and placed in an oven for temperature conditioning and blow molding. A rod is used inside the parison, in combination with high air pressure,

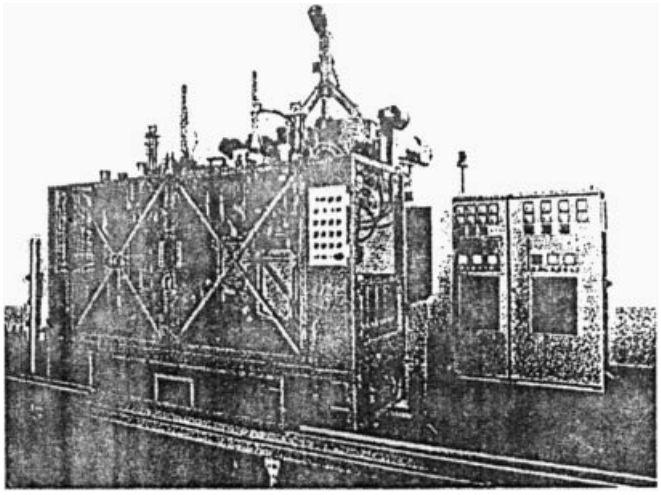

Fig. 39. Bekum BM04D continuous extrusion blow molder for the manufacture of biaxially oriented PVC bottles. Production rate for 1-L bottle is 2000 per h; maximum bottle size is 2 L. Courtesy of Bekum Plastic Machinery, Inc.

to complete the stretch (see Fig. 38). Injection stretch blow molding is commonly used for PET resin.

The extruded parison stretch process can use either the one- or two-step method. In the former, a parison is extruded and fed directly into an oven for conditioning. After conditioning, the parison is cut into lengths. Mechanical fingers grab both ends and stretch the parison. The two mold halves close, whereupon air pressure expands the stretched parison against the mold cavity. In the two-step method, the extruded tube is cooled and cut to length. Later, the cut tubes are placed in an oven for conditioning. This technique is used mainly for PP, and occasionally for PVC.

With the extrusion blow stretch process, the parison is shaped and temperature-conditioned in a preform cavity in the same way a bottle is extrusion blow-molded. From this preform cavity, the parison is transferred to the bottle cavity where a rod and air pressure combine to stretch and expand the resin. PVC is most often stretch blow-molded with this process. Although the one-step method is the most common (see Fig. 39), a two-step technique, in the same fashion as the others, is feasible.

PET is the second largest volume resin used in the blow-molding industry. HDPE is first, with a 57% share of the blow-molding market today. PET has 33% of the blow-molding market and is growing. Thus, all the other resins combine for 10% of the blow-molding market.

As stated previously, stretch blow molding impacts clarity, top load strength, drop impact resistance, improved barrier, and will allow approximately 15% or greater reduction in material usage for the same size container.

In stretch blow molding, there are two ratios that multiply together to provide the blow up ratio BUR. In extrusion blow molding, there is only the hoop ratio (that is the blow-up ratio). In stretch blow molding there is the hoop that is multiplied by the axial ratio. Thus, BUR = Hoop ratio $\times$ axial ratio.

The hoop ratio is the most important. If the product to be packaged is pressurized as soft drinks, carbonated water, and beer, the hoop ratio should be at least 10 or higher. The *hoop ratio* is defined as the ratio of the largest inside diameter (D_1) of the blown article to the inside diameter (D_2) of the parison or preform.

The *axial ratio* is also very important as this provides vertical strength, material distribution, improved barrier, and allows for raw material savings. Usually, the axial ratio should be at least 1.7 with greater than 2 preferred. The *axial ratio* is defined as the axial length (A_1) where the actual axial stretch is initiated in the preform measured to the inside bottom of the bottle to be produced divided by the axial length (A_2) of the preform as it is measured from the point where stretching is initiated to the inside bottom of the preform.

The BUR is used to determine the wall thickness that would be necessary in the precursor or preform. If the BUR is 10, and the desired minimum wall thickness is 0.38 mm, then the BUR $\times$ the desired wall thickness, would indicate that the minimum wall thickness in the preform should be 3.8 mm since the thickness will be expanding 10 times. The total BUR is equal to the hoop ratio times the axial ratio.

To check if the orientation is correct, a dog bone can be cut from the stretch blow-molded PET container and a tensile test conducted on an Instron or similar machine. A dog bone shape is cut in the hoop direction and one is cut in the axial direction. PET has a base strength of approximately 46 MPa (6700 psi). If the hoop ratio is 5, then in the container in the hoop direction, the tensile strength should be approximately 231 MPa (33,500 psi). If the axial ratio is 2, then the tensile strength in the vertical direction would approximately be 92 MPa (13,400 psi).

In order to achieve these results, the stretch blow molding has to be performed when the heated preform's body is within the orientation window for the polymer that is to be stretch blow-molded. A list of the orientation temperatures for specific polymers follows:

Material	Orientation temperature, °C
PP	128
PAN	124
POM	160
PVC	100
PET	95
PS	150

It is important to note that each polymer listed has specific stretch ratios and if exceeded the polymer will fail.

Material	Stretch ratio	Orientation temperature range, °C
PET	16/1	90–115
PVC	7/1	99–110
PAN or AN	12/1	115–127
PP	6/1	127–138
PS (Crystal)	12/1	143–160

Table 5. Gas and Water Vapor Barrier Properties of Glass-Clear Resins

Polymer	O_2[a]	CO_2[b]	Water[c]
Oriented PVC via extrusion blow molding (high impact)	9.0	16.5	0.7
Oriented PET	11.1	22.2	1.5
Oriented PVC via extrusion blow molding (normal impact)	9.6	5.2	1.1
Nonoriented PVC via extrusion blow molding (high impact)	12.2	35.7	1.5
Nitrile	1.1	1.3	4.4
PC	215.0	400.0	9.0

[a] cc/mL/24 h/atm/100 in.^{2}/73°F.
[b] g/mL/24 h/atm/100 in.^{2}/100°F, 90% RH.
[c] Test results provided by Occidental Chemical Corp.

Stretch blow-molded containers of AN, PVC, and PET may have an average wall thickness of 0.23–0.64 mm (0.009–0.025 in.) Normal blow molding would call for an average wall thickness of 0.46–0.5 mm (0.018–0.020 in).

As noted, each polymer has a temperature at which the heated preform or parison should be stretch blow-molded to achieve maximum orientation properties. Each polymer exhibits its own natural stretch ratio. Orientation of polymers is a study by itself, and there are references to in-depth study of specific polymers (13) (see also, FILMS, ORIENTATION).

Table 5 depicts barrier properties of several stretch orientable polymers and their barrier improvements obtainable through stretch blow molding (see BARRIER POLYMERS).

PET has grown in its use because of several properties possessed by this polymer which no other stretch blow-molded polymer possesses. PET has what is referred to as self-leveling. Since PET work hardens similar to a metal, as it stretches out, the material stretching becomes stronger than the material next to it and so it waits until the material next to it stretches and becomes stronger. Thus, the term *self-leveling*. No other polymer possesses this feature. All the other polymers behave as bubble gum when they are being blow-molded.

Another unique property of PET is that it can be heat set. Heat set is achieved by either of two methods. Normally, a PET stretch blow-molded container cannot be subjected to heat above approximately 54°C (130°F) because of distortion. This relates to the fact that the glass transition of PET is approximately 68–71°C (155–160°F).

However, this can be altered by inducing the PET stretch blow-molded container to become more crystalline. A quality 2-L PET soda container will have approximately 14–22% crystallinity. This crystallinity is induced by heating the preform and through the orientation. To increase the crystallinity within the wall of the container, the container may be blow-molded in a hot blow mold in the range of 124–155°C, with the bottom plug or push up at approximately 68–88°C. When produced in a hot blow mold, the crystallinity with in the wall of the stretch blow-molded container can be increased to be in the range of 28–32%. There is a loss in orientation because of blowing in a hot blow mold. The heat set stretch blow-molded container is tested fresh. It is filled with hot water to the top of the finish at a temperature of 90°C. It cannot distort nor shrink greater than 2% when dimensions are checked before and after the hot fill test. This ensures the container will pack a 85°C hot fill product such as juice and sport drinks. An aged container

over 24 hours is checked using 85°C hot water. There are many other quality assurance tests performed and produces such as Schmalbach Lubeca, Graham, Ball Corp, and Crown Cork & Seal have their own test procedures.

Other Blow-Molding Operations

Many related operations have been used to improve blow molding, eg, in-mold labeling, fluorination of surface, and internal cooling.

In-Mold Labeling. A label with a heat-activated adhesive is automatically placed into the mold cavity and held by a vacuum. The expanding hot parison activates the adhesive to create a strong bond.

Some of the advantages of the process include a stiffer, stronger structure, bottle-weight reduction, improved label appearance, elimination of high speed complex labeling equipment, and varied package opportunities. Bottle weight is often reduced without impairing performance. The strong bond improves label appearance by eliminating blisters and wrinkles. The pick-and-place mechanism used to place the label into the mold cavity, although somewhat complex, is often simpler than using high speed equipment for labeling on the filling line. New package-design opportunities are created with the possibility of placing the label closer to or around the bottle edges, which could further increase strength.

However, with in-mold labeling, production efficiency can suffer from the slower cycle and the complexities of the process. The scrap is more valuable and costly to reclaim. Very high production runs are required to justify the investment.

Fluorination. Fluorination surface treatment improves the resistance of PE to nonpolar solvents. A barrier is created by the chemical reaction of the fluorine and the PE, which forms a thin (20–40 mm) fluorocarbon layer on the bottle surface. Two systems are available. The in-process system uses fluorine as a part of the parison expand gas in the blowing operation. A barrier layer is created only on the inside. In the post-treatment system, bottles are placed in a chamber filled with fluorine, and a barrier layer forms on both inside and outside surfaces.

This surface treatment allows low cost blow-molded PE bottles to be used for paint, paint thinner, lighter fluid, polishes, cleaning solvents, cosmetics, toiletries, etc, and higher cost resins or coextrusion processes are not always necessary. For floorination to be effective, the parison temperature must be greater than 195°C.

Internal Cooling. Normally, a blow-molded part is cooled externally by the mold cavity, forcing heat to travel through the entire wall thickness. With the poor thermal conductivity of plastic resins, molding-cycle times of heavy parts can be lengthy. Internal cooling systems are designed to speed mold cooling, thus reducing costs by removing some heat from the inside. Three basic systems have been developed: liquefied gas, supercold air with water vapor, and air-exchange methods.

In the liquefied-gas system, liquid carbon dioxide or nitrogen is atomized through a nozzle in the blow pint into the bottle immediately after the parison has been expanded. The liquid quickly vaporizes, removing heat, and exhausts at the end of the cycle. This method has increased production rates by 25–35%. A disadvantage is the cost of the liquefied gas. If consumption is not precisely controlled, the cost saving is small.

The supercold-air system with water vapor is similar. A stream of very dry, subzero air expands the parison, circulating through the bottle and exhaust.

Immediately after the parison has expanded, a fine mist of water is injected into the cold air stream and turns into snow. As the snow circulates through the container, it melts and vaporizes. At the end of the molding cycle, the water mist is stopped, permitting the circulating air to dry the interior before the mold is opened and the article is removed. Production rates can be improved as much as 50%.

The air-exchange system is far simpler. Here, plant air, after the parison has been expanded, is circulated through the bottle and is exhausted continuously. Differential pressure inside the bottle is maintained at 550 kPa (80 psi) to keep the parison in contact with the mold cavity. Production rates, however, are increased by only 10–15%.

More expensive internal cooling systems are often not justifiable with today's equipment because most blow-molding machines do not have the additional extruder capacity to support the high production rate. This is particularly true for the heavier bottles that would benefit most. As a result, only the low cost air-exchange systems have been accepted.

With the exception of larger industrial blow molds cast from aluminum (typically No. A356), most extrusion blow molds today are cut from No. 7075 or No. 6061 aluminum or from No. 165 or No. 25 beryllium-copper. The latter is corrosion-resistant and very hard, making it the choice for PVC blow molding. However, compared with aluminum, it weighs about three times as much, costs about six times as much per cubic centimeter, and requires about one-third more time to machine. In addition, thermal conductivity is slightly lower (see Table 6). For polyolefin blow molding, some mold makers combine the materials by inserting beryllium-copper into the pinch-off area of an aluminum cavity, thus gaining a lightweight, easy-to-manufacture mold with excellent thermal conductivity and hard pinch-off areas.

Table 6. Blow-Mold Tool Materials

Material	Hardness[a]	Tensile strength, MPa[b]	Thermal conductivity, W/m·K
Aluminum			
No. A356	BHN-80	255	151
No. 6061	BHN-95	275	168
No. 7075	BHN-150	460	105
Beryllium-copper			
No. 25 and 165	HRC-30 BHN-285	930	105
Steel			
No. O-1 and A-2	HRC-52-60 BHN-530-650	2000	35
No. P-20	HRC-32 BHN-298	1000	37

[a]HRC: Rockwell hardness (C scale); BHN: Brinell.
[b]To convert Mpa to psi, multiply by 145.

Unlike injection blow molds, which are mounted onto a die set, extrusion blow molds are fitted with hardened-steel guide pins and bushings to ensure that the two mold halves are perfectly matched. Dies, mandrels, blow-pin cutting sleeves, and neck-ring striker plates are made from tool steel hardened to 56–58 HRC.

Guidelines. Guidelines have been mentioned throughout this article in the form of process and tooling limitations, such as parison blow-up ratios, ovality ratios, tooling sizes, and so forth. Product design begins with a clear understanding of process.

Most blow-molded articles perform better with rounded, slanted, and tapered surfaces. Square or flat surfaces with sharp corners are undesirable. Wall thickness can vary considerably from side panels to corners. Corners become thin and weak, heavy side panels thick and distorted. Flat panels are not uniform and flat shoulders offer little strength. Highlight accent lines should be "dull" with a radius of 1.5 mm or more. If they are sharper, the parison does not penetrate, and trapped air marks result along the edge.

The blow-up ratio of 4:1 for extrusion blow-molded bottles or parts is considered a maximum. This applies overall and to separate sections as well. For example, bottle handles that are deeper than they are wide across the mold-parting face are difficult to mold and are often thin and weak.

Ribs do not always stiffen. Blow-molded ribs often increase surface area and reduce wall thickness, creating a flexible-bellow or accordion effect. Flexing may affect "hinge" points. Proper design prevents this.

Designers must be familiar with bottle-performance tests. The Society of the Plastics Industry has recommended 21 standard practices; the most important are vertical compression or top-load strength, drop-impact resistance, product compatibility and permeability, closure torque, and top-load stress-crack resistance.

Blow-molding process conditions can influence not only bottle dimensions, but also bottle volume. HDPE bottles shrink, with 80–90% of the shrinkage taking place in the first 24 h. Lighter-weight bottles use less plastic for a given capacity and bulge more. A 4-L bottle weighing 5 g less increases about 12 mL in volume—5 mL for the plastic and 7 mL for bulge. Shorter cycle times, lower parison-expansion air pressure, and lower melt and mold temperatures reduce bottle volume. Storage temperature is very important. After 10 days, bottles stored at 60°C change more than bottles stored at 20°C.

The guidelines will continue to change with the use of the computer with CAD flow analysis, blow simulation, and new talent in the industry. The future is bright.

CHITIN AND CHITOSAN

Introduction

Chitin is a structural polysaccharide widely found in nature. Chitin occurs as highly ordered microfibrils in many species, in a variety of arrangements, from diatom spines to cell wall components of many fungi and yeast. It is also a principal component in the exoskeleton of insects and marine invertebrates such as *Arthropoda* and *Mollusca*. Chitin is a homopolymer of 1-4 linked 2-acetamido-2-deoxy-β-D-glucopyranose, although some of the glucopyranose residues are deacetylated and occur as 2-amino-2-deoxy-β-D-glucopyranose. When chitin is deacetylated to about 50% of the free amine form, it is referred to as chitosan. Figure 1 indicates the copolymeric nature of this material. Chitosan is rarely found in nature but does occur in dimorphic fungi such as *Mucor rouxii* wherein it is formed by the action of a deacetylase enzyme on chitin. Most chitosan is obtained by the chemical or enzymatic treatment of chitin obtained from the shell of commercially harvested *Arthropoda*, such as shrimp and crab.

Chitin was first isolated from mushroom tissue and named "fungine" in 1811 by Braconnot, a French botanist. A similar material was isolated by Odier from insect exoskeleton, which he termed "chitine" (1). Chitin is considered the second most plentiful biomaterial, following cellulose. The annual production of chitin biomass has been estimated at 1×10^{13} kg worldwide (2). This has led to considerable scientific and technological interest in chitin and chitosan. Chitosan has become the preferred commercial form of this material as it is more tractable than chitin. Chitin is insoluble in most common solvents, whereas chitosan dissolves in many common aqueous acidic solutions. Chitosan has found applications in many primary industries such as agriculture, paper, textiles, and wastewater

treatment. Chitosan is also under study for medical and pharmaceutical uses. It has also become a popular nutritional dietary additive (3).

Biosynthesis

The synthesis of any polysaccharide involves the addition of an activated monomeric sugar to the end of a growing polysaccharide chain by an enzyme mediated mechanism (4). In higher plants, algae, and photosynthetic bacteria (autotrophic organisms), polysaccharides are produced by a reductive metabolic pathway beginning with water, carbon dioxide, and light. In nonphotosynthetic bacteria, lower plants, fungi, and animals (heterotrophic organisms), they are synthesized from ingested foods. Chitin synthase catalyzes the polymerization of activated *N*-acetyl-glucosamine monomer (5,6).

Most studies of chitin synthesis and microfibril assembly have involved easily cultured unicellular fungi, protists, and algae, which have simple biochemical pathways. Insect and fungi chitin biosyntheses have been perceived as a route to the development of new pesticides as well as for monitoring the environmental impact of these biocides in crustacea (4). Post-polymerization deacetylation by chitin deacetylase converts chitin to chitosan in nature (7). The completion of the biological cycle is accomplished with chitinases and chitosanases, which ultimately degrade chitin and chitosan to their corresponding sugars (8–10).

Chitin and chitosan occur in a wide range of disparate organisms (Table 1). In crustaceans and insects most of the biosynthesis of chitin occurs in the layer of epidermal cells lying just under the cuticle (exoskeleton). Chitin usually occurs in the presence of other cellular materials such as glucans, proteins, and calcium carbonate. One of the purest forms of chitin is the spike of some centric diatoms, such as *Thalassiosira fluviatilis* (5). Some algae also produce a 100% N-acetylated chitin (17). Chitosan is always obtained by the action of a deacetylase on chitin. Figure 2 illustrates the high degree of organization found in native chitin microfibrils.

In animals, chitin biosynthesis begins with glucose. Glucose is phosphorylated, aminated, N-acetylated, and then converted to *N*-acetyl-uridine diphosphate (UDP)-glucosamine. Chitin is polymerized by the activated monomer *N*-acetyl-UDP-glucosamine. The polymerization is driven by the scission of the phosphoester bond. A similar pathway is involved in fungi. The gene fragments

coding for chitin synthase have been sequenced for many fungi and classified (23). Chitin synthase is an integral membrane protein. It is oriented such that its carboxyl terminus is exposed to the cytoplasmic side of the membrane (24).

Chitin deacetylase catalyzes the hydrolysis of the *N*-acetyl group in chitin. A chitin deacetylase has been purified from *M. rouxii* and identified as a high mannose glycoprotein requiring (at minimum) a tetramer of chitin sugars for catalysis (7). Chitin deacetylase is found outside the plasma membrane and is associated with the nascent chitin chains during fungal chitin biosynthesis. Chitin deacetylation may also be a fungal defense mechanism, as chitosan is more resistant to plant chitinase defense mechanisms.

Isolation

Chitin and chitosan rarely occur in a pure, easily isolated form. A substantial effort has been made to develop chemical, mechanical, and enzymatic methods to obtain purified materials (25). The usual method of obtaining chitin involves the chemical treatment of shell fish wastes from the crab and shrimp industries. The first step is to demineralize the shell with dilute hydrochloric acid at room temperature. This is followed with a deproteinization step with warm dilute caustic. This yields a partially deacetylated chitin, which may then be further deacetylated to chitosan. Figure 3 shows the underlying chitin matrix in the crab shell and its microfibrillar

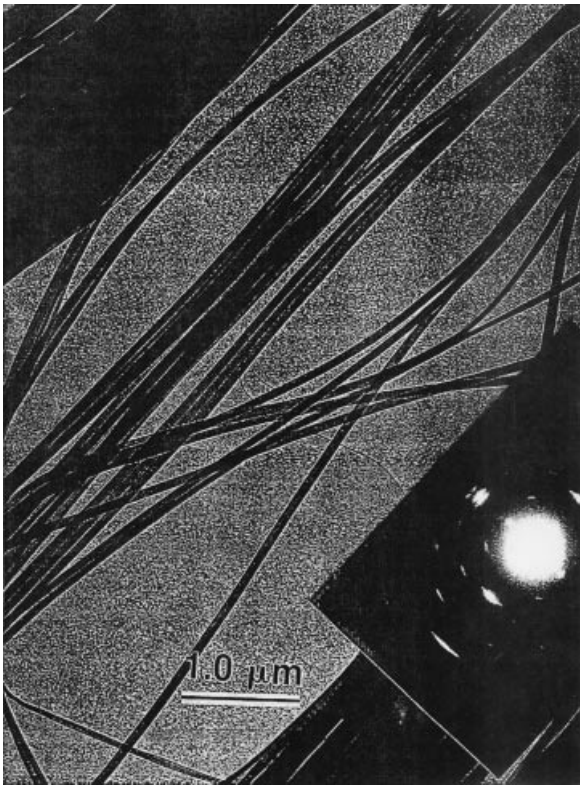

Fig. 2. Chitin usually occurs in the form of microfibrils in many organisms. Shown here are β-chitin microfibrils from *Tevnia jerichonana*, a deep sea hydrothermal vent worm. The insert is a typical electron diffractogram oriented with respect to the bundle. The image was obtained by transmission electron microscopy (TEM) after protein removal (22). Reproduced with permission.

structure. This chitin is termed α-chitin because of its crystal structure (see next section). Treatment of this chitin with 50% NaOH for 1–3 h at 120°C gives a 70% deacetylated chitin (chitosan), which is soluble in many dilute acids. Repeating this step can give deacetylation values up to 98%.

A more reactive form of chitin is obtained from squid pens (15). This β-chitin (see next section) is easily isolated and has a looser chain packing in the crystal, accounting for its higher reactivity and solubility in formic acid. The isolation of β-chitin is accomplished by first washing the squid pens in 1 *M* HCl for 12 h, followed by a 12-h treatment with 2 *M* NaOH. The final step is to heat the pens at 100°C for 4 h in fresh 2 *M* NaOH. This procedure yields 35% chitin from the mass of the pens. The degree of acetylation may be up to 92%.

Properties

Physical. Chitin occurs naturally as one of three crystalline forms, known as α-, β-, and γ-chitin. The unit cell parameters, determined by x-ray diffraction,

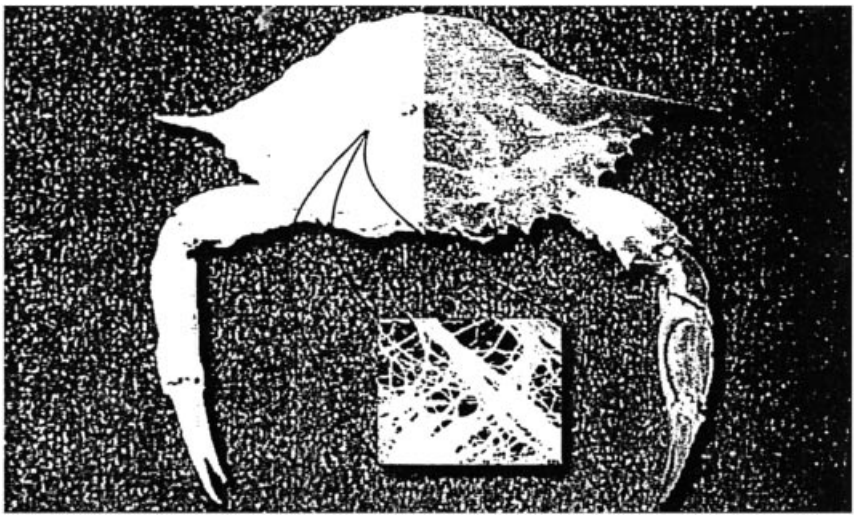

Fig. 3. Chitin and chitosan are commonly isolated from the shells of crab and shrimp. On the right-hand side is the original, cooked crab shell. On the left-hand side is the underlying matrix of chitin, after the proteins and minerals have been removed. Chitin is biosynthesized as an ordered assembly of chains yielding microfibrils, which are seen in the scanning electron micrograph insert. The scale bar in the insert is 2000 nm.

are given in Table 2. The α- and γ-chitin forms are defined as antiparallel stack unit cell structures. The β-form is similar to Cellulose I and assigned a parallel stack structure (16). Chitin is mostly found as either the α- or β-form. The α-form has a strong, three-dimensional hydrogen bond network, which makes the swelling and dissolution of α-chitin difficult. The β-form lacks hydrogen bonding between the stacked planes of the parallel chitin chains. This allows for the easy formation of hydrates and accounts for the higher reactivity of the β-chitin.

Chitosan is also found in different crystalline or polymorphic forms. The unit cell dimensions for these different forms are shown in Table 2. They are obtained by different processing conditions. Chitosan is not usually found completely deacetylated; hence, it has some of the characteristics of a random copolymer. When the deacetylation of the chitin is less than 90%, the crystallization is hindered, and the chitosan has a lower degree of crystallinity than the original chitin.

Table 2. Unit Cell Parameters for Chitin and Chitosan

			Unit cell parameters			
Form	Source	Density, g/cm^3	a, nm	b, nm	c, nm	Reference
α-Chitin	Lobster tendon	1.46	0.474	1.886	1.032	26
β-Chitin	Diatom spines	1.46	0.485	0.926	1.038	27
γ-Chitin	Loligo stomach	1.47	0.47	2.84	1.03	16
Chitosan I	Shrimp shell	1.23	0.776	1.091	1.03	28
Chitosan II	Shrimp shell	1.18	0.44	1.00	1.03	29

The two polymeric characteristics that are the most important for chitin/chitosan solubility are the degree of deacetylation and the molecular weight. Chitin is insoluble in most solvent systems. Chitosan, having at least 50% of its repeat groups deacetylated, is soluble in aqueous acidic solution existing as a randomly coiled cationic polyelectrolyte. Chitin and chitosan have an extensive hydrogen bonded network in the solid state, requiring solvents which either induce interchain repulsions or disturb intermolecular hydrogen bonding for dissolution.

Protonation of the amine group found in the deacetylated repeat units of chitosan provides a means of introducing interchain coulombic repulsions promoting dissolution. Highly deacetylated chitosan, having a pK_a of approximately 6.5, requires a pH lower than 6 for complete dissolution. However, with increasing acetyl content the pK_a of residual amine groups increases and is believed to approach a value slightly greater than 7.5 (29). As a result of this pK_a shift, chitosan with a degree of deacetylation of 50% is soluble in neutral water. Upon further increases in acetyl content, the interpolymeric attractions dominate, and the material (chitin) is insoluble in water with the addition of acid despite the protonation of accessible amine groups. Chitosan is not soluble in diprotic acids such as sulfuric acid. The divalent sulfate anion facilitates interchain ionic attractions preventing dissolution and forming ionic cross-links.

Chitin is soluble in *N*,*N*-dimethylacetamide–5% LiCl, *N*-methyl-2-pyrrolidone–5% LiCl, and mixtures of trichloroacetic acid with chlorinated hydrocarbons (ie, chlorinated methanes and ethanes) (30). Generally, the solubilities of chitin and chitosan decrease with increases in molecular weight. Oligomers of chitin and chitosan with a degree of polymerization of 8 or less are water soluble regardless of pH. Many derivatives of chitin and chitosan, which have wide solubility characteristics, have been synthesized.

Chemical. A large number of chitin and chitosan derivatives have been synthesized through modification of the primary (C-6) and secondary (C-3) hydroxyl groups present on each repeat unit, including amine (C-2) functionality existing on deacetylated units (31). Reactions typical of hydroxyl and amine groups (such as acylations with acid chlorides and anhydrides) including urethane and urea formation respectively, are feasible with isocyanates. The primary amine can be quaternized by alkyl iodides or converted to an imine with a variety of aldehydes and ketones that can subsequently be reduced to an N-alkylated derivative. Chitin and chitosan are reactive with a variety of alkyl chlorides after treatment with concentrated NaOH. Important derivatives such as carboxymethylated chitin and chitosan are commonly produced in this manner with the addition of sodium chloroacetate.

Chitin and chitosan have been chemically modified by graft copolymerization using a variety of monomers ("grafting from") and telechelic polymers ("grafting onto"). *"Grafting from" techniques* have predominantly utilized either a free-radical mechanism with vinyl monomers such as styrene, methyl methacrylate, methyl acrylate, acrylic acid, and acrylamide, or a ring-opening mechanism (initiated by free amine groups) with D,L-alanine and γ-methyl L-glutamate *N*-carboxyanhydrides (32). Vinyl grafting has been initiated with techniques involving the ceric ion (Ce^{4+}), Fenton's reagent (Fe^{2+}/H_2O_2), and γ-irradiation. *"Grafting onto"* methods have bonded poly(ethylene glycol) (33) or poly(2-methyl-2-oxazoline) (34) chain ends to the trunk polymer. For example, poly(ethylene glycol)

was synthesized with an activated carboxylic acid chain end capable of forming an amide linkage with free amine groups along the chitin/chitosan backbone. The range of possible chitin and chitosan modifications, using either lower molecular weight reagents or graft copolymerizations, allows modification of chitin and chitosan solubility, miscibility with other materials, conductivity, and moisture absorbency.

Biological. A wide range of hydrolytic enzymes lead to the biodegradability of chitin and chitosan. Within an organism, directed degradation by chitinases are involved in fungal autolysis and the molting of arthropod cuticle. Other chitinases are abundantly secreted into the environments of plants and microbes as part of their defense and feeding mechanisms. In bacteria, chitinases play a role in nutrition and parasitism. The major groups of enzymes degrading chitin and chitosan have been classified and described (4,8–10). Many studies have also utilized lysozyme, an easily obtainable hydrolytic enzyme, found in the lymphoid system of vertebrates. Lysozyme shows hydrolytic activity over a range of deacetylation values for chitin and chitosan.

Generally, the complete hydrolysis of chitin to *N*-acetyl-glucosamine requires the consecutive action of two chitinase enzymes. These are frequently found together in plant and animal species as well as bacteria and fungi. Usually, the chitin is degraded to oligosaccharides and *N*,*N*′-diacetylchitobiose by endochitinase enzymes. Chitobiases then hydrolyze these products to monomeric *N*-acetyl-glucosamine. Exochitinases, which directly degrade chitin to chitobiose, are also known. The same is also found for chitosanases.

In arthropods, synthesis and degradation of chitin occurs at different stages of the molting cycle and is hormonally controlled. During the molt, the rate of chitin synthesis is slowed by molting hormones (ecdysteroids) that also stimulate the production of chitinases. Many animals and marine microorganisms have a high digestive capacity for chitin. In seawater, the presence of secreted chitinases from microorganisms leads to the near total degradation of crustacean chitin in shallow water sediments within 4 months in temperate regions.

Processing

Chitin is usually obtained as a powder or a flake upon isolation from crab shell, fungi, or algae. Further processing is difficult because of the lack of simple solvents for chitin. However, chitosan is easily solubilized and formed into shaped articles such as films (membranes), fibers, and gel microspheres (30,35). Chitosan is conveniently dissolved in an aqueous 5 vol% acetic acid solution, in the form of a cationic polyelectrolyte. This ability to develop basic properties in solution gives chitosan its uniqueness among common polysaccharides. Chitin and chitosan are also easily treated with acids and hydrolytic enzymes to yield useful sugars and oligomers.

Economic Aspects

A worldwide industry has developed around the production and uses of chitin and chitosan. Shrimp and crab shell wastes pose local waste disposal problems

in many areas. The seasonal harvesting of these crustacea has created problems for an economic, year-round chemical production of chitin and chitosan, in some regions though. In the United States, there are several producers who manufacture and import chitosan. These include Vanson, Inc., DCV, Inc., Biopolymer Engineering, Inc., and Marine Polymer Technologies. There are also industries manufacturing chitin and chitosan in many countries in almost every continent. In particular, Japan, China, and Norway have well-established companies. Chitin and chitosan are still in the stage of a speciality chemical and is sold mostly in the form of chitosan powder, at $25–50/kg, depending on purity. The primary uses are in the water treatment, paper, and agricultural industries. It is also sold as a dietary additive worldwide. Speciality producers offer very pure chitin and chitosan derived from algae and squid pen. These are primarily employed in biomedical research and biomedical products.

Specifications and Analytical Methods

Chitin and chitosan are natural products, commercially available from many sources as mentioned previously. It is usually found in the presence of proteins, calcium carbonate, and perhaps other polysaccharides. Thus, its quality ranges from crude extracts to high purity material. Many of the properties of chitin and chitosan are dependent on the degree of deacetylation. The distribution of *N*-acetyl groups in these polymers is also expected to have an influence on the properties.

Most spectroscopic and titration methods have been employed to determine these values and were listed by Rathke (36). The structural differences between chitin polymorphs have been studied by nmr and ir (37,38). Conductometric titrations have been confirmed by solid state nmr to be an accurate but easy method to determine the degree of deacetylation of chitosan (39).

The molecular weight and its distribution are also important. Commercial chitosan samples may have molecular weights up to 4×10^6 Da. The Mark Houwink equation $[\eta] = kM_v{}^a$ is used to obtain a viscosity average molecular weight. However, the values of k and a are most likely functions of the degree of deacetylation (21). Gel permeation chromatography is also suited for the determination of chitosan molecular weight and polydispersity (21).

Health and Safety Factors

The benefits of chitosan as a dietary fiber have been recognized (3,40,41). Chitin and chitosan have very low toxicity. Studies on the oral administration of chitosan indicates that it may have beneficial actions on osteoarthrosis, body weight control, and the lowering of blood plasma cholesterol levels. Chitosan's complexation with bile acids helps block the absorption of lipids. Both materials have been granted approval for different food additive uses for humans and animals in several countries. The corresponding sugars of these polysaccharides, glucosamine, and *N*-acetyl-glucosamine are also of interest. In many circumstances it is these sugars which have the observed biological activity. Tissue and animal studies

indicate that chitin and chitosan promote wound healing and increase immune response, but these claims need to be validated by human clinical trials. Certain medical precautions should be observed, however, with long-term ingestion of high doses of chitosan to avoid potential adverse metabolic effects (3).

Uses

Chitin is mainly used as a powder and as a precursor to chitosan. However, the unusual aminopolysaccharide structure of chitosan has led to many potential applications. The ease of processing chitosan into shaped articles, coupled with its ease of chemical derivatization, makes it a versatile material. The specificity of chitin and chitosan's structure is also important for many biological applications involving the binding and purification of many proteins.

Chitin and chitosan have potential in agricultural applications because of their ability to increase crop yields. The presence of chitosan appears to enhance plant reproduction (42), and coating seeds with chitin/chitosan activates the secretion of plant chitinases into the environment providing extra protection from harmful pests.

Incorporating chitin and chitosan into different aspects of the food industry has received considerable attention (43). The antibacterial and antifungal properties of chitin and chitosan have potential in reducing the amount of synthetic food preservatives. N,O-carboxymethylated chitosan, a water soluble derivative, has also been found to possess antifungal activity. The most probable means of application are either through packaging wraps or directly as food coatings. Chitin and chitosan films are improvements to synthetic wraps as a result of the reduction in oxygen permeability and increased moisture transfer. Chitosan films have also decreased the level of browning in physically damaged fruits.

In regard to nutritional value, chitin and chitosan oligomers have been observed to lower cholesterol and exhibit antitumor activity. "Fat-blockers" containing chitosan are currently on the market (40). The amine groups along the polymer backbone form carboxylate-protonated amine complexes with fats which are subsequently excreted from the body because of chitosan's lack of digestibility in humans.

Chitosan has potential applications in various wastewater treatments (44). Chitosan is a natural chelating polymer as a result of the amine group (C-2) and the adjacent hydroxyl group (C-3), and thus could be used to remove transition metal ions from wastewater streams. Some important factors that affect the level of ion removal are the degree of deacetylation, pH, and surface area of the chitosan substrate. Since protons compete for amine sites, the metal ions can be removed from the chitosan backbone by lowering the pH. Chitosan beads cross-linked with gluteraldehyde appear to be a more practical physical form because of its lack of solubility at low pH and its higher surface area.

Chitosan can be used as a flocculating agent for food processing streams. Having a partial positive charge in water, chitosan can break down food particles comprised of a protein-based colloidal suspension possessing a partial negative charge. Suspended solids can be coagulated by chitosan, collected, and used as a protein source for animal feed.

Anionic dyes can be removed from textile effluent streams at acidic pH with chitosan through protonated amine complexation with anionic dye sites. Phenols are common waste products in paper processing. Application of mushroom enzyme tyrosinase to the stream specifically converts phenols into quinones, which can subsequently be absorbed by chitosan. Toxic polychlorinated biphenols (PCBs), commonly used in plastic processing and lubricants, are a significant source of water contamination. Although the nature of the interaction is not currently known, chitosan treatment shows potential in lowering PCB concentrations.

Research on the use of chitosan for drug delivery indicates promise in oral, parenteral, transdermal, ocular, and nasal applications (45). Generally, chitosan has low toxicity with excellent mucoadhesion properties. Cross-linked chitosan has potential in tablet form because of its low solubility in the stomach. The same effect can be obtained by incorporating hydrophobic coatings on chitosan microspheres. Chitosan gels and films exhibit sustained release of various drugs useful for wound dressings and colon treatments. Many other examples of drug delivery applications of chitosan have been reviewed (46), and chitosan peroral peptide delivery systems have been described (47). Other pharmaceutical applications of chitosan and the mechanisms of action for various *in vitro* and *in vivo* models have been outlined and discussed (48).

The direct application of chitin and chitosan to wounds stimulates several different physiological activities (49). The presence of chitin and chitosan on the wound surface stimulates macrophage activity for the secretion of lysozyme and human chitinase, enzymes which breakdown chitin-based pathogens to prevent infection. The chitin/chitosan present in the wound dressing is thus simultaneously hydrolyzed to chitooligomers, which further stimulate collagen deposition and other macrophage functions, namely nitric oxide and tumor necrosis factor production.

Hemodialysis utilizes film and hollow fiber membranes to remove solutes and water from patients suffering from kidney failures. The excellent fiber and film forming properties of chitosan have led to many studies on its use for this purpose (30,50). Chitosan may be blended with other polymers to give permeability control and to improve blood compatibility.

CHROMATOGRAPHY, AFFINITY

Introduction

One of the most important developments in enzymology has been the introduction of a rapid and highly efficient means of protein purification utilizing the highly selective ability of enzymes to recognize certain biological compounds or their analogues. This technique, termed *affinity chromatography*, involves the immobilization of an appropriate ligand in such a way that the enzyme is still capable of recognizing and binding to the immobilized form of the ligand, whereas "contaminating proteins" have no such recognition. Virtually hundreds of proteins have been purified in this way, using a wide variety of bioligands immobilized in a matrix; enzyme inhibitors, coenzymes, antibodies, and even other enzymes may be useful bioligands in the purification of a particular protein (1). A classification of the types of affinity chromatography is as follows (2):

Bioselective adsorption is the process where the affinity is based on biologically relevant binding. It includes group-specific ligands, eg, lectins and nucleotide cofactors (NAD, AMP), and specific ligands, eg, certain less common cofactors (vitamin B_{12}), receptor proteins, and antibodies as used in immunosorbents.

Chemiselective adsorption is the process where the affinity is based on chemically defined nonbiological interactions. It includes hydrophobic chromatography, ion-exchange chromatography, covalent chromatography (active thiols, Hg^{2+}, etc), and borate complexes.

The basic application of affinity chromatography involves several steps, as illustrated in Figure 1. First, the necessary affinity-chromatographic packing, or bioselective adsorbent, as it may be more appropriately termed, is synthesized. Next, a cell-free extract containing the desired enzyme is prepared. This extract is freed of any endogenous substrate or biomolecule that might compete with the

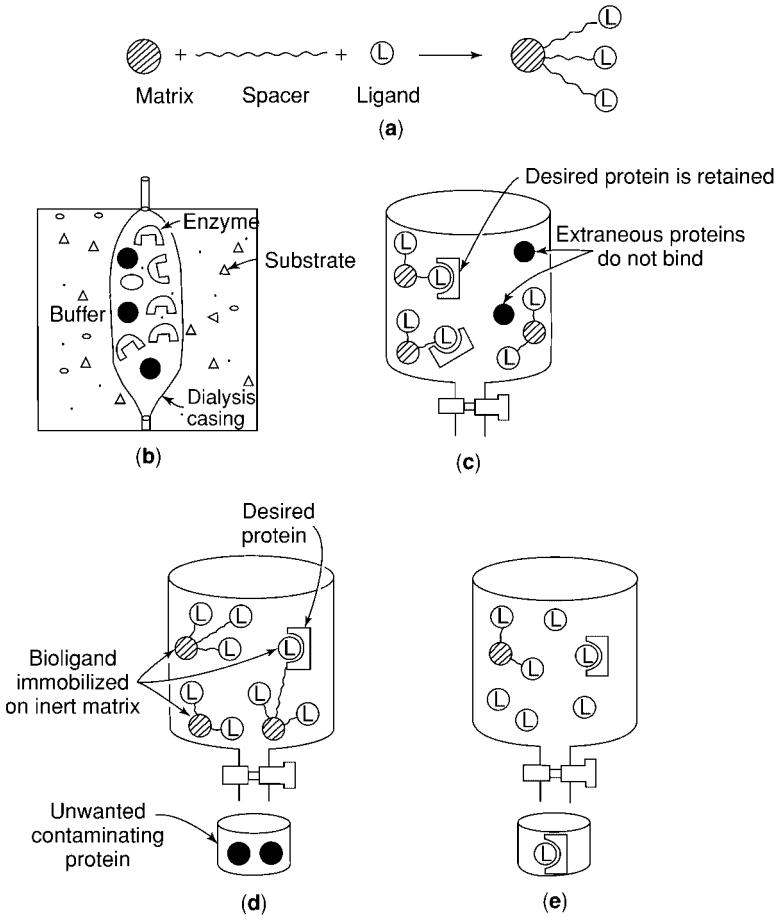

Fig. 1. The steps of affinity chromatography: (**a**) A bioligand is immobilized; (**b**) A crude extract is prepared and freed from endogenous substrate; (**c**) The substrate-free extract is applied to the chromatographic packing of immobilized bioligand from step (**a**); (**d**) Unwanted protein is removed by washing; and (**e**) The desired protein is eluted, possibly with a soluble bioligand (2).

enzyme for the adsorbent. This is normally achieved by dialysis or enzyme precipitation. The crude extract is applied to the column, and contaminating proteins, which ideally have no affinity for the column under the conditions employed, are removed by washing. The protein to be purified remains bound to the column because of its affinity for the immobilized ligand. It is subsequently removed by eluting the column with a solution of the free ligand. Alternatively the enzyme may be eluted by altering the chromatographic conditions, ie, pH, ionic strength, dielectric constant, etc, in such a way that the enzyme no longer retains its affinity for the immobilized ligand.

Efficient purification by affinity chromatography depends on the nature of the ligand, the methods used in the preparation of the chromatographic packing,

the type of inert matrix, and the methods for both attaching the ligand to the matrix and eluting the enzyme from the bioselective adsorbent. Nonspecific adsorption of proteins, which can be defined as the retention of proteins by some general factor, eg, ion exchange, hydrophobic interactions, and charge-transfer complexation, may cause a large variety of proteins to be nonspecifically retained.

Finally, it must be decided whether affinity chromatography is employed primarily for purification or primarily as a method for studying enzyme–substrate interaction. The choice of the final system to be used is governed by the nature of the application.

Matrices

The selection of an appropriate inert matrix is of great importance and depends on the type of separation desired. Large columns, or those employed under high pressure, require beads with high mechanical stability. Affinity purification as a final step following a long series of conventional procedures requires a small column. When affinity chromatography is employed in the last stages of purification as a "polishing" step, high yields of the valuable partially purified enzyme are especially important. Even a small percentage of nonspecific adsorption or protein denaturation on the column would limit the usefulness of the procedure. For this reason a hydrophilic, nonionic matrix with little capacity for nonspecific adsorption is essential.

Nonspecific adsorption must not occur in the "derivatized" matrix, even though the untreated matrix might have considerable nonspecific adsorption. For example, virgin glass adsorbs enzymes in an active form, yet dextran-coated glass or glass treated with hydrophilic silanes exhibits little or no adsorption (4) of ribonuclease and other proteins.

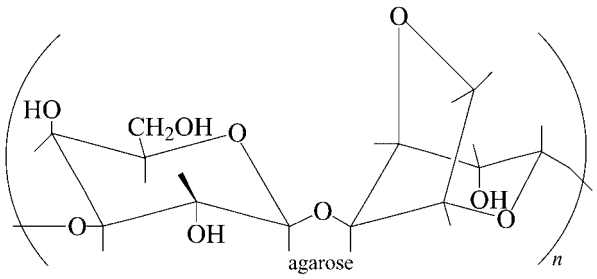
In high performance liquid affinity chromatography (hplac), a rapidly growing technique, the matrix must be mechanically stable and capable of sustaining very high pressures. High pressure chromatography resins of the Trisacryl or TSK-type may supplement the silica-based hplac matrices. Several activated resin forms are commercially available (Pierce Chemical Co., Rockford, Ill.).

The most widely used matrix is beaded agarose, a common gel-permeation chromatography packing used chiefly because of the hydrophilicity of the underivatized matrix (5). It might be thought that derivatized agarose would not have more nonspecific adsorption than its untreated counterpart. However, this is not the case, and this observation confirms that it is the derivatized chromatographic packing, and not the matrix, that must possess the appropriate properties for a bioselective adsorbent.

In addition to mechanical stability and nonspecific adsorption, the chemical stability and ease of derivatization of the matrix must be considered. Agarose provides the least nonspecific adsorption, fair chemical stability, and a rather poor and often limiting mechanical stability whereas controlled-pore glass provides the greatest mechanical stability and ease of derivatization, with acceptable capacity but often with unacceptable amounts pf nonspecific adsorption.

Other matrices have certain advantages and disadvantages for specific applications. Regenerated cellulose, polyacrylamide, and cross-linked dextrans generally yield high capacity adsorbents as defined chemically, ie, the amount of ligand bound per gram, but often much of their surface is not available to large macromolecules; thus the effective capacity, ie, the amount of ligand accessible to a particular enzyme, is generally low. In other words, many of the ligands are buried in the matrix in such a way so as to be inaccessible to the enzyme.

Agarose. This material is among the most useful matrices for affinity chromatography. It is a linear polysaccharide containing alternating residues of D-galactose and 3,6-anhydro-L-galactose (6).



Agarose is prepared by mixing a hot aqueous solution of specially purified agar (2–6%) with an organic solvent, eg mineral oil, and a small amount of detergent. The aqueous solution is mixed rapidly with the organic phase to form droplets that, upon cooling, form agarose beads (7). These beads are fragile even to the touch. Cross-linking with epichlorohydrin increases their strength but decreases porosity.

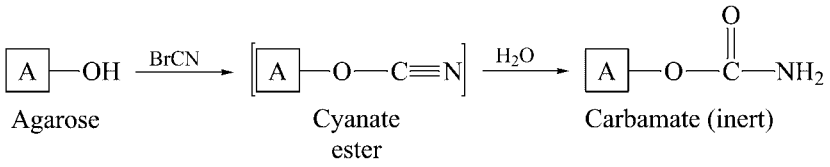
The agar base, and thus agarose, is a naturally occurring polysaccharide with many ionic residues, chiefly carboxylate and sulfate, which are removed by hydrolysis and reduction. Commercial agarose beads contain up to 0.37% sulfur (8), indicating the presence of a significant number of ionic groups in commercial agarose.

Agarose also presents other problems: It lacks thermal stability, cannot be dried or frozen readily, and shrinks and swells upon changes of ionic strength or dielectric constant of the medium, especially in the presence of organic solvents. Thus, commercial agarose is completely soluble in dimethyl sulfoxide at 100°C or in 4 *M* sodium iodide, whereas agarose cross-linked with epichlorohydrin is essentially unaffected under the same condition (<1% soluble) (8).

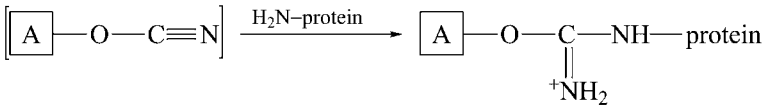
Agarose is frequently used as the cyanogen bromide derivative. This activated matrix reacts with proteins and other molecules with amino groups (5,9–11) and covalently couples them to the agarose surface.

The most serious problem encountered with agarose is the formation of an unstable isourea function from the reaction of cyanogen bromide-activated agarose with primary amines. This isourea forms a positively charged derivative:

Activation:



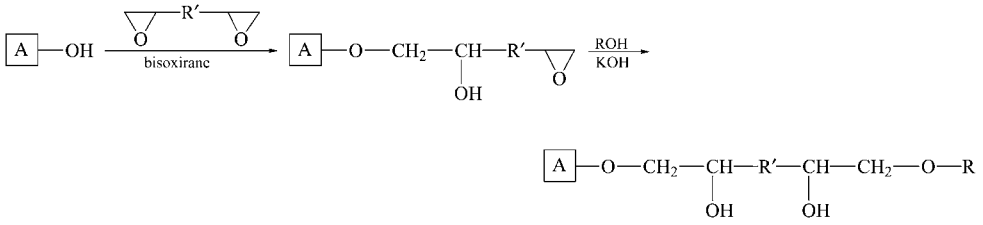
Coupling:



Until 1973 the ionogenic nature of cyanogen bromide-activated agarose was not known, and many early investigations using this method must be examined closely. Furthermore, it should be noted that cyanogen bromide is toxic and presents an explosion hazard when impure.

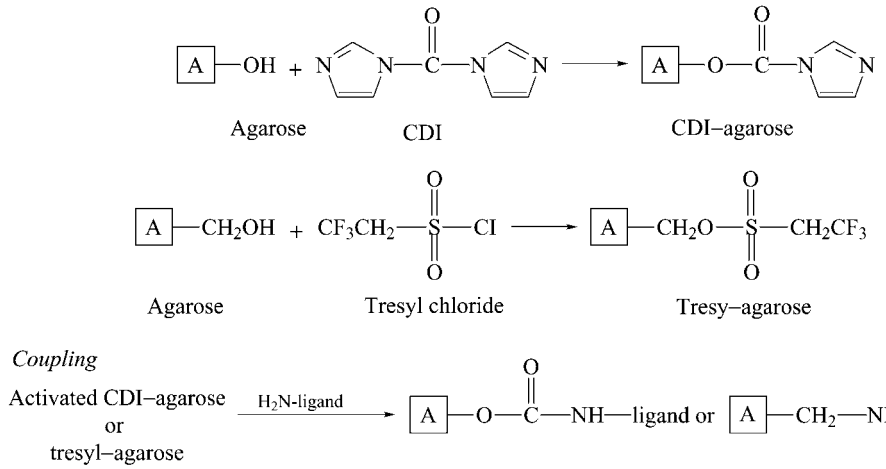
Derivatized agarose often possesses ion-exchange properties in addition to, if not in place of, bioselective adsorption. In many instances it is suspected that what was hitherto thought to be a purification based on bioselective adsorption, or affinity chromatography, was in reality a specifically tailored ion-exchange chromatography, which may or may not have given better results than classical ion-exchange methods (12).

Even though there is some question about the mode of action of some bioselective adsorbents based on cyanogen bromide activation, enzymes can be purified by ligands coupled to cyanogen bromide-activated agarose. However, there are many methods for derivatizing agarose that are not ionogenic. Coupling can be employed by means of bifunctional reagents, including bisoxiranes, eg, 1,4-bis(2,3-epoxypropoxy)butane, and diphenyl sulfone (13). The reactions of bisoxiranes are shown below:

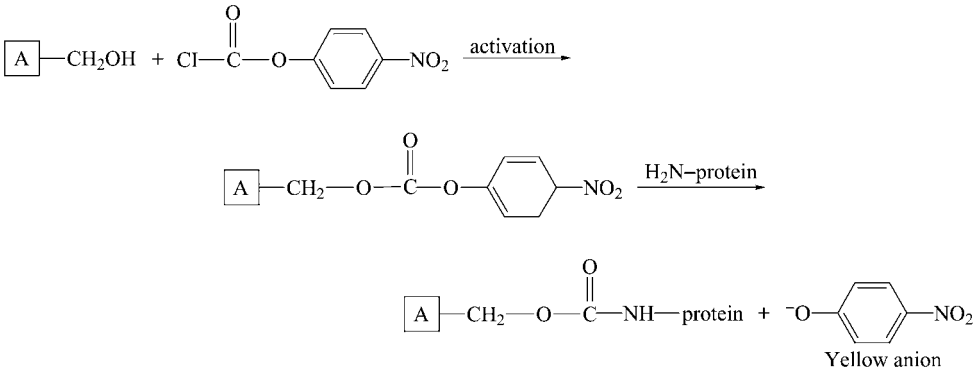


where R is the ligand to be attached to the agarose.

Other activation methods are performed with carbonyldiimidazole or tresyl chloride (14); both yield uncharged materials. Coupling with carbonyldiimidazole (CDI) is very rapid, but the bond formed, a substituted carbamate, is not as stable as the secondary amine formed with the slower tresyl chloride.



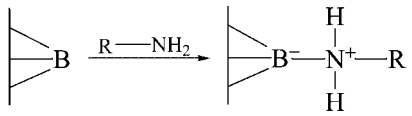
A group of activation reagents similar to CDI have been developed in Israel (11). They resemble phosgene and produce immobilized enzymes with bonds identical to those produced by CDI. One of their advantages is that *p*-nitrophenyl chloroformate can be used to prepare an activated matrix that has the property of releasing the yellow *p*-nitrophenol anion as coupling occurs, thereby permitting one to easily monitor the reaction visually:



Controlled-Pore Glass. Many bioselective adsorption separations can be performed on columns of porous glass with excellent results (2).

Controlled-pore glass was developed when it was discovered that borosilicate glass heated to 700–800°C separates into borate and silicate phases (15,16). The borate phase is removed by an acid etching process, leaving a porous 96% silica network. These pores, ca 4.5 nm in diameter, can be enlarged by additional alkali etching to produce porous silica beads with nominal pore diameters of 4.5–2500 nm. The pore distribution (±10%) is the most uniform of any porous chromatographic support. Controlled-pore glass with pore diameters above 250 nm are generally too friable for chromatographic application, although large-pore-diameter glass, up to about 400 nm, has been employed.

Another type of inorganic matrix that is similar to controlled-pore glass but considerably less expensive can be prepared by fusing inorganic compounds such as finely pulverized silica and zirconium oxide to form a porous body. Although the pore distribution is less uniform, the surface composition is almost uniform; in the case of silica, the surface is nearly 100% silica. Controlled-pore



glass is 96+% silica, but alkali leeching facilitates the migration of boron to the surface, which may in fact contain as much as 30% boron (15). The numerous boron Lewis acid sites that result may adsorb ammonia or nucleophiles such as protein amines to yield positively charged centers, both of which lead to nonspecific adsorption

Early synthetic procedures for preparing glass for affinity chromatography or enzyme immobilization involved refluxing γ-aminopropyltriethoxysilane with the beads (17) under various conditions; the beads were coated with multiple layers of silane, which were not as stable as desired. A more stable layer is obtained by employing aqueous silanization at pH 3.75 and 75°C (17). Nonetheless, aminoalkyl glass, or any other silanized glass material, is unstable in aqueous solution at pH values much above 7. Similar materials prepared from zirconium oxides are, conversely, stable in base and labile in acid.

Some derivatives of aminopropyl glass exhibit nonspecific adsorption in certain enzyme preparations, others do not (18). Nonspecific adsorption is minimized by coating the glass with glycidoxypropyltrimethoxysilane, followed by appropriate treatments to yield a highly stable glass with a hydrophilic surface because of the presence of hydroxyl groups in the coating. This surface can be further derivatized in a manner similar to that used for agarose, although the same reservation expressed above for cyanogen bromide activation of agarose, namely its ionogenic nature, applies to glycidoxy controlled-pore glass.

β-Galactosidase has been purified from cell-free extracts of *Aspergillus niger* (19) by using a bioselective adsorbent consisting of the inhibitor β-aminophenyl-β-D-thiogalactose coupled to controlled-pore glass by means of an amide linkage using a soluble carbodiimide as the coupling reagent. However, the same matrix prepared with aniline as a ligand in place of the inhibitor results in a substantial purification of β-galactosidase (20). The aniline-modified material has a capacity 75% of that containing the bound inhibitor and produces β-galactosidase with about 50% of the specific activity of that produced with the affinity packing consisting of inhibitor-controlled-pore glass. A combination of ionic and hydrophobic forces results in a reasonably selective adsorbent whose function is not totally based upon enzyme-active site–inhibitor interaction. The exact nature of the interactions are not known.

Deoxyribonucleic acid (DNA) and ribonucleic acid (RNA) polymerases have been separated and purified on DNA-glass columns, effecting more rapid purification than affinity chromatography on DNA–cellulose (21,22). The DNA is coupled

to aminopropyl glass beads, using the method for covalent coupling of DNA to cellulose with a soluble carbodiimmide as the coupling reagent (23).

Silica and porous glass can be used as matrices for hplac (24–26). In this technique, where mechanical stability under pressure is critical and pH changes are transient, porous silica matrices are useful.

Cellulose. A widely used DNA affinity-chromatography procedure (21) depends upon the physical trapping of DNA fibers in a mesh of cellulose fibers. The DNA–cellulose is prepared by drying DNA and cellulose together in an appropriate buffer, followed by washing the untrapped DNA. However, as one might expect from a method involving physical trapping, DNA slowly elutes.

Bulk cellulose is a poor affinity-chromatographic matrix; its principal advantage is its low cost. This is rarely an overriding consideration since the enzymes to be purified are usually expensive. Cellulose was employed in 1953 in one of the earliest affinity-chromatography separations, where tyrosinase was purified on a column of aromatic cellulose ethers (27). Currently, cellulose (28) or related polysaccharides (29) are used in a number of applications as a bioselective adsorbent including DNA–cellulose for the purification of DNA-binding proteins.

Polyacrylamide. Polyacrylamide is familiar to most biochemists, since it serves as the support for polyacrylamide gel electrophoresis and a medium for gel-permeation chromatography (see also ACRYLAMIDE POLYMERS).

For the latter purpose, preformed spherical beads, Biogel-P, are available from Bio-Rad Laboratories, Richmond, California. These beads are hydrophilic and chemically stable and have a uniform pore diameter and mesh size. These desired traits, and the fact that the polyacrylamide beads are readily derivatized, suggest that it should be an excellent affinity-chromatographic support. In fact, it is not often used because the beads are not sufficiently porous to permit proteins to have access to ligands bound within the beads. The lack of normal porosity for polyacrylamide beads is aggravated by the shrinkage of the gel occurring upon derivatization. As a result, the effective capacity of polyacrylamide gel is very low for all except the smallest enzymes.

Several derivatives of polyacrylamide have been formulated that have the capacity for much larger pore sizes and less shrinkage upon derivatization. Trisacryl, a product of LKB–IBF, is the polyamide of Tris, tris(hydroxymethyl)aminomethane, and acrylic acid. It is a promising matrix material that can be derivatized by all of the methods available for agarose but with far greater mechanical stability. Czechoslovakian investigators have prepared other hydrophilic gels based on hydroxyalkylmethacrylates (30). These supports exhibit increased porosity, with exclusion limits of up to a molecular weight of 10^8.

An interesting application of polyacrylamide has been in the technique of affinity electrophoresis, where enzymes are purified on a support medium containing an immobilized bioselective adsorbent (31). This technique has two advantages over affinity chromatography: A highly porous polyacrylamide can be employed because the material does not assume a spherical form but is cast in a glass or plastic supporting-gel tube; and the separation of two or more substances with similar affinity for the same ligand is greatly increased since charge and gel-permeation effects, as well as bioselective adsorption, contribute to the migration of proteins. Phytohemagglutinins have been purified by electrophoresis on acrylamide-derived gels prepared from alkenyl-*O*-glycosides and a

bisacrylamide (32). The phytohemagglutinins have also been separated by bioselective adsorption chromatography with a similar glycoside-containing polyacrylamide gel derivative (32).

Other Matrices. A large number of other matrices have been employed, including starch (33), cross-linked dextrins (34,35), a vinyl maleimide polymer (36), chitin (37), mannan (38), and insolubilized proteins (39). The number of potential matrices is almost limitless, and most of the matrices used for immobilization of enzymes have potential application in bioselective adsorption. Among these are nylon (40), metal oxides (41), maleic anhydride–ethylene co-polymers (42), and polystyrene derivatives (43). Few of these have been used because of their potential for nonspecific adsorption either by charge, as with the metal oxides, or by hydrophobic interactions (as would be the case with polystyrene). The derivatized matrix must be free of nonspecific adsorption. Proper derivatization can eliminate nonspecific adsorption or, as with cyanogen bromide activation, create nonspecific adsorption in matrices having no prior nonspecific adsorption properties.

Ligands

The ligand to be immobilized can be an inhibitor, a substrate, substrate analogue, coenzyme, or any other biomolecule with an affinity for a specific site (active site, allosteric site, membrane-binding site, etc) on the protein to be purified. Such biomolecules are usually small (mol wt 500), although macromolecules have been successfully employed, eg, with the purification of soybean trypsin inhibitor on immobilized trypsin as a bioselective adsorbent. The precise type of ligand for any purification is dictated by the nature of the enzyme and the aim of the investigation.

The ligand must have sufficient affinity for the enzyme being purified to retain it on the ligand–matrix complex (44). In addition, the bioselective adsorption of the enzyme to the ligand must exceed the nonspecific adsorption of the proteins to the matrix under the conditions of the preparation. Even under optimum conditions, some nonspecific adsorption is certain to occur. Enzyme adsorption is due to a bioselective component and heterologous, nonspecific factors (45).

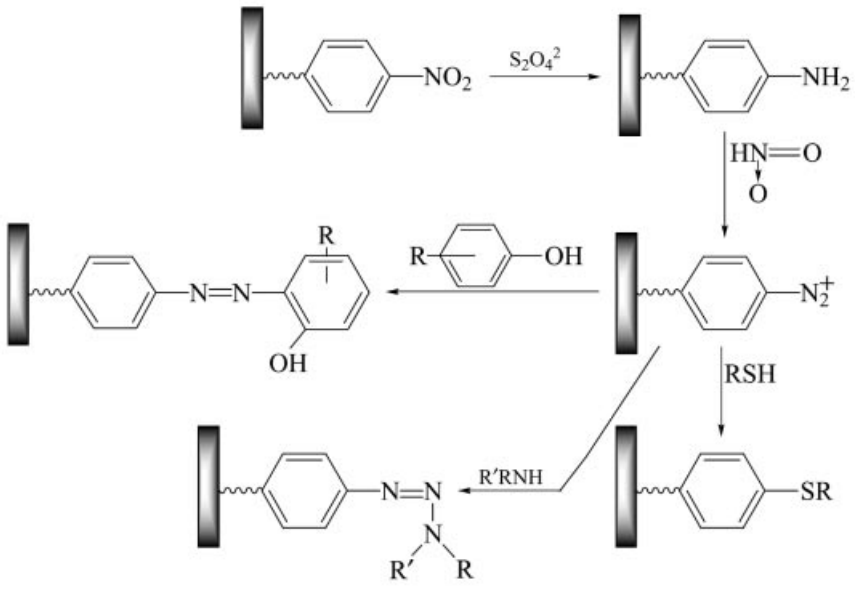
By altering the chromatographic conditions, eg, ionic strength, pH, and dielectric constant, the ability of the enzyme to be specifically adsorbed is enhanced and/or the nonspecific adsorption is decreased. For example, the bioselective affinity of lipoamide dehydrogenase on propyllipoamide glass has been shown to increase with the addition of 10% acetone to the aqueous enzyme solution.

A good example of the use of an organic solvent in the elution buffers to eliminate nonspecific binding is the purification of lactate dehydrogenase on N^6-(6-aminohexyl)-AMP-agarose (46). When lactate dehydrogenase is purified on this bioselective adsorbent, yields of only 60% are obtained by elution with the reduced form (NADH) of nicotinamide adenine dinucleotide (NAD^+). Addition of ethylene glycol, and thus further alteration of the dielectric constant of the elution buffer, was shown to change the conformation of the enzyme, thus lowering its affinity for the immobilized (NAD^+) analogue. The enzyme was eluted from the column with buffers containing about 43% ethylene glycol, with a recovery of about 45% of the activity.

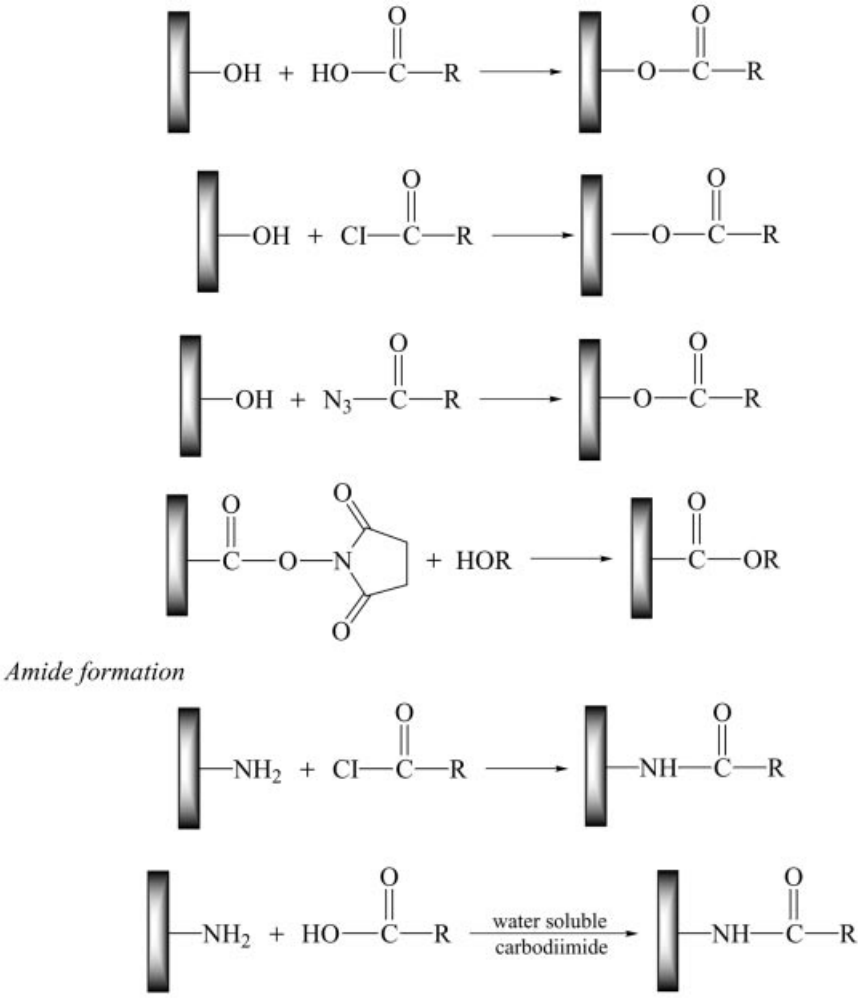
The corollary to the requirement of a sufficiently large ligand–enzyme attraction or binding energy for enzyme retention is that the enzyme–ligand binding must be loose enough to permit dissociation of the enzyme from the column under appropriate conditions. Such binding can be so tight that enzyme dissociation is extremely difficult. For example, uterine estradiol-receptor proteins can be removed from serum or uterine cellular extracts by exposure to estradiol coupled to various matrices, eg, cellulose, glass, agarose, or a vinyl maleimide polymer (36,44,47,48), but estradiol-receptor protein is not eluted from the bioselective adsorbent by an appropriate method, eg, elution with free estradiol, changes in pH or ionic strength, or even the use of mild denaturants. Normal affinity chromatography is precluded by the inability to elute the purified enzyme-immobilized enzyme complex. Purification can be successful using estradiol immobilized on agarose by an azo linkage. Uterine cell extracts are applied to this column and unbound proteins are removed. The estradiol-receptor protein–adsorbent complex is then treated with hydrosulfite to cleave the azo linkage between the agarose and the coupled estradiol, and the resulting estradiol-receptor complex is freed of estradiol by extensive dialysis.

Attachment. Numerous methods of attachment of ligands or spacer arms to the appropriate matrix are given in References 44 and 49–52. Attachment must be performed in such a way that few charged, ionogenic, or hydrophobic residues remain after derivatization. This fact has only recently been appreciated, and therefore must be kept in mind when reviewing the earlier literature. Cyanogen bromide or bisoxiranes can be employed in reactions similar to those shown earlier for matrix activation. Other methods include azo coupling (51), ester formation (51,52), and amide formation (52).

Azo coupling



Ester formation



Spacer Arms between Matrix and Ligand. Although a ligand may be directly attached to an activated matrix, an intervening organic group usually serves as the point of attachment and/or as a "spacer" or "arm" to separate the ligand from the matrix. For example, when a series of eight agarose–insulin complexes were used for the purification of insulin-receptor protein, the derivative with the longest spacer arm was the most effective (53). Similarly, guanine deaminase was not retained by the inhibitor, 9-phenyl-guanine, when it was bound directly to cyanogen bromide-activated agarose, whereas it is retained when the affinity packing contains a—OCH_2CH_2—spacer arm between the ligand and the matrix (54).

The spacer arm positions the ligand a certain distance from the matrix in order to reduce steric interference from the matrix (see Figs. 2a and 2b). Occasionally a spacer arm may interfere with the bioselective adsorption process because hydrophobic ligands fold back (Fig. 2c).

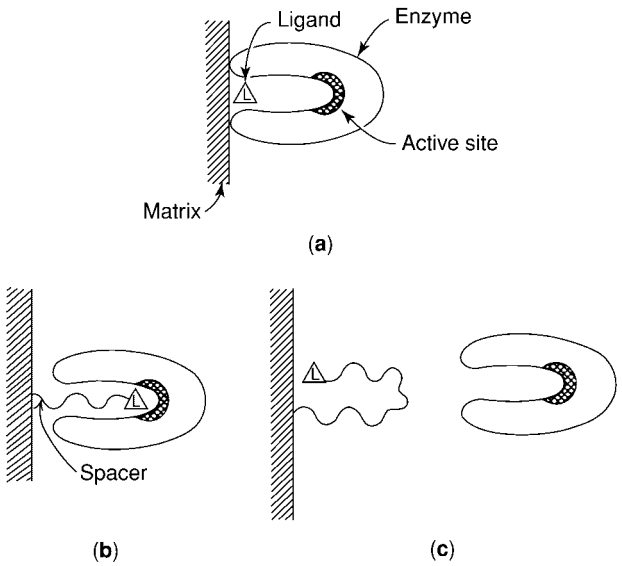


Fig. 2. (**a**) Direct ligand attachment, little or no ligand–enzyme interaction; (**b**) Ligand attachment through a spacer molecule, true ligand–enzyme interaction; and (**c**) Spacer arm too long, the effective distance of ligand from matrix is too short to permit adequate ligand–enzyme interaction.

Spacers are not always needed, and if possible, should not be incorporated in the packing since they can contribute to nonspecific adsorption. Early investigators often ignored spacer–enzyme interactions, and many results are obscured by the ion-exchange effect of spacers. Ion-exchange has been observed when neuraminidase is purified on a column of *p*-aminophenyloxamic acid coupled to agarose. Neuraminidase was initially reported to be retained (55) and specifically eluted from such a column at pH 5.5, but it has since been shown that these preparations yield neuraminidase contaminated with hemagglutinin, hemolysin, and phospholipase C (56). If the purification is performed at pH 7.5, only the sialidase is retained by the column. This suggests strongly that chiefly ion exchange is operating at pH 5.5; at pH 7.5 bioselective adsorption predominates.

On the other hand, the use of long hydrophobic side chains as spacers may lead to nonspecific hydrophobic protein–spacer interactions. These observations show that the spacer, as all other components of the system, must have minimal interaction with protein molecules. They also demonstrate that appropriate controls are required to demonstrate that the chromatographic separation is solely a result of bioselective adsorption.

Hydrophobic Chromatography. The observation that affinity chromatography separations were attributed chiefly to hydrophobic interaction between the spacers and one or more enzymes (57) stimulated the development of so-called hydrophobic chromatography (58). Similar to ion exchange, hydrophobic chromatography depends upon chemiselective adsorption, in this case hydrophobic interaction between the enzyme and an alkyl or aromatic arm bound to an agarose matrix. Affinity chromatography on such materials frequently

yields active enzyme preparations in cases where conventional ion-exchange chromatography results in substantial, if not total, enzyme denaturation. Thus, α-isopropylmalate isomerase was purified in the presence of high concentrations of ammonium sulfate and glycerol, both of which stabilize the enzyme (59). The glycerol serves to weaken the affinity of the enzyme for the matrix, whereas ammonium sulfate increases binding.

Applications

Applications of affinity chromatography include (60)

(1) Protein purification
   a. Enzymes
   b. Antibodies and antigens
   c. Binding or receptor proteins
   d. Complementary proteins
   e. Repressor proteins
(2) Separative procedures
   a. Cells and viruses
   b. Denatured and chemically modified proteins from native proteins
   c. Nucleic acids and nucleotides
(3) Concentration of dilute protein solutions
(4) Storage of otherwise unstable proteins in immobilized form
(5) Investigation of kinetic sequences and mechanisms
(6) Medical applications
   a. Extracorporeal adsorbents
   b. Immunoassays

The most spectacular applications of affinity chromatography are in therapeutic and clinical uses. For example, immunoadsorption chromatography has been used to treat familial hypercholesterolemia (61) by passing the hypercholesterolemic blood through an extracorporeal shunt consisting of a blood cell separator and, on the plasma side, an immunosorbent column containing antibodies to plasma low density lipoprotein (LDL), and finally back to the blood supply.

Because elevated blood cholesterol concentrations, which cause heart attacks in the victims, are directly related to high LDL levels, the removal of LDL-cholesterol in the extracorporeal shunt effects considerable relief from hypercholesterolemia. After saturation, the immunosorbent anti-LDL column is removed from the extracorporeal shunt and regenerated by elution of the LDL with glycine–HCl buffer at pH 3.0 (see Fig. 3).

Other important clinical applications include solid-phase (heterogeneous) immunoassays (62). These are widely used in therapeutic drug monitoring, pregnancy testing, and allergy testing, among others, as well as in research.

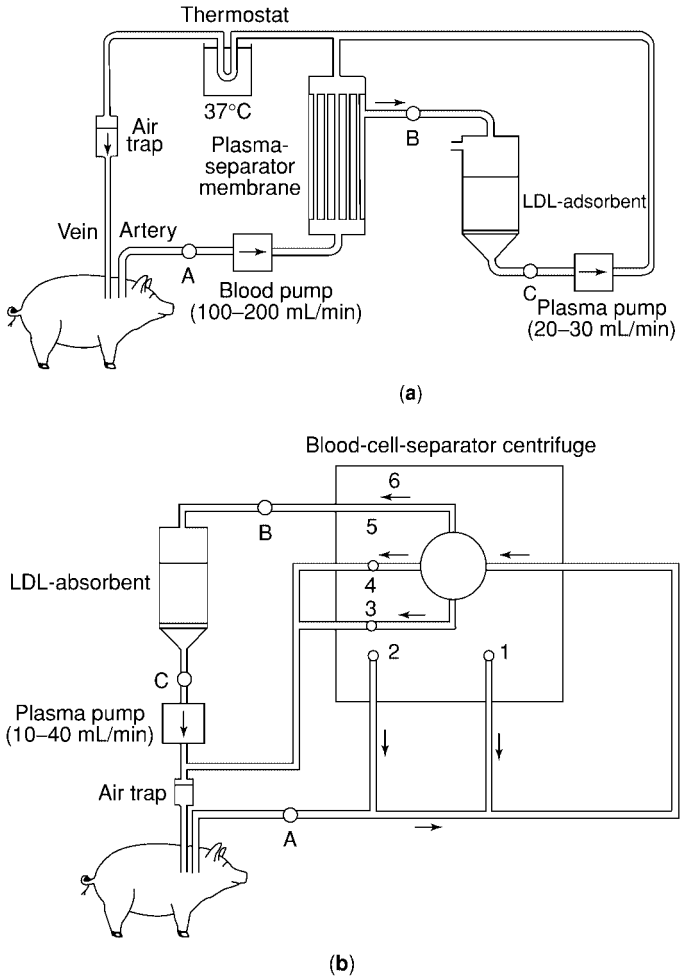

Fig. 3. Plasma-separator-membrane system and LDL adsorbent (**a**) and the continuous-flow blood-cell-separator centrifuge and immunoadsorbent column (**b**) in the arteriovenous shunt. Samples were derived from the flow system at A, B, and C in time intervals of 40 min. Pumps of the blood-cell-separator centrifuge (**b**): 1, citrate anticoagulant (1–3 mL/min); 2, heparin (1 mL/min, 80,000 units/L of saline); 3, leukocytes; 4, erythrocytes (10–40 mL/min); 5, plasma (10–40 mL/min); 6, lubrication (1 mL/min, 2000 units of heparin/L of saline) (51).

The largest single application of affinity chromatography is the purification of enzymes and other proteins. As the biotechnological revolution has proceeded, the demand for new DNA-related enzymes has increased. Many of these are only available by means of DNA-affinity chromatography. For example, thermophilic DNA-ligase can be purified (63) from *Thermus thermophilus*, using DNA–cellulose chromatography as the key step. This enzyme, unlike many classical DNA ligases, is extremely heat stable and withstands 37°C for 1 week and 65°C for 2 days. This is only one of hundreds, if not thousands, of enzymes prepared by means of affinity chromatography that have been commercialized or have commercial potential.

An area of growing importance is the purification of fusion proteins produced by fusing the coding sequence for a desired protein with a second sequence, or "tag," engineered for the future purification of the fusion product. Usually a unique sequence is inserted between these two such that the desired protein can readily be cleaved from the tag using a very selective protease.

While many such tag sequences exist, the most popular is a poly-6-histidine that readily binds via a chemiselective process to an immobilized metal ion chelating column or "IMAC" (64,65).

Excellent examples are the purification of recombinant chloramphenicol acetyltransferase, dihydrofloate reductase, and green fluorescent protein, each one of which was fused to a natural polyhistidine tag consisting of a 19 amino acid sequence from lactate dehydrogenase (66). All three fusion proteins were purified on a Co^{2+}-carboxymethylaspartate agarose "Superflow." The latter is synthesized from Superflow agarose, which is one of the new generation highly cross-linked matrices produced for commercial high flow rates and high dynamic capacities. Purities greater than 95% could be obtained with yields greater than 75%.

The enzyme β-galactosidase was purified directly from crude cell extracts using expanded bed chromatography on another second generation matrix, Ni^{2+} loaded streamline chelating resin. The natural histidine content of the enzyme permitted the enzyme to be recovered in almost 90% yield and 5.95-fold purification from a crude unclarified cell extract (67).

β-Galactosidase, the enzyme missing in Gaucher's disease, has been the subject of numerous affinity-chromatographic preparations, both because of its clinical importance and its potential use in the food industry. Reports on β-galactosidase purification by affinity chromatography have been obscured because a weak inhibitor, *p*-aminophenyl-β-D-thiogalactose, was used as ligand in many of the earlier studies. These purifications of this enzyme using this inhibitor occur through a combination of ion-exchange and hydrophobic chromatography (12,57). For example, β-galactosidase was purified on alkyl amine-glass coupled to *p*-aminophenyl-β-D-thiogalactose via malonic and azelaic spacer arms (20). With a control column containing aniline coupled to the controlled-pore glass in the same way as the inhibitor, significant purification of the enzyme was obtained. Similar results were found with aniline, or the inhibitor *p*-aminophenyl-β-D-thiogalactose, coupled to agarose or glass by means of an anilide or azo linkage.

A growing tendency in affinity chromatography is to utilize combinatorial libraries and phage display techniques to identify new ligands for protein purification.

For example, the recombinant human insulin precursor protein, M13, has been purified by using a biomimetic ligand produced using a combinatorial system (68). Initially the x-ray structure of the protein was used to design a ligand that putatively would bind to a known portion of the protein sequence. This was followed by combinatorial synthesis of a group of ligands similar to the designed ligand based on the reaction of various amines with cyanuric acid (trichlorotriazine) bound through one of its reactive chlorine residues to amino agarose. The amines reacted sequentially with the remaining reactive chlorine residues, yielding completely substituted triazines bound to agarose. When these were screened for their M13 protein binding ability, the result was an affinity matrix used to purify the protein to over 95% purity with a recovery above 90%.

Similarly small protein ligands have been created by selection from randomized Protein A receptor domain using phage display selection techniques from about a 40-million-member library (69). The selected peptides, termed *affibodies*, were so stable that the peptides, immobilized on HiTrap NHS Sepharose, could be repetitively sanitized by treatment with 0.5 *M* sodium hydroxide.

Lastly, affinity chromatography has been utilized as a basic research tool to study proteins and enzymes. In one such study heparin–agarose was used to purify the heparin–binding domain of platelet thrombospondin (70). The thrombospondin was first purified from outdated blood platelets using successive affinity chromatography on heparin–agarose and gelatin–agarose. The purified enzyme was then partially proteolytically digested with thermolysin or plasmin. The lysate was chromatographed on heparin–agarose to yield purified heparin-binding fragments.

Similarly, the dissociation constant of staphlococcal nuclease was determined for free and matrix-bound thymidine-3′-(*p*-aminophenylphosphate)- 5′-phosphate, a competitive inhibitor of staphlococcal nuclease (71). The dissociation constant for the soluble ligand that was determined by using quantitative affinity chromatography closely correlated with the value determined by traditional techniques. An affinity chromatographic method was used for kinetic studies of lactate dehydrogenase (72). The enzyme was applied to a bioselective matrix consisting of oxamate covalently coupled to agarose in the presence or absence of the reduced form (NADH) of NAD. With NADH present at concentrations of 10^{-2} *M* or higher, the enzyme was retained, but when NADH was removed from the elution buffer, the enzyme was eluted. This confirms the previous hypothesis of a compulsory-ordered mechanism for lactate dehydrogenase, that is, a mechanism in which NADH binding must precede substrate binding. Further studies using the same procedure demonstrated that the nicotinamide portion, but not the adenosine portion, of NADH was needed for the substrate–enzyme interaction.

Immobilized Biochemicals. Immobilized biomolecules, or bioreagents, are being synthesized in increasing numbers. For example, dihydroxyboryl cellulose has been employed to purify and study sugars and nucleic acids. Aminopropyl glass and its *p*-phenylene diisocyanate derivative have been employed as a support for solid-phase Edman degradation of peptides (73). Enormous advances including the synthesis of an active enzyme, ribonuclease A (74), have been made in the synthesis of peptides by the Merrifield solid-phase method.

A mild reducing agent, the dihydrolipoyl derivative of aminopropyl glass, has been employed for the reduction of various protein and peptide disulfides (18). An immobilized mild oxidizing reagent has also been prepared by the azo coupling of methylene blue to porous glass (75). This reagent photolytically catalyzes the formation of singlet oxygen, which in turn oxidizes protein methionyl, tyrosyl, and tryptophenyl residues. Under certain conditions this can be limited to the oxidation of methionine. When lysozyme, for example, is photo-oxidized in the presence of methylene blue in 84% acetic acid, only 5% of the activity is retained (76). This reduction results from the oxidation of one protein methionine to methionine sulfoxide, a process that is reversed by reducing the enzyme methionine sulfoxide with thiols, thus restoring 85% of the original activity.

Numerous other examples of both bioselective adsorption and the use of immobilized biomolecules have been reported. Many new applications can be anticipated in the near future.

CHROMATOGRAPHY, HPLC

Introduction

High performance liquid chromatography (hplc) is a powerful tool for characterization of synthetic and natural polymers by separating individual fractions by molecular weight, chemical composition, functional groups, etc. It is also used for isolation and purification of biopolymers and analysis of additives in complex polymer formulations. As in any chromatographic technique, separation occurs due to thermodynamic partitioning between the sample components in the mobile and stationary phases. In hplc, this process takes place in solution inside a chromatographic column packed with inorganic (usually, silica-based) or organic (synthetic resin, such as polystyrene–divinyl benzene and acrylic-based) porous particles, capable of resisting the high pressure created by a moving liquid (mobile phase) mechanically pumped through the column. Depending on application, isocratic (constant mobile phase composition) or gradient (variable composition) modes of separation can be employed, which significantly extends the capabilities of the technique.

Column liquid chromatography has been used for more than 60 years for analytical and preparative separations of polymers. Baker–Williams Fractionation, introduced in the mid-1950s, employed both temperature and solvent gradients to separate polymer fractions according to solubility through multiple precipitation–redissolution steps. This technique has been significantly improved in the last two decades and is still used for fractionation of synthetic copolymers and polymer blends under the term high performance precipitation liquid chromatography (hpplc). Dramatic changes in instrumentation and column preparation for liquid chromatography in 1970s, as well as better understanding of the mechanisms of separation, had a dramatic impact on polymer separation approaches.

Encyclopedia of Polymer Science and Technology. Copyright John Wiley & Sons, Inc. All rights reserved.

Thus, a new technique Chromatography, SEC (a.k.a. gel-permeation chromatography for organic solutions or gel-filtration chromatography for aqueous mobile phases) emerged at that time as a premier method for molecular weight distribution (MWD) determination of synthetic and natural polymers. Since the early 1970s, sec as well as traditional types of hplc (reversed-phase, ion-exchange, hydrophobic-interaction, and affinity chromatography) have been widely used for analysis of proteins and other biopolymers. For two decades, normal- and reversed-phase chromatography have attracted significant interest as methods of separation of synthetic copolymers and polymer blends by chemical composition. Two-dimensional hplc techniques (also called chromatographic cross-fractionation) have been used for most complete polymer characterization in recent years. Thus, consequently coupling two different modes of chromatographic separation can result in determination of both molecular weight and chemical composition distributions of synthetic copolymers.

Instrumentation for HPLC

Each contemporary hplc instrument consists of a pump for solvent delivery, an injector device for sample introduction, column(s) for sample separation, detector(s) for visualization of the separated components (solutes), and a computer for system control and data acquisition and reduction, as depicted in Figure 1. Precise temperature control of columns and some other parts of a chromatographic system becomes an important prerequisite for a successful separation.

Solvent Delivery. The function of the solvent delivery system is to deliver the mobile phase (eluent) through the chromatograph, accurately and reproducibly. The most popular are reciprocating-piston pumps, usually with two

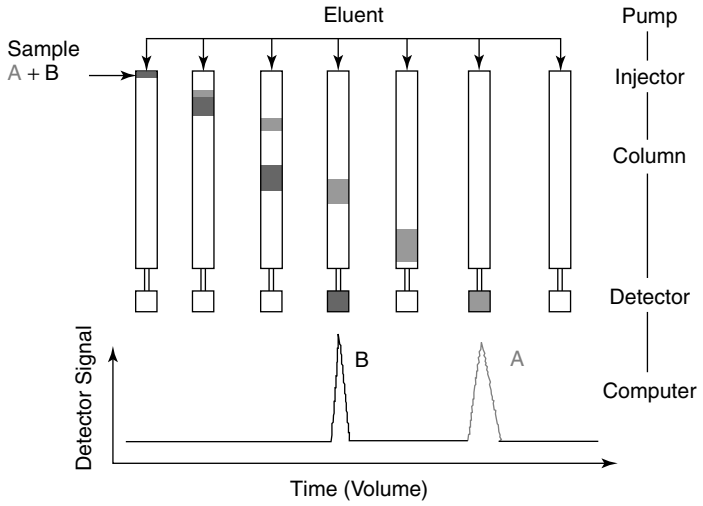

Fig. 1. Schematic presentation of separation of two components, A and B. Reprinted from Ref. 1 with permission.

pump heads containing two sets of moving parts: the check valves and seal-piston assembly. For analytical chromatography, such pumps can deliver liquid at a flow rate from 100 μL/min up to 10 mL/min. Microscale capillary chromatography needs syringe (positive displacement) pumps with capability to produce a flow rate as low as 1 μL/min, while preparative chromatography utilizes flow rates up to 50 mL/min. Gradient pumping system is capable of delivering more than one solvent during an analysis with variable mobile phase composition. The blending of the solvents can occur in one of two ways: high pressure mixing or low pressure mixing. In the former case the solvents are mixing on the injector side, while in the latter case the mixing takes place at atmospheric pressure and a single high pressure solvent delivery system is used to pump the mixture.

Accurate and reproducible eluent flow rate and composition are important prerequisites for successful separation and detection. This is achieved in contemporary "intelligent" pumps through completely independent, digitally controlled piston drives. The sophisticated, software-driven mechanism produces pulse-free eluent delivery, compensates for changes in eluent viscosity, and automatically purges any gaseous mobile phase, thereby enhancing performance for both isocratic and gradient applications (2). The quality of solvents affects the accuracy of flow and baseline noise. On-line solvent filtering and degassing become the necessary elements of any commercial hplc system.

Sample Introduction. To minimize the dispersion and broadening of peaks, sample solution must be injected as a sharp plug with minimal interruption of flow. Typically, two-position six-port valves are used for sample injection, which may be operated manually or automatically (such as in an autosampler, where the sample is introduced from a sample vial held in an injection station). While the general intention is to keep the injection volume as small as possible, the limits are imposed by column dimensions, the sensitivity of detectors, and the nature of separation. An additional factor is the concentration of the analyte, which for high molecular weight species may often be selected very low to reduce solution viscosity and avoid intermolecular interaction.

Stationary and Mobile Phases. Chromatographic columns provide the means for polymer fractionation or separating mixtures into components. The selectivity, capacity, and efficiency of the columns are all affected by the nature of the packing material. Most modern hplc packings are porous spherical microparticles with 3- to 10-μm size. The efficiency of a column increases with decreasing particle size, but so does the backpressure, which usually cannot exceed 27.2 MPa (4000 psi) on traditional instruments. The use of new generation of ultra-high pressure chromatographs with backpressure up to 690 MPa (100,000 psi) can potentially reduce the particle size up to 1 μm or lower. In general, silica-based columns can withstand higher pressure as compared with resin-based columns.

Pores (mean diameter usually from 6 to 100 nm) play a crucial role in hplc, as they provide the surface where retention and hence separation occur. The chemical structure of the surface determines the thermodynamic "environment" for the analyte in thin surface layer (stationary phase) and in such a way determines the mechanism of retention. Flexible macromolecules approaching the internal surface of a solid particle change their spatial conformations because of steric interaction, which plays an important role in any mode of polymer chromatography. This interaction restricts the fluctuation motion of a macromolecule, decreases its

conformation entropy, and effectively reduces the retention. In sec, where particles with inert surface are used and the size of macromolecules is comparable with the internal pore diameter, steric interaction is dominant and separation occurs according to size of macromolecules. All other modes of polymer chromatography also exploit enthalpic (attraction) specific interactions between macromolecules and the functional groups on the surface. For this reason they are often lumped together as interaction polymer chromatography (ipc). The name "adsorption polymer chromatography" is also used because the size of macromolecules usually far exceeds the size of the surface functional groups participating in interaction, and retention has the adsorption mechanism.

The nonsteric interactions in ipc depend on the chemical structure of the analyte, and also on nature of stationary and mobile phases. In normal- or reversed-phase hplc, neutral solutes are separated on the basis of their polarity. In the former case, polar stationary phases are employed (eg, bare silica with polar silanol groups) and less polar mobile phases based on nonpolar hydrocarbons are used for elution of the analytes. Solvent selectivity is controlled by adding a small amount of a more polar solvent, such as 2-propanol or acetonitrile or other additives with large dipole moments (methylene chloride and 1,2-dichloroethane), proton donors (chloroform, ethyl acetate, and water), or proton acceptors (alcohols, ethers, and amines). Correspondingly, the more polar the solute, the greater is its retention on the column, yet increasing the polarity of the mobile phase results in decreased solute retention.

The opposite situation takes place for reversed-phase separation, when nonpolar stationary phase is accompanied by a polar mobile phase, typically water, to which a less polar solvent such as acetonitrile or methanol is added, and solvent selectivity is controlled by the nature and amount of the added solvent. As a result, a decrease in the polarity of the mobile phase leads to a decrease in solute retention. Many organic polymers are not soluble in water, and other polar solvents can be used. Thus, the combination of acetonitrile as an initial solvent with addition of tetrahydrofuran (THF) can be used in reversed-phase separation of many styrene-based copolymers and acrylic polymers. Modern reversed-phase chromatography typically refers to the use of chemically bonded stationary phases, where functional groups, such as alkyl ($-CH_3$, $-C_4H_9$, $-C_8H_{17}$, and $-C_{18}H_{37}$) groups, phenyl ($-C_6H_5$) groups, cyano [$-(CH_2)_3CN$] groups, and amino [$-(CH_2)_3NH_2$)] groups, are bonded to the silica. Note that some of these bonded packings, such as those with cyano- and amino-groups, as well as diol groups [$-(CH_2)_3OCH_2CH(OH)CH_2OH$], can also be used in normal-phase separations, as they contain moderately polar moieties. The same stationary phases are also used for separation of biomolecules in hydrophobic-interaction chromatography. Weak nonionic interactions between hydrophobic portions of proteins and nonpolar moieties of the stationary phase have an entropic nature and are highly sensitive to salt concentration in a totally aqueous, buffered mobile phase of high ionic strength.

In ion-exchange chromatography, the ionic species, such as proteins or synthetic polyelectrolytes, are separated on the basis of differences in electric charge. The stationary phases with ionic groups (fixed ions) are employed, and the mechanism of retention is the electrostatic attraction of ionic solutes in solution to opposite charged ions (anions or cations) on the stationary phase support. The stationary phase for ion-exchange chromatography is called ion exchanger and

is classified as an anion-exchange material when the fixed ion carries a positive charge, and as a cation exchanger in the opposite case. There are strong and weak ion exchangers depending on the pH range over which the stationary phase can retain the charge on the fixed ion. Acrylic-based copolymers treated with an appropriate reagent to produce the desired functional group are the most used ion exchanger because of wider pH range (pH 1–13) and higher ion-exchange capacity as compared with silica-based columns (pH 2–8). Eluents for ion-exchange chromatography are aqueous solutions of salts with small addition of organic solvent. Selectivity in the separation of polyelectrolytes may be varied by changing either the pH of the mobile phase or the nature or concentration of the displacing (competing) ions.

Chromatography, SEC is used for the separation of biomolecules on the basis of the lock-and-key mechanism prevalent in biological systems.

Detectors. When separated macromolecules leave the column, they are detected by one or more on-line electrical devices with signals proportional to the concentration of the analyte. In all hplc detectors, the eluent flows through a measuring cell, where the change of a physical or chemical property with elution time is detected. Each monitored trace represents a chromatogram: a set of chromatographic peaks separated by baseline regions. The sensitivity (the ratio of peak height to the sample concentration), signal-to-noise ratio (the amount of signal visible above the baseline noise), as well as linear dynamic range (maximum linear response divided by the detector noise) are the most important characteristics of any detector.

Ultraviolet (uv) absorption photometers capable of absorbing light at a selected wavelength (in the range 190–350 nm for uv detectors, or 190–700 nm for uv/Visible detectors) are the most popular detectors in hplc of both synthetic and biological polymers. In case of proteins, wavelengths that are typically monitored include the regions of absorbance of peptide bonds (210–220 nm), and tyrosine and tryptophan side chains (ca 280 nm). Many synthetic polymers also contain chromophoric groups. Variable-wavelength and photodiode array detectors have the advantage that more than one wavelength can be monitored during a single run. Photodiode array detectors allow for simultaneous measurement of an entire uv spectrum at any point of the chromatogram, which can aid in peak identification. Among other selective (solute property) detectors used in hplc of polymers are fluorescence and IR photometers. For example, fluorescence detectors can provide higher sensitivity, as well as greater selectivity, in the detection of proteins containing tyrosine and tryptophan residues that have intrinsic fluorescence. Both types of detectors are limited to certain mobile phases. A good alternative is off-line coupling of ftir to hplc system using an evaporative interface (3). In such a system, the eluent is sprayed onto a Germanium disc, which can be transferred to any ftir spectrometer to yield the full spectrum information over any peak of the chromatogram. The same principle is applied also to the matrix-assisted laser desorption/ionization mass spectrometer, which otherwise is difficult to couple to the hplc system (4).

A few universal (bulk property) detectors are of frequent use in hplc of polymers. Refractive index detector is limited to isocratic elution and is utilized primarily in sec. The same is true for the recently introduced density detector based on mechanical oscillator principle (B. Trathnigg in Ref. 4). Evaporative light

scattering detector (ELSD) becomes very popular in nonaqueous gradient elution of synthetic copolymers and polymer blends (3). The eluent is nebulized, and the solvent is evaporated from the droplets. Each droplet containing nonvolatile material will form a particle, which scatters the light while crossing a light beam. This detector has significant advantages over the uv detector for ability to work with aliphatic polymers without chromophore groups, and also for its applicability to practically any mobile phase which does not contain a nonvolatile buffer. Despite these obvious merits, ELSD cannot be considered as an ultimate choice for quantitation because of nonlinear concentration response, which depends on numerous factors such as chemical nature of the sample including its molar mass and chemical composition, the eluent composition, viscosity and surface tension, and operating conditions. Coupling ELSD to another detector can help to solve these problems with quantitation.

The quadrupole mass spectrometers, single-quadrupole (MS) or triple-quadrupole (MS–MS), have proved to be the detectors of choice for interfacing with chromatographs. The resulting combinations LC–MS or LC–MS–MS have become very popular among protein scientists. Soft ionization methods, such as electrospray ionization and matrix-assisted laser desorption, are used extensively for biopolymers and some ionic synthetic polymers (5). The interface usually requires the use of very low flow rates (below 10 μL/min) and therefore necessitates capillary chromatographic equipment, or a sample splitter. Miniaturization of separation with laboratory-on-a-chip technology and microfluidics with nanoscale columns can additionally improve the compatibility of column chromatography with mass spectrometry detection.

In addition to the widespread use of mass spectrometry as a detection technique, scientists report investigations of other spectroscopic techniques such as nuclear magnetic resonance (nmr) and inductively coupled plasma mass spectrometry. These emerging technologies in a few years may have a major impact as on-line detection methods for characterizing both synthetic and biological polymers. Miniaturization of separation makes these detectors more feasible for on-line coupling. Using internal reflectance spectroscopy to study molecular interactions at phase surfaces has helped researchers to understand retention mechanisms and to confirm or expand chromatographic data.

Data Treatment. The traditional hplc method involves two types of data analysis: qualitative (peak identification) and quantitative (determining the analyte concentration). Both analyses require specific data manipulations, such as matching retention times, peak integration and peak calibration. The use of spectroscopic detectors (photodiode array, ftir, and mass spectrometry) suggests additional mathematical procedures because of the necessity to manipulate with uv-, ftir-, and MS-spectra and corresponding library matching (6). Most commercial chromatographic software packages contain necessary functionalities and can be applied to hplc of proteins, peptides, and DNAs. The characterization of other natural and all synthetic polymers is a much more difficult problem, which includes calculating the distributions of different macromolecular parameters, such as molecular mass, chemical composition, branching frequency and end group functionality, from raw chromatograms. This involves additional calibration procedures (column calibration), calculation of statistical moments of distributions, etc. Two-dimensional chromatographic cross-fractionation of synthetic copolymers

requires the construction of two-dimensional distributions to characterize the copolymer heterogeneity (7).

Retention Mechanism and Modes of Separation

Isocratic Elution. Contrary to sec, where any nonsteric effects are undesirable and suppressed, week nonsteric adsorption interactions between a solute and a stationary phase play a dominant role in ipc. The best way to demonstrate the difference between size-exclusion and interaction (adsorption) modes of polymer separation is to use the so-called molecular weight calibration curves (log M vs V, where M is the molecular weight, and V is the elution volume) depicted in Figure 2. The set of narrow polydispersity polystyrene samples with molecular weights from several hundred up to million were subjected to isocratic elution on the reversed-phase column (silica bonded with octadecyl chains) with different acetonitrile/tetrahydrofuran (ACN/THF) mixtures as eluents. THF is less polar than ACN (polarity parameters 4.0 and 5.8, respectively). Pure THF completely suppresses nonpolar interactions between polystyrene and alkyl chains on silica, and conventional sec behavior is obtained, that is, elution time increases with decreasing molar mass of the sample. The separation occurs within pore volume $V_P = V_T - V_0$, where V_T is the liquid volume inside the column and V_0 is the interstitial volume between particles. The steric interactions prevail until the amount of ACN in the mobile phase reaches ca. 50%. After that, a completely reversed retention behavior is obtained, which is typical for the adsorption mode of separation, when retention volume V_R exceeds V_T. At 45 and lower % THF, retention

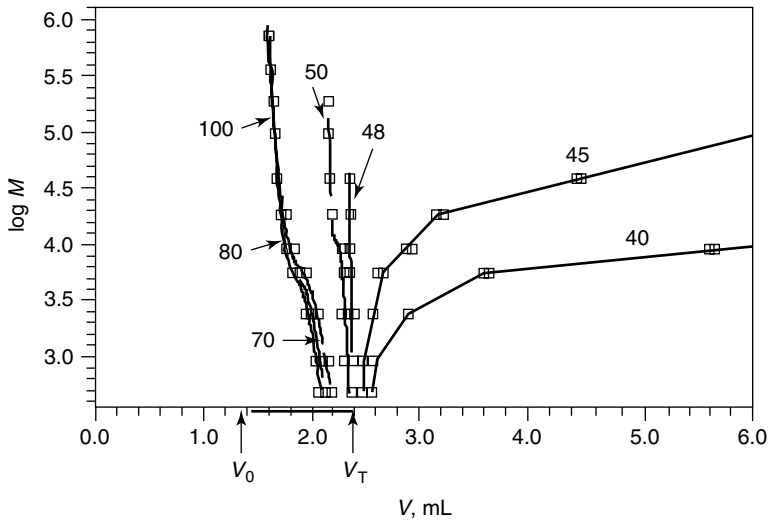

Fig. 2. Transition from size-exclusion to adsorption mode for isocratic elution of polystyrene samples with low polydispersity. Column: Nova-Pak C_{18} (Waters Corporation, USA), mobile phase: THF/ACN mixtures (numbers on the graph represent vol% THF), 1 mL/min, detector: ELSD Model 500 (Alltech Corp.).

dramatically increases with molecular weight and becomes extremely sensitive to the eluent composition, so that high molecular weight fractions are practically irreversibly retained by the column. For this reason, the IPC separation of high molecular weight polymers is usually performed in gradient mode.

It is important to note the elution at 48% THF: Retention becomes completely independent of molecular mass, and all fractions elute with the column's liquid volume V_T. At this transition point, which is termed critical point of adsorption (CPA), entropy driven size-exclusion effects are completely compensated by enthalpic adsorption interactions. Although both types of interaction strongly depend on molecular weight, this mutual compensation phenomenon leads to molecular weight independent retention at CPA. This phenomenon allows for practical implementation of isocratic polymer separation other than sec. Thus, because of chromatographic "invisibility" of a main polymer chain, effective separation of telechelic polymers based on types of end-groups can be performed (Ref. 7, p. 125). The same principle is applied for isocratic separation of some block copolymers (Ref. 7, p. 151).

The isocratic separation at CPA requires very careful control of chromatographic conditions, such as the quality of stationary phase, mobile phase composition, and temperature, because of high sensitivity of retention to these parameters, especially for polymers with high molecular weight. Another limitation of the techniques is associated with the dynamic effects. The success of separation depends on the ability of all macromolecules to penetrate all pores (the same way as the solvent molecules). But small diffusion coefficients and steric restrictions make the equilibration time for large macromolecules and narrow pores unreasonably long. Because of this, the use of isocratic separation at CPA is practicable only when the internal pore diameter exceeds the size of macromolecules in solution.

Gradient Elution. In gradient mode, the elution strength of the mobile phase is gradually increased within the chromatographic run to facilitate the elution of strongly retained compounds. This is especially important for high molecular weight polymers that otherwise are practically irreversibly retained by the column in the adsorption mode. Such gradient can be performed by changing the chemical composition, ionic strength or pH of the eluent, or even temperature. In protein separation, the salt gradient is used in both hydrophobic-interaction and ion-exchange chromatographies. During the chromatographic run, the salt concentration is decreased in the former case and increased in the latter one.

Typical reversed-phase gradient elution of synthetic polymers is demonstrated in Figure 3 for the same set of polystyrene samples as in Figure 2. The increase in eluent strength is achieved by linear increase of the concentration of less polar THF in the mobile phase that allows the elution of all polystyrenes within 8 min. The elution of lower molecular weight samples (below 10,000 Da) occurs in the adsorption mode at low content of THF in the mobile phase, and strongly depends on molecular weight. Excellent resolution for polystyrene oligomers in this mode allows one to distinguish between fractions with different end groups (double peaks on the chromatograms). In contrast, all higher molecular weight polystyrenes have practically the same elution volume, which coincides with the volume where eluent reaches its CPA (48% THF). The principle that gradient elution of high molecular weight polymers occurs at CPA has been introduced

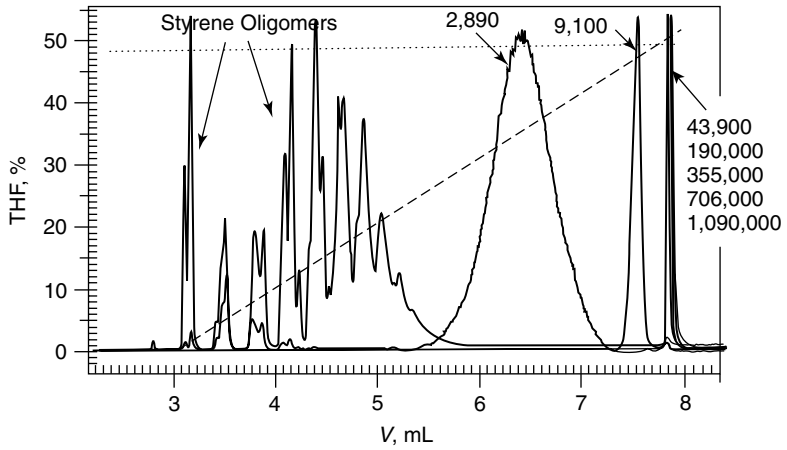

Fig. 3. Gradient elution of polystyrene samples from Figure 1. The same chromatographic system and conditions as in Figure 1, except eluent gradient: 100% ACN to 100% THF over 10 min (dashed line). Numbers on the graph: molecular weights of individual polystyrenes. Broken line: critical point of adsorption (48% THF).

recently (8). It provides the basis for gradient separation of copolymers and polymer blends by chemical composition. Each compositionally homogeneous fraction of a copolymer or a polymer blend elutes at its own CPA independently of molecular weight. By this means, gradient elution produces the chemical composition distribution of copolymers and polymer blends.

In general, gradient elution is a much more versatile technique for polymer separation as compared with isocratic elution at CPA Pore and particle sizes and hence dynamic effects do not impose such significant restrictions. Macromolecules do not need to penetrate the entire pore volume, and elution at CPA is achieved when their size exceeds the pore diameter. Gradient run allows for a sample precipitation on the frit or inlet of the column, when starting eluent is a nonsolvent for the polymer. This is a rather common situation because the solubility window for many polymers is relatively narrow, and the eluent with a poor elution strength often has a poor thermodynamic quality. This is true even for some proteins (membrane proteins or collagen), which can precipitate at the intermediate stage of the gradient separation. However, the elution of different components of a polymer sample still follows the rules of gradient separation described in the previous paragraph as soon as all polymer fractions are redissolved and adsorbed by the column during the chromatographic run. Only if macromolecules elute without any adsorption interactions immediately after redissolution, as in hpplc, the separation based solely on polymer solubility occurs. In this case, retention always strongly depends on molecular weight and concentration of the sample (9).

Multidimensional Separation. In some cases, a single separation step is not enough to complete the analysis of biological or synthetic polymers. In this case, coupling two or more different modes of separation involving column-switching mechanism is widely used in multidimensional polymer

chromatography. This approach provides the opportunity to simplify complex mixtures before their characterization by spectroscopic techniques, especially LC–MS and LC–MS–MS. A typical example is the combination of ion-exchange or size-exclusion separation with reversed-phase chromatography in protein purification (10). Gradient or isocratic elution at CPA followed or preceded by size-exclusion separation is often used in chromatographic cross-fractionation of synthetic polymers (11). The use of ipc as a first step is a more feasible way to achieve the true two-dimensional characterization of copolymers or polymers with functional groups, because it allows for molecular weight independent separation by chemical composition or by other structural differences in macromolecules. Size of macromolecules in each compositionally homogeneous fraction obtained after the first separation, is directly related to molecular weight thereof, and the following size-exclusion separation of all these fractions can complete the cross-fractionation.

The coupling of two modes of polymer separation can be achieved off-line or on-line. In the former case fractions from one chromatographic system are transferred to another system manually, in the second one, automatically, when the eluent from the first instrument flows through the injection valve of the second instrument. The most sophisticated automatic two-dimensional chromatographic systems employ two six-port valves or one eight- or even ten-port injection valve (10). Two storage loops make it possible to collect fractions continuously without losses. The proper coordination of the flow rates in consecutive chromatographic steps is an important feature of any automated system. Thus, in chromatographic cross-fractionation, the collection time of one hplc fraction should coincide with the analysis time in the following sec step (Ref. 7, p. 198).

Theory of Polymer Chromatography

Thermodynamic Treatment. Each component of a polymer sample injected in the chromatographic system can be characterized by its retention volume V_R, ie, the volume of solvent that passes through the column from the time of sample injection to the detection of the corresponding peak. To eliminate the variability of retention caused by operational variance of the flow rate, mobile phase, or other parameters, the normalized quantity $k = (V_R - V_T)/V_T$ (capacity factor) is often used instead of V_R. The resolution of the chromatographic system, ie, its ability to discriminate between individual macromolecules, depends on the selectivity of separation, which is described by the ratio of corresponding capacity factors.

The basic assumption in any chromatographic theory is that retention is determined by the thermodynamic factors. In such a way, mobile and stationary phases are interpreted as true thermodynamic phases with volumes V_M and V_S, respectively, so that retention volume depends on the partition (distribution) equilibrium coefficient K of the solute in these two phases: $V_R = V_M + KV_S$. By definition, all enthalpic and entropic interactions between the macromolecules and the chromatographic surface occur in the stationary phase. If the size of macromolecules in solution is comparable with the internal diameter of pores, the entire pore volume represents the stationary phase, $V_S = V_P$, yet the mobile phase is formed by the interstitial volume only, $V_M = V_0$. This is not always the case for

gradient separation of peptide or proteins, when the pore diameter usually far exceeds the size of compact macromolecules, and practically the entire liquid volume, $V_T = V_0 + V_P$, represents the mobile phase.

The role of thermodynamic theory is to relate the distribution coefficient K (or free energy change due to solute sorption on the stationary phase) to the parameters describing the configurational and conformational structure of a macromolecule (such as molecular weight, chemical composition and shape), as well as temperature, pore geometry, mobile phase composition, etc. These parameters determine the entropy of steric interaction and the energy of multipoint nonsteric interactions between the macromolecule and the surface, and in this way affect the retention.

Construction of a universal thermodynamic model for chromatographic separation of proteins and other biological polymers is hardly probable because of the complexity of chemical and spatial structure of such macromolecules, which can undergo a diversity of conformational transitions during separation. Even for small peptides composed of 5–15 amino acids, which are assumed to exist in solution as a random coil, amino acid identity and position, as well as peptide sequence, all play an extremely important role in retention. Nevertheless, semiquantitative approaches applied to specific modes of separation often allow for understanding the mechanism of separation, as well as the effect of operating parameters such as salt type and concentration, temperature, nature of packing material, organic modifiers, and pH. Examples are the solvophobic (12) and preferential interaction (13) theories applied to hydrophobic interaction and reversed-phase chromatography of proteins (14). Several useful retention models exist in ion-chromatography, where the equilibria, which govern ion-exchange separations, are generally well understood (1).

In the case of synthetic polymers, a simple continuous random-flight model of a flexible polymer chain allows for quantitative consideration of the chromatographic process in a rather general way (15). The theory provides a simple analytical expression for the distribution constant K of a macromolecule penetrating the slit-like or cylindrical pore and interacting with its walls, in terms of macromolecule and pore sizes, and a segment energy of nonsteric interactions between the macromolecule and stationary phase. Depending on the mobile phase composition, the competition between steric (repulsive) and nonsteric (attractive) interactions may produce either size-exclusion, $K<1$, or adsorption, $K>1$, modes of separations, yet the intermediate condition, $K=1$, represents the critical mode of adsorption, where both types of interaction counterbalance each other (see Fig. 2).

Present models of gradient elution (16) assume that migration in gradient mode occurs in the same way as for isocratic elution. That is, given the dependence of K on eluent composition, which changes during the mobile phase gradient, one can calculate the gradient elution volume for gradients with various slopes and shapes using the well-known mass-balance integral equation (17). The results of such calculations applied to gradient separation of polymer homologous series can explain (8) the peculiarities depicted in Figure 3. Thus, the combination of molecular–statistical theory of dilute polymer solutions in confined (porous) media with conventional chromatographic theory produces a valuable tool in elucidating the polymer chromatography (8). Recent extension (18) of the concept

on copolymers and stationary phases with heterogeneous surface (which actually is inherent in most if not all of available sorbents) significantly improves the feasibility of the theory for separation of complex polymer formulations.

Dynamic effects. Besides the thermodynamically driven selectivity, the resolution of the chromatographic system depends also on dynamic (kinetic) factors that determine the efficiency of separation. These factors cause the broadening of the chromatographic peaks so that even peaks from individual compounds such as proteins have a finite width. For polydisperse polymers this chromatographic peak broadening (or bandspreading) is usually hidden by the overall polymer distribution, but still can produce erroneous results if no correction has been made to compensate for this effect.

The major contributor to peak broadening in polymer chromatography is a "stagnant" mobile phase mass transfer, that is, kinetics hindrance due to penetration of macromolecules into the pores of the support packings. The molecular diffusion is the only way for macromolecules to reach the internal surface of pores, whereas the migration in interstitial volume is governed by the convection mechanism. The effect of bandspreading tends to diminish with the ratio of characteristic times of these two processes, $t_D = L^2/D$ (L is the average length of pores, D is a solute diffusion coefficient), and $t_0 = V_0/F$ (F is the flow rate). The diffusion coefficient of macromolecules inside pores drops rapidly as molecular weight increases, and so does peak broadening. As the length of an individual pore is usually comparable with the size of a particle [exception is perfusive particles, which contain very broad flow-through pores with only shallow diffusive pores and are mostly used in preparative chromatography 19], the most popular solution to date for minimizing the problem in biological applications is the use of small porous particles of 2–5 μm so that the depth of the stagnant pools is not excessive (20). It is significant that in gradient separation of synthetic polymers the internal surface area is not so important, and separation usually takes place only at the inlet of very narrow pores, which significantly reduces the dynamic effects.

Applications

Separation of Biological Polymers. The development of wide-pore bonded-phase packings has dramatically affected the separation of biopolymers in the life sciences and biotechnology (21). Nevertheless, several factors should be taken into account in selecting the optimum mechanism of separation for a specific application. Reversed-phase chromatography is the most popular mode for separation of peptides because of exceptional selectivity and resolution. But in case of proteins, hydrophobic interaction is often the method of choice because of the much milder effect on solute conformation. Many proteins are denatured by acids or organic solvents, as well as by the alkyl chain of the bonded phase, the usual constituents of the reversed-phase separation (22). These conformational transitions may cause additional chromatographic problems, such as peak broadening, multiple peaks, poor sample recovery, and ghosting, if the conformational transition time is of the same order as the migration time (23). Hydrophobic interaction chromatography as well as ion-exchange chromatography have been

predominantly used to analyze proteins, nucleic acids, and other biological macromolecules when maintenance of the three-dimensional structure is a primary concern (24).

With the human genome now sequenced (primarily by capillary electrophoresis technology), scientists are turning their attention to proteomics. The term *proteome* has been introduced to define the full complement of proteins in a cell. It also requires a description of the localization, concentration, and multisubunit association of each of these proteins (25). The multidimensional hplc with automated column switching technology can successfully complement the more conventional approaches to protein separation, such as two-dimensional gel electrophoresis, which usually involve many manual steps and are not conducive to high throughput applications.

Separation of Synthetic Polymers. Interest in interaction polymer chromatography as a technique complementary to sec for characterization of synthetic polymers and polymer blends has quickened in recent years. The principle difference between these two methods is depicted in Figures 4 and 5, where three polymers with close average molecular weights, as well as the equimolar blend of these polymers were subjected to isocratic size-exclusion and gradient reversed-phase separations, respectively. In the first case (Fig. 4), only molecular weight information is available from the chromatograms, the result of second separation (Fig. 5) reveals the individual components, ie, chemical composition of the blend. This way, many statistical, block and graft copolymers and blends were fractionated by chemical compositions in gradient mode on both

normal- and reversed-phase columns, without any practical limitations on the molecular weight of polymers [see reviews in Refs. 7, 11 (chapt. 9), and 26–29]. On the other hand, several reported (7) isocratic separations of block copolymers at CPA were limited by the oligomeric range of molecular weights. Many recent publications deal with two-dimensional characterization of copolymers, where the molecular weight independent separation is achieved by ipc as the first step (7,30,31).

To summarize briefly, in spite of solid age, hplc of polymers remains the workhorse of the biotechnology and chemical industries, and at the same time presents a fruitful field for future development and improvement.

CHROMATOGRAPHY, SIZE EXCLUSION

Introduction

A polymeric product contains chains of varying lengths because of the statistical nature of polymerization processes. All synthetic polymers, and many natural polymers, have a molecular weight distribution (MWD), which may be represented by the differential weight distribution $w(M)$ as a function of molecular weight M (1). From the normalized distribution $w(M)$, the number-, viscosity-, and weight-average molecular weights, M_n, M_v, and M_w respectively, are calculated from the relations

$$M_n = 1/\left(1/M\right) w\,(M)\ \mathrm{d}M \tag{1}$$

$$M_v^a = M^a w\,(M)\ \mathrm{d}M \tag{2}$$

$$M_w = M w\,(M)\ \mathrm{d}M \tag{3}$$

Here, a is the exponent in the Mark–Houwink dilute solution viscosity equation

$$[\eta] = K M_v^a \tag{4}$$

where $[\eta]$ is the intrinsic viscosity (dL/g) and K is a constant. Higher moments of the distribution curve may also be used to derive the z and $z+1$ average molecular weights (1) (Molecular weight determination (GPC, osmometry)).

Various methods are available for the determination of average molecular weight (2), but the three averages in equations 1–3 cannot define a distribution

Encyclopedia of Polymer Science and Technology. Copyright John Wiley & Sons, Inc. All rights reserved.

within a polymer having many components. The polydispersity defined as M_w/M_n can provide an indication of the width of the MWD, but does not disclose distribution shape. Two polymers may have the same average molecular weight but quite different MWD. However, measurement of a specific average molecular weight is quite useful for correlation with polymerization kinetics and with a range of solution and bulk properties. Inevitably, attention was therefore directed to polymer fractionation as a means of determining MWD (see FRACTIONATION). The classical experiment is preparative fractionation from which a cumulative weight distribution $I(M)$, and hence $w(M)$, is calculated from the weights and average molecular weights of the isolated fractions. By the mid-1960s, a range of fractionation methods was available (3,4), but the limitations of most of these were well recognized. In particular, for polymer fractionations relying on the molecular weight dependence of polymer solubility, the experimental methods were inefficient, tedious, and time consuming.

Size exclusion chromatography (SEC) is now established as the most popular and convenient method for analytical polymer fractionation. Reliable and reproducible chromatograms are obtained in relatively short time (elution < 1 h), permitting routine characterization and effective application to quality control. In retrospect, it is perhaps surprising that SEC as a characterization method was not established earlier. The characteristic separation of short chains having elution times higher than those of long chains had been reported by a number of workers in the published literature between 1935 and 1958 (5). The major advance by Porath and Flodin (6) provided effective demonstration that polymers may be separated by the size dependence of the degree of solute penetration into a porous packing. Their technique was named gel filtration (GF) involving cross-linked dextran gels, which are soft and highly swollen networks for separations of water-soluble polymers. The description of analytical gel permeation chromatography (GPC) by Moore (7), and the subsequent availability of commercial instrumentation (8), attracted widespread interest. Moore made two important contributions. First, he prepared versatile porous cross-linked polystyrene/divinylbenzene (PS/DVB) gel particles covering a wide range of pore diameters for separations of synthetic polymers in organic media. These rigid gels (particle diameter d_p exceeding 50 μm) had good mechanical stability and were packed in columns (length 120 cm) which could be operated at high pressures and fast flow rates. The second contribution was the direct coupling of an on-line refractometer to the GPC column (or columns) in order to measure continuously the concentration of the polymer in the eluent. A chromatogram as recorded by a differential refractive index (DRI) detector is thus a record of molecular size distribution as a function of elution (or retention) time (or volume), and so the recovery and characterization of fractions were avoided.

Initial work in GPC focused on the conversion of a chromatogram to an accurate MWD. Column calibration methodologies were developed, and concentration detectors based on infrared (IR) and ultraviolet (UV) spectrophotometers and on evaporative light scattering were introduced. It was not until 1979 that a suitable reference book became available (9), by which time the term SEC had become widely accepted. The main advance during this decade was to identify conditions for high performance separations. The advantages of microparticulate rigid gels (particle diameter ~ 10 μm) were demonstrated, resulting in the use of short

columns (30 cm) so that elution times were much reduced. In the next 10 years up to 1990, instrumentation for multiangle laser-light scattering and differential viscometry appeared. These molecular size detectors, which generate on-line molecular weight data as a function of elution time, may be coupled to the SEC column system, and in conjunction with an on-line concentration detector permit the computation of MWD and average molecular weights. Examples of these advances are detailed in several books (10–12). The principles, practice, and applications of SEC are emphasized here, and further details on these and other aspects can be found in two recent books (13,14).

Principles of SEC

The resolution of solute molecules in a complex mixture by a chromatographic method depends on two types of processes. *The separation process* in the stationary phase controls the differential migration of the molecules, and in the SEC case includes all the mechanisms that may determine the permeation of molecules in the column packing. *The dispersion process*, which generally consists of at least two mechanisms, determines the band broadening of one type of molecule, and this broadening is influenced by molecular diffusion and column packing. In the determination of MWD and average molecular weights by SEC, an important part of data interpretation is the establishment of a correct calibration relation between the molecular weight M of a polymer and retention volume V_R. An understanding of the separation process is necessary because of the prevalent use of universal calibration methods, which assume that SEC separations are controlled solely by an exclusion mechanism. An understanding of the dispersion process is also required because the experimental chromatogram will always correspond to a distribution of molecular weights, which is too broad because of band broadening of all components in a polymer. Experimental conditions have to be chosen to minimize chromatogram broadening in order to optimize accuracy of molecular weight data and to obtain high resolution separations of low polymers, prepolymers, and small molecules.

Separation Mechanism. The basic separation mechanism in SEC assumes that the column packing is "inert," and interactive mechanisms that might contribute to retention behavior are neglected. The size exclusion mechanism is dependent on solute access to pore volume within gel particles determined by pore size distribution and solute size. Consequently, all solute molecules are eluted within one column solvent volume, corresponding to the sum of the interstitial (or void) volume V_0 of solvent between porous gel particles, defined as the volume of the mobile phase, and the volume V_i of solvent within the porous gel particles, defined as the volume of the stationary phase. Retention is given by the equation

$$V_R = V_0 + K_{SEC} V_i \tag{5}$$

where the distribution coefficient K_{SEC} represents the fraction of stationary phase solvent that is accessible to the solute. For very large molecules, the value of K_{SEC} will be zero at the exclusion limit because the sizes of these molecules prohibit solute diffusion into the gel pores. Very small molecules, on the other hand, have

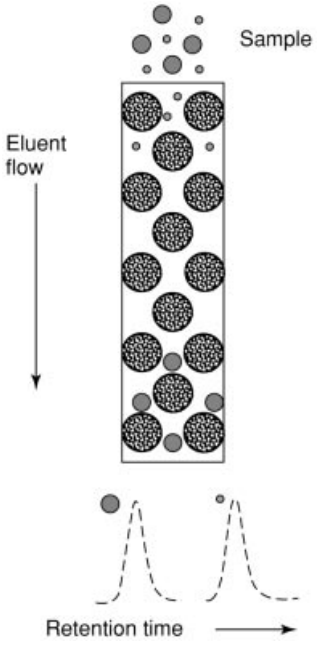

Fig. 1. Simple representation of the separation mechanism in SEC, showing larger molecules eluting faster than smaller molecules.

total access to both stationary and mobile phases, ie, K_{SEC} is unity at the permeation limit. As the chromatographic column is washed with solvent, the large molecules are eluted first, followed by solutes of decreasing size, which penetrate an increasing fraction of the solvent within gel particles. These observations are illustrated in Figures 1 and 2.

Practical separations with a porous column packing in SEC are performed close to equilibrium conditions. Elutions are performed at flow rates around 1 mL/min when V_R is independent of flow rate. Although many theoretical models have been proposed for polymer separations in SEC, thermodynamic treatments provide a sound representation of separation behavior. For a separation operating at equilibrium conditions, the standard free-energy change ΔG^0 for the transfer of solute molecules from the mobile phase to the stationary phase at constant temperature T is related to K_{SEC} by

$$\Delta G^0 = \Delta H^0 - T\Delta S^0 = -RT \ln K_{SEC} \tag{6}$$

where R is the gas constant and ΔH^0 and ΔS^0 are the standard enthalpy and entropy differences between the phases, respectively. Thermodynamic theories for SEC (15–18) calculate the pore volume accessible to a solute of given size in solution in terms of pore size for various models of pore shape. Such a treatment may be regarded as an excluded volume problem in which small solutes are permitted close approach to a pore surface whereas larger solutes have a larger exclusion

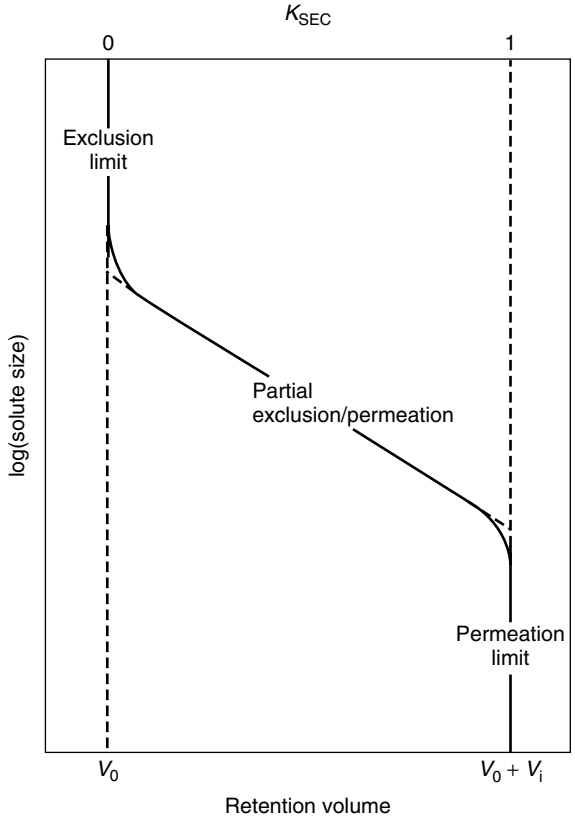

Fig. 2. Calibration curve for a size exclusion mechanism, presuming an inert column packing.

zone. Presuming that the pore surface is indeed inert, then ΔH^0 will be zero and the distribution coefficient is defined by

$$K_{SEC} = \exp(\Delta S^0/R) \tag{7}$$

Therefore, K_{SEC} is considered to be the fraction of accessible solute arrangements within the porous packing to those within the mobile phase, and represents loss in conformational entropy on solute transfer to a pore. Thermodynamic theories demonstrate for various solute types, namely sphere, rod, and random coil, and various pore geometries, such as lamellar and cylindrical shapes, that K_{SEC} for polymer separations may be generalized in terms of the relation

$$K_{SEC} = \exp(-sL_p/2) \tag{8}$$

where L_p is the mean external length or molecular projection, eg, L_p is equal to the diameter D of a sphere, and s is the surface area per unit pore volume. These treatments of size exclusion therefore suggest that for a column containing a given packing a characteristic molecular parameter L_p will represent the behavior of all solutes.

Equilibrium theories therefore predict that the behavior of all polymers can be represented by a universal size parameter. Benoit and co-workers (19) showed that solute size should be the hydrodynamic volume V_h of a polymer molecule in solution defined by Einstein's equation

$$V_h = 40[\eta]M/N_0 \tag{9}$$

where N_0 is Avogadro's number (see Fig. 2). It follows that a plot of $\log [\eta]M$ vs V_R should be a universal calibration plot for all polymers, and many experimental studies of a wide range of polymer-solvent-packing combinations have been performed, confirming the validity of this approach (20). Consequently, a molecular weight calibration curve for one polymer may be calculated from a calibration curve established with polymer standards. The calibrations are related by the expression

$$\log M_p - \log M_{ps} = \log [\eta]_{ps}/[\eta]_p \tag{10}$$

where p refers to the polymer and ps to an experimental study with well-characterized standards having narrow MWD.

Separations of polymers in organic media with cross-linked PS/DVB gels are generally performed with an eluent which is a good solvent for polystyrene. As long as this eluent is also a good solvent for a polymer, then interactive mechanisms are relatively unimportant compared with size exclusion, and it is reasonable to presume that ΔH^0 is about zero for separations with cross-linked PS/DVB gels. However, there are combinations of polymer and eluent, dependent on the polarities of these components and good/poor solvency of the eluent, for which plots of $\log [\eta]M$ vs V_R are displaced to high V_R, indicating the presence of a secondary mechanism such as adsorption (21). Thus, it is possible to conceive of columns of cross-linked PS/DVB gels operating by two limiting mechanisms dominated by size exclusion on the one hand (entropic effect) and by adsorption on the other (enthalpic effect). These two limiting behaviors could be controlled by adjusting the mobile phase, and could be represented by the retention equation

$$V_R = V_0 + K_{SEC}V_i + K_{ads}s_{ads} \tag{11}$$

where K_{ads} is the distribution coefficient for the adsorption mechanism and s_{ads} is an equivalent volume related to the available surface area for the eluting polymer. Therefore, a column will function solely in the adsorption mode for $K_{SEC} = 0$ and $K_{SEC} = 1$, although the appropriate value of s_{ads} for the stationary phase for each limiting case will need to be defined in equation 11.

When there is a mixed mechanism consisting of a primary mechanism, which is size exclusion, ie $0 < K_{SEC} < 1$, and a secondary interaction mechanism, then retention can be defined by (22,23)

$$V_R = V_0 + K_{SEC}K_pV_i \tag{12}$$

where K_p is the distribution coefficient for polymer–gel interactions. Therefore, equations 5 and 12 are identical for $K_p = 1.0$. Consequently, it can be suggested that values of K_p are given by

$$K_p = \exp\left(-\Delta H^0/RT\right) \tag{13}$$

Equation 12 has been shown to be a reasonable representation of a mixed mechanism for polymers in organic media separating on cross-linked PS/DVB gels (21,22).

Water-based polymers have aqueous solubility based on hydrophilic functionalities and/or ionic groups, and are likely to contain hydrophobic segments. Because aqueous separations require the column packing to have a polar surface, with or without ionic groups, a range of polymer–substrate interactions may occur, giving rise to various secondary retention mechanisms. For example, separations may involve ion exchange, ion exclusion, ion inclusion, intramolecular interaction, and adsorption (to include hydrogen bonding and hydrophobic interactions) (12,14). To establish the validity of universal calibration for water-based polymers, the choice of aqueous SEC system requires considerable care. For anionic polyelectrolytes separating on inorganic packings, conditions involving addition of electrolyte to the mobile phase have been established in order to minimize intrachain interactions and interactions between ionic groups on the polyelectrolyte and charges on the surface of the column packing. However, this methodology fails for cationic polyelectrolytes requiring modified inorganic packings with bonded phases. Alternatively, polymer-based packings may be preferred because by analogy with GF matrices rigid macroporous polymeric gels may be much less susceptible to secondary interaction effects. The absence of charged sites may result in a tendency toward hydrophobic interactions, in which case it may be necessary to introduce an organic modifier such as methanol or glycerol to the mobile phase. In practice, the choice of composition of an aqueous mobile phase for a specific polymer with a column packing may not be straightforward, and a balance between the need to increase ionic strength to reduce ionic interactions and to lower electrolyte concentration to limit hydrophobic interactions may have to be determined. Guidelines for minimizing secondary interactions for water-based polymers for a polymer-based packing are provided in Table 1.

Dispersion Mechanisms. A measure of the efficiency of a chromatographic column is the plate number N. Various procedures exist for calculating N from an experimental chromatogram (9), and equation 14 is commonly utilized

$$N = 5.54(V_R/W_{0.5})^2 \tag{14}$$

where V_R is computed from the point of application of the solution of polymer into the column to the appearance of the peak height maximum of the chromatogram and $W_{0.5}$ is the width of the chromatogram at half height. This procedure assumes that the chromatogram is symmetrical corresponding to a normal error (or Gaussian) function. The plate number is a popular way of measuring column efficiency, and a typical microparticulate packing with $d_p \sim 10$ μm will generate a value $N > 30{,}000$ plates/m for a solute eluting at $V_R = V_0 + V_i$.

Table 1. Secondary Interactions in Aqueous SEC

Type	Symptom	Action
Ionic exclusion	Peaks elute early, maybe before SEC exclusion limit	Modify eluent, addition of salt, and/or pH adjustment
Ionic adsorption	Peaks elute late, maybe after SEC permeation limit, peak tailing or no peaks detected	Modify eluent, addition of salt, and/or pH adjustment
Ionic inclusion	Peak at total permeation due to salt even though samples prepared in eluent	Recognize salt peak, do not include in sample integration
Hydrophobic adsorption	Peaks elute late, maybe after SEC permeation limit, peak tailing or no peaks detected	Modify eluent, addition of organic modifier (check column compatibility)

If a polymer sample contains several species of very different sizes, then peaks for each monodisperse species will be obtained when $W_{0.5}$ is minimized. However, because of the SEC elution volume range defined by $0 < K_{SEC} < 1.0$, high efficiency columns are required for high resolution separations. It can be estimated that an SEC column operating at 40,000 plates/m has a maximum resolution of 40 peaks (24). For the case of two monodisperse solutes 1 and 2 having different sizes, column resolution R_s is given by

$$R_s = 2\,(V_{R2} - V_{R1})\,/\,(W_1 + W_2) \tag{15}$$

where V_{R2} and V_{R1} are retention volumes and W_1 and W_2 are peak widths at the base of a chromatogram. The numerator in equation 15 will depend on separation power, which is inversely proportional to the slope D_2 of the plot of log M vs V_R defined by

$$\log M = D_1 - D_2 V_R \tag{16}$$

The values of D_1 and D_2 will depend on the pore size distribution of the packing, gel capacity, ie pore volume, and on column length L, and these parameters need to be optimized to increase separation power, and therefore peak resolution. Variables influencing the denominator in equation 15 are discussed in connection with equation 19.

The definition of R_s can be extended by considering molecular weight differences, in terms of the slope D_2 as defined by equation 16. It follows that a general measure of SEC resolution may be developed (9), and the specific resolution R_{sp} was proposed

$$R_{sp} = 0.576/\,(D_2\sigma) \tag{17}$$

where σ is the standard deviation of a Gaussian peak with $4\sigma = W_1 = W_2$ and will vary with M. In practice, important parameters are D_2, L, d_p, and σ, chosen so that R_{sp} exceeds unity. Examples of column performance data are

presented in Table 2 for a range of column types operating at an eluent flow rate of 1 mL/min.

Theoretical interpretations of column efficiency consider dispersion mechanisms of solutes in the mobile and stationary phases. These mechanisms influence the dependence of the height equivalent to a theoretical plate, or just plate height H, on the linear flow velocity u of the eluent. The value of H may be determined from an experimental separation from the equation

$$H = L/N \tag{18}$$

The basic concepts for general chromatographic separations (25) can be applied to SEC (9). For separations of polymers, it was proposed that only two column dispersion terms influence H (26,27), namely eddy diffusion in the mobile phase and mass transfer in the stationary phase. The expression for H for a permeating monodisperse high polymer is

$$H = 2\lambda d_p + \left[r\left(1-r\right)ud_p^2/30D_s\right] \tag{19}$$

where λ is a constant (close to unity) characteristic of the packing, r is the retention ratio defined by V_0/V_R, and D_s is the diffusion coefficient of the solute in the stationary phase. Column dispersion by eddy diffusion, represented by the first term in equation 19, arises because solute molecules reside in different streamlines with reference to their proximity to particles of the column packing. Column dispersion by mass transfer, represented by the second term in equation 19, arises because at any instant a fraction of the molecules will be within the porous column packing and are left behind by the remaining fraction in the mobile phase.

Equation 19 identifies the experimental variables that have to be considered in optimizing separations for reduced chromatogram broadening for high polymers and for improved resolution of peaks for low polymers and small molecules. The two column dispersion terms clearly demonstrate how lowering d_p will maximize column efficiency. For low polymers the mass transfer term will not be too significant because D_s is high, so that fast separations may be performed with little loss in efficiency. Larger polymers that have lower values of D_s will have higher mass transfer dispersion. Therefore, a much more significant rise in H as u increases

will be observed as molecular weight increases, and so high speed separations for high polymers will operate with considerable broadening of a chromatogram.

These predictions can be compared with experimental studies of polystyrene standards (26,27). However, all synthetic polymers will have an MWD, and it is necessary to include a polydispersity contribution to the experimental value of H. This is achieved by extending equation 19 to include a third term, presuming that the permeating polymer has a logarithmic normal distribution for the MWD. With this addition it is observed that equation 19 provides a good representation of experimental results for plots of H vs u.

In practice, a polydisperse polymer having a range of solute sizes generates an SEC chromatogram which may be considered as a collection of a large number of overlapping Gaussian peaks. Because of dispersion mechanisms, the tails of the chromatogram result from broadening alone and so the computed $w(M)$ distribution is broader than the true MWD. Various correction methods have been proposed to transform the experimental chromatogram into an MWD (4). However, it is not necessarily easy to achieve reliable corrected chromatograms before calculating a $w(M)$ distribution. The alternative approach is to reduce the level of column dispersion in order to minimize broadening of a chromatogram for a polydisperse polymer, according to the parameters in equation 19. If the optimum separations can be achieved, then calculations of broadening corrections can be omitted.

SEC Column Technology

SEC column packing materials, based on porous particles of a variety of substrates, are commercially available from a large number of suppliers (13). In the field of organic-soluble, mainly synthetic, polymers, column technology was initially developed using both porous silica and porous PS/DVB particles as the stationary phase. Although in the early days, columns of porous silica emerged as popular candidates, mainly because silica was well established in liquid chromatography (LC), the production of very highly cross-linked PS/DVB particles with well-controlled pore size and particle size distribution, and excellent temperature and mechanical stability, led to their dominance in the field, which continues today (28). The continued refinement of PS/DVB particle technology has produced smaller particle size packings (typically 5–10 μm), resulting in more efficient columns and subsequent reductions in analysis times to typically 20–40 min. Recent years have heralded the emergence of 3 μm columns exhibiting extremely high efficiency (>80,000 plates/m), which have particular application in the very low molecular weight SEC separation range, competing with other types of LC for the resolution of small molecules (29).

Columns for aqueous SEC have also been developed based on porous silica and porous polymeric stationary phases. Columns of silica have excelled in the field of monodisperse biopolymer separations (eg proteins and peptides) offering very specific pore size distributions and small particle size for high resolution. High performance packings, consisting of rigid hydrophilic polymeric particles, were introduced in the early 1980s and offered considerable improvements in both column efficiency and chemical and mechanical stability compared to the

early GF columns of soft polymeric networks. The continued development of high performance, hydrophilic stationary phases has expanded the use of SEC for the characterization of synthetic water-soluble polymers as they exhibit a much larger separation range and better linearity of calibration curves, and much lower adsorption effects compared to silica packings. In light of environmental issues, the requirement to produce water-soluble polymers has in recent years significantly increased the level of interest in aqueous SEC.

SEC column packing materials are generally represented by a characteristic calibration curve produced using a series of polymer standards. Typical calibration curves for individual pore size columns, as illustrated in Figures 3a and 4 for SEC columns with organic and aqueous eluents respectively, exhibit a

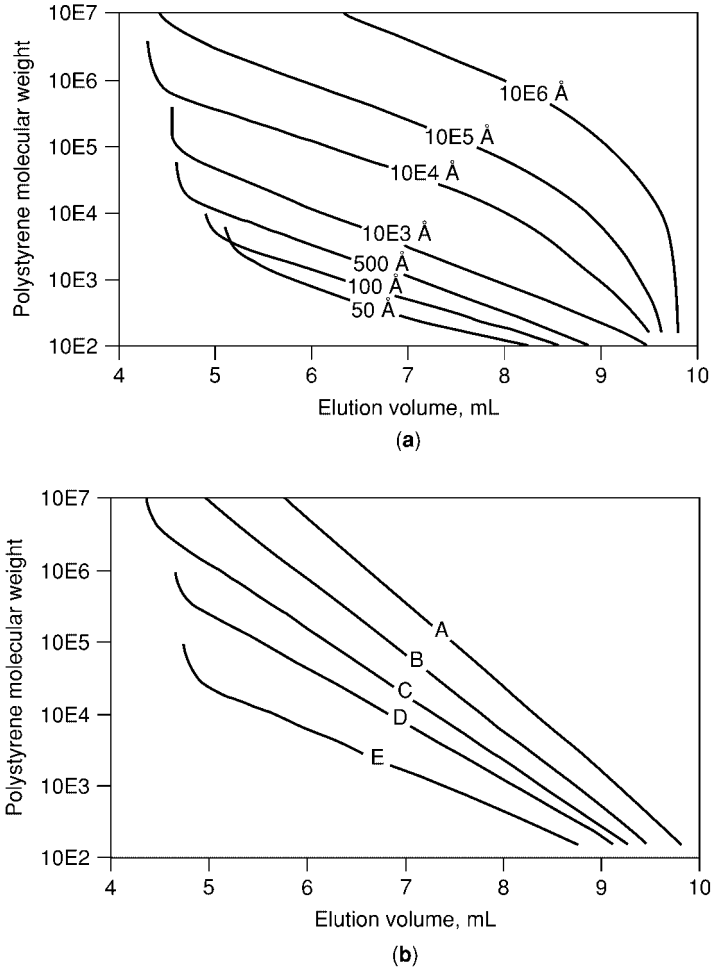

Fig. 3. Calibration curves for columns of PLgel for organic SEC at ambient temperature: (**a**) a range of individual pore size columns designated 50 Å to 10E6 Å, (**b**) a range of mixed gel columns designated A to E. Eluent: THF, flow rate: 1 mL/min, calibrants: polystyrene standards.

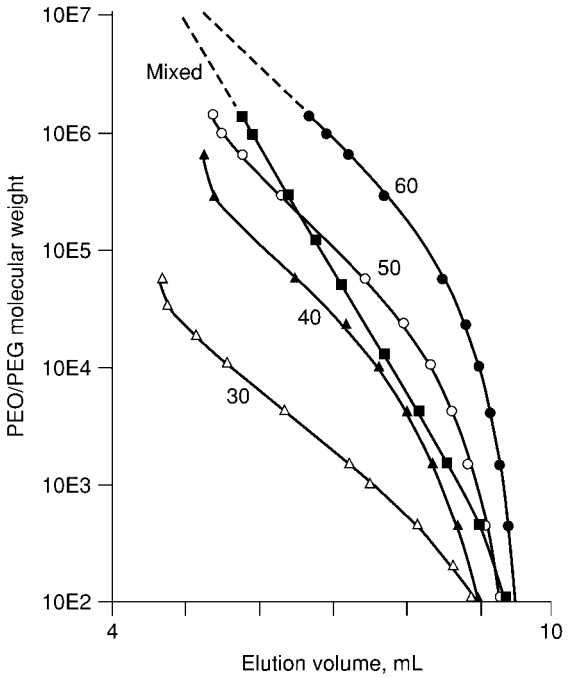

Fig. 4. Calibration curves for columns of PLaquagel-OH, designated 30 (△), 40 (▲), 50 (○), 60 (●), and Mixed (■), for aqueous SEC at ambient temperature. Eluent: water, flow rate: 1 mL/min, calibrants: poly(ethylene oxide/glycol) standards.

reasonably linear region spanning 1–2 decades in molecular weight, which defines the optimum resolving range of that type of packing material. Most commercial polymers exhibit a broad MWD demanding a very wide resolving range. Traditionally, this was achieved using combinations of several different individual pore size columns, but nowadays the use of mixed gel columns (where a homogeneous blend of individual pore size media is packed into the columns) is widespread (30). This approach provides a linear calibration curve (as illustrated in Fig. 3b and 4) over a specified molecular weight range, simplifies column selection, and minimizes replacement stock.

Typical column dimensions for SEC are length of 25–30 cm and internal diameter of 7–8 mm. SEC is normally a multicolumn technique and sets of two to five columns are used routinely. It is a requirement that the column technology should provide widespread solvent compatibility and good mechanical strength for durability across a wide range of applications.

Eluent Selection

The primary consideration in eluent selection is that the polymer must be fully dissolved for SEC analysis. A diverse range of organic solvents can be used for SEC, covering a wide range of polarity from hydrocarbons through to alcohols.

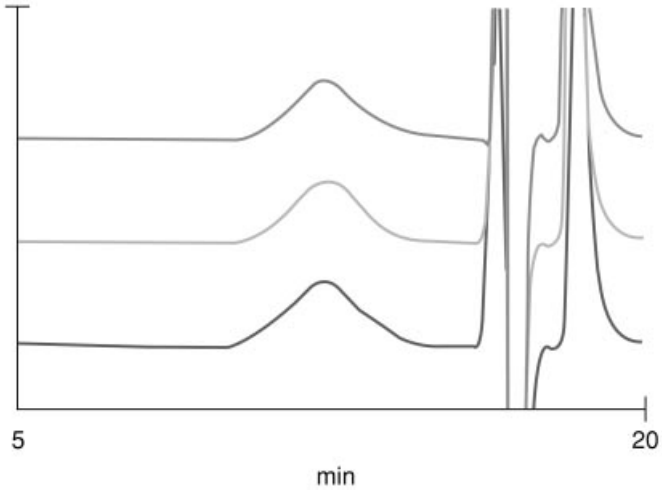

Fig. 5. Aqueous SEC analysis of three samples of chitosan at ambient temperature. Columns: 2 × PLaquagel-OH MIXED 8 μm 300 × 7.5 mm, eluent: 0.5 *M* $NaNO_3$/0.01 *M* NaH_2PO_4/pH 2, flow rate: 1 mL/min, detector: DRI.

The physical characteristics of the organic solvent selected must be taken into consideration with respect to detection, for instance, the refractive index of the solvent if DRI is to be used, or the UV or IR spectrum of the solvent if spectrophotometric detection at a given wavelength is to be employed. Furthermore, the viscosity of the eluent is important; if it is relatively high, then the SEC separation may need to be carried out at elevated temperature in order to reduce the eluent viscosity, thus decreasing column operating pressure and improving mass transfer. In aqueous SEC, many water-soluble polymers contain charged species or relatively hydrophobic groups which are likely to give rise to sample-column packing interactions in the SEC separation. Such nonsize exclusion behavior as shown in Table 1 must be suppressed if SEC is to be used for determination of MWD, and this can be achieved by modification of the eluent. Water containing salts and buffers successfully inhibit ionic interactions and the addition of a minor volume of organic solvent (eg methanol) is used to suppress hydrophobic interactions between the polymer and the column packing material. A typical aqueous SEC separation is illustrated in Figure 5.

Instrumentation

An SEC system consists of a solvent reservoir, an isocratic pump to deliver the eluent, an injection system to introduce the sample without interrupting the eluent flow, SEC columns to perform the fractionation, a detector which, in its simplest form, detects the concentration of the solute, and a form of data logging to record detector response as a function of elution time (11).

Pumping/Injection Systems. Because of the dependence of the technique on the precise measurement of elution volume, the pumping system must

be capable of delivering eluent at a constant volumetric flow rate, independent of back pressure or temperature. The accuracy of the flow rate at which the solvent is delivered is less important than the consistency, since very small variations in flow rate can cause large errors if SEC is to be used for characterization of MWD. Beyond the limits of acceptable pump performance, it is common practice to inject an internal standard or marker such that corrections for flow rate variation can be made to improve repeatability of results. When viscosity and light scattering detectors are employed in the SEC experiment, it is also preferable for the pumping system to exhibit minimal pulsations in pressure through the system so as to improve detector baseline stability.

A two position injection valve, either manually or automatically actuated, is usually employed for SEC, as for other forms of LC. The injection loop volume should be minimized in order to avoid chromatogram broadening as a result of dispersion in the injector. This is particularly the case when using SEC columns packed with very small particles, where the column efficiency is very high. However, in the case of solutions of medium to high molecular weight polymer, attempts to increase detector response by increasing sample concentration should be avoided as the increase in solution viscosity may result in a change in elution volume and additional dispersion as a result of viscous streaming. In these cases, it is necessary to increase the injector loop volume rather than increase the solute concentration if additional detector response is required. As a rule of thumb, an injection volume of 50 μL per column length of 30 cm in SEC is deemed to be a good compromise between minimal dispersion and maximum detector response.

Concentration Detectors. In the simplest SEC system, the concentration of the sample eluting from the columns must be measured via some appropriate form of detector. The most commonly used type of concentration detector is the DRI detector in which the difference in refractive index between pure solvent and the eluent flowing from the separating columns is measured. The response from the DRI detector is proportional to concentration, assuming that the specific refractive index increment (dn/dc) for the eluting polymer is constant. Because short chain polymers might have a molecular weight dependent dn/dc, a correction for the measured DRI response might have to be considered. In the case of heterogeneous samples (eg block copolymers and formulated materials), where the dn/dc for different components may vary as a function of elution volume, DRI may not be the most appropriate choice of concentration detector. DRI detectors are very sensitive to fluctuations in temperature and pressure, and baseline stability can be problematic if the system is not well conditioned. However, this type of detector does have broad general application and is relatively low in cost.

Detectors operating on the principle of absorption of incident UV or IR radiation are also used in SEC. These detectors rely on the polymer containing functional groups that give rise to specific absorption at the wavelength of the incident radiation and therefore are limited to certain applications where the polymer contains a UV chromophore or has a characteristic IR absorption band. Furthermore, the extensive use of a diverse range of organic solvents for SEC can restrict the use of UV or IR detectors as the background absorption from the solvent itself can be significant enough to mask out any contribution from the sample itself. Both UV

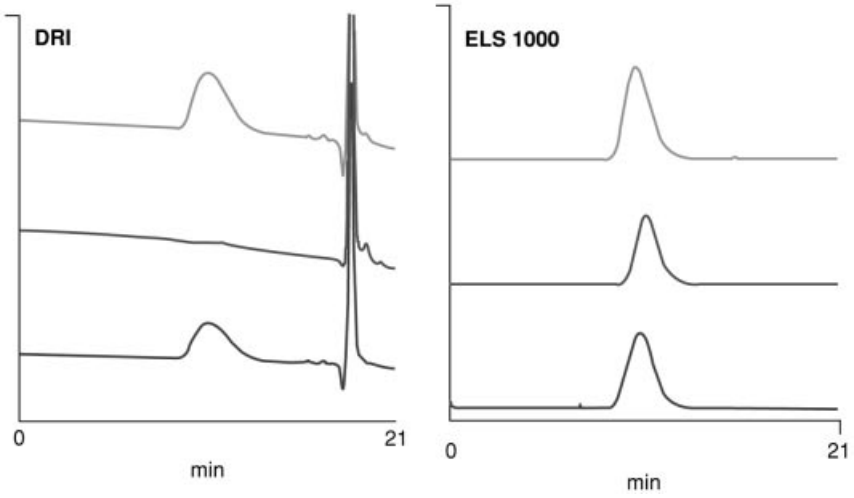

Fig. 6. Comparison of detector responses for DRI and ELSD in the analysis of PS (top), PDMS (middle), and PS/PDMS blend (bottom) at ambient temperature. Columns: 2 × PLgel 5 μm MIXED-C 300 × 7.5 mm, eluent: THF, flow rate: 1 mL/min.

and IR detectors can be useful for the characterization of copolymers using dual detection, as the wavelength of the detector can be tuned to respond specifically to one moiety.

The evaporative light scattering detector (ELSD) has found increasing application in SEC over the last decade or so. In this device, the eluent stream is mixed with an inert nebulizer gas to form a continuous stream of droplets that pass through an evaporation chamber where the volatile solvent is driven off leaving a plume of solute particles. The concentration of solute is determined by the amount of light obscured by the particles as they pass through the optical chamber of the device. This detector is often referred to as more "universal" than the others mentioned above, since it does not rely on the characteristics of the solute and is less affected by the choice of eluent. This is graphically illustrated in Figure 6, which compares detector outputs from DRI and ELSD for the analysis of a blend of polystyrene (PS) and polydimethylsiloxane (PDMS) using tetrahydrofuran (THF) as eluent. In this case, there is a reasonable difference in refractive index between the THF and PS, giving a positive peak response. However, PDMS is isorefractive with THF and no peak is detected by DRI; hence the PS/PDMS blend results in a chromatogram that reflects only the PS portion of the sample. However, in the case of the ELSD, where eluent is evaporated, all solutes result in a positive response and the chromatograms of PS, PDMS, and the blend are suitable for quantification purposes.

Molecular Weight Sensitive Detectors. Light scattering and viscometry are two classical techniques routinely applied to the characterization of polymers in solution (2). When operated in a flow through mode, so-called molecular weight sensitive detectors can be combined with the SEC separation to provide direct measurement of molecular weight (light scattering) or a property related

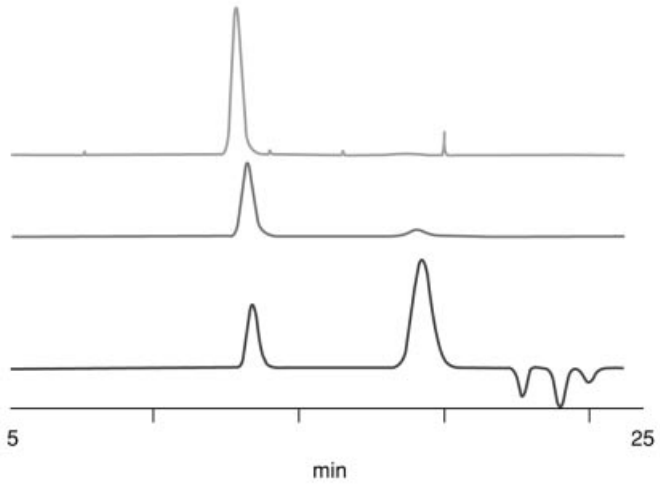

Fig. 7. Comparison of detector sensitivity for DRI (bottom), viscosity (middle), and light scattering (top) for two narrow PS standards (M_{peak} 186,000 and 1260). Columns: 2 × PLgel 5 μm MIXED-C 300 × 7.5 mm, eluent: THF, flow rate: 1 mL/min, temperature: 40°C.

to molecular weight (intrinsic viscosity), providing more accurate determination of molecular weight as well as facilitating the study of polymer architecture. The molecular weight sensitivity of such detectors compared to a conventional DRI concentration detector is illustrated in Figure 7.

In light scattering measurements, the intensity of scattered light from the polymer is expressed in terms of the excess *Rayleigh factor* R_θ, which is defined as the scattering intensity of the polymer solution to the scattering intensity of the solvent at a given angle θ. In practice for an SEC detector, R_θ is the measured response above the baseline, that is the detector output when there is no sample in the eluent exiting from the column. The general light scattering equation

$$R_\theta = cM_w(dn/dc)^2K \tag{20}$$

is applicable to on-line SEC measurements, where c is the polymer concentration and K is an optical constant.

SEC detectors are available with single, dual, and multiple angles at which the light scattering measurements are made and in each case the data treatment will vary slightly to accommodate the number of angles. In all cases the light scattering detector is used to determine the M_w of each fraction of the polymer as it elutes from the column, and by making a direct measurement of molecular weight, precludes the necessity to perform a column calibration. In order to calculate MWD, the concentration of each fraction must also be determined, and thus it is necessary to employ a concentration detector (usually DRI) as well as the light scattering detector in the SEC system. The sensitivity of light scattering detectors generally falls rapidly below around $M_w = 10{,}000$. However, below this limit the choice of solvent may be manipulated in order to increase dn/dc for a given polymer type and also the solute concentration for low molecular weight

polymers can generally be increased with no deterioration in chromatographic performance.

Viscometric detectors generally consist of one or more precision manufactured stainless steel capillaries through which the eluent from the SEC column flows and across which a pressure differential can be measured. Therefore, according to Poiseuille's law

$$P = \frac{8L\eta \mathrm{F}}{Pr^4} \tag{21}$$

where L and r are the length and radius of the capillary, F is the flow rate, and P is the pressure drop measured across the capillary. The specific viscosity (η_{sp}) of a polymer solution passing through the detector can be determined as a function of elution volume or time. Once again, an additional concentration detector is required in order to precisely determine the concentration of each eluting fraction such that a value of $[\eta]$ can be determined according to

$$[\eta] = \eta_{sp}/c \qquad (\text{when } c \text{ approaches zero}) \tag{22}$$

The measurement of $[\eta]$, also abbreviated IV, permits the determination of molecular weight of the polymer under investigation according to the principle of universal calibration, using hydrodynamic volume as defined in equation 9 as long as this polymer type is eluting by a size exclusion mechanism.

Conventional SEC calibration curves derived using different polymer types will yield polymer specific calibration plots of log M versus retention time as illustrated in Figure 8a. However, if an on-line viscometer is employed to measure $[\eta]$ directly, then the universal calibration plot of log $[\eta]M$ versus retention time will hold for any polymer type so long as the separation mechanism is based on size exclusion only, as illustrated in Figure 8b. Thus, having constructed a universal calibration using well-characterized polymer standards, any type of polymer can be analyzed, and by measuring $[\eta]$ on-line after the separation, the molecular weight of each eluting fraction can be obtained from the universal calibration plot.

In addition to the measurement of molecular weight, both light scattering and viscosity detectors permit the study of polymer architecture, eg branching. Figure 9 shows a series of typical Mark–Houwink plots for polyethylene samples derived from triple detector data (ie DRI, light scattering, and viscosity). A linear unbranched polyethylene results in a straight line plot where the slope and intercept equal the Mark–Houwink constants a and log K respectively. If the polyethylene is branched, the branched polymer will have relatively higher segment density compared to a linear polymer of equivalent molecular weight, resulting in a decrease in intrinsic viscosity. The ratio of the intrinsic viscosity of the branched polymer compared to a linear analogue will be dependent on the degree of polymer branching. Previous reference to concentration detectors for samples having compositional heterogeneity indicates that careful selection of a single

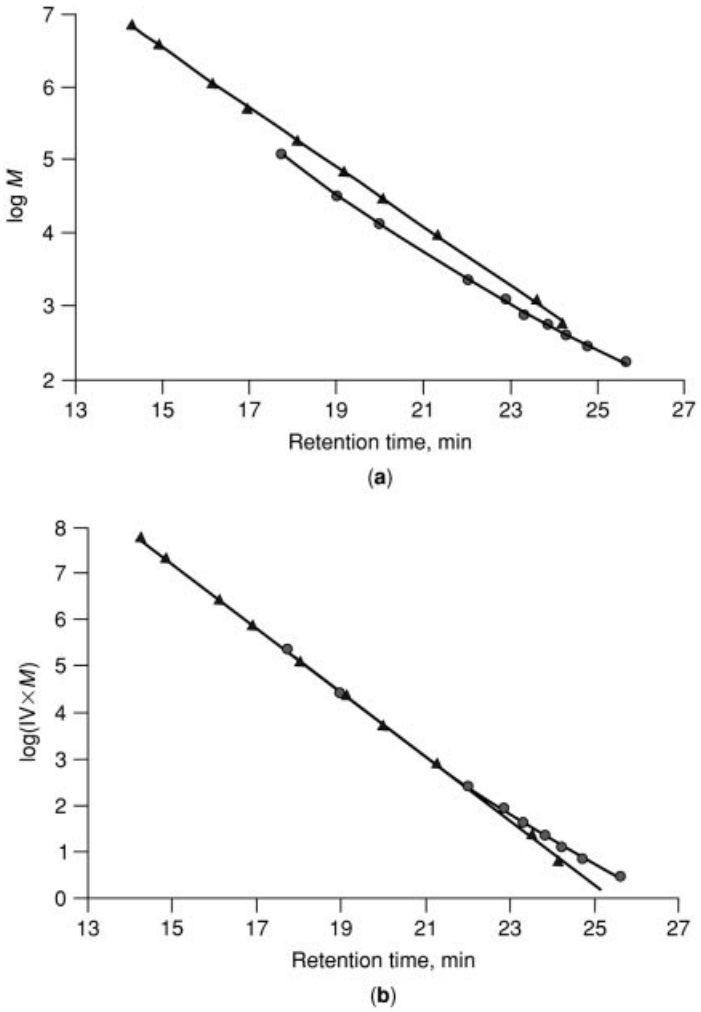

Fig. 8. Comparison of (**a**) conventional SEC calibration and (**b**) universal calibration, generated for polystyrene and polyethylene standards. Columns: 3 × PLgel 10 μm MIXED-B 300 × 7.5 mm, eluent: TCB, flow rate: 1 mL/min, temperature: 160°C. ▲ Polystyrene; ● polyethylene.

detector or dual detectors, together with light scattering or viscometric detectors, will be necessary for characterizing specific copolymers and blends.

Data Treatment

A primary application of SEC is for the determination of MWD (31). In this approach the raw data chromatogram obtained as output from the concentration detector is divided into a number of time slices of equal width, as shown in Figure 10.

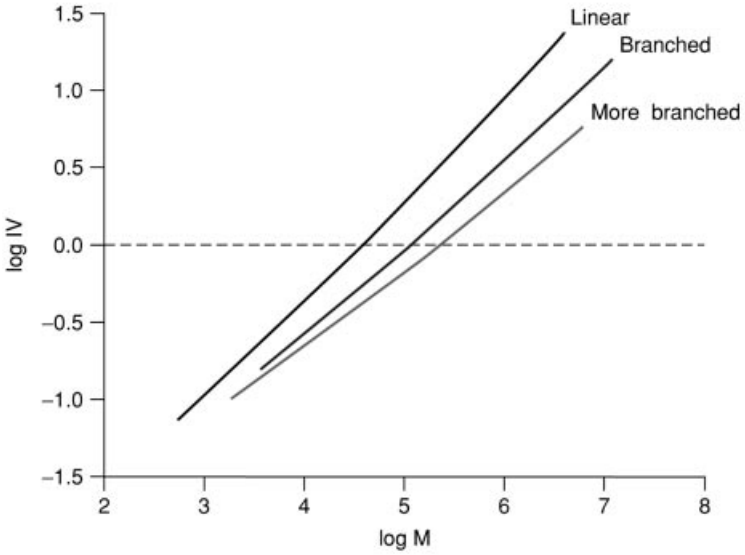

Fig. 9. Mark–Houwink plot from SEC with triple detection indicating linear polyethylene and polyethylenes with increasing degree of branching.

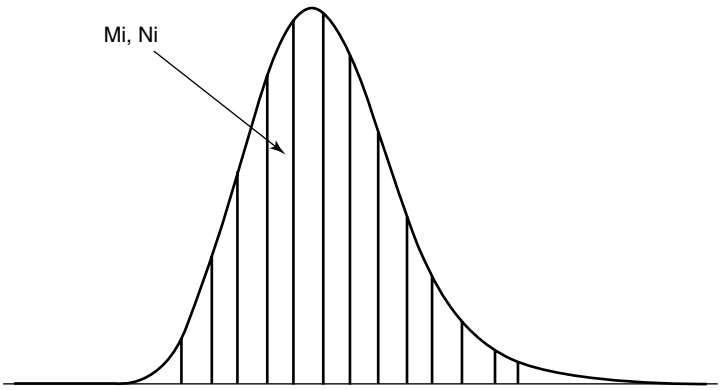

Fig. 10. Chromatogram from SEC indicating time slices for data manipulation.

For polydisperse samples the number of time slices must be selected in order that the computed average molecular weights will be unaffected by the number of time slices used. Since the introduction of high capacity computers with modern SEC software, this is nowadays not a limitation for samples with narrow and broad distributions. An average molecular weight is assigned to each time slice and it is *assumed* for computational purposes that each time slice is *monodisperse* in molecular weight. A table is constructed with one row assigned to each time slice i and containing values for retention volume, area A_i, cumulative area, molecular weight M_i, A_i/M_i, and $A_i \times M_i$. The area of each slice is assumed to represent the

mole fraction N_i (or number fraction) of each mondisperse species in Figure 10. The moments of the distribution, and hence the average molecular weights, can then be calculated:

$$\text{Number average } M_n = \frac{\sum A_i}{\sum A_i / M_i} \tag{23}$$

$$\text{Weight average } M_w = \frac{\sum A_i M_i}{\sum A_i} \tag{24}$$

$$z \text{ average } M_z = \frac{\sum A_i M_i^2}{\sum A_i M_i} \tag{25}$$

When light scattering detection is employed, M_i can be measured instantaneously for each slice in the chromatogram.

Calibration Methods. In the absence of a light scattering detector, the calculation of MWD and average molecular weights from an experimental chromatogram necessitates the determination of the relationship

$$\log M = f(V_R) \tag{26}$$

or, for a constant flow rate through the system

$$\log M = f(t_R) \tag{27}$$

where t_R is retention time. Thus, a value of molecular weight can be assigned to each eluting slice based on its retention time or volume, and the MWD can be calculated. To achieve this, the column set used for the analysis must be calibrated, most commonly using a series of narrow polydispersity, well-defined polymer standards to establish the relationship. Narrow polydispersity standards, where M_w/M_n is typically less than 1.1, are available in a reasonably wide range of polymer types for both organic and aqueous SEC, for example, polystyrene, poly(methyl methacrylate), poly(ethylene oxide), and polysaccharide. Such standards must be characterized using a combination of techniques including SEC, since it is the peak molecular weight of the standard (M_{peak}) that should be plotted against peak retention time. Because of the relatively high efficiency of modern SEC columns and the narrow polydispersity of the calibrants, several standards are usually chromatographed together to save time, as illustrated in the upper part of Figure 11. This gives a conventional SEC calibration curve relating molecular weight to retention time for that specific polymeric calibrant type, as shown in the lower part of Figure 11, and in the application of this curve any molecular weight values calculated for unknown polymer samples must be quoted as relative values.

If narrow polydispersity polymer standards are not available for the polymer type under investigation, a calibration can still be established by applying the principle of universal calibration. For a chromatographic system containing a

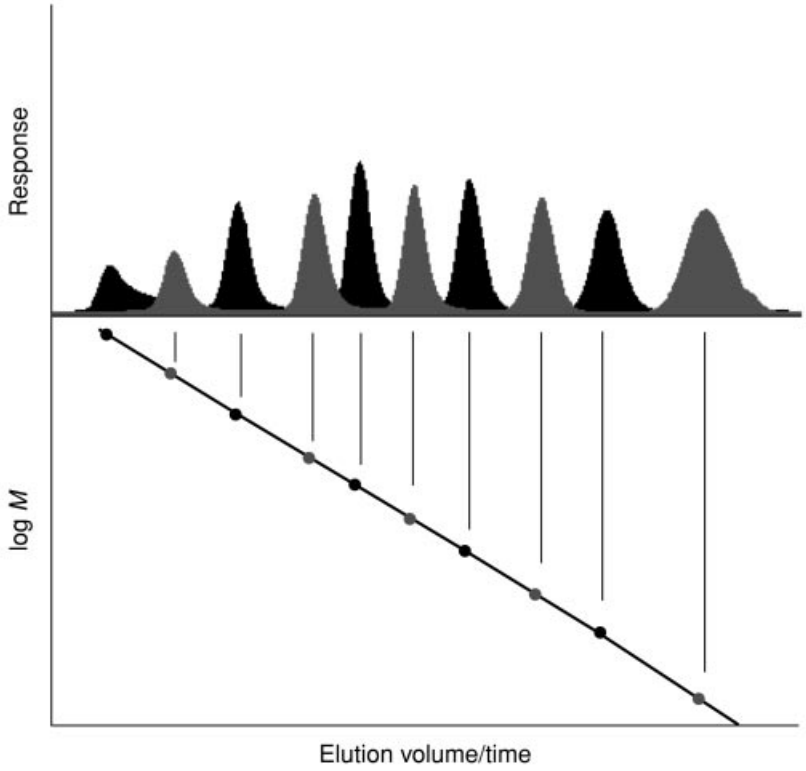

Fig. 11. Separation of narrow polymer standards of low polydispersity, and subsequent SEC calibration plot.

viscosity detector, an on-line measurement of intrinsic viscosity can be determined for any polymer type, and hence be converted to a calibration of log M_p against V_R according to equation 10. Alternatively, this approach can be modified by incorporating constants from the Mark–Houwink relation represented by equation 4, and by rearranging equation 10 it can be shown that

$$\log M_p = \left[\left(1+a_{ps}\right) / \left(1+a_p\right) \right] \log M_{ps} + \left[1/\left(1+a_p\right)\right] \log \left(K_{ps}/K_p\right) \qquad (28)$$

Values for the Mark–Houwink parameters K and a have been tabulated (14), and should be utilized where the solvent and temperature are appropriate. If only a value for M_n for a sample is required, then the method proposed by Goldwasser (32) can be applicable. This method requires the establishment of a universal calibration curve in conjunction with a viscometric detector without the need for a concentration detector or Mark–Houwink constants.

Software packages include calibration methods based on well-characterized reference materials with an MWD that may be somewhat broader than a narrow standard or with polydispersities exceeding 1.5. For calibrants with $M_w/M_n < 1.5$,

M_{peak} is close to M_w or M_v, which can be used in plotting the calibration curve, whereas for $M_w/M_n > 1.5$ search methods are required to generate a calibration curve over the range of M for the reference material (20).

COATING METHODS, SURVEY

Introduction

Coating process technology is in widespread use because there are few single materials that are suitable for the intended final use without treating the surface (1–7) to meet all the functional needs and requirements of the product. The modification is accomplished by applying a coating or series of coatings to the material—the substrate—to improve its performance and make it more suitable for use, or to give it different characteristics. The coating process is defined here as replacing the air at a substrate with a new material—the coating.

Typical coatings are the paints and the diverse surface coatings used to protect houses, bridges, appliances, automobiles, etc. These coatings protect the surface from corrosion and degradation, and may provide other functional advantages such as making the materials waterproof or flameproof, and improving the appearance. Adhesives are applied to paper or plastic to produce labels and tapes for a variety of uses. A thin layer of adhesive is coated onto paper to produce self-sticking note pads. Glass windows are coated with a variety of materials to make them stronger and to control light penetration into the structure. High energy lithium batteries contain coated structures. Plastic food wrap has layers to reduce oxygen penetration and retain moisture for the product to retain its freshness. Packaging materials for electronic products are coated with antistatic compounds to protect the sensitive components. Other important coated products are photographic films for medical, industrial, graphic arts, and consumer use; optical and magnetic media for audio and visual use data storage; printing plates; and glossy paper for magazines.

Encyclopedia of Polymer Science and Technology. Copyright John Wiley & Sons, Inc. All rights reserved.

Several industries are based on coating process technology. Printing itself is a coating process, and much of the paper used in the printing industry had previously been coated to improve its gloss, strength, and ink acceptability. Lithographic printing plates for printing presses are photosensitive coatings on aluminum. Photographic film, itself a coated product, is used to expose the plates, set the type, and prepare the printed pictures. The entertainment industry uses magnetic tape, silver halide film, and coated optical disks to record the material for distribution to the consumer. The electronics industry uses coated products such as photoresist films to fabricate circuit boards and to add functionality to the circuit boards. The computer industry stores information on coated magnetic structures such as hard drives and floppy disks.

Coating Machines

The basic steps in continuously producing a coated structure are

(1) preparing the coating solution or dispersion
(2) unwinding the roll of substrate
(3) transporting it through the coater
(4) applying the coating from a solvent, or as a liquid to be cross-linked, or from the vapor
(5) drying or solidifying the coating
(6) winding the final coated roll
(7) converting the product to the final size and shape needed

Other operations that are often used are

(1) surface treatment of the substrate to improve adhesion
(2) cleaning of the substrate prior to coating, to reduce contamination
(3) lamination, where a protective cover sheet is added to the coating structure.

Different types of machinery are used to produce coated products. Depending on the substrate, they can be web coaters, sheet coaters, and coaters for nonflat applications. Web coaters, the most prevalent, coat onto continuous webs of material. Magnetic tapes, window films, wallpaper; barrier coatings for plastic films, and many printed goods are all produced using this process. A typical web coater with all the process steps is shown in Figure 1.

These machines are commercially available in sizes from pilot coaters using narrow webs, 6–24 in. wide, and running at low speeds, 10–50 ft/min, to production machines using wide webs, over 5 ft wide and coating at 500–5000 ft/min. A typical pilot coater is shown in Figure 2.

Sheet coaters are available to coat individual sheets. Many printing operations and all copying machines are sheet-fed. Sheet coaters are also used as laboratory coaters to develop new products where many different solutions need to be coated and only small volumes of sample are available. These methods use a variety of devices such as draw-down blades, dies, or wire-wound rods to spread

a uniform layer of solution across the web. Most applicators can provide wet coverages of 0.2–50 mil (5–1270 μm). Spray coaters may also be used to coat sheets. The coated webs or sheets are then dried by ambient air or in an oven. Laboratory automated sheet coaters are available. These give better reproducibility and control but are more expensive than hand applicators. They can be coupled to feed directly into dryers, with the temperature and residence time controlled, as shown in Figure 3.

Fig. 3. Laboratory bench-top coater. Courtesy of Werner Mathis.

In nonweb applications the coating is applied to a specific part at the end of the fabrication process. The part is usually three-dimensional and of varying shape. Automobiles, appliances, and steel structures all have the coating applied to the individual items as they are being built. It should be noted that many smaller steel items are made from prepainted sheet steel.

Coating Processes

The application of a liquid to a traveling web or substrate is accomplished by one of the many coating methods. Widely used commercial coating methods are reverse roll, wire-wound or Mayer rod, direct and offset gravure, slot die, blade, hot melt, curtain, knife over roll, extrusion, air knife, spray, rotary screen, multilayer slide, coextrusion, meniscus, comma and microgravure coaters (based on analysis of methods reported by coaters in various trade sources). Each of these has many designs and hardware arrangements leading to many specific coating configurations. Powder coating is covered in the article Coating Methods, Powder Technology.

The choice of the method depends on the nature of the support to be coated, the rheology of the coating fluid, the solvent, the wet-coating weight or coverage desired, the needed coating uniformity, the desired coating width and speed; the number of layers to be coated simultaneously, cost considerations, environmental considerations, and whether the coating is to be continuous or intermittent.

The method should be chosen based on the specific requirements. Often a method is selected based on the availability of a specific coating applicator, even though it may not be the best choice. All applicators can apply a coating at some conditions. Much time and money can be wasted by trying to make the product by a process that is not suitable. The coating window may be too narrow at the conditions selected, or it may be impossible to ever obtain a quality coating. The successful process will provide defect-free film over a wide range of conditions. A process that works well at low speeds in the laboratory may not be appropriate for a manufacturing plant coating at high speeds, and conversely, a high speed coating process may not be appropriate for laboratory trials.

The first step in the selection proces is to establish the requirements for the product to be coated. These requirements are then matched with the capabilites of the process and the best methods are evaluated experimentally to determine the one to use. Some of the basic characteristics of the principal coating processes are listed in Table 1.

The processes are grouped according to the principle used to control the coverage or coating weight of the coating and its resulting uniformity. We have three groupings, but there are no generally accepted definitions of the terminology we use: self-metered, premetered and hybrid. Self-metered processes are those in which the coverage is a function of the liquid properties and the system geometry, the web speed, the roll speeds, and any doctoring device. Examples are dip coating in which viscosity and web-speed control coverage, and blade and air knife coating in which excess is applied and then removed. Premetered processes deliver a set flow rate of solution per unit width to the applicator and all the material is transferred to the web. If a smooth coating is obtained then the coverage is fixed.

Table 1. Summary of Coating Methods[a]

Process	Viscosity, mPa·s (=cP)	No. of layers	Wet thickness, μm	Coating accuracy, %	Max. speed, m/min
Self-metered					
Rod	20–1000	1	5–50	10	250
Dip	20–1000	1	5–100	10	150
Forward roll	20–1000	1	10–200	8	150
Reverse roll	100–50,000	1	5–400	5	400
Air knife	5–500	1	2–40	5	500
Knife over roll	100–50,000	1	25–750	10	150
Blade	500–40,000	1	25–750	7	1500
Premetered					
Slot	5–20,000	1–3	15–250	2	500
Extrusion	50,000–5,000,000	1–3	15–750	5	700
Slide	5–500	1–18	15–250	2	300
Curtain	5–500	1–18	2–500	2	300
Hybrid					
Gravure, direct	1–5000	1	1–25	2	700
Gravure, offset	100–50,000	1	5–400	5	300
Microgravure	1–4000	1	1–40	2	100

[a]Values given are only guidelines.

Hybrid processes use features of both self- and premetered coating to achieve coating weight control. Gravure is an example of this method. The cell transfer determines coverage but doctoring is used to remove excess fluid from the gravure cylinder.

In most coating operations a single layer is coated. When more than one layer must be applied one can make multiple passes, or use tandem coaters where the next layer is applied at another coating station immediately following the dryer section for the previous layer, or a multilayer coating station can be used. Slot, extrusion, slide, and curtain coaters are used to apply multiple layers simultaneously. Slide and curtain coaters can apply an unlimited number of layers simultaneously, whereas slot coaters are limited by the complexity of the die internals and extrusion coaters by the ability of the combining adapter, ahead of the extrusion die, to handle many layers.

The precision or uniformity of the coating is very important for some products such as photographic or magnetic coatings. Some processes are better suited for precise control of coverage. When properly designed, slot, slide, curtain, gravure, and reverse-roll coaters are able to maintain coverage uniformity to within 2%. In many of the other coating processes the coverage control may be only 10%. Table 1 lists generally accepted attainable control.

The substrates or support coated on include paper and paper board, cellophane, poly(ethylene terephthalate), poly(ethylene naphthalate), polyethylene, polypropylene, polystyrene, poly(vinyl chloride), poly(vinyl fluoride), poly(vinylidene fluoride), polyimide, metal foils, woven and nonwoven fabrics, fibers, and metal coils. The surfaces of these supports can be impervious as in plastic films, or there may be a pore structure such as in paper. Primer coatings

may be applied to seal these pores to give a uniform surface for the coating and to improve adhesion. The surfaces can also be modified with surface treatments such as flame treatment, plasma treatment, or corona discharge. These treatments increase the surface energy, thereby improving wetability and adhesion.

The web coating process can be used for intermittent coatings, such as in the printing process and to form coated batteries, as well as for the more common continuous coatings such as photographic films. In general, there is an ideal coater arrangement for any given product. However, most coating machines produce many different products and coating thickness and the machine is therefore usually a compromise made for the several applications.

Limits of Coatability. In any coating process there is a maximum coating speed above which coating does not occur. At higher speeds air is entrained, resulting in many bubbles in the coating, or in ribs and finally rivulets, or in wet and dry patches. In slot coating below a critical speed, to coat thinner often means to coat slower. Above the critical speed the minimum thickness depends only on the gap. Above some higher speed a coating cannot be made (5). Using bead vacuum, thinner coatings can be obtained. Similar effects were found in slide coating, except the critical speed is never reached (6). The maximum coating speed in slide coating for thick coatings, where no bead vacuum or electrostatic assist is used, is identical to the velocity of air entrainment for a tape plunging into a pool of coating fluid. Lower viscosity liquids can be coated faster and thinner. Polymer solutions can be coated at higher speeds than Newtonian liquids. These phenomena have been explained in terms of a balance of forces acting on the coating bead, ie, the coating liquid in the region where it first makes contact with the web (7). Stabilizing forces are mainly bead vacuum or electrostatic assist, if used. The destabilizing forces are primarily the drag force on the coating liquid and the momentum of the air film carried along by the web. Thus, with no bead vacuum or electrostatic assist, there is a net destabilizing force which is balanced by the cohesive strength of the liquid. Limits of coatability occur in all coating operations but under different conditions in each process. A good description of the window of coatability in slot coating can be found in Reference 8.

The air entrainment velocity for plunging tapes does not depend on the wettability of the surface, but does increase with surface roughness (9,10). Presumably the rough surface lets air that would otherwise be entrained escape in the valleys between the peaks that are covered with coating liquid (11). In the converting industry, which involves coatings on rough and porous paper surfaces, much higher (up to 25 m/s) coating speeds can be attained than in photographic coatings on smooth plastic films. Although the wettability itself plays little or no role in coatability, it does play an extremely important role in coating. On a nonwetting surface, immediately after coating, the fluid will dewet and ball up into distinct islands.

Knife and Blade Coatings. Knife and blade coatings are in many ways similar. In both cases the knife or the blade doctors off excess coating that has been put on the web. Knives are usually held perpendicular to the web, whereas blades are usually tilted so that they form an acute angle with the incoming web. Typically blades are thin, only 0.2–0.5 mm thick, and can be rigid or flexible (of spring steel). Knives are thicker and are always rigid. Blades, being thinner, wear faster and have to be changed relatively often, perhaps two to four times a

day. Blades are always pressed against the web, which is supported by a backing roll either made of chrome-plated steel or rubber-covered. Knives may be pressed against web on a rubber-covered backing roll; they may be pressed against the unsupported web which is held taut by the tension in the web; or they may be held at a fixed gap from the web that is supported by a backing roll.

The ends of the knives can be square, beveled or rounded. If the end is square and parallel to the web, if the upstream face is perpendicular to the web, and if there is a fixed gap between the end of the knife and the web, then the wet coverage is exactly one-half the gap. On the other hand, if there is a low angle in a converging section of the knife or of the blade, leading up to a tight gap as there is for many knives and for all bent blades, then strong hydrodynamic forces build up and tend to lift the knife or blade away from the web. This forces more fluid under the knife or blade, so that the coated thickness is greater than half the gap.

In all cases of knife and blade coatings, except in knife coating at a fixed gap, a rigid member and a flexible member are pressed together. The flexible member can deflect to allow for nonuniformities in the web. In knife coating and beveled blade coating, the knife or blade is rigid, and the unsupported web or the web on a rubber-covered roll is flexible. In bent blade coating the blade is flexible and the web on the roll is rigid or relatively rigid as in the case of a rubber-covered roll. Knife coating against unsupported web is more difficult to control than the other knife- and blade-coating techniques because, here, the web tension is a very important variable.

The simplest and least expensive, but still effective, coating method is knife coating, either against a backing roll or on unsupported web. Coating against a backing roll is more accurate, as it is independent of web tension. The knife, held perpendicular to the web, acts as a doctor blade and removes excess coating liquid. The coating can be applied by any convenient method, such as with an applicator roll, or by pumping the fluid into a pool formed by the web, the knife, and two end dams. The control of the coverage is by proper positioning of the knife. The unsupported knife shown in Figure 4a is used for coating open fabric webs where coating penetration is desired or cannot be prevented. A full width endless belt can be used to support a weak web and pull it through the knife area without tearing so as to overcome the drag of the knife.

The knife over roll coater (Fig. 4b) is probably the most common of the knife coaters. It is simple and compact. The driven back-up roll may be precision-made

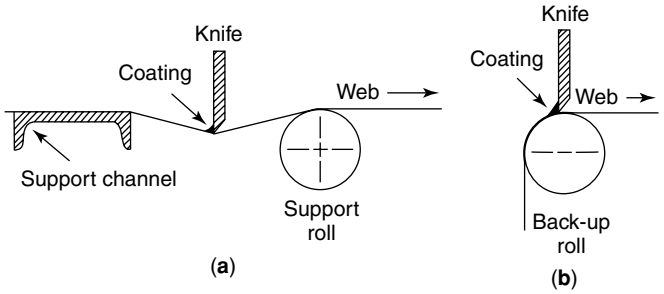

Fig. 4. (**a**) Unsupported knife; (**b**) knife over roll.

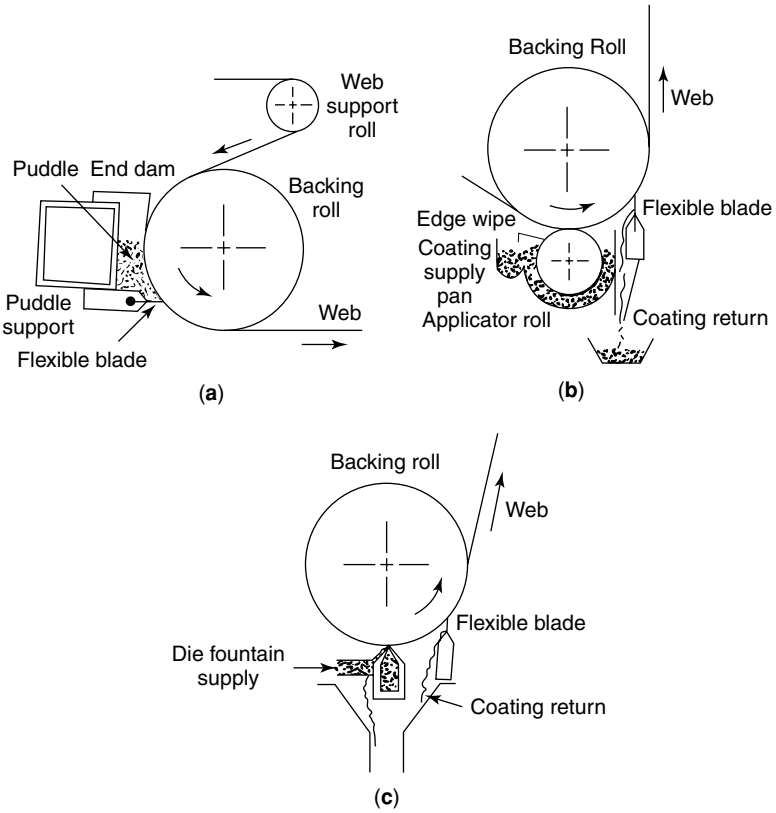

Fig. 5. (**a**) Puddle coater; (**b**) roll applicator blade coater; (**c**) fountain blade coater.

and chrome-plated, having a controlled gap between the web and the knife. The backing roll may also be rubber-covered, the knife pressing against the web. Here the coating weight is determined by the pressure against the knife. Higher pressures give lower coating weights.

Knife coaters can apply high coverages, up to 2.5-mm wet, and can handle high viscosities, up to 100,000 mPa·s (=cP). They tend to level rough surfaces rather than give a uniform coverage, a characteristic that can be desirable or not depending on the needs of the finished coating. Streaks and scratches are hard to avoid, especially using high viscosity liquids.

Blade Coating. Flexible blade coaters can be used either with a downward moving web, as shown in Figure 5a, or with an upward moving web, as shown in Figure 5b. As with knife coaters there are many ways of feeding the metering blade. A puddle behind the blade is shown in Figure 5a, a forward turning applicator roll in Figure 5b, and a slot applicator or die fountain in Figure 5c. Jet fountains, where the coating liquid spurts out to the web 25–50 mm away, are occasionally used.

Blade coaters are commonly used on pigmented coatings. They have the unique feature of troweling in the low areas in a paper web, thus producing a coated surface that has excellent smoothness and printing qualities. The backing

roll is usually covered with resilient material and is driven at the same speed as the web to stabilize the web and draw it past the blade. A replaceable blade is rigidly clamped at one end and the unsupported end is forced against the substrate. The wet coverage is adjusted by varying blade thickness, the blade angle, and the force pushing the blade against the substrate. The force on the blade can be obtained by various means: a rubber tube between the blade and a rigid member can be inflated with varying air pressures or the blade holder can be rotated so as to apply a greater or lesser force at the tip, while keeping constant the angle the blade tip makes with the web.

As the force on the blade increases, and as the force is concentrated at the blade tip, the wet coverage decreases rapidly. However, further increases in force bend the blade and a larger area of the blade presses the liquid against the web. Increasing the loading of the blade then causes the tip to lift up and the coverage now increases. At further increases in load the coverage again decreases.

The beveled blade coater uses a rigid blade held at an angle of 40–55° to the web. The end of the blade is parallel to the substrate and pressed against it. If initially the end of the blade is not parallel to the web, it soon is as a result of abrasion by the pigmented fluid. When the loading on the blade increases, the wet coverage decreases. With the same force but using a thicker blade, the pressure, or force per unit area, on the coating fluid between the blade and the web decreases and the coverage increases.

In the rod–blade coater unit, a rod is mounted at the end of the blade. This coater behaves more like the beveled blade coater than a flexible blade coater.

Two-Blade Coaters. In order to coat both sides of a web simultaneously, two flexible blade coaters can be used back-to-back, ie, with both blades pressing against each other and the web between them. The web usually travels vertically upward. Different coatings can be applied on each side of the web. The blades tend to be thinner and more flexible than the standard blades and the angle to the web is lower. The web has to have sufficient tensile strength to be pulled through the nip.

Simultaneous coatings can also be made with one flexible blade against the web on the roll, where the web moves downward. On one side the coating fluid is supplied to a puddle in front of the blade, and on the other side the fluid is carried into the nip by the roll. Edge dams between the web and the blade and between the web and the roll keep the fluid contained. The roll may rotate faster than the web. Figure 6 shows a version where the fluid on the roll side is supplied by a transfer roll.

Air-Knife Coater. The air-knife coater is a versatile coating process in use for a wide range of products. A coating pan and roll are used to apply the coating solution and then an air knife is positioned after the pan to regulate the final wet-coating weight by applying a focused jet of air to the web. The excess solution is collected in an overflow pan and can be either recirculated and used again or scrapped. The air knife can function either in the precision or in the squeegee mode. These give very different types of coating and performance characteristics, although the same name is used for both processes.

In the precision mode, the air knife uses low pressures and doctors off some of the coating to control the coating weight and to level the surface to give a uniform coating of reasonable quality. The coating weight is a function of web

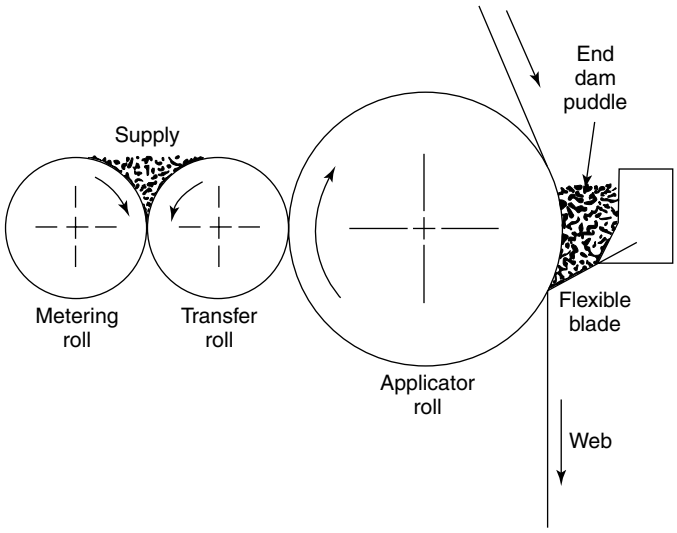

Fig. 6. Billblade with transfer rolls.

speed, viscosity of solution, surface tension, and air-knife pressure. This precision mode has been used to coat photographic films where the air velocities are 13–130 m/min and air pressures are 50–2500 Pa (0.2–10 in. of water) to give 1- to 200-μm wet thickness.

In the squeegee mode, the air knife operates at much higher pressures and coating speeds than in the precision mode and effectively doctors off the majority of the coating. This process is used for porous supports, such as paper, where the coating is absorbed into the voids. After the air knife, which effectively functions as a leveling device, the coating solids remain in the voids and in a thin surface layer.

The advantages of the air-knife process are low initial cost, versatility for coating a variety of webs and solutions, ease of changing and maintaining the coating, and the good coating quality. The disadvantages are the noise and contamination problems created by the air stream and the resulting spray, solution viscosity limitations, a somewhat restricted coating weight range, and the high cost to operate the air blowers.

Wire-Wound Rod Coating. The wire-wound rod coater shown in Figure 7, called a Mayer rod, meters off excess applied coating solution. The rod is often rotated to increase its life by causing even wear and to prevent particles from getting caught under the rod and causing streaks. Normal rotation is in the reverse direction to the web travel. The wire size controls the coating weight. As the rod has an undulating surface because of the wire, one would expect the coating to have a similar unevenness. However, the down-web lines that form are frequently spaced at other than the wire diameter and are due to ribbing. If the solution is not self-leveling, a smoothing rod may be used to smooth out the surface. Rod coaters are best used with low viscosity liquids.

From the geometry of the wire-wound rod, one would expect the wet thickness to be 10.7% of the wire diameter. It is frequently less. It has been shown that with

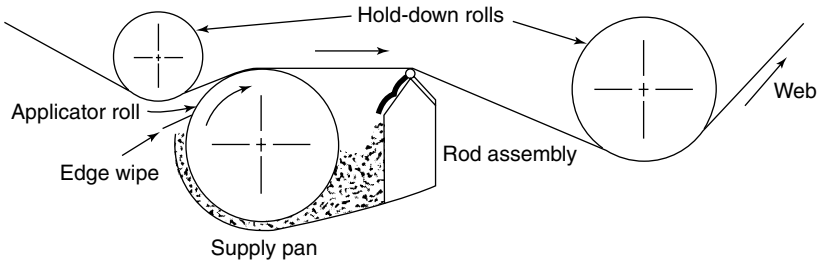

Fig. 7. Wire-wound rod coater.

increasing load on the rod the wet thickness decreases to about 7% of the wire diameter (11).

Rod coaters are commonly used for low solids, low viscosity coatings such as those used to coat adhesives and barrier layers on poly(vinylidene chloride) carbon paper and silicone release papers. Coating weights range from 1.5–10 g/m^2, and speeds are as high as 300 m/min. The wire-wound rod can be held against unsupported web, as shown in Figure 6, or against a backing roll. When used against unsupported web the web tension affects the coverage. Coating rods are compact, simple, and inexpensive, but wear rapidly when used with abrasive fluids.

Roll Coating.

Meniscus or Bead-Roll Coater. One of the simplest and most widely used coaters is the meniscus or bead-roll coater (Fig. 8). In this process the web passes over a backup roll that is just above the liquid level in a pan. A meniscus or coating bead is formed between the web and the coating solution by raising the pan, and the solution transfers to the web. The coverage is determined by the viscosity of the solution and the coating speed. The pan design is very critical and a variety of configurations are available. The coating speed is very slow, only about 10 m/min on low viscosity liquids. High quality optical coatings may be produced. These coaters have also been used for adhesives.

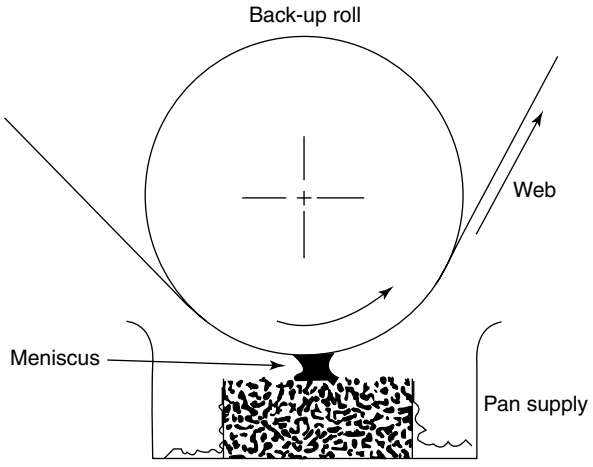

Fig. 8. Pan-type Meniscus coater.

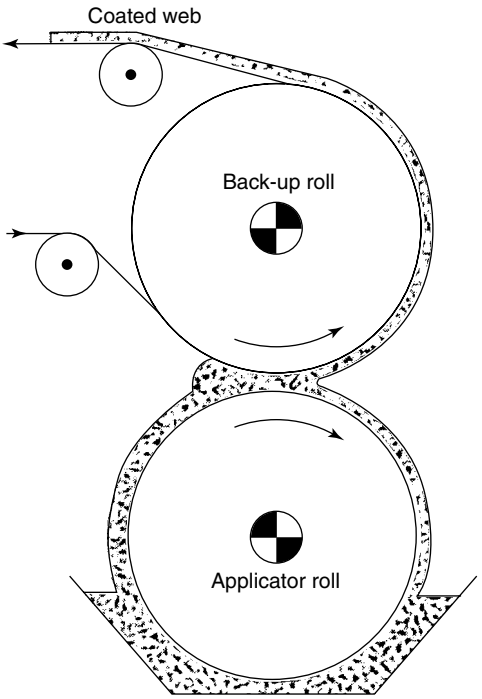

Fig. 9. Two-roll forward-roll coater (12).

Kiss Coaters. In kiss coating fluid is transferred from a rotating applicator roll, called a kiss roll, to unsupported web. There are many types of kiss coaters. The kiss roll can turn in the direction of the web or in the reverse direction, but usually operates in the web direction. Kiss coaters are tension sensitive and are often used to apply excess coating prior to a metering device.

Forward-Roll Coaters. In forward-roll coating the web passes between two rolls rotating in the same direction, the applicator roll and the backing roll. The applicator roll drags fluid into the nip, as shown in Figure 9 (12). The fluid exiting the nip splits in two, with some adhering to the web and some to the applicator roll. One might expect that if both rolls are rotating at the same surface speeds, then the fluid between them should move at that same speed and the flow rate per unit width through the nip, q, would equal the product of the surface speed, U, and the gap in the nip, G. Actually it is more than this because of the buildup of pressure as the fluid approaches the nip, which produces a greater flow. The dimensionless flow rate γ is defined as the ratio of the actual flow rate per unit width to GU, the "expected" value, or

$$\gamma = \frac{q}{GU}$$

where U is now the average surface speed of the two rolls. The dimensionless flow rate is approximately equal to 1.3 to 0.5, depending upon conditions.

Each roll carries away some of the flow. The ratio of film thickness on the two rolls, t_2/t_1, depends on the speed ratio, and for Newtonian fluids is

$$t_2/t_1 = (U_2/U_1)^{0.65}$$

where the subscript 1 corresponds to the web and the subscript 2 to the applicator roll. The total flow through the gap per unit width, q, is equal to the sum of the flow on the web, t_1U_1, and that on the exit side of the applicator roll, t_2U_2. With shear-thinning fluids, when the roll speeds differ the split is more symmetrical than the equation indicates.

In forward-roll coating it is fairly common to have an instability called *ribbing*, where the coating thickness varies sinusoidally across the web and the coating looks as if a giant comb were dragged down the wet coating. Ribbing occurs when the *capillary number*, Ca, the ratio of viscous to surface forces, exceeds a certain value, depending on the gap-to-diameter ratio. The capillary number is

$$Ca = \eta U/\sigma$$

where U is the average surface speed of the two rolls, η is the viscosity of the coating fluid, and σ is the surface tension.

It is very difficult to avoid ribbing in forward-roll coating. When the fluid is not self-leveling, a smoothing bar is often used to smooth out the ribs. It has been found that a fine wire or thread stretched across the gap exit and touching the liquid eliminates ribbing (10).

Reverse-Roll Coating. Reverse-roll coating is an extremely versatile coating method and can give a very uniform, defect-free coating (12–1200 μm thick) at a very wide range of coating speeds, using coating fluids with viscosities ranging from low to extremely high. In reverse-roll coating, the coating fluid is applied to the applicator roll by any of a number of techniques, such as having the applicator roll rotate in a pan of fluid, using a fountain roll or a fountain or slot die. The excess fluid is then metered off by a reverse-turning metering roll and the remaining fluid is completely transferred to the web traveling in the reverse direction. Two of the many possible configurations are shown in Figure 10.

All the flow remaining on the applicator roll after it rotates past the metering roll is transferred to the web; therefore it is important to know what this flow is. The thickness of the metered coating on the applicator roll, t_a, is found to be a function of the gap, of the ratio of the speed of the metering roll to that of the applicator roll, and of the capillary number based on the applicator roll speed (Fig. 11).

In reverse-roll coating, as in forward-roll coating, instabilities can form. However, it is possible to obtain defect-free coatings at high coating speeds. Sometimes increasing the speed can lead to a smooth coating when a ribbing condition is present.

Another defect, called cascade or seashore, can form in reverse-roll coating. This defect is caused by the entrapment of air under certain conditions and can appear in the metered flow on the applicator roll. An operability diagram, showing the region of stable flow as well as the regions where these defects form, is given in Figure 12 for two gaps. The region where stable coatings can be made is at

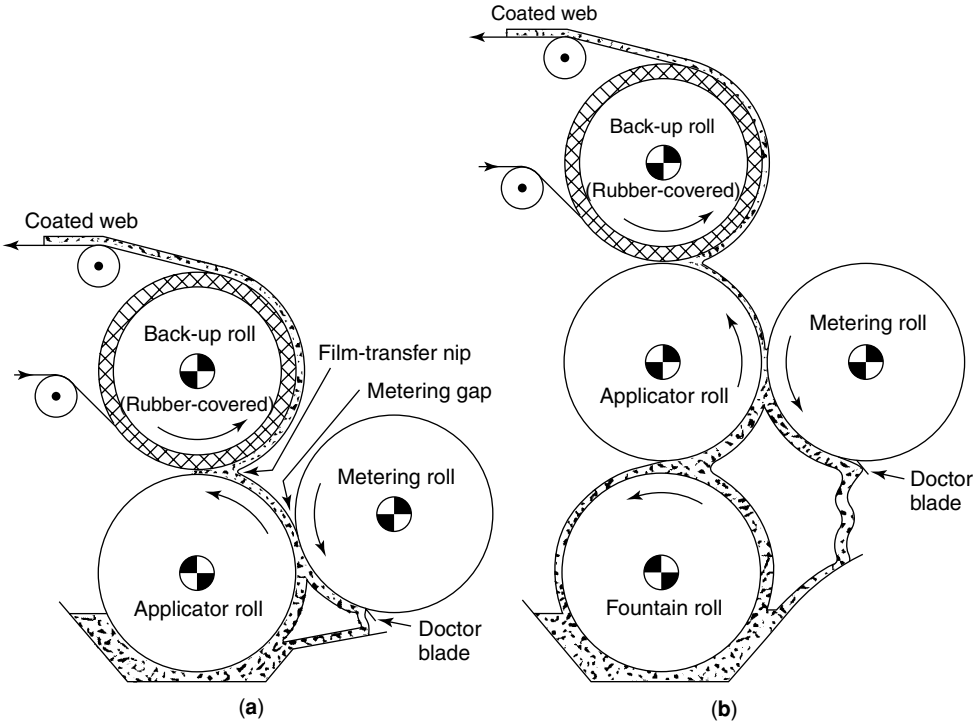

Fig. 10. Pan-fed reverse-roll coaters: (**a**) three roll; (**b**) four roll (12).

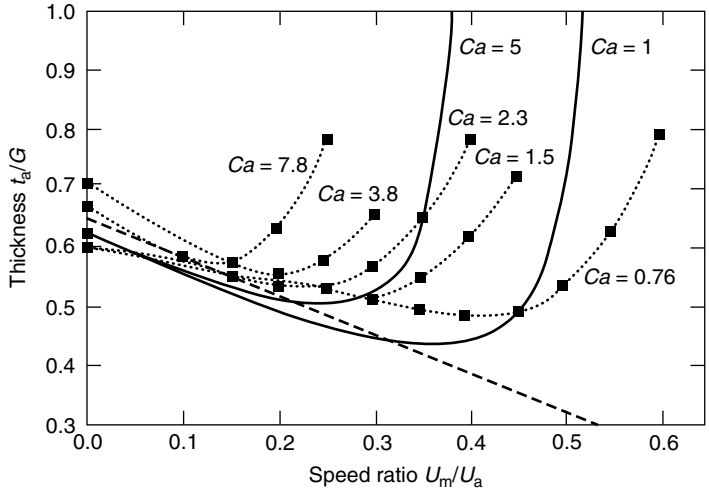

Fig. 11. Reverse-roll, metered film thickness on the applicator roll divided by gap, t_a/G, as a function of the ratio of the metering roll speed U_m to applicator roll speed U_a for various capillary numbers based on U_a. (—) represents theoretical values; (· · ·) experimental ones; and (- - -) is the lubrication model (12).

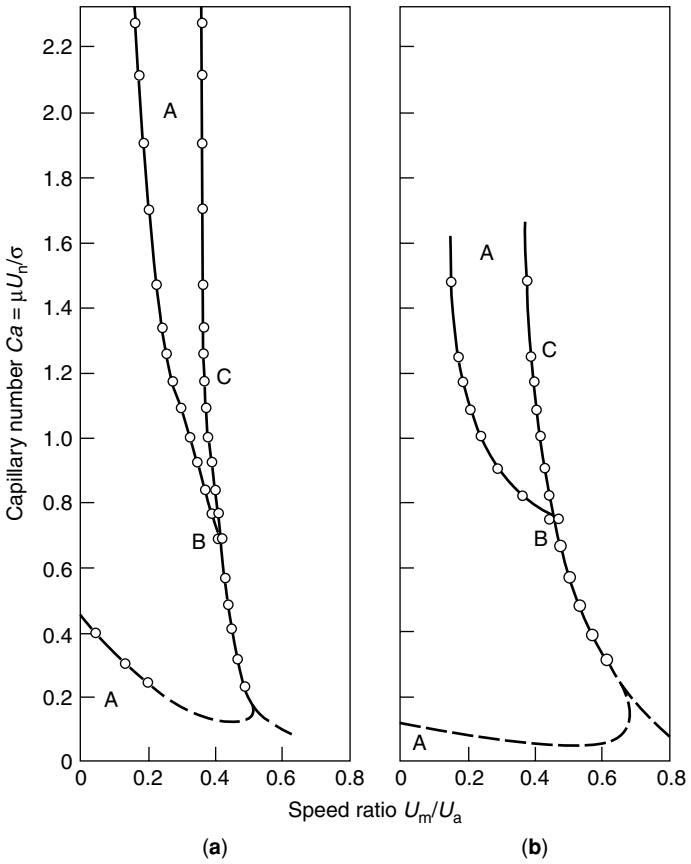

Fig. 12. Operability diagram for reverse-roll coating, where A represents a stable coatings area; B, ribbing; and C, cascade; for (**a**) a gap $G = 750$ μm and (**b**) a gap $G = 250$ μm (12).

high capillary numbers, ie, at high speeds. There is also a stable region at very low speeds, but low speeds are not usually desirable. The principal advantage of reverse-roll coating is that conditions can be adjusted to give a stable, defect-free coating at high coating speeds. Using precision bearings, reverse-roll coaters can lay down as uniform a coating as any coating process, about $\pm 2\%$.

Gravure Coating. Gravure coating is an accurate way of coating thin (1- to 25-μm wet coverage) layers of low [10–5000 mPa·s (=cP)] viscosity liquids. The coating liquid is picked up by a patterned chrome-plated roll, the excess doctored off and the liquid transferred from the filled cells to the web. Figure 13 illustrates two types of gravure coaters. In direct gravure the liquid is transferred directly from the gravure roll to the web. In offset gravure the liquid in the cells is first transferred to a rubber-covered offset roll before the final transfer to the web. In reverse gravure the gravure roll or the offset roll turns in the reverse direction with respect to the web. In differential gravure the forward rotating gravure cylinder runs at a different speed than the backing or impression roll. However, the web does not have to be held against a backing or impression roll; it can also be

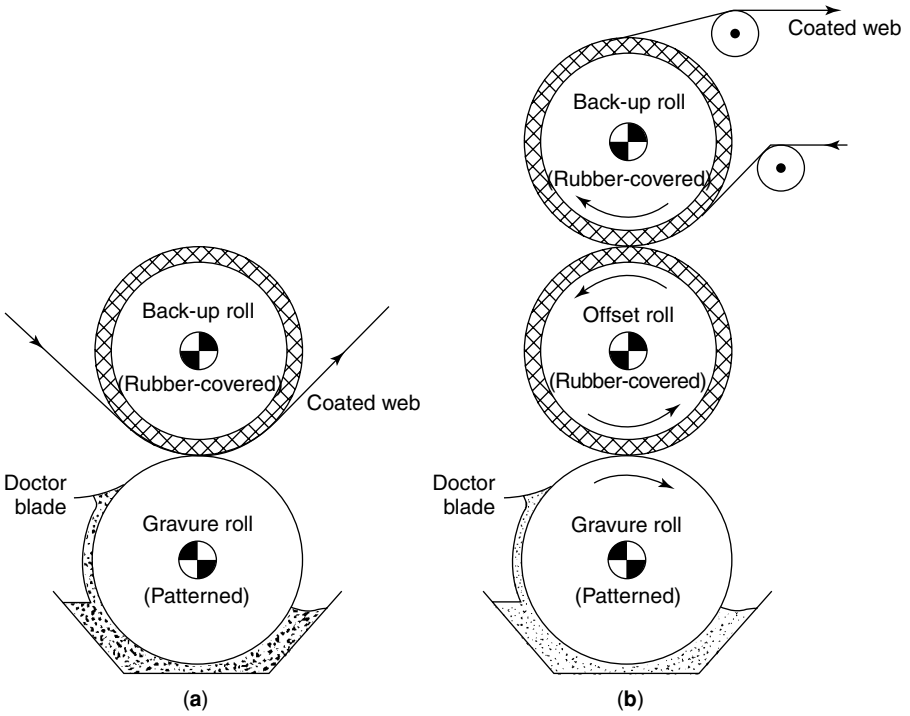

Fig. 13. Gravure coaters (**a**) direct; (**b**) offset (12).

unsupported, as in kiss coating. The coating liquid can be applied to the gravure roll by a number of methods, not just by the pan-fed system illustrated.

The three common cell patterns for the gravure cylinder are illustrated in Figure 14. The pyramidal and quadrangular cells are similar, except that the quadrangular has a flat, not a pointed, bottom in order to empty easier. The trihelical pattern consists of continuous grooves spiraling around the roll, usually at a 45° angle. The volume factor is the total cell volume per unit area, and has units of height, typically ranging from 4 to 300 μm. The fraction of the cell volume that transfers varies greatly, depending on the system. With high impression roll pressures, about 58% of the cell volume normally transfers. The cell pitch or count is the number of cells per centimeter measured perpendicular to the pattern and usually ranges from 4 to 160 cm^{-1}. The pattern is made by mechanical engraving, chemical etching, electromechanical engraving, or laser etching.

After the gravure cylinder is coated with coating liquid, the excess is doctored off, normally using a 01- to 0.4-mm spring steel blade. Usually the doctor blade makes a 55–70° angle with the incoming gravure roll surface and is oscillated 6–50 mm to give even wear and to dislodge dirt that could cause streaks. A reverse-angle doctor blade can also be used. It often makes an angle of 65–90° with the exiting surface. This blade does not have to be loaded against the cylinder face because fluid forces press the blade against the surface, and so the reverse blade can be made of softer materials, such as bronze or plastic. There is no need to oscillate

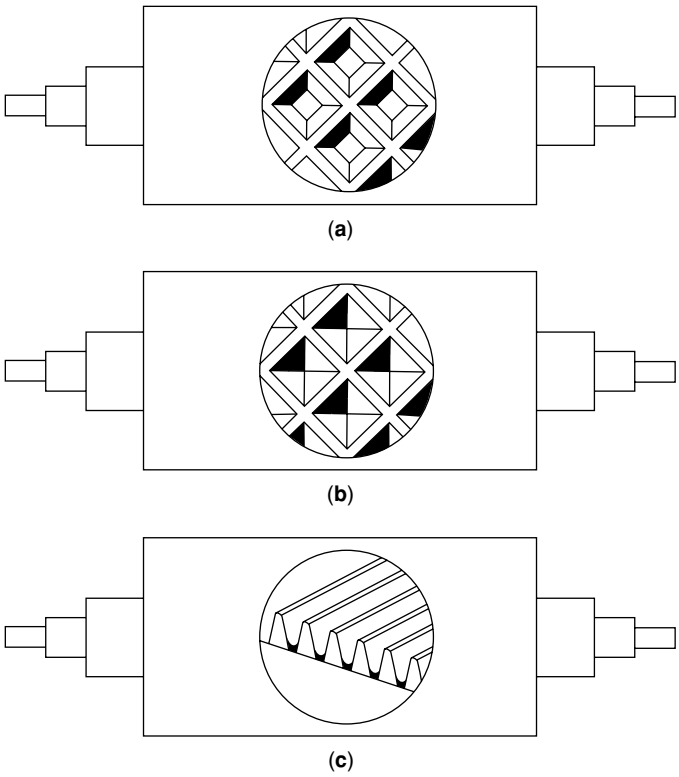

Fig. 14. Common cell patterns in gravure coating: (**a**) quadrangle; (**b**) pyramid; and (**c**) trihelical (2).

this blade because in this position it cannot trap dirt; however, the standard blade is felt to do a better job of doctoring.

As with the flexible-blade coater, a softer doctor blade or one having a lower loading and an almost smooth cylinder with a shallow pattern allows excess liquid to pass through. A stiff, highly loaded blade against a cylinder having a large volume factor (cell volume per unit area) wipes the surface clean. The gravure roll has to be heavily loaded against the backup or impression roll in order to achieve good transfer to the web. The usual force is about 2000–20,000 N/m.

The most important factor in determining the transfer or web pickup is the gravure pattern design. The cell pitch controls the stability of web pickup. The leveling of the coating can be a problem. Large spacing between cells often results in printing of the cell pattern, rather than a uniform coating. Reverse and differential gravure tend to give better leveling. A smoothing bar can also be used.

A very useful new gravure coating technique is the Micro-gravure™ technique, which was introduced in the early 1990s. It is intended for low coating weight products on light gauge films for imaging, electronics, packaging, batteries, and other specialty applications. The unique features are the use of small diameter rolls, 20–50 mm versus 150–300 mm for conventional gravure. This results in a small stable bead, which when combined with reverse application gives very good quality and a low coating weight. A typical configuration is shown in Figure 15.

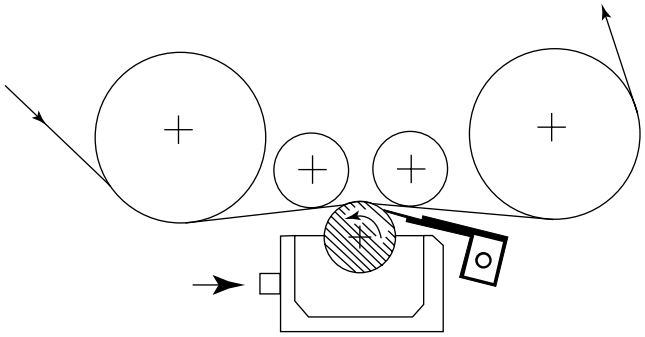

Fig. 15. Side view sketch of Micro-Gravure™ coating head. Courtesy of Yasui-Seikei.

Dip Coating. Dip coating is one of the oldest coating methods in use. Using continuous webs, the web passes under an applicator roll partially submerged in a pan of the coating fluid. The web is thus actually dipped into the coating solution. A doctor blade may be used to remove excess fluid if a reduction in the wet coating weight is desired. Otherwise the coverage is determined by coating speed and the characteristics of the liquid. The coverage increases with increasing viscosity and coating speed. Surface tension has a relatively small effect.

Dip coating is very commonly used for coating continuous objects that are not flat, such as fibers and for irregularly shaped discrete objects. Drops of coating at the bottom of dip-coated articles may be removed by applying electrostatic forces as the article is moved along a conveyor.

Extrusion. Extrusion coating and slot coating are in principle very similar. In extrusion coating a high viscosity material, often a polymer melt, is forced out of the slot of the coating die onto a substrate where it is cooled to form a solid coating. As can be seen in Figure 16a, the highly viscous liquid does not wet the lips of the die. Similarly in slot coating, a relatively low viscosity liquid, usually under several thousand mPa·s (=cP), often a polymer solution, is forced out of the slot and onto the web. In slot coating the coating liquid does wet the lips of the die, as shown in Figure 16b. Some engineers use the terms slot coating and extrusion coating interchangeably.

Extrusion coating is often used in food packaging where vapor and oxygen barriers are required and heat sealability is desired. The expanding food packaging industry is the direct result of packaging improvements that can be attained from improving the surface and physical characteristics of a flexible web by extrusion coating.

Because of the high viscosities involved in extrusion coating, the coating die and the auxiliary equipment are massive. An extruder is needed to heat and melt the thermoplastic polymer, the die is heated by electric heaters, and the die also contains adjusting bolts every 10 cm or so across the width that control the lip openings to try and obtain a uniform cross-web coverage. Internal choker bars controlled by bolts may also be used to adjust the uniformity. The bolts may be computer controlled. There may also be a laminating station to combine the plastic sheet with a substrate and to cool the laminate. The plastic may leave the die at about 175°C and may be about 0.5 mm thick. It is then elongated by

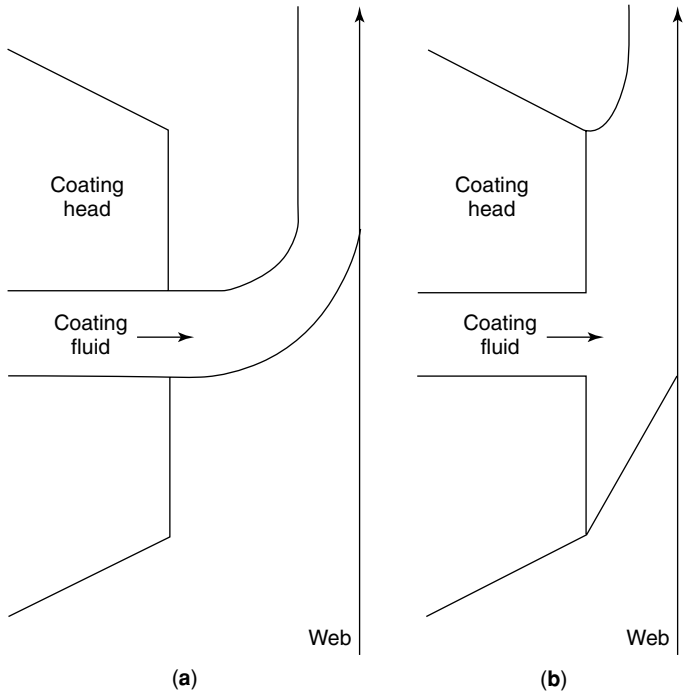

Fig. 16. Comparison of (**a**) extrusion coating and (**b**) slot coating.

the pulling effect of the faster-moving substrate which it joins in the pressure nip in the laminating section. The elongation reduces the width of the extruded film by perhaps 2–6 cm and reduces film thickness to approximately 12–25 μm before it makes contact with the substrate.

Good temperature control of the plastic and pressure control ahead of the coating die is important to the success of the coating. Variations in temperature lead to irregularities in the coating thickness both in the machine direction and across the web. Thickness variations in the cross-web direction can be reduced by adjusting the slot opening via the adjusting bolts and use of choker bars. The extruded film width is adjustable by external deckles to block off the exit of the die. In the laminator the nip helps to promote bonding, before chilling the molten plastic. The driven chill roll is chromium or nickel plated and can have a mirror, matte or an embossed surface. Once the extruded film passes through the laminating nip, it takes on the finish of the chill roll. The chill roll is 60–90 cm in diameter with perhaps a 120° wrap and utilizes refrigerated water to reduce the film temperature to about 65°C before the film is stripped. To improve adhesion of the extruded film to the substrate, adhesion-promoting "primers" are usually applied to the web before the laminator. Priming can be electrostatic (corona treatment), chemical, or in the form of ozone treatment. Coating weights are controlled by the line and extruder speeds, but in many cases the chill roll capacity limits the maximum thickness that can be obtained. Extrusion coating lines operate at speeds up to 1000 m/min and can apply 10–30 g/m^2 of coating.

Slot Coating. Slot coating (Fig. 16b) involves a relatively low viscosity fluid, under perhaps 10,000 mPa·s (=cP) and uses much simpler equipment than extrusion coating. An ordinary pump or a pressurized vessel feeds the fluid through a flow meter and control valve to the coating die, which often operates at room temperature. If heating is required, water flowing through internal channels is usually adequate. Because of the simple rheologies of the fluids, the die can be designed to give uniform flow across the width with no adjustments. In fact, an adjustable die should be avoided. It is not difficult to design the die to give uniform flow, but it is very difficult to make the exactly correct adjustments. Because the viscosity is relatively low the pressures within the die are also relatively low, and the die can be much less massive than an extrusion die and still withstand the spreading forces.

Normally the web is supported by the backing roll in slot coating. However, for very thin coatings, under about 15-μm wet, the gap between the coating lips and the web becomes very tight, under about 100 μm, and the system becomes difficult to control and operate. The runout of the bearings can become a significant fraction of the gap. Dirt can hang up in the gap to cause streaks. If the web contacts the coating die the web can tear, causing a shutdown of the operation. Coating against unsupported or tensioned web should be used for very thin coatings. In this case web tension becomes an important variable.

In slot coating, bead vacuum is often used to increase the window of coatability, that is to allow thinner coatings and perhaps to allow coatings at higher speeds. A vacuum box is placed under the coating die and a vacuum of up to about 1000 Pa (4 in. of water) is pulled by a vacuum fan. Higher vacuums may be needed for higher viscosity liquids. There should be a tight vacuum seal against the sides or ends of the rotating backing roll, but no rubbing contact where the web enters the vacuum chamber in order to prevent scratches. The air in the vacuum chamber can resonate as in a musical instrument. These pressure fluctuations can cause chatter at wide gaps. The air leakage should be kept as small as possible to reduce the amplitude of the pressure fluctuations.

Curtain Coating. Curtain coating is used to deliver coating liquid in a falling sheet or curtain to the substrate, which moves through the curtain at the coating speed. In one version a slot coating head is aimed downward and the coating emerges as a falling film or sheet as seen in Figure 17. The curtain thickness is controlled by the feed rate and by precise adjustments of the slot opening. The vertical distance of the coating die above the substrate can be adjusted. The falling curtain is protected from stray air movements by transparent enclosure sheets. Coating thicknesses as low as 12 μm are possible when coating with lacquers or with low viscosity wax melts, and are as low as 20 μm with hot-melt compositions of higher viscosity. There is no problem in obtaining heavier coating coverages.

Air-bubble entrapment may occur in the case of a gravity-applied continuous coating over an impermeable substrate. Bubbles may also be caused by moisture vaporization from the substrate. Remelting of the coating may minimize the bubble defects. Curtain-coating equipment of this design is capable of operation at substrate speeds up to 500 m/min.

Curtain-coating equipment is also available in which the falling curtain is generated by overflow from an open weir. The coating is delivered to the open weir uniformly across its width by a pipe having diffuser jet openings. As the coating

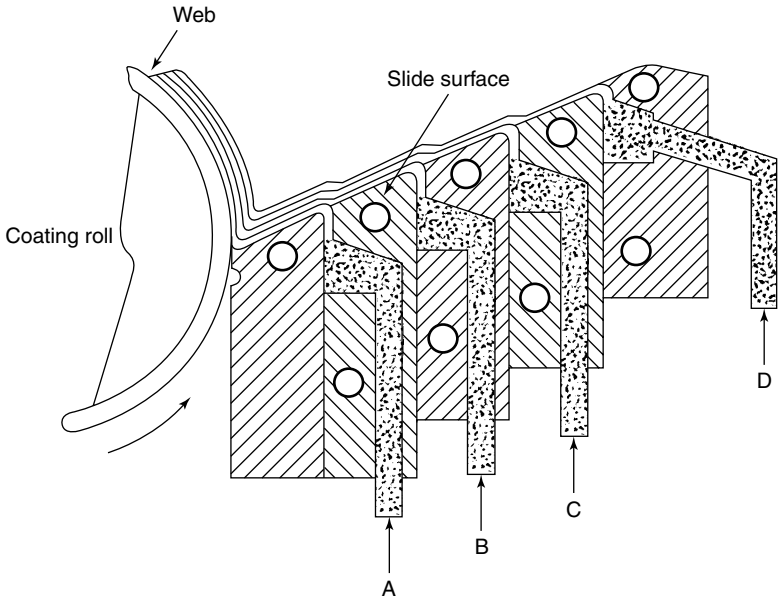

Fig. 17. A slide coater where A, B, C, and D correspond to the inlets for the liquids for layers 1, 2, 3, and the top layer, respectively (8,13).

overflows the low side of the weir, it travels down a short flat skirt before dropping. The thickness of the falling curtain is adjusted by precise control of the rate of delivery of coating to the weir. Hot-melt coatings can also be applied by the open weir, as in the slot die. Because there is no close restriction to flow as in the slot die, the open weir does not tend to form scratches or coating streaks because of crusting or coating hang-up in the slot opening. When applying hot-melt coating formulations the coating supply is held in a reservoir at a temperature that does not thermally degrade the material during its residence. The coating is brought to this temperature using heat exchangers as it is pumped to the weir. Weir-type equipment is recommended for operation at substrate speeds up to 400 m/min. The coating fluid not carried away on the coated surface falls into a collection trough for recirculation.

Curtain coating is adaptable for coating irregularly sized sheets such as slotted cut-out corrugated carton blanks or sheets of plywood, as well as for continuous substrates. Coatings may also be applied to uneven geometric shapes such as blocks. The principal limitation of curtain coating is that a high flow rate of about 0.5–1.5 $cm^3/(s \cdot cm$ width) is needed to maintain an intact curtain. Usually about double this minimum is desirable. Thus, to obtain a thin coating, high coating speeds are required. Curtain coating is inherently a high speed process and the curtain will not form at low speeds or flow rates.

Multilayer Methods

Slide Coating. Slide coating is the primary method for simultaneously coating a multilayer structure. A slide coater, illustrated in Figure 17, can coat an

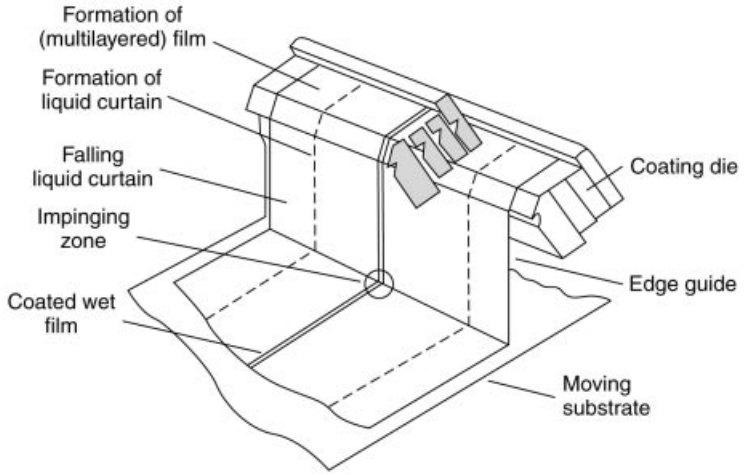

Fig. 18. Curtain-coating apparatus (13).

unlimited number of top layers, 18 or more, simultaneously. Each layer flows out onto the slide yet does not mix with the other layers as they all flow together down the slide, across the gap, and onto the web, all in laminar motion. Slide coating is extensively used in coating photographic films and papers, both color and black and white. In color films, nine or more layers are coated simultaneously.

Instabilities can form on the slide in the form of interfacial waves, which may disturb the desired laminar flow and cause mixing. The closer the physical properties of all the layers are, the closer the system resembles a single layer in which internal waves do not form. The densities of the individual layers are always reasonably close to each other, and are usually not subject to control. The viscosities of adjacent layers should generally not vary by too much (14). It has been suggested that to avoid these waves the ratio of the viscosity of a layer to that of the adjacent lower layer should be more than 0.7 and less than 1.5 or 2 (15). However, if the ratio is above 10, waves again do not form. The bottom layer should have the lowest viscosity to reduce drag forces and allow higher coating speeds.

As with slot coating, a slight vacuum (up to 1 kPa for the usual low viscosity fluids) under the coating bead aids in coating by allowing thinner coatings and higher coating speeds. The bottom edge of the slide should be sharp and have a small radius of curvature, no more than about 50 μm or so, to pin the bottom meniscus and reduce the chance of cross-web barring or chatter.

Precision Multilayer Curtain. A variation of curtain coating can also be used to produce multilayer coatings. A slide is used to generate the multilayer structure which then flows over an added lip of the die to form a curtain. Edge guides are used to prevent the curtain from necking in because of surface tension. For precision coating the curtain has to be completely uniform across the width. Precision multilayer curtain coating is used to coat color photographic materials. This is illustrated in Figure 18. In most precision coatings the curtain is narrower than the web.

Slot Coating. Multiple layers can be coated simultaneously from a slot-coating die with multiple slots. The layers come together in the coating bead to form the final coating. Multiple layers in slot coating work well, but the die internals are complicated, especially when more than two layers are involved. This technique is particularly useful for coating of organic solvent systems, since the enclosed bead minimizes evaporation.

Extrusion Coating. In the most popular method of multilayer extrusion coating, the several layers come together before the coating die in a combining adapter or block, and then exit as one stream into the extrusion die (see EXTRUSION). The extrusion die is a standard single layer die, except that the feed port is rectangular to match the dimensions of the rectangular sandwich formed in the combining adapter. The separate layers remain distinct in the combining adapter and in the die. As long as the viscosity ratios are no greater than about 3:1 under processing conditions, the layer uniformity should be acceptable.

Multilayer extrusion provides the unique capability of producing layers of different resins to give superior functional properties. For example, an inexpensive resin can be used as the core of a three-ply extrudate, the outer plies being more expensive but also much thinner than if extruded alone (see COEXTRUSION).

Discrete Surface-Coating Methods

A variety of coating techniques are available to coat surfaces which are planar and have irregular surfaces.

Spray Coating. Coatings may be applied by spraying the coating material onto the object to be coated, which may be irregularly shaped with compound curves and with sharp edges. Many coating powders of suitable dielectric constant may be electrically polarized so that the powders are attracted to a grounded or oppositely charged surface. The object may then be heated to fuse the powders into a continuous film.

Dip Coating. The dip-coating technique described for webs can also be used to coat discrete surfaces such as toys and automotive parts. The item to be coated is suspended from a conveyor and dipped into the coating solution. The item is then removed; the coating drains and then levels to give the desired coverage. The object is then dried or cured in an oven.

Spin Coating. Spin coating is used to produce a thin uniform coating on discrete supports. In this process the coating fluid, usually a colloidal suspension, is placed on a horizontal substrate which rests on a rotating platform. The speed of the platform is increased to the desired level, which can be as high as 10,000 rpm. Centrifugal forces drive much of the coating off the support, leaving a thin, uniform film behind. In addition, the coating is drying during the process and as a result the viscosity increases, resistance to flow occurs, and a level thin coating is left. The coating chamber can provide hot air to the coating to dry or cure the remaining film. Additional coatings of different coating materials can be applied to develop a multilayer structure. This process is used to coat structures such as photomasks, magnetic disks, optical coatings, and a variety of layered products in the microelectronics industry.

Vacuum Deposition Techniques. Thin coatings are applied to a variety of substrates for use on semiconductors, ceramics, and electrooptical devices, using a wide variety of vacuum deposition techniques. Vacuum deposition is a rapidly advancing area of coating technology. In these processes the support to be coated is placed in a vacuum chamber which contains the coating material. Typically the coating material is a metal such as aluminum, gold, or tungsten. A high vacuum is then pulled; electrical energy or an electron beam is applied to heat the metal which evaporates off to deposit on the substrate. In sputtering, an ion beam is used to knock off atoms of the metal at lower temperatures. Individual supports, such as a target to be examined in a scanning electron microscope, or a continuous web, such as in making metallized poly(ethylene terephthalate), can be used. The coatings can be continuous, or patterns or electrical circuits can be made if the support is masked.

There are several vacuum processes such as physical vapor deposition, chemical vapor deposition, sputtering, and anodic vacuum arc deposition. Materials other than metals, such as tetraethylorthosilicate, silane, and titanium aluminum nitride, can also be applied.

Patch Coating

It is sometimes necessary to coat patches of material on a web, such as coating the anode and cathode in batteries and in fuel cell membranes (Fig. 19). With these products an uncoated border is required around the coating to prevent a short circuit. Gravure coating is well suited for this purpose because the desired pattern can be etched into the gravure cylinder. Slot-coating techniques are also used (16). With slot coating there is the problem, however, of nonuniform coverage at the start and end of the patch, and the thicker edges along the sides. The start and end problems may be minimized by carefully controlling the flow with pumps and valves.

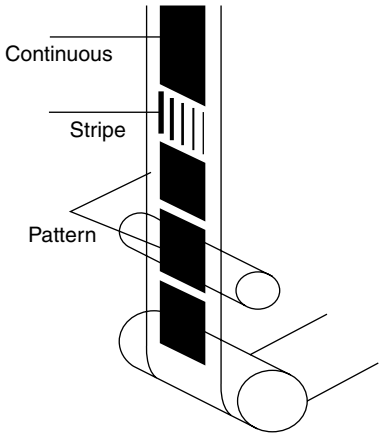

Fig. 19. Patch coating.

Coating Process Mechanisms

One of the principal advances in the coating process area in the 1980–1990s was the development of techniques to understand and define basic coatings mechanisms. This has led to improved quality and a wider range of utility for most coating techniques. This has involved the computer modeling of the coating process and the development of visualization techniques to actually see the flows in the coating process. The flow patterns predicted by the computer models can be verified by the visualization techniques.

Free surfaces and interfaces make the physics of coating flow systems extremely difficult to model by classical mathematical methods. As a result, coater designs and parameter ranges for defect-free coating have traditionally been determined through expensive and time-consuming statistical experimentation. Therefore coating developed largely as an art rather than a science. The ability to model the coating process by using modern methods of numerical and functional analysis, and to explain many of the complex mechanisms of coating instabilities and the resulting defects, is thus refreshing.

The most successful models are based on the finite element method. The flow is discretized into small subregions (elements) and mass and force balances are applied at each node. The result is a large system of equations, the solution of which usually gives the velocity and pressure of the coating liquid in each element and the location of the unknown free surfaces. The smaller the elements, the more the equations, which are often in the range from 10,000 to upwards of 100,000.

It is now possible to simulate steady transversely uniform flows of Newtonian or non-Newtonian liquids by using commercially available software packages such as FIDAP, NEKTON, FLUENT, PHOENICS, and POLYFLOW. Using these codes it is possible to locate regions of flow recirculation that may cause coating defects as a result of the increased residence time of solution. The free-surface handling capabilities of currently available commercial codes are limited to relatively simple steady flows and the transient response to specified transversely uniform disturbances. For a steady uniform flow to exist in nature, however, it should be able to recover from all small disturbances, such as building vibrations and the molecular fluctuations that are always present. Flow instabilities resulting in defects such as ribbing cannot be predicted by commercial software. Using more advanced methods developed first at the University of Minnesota and now in widespread use (17–20), it is now possible to predict most coating flow instabilities including bead break-up, flooding, cross-web barring (chatter), down-web ribbing, and diagonal chatter. It is also possible to follow the longtime development of the resulting defects and to explore parameter ranges of stable, defect-free operation (coating windows) at a fraction of the cost of the actual physical experiments. In a computer model the geometry can be quickly changed without having to construct expensive new parts. Considerable time and cost savings can be realized by optimizing coating systems computationally.

Experimental techniques to visualize flows have been extensively used to define fluid flow in pipes and air flow over lift and control surface of airplanes. More recently this technology has been applied to the coating process and it is now possible to visualize the flow streamlines (15,21). The dimensions of the flow field are small, and the flow patterns both along the flow and inside the flow are important. Specialized techniques involve generating small hydrogen bubbles

using fine electrodes and injecting dyes in the regions of interest; optical sectioning is then required to observe and to photograph these flows.

A stereo zoom microscope having a very small depth of field and a clear window on the side of the applicator is employed. Fiber optic cables may be used for remote viewing. Accurate control of the light level and position is needed to reduce reflections that may mask the details of the flow field. The microscope is focused at varying points and flow nonuniformities are recorded. Using this technique, air entrainment, flow recirculation in the bead, curtain-coating formation, and the teapot effect have all been visualized for many types of slot, slide, and curtain coatings. This information leads to an improved understanding of the coating process. The same technology can also be applied to many other types of coating.

Drying and Solidification

The coating solution after application is in the liquid state and must be solidified. For coating with solvents, including water, this is brought about by removing the solvent, ie, drying. The drying process after the application of the coating is as important as the coating process itself. The properties of the coating are not complete until solidification has occurred. The coated film or web is transported through the dryer where the properties of the coating can either be enhanced or deteriorated by the drying process. Drying of coatings involves the removal of the inert inactive solvent used to suspend, dissolve, or disperse the active ingredients of the coating, which include polymeric binder, pigments, dyes, slip agents, hardener, coating aids, etc. Coating solvents range from the easy-to-handle water to flammable and toxic organic materials. Drying must occur without adversely affecting the coating formulation while maintaining the desired physical uniformity of the coating.

For polymer melts and for certain materials that gel on cooling, such as gelatin solutions, the temperature is lowered to solidify the coatings. With gelatin gels drying is still necessary. Similar hardware can be used for both heating and evaporation and for cooling, since they are both heat transfer devices.

While drying is a physical process involving only solvent removal, solidification can occur by cross-linking liquid monomer or liquid low molecular weight polymer. This can be accelerated by catalysts or can be accomplished by an electron-beam or uv radiation. This cross-linking process is called *curing*. Material coated from solution often also undergoes curing to improve the physical properties of the dried coating. Thus both curing and drying may occur in the dryer. This takes place with aqueous gelatin coatings which are cured using aldehyde cross-linkers. The cross-linking starts in the dryer.

The dryer provides heat to volatilize the solvent and a means to carry the solvent away from the coating. Efficient hardware is used to minimize energy costs. The dryers may be equipped with the appropriate pollution abatement devices to meet both OSHA and EPA standards. Dryers commonly use hot air both to provide heat and to carry away the solvent. The air may be heated by steam or by heat exchange with flue gases. Flue gases from the combustion of natural gas may be used directly in place of hot air. Infrared radiant energy from gas combustion or electric resistance heaters is sometimes used. Conduction heat transfer from heated

drums is also used. The choice depends on availability of supply, the temperature range desired, and costs. Dryers can also use other sources of energy such as microwaves or radio-frequency waves. However, air is still needed to carry off the evaporating solvent. Radiant energy tends to be more expensive and is only used in special circumstances. If the coating can react with oxygen or if the solvents are flammable, inert gases such as nitrogen may be used in place of the air.

Because the evaporation of the solvent is an endothermic process, heat must be supplied to the system through conduction, convection, radiation, or a combination of these methods. The total energy flux into a unit area of coating, q_t, is the sum of the fluxes resulting from conduction, convection, and radiation.

Although heat transfer by conduction from heated drums is used extensively in the paper industry, convective heat transfer is very popular and used in most coating operations. Here the main focus is on convective heat transfer.

The rate of convective heating can be estimated as

$$q_{\text{convection}} = hA\Delta t$$

where A is the area (m^2), h is the heat-transfer coefficient [$W/(m^2 \cdot K)$], q is the rate of heat transfer (W), and Δt is the temperature difference between the hot gas and the coating (K).

The heat-transfer coefficient is a key property of the dryer. It is controlled by the nozzle geometry and spacing, the distance from the web, and the velocity of the air. The evaporation rate is the rate at which heat is supplied for evaporation (heat also goes into heating the coating and the web) divided by the latent heat of vaporization of the solvent.

Air Impingement Dryers. Air impingement dryers, the most widely used for drying coated webs, basically consist of a heat source and heat exchangers (unless hot flue gas from combustion of natural gas is used), fans to move the air, ducts and nozzles or air delivery devices positioned close to the web, and solvent removal ducts. If all the air is recirculated, then equipment to remove solvent from the air is also provided. Figure 20 shows a typical dryer. In addition, there are controls for the air temperature and the air velocity from the nozzles and, in some cases, for the solvent level in the drying air. There may also be controls to keep the solvent concentration well below the lower explosive unit. Dryers often have separate sections or zones where the air temperature and velocity (and perhaps solvent level) can be controlled independently.

The dryer must also transport the web through the dryer using a combination of driven and idler rolls. The web path can be either horizontal or vertical, or, with the appropriate web-turning devices, fold back upon itself to conserve space. The idler rolls in single-sided dryers should be spaced so that there is enough wrap for the web to turn the rolls, and the coating should be kept within the effective area of the nozzles. Sometimes the web slips on the idler rolls and gets scratched. To prevent this the idler rolls can be driven by tendency drives which have two sets of bearings. The axle is driven at approximately the speed of the web, and the roll idles at this speed on a separate set of bearings. The driven web then easily brings the roll to the exact speed of the web. Tendency drives are needed for light webs. Typically the web should be within six to seven nozzle slot widths of the impingement nozzles.

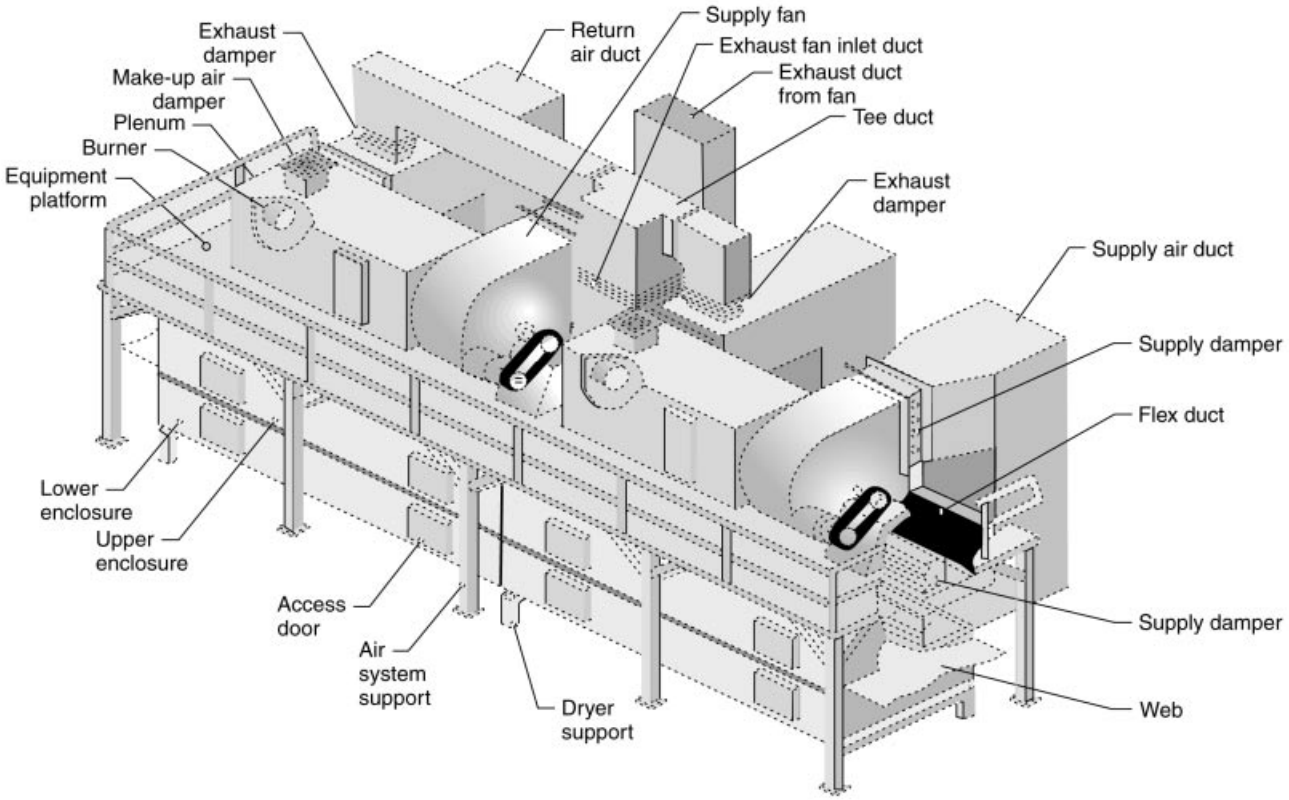

Fig. 20. Dryer components of a top mounted air system dryer. Courtesy of MEGTEC Systems.

In these single-sided dryers, the air impinges only on the coated side, heating and drying from that side only. The air can be delivered to the web from plenums with slots, with holes, or from specially designed nozzles. In a basic configuration the nozzles and idler rolls are contained in insulated boxes to minimize heat losses, solvent escape, and noise. The efficiency of the dryers depends on the heat transfer coefficient, the air usage, the temperatures used, and the solvent level. Wet coatings flow easily and the drying air should not disturb them.

The two-sided or floater dryer is now most often used. In this configuration the roll transport system in the dryer is replaced with air nozzles on the back side of the web so that the air transports and supports the web as well as heating and drying it from both sides. When impervious webs are used, while the heating is from both sides, the drying is only from the coated side. The two-sided heat transfer results in higher drying rates and thus shorter dryers, while eliminating problems of scratching from the idler rolls. However, more air is used.

Two types of floater nozzles are currently in use. One, based on the Bernoulli principle, is used in the airfoil flotation nozzles in which the air flows from the nozzle parallel to the web and the high velocities create a reduced pressure, which attracts the web while keeping it from touching the nozzles. The other uses the Coanda effect to create a flotation nozzle where the air is focused and follows the contours of surface of the air bar chamber, thus creating a pressure pad which supports the web, as shown in Figure 21.

Air flotation dryers have excellent heat-transfer coefficients, give very uniform drying across the web, and give excellent web stability. They can be used for a wide range of web types and tensions, and tend to be quieter, and thus pose less noise problems than the higher velocity single-sided dryers. Floater dryers are totally enclosed and compact so that they are clean and cause less dirt defects in the coating.

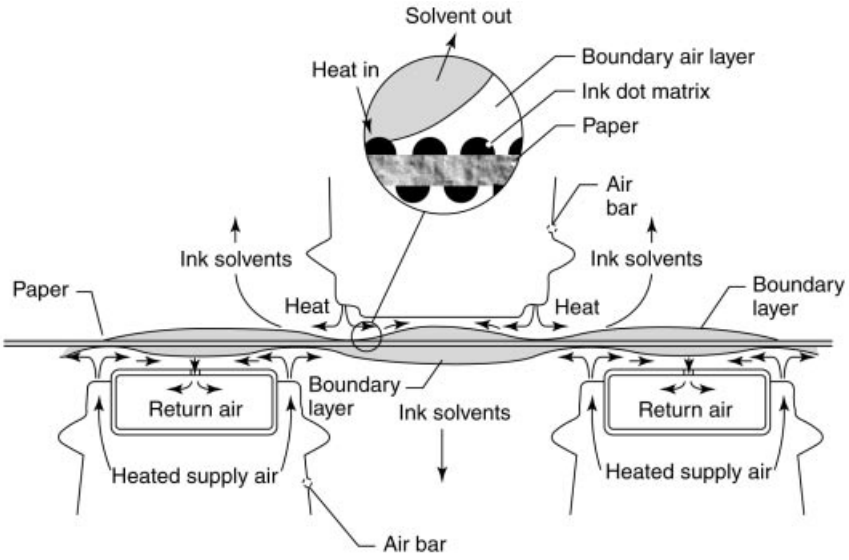

Fig. 21. Coanda effect air bars. Courtesy of MEGTEC Systems.

Single-sided dryer air velocities are 150–600 m/s, giving heat-transfer coefficients of 30–140 W/(m^2·K). Floater dryers operate at slightly lower (150–500 m/s) slot velocities, and have higher [50–275 W/(m^2·K)] heat-transfer coefficients based on the same single-sided web area.

Contact or Conduction Dryers. Coatings on webs, as well as sheets of newly formed paper, can be dried by direct contact with the surface of a hot drum. The drum is usually heated by steam. Here conduction is used to transfer the heat. Air still has to be supplied to carry away the solvent vapors. Drums can also be used to rapidly cool warm extruded films, to increase the viscosity, and to solidify the film.

Radiation Drying. Infrared or microwave radiation can supply concentrated energy to the web to evaporate the solvent, but air must still be used to carry away the solvent. These techniques provide a high heat input over short distances. Often Infrared is used in conjunction with convection dryers. It is often used at the start of drying to rapidly solidfy the coating, with the balance of drying done in convection oven. This can be cost efficient. Infrared heaters can be placed between the air nozzles. This increases the drying rate and thus the production rate without increasing the length of the dryer, and without requiring additonal air handling systems. Use of Infrared heating is most effective in the first sections of the dryer, in the constant rate period, where the coating is coolest and most of the added heat, including that by Infrared radiation, goes to evaporate the solvent. In the falling rate period in most cases the drying rate is the rate of diffusion of the solvent to the surface, which is influenced only by the temperature. Infrared heating can only raise the temperature faster, which usually has just a minor effect.

Pollution Control. The solvent removed during drying is frequently a pollutant and the exhaust air must be treated to ensure that it meets government standards before being discharged to the atmosphere. The two basic approaches to treating the air are to recover the solvent for reuse and to convert it by burning to compounds which can safely be discharged. The basic solvent recovery systems involve condensation or adsorption in a charcoal bed. After recovery the solvent needs to be purified before reuse. For combustion of the exhaust sovent both thermal and catalytic systems are used. Pollution control systems are an essential part of the drying process and are available from dryer manufacturers. One should reduce the amount of volatile solvents in the coating process by coating as concentrated a coating fluid as possible. One should also investigate changing to a water-based system.

Modeling Convection Drying. Models of the drying process have been developed to estimate whether a particular coating can dry under the conditions of an available dryer. These models can be run on personal computers.

To model convection drying in the constant rate period both the heat transfer to the coated web and the mass transfer from the coating must be considered. The heat-transfer coefficient can be taken as proportional to the 0.78 power of the air velocity or to the 0.39 power of the pressure difference between the air in the plenum and the ambient pressure at the coating. The improvement in heat-transfer coefficients in dryers since the 1900s is shown in Figure 22. The mass-transfer coefficient for solvent to the air stream is related to the heat-transfer coefficient by the Chilton–Colburn analogy (23,24):

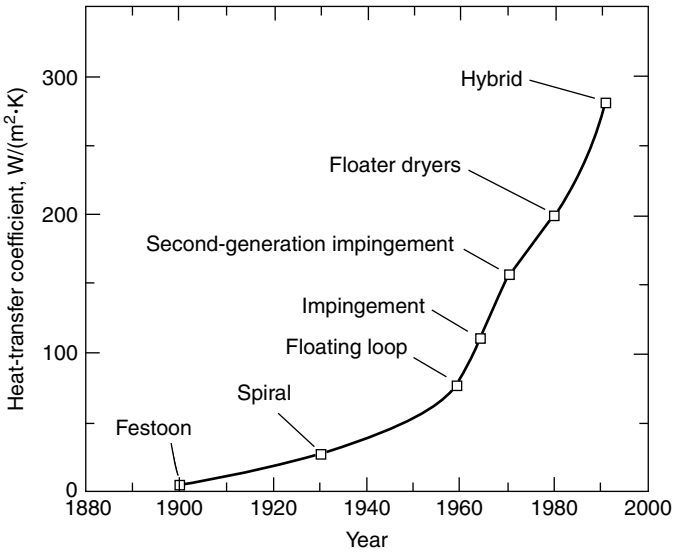

Fig. 22. Improvement in dryer heat-transfer coefficients over time (22). To convert W/(m^2·K) to Btu/(h·ft^2·°F), multiply by 0.176.

$$\frac{h}{\rho c_p k_m} = N_{Le}^{2/3}$$

where c_p is the heat capacity of the air [J/(kg·K)], h is the heat transfer-coefficient [W/(m^2·K)], k_m is the mass-transfer coefficient {kg/[s·m^2·(kg/m^3)]}, N_{Le} is the Lewis number, equal to the thermal diffusivity of the air divided by the mass diffusivity of solvent vapors in the air, and ρ is the density of the air (kg/m^3).

The total heat transfer to the coated web is then equated to the heat consumed by the evaporating solvent and the heat used in heating the web and the coating. This allows calculation of the temperature of the coated web (14,25). For single-sided drying, the equilibrium constant rate web temperature is the wet-bulb temperature of the air for that particular solvent. In the constant rate period of drying the coating behaves as if it were a pool of solvent. When dry patches appear on the surface, the rate of drying decreases and the falling rate period begins.

Modeling the falling rate period is more difficult, because the drying rate then depends on the mechanisms occurring within the coating. In coating on impervious webs the rate-limiting process is diffusion; in porous coatings and coatings on porous paper it may be capillary action. In aqueous coatings most of the drying occurs in the constant rate period; for organic solvent systems most of the drying occurs in the falling rate period, to the extent that in some cases the constant rate period is over before the coated web enters the dryer. In the falling rate period all the solvent that reaches the surface evaporates; thus the rate of diffusion to the surface is the rate of evaporation (if diffusion is the transport mechanism).

The higher the air temperature, the more rapid the drying. However, there are temperature limitations both for the web and for the coating. Plastic films should not be heated above their glass-transition temperature (the softening

point) to prevent distortion and stretching. The coatings themselves may have a maximum temperature above which the coating may degrade. Many photographic coatings, for example, should not be heated above about 50°C.

Rheology. Rheology is the science of deformation and flow of matter. Because the coating process creates shear and extensional stresses in the coating fluid, the rheological properties of coating liquids are important factors in the selection and successful running of a coating operation. The coating hardware exposes the coating solution to a wide range of shear rates (Table 2). As a first approximation, the extensional rates would be of the same order as the shear rates. Shear and extension affect the properties of the solution. Therefore, the rheological properties, the deformation and flow under stress, are important factors in the selection and successful running of a coating operation.

The shear or dynamic viscosity is the ratio of shear stress to shear rate, and measures the resistance of the fluid to flow while undergoing shear. The common unit of viscosity is centipoise (cP). One cP is the same as 1 mPa·s. A high viscosity solution flows slowly. The shear rate is the rate of change of velocity with distance in the direction perpendicular to flow and can be crudely approximated by the coating speed divided by a coating gap. In coating flows it can reach values over 10^5 s^{-1}. In simple or Newtonian fluids the viscosity is a constant and does not change with shear rate. However, it is not constant in dilute polymer solutions, where the shape of the polymer molecules distort with shear. The spherical shape of a random coil becomes elongated in the direction of flow and so offers less resistance to flow. Thus the viscosity decreases with shear rate. At very low shear rates, such that the shape of the molecules has not yet changed, the viscosity is constant at its zero shear value. At high shear rates where the molecules are fully elongated, such that they cannot offer less resistance with increasing shear, the viscosity is again constant, now at its infinite shear value (assuming the molecule

is not destroyed by the mechanical forces). Almost all coating fluids contain dissolved polymers and are shear thinning.

Extensional or stretching flows are also very important in coating. The extensional viscosity is the ratio to the tensile stress in the fluid to the extension rate. Fluids can support a tensile stress when they are in motion. If you put a finger in a jar of honey and withdraw it, a strand of honey will be carried along by the finger. If you stop moving the finger the honey will fall back in the jar. But while in motion the honey will be in tension. With Newtonian fluids the extensional viscosity is three times the shear viscosity. When polymer solutions are stretched slowly, the molecules can relax, disentangle, and slip past each other. At higher extension rates they do not have time to relax and disentangle, and the extensional viscosity increases. This aids the coating process, and polymer solutions are easier to coat than Newtonian fluids of the same low shear viscosity.

The extensional thickening of polymer solutions is one form of viscoelastic behavior. This ability to support a tensile stress can also be demonstrated in a tubeless syphon with dilute aqueous solutions of polymers such as polyacrylamide or polyethylene oxide. If you suck up solution with a medicine dropper attached to a water aspirator and then lift the dropper out of the solution, the solution will still be sucked up. In shear, viscoelastic fluids develop normal stresses, which causes rod climbing on a rotating shaft, as opposed to the vortex and depressed surfaces that form with Newtonian liquids. Polymer solutions and semiliquid polymers exhibit other viscoelastic behaviors, where, on short time scales, they behave as elastic solids. "Silly putty," a childrens toy, can be formed into a ball and will slowly turn into a puddle if left on a flat surface. But if dropped to the floor it bounces.

Concentrated dispersions may be shear thickening, as opposed to the shear thinning of dilute polymer solutions. Some materials, such as latex paints, tend to form a structure. As the structure breaks down with shearing action, the viscosity decreases. Such materials are thixotropic. Some fluids have a yield stress. A thorough characterization of the rheology may require a number of different measurements.

Surface Forces. Because fresh surface is created during coating, surface forces are involved. These are normally expressed as surface tension, in dyn/cm, which is identical to mN/m. Surface tension is identical to surface energy, expressed as erg/cm^2 or mJ/m^2. Whether we call it surface tension or surface energy is a matter of personal preference. Surface tension gives rise to a higher pressure on the concave side of a curved interface; thus the pressure on the inside of a drop is higher than on the outside. This higher pressure is called capillary pressure. It can be used to explain the shape of some coating beads.

In coating, the coating fluid should spread out on the support. For this to occur the surface tension of the fluid should be low and the surface energy of the support should be high. The contact angle in a drop of fluid on the surface, between the surface of the support and the surface of the fluid measured through the fluid, is a measure of the ability of the fluid to wet the surface. This contact angle should be low.

The surface energy of the support may be increased by oxidizing it, such as in a flame (flame treatment) or in an electrical discharge (corona treatment). Flame treatment is permanent, but for many polymers corona treatment is labile—after a matter of hours or days the surface energy decreases toward its original value.

Because of this, corona treatment is done in-line, before the coating stand. High energy coatings may be applied to the support, such as the subbing often used on supports for photographic coatings.

The surface tension of a fluid containing surfactants varies with the age of the surface. As surfactant diffuses to the surface it lowers the surface tension; fresh surfaces have the higher surface tension of the solvent. The time for the surface to reach equilibrium varies from a number of milliseconds to several hours, depending on the system. The surface tension as a function of time is called the dynamic surface tension.

Similarly, the contact angle of a fluid on a support depends on whether the fluid is stationary or is moving, and at what speed. The contact angle for a stationary drop is lowest; as one coats faster in a coating operation the dynamic contact angle increases. When the coating speed increases to the point where the dynamic contact angle is 180°, air will be entrained and one can no longer coat.

Commercial Availability. All of the many types of coaters and dryers discussed herein are commercially available from many different vendors. These vendors usually have pilot facilities so that new coating and drying techniques can be easily tested. Contract coating companies, specializing only in coating, also exist.

COATINGS

Introduction

Coatings are ubiquitous in an industrialized society. U.S. shipments of coatings in 1999 were about 5.7×10^6 m^3, having a value of $18 billion (1). Coatings are used for decorative, protective, and/or a functional purpose on many kinds of surfaces. The low gloss paint on the ceiling of a room is used for decoration, but it also diffuses light. The coating on the outside of an automobile adds beauty to it and also protects it from rusting. The coating on the inside of a beer can protects the beer from the can; in soft drink cans, the interior coating protects the can from the beverage. Other coatings reduce growth of barnacles on ship bottoms, protect optical fibers against abrasion, and so on.

Traditionally, coatings changed slowly in an evolutionary response to new performance requirements and competitive pressures. An important reason for the slow rate of change was the difficulty in predicting product performance. In recent years, there has been increasing research on understanding the basic relationships between composition and performance to permit more rapid responses to the needs for change. Since about 1965, the pace of technical change has increased. A major reason for change has been to reduce VOC (volatile organic compound) emissions. Other factors are the cost of energy for heating curing ovens requiring lower temperature curing, increasingly stringent regulations of the use of potentially toxic materials, and increased performance requirements.

Various approaches to meet the new requirements, particularly to reduce VOC emissions, are being pursued. The use of waterborne coatings has increased substantially and has surpassed solventborne in volume. Latex paints have been used for many years in architectural coatings. These coatings have had less solvent than traditional solventborne paints but still contained significant amounts

of solvent. Low solvent and solvent-free latex paints are being introduced. Use of waterborne industrial coatings has been dramatically expanded. Solventborne coatings are still used but solvent levels are being reduced. In many applications, high solids coatings have been successfully adopted. Research is currently directed to making solvent-free coatings. A growth area has been the use of powder coatings for industrial purposes. In many applications, use of powder coatings permits complete elimination of solvent emissions. Radiation curable coatings, particularly uv-cured coatings, have also grown particularly for clear coatings on heat-sensitive substrates. They are solvent free and very low levels of energy are required for curing.

Film Formation

Most coatings are applied as liquids and converted to solid films after application. Powder coatings are applied as solid particles, fused to a liquid, then forming a solid film. Almost all the polymers used in coatings are amorphous and the term solid has no absolute meaning. A useful definition of a solid film is that it does not flow significantly under the pressures to which it is subjected during testing or use. A film can be defined as solid under a set of conditions by stating the minimum viscosity at which flow is observable in the specified time interval. For example, it is reported that a film is dry-to-touch if the viscosity is greater than about 10^6 mPa·s (2). A film resists blocking when two coated surfaces are put against each other for 2 s under a mass per unit area of 1.4 kg·cm^{-3} (20 psi), when the viscosity is greater than 10^{10} mPa·s.

A way to form films is to dissolve a polymer in solvent(s) at a concentration needed for application, apply the coating, and allow the solvent to evaporate. In the first stage of solvent evaporation, the rate of evaporation is essentially independent of the presence of the polymer. As solvent evaporates, viscosity increases, T_g increases, free volume decreases, and the rate of loss of solvent becomes dependent on how rapidly solvent molecules can diffuse to the surface of a film. If a film is formed at 25°C from a solution of a polymer that, when solvent free, has a T_g greater than 25°C, the film retains considerable solvent even though it is a hard "dry" film.

Less solvent is needed for a coating based on solutions of lower molecular weight thermosetting resins. After application, the solvent evaporates, and chemical reactions cause cross-linking. The number-average functionality $\bar{f}_n$ has to be over 2, and the amount of monofunctional resin should be minimal for good properties. A problem with thermosetting systems is the relationship between stability during storage and time and temperature required to cure a film after application. Generally, it is desirable to store a coating for many months without a significant increase in viscosity. After application, one would like to have the cross-linking reaction proceed rapidly at the lowest possible temperature. Reaction rates depend on concentration and are reduced by dilution with solvent and increase as solvent evaporates; cross-linking in the applied film after solvent evaporation is initially faster than during storage. As formulations shift to higher solids, there are higher concentrations of functional groups, and there is greater difficulty in formulating storage-stable coatings. To minimize the temperature required for curing while

maintaining adequate storage stability, it is desirable to select cross-linking reactions for which the rate depends strongly on temperature. Arrhenius equations have been used to calculate what orders of magnitude of E_a and A are required to permit various combinations of storage times and curing temperatures (3). Such calculations show that to formulate a coating stable for 6 months at 30°C, the calculated kinetic parameters become unreasonable if cure is desired in 30 min below about 120°C. No known chemical reactions have a combination of E_a and A that would have a lower cure temperature while maintaining a 6-month stability. More reactive combinations can be used in two package (2K) coatings, in which one package contains a resin with one of the reactive groups and the second package contains the component with the other reactive group. The packages are mixed shortly before use. 2K coatings are used commercially on a large scale. 2K coatings have the analogous problem of pot life—the time after the two packages are mixed that the viscosity stays low enough for application.

Design of stable coatings that cure at lower temperatures or shorter times must be based on factors other than kinetics. Several approaches are used, including use of blocked reactants or catalysts where the blocking group volatilizes with heat, moisture, or oxygen curing; use of a volatile inhibitor; use of a cross-linking reaction that is a reversible condensation reaction involving loss of a volatile reaction product with some of the monofunctional volatile reactant used as solvent; use of a reactant that undergoes a phase change over a narrow temperature range; and uv curing.

Another consideration is the effect of the availability of free volume on reaction rates and reaction completion. If the diffusion rate is greater than the reaction rate, the reaction will be kinetically controlled. If the diffusion rate is slow compared to the kinetic reaction rate, the rate of the reaction will be mobility controlled. If the temperature is well below T_g, the free volume is so limited that the polymer chain motions needed to bring unreacted groups close together are very slow, and reaction virtually ceases. Since cross-linking starts with low molecular weight components, T_g increases as the reaction proceeds. If the initial reaction temperature is well below the T_g of the solvent-free coating, little or no reaction can occur after solvent evaporation and a "dry" film forms merely as a result of solvent evaporation, without much cross-linking. The result is a weak, brittle film. Mobility control is less likely in baking coatings because the final T_g of the film is below the baking temperature. In powder coatings, mobility control of reaction can be a limitation, since the initial T_g of the reactants has to be over 50°C so that the powder will not sinter during storage. The effect of variables on mobility control of reaction rates has been studied (4).

Dispersions of insoluble polymer particles form films by coalescence of the particles. The largest volume of such coatings use latexes as a binder. The lowest temperature at which coalescence occurs to form a continuous film is called its *minimum film-formation temperature* (MFFT). A major factor controlling MFFT is the T_g of the polymer particles. The MFFT of latex particles can be affected by water, which can act as a plasticizer (5). Most latex paints contain volatile plasticizers, coalescing solvents, to reduce MFFT. The mechanism of film formation from latexes has been extensively studied; the papers in References 6–9 review various theories associated with it. Film formation occurs by three overlapping steps: evaporation of water and water-soluble solvents that leads to a close packed

layer of latex particles; deformation of the particles leading to a continuous, but weak, film; and interdiffusion, a slow process in which the polymer molecules cross the particle boundaries and entangle, strengthening the film. A review paper discusses factors affecting development of cohesive strength of films from latex particles (10). The extent of coalescence has been studied by small-angle neutron scattering, direct energy transfer of particles labeled with fluorescent dyes, and scanning probe microscopy. Coalescing solvents have been necessary to formulate latex coatings to form films at low temperatures while resisting blocking at higher temperatures. Environmental regulations are limiting permissible emissions of VOC. See section on Latexes for discussion.

Flow

Flow properties control application and appearance of films. In brush application of paint, flow properties govern settling of pigment during storage, how much paint is picked up on the brush, film thickness applied, and leveling and sagging of the film. Reference 11 reviews flow of coatings. (see also RHEOOPTICAL MEASUREMENT)

Viscosity of Solutions. The viscosity of liquids depends on free volume availability. When a stress is applied, movement to relieve the stress is favored, and the liquid flows through free volume holes. Temperature dependence of viscosity for low molecular weight resins and their solutions has been shown to fit a Williams–Landel–Ferry (WLF) equation, equations (1), (12,13).

$$\ln \eta = 27.6 - \frac{A(T - T_g)}{B + (T - T_g)} \tag{1}$$

Generally, in designing resins lower T_g will lead to a lower viscosity of the resins and their solutions. Exceptions have been reported for some high solids acrylic resins made with a comonomer that has a bulky group, such as isobornyl methacrylate (14), have low viscosities at high solids even though they have high T_g values.

Equations have been proposed to express the relationships between concentration and viscosity of resin solutions. Equation (2), in which w_r is weight fraction resin and the k's are constants, has been shown to fit over a wide range of concentrations (12). Over narrower ranges of concentration, a simpler equation, equation (3), gives reasonable fits with the experimental data.

$$\ln \eta_r = \frac{w_r}{k_1 - k_2 w_r + k_3 w_r^2} \tag{2}$$

$$\ln \eta_r = \frac{w_r}{k_1 - k_2 w_r} \tag{3}$$

Log of viscosity of narrow average molecular weight resins dissolved in good solvents increases with the square root of molecular weight in the range of viscosities between about 0.01 and 10 Pa·s (12,15). In poor solvent–resin combinations, clusters of resin molecules form, and viscosity is higher. In solutions in good

solvents, flow is generally Newtonian. In many cases, flow of more concentrated resin "solutions" in poor solvents is non-Newtonian because shear can break up or distort resin clusters. Intermolecular hydrogen bonding between carboxylic acid-functional resin molecules is particularly strong and solvent effects on the viscosity of acid-substituted resins are large (16).

Viscosity of Liquids with Dispersed Phases. When a small amount of a dispersed phase is present, there is only a small effect on viscosity; as the volume of dispersed phase increases, there is a sharply increasing effect. When the system becomes closely packed with particles, viscosity approaches infinity. Equation (4) shows the effects of variables on viscosity, where η_e is the viscosity of the continuous or external phase, K_E is a shape constant, V_i is the volume fraction of internal phase, and ϕ is the packing factor.

$$\ln \eta = \ln \eta_e + \frac{K_E V_i}{1 - V_i/\phi} \tag{4}$$

The *packing factor* is the maximum volume fraction of internal phase when the particles are randomly close-packed and external phase just fills all the interstices between the particles. The shape constant K_E for spheres is 2.5. Many of the particles in coatings are spheres or are close to being spheres. For uniform diameter spheres, the value of ϕ is 0.637 and is independent of particle size. The packing factor depends strongly on particle size distribution: the broader the particle size distribution, the higher the packing factor. Figure 1 shows a plot of a typical dispersion (17).

The viscosity of dispersions of nonrigid particles does not follow equation (4). When a shear stress is applied to such a dispersion (eg, an emulsion), the particles can distort. When the particles are distorted, the shape constant changes to a lower value and the packing factor increases (18); both changes lead to a decrease in viscosity. Such systems are thixotropic since, depending on the difference between the viscosities of the internal and external phases, there is time dependency of the distortion of the particles and, hence, a decrease in viscosity as a function of time at a given shear rate. Time dependency can be studied using viscoelastic deformation analysis (19). The viscosity of dispersions is also affected by particle–particle interactions. If clusters of particles form, the viscosity of the dispersion increases; if the clusters separate when shear is exerted, the viscosity drops. Examples of such shear thinning systems are flocculated pigment dispersions.

Extensional Flow. Another mode of flow encountered in coating application is extensional flow. When a fiber passes through a spinneret, the mode is shear flow. The fiber is pulled after leaving the spinneret, extending the fiber. The flow is extensional flow, and the resistance to flow is extensional viscosity. The symbol used for extensional viscosity is $\eta*$. In Newtonian fluids, $\eta*/\eta = 3$. Extensional flow in coating application is encountered when applying coatings by direct roll coating. In the nip, the coating is under pressure; as the coating comes out of the nip, the roller is moving up away from the film, and flow is extensional. As the film stretches, it splits; small imbalances of pressures lead to variations in the timing of film splitting. If the extensional viscosity is relatively low, the film splits quickly, leaving a ridged film. However, with higher extensional viscosity, fibers grow; longer fibers tend to split in two places, resulting in formation of droplets, which

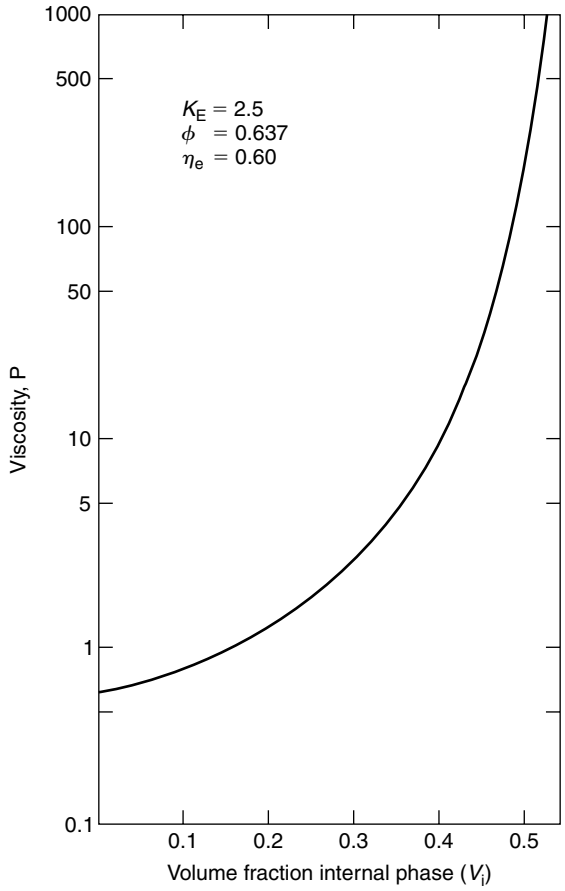

Fig. 1. The effect of increasing volume fraction of noninteracting spherical particles on the viscosity of a dispersion. From Ref. 17, with permission.

are thrown out into the air. This is called *misting* or *spattering*,. Reference 17 discusses the relationship of variables and extensional viscosity effects in roll coating.

Extensional flow can also be encountered in spray application. If, for example, a solution of a thermoplastic acrylic resin with $\bar{M}_w$ above about 100,000 is sprayed, instead of droplets coming out of a spray gun orifice, fibers emerge. The "strength" of the solution is high enough for the stream of coating to stay as a fiber rather than to form droplets. Reference 21 discusses extensional viscosity phenomena in spray application.

Mechanical Properties

Coating films should withstand use without damage. The coating on the outside of an automobile should not break when hit by a piece of flying gravel. The coating on

the outside of a beer can must not abrade when cans rub against each other during shipment. The coating on wood furniture should not crack when the wood expands and contracts as a result of changing temperatures or swelling and shrinkage from changes in moisture content of the wood. The coating on aluminum siding must be flexible enough for fabrication of the siding and resist scratching during installation on a house. A methodology for considering the factors involved in service life prediction has been given (22). A monograph (23) discusses problems of predicting service lives and proposes reliability theory methodology for database collection and analysis.

Basic Mechanical Properties. Understanding relationships between composition and basic mechanical properties of films can provide a basis for more intelligent formulation. Reference 24 is a good review paper. In ideal elastic deformation a material elongates under a tensile stress in direct proportion to the stress applied. When the stress is released, the material returns to its original dimensions essentially instantaneously. An ideal viscous material elongates when a stress is applied in direct proportion to the stress, but does not return to its original dimensions when the stress is released. Almost all coating films are viscoelastic—they exhibit intermediate behavior. Figure 2 shows a schematic plot of the results of a stress–strain test, in which a coating film is elongated (strain) at a constant rate and the resulting stress is recorded as percent elongation. The ratio of stress to strain is the *modulus*. In the initial part of this plot, modulus is independent of strain. However, as strain increases, the modulus depends on the strain. The end of the curve signifies that the sample has broken. This point is defined in two ways: *elongation-at-break*, a measure of how much strain is withstood before breaking; and the *tensile strength*, a measure of the stress when the sample breaks. The area under the curve represents the work-to-break (energy per unit volume). Commonly, as shown in Figure 2, at an intermediate strain, the stress required for further elongation decreases. The maximum stress at that point is called the *yield point*. Yield point can be designated in two ways: elongation-at-yield and yield strength.

Elastic deformation is almost independent of time and temperature. Viscous flow is time and temperature dependent; the flow continues as long as a stress is applied. Viscoelastic deformation is dependent on the temperature and the rate at which a stress is applied. If the rate of application of stress is rapid, the response can be primarily elastic; if the rate of application of stress is low, the viscous component of the response increases and the elastic response is lower. Similarly, if the temperature is low, the response can be primarily elastic; at a higher temperature, the viscous response is greater.

Stress–strain analysis can also be done dynamically by using instruments that apply an oscillating strain. The stress and strain vary according to sine waves. Stress and phase angle difference between applied strain and resultant measured stress are determined. For an ideal elastic material, the maximums and minimums occur at the same angles and the phase shift is 0°. For a Newtonian fluid, there would be a phase shift of 90°. Viscoelastic materials show an intermediate response. If the elastic component is high, the phase shift δ is small; if the elastic component is low compared to the viscous component, the phase shift is large. The phase shift, along with the maximum applied strain ε_0 and the maximum measured stress σ_0, is used to calculate the dynamic properties. Storage modulus E'

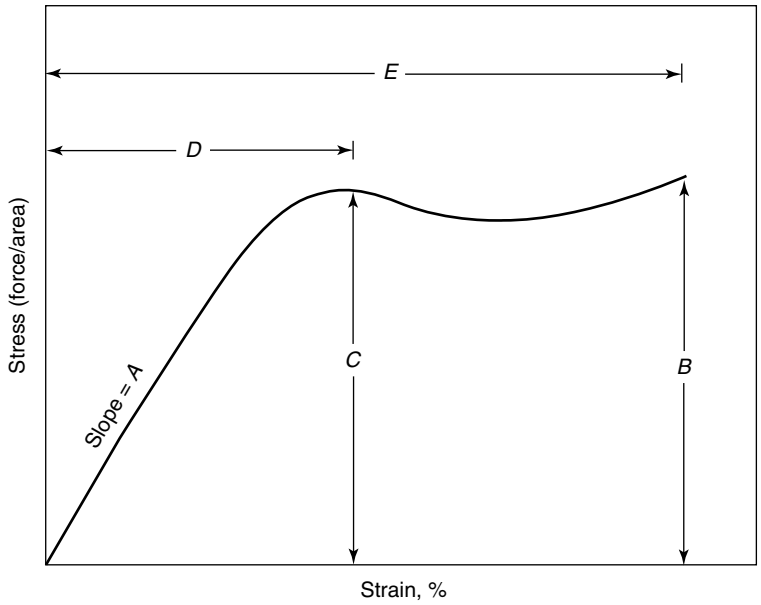

Fig. 2. Stress–strain plot. A is initial modulus, B is elongation-to-break, C is yield strength, D is elongation-to-break, and E is tensile strength. From Ref. 25, with permission.

is a measure of elastic response: $E' = (\sigma_0 \cos \delta)/\varepsilon_0$. Loss modulus E'' is a measure of the viscous response: $E'' = (\sigma_0 \sin \delta)/\varepsilon_0$. The square of the total modulus equals the sum of the squares of the storage and loss moduli. The ratio E''/E' is called loss tangent, since all of the terms cancel except the ratio $\sin \delta/\cos \delta$, corresponding to the tangent of an angle, $\tan \delta$, commonly called tan delta.

Dynamic mechanical analysis (qv) has the advantage over stress–strain studies that the elastic and viscous components of modulus can be separated. The higher the frequency of oscillation, the greater the elastic response and the smaller the phase angle; the lower the frequency, the greater the viscous response and the larger the phase angle. Generally, it is possible to run experiments over a range of frequencies in dynamic tests wider than the range of rates of application of stress possible in linear stress–strain experiments. Dynamic testing can be done over a wider range of temperatures and rates of heating. In dynamic tests, it is not possible to determine tensile-at-break, elongation-at-break, or work-to-break, since the sample must remain unbroken.

Formability and Flexibility. Many coated products are subjected to mechanical forces either to make a product, as in forming bottle caps or metal siding, or in use, as when a piece of gravel strikes the surface of a car with sufficient force to deform the steel substrate. To avoid film cracking, the elongation-at-break must be greater than the extension of the film. Cross-linked coatings have low elongations-at-break when below T_g. The T_g of cross-linked polymers depends on structure of the segments between cross-links, cross-link density (XLD), amount of dangling chain ends, and the extent of cyclization of the backbone (26).

The relationship between XLD and modulus for melamine–formaldehyde (MF) cross-linked films has been shown (27). As shown in equation (5), in which

ν_e is XLD expressed as the number of moles of elastically effective network chains per cubic centimeter of film. Since E'' is low at temperatures well above T_g, $E \approx E'$. XLD can also be calculated from the extent of swelling of a film by solvent. While cross-linked films do not dissolve in solvent, solvent dissolves in a cross-linked film. As cross-links get closer together the extent of swelling decreases. Equation (5) can be used to predict the storage modulus above T_g from the XLD.

$$E = 3\nu_e RT (T \gg T_g) \tag{5}$$

Properties are affected by the extent to which cross-linking has been carried to completion. Incomplete reaction leads to lower XLD and, hence, lower storage modulus above T_g. The extent of reaction can be followed by determining storage modulus as a function of time (28). Thus, one can, at least in theory, design a cross-linked network to have a desired storage modulus above T_g by selecting an appropriate ratio of reactants of appropriate functionality.

An additional factor that can affect the mechanical properties of polymeric materials is the breadth of the T_g transition region (29). The same effect can be seen in tan delta plots, which exhibit various breadths. Broad tan δ peaks are frequently associated with heterogeneous polymeric materials. Blends of different thermoplastic resins often display two distinct T_g's because of phase separation. Other blends of thermoplastics have a single, often broad, T_g, when phase separation is indistinct. For thermosetting polymers, the T_g transition region is generally broader than for thermoplastics. Breadth of the distribution of chain lengths between cross-links is a factor, and blends of thermosetting resins such as acrylics and polyesters often display a single, broad T_g transition. As a rule, materials with broad and/or multiple T_g's have better impact resistance than comparable polymers with a sharp, single T_g.

When a cross-linked film on a metal substrate is deformed by fabrication, it is held in the deformed state by the metal substrate. As a result, there is a stress within the film, acting to pull the film off the substrate. Stress within films can also arise during the last stages of solvent loss and/or cross-linking of films (30). It is common for coatings to become less flexible as time goes on. Particularly in air-dried coatings, loss of the last of the solvent may be slow. If the cross-linking reaction was not complete, the reaction may continue, decreasing flexibility. Another possible factor with baked films is densification. If a coating is heated above its T_g and then cooled rapidly, the density is commonly found to be lower than if the sample had been cooled slowly (31). During rapid cooling, more and/or larger free-volume holes are frozen into the matrix. On storage, the molecules slowly move and free volume decreases, causing densification; it is also called *physical aging*. To achieve the desired properties of baked films, some minimum time at a temperature is required, but overbaking can lead to excessive cross-linking. There is a cure window, and within this set of time and temperature satisfactory properties are obtained. High solids acrylic/MF coatings have narrower cure windows than conventional solids coatings.

Abrasion and Mar Resistance. *Abrasion* is the wearing away of a surface; *marring* is a disturbance of a surface that alters its appearance (see WEAR). A study of the mechanical properties of a series of floor coatings with known wear life concluded that work-to-break values best represented the relative wear lives

(32,33). Studies of automobile clear coats have shown that wear resistance increases as energy-to-break of films increases (34). Wear tends to increase as the angle of application of stress decreases. Urethane coatings generally exhibit superior abrasion resistance combined with solvent resistance. This combination of properties may result from the presence of intersegment hydrogen bonds in addition to the covalent bonds. At low levels of stress, hydrogen bonds act like cross-links, reducing swelling on exposure to solvent. At higher levels of stress, the hydrogen bonds dissociate, permitting the molecules to extend without rupturing covalent bonds. When the stress is released, the molecules relax and new hydrogen bonds form. Urethanes are used as wear layers for flooring, as well as topcoats in aerospace applications, where this combination of properties is desirable.

The coefficient of friction of a coating can affect abrasion resistance. Abrasion of the coating on the exterior of beer cans during shipment can be minimized by incorporation of a small amount of incompatible wax or fluorosurfactant in the coating. Another variable is surface contact area. Incorporation of a small amount of a small particle size SiO_2 pigment in a thin silicone coating applied to plastic eyeglasses reduces abrasion. The pigment particles reduce contact area, permitting the glasses to slide more easily over a surface.

Marring is a near-surface phenomenon; even scratches less than 0.5 μm deep can degrade appearance. Marring is a main problem with automobile clear topcoats. In going through automatic car washes, the surfaces of some clear coats are visibly marred and lose gloss (35). Mar resistance is a requirement in coatings for floors and for transparent plastics. The physics of marring is complex; various models have been proposed to describe what happens to a viscoelastic material when a hard object is drawn over its surface. Plastic deformation and fracture lead to marring. The responses can be quantitatively measured by scanning probe microscopy (36). In general, MF cross-linked acrylic clear coats are more resistant to marring than isocyanate cross-linked coatings, but MF cross-linked coatings have poorer environmental etch resistance. Coatings can be made hard enough so that the marring object does not penetrate into the surface, or they can be made elastic enough to bounce back after the marring stress is removed. If the hardness strategy is chosen, the coating must have a minimum hardness; however, such coatings may fail by fracture. Film flexibility is an important factor influencing fracture resistance (37). Maximum mar resistance results from coatings having as high a yield stress as possible without being brittle; high yield stress minimizes plastic flow and avoidance of brittleness minimizes fracture (38). Reference 38 provides a review of the relation of bulk mechanical properties of coatings to mar resistance.

Test Methods. Field applications on a small scale and under especially stringent conditions accelerate possible failure. Traffic paints are tested by painting stripes across the lanes of traffic instead of parallel to traffic flow. Automobiles are driven on torture tracks with stretches of gravel, through water, under different climatic conditions. Sample packs of canned goods are made; the linings are examined for failure and the contents evaluated for flavor after storage.

Many tests have been developed to simulate use conditions in the laboratory. An example is a gravelometer to evaluate resistance of coatings to chipping of automotive coatings when struck by flying gravel. Pieces of standard shot are

propelled at the coated surface by compressed air under standard conditions. The tests have been standardized by comparison to a range of actual results and give reasonably good predictions of actual performance. A more sophisticated instrument, a precision paint collider, which permits variations in angle and velocity of impact and temperature, has been described (39).

Many empirical tests are used to test coatings. In most cases, they are more appropriate for quality control than performance prediction. ASTM tests of importance to the coatings field are in Volumes 06.01, 06.02, and 06.03: *Paint—Tests for Formulated Products and Applied Coatings*. Many people believe the tests are more precise than they proved to be in ASTM round robin tests (40). An excellent reference book is the *Paint and Coating Testing Manual* (*Gardner-Sward Handbook*) (41). It gives descriptions of test methods and summaries of each main class of properties.

Exterior Durability

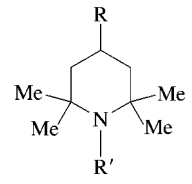
The primary ways of degradation on exterior exposure are photoinitiated oxidation and hydrolysis resulting from exposure to sunlight, air, and water.

Photointitiated Oxidative Degradation. Exterior coatings should exclude resin components that absorb uv radiation at wavelengths longer than 290 nm or that are readily oxidized. Photoinitiated oxidation of polymers proceeds by a chain reaction. Absorption of uv produces highly energetic photoexcited states that undergo bond cleavage to yield free radicals that undergo a chain reaction with O_2 (autoxidation), leading to polymer degradation. Functional groups in a coating that promote hydrogen abstraction by free radicals should be minimized. Aromatic groups with directly attached heteroatoms, as in aromatic urethanes and bisphenol A (BPA) epoxies, absorb uv above 290 nm and undergo direct photocleavage to yield free radicals that participate in oxidative degradation.

Ultraviolet absorbers and antioxidants are used to stabilize films. Reference 42 reviews photostabilization and thermal stabilization of coatings. A uv absorber converts uv energy into thermal energy. One cannot eliminate uv absorption by the resin by adding a uv absorber; it reduces absorption by the binder to slow the rate of photodegradation reactions. Since absorption increases as the path length increases, uv absorbers are most effective in protecting the lower parts of a film or substrate (eg, a base coat, wood, or plastic under a clear top coat containing an absorber) and least effective in protecting at the air interface. A uv absorber should have very high absorption of uv radiation from 290 through 380 nm and no absorption above 380 nm. Substituted 2-hydroxybenzophenones, 2-(2-hydroxyphenyl)-2*H*-benztriazoles, are the most used uv stabilizers. A requirement of a uv stabilizer is permanence. There can be physical loss by vaporization, leaching, or migration and/or chemical loss by photochemical reactions of the stabilizer. If a uv stabilizer has even a small vapor pressure, it slowly volatilizes. Longer term physical permanence may be achieved by using oligomeric photostabilizers or polymer-bound stabilizers.

Antioxidants are classified into two groups: preventive and chain-breaking antioxidants. Preventive antioxidants include peroxide decomposers, which reduce hydroperoxides to harmless products. Examples are sulfides and phosphites

that are oxidized to sulfoxides and phosphates. Metal complexing agents are preventive antioxidants that tie up transition metal ions present as contaminants that catalyze conversion of hydroperoxides into radicals. The most widely used chain-breaking antioxidants are hindered amine light stabilizers (HALS)—amines with two methyl groups on each of the two alpha carbons; most are derivatives of 2,2,6,6-tetramethylpiperidine, as shown in general formula (**1**). They act as free-radical traps to break the photoxidation chain reaction (43).



(R′ = H, alkyl, alkanoyl, alkoxy)

1

HALS derivatives undergo photoxidative conversion into nitroxyl radicals ($R_2NO\cdot$) that react with carbon-centered radicals by disproportionation and combination to yield corresponding hydroxylamines and ethers. The hydroxylamines and ethers, in turn, react with peroxy radicals to regenerate nitroxyl radicals. HALS derivatives interfere with propagation steps involving both carbon-centered and peroxy radicals in autoxidation. A variety of HALS compounds are available. The "R" in general formula (**1**) is often a diester group that joins two piperidine rings; this increases molecular weight, decreasing volatility. The first commercial HALS compounds had R′ = H. Later versions with R′ = alkyl exhibit better long-term stability. Both of these types are basic and interfere with acid-catalyzed cross-linking reactions, such as with MF resins. Hydroxylamine ethers (R′ = OR″) such as an octyl ether is a HALS with low basicity that converts rapidly to nitroxyl free radicals (44). HALS compounds, especially with R′ = H, can accelerate degradation of polycarbonate plastics. Combinations of uv absorbers and HALS compounds act synergistically (45). Ultraviolet absorbers are inefficient at protecting the outer surface of a film; HALS compounds effectively scavenge free radicals at the surface. Analysis of films after exterior exposure shows that significant amounts of HALS derivatives remain after 2 years of black box Florida exterior exposure. With clear coat–base coat finishes, a major mode of failure is delamination between topcoats and base coat, primer, or plastic substrate (46). Application of sufficient film thickness and proper choice of uv stabilizers and HALS are needed to avoid delamination.

Many pigments absorb uv radiation. The strongest uv absorber known is fine particle-size carbon black. Many carbon blacks have structures with multiple aromatic rings and, in some cases, phenol groups on the pigment surface. Such black pigments are both uv absorbers and antioxidants. Coatings of thickness 50 μm pigmented with fine particle size, transparent iron oxide pigment absorb virtually all radiation below about 420 nm (47). It is useful in wood stains, since the pigmented transparent coating protects the wood from photodegradation.

TiO_2 absorbs uv strongly, but it can accelerate photodegradation of films, causing chalking of coatings—degradation of the organic binder and exposure of unbound pigment particles on the film surface that rub off easily. Degradation

of the binder is enhanced by interaction of photoexcited TiO_2 with oxygen and water to yield oxidants (48). Anatase TiO_2 is more active in promoting oxidative degradation than rutile TiO_2. The photoactivity of TiO_2 pigments is reduced by coating the pigment particles with a thin layer of silica and/or alumina. Chalking reduces gloss, since the film becomes rougher. In paints containing both TiO_2 and color pigments, chalking results in color changes as a result of the gloss loss; the higher surface reflectance of the low gloss films gives weaker colors. However, loss of gloss does not necessarily correlate with ease of chalking (49). Initial gloss loss in some TiO_2 pigmented coatings results from film shrinkage, which, in some cases, is greater with more resistant grades of TiO_2.

Hydrolytic Degradation. A general ordering of groups subject to hydrolysis is esters > ureas > urethanes ≫ ethers, but activated ethers in MF cross-linked hydroxy-functional resins, are more reactive than ureas and urethanes. The tendency to hydrolyze can be reduced by steric hindrance, for example, by alkyl groups in the vicinity of the susceptible groups, such as esters. The lower the water solubility of the diacid or diol used to make a polyester, the greater the resistance to hydrolysis (50). Phthalate esters are more readily hydrolyzed under acidic conditions than isophthalate esters. Hydrolysis of polyesters results in backbone degradation. Backbones of (meth)acrylic resins are resistant to hydrolysis, since the linkages are carbon–carbon bonds.

Base coat–clear coat finishes for automobiles are subject to environmental etching. Small spots appear in the clear coat surface in a warm climate with acidic rain. The spots are uneven, shallow depressions from hydrolytic erosion of resin in the area of a droplet of acidic water. Several factors are involved in differences in resistance to environmental etching (51). Since urethane linkages are more resistant to acid hydrolysis than the activated ether cross-links obtained with MF resins, generally urethane–polyol clear coats are less susceptible to environmental etching. Temperature, T_g, and surface tension are also important.

Silicone coatings are subject to hydrolysis at cross-linked sites, where silicon is attached to three oxygens (52,53). The reaction is reversible, and cross-links can hydrolyze and reform. If a silicone-modified acrylic coating is exposed to water over long periods or is used in a climate with very high humidity, the coating softens. MF resin as a supplemental cross-linker minimizes the problem.

Other Modes of Failure. When paint is applied to wood, it must be able to withstand the elongation that results from the uneven expansion of wood grain when it absorbs moisture. A problem of exterior, oil-based house paints on wood siding is *blistering*. The blistering results from accumulation of water in the wood beneath the paint layer. The vapor pressure of the water increases with heating by the sun, and blisters form to relieve the pressure. Since latex paints have higher moisture vapor permeability than oil-based paints, the water vapor can pass through a latex paint film. The high moisture vapor permeability of latex paint films can lead to failures of other types. If calcium carbonate fillers are used in an exterior latex paint, frosting can occur. Water and carbon dioxide permeate into the film, dissolving calcium carbonate by forming soluble calcium bicarbonate, which diffuses out of the film. At the surface, the calcium bicarbonate is converted back to a deposit of calcium carbonate.

Dirt retention can be a problem with exterior gloss latex paints. Latex paints must be designed to coalesce at relatively low application temperatures.

At warmer temperatures, soot and dirt particles that land on the paint surface cannot be washed off by rain. Dirt pickup is less for paints formulated with higher T_g polymers (54).

Testing. No test is available that reliably predicts the exterior durability of coatings, partly due to the wide variety of environments and application conditions (see WEATHERING). The limitations of accelerated tests, the need for data based on actual field experience, and methods of building a database are described in Reference 23. Use of reliability theory using statistical distribution functions of material, process, and exposure parameters for predicting exterior durability of automotive coatings has been recommended (46). Reference 55 reviews various test methods.

The most reliable accelerated tests are outdoor fence exposures of coated panels carried out in several locations with different environments. Reference 56 reviews testing of exposed panels. Southern Florida has a subtropical climate with high humidity, temperature, and sunshine level. Arizona has more hours of sunshine per year and a higher average daily high temperature, but lower humidity. The differences between exposure conditions in Florida and Arizona have been reviewed (57). Test specimens are examined periodically. Part of the coating is cleaned for comparison. Ease of cleaning, change in gloss, change in color, degree of chalking, and gross film failures are reported. Film degradation is accelerated using black box exposure. Panels are mounted at 5° to the horizontal on black boxes. Increase in the temperature of the coating accelerates degradation. The temperature increase and the extent of acceleration vary from coating to coating with color.

Results can be obtained in shorter times by using Fresnel reflectors to concentrate sunlight on test panels. High intensity is achieved by reflecting sunlight from moving mirrors that follow the sun to maintain a position perpendicular to the sun's direct beam radiation (57). They enhance the intensity of sunlight on the panel surfaces by a factor of 8 over direct exposure; it is said to accelerate degradation rates 4–16 times the rate for nonaccelerated exposure.

Chemical changes begin before physical changes become evident. Studies of chemical changes help determine the mechanism of failure, providing a basis for formulating more resistant coatings. References 44 and 58 provide reviews of various approaches. Electron spin resonance (esr) spectrometry can monitor changes in free-radical concentrations within a coating. The rate of disappearance of stable nitroxyl radicals has been correlated with loss of gloss in long-term Florida exposure (45). Use of ESR spectrometry to monitor the rate of disappearance of nitroxyl radicals in acrylic/MF coatings allows calculation of photoinitiation rates (PR) of free-radical formation, which were found to correlate with rates of gloss loss (GLR): $\mathrm{GLR} \propto (\mathrm{PR})^{1/2}$. Photoinitiation rates have been used to evaluate experimental conditions for the synthesis of acrylic polyols on the exterior durability of the acrylic/MF coating (59). Electron spin resonance spectrometry has been used to study photostability of coating films by determination of free-radical concentration after uv irradiation of films at a temperature of 140 K, well below T_g (59). Fourier transform infrared (ftir) spectroscopy is used to follow chemical changes on a surface (60). Photoacoustic-ftir spectroscopy; has also been used; it has the advantages that the sample does not have to be removed from the substrate and the film can be analyzed at different depths within a film (61).

Many laboratory devices for accelerating degradation are available. See Reference 62 for descriptions of various devices and their advantages and disadvantages. They expose panels to uv sources with different wavelength distributions and the panels are subjected to cycles of water spray (or high humidity). Although these tests are widely used, results frequently do not correlate with actual exposure results. The predictive value of accelerated weathering with artificial light sources is particularly questionable when a light source includes wavelengths less than 290 nm. Variability of performance of the test instruments can also be a problem, especially when comparing results from laboratory to laboratory (63). An evaluation of accelerated weathering devices for a polyester–urethane coating, using photoacoustic-ftir spectroscopy, concluded that none of the conventional devices were suitable (64). Many examples of reversals of results comparing coatings with known exterior durability with laboratory tests have been found. Stabilizer loss by volatilization may be insignificant in an accelerated test, but very important over the long time periods of actual use.

Adhesion

Adhesion is an essential characteristic of most coatings. A coatings formulator thinks how hard is it to remove the coating? But, a physical chemist thinks of the work required to separate the interface. The latter is only one aspect of the former. Removal of a coating requires breaking or cutting through the coating and pushing the coating out of the way, as well as separating the coating from the substrate.

With a very smooth interface between coating and substrate, the only forces holding the substrate and coating together are the interfacial attractive forces. With a rough surface on a microscopic scale, the contact area between the coating and the rough substrate is larger than the geometric area and penetration of coating into undercuts adds mechanical strength. Surface roughness can be a disadvantage; if the coating does not completely penetrate into the microscopic pores and crevices in the surface, dovetail effects are not realized, and interfacial contact area can be smaller than the geometric area. The viscosity of the continuous phase of the coating is a significant factor controlling penetration. Coatings with low viscosity external phases, slow evaporating solvents, and slow cross-linking rates give better adhesion. Because of the drop in viscosity by heat, baked coatings give better adhesion than do air-dried coatings. Viscosity of resin solutions increases with molecular weight; one would expect that lower molecular weight resins would provide superior adhesion. This hypothesis has been confirmed in the case of epoxy resin coatings on steel (65).

Internal stresses act to reduce adhesion; less external force is required to disrupt the adhesive bond. As film formation proceeds, T_g rises and free volume is reduced; the film becomes fixed in unstable conformations, and internal stress increases (66). The stress can build up sufficiently so that spontaneous delamination occurs (67). Stresses also result from volume expansions, such as swelling of films by exposure to high humidity (67) or water immersion (68). As the rate of cross-linking increases, stresses increase, since less time is available for

polymer relaxation to occur. An extreme example is uv curing of acrylated resins by free-radical polymerization in a fraction of a second.

Nonuniform curing, film defects, and imperfections in the film, can lead to localized stresses that can lead to fractural failure (69). Stress applied to that part of the film concentrates at an imperfection, increasing the probability of forming a crack; the crack propagates to the coating–substrate interface, leading to delamination. Pigment particles with sharp crystal corners and air bubbles are examples of potential sites for concentration of stresses. On the other hand, incorporation of particles of rubber may lead to dissipation of stresses.

Wetting is a significant factor in adhesion. If a coating does not spread spontaneously over a substrate surface so that there is intermolecular contact between the substrate surface and the coating, there will be no contribution to adhesion. The relationships between wetting and adhesion have been extensively studied (70). A liquid spreads spontaneously on a substrate if the surface tension of the liquid is lower than the surface free energy of the solid. Additives with single polar groups and long hydrocarbon chains in coatings can result in poor adhesion since they get preferentially absorbed on a metal surface, resulting in poor adhesion between the coating and a monolayer of additive. An example is the poor adhesion to steel that results from use of dodecylbenzenesulfonic acid [27176-87-0] as catalyst. Adhesion of latex films can be affected by a layer of surfactant forming at the interface between the coating and the substrate (71).

The metal and its surface characteristics affect adhesion; Reference 72 is a review of metal surface characteristics, cleaning, and treatments. The surface tension of a clean metal surface is higher than that of any potential coating. Oils and soluble salts must be removed from the surface. Steel surfaces are generally given a metal phosphate conversion treatment. The resulting mesh of crystals on the surface of the steel increases the interfacial area for interaction, and the hydrogen-bond interactions between the phosphate crystals and the resin molecules are stronger than those between the steel surface and the resin molecules. The last rinse has contained a low concentration of chromic acid to protect against corrosion. Because of the toxic risks of hexavalent chromium, replacements for the chromate rinse are being sought. Over zinc phosphate, a rinse of 0.5% trimethoxymethylsilane with H_2ZrF_6 at pH of about 4 is reported to give better performance than a chromic acid rinse (73). Plasma polymerization of trimethylsilane on the surface of cold-rolled steel provides corrosion protection (74). Also, plasma polymerization of hexamethyldisiloxane in the presence of oxygen is under investigation (75). Bis(trisilylalkoxy)alkanes are being investigated to treat the surface of steel to increase adhesion (76). Clean steel is rinsed with water, and then the wet steel is dipped first in an aqueous solution of bis(trimethoxysilyl)ethane (BTSE) and then in an aqueous solution of a reactive silane. The BTSE reacts with water and hydroxyl groups on the steel and silanols from other molecules of BTSE to give a water-resistant anchor to the steel. The reactive silane reacts with other silanol groups from the BTSE, and the reactive group can react with a coating binder.

For many applications, aluminum requires no treatment other than cleaning. If there will be exposure to salt, surface treatment is necessary. Most treatments for aluminum have been chromate treatments. See Reference 72 for further discussion. In the past several years, many chrome- and cyanide-free proprietary

aluminum conversion coatings have been developed with equivalent performance to chrome coatings. Electrodeposited cerium oxide conversion coats show promise (77).

To provide greater protection against corrosion, steel coated with zinc is widely used in construction and automobiles. There can be large variations in adhesion, depending on the condition of the zinc layer of the galvanized steel. If zinc-coated steel has been exposed to rain or high humidity, surface oxidation leads to formation of ZnO, $Zn(OH)_2$, and $ZnCO_3$; they are basic and somewhat soluble in water. It is important to use saponification-resistant resins in primers for galvanized steel. Reference 78 reviews coating of galvanized steel. Treating the surface of galvanized steel with a solution of zirconium nitrate, followed by treatment with *N*-aminoethylaminopropyltrimethoxysilane, is reported to be a good pretreatment for galvanized steel for coil coating (79).

The surface of clean steel is not iron; rather, hydrated iron oxides are present as a monolayer (80). Adhesion to this surface is promoted by developing hydrogen bonds between groups on the resin molecules and the oxide and hydroxide groups on the surface of the steel. Adhesion is promoted by using resins having multiple hydrogen-bond donor and acceptor groups. Best results are obtained with hydrogen-bond donor groups are scattered along a resin chain. Adsorption of resin molecules occurs with loops and tails sticking up from the surface so that some of the polar groups are adsorbed on the surface and some on the loops and tails, where they interact with the rest of the coating. BPA epoxy resins and their derivatives commonly provide excellent adhesion to steel. These resins have hydroxyl and ether groups along the chain, which can provide for interactions with both the steel surface and the other molecules in the coating. The backbone consists of alternating flexible 1,3-glyceryl ether and rigid BPA groups; the combination provides the flexibility necessary to permit multiple adsorption of hydroxyl groups on the surface of the steel, along with rigidity to prevent adsorption of all of the hydroxyl groups. References 65 and 81 discuss effects of variations in epoxy resin composition on adhesion. Amine and phosphate groups on the resin particularly improve adhesion in the presence of water.

Surface analysis is useful in understanding factors affecting adhesion. The surfaces of steels have been studied by Auger analysis. In some cold-rolled steels organic compounds become imbedded in the surface of the steel during coil annealing. If this happens, it becomes difficult to apply high quality phosphate conversion treatments on the steel (82). X-ray photoelectron spectroscopy (xps) is used to study the surface of steel from which a coating has been removed and the underside of the coating that was in contact with the steel. The site of failure occurred can be identified—that is, whether failure was between the steel and the coating or between the main body of the coating and a monolayer of material on the surface of the steel. Other valuable analytical procedures for thin surface layers are attenuated total reflectance (atr) and ftir spectroscopies.

Stronger interactions with the substrate surface are possible by forming covalent bonds. Reactive silanes enhance adhesion of coatings to glass (83). In an epoxy-amine coating for glass, one can add 3-aminopropyltrimethoxysilane. The trimethoxysilyl group reacts with silanol groups on the surface of the glass to generate siloxane bonds. The trimethoxysilyl groups also react with water to produce silanol groups that react with remaining methoxysilyl groups to generate

polysiloxane groups at the glass surface. The terminal amine groups react with epoxy groups in the resin so that the coating is multiply bonded to the surface of the glass. Resins with acetoacetic ester substituents can coordinate with ferric salts. Reports indicate improvement in adhesion and corrosion protection (84).

With many plastics there is a problem wetting the surface with a coating. Wetting can be affected by mold release agents on a molded plastic part. Polyolefins have low surface free energies. Adhesion to polyolefins generally requires treatment of the surface to increase its surface free energy. Oxidation of the surface generates polar groups that increase surface free energy and provide hydrogen-bond acceptor and donor groups for interaction with coating resin molecules. A variety of processes are used to treat the surface (85,86). The surfaces can be oxidized by flame treatment; corona discharge or chemical oxidizing treatments are effective. Adhesion to untreated polyolefins can be assisted by applying a thin tie coat of a low solids solution of a chlorinated polyolefin or chlorinated rubber. The various approaches and results of various types of surface analysis have been reviewed (85). See Reference 87 for further discussion of surface treatments.

Curing at a temperature above the T_g of the plastic enhances adhesion by migration of resin molecules into the surface of the plastic. In some cases, heating the plastic substrate above its T_g is not feasible because the plastic substrate undergoes heat distortion. Solvents in the coating that are soluble in the plastic can enhance adhesion by lowering its T_g. The solvents should evaporate slowly to permit time for penetration to occur. Fast evaporating solvents, such as acetone, can cause crazing of thermoplastics, such as polystyrene and poly(methyl methacrylate). *Crazing* is the development of many minute surface cracks.

Adhesion to other coatings, intercoat adhesion, requires the surface tension of the coating to be lower than the surface free energy of the substrate coating. Polar groups in both coatings permit hydrogen bonding; in the case of thermosetting coatings, covalent bonding enhances intercoat adhesion. Curing temperatures above T_g, use of compatible resins, and solvents in the coating that can swell the substrate coating enhance intercoat adhesion. Coatings with lower XLD are more swollen by solvents. Sometimes, one can undercure the primer thus having a lower XLD when the topcoat is applied. Cure of the primer is completed when the topcoat is cured.

Primers with low gloss have rougher surfaces and are easier to adhere to. When possible, increasing the pigment loading of a primer above critical pigment volume concentration (CPVC) facilitates adhesion of a topcoat. Above CPVC, the dry film contains pores; when a topcoat is applied, vehicle from the topcoat penetrated into the pores, giving a mechanical anchor.

Testing. Formulators use a penknife to see how hard it is to scrape a coating from a substrate. While a penknife in the hand of an experienced person can be a valuable tool, there is no good way of assigning a numerical value to the results. A variety of methods for evaluating the adhesion of coatings have been investigated (88). None are very satisfactory. The most useful is a direct pull test. A rod is fastened perpendicular to the upper surface of the coated sample with an adhesive. The panel is fastened to a support with a perpendicular rod on its back and an Instron Tester is used to measure the tensile force to pull the coating off the substrate. A potential complication is cohesive failure of the coating; no information on adhesion is obtained. One must exercise caution in interpreting the results

even when the sample appears to have failed adhesively at the substrate–coating interface. Sometimes, when no coating can be seen on the substrate surface after the test, there is a monolayer of material from the coating left on the substrate surface. Surface analysis is useful in determining the locale of failure and the identity of the adsorbed material. Fairly often, there is a combination of adhesive and cohesive failure when an initial crack propagates down to the interface. See Reference 88 for discussion of the effect of variables on test results.

Adhesion can be affected by the angle of application of stress. An instrument called STATRAM II has been devised to combine a normal load and lateral traction to measure friction induced damage (89). Optical measurements are combined with measurements of total energy consumed during the scraping process. The test has been used to study delamination of coatings when plastic automobile bumpers rub together or scrape against solid objects. In many cases, cohesive failure of the plastic occurred near the surface of thermoplastic olefin (TPO), rather than adhesive failure between the coating and the substrate. Composition of coatings, especially solvents, can affect the structure of the upper layer of the plastic.

The most widely used test is the crosshatch test. Using a device with 11 sharp blades, a scratch mark pattern is made across the sample, followed by a second set cut perpendicular to the first. A strip of pressure-sensitive adhesive tape is pressed over the pattern of squares and pulled off. The test distinguishes between samples having poor adhesion and those having fairly good adhesion, but is not very useful in distinguishing among higher levels of adhesion. See Reference 88 for discussion of the variables affecting the test.

Corrosion Protection by Coatings

Steel corrodes by electrochemical reactions. In the presence of oxygen, at anodic areas ferric ions and at cathodic areas hydroxyl ions are formed. Aluminum generally corrodes more slowly than steel because of a dense, coherent layer of aluminum oxide. However, aluminum corrodes more rapidly than iron under either highly acidic or basic conditions. Also, salt affects the corrosion of aluminum more than it affects the corrosion of iron. Galvanized steel is protected since zinc acts as a sacrificial anode and a barrier preventing water and oxygen from reaching the steel surface.

Corrosion Protection by Intact Films. Coatings can be effective barriers to protect steel when a coating can be applied to cover all of the surface and remains intact in service. An important factor is wet adhesion. If water displaces the film, corrosion starts generating ions, giving an osmotic cell under the film (90). Osmotic pressure provides force to remove more coating from the substrate. Amine and phosphate groups are particularly effective polar substituents for promoting wet adhesion. Epoxy phosphates have been used to enhance the adhesion of epoxy coatings on steel (81). Primers made with saponification-resistant vehicles give better corrosion protection than primers made with vehicles that saponify readily (91).

Low water and oxygen permeability increase corrosion protection. Many factors affect permeability of coating films to water and oxygen (92). Coatings with a T_g above the temperature at which corrosion protection is desired reduce

permeability. The higher T_g values of baked coatings is another factor in their superior corrosion protection. Higher XLD leads to lower permeability. Permeability is affected by the solubility of water in a film. Water solubility in halogenated polymers is low; hence vinyl chloride and vinylidene chloride copolymers and chlorinated rubber are often used in formulating topcoats for corrosion resistance. The effect of pigmentation and other variables is reviewed in Reference 93. Water permeability decreases as pigment volume concentration (PVC) (up to CPVC) increases. Pigments with platelet shaped particles reduce permeability rates when they are aligned parallel to the coating surface (94). Leafing aluminum is frequently used. A Monte Carlo simulation model of the effect of several variables on diffusion through pigmented coatings has been devised (95).

Corrosion Protection by Nonintact Films. In many end uses, there will be breaks in the films. Then it is desirable to design coatings to suppress electrochemical reactions. If there are gouges through the film down to bare metal, and wet adhesion is not adequate, water creeps under the coating, and the coating comes loose from the metal over a wider area. Poor hydrolytic stability exacerbates the situation.

Passivating pigments form a barrier layer over anodic areas. The pigments must have some minimum solubility; however, if the solubility is too high, the pigment leaches out of the coating film too rapidly. Red lead [1314-41-6] in oil primers is used for air-dry application over rusty, oily steel. Toxic hazards of red lead restrict its use and regulations can be expected to prohibit its use. The utility of chromate pigments for passivation is well established. Chromate ions must be in aqueous solution. Zinc yellow [85497-55-8] pigment has been widely used in primers. Strontium chromate is sometimes used in primers, especially latex paint primers. Soluble chromates are human carcinogens. They must be handled with appropriate caution. In some countries, their use has been prohibited and prohibition worldwide is probable in the future. Basic zinc and zinc–calcium molybdates, barium metaborate, zinc phosphate, and calcium and barium phosphosilicates, and borosilicates are examples of replacement pigments (96).

Zinc-rich primers contain high levels (over 80 wt%) of powdered zinc. Zinc content exceeds CPVC to assure electrical contact between the zinc particles and with the steel. The film is porous, permitting water to enter, and thus completing the electrical circuit. The zinc serves as a sacrificial anode, and zinc hydroxide is generated in the pores. Vehicles for zinc-rich primers must be saponification resistant. Epoxy resins are used in organic primers. However, the most widely used vehicles are tetraethylorthosilicate (silicic acid tetraethyl ester) [78-10-4] and oligomers derived from it by partial hydrolysis. Alcohol is used as the principal solvent to maintain package stability. After application, the alcohol evaporates, and water from the air completes the hydrolysis of the oligomer to yield a film of polysilicic acid, partially converted to zinc salts. Waterborne zinc-rich primers have been developed using sodium, potassium, and/or lithium silicate solutions in water as the vehicle.

Evaluation and Testing. There is no laboratory test available to predict corrosion protection performance of a new coating system. Suppliers and end users of coatings for such applications as bridges, ships, chemical plants, and automobiles have collected data correlating performance of different systems over many years. These data provide a basis for selection of current coatings

systems for particular applications and insight into how new coatings could be formulated.

Panels are exposed on ocean beaches. The difficulties in such tests are discussed in Reference 97. The steel used is a critical variable (98). Film thickness, evenness of application, flash-off time, baking time and temperature, and many other variables affect performance. Results obtained with laboratory panels can be quite different than results with actual production products. It is desirable to paint test sections on ships, bridges, and chemical storage tanks, and observe their condition over the years.

Since wet adhesion is critical for corrosion protection, techniques for studying wet adhesion can be useful. Electrochemical impedance spectroscopy (eis) is used to study coatings on steel. Many papers (99,100) are available, covering various applications of eis. When a coating film begins to delaminate, there is an increase in apparent capacitance. The rate of increase of capacitance is proportional to the amount of area delaminated by wet adhesion loss. Onset of delamination can be determined by eis studies (101). Results of eis tests are subject to considerable variation (102). Other problems with eis are discussed in Reference 103.

There have been many attempts to develop laboratory tests to predict corrosion protection by coatings. The most widely used test is the salt spray test (ASTM method B117-95). Coated steel panels are scribed through the coating and hung in a chamber with a mist of 5% salt solution at 100% RH at 35°C. The scribe is examined to see how far from the scribe mark the coating is undercut. It has been repeatedly shown that there is little correlation between salt spray tests and actual performance of coatings (104,105). Since with intact films the first failure is blister formation, so humidity resistance tests are widely used (ASTM method D2247-94). They give comparisons of wet adhesion. Alternating high and low humidity causes faster blistering than continuous exposure to high humidity. A large number of humidity cycling tests have been described, involving repeated immersion in warm water and removal for several hours. Prohesion test has been reported to correlate better with actual performance than the standard salt spray test (106); however, other results show poor correlation (107). Another cycling test is the Society of Automotive Engineers test (SAE J-2334).

Resins and Cross-linkers

Latexes. A *latex* is a dispersion of polymer particles in water. Molecular weights of polymers prepared by emulsion polymerization are generally high; $\bar{M}_w$ of 1,000,000 or higher is common. The molecular weight does not affect the viscosity of the latex. Latex viscosity is governed by the viscosity of the medium in which the polymer particles are dispersed, by the volume fraction of particles, and by their packing factor. Latexes are used as the vehicle in a majority of architectural coatings. A growing part of the original equipment manufacture (OEM) product and special purpose coatings markets is latex based.

Acrylic latexes are used for exterior paints because of their resistance to photodegradation and hydrolytic stability. Acrylic latex paints are useful for alkaline substrates such as masonry and galvanized metal. Acrylic and styrene–acrylic

latexes are being used increasingly for industrial maintenance coatings. Acrylic latexes are finding increasing interest for kitchen cabinet finishes and for OEM automotive applications.

Latex paint formulations include coalescing solvents; VOC regulations require use of less coalescing solvent. Various modifications in preparation of latexes have been suggested for reduction of coalescent (108–110). A promising approach is use of thermosetting latexes. A low T_g thermosetting latex permits coalescence without addition of a coalescing solvent. After film formation, cross-linking increases modulus to give block resistance. If a significant degree of cross-linking occurs before application, coalescence will be adversely affected. Hydroxy-functional latexes can be formulated with MF resins or a water-dispersible polyisocyanate for wood and maintenance coatings (111). Carboxylic acid-functional latexes can be cross-linked with carbodiimides (112), or polyfunctional aziridines (113). *m*-Isopropenyl-α,α-dimethylbenzyl isocyanate (TMI) [1-(1-isocyanato-1-methylethyl)-3-(1-methylethenyl)benzene] [2094-99-7] reacts slowly with water and can be used to make thermosetting latexes (114).

Other thermosetting latexes cross-link at room temperature and are storage stable. Carboxylic acid-functional latexes can be cross-linked with β-(3,4-epoxycyclohexyl)ethyltriethoxysilane (115). A combination of amine-functional and epoxy-functional latexes gives stable one package coatings (116). A latex with allylic substitution cross-links on exposure to air (117). Hybrid alkyd/acrylic latexes are prepared by dissolving an oxidizing alkyd in the monomers used in emulsion polymerization (118). Stable thermosetting latexes can be prepared using triisobutoxysilylpropyl methacrylate as a comonomer (115).

Vinyl acetate (VAc) (acetic acid ethenyl ester) [108-05-4] is less expensive than (meth)acrylate monomers. VAc latexes are inferior to acrylic latexes in photochemical stability and resistance to hydrolysis and are used in flat wall paints. Reference 119 discusses use of a variety of vinyl esters in latexes. The polymers are more hydrophobic than VAc homopolymers and have superior hydrolytic stability and scrub resistance. Reference 120 reports the advantages of using vinyl versatate in both VAc and acrylic copolymers.

Amino Resins. Melamine (1,3,5-triazine-2,4,6-triamine) [108-78-1] is reacted with formaldehyde [50-00-0] and alcohols to make melamine–formaldehyde (MF) resins, the most widely used cross-linkers for baked coatings. The ethers groups are activated toward nucleophilic substitution by the neighboring N. Hydroxyl, carboxylic acid, urethane, and phenols with an unsubstituted ortho position react (see AMINO RESINS).

A variety of MF resins are made with differences in the ratio of functional groups, the alcohol, and the degree of polymerization, $\bar{P}$. MF resins are classified into two broad classes: I and II. Class I resins are made with relatively high ratios of formaldehyde to melamine, and most of the nitrogens have two alkoxymethyl substituents. All the resins contain some oligomers; the lowest viscosity ones have high hexamethoxymethylmelamine (HMMM) contents. Class I resins tend to provide tougher films than Class II. Strong acid catalysts are required. Class II resins are made with smaller ratios of formaldehyde to melamine, and many of the nitrogens have only one substituent. The predominant reactive group present in Class II resins is $-NHCH_2OR$. They yield cross-linked films at temperatures lower than that for Class I resins and are catalyzed by weak acids. Some grades of

TiO_2 lead to loss of catalyst activity. Silicon dioxide treated TiO_2 is preferable to aluminum oxide treated TiO_2.

Hydroxy-functional acrylic and polyester resins are most commonly cross-linked by MF resins. The hydroxyl groups of polyols react either by transetherification with the activated alkoxymethyl groups or by etherification with methylol groups of MF resins to form new ether cross-links. The reactions are reversible, but are driven toward cross-linking by volatilization of the monofunctional alcohol or water produced. Rates of reaction with hydroxyl groups depend on the structure of the polyol and the MF resin, the type and amount of catalyst, and the temperature. The rates of development of solvent resistance and film hardness when a fractionated Class I resin with about 95% HMMM was used to cross-link polyester resins made with cyclohexanedimethanol (CHDM) (1,4-dimthylolcyclohexane) [27193-25-5], neopentyl glycol (NPG) (2,2-dimethyl-1,3-propanediol) [126-30-7], and hexylene glycol (HG) (1,6-hexanediol) have been reported (121). CHDM polyesters are most reactive, NPG polyesters are a close second, and HG polyesters are least reactive. During acid-catalyzed cross-linking with polyols, reactions between MF resin molecules also occur. These self-condensation reactions form methylene and dimethylene ether bridges. Both self- and cocondensation reactions contribute to the film properties. With strong acid catalysis, the apparent rate at which Class I resins react with most polyols by cocondensation is faster than by self-condensation. With Class II resins, the rates of cocondensation and self-condensation are similar. In high solids coatings in which the hydroxy equivalent weight is high and the average functionality of the polyol is low, curing is sensitive to variations in cure temperature and time, that is cure window (122). Carboxylic acid-functional resins react with MF resins to form ester derivatives; the reaction is slower than with hydroxyl groups.

Stability is somewhat improved by addition of small quantities of amines. Class II resins generally give poorer package stability than Class I resins. Primary or secondary amines, which react with formaldehyde, should not be used with Class II resins. Use of monofunctional alcohol as part of the solvent extends the storage stability. It is desirable to utilize the same alcohol that is used to synthesize the MF resin. If a different alcohol is used, undesirable changes may occur; if 1-butanol [71-36-3] is used in the solvent with a methoxymethylmelamine resin, the cure response gradually becomes slower as the proportion of butyl ether increases.

Benzoguanamine (6-phenyl-1,3,5-triazine-2,4-diamine) [91-76-9] is used to make benzoguanamine-formaldehyde (BF) resins that give cross-linked films with greater resistance to alkali and alkaline detergents than MF resins. Exterior durability of BF-based coatings is poorer. BF resins are used for applications such as washing machines and dishwashers.

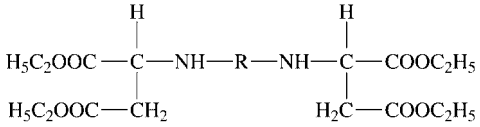
Urea–formaldehyde (UF) resins are made with different ratios of formaldehyde to urea and different alcohols. UF resins are the most economical and most reactive amino resins. With sufficient acid catalyst, coatings formulated with UF resins cure at ambient or mildly elevated temperatures. The coatings have poor exterior durability. UF resins are used in coatings for temperature-sensitive substrates, such as wood furniture, paneling, and cabinetry.

Glycoluril (tetrahydroimidazo[4,5-*d*]imidazol-2,5-(1*H*, 3*H*)-dione) [496-46-8] reacts with formaldehyde and alcohols to form glycoluril–formaldehyde (GF) resins (123). The tetramethyl ether resin is used as a cross-linker in powder

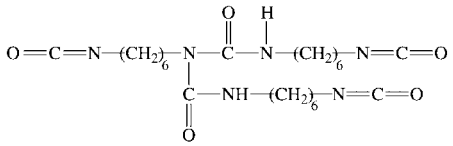
coatings. In solution coatings, ethyl and butyl ethers are used. GF resin coatings have greater flexibility than MF coatings; they are used in applications such as coil coatings and can coatings. GF resins evolve less formaldehyde during cure. GF cross-linked polyols are more resistant to hydrolysis under acidic conditions than MF cross-linked polyols.

Binders Based on Isocyanates. Isocyanates react with any active hydrogen compound. The largest use of polyisocyanates is as cross-linkers for hydroxy-functional acrylic and polyester resins to make urethane coatings. The high reactivity permits ambient or low temperature curing. Because of the intermolecular hydrogen bonding, polyurethanes generally have good abrasion resistance (see ISOCYANATE–DERIVED POLYMERS; URETHANE COATINGS).

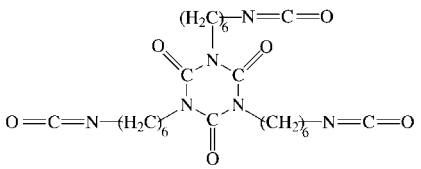
Isocyanates react with water to yield ureas and CO_2. Isocyanates react with amines to give urea derivatives. Reaction of most amines is too rapid for use in coatings; however, hindered diamines with lower reactivity have been developed. Polyaspartic esters are used in very high solids coatings (124). Reaction with ketimines and aldimines gives a mixture of a urea from hydrolysis of the ketimine or aldimine and a cyclic unsaturated urea. Aldimines are less reactive with water than ketimines and so a higher ratio of the direct reaction product is obtained. They are used in high solids 2K coatings (124).



The aromatic diisocyanates most widely used in coatings are bis(4-isocyanatophenyl)methane (MDI) [101-68-8] and toluene diisocyanate (TDI) (2,4-diisocyanato-1-methylbenzene) [584-84-9]. MDI is used in making polyurethanes such as in electrodeposition primers. TDI is used to make cross-linkers such as a low molecular weight trimethylolpropane (TMP) [2-ethyl-2-(hydroxymethyl)-1,3-propanediol] [77-99-6] derivative. The higher molecular weight minimizes toxic hazards and the higher functionality increases the rate of cure. Aromatic isocyanate based coatings turn yellow on exposure. The principal aliphatic isocyanates used are 1,6-hexamethylene diisocyanate (HDI) (1,6-isocyanatohexane) [822-06-0], bis(4-isocyanatocyclohexyl)methane (H_{12}MDI) [5124-30-1], and isophorone diisocyanate (IPDI) [(5-isocyanatomethyl)-1,3,3-trimethylcyclohexane] [4098-1-9]. To reduce toxic hazard and increase functionality, HDI is converted to HDI biuret or HDI isocyanurate. The linear hydrocarbon chain gives flexible coatings. IPDI is used primarily as the isocyanurate derivative; the cyclic structure gives more rigid coatings.



HDI-Biuret



HDI- Isocyanurate

Specialty isocyanates such as tetramethyl-*m*-xylidene diisocyanate (TMXDI) [2778-42-9] and TMI are used in smaller volumes. They have aromatic rings, but give color retention and exterior durability equivalent to aliphatic isocyanates. Since the isocyanato group is on a tertiary carbon, the reactivity is lower than that of less sterically hindered aliphatic isocyanates. TMXDI is offered as a low molecular weight prepolymer with TMP. TMI is used as a comonomer with acrylic esters to make 2000–4000 molecular weight copolymers with 40–50 mol% TMI; thus each molecule has several isocyanate groups (125).

Reaction of isocyanates with alcohols is catalyzed by tertiary amines, metal salts and chelates, organometallic compounds, acids, and urethanes. The most widely used catalysts for reaction with hydroxyl groups are diazabicyclo[2.2.2]octane (DABCO) and dibutyltin dilaurate (DBTDL) [dibutylbis[1-(oxododecyl)oxy]stannate] [77-58-7]. Combinations of DABCO and DBTDL act synergistically. With tin catalysts, the reactivity of aliphatic isocyanates is similar to that of aromatic isocyanates. Carboxylic acids inhibit catalysis by organotin compounds; volatile acids are used to increase pot life without affecting cure rate. Reaction of amines and imines with isocyanates is catalyzed by carboxylic acids and water; since organotin compounds complex with acids, they decrease reactivity (124). CO_2 generated by reaction with water can reduce gloss or result in bubbling. It is desirable to use catalysts such as zirconium acetoacetate $Zr(AcAc)_4$ in waterborne coatings that selectively catalyze reaction with hydroxyl groups (126).

The largest volume of urethane coatings is 2K coatings. One package contains the polyol (or other coreactant), pigments, solvents, catalyst(s), and additives; the other contains the polyisocyanate and moisture-free solvents. The principal reaction is formation of urethane cross-links; some urea cross-links result from reaction with water. Urethane coatings for maintenance paint applications are generally cured at ambient temperatures; those for automobile refinishing and aircraft applications are cured at ambient or modestly elevated temperatures. A N=C=O/OH ratio of 1.1:1 usually gives better film performance than a 1:1 ratio since part of the N=C=O reacts with water to give urea cross-links. Aircraft coatings are often formulated with N=C=O/OH ratios as high as 2:1 to have longer pot life. If very fast cure at relatively low temperatures is needed, reactive coreactants and/or high catalyst levels are used and applied using spray equipment, in which the two packages are fed to a spray gun by proportioning pumps and mixed inside the gun just before they are sprayed.

Blocked isocyanates permit making coatings that are stable at ambient temperature; when baked, the monofunctional blocking agent is volatilized and the coreactant is cross-linked. An extensive review of blocked isocyanates, their reactions, and uses is available (127). The blocking agents most widely used are phenols, oximes, alcohols, ε-caprolactam (hexahydro-2*H*-azepin-2-one) [105-60-2], 3,5-dimethylpyrazole, 1,2,4-triazole, and diethyl malonate (propanedioic acid diethyl ester) [105-53-3]. A variety of catalysts are used: DBTDL is most widely used but many other catalysts have also been used. Bismuth tris(2-ethyl hexanoate) has been particularly recommended (128). In electrodeposition primers, DBTDL has insufficient hydrolytic stability, and tributyltin oxide is an example of an alternate catalyst (129). Cyclic amidines, such as 1,5-diazabicyclo[4.3.0]non-5-ene, are reported to be superior catalysts for use with uretdione cross-linkers in powder coatings (130).
